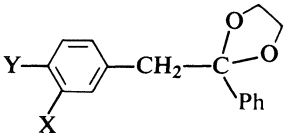
The photochemistry of nitroaromatic compounds has been a topic of continued interest and several reviews (1–4) summarize the photochemical behaviour of this functional group in solution. Many photoreactions of nitro compounds are known to proceed via radical intermediates which in many examples (e.g., photoreduction) are formed via initial hydrogen transfer to the photoexcited nitro group, consistent with the notion of an electrophilic n,π^* reactive state of the nitro group (5). In this work, we report several closely related photochemical reactions of appropriately substituted nitroaromatic compounds which are observed only in aqueous solution and are best explained by proposing the formation of nitrobenzyl carbanion and oxocarbocation (or oxocarbocation-derived) intermediates, via an excited state configuration other than the usual n,π^*. One of these reactions appears suited for direct photogeneration of a variety of dioxocarbocations and hemi-orthoesters in aqueous solution, which is amenable for flash-photolysis study. These results provide new insights into the intriguing photobehaviour of nitroaromatic compounds in aqueous solution (6–9).

	R^1	R^2	X	Y
1	H	H	NO_2	H
2	H	H	H	NO_2
3	H	Ph	H	NO_2
4	H	Ph	NO_2	H
5	CH_3	Ph	H	NO_2
6	H	H	H	H

Whereas nitroaromatic compounds **1**–**4** are photostable in a variety of organic solvents (e.g., CH_3CN, MeOH, diethyl ether, benzene), they react with moderate efficiencies (*vide infra*) in aqueous solution in a manner suggestive of a retro-aldol pathway, as shown in Scheme 1 for the reaction of 2-(*p*-nitrophenyl)-1-phenylethanol **3**. In a typical experiment, 100 mg of the substrate is dissolved in aqueous CH_3CN (100 mL; 10–30% CH_3CN; pH 1–14) and saturated with oxygen-free argon. Photolyses were carried out using quartz vessels in a Rayonet photochemical reactor (300 nm lamps). The photolyzed solutions were worked up by CH_2Cl_2 extraction, after adding NaCl. Typical photolysis times were 20–60 min, which gave conversions of 20–50%, depending on the substrate. Mass balances were >90%, except for experiments carried out at high pH, where some decomposition of benzaldehyde product (from **3** and **4**) was observed. However, under dilute conditions (10^{-4} *M*), the benzaldehyde product was found to be stable for several days at high pH. The structures of the products were characterized via standard spectroscopic techniques. The formation of *p*,*p*′-dinitrobibenzyl as a product is evidence for a *p*-nitrobenzyl carbanion intermediate on photolysis, since Russell and Buncel and their respective co-workers have shown in earlier work (10–13) that this compound is formed via the *p*-nitrobenzyl carbanion generated under more strongly basic conditions. The mechanism for the formation of *p*,*p*′-dinitrobibenzyl from the *p*-nitrobenzyl carbanion has been studied in some detail (10–12) in which the first step is believed to involve the ejection of an electron from the carbanion to give *p*-nitrobenzyl radical. The electron acceptor may be a molecule of substrate or *p*-nitrotoluene product (10–12). The reaction conditions employed for the photolysis (maximum pH = 14) do not permit any significant deprotonation of *p*-nitrotoluene,



7 X = NO_2; Y = H
8 X = H; Y = NO_2

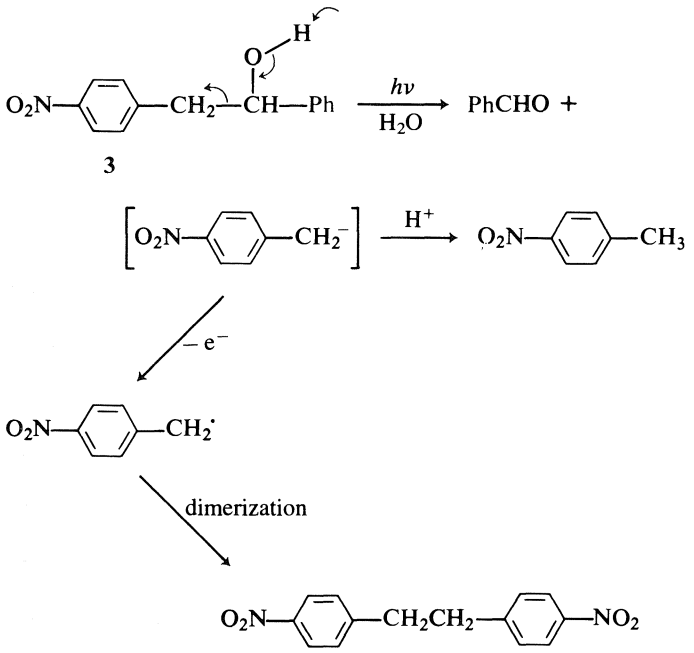
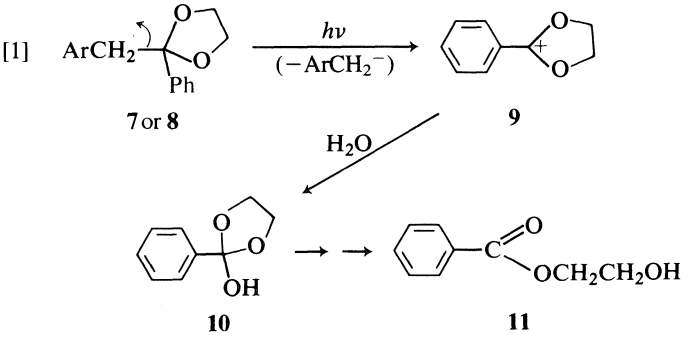


SCHEME 1

as shown by control experiments. In addition, *p*-nitrotoluene is photostable under the reaction conditions. Thus the *p*-nitrobenzyl carbanion is generated photochemically and reacts in a similar manner as the species generated under much more basic conditions. For example, in addition to dimerization to give *p,p'*-dinitrobibenzyl, we have found that if the photolysis is run under the presence of oxygen, the major product is *p*-nitrobenzoic acid, which is the known oxygenation product of the *p*-nitrobenzyl carbanion (11). The relative amounts of *p*-nitrotoluene vs. *p,p'*-dinitrobibenzyl formed (i.e., the relative rates of partitioning of the photogenerated *p*-nitrobenzyl carbanion by protonation (to give *p*-nitrotoluene) and by electron ejection (to give *p,p'*-dinitrobibenzyl)) is under study. Initial results indicate that the relative rates of the above two competing processes are dependent on the basicity of the medium. Additional evidence for a retro-aldol pathway (Scheme 1) is the observation that compound **3** reacts more efficiently in H_2O than in D_2O, as measured by relative quantum yields for benzaldehyde formation ($\Phi_{H_2O}/\Phi_{D_2O} = 1.3 \pm 0.05$). This observation is consistent with a primary isotope effect for deprotonation of the O—H(D) bond in the retro-aldol-type transition state. Successful triplet sensitization experiments using sodium benzophenone-2-carboxylate (λ_{excit} = 350 nm) for several compounds would suggest triplet state reactivity for these reactions, which is usually the norm for many nitroaromatic compounds (3).

Photolysis of the *meta*-isomer **4** in the absence of oxygen gave only benzaldehyde and *m*-nitrotoluene as the products, which indicates that the photogenerated *m*-nitrobenzyl carbanion does not react via the Russell mechanism (10–12). Compounds **1** and **2** react in an analogous manner as above but both **5** and **6** failed to react. These results indicate that a nitro group is necessary, in addition to the presence of a hydroxyl group at the 1-position for reaction in structures of the type **1**–**6**. However, both acetals **7** and **8** were found to react to give the nitrobenzyl carbanion-derived products (as above) and hydroxy ester **11**. The formation of **11** is best explained by reaction [1], in which the photoreaction initially generates a highly stabilized



dioxocarbocation **9** (and the corresponding nitrobenzyl carbanions). Carbocation **9** subsequently reacts with water to give hemi-orthoester **10**, which on further hydrolysis gives hydroxyester **11**. Thus the availability of two oxygens to stabilize the incipient carbocation is sufficient to cause reaction whereas one oxygen (in **5**) was insufficient. This observation clearly demonstrates that the reaction proceeds via a heterolytic mechanism. Additional evidence for a heterolytic retro-aldol type pathway is suggested by the variation of quantum yields for reaction (product formation) as a function of pH of the solution. Quantum yields were measured via uv spectrophotometry, by monitoring the formation of benzaldehyde (for **3** and **4**) at 252 nm or hydroxyester **11** at 230 nm (for **9** and **10**). For compounds **1** and **2**, small scale preparative photolyses were used. Potassium ferrioxalate actinometry was employed in all cases for the measurement of light intensity (λ_{excit} = 300 nm). The results are shown in Fig. 1 for several derivatives. The striking variations in quantum efficiencies observed with pH suggest a variety of mechanistic possibilities of reaction. For example, for the acetal derivative **8**, where no pH dependence was observed, a mechanism involving unimolecular heterolytic cleavage of the benzylic C—C bond is suggested. However, for alcohol **3**, there are distinctly two mechanistic regimes: one at high pH and the other below pH 11. In high pH, hydroxide ion catalysis of reaction (first step in Scheme 1) is important and at lower pH, water replaces hydroxide ion as the deprotonating base. For alcohol **2**, reaction is not observed below pH 11 which indicates that water is ineffective as the deprotonating base for

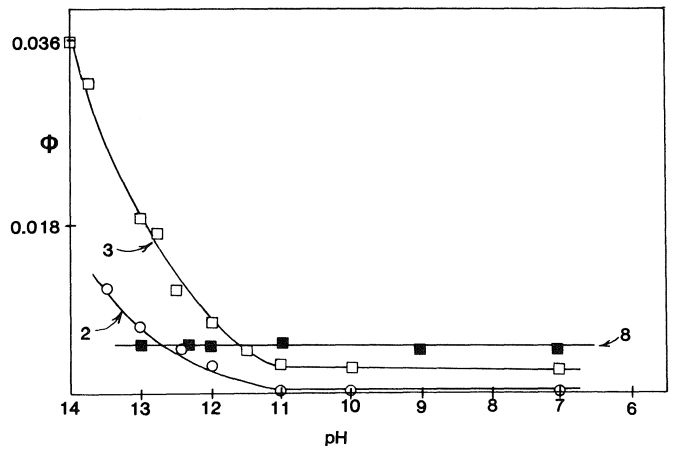


FIG. 1. Product quantum yields for retro-aldol reactions of compounds **2**, **3**, and **8** (λ_{excit} = 300 nm; 10% CH_3CN as cosolvent except for **8**, where 30% CH_3CN was used). The quoted pH is the basicity of the aqueous portion). Selected quantum yields at pH 7: 0.000 for **2**, 0.0025 for **3**, and 0.005 for **8**; at pH 12: 0.003 for **2**, 0.0072 for **3**, and 0.005 for **8**; at pH 13: 0.007 for **2**, 0.018 for **3**, and 0.006 for **8**.

this compound. Not shown in Fig. 1 is the observation that the *meta* isomers are about two times more reactive than the corresponding *para* isomers, as indicated by their quantum yields. This is suggestive of a selective *meta* transmission of ionic charge of photoexcited nitroaromatic compounds, initially reported by Zimmerman and Somasekhara (14).

Although the decarboxylation of several (nitrophenyl)acetic acids has been reported by Margerum and Petrusis (15), the present study indicates that this type of chemistry — in which the nitrobenzyl carbanion acts as photolabile leaving group in aqueous solution — is quite general for suitably substituted nitroaromatic compounds, which are amenable for detailed mechanistic studies.

Les complexes *cis*- et *trans*-$Co(en)_2(S_2O_3)_2^-$ (en = éthylènediamine), *cis*- et *trans*-$Co(en)_2(SO_3)_2^-$, *cis*- et *trans*-$Co(en)_2Cl_2^+$, *cis*-$Co(en)_2(N_3)_2^+$, *cis*-$Co(en)_2(SO_3)(N_3)^0$, $Co(en)_2(S_2O_3)(N_3)^0$ et $Co(en)_2(S_2O_3)(OH_2)^+$ ont été préparés par chromatographie en phase liquide à haute performance. Une bonne résolution a été obtenue sur colonne d'octadécyldiméthylsilane à phase inversée C-18-μ-Bondapak, en utilisant des cations de tributyl méthyl ammonium et des anions d'octyl sulfonate. L'efficacité et la vitesse de résolution étaient supérieures à celles obtenues sur colonne échangeuse d'ions Partisil SCX.
[Traduit par la revue]

Introduction

The separation of neutral and cationic Co(III) complexes of the type $[Co(en)_2X,Y]^{n+}$ (n = 0, 1, 2) by reversed-phase high-performance liquid chromatography (rp-hplc) and high-performance ion exchange chromatography (hpiec) have been reported (1–6).

The use of rp-hplc for the separation of $[Co(en)_2X,Y]^n$ complexes with n = 0, 1−, 1+ has not been reported before. We chose to investigate these compounds because of our interest in the kinetic and mechanistic aspects of Co(III) complexes in general (7). An hplc technique was used here because the compounds (e.g. *trans*-$Co(en)_2(S_2O_3)_2^-$, $Co(en)_2(S_2O_3)(N_3)^0$, and $Co(en)_2(S_2O_3)(OH_2)^+$) have generally similar physical and spectral properties and half-lives of the order of 10^2 min.

Experimental

Materials and apparatus

Analar grade perchloric acid was used to adjust the eluent pH to 5 using a Pye Unicam pH meter fitted with a glass electrode. G.P. grade tributylmethylammonium bromide, lithium perchlorate, sodium perchlorate and octylsulphonate were used as received. Separations were carried out on a μ-Bondapak C_{18} reversed-phase column (25 × 0.5 cm) which was end-capped with trimethylsilane. Some experiments were carried out using a Partisil μm SCX ion exchange column. The columns were equilibrated for at least 15 min with the required eluent. All runs were carried out using a constant eluent composition. The columns when not in use were thoroughly flushed with methanol.

The chromatograms were recorded with a Perkin-Elmer Model 3B chromatograph with flow rate of 1 cm^3 min^{-1}. Samples of 20-μL volume (10^{-3} M) were introduced by a Rheodyne valve and the peaks detected by uv spectroscopy at 254 nm and integrated with a Hewlett-Packard integrator. The eluents were made up in water or in methanol–water mixtures and filtered through Millipore 1.2-μm porosity filters before use.

Complexes

All bis(ethylenediamine)cobalt(III) complexes were prepared by standard procedures; their elemental analyses are given in Table 1. All microanalyses were performed by analytical services in the Department of Chemistry at Queen University of Belfast (N. Ireland). The compounds are *cis*-$Li[Co(en)_2(S_2O_3)_2]$ (8), *trans*-$Na[Co(en)_2(S_2O_3)_2]$ (9), *cis*-$Na_2[Co(en)_2(SO_3)_2]$ $ClO_4.3H_2O$ (10), *trans*-$Na[Co(en)_2(SO_3)_2].3H_2O$ (10), *cis*-$[Co(en)_2(N_3)_2]$ NO_3 (11), *cis*-$[Co(en)_2Cl_2]$ $Cl.H_2O$ (10), *trans*-$[Co(en)_2Cl_2]Cl$ (12), and *cis*-$[Co(en)_2(N_3)(SO_3)]$ (10).

A solution of the complex $[Co(en)_2(S_2O_3)(OH_2)]$ was prepared using Deutsch's method (9). In a typical preparation 0.04 M *trans*-$Na[Co(en)_2(S_2O_3)_2]$ was oxidized with 0.06 M I_3^- (pH = 5, $HClO_4$) in 2 mL of water. The reaction mixture was loaded onto a sephadex sp-25 cation exchange column (Na^+ form, 2 cm id × 25 cm), and the bands eluted with 0.25 M $NaClO_4$. The required green band of the complex $[Co(en)_2(S_2O_3)(OH_2)]$ was collected and its concentration calculated, allowing for dilution. The agreement between the obtained and reported (9) absorptivity values (Table 2) suggest that conversion is practically stoichiometric.

A solution of the complex $[Co(en)_2(S_2O_3)(N_3)]$ was prepared by allowing 10^{-3} M *trans*-$[Co(en)_2(S_2O_3)_2]$ or $[Co(en)_2(S_2O_3)(OH_2)]$ to react with 0.1 M NaN_3 at 25°C for 24 h. High-performance liquid chromatography was used to monitor the percentage of the reactant and the product during the course of the reaction until the reactant peak disappeared. The spectrum of the product was recorded and its molar absorptivity values obtained (Table 2). On the other hand, reaction of the product with $S_2O_3^{2-}$ ions regenerated the complex $[Co(en)_2(S_2O_3)_2]$, which indicates that the product in solution is actually $[Co(en)_2(S_2O_3)(N_3)]$.

Results and discussion

The octahedral complexes reported here exist as cations, anions, and uncharged species in solution. Most are stable towards dissociation (14*a*, 15). However, some are more labile. A kinetic study (16) of *trans*-$Co(en)_2(SO_3)_2^-$ established that the complex ion undergoes rapid acid or base hydrolysis to form the $Co(en)_2(SO_3)(OH_2)^+$ ion. In contrast to *trans*-$Co(en)_2(SO_3)_2^-$, *cis*-$Co(en)_2(SO_3)_2^-$ is not labile with respect to hydrolysis and exchange reactions (16). On the other hand, it is reported (17) that the *cis* form of the complex $Co(en)_2(S_2O_3)_2^-$ isomerizes to the *trans* form in neutral aqueous medium (pH ~ 6–6.3), as shown by a change in the spectrum from the *cis* to the *trans* form after 2–3 days at room temperature. The *trans* form isomerizes to the *cis* in basic solution only (8) (pH ~ 7–11), and above pH 11 base hydrolysis becomes prominent. The

[b]From ref. 9.
[c]From ref. 13.

conclusion from these observations is that the complexes under investigation are quite stable at pH 5, so that the hplc technique can be utilized for their separation from the complex *trans*-$Co(en)_2(SO_3)_2^-$ and to a lesser extent from its derivative *trans*-$Co(en)_2(SO_3)(N_3)^0$.

A complete analysis using an ion exchange or ion pair column would require one portion for the anion and a second for the cation separation. The positively charged complexes were ion-paired with octylsulphonate anions ($C_8H_{17}SO_3^-$), while the negatively charged complexes were paired with tributylmethylammonium cations ($NMeBu_3^+$) to provide suitable retention for separation on a C_{18} bonded (ODS) column. Some complexes were eluted from a Partisil SCX ion exchange column with ClO_4^- anions. The data presented in Table 3 are representative of the performance of the columns in use. Results obtained using 0.3% by weight tributylmethylammonium cation as pairing ion and a reverse phase ODS column are given in Fig. 1. The void volume of the column was about 2.2 cm^3. The cation complexes (*a*) and (*b*) eluted at about 3 cm^3, a volume slightly exceeding the void volume. This indicates that hydrophobic interactions between these complexes and the C_{18} layer are insignificant. The unexpected order of the negatively charged complex (c) may be due to rapid hydrolysis into $[Co(en)_2(SO_3)(OH_2)]^+$ as mentioned before. The bonded hydrocarbon surface layer and the eluent electrolyte have the effect of reducing the column's capacity for uncharged hydrophilic complexes. This leads to the early separation shown in Fig. 1.

The separation of the negatively charged complexes (e) or (f) from (g) has been achieved. The separation of (e) from (f) is poor. Both possess the *cis* form and a single negative charge. Retention times follow the order e < f < g i.e.: *cis*-$Co(en)_2(SO_3)_2^-$ < *cis*-$Co(en)_2(S_2O_3)_2^-$ < *trans*-$Co(en)_2(S_2O_3)_2^-$.

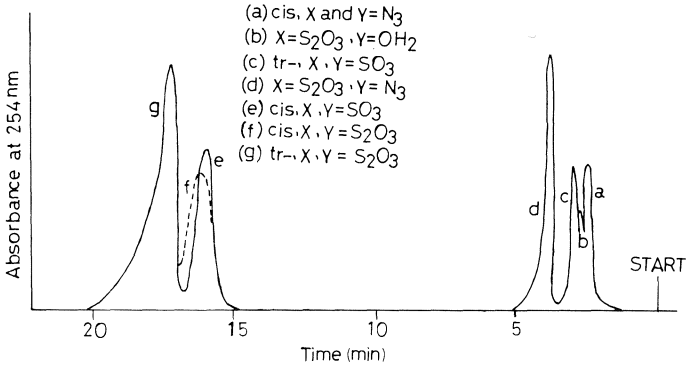

FIG. 1. Chromatogram of a mixture of $[Co(en)_2XY]^n$ complexes (ODS column, 0.3% $NMeBu_3^+$ in water, flow rate 1 $cm^3\ min^{-1}$, chart speed 0.5 cm min^{-1}).

The basicity of SO_3^{2-} ($pK = 7.2$) (18) is much greater than that of $S_2O_3^{2-}$ ($pK = 2.5$) (18). Consequently, the reactivity of SO_3^{2-} far exceeds that of $S_2O_3^{2-}$, giving a fast rate of retention in comparison with $S_2O_3^{2-}$. On the other hand, the order of the size of the stability constants (14*a*) of the complexes of the nucleophiles SO_3^{2-} and $S_2O_3^{2-}$ with the soft acid CH_3Hg^+ is $S_2O_3^{2-} > SO_3^{2-}$, which is in accord with the retention shown above.

Figure 2 shows the separation of the complexes using an ODS column and octylsulphonate in 10% MeOH as eluent. Each complex is clearly separated from the others. The negatively charged complex (a) is eluted at the void volume of the column followed by the uncharged compounds (b) and (c). Compound (b) shows another unidentified small peak at 4.7 cm^3. The positively charged complexes elute in the order d < e < f < g, i.e.: $Co(en)_2(S_2O_3)(OH_2)^+$ < *cis*-$Co(en)_2Cl_2^+$ < *cis*-$Co(en)_2(N_3)_2^+$ < *trans*-$Co(en)_2Cl_2^+$.

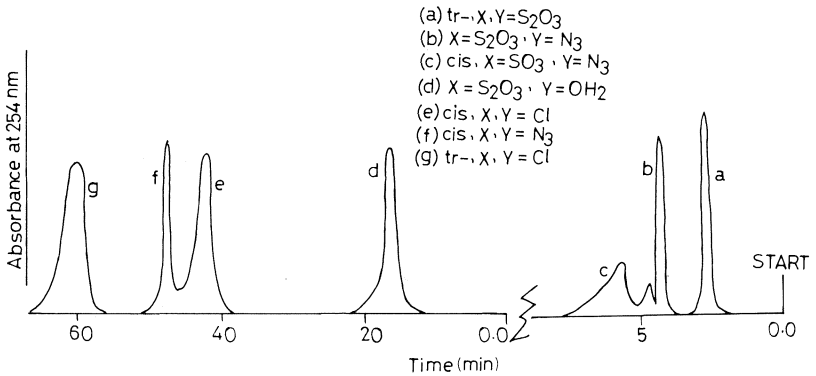

FIG. 2. Chromatogram of a mixture of $[Co(en)_2XY]^n$ complexes (ODS column, 0.2% $C_8H_{17}SO_3^-$ in 10% MeOH, flow rate 1 cm^3 min^{-1}, chart speed 0.5 cm min^{-1}).

This order is consistent with the hydrophobicity order of these compounds and with the ability of the added anion to interact with the C_{18} stationary phase and to form an ion pair with the cation complex. Such interactions have been discussed by Bidlingmeyer *et al.* (19), and may lead to the formation of species of different counter-ion stoichiometry which have sufficient lifetime on the matrix of the stationary phase to allow separation. Moreover, the basicity of N_3^- ($pK = 4.7$) (14*b*) is greater than Cl^- and H_2O ($pK = -4$ and -1.7, respectively) (14*b*). This is in agreement with the elution order of $Co(en)_2(S_2O_3)(OH_2)^+$ and *cis*-$Co(en)_2Cl_2^+$ but not with that of *trans*-$Co(en)_2Cl_2^+$. The difference between *cis*- and *trans*-$Co(en)_2Cl_2^+$ may be due to electrostatic repulsion of the negative ligand Cl^-, which would appear to be greater in the *cis* position than in the *trans* because of the smaller distance of separation (14*c*).

The sharpness observed for the peak of compound (f) is difficult to rationalize on steric ion pairing or stationary phase interaction grounds and a complex set of parameters probably combine. This requires more investigation for clarification. In an attempt to reduce the retention time of the cationic complexes (Fig. 2), the percentage of MeOH was raised to 30%, but this tended to dwarf the differences between the complexes and the extent of separation declined.

Use of a partisil high performance ion exchange column and aqueous ClO_4^- as anion gave in general poor results. Elution times were shorter than for those obtained by rp-hplc, with broad peaks and poor resolution. The elution order was the same as observed using an ODS column. On increasing the anion concentration from 0.1 to 0.2 *M*, the negatively charged complexes *cis*- and *trans*-$Co(en)_2(S_2O_3)_2^-$ eluted with somewhat longer retention times and the uncharged complex $Co(en)_2(S_2O_3)(N_3)^0$ eluted in a shorter time, but the discrimination between the three complexes was not as good. The positively charged complexes *cis*-$Co(en)_2(N_3)_2^+$ and $Co(en)_2(S_2O_3)(OH_2)^+$ had smaller retention times than were observed with 0.1 *M* ClO_4^- and the peaks overlapped. This phenomenon was noted before (2), and was found to be due to interactions between the different complexes, the reagent, and the stationary phase.

Overall, the results obtained may be of value to those contemplating the use of rp-hplc for separating complexes similar to those investigated here.

On why some low-energy decomposition pathways of simple ketone molecular ions do not give rise to metastable peaks. A reappraisal

PETER J. DERRICK AND STEEN HAMMERUM

School of Chemistry, University of New South Wales, Kensington NSW 2033, Australia, and Department of General and Organic Chemistry, University of Copenhagen, The H.C. Ørsted Institute, DK-2100 Copenhagen Ø, Denmark

Received November 21, 1985

PETER J. DERRICK and STEEN HAMMERUM. Can. J. Chem. **64**, 1957 (1986).

The concept of minimum rate constants, $k(E)_{min}$, for unimolecular decompositions does not, according to the quasi equilibrium theory (QET), provide a rationalisation of the occurrence of the higher energy reaction, loss of methyl, rather than the more favorable process, loss of methane, from metastable butanone and 3-methylbutanone molecular ions.

PETER J. DERRICK et STEEN HAMMERUM. Can. J. Chem. **64**, 1957 (1986).

En se basant sur la théorie des quasi-equilibres le concept des constantes de vitesses minimales ($k(E)_{min}$) appliqué aux décompositions unimoléculaires ne fournit pas de rationalisation pour l'existence de la réaction de la perte d'un radical méthyle, qui demande plus d'énergie que la réaction plus favorable impliquant la perte d'une molécule de méthane, à partir des ions moléculaires métastables de la butanone et de la méthyl-3 butanone.

[Traduit par la revue]

In 1976 Cooks *et al.* (1) pointed out that some ketone molecular ions eliminate simple alkanes in the microsecond time-domain, because, they suggested, these are decomposition pathways with low energy requirements and such decompositions predominate at these times. The loss of alkane molecules from certain ketones had been noted previously (2), but many small ketone radical cations react predominantly by the loss of alkyl radicals through α-cleavage. The loss of an alkyl is not always straightforward, as demonstrated by McAdoo, McLafferty, and Smith (3), who proposed that the loss of $CH_3^{\bullet}$ from certain $(C_3H_6O)^{+\bullet}$ ions constituted an example of non-ergodicity. The decomposing $(C_3H_6O)^{+\bullet}$ ions were said to have the acetone structure having been formed by isomerization of the enol ions, $(CH_3C(OH)=CH_2)^{+\bullet}$, and the loss of $CH_3^{\bullet}$ gave rise to the only significant metastable peak. The extensive discussion over the next fourteen years of this proposed example of non-ergodicity has been reviewed recently (4), and the conclusion reached that there is no reasonable alternative explanation for the particular characteristics of the $(C_3H_6O)^{+\bullet}$ system. However, the $(CH_3COCH_3)^{+\bullet}$ ion formed by electron ionization of acetone exhibits only one significant metastable peak, which is due to the loss of CH_4 (1, 5). The apparent contradiction has been resolved on the basis of the different internal energy contents (5). The $(CH_3COCH_3)^{+\bullet}$ ions formed by the isomerization of $(CH_3C(OH)=CH_2)^{+\bullet}$ have more internal energy, and they decompose by losing $CH_3^{\bullet}$. The acetone molecular ions that remain undecomposed after microseconds have less internal energy, and they decompose by losing CH_4. That is to say, the $k(E)$ vs. E curves cross. An analogous situation arises with the $(C_5H_{10}O)^{+\bullet}$ system (6–8), where the $(CH_3CH_2COCH_2CH_3)^{+\bullet}$ ions formed by electron ionization of 3-pentanone lose C_2H_6, while the $(CH_3CH_2COCH_2CH_3)^{+\bullet}$ ions formed by isomerization of its enol lose $C_2H_5^{\bullet}$. The latter reaction has also been suggested (7) to exhibit non-ergodic behaviour, but this claim has been shown (8) to be without substance.

$$CH_3^{\bullet} + CH_3CO^+ \leftarrow CH_3COCH_3^{+\bullet} \rightarrow CH_4 + CH_2{=}C{=}O^{+\bullet}$$

$$C_2H_5^{\bullet} + CH_3CH_2CO^+ \leftarrow CH_3CH_2COCH_2CH_3^{+\bullet} \rightarrow C_2H_6 + CH_3CH{=}C{=}O^{+\bullet}$$

The $(C_4H_8O)^{+\bullet}$ ion differs from $(C_3H_6O)^{+\bullet}$ and $(C_5H_{10}O)^{+\bullet}$ in metastable ion characteristics (9). The $(C_4H_8O)^{+\bullet}$ keto-ion formed by the isomerization of 2-butanone enol ions loses both CH_3 and $C_2H_5^{\bullet}$ (10), and it has been suggested (11, 12) on the basis of energy release that these reactions are also non-ergodic. The $(C_4H_8O)^{+\bullet}$ ions formed by electron ionization of 2-butanone also lose both $CH_3^{\bullet}$ and $C_2H_5^{\bullet}$ in the microsecond time-frame. What is remarkable is that the 2-butanone molecular ion loses neither CH_4 nor C_2H_6, even though the loss of CH_4 is endoergic by only 30 kJ mol^{-1} (cf. the loss of $CH_3^{\bullet}$, 60 kJ mol^{-1}; the loss of $C_2H_5^{\bullet}$, 100 kJ mol^{-1}) (see Appendix). A similar situation arises with the 3-methyl-2-butanone molecular ion (13, 14), which also does not lose CH_4. This reaction should be approximately thermoneutral (cf. the loss of $CH_3^{\bullet}$, 65 kJ mol^{-1}; the loss of $C_3H_7^{\bullet}$, 100 kJ mol^{-1}) (see Appendix).

$$CH_3^{\bullet} + CH_3CH_2CO^+ \leftarrow CH_3COCH_2CH_3^{+\bullet} \not\rightarrow CH_4 + CH_3CH{=}C{=}O^{+\bullet}$$

$$CH_3^{\bullet} + (CH_3)_2CHCO^+ \leftarrow CH_3COCH(CH_3)_2^{+\bullet} \not\rightarrow CH_4 + (CH_3)_2C{=}C{=}O^{+\bullet}$$

An explanation involving the idea of minimum rate constants, $k(E)_{min}$, has been advanced (14) to account for the absence of the loss of CH_4 from the molecular ions of 2-butanone and 3-methyl-2-butanone. Consider the QET expression,

$$k(E) = \sigma G^*(E - E_0)/(hN(E))$$

$k(E)$ assumes a near-minimum but non-zero value, $k(E)_{min}$, at the threshold when $\sigma G^*(E - E_0) = 1$. The explanation (14) supposes that the $k(E)$ vs. E curves for the loss of CH_4 and the loss of $CH_3^{\bullet}$ from either the 2-butanone or 3-methyl-2-butanone molecular ions are as shown in Fig. 1. Curve *A* representing the loss of $CH_3^{\bullet}$ has $k(E)_{min} < 10^6$ s^{-1}; curve *B* representing the loss of CH_4 has $k(E)_{min} > 10^6$ s^{-1}. The argument (14) upon which the explanation rested was that, if $k(E)_{min}$ is greater than 10^6 s^{-1} for a decomposition, no metastable peak will be observed for that decomposition, because no ions will react at the appropriate rates. If this argument were valid, it would follow directly from Fig. 1 that the loss of CH_4 ought not be observed. We wish to point out that this argument is incorrect when a metastable peak is observed for some competing reaction whose $k(E)$ curve lies below that of the non-observed process, as in Fig. 1. Figure 1 shows that molecular ions with internal energies E_1 to $E_1 + \Delta E$, corresponding to rate constants $k(E) = 10^5$ s^{-1} and 10^6 s^{-1} on curve *A*, would largely

Printed in Canada

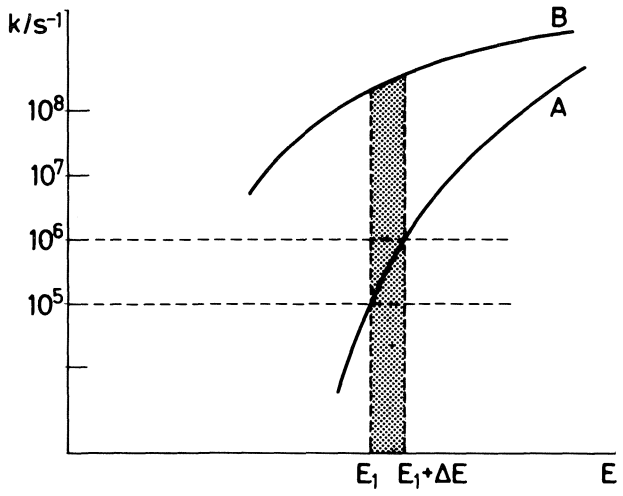

FIG. 1. Schematic representation of the variation of $k(E)$ with E for a situation where two competing reactions have $k(E)_{min} < 10^6\ s^{-1}$ (curve A) and $k(E)_{min} > 10^6\ s^{-1}$ (curve B), respectively; ions with internal energies E_1 to $E_1 + \Delta E$ will decompose predominantly by the path represented by curve B.

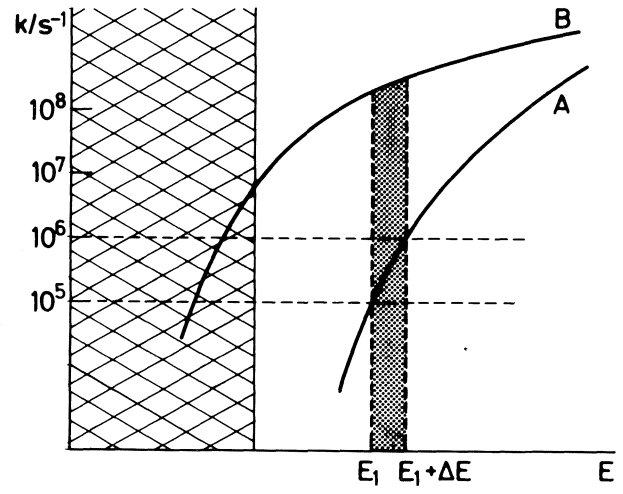

FIG. 2. Schematic representation of the variation of $k(E)$ with E for two competing reactions for a situation where no molecular ions have internal energies in the shaded energy region; ions with internal energies E_1 to $E_1 + \Delta E$ will decompose predominantly by the path represented by curve B.

decompose in times of the order of nanoseconds by losing CH_4 (curve B). Only a very small proportion of such molecular ions would survive long enough to enter the field-free region of the mass spectrometer (i.e., be undecomposed after microseconds), but *these would still decompose predominantly by losing CH_4*.

To demonstrate this point, it is sufficient to consider ions with a discrete energy E_1 (Fig. 1). Let the rate constants for losing $CH_3^\bullet$ and CH_4 at this energy be $k(E_1)_A$ and $k(E_1)_B$, respectively, and let the metastable time-window be from, say, $t_1 = 1\ \mu s$ to $t_2 = 10\ \mu s$. The number of ions, N_A and N_B, decomposing to lose $CH_3^\bullet$ and CH_4, respectively, in this time-window are (15):

$$N_A = \int_{t_1}^{t_2} k(E_1)_A N_0 \{\exp -[k(E_1)_A + k(E_1)_B]t\}dt$$

and

$$N_B = \int_{t_1}^{t_2} k(E_1)_B N_0 \{\exp -[k(E_1)_A + k(E_1)_B]t\}dt$$

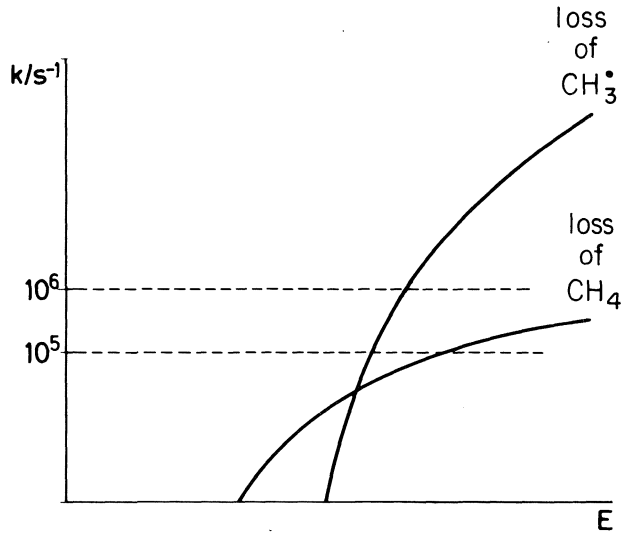

FIG. 3. Schematic representation of the variation of $k(E)$ with E for the competing reactions of $(CH_3COCH_2CH_3)^{+\bullet}$, showing presumed crossing below $10^5\ s^{-1}$.

where N_0 is the original number of molecular ions formed at $t = 0$. Other decomposition pathways can be neglected. The ratio of the number of ions decomposing by losing $CH_3^\bullet$ to those by losing CH_4 is then

$$\frac{N_A}{N_B} = \frac{k(E_1)_A}{k(E_1)_B}$$

and in Fig. 1, $k(E_1)_A/k(E_1)_B < 10^{-2}$. Therefore the intensity for the loss of CH_4 should exceed that for the loss of $CH_3^\bullet$ by a factor greater than 10^2. The $k(E)$ curves in Fig. 1 may be used to estimate relative metastable peak intensities by locating the energy range corresponding to $k(E) = 10^5\ s^{-1}$ or $10^6\ s^{-1}$ (depending on the time-window) for the lowest energy curve, i.e., the curve which crosses the $k = 10^5\ s^{-1}$ and $k = 10^6\ s^{-1}$ lines at the lowest energy. Approximate relative metastable intensities are then obtained by making *vertical* comparisons on the $k(E)$ diagram. That is to say, compare the $k(E)$ values for different decompositions at the energy range located.

A variation of this explanation has also been discussed (14). Here curve B continues below $k(E) = 10^5/10^6\ s^{-1}$, but there are no molecular ions in the shaded energy region (Fig. 2). In this case, the proposal (14) that the loss of $CH_3^\bullet$ would give rise to a metastable peak is unsound for the same reasons as before.

There are two plausible lines of explanation within the framework of the QET for why the loss of $CH_3^\bullet$ is observed but the loss of CH_4 is not with 2-butanone molecular ions. One is that the energies (heats) of reaction do not accurately reflect the critical energies. Thus if the critical energy for the loss of CH_4 were greater than that for the loss of $CH_3^\bullet$, the observations would be readily explained. This would mean that there was a significant reverse critical energy for the loss of CH_4. There could also be a reverse critical energy for the loss of $CH_3^\bullet$, but it would need to be much smaller than that for the loss of CH_4.

There is no evidence that the loss of CH_4 from the acetone molecular ion would have a significantly greater reverse critical energy that the loss of $CH_3^\bullet$. Baer[1] has found that the loss of CH_4 has a slightly lower onset than does the loss of $CH_3^\bullet$. It thus seems unlikely that the loss of CH_4 from 2-butanone molecular ion has a significant reverse critical energy.

[1]T. Baer. Private communication to C. Lifshitz (16).

The other explanation would be that the $k(E)$ curves for the loss of $CH_3^{\bullet}$ and the loss of CH_4 cross below about $k(E) = 10^5\ s^{-1}$. With both $(CH_3COCH_3)^{+\bullet}$ and $(CH_3CH_2COCH_2CH_3)^{+\bullet}$, it is generally believed that the $k(E)$ curves for the loss of alkyl and the loss of alkane do cross. It is, therefore, not unreasonable to consider that there is a similar crossing of $k(E)$ curves for $(CH_3COCH_2CH_3)^{+\bullet}$. In this case, however, the crossing would be below rather than above $10^5\ s^{-1}$ (see Fig. 3).

Appendix

Heats of formation employed (all numbers are 298 K values). $\Delta H_f(CH_3COCH_3^{+\bullet})$, $\Delta H_f(CH_3CH_2COCH_3^{+\bullet})$, $\Delta H_f((CH_3)_2CHCOCH_3^{+\bullet})$, and $\Delta H_f(CH_3CH_2COCH_2CH_3^{+\bullet})$ have been taken as 719, 676, 635, and 640 kJ mol^{-1}, respectively (17). $\Delta H_f(CH_4)$ and $\Delta H_f(C_2H_6)$ are taken to be -75 and -84 kJ mol^{-1}, respectively (18). $\Delta H_f(CH_3^{\bullet})$, $\Delta H_f(C_2H_5^{\bullet})$, and $\Delta H_f(C_3H_7^{\bullet})$ are taken to be 144, 117, and 80 kJ mol^{-1}, respectively (19). $\Delta H_f(CH_3CO^+)$ has been taken as 657 kJ mol^{-1} (20), and $\Delta H_f(CH_2CO^{+\bullet})$ has been placed at 870–880 kJ mol^{-1}, on the basis that the adiabatic IE is 9.61 eV (17) and $\Delta H_f(CH_2CO)$ is -48 kJ mol^{-1} (18). $\Delta H_f(CH_3CH_2CO^+)$ and $\Delta H_f((CH_3)_2CHCO^+)$ have been taken as 591 (21) and 554 kJ mol^{-1} (17). $\Delta H_f(CH_3CHCO^{+\bullet})$ has been estimated to be 775–785 kJ mol^{-1} on the basis that the adiabatic IE is 8.95 eV (22) and that $\Delta H_f(CH_3CHCO)$ is -86 kJ mol^{-1} (21). $\Delta H_f((CH_3)_2CCO^{+\bullet})$ has been estimated to be 700–710 kJ mol^{-1} on the basis that the adiabatic IE is 8.38 eV (22) and that $\Delta H_f((CH_3)_2CCO)$ is -105 kJ mol^{-1} (estimated).

Ion–ion–solvent interactions in aqueous ionic cosolvent systems. I. Transfer thermodynamics of hydrogen chloride in aqueous sodium nitrate solutions from emf measurements

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, BIJOY P. CHAKRAVARTI, AND KIRON K. KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta-700 032, India

Received May 29, 1985[2]

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, BIJOY P. CHAKRAVARTI, and KIRON K. KUNDU. Can. J. Chem. **64**, 1960 (1986).

Standard potentials (E^0) of the Ag–AgCl electrode have been determined in 1, 2, and 4 *m* $NaNO_3$ + water mixtures at five equidistant temperatures ranging from 15–35°C from the emf measurements of the cell: Pt, H_2 (g, 1 atm)/HCl (*m*) $NaNO_3$ + water/AgCl–Ag. These values have been used to evaluate the transfer energetics (ΔG_t^0, $T\Delta S_t^0$, and ΔH_t^0) accompanying the transfer of 1 mole of HCl from the standard state in water to the standard state in each of the $NaNO_3$ + water mixtures. Transfer free energies ΔG_t^0 of HCl and that of the individual ions obtained from a separate study, and those obtained after correcting the "cavity effect" and Born-type electrostatic effect, as estimated tentatively by the scaled-particle theory (SPT) and simple Born equation respectively, have been discussed in the light of ion–ion–solvent interactions. The observed $T\Delta S_t^0$–composition profile as well as that obtained after correcting for the "cavity effect" were examined in the light of semiquantitative theory proposed by Kundu *et al.* earlier and are found to substantiate this theory.

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, BIJOY P. CHAKRAVARTI et KIRON K. KUNDU. Can. J. Chem. **64**, 1960 (1986).

Opérant avec des mélanges 1, 2 et 4 m de $NaNO_3$ dans de l'eau et à cinq températures équidistantes allant de 15 à 35°C et en se basant sur des mesures de fem de la cellule |Pt, H_2(g, 1 atm)/HCl(*m*) $NaNO_3$ + eau/AgCl–Ag|, on a déterminé les potentiels standards (E^0) de l'électrode Ag–AgCl. On a utilisé ces valeurs pour évaluer les énergies de transfert (ΔG_t^0, $T\Delta S_t^0$ et ΔH_t^0 qui accompagnent le transfert de 1 mole de HCl de son état standard dans l'eau vers l'état standard de chacun des mélanges $NaNO_3$ + eau. A la lumière d'interactions ion–ion–solvant, on discute des énergies libres de transfert ΔG_t^0 du HCl ainsi que de celles des ions individuels qui ont été obtenues au cours d'une étude séparée de même que celles obtenues après avoir corrigé les valeurs pour l'«effet de cavité» et pour l'effet électrostatique du type de Born qui ont respectivement été évalués sur une base préliminaire en faisant appel d'une part à la théorie des particoles et d'autre part à une équation de Born simple. A la lumière de la théorie de Kundu et de ses associés qui a été proposée antérieurement, on a examiné les corrélations qui existent entre la composition et les valeurs de $T\Delta S_t^0$ ainsi que celles obtenues après avoir apporté des corrections pour l'«effet de cavité»; on a trouvé que les résultats sont en accord avec la théorie.

[Traduit par la revue]

Introduction

It is well recognized that thermodynamic quantities, especially transfer enthalpies and entropies of electrolytes and non-electrolytes, often provide useful information regarding the structuredness of solvents (1–12). There have been extensive studies (9–14) on the thermodynamics of hydrogen halides (HX), alkali halides (MX), and the related ion–solvent interactions, solvent structuredness, etc., in a host of aquo-organic solvent systems. However, apart from a few studies (15) by Bates and co-workers in synthetic sea water systems, parallel studies on aquo-ionic cosolvent systems are yet a fairly untrodden field, although a number of studies have been made from the point of mixed electrolyte properties (16, 17). In fact, it would be highly interesting and useful to treat aqueous electrolyte solutions of any molality as an individual solvent and the infinitely dilute solution of the solute in that solvent as the standard state, exactly similar to what is being done in aquo-organic solvent systems. It is hoped that the transfer free energies derived in this way will help show the ion–ion–solvent interactions from a new angle and the transfer entropies will help show solvent structuredness with extra confidence as hydrophilic ions are well known three dimensional (3D) structure breakers of water (18, 19), although ions with larger ionic force field induce overall structural order round them and hence are tacitly designated as "structure makers" (18, 19).

Moreover, simple aquo-ionic cosolvent systems are also likely to serve as precursors to suitable model systems of highly complex physiological fluids (20*a*) on the one hand and sea water (20*b*) on the other. So, comprehensive studies on different physico-chemical properties including transfer thermodynamics of HX, MX, and other selected electrolytes and non-electrolytes etc. in different aquo-ionic cosolvent systems should prove immensely useful, particularly in imparting far-reaching implications which will help us to understand the complex processes in bio-fluids or in sea water.

Therefore, as part of the systematic studies that have been taken up for the first time, we are now reporting transfer thermodynamics of HCl in the aquo-ionic solvent system comprising 1, 2, and 4 *m* $NaNO_3$. This has been determined from emf measurements of the cell [A]

[A] Pt, H_2 (g, 1 atm)/HCl (*m*), $NaNO_3$ + water/AgCl–Ag

at five equidistant temperatures ranging from 15–35°C.

The choice of NaCl instead of $NaNO_3$ as the ionic cosolvent would have been more useful from the point of physiological fluid/sea water. But the response of Ag–AgX (X = Cl, Br or I) electrodes to the small concentration of solute halide ions in presence of overwhelming concentration of solvent Cl^- is likely to be rather sluggish. Secondly, the behaviour of HCl or other chlorides even in the assumed standard state in each cosolvent mixtures is likely to be complicated by the common-ion type effects. On the other hand, structural characteristics of aqueous solutions of various nitrate salts including $NaNO_3$ are fairly well known (21, 22). Studies in nitrate solutions should thus help us to understand the behaviour of HCl and other solutes in this aquo-ionic cosolvent system. More importantly, systematic studies on the activity coefficients of HCl or other halides in this

type of aquo-ionic system but based on water as the standard state, are likely to initiate a new series of studies on Harned's rule (16) involving quarternary ionic mixtures.

Experimental

Sodium nitrate (A.R., B.D.H.) was used after drying at 150°C and then cooled in a vacuum desiccator. Water used was triply distilled. Solvents of various molalities were prepared by mixing the components by weight. Cell design, electrode and solution preparation and experimental procedures were similar to those described earlier (7, 23). Equilibrium at the lowest temperature was reached within 3–4 h of the commencement of hydrogen bubbling after which emf data at successively higher temperatures were recorded. The criterion of equilibrium in each case was ±0.2 mV per h. The equilibrium emf data at 25°C agreed within ±0.3 mV of the previous data when tested back at the end of the experiment.

Solvent densities (d_s) at different temperatures were measured with a pyknometer of 15 cm^3 capacity, having a 15 cm long neck made up of 1 mm bore capillary tubing and graduated into 1 mm divisions. The values thus obtained are listed in Table 1. The vapour pressure (p_s/mm Hg) of the different solvent mixtures at different temperatures were obtained with the help of the approximate relation [1] (24)

$$[1] \quad \log (p_s)_t = \log (p_w)_t - \frac{M_w}{1000}\frac{m\phi}{2.303}$$

where $(p_w)_t$ is the vapour pressure of pure water (25) at the temperature, M_w the molecular weight of pure water, and ϕ is the osmotic coefficient of $NaNO_3$ solution of molality m, the required values of ϕ being obtained from literature (26). The values so obtained are given in Table 1. The dielectric constant (ϵ_s) values of the solvents (27) are known only at 25°C as are given in Table 1. The values of mean molar mass (M_s) of the solvents are also given in Table 1.

Results

The emf (E) values of the cell (A) (corrected for pH_2 = 1 atm) for molality m of HCl are given elsewhere.[3] As in pure water and aquo-organic solvents these values are related to the standard potential of the cell on molal scale E^0_m by eq. [2]

$$[2] \quad E = E^0_m - 2k \log m - 2k \log (\gamma_\pm)_{HCl}$$

where $(\gamma_\pm)_{HCl}$ is the mean molal activity coefficient of HCl and $k = 2.303\,RT/F$. The E^0_m values at different temperatures in each solvent were determined by use of curve fitting technique of Sen *et al.* (28) with the polynomial [3]

$$[3] \quad E + 2k \log m = E^{0\prime}_m = E^0_m + 2k \log (\gamma_\pm)_{HCl} = E^0_m + Am^{1/2} + B(m^{1/2})^2 + C(m^{1/2})^3$$

using a FORTRAN program and a B 6700 computer. Notably, as in aquo-organic solvents, the standard state is so chosen that at infinitely dilute solution of HCl in each of the solvent compositions of the mean activity coefficient $(\gamma_\pm)_{HCl}$ is taken to be unity. The values of E^0_m (molal scale) and the coefficients A, B, and C as obtained are listed in Table 2. The average standard deviation of these values is ±0.3 mV.

The E^0_m values at different temperatures for each of the solvent mixtures were then fitted into E^0_m–temperature quadratic equation [4]

$$[4] \quad E^0_m = a + b(t - 25) + c(t - 25)^2$$

by the method of least squares, where t is the temperature in °C. The coefficients a, b, and c for different ($NaNO_3$ + water) solvents are given in Table 3. The coefficients of eq. [4] for water were obtained by using the data of Bates *et al.* (29) and are listed in Table 3.

Standard free energy (ΔG^0_t), entropy (ΔS^0_t), and enthalpy (ΔH^0_t) changes accompanying the transfer of 1 mole of HCl from the standard state in water (w) is that in each of the ionic cosolvent compositions (s), i.e. of the process HCl (w) → HCl (s) were computed on the mole fraction scale at 25°C by the usual relations [5]–[7]

$$[5] \quad \Delta G^0_t = -F[(E^0_m)^{25}_s - (E^0_m)^{25}_w] - 2RT \ln M_s/M_w$$

[3] A complete set of the data referred to above may be purchased from the depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]The coefficients a, b, and c of eq. [4] for water have been calculated with the help of E_m^0 values at different temperatures taken from ref. 29.

[6] $$\Delta S_t^0 = F(b_s - b_w) + 2F(t - 25)(c_s - c_w) + 2R \ln M_s/M_w$$

[7] $$\Delta H_t^0 = \Delta G_t^0 + T\Delta S_t^0$$

and are listed in Table 3. The estimated uncertainties (30) in ΔG_t^0 and ΔS_t^0 values are ±0.03 kJ mol^{-1} and ± 2 J K^{-1} mol^{-1}, respectively.

Discussion

From Fig. 1 it can be seen that ΔG_t^0–composition profile of HCl exhibits a slight roller-coaster type behaviour. This is possibly due to the involved opposite effects of the constituent ions. That this is partly true is evident from the ΔG_t^0–composition profiles for H^+ and Cl^- (Fig. 1), as obtained by use of the modified form of the widely-used tetraphenylarsonium tetraphenylborate reference electrolyte assumption (31) described in another paper (32).

As these profiles show, while $\Delta G_t^0(H^+)$ values are more or less increasingly positive with a slight hump around 1 m $NaNO_3$, $\Delta G_t^0(Cl^-)$ values decrease sharply till 1 m $NaNO_3$ and then remain almost invariant up to 4 m. Apparently, while H^+ is increasingly destabilized, Cl^- remains stabilized in these solvents compared to that in water. The breaks in destabilization of H^+ or stabilization of Cl^- around 1 m $NaNO_3$ are seemingly the result of change in solvating capacities of the aqueous $NaNO_3$ solutions and the superimposed destabilizing Born-type electrostatic effect on both the ions, because of the difference between the bulk dielectric constants of the solvents concerned.

Notably, as per our assumed standard state, at infinite dilution of HCl in each of the compositions of the ionic cosolvent system $(\gamma_\pm)_{HCl} = 1$. This implies that just as in the aquo-organic cosolvents, the interactions between water and oragnic cosolvents do not influence the ideal behaviour of HCl, so do the interactions of the ionic constituents of the ionic cosolvent among themselves or with water molecules in the respective solvent compositions. Consequently, $\Delta G_t^0(i)$ values accompanying the transfer of either of the ions from the standard state in the reference solvent, water to the corresponding state in any of the cosolvent compositions are likely to be governed by the net effects of attractive ion–ion interactions between the oppositely charged ions of the solute and ionic cosolvent species, viz. H_3O^+ and NO_3^- and Cl^- and Na^+ and the repulsive interactions between the similarly charged ions viz. H_3O^+ and Na^+ and Cl^- and NO_3^-, relative to those in water.

As expected (18–22), due to their small size and large ionic force field, Na^+ ions are to some extent hydrated. But being relatively large in size and having the formal charge delocalized on three O-atoms, NO_3^- ions are comparatively less hydrated (18–22) or even unhydrated as the negative value of the viscosity B-coefficient and the positive value of dB/dT data (18*b*) suggest. The observed increased stabilization of Cl^- therefore suggests that the resulting attractive interaction of Cl^- and $(Na^+)_{aq}$ over the repulsive interaction of Cl^- and NO_3^- exceeds the Cl^-–H_2O interaction in pure water. This is probably due to the fact that H_2O molecules in the hydration cosphere round Na^+ have more protonic character (δ^+) than that in pure water and hence are likely to induce more "acid–base" type (33) short-range attractive interaction with Cl^- than that in pure water. The observed increased destabilization of H^+, on the other hand, suggests that the attractive interaction of H_3O^+ (rather than the bare proton) with delocalized (δ^+) charge on three H atoms, and the NO_3^- with delocalized (δ^-) charge on three O atoms is overcome by the possible larger repulsive interaction between H_3O^+ and $(Na^+)_{aq}$. This is because the repulsive effect of more protonic character of the H_2O molecules in the hydration cosphere of Na_{aq}^+ might exceed the attractive interaction of H_3O^+ with NO_3^-. Besides, the repulsive interaction is also likely to be augmented by the larger stability of H_3O^+ in pure water because of its intrinsic structural propensity towards pure water.

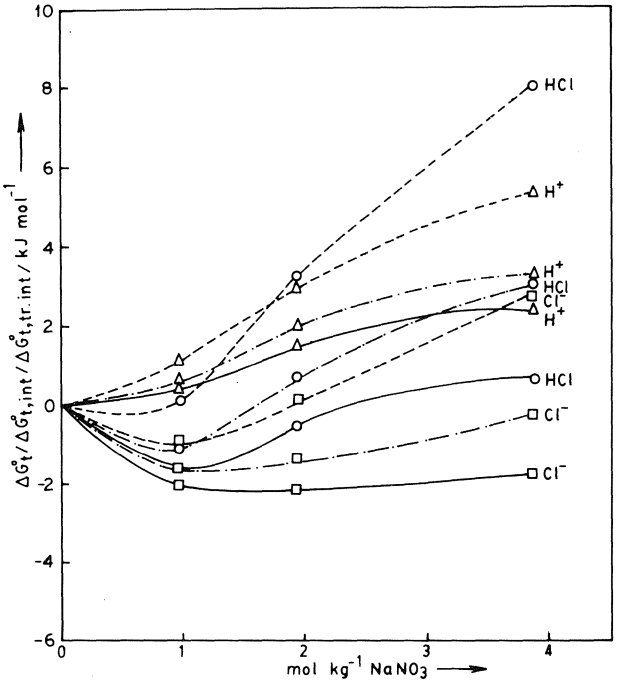

FIG. 1. Variation of ΔG_t^0(—), $\Delta G_{t,int}^0$(---), and $\Delta G_{t,tr.int}^0$ (-·-·-) of HCl (○), H^+ (△), and Cl^- (□) with molality of $NaNO_3$ in aqueous $NaNO_3$ solution.

The observed humps/breaks in ΔG_t^0–composition profiles of H^+ and Cl^- around 1 *m* $NaNO_3$ are possibly associated with the change in solvating species of this ionic solvent system. This is because, as various spectroscopic evidences referred to earlier (21, 22) indicate, around 0–1.5 *m* $NaNO_3$ solution constituent ions mostly exist as Na_{aq}^+ and $(NO_3^-)_{aq}$. But around 1.5 to 6 *m* $NaNO_3$ these ions are increasingly replaced by solvent-separated ion-pairs like $^-O_3N(H_2O)_nNa^+$. Evidently, alteration in the solvating characteristics due to the change in the solvating species is likely to induce some breaks in the relative solvation of the cations and anions, as observed.

Entropies of transfer

Since $T\Delta S_t^0$(HCl) rather than H_t^0(HCl) should be more informative regarding the structuredness of the solvents (2), let us discuss the observed $T\Delta S_t^0$(HCl)–composition profile at 25°C as illustrated in Fig. 2, where ΔH_t^0– and ΔG_t^0–composition profiles are also illustrated for the sake of comparison. Strikingly enough, unlike ΔG_t^0, both $T\Delta S_t^0$– and ΔH_t^0–composition profiles exhibit maxima around 1 *m* $NaNO_3$. This is of course contrary to the smooth downward trends observed in the cases of non-electrolytes like benzoic acid (HBz) in aqueous LiCl and KBr (7*d*) or *p*-nitroaniline (pNA) in aqueous KBr (7*e*) and as expected from the 3D structure breaking propensity of $NaNO_3$ (16, 18*b*) if water would have been the sole solvating species. Evidently, complex structural contributions are involved in the transfer of HCl, unlike that of HBz or pNA where the solvating species are water molecules alone. Thus careful analysis of ΔS_t^0(HCl) is in order.

Following Kundu *et al.*'s (7*a*, 34) four-step transfer process, if we assume that $\Delta S_{t,\text{non-Born}}^0$(HCl) involves (*1*) break down of hydration sphere round H^+ and Cl^- in water with an increase in entropy, ΔS_1^0; (*2*) formation of characteristic 3D structure of water with a decrease to entropy, $-\Delta S_2^0$; (*3*) break down of relevant structure of $NaNO_3$ + water solution or relevant solvation shell round Na^+ or NO_3^- to solvate the transferred ions with an increase in entropy, $+\Delta S_3^0$; and (*4*) formation of solvation spheres round the incoming ions in $NaNO_3$ solutions of the cosolvent and their interactions with oppositely charged ionic constituents with a decrease in entropy, $-\Delta S_4^0$, then

$$[8]\quad \Delta S_{t,\text{non-Born}}(\text{HCl}) = \sum_{i=1}^{i=4} \Delta S_i^0 = \Delta S_1^0 - \Delta S_2^0 + \Delta S_3^0 - \Delta S_4^0$$

Since steps (*1*) and (*2*) refer to water, $(\Delta S_1^0 - \Delta S_2^0)$ should be a constant positive quantity. So, the overall positive or negative magnitudes of $(\Delta S_3^0 - \Delta S_4^0)$ will dictate $\Delta S_{t,\text{non-Born}}^0$(HCl) which again will depend on the relative affinity of H^+ and Cl^- ions towards the solvating components of aqueous $NaNO_3$ solutions, besides the relative structuredness of aqueous $NaNO_3$ solutions.

As indicated earlier, in the lower concentrations of $NaNO_3$ (up to about 1.5 *m*) the prevalent ionic species are free Na^+_{aq} and $(NO^-{}_3)_{aq}$. ΔS_3^0 is likely to be a large positive quantity and consequently the amalgamated effects of $\Delta S_{t,\text{Born}}^0$(HCl) and $(\Delta S_1^0 - \Delta S_2^0 + \Delta S_3^0)$ are likely to be greater than $-\Delta S_4^0$, thus imparting an increasingly positive trend of ΔS_t^0(HCl), as observed. But after 1.5 *m* the prevalent ionic species in $NaNO_3$ solution are solvent-separated ion-pairs such as $^-O_3N(H_2O)_nNa^+$ (21, 22), ΔS_3^0 might be less positive as H^+ and Cl^- are likely to be solvated respectively through NO_3^- and Na^+ of the solvent-separated ion-pairs. Thus $(\Delta S_3^0 - \Delta S_4^0)$ becomes increasingly negative and possibly overcomes the effect of positive magnitudes of $(\Delta S_1^0 - \Delta S_2^0)$, thus resulting in a sharp fall in $T\Delta S_t^0$ after exhibiting a maximum around 1 *m* $NaNO_3$. The observed upward trend beyond 3 *m* $NaNO_3$, however, is possibly attributable to the amalgamated effects of superimposed "cavity effect" (7*d*, 7*e*, 35) and Born-type electrostatic interactions, both of which should be increasingly larger in magnitudes at higher compositions.

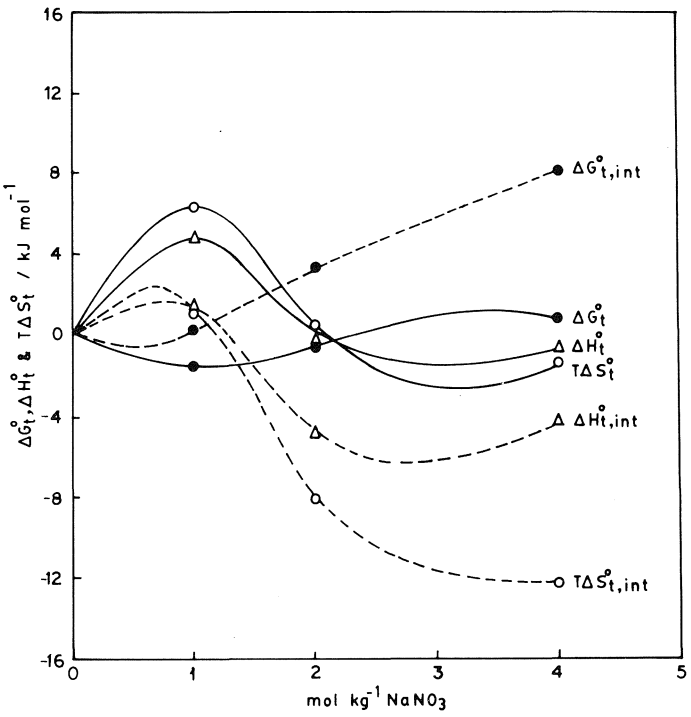

FIG. 2. Variation of ΔG_t^0 (○), ΔH_t^0 (△), and $T\Delta S_t^0$ (○) (all solid lines) and $\Delta G_{t,\text{int}}^0$ (○), $\Delta H_{t,\text{int}}^0$ (△), and $T\Delta S_{t,\text{int}}^0$ (○) (all broken lines) of HCl with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

Although computation of Born-type electrostatic contribution for ΔS_t^0 is not feasible at this stage as dielectric constants at different temperatures are not known for this solvent system, that for "cavity effect" is feasible and should be rewarding.

This is because, as indicated by various authors (35–40), ΔP_t^0 (P = G, S, or H) is composed of two parts, where one part ΔP_t^0(cav) is associated with the creation of a cavity of suitable size to accommodate the solute and the other part ΔP_t^0(int) is associated with the interaction of the solvent molecules surrounding the cavity among themselves as well as the solute, both relative to that in water, i.e.

$$[9]\quad \Delta P_t^0 = \Delta P_t^0(\text{cav}) + \Delta P_t^0(\text{int})$$

The scaled particle theory (SPT) (37), though originally used to compute the "cavity effect" of some thermodynamic quantities for some non-ionic apolar solutes in water, is also increasingly used (7*d*, 7*e*, 35–40) for solutes, (apolar (37, 38) and polar (7*d*, 7*e*), and large (13*e*–*h*, 35, 39, 40) and small (13*e*–*h*, 36) ions. It is used not only in water, organic solvents and their aqueous mixtures, but also in aqueous ionic solutions (40). Thus following a procedure exactly similar to that in the cases of HBz and pNA (7*d*,*e*) in various ionic and non-ionic cosolvent systems, we have computed the molar free energy, enthalpy, and entropy of cavity formation for H_3O^+ and Cl^- with the help of SPT relations. The values of ΔG_t^0(cav), $T\Delta S_t^0$(cav), and ΔH_t^0(cav) obtained at T = 298.15 K on mole

TABLE 4. Values of free energy ($\bar{G}_c$) and enthalpy ($\bar{H}_c$) of cavity formation of H^+ and Cl^- and ΔG_t^0(cav) of ΔH_t^0(cav) and $T\Delta S_t^0$(cav) of HCl and the required solvent parameter α and $\Delta G_{t,Born}^0$(i) of H^+ and Cl^- in different $NaNO_3$ + water mixtures at 25°C

[a]The required diameters of "a" of H_2O, Na^+ and NO_3^- of the solvent constituents are taken to be 0.276 (39), 0.192 (25), and 0.248 (42) nm, respectively, and those of the solute H^+ and Cl^- to be 0.276 (41) and 0.362 (25) nm, respectively. Also vide ref. 7d,e, where $\bar{G}_c$ and $\bar{H}_c$ are denoted as $\bar{G}$(cav) and $\bar{H}$(cav), respectively, and $\alpha = -\mathrm{d} \ln d_s/\mathrm{d}T$.

[b]The required values of the scale effect, i.e., $RT \ln V_w/V_s$ are obtained from density data of the solvents given in Table 1.

[c]The required radii of H^+ and Cl^- are taken as 0.276 and 0.181 nm (41) and the dielectric constant ϵ_s from Table 1.

fraction scale are given in Table 4. The transfer energies ΔG_t^0(int)–, $T\Delta S_t^0$(int)–, and ΔH_t^0(int)–composition profiles of HCl are illustrated in Fig. 2 and the ΔG_t^0(int)–composition profiles for H^+ and Cl^- obtained from another paper (32) in Fig. 1.

Thus it can be seen from Fig. 1 that ΔG_t^0(int)–composition profiles of both H^+ and Cl^- are shifted increasingly upward from the corresponding profiles of ΔG_t^0, which imply that both the ions are relatively more stabilized due to "cavity" effect. Again, if we tentatively compute the Born-type electrostatic effect $\Delta G_{t,Born}^0$ resulting essentially from the difference of dielectric constants of the solvents concerned, using the simple Born equation (41), and subtract from the respective ΔG_t^0(int) values of H^+ and Cl^-, we find that the resulting $\Delta G_{t,tr.int}^0$(i) ($= \Delta G_{t,int}^0$(i) $- \Delta G_{t,Born}^0$(i)) composition profiles are again shifted downward (Fig. 1). This leads us to conclude that in the case of small ions like H^+ and Cl^-, although ΔG_t^0(cav) plays an important role, the opposing Born-type electrostatic interaction nullifies the cavity effect to a large extent, at least where the dielectric constant of the solvents decreases with compositions and that the cavity effect for non-electrolytes in particular, plays a significant role in dictating the observed ΔG_t^0 values.

Again from Fig. 2, it can be observed that $T\Delta S_t^0$(int)–composition profile though still retains the "characteristic maxima" at the lower composition region, after about 1 m $NaNO_3$ the profile takes a more downward trend than the corresponding $T\Delta S_t^0$–composition profile. This indicates that the "cavity effect" plays a fairly important role in dictating the overall transfer entropic behaviour of HCl in this ionic solvent system and possibly in aquo-organic solvent systems as well. The observed downward trend of the profile at higher compositions is consistent with increased order around H^+ and Cl^- with interacting oppositely charged ionic constituents of the ionic cosolvent as well as the expected 3D-structure breaking of water due to packing imbalance. But whether small additions of $NaNO_3$ would break down 3D structure of water will be evident if the Born-type electrostatic effect, $T\Delta S_{t,Born}^0$(HCl) (41) is increasingly positive in this solvent system. Admittedly, since the temperature coefficient of the dielectric constant (ϵ_s) is not known for this salt solution, it is not feasible to compute Born-type electrostatic contributions, $\Delta S_{t,Born}^0$ and hence to predict the real nature of $T\Delta S_{t,tr.int}^0$ ($= T\Delta S_{t.int}^0 - T\Delta S_{t,Born}^0$)–composition profile. However, as per tenets of the four-step transfer process proposed earlier (7*a*) for aquo-organic solvents, the relative order of the corresponding profiles for HX (X = Cl, Br, and I) at least, is likely to reflect the 3D structure breaking/making propensity of $NaNO_3$.

Thus, just as $\Delta S_{t,int}^0$ rather than ΔS_t^0 for a non-electrolyte like HBz (7*d*) or pNA (7*e*) conformed to the dictation of Kundu *et al.*'s theory for solvent structuredness, $\Delta S_{t,tr.int}^0$ rather than $\Delta S_{t,int}^0$ or ΔS_t^0 of ionic solutes, as the present results suggest, should really stand for the overall entropy changes involved in Kundu *et al.*'s four-step transfer process. It is therefore concluded that the "cavity effect" significantly contributes to the observed ΔS_t^0 and the rest ΔS_t^0(int) in the case of non-electrolytes and $\Delta S_{t,tr.int}^0$ in the case of electrolytes, being appertained more to the theory, should give a better reflection of the solvent structural features relative to that in water. Admittedly of course, the magnitudes of both cavity effect and Born-type electrostatic interaction are somewhat tentative because of various limitations and uncertainties. Yet the conclusions based on the relative trends of the different propensities are likely to be meaningful.

MIGUEL A. POSTIGO, JOSÉ L. ZURITA, MARÍA L. G. DE SORIA, and MIGUEL KATZ. Can. J. Chem. **64**, 1966 (1986).

Densities, refractive indices, viscosities, enthalpies, vapor–liquid equilibria, and surface tensions were determined for the *n*-pentane + dichloromethane system at 298.15 K. From the experimental results, excess molar volumes, excess viscosities, excess molar enthalpies, excess molar Gibbs free energies, and excess surface tensions were calculated. From these data, qualitative information could be obtained about the interaction between both chemical species.

MIGUEL A. POSTIGO, JOSÉ L. ZURITA, MARÍA L. G. DE SORIA et MIGUEL KATZ. Can. J. Chem. **64**, 1966 (1986).

Opérant à 298,15 K, on a déterminé les densités, les indices de réfraction, les viscosités, les enthalpies, les équilibres vapeur/liquide et les tensions superficielles du système *n*-pentane + dichlorométhane. A l'aide des données expérimentales, on a calculé les volumes molaires en excès, les viscosités en excès, les enthalpies molaires en excès, les ènergies libres molaires de Gibbs en excès et les tensions superficielles en excès. Sur la base de ces données, on en a déduit des informations qualitatives relativement aux interactions entre les deux espèces chimiques.

[Traduit par la revue]

Introduction

Excess properties such as v^E (excess molar volume); η^E (excess viscosity); h^E (excess molar enthalpy); g^E (excess molar Gibbs free energy), and σ^E (excess surface tension) have been studied to obtain information about the interaction between the molecules of the system *n*-pentane (1) + dichloromethane (2) at 298.15 K.

This work is a continuation of our research on the thermodynamic properties of binary liquid mixtures of non-electrolytes (1–3).

Densities, refractive indices, viscosities, enthalpies, vapor–liquid equilibria, and surface tensions at different mole fractions for this system were measured. In this system component (1) is non-polar and component (2) is highly polar without association in the pure state.

Experimental

The methods used in our laboratory have been described previously (1–3). Densities were determined with a Robertson specific gravity bottle. The total pycnometer volume was about 20 mL; calibration was done with doubly distilled water with an error of ± 0.1 kg m^{-3}. All weighings were made on a H315 Mettler balance. A thermostatically controlled bath (constant to ± 0.01°C) was used. Temperatures were read from calibrated thermometers. Refractive indices for the sodium D line of the pure components and of the mixtures were determined with a Jena dipping refractometer with an estimated error of ± 0.00002.

Viscosities of the pure liquids and of the mixtures were determined with a Cannon-Fenske viscosimeter calibrated with doubly distilled water and benzene. Kinetic energy corrections were applied to viscosity data. The estimated error was ± 0.005 mPa s. During measurements, both the pycnometer and the viscosimeter were maintained in the bath until at least two consecutive values of the liquid height in the capillaries of the flow time, indicated that the sample had reached the temperature of the bath.

The adiabatic calorimeter described by Loiseleur *et al.* (4) was used with some modifications to determine the change of enthalpy. The estimated error was ± 5 J mol^{-1}.

Vapor–liquid equilibria data were determined by using a modified version of the equilibrium still described by Boublik and Benson (5), with an estimate error of ± 0.05 kPa in pressures. Pressures were determined from boiling points of water in a ebulloscope adapted to the equipment. Temperatures were read with a Digitec thermometer to 0.01°C. Compositions of liquid phases and condensed vapor phases were determined by measuring refractive indices. Finally, surface tensions of the pure liquids and their binary mixtures were determined by the maximum bubble pressure method (6). The bubbler was calibrated with benzene (Baker puriss.) assuming a surface tension of 28.10×10^{-3} N m^{-1} for that material at 298.15 K. Values of the surface tension were generally reproducible to $\pm 0.05 \times 10^{-3}$ N m^{-1}.

Materials and solutions

n-Pentane Carlo Erba (puriss.) was distilled over phosphorous pentoxide and the middle fraction was collected and dichloromethane Merck (puriss.) was fractionally distilled over anhydrous calcium chloride and the middle colorless fraction was collected. Mixtures were prepared by mixing weighed amounts of the pure liquids. Caution was taken to prevent evaporation.

Results

The experimental results for the pure liquids are reported in Table 1 together with the values from the literature for comparison.

The excess thermodynamic functions were calculated with the following equations:

$$[1] \quad v^E = v - (x_1 v_1 + x_2 v_2)$$

$$[2] \quad \eta^E = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

$$[3] \quad h^E = h - (x_1 h_1 + x_2 h_2)$$

$$[4] \quad g^E = RT(x_1 \ln \gamma_1 + x_2 \ln \gamma_2)$$

$$[5] \quad \sigma^E = \sigma - (x_1 \sigma_1 + x_2 \sigma_2)$$

where v, v_1, and v_2 are the molar volume of the system and of the pure components; η, η_1, and η_2 are the viscosity of the mixtures and of the pure components; h, h_1, and h_2 are the molar enthalpy of the mixtures and of the pure components; γ_1 and γ_2 are the activity coefficients of the components in the liquid phase, and σ, σ_1, and σ_2 are the surface tension of the mixtures and of the pure components.

The molar volume of the mixtures is defined by:

$$[6] \quad v = (x_1 M_1 + x_2 M_2)/\rho$$

where M_1 and M_2 are the molar weights of the components and ρ the density of the solution.

Table 2 shows the experimental values of densities, refractive indices, viscosities, enthalpies, and surface tensions for this binary system at various mole fractions in a wide range of concentrations.

The activity coefficients of the components in the liquid phase are related to the vapor–liquid equilibria by the following equation:

$$[7] \quad \ln \gamma_i = \ln \frac{y_i p}{x_i p_i} + (B_{ii} - v_i)(p - p_i)/RT + (1 - y_i)^2 \frac{p\delta}{RT}$$

where x_i and y_i are the mole fractions in the liquid and vapor phase respectively; p_i is the vapor pressure of the component i; p is the total pressure of the mixture, and δ is given by the following equation:

$$[8] \quad \delta = 2B_{12} - B_{11} - B_{22}$$

B_{11} and B_{22} are the virial coefficients of the pure components and B_{12} is the cross virial coefficient. For *n*-pentane, $B_{11} = -1.184 \times 10^{-3}$ m^3 mol^{-1}; for dichloromethane, $B_{22} = -0.862 \times 10^{-3}$ m^3 mol^{-1}, and $B_{12} = -0.920 \times 10^{-3}$ m^3 mol^{-1}. These virial coefficients were estimated by the method of Hayden and O'Connell (7).

Table 3 shows the experimental values of mole fractions, pressures, and activity coefficients for this system.

Each set of results of the excess thermodynamic properties were fitted with a Redlich–Kister form of the type:

$$[9] \quad X^E = x_1(1 - x_1) \sum_{j=1}^{n} a_j (1 - 2x_1)^{j-1}$$

The method of least squares was used to determine the values of the coefficients a_j. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with:

$$[10] \quad \epsilon = [\Sigma (X^E_{obs} - X^E_{cal})^2/(n_{obs} - n)]^{1/2}$$

The values adopted for the coefficients and the standard error of the estimate associated with the use of eq. [10] are summarized in Table 4.

Figure 1 shows the experimental values for the v^E, η^E, and σ^E while Fig. 2 shows the experimental values of h^E and g^E. The excess molar entropy is given by the following equation:

$$[11] \quad s^E = (h^E - g^E)/T$$

and the curve Ts^E at 298.15 K is also shown in Fig. 2. The

continuous curves were calculated from eq. [9] using these values for the coefficients.

Discussion

Figure 1 shows positive excess volumes over the whole concentration range. Several effects may contribute to the values of v^E, such as the breaking of liquid order on mixing, unfavorable interaction between groups, differences in molecular volumes, and differences in free volumes between liquid components (8). The two first effects produce a positive excess volume and considering that neither of the components exhibits hydrogen bonding in the pure state, dispersion forces must be dominant (9). Generally, a positive excess volume corresponds to a negative excess viscosity as in this system. More qualitative evidence of this interaction is the large excess enthalpy for this system, about 1400 J mol^{-1} at $x_1 \cong 0.4$

Dichloromethane is a polar molecule which induces a dipole moment on non-polar molecules like *n*-pentane, due to the inductive effect of the chloro group. The endothermic effect of rupture of molecular order is corroborated by the excess free energy and molar entropy, both of which are positive, but smaller than h^E.

Normally, due to Gibbsean enrichment of the component with lower surface tension in the surface phase, σ^E is negative for most binary mixtures of non-polar, small sized or non-associated components. In this case, *n*-pentane is non-polar, then, enrichment of the surface area with *n*-pentane produces a negative σ^E.

La décomposition thermique de l'azidoformiate d'éthyle dans un excès de téréphtalate de diméthyle (TDM) (**1**) et dans l'anhydride acétique comme solvant conduit à la formation de *N*,*N*-dicarbéthoxy dicarbométhoxy-4,8 diaza-2,6 bicyclo[3.3.0]octadiène-3,7 (**3**) aux côtés de la *N*-carbéthoxy dicarbométhoxy-2,5 1*H*-azépine (**2**) et du *N*-(dicarbométhoxy-2,5 phényl) carbamate d'éthyle (**4**). On a déterminé la structure du diazabicyclooctadiène (**3**) en se basant sur des données spectrales, sur des analyses élémentaires et sur la diffraction des rayons-X.

[Traduit par la revue]

Introduction

The thermal decomposition of ethyl azidoformate in benzene, toluene, chlorobenzene, biphenyl, *o*-, *m*-, and *p*-xylenes has been shown to form the corresponding *N*-carbethoxy-1*H*-azepine (1, 2). The synthesis of azepines using the nitrene generated from azidoformate has also been reported by Hafner and Konig (3) and Lwowski *et al.* (4). These authors have mainly dealt with the nitrene insertion into aromatic substrate bearing electron-donating substituents. Formation of *N*-(*p*-toluenesulphonyl)-1*H*-azepine by the thermolysis of *p*-toluenesulphonylazide in benzene and the kinetic study of the reaction were reported by us (5*a*, 5*b*). The nitrene generated by the thermolysis of *p*-toluenesulphonylazide has been shown to react with dimethyl terephthalate (DMT) resulting in the formation of *N*-*p*-toluenesulphonyl-2,5-dicarbomethoxy-1*H*-azepine (5*c*). It has been indicated that the stabilising influence of the electron-withdrawing carbomethoxy substituent on the benzaziridine intermediate complex, leads preferentially to the formation of the *N*-sulphonyl-1*H*-azepine (6*a*). In this paper, the formation of a new heterocyclic compound *N*,*N*-dicarbomethoxy-2,6-diazabicyclo[3.3.0]octa-3,7-diene (3) by the thermolysis of ethyl azidoformate in DMT has been described.

Results and discussion

Thermolysis of ethyl azidoformate was initially carried out in molten DMT (**1**) at 160°C at atmospheric pressure which resulted in an *explosive reaction* with visible flame (6*b*). Thermolysis was therefore carried out in acetic anhydride, apparently a good solvent for this reaction. Acetic anhydride not only absorbed the heat of the reaction but also provided the critical reaction temperature. Thus, the reaction of ethyl azidoformate with DMT (1) in refluxing acetic anhydride yielded in addition to *N*-carbethoxy-2,5-dicarbomethoxy-1*H*-azepine (**2**) and ethyl *N*-(2,5-dicarbomethoxyphenyl)carbamate (**4**), a bicyclic heterocycle containing two nitrogen atoms, the structure of which has been established as *N*,*N*-dicarbethoxy-4,8-dicarbomethoxy-2,6-diazabicyclo[3.3.0]octa-3,7-diene (**3**) on the basis of spectral, elemental, and X-ray crystallographic analyses. The identity of the carbamate (**4**) was confirmed by an unambiguous synthesis from dimethyl amino terephthalate. A similar observation involving the formation of diazabicyclo-octadienes by the reaction of a nitrene with 1,4-di-*tert*-butyl or 1,4-di-isopropyl benzenes has been reported recently (7*a*). In a more recent work, the synthesis of dihydropyrrolo[3,2-*b*] pyrrole starting from 1,4-bis(trimethylsilyl)benzene, a 10π-aromatic compound which incorporates the diazabicyclo[3.3.0] framework, has been reported (7*b*).

The uv spectrum of azepine (**2**) shows a low intensity broad band at 350 nm, which extends into the visible region giving the compound its yellow colour. The ir absorption bands at 1470 cm^{-1} (strong) and 1640 cm^{-1} (weak) for **2** are characteristic of cyclic conjugated double bonds of the azepine ring. In the ir spectrum of **3**, the C=C and C—H stretching vibrations are manifested as sharp absorptions at 1610 cm^{-1} and 3100 cm^{-1}, respectively. In the ^{1}H-nmr spectrum, the azepine ring protons of **2** appear as a multiplet at 6.0 to 7.2 ppm. The alternative azepine, **5**, which should have highly symmetrical ^{1}H-nmr pattern (two singlet peaks appearing for protons at C(2)/C(7) and C(4)/C(5), respectively) could not be isolated from the reaction mixture in spite of several careful attempts to do so. ^{1}H-nmr spectrum of **3** shows a sharp singlet at 5.6 ppm integrating for two protons at 1,5-*cis* junction whereas those at C(3) and C(7) are seen as a sharp singlet at 7.3 ppm. The down-field shift into the aromatic region is caused by the presence of the electron-withdrawing carbomethoxy substituents.

The X-ray crystallographic data show that molecule **3** is under steric strain, since the two five-membered dihydropyrrole rings are inclined at an angle of 66.9°. Apparently, this strain is released during the mass spectral fragmentation of **3** with the formation of aromatic product ions. The mass spectrum of **3** shows strong molecular ion at m/z 368 (Scheme 1). The steric strain in the molecular ion is released by homolytic cleavage of C(1)—C(5) bond which is β to the ionised nitrogen atom at 2

(or 6) position, generating radical centre at C(5) (or C(1)) carbon atom (**3***a*). Loss of carbethoxy radical from **3***a* generates a strong peak at *m/z* 295, attributable to the cation **3***b*. The elimination of hydrogen cyanide from **3***b* gives rise to radicals at C(4) and C(7), respectively. Subsequent bond formation generates the *N*-substituted pyridinium cation **3***c* (*m/z* 268). The stepwise loss of carbon dioxide and ethylene molecules results in the formation of strong 3,5-dicarbomethoxy pyridinium cation at *m/z* 196.

The 2,6-diazabicyclo[3.3.0] framework, the 1,5-*cis* junction, and the positions of the two carbomethoxy substituents in **3** were firmly established by X-ray crystallographic analysis.

X-ray crystallography

Crystal data

$C_{16}H_{20}N_2O_8$ fw = 368.35

Monoclinic, a = 15.976(1), b = 4.561(1), c = 28.024(3) Å, β = 120.30(1)°, V = 1763.07 Å^3, $A2/a$ (standard $C2/c$), Z = 4, ρ_c = 1.39, ρ_o = 1.39 mg M^{-3} (flotation in KI solution), MoKα (λ = 0.7107 Å), T = 293 K, $F(000)$ = 776.0.

Crystals of **3** were found to be very soft and tend to bend on cutting. It is interesting to note that these bent crystals diffracted weakly and also indicated reflections which otherwise are systematically absent for the monoclinic ($A2/a$) space group. However, it was possible to procure an uncut crystal of size 0.06 × 0.1 × 0.6 mm which diffracted well and showed no "unusual" reflections.

Data collection was done on an Enraf-Nonius CAD4F-11M diffractometer. The intensity data (1545 reflections were measured, 883 of which were judged significant $|F_o| \geq 3\sigma|F_o|$) were collected with ω/2θ scan technique, scan speed 1°/min up to θ = 23.5°. During the data collection, three standard reflections (6 0 0, $\bar{4}\,\bar{2}\,\bar{2}$, 0 0 10) showed statistical variation within ±2% in intensity, *hkl* range *h*, 0 to 17; *k*, 0 to 5; *l*, −31 to 31; data were not corrected for absorption (μ = 1.21 cm^{-1}). The lattice parameters were refined using 25 reflections (12° ≤ θ ≤ 21°).

The structural aspects were studied by direct methods using MULTAN-78 (Main *et al.*, 1978) (8). A full-matrix least-squares refinement of a scale factor, positional and anisotropic thermal parameters (isotropic thermal parameters for H atoms; located from a difference map) using program LALS (Gantzel *et al.*, 1961) (9*a*) resulted in a final R ($R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$) of 0.032 for 883 reflections with $|F_o| \geq 3\sigma|F_o|$. A Cruickshank type weighting scheme was used with $W = (7.0 + 1.0|F_o| \pm 0.009|F_o|^2)^{-1}$. The final difference Fourier map has $\Delta\rho < |0.3|$ e Å^{-3} and thus is of no chemical significance. The atomic parameters with their esd's and equivalent isotropic temperature factors for non-hydrogen atoms are listed in Table 1. Table 2 gives the bond length and bond angles involving non-hydrogen atoms. List of structure factors, anisotropic thermal parameters, H atom positions with isotropic temperature factor tables are in the Depository of Unpublished Data.[5] Atomic scattering factors are taken from the International tables for X-ray crystallography (9*b*).

Each half of the molecule (x, y, z) is related by symmetry to the other half ($\frac{1}{2} - x$, y, z). Figure 1 gives a perspective view of the molecule along with crystallographic numbering. The dihydropyrrole rings of the diazabicyclo[3.3.0]octa-3,7-diene adopt an "envelope" conformation. The dihedral angle between the best planes through the two five-membered rings is 66.9°. The molecules are held together in the crystal structure by pure van der Waals interactions.

The singlet carbethoxy nitrene (**I**) generated by thermolysis of ethyl azidoformate adds to the aromatic double bond of DMT to produce a benzaziridine intermediate (**I′**) (Scheme 2). The attack preferentially takes place at the carbon atom bearing the carbomethoxy substituent. The benzaziridine intermediate (**I′**) undergoes sigmatropic ring opening to give rise to the azepine (**2**). The C—N bond fission followed by aromatisation yielded the carbamate (**4**). The alternative structure (**5**) for the azepine (**2**) has been ruled out on the basis of the ^{1}H-nmr spectrum, as discussed earlier. The azepine (**5**) could neither be

detected nor isolated in spite of several careful attempts to do so. The thermolysis of *p*-toluenesulphonylazide in DMT under nitrogen pressure of 62 atm yielded *N*-(*p*-toluenesulphonyl)-2,5-dicarbomethoxy-1*H*-azepine in 71% yield. Formation of 3,6-dicarbomethoxy isomer was not detected (6*b*). Further, the diazabicyclooctadiene (**3**) cannot be a product of reaction of carbethoxy nitrene with the azepine (**2**). The mechanistic considerations would have given rise to the structure (**6**) starting from **2** whereas the positions of the carbomethoxy substituents were firmly established as in **3** by X-ray analysis. The diazabicyclooctadiene (**3**) could not be detected in the products resulting from the reaction of the azepine (**2**) with equimolar proportion of ethyl azidoformate under identical reaction conditions.

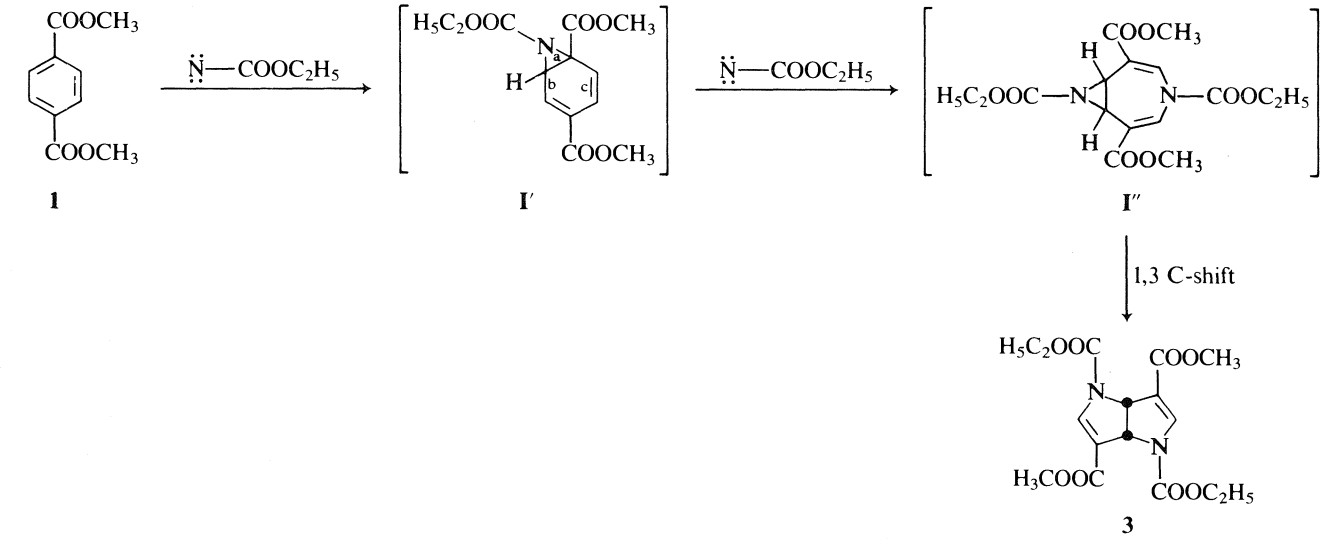
In light of the above comments, a probable reaction pathway for the formation of **3** has been shown in Scheme 2. The approach of the carbethoxy nitrene to the benzaziridine intermediate (**I′**) triggers a nitrogen walk from bond *a* to bond *b* and the nitrene adds across double bond *c* in a concerted manner. The concerted sequence of reactions is also accompanied by a simultaneous ring opening, eventually giving rise to the azahomoazepine intermediate (**I″**). The diazabicyclooctadiene (**3**) is then formed from a 1,3-carbon migration of (**I″**).

Experimental

Melting points were recorded in capillary tubes. Ultraviolet spectra were recorded on a Perkin-Elmer 350 spectrophotometer, ir spectra on a Perkin-Elmer 221 spectrophotometer, ^{1}H-nmr spectra on a Varian T-60 spectrometer using TMS as the internal standard, and mass spectra on a CEC-21-110-B double focussing spectrometer using direct inlet gas system. Petroleum ether used was of the boiling range 60–80°C. Ultraviolet wavelength maxima are in nm, ir frequencies are in cm^{-1}, and chemical shifts are in δ ppm.

Ethyl azidoformate

An aqueous solution of sodium azide (25 g, 0.38 mol) in water (70 mL) was added gradually over 1 h to ethyl chloroformate (17 g, 0.11 mol) under stirring, at room temperature. The reaction mixture was stirred further for 3 h. The organic layer was separated, washed with water, and distilled carefully under reduced pressure at 50°C to obtain ethyl azidoformate as a colourless liquid, in quantitative yield.



SCHEME 2

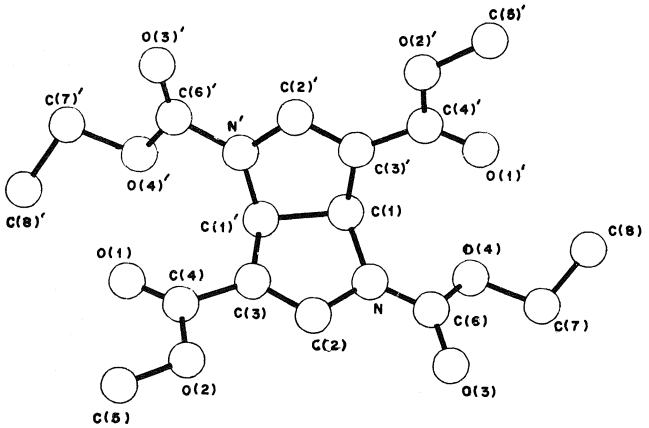


FIG. 1. A perspective view of diazabicyclooctadiene **3**.

N-*Carbethoxy-2,5-dicarbomethoxy-1* H-*azepine* (**2**)

A mixture of DMT (**1**) (40 g, 0.20 mol) and acetic anhydride (140 mL) was heated to reflux temperature (135°C) under stirring. Ethyl azidoformate (4 g, 0.034 mol) was added gradually over a period of 0.5 h. The reaction mixture was maintained at reflux for 2 h. At the end of the reaction, the acetic anhydride was removed under reduced pressure. The residual mass was subjected to fractional crystallisation in benzene, when the less soluble DMT crystallised out. In this manner, 30 g of unreacted DMT was recovered. The residual liquor from the crystallisations was adsorbed on silica gel and chromatographed through a silica gel column. Initial elution with petroleum ether gave more of the unreacted DMT (0.5 g). Next elution with petroleum ether – benzene (1:1) and recrystallisation from petroleum ether yielded deep yellow crystals of **2** (0.1 g, 1%) mp 93°C; uv (MeOH): 230 (log ϵ, 4.38) and 350 (3.28); ir (Nujol): 3000, 1701, 1640, 1587, 1450, 1316, 1268, 1180, 1130; ^{1}H-nmr ($CDCl_3$): 1.3 (t, 3H, —CH_3 of COOEt), 3.7 (s, 6H, $COOCH_3$), 4.3 (q, 2H, CH_2), 6.0 (d, 2H, C_3—H and C_6—H), 6.7 (m, 1H, C_4—H), and 7.2 (m, 1H, C_7—H); ms: m/z 281 (M^+, 100%), 250 (58), 208 (72), 207 (85), 180 (32), 178 (58), 149 (59), 122 (22). *Anal.* calcd. for $C_{13}H_{15}NO_6$: C 55.5, H 5.3, N 4.9; found: C 55.4, H 5.4, N 4.8.

N,N-*Dicarbethoxy-4,8-dicarbomethoxy-2,6-diazabicyclo[3.3.0]octa-3,7-diene* (**3**)

The chromatography of the reaction mass was continued with petroleum ether – benzene (1:1) as eluent. The compound **3** eluted out and was recrystallized from petroleum ether to yield colourless needles of **3** (0.15 g, 2.2%), mp 103°C; uv (MeOH): 260 (log ϵ, 3.55); ir (Nujol): 3100, 1710, 1620, 1460, 1250, 1030; ^{1}H-nmr ($CDCl_3$): 1.3 (t, CH_3 of COOEt), 3.7 (s, 6H, $COOCH_3$), 4.2 (q, 4H, CH_2 of COOEt), 5.6 (s, 2H, C_1-H and C_5-H) and 7.3 (s, 2H, C_3-H and C_4-H); ms: m/z 368 (M^+, 100%), 337 (55), 295 (28), 268 (48), 250 (18), 196 (55), 193 (58), 192 (59), 164 (58), 163 (42), 159 (50), 149 (35), 137 (38), 132 (39), 77 (25). *Anal.* calcd. for $C_{16}H_{20}N_2O_8$: C 52.2, H 5.4, N 7.6; found: C 52.3, H 5.6, N 7.5.

Ethyl N-*(2,5-dicarbomethoxyphenyl)carbamate* (**4**)

The chromatography was continued with benzene as eluent. The carbamate (**4**) eluted out and was recrystallised from petroleum ether to yield colourless needles of **4** (0.03 g, 0.33%), mp 134°C; ir (Nujol): 3300, 1750, 1730, 1710, 1600, 1450, 1320, 1250; ^{1}H-nmr ($CDCl_3$): 1.3 (t, 3H, CH_3 of COOEt), 4.0 (s, 6H, CH_3 of COOMe), 4.3 (q, 3H, Ar-H); ms: m/z 281 (M^+, 100%), 250 (92), 208 (95), 192 (92), 181 (88), 180 (92), 149 (78), 122 (20), 129 (98). *Anal.* calcd. for $C_{13}H_{15}NO_6$: C 55.5, H 5.3, N 4.9; found: C 55.4, H 5.4, N 5.0.

Dimethyl nitroterephthalate

DMT was nitrated by a procedure already reported (10). The dimethyl nitroterephthalate was recrystallised from ethanol as a white solid, mp 76°C (lit. (11) mp 76°C).

Dimethyl aminoterephthalate

The nitro derivative (10 g, 0.04 mol) was taken in methanol (200 mL) contained in a glass bottle mild pressure reactor. Palladium on carbon (12% w/w) (0.5 g) as catalyst was added to the mixture. The reactor was pressurised to 3 atm with hydrogen and maintained at room temperature with shaking for 2 h. The reaction mixture was filtered to remove the catalyst and methanol was removed by distillation. The crude reaction mixture was taken in benzene (300 mL) and extracted with dilute hydrochloric acid (20% w/w). The aqueous layer was separated out and neutralised with sodium carbonate solution (20% w/v). The amino derivative precipitated out and was crystallised from ethanol to yield pale yellow needles of dimethyl aminoterephthalate, (3.5 g, 40%), mp 134°C (lit. (12) mp 134°C).

Ethyl N-*(2,5-dicarbomethoxyphenyl)carbamate* (**4**)

A mixture of dimethyl aminoterephthalate (0.1 g, 0.00048 mol), ethyl chloroformate (100 mL) and sodium carbonate (0.1 g) was refluxed for 16 h. Excess ethyl chloroformate was distilled off under reduced pressure. The residue was recrystallised from petroleum ether to yield colourless needles of the carbamate (**4**), (0.05 g, 43%), mp 134°C.

Étude par résonance magnétique nucléaire du platine-195 de la réaction de *cis*-[Pt(éthylméthylsulfoxyde)$_2$Cl$_2$] avec un sel d'argent

F. D. Rochon et Louise Girard

Département de chimie, Université du Québec à Montréal, C.P. 8888, succursale A, Montréal (Qué.), Canada H3C 3P8

Reçu le 18 juillet 1985[1]

F. D. Rochon et Louise Girard. Can. J. Chem. **64**, 1974 (1986).

Les produits de la réaction du *cis*-[Pt(EMSO)$_2$Cl$_2$] (EMSO = éthylméthylsulfoxyde) avec le sulfate d'argent, ont été étudiés par la résonance magnétique nucléaire du ^{195}Pt. Les résultats ont mis en évidence l'existence de plusieurs espèces en solution aqueuse. L'étude a porté sur des réactions effectuées dans différentes conditions de pH et sur des produits de réaction neutralisés à différents degrés. De plus, les spectres de deux oligomères isolés ont été enregistrés. Le dimère et le trimère à ponts hydroxo produisent un signal autour de −2900 ppm tandis que les espèces monomériques hydrolysées ont des signaux autour de −3200 ppm. Cette étude a permis d'établir un profil semi-quantitatif des différents équilibres en solution.

F. D. Rochon and Louise Girard. Can. J. Chem. **64**, 1974 (1986).

The products of the reaction of *cis*-[Pt(EMSO)$_2$Cl$_2$] (EMSO = ethylmethylsulfoxide) with Ag_2SO_4 were studied by ^{195}Pt nuclear magnetic resonance. The results have shown the presence of several species in aqueous solution. The reactions were done at different conditions of pH. The spectra of two isolated oligomers were also measured. The hydroxy-bridged dimer and trimer show a signal around −2900 ppm while the hydrolyzed monomers have signals around −3200 ppm. A semi-quantitative profile of the different equilibria in solution is suggested.

Introduction

Les ligands sulfoxydes possèdent deux sites donneurs, mais dans le cas du platine, un métal mou, la coordination s'effectue exclusivement par l'atome de soufre.

Nous avons récemment étudié les réactions des complexes de platine de type *cis*-[Pt(L)$_2$X$_2$] (L = sulfoxyde et X = Cl ou I) avec des sels d'argent (1). Des monomères *cis*-[Pt(L)$_2$(ClO$_4$)$_2$] et *cis*-[Pt(L)$_2$SO$_4$], des dimères à ponts hydroxo, *cis*-[(L)$_2$Pt(OH)$_2$Pt(L)$_2$]$^{2+}$, et possiblement un trimère ont été isolés et caractérisés par spectroscopie infrarouge et par résonance magnétique nucléaire du proton. Afin de confirmer les différentes espèces oligomériques, nous avons entrepris une étude par rmn du platine-195. La bonne sensibilité de ce noyau, combinée à une haute fréquence de résonance et une bonne abondance naturelle, facilite l'étude par rmn de cet isotope.

Nous avons étudié les produits de la réaction entre *cis*-[Pt(EMSO)$_2$Cl$_2$] (EMSO = éthylméthylsulfoxyde) et Ag_2SO_4 dans D_2O. Les résultats ont montré la présence de plusieurs espèces en solution. Plusieurs facteurs tels que pH, concentration, température et temps de réaction ont une influence très importante sur les différents équilibres et sur la vitesse d'oligomérisation des complexes. La rmn du ^{195}Pt a permis de mieux visualiser ces équilibres qui seront discutés plus bas.

Partie expérimentale

Les spectres rmn du platine-195 ont été mesurés sur un spectromètre Bruker WH400. Les spectres ont été découplés du proton, utilisant un découplage à deux niveaux. Les spectres ont été obtenus à différentes largeurs spectrales 31 250–50 000 Hz avec une durée d'impulsion de 40 μs et un nombre d'accumulations de 400 à 3281. Les concentrations des solutions étaient d'environ 0,3 *M* en platine. Une solution de K_2PtCl_4 (0,415 g dans 3 mL D_2O) a servi de référence externe. Les déplacements chimiques rapportés dans cette publication sont relatifs à Na_2PtCl_6 (K_2PtCl_4 : δ = −1628 ppm (2)).

Les complexes *cis*-[Pt(EMSO)$_2$Cl$_2$], *cis*-[(EMSO)$_2$Pt(OH)$_2$Pt(EMSO)$_2$](SO$_4$) et (*cis*-[Pt(EMSO)$_2$(OH)]$_3$)$_2$(SO$_4$)$_3$ ont été préparés par la méthode décrite précédemment (1).

Résultats et discussion

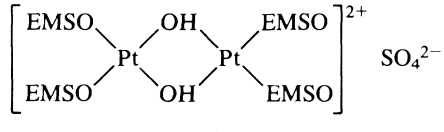
Un complexe binucléaire à ponts hydroxo a été isolé selon les réactions suivantes:

cis-[Pt(EMSO)$_2$Cl$_2$] + Ag_2SO_4

↓ H_2O

espèces ioniques hydrolysées

↓ pH ≈ 6,5, $Ba(OH)_2$



Ce complexe est blanc et insoluble dans l'éthanol. Lors de la synthèse, un autre composé, de couleur jaune et soluble dans l'éthanol, a été isolé. L'analyse élémentaire a montré la même composition. Mais les propriétés physiques et les spectres infrarouges des deux composés sont différents. Les spectres rmn protoniques des deux produits montrent les mêmes déplacements chimiques mais les pics du composé jaune sont beaucoup plus larges. Nous avons émis l'hypothèse que le composé jaune était un trimère à ponts-hydroxo (*cis*-[Pt(EMSO)$_2$(OH)]$_3$)$_2$(SO$_4$)$_3$) (1). L'élargissement des pics en rmn protonique serait causé par un processus de réarrangement du cation qui est stéréochimiquement non rigide en solution comme observé pour le complexe *cis*-[Pt(NH$_3$)$_2$(OH)]$_3^{3+}$ (3).

Les spectres rmn du ^{195}Pt des deux oligomères isolés sont montrés à la figure 1 (a et b). Un seul signal apparaît dans chacun des cas : à −2891 ppm pour le dimère et −2906 ppm pour le trimère. La proximité de ces deux pics pourrait mettre en doute l'existence de deux espèces différentes. Cependant, d'une part, les propriétés caractéristiques différentes (solubilité, point de fusion, couleur et spectre infrarouge) des deux complexes, et d'autre part, l'absence de tout autre signal dans le spectre rmn, semblent suggérer la présence de deux composés distincts. Le signal du trimère est très large probablement à cause du processus de réarrangement du cation mentionné plus haut. Il est également possible que le petit signal observé pour le trimère

1. Revision reçue le 14 avril 1986.

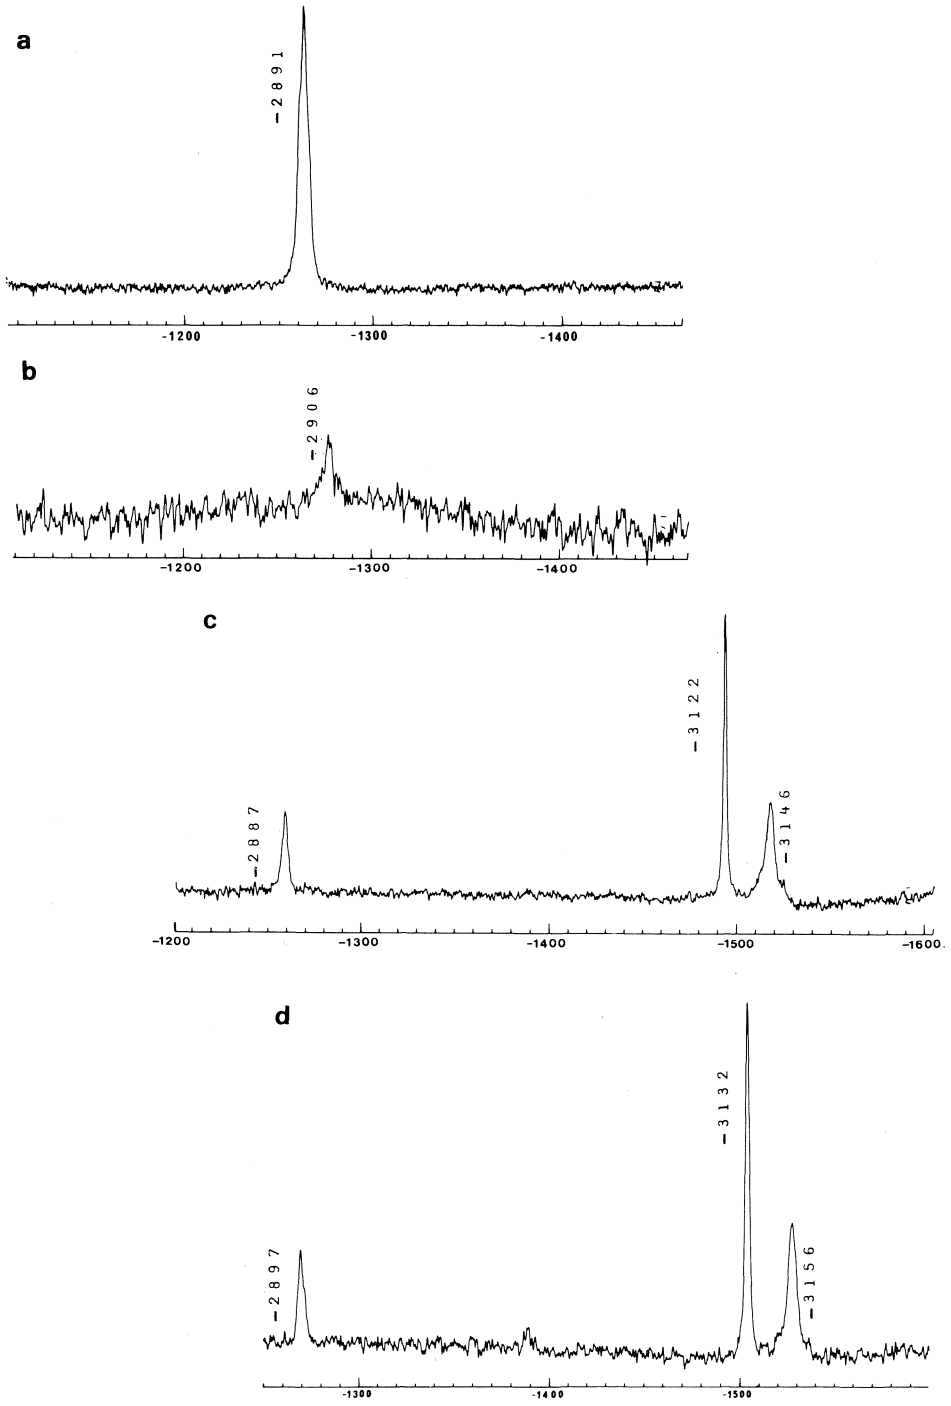


FIG. 1. Spectres rmn ^{195}Pt; (a) dimère isolé et redissous dans D_2O; (b) trimère isolé et redissous dans D_2O; (c) $[Pt(EMSO)_2Cl_2]$ + Ag_2SO_4 dans D_2O fraîchement préparé, sans ajustement de pD (~1,9); (d) réaction dans H_2SO_4 pD = 1.

soit causé par une petite quantité de dimère dans le trimère et que le signal de ce dernier soit trop large pour être détecté.

Une étude de la réaction entre *cis*-$[Pt(EMSO)_2Cl_2]$ et Ag_2SO_4 (rapport 1:1), en milieu D_2O, a ensuite été entreprise directement dans le tube de rmn. Le pD obtenu lors du mélange des deux réactifs est d'environ 1,9. Le spectre d'une solution fraîchement préparée est montré à la figure 1c. Ce spectre met en évidence la formation de plusieurs espèces lors de la réaction. Après sept jours à la température ambiante, le spectre avait peu changé, montrant ainsi la stabilité des espèces dans ces conditions. Seul le pic à −2887 ppm semble avoir augmenté. Ce signal correspond au dimère, tandis que les pics à −3122 et −3146 ppm sont attribués à des espèces monomériques. Le monomère *cis*-$[Pt(EMSO)_2SO_4]$ est probablement hydrolysé en solution aqueuse sous les formes *cis*-$[Pt(EMSO)_2(H_2O)SO_4]$, *cis*-$[Pt(EMSO)_2(H_2O)_2]^{2+}$ et *cis*-$[Pt(EMSO)_2(H_2O)(OH)]^{+}$. L'espèce monoaquo-monohydroxo s'oligomérise en dimère et éventuellement en trimère (1). L'oligomérisation est plus importante après quelques jours même en pH acide.

Il est difficile d'attribuer sans ambiguïté les signaux des espèces monomériques. Gill et Rosenberg (4) ont observé un seul signal pour les trois espèces monomériques hydrolysées $[Pt(dach)(H_2O)_2]^{2+}$, $[Pt(dach)(H_2O)(OH)]^{+}$ et $[Pt(dach)(OH)_2]$ (dach = *trans*-diamino-1,2 cyclohexane, et l'anion = NO_3^-).

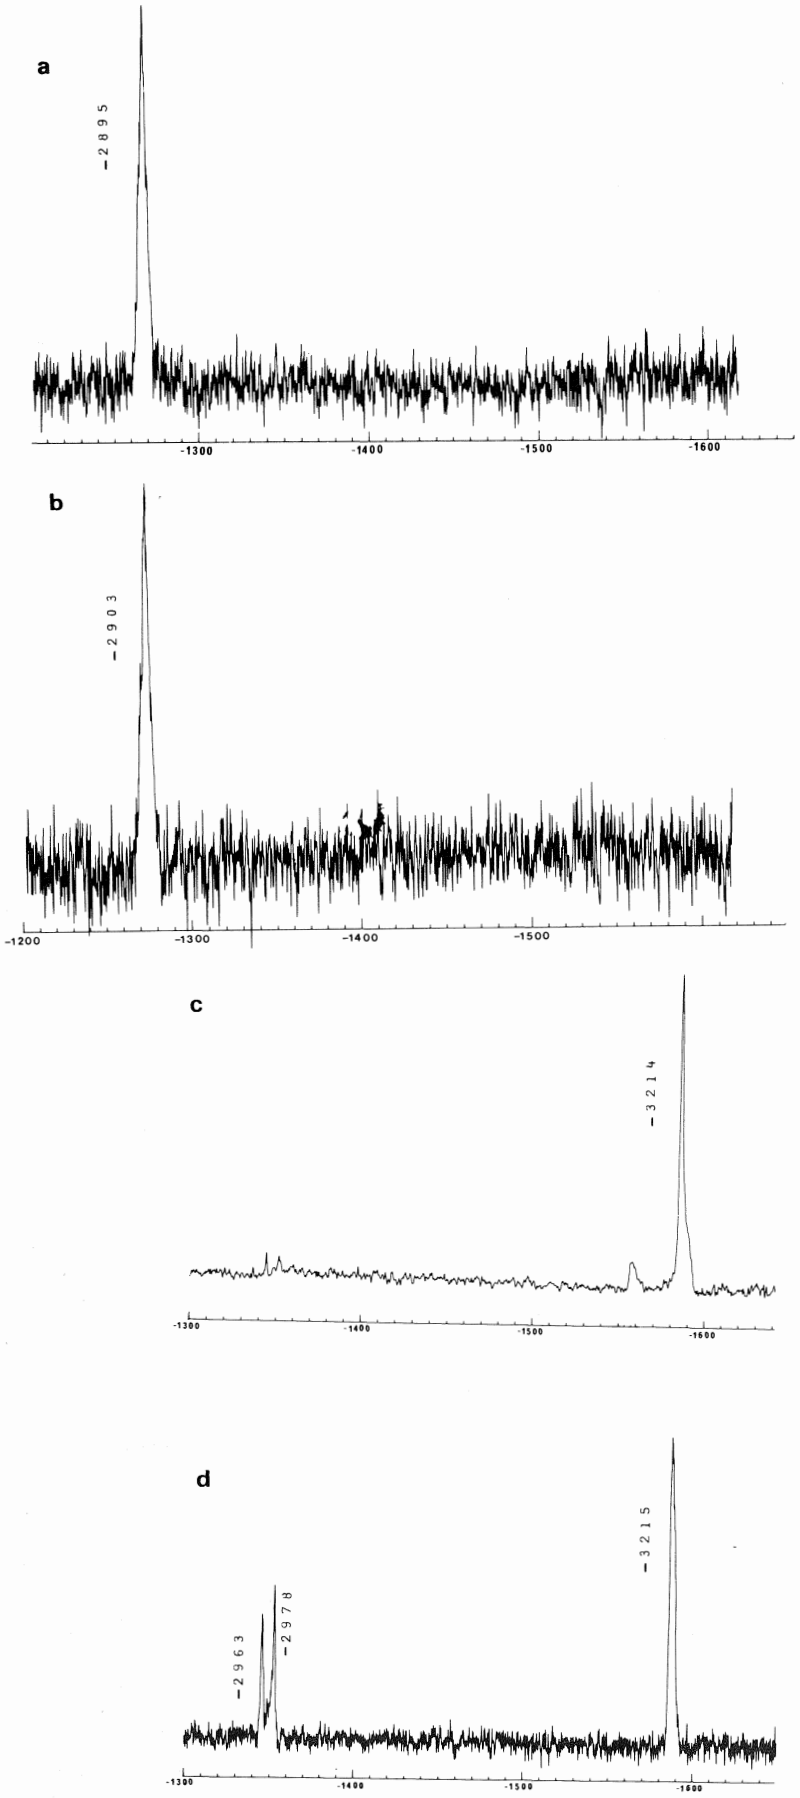

FIG. 2. Spectres rmn ^{195}Pt; (a) réaction dans D_2O, pD ajusté à 3,9 avec KOH; (b) réaction dans D_2O, pD ajusté à 5,0 avec KOH; (c) réaction dans KOH pD = 9–10; (d) *cis*-$[Pt(EMSO)_2Cl_2]$ hydrolysé dans une solution fraîchement préparée KOH pD = 10–12.

TABLEAU 1. Déplacements chimiques en rmn du ^{195}Pt des différentes espèces en solution aqueuse

Espèce	δ (ppm)
K_2PtCl_4	−1628[a]
$[Pt(EMSO)_2OH]_2^{2+}$	−2887
$[Pt(EMSO)_2OH]_3^{3+}$	−2906
$[Pt(EMSO)_2(H_2O)_2]SO_4$	−3146
$[Pt(EMSO)_2(OH)_2]$	−3213
$[Pt(EMSO)_2(H_2O)(SO_4)]$	−3122
cis-$[Pt(EMSO)Cl(OH)_2]$[b]	−2978
trans-$[Pt(EMSO)Cl(OH)_2]$[b]	−2963

Ces espèces participent à un équilibre acide–base par échange de proton (ou D^+ dans D_2O) et un seul signal est observé en rmn du ^{195}Pt. Ces auteurs ont observé une variation de la position du signal selon le pH. Ils ont assumé qu'à des pH extrêmes (2,5 et >9), les espèces présentes sont l'espèce protonée $[Pt(dach)(H_2O)_2]^{2+}$ observée à −1898 ppm et déprotonée $[Pt(dach)(OH)_2]$ observée à −1796 ppm. Dabrowiak *et al.* (5) ont fait une étude par rmn du ^{195}Pt de l'hydrolyse (pD = 3) d'un complexe sulfato avec le di(aminométhyl)-1,1 cyclohexane (A). Ils ont attribué un pic à −1835 ppm à l'espèce partiellement hydrolysée, $[Pt(A)(H_2O)SO_4]$, et celui à −1860 ppm à $[Pt(A)(H_2O)_2]^{2+}$. Appleton *et al.* (6) ont également attribué un pic à −1550 ppm à l'espèce *cis*-$[Pt(NH_3)_2(H_2O)SO_4]$ à un champ légèrement plus bas que le signal de *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ observé à −1584 ppm. Ce même groupe de chercheurs a aussi observé un pic à 74 ppm attribué à l'espèce $[Pt(H_2O)_3SO_4]$, c'est à dire à un champ un peu plus bas que le signal de $[Pt(H_2O)_4]^{2+}$ (7). En nous basant sur ces travaux, nous avons attribué le signal observé à −3122 ppm, pour nos complexes, à l'espèce $[Pt(EMSO)_2(H_2O)SO_4]$ et celui à −3146 ppm, à $[Pt(EMSO)_2(H_2O)_2]^{2+}$.

Afin de confirmer cette hypothèse, des spectres de réactions effectuées dans différentes conditions de pH ont été mesurés. La réaction effectuée en milieu acide pD = 1 (fig. 1d) ne montre pas de variation dans les proportions des différentes espèces. Les spectres des produits de réaction amenés à des pD de 3,9 et 5,0 (fig. 2 (a et b)) avec KOH, montrent un seul signal aux environ de −2898 ppm, indiquant ainsi une oligomérisation complète. La dimérisation de l'espèce monohydroxo-monoaquo semble donc trés rapide. Le spectre de la réaction effectuée en solution basique (KOH) à un pD de 9–10, montre un seul pic à −3214 ppm (fig. 2c) dû à l'espèce déprotonée dihydroxo, *cis*-$[Pt(EMSO)_2(OH)_2]$. Ce complexe peut aussi être préparé à partir de *cis*-$[Pt(EMSO)_2Cl_2]$ dissous dans une solution de KOH 1*M* (fig. 2d). En effet ce complexe s'hydrolyse et donne une espèce dihydroxo à −3215 ppm et deux autres espèces à −2963 et −2978 ppm. Ces pics, n'apparaissant dans aucun autre spectre, ont été attribués à des espèces chlorées déprotonées, soit *cis*- et *trans*-$[Pt(EMSO)Cl(OH)_2]$. Le spectre rmn protonique du composé *cis*-$[Pt(EMSO)_2Cl_2]$ dissous dans KOH a montré la présence de EMSO libre en plus du ligand lié. La proportion de EMSO libre est d'environ 25–30% pour une solution fraîchement préparée et environ 50% pour une solution vieille de 24 h. L'espèce $[Pt(EMSO)Cl(OH)_2]$ devrait montrer un signal en rmn du platine-195 à un champ plus faible que $[Pt(EMSO)_2(OH)_2]$. En effet, dans une série semblable, la résonance métallique bouge vers les hauts champs selon l'ordre $S > N > Cl^- > O$ (8). Donc lorsqu'un ligand lié par le soufre dans $[Pt(EMSO)_2(OH)_2]$ est remplacé par un ligand chlorure, le signal devrait apparaître à un champ plus faible, ce que nous avons observé.

Les deux signaux observés à −2963 et −2978 ppm sont donc attribués aux deux isomères $[Pt(EMSO)Cl(OH)_2]$, mais il est difficile de savoir avec exactitude quel isomère correspond à chaque signal. Kerrison et Sadler (9) ont mesuré le spectre rmn du platine-195 des deux paires d'isomères *cis*- et *trans*-$[Pt(DMSO)(NH_3)Cl_2]$ ($\Delta\delta$ = 21 ppm) et *cis*- et *trans*-$[Pt(DMSO)(NH_3)_2Cl]$ ($\Delta\delta$ = 21 ppm). Ces auteurs ont attribué le signal observé à plus bas champ à l'isomère où le ligand DMSO est en position *trans* du ligand chlorure. En se basant sur ces résultats, nous pouvons suggérer que le signal observé à −2963 ppm correspond à la résonance de l'isomère *trans*-$[Pt(EMSO)Cl(OH)_2]$, tandis que le signal à plus haut champ (−2978 ppm) correspond à la résonance de l'isomère *cis*-$[Pt(EMSO)Cl(OH)_2]$.

Le tableau 1 montre de façon globale les déplacements chimiques des différentes espèces. Ces valeurs sont régies par la dominance du terme σ sur les déplacements chimiques. La principale contribution à la constante de blindage d'un noyau de métal lourd tel que le platine englobe 2 termes ($\sigma = \sigma_p + \sigma_d$) où σ_p et σ_d sont les contributions paramagnétiqes et diamagnétiques au blindage. Pour un noyau lourd σ_p est prédominant. Ramsey (10) a défini ce terme, qui a été évalué pour ^{195}Pt par Dean et Green (11). À l'aide de cette relation, Gill et Rosenberg (4) ont interprété le déplacement chimique des espèces diaquo (−1898 ppm) et dihydroxo (−1796 ppm) en terme de degré de convalence de la liaison Pt—OD_2 et PT—OD. D_2O étant plus polarisable que OD^-, l'accroissement du degré de covalence du lien Pt—OD_2 résulte en une diminution de δ. Cependant, nos observations des signaux pour $[Pt(EMSO)_2(H_2O)_2]^{2+}$ (δ = −3146 ppm) et $[Pt(EMSO)_2(OH)_2]$ (δ = −3214) montrent un déplacement inversé du complexe dihydroxo relativement au complexe diaquo. Par contre, nos résultats sont en accord avec ceux obtenus par Gröning, Drakenberg et Elding (12), qui ont observé un signal pour *trans*-$[PtCl_2(H_2O)_2]$ à δ = −630 ppm et pour *trans*-$[PtCl_2(OH)_2]^{2-}$ à δ = −675 ppm. Ce phénomène suggère donc une explication plus complexe que celle suggérée par Gill et Rosenberg (4) et tenant compte de l'influence du second ligand.

Le signal du dimère $[Pt(EMSO)_2OH]_2$ apparaît à un champ plus bas (259 ppm) que celui du monomère $[Pt(EMSO)_2(H_2O)_2]^{2+}$ comme observé dans les complexes avec NH_3 (431 ppm (13)) et *trans*-dach (436 ppm (4)). Par contre, contrairement à nos résultats, ces auteurs ont observé un trimère à 78 ppm (13) et 141 ppm (4) du monomère diaquo.

La rmn du ^{195}Pt a permis de mieux visualiser les équilibres en jeu lors de la réaction entre les complexes *cis*-$[Pt(EMSO)_2Cl_2]$ avec Ag_2SO_4. Plusieurs auteurs (4, 13–15) ont étudié les différents équilibres du système *cis*-$[Pt(L)_2Cl_2]$ (L = amine) avec un sel d'argent en solution aqueuse et ont mis en évidence une variété d'espèces mononucléaires et polynucléaires. À ce jour, les complexes avec les sulfoxydes n'ont pas encore fait l'objet d'une telle étude.

Pour les complexes avec des amines, l'espèce diaquo *cis*-$[Pt(L)_2(H_2O)_2]^{2+}$ est prédominante à des petits pH, tandis que l'espèce dihydroxo *cis*-$[Pt(L)_2(OH)_2]$ apparaît en forte proportion à pH élevé. La molécule d'eau est un excellent groupe sortant et la formation de l'espèce monoaquo-monohydroxo, *cis*-$[Pt(L)_2(H_2O)(OH)]$, est prédominante à un pH intermédiaire entre pK_{a1} et pK_{a2} qui se situent pour différentes amines à 5,56–6,14 et 7,32–7,56 (4, 10, 16) respectivement. L'espèce monoaquo-monohydroxo est l'intermédiaire dans la formation d'oligomères à ponts hydroxo. En effet, la réaction

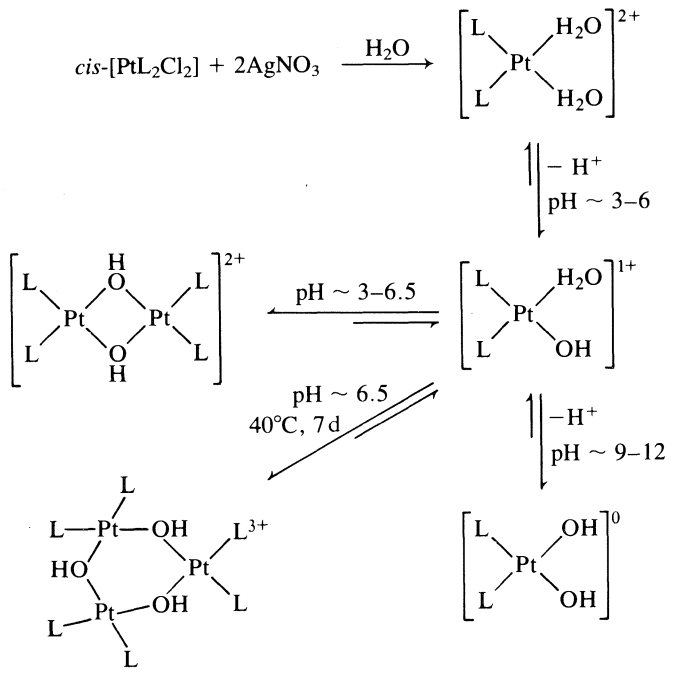

FIG. 3. Profil semi-quantitatif des différents équilibres en solution.

d'oligomérisation est plus rapide dans la région de pH neutre. L'ion hydroxo lié au platine, est encore un bon nucléophile et peut agir comme ligand ponté formant ainsi un complexe binucléaire ponté par deux ligands hydroxo.

Les équilibres des complexes avec des sulfoxydes semblent être semblables à ceux des complexes avec des amines. Lors de la mise en réaction du complexe *cis*-[Pt(sulfoxyde)$_2$Cl$_2$] avec un sel d'argent, le pH de la solution décroît immédiatement de façon radicale de 6,5 à environ 1,5. Ce pH acide indique la formation d'espèces déprotonées telles que le monomère monoaquo-monohydroxo et des oligomères à ponts hydroxo. Ces espèces ont été observées dans le spectre rmn du ^{195}Pt (fig. 1c sans ajustement de pH). Le dimère se forme spontanément et sa proportion augmente en neutralisant la solution. Aprés environ une heure à des pH de 3,9 à 6, la proportion de dimère est près de 100% (figures 2a, 2b).

La formation du trimère est favorisée à haute concentration, à pH neutre, à température plus élevée (40°C) et à un plus long temps de réaction (1 semaine). La figure 3 montre schématiquement l'influence de différents paramètres sur les proportions des différentes espèces en solution. La molécule H_2O est un excellent groupement sortant, mais l'hydroxyde ponté ne l'est pas. Dans les complexes hydroxo pontés, l'affinité de l'hydroxyde pour le platine(II) est approximativement celle de NH_3 (17).

La préparation sélective des complexes est basée sur leur différence de solubilité et sur des conditions de réaction appropriées (1). De façon générale, les dimères avec sulfoxydes sont moins solubles dans l'eau que les trimères. La même tendance a été observée pour le dimère et le trimère avec NH_3 (18), alors qu'avec *trans*-diamino-1,2 cyclohexane (4), des solubilités inverses ont été observées.

Avec le sulfate comme contre-ion, les complexes dimériques et trimériques avec des sulfoxydes sont formés, mais contrairement aux nitrates, la proportion de trimère est importante (1). Faggiani *et al.* (19) ont observé le même phénomène pour les sels de sulfate et de nitrate des trimères avec NH_3. Ils ont attribué cette différence à l'arrangement différent des deux cations trimériques. En effet, à l'état solide l'arrangement stérique du cation dans le sel nitrate semble plus tendu que dans le sel sulfate. Nous croyons également que dans les complexes avec des sulfoxydes, le cation du trimère dans le sel sulfate serait moins tendu et plus facile à isoler que le sel nitrate ou perchlorate. Nous avons tenté de préparer des monocristaux des trimères afin d'en déterminer la structure cristalline, mais sans succès jusqu'à maintenant. Par contre, nous avons déterminé la structure cristalline de deux dimères, *cis*-[Pt(DMSO)$_2$(OH)]$_2$(ClO$_4$)$_2$ (20) et *cis*-[Pt(TMSO)$_2$(OH)]$_2$(NO$_3$)$_2$ (TMSO = tétraméthylènesulfoxyde) (21). Le cation des deux dimères est très semblable mais contrairement aux ions perchlorates, les ions NO_3^- sont très désordonnés. De plus, le système de ponts hydrogènes impliquant les anions est différent.

Remerciements

Nous remercions le Conseil de recherches en sciences naturelles et en génie du Canada et le Ministère de l'Education (FCAR) pour l'aide financière apportée à ce projet.

Received June 17, 1985[3]

AFAF KAMAR, ALEXANDER BALDWIN YOUNG, and RAYMOND EVANS MARCH. Can. J. Chem. **64**, 1979 (1986).

The evolution of ion species by unimolecular and bimolecular reactions, both concurrent and sequential, has been investigated for each of 2-propanone, d_6-2-propanone, 4-hydroxy-4-methyl-2-pentanone, and 4-methyl-3-penten-2-one. Infrared multiphoton dissociation (IRMPD) has been used in order to differentiate between gaseous ionic isomers. It is concluded that the isomeric species, protonated 2-propanone dimer and protonated 4-hydroxy-4-methyl-2-pentanone, both of m/z 117, are of different structures. The ion species $C_6H_{11}O^+$ of m/z 99, and its perdeuterated analogue, which is observed in all three systems, may exist in two forms, one of which is unique to 2-propanone while an alternative form appears to be common to 4-hydroxy-4-methyl-2-pentanone and 4-methyl-3-penten-2-one. The ion species of m/z 83 ($C_5H_7O^+$) which is observed only in the latter two systems only could not be differentiated and may have a common structure. In the protonated dimers of 2-propanone and 4-hydroxy-4-methyl-2-pentanone, evidence obtained by IRMPD indicates that the activation energy for dedimerization (134 kJ mol^{-1}) is less than that for the dehydration process.

AFAF KAMAR, ALEXANDER BALDWIN YOUNG et RAYMOND EVANS MARCH. Can. J. Chem. **64**, 1979 (1986).

On a étudié l'évolution des espèces ioniques provenant de réactions unimoléculaires ainsi que bimoléculaires, tant des réactions qui se produisent d'une façon concurente que séquentielle, de la propanone-2, de la propanone-2-d_6, de l'hydroxy-4 méthyl-4 pentanone et de la méthyl-4 pentène-3 one-2. Dans le but de distinguer les divers isomères ioniques gazeux, on a fait appel à la dissociation multiphotonique infrarouge (DMPIR). On en conclut que les espèces isomères dimères protonés de la propanone-2 et de l'hydroxy-4 méthyl-4 pentanone-2 protonée, de m/z = 117, possèdent deux structures différentes. L'espèce ionique $C_6H_{11}O^+$, de m/z = 99, et celle de son analogue perdeutéré qui est observée dans les trois systèmes peut exister sous deux formes; l'une est unique à la propanone-2 alors qu'une autre forme semble être commune à l'hydroxy-4 méthyl-4 pentanone-2 et à la méthyl-4 pentène-3 one-2. Les espèces ioniques de m/z = 83 ($C_5H_7O^+$), qui ne sont observées que dans les deux derniers systèmes, ne présentent pas de différences et possèdent peut être la même structure. Dans le cas des dimères protonés de la propanone-2 et de l'hydroxy-4 méthyl-4 pentanone-2, on a obtenu des données à l'aide de la DMPIR à l'effet que l'énergie d'activation pour la dédimérisation (134 kJ mol^{-1}) est plus faible que celle requise pour le processus de deshydratation.

[Traduit par la revue]

Introduction

Previous studies employing slow Infrared Multiphoton Dissociation (IRMPD), as a probe of activation energy hierarchies in the gas phase photolysis of proton-bound dimers, have been carried out with each of 2-propanol (1–4), ethanol (5), 1-butanol (6), and deuterated propanols (7). With proton-bound alcohol dimers it is possible to determine in some degree the hierarchy of activation energies among the reaction channels leading to loss of alkene, water, and monomer or parent molecule. With the proton-bound dimers of 2-propanone and 4-hydroxy-4-methyl-2-pentanone studied here, it is possible to assess the activation energy hierarchy for loss of water and monomer. IRMPD may be used also to differentiate between isomeric ion species in the gas phase. The distinguishing criteria for photochemical differentiation are relative absorptivity at the wavelength available for laser irradiation and, of greater importance, the photoproduct distribution, i.e. the ionic species produced and their relative intensities. In some cases it is informative to photolyze the species of interest in both the ground state and in its nascent state; nascent ion internal excitation is enhanced by multiple photon absorption to access reaction channels of higher activation energy, limited in practice, by competition between laser fluence and collision frequency.

The ion-chemistry for each of 2-propanone, 4-hydroxy-4-methyl-2-pentanone, and 4-methyl-3-penten-2-one is presented here. These three compounds are related in the following ways: the proton-bound dimer of 2-propanone is isomeric with protonated 4-hydroxy-4-methyl-2-pentanone and the ion structures could be identical if aldol condensation occurs in the gas phase; an ion species of m/z 99 ($C_6H_{11}O^+$) is produced in both of the above systems and is isomeric with protonated 4-methyl-3-penten-2-one; and lastly an ion species of m/z 83 ($C_5H_7O^+$) is observed only with 4-hydroxy-4-methyl-2-pentanone and 4-methyl-3-penten-2-one and is conspicuously absent in 2-propanone. Thus these three compounds present an opportunity for isomer differentiation using the techniques of ion storage and IRMPD.

Experimental

Although the basic apparatus has been described previously (1–3), a brief description of the technique used in this work is presented here. A three-dimensional quadrupole ion store (QUISTOR) mounted in place of the ion source of a conventional quadrupole mass filter (Vacuum Generators QXK 400), serves as the reactor in which ion/molecule reactions take place over the period 0–200 ms. The ring electrode of the QUISTOR has two central perforations diametrically opposed. A low power CW CO_2 laser beam is directed through a sodium chloride window and through the first ring perforation, of diameter 3 mm. The beam passes radially through the centre of the QUISTOR and totally illuminates the ion cloud which rapidly becomes tightly focused at the centre of the device. A portion of the beam passes through the perforation at the opposite side of the ring electrode and is monitored externally through a second sodium chloride window. The remainder of the beam is thought to undergo multiple reflections within the QUISTOR. The laser beam is chopped mechanically and phase-locked with the pulsing sequence as shown in Fig. 1.

The repetition rate of the pulse sequence is controlled by a square-wave generator (Heathkit SG 18A). The laser beam is interrupted by a PAR 222 chopper phase-locked to the square-wave generator. A range

[3]Revision received February 21, 1986.

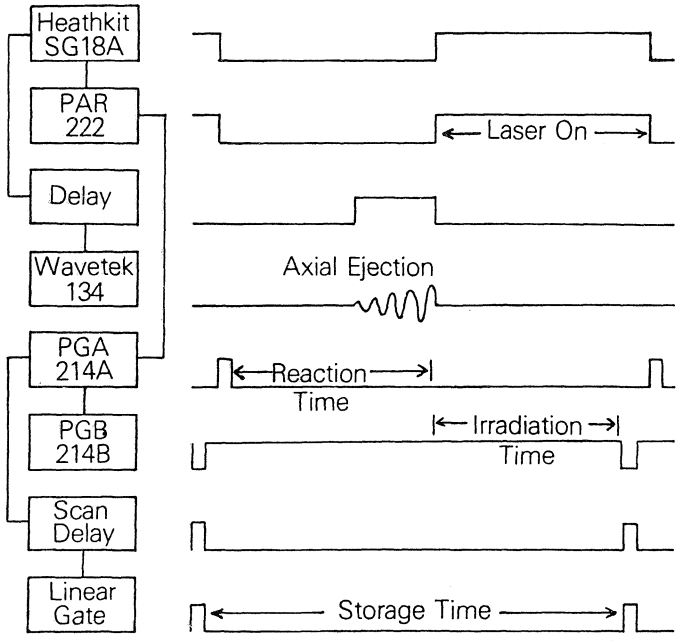

FIG. 1. Pulse sequence used in IRMPD with axial ejection employed to isolate an ionic species of interest by removal of all lower m/z ions prior to laser irradiation.

of total storage times was effected using chopper wheels with a variety of wheel apertures, while variation of the laser irradiation period within a fixed total storage time was achieved with chopper wheels of different light-to-dark ratio. The mechanical chopper triggers the creation pulse (Hewlett Packard pulse generator 214B, PGA) which triggers in turn the extraction pulse (PGB) and a Brookdeal scan delay generator (9425) which provides a detection pulse to drive a linear gate (Brookdeal 9415). The square-wave generator also drives a delay pulse generator which triggers in turn a Sweep Generator (Wavetek 134) which is then used to remove, by axial ejection (8), ions of mass-to-charge ratio less than that of protonated dimer prior to laser irradiation.

The ion abundances are obtained by recording mass spectra at zero storage (electron impact) and at a variety of storage times; the relative ion intensities are calculated for each species at each storage time to yield the data points shown in the figures. The temporal variation of the intensity of each ion species was checked by single ion monitoring over the storage period employed.

2-Propanone (acetone)

Ion/molecule chemistry

The ion chemistry of 2-propanone has been studied previously by Munson (9) and by Blair and Harrison (10), and is re-examined here both to resolve the minor differences between the findings of these two groups and to provide a basis for explanation of our photodissociation results obtained with proton-bound dimers of 2-propanone and 4-hydroxy-4-methyl-2-pentanone. Munson employed a variable pressure source and reported on secondary ion intensities as a function of pressure only. Blair and Harrison, in an electron beam trapping study with a trapping period of 3 ms, used an ionizing electron energy sufficient to produce only $(CH_3)_2CO^{+\cdot}$ and CH_3CO^+ as primary ions, with the former comprising 70% of the primary ion abundance. Protonated parent molecules, m/z 59, are produced by reactions of the primary ions

$$[1]\quad \underset{m/z\ 58}{(CH_3)_2CO^{+\cdot}} + (CH_3)_2CO \rightarrow \underset{m/z\ 59}{(CH_3)_2\overset{+}{C}OH} + CH_3\dot{C}OCH_2$$

$$[2]\quad \underset{m/z\ 43}{CH_3CO^+} + (CH_3)_2CO \rightarrow \underset{m/z\ 59}{(CH_3)_2\overset{+}{C}OH} + CH_2CO$$

The proton-bound dimer m/z 117 is produced continuously with either increasing pressure or increasing storage time by reaction with parent neutrals

$$[3]\quad \underset{m/z\ 59}{(CH_3)_2COH^+} + (CH_3)_2CO \rightleftharpoons \underset{m/z\ 117}{[(CH_3)_2CO]_2H^+}*$$

where * denotes a degree of internal excitation. The nascent proton-bound dimer may then be either collisionally deactivated

$$[4]\quad \underset{m/z\ 117}{[(CH_3)_2CO]_2H^+}* \xrightarrow{M} \underset{m/z\ 117}{[(CH_3)_2CO]_2H^+} + M$$

or may dissociate

$$[5]\quad \underset{m/z\ 117}{[(CH_3)_2CO]_2H^+}* \rightarrow \underset{m/z\ 101}{CH_3CO(CH_3COCH_3)^+} + CH_4$$

$$[6]\quad \underset{m/z\ 117}{[(CH_3)_2CO]_2H^+}* \rightarrow \underset{m/z\ 99}{C_6H_{11}O^+} + H_2O$$

An alternative and preferred mechanism for the formation of m/z 101, is the clustering reaction

$$[7]\quad \underset{m/z\ 43}{CH_3CO^+} + (CH_3)_2CO \rightarrow \underset{m/z\ 101}{(CH_3)_2CO\text{---}\overset{+}{H}\text{---}OCCH_2}*$$

which is then collisionally stabilized. This species may be regarded as the product of a mixed associative ion (or a heterogeneous proton-bound dimer) of ketene proton-bridged to 2-propanone. Mixed associative ions of ketene with methanol, ethanol, and 2-propanol have been reported previously (11). The stabilization of this mixed associative ion, m/z 101, may require a reactant CH_3CO^+ of modest internal excitation only, which would account for the fact that it was observed by Blair and Harrison under their conditions of low ionizing electron energy, but not by Munson who employed ionizing electrons of 70 eV and a high pressure source. The $CH_3CO(CH_3COCH_3)^+$ product reacts slowly at longer reaction times to produce the proton-bound dimer ion in a ligand replacement reaction

$$[8]\quad \underset{m/z\ 101}{CH_3CO(CH_3COCH_3)^+} + CH_3COCH_3 \rightarrow \underset{m/z\ 117}{[(CH_3)_2CO]_2H^+} + CH_2CO$$

The species of m/z 99 formed by loss of water in the dissociation of the protonated dimer, reaction [6], was tentatively identified by Munson as protonated 4-methyl-3-penten-2-one. Since the proton-bound dimer of 2-propanone is isomeric with protonated 4-hydroxy-4-methyl-2-pentanone, it was plausible to propose that gaseous ion reactions may be observed which correspond with solution ionic reactions in which the acid-catalyzed formation of 4-hydroxy-4-methyl-2-pentanone and 4-methyl-3-penten-2-one is observed from 2-propanone. The requirement of reactant excitation in order for reaction [6] to proceed in a manner which is endothermic for ground state reactants would explain the observation of m/z 99 by Munson but not by Blair and Harrison.

In the work reported here and shown in Fig. 2, both species of m/z 99 and m/z 101 were observed as the ions were created with ionizing electrons of 70 eV and the reactions of both excited and ground state (collisionally cooled) CH_3CO^+ ions were monitored.

Perdeuterated 2-propanone was investigated also as there was some interest in the infrared relative absorptivity of deuteron-bound deuterated dimer ions $[(CD_3)_2CO]_2D^+$, m/z 130.

The ion profiles obtained with 2-propanone and d_6-2-propanone are similar in general form as shown in Figs. 2 and 3.

In 2-propanone, the ions of m/z 99 may be formed by the loss of water, reaction [6], while ions of m/z 101 may be formed by reaction [5] and/or reaction [7] to yield $C_6H_{11}O^+$ and $C_5H_9O_2^+$, respectively. The corresponding product ions in d_6-2-propanone will be $C_6D_{11}O^+$ and $C_5D_9O_2^+$, respectively, formed in reactions [9], and [10] and/or [11] to produce isobaric species of m/z 110.

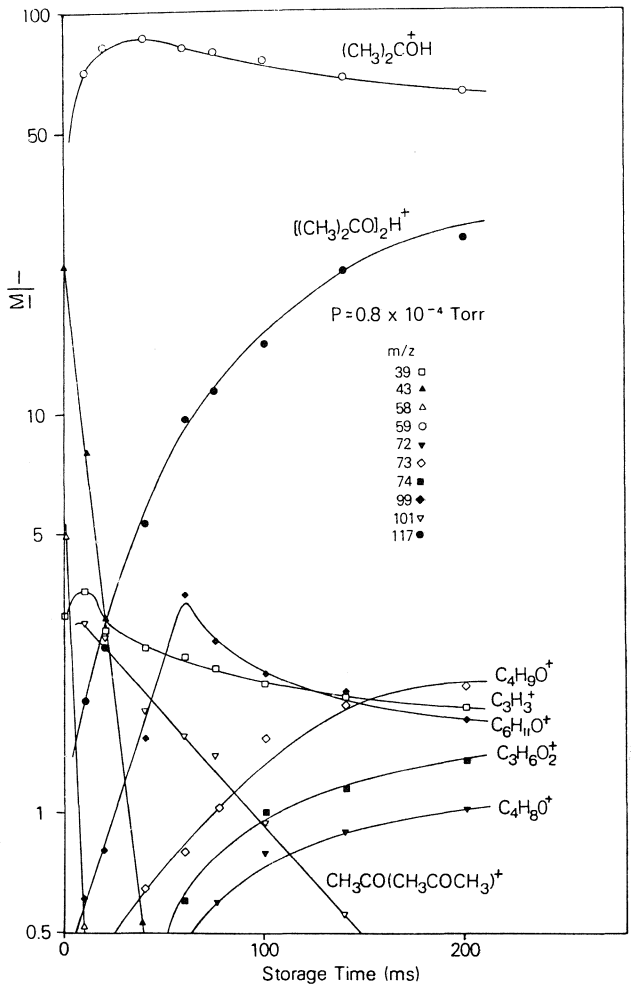

FIG. 2. Variation in the logarithm of normalized ion abundances in 2-propanone with storage time 0–200 ms, 0.8×10^{-4} Torr.

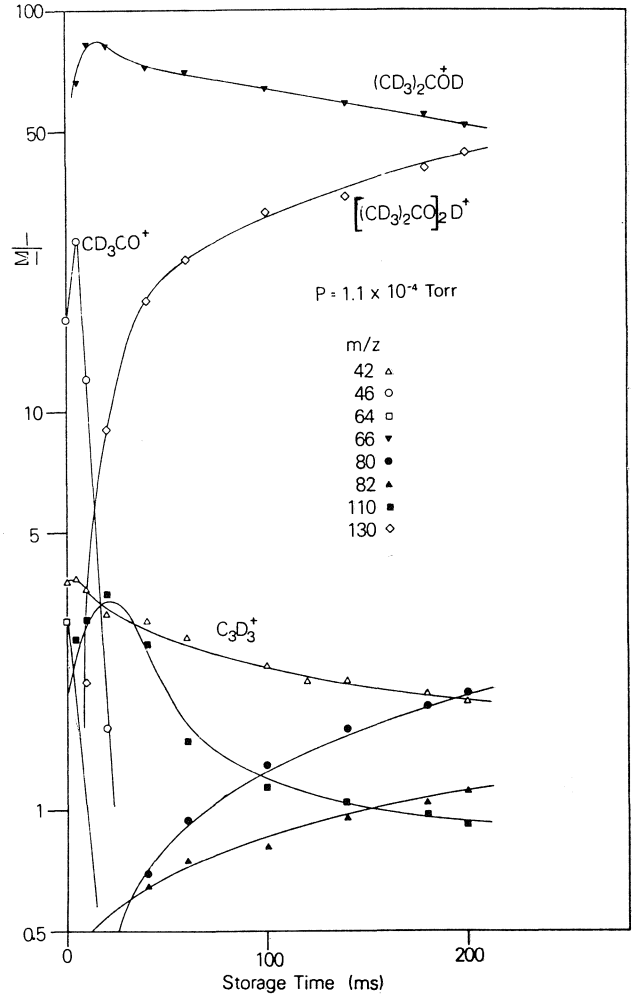

FIG. 3. Variation in the logarithm of normalized ion abundances in perdeutero-2-propanone with storage time 0–200 ms, 1.1×10^{-4} Torr.

[9] $[(CD_3)_2CO]_2D^+* \rightarrow C_6D_{11}O^+ + D_2O$
m/z 130 m/z 110

[10] $[(CD_3)_2CO]_2D^+* \rightarrow C_5D_9O_2^+ + CD_4$
m/z 130 m/z 110

[11] $CD_3CO^+ + (CD_3)_2CO \rightarrow (CD_3)_2CO\text{---}\overset{+}{D}\text{---}OCCD_2$
m/z 46 m/z 110

Thus the ion profile for m/z 110 in Fig. 3 is a composite of the two isobaric ions.

While the ions of m/z 80 and m/z 82 observed in d_6-2-propanone were of low relative intensity, they can be reconciled with the observation of ions of m/z 72, 73, and 74 in 2-propanone as shown in Fig. 2.

(*i*) Let us examine the possible origin for m/z 82 in d_6-2-propanone. The $C_5D_9O_2^+$ species may lose CO or C_2D_2 to produce $C_4D_9O^+$ and $C_3D_7O_2^+$, respectively. The corresponding ions in 2-propanone would be $C_4H_9O^+$, m/z 73 and $C_3H_7O_2^+$, m/z 75. The latter species was not observed therefore $C_5D_9O_2^+$ does not lose C_2D_2.

The isobaric $C_6D_{11}O^+$ ion may lose CO to produce $C_5D_{11}^+$ or lose C_2D_2 to produce $C_4D_9O^+$. The corresponding ions in 2-propanone would be $C_5H_{11}^+$, m/z 71, which was not observed, and $C_4H_9O^+$, m/z 73, which was observed. Thus we conclude that either reaction [12]

[12] $C_5D_9O_2^+* \rightarrow C_4D_9O^+ + CO \qquad \Delta H_{12}$

or reaction [13]

[13] $C_6D_{11}O^+* \rightarrow C_4D_9O^+ + C_2D_2 \qquad \Delta H_{13}$

occurs or both occur, where ΔH_{12} and ΔH_{13} are the enthalpy changes for reaction [12] and [13], respectively. As either reaction [12] or reaction [13] may account for the observations, it is appropriate to consider the energetics of the processes bearing in mind that a small fraction of stored ions may acquire translational energy from the three-dimensional quadrupole field and produce minor amounts of fragment ions in super-thermal collisions. As reactions [12] and [13] produce a common daughter ion with an assumed common structure, and the heats of formation of CO and C_2H_2 are -110 and 227 kJ mol^{-1}, respectively, then for reaction [13] to occur the heat of formation of $C_6D_{11}O^+$ plus internal excitation must exceed the heat of formation of $C_5D_9O_2^+$ plus internal excitation of 337 kJ mol^{-1}, provided that $\Delta H_{12} = \Delta H_{13}$. Thus the occurrence of reaction [13] is less probable than reaction [12].

(*ii*) In a similar examination of the origin of m/z 80 in d_6-2-propanone, the $C_5D_9O_2^+$ may lose $C_2D_3^\bullet$ or $CDO^\bullet$ to produce $C_3D_6O_2^{+\bullet}$ or $C_4D_8O^{+\bullet}$, respectively. The corresponding product ions in 2-propanone are $C_3H_6O_2^{+\bullet}$, m/z 74, and $C_4H_8O^{+\bullet}$, m/z 72, both of which were observed.

Thus as m/z 74 was observed in 2-propanone, we conclude that reaction [14] occurs

[14] $C_5D_9O_2^+* \rightarrow C_3D_6O_2^{+\bullet} + C_2D_3^\bullet$

The observation of m/z 72 in 2-propanone may be explained by the analogous reactions to either

[15] $C_5D_9O_2^+* \rightarrow C_4D_8O^{+\bullet} + CDO^\bullet$

or

[16] $C_6D_{11}O^+* \rightarrow C_4D_8O^{+\cdot} + C_2D_3^{\cdot}$

or both.

The heats of formation of $HCO^{\cdot}$ and $C_2H_3^{\cdot}$ are reported as 33.9 and 332 kJ mol^{-1}, respectively (12). The observation of m/z 74 infers that the heat of formation of $C_3D_6O_2^+$ is some 332 kJ mol^{-1} less than the heat of formation of $C_5D_9O_2^+$ plus internal excitation when reaction [14] is thermoneutral. By an argument similar to that presented above for reactions [12] and [13], it can be shown that for reaction [16] to occur the heat of formation of $C_6D_{11}O^+*$ must exceed that of $C_5D_9O_2^+*$ by some 298 kJ mol^{-1} again provided that the enthalpy changes for reactions [15] and [16] are similar. Thus the occurrence of reaction [16] is less probable than reaction [15].

The observation of $C_3H_3^+$ as a persistent ion species in each of the systems studied here is in keeping with previous observations of this species wherever the parent molecule has a 2-propyl grouping. The reactivity of $C_3H_3^+$ is discussed elsewhere (13).

Photochemical studies

The IRMPD of the collisionally relaxed proton-bound dimer of 2-propanone yielded but a single photodissociative channel, as is

[17] $\underset{m/z\ 117}{[(CH_3)_2CO]_2H^+} \xrightarrow{nh\nu} \underset{m/z\ 59}{(CH_3)_2\overset{+}{C}OH} + (CH_3)_2CO$

shown in Fig. 4, that of protonated 2-propanone.

In this figure, two sets of experiments are shown; the first experiment employing an initial ionization period followed by 45 ms of ion–molecule reaction time, wherein the proton-bound dimer ion is produced. Axial ejection removes all ionic species of $m/z < 117$, isolating the dimer in the trap. These isolated dimers possess a range of internal energies and some undergo thermal unimolecular dissociation to produce the protonated parent m/z 59 during the 80 ms following isolation and prior to ejection and mass analysis. In the second experiment shown as solid lines in Fig. 4, the dimer is irradiated at 944 cm^{-1} for the 80 ms period following its isolation in the QUISTOR, then the trap population is ejected and mass analyzed.

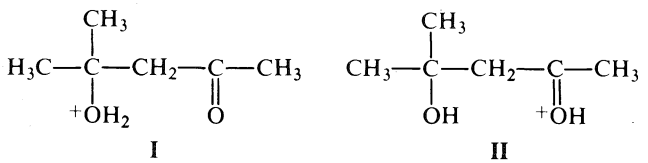
The period of laser irradiation was varied from 50 to 100 ms, that is one half the total storage time, and in each case greater than 90% of the proton-bound dimers were dissociated. As proton-bound dimers are being produced continually, the ions irradiated will have a range of ages and internal energies. As but a single photoproduct was obtained we conclude that the energies of activation for reactions [5] and [6] exceed that of reaction [17] which is reported to be 134 kJ mol^{-1} (14). While precise measurements of the cross-section for photodissociation (σ_D) were not made, the high absorptivity at 944 cm^{-1} of proton-bound dimers of 2-propanone is comparable to that of 2-d_1-2-propanol (7). This high absorptivity is remarkable as neutral 2-propanone has negligible absorption in the vicinity of 944 cm^{-1}.

In contrast the deuteron-bound dimer of d_6-2-propanone exhibited somewhat lower absorptivity in that approximately 40% only of this species was photodissociated under similar conditions; reduced absorptivity in perdeutero-2-propanol has been observed (7) also. As expected, a single photoproduct, deuteron-bound d_6-2-propanone, was observed upon IRMPD.

4-Hydroxy-4-methyl-2-pentanone (diacetone alcohol)

Ion/molecule chemistry

The ion chemistry of 4-hydroxy-4-methyl-2-pentanone obtained at a pressure of 6×10^{-5} Torr is depicted in Fig. 5 where it is seen that the predominant second order product ion at long storage times is the protonated parent molecule, $(CH_3)_2C(OH)CH_2\overset{+}{C}OHCH_3$, m/z 117. Of the two possible structures for the m/z 117 ion structure **II** is



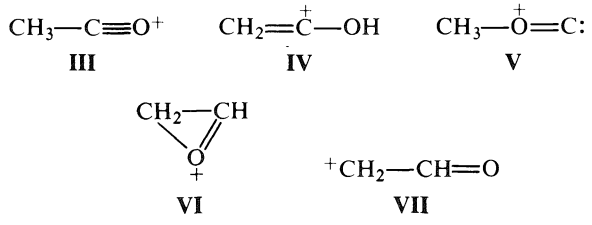
I **II**

recommended by Parker *et al.* (15) on the basis of collisionally activated dissociation (CAD) studies. The base peak in the electron impact mass spectrum, i.e. 38% relative ion intensity at zero storage time, is due to CH_3CO^+, m/z 43; this primary ion reacts rapidly along with other minor primary ions during the first 20 ms principally by proton transfer reactions such as

[18] $\underset{m/z\ 43}{CH_3CO^+*} + (CH_3)_2C(OH)CH_2COCH_3 \rightarrow (CH_3)_2C(OH)CH_2\overset{+}{C}OHCH_3* + CH_2CO$
$m/z\ 117$

where * denotes a degree of internal excitation.

At this juncture, it is appropriate to consider the nature of the $C_2H_3O^+$ species which is observed in the electron impact fragmentations of simple oxygen-containing molecules. In the 2-propanone system discussed above, it was suggested that the stabilization and subsequent observation of the ion of m/z 101 may require a reactant CH_3CO^+ of but modest internal excitation, while in the 4-hydroxy-4-methyl-2-pentanone system it is evident from Fig. 5 that two forms of $C_2H_3O^+$ exist which differ in reactivity. The temporal variation of the ion abundance of m/z 43 in Fig. 5 clearly shows two linear components in the decay curve; the bimolecular rate constant derived from the steep component is almost an order of magnitude greater than that derived from the shallow component. While one form of $C_2H_3O^+$ may derive its greater reactivity by virtue of internal energy, it is improbable that the internal energy of some 90% of the initial $C_2H_3O^+$ abundance would survive the many collisions by which deactivation could occur. The co-existence of $C_2H_3O^+$ in three structures from a single precursor has been reported (16). While as many as eleven possible isomeric structures for $C_2H_3O^+$ have been examined recently, only five structures will be considered here.



III **IV** **V**

VI **VII**

Of the potential $C_2H_3O^+$ above, the acetyl cation (**III**), 1-hydroxyvinyl cation (**IV**) and oxiranyl cation (**VI**) have been well characterized as being stable, observable species (16–18); the acetyl cation is the lowest energy isomer. The 1-hydroxyvinyl cation (**IV**) was found to lie 181 kJ mol^{-1} above **III**, with a barrier to rearrangement by

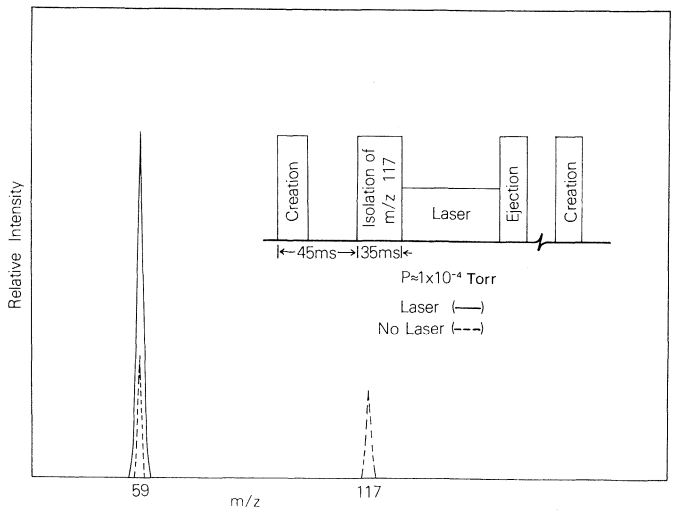


FIG. 4. Experimental sequence and results from IRMPD of 2-propanone protonated dimers at 1.0×10^{-4} Torr. Dashed lines correspond to the ion intensities in an experiment wherein the laser was blocked, solid lines correspond to ion intensities obtained with laser irradiation at 944 cm^{-1} for the latter 80 ms of the experimental period.

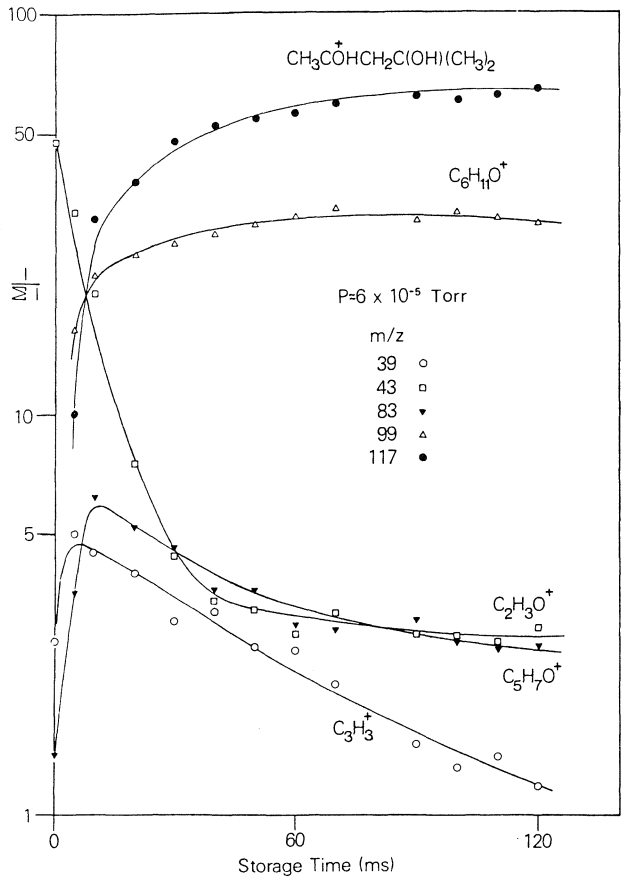

FIG. 5. Variation in the logarithm of normalized ion abundances in 4-hydroxy-4-methyl-2-pentanone with storage time 0–120 ms, 6×10^{-5} Torr.

successive 1,2-hydrogen shifts of 287 kJ mol^{-1} (19). CH_3OC^+ (**V**) was found to be the third lowest isomer in energy of the $C_2H_3O^+$ ions examined, lying 216 kJ mol^{-1} above CH_3CO^+ (**III**) (19). There appears to be no experimental study of CH_3OC^+. The results of a recent study (16) of metastable peak intensities and shapes and collision induced processes over a range of pressures provide unequivocal evidence for identification of the acetyl (**III**), 1-hydroxyvinyl (**IV**) and oxiranyl (**VI**) cations. The oxiranyl cation was predicted (19) to be 244 kJ mol^{-1} above **III** with a barrier to rearrangement of 85 kJ mol^{-1}, while **VII** was predicted to collapse without activation energy to either **VI** or **III**.

The acetyl cation **III** is known to react rapidly with oxygen-containing molecules such as 2-propanone (20). In previous studies we have noted the rapid reaction of primary $C_2H_3O^+$ cations in 1- and 2-propanol and in tetrahydrofuran (unpublished work by the authors) and conclude that this ion must be of structure **III**. However, the ion chemistry of the 1- and 2-propanol and tetrahydrofuran systems, following the initial decay of the acetyl cation, is characterized by a steady accumulation of a $C_2H_3O^+$ cation which is presumed to be of a different but unspecified structure.

While it is proposed that $(CH_3)_2C(OH)CH_2COHCH_3^+$, m/z 117, is formed with excess internal excitation in reaction [18] from an excited acetyl ion in order to explain the subsequent unimolecular dissociation of m/z 117, some discussion of the proton affinities of 4-hydroxy-4-methyl-2-pentanone and ketene would be useful here. The proton affinity of the former does not appear in the literature (22) but has been determined in this laboratory (23) to be 831 ± 0.8 kJ mol^{-1} (198.7 ± 0.2 kcal mol^{-1}), while the proton affinity for ketene is 828 kJ mol^{-1} (22). Thus for ground state acetyl ions from which a proton is transferred and ketene remains, the reaction is virtually thermoneutral.

The excited protonated parent molecules formed may then be collisionally deactivated.

[19] $(CH_3)_2C(OH)CH_2COHCH_3^{+*}$ (m/z 117) $\xrightarrow{M}$ $(CH_3)_2C(OH)CH_2\overset{+}{C}OHCH_2 + M$ (m/z 117) **II**

where M represents a collision partner, or may dissociate

[20]  + H_2O

(m/z 117 → m/z 99) **VIII**

to give m/z 99 of structure **VIII** which is that of protonated mesityl oxide (4-methyl-3-penten-2-one). The excited **VIII** may then either be collisionally deactivated or eject CH_4 to produce an ion of m/z 83

[21] 
(m/z 99 → m/z 99)

[22]  + CH_4

(m/z 83) **IX**

The possibility of CH_4 loss occurring initially from m/z 117 followed by loss of H_2O to produce m/z 83 is rejected as no species of m/z 101 was detected. Although the species of m/z 99 and m/z 83 have been observed previously (15), neither the structures of these ions nor the identities of the neutral fragments ejected have been investigated further except for an attempt to photodissociate m/z 99 by multiphoton absorption as discussed below.

The principal minor primary ions, m/z 57, 59, 98, and 101 reacted rapidly during the first 10 ms and linear plots of the logarithm of ion intensities with time have been omitted from Fig. 5 so that the ion profiles of the more stable ions may be portrayed clearly. After the first 20 ms of reaction time, the remaining unreacted m/z 43 ions isomeric with CH_3CO^+ reacted slowly along with ions of m/z 83 and 99 in proton transfer reactions to produce the protonated parent molecule, m/z 117. At pressures higher than 6×10^{-5} Torr, proton-bound dimers of 4-hydroxy-4-methyl-2-pentanone of m/z 233 were observed.

Photochemical studies

IRMPD of $(CH_3)_2C(OH)CH_2\overset{+}{C}OHCH_3$, m/z 117, was carried out as described earlier. Two photoproducts as depicted in Fig. 6 were observed.

[23] $(CH_3)_2C(OH)CH_2\overset{+}{C}OHCH_3$ (m/z 117) $\xrightarrow{nh\nu\ 10\%}$ $C_2H_3O^+ + C_4H_{10}O$ (m/z 43)

[24] $\xrightarrow{n'h\nu\ 90\%}$ $C_6H_{11}O^+ + H_2O$ (m/z 99)

where n and n' are the minimum number of photons ($h\nu$) necessary to overcome the activation energy barriers for reactions [23] and [24], respectively. IRMPD has been shown to be a useful probe of activation energy hierarchies when ground state reactants are irradiated. It is concluded from the observed ratio of photoproducts obtained with 33 ms of laser irradiation that the activation energy for reaction [24] is less than that for reaction [23]; this conclusion is supported by the observation that with prolonged laser irradiation, the fractional yield of reaction [23] can be increased.

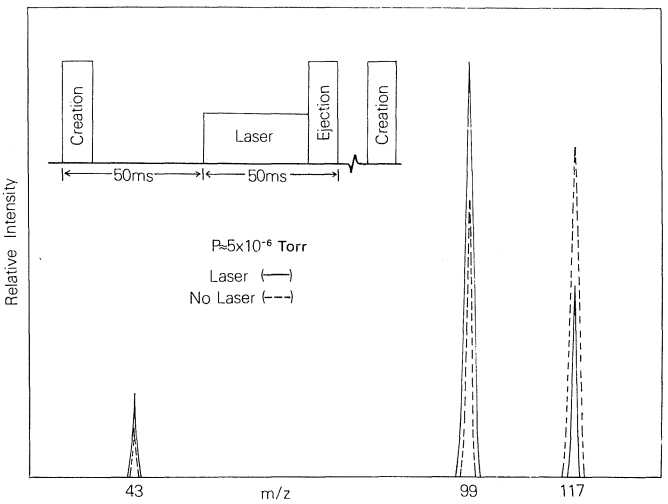

FIG. 6. Experimental sequences and results from IRMPD of protonated 4-hydroxy-4-methyl-2-pentanone at 6×10^{-5} Torr. Dashed lines correspond to the ion intensities obtained in an experiment wherein the laser was blocked, solid lines correspond to ion intensities obtained with laser irradiation at 944 cm^{-1} for the latter 50 ms of the experimental period.

In the discussion above of the ion chemistry of 4-hydroxy-4-methyl-2-pentanone, it was assumed that the unreactive form of $C_2H_3O^+$ had been produced as a fragment ion upon electron impact. However, during experiments using axial ejection in which all ion species of $m/z < 117$ are ejected from the QUISTOR, it was observed that a relatively unreactive form of $C_2H_3O^+$ was generated by dissociation of protonated parent molecules, as shown in reaction [25] which is the thermal analogue of the photochemical process, reaction [23].

It is of interest to speculate on the possibility that the products of reactions [23] and [25] are derived from the protonated keto form via a 4-centred elimination

[25] 
$\longrightarrow CH_2{=}\overset{+}{C}{-}OH + (CH_3)_3COH$
m/z 43

whereas the products of reaction [24] are derived from the protonated enol form via a 6-centred elimination as depicted in reaction [20]. As activation energies for 6-centred rearrangements are generally lower than those for 4-centred, then the above speculative mechanistic argument is consistent with the IRMPD results.

Let us consider now the structures of protonated 4-hydroxy-4-methyl-2-pentanone and the isomeric cation formed by the addition of 2-propanone to protonated 2-propanone which has been identified in reaction [3] as a proton-bound dimer. Parker *et al.* (15) found a qualitative similarity between the relative ion abundances in the self-chemical ionization mass spectrometry (self-CIMS) of 2-propanone and that of 4-hydroxy-4-methyl-2-pentanone; the relative ion abundances are tabulated in ref. 15 and reproduced here as stick form mass spectra in Fig. 7. Furthermore, the same workers found that the CAD spectrum of the m/z 117 ion, obtained with the magnetic (B) and electric (E) sectors linked so as to maintain a constant B/E value, gave the same daughter ions for both 2-propanone and 4-hydroxy-4-methyl-2-pentanone although no spectra were given. On the basis of the self-CIMS spectra and the CAD B/E linked-scan spectra, Parker *et al.* concluded that the two species of m/z 117 had a common structure and that protonated 2-propane must undergo an aldol condensation with 2-propanone in the gas phase identical with that of the acid-catalyzed condensation of 2-propanone in the solution phase.

Relative ion intensities obtained by self-CIMS should be comparable with those of a particular storage time as obtained in this work.

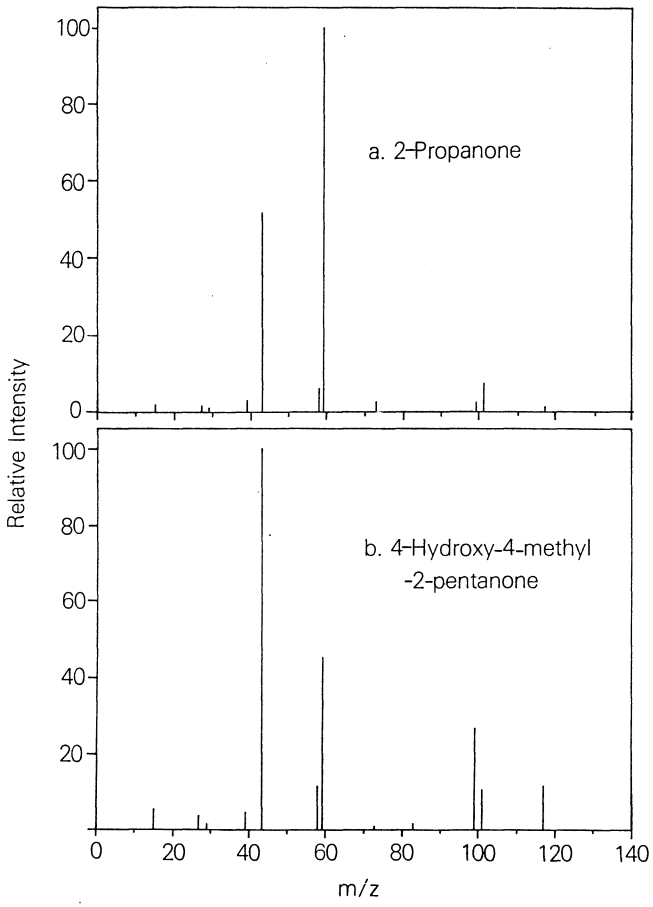

FIG. 7. Relative abundances for self-CIMS of (*a*) 2-propanone and (*b*) 4-hydroxy-4-methyl-2-pentanone.

Although the pressures and residence times in various sources may differ, the dependence of ion intensities on the product of pressure (raised to the power of the reaction order) and time permit a ready comparison. Thus the relative ion intensities shown in Fig. 7*a* and *b* correspond to a storage time of ~5 ms in each of Figs. 2 and 5, respectively. There is, however, a disparity in the ion abundances of m/z 58 and m/z 59 in Fig. 7*b*; only negligible abundances of these ions were observed in our QUISTOR studies.

We are not convinced that an aldol condensation occurs in the gas phase with 2-propanone on the basis of the evidence shown in Fig. 7. On the contrary it has been shown that IRMPD of protonated 4-hydroxy-4-methyl-2-pentanone, m/z 117, isolated in the QUISTOR yielded two photoproducts m/z 43 and m/z 99 (reactions [23] and [24]), whereas IRMPD of proton-bound 2-propanone dimers, m/z 117, carried out under identical conditions, yielded but the single photoproduct, m/z 59 (reaction [17]).

Thus we conclude that the structures of the ion species of m/z 117 obtained in these two systems are different, and that an aldol condensation does not occur with 2-propanone in the gas phase.

The species of m/z 99 was irradiated by the laser for periods of 33 ms, 50 ms, and 100 ms which is the entire period of its genesis yet no photodissociation products were observed. Thus it is concluded that the m/z 99 species is virtually transparent to the laser irradiation at the wavelength employed. It had been anticipated that photodissociation of the m/z 99 species would lead to the formation of the m/z 83 species by the photochemical reaction similar to reaction [22]. As no such species as m/z 83 was observed even from nascent m/z 99 ions it was concluded that the m/z 99 species is transparent at the laser wavelength.

At higher pressure, protonated 4-hydroxy-4-methyl-2-pentanone reacts with parent neutrals to form the proton-bound dimer, m/z 233.

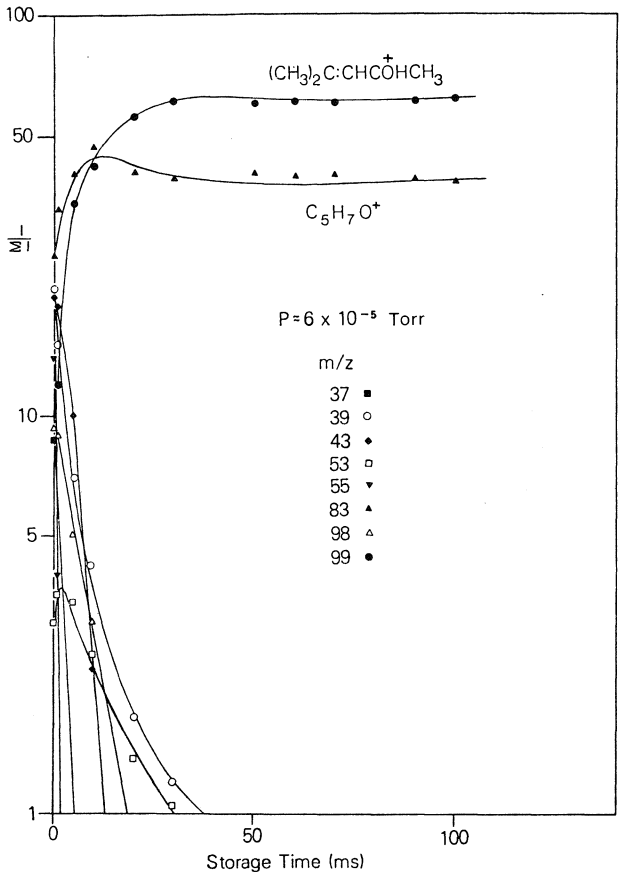

FIG. 8. Variation in the logarithm of normalized ion abundances in 4-methyl-3-penten-2-one with storage time 0–100 ms, 6×10^{-5} Torr.

In addition, ions were observed at m/z 215 $[2M + 1 - H_2O]^+$, m/z 175 $[2M + 1 - 58]^+$, and m/z 157 $[2M + 1 - H_2O - 58]^+$. Isolation of the proton-bound dimer was beyond the limit of the ramped rf sweep for axial ejection, thus it was not possible to isolate m/z 233 for irradiation. The intensities of all of the above species were diminished by IRMPD. As the fractional dissociation of the $[2M + 1 - H_2O]^+$ species exceeded that of the $[2M + 1]^+$ species, we conclude that the former is a mixed associative dimer and the activation energy for dehydration of $[2M + 1]^+$ exceeds that for the dedimerization process.

[26] $[(CH_3)_2C(OH)CH_2COCH_3]_2H^+ \xrightarrow{nh\nu}$
$(CH_3)_2C(OH)CH_2\overset{+}{C}OHCH_3 + (CH_3)_2C(OH)CH_2COCH_3$

The thermal and photochemical reactions of $[2M + 1]^+$ will be compared with those in the α,ω-hydroxy thiols in a forthcoming publication in this journal.

4-Methyl-3-penten-2-one (mesityl oxide)

Ion/molecule reactions

It was decided to investigate the ion chemistry of 4-methyl-3-penten-2-one (mesityl oxide) as the structure of protonated 4-methyl-3-penten-2-one was proposed for the major unimolecular product of protonated 4-hydroxy-4-methyl-2-pentanone and for the ion formed by loss of water from the proton-bound dimer of 2-propanone [9]. Furthermore the ion chemistry of this compound is not evident in the literature. The temporal variation of ion intensities of 4-methyl-3-penten-2-one at a pressure of 6×10^{-5} Torr is shown in Fig. 8.

The base peak in the electron impact mass spectrum is due to m/z 83 while the other major ions were observed at m/z 39, 43, and 55 in order of decreasing relative intensity. Minor ions (<10%) which were observed were the molecular ion of m/z 98, and m/z 53.

The molecular ion reacted rapidly and completely within 10 ms presumably by proton transfer to form protonated 4-methyl-3-penten-2-one

[27] $(CH_3)_2C{=}CHCOCH_3^{+\bullet} + (CH_3)_2C{=}CHCOCH_3$
m/z 98
$\rightarrow (CH_3)_2C{=}CH\overset{+}{C}OHCH_3 + C_6H_9O$
m/z 99

Within 40 ms of storage all primary ions save m/z 83 reacted completely also presumably to form m/z 99. Only the reactive form of $C_2H_3O^+$, CH_3CO^+, was observed in this system. The species of m/z 53, $C_4H_5^+$, rose slightly in intensity during the rapid decay of the molecular ion then reacted slowly and completely.

The intensity due to the protonated 4-methyl-3-penten-2-one rose rapidly during the first 20 ms of storage (or reaction) time to become the dominant ion in the system. It reached a maximum intensity after 40 ms and proved unreactive for the duration of the storage time. The intensity of another ion, m/z 83, increased initially, then after 40 ms of storage, remained constant. The behaviour of m/z 99 and m/z 83 suggests that the proton affinity of the neutral species C_5H_6O (82 mu) must be greater than that of 4-methyl-3-penten-2-one. The proton affinity of the latter compound also is not in the literature, but has been determined in this laboratory (23). Proton-bound dimer ions of m/z 197 were not observed.

Photochemical studies

The protonated molecule, m/z 99, was isolated and subjected to laser irradiation but no photoproducts were observed; this species is thought also to be transparent at the laser wavelength.

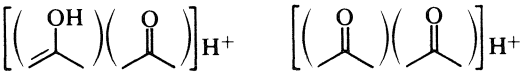
Discussion

The structure of m/z 99 in 2-propanone constitutes a problem. The loss of H_2O from a proton-bridged 2-propanone dimer of m/z 117 must be explained. It has been demonstrated earlier by IRMPD that the structure of the proton-bound dimer of 2-propanone must differ from that of protonated 4-hydroxy-4-methyl-2-pentanone, m/z 117. It is significant here that the dehydration channel for the proton-bound 2-propanone dimer is not accessed by laser irradiation. In an attempt to explain the dehydration channel in the 2-propanone dimer which is observed thermally only, we have considered the keto and enol forms of protonated 2-propanone. MINDO/3 calculations show the latter to be less stable by 110 kJ mol^{-1} (15), hence relaxed protonated 2-propanone is expected to exist as the keto form, structure **X**, as opposed to the isomeric enol, structure **XI**.

X **XI**

It is important to recognize that nascent proton-bound 2-propanone dimers contain a minimum of 134 kJ mol^{-1} (14) excess internal energy if formed from fully relaxed neutrals and protonated monomers.

As the protonated monomers, m/z 59, are formed via exothermic proton transfer reactions, the nascent dimers may contain more than 134 kJ mol^{-1} and may isomerize to form a mixed keto–enol species of structure **XII** as opposed to the anticipated fully relaxed structure **XIII**.



XII **XIII**

While either isomer may dedimerize to produce m/z 59, the elimination of water is more easily rationalized from the high energy structure, **XII**, as shown in reaction [28].

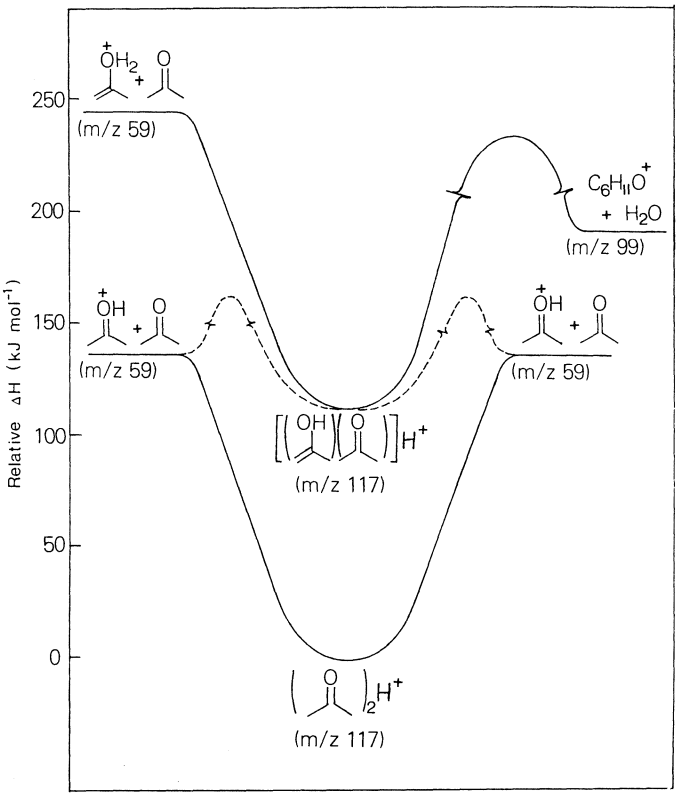


FIG. 9. Schematic energy profile for rearrangements involving the proton-bound dimer of 2-propanone.

[28] 
XII

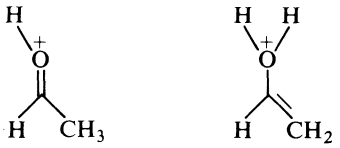
In Fig. 9, the relative enthalpies (ΔH) of the major ionic species derived from 2-propanone are shown. The height of the barrier leading to the formation of the dehydration product, m/z 99, is unknown, as is the activational energy requirement to form the enol.

The apparent difference between the observed products of thermal and photolysis reactions, as shown in Figs. 2 and 4, respectively, may be explained by noting that in the photolysis experiment, all ions of $m/z < 117$ were removed, leaving "aged" or partially relaxed dimer ions at 80 ms of storage time which were subsequently photolyzed. In Fig. 2 it is apparent that thermal genesis of m/z 99 reaches a maximum at ~70 ms storage time, hence the "aged" dimers photolyzed at the onset of laser irradiation in the IRMPD study contain insufficient internal energy for the dehydration process. It has been demonstrated that in slow IRMPD, laser pumping of vibrational states is slower than the rate of unimolecular dissociation (7), hence solely the reaction channel of lowest activation energy will be accessed if relaxed species are irradiated and the activation energy requirements for competing channels differ by at least the energy of the photon employed. The IRMPD results demonstrate that the dedimerization reaction is of lower E_a than dehydration in proton-bound 2-propanone dimers.

The structure of m/z 99 in 4-methyl-3-penten-2-one may be either that of the keto, **XIV** or the enol **XV**. Structure **XIV** is the

XIV **XV**

preferred form as it is presumably the more stable of the two and it lacks a β-hydrogen. The presumption of greater stability of **XIV** relative to **XV** is based on a comparison of the energies of protonated acetaldehyde, **XVI** and protonated vinyl alcohol, **XVII**



XVI **XVII**

The heat of formation of protonated acetaldehyde is given by

[29] $\Delta H_f(\mathbf{XVI}) = \Delta H_f(CH_3CHO) + \Delta H_f(H^+) - PA(CH_3CHO)$

where PA is the proton affinity. Similarly

[30] $\Delta H_f(\mathbf{XVII}) = \Delta H_f(CH_2{=}CHOH) + \Delta H_f(H^+) - PA(CH_2{=}CHOH)$

Thus for **XVI** to be thermodynamically more stable than **XVII** and, by analogy, **XIV** to be more stable than **XV**, $\Delta H_f(\mathbf{XVII}) - \Delta H_f(\mathbf{XVI})$ should be greater than zero, that is

[31] $\Delta H_f(CH_2{=}CHOH) + PA(CH_3CHO) - \Delta H_f(CH_3CHO) - PA(CH_2{=}CHOH) > 0$

$\Delta H_f(CH_2{=}CHOH)$ lies in the range $-(111\text{–}125)$ kJ mol^{-1} (24)

$PA(CH_3CHO) = 781$ kJ mol^{-1} (22)

$\Delta H_f(CH_3CHO) = -166$ kJ mol^{-1} (25)

The $PA(CH_2{=}CHOH)$ is reported (26) as 47–54 kJ mol^{-1} less than $PA(C_2H_5OH)$ which is given (22) as 788 kJ mol^{-1}; hence $PA(CH_2{=}CHOH)$ lies in the range 734–741 kJ mol^{-1}. As the sum of the thermodynamic quantities in eq. [31] lies in the range 81–102 kJ mol^{-1}, structure **XIV** is probably more stable than **XV**. The presence of a β-hydrogen is required for the elimination of water from protonated ketones (27) and, since neither structure **XIV** nor **XV** has a β-hydrogen, dehydration is not expected and no dehydration product (m/z 81) was observed. Apart from the energy consideration discussed above, no distinction may be made at this time between the keto and enol tautomers for the identity of m/z 99.

The identity of m/z 99 derived via dehydration of protonated 4-hydroxy-4-methyl-2-pentanone, m/z 117, was proposed earlier as **XIV** above, and as such further dehydration was neither expected, nor observed.

The structure of m/z 83 produced from protonated 4-methyl-3-penten-2-one is proposed as **IX** as shown in the alkane elimination reaction [22].

[22] 
XIV **IX**

TABLE 1. Activation energies for α-cleavage reactions of ionized methyl ketones estimated from the appearance energy of the α-cleavage product and the ionization energy of the methyl ketone

α-Cleavage reaction	AE (eV)	1E[a] (eV)	AE − 1E ~ E_a
 → ·CH_3 + $C_2H_3O^+$	10.3–10.4[a]	9.7	0.6–0.7
 → ·CH_3 + $C_3H_5O^+$	10.22[a]	9.5	0.7
 → ·CH_3 + $C_4H_7O^+$	10.03[b]	9.40	0.63

 → ·CH_3 + $C_5H_9O^+$	9.4[a]	9.2–9.4	0–0.2
 → ·CH_3 + $C_5H_9O^+$	9.8[b]	9.30	0.50
 → ·CH_3 + $C_3H_3O^+$	10.4[a]	10.1–9.6	0.3–0.8

[a]Reference 28.
[b]Reference 21.

The protonated ketone, **XIV**, may also eliminate isobutene, as shown in reaction [32];

[32]  + CH_3CO^+ ΔH = 136 kJ mol^{-1} (m/z 43)

XIV

however, no trace of m/z 43 was observed, thus reaction [32] is of higher E_a than reaction [22]. The enthalpy change for reaction [22] is not known as the heat of formation of m/z 83 of structure **IX** is not available. However, an estimate of the activation energy may be obtained by examination of the ionization energy (IE) of a number of ketones and the appearance energy (AE) for the α-cleavage reaction

[33] 
As the energy of activation may be approximated by the expression

[34] $E_a \approx$ AE − IE

it is apparent from Table 1 that as the alkyl (or alkenyl) group, R, is extended the activation energy of the reaction is diminished. Thus it seems probable that the heat of formation of m/z 83 is less than that for CH_3CO^+ in reaction [32]; however, it has been brought to our attention that such may not be the case as $\Delta H_f^0(CH_3CO^+)$ in some 240 kJ mol^{-1} less than $\Delta H_f^0(CH_2{=}CHCO^+)$ although the AE − IE values in Table 1 suggest otherwise. Therefore, despite a lower ΔH_f^0 for methane than for isobutene in reaction [32], the enthalpy hierarchy between reactions [22] and [32] may not be satisfactorily established.

The structure of m/z 83 formed from protonated 4-hydroxy-4-methyl-2-pentanone is also proposed as **IX** above. Although m/z 43 was observed both thermally and photolytically from the protonated hydroxy ketone, m/z 117, IRMPD of the isolated m/z 117 demonstrated that m/z 43 was derived directly from the protonated parent, rather than from its dehydration product, m/z 99.

The Claisen rearrangement of 1,4-bis(*m*-methoxyphenoxy-)2-butyne

E. KIEHLMANN,[1] E. P.-M. LI, AND J. G. MILLAR[2]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received December 2, 1985

E. KIEHLMANN, E. P.-M. LI, and J. G. MILLAR. Can. J. Chem. **64**, 1989 (1986).

The Claisen rearrangement of 1,4-bis(*m*-methoxyphenoxy-)2-butyne (**1***b*) gives four isomeric dimethoxy-6*H*-benzofuro[3,2-*c*]-6a,11a-dihydro-11a-methylbenzopyrans (**3**), three dimethoxy-4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofurans (**4**), and, in the presence of acid, three dimethoxy-5a,10b-dihydro-5a,10b-dimethylbenzofuro[2,3-*b*]benzofurans (**5**), which have been separated and identified by proton and ^{13}C nmr spectroscopy. Based on the isolation of two chromene intermediates and their conversion to **3** and **4**, as well as the isomerization of **3** to **4** and **4** to **5**, a "double Claisen" mechanism is proposed. The reaction is not regiospecific but the two [3,3] sigmatropic shifts occur preferentially to the *para* positions of the methoxy substituents.

E. KIEHLMANN, E. P.-M. LI et J. G. MILLAR. Can. J. Chem. **64**, 1989 (1986).

La transposition de Claisen appliquée au bis(*m*-méthophénoxy)-1,4 butyne-2 (**1***b*) conduit à quatre diméthoxy 6*H*-benzofuro[3,2-*c*] dihydro-6a,11a méthyl-11a benzopyrannes isomères (**3**), à trois diméthoxy dihydro-4b,9b diméthyl-4b,9b benzofuro[3,2-*b*] benzofurannes (**4**) et, en présence d'acides, à trois diméthoxy dihydro-5a,10b diméthyl-5a,10b benzofuro[2,3-*b*] benzofurannes (**5**) qui ont été séparés et identifiés par spectroscopie rmn ^1H et ^{13}C. En se basant sur le fait que l'on a isolé deux chromènes intermédiaires, que ceux-ci ont pu être transformés en **3** et **4** et que l'on a pu réaliser les isomérisations **3** → **4** et **4** → **5**, on propose un mécanisme impliquant un «double Claisen». La réaction n'est pas régiospécifique; toutefois les deux déplacements sigmatropiques [3,3] se produisent préférentiellement vers les positions *para* des substituants méthoxy.

[Traduit par la revue]

Introduction

The Claisen rearrangement of aryl propargyl ethers is a convenient route for the preparation of chromenes (1, 2). With 1,4-bis(aryloxy-)2-butynes it yields 6*H*-benzofuro[3,2-*c*]-6a,11a-dihydro-11a-methylbenzopyrans (short: 11a-methylpterocarpans **3**) and varying amounts of isomeric 4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofurans (short: benzofuro[3,2-*b*]benzofurans **4**) and 5a,10b-dihydro-5a,10b-dimethylbenzofuro[2,3-*b*]benzofurans (short: ketals **5**). Mechanistic studies have demonstrated the intermediacy of chromenes (3–5) in the formation of 11a-methylpterocarpans, and the high thermodynamic stability of the cyclic ketals **5**, which are generally isolated as end products after long reaction times at high temperatures (4–8), especially in the presence of acid catalysts (Scheme 1).

In view of the occurrence of pterocarpans in various plant tissues and of their antifungal activities (9, 10), we were primarily interested in adapting this reaction to the synthesis of 11a-methyl analogs of natural phytoalexins, such as 11a-methylhomopterocarpin (**3***b*), in order to study their chemical and biological properties. Since the 1,3-dioxygenated aromatic substitution pattern (resorcinol type) is typical of all natural pterocarpans, we selected as starting material 1,4-bis(*m*-methoxyphenoxy-)2-butyne (**1***b*), which is readily obtained from 1,4-dichloro-2-butyne and *m*-methoxyphenol (11). In contrast to the *ortho*- and *para*-disubstituted aryloxy-2-butynes used by all previous investigators, *meta*-disubstituted compounds can give two regioisomers (*ortho* or *para* to the methoxy substituent) in each of the two [3,3] sigmatropic shifts (Scheme 2), leading to the possibility of formation of four isomeric 11a-methylpterocarpans **3**, three isomeric benzofuro[3,2-*b*]benzofurans **4**, and (or) three isomeric cyclic ketals **5**, unless one or both steps are regiospecific. Therefore, the main goals of our project were the determination of the product distribution, identification of each isomer formed, and the optimization of reaction conditions (time, temperature, solvent, and catalyst) in favor of one or two isomers of the desired structure **3**. Recent publications on the proton and ^{13}C magnetic resonance parameters of a series of *ortho*- and *para*-substituted benzofurobenzofurans **4** and **5** (12), on an efficient procedure for their synthesis (5), and on the regiochemistry of the Claisen rearrangement of several *meta*-substituted allyl and propargyl ethers (13, 14) prompt us now to report our results.

Results

Preliminary experiments established that, on reflux in *N*,*N*-diethylaniline for several hours, 1,4-bis(*m*-methoxyphenoxy-)2-butyne (**1***b*) rearranges to six heterocyclic isomers (subsequently identified as **3***b*, **3***c*, **3***d*, **3***e*, **4***b*, and **4***c*, see Scheme 1) whose ratio is a function of reaction time and temperature. Although some of the starting material (approximately 20%) reacted during passage through the capillary column, the rearrangement products were found to be stable to the conditions employed for gas chromatographic analysis. At 225°C, all four dimethoxy-11a-methylpterocarpans (**3**) and smaller amounts of the two dimethoxybenzofuro[3,2-*b*]benzofurans **4***b* and **4***c* were present after 1.5 h, and **4***b* and **4***c* constituted the major products at the time of complete consumption of **1***b* (2.5 h). Continued monitoring revealed a gradual increase in the **4**/**3** ratio as the reaction progressed, leading to a mixture containing approximately equal quantities of **3***b*, **3***c*, and **4***b* in addition to the minor components **3***d*, **3***e*, and **4***c* after 6.5 h. The predominance of **4***b*, reduced percentages of **3***c*, **3***d*, and **3***e*, and the complete absence of **3***b* at the end of the reaction (29 h) indicate that all pterocarpans isomerize gradually to benzofuro[3,2-*b*]benzofurans, with the rate of the **3***b* → **4***b* interconversion being particularly rapid. Lowering the temperature from 225 to 210°C slowed down this process but gave otherwise similar results: six major isomers after 4.5 h, with **3***b* and **4***b* as main components, and a final product mixture containing **3***b*, **3***c*, **3***d*, **3***e*, **4***b*, and **4***c* in the approximate molar ratio 2:2:2:1:4:2. The individual components were isolated by liquid chromatography, as described in the experimental section, and the composition was verified by integration of the peak areas of the methoxy and angular methyl protons (3.8 and 1.7 ppm, respectively) in the nmr spectrum.

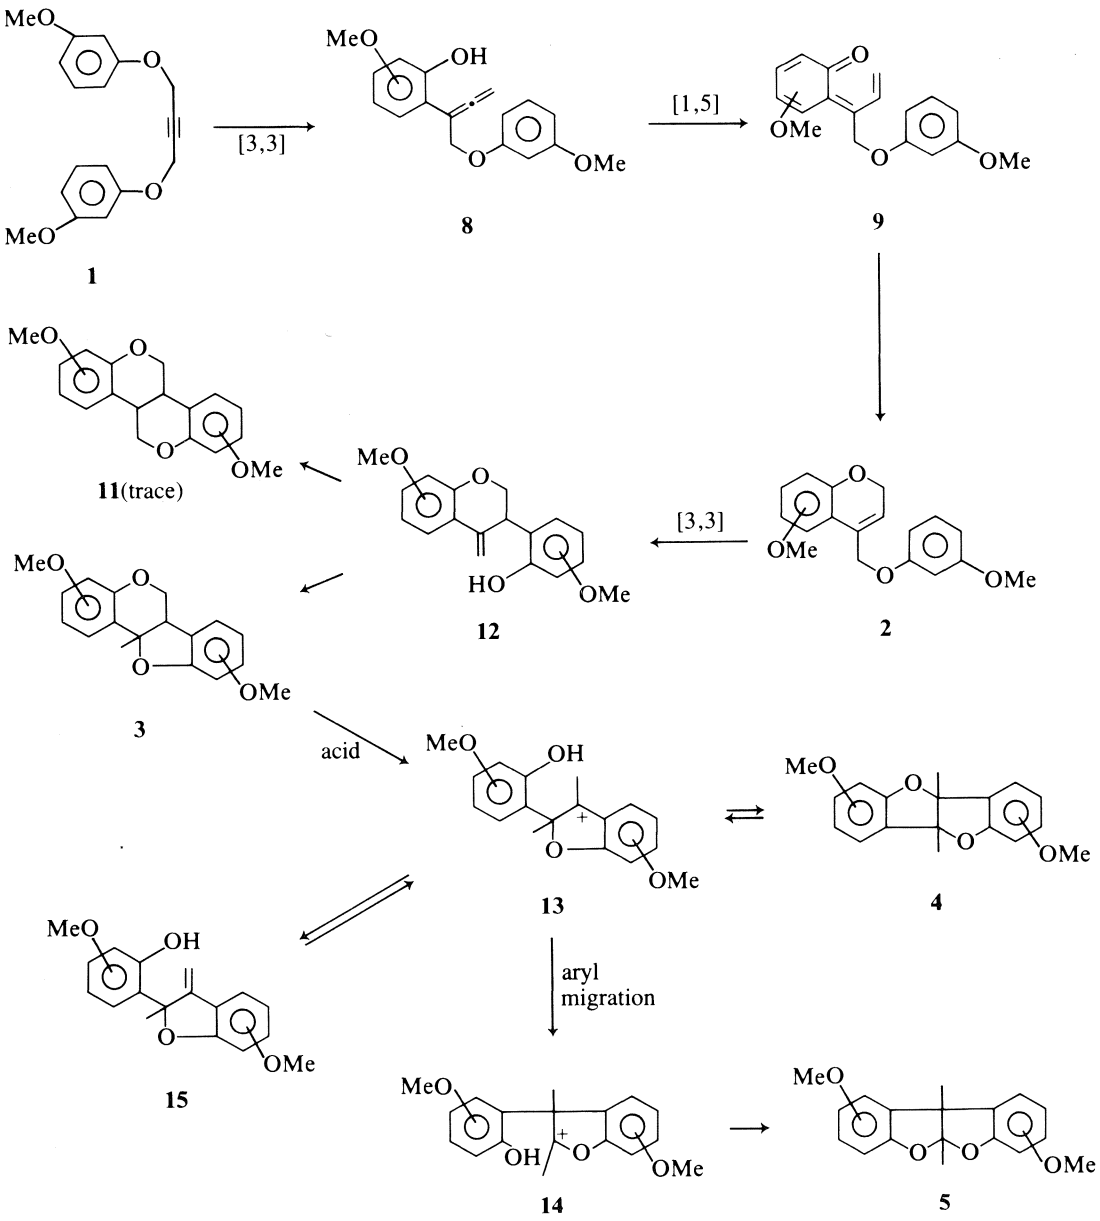
SCHEME 1

15 min at 210°C revealed the presence of three intermediates (in addition to 34% starting material and 4% **4***b*), which were identified as 5- and 7-methoxy-4-(*m*-methoxyphenoxymethyl-)2*H*-chromene **2***b* and **2***d* (14% each) and a mixture of several isomeric dimethoxy-4b,5,10b,11-tetrahydrobenzopyrano[4,3-*c*]benzopyrans **11** (6%). Chromene **2***b* was found to rearrange cleanly to a mixture of **3***b*, **3***c*, **4***b*, and **4***c* (molar ratio 3:2:3:1) within 4 h (210°C), thus confirming its true intermediacy in the reaction (3, 4) and the irreversibility of the first Claisen rearrangement step.

The addition of *p*-toluenesulfonic acid (PTS) to a mixture of approximately equimolar quantities of 11a-methylpterocarpans (**3***b*, **3***c*, **3***d*, and **3***e*) and benzofuro[3,2-*b*]benzofurans (**4***b* and **4***c*) in refluxing *N*,*N*-diethylaniline leads to rapid conversion of the former to the latter, reaching constant composition (40% **4***b* and 35% **4***c*) after 2.5 h at 225°C or 6.5 h at 210°C. As in the absence of acid, **3***b* was observed to rearrange most rapidly and **3***e* most slowly. Adding the acid catalyst to the 1,4-diaryloxy-2-butyne at the beginning of the reaction and monitoring the composition over a 13-h period (210°C) gave similar results: after 1.5 h, before complete consumption of the starting material, **2***b* constituted the main product and the three benzofuro[3,2-*b*]benzofurans outweighed the four methylpterocarpan isomers by a factor of four. By the end of the reaction (13 h), the chromene and the pterocarpans had all but disappeared while the percentages of **4***b*, **4***c*, and **4***e* had increased substantially. The slow buildup of the **4***e* concentration at the expense of **3***e* was particularly noticeable. As expected, the chromene **2***b* rearranged to **4***b* and **4***c* (2:1) under acid-catalyzed conditions, while pure **3***d* yielded only **4***c*. The latter observation represents the first direct experimental evidence for the previously postulated (4, 5) isomerization of **3** to **4**, probably via a 2-aryl-3-exomethylene-2,3-dihydro-benzofuran (**15**). The gas chromatograms of the mixtures formed in the presence of *p*-toluenesulfonic acid exhibited an unexpected small peak, possibly due to this elusive intermediate; however, all our attempts to isolate a pure sample by liquid chromatography or to trap it in the form of its acetate by performing the reaction in quinoline/acetic anhydride (5) failed.

In refluxing *N*-methylaniline (bp 196°C) the rearrangement proceeded much more slowly, with the product distribution being virtually identical to that observed in *N*,*N*-diethylaniline.



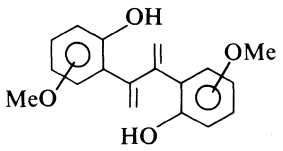
SCHEME 2

Similar results were obtained in decalin (bp 190°C) except that the proportion of methylpterocarpans during the early stages of the reaction was larger than in the other two solvents. Heating **1** to 200°C in the absence of solvent led to rapid formation of **4***b* and **4***c* without accumulation of significant quantities of **3** at an intermediate stage. Most of the starting material was recovered when silver tetrafluoroborate was used in place of *p*-toluenesulfonic acid under mild conditions (CH_2Cl_2, 7 h). Bates and Jones (4) found 1,4-bis(*o*-methoxyphenoxy-)2-butyne to be similarly inert, in sharp contrast to the high reactivity of the corresponding *para* isomer. With aluminum chloride as catalyst, **1***b* rearranged smoothly (in refluxing dichloromethane) to a mixture of **4***b*, **4***c*, and the corresponding ketals **5***b* (major product) and **5***c*. To test whether the latter two compounds are formed from **4***b* and **4***c*, respectively, by a pinacole-type rearrangement (5–7), we subjected each of the three benzofuro[3,2-*b*]benzofuran isomers separately to the same reaction conditions and observed no reaction with **4***b*, partial conversion of **4***c* to **5***c*, and complete conversion of **4***e* to **5***e*; the reactions were accompanied by some ether cleavage, as noted previously (4). The unsubstituted 4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofuran (**4***a*) was also found to isomerize to the corresponding ketal (**5***a*) with aluminum chloride.

Discussion

Our results show that the Claisen rearrangement of 1,4-bis(*m*-methoxyphenoxy-)2-butyne (**1***b*) proceeds by a mechanism very similar to that of the previously studied *ortho*- and *para*-substituted 1,4-diaryloxy-2-butynes. However, the simple sequential pathway **1** → **2** → **3** → **4** → **5** established by Balasubramanian and co-workers (5) for the latter must be modified for the analogous isomerization of **1***b* because it does not explain the direct conversion of **3** to **5**, bypassing **4**, nor does it account for the important role played by acid catalysts in the ring contraction of **3**. We believe that Lewis acids are essential for the formation of the ketals **5**. Various free phenolic intermediates (e.g., **8**, **12**) may act as proton source and *N*,*N*-diethylaniline or polyethylene glycol PEG-200 (5) as

efficient proton carriers when no catalyst is added. The relatively large proportion of methylpterocarpans **3** formed in decalin, a nonpolar solvent, appears to support this conclusion. In contrast to the results reported by Bates and Jones (4) for **1***c* and **1***d*, we have found that **1***b* yields substantial quantities of benzofuro[3,2-*b*]benzofurans under virtually all thermal and catalyzed reaction conditions, even during the initial phase without added catalyst and at the end of the reaction with aluminum chloride. Therefore, we feel that intermediates such as **9** or **10** cannot be excluded (although they could not be



10

isolated), and that the observed products result from several competing pericyclic and ionic pathways (Scheme 2).

In the first step, a concerted [3,3] sigmatropic shift leads to the formation of an allene as postulated by Schmid and coworkers (in ref. 15). Though unstable, such structures have actually been isolated (2) in the Claisen rearrangement of several aryl propargyl ethers to chromenes. The presence of large quantities of chromenes (**2**) shortly after the start of the reaction indicates that the second step involves a rapid [1,5] hydrogen shift, to yield the ω-vinylquinone methide **9**, and subsequent electrocyclic ring closure. As an alternate possibility, **8** may undergo another Claisen rearrangement to a 2,3-diarylbutadiene (**10**) from which **3**, **4**, and the minor by-product **11** could be formed directly by two successive cyclizations (16).

The further course of the reaction depends to a large extent on the availability of protons. Chromene **2** is converted to methylpterocarpan **3** (and traces of **11**) via a 3-aryl-4-exomethylenebenzopyran (**12**) by a second [3,3] sigmatropic shift (normal Claisen rearrangement) and a homodienyl [1,5] sigmatropic shift (abnormal Claisen rearrangement) (10), and the latter undergoes irreversible ring contraction to a benzofurobenzofuran (**4** and (or) **5**). The rate acceleration observed on addition of Lewis acids suggests the formation of a common resonance-stabilized benzylic carbocation intermediate (**13**) by acid-catalyzed cleavage of the pyran ring of **3** (4). The pronounced dependence of the **3** → **4** and **4** → **5** interconversion rates on the positions of the methoxy groups may be due to a combination of steric and electronic substituent effects on the lifetime of this cation and the migratory aptitude of the disubstituted aryl group in the pinacole-type rearrangement leading to ketal **5**. We hope that molecular energy and charge density calculations currently in progress will lead to a better understanding of the driving forces for these two isomerizations. The 2-aryl-3-exomethylene-2,3-dihydrobenzofuran **15** is probably the unidentified intermediate detected in all reactions catalyzed by *p*-toluenesulfonic acid (5). Benzofurobenzofuran ring systems (**4** and **5**) are apparently more stable than benzofurobenzopyrans (**3**), and the unusual thermodynamic and chemical stabilities of **4***b* and **5***e* are particularly noteworthy.

Because of our interest in the synthesis of analogs of specific naturally occurring pterocarpans, we carefully analyzed variations in the product distribution as a function of solvent, catalyst, reaction time, and temperature. Unfortunately we could not identify a single set of conditions producing a specific 11a-methylpterocarpan isomer (**3***b*, **3***c*, **3***d*, or **3***e*) in high yield and purity such as to obviate elaborate chromatographic separation procedures. The Claisen rearrangement of **1***b* is clearly not regiospecific, in agreement with the widely fluctuating isomer ratios reported in the literature for the chromanes and chromenes formed in the corresponding reactions of other *meta*-substituted allyl and propargyl aryl ethers (13, 14, 17). However, it can be stated that the two [3,3] sigmatropic shifts occur preferentially to the aromatic carbon *para* to the methoxy group, i.e., the sterically least crowded isomers **3***b* and **4***b* constitute the major portion of the product mixture in all experiments.

The nmr spectra of the heterocyclic Claisen rearrangement products exhibit several interesting features. Complete analysis of the aromatic proton region has generally not been possible before the advent of high resolution spectroscopy at high frequencies (200–400 MHz), explaining the scarcity of literature data on di- and trisubstituted benzenes. Tables 1 and 2 summarize the proton chemical shifts and coupling constants of the 13 compounds prepared in our laboratory and include the spectral parameters of 3,8-dimethoxy-4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofuran **4***f* (12), 2,9-dimethoxy-5a,10b-dihydro-5a,10b-dimethylbenzofuro[2,3-*b*]benzofuran **5***f* (4), homopterocarpin **6***a* (18), and variabilin **6***b* (19) for comparison.

d: R—R′ = —CH:CH—, R″ = H

Focussing first on the clearly recognizable and well-separated methoxy and angular methyl singlets, we found that a methoxy group *ortho* to the point of attachment of the benzylic carbon (e.g., in **3***e*, **4***e*, **5***e*) invariably resonates at lower field (by 0.10–0.18 ppm) than the corresponding *para*-methoxy protons (e.g., in **3***b*, **4***b*, **5***b*), and that in **5** the angular methyl group attached at the ketal carbon (Me-5a) resonates at lower field strength than Me-10b. The aromatic *meta* protons (relative to the position of MeO attachment) absorb considerably downfield (by 0.6–0.8 ppm) from the corresponding *ortho* and *para* protons in all compounds while the latter were frequently difficult to distinguish from each other. To determine their chemical shifts, we ran several spectra in acetone-d_6, which gave a better separation of their peaks and permitted measurement of their coupling constants. In the unsubstituted compounds (**3***a*, **4***a*, **5***a*), saturation of the angular methyl protons (nuclear Overhauser effect) identified the lowfield multiplet as belonging to the proton adjacent to the position of attachment of the benzylic carbon, and decoupling experiments established that the resonance shifts gradually upfield in the order H-1/H-3/H-2/H-4 (H-1 arbitrarily defined as the proton absorbing at lowest field). This general trend and the close agreement of our chemical shifts with those reported by Ramah *et al.* (12) prompt us to propose a correction of the H-2 (from δ 7.25 to δ 6.95) and H-3 assignments (from δ 6.95 to δ 7.25) for 4b,9b-dihydrobenzofuro[3,2-*b*]benzofuran (20).

Comparing the substituted heterocycles with their unsubsti-

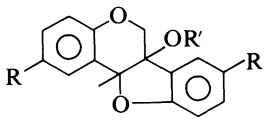
tuted counterparts, MeO substitution can be seen to have little effect on the δ values of the nonaromatic protons except that an upfield shift of H-6a (**3***d* and **3***e*) and H-6 (**3***b* and **3***d*) is observed on introducing a methoxy group at C-1 and C-9 (of **3***a*), respectively. Unsymmetrical MeO substitution separates the originally degenerate angular methyl resonances of **4***a* (1.78 ppm) by 0.16 ppm (**4***c*), with the upfield singlet (1.73 ppm) being due to Me-4b as proved by nOe enhancement of H-4. Interestingly, the methyl protons of the unsubstituted ketal **5***a* (6, 8, 12) and its 1,10-dimethoxy derivative (**5***e*) absorb at nearly identical field strengths. Analysis of the changes in the aromatic proton signal positions induced by methoxy substitution reveals a remarkably good agreement with published additivity parameters (12, 21): an upfield shift of 0.06 ± 0.01 or 0.15 ± 0.01 ppm (depending on whether MeO is *ortho* or *para* to the benzylic carbon) for *meta*, 0.45 ± 0.05 for *ortho*, and 0.35 ± 0.03 for *para* protons.

Focussing on the splitting patterns (Table 2), the two vicinal coupling constants (5 and 10 Hz) of the methylene group of **3** identify the upfield proton as axial and the downfield proton as equatorial, with the C—H_6/C—H_{6a} dihedral angle approaching 180° (18). We attribute the increase in J_{6ax-6a} from 9.3 to 10.7 Hz on MeO substitution at C-1 to rotation around the C_{6a}—C_6 bond leading toward a half-chair conformation, caused by van der Waals repulsions between ring C and the bulky methoxy group. With regard to the stereochemistry at the B/C ring junction, we concur with the conclusion of previous authors (4, 22) that the *cis* structures are less strained than their *trans* isomers and are formed exclusively, i.e., the cyclization steps of the Claisen rearrangement and the aryl migration leading to **5** are stereospecific. This interpretation is supported by the X-ray crystallographic determination of the structures of phaseolin (23), 1,3,4b,6,8,9b-hexamethyl-4b,9b-dihydrobenzofuro[3,2-*b*]benzofuran (24), and 5a,10b-dihydrobenzofuro[2,3-*b*]benzofuran (25). Table 2 shows that *ortho* coupling constants are generally large (8.0–8.5 Hz), and *para* coupling is negligible (<0.2 Hz) except for **3***a* and **4***a* (0.3–0.5 Hz). *Meta* coupling across a methoxy-substituted carbon is considerably stronger (2.3–2.7 Hz) than across an unsubstituted carbon (0.6–0.7 Hz). In the unsubstituted heterocycles, one can clearly distinguish three *ortho* and two *meta* couplings, three of which we have assigned to different proton pairs (J_{12} and J_{34} of **4***a*, J_{13} of **5***a*) than Ramah *et al.* (12). The long-range benzylic coupling (26) between H-6a and the four aromatic hydrogens of ring D (0.3–0.8 Hz) was particularly useful for the assignment of the proton signals in the spectrum of **3***a*. Among the four methoxy-substituted 11a-methylpterocarpans, only H-7 of **3***d* and H-9 of **3***c* were similarly split by the benzylic hydrogen.

Though the proton nmr spectra permitted unambiguous identification of the 12 major Claisen rearrangement products of 1,4-bis(*m*-methoxyphenoxy-)2-butyne, we also examined the ^{13}C spectra of those compounds that could be readily obtained in high yield and purity to verify our structural assignments and to generate additional reference data for the structure elucidation of natural and synthetic pterocarpans. The ^{13}C chemical shifts of 11 compounds prepared in our laboratory and 8 closely related compounds reported in the literature (8, 10, 12, 27, 28) are listed in Table 3.

It can be seen that the heterocyclic ring carbons resonate at frequencies that are characteristically different for the three ring systems under investigation, thus permitting a clear distinction. The C-6, C-6a, C-11a, and Me-11a signals of the methylpterocarpans **3** appear at 66.5 ± 0.5, 48.0 ± 1.0, 83.9 ± 0.7, and 26.2 ± 1.4 ppm, respectively, the angular methyl peaks of the benzofurobenzofurans at 19.5 ± 1.4 ppm, and the benzylic carbons of **4** and **5** at 96.8 ± 0.9 and 56.7 ± 0.7 ppm, respectively. The latter resonance is close to but not overlapping with the methoxy peaks (55.5 ± 0.4 ppm), which can also be readily distinguished from it by their higher intensity. Similarly, the ketal carbon of **5** gives rise to a low-intensity, substituent-independent singlet between 124.0 and 125.0 ppm while the high-intensity peaks due to the unsubstituted aromatic carbons (97.0–132.8 ppm) appear as doublets in the off-resonance decoupled spectra.

Although the ^{13}C spectra of the unsubstituted compounds have been reported before, we recorded them again in order to verify the peak assignments. In the event, our values agree well with those listed by Ramah *et al.* (12) for **4***a* and **5***a* (except for a small deviation of 0.4 ppm for C-5a and C-10b of **5***a*), but the previously published ^{13}C assignments for **3***a* (10) were found to be incorrect. As expected, the oxygen-substituted carbons resonate farthest downfield (154.5 and 158.4 ppm), with the higher value most likely due to C-10a on the basis of a comparison to the corresponding carbon in the structurally similar **4***a* (158.5 ppm). C-6b and C-11b resonate at 125.5 and 126.5 ppm; their individual assignments, however, remain uncertain. The unsubstituted aromatic carbons are readily recognized by their high intensities, and the D-ring signals by the excellent match of their absorption positions with those of the comparable benzofuran carbons of **4***a* and **5***a*. Confirmation of the CH assignments was obtained by correlation of the proton and carbon chemical shifts. Based on this analysis of the 11a-methylpterocarpan spectrum, we propose a similar revision (as listed in Table 3) of the previously reported (10) peak assignments for 6a-hydroxy-11a-methylpterocarpan (**7***a*).



7

a: R = R′ = H
b: R = OMe, R′ = Ac

Analysis of the spectra of the methoxy-substituted compounds was considerably aided by the independence of the ring A and ring D carbon signals, i.e, variation of the substitution pattern in one ring has little, if any, effect on the carbon chemical shifts of the other. The virtual identity of the D-ring chemical shifts measured for the substrate pairs **3***b* and **3***d*, **4***c* and **4***e*, **5***c* and **5***e*, and for the A-rings of **4***b* and **4***c* illustrates this point. In conjunction with the experimentally determined substituent increments discussed below, it permitted us to assign the peaks with reasonable confidence. It is well known (29) that in simple benzene derivatives a methoxy group strongly deshields the directly attached aromatic carbon (±30.2 ppm), shields the *ortho* and *para* positions (by −15.5 and −8.9 ppm, respectively), and has little effect on the *meta* position. In more complex molecules, methoxy groups have been observed to induce different shifts of the resonance signals of two nonequivalent *ortho* (or *meta*) carbons (28). Therefore, indiscriminate application of the average additivity parameters may lead to erroneous conclusions unless the model compounds are chosen carefully.

We have found that the methoxy-substituted carbon is deshielded by 31.5 ± 0.5 ppm if located *para*, and by 33.8 ± 1.0 ppm (except C-1 of **3***d*) if located *ortho* to the benzylic

[f]Assignments uncertain.

carbon. The former value is in excellent agreement with the shift of 31.5–32.5 ppm reported for the natural pterocarpans **6** (27, 28) relative to their unsubstituted 11a-methyl analog. Good agreement with **6** is also observed for the methoxy-induced *ortho* shift, which varies between −11.7 and −15.7 ppm in the benzopyran ring system (ring A of **3**) but remains in the narrower range of −13.0 to −14.6 ppm in all benzofurans. When an MeO group is introduced at the sterically less accessible peri position (next to the benzylic carbon), the resonance signal of the adjacent unsubstituted carbon is shifted upfield by 17.0–17.3 ppm. Unsubstituted *meta* carbons are weakly affected (−0.2 – +1.1 ppm) by the introduction of a methoxy group, while the absorption of oxygen-substituted *meta* carbons is shifted downfield by 1.0–1.8 ppm. *Para*-methoxy substitution leads to a downfield shift of the peaks due to absorption by both unsubstituted (6.8–7.4 ppm) and alkyl-substituted carbons (7.5–8.5 ppm). Using these refined shift parameters, we have obtained reasonable agreement between calculated and experimental values only by revising several assignments made by Donnelly (10) for **3***f* and **7***b*; analogous reassignments have already been proposed by Ramah *et al.* (12) for **4***f*.

Thus the structures of the isomeric rearrangement products isolated in our laboratory are firmly supported by their nmr spectra. Their mass spectra feature prominent molecular ion and methyl cleavage ($M - 15$) peaks but no significant differences in the fragmentation patterns that would allow a distinction between the different heterocyclic ring systems. In conclusion, the dimethoxy-11a-methylpterocarpans formed by Claisen rearrangement of 1,4-bis(*m*-methoxyphenoxy-)2-butyne are accompanied by and readily converted to more stable dimethoxybenzofurobenzofurans. Since the reaction cannot be stopped at the benzofurobenzopyran stage and the isomeric products are difficult to separate, it is not considered as a convenient route for the synthesis of 11a-methyl analogs of natural pterocarpans.

Experimental

Melting points (uncorrected) were recorded on a Fisher–Johns melting point apparatus, mass spectra (70 eV) on an HP-5985 quadrupole instrument, and nmr spectra on a Bruker spectrometer (400 MHz); chemical shifts were referenced to the center solvent (chloroform) line and corrected (+7.258 ppm for ^{1}H, +77.0 ppm for ^{13}C) to TMS. Gas chromatographic analyses were carried out on a Hewlett–Packard instrument (model HP-5890A) with integrator (model HP-3392A) and 15-m DB-1 capillary column (temperature programmed to increase from 150 to 250°C at 20°/min, carrier gas helium). For other chromatographic separations we used the following systems: (a) analytical tlc in toluene/ethyl acetate (49:1, solvent A), dichloromethane, hexanes/ether/methanol (96:10:4, solvent B), or dichloromethane/hexanes (85:15, solvent C) on Merck Kieselgel 60F-254 (0.2 mm) DC-Plastikfolien; (b) preparative tlc on Merck Silica Gel 60HF254+366; (c) flash chromatography on Kieselgel 60 (230–400 mesh) with the same solvents; and (d) hplc on Partisil-M9/ODS-2 with methanol/water/acetic acid (85:15:0.6) at a flow rate of 4.0 mL/min. Elemental analyses were performed on a Carlo Erba Elemental Analyzer Model 1106; $C_{18}H_{18}O_4$ requires 72.47% C and 6.08% H.

1,4-Bis(m-*methoxyphenoxy-)2-butyne* (**1**b)

Into a 500-mL three-necked round-bottom flask equipped with reflux condenser and mechanical stirrer were placed 150 mL reagent-grade acetone (dried over K_2CO_3 and freshly distilled), 57.9 g (0.419 mol) anhydrous potassium carbonate, and 43.4 g (0.350 mol) freshly distilled (bp 126–128°C/14 Torr; 1 Torr = 133.3 Pa) *m*-methoxyphenol (Aldrich, technical, purified as described in ref. 30). A solution of 16.05 g (0.1305 mol) freshly distilled (bp 72°C/23 Torr) 1,4-dichloro-2-butyne (Aldrich) in 50 mL acetone was added with stirring, and the dark-colored reaction mixture was stirred and refluxed for 25 h. The product mixture obtained after cooling, filtration, and evaporation of the solvent was dissolved in 125 mL ether, washed with 2 *M* KOH (3 × 50 mL) and water (2 × 50 mL), and dried ($MgSO_4$). Evaporation of the ether yielded 15.19 g of dark brown liquid which was fractionated at 0.05–0.10 Torr to give 12.05 g (40.5 mmol, 31%) 1,4-bis(*m*-methoxyphenoxy-)2-butyne boiling at 170–180°C; nmr (ppm): 7.17 (t, *J* 8.3 Hz, H-5), 6.53 (m, H-2,4,6), 4.71 (s, CH_2), and 3.77 (s, OMe). *Anal.* found: 72.29% C, 6.25% H. A small amount of 1-chloro-4-(*m*-methoxyphenoxy-)2-butyne was isolated from the low-boiling fraction (1.16 g) collected at 90–165°C/0.1 Torr; nmr (ppm): 7.17 (t, *J* 8 Hz, H-5), 6.49–6.62 (m, H-2,4,6), 4.71 (t, *J* 2 Hz, $ArOCH_2$), 4.15 (t, *J* 2 Hz, CH_2Cl), and 3.77 (s, OMe). *Anal.* calcd. for $C_{11}H_{11}ClO_2$: C 62.72, H 5.26; found: C 62.95, H 5.42. Unreacted *m*-methoxyphenol (28.9 g, 233 mmol) was recovered from the alkaline washings by acidification (concentrated HCl) and ether extraction.

11a-Methylpterocarpan (**3**a) *and 4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofuran* (**4**a)

These two compounds were prepared from 1,4-diphenoxy-2-butyne (11) as described in the literature (8, 22) and separated by fractional crystallization from ethanol, yielding pure **3***a*, mp 126–128°C (lit.(8) mp 124–125°C) and **4***a*, mp 128–129°C (lit.(8) mp 126–129°C).

*Rearrangement of 1,4-bis(*m*-methoxyphenoxy-)2-butyne* (**1**b)

(*a*) Without acid: In a 200-mL three-necked round-bottom flask fitted with nitrogen inlet tube, condenser, and thermometer, a solution of 8.69 g (29.1 mmol) 1,4-bis(*m*-methoxyphenoxy-)2-butyne (**1***b*) in 63 mL freshly distilled *N*,*N*-diethylaniline was heated under nitrogen at 210°C for 24 h. The originally yellow solution turned orange after one hour. Eight 50-μL samples were withdrawn at suitable time intervals for gc analysis. After cooling and addition of 200 mL ether, the solvent was removed by acidification and extraction with 10% HCl (3 × 200 mL) and water (5 × 50 mL), the organic layer was dried ($MgSO_4$), and the solvent evaporated to give 7.42 g (86%) of a brown viscous liquid. Gas chromatographic separation and mass spectrometric analysis showed the presence of six major components: 12.8% **3***b* (*m*/*z* 298 (35), 283 (100)), 11.0% **3***c* (*m*/*z* 298 (42), 283 (100), 267 (21)), 12.1% **3***d* (*m*/*z* 298 (46), 283 (100), 267 (14)), 6.9% **3***e* (*m*/*z* 298 (33), 283 (76), 267 (14), 162 (100)), 25.9% **4***b* (*m*/*z* 298 (32), 283 (100)), and 14.6% **4***c* (*m*/*z* 298 (47), 283 (100), 267 (32)). The composition was verified by integration of the methoxy and angular methyl peak areas in the ^{1}Hmr spectrum: 14% **3***b*, 13% **3***c*, 11% **3***d*, 7% **3***e*, 23% **4***b*, 10% **4***c*, and 2% **4***e*. Flash chromatography (solvent A) separated the mixture into four fractions (in order of elution): (*1*) a small quantity of material tentatively identified as a mixture of several isomeric dimethoxy-4b,5,10b,11-tetrahydrobenzopyrano[4,3-*c*]benzopyrans (**11**) on the basis of the absence of angular methyl protons in its ^{1}Hmr spectrum and the appearance of resonance signals (at 4.21, 4.28, 4.38, 2.56, 2.79, and 2.86 ppm) characteristic of the methylene and benzylic protons of this rare class of compounds (20, 31); (*2*) **3***c* (*Anal.* 72.35% C, 5.85% H), which was further purified by hpcl; (*3*) the major fraction from which **3***b* (*Anal.* 72.55% C, 6.23% H), **3***e* (contaminated with **4***c*), **4***b*, and **4***c* were obtained by repeated flash chromatography (solvent C); and (*4*) **3***d*, which was purified by preparative tlc (solvent A) and recrystallized from methanol (mp 110–113°C; *Anal.* 72.33% C, 5.91% H). Work-up of a large aliquot after 15 min reflux, followed by flash chromatography (solvent A) and preparative tlc (solvent B), yielded samples of 7-methoxy-4-(*m*-methoxyphenoxymethyl-)2*H*-chromene (**2***b*): *m*/*z* 298 (38), 191 (23), 161 (52), 77 (100); nmr (ppm): 3.78 and 3.79 (2s, OMe), 4.78 (q, *J* 1.3 Hz, $ArOCH_2$), 4.82 (dt, *J* 1.3 and 3.6 Hz, 2-CH_2), 5.80 (tt, olefinic CH), 7.11 (d, *J* 8.4 Hz, H-5), 7.21 (t, *J* 8.4 Hz, H-5′), 6.54–6.60 (m, H-2′,4′,6′), 6.43 (d *J* 2.5 Hz, H-8), and 6.46 (dd, H-5), and its 5-methoxy isomer **2***d* (contaminated with **11** and **3***c*); nmr (ppm): 3.76 and 3.79 (2s, OMe), 4.63 (dt, *J* 1.8 and 4.2 Hz, 2-CH_2), 5.04 (q, *J* 1.8 Hz, $ArOCH_2$), 5.97 (septet, olefinic H), and 6.3–7.4 (m, aromatic H).

(b) With *p*-toluensesulfonic acid (PTS): Repetition of the Claisen rearrangement in the presence of 10 mol% PTS gave a product mixture containing (time:%) **4***c* (1.5 h:14, 6 h:30, 13 h:31), **4***b* (1.5 h:16, 6 h:33, 13 h:36), **2***b* (1.5 h:31, 6 h:11, 13 h:4), an unidentified intermediate (1.5 h:8, 6 h:7, 13 h:8), **4***e* (1.5 h:3, 6 h:5, 13 h:6), and minor quantities of the four pterocarpan isomers **3** (1.5 h:9, 6 h:7, 13 h:4). Pure **4***e* (mp 187–190°C from methanol; *Anal.* 72.69% C, 6.19% H) was isolated from the final mixture (86% crude yield) by flash chromatography with dichloromethane.

(c) With aluminum chloride: In a two-necked 50-mL round-bottom flask fitted with condenser, drying tube, and nitrogen inlet tube, a solution of 250 mg (8.38 mmol) 1,4-bis(*m*-methoxyphenoxy-)2-butyne in 10 mL dichloromethane was mixed with an equimolar amount of aluminum chloride and magnetically stirred for 3 h at 25°C. After another 5 h reflux, washing with 3 *N* HCl, 1 *N* NaOH, and water, drying ($MgSO_4$), and solvent evaporation, 165 mg (66%) of a viscous brown oil remained, which was found (by gc analysis) to contain 25% **5***b*, 15% **4***b*, 8% **4***c*, and 17% unreacted starting material, together with small quantities of isomers. Gas chromatographic monitoring showed a gradual increase of the (**4** + **5**)/**3** ratio with time. Flash chromatography (dichloromethane) gave **4***b* and **5***b* (71.98% C, 6.55% H) for spectroscopic identification.

*Rearrangement of 7-methoxy-4-(*m*-methoxyphenoxymethyl-)2*H*-chromene (**2**b)*

A solution of 20 mg **2***b* in 1 mL *N*,*N*-diethylaniline was heated under nitrogen to 210°C, and its composition was monitored by gc over a period of 6 h. After 4 h the mixture contained 24% **4***b*, 22% **3***b*, 15% **3***c*, 10% of an unidentified by-product, and 7% **4***c*. On addition of a few milligrams PTS and another 2 h reflux, **3***b* and **3***c* disappeared and the percentages of **4***b* and **4***c* increased to 36% and 19%, respectively.

*2,9-Dimethoxy-4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofuran (**4**c) from 1,9-dimethoxy-11a-methylpterocarpan (**3**d)*

The thermal stability of **3***d* in the absence of acid was tested by subjecting a 30-mg sample, dissolved in 1.0 mL *N*,*N*-diethylaniline, to the Claisen rearrangement conditions (210°C/50 min); no reaction was observed (gc analysis). One hour after the addition of 5 mg PTS, more than half of the starting material had been converted to **4***c*, and after another 21 h at 190–210°C the reaction mixture contained 79% **4***c* and small amounts of two unidentified compounds (9 and 4% respectively). The structure of the major product (**4***c*: 72.26% C, 6.01% H) was confirmed by ^{1}Hmr after work-up (as described above) and purification by preparative tlc (solvent B).

*5a,10b-Dihydro-5a,10b-dimethylbenzofuro[2,3-*b*]benzofuran (**5**a) from 4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofuran (**4**a)*

An equimolar quantity of aluminum chloride was added to a solution of 83 mg (0.35 mmol) **4***a* in 4.0 mL dichloromethane. After 24 h of magnetic stirring at 25°C the purple solution was extracted with 1 *N* HCl and water, dried ($MgSO_4$), and distilled to obtain 80 mg (96%) of a beige solid that yielded pure **5***a*, mp 135–136°C (previously reported (8) as 195–196°C), on recrystallization from ethanol.

*Rearrangement of dimethoxy-4b,9b-dihydro-4b,9b-dimethylbenzofuro[3,2-*b*]benzofurans (**4**) to dimethoxy-5a,10b-dihydro-5a,10b-dimethylbenzofuro[2,3-*b*]benzofurans (**5**)*

Reflux of a solution of 27 mg (0.09 mmol) **4***e* in 1.5 mL dichloromethane (under nitrogen) with 0.12 mmol aluminum chloride for one hour, extraction with 1 *N* HCl, 1 *N* NaOH, and water, drying ($MgSO_4$), and solvent evaporation gave 23 mg (85%) of a semisolid residue containing 67% **5***e* and 20% unreacted starting material (by gc and ^{1}Hmr analysis). Continued reflux in chloroform (5 h) with fresh aluminum chloride raised the **5***e*/**4***e* ratio to 4:1 while further extension of the reaction time (69 h) resulted in partial ether cleavage (4). Similar treatment of **4***c* (70 h at 25°C in dichloromethane) yielded a viscous brown oil (77% yield) containing more than 80% **5***c*, while **4***b* did not react.

Proton magnetic resonance spectra of catechin and bromocatechin derivatives: C_6- vs. C_8-substitution

E. KIEHLMANN AND A. S. TRACEY
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received February 18, 1986

E. KIEHLMANN and A. S. TRACEY. Can. J. Chem. **64**, 1998 (1986).

The ^{1}Hmr spectra of 20 catechin derivatives substituted at C-6/C-8 by bromine and/or hydrogen and at oxygen by methyl, acetyl, and/or hydrogen have been analyzed in deuterated acetone, acetonitrile, and chloroform. Because of its dependence on the nature of the solvent and of the oxygen substituent, the difference between H-6 and H-8 chemical shifts has been found to be an unreliable criterion for the distinction between 8-bromo and 6-bromo isomers. In methylated catechins, double irradiation of H-8 and H-6 enhances one (MeO-7) and two (MeO-5 and MeO-7) methoxy signals, respectively, via the nuclear Overhauser effect. This permits unambiguous assignment of chemical shifts to all ring A protons. The H-6 and H-8 resonance frequencies of catechin have been determined by decoupling of the OH-5 and OH-7 protons.

E. KIEHLMANN et A. S. TRACEY. Can. J. Chem. **64**, 1998 (1986).

Utilisant l'acétone deutériée, l'acétonitrile et le chloroforme comme solvants, on a analysé les spectres de rmn du ^{1}H des dérivés de la catéchine substitués en position C-6/C-8 par le brome et/ou l'hydrogène et sur l'oxygène par des groupes méthyle, acétyle et/ou hydrogène. La différence entre les déplacements chimiques des protons H-6 et H-8 ne constitue pas un critère valable de distinction entre les isomères bromo-6 et bromo-8 puisqu'elle dépend de la nature du solvant et des substituants fixés sur l'oxygène. L'irradiation double des protons H-8 et H-6 des catéchines méthylés augmente respectivement les signaux d'un groupe méthoxy (MeO-7) et de deux groupes méthoxy (MeO-5 et MeO-7) via l'effet Overhauser nucléaire. Ceci permet d'identifier sans ambiguïté les déplacements chimiques de tous les protons du cycle A. On a déterminé les fréquences de résonance des protons H-6 et H-8 de la catéchine en découplant les protons OH-5 et OH-7.

[Traduit par la revue]

Introduction

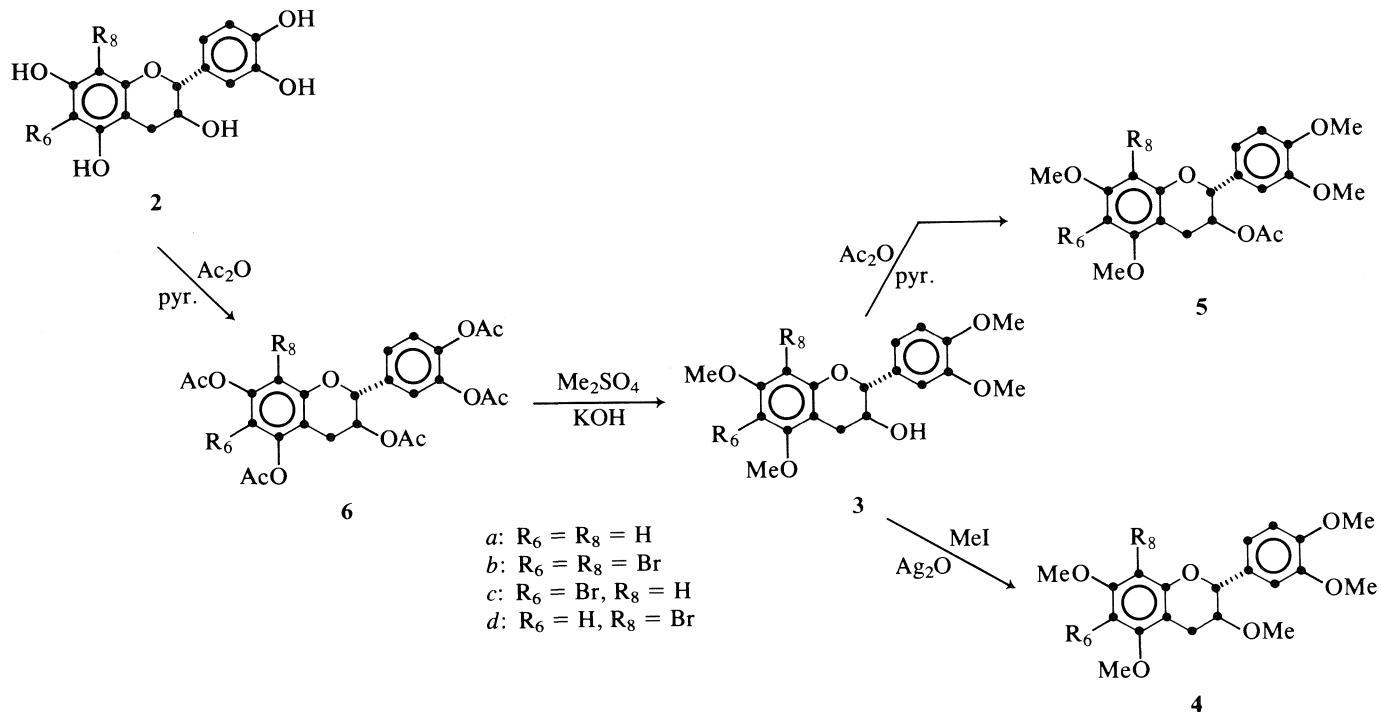
Ever since the isolation and structure elucidation of the first dimeric procyanidins by Weinges *et al.* (1) and their first synthesis (2, 3), unambiguous determination of the position of the interflavanoid linkage, i.e., the carbon atom of ring A of the terminal catechin or epicatechin unit (C-6 or C-8) that is bonded to C-4 of a second flavanoid, has remained problematic. This applies even to simple monoflavanoids such as monobromotetra- and penta-*O*-methylcatechin, for which Weinges (1, 3) postulated the 8-bromo structure on the basis of the greater steric accessibility of C-8 relative to C-6 in electrophilic aromatic substitution. It was not until 1977 (4) and 1985 (5) that the configurations of 8-bromo-3′,4′,5,7-tetra-*O*-methylcatechin (**3***d*) and 6-bromo-3,3′,4′,5,7-penta-*O*-methylcatechin (**4***c*) were proven by X-ray structure analysis. Due to the difficulty of obtaining di- and oligomeric flavanoids in crystalline form (6), this technique is clearly inconvenient for routine application to proanthocyanidins. Chemical correlation with authentic samples and nmr spectroscopy have, therefore, been most widely used to establish the substitution pattern in new natural and synthetic products.

Hundt and Roux (7, 8) derived several empirical nmr parameters from the proton spectra of 11 pairs of simple 6- and 8-monosubstituted tetra-*O*-methylcatechins (**1**) and established characteristic non-overlapping regions for the H-8 (6.32–6.47) and H-6 (6.10–6.22) resonance signals in chloroform. Carbon-13 and various different proton chemical shifts (9–12) and coupling constants (13) have been used by other researchers to identify the position of flavanyl and benzyl substituents in ring A of catechin derivatives. However, the observed chemical shift differences are usually small and the ^{1}Hmr parameters of most diflavanoid methyl ether acetates do not fall inside the relative and absolute ranges determined for monoflavanoids (8) if one assumes (14–16) that assignment of the position of the interflavanoid linkage can be based *solely* on the downfield chemical shift of H-8 of one regioisomer relative to H-6 of the other. Since the validity of this basic assumption has not been proved for diflavanoids by independent structure determination, e.g., X-ray diffraction or unambiguous synthesis, and the successful application of this comparative technique depends critically on the availability of the twin regioisomer of any new natural or synthetic procyanidin, the development of absolute distinction criteria appears prudent. With this goal in mind, we decided to synthesize all 15 6-bromo-, 8-bromo-, and 6,8-dibromo derivatives of catechin, 3′,4′,5,7-tetra-*O*-methylcatechin, 3,3′,4′,5,7-penta-*O*-methylcatechin, 3-acetyl-3′,4′,5,7-tetra-*O*-methylcatechin and catechin pentaacetate (eq. [1]), and the 4 non-brominated parent compounds, determine their structures by chemical correlation with authentic samples of **3***d* (4) and **4***c* (5), and record, analyze, and correlate their ^{1}Hmr spectra at 400 MHz in three different solvents.

Results and discussion

The ^{1}Hmr data listed in Tables 1–4 confirm the validity of the empirical rules proposed by Hundt and Roux (8) for the distinction between 6- and 8-substituted tetra-*O*-methylcatechins. However, we found that these criteria cannot be applied without modification to the corresponding peracetates in chloroform (17) or free phenols in acetone. For example, while the trends in the chemical shift difference $\Delta\delta$(H-2/6 or 8) and in the ratio $\Delta\delta$(H-2/4a)/$\Delta\delta$(H-2/6 or 8) are the same as for the corresponding methylated compounds, their magnitudes are considerably reduced, viz., from $\Delta\delta$(H-2/8) − $\Delta\delta$(H-2/6) = 0.41–0.52 for **3***c*/**4***c*/**5***c* vs. **3***d*/**4***d*/**5***d* to 0.24 for **6***c* vs. **6***d* and only 0.04 for **2***c* vs. **2***d*, and from $\Delta\delta$(H-2/4a)/$\Delta\delta$(H-2/6) − $\Delta\delta$(H-2/4a)/$\Delta\delta$(H-2/8) = 0.62–1.63 for **3***d*/**4***d*/**5***d* vs. **3***c*/**4***c*/**5***c* to 0.41 for **6***d* vs. **6***c* and 0.19 for **2***d* vs. **2***c*. The H-2 protons of 6-bromocatechin (**2***c*) and its pentaacetate (**6***c*) resonate slightly upfield (4.61 and 5.16 ppm) relative to the corresponding protons of the 8-bromo isomers **2***d* (4.77 ppm)

[1]



and **6***d* (5.33 ppm), and the H-4a signals are shifted slightly downfield (2.91 and 2.88, respectively, for **2***c* and **6***c* vs. 2.84 for **2***d* and **6***d*), as observed with greater magnitude for the methylated compounds, but the positions of the signals for the residual ring A protons are nearly identical for the acetates **6***c* (6.75 ppm) and **6***d* (6.69 ppm) and actually reversed for the free phenols, i.e., H-8 of **2***c* absorbs *upfield* (6.11 ppm) from H-6 of **2***d* (6.23 ppm). Changing the solvent from chloroform to acetone generally reduces the magnitude of the chemical shift differences between C_6- and C_8-substituted isomers. It is concluded that both the absolute and relative ^{1}Hmr parameters depend not only on the position of the bromine substituent (C-6 vs. C-8) but also on the solvent and the nature of the substituent attached to the phenolic oxygens. Magnetic anisotropy effects caused by a second flavanoid unit linked to C-6 or C-8 of catechin would make the chemical shift of the remaining ring A proton even less predictable. As all of these factors must be taken into account, great caution is advisable in making structural assignments based solely on chemical shift criteria.

While the coupling constants J_{23} and J_{34b} are seen to be larger for the 6- than for the 8-bromocatechins (Table 4), their predictive power for the differentiation between regioisomeric flavanoids is also questionable. The high degree of conformational flexibility of the heterocyclic ring (18) leads to J variations that depend not only on the nature and position of the substituents attached at C-3 and at the ring A carbons but also on the solvent used in the nmr experiment.

We therefore concentrated our efforts on a search for spectral parameters that could serve as absolute criteria for unambiguous structure assignments to single compounds, without the need for comparative data of their regioisomers. For example, the shift of the residual ring A proton signal on changing the nmr solvent may be of diagnostic value if it can be demonstrated to be equally applicable to catechin derivatives containing substituents other than bromine. The replacement of chloroform by acetone results in a large downfield shift (by 0.23–0.28 ppm) of the H-6 singlet of all three methylated 8-bromocatechins (**3***d*, **4***d*, and **5***d*) but only a small downfield shift (by 0.01–0.07 ppm) of the H-8 singlet of the corresponding 6-bromo isomers (**3***c*, **4***c*, and **5***c*). The same phenomenon is observed to a lesser degree for the non-brominated parent compounds (**3***a*, **4***a*, and **5***a*) for which the corresponding solvent change induces a small downfield shift (0.02–0.06 ppm) of the H-6 and a small upfield shift (0.05–0.10 ppm) of the H-8 signal. This indicates a preferred orientation of the acetone molecules with respect to the bromine, leading to more effective paramagnetic deshielding of H-6 in 8-bromocatechins than of H-8 in 6-bromocatechins. Such anisotropic solvent shifts are known to be a function of the distance between the nucleus under observation and the polar substituent, and of the dipole moment of the solute as well as the shape and dielectric constant of the solvent (19), and have aided previous investigators (20), mainly using chloroform and benzene, in the assignment of methoxy proton resonances.

Studies of the nuclear Overhauser effect (nOe) suggest a convenient method for the distinction between 6- and 8-substituted isomers, which should be of general applicability and independent of the nature of the substituent (Table 5). Double irradiation of the H-6 resonance frequency of any C_8-substituted 5,7-di-*O*-methylcatechin derivative increases the intensities of both methoxy signals, while H-8 irradiation of a C_6-substituted compound enhances only the one methoxy signal (MeO-7) positioned in its close physical proximity. The same phenomenon is observed for the C_6/C_8-unsubstituted derivatives **3***a*, **4***a*, and **5***a*, in which case H-6 saturation is found to enhance the MeO-5 more than the MeO-7 signal. These differences in the magnitude of the nOe effect confirm that the 5-methoxy group is preferentially oriented toward H-6 to minimize steric interactions with the C-4 hydrogens, and that in the monobromo compounds the 7-O-methyl group points away from the bulky bromine substituent (5). Chloroform was chosen as solvent for these experiments since it provides the best resolution of the methoxy signals. We have thereby firmly established

[a]Solvent: $CDCl_3$.

that in all methylated catechins, whether monobrominated or unsubstituted at C-6/C-8, H-6 resonates upfield from H-8 in chloroform, as proved for penta-*O*-methylcatechin (**4***a*) by regiospecific deuteration by Weinges *et al.* (21) and postulated for the structurally closely related tetra-*O*-methyl derivatives **3***a* and **5***a* by Haslam and co-workers (22) and Roux (14). To determine the ring A aromatic proton chemical shifts of **3***a*, **4***a*, and **5***a* in acetone and acetonitrile, we calculated the shift increments for H-6 and H-8 due to monobromination at C-8 and C-6, respectively. Due to the structural rigidity of the aromatic ring, the effect of replacing one hydrogen by bromine (e.g., H-8) on the chemical shift of the other (e.g., H-6) should be the same for all three compounds in a given solvent. In the event, 8-bromination was found to shift the H-6 resonance downfield by 0.06 ppm in $CDCl_3$, 0.18 ppm in CD_3CN, and 0.27–0.28 ppm in acetone-d_6, while 6-bromination shifts the H-8 resonance downfield by 0.23–0.24, 0.33, and 0.35–0.36 ppm, respectively, in the same three solvents. Thus a bromine substituent at C-6 has a larger deshielding effect on H-8 than 8-Br on H-6. The proton assignments based on this concept of additivity of substituent effects (23) are readily verifiable by nOe experiments or by running the ^{1}Hmr spectra in binary mixtures of acetonitrile or acetone with chloroform and plotting the H-6/H-8 chemical shift differences as a function of solvent composition. It is noteworthy that in acetone solution, in contrast to chloroform, H-6 of all three non-brominated methyl derivates of catechin resonates *downfield* from H-8.

As a corollary of the nOe studies, the frequencies of enhancement define the resonance positions of the 5- and 7-methoxy protons of the non-brominated compounds **3***a*, **4***a*, and **5***a* and the 7-methoxy protons of the 6-bromo derivatives **3***c*, **4***c*, and **5***c* (see Table 6). The 5-methoxy protons of the latter give rise to characteristically narrow lines, due to the absence of weak long-range *ortho* coupling (24), and are thereby distinguishable from the two methoxy groups of ring B. Finally, a distinction between the 5- and 7-methoxy singlets of the 8-bromocatechins **3***d*, **4***d*, and **5***d* is possible by calculation of the substituent increments relative to their non-brominated

analogs. A bromine atom at C-8 deshields the adjacent 7-methoxy protons more strongly (by 0.14–0.15 ppm) than 6-Br (0.08–0.09 ppm), while neither C_6- nor C_8-bromination has much effect (0.01–0.04 ppm downfield shift) on the absorption position of the 5-methoxy group. The close proximity of the latter to the C-4 hydrogens makes it more sensitive than MeO-7 to conformational changes in the heterocyclic ring caused by different C-3 substituents (OH vs. OMe vs. OAc). The ring B methoxy protons were found to resonate consistently in the narrow range between 3.84 and 3.91 ppm.

The assignment of specific resonance frequencies to H-6 and H-8 of catechin presented a particularly challenging problem because rapid chemical exchange gives rise to a broad OH absorption peak (near 8.0 ppm) that is ill-suited for nOe or decoupling experiments. However, a trace of cadmium nitrate added to the substrate solution in acetone reduces the exchange rate (25) to such an extent that the phenolic protons appear as four sharp, well-separated lines (8.280, 8.096, 7.984, and 7.928 ppm). Thus, gated decoupling of OH-5 (8.280 ppm) becomes possible and, if limited to only one second during each eight-second scan, permits the buildup of an nOe factor for the adjacent H-6 resonance signal (6.011 ppm) before any significant exchange with the other hydroxy protons has occurred. Since, under the same conditions, saturation of the OH-7 proton at 8.096 ppm increases the intensities of *both* the H-6 and the H-8 doublet, the chemical shifts of these two protons are clearly identified. The previously published assignments of 5.88 ppm to H-6 and 6.02 ppm to H-8 (22) must therefore be reversed. The readily observable faster decrease of the upfield signal intensity on exposure of catechin solutions to D_2O in the presence of acid or base catalysts shows that electrophilic substitution occurs preferentially at C-8, in agreement with the results of bromination studies (8, 9, 26).

In catechin pentaacetate (**6***a*) the aromatic ring A protons resonate at 6.592 and 6.654 ppm (in $CDCl_3$). The assignments of the downfield doublet to H-6 and the upfield doublet to H-8 reported in the literature (22, 27) are not supported by experimental evidence and remain uncertain. We have been unable to duplicate the stronger nOe effect of H-6 relative to H-8 on H-4 claimed by Outtrup and Schaumburg (28). However, lineshape analysis before and after decoupling indicates weak long-range coupling between H-6 and H-4 in **3***d* and between H-8 and H-4 in **4***c* and **5***c*.

In summary, nOe difference spectra are eminently suitable for the distinction between 6- and 8-substituted catechin derivatives. The applicability of this technique to the structure elucidation of natural procyanidins and their degradation products awaits testing on authentic samples of regiospecifically synthesized diflavanoids. Synthetic work toward this goal is currently in progress.

Experimental

Catechin (**2***a*) and its three bromination products **2***b*, **2***c*, and **2***d* (26) were derivatized by standard literature procedures (29). Under the neutral or alkaline conditions employed, no bromine migration by Wessely–Moser rearrangement or reversed electrophilic aromatic substitution (8) was observed. The complete spectral identity of the tetra-*O*-methyl derivatives **3***a* and **3***c* obtained by our procedure and the more commonly employed methylation with diazomethane (9, 30) proved that the acetate hydrolysis in strong alkaline medium is not accompanied by epimerization (5). Anhydrous catechin (**2***a*) was obtained by drying commercial catechin hydrate (Sigma) under vacuum (110°C/12 h). The catechin derivatives were identified by chemical correlation (eq. [1]), ^{1}Hmr (Tables 1–4), X-ray diffraction (compound **4***c* (5)), carbon/hydrogen analysis (agreement with calculated values within ±0.3%), and melting points (agreement with literature values within ±2°): **3***a*, **4***a*, **5***a*, **6***a* (29*c*), **2***b*, **2***c*, **2***d* (26), **3***b*, **3***d*, **4***b*, **4***d* (21), **6***b*, **6***c*, **6***d* (9), and **3***c*, **5***b* (mp 145–148°C), **5***c* (mp 106–108°C), **5***d* (mp 165–167°C) (8).

Nuclear magnetic resonance spectra of 0.03 *M* substrate solutions in acetone-d_6, chloroform-*d*, and acetonitrile-d_3 were recorded on a Bruker 400-MHz FT spectrometer at a probe temperature of 30°C. Chemical shifts are reported in ppm (±0.005) downfield from TMS. Samples for nOe difference spectra were degassed immediately prior to the experiment. Cadmium nitrate monohydrate (approximately 100 ppm) was added to a 0.10 *M* solution of catechin in acetone-d_6 to resolve the OH signals; the cadmium salt concentration had no effect on the chemical shifts of other protons. To correlate H-6 and H-8 resonance frequencies of non-brominated catechins in different solvents, substrate solutions were prepared in binary solvent mixtures and the chemical shift differences $\Delta\delta$(H-6/8) plotted versus solvent composition. The free phenolic compounds **2***a*, **2***b*, **2***c*, and **2***d* were found to be insoluble in chloroform and sparingly soluble in acetonitrile; their solubilities in acetonitrile, as well as spectral resolution, were improved by addition of 10% D_2O (by volume).

Mobilities of thermal cations in argon and xenon gases: temperature and field dependence

NORMAN GEE AND GORDON R. FREEMAN
University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 11, 1986

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **64**, 2006 (1986).

In argon at $n = (2–6) \times 10^{24}$ molecules/m^3, the density-normalized mobility $n\mu$ of argon cations at low electric field strengths E/n is constant from 150 to 300 K; at >300 K $n\mu$ increases. The increase was smaller when the "effective" temperature T_{eff} of the ions was increased by applying higher E/n at 300 K. At 630 K, $(n\mu)_T/(n\mu)_{T_{\text{eff}}} = 1.6$, whereas in xenon it was 2.7, and in helium 1.0. The difference in behavior is attributed to the main ions being dimers Y_2^+; in argon and xenon collision-induced dissociation can occur:

$$Y^+ + 2Y \rightarrow Y_2^+ + Y$$

$$Y_2^+* + Y \rightarrow Y^+ + 2Y$$

where * indicates excess kinetic energy acquired by acceleration in the electric field. The dissociation energies of He_2^+, Ar_2^+, and Xe_2^+ are 2.3, 1.3, and 0.7 eV, respectively. Dissociation of He_2^+ is negligible because of its large dissociation energy. Dissociation of Y_2^+* and reformation of Y_2^+ is equivalent to the inelastic de-excitation of Y_2^+*.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **64**, 2006 (1986).

Dans l'argon, à des valeurs de n = (2 à 6) $\times 10^{24}$ molecules/m^3 et à de faibles champs électriques (E/n), la mobilité normalisée pour la densité ($n\mu$) des cations d'argon est constante de 150 à 300 K; à des températures >300 K, la valeur de $n\mu$ augmente. L'augmentation est plus faible lorsqu'on augmente la température "effective" (T_{eff}) des ions en appliquant des valeurs de E/n à 300 K. A 630 K, $(n\mu)_T/(n\mu)_{T_{\text{eff}}} = 1{,}6$ alors que dans le xénon cette valeur était égale à 2,7 et que dans l'hélium elle est égale à 1,0. On attribue cette différence de comportement au fait que les ions principaux seraient des dimères Y_2^+; dans l'argon et le xénon, il peut se produire une dissociation induite par des collisions:

$$Y^+ + 2Y \rightarrow Y_2^+ + Y$$

$$Y_2^+* + Y \rightarrow Y^+ + 2Y$$

dans lesquelles * indique l'énergie cinétique en excès qui est acquise par l'accélération dans le champ électrique. Les énergies de dissociation de He_2^+, Ar_2^+ et Xe_2^+ sont respectivement 2,3, 1,3 et 0,7 eV. A cause de son énergie de dissociation élevée, la dissociation du He_2^+ est négligeable. La dissociation du Y_2^+* et la reformation de Y_2^+ est équivalente à une dé-excitation inélastique du Y_2^+*.

[Traduit par la revue]

Introduction

Collisions between noble gas dimer cations Y_2^+ and atoms Y are not purely elastic (1). It has been suggested that cation–atom exchange occurs, which causes the ion mobility at low energies to be smaller than the polarization limit. Such exchange was originally proposed for the drift of H_3^+ in H_2 (2), where the temperature dependence was much different from that expected in the absence of exchange (3*a*).

The ion–molecule collision energy can be varied by increasing the gas temperature T while keeping the density-normalized field strength E/n small, or by sufficiently increasing E/n while holding T constant. For simple systems such as potassium ions in argon gas, where the collisions are elastic, the mobility is the same when the low field T equals the high field T_{eff} (4). However, when inelastic collisions occur, the mobility at a high field T_{eff} is lower than that at the equivalent low field T (5, 6). Such a mobility difference might result from cation–atom exchange ($Y_2^+ + Y \rightarrow Y + Y_2^+$) or inelastic collisions in the drift of Y_2^+ through Y.

Mobility values have been reported for Ar_2^+ in Ar (1, 7) and for Xe_2^+ in Xe (1) against T_{eff}, where the gas temperature was constant. This work reports mobility values obtained at low E/n where the cations are in thermal equilibrium with the gas, and T was increased.

Experimental

A. Materials

The argon was Matheson Ultra High Purity (≥99.999%). The xenon (≥99.995%) was from the Gas Dynamics Division of Liquid Carbonic Canada Ltd. Samples were transferred into a grease-free vacuum rack through a vacuum-tight valve that was welded to a flexible stainless steel tube, which was in turn welded to a Kovar seal. Further purification of the gases was effected by passage through freshly activated silica gel, followed by exposure to a series of freshly generated potassium mirrors in 2-L bulbs at room temperature for at least one month.

B. Production of cations

Cations were generated in parallel plate conductance cells by bombarding the samples with 100 ns pulses of X-rays from a 1.7 MeV Van de Graaff accelerator. The simultaneously generated electrons were removed with a collecting field (8). Drift distances of 4.80 to 10.58 mm were used.

Cations were not mass identified in the present work, but previous mass identified measurements in argon (1), and a non-mass identified ion study in xenon at different densities (9), concluded that at higher T the cations are Y_2^+. At the densities used in our work, $0.97 \leq n/10^{24}$ molecules m$^{-3} \leq 14.2$, the Ar^+ or Xe^+ initially formed would attach other molecules (1, 9*a*).

The dimer cation is thermally stable with a binding energy ~1 eV (1, 10). The Ar_2^+ cation dominates at $T_{\text{eff}} \gtrsim 194$ K and $0.7 \leq n/10^{24} \leq 4$, but multimers form by reaction [1] at lower temperatures; the exchange rate is rapid compared to drift times (1).

[1] $\quad Ar_j^+ (j \geq 2) + 2Ar \rightleftharpoons Ar_{j+1}^+ + Ar$

Multimers in xenon gas persist to higher T and lower n than in argon (11): at 4×10^{24} molecules/m^3 Xe_2^+ cations do not dominate the mobility until $T_{\text{eff}} \gtrsim 304$ K (9), which is 110 K higher than was needed in argon.

Hence, in this work the mobility measured at $n < 4 \times 10^{24}$ molecules/m^3 and at $T \gtrsim 194$ K in argon, or at $T \gtrsim 304$ K in xenon, is

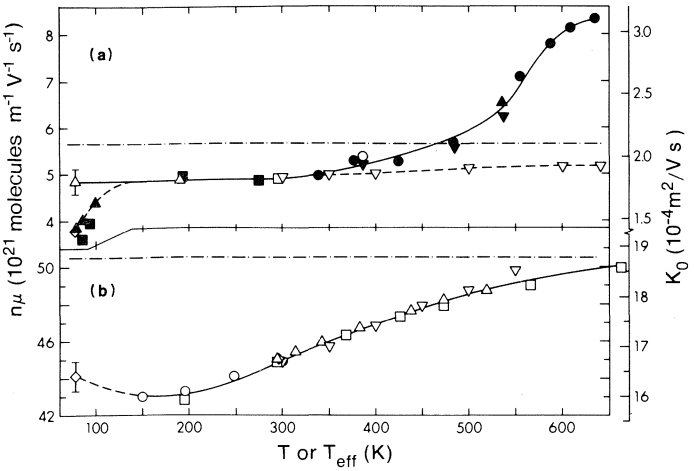

FIG. 1. Density-normalized mobilities of ions as a function of temperature at ($n/10^{24}$ molecules m^{-3}, reference). Present ions and those of ref. 7 not mass identified, but ref. 7*a* considered them to be established as Ar_2^+. Reference 7*a* measurements were at 300 K, and T_{eff} calculated from eq. [2]. Mass spectral study (1) indicated that Ar_2^+ dominates at $T > 178$ K. △, Ar_2^+ at $T_{eff} \doteq 190$ K ($T = 77$ K, 55 Td) and 9.4×10^{22} molecule/m^3, and at 77 K as estimated from the density dependence of μ measured at ~10 Td. ▲, ■, and ◇ at $T \leq 100$ K are Ar_j^+ ($j > 2$). (*b*) *Helium*: △ (0.075 to 2.0, 1); ▽ (<1, 7*a*); □ (0.13 to 0.40, 13); ○ (0.8, 14); ◇ (0.097 to 12.6, 15). ◇, mass identified as He_2^+ in some runs. Other measurements not mass identified, but He_2^+ considered as established. ▽ and △, $T_{eff} > 300$ K calculated from eq. [2]. ·····, $n\mu_{pol}$ (eq. [3]) for Ar_2^+ in Ar and He_2^+ in He.

attributed to the dimer cations. At lower T, multimer formation occurs and the mobility is due to a mixture Y_j^+ ($j \geq 2$).

C. Methods

The conductance cells were similar to the low pressure cells described earlier (8*b*). Temperature control and measurement (8), voltage source and signal amplifier (8*a*), and the time of flight method for obtaining the mobility μ (8*a*) were described in the references indicated. The current-time signals are like that in Fig. 1 of ref. 8*a*.

At pressures used in this work, densities were calculated by assuming the ideal gas law. Checks using the van der Waals equation (12) showed no deviation from ideality.

The cells were baked under vacuum at $T > 650$ K prior to each experiment, but the possibility of further outgassing during measurements, or of other contamination of the samples, was checked for by the method of ref. 8.

Results

Ion flight times were measured with positive and then negative applied voltages, to check for effects of strain voltage in the cell. The values obtained were the same within ~3%, and the average was used at each field strength.

A. Field independence

The cation mobilities were independent of field strength over the range used, which was 0.36–26 Td in argon, and 0.9–37 Td in xenon (Td = 10^{-21} V m^2/molecule). At these fields the cations are essentially in thermal equilibrium with the gas.

The effective temperature of ions that have drift velocity $v_d = \mu E$ and undergo only elastic collisions with the molecules is (7):

$$[2] \quad T_{eff} = T + Mv_d^2(1 + \beta)/3k_B$$

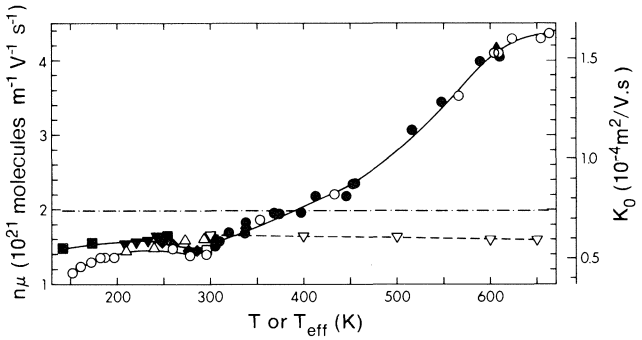

FIG. 2. Density-normalized mobility of ions in xenon as a function of temperature at ($n/10^{24}$ molecules m^{-3}, reference). ◆ (0.97, this work); ■ (1.33, this work); ▼ (1.89, this work); ▲ (2.00, this work); ● (3.09, this work); ○ (11.5, this work); ▽ (<0.1, 1); △ (1.33, 9*a*). □, average of 13 present measurements, (1.46 ± 0.02)10^{21} molecules m^{-1} V^{-1} s^{-1} at $0.97 \leq n/10^{24} \leq 3.09$ at 296 ± 1 K. At $T >$ 300 K the ions were probably predominantly Xe_2^+ (see text). At $T <$ 300 K the ions were probably mixtures of Xe_j^+ ($j \geq 2$). ·····, $n\mu_{pol}$ (eq. [3]) for Xe_2^+ in Xe.

where M is the molecular mass of the gas, β is a correction (often set to zero) based on d ln $(n\mu)$/d ln (E/n), and k_B is Boltzmann's constant. Equation [2] predicts that $T_{eff} = 1.05T$ at ~20 Td in argon and ~35 Td in xenon. The occurrence of inelastic collisions would increase the field necessary to achieve $T_{eff} = 1.05T$. The observed results are therefore consistent with eq. [2].

B. Temperature dependence

Each reported value of $n\mu$ is the average of at least ten measurements at different positive and negative applied voltages.

The value of $n\mu$ in argon decreased from 8.3×10^{21} molecules m^{-1} V^{-1} s^{-1} at 634 K towards a constant value 4.9×10^{21} molecules m^{-1} V^{-1} s^{-1} at $T \leq 300$ K (Fig. 1*a*). At $T \leq$ 100 K, $n\mu$ decreased further; the gas densities were 3.1 and 4.6×10^{24} molecules/m^3. Values from refs. 1 and 7 are included for comparison. The present value at 295 K agrees within 1% with that reported for Ar_2^+ in Ar at that temperature (7).

Mobilities of ions in the gas phase are commonly reported as K_0 (m^2 V^{-1} s^{-1}), which corresponds to μ at a density of 1 atm at STP (1 amagat, $n = 2.69 \times 10^{25}$ molecules/m^3). Values of K_0 are displayed on the right side of the figure for comparison.

In xenon the variation of $n\mu$ with temperature (Fig. 2) is qualitatively similar to that in argon. Values from refs. 1 and 9*a* are within about 10% of the present ones at $T \lesssim 300$ K.

The increase of $n\mu$ with T in helium (13–15) is shown in Fig. 1*b* for comparison. The relative variation decreases in the order Xe > Ar > He.

Discussion

A. Polarization limit

When scattering is dominated by the polarization potential, as in the case when $T_{eff} \rightarrow 0$, the value of $n\mu$ is determined by the polarizability α of the scatterer and the reduced mass M_r of the collision pair (3*b*). Expressed in SI units it reduces to

$$[3] \quad n\mu_{pol} = 1.60 \times 10^{-11}/(\alpha M_r)^{1/2}$$

where the units are $n\mu_{pol}$ (molecules m^{-1} V^{-1} s^{-1}), α (C m^2 V^{-1}), and M_r (kg/molecule). The commonly listed values of polarizability in units of cm^3 correspond to the SI quantity $\alpha/4\pi\epsilon_0$ (17), where ϵ_0 is the electric permittivity of

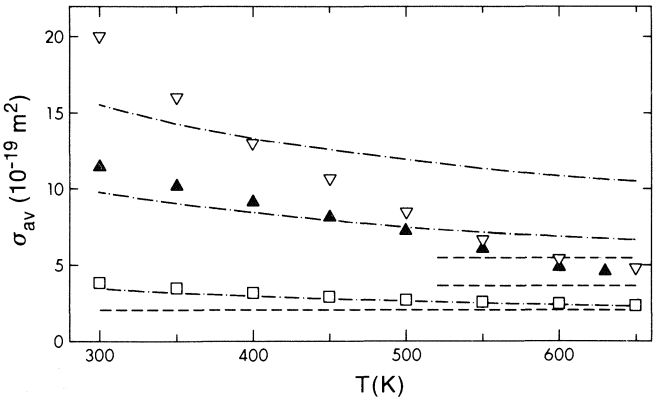

FIG. 3. Average cross sections of Y for scattering Y_2^+, estimated from the full lines in Figs. 1 and 2. □, He; ▲, Ar; ▽, Xe. ·····, σ_{pol} calculated from eqs. [5] and [3]. ---, neutral hard sphere cross sections σ_{hs}, calculated from Lennard–Jones collision radii (16). In all cases He has the lowest cross section and Xe the highest.

vacuum; the conversion factor $cm^3 \rightarrow C\,m^2\,V^{-1}$ is $1.11 \times 10^{-16} C\,m^2\,V^{-1}\,cm^{-3}$.

The values of α ($10^{-40} C\,m^2\,V^{-1}$) are 0.228, 1.82, and 4.49 for He, Ar, and Xe, respectively (18), and the corresponding values of $n\mu_{pol}$ (10^{21} molecules $m^{-1}\,V^{-1}\,s^{-1}$) for Y_2^+ in Y are 50, 5.7, and 2.0. These values are shown as dash–dot lines in Figs. 1 and 2.

As previously noted (1), the observed $n\mu$ at ~300 K is smaller than $n\mu_{pol}$ in all three gases (Figs. 1 and 2). The low mobility was attributed to resonant ion–atom exchange (14, 19), as was postulated for H_3^+ in H_2 (2).

B. Effect of temperature

In Ar and Xe the value of $n\mu$ for thermal ions increased above the value of $n\mu_{pol}$ at $T > 500$ and 400 K, respectively (Figs. 1*a* and 2). When the ion temperature T_{eff} was increased by increasing E/n (and hence v_d, eq. [2]), the value of $n\mu$ remained below $n\mu_{pol}$ (Figs. 1*a* and 2). In He the value of $n\mu$ approached that of $n\mu_{pol}$ when either T or T_{eff} approached 700 K (Fig. 1*b*), so the crossover temperature increases in the order Xe < Ar < He.

The product $n\mu$ is related to the average momentum transfer cross section (3*c*, 21):

$$[4] \quad \sigma_{ave} = \langle v^3 \sigma_m \rangle / \langle v^3 \rangle,$$

where σ_m is the momentum transfer cross section and v is the relative velocity of the ions with respect to the molecules;

$$[5] \quad n\mu = \left(\frac{3e}{4M_r}\right) \frac{1}{\langle v \rangle \sigma_{ave}}$$

where e is the protonic charge, and for a Maxwellian distribution of velocities $\langle v \rangle = (8k_B T/\pi M_r)^{1/2}$.

The value of σ_{ave} decreases with increasing T (Fig. 3). The experimental values of σ_{ave} are compared with those expected from the polarization potential, σ_{pol}, and the hard sphere potential, σ_{hs}. The latter are approximated by the Lennard–Jones neutral atom collision cross sections (16).

At 650 K σ_{ave} is similar to σ_{hs} in all three gases. In helium, which has a relatively small polarizability, σ_{pol} is only 11% greater than σ_{hs}; the difference increases to 67% at 300 K. The value of σ_{ave} in helium is nearly equal to σ_{pol} at all temperatures.

As T is decreased below 650 K, in argon and xenon σ_{ave} increases towards σ_{pol} and crosses above it below 500 K in argon, and below 400 K in xenon. The rate of increase at $T <$ 500 K is greater in xenon than in argon. At 300 K the ratio $\sigma_{ave}/\sigma_{pol}$ equals 1.10 in helium, 1.16 in argon, and 1.29 in xenon (Fig. 3). The increase in σ_{ave} is not caused by clustering, because in xenon at 278 K a 12-fold increase of n caused only a 5% decrease of $n\mu$ (Fig. 2). The ions can be assumed to be Y_2^+ in each of the gases at 300–600 K.

The dimer ion probably dominates down to at least 150 K in the gases at $n = 1 \times 10^{24}$ molecules/m^3. The values of the ratio $\sigma_{ave}/\sigma_{pol}$ at 150 K are 1.17, 1.17, and 1.32 in helium, argon, and xenon, respectively, similar to those at 300 K.

C. Inelastic collisions

When T_{eff} was increased by increasing E/n in helium, $n\mu$ had the same value as when the gas T was increased the same amount (Fig. 1*b*). However, when the field was used to increase T_{eff} in argon, $n\mu$ increased more slowly than when the gas T was increased (Fig. 1*a*). In xenon, increasing T_{eff} with the field actually caused $n\mu$ to decrease slightly (Fig. 2). These results indicate that, although inelastic processes can be ignored in He_2^+–He collisions, they become progressively more important on going to argon and xenon.

The Y—Y^+ dissociation energy is 2.3 eV in helium (10*a*), 1.3 eV in argon (10*c*), and ~0.7 eV in xenon (10*b*). While the He_2^+ is stable under all the conditions used in the mobility experiments, it seems that when the argon and xenon ions were heated above the gas temperature by applying a high electric field, some collision-induced dissociation occurred.

$$[6] \quad Ar_2^+* + Ar \rightarrow Ar^+ + 2Ar$$

$$[7] \quad Xe_2^+* + Xe \rightarrow Xe^+ + 2Xe$$

where the asterisk designates excess translational energy. The mobilities of the monomer cations are 20–30% lower than those of the dimers (7*a*, 9*b*). The dimers would form again,

$$[8] \quad Y^+ + 2Y \rightarrow Y_2^+ + Y$$

so a major effect of reactions [6] and [7] would be deenergization of Y_2^+, which means the reduction of T_{eff}. Reactions [6]–[8] are inelastic processes which invalidate eq. [2]. As process [8] is a three body reaction $n\mu$ might not be independent of n if a wider range of density than that in the present study is used.

This de-energization does not occur when the cation energy is increased by increasing T, although dissociation/association can occur. Increasing T increases the energy of both Y_2^+ and Y, whereas a high E/n increases only the energy of the ions. The relative collision energy is increased in both cases but the average energy transfer depends on the average energy difference between cation and molecule. At low E/n and a given T the average cation energy and the average molecule energy both equal thermal energy; the average net energy transfer is zero (6, 20).

In argon the value of $d(n\mu)/dT_{eff}$ remains positive, so the contribution of the monomer ions to the measured mobility can be neglected. It is assumed that the inelastic collisions simply have the effect of reducing T_{eff} towards the gas temperature T. Then the ratio ζ of the collision integral for inelastic energy loss to that for momentum transfer can be obtained from (6, 20):

$$[9] \quad \zeta = \frac{m}{M}\left(\frac{T_{eff}}{T} - 1\right)$$

where m is the ion mass, M the neutral atom mass, T_{eff} is

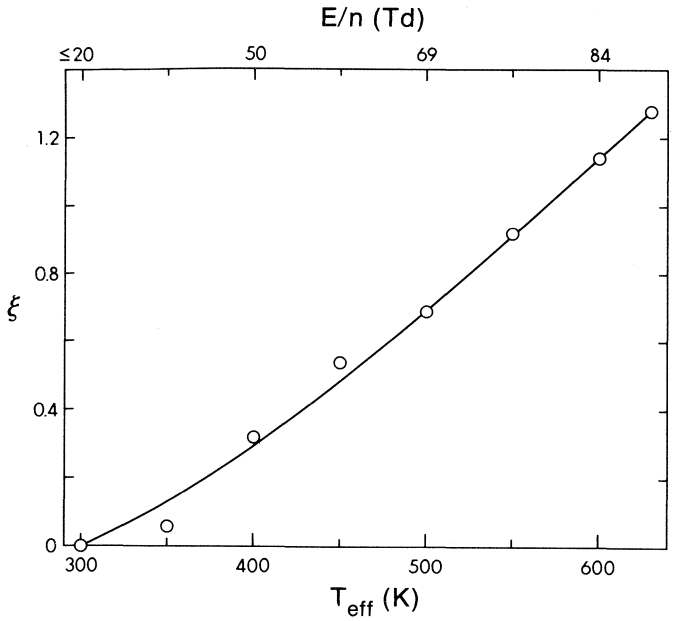

FIG. 4. Ratio of collision integral for inelastic energy loss to that for momentum transfer for Ar_2^+ in Ar at $T = 300$ K. T_{eff} was calculated from eq. [2]. Data from Fig. 1*a*.

calculated from eq. [2] for the observed $n\mu$ and E/n, and T is the gas temperature at which the same $n\mu$ is obtained at low fields. The value of ζ characterizes (but does not equal) the fractional energy loss due to inelastic collisions (6). For Ar_2^+ in Ar at 300 K, $\zeta = 0.0$ at $E/n \leq 20$ Td and increased to 1.28 at 88 Td (Fig. 4). For $T_{eff} = 630$ K the actual equivalent thermal ion temperature was 384 K.

Cobalt carbonyl catalyzed reaction of mercaptans with Schiff bases and carbon monoxide

SHLOMO ANTEBI AND HOWARD ALPER[1]

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received February 5, 1986

SHLOMO ANTEBI and HOWARD ALPER. Can. J. Chem. **64**, 2010 (1986).

Thiophenols and *p*-methylbenzyl mercaptan react with Schiff bases and carbon monoxide in benzene, in the presence of cobalt carbonyl, to give amides as the principal products. These amides arise from cleavage of the carbon–nitrogen double bond of the reactant imine. The reaction is applicable to a variety of Schiff bases (i.e. aliphatic, benzylic, aromatic). Thioesters and olefins are usually obtained as reaction by-products.

SHLOMO ANTEBI et HOWARD ALPER. Can. J. Chem. **64**, 2010 (1986).

Les thiophénols et les *p*-méthylbenzyles mercaptans réagissent avec les bases de Schiff et le monoxyde de carbone dans le benzène, en présence de cobalt carbonyle pour donner des amides comme produits majoritaires. Ces amides proviennent du clivage de la double liaison carbone–azote de l'imine. La réaction peut s'appliquer à différentes bases de Schiff (i.e. aliphatique, aromatique, benzylique). On obtient habituellement des thioesters et des oléfines comme produits secondaires.

[Traduit par la revue]

Mercaptans have been employed as substrates in several metal-catalyzed carbonylation reactions. Benzylic mercaptans and thiophenols can be carbonylated to carboxylic esters, with concurrent desulfurization, by means of cobalt carbonyl in aqueous alcohol (1, 2). However, if the latter reaction is conducted in the presence of a conjugated diene, then thioesters are formed in good yields. While the diene has a significant

$$RSH + CO \xrightarrow[Co_2(CO)_8,\ C_6H_6/H_2O]{\text{diene, 185–190°C}} RCOSR + COS$$

55–61 atm.

influence on the course of the mercaptan – carbon monoxide reaction, the hydrocarbon is not incorporated in the product (3). However, the diene does participate when thiophenols are treated first with synthesis gas and then with carbon monoxide, in the presence of cobalt carbonyl and pyridine, the heterocyclic base being essential for this reaction. In this manner, 1,3-butadiene reacts with thiophenol and carbon monoxide to give isomeric pentenoic acid phenyl thioesters (4). Thioesters are also obtained by treatment of a monoolefin with mercaptan, carbon monoxide, and a palladium(II) catalyst (5).

Since a conjugated diene had an important influence on the course of the cobalt carbonyl catalyzed carbonylation of mercaptans, it was of interest to determine the effect of other unsaturated moieties on this reaction. We now wish to report that Schiff bases undergo interesting reactions with thiols and carbon monoxide, in the presence of the cobalt catalyst.

Results and discussion

Treatment of *p*-thiocresol (**1**, R = *p*-$CH_3C_6H_4$) with *N*-benzylidenemethylamine (**2**, R′ = Ph, R″ = CH_2), carbon monoxide, and a catalytic amount of cobalt carbonyl in benzene, at 850 psi and 170–180°C, afforded *N*-methyl-*p*-toluamide **3**, R = *p*-$CH_3C_6H_4$, R″ = CH_3, as the major product. This product results from carbon–nitrogen double bond cleavage of the Schiff base. One of the by-products is the amide **4**, R = *p*-$CH_3C_6H_4$, R′ = Ph, R″ = CH_3 containing all of the former Schiff base unit. Other by-products are formed, the most noteworthy being stilbene (**5**, R′ = Ph) and carbonyl sulfide (ms: *m*/*e* 60). The product yields for this and for other

$$\underset{\mathbf{1}}{RSH} + CO + \underset{\mathbf{2}}{R'CH{=}NR''} \xrightarrow[850\ \text{psi}]{Co_2(CO)_8/C_6H_6/H_2O,\ 170\text{–}180°C} \underset{\mathbf{3}}{RCONHR''} + \underset{\mathbf{4}}{RCONR''(CH_2R')} + \underset{\mathbf{5}}{R'CH{=}CHR'} + COS$$

Schiff base-mercaptan reactions are listed in Table 1. Amides were not formed in the absence of the metal catalyst.

The carbonylation reaction is applicable to a variety of Schiff bases including those bearing primary, secondary, and tertiary alkyl, as well as benzylic groups, and affords amides (**3**) in moderate yields. Methoxy and bromine substituents on the benzene ring of the thiophenol do not interfere with the reaction. While the reaction does not proceed when an aliphatic mercaptan is used, it does occur using a benzylic mercaptan (**1**, R = *p*-$CH_3C_6H_4CH_2$) as the reactant. The optimum ratio of Schiff base to mercaptan is 1.0–1.2/1.0 while that of **1**/$Co_2(CO)_8$ is 6–10/1.

Several types of thioesters are formed as by-products in most of these reactions. One class of thioester, RCOSR, is the anticipated product assuming that the Schiff base functions in an analogous manner to that observed using a conjugated diene (3). However, thioesters of type $RCOSCH_2R'$ are also formed, where CH_2R' arises from the Schiff base. It is interesting to note that aromatic hydrocarbons (2) are not detected in any of these reactions. While most of the R group of the thiol is generally accounted for in these reactions, the fate of some of the Schiff base — particularly the NR″ portion — is unknown. It has previously been reported that Schiff bases, **2**, where R′ is aromatic, experience carbonylation to phthalimidines when **2** is exposed to a catalytic quantity of $Co_2(CO)_8$ in benzene at 100–200 atom and 200–230°C (6). Phthalimidines were not formed in any Schiff base – mercaptan carbonylation reaction catalyzed by $Co_2(CO)_8$.

A possible mechanism for the formation of the amide **3** is outlined in Scheme 1. The initial steps of the proposed pathway — i.e. reaction of mercaptan with cobalt carbonyl

to give **6** and $HCo(CO)_4$, as well as the carbonylation of **6** to **7**, followed by elimination of carbonyl sulfide (**8**) and carbonylation to **9** — are identical to those postulated in the conversion of mercaptans to thioesters (3). Complex **11** may arise from **2** either by direct addition of **9** (7) or by a two-step pathway as illustrated in Scheme 1. It is conceivable that the hydridotetracarbonylcobalt can react in two different ways. It may protonate **11** affording **12** with subsequent carbon–nitrogen bond cleavage giving the amide **3**, which is the major product, and a binuclear cobalt complex **13**. The latter may serve as the source of the olefin **5**, either via a free or a complexed carbene. The cobalt hydride, $HCo(CO)_4$, can alternatively cleave the carbon–cobalt bond of **11**, affording the amide **4**.

In conclusion, carbonyl-containing compounds (amides, thioesters) are obtained in good combined yields from the cobalt carbonyl catalyzed reaction of thiophenols and p-methylbenzyl mercaptan with Schiff bases and carbon monoxide.

Experimental section

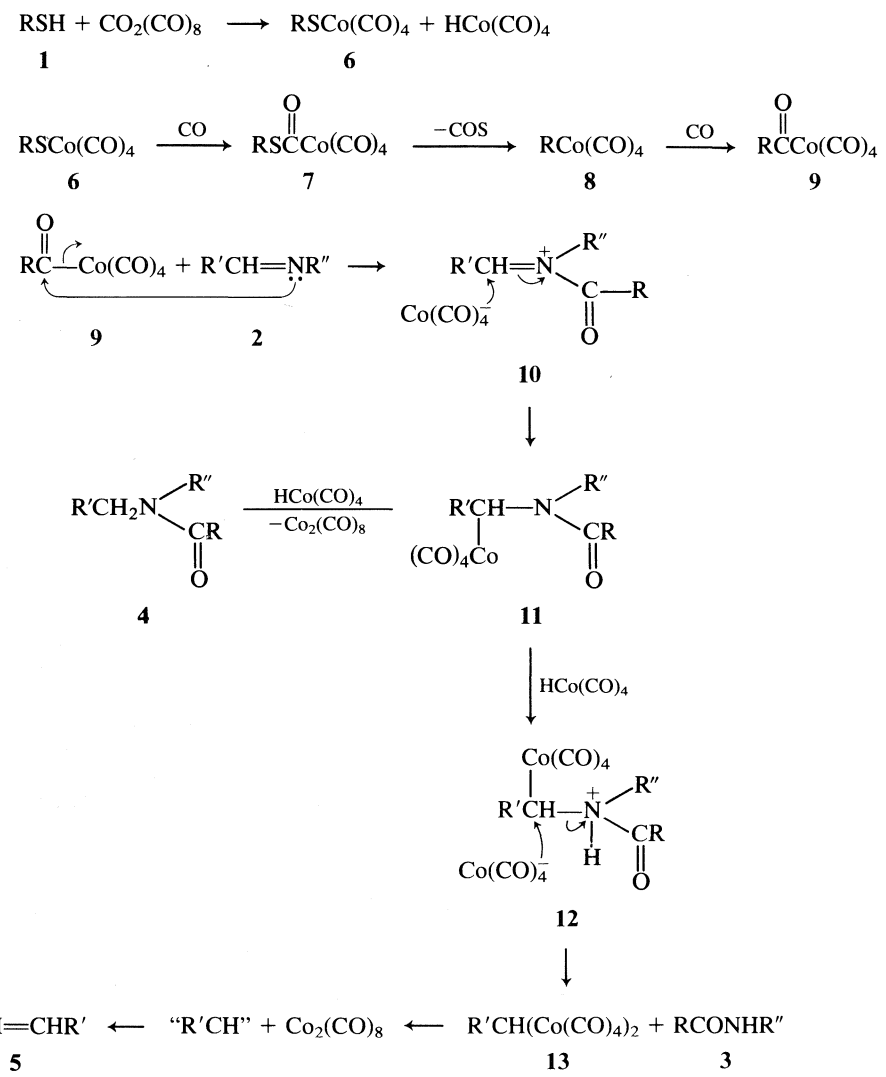
General

All of the mercaptans, and *N*-benzylidenemethylamine, were commercial materials and were distilled or recrystallized prior to use. The other Schiff bases were synthesized from the appropriate carbonyl compounds and amines following standard methodology (8). Cobalt carbonyl was obtained from Strem Chemical Co. and was used as received. Solvents were dried by standard methods (e.g. benzene was dried using sodium benzophenone ketyl).

Melting point determinations were made using a Fisher-Johns apparatus. Infrared spectra were recorded on a Perkin Elmer 783 spectrometer, and mass spectral determinations were made using a VG 5050 micromass spectrometer. Nuclear magnetic resonance spectra were recorded on Varian EM-360 and/or XL-300 spectrometers. Gas chromatographic determinations were made on a Varian Vista 6000 gas chromatograph (flame ionization detector) equipped with a 3% OV-17 on Chromosorb W column (110°C; 10°/min to 300°C).

Representative procedure for the reaction of mercaptans with Schiff bases and carbon monoxide

A 125 mL stainless steel autoclave (Parr Instrument Co.) was charged with 1.24 g (10 mmol) of p-thiocresol (**1**, R = p-$CH_3C_6H_4$), cobalt carbonyl (0.45 g, 1.33 mmol), **2**, R′ = $(CH_3)_2CH$, R″ = n-C_4H_9 (1.52 g, 12.0 mmol), and 30 mL of anhydrous benzene. The bomb was filled and evacuated three times with carbon monoxide, and then pressurized with CO to 850 psi. The reaction mixture was stirred overnight at 180°C (pressure increased to 1100–1300 psi), and then cooled to room temperature. The gas was evacuated, the reaction mixture was filtered, and the filtrate was concentrated using a rotary evaporator. Separation of the products was achieved by preparative thin layer chromatography with silica gel, using 3:1 hexane – ethyl acetate as the developer. The first fraction was the amide **3**, R = p-$CH_3C_6H_4$, R″ = n-C_4H_9, obtained in 40% yield (0.763 g). Ir ν(NH) 3420 cm^{-1}, ν(CO) 1660 cm^{-1}; nmr δ ($CDCl_3$) 1.0–1.5 (m, 7H, C_3H_7), 2.32 (s, 3H, CH_3), 3.30 (m, 2H, CH_2), 6.58 (s (br), 1H, NH), 7.1–7.5 (AB quartet, 4H, aromatic protons); ms (m/e) 191 $[M]^+$, 176 $[M - CH_3]^+$, 119 $[p$-$CH_3C_6H_4CO]^+$; the gc retention time was 10.44 — spiking with an authentic sample provided further evidence for the assigned structure. The thioester p-$CH_3C_6H_4COSCH_2CH(CH_3)_2$, was isolated in 20% yield (0.42 g) from the second band. Ir ν(CO) 1665 cm^{-1}; nmr δ ($CDCl_3$) 1.20 (d, 6H, CH_3), 1.80 (m, 1H, CH), 2.32 (s, 3H, CH_3), 2.94 (d, 2H, CH_2), 7.50 (AB quartet, 4H,



SCHEME 1

aromatic protons); ms (*m/e*) 208 $[M]^+$, 152 $[M - C_4H_8]^+$, 119 $[p\text{-}CH_3C_6H_4CO]^+$. The third fraction was identified as *p*-tolyl disulfide, by comparison of spectral data and gc retention time with an authentic sample. Yield: 0.081 g (7%).

The same reaction and work-up procedure was used in the other cases, with product identification and purity ascertained by comparison of spectral data and retention times with those of authentic materials.

The optimum ratios of reactants and catalyst were determined from numerous experiments covering a Schiff base to mercaptan ratio ranging from 1.0/2.0 up to 2.0/1.0, and a ratio of **1**/$Co_2(CO)_8$ ranging from 1–100/1.

Received March 10, 1986

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **64**, 2013 (1986).

The mechanisms of long-range spin–spin coupling constants involving the methylene protons and the ^{13}C nucleus of the cyano group are discussed for benzyl cyanide. Analysis of the ^1H nmr spectrum of benzyl cyanide-8-^{13}C in benzene-d_6 solution yields $^nJ(H,CH_2)$ and $^nJ(H,^{13}CN)$ for $n = 4$–6. Similar data are reported for the 2,6-dichloro and 2,6-difluoro derivatives, together with some sign determinations. $^nJ(^{13}C,^{13}CN)$, $n = 1$–5, are given for the three compounds. It is shown that all these parameters are consistent with a small barrier to internal rotation about the C_{sp^2}—C_{sp^3} bond in benzyl cyanide in solution. Computations at various levels of molecular orbital theory agree that this barrier is small. The $^nJ(^{13}C,^{13}CN)$ imply a stabilization in polar solvents of the conformation in which the cyano group of benzyl cyanide lies in a plane perpendicular to the benzene plane. The molecular orbital calculations indicate a predominantly twofold nature of the internal barrier, although a significant fourfold component is also present. The coupling constants cannot discern the presence of the fourfold component for benzyl cyanide nor for its 2,6-difluoro derivative. $^1J(^{13}C,^{13}CN)$ is solvent dependent. A table of the computed sidechain geometries is appended.

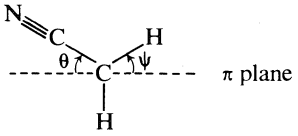
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **64**, 2013 (1986).

On discute du mécanisme des constantes de couplage spin–spin à longue distance impliquant les protons méthyléniques et le noyau de ^{13}C du groupe cyano du cyanure de benzyle. L'analyse du spectre de rmn du ^1H du cyanure ^{13}C-8 de benzyle en solution dans le benzène-d_6 donne des constantes $^nJ(H,CH_2)$ et $^nJ(H,^{13}CN)$, $n = 4$–6. On rapporte des données semblables dans le cas des dérivés dichloro-2,6 et difluoro-2,6 ainsi que quelques déterminations de signes. On donne les valeurs de $^nJ(^{13}C,^{13}CN)$, $n = 1$–5 de ces trois composés. On montre que tous ces paramètres correspondent à une faible barrière interne à la rotation autour de la liaison C_{sp^2}—C_{sp^3} du cyanure de benzyle en solution. Les calculs à différents niveaux de la théorie des orbitales moléculaires confirment cette faible barrière. La constante $^nJ(^{13}C,^{13}CN)$ implique dans les solvants polaires, une stabilisation de la conformation dans laquelle le groupe cyano du cyanure de benzyle se situe dans un plan perpendiculaire a celui du benzène. Les calculs d'orbitales moléculaires indiquent que la barrière interne est double de façon prédominante, en dépit de l'existence d'un constituant quaternaire important. Les constantes de couplage ne permettent pas de discerner la présence d'un constituant quaternaire dans le cyanure de benzyle et dans son dérivé difluoro-2,6. La constante de couplage $^1J(^{13}C,^{13}CN)$ dépend du solvant. On ajoute une table contenant les géométries théoriques des chaînes latérales.

[Traduit par la revue]

Introduction

The motion of the cyanomethyl group about the sp^2–sp^3 carbon–carbon bond in benzyl cyanide or its derivatives has been investigated by measurements of birefringence, spin-lattice relaxation rates, and of long-range spin–spin coupling constants (1–5). The Kerr constant of benzyl cyanide in CCl_4 solution (1) is consistent with a conformational angle, θ, of 44° (see **1**) or with essentially free internal rotation. The temperature



1

dependence of the spin-lattice relaxation rate of ^{14}N in neat 4-methylbenzyl cyanide has been interpreted to give an activation energy of 6.3 kJ/mol for the internal reorientational motion of the cyanomethyl group (2). A similar experiment for a 50 mol% solution in *m*-xylene gives an activation energy of 5.0 kJ/mol. The spin-lattice relaxation rates of ^2H in neat α,α-dideuterobenzyl cyanide yield about 10 kJ/mol for this activation energy (3). These numbers are probably sensitive to the details of the model employed to separate the contributions of internal and overall molecular reorientational motions to the relaxation rates; a study of ^{13}C relaxation rates in benzyl cyanide does not attempt such a separation (4).

The long-range spin–spin coupling constant over six formal bonds between methylene protons and *para* ring protons in 3,5-dichlorobenzyl cyanide, dissolved in a mixture of C_6D_6, $CDCl_3$, and CS_2, yields an apparent twofold internal rotational potential of 1.0 ± 0.8 kJ/mol (5). The bottom of the potential lies at θ = 90° in **1**. If a value of $^6J(H,CH_2)$ of −1.20 Hz is taken, as deduced later in the present paper, the barrier is essentially zero in this compound. Again, the six-bond coupling involving ^{19}F in 4-fluorobenzyl cyanide in CS_2 solution has been taken to mean that V_2 is 1.9 ± 0.8 kJ/mol, also with a θ of 90° at the minimum (5). These small barriers are consistent with the Kerr effect measurements, but not with those of spin-lattice relaxation rates.

However, the dipole moment of benzyl cyanide in benzene solution is 3.5 D (6) and, although that of methyl cyanide is also 3.5 D (7), therefore suggesting very small perturbations of the π electrons in the former, the presence of polar aromatic C–halogen bonds might cause appreciable perturbations of the phase or magnitude of the internal rotational potential. Furthermore, it is not known that the latter is purely twofold, while the model used to derive the barriers from the long-range spin–spin interactions assumed (5) a twofold potential. The presence of a 300-MHz spectrometer in this laboratory now allows the analysis of the ^1H nmr spectrum of benzyl cyanide itself, at least in benzene solution.

Accordingly, we report the analysis of the ^1H nmr spectrum of benzyl cyanide-8-^{13}C, yielding long-range $^1H,^1H$ and $^1H,^{13}C$ coupling constants. Together with the corresponding $^{13}C,^{13}C$ coupling parameters, they provide a data set amenable to a

[c]This coupling is negative (15) and the signs of $^{4,5,6}J$(H,C) are assumed to be those determined for $^{5,6}J$(H,C) in 2,6-dichlorobenzylcyanide-8-^{13}C (Table 3) and calculated for ^4J(H,C) by INDO MO FPT (see text).
[d]^1J(^{13}C,^{14}N) could not be determined (4) because the ^{13}C peak is broad (quadrupolar ^{14}N relaxation rate).

discussion of coupling mechanisms, guided by the results of INDO MO FPT computations. Corresponding measurements on 2,6-dichloro- and 2,6-difluorobenzyl cyanide-8-^{13}C yield estimates of the extrema in the angle dependence of the long-range coupling constants. These are combined with extensive molecular orbital calculations of the nature of the internal rotational potentials to provide a description of the reorientational motion of the cyanomethyl group in the three compounds.

Experimental

Benzyl cyanide-8-^{13}C (99 at.% ^{13}C) came from MSD Isotopes, as did KCN enriched to 99 at.% in ^{13}C. The latter was used to prepare 2,6-difluoro- and 2,6-dichlorobenzyl cyanide-8-^{13}C from the corresponding bromide (Aldrich). The bromide was dissolved in acetone and warmed to 50°C. An aqueous solution of the potassium cyanide was slowly added while stirring the acetone solution. The mixture was held at 50°C for 1 h, was diluted with water, and extracted with ether. The product gave characteristic ^{1}H and ^{13}C nmr spectra, displaying splittings arising from the ^{13}C nucleus of the cyano group.

Degassed samples for nmr measurements were prepared in a manner recently described in detail (8). The ^{1}H and ^{13}C nmr spectra were accumulated on a 300-MHz Bruker spectrometer, also in the way described before (8). Relative signs of some coupling constants were obtained via partial decoupling procedures (9).

INDO MO FPT (10, 11) computations of coupling constants were performed on an AMDAHL V8 system. Geometry-optimized energies as a function of θ utilized the computer programs MONSTERGAUSS (12) and GAUSSIAN 80 (13).

Results and discussion

Spectral analyses

The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (14) and the ensuing spectral parameters appear in Tables 1 and 2. The chemical shift dispersion for benzyl cyanide-8-^{13}C was large enough for a reasonably reliable analysis only in benzene-d_6. ^{13}C{^{1}H} experiments yielded the signs of ^nJ(H,^{13}CN) parameters in Table 3. Figure 1 demonstrates the partial decoupling experiments, leading to the sign of ^4J(^{13}C,^{13}CN) in 2,6-dichlorobenzyl cyanide-8-^{13}C.

INDO MO FPT computations

For long-range spin–spin coupling constants, ^nJ, where n represents the formal number of bonds intervening between the coupled nuclei, the INDO MO FPT formulation usually gives the correct qualitative θ dependence when $n \geq 3$. Quantitative reproduction of the magnitudes of $^{4,5,6}J$ is not expected for coupling between sidechain nuclei and nuclei in the benzene moiety because of the parameterization of this semiempirical method and because the geometry assumed in the computation may well be different from the true geometry.

Nevertheless, $^6J(H,CH_3)$ in toluene is very nearly quantitatively reproduced by such calculations (16). For this molecule, $^{5,6}J$(H,CH$_3$) have been written (17) as eqs. [1] and [2].

$$[1]\quad {}^6J(H,CH_3)/\text{Hz} = -1.20\sin^2\psi = {}^6J^{\pi}_{90}\sin^2\psi$$

$$[2]\quad {}^5J(H,CH_3)/\text{Hz} = 0.336\sin^2\psi + 0.322\sin^2(\psi/2) = {}^5J^{\pi}_{90}\sin^2\psi + {}^5J^{\sigma}_{180}\sin^2(\psi/2)$$

In eq. [1], $^6J^{\pi}_{90}$ is the magnitude of $^6J(H,CH_3)$ when the C—H bond of the sidechain lies in a plane perpendicular to the ring. Accordingly, $^6J(H,CH_3)$ is a σ–π coupling constant and arises from a hyperconjugative interaction between the σ electrons in the C—H bonds of the sidechain and the π electrons in the phenyl group. Similar remarks apply to $^5J^{\pi}_{90}$ in eq. [2]. $^5J^{\sigma}_{180}$ arises from a σ electron mechanism and has a maximum for an all-*trans* arrangement of the intervening bonds.

Equation [3] has been proposed (18) for $^4J(H,CH_3)$.

$$[3]\quad {}^4J(H,CH_3)/\text{Hz} = -1.08\sin^2\psi - 0.32\cos^2\psi$$

INDO MO FPT computations (17) agree that $^4J(H,CH_3)$ is indeed dominated by a σ–π mechanism. Equation [4] indicates a small σ electron component, varying as $\cos^2\psi$.

In a benzyl derivative, an electronegative substituent (19) will polarize the C—H bonds in the methylene group, thereby decreasing the hyperconjugative interaction and reducing the magnitude of $^6J^{\pi}$. Qualitatively, the INDO MO FPT formulation agrees with this reduction (19). It is interesting, therefore, that for benzyl cyanide our calculations indicate *no* reduction of $^6J^{\pi}$ relative to toluene, perhaps an increase of 0.005 Hz at θ = 90°. Confirmatory evidence comes from a plot (20) of $^6J(H,CH_2)$ against the electronegativity of the substituent, X, in a series of 2,6-dichlorobenzyl X compounds. For X = CN, the smallest deviation from the roughly linear plot occurs if the cyano group is taken to have the same electronegativity as hydrogen. One might speculate as to the reason for these results;

		Largest difference	0.029

[a]In Hz to high frequency of internal TMS.
[b]Numbers in parentheses are standard deviations in the last significant figure.
[c]The signs of ^5J(H,C) and ^6J(H,C) are given relative to ^2J(H,C) which is negative (15), and were determined by $^{13}C\{^1H\}$ experiments in which the methylene protons were decoupled in turn for the two spin states of ^{13}C.

the discussion below assumes the empirical and semiempirical results above.

Turning to $^{4,5,6}J(H,^{13}CN) \equiv {}^{4,5,6}J$(H,C), the INDO MO FPT numbers display a dependence entirely similar to that for $^{4,5,6}J(H,CH_3)$ in toluene (16) and hence are not tabulated here. For the STO 3G MO geometry (see below), $^6J_{90}$(H,C) is computed as −0.756 Hz and happens to agree quantitatively with the estimate arrived at below. Furthermore, ^5J(H,C) can be shown to obey an equation of type [2] in the manner discussed for $^5J(H,CH_3)$ previously (17, 21). It is unlikely that the theoretical values of $^5J^{\pi}_{90}$ and $^5J^{\sigma}_{180}$ are quantitatively correct (17, 21). Empirical estimates are given below.

The INDO MO FPT computations imply that $^{4,5,6}J(H,CH_2)$ and $^{4,5,6}J$(H,C) in benzyl cyanide have the same angle dependence, although naturally the coefficients of $\sin^2\theta$ and $\sin^2(\theta/2)$ will be different for the two kinds of coupling constants. The experimental data support this conclusion, as discussed below.

Turning to $^{3,4,5}J(^{13}C,^{13}CN) \equiv {}^{3,4,5}J$(C,C), using the STO 3G MO geometries for benzyl cyanide, the INDO MO FPT computations can be reproduced by eqs. [4]–[6], errors at the 95% confidence interval.

$$[4]\quad {}^3J(C,C)/Hz = 3.07(1) - 1.04(2)\sin^2\theta + 2.54(2)\sin^2(\theta/2)$$

$$[5]\quad {}^4J(C,C)/Hz = -0.32(4) - 2.19(6)\sin^2\theta + 0.51(6)\sin^2(\theta/2)$$

$$[6]\quad {}^5J(C,C)/Hz = 0.18(1) + 2.30(3)\sin^2\theta$$

Normally, the Karplus equation (22) for a vicinal coupling constant is written as $^3J = A\cos 2\theta + B\cos\theta + C$, in which θ is zero for an eclipsed arrangement of the end-bonds. Of course, eq. [4] is equivalent to the usual Karplus formulation because of trigonometrical identities. In this discussion the formulation used in eq. [4] is more convenient. For free rotation about the C_{sp^2}—C_{sp^3} bond, $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ are both 0.5 and eq. [4] suggests 3.8 Hz for such a situation. If $\langle\sin^2(\theta/2)\rangle$ approaches unity, corresponding to θ approaching 90°, then ^3J should decrease to 3.3 Hz, according to eq. [4]. Of course, this prediction depends crucially on the true values of the coefficients in eq. [4], assuming that the functional form is correct. Apparently, the noncontact contributions to ^3J(C,C) in a molecule of this kind are rather small (23) and will not much alter the general form of eq. [4].

In contrast, the angle-independent terms in eqs. [5] and [6] are probably artifacts of the computations, as discussed before for a variety of long-range coupling constants (16, 19, 24). ^4J(C,C) appears to have a negative σ–π component, proportional to $\sin^2\theta$, and a small, positive σ component. ^5J(C,C)

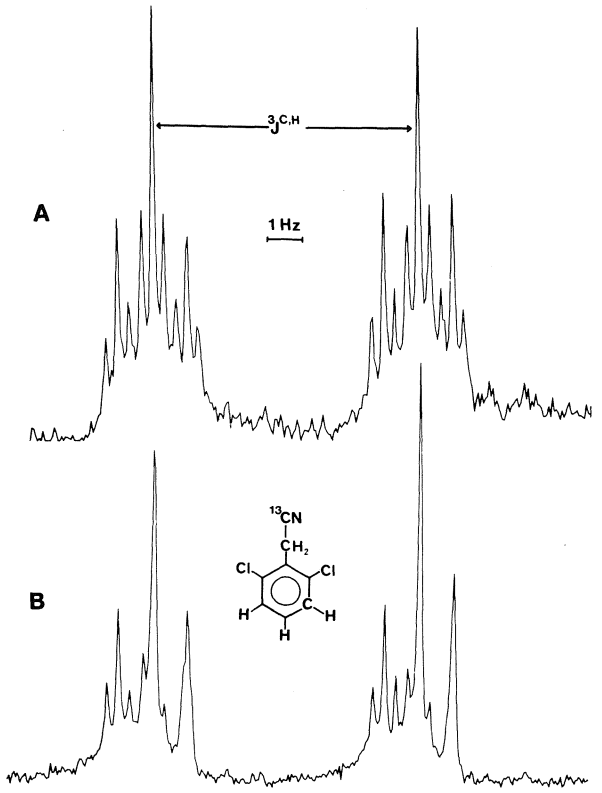

FIG. 1. Half of the ^{13}C nmr spectrum of C-3 in 2,6-dichlorobenzyl cyanide-8-^{13}C, as a 7.1 mol% solution in acetone-d_6, is shown in A. The oscillator frequency is 75.486 MHz and the probe temperature is 300 K. The pair of multiplets is separated by 8 Hz, due to a coupling interaction with H-5. The dominant triplet structure arises from the near equality in the magnitudes of ^2J(H-4,C-3) and ^4J(C-3,^{13}CN). The small triplet spacings of about 0.35 Hz are caused by ^4J(C-3,CH_2). In B the low frequency multiplet of the methylene protons is being irradiated (^2J(CH_2,^{13}CN) is −11.1 Hz). The ^{13}C triplets at low frequency collapse (partial decoupling experiment). Hence ^2J(CH_2,^{13}CN)/^4J(C-3,^{13}CN) > 0.

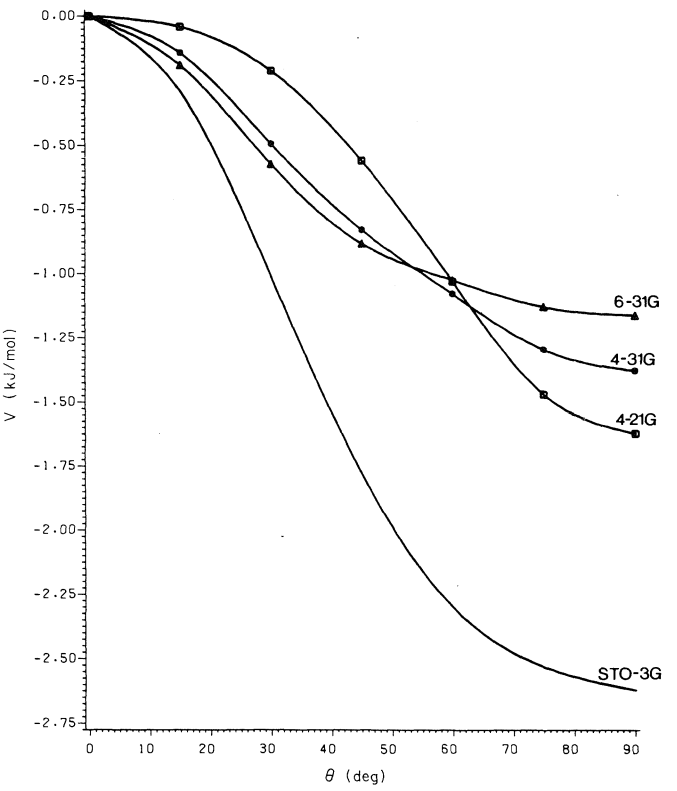

FIG. 2. The relative energies of the optimized geometries of benzyl cyanide are plotted against the dihedral angle θ, which is zero when the cyano group lies in the benzene plane. The calculated internal rotational potentials are discussed in the text. The larger basis sets yield the lower internal barriers. For 6-31G, $V(\theta)$/kJ mol^{-1} = $-1.076(3)\sin^2\theta - 0.293(3)\sin^2 2\theta - 0.084(3)\sin^2 3\theta$, the minimum energy being −361.327 917 au. The barrier height is 1.16(1) kJ/mol.

is computed to be a σ−π coupling constant, analogous to $^5J(C,CH_3)$ in toluene (25–27), but with a magnitude too large at θ = 90° (see below). It is noted that similar computations of ^nJ(C,C) are available for phenylacetic acid (28).

These theoretical considerations provide a guide to the use of $^nJ(H,CH_2)$, $^nJ(H,^{13}CN)$, and $^nJ(^{13}C,^{13}C)$ in the conformational deductions below.

Molecular orbital computations

With rather extensive geometry-optimization procedures, but constraining the carbon framework of the phenyl group to a regular hexagon, the energies of benzyl cyanide as a function of θ yield eq. [7] at the STO 3G level of molecular orbital theory.

$$[7]\quad V(\theta)/\text{kJ mol}^{-1} = -2.597(6)\sin^2\theta - 0.477(6)\sin^2 2\theta = V_2\sin^2\theta + V_4\sin^2 2\theta$$

The energies were computed at intervals of 15° (−357.018 970 au at θ = 0°) and the seven values gave a best fit to a potential containing twofold and fourfold components. The numbers in parentheses in eq. [7] represent the uncertainties at the 95% confidence level. The term in V_4 amounts to nearly 20% of V_2 and the conformation of minimum energy has the cyano group lying in a plane perpendicular to the benzene plane. For a complete geometry optimization, carried out at 0° and 90°, the amplitude of $V(\theta)$ becomes 2.51 kJ/mol, insignificantly different from eq. [7].

Repetition of the computations with the 4-21G basis set gave V_2 and V_4 as −1.634(4) and 0.266(4) kJ/mol, respectively, while the 4-31G basis set yielded a set of energies which were best fit with V_2, V_4, and V_6 as −1.312(5), −0.131(5), and −0.62(2) kJ/mol. Finally, the 6-31G basis predicted V_2, V_4, and V_6 as −1.076(3), −0.293(3), and −0.084(3) kJ/mol, respectively. The minimum energies for the 4-21G, 4-31G, and 6-31G bases were −360.709 315, −360.944 650, and −361.327 917 au, respectively. Apparently the internal rotational barrier in benzyl cyanide is rather small and contains an appreciable fourfold, in addition to the dominant twofold, component. Figure 2 displays the computed rotational potentials.

As expected, the computed barrier in 2,6-difluorobenzyl cyanide at the STO 3G level increases in magnitude relative to benzyl cyanide, V_2 and V_4 being −9.86(3) and −2.35(3) kJ/mol, respectively. The minimum energy is −551.934 111 au. In the presence of two *ortho* chlorine substituents, the best fit to the STO 3G MO energies has V_2 as −29.6(5) kJ/mol and a minimum energy of −1265.009258 au. Inclusion of a fourfold component does not improve the fit, but it must be stated that the smooth curve through the computed energies displays a somewhat "flat top" near 90°.

Computations with other basis sets were not done for the two benzyl cyanide derivatives because they were too expensive.

In the discussion below, the presence of a fourfold term in the internal rotational potential modifies the experimental estimates

of the conformational potential deduced from the long-range coupling constants.

Internal barriers in solution based on ^{6}J(H,CH$_2$) and ^{6}J(H,C)

In 2,6-dichlorobenzyl cyanide, V_2 is calculated as 29.6(5) kJ/mol. At 300 K a hindered rotor model (29) yields $\langle\sin^2\theta\rangle$ as 0.955 for a V_2 of 29.6 kJ/mol (51 free rotor basis functions). A harmonic oscillator basis has $\langle\sin^2\theta\rangle$ as 0.957. A V_2 as high as 38 kJ/mol corresponds to a $\langle\sin^2\theta\rangle$ of 0.965 and this drops to 0.934 for a V_2 of 21 kJ/mol. It will be assumed that $\langle\sin^2\theta\rangle$ in this compound is 0.955. ^6J(H,C) is −0.718(5) Hz, corresponding to a $^6J_{90}$ of −0.752(5) Hz. In benzyl cyanide-8-^{13}C, ^6J(H,C) is −0.364(4) Hz. It follows that $\langle\sin^2\theta\rangle$ is 0.484(8). This number implies that the conformer of lowest energy has a θ of 0°. If the internal barrier were purely twofold, it would be only 0.3(1) kJ/mol, a zero barrier corresponding to 0.5 for $\langle\sin^2\theta\rangle$. A fourfold component amounting to 20% of the twofold magnitude and of the same sign (see eq. [7]), will alter $\langle\sin^2\theta\rangle$ insignificantly for such a small barrier. In view of the possible error in $^6J_{90}$(H,C), which is not known but must be finite, it is concluded that essentially free internal rotation occurs in benzyl cyanide-8-^{13}C in benzene-d_6 solution. If, for example, it is assumed that the barrier in 2,6-dichlorobenzyl cyanide is very large indeed, so that $\langle\sin^2\theta\rangle$ is effectively unity, then its value in benzyl cyanide becomes 0.507 and corresponds to a θ of 90° for the conformation of lowest energy in benzene-d_6 solution. The apparent twofold barrier is then 0.1 kJ/mol.

This conclusion can be checked by means of ^6J(H,CH$_2$), which is −0.585(3) Hz in the same solution. Based on the discussion in a previous section, $^6J_{90}$(H,CH$_2$) is −1.20(2) Hz. Hence $\langle\sin^2\psi\rangle$ is 0.488(10) Hz, confirming the very flat internal rotational potential, but implying a minimum energy at θ = 90° and a V_2 of 0.4(4) kJ/mol. For the 3,5-dichlorobenzyl cyanide, dissolved in a mixture of C_6D_6, $CDCl_3$, and CS_2, ^6J(H,CH$_2$) is −0.60(1) Hz (5), implying only a small perturbation of the potential by the *meta* substituents. This result contrasts with those found for benzyl fluoride and 3,5-dichlorobenzyl fluoride (19).

In the 2,6-dichloro derivative, ^6J(H,CH$_2$) is −0.334(3) Hz, corresponding to a $\langle\sin^2\theta\rangle$ of 0.278(7) if $^6J_{90}$(H,CH$_2$) is −1.20(2) Hz. Because $\langle\sin^2\theta\rangle = 1.5 - 2\langle\sin^2\psi\rangle$ (see **1**), the $\langle\sin^2\theta\rangle$ of 0.955 Hz, deduced above, yields $\langle\sin^2\psi\rangle$ as 0.273(3). However, a careful analysis of the ^{1}H nmr spectrum of 2,6-dichlorotoluene in CS_2 solution gave ^6J(H,CH$_3$) as −0.630(1) Hz, implying $^6J_{90}$(*H*,C*H*$_3$) as −1.26(2) Hz in the presence of two *ortho* chlorine substituents. Then $\langle\sin^2\psi\rangle$ becomes 0.263(7), now somewhat lower than deduced from $\langle\sin^2\theta\rangle$. Better agreement is perhaps not to be expected in view of measurement and other errors.

All these comparisons suggest that a barrier in 2,6-difluorobenzyl cyanide is derivable from ^6J(H,C) and ^6J(H,CH$_2$), which are −0.656(2) Hz and −0.390(2) Hz, respectively. Hence $\langle\sin^2\theta\rangle$ is 0.872(8) and $\langle\sin^2\psi\rangle$ is 0.325(7). These numbers correspond to apparent twofold barriers of 11.8(6) and 10.3(9) kJ/mol, respectively. In 2,6-difluorotoluene in CS_2 solution, ^6J(H,CH$_3$) is −0.623(5) Hz (30), implying a $^6J_{90}$(H,CH$_2$) of −1.25(2) Hz, a $\langle\sin^2\psi\rangle$ of 0.312(7), and an apparent V_2 of 12.1(9) kJ/mol. Although this value of $\langle\sin^2\theta\rangle$ is in better agreement with $\langle\sin^2\theta\rangle \equiv 1.5 - 2\langle\sin^2\psi\rangle$ than that deduced from $^6J_{90}$(H,CH$_2$) = −1.20(2) Hz, one might also expect an *ortho* substituent perturbation of ^6J(H,C). There is no clear way to establish such a perturbation. The MO barrier implies a V_4/V_2 ratio 0.24. Such a ratio and a $\langle\sin^2\theta\rangle$ of 0.87(1) correspond to a V_2 of 19.5(5) and a V_4 of 4.5(4) kJ/mol, quite different from the magnitude indicated by the MO computations. One might note that one of the larger basis set calculations for benzyl cyanide itself has a different sign of V_4/V_2 than does the STO 3G, minimal basis computation. Suppose, for example, that V_4/V_2 is −0.24 for the 2,6-difluoro derivative. Then a $\langle\sin^2\theta\rangle$ of 0.872(8) fits V_2 and V_4 of 9.0(3) and −2.2(3) kJ/mol, respectively, implying a barrier *height* of 9.0(3) kJ/mol (the fourfold component is zero at θ = 90°). On the other hand, if V_4/V_2 is positive, then the height of the barrier is 19.5(5) kJ/mol.

Unfortunately, these two combinations of V_2 and V_4 cannot be distinguished on the basis of $\langle\sin^2\psi\rangle$. The C—H and C—C bonds do sample different regions of the internal rotational potential. However, at least for the present situation, the sampling leads to a $\langle\sin^2\psi\rangle$ of 0.315 for $V_4/V_2 > 0$ and to 0.314 for $V_4/V_2 < 0$. Furthermore, the numbers are not sufficiently different from the experimental value of 0.325(7) so as to provide evidence for the absence of V_4.

^{5}J(C,C) as a conformational indicator

Equation [6] is taken as theoretical support for a σ–π mechanism for ^5J(C,C). Then its value of 1.08(1) Hz for 2,6-dichlorobenzylcyanide-8-^{13}C in benzene-d_6 solution implies ^5J(C,C) = $^5J_{90}\langle\sin^2\theta\rangle$ where $^5J_{90}$ is 1.08(1)/0.955 or 1.13(1) Hz. It follows that $\langle\sin^2\theta\rangle$ for benzyl cyanide in benzene solution is 0.51(1)/1.13(1) or 0.45(1), corresponding to an apparent twofold barrier of 1.0(3) kJ/mol. Furthermore, the conformer of lowest energy has θ = 0°, as indicated by ^6J(H,C) but not by ^6J(H,CH$_2$). If the barriers indicated by the three coupling constants are treated on an equal footing, then it follows that the barrier in benzyl cyanide in benzene-d_6 solution at 300 K is 0.3(3) kJ/mol, the in-plane conformer having the lowest energy.

For the 2,6-difluoro derivative, ^5J(C,C) corresponds to an apparent V_2 of 9.6 ± 1.2 kJ/mol, but again its value cannot discriminate between this estimate and a combination of V_2 and V_4.

Concerning ^{4,5}J(H,CH$_2$) and ^{4,5}J(H,C) in benzyl cyanide-8-^{13}C

Because $\langle\sin^2\theta\rangle$ and $\langle\sin^2\psi\rangle$ are so very near 0.5 in benzyl cyanide, it should be possible to rationalize all the observed long-range couplings involving the ring protons and the side-chain methylene protons or ^{13}C nucleus in terms of equations of type [1]–[3]. This statement follows because the INDO MO FPT computations strongly imply that these couplings have the same qualitative conformational dependence. On the assumption that, as discussed in previous sections, ^6J(H,CH$_2$) is −1.20(2) Hz at θ = 90° and that ^6J(H,C) is −0.752(5) Hz, their ratio follows as 0.627(15). Hence, the ratio of the observed coupling constants (Table 1) should be the same and is indeed 0.622(10).

Again, because ^4J is dominated by the σ–π electron term, the ratio for ^4J(H,C) to ^4J(H,CH$_2$) is expected to be similar to the ratio of the ^6J values. The observed ratio is 0.647(8). The discrepancy can be attributed to differing σ electron components, which become $-0.40\langle\cos^2\psi\rangle$ and $-0.29\langle\cos^2\theta\rangle$ for ^4J(H,CH$_2$) and ^4J(H,C), respectively (use eq. [3] and experimental values, assuming $\langle\sin^2\theta\rangle = \langle\sin^2\psi\rangle = 0.5$).

By way of contrast, ^5J consists of σ and σ–π contributions of similar magnitude. The latter can be taken as that in toluene for ^5J(H,CH$_2$) and as 0.622 of this for ^5J(H,C). Consequently, ^5J(H,CH$_2$) becomes (Table 1) 0.134 Hz, while ^5J(H,C) is

TABLE 4. The ^{13}C nmr chemical shifts and $^{13}C,^{13}C$ coupling constants at 75.486 MHz and 300 K for benzyl cyanide-8-^{13}C and its derivatives

[a]For a 5 mol% solution in CS_2 solution containing ca. 30 vol% of C_6D_{12}.
[b]For an 11 mol% solution in benzene-d_6 in ppm relative to internal TMS. The shifts are reproducible to 1 ppb and the coupling constants to within 0.01 Hz.
[c]For a 3.0 mol% solution in acetone-d_6.
[d]3.0 mol% in benzene-d_6.
[e]7.1 mol% in acetone-d_6.
[f]5.0 mol% in benzene-d_6. The couplings in Hz to ^{19}F are $^1J(C,F) = -250.04$, $^2J(C\text{-}1,F) = 19.29$, $^3J(CH_2,F) = \pm 4.41$, $^3J(C\text{-}2,F) = 6.90$, $^2J(C\text{-}3,F) + {}^4J(C\text{-}3,F) = 25.02$, $^3J(C\text{-}4,F) = 10.12$, $^4J(CN,F) = \pm 1.01$ Hz.
[g]These signs, see Fig. 1, are assumed also for those given in other columns and agree with theoretical calculations.

0.126 Hz. Accordingly, for benzyl cyanide one has eqs. [8] and [9].

$$[8]\quad {}^5J(H,CH_2)/Hz = 0.336\langle \sin^2 \psi\rangle + 0.268\langle \sin^2 (\psi/2)\rangle$$

$$[9]\quad {}^5J(H,C)/Hz = 0.209\langle \sin^2 \theta\rangle + 0.252\langle \sin^2 (\theta/2)\rangle$$

A test of such equations can be had from, for example, 2,6-difluorobenzyl cyanide-8-^{13}C. However, it is known that *ortho* fluorine substituents increase the σ component of $^5J(H,CH_2)$, it being 0.270 Hz in 2,6-difluorotoluene compared to 0.161 Hz in toluene (17, 21). If this increase is factored into eq. [8], then $^5J(H,CH_2)$ is computed as 0.334 Hz, the observed value being 0.328(1) Hz. The $\langle \sin^2 \psi\rangle$ is taken from Table 5 and $\langle \sin^2 (\psi/2)\rangle$ is 0.5, the value for twofold and fourfold barriers of any magnitudes. It is not known how the substituents would alter the components of $^5J(H,C)$. Equation [9] yields $^5J(H,C)$ as 0.308 Hz, while 0.329(2) Hz is observed, perhaps implying an increased σ component. On the other hand, $^5J(H,C)$ in the 2,6-dichloro derivative is calculated as 0.326 Hz, whereas the observed value is 0.331(3) Hz. Rather more data are needed to reach firm conclusions, although most of the increase of 0.1 Hz in $^5J(H,C)$ observed in going from benzyl cyanide to its two derivatives is reproduced by the implied coupling mechanism.

$^{2,3,4}J(^{13}C,^{13}CN)$ mechanisms

In toluene, $^2J(C\text{-}1,CH_3)$ is −5.97 Hz (25) and INDO MO FPT values (26) for this coupling are reproduced by $-5.93 - 2.21 \sin^2 \psi$. Of course, $\langle \sin^2 \psi\rangle$ is 0.5 in toluene and hence the theoretical numbers overestimate the magnitude of the coupling constant by 1.06 Hz. The present INDO values for $^2J(C,C)$ obey $^2J(C,C)/Hz = -7.16 - 1.31 \sin^2 \theta$. For the benzene solutions in Table 4, and from the values of $\langle \sin^2 \theta\rangle$ in Table 5, the empirical equation for $^2J(C,C)$ is $|^2J(C,C)/Hz| = 2.2(1) + 2.7(1) \sin^2 \theta$.

The theoretical numbers for $^3J(C,C)$ are fit by $3.1(1) - 1.0(2) \sin^2 \theta + 2.5(2) \sin^2 (\theta/2)$, a Karplus equation, just as in toluene the $^3J(C\text{-}2,CH_2)$ values given by theory (26) are reproduced by $4.89(3) - 1.44(4) \sin^2 \theta + 3.18(4) \sin^2 (\theta/2)$. The experimental numbers in Tables 4 and 5 for benzene solutions cannot yield the coefficients of $\sin^2 (\theta/2)$ because the latter is 0.5 for any combinations of V_{2n}, where n is an integer. However, they yield $^3J(C,C)/Hz = 4.3(2) - 2.3(1) \sin^2 \theta$,

TABLE 5. Internal rotational potentials in benzylcyanide-8-^{13}C and its two derivatives in benzene-d_6 solution

[a]The theoretical value of V_2 is used to derive $^6J_{90}(H,C)$ and $\langle \sin^2 \theta\rangle_H^C$. See text.
[b]The value of V_2 obtained from $^6J(H,CH_2)$ assuming a $^6J_{90}(H,CH_2)$ of −1.20(2) Hz.
[c]The theoretical value of V_2 is used to find $^5J_{90}(C,C)$ and $\langle \sin^3 \theta\rangle_C^C$.
[d]Implying that in the conformation of lowest energy, the cyano group lies in the benzene plane.
[e]Implying that the cyano group prefers the plane perpendicular to the benzene ring. To obtain agreement with $\langle \sin^2 \theta\rangle^C = 1.5 - 2\langle \sin^2 \psi\rangle_H^H$, one needs $\langle \sin^2 \psi\rangle_H^H$ as 0.508 or $^6J_{90}(H,CH_2)$ as 1.15(2) Hz. See text for a fuller discussion.
[f]With a $^6J_{90}(H,CH_2)$ of −1.25(2) Hz. See text.

implying rather minor intrinsic perturbations from the ring substituents attached to the coupled carbon nucleus.

Turning to ^4J(C,C) in benzyl cyanide-8-^{13}C, the INDO numbers are represented by ^4J(C,C)/Hz = $-0.32(4) - 2.19(6)\sin^2\theta + 0.51(6)\sin^2(\theta/2)$, implying a positive coupling only when θ is 180°, that is, for an all-*trans* arrangement of the intervening bonds. It is conceivable that the constant term in this equation is an artifact of the computation, as found for $^5J(H,CH_3)$ in toluene (16). The data in Tables 4 and 5 cannot be used to rule out a constant term. They do yield $0.5 - 1.6\sin^2\theta$ for the behaviour of ^4J(C,C), a result perhaps most consistent with a vanishing ^4J(C,C) at $\theta = 0°$ (all-*cis*). The best fit is obtained for a negative value of ^4J(C,C), −0.19 Hz, in benzyl cyanide itself in benzene-d_6 solution.

The solvent dependence of the internal barrier in benzyl cyanide

In benzyl fluoride (19) the perpendicular conformer ($\theta = 90°$ for C—F) is stabilized by approximately 2 kJ/mol when the solvent is changed from CS_2 to acetone, qualitatively as expected from electrostatic considerations because this conformer has a higher computed dipole moment than the one with $\theta = 0°$. The internal rotational barrier in benzyl fluoride is small, comparable in magnitude with that computed for benzyl cyanide, except that the most stable conformer has $\theta = 0°$ in the former for the isolated molecule. In benzyl fluoride, all the long-range coupling constants, J(C,F), J(H,F), and $J(H,CH_2)$, are in agreement as to the solvent-induced change in the internal rotational potential (19). Unfortunately, the ^{1}H nmr spectrum of benzyl cyanide at 300 MHz yields to analysis only in benzene-d_6 solution. Therefore $^nJ(H^{13}CN)$ and $^nJ(H,CH_2)$ are not available for other solvents, leaving only ^nJ(C,CN) as indicators of the conformational changes induced by solvents.

The dipole moments of benzyl cyanide are computed as 3.17 and 3.26 D for $\theta = 0$ and 90°, respectively, at the STO 3G level of MO theory. The observed dipole moment in benzene solution is 3.50 D at 298 K, that of methyl cyanide also being 3.5 D in the same solvent. Qualitatively, then, the perpendicular conformer should be more stable in acetone that in CS_2 solution.

The ^nJ(C,CN) of benzyl cyanide in CS_2/C_6D_{12}, benzene-d_6, and acetone-d_6 solutions are given in Table 4. Qualitatively, their values do indeed indicate increased stability of the more polar conformer in acetone-d_6. In terms of the discussion in the previous section, ^2J(C,C) and ^3J(C,C) should decrease in magnitude when the perpendicular conformer is stabilized by solvent, while $^{4,5}J$(C,C) should increase, in congruence with observation.

Quantitatively, based on ^5J(C,C), $\langle\sin^2\theta\rangle$ changes from 0.44(1) in CS_2/C_6D_{12} to 0.51(1) in acetone-d_6 solutions. Therefore the apparent V_2 changes from 1.3(4) kJ/mol, the in-plane conformer being of lowest energy in the nonpolar solvent mixture, to 0.2(2) kJ/mol in acetone-d_6 solution with a possibly slight preference for the perpendicular conformer.

On the assumption that the two conformers differ in their dipole moments by a maximum of 0.2 D, the perpendicular conformer having one of 3.6 D, the reaction field model (31) implies that the perpendicular conformer is stabilized by 0.5 kJ/mol in the CS_2 solution and by 0.8 kJ/mol in acetone-d_6 solution. More than semiquantitative agreement with the measurements above is not expected (31), nor was it found for benzyl fluoride (19). What is certain from the measurements of ^5J(C,C) is the increased stability of the perpendicular conformer in the more polar solvent by 1.5(3) kJ/mol, this number being insensitive to the error in $^5J_{90}$(C,C).

Intrinsic solvent perturbations of $^nJ(C,C)$

Comparison of ^nJ(C,C) values, $n = 2$–5, for 2,6-dichlorobenzyl cyanide-8-^{13}C in benzene-d_6 and acetone-d_6 solutions in Table 4 suggests their insensitivity to solvent polarity. The barrier to internal rotation in this molecule is very high relative to benzyl cyanide, so that significant differences in the magnitudes of these coupling constants in the two solvents would be attributable to an intrinsic perturbation of coupling mechanisms by solvent molecules. Consequently, the solvent dependence of these coupling constants in benzyl cyanide can be assigned to conformational changes, that is, to perturbations of the internal rotational potential.

However, ^1J(C,C) does evince an intrinsic solvent dependence as well as a sensitivity to the presence of *ortho* substituents (Table 4). The original INDO MO FPT computations (4) of ^1J(C,C) predict a smaller value for the conformer defined by $\theta = 90°$. In that event, the decrease of 1.3 Hz in ^1J(C,C) in benzyl cyanide on moving from nonpolar to polar solutions is in qualitative agreement with conclusions in the previous section. However, much of this decrease may well arise from an intrinsic solvent perturbation because ^1J(C,C) decreases by 0.7 Hz between benzene-d_6 and acetone-d_6 solutions for the 2,6-dichloro derivative. Furthermore, the values are larger than for benzyl cyanide in the same solvents, presumably a substituent perturbation. Its presence is emphasized by the value of ^1J(C,C) in the 2,6-difluoro derivative, being larger than any other in Table 4. The present solvent perturbations of $^1J(CH_2, C{\equiv}N)$ join those known for a variety of other one-bond coupling constants (32–37).

Conclusions

Ab initio molecular orbital calculations and long-range ^{1}H,^{1}H; ^{1}H,^{13}C; and ^{13}C,^{13}C spin–spin coupling constants agree that the internal barrier to rotation about the C_{sp^2}—C_{sp^3} bond in benzyl cyanide is small relative to kT at ambient temperatures. The molecular orbital calculations have the conformer of lowest energy as that with the cyano group perpendicular to the benzene plane, whereas in benzene solution the coupling constants imply that this conformer has the cyano group in the benzene plane. The coupling parameters indicate a stabilization of the perpendicular conformer by polar solvents. For 2,6-difluorobenzyl cyanide the coupling constants cannot discriminate between a purely twofold barrier and one containing an additional fourfold component, as computed by molecular orbital methods. However, they do indicate a substantial barrier and the conformer of lowest energy.

Appendix

A referee requested some computed geometrical data and these are given in Table A1. The sidechain geometry is characterized for the most stable conformations, those in which the cyano group lies in a plane perpendicular to the benzene plane. As expected, the bond lengths and angles are somewhat basis dependent. For comparison, the C—C bond length in methyl cyanide is 1.458 Å and that of the C≡N bond is 1.157 Å (38). According to the STO 3G MO computations, the *ortho* halogen substituents cause rather small changes in the sidechain geometry.

Received April 9, 1986

JOHN ALFRED STONE, XIAOPING LI, and PATRICIA ANNE TURNER. Can. J. Chem. **64**, 2021 (1986).

The proton affinities (PA) of some methylaromatic compounds and the rates of proton transfer reactions have been measured using high pressure mass spectrometry. The equilibria studied were of the form $B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$. Van't Hoff plots yielded the following PA values (kcal mol^{-1}) relative to PA(ethylacetate) = 200.7 as standard: mesitylene 201.0, 1,2,3,5-tetramethylbenzene 203.2, pentamethylbenzene 204.4, hexamethylbenzene 206.6. ΔS^0 values for the proton transfer equilibria are not fully determined by changes in rotational symmetry numbers and it is suggested that vibrational and torsional changes must be considered. Proton transfer is slow in both the forward (exothermic) and reverse (endothermic) directions and, in addition, for all except the most endothermic reaction studied (1,2,3,5-tetramethylbenzene + protonated hexamethylbenzene) the rate constants for proton transfer increase with decreasing temperature. Such behaviour can be associated with the potential energy profile along the reaction coordinate for the reaction. A limited number of charge transfer experiments involving molecular ions ($B_1^+ + B_2 \rightleftharpoons B_1 + B_2^+$) showed that reaction occurs at every collision in the forward (exothermic) direction and the reaction efficiency in the reverse (endothermic) direction is small but increases with increasing temperature.

JOHN ALFRED STONE, XIAOPING LI et PATRICIA ANNE TURNER. Can. J. Chem. **64**, 2021 (1986).

On a mesuré les affinités pour le proton (AP) de quelques composés aromatiques méthylés ainsi que les vitesses des réactions de transfert de proton, en utilisant la spectrométrie de masse à haute pression. Les équilibres étudiés sont de la forme $B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$. Les courbes de Van't Hoff donnent les valeurs suivantes des AP (kcal mol^{-1}) par rapport à celle de l'acétate d'éthyle = 200,7 utilisé comme standard : mésithylène = 201,0; tétraméthyl-1,2,3,5 benzène = 203,2; pentaméthylbenzène = 204,4; hexaméthylbenzène = 206,6. Les variations des nombres de symétrie rotationnelle ne déterminnent pas complètement les valeurs de ΔS^0 des équilibres de transfert du proton et on suggère que les changements dans la vibration et la torsion doivent être pris en considération. Le transfert du proton est lent dans la réaction directe (exothermique) et inverse (endothermique) et de plus dans tous les cas étudiés, à l'exception de la réaction la plus endothermique (tétraméthyl-1,2,3,5 benzène + hexaméthylbenzène protoné), les constantes de vitesse de transfert du proton augmentent lorsque la température diminue. On peut associer un tel comportement à l'allure de la courbe d'énergie potentielle en fonction de la progression de la réaction. Un nombre limité d'expériences de transfert de charges impliquant les ions moléculaires ($B_1^+ + B_2^+ \rightleftharpoons B_1 + B_2^+$) montre que la réaction se produit pour chaque collision dans la réaction directe (exothermique) et l'efficacité de la réaction inverse (endothermique) est faible, mais elle augmente quand la température augmente.

[Traduit par la revue]

Introduction

Many proton affinity (PA) values for neutral molecules have been obtained in the last fifteen years, usually by proton-transfer equilibrium techniques. The majority of the measurements have been made using either ion cyclotron resonance (icr) or pulsed electron beam, high pressure mass spectrometry (HPMS) (1). Icr is limited in temperature range and most measurements are made at an ambient temperature of about 320 K which is determined by the heating effect of an electron emitting filament. The pressures in icr studies are in the range 10^{-5}–10^{-6} Torr (1 Torr = 133 Pa). HPMS studies are usually conducted over a range of pressures (0.5–5 Torr) and a range of temperatures (300–600 K).

The equilibria studied by both techniques are of the form

[1] $$B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$$

B_1 and B_2 are gas phase bases. It is assumed that the measured equilibrium ion currents $i_{B_1H^+}$ and $i_{B_2H^+}$ are proportional to the respective ion concentrations and hence, knowing the ratio of neutral concentrations from the sample composition, the equilibrium constant K is obtained where K is defined as

[2] $$K = \frac{i_{B_2H^+}[B_1]}{i_{B_1H^+}[B_2]}$$

The standard free energy change at the temperature of measurement (T) is

[3] $$\Delta G^0 = -RT \ln K = \Delta H^0 - T\Delta S^0$$

ΔH^0, the standard enthalpy change for reaction [1] is, by definition, the difference in proton affinities of B_1 and B_2, i.e., $\Delta H^0 = PA(B_1) - PA(B_2)$ where PA(B) is ΔH^0 for the reaction

[4] $$BH^+ \rightarrow B + H^+$$

In icr studies, ΔH^0 must be obtained from ΔG^0 using calculated ΔS^0 values because the temperature range available is usually very small. The usual simplifying assumption made in such calculations is that only changes in rotational symmetry numbers (σ) are important and ΔS^0 is adequately approximated by (2)

[5] $$\Delta S^0 = R \ln \frac{\sigma_{B_1H^+}\sigma_{B_2}}{\sigma_{B_2H^+}\sigma_{B_1}}$$

This equation may not be adequate for some systems such as those in which internal rotations are lost or gained upon protonation and those for which there are significant changes in moments of inertia or vibrational frequencies (3).

Although HPMS does not suffer from a limited temperature range, the tendency of protonated bases to solvate at the high pressures employed requires that many equilibrium measurements be carried out at high temperature (often ~600 K) when solvation is minimal. For such studies the entropy changes must also be calculated and it is gratifying that low temperature icr and high temperature HPMS results using calculated entropies usually yield proton affinities in good agreement with each other.

Proton transfer equilibria can be studied over a large temperature range by HPMS only for systems in which solvation of ions is not a problem at lower temperatures. Such measurements have been made for benzene and halogenated benzenes using both HPMS (4, 5) and icr (6), the latter over a more limited temperature range. All the measured ΔS^0 values are in good agreement with each other and with the ones calculated from eq. [5] when "reasonable" assumptions are made regarding the sites of protonation. Some fairly small differences between experimental and calculated values were ascribed to the possibility of protonation at more than one site (5).

A recent investigation (7) has presented evidence for very large entropy changes in proton transfer equilibria involving monohalogenated toluenes. The idea of localized protonation sites was not sufficient to explain these values and the authors proposed that "dynamic" protonated structures may be present in certain of the systems (1,2- and 1,4-halotoluenes), the hydrogen atom being shared by two or more of the adjacent ring carbon atoms which bear no substituents. Such "dynamic" structures have been postulated to be present when aromatics are dissolved in super-acid media (8, 9).

When such "dynamic" structures are possible or when more than one protonation site is present in an aromatic base, it is not possible to check the adequacy of eq. [5] for aromatic compounds in particular and bases in general. This paper reports the results of a study of proton transfer equilibria involving some of the higher methylbenzenes, mesitylene to hexamethylbenzene, in which the sites of protonation should be unambiguous. The equilibria have been studied over as wide a temperature range as possible and in addition the rate constants for proton tranfer reactions in both forward and reverse directions have been measured. Since methane chemical ionization yields not only protonated methylbenzenes but also methylbenzene molecular ions, it has been possible in a few cases to also measure differences in ionization energies and rate constants for electron transfer.

Experimental

All experiments were carried out using the pulsed electron beam, high pressure ion source mass spectrometer which has been described in detail elsewhere (10). All the required compounds were available from commercial sources and were used without further purification. The 1,2,3,5-tetramethylbenzene (TMB) and 1,3,5-trimethylbenzene (MES) could have been contaminated with small amounts (<2 mol%) of structural isomers but since it was determined that both compounds were much more basic than any of their isomers, the presence of such impurities at these concentrations is not of significance. Pentamethylbenzene (PMB) and hexamethylbenzene (HMB) contain no structural isomers.

Samples of two bases were made up by weighing and where necessary were dissolved in benzene as solvent. The temperatures of the sample oven and its connecting line to the ion source were raised to 420 K to prevent problems with sample condensation. Most experiments were carried out at ion source pressures of 4–5 Torr, the bulk of the gas being methane.

Results and discussion

Methane chemical ionization spectra

The major ions in methane at pressures in the range 1–5 Torr are CH_5^+ and $C_2H_5^+$. Both react with aromatic hydrocarbons by proton transfer and $C_2H_5^+$ can also add to the aromatic ring (11). The chemical ionization (CI) spectra of alkyl aromatics (M) contain not only MH^+ and $MC_2H_5^+$ but also significant peaks due to $(M - 1)^+$ and M^+. As the number of alkyl groups on the ring increases the relative intensity of MH^+ decreases while that of $(M - 1)^+$ increases (12). We confirm these results and also find that the intensity of M^+, always small (less than 5% of the base peak), does increase slightly with an increase in the number of methyl groups on the aromatic ring. The origin of this ion is not known; its relative intensity appears to be independent of the concentration of aromatic.

In order to reduce the rate of positive ion diffusion to the ion source walls it was found advantageous to use an electron capture reagent to set up a positive–negative ion plasma rather than work with the positive ion – electron plasma formed by electron impact. The use of SF_6 yielded an enhanced ion signal and also considerably increased the average residence time of ions in the source. SF_6 was the agent of choice but its presence did affect the spectra by increasing the relative intensity of M^+, mainly at the expense of MH^+. In addition, benzene was used as solvent for PMB and HMB and this also affected the initial intensity ratios of $(M - 1)^+$, M^+, and MH^+.

SF_6 is rapidly protonated by CH_5^+ yielding SF_5^+

$$[6] \quad CH_5^+ + SF_6 \rightarrow CH_4 + (SF_6H^+)^*$$

$$[7] \quad (SF_6H^+)^* \rightarrow SF_5^+ + HF$$

The ionization energy of SF_5 is 10.5 eV (13) so that charge transfer to benzene (IP = 9.24 eV) and all the methylbenzenes (IP < 9.24 eV) (14) is exothermic. For example, TMB in CH_4 yields $(M - 1)^+$ (25%), M^+ (5%), and MH^+ (70%) at 464 K. These values are independent of ion source pressure (1–5.5 Torr) but $(M - 1)^+$ does increase slightly with increasing temperature. In the presence of 1 mol% SF_6, the spectrum changes to $(M - 1)^+$ (20%), M^+ (30%), and MH^+ (50%). $(M - 1)^+$ arises from protonation of a methyl substituent of the aromatic ring followed by loss of H_2. Benzene, having no methyl groups, yields no $(M - 1)^+$ peak and when present due to use as a solvent for the methylbenzenes, diminishes the $(M - 1)^+$ and increases the MH^+ intensity of the methylbenzenes. CH_5^+ reacts mainly with solvent C_6H_6 which is present in greater concentrations than the alkyl aromatics. Proton transfer from $C_6H_7^+$ to the methylbenzenes gives MH^+ in a process of much lower exothermicity than that involving CH_5^+ and protonation of methyl does not occur. For example HMB in benzene as solvent and in the presence of SF_6 yields $(M - 1)^+$ (2%), M^+ (11%), and MH^+ (87%) at 465 K. A typical CIMS spectrum is shown in Fig. 1.

Equilibrium measurements

Proton transfer was found to occur at less than the collision rate in all the methylbenzene binary mixtures studied. In order to achieve proton transfer equilibrium in the available ion residence time it was necessary to use relatively large concentrations of the alkyl benzenes in the ion source and this necessitated making up relatively high concentrations of these compounds in methane in the sample reservoir. The least volatile of the alkyl benzenes studied, HMB, is calculated to have a vapour pressure of ~0.9 Torr at 370 K (15) and in order to obtain a sufficient safety margin and prevent condensation in the reservoir and lines, the latter were kept at 420 K and the minimum ion source temperature employed was 370 K.

Figure 2 shows a typical plot of normalized ion intensity versus time for a mixture of HMB and PMB in methane at 601 K and 4.1 Torr. There are three pairs of ions to consider viz. $(M - 1)^+$, M^+, and MH^+ and in the figure both M^+ and MH^+ have been corrected for isotopic contributions from $(M - 1)^+$ and M^+, respectively.

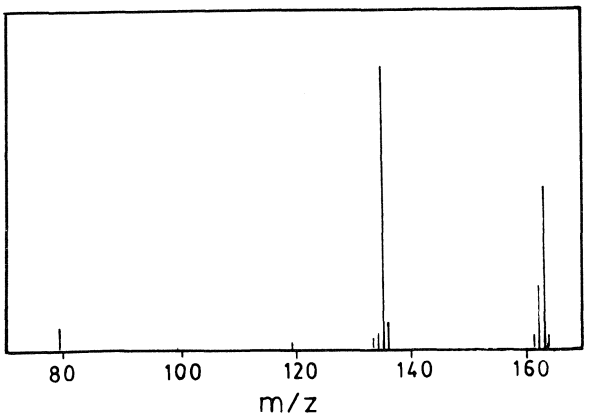

FIG. 1. Mass spectrum of TMB/HMB/SF_6/CH_4 ($1.7 \times 10^{-4}/3.6 \times 10^{-5}/10^{-3}/1$) at 4.22 Torr and 598 K. The major peaks and their m/z values are $C_6H_7^+$ (79), $TMBH^+$ (135), HMB^+ (162), $HMBH^+$ (163).

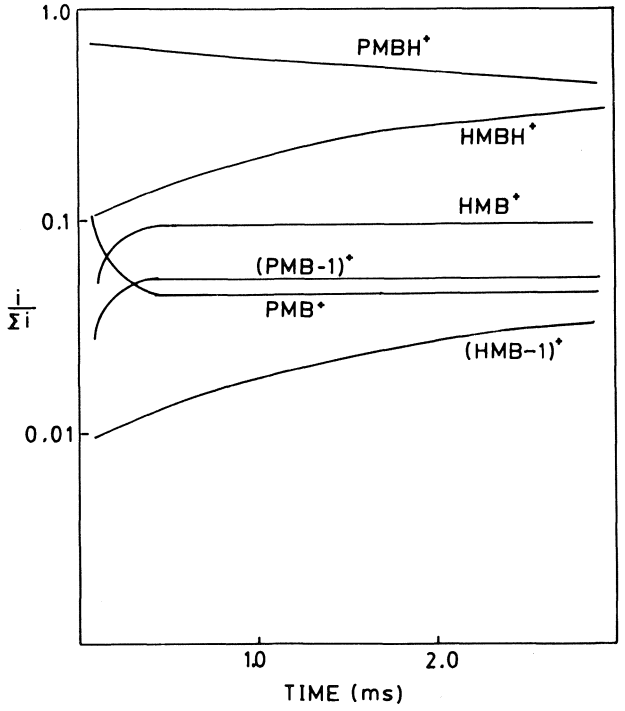

FIG. 2. Normalized ion intensities as functions of time after a 50 μs ionizing pulse of electrons for a mixture of composition PMB/HMB/C_6H_6/SF_6/CH_4 ($8 \times 10^{-4}/1 \times 10^{-4}/5 \times 10^{-3}/10^{-3}/1$) at 3.8 Torr and 602 K.

After a very short time (~0.5 ms) the normalized intensities of HMB^+ and PMB^+ are independent of time, suggesting that charge transfer equilibrium has been attained.

[8] $C_6H(CH_3)_5^+ + C_6(CH_3)_6 \rightleftharpoons C_6H(CH_3)_5 + C_6(CH_3)_6^+$

This was confirmed in the usual manner by determining that the calculated equilibrium constant K was independent of ion source pressure and of the ratio of concentrations of PMB and HMB.

$$[9] \quad K = \frac{[C_6(CH_3)_6^+][C_6H(CH_3)_5]}{[C_6H(CH_3)_5^+][C_6(CH_3)_6]} = \frac{i_{C_6(CH_3)_6^+}[C_6H(CH_3)_5]}{i_{C_6H(CH_3)_5^+}[C_6(CH_3)_6]}$$

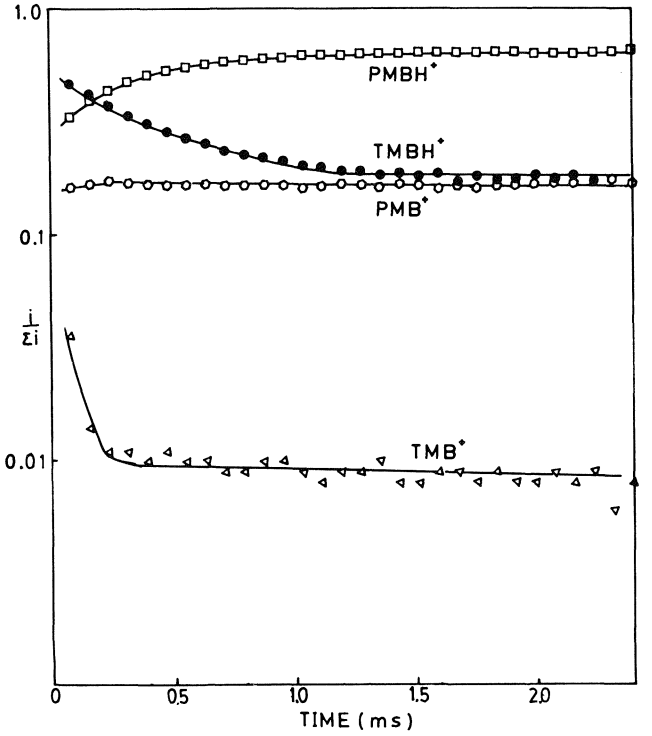

FIG. 3. Normalized ion intensities as functions of time after a 50 μs ionizing pulse of electrons for a mixture of TMB/PMB/C_6H_6/SF_6/CH_4 ($1.2 \times 10^{-4}/5.8 \times 10^{-4}/5 \times 10^{-3}/10^{-2}/1$) at 3.9 Torr and 586 K.

In the expression for K, i is a normalized ion current.

Although the M^+ ions in Fig. 2 rapidly come into equilibrium with each other, the $(M - 1)^+$ ion intensities are apparently approaching equilibrium values only at the longest time shown (3 ms), while the MH^+ ions are not in equilibrium even at this long time. $(M - 1)^+$ ions, because of their low intensity, were not studied further. Proton transfer equilibria could be studied by the judicious choice of relative and total ion-source concentrations of alkylbenzenes. Figure 3 shows one such run involving TMB and PMB when equilibrium (reaction [10]) is achieved after ~1.6 ms.

[10] $C_6H_3(CH_3)_4^+ + C_6H(CH_3)_5 \rightleftharpoons C_6H_2(CH_3)_4 + C_6H_2(CH_3)_5^+$

It is to be noted that the equilibrium between $(M - 1)^+$ ions is not shown and that the charge transfer reaction involving M^+ ions has essentially achieved equilibrium at all but the shortest recorded reaction time.

Equilibrium constants for equilibria of the form

[1] $B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+$

were measured over the temperature range 400–600 K. The equilibrium constants at a given temperature were independent of both the ratios of base concentrations over at least a variation of a factor of five and of ion source pressures in the range 2–5 Torr.

A typical van't Hoff plot of ln K vs. $1/T$ is shown in Fig. 4. The slope of such a plot has the value $-\Delta H^0/R$ and the intercept yields $\Delta S^0/R$. The results obtained for the four methylbenzenes are shown in Table 1. In order to more securely tie the results to standard proton affinity tabulations, the equilibrium between MES and ethylacetate was examined and the resulting thermodynamic data for this equilibrium are also shown.

The internal consistency of the ladder of ΔH^0 values is very good and well within the experimental precision. These results

[c]Uncertainty is one standard deviation from a linear least squares analysis.
[d]Evaluated data from ref. 3.
[e]Data in parentheses calculated from eq. [5] assuming all methyl carbons are in the plane of the aromatic ring.

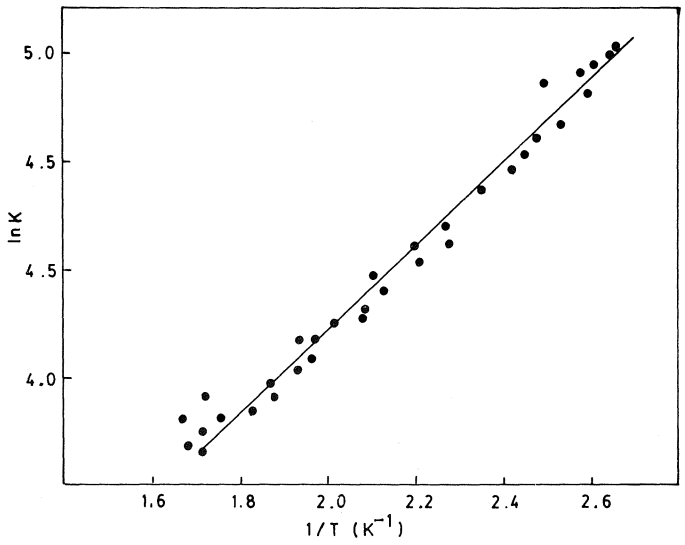

FIG. 4. The van't Hoff plot for the proton transfer equilibrium $MESH^+ + PMB \rightleftharpoons MES + PMBH^+$. A least-squares analysis yields $\Delta H^0 = -3.54 \pm 0.10$ kcal mol^{-1} and $\Delta S^0 = 0.27 \pm 0.21$ cal K^{-1} mol^{-1}.

confirm that proton affinity does increase with increase in the number of methyl groups on the aromatic ring. In the course of this work some experiments were performed with 1,2,4-trimethylbenzene and with 1,2,4,5- and 1,2,3,4-tetramethylbenzenes. We choose not to report the results of these experiments because the samples were impure and equilibria were not sufficiently clearly defined but we did find that, as for the isomeric xylenes (16), proton affinity is a function of both the number and the position of the methyl groups. Suffice to say, the proton affinity of 1,2,4-trimethylbenzene is ~2.4 kcal mol^{-1} less than that of MES and the above-mentioned tetramethylbenzenes have proton affinities lower than that of TMB.

The proton affinities of MES and HMB have been measured by Taft and co-workers; their values are cited in ref. 3. The measurements were made by icr techniques at a temperature which was initially stated to be 300 K but is to be corrected to 320 K. The corrected proton affinity difference obtained by Taft using a value of ΔS^0 calculated according to eq. [5] is PA(HMB) − PA(MES) = 6.15 kcal mol^{-1}. There is therefore good agreement with the value of 5.6 kcal mol^{-1} in Table 1.

Taft and co-workers (16) also suggested that the effects of methyl groups in stabilizing the proton on the ring depend on position and are additive and calculable since protonation always occurs at the most favourable site. For example, since the difference between the proton affinities of benzene and toluene is 7.6 kcal mol^{-1} and on the assumption that protonation occurs *para* to methyl, a *p*-methyl group is stabilizing to this extent. Similarly, since the proton affinity of *m*-xylene is 14.0 kcal mol^{-1} greater than that of benzene and the proton will be most effectively stabilized by one methyl at the *para* position and one at the *ortho* position relative to the site of protonation then an *o*-methyl stabilizes to the extent of 14.0 − 7.6 = 6.4 kcal mol^{-1}. Using data for *p*-xylene, it is readily shown that the stabilization afforded by a *m*-methyl is 2.6 kcal mol^{-1}. The stabilization afforded by an *ipso*-methyl was assigned a value of less than or equal to 1.2 kcal mol^{-1}, this value being based on calculation. In Table 2 we have used the upper limit of 1.2 kcal mol^{-1} in a comparison of experimental and calculated proton affinity values, all relative to benzene. For internal consistency the experimental result are referenced to PA(MES) being 19.4 kcal mol^{-1} greater than that of benzene (3).

The calculated results are all slightly higher than the experimental values by 1–1.7 kcal mol^{-1}. The calculated order of PA values is certainly in agreement with experiment and the additivity principle is certainly a reasonable method for the prediction of proton affinities of the methylbenzenes. It is also to be noted that the PA values which may be calculated but which

TABLE 2. Experimental and estimated proton affinities relative to benzene

Compound	Δ(PA)(expt)	Δ(PA)(est)[a]
Hexamethylbenzene	25.1	26.8
Pentamethylbenzene	24.9	25.6
Tetramethylbenzene	21.6	23.0
Mesitylene	19.4[b]	20.4

[a]Estimated as described in text.
[b]PA(mesitylene) − PA(benzene) = 19.4 kcal mol^{-1} from ref. 3.

are not shown, for 1,2,3,4- and 1,2,4,5-tetramethylbenzene correctly predict values lower than that of TMB while 1,2,4-trimethylbenzene is correctly predicted to have a lower PA value than that of MES.

PA(HMB) − PA(PMB) = 2.2 kcal mol^{-1} shows a significant stabilization afforded by an *ipso*-methyl. Protonation of HMB to give a localized, tetrahedral $HCCH_3$ group, for which nmr evidence has been found at 190 K in super acids, leads to a distorted structure (8). At higher temperature the nmr studies suggested that there was a rapid H transfer amongst ring positions so that all sites became equivalent. Later studies confirmed this finding (9). Protonation of PMB in HF/BF_3 yielded only one isomeric $C_6(CH_3)_5H_2^+$ at temperatures from 213 to 293 K. This showed that the added proton is indeed localized at the only available C—H site yielding what is essentially a methylene group with charge delocalization over the rest of the ring (18). These studies suggest that the basicity of a ring carbon is considerably decreased by a CH_3 substituent and that the favoured sites of protonation will always be unsubstituted ones. Fernandez, Jennings, and Mason have taken this idea one step further and produced some evidence that "dynamic" ion structures are present in the gas phase (7). They found anomalously high entropy changes for proton transfer reactions involving, 1,2 and 1,4 halotoluene isomers, the extreme example cited being a value of −13.4 cal K^{-1} mol^{-1} for transfer from *p*-chlorotoluene to *o*-fluorotoluene. This value is to be compared with the value of −1.4 cal K^{-1} mol^{-1} calculated from rotational symmetry changes. They suggest that for the 1,4 compound in particular, no available (i.e. unsubstituted) protonation site is strongly favoured over any other and that there are relatively high energy barriers at the unfavoured carbon atoms. The low energy barrier between adjacent unsubstituted sites allows "internal translation" of H and hence a substantial decrease in entropy when this translational mode is lost.

Should such internal translation effects be expected in the present study? Each of MES, TMB, and PMB has only one type of preferred site for protonation and in TMB and MES in which there are respectively two and three equivalent sites, these sites are separated by unfavoured sites. HMB has six equivalent sites and it could be argued that internal translation should therefore be facile and anomalous entropy effects should be observed. Alternatively, it could be argued that the H should be localized since the adjacent methyls block movement from the site of protonation. Table 1 confirms that there are no anomalously high values of ΔS^0 for any of the equilibria studied and therefore that hydrogen translation is not a factor in these systems. Moreover, if "internal translation" can occur then it should surely be most improtant for benzene. However, we known of no experimental results showing anomalous entropy effects in proton transfer equilibria involving this molecule.

The ladder of standard entropy differences is internally self consistent and in some cases the ΔS^0 values are reasonably close to those calculated using rotational symmetry numbers (eq. [5]). Symmetry numbers were chosen using the assumption that all methyl group are in the plane of the aromatic ring except when an *ipso* H is present ($HMBH^+$). The precision quoted for the experimental results is one standard deviation and even allowing for this optimistic precision it is seen that some results (e.g. $MESH^+$ + PMB) are not adequately described by eq. [5]. The applicability of non-planar structures was considered since calculation has shown that in HMB alternate methyls are slightly above and below the ring which is also slightly puckered (19). Such puckering probably occurs whenever there are adjacent methyls. The agreement between experimental and calculated ΔS^0 values was even poorer when such distorted structures were used.

TABLE 3. Enthalpy and entropy changes for the charge transfer reaction $B_1^+ + B_2 \rightleftharpoons B_1 + B_2^+$

B_1	B_2	$-\Delta H^0$ (kcal mol^{-1})	$-\Delta S^0$ (cal K^{-1} mol^{-1})	Δ(IP)[a] (kcal mol^{-1})
TMB	HMB	6.6 ± 1.0	1.4 ± 2.2	10.6
PMB	HMB	4.1 ± 0.2	1.0 ± 0.3	6.7

[a]Calculated difference in ionization energy from ref. 14.

The total entropy change, ΔS^0, in a proton transfer reaction has four contributions if the proton is always localized at the most favourable site and "internal translation" need not be considered

$$[11] \quad \Delta S^0 = \Delta S^0_{elec} + \Delta S^0_{vib} + \Delta S^0_{rot} + \Delta S^0_{trans}$$

ΔS^0_{elec} is zero for the reactions studied and the calculated ΔS^0_{trans} is negligibly small for these relatively massive molecules. The addition of a proton to any of the molecules leads to only small geometry changes and will not significantly change the moments of inertia; ΔS^0_{rot} will therefore be given by eq. [5]. The differences between the experimental entropies and calculated ΔS^0_{rot} values must therefore be due to non-zero values of ΔS^0_{vib}. The methylbenzenes with adjacent methyl groups will, like HMB (19), have some low frequency torsional and puckering modes which are strongly coupled in the neutral molecule and which will be altered upon protonation when tetrahedral geometry is approximated at one of the ring carbons. Insufficient information is available to prove that the resulting changes in vibrational frequencies together with rotational symmetry number changes do indeed account for the entropy charges observed. It is apparent, however, that calculations of ΔS^0 for the methylbenzenes using eq. [5] above are not adequate.

Data for charge transfer are in Table 3. There are insufficient results to obtain good thermodynamic data since, as noted before, the reactions were very fast and precision was not as good as for proton transfer. The two ΔH^0 values obtained correspond to the difference in vertical ionization energies between PMB and HMB and between TMB and HMB. The ionization potentials for the higher methylbenzenes are not known with precision. Calculation suggests that the ionization energy decreases linearly with the number of methyl groups on the ring, with energy differences of 10.6 kcal mol^{-1} between PMB and HMB and 6.7 kcal mol^{-1} between TMB and PMD (14). These values are almost a factor of two greater than the present ones. We are carrying out further experiments on these charge transfer reactions to determine whether these initial values are reliable.

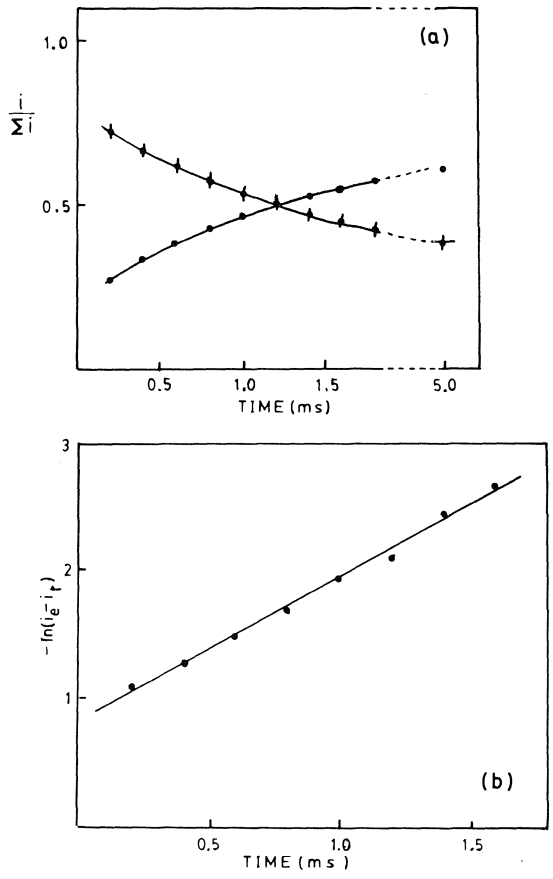

FIG. 5. Kinetic data for the proton transfer reaction $TMBH^+ + PMB \rightleftharpoons TMB + PMBH^+$ at 571 K and an ion source pressure of 3.99 Torr: (*a*) The normalized ion intensities ● $TMBH^+$, ● $PMBH^+$; (*b*) kinetic data plotted according to eq. [14]. Sample composition $TMB/PMB/C_6H_6/CH_4$ ($2.9 \times 10^{-4}/1.8 \times 10^{-4}/5 \times 10^{-3}/10^{-2}/1$).

The kinetics of proton and charge transfer

Proton transfer between the methylaromatics was found to be slow, especially at the higher temperatures. Such was not the case for charge transfer involving the molecular ions which were generated mainly by electron transfer to SF_5^+. The kinetics of charge transfer between the aromatics was studied, when possible, under experimental conditions which were optimized for proton transfer studies. In such circumstances charge transfer equilibrium was often set up too rapidly for meaningful kinetic data to be obtained since relatively high concentrations of the aromatics were used in the proton transfer studies.

Rate constants for proton transfer

Both the forward and reverse rate constants were determined for proton transfer reactions of the form of reaction [1]. A typical graph of the pertinent normalized data for such a system is shown in Fig. 5*a* for the reaction

$$[12] \quad TMBH^+ + PMB \underset{k_-}{\overset{k_+}{\rightleftharpoons}} TMB + PMBH^+$$

Since the concentrations of PMB and TMB are very much greater than those of $TMBH^+$ and $PMBH^+$ they remain constant and the reaction may be written as a reversible reaction which is first order in each direction

$$[13] \quad TMBH^+ \underset{k_-'}{\overset{k_+'}{\rightleftharpoons}} PMBH^+$$

where $k_+' = k_+[PMB]$ and $k_-' = k_-[TMB]$. This form is treated by the standard method for reversible first order reactions (20) to yield the integrated form

$$[14] \quad \ln \frac{i_e - i_0}{i_e - i_t} = -(k_+' + k_-')t$$

where i_e, i_0, and i_t are respectively the normalized $TMBH^+$ or $PMBH^+$ ion currents at equilibrium and at times zero and t. The approach to equilibrium is a first order process with pseudo rate constant $(k_+' + k_-')$. Since the equilibrium constant is equal to k_+'/k_-' then each of k_+' and k_-' may be determined and from the known concentrations of neutrals in the ion source, k_+ and k_- may be calculated. Figure 5*b* shows the linear plot of $-\ln(i_e - i_t)$ against t for the data in 5*a* which has slope $(k_+' + k_-')$. Such an analysis was also carried out for the charge transfer reactions when data were available. The results from this method of deriving rate constants were compared with those from the more usual method which employs the slope of the linear decay obtained from a plot of the logarithm of the normalized ion intensity versus time e.g. for reaction [12].

$$[15] \quad \frac{i_t}{i_0} = -k_+[PMB]t = -k_+'t$$

This method could only be applied satisfactorily to the fastest, most exothermic proton transfer reactions under conditions when the reverse reactions were not significant. The results obtained by the two methods are in reasonable agreement. For the TMB/PMB system for which the measured exothermicity is low ($\Delta H^0 = -1.24$ kcal mol^{-1}) the back reaction was obviously of significance and the linear decay method yielded somewhat lower values.

The results obtained for the five systems studied are shown in Figs. 6–10 in which reaction efficiency is plotted against the logarithm of the absolute temperature. The reaction efficiency is defined as k/k_c where k is the measured rate constant and k_c is the rate constant for collision as calculated by the Average Dipole Orientation (ADO) theory of Su and Bowers (21). The proton transfer reactions under study involve molecules with quite large polarizabilities and very small or no dipole moments. k_c values are therefore all in the range 1.15–1.28×10^{-9} cm^3 molecule^{-1} s^{-1} with very little temperature dependence.

Several generalizations can be made regarding these kinetic results. The difference between the forward and the reverse rate constants is greatest for the reactions with highest exothermicity as expected, since

$$\frac{k_+}{k_-} = K = \exp\left[-\frac{\Delta G^0}{RT}\right]$$

and ΔG^0 is roughly proportional to ΔH^0 when ΔS^0 is small. In no case is proton transfer efficient, the maximum reaction efficiencies in the forward direction being for the two most exothermic reactions at the lowest temperature employed. All reactions, both forward and reverse, with the exception of $TMBH^+ + HMB$, show a negative coefficient of reactivity, i.e., the rate constant increases with decrease of temperature. The plots of log k vs. log T are linear as are plots of ln k vs. $1/T$. The latter Arrhenius type plots yield small (~2 kcal mol^{-1}) negative "activation" energies, the one exception being $TMBH^+ + HMB$ with a positive activation energy of 0.76 kcal mol^{-1}. The efficiencies of proton transfer at 400 K and 600 K are plotted against the overall change in free energy for reaction, ΔG^0, in Fig. 11. The two curves are

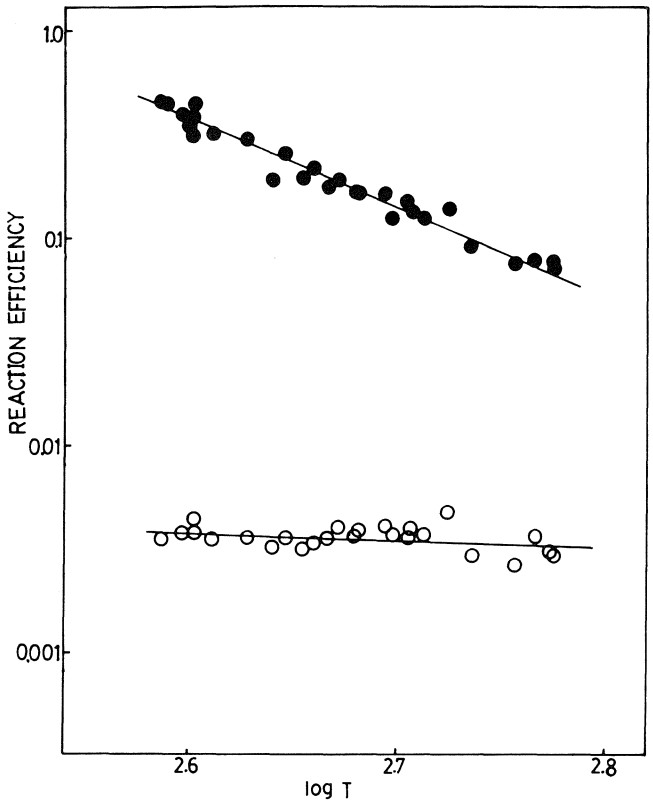

FIG. 6. The variation of reaction efficiency with temperature for the reaction $MESH^+ + PMB \rightleftharpoons PMBH^+ + MES$. ● Forward reaction, ○ reverse reaction.

similar to the one obtained at 298 K by Bohme and co-workers (22) for a series of proton transfer reactions encompassing a much wider range of ΔG^0 in the negative direction and approximately the same range in the positive direction. They found that the reactions were 100% efficient when $\Delta G^0 \leqq -10$ kcal mol^{-1}. We have no data for 298 K but extrapolation of the plots of log (k_f/k_c) vs. log T to log 298 for the two most exothermic reactions yields efficiencies very close to unity. Obviously efficiency will not be unity at higher temperatures until ΔG^0 is considerably more negative than the values for any of the reactions studied in this work. Figure 11 emphasizes that a positive temperature coefficient of reaction efficiency (k/k_c increasing with increasing temperature) occurs only when ΔG^0 (and ΔH^0) is significantly positive.

Slow, exothermic proton transfer reactions have been described by Brauman and co-workers (23, 24) and Meot-Ner (25). The latter demonstrated negative temperature coefficients for the forward (exothermic) rate constants. Kebarle (26) has succinctly outlined the basic types of reactions in which such behaviour should be observed and has discussed briefly the theory of such reactions. Central to the theory is a model involving the formation of an ion–molecule collision complex which is sufficiently long-lived that its energy is completely randomized over all accessible levels. The total energy includes the excitation energy generated by the ion–molecule interactions. The inefficiency of the reactions is due to the rate of dissociation of the excited complex to regenerate reactants being greater than chemical reorganization to give products. The explanation for this behaviour is based on the shape of the potential energy profile along the reaction coordinate. In order to make quantitative predictions about such reactions this profile and the characteristics of the complex at pertinent points on the

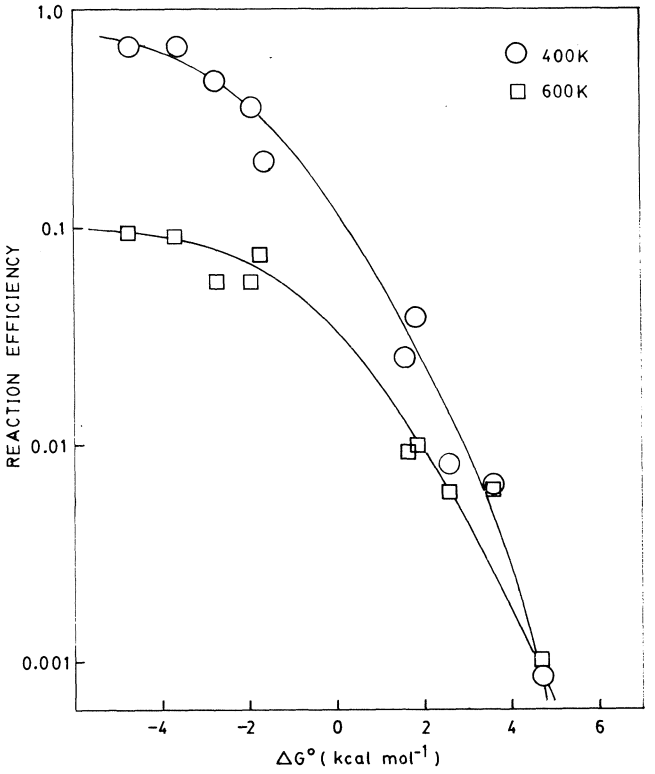

FIG. 11. The variation of reaction efficiency with standard free energy change for proton transfer reactions.

profile must be known. Since the reactions under study involve relatively complex ions and molecules whose mode of association is not known, only qualitative arguments in support of the proposed reaction mechanism can be made.

The potential energy profile along the reaction coordinate (Fig. 12) is for the generalized proton transfer reaction.

[16] $B_1H^+ + B_2 \rightleftharpoons B_1H^+\cdots B_2 \rightleftharpoons B_1\cdots{}^+HB_2 \rightleftharpoons B_1 + HB_2^+$

The two potential wells correspond to the two ion–neutral association complexes $B_1H^+\cdots B_2$ and $B_1\cdots{}^+HB_2$. The central maximum corresponds to a chemical transition state of the form $B_1\cdots\overset{+}{H}\cdots B_2$ for the proton transfer step. Although the potential profile cannot be described with any exactitude, its qualitative features are known. The ions involved, protonated aromatics, have considerable charge delocalization and indeed the CH_2 or $CHCH_3$ group formed by the addition of a proton to the aromatic ring will have some tetrahedral character with little of the charge present at this site (27, 28). There will be a significant fraction of the charge on the methyl groups as was calculated for the toluenium ion (27). This charge delocalization will lead to a very low stability for the ion-molecule association complexes, i.e., both potential wells are very shallow. No stabilized complexes ($B_1\cdots HB_2^+$ or $B_2\cdots HB_1^+$) were observed with these protonated aromatics, even at temperature as low as 298 K. An enthalpy of dissociation of 11.0 kcal mol^{-1} has been reported for $C_6H_7^+\cdot C_6H_6$ which suggested that in such aromatic dimers the binding is purely electrostatic (29). The association complexes formed in the present case will probably be more weakly bound since the methyl groups will inhibit close approach of ion and neutral and negate the increased polarizability due to methyl groups. The geometry of the entities $B_1H^+\cdots B_2$ and $B_1\cdots HB_2^+$ are open to conjecture. If the charge remains delocalized over much of the ion then although the maximum

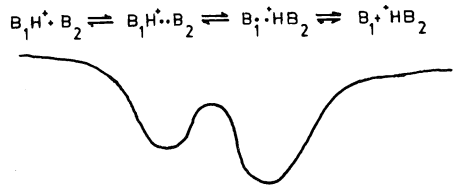

FIG. 12. The reaction coordinate for proton transfer between polymethyl aromatics.

polarizability of aromatic molecules is in the plane of the ring (30), the maximum electrostatic interaction energy will be obtained if the aromatic rings can form a sandwich even though the methyl groups will sterically hinder anything but a very loose association. Interaction of the two rings via a proton bridge would lead to loss of charge delocalization on one ring with little compensating stabilizing delocalization on the other. Such a geometry, although not likely for $B_1 \cdots {}^+HB_2$, would of necessity be the transition state for proton transfer. The proton is probably transferred via a transition state involving interaction with the π orbitals of the rings. A π complex has been suggested as the transition state for intramolecular proton transfer with a calculated activation energy of 8 kcal mol^{-1} (28). The central ptoential barrier in Fig. 12 corresponds to the activation barrier for transfer of a proton, from an essentially sp^3 carbon in $B_1H^+ \cdots B_2$ via the π bound state $B_1 \cdots \overset{+}{H} \cdots B_2$. The height of the barrier will probably be less than that for intramolecular transfer because of the participation of the second aromatic ring but the zero point energies associated with the new vibrations or severely hindered methyl rotations replacing free rotations will increase the fixed energy and raise the energy level of the reaction coordinate at the barrier maximum.

Proton transfer between the methyl benzenes satisfies more than one of the criteria for slow proton transfer, viz., very low exothermicity, a decrease of rotational freedom on complex formation, and a central chemical barrier (26). The initially formed chemically activated complexes, in both the forward direction, $(R_1H^+ \cdots R_2)$, and the reverse direction, $(R_1 \cdots {}^+HR_2)$ may either cross the central barrier or return to reactants by crossing the centrifugal barrier. The much higher density of states of the complex at the latter barrier favours dissociation to the reactants. Increasing temperature increases the importance of this density of states relative to those at the central barrier and hence the rate constants show a negative temperature dependence. This is also apparently true in the endothermic direction as well for all but one ion–molecule reactant pair. This is one of the two most endothermic reactions, viz. TMB + $PMBH^+$, the other, MES + $PMBH^+$ having only a very slightly negative temperature dependence. For TMB + $HMBH^+$ the activation energy, obtained from an Arrhenius plot is 0.76 kcal mol^{-1}, a value considerably lower than the measured enthalpy change for the reaction (3.5 kcal mol^{-1}). It is obvious from these results that an endothermic reaction does not necessarily have a rate constant which increases with increasing temperature, when the endothermicity is small the shape of the potential energy profile is equally important.

The two forward (exothermic) charge transfer reactions studied are more exothermic than the corresponding proton transfer reactions involving the same neutrals and all proceed with close to 100% efficiency and with very little if any, temperature dependence. This is in accord with the results of Meot-Ner and Field using a variety of lower alkylbenzenes (17). The two reverse reactions show a normal, positive temperature dependence, i.e., the rate increases with increasing temperatures. Since electron transfer can occur over a much greater distance than proton transfer, a long-lived complex is not necessary and considerations applied to the proton transfer reactions are not appropriate to charge transfer. The data are typical of fast charge transfer reactions which lends credence to the validity of the proton transfer data.

Conclusions

The relative basicities of methylbenzenes increase with increasing number of methyl groups. The relative proton affinities determined using van't Hoff plots are not in agreement with those obtained using calculated entropy differences based only on changes in rotational symmetry numbers. Although such calculations are usually found to be adequate for less complex bases, the results obtained here suggest that acceptable calculated ΔS^0 values will only be obtained when changes in molecular vibrational levels and the coupled methyl torsional levels are included.

The measured rate constants show that proton transfer is inefficient except at low temperatures and when ΔG^0 is negative by $\geqq 4$ kcal mol^{-1}. A negative temperature coefficient of the reaction efficiency is observed for both the exothermic forward direction and the endothermic reverse direction. There is only one exception to the latter; the most endothermic reaction studied (TMB + $HMBH^+$) shows a slight positive temperature coefficient. Such behaviour in near thermoneutral proton transfer reactions may not be exceptional and we are presently investigating whether it is the rule rather than the exception.

Janovsky reactions between cyclopentadienyliron complexes of substituted benzenes and carbanions derived from ketones[1]

RONALD G. SUTHERLAND, RATAN L. CHOWDHURY, ADAM PIÓRKO, AND CHOI CHUCK LEE
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received December 20, 1985

RONALD G. SUTHERLAND, RATAN L. CHOWDHURY, ADAM PIÓRKO, and CHOI CHUCK LEE. Can. J. Chem. **64**, 2031 (1986).

Janovsky reactions were carried out between various η^6-substituted benzene-η^5-cyclopentadienyliron cations containing at least one electron-withdrawing substituent in the complexed arene and the enolate-carbanion derived from acetone, butanone, or 3-pentanone. Highly colored adducts were obtained from reactions of the cyclopentadienyliron (CpFe) complexes of nitrobenzene, cyanobenzene, *p*-tolylsulfonylbenzene, benzoylbenzene, *o*-, *p*-, or *m*-nitrotoluene, and *o*-, *p*-, or *m*-dichlorobenzene with acetone in aqueous KOH, the products being derived from *exo*-addition of the acetonyl anion regioselectively at a position *ortho* to an electron-withdrawing substituent. For example, reaction of the η^6-nitrobenzene-η^5-cyclopentadienyliron cation (**1***a*) with acetone in aqueous KOH gave (*R*,*S*)-(1-5-η^5-1-nitro-6-*exo*-(2-oxo-1-propyl)-cyclohexadienyl)(η^5-cyclopentadienyl)iron (**2***a*), isolated as a purple solid. Similarly, reaction of the nitrobenzene complex **1***a* with 3-pentanone in aqueous KOH gave two diastereomeric adducts, (*R*,*R*-*S*,*S*)- and (*R*,*S*-*S*,*R*)-(1-5-η^5-1-nitro-6-*exo*-(3-oxo-2-pentyl)-cyclohexadienyl)(η^5-cyclopentadienyl)iron (**11***a*, *b*). Reactions of the CpFe complexes of chlorobenzene and *o*- or *p*-dichlorobenzene with butanone in aqueous KOH were also investigated. In each case, three Janovsky adducts, two being diastereomers, were obtained from addition of the two carbanions derived from loss of either α-proton of butanone. Potential synthetic applications via these Janovsky adducts are pointed out since their treatment with ammonium ceric nitrate could lead to demetallation–oxidation; for example, (2,5-dichlorophenyl)propanone, a new compound, was obtained from the adduct formed between the *p*-dichlorobenzene complex and the acetonyl anion.

RONALD G. SUTHERLAND, RATAN L. CHOWDHURY, ADAM PIÓRKO et CHOI CHUCK LEE. Can. J. Chem. **64**, 2031 (1986).

On a effectué la réaction de Janovsky entre divers cations benzène η^6-substitués cyclopentadiényl-η^5 de fer contenant au moins un substituant électro-attracteur dans le complexe arène et les carbanions énoliques dérivés de l'acétone, de la butanone ou de la pentanone-3. On obtient des adduits fortement lors des réactions des complexes cyclopentadiényles de fer (CpFe) et du nitrobenzène, du cyanobenzène, du *p*-tolylsulfonylbenzène, du benzoylbenzène des *o*-, *p*- ou *m*-nitrotoluène et des *o*-, *p*- ou *m*-dichlorobenzène avec l'acétone dans du KOH aqueux. Les produits proviennent d'une addition *exo* régiosélective de l'anion acétonyle en position *ortho* d'un substituant électro-attracteur. Par exemple, la réaction du cation nitro-η^6 benzènecyclopentadiényle-η^5 de fer (**1***a*) avec l'acétone dans du KOH aqueux donne du (nitro-1 (oxo-2 propyl-1)-*exo*-6 cyclohexadienyl-η^5-1,5) (cyclopentadiényl-η^5) de fer (*R*,*S*) (**2***a*) qui a été isolé sous la forme d'un solide de couleur pourpre. Le complexe **1***a* du nitrobenzène réagit de la même façon avec la pentanone-3 dans du KOH aqueux pour donner deux adduits diastéréoisomères soit les nitro-1 (oxo-3 pentyl-2)-*exo*-6 (cyclohexadiényl-η^5-1,5) (cyclopentadiényl-η^5) de fer (*R*,*R*-*S*,*S*) et (*R*,*S*-*S*,*R*) (**11***a*, *b*). On a également étudié les réactions des complexes de CpFe du chlorobenzène et du *o*- ou du *p*-dichlorobenzène avec la butanone dans du KOH aqueux. Dans chaque cas, on obtient trois adduits de Janovsky, dont deux sont des diastéréoisomères, qui proviennent de l'addition de deux carbanions provenant de la perte de l'un des protons en α de la butanone. On met en évidence les possibilités de synthèse à partir des adduits de Janovsky puisque leur réaction avec le nitrate d'ammonium cérique peut conduire à une démétallation oxydante. Par exemple, on obtient la (dichloro-2,5 phényl)propanone, un nouveau composé, à partir de l'adduit formé entre le complexe du *p*-dichlorobenzène et l'anion acétonyle.

[Traduit par la revue]

The reactions of nitroarenes with nucleophiles continue to be the topic of many investigations and these reactions have been the topic of several recent reviews (2–4). One of the more intriguing of such reactions is the Janovsky reaction,[2] which involves the addition of a carbanion derived from ketones, such as acetone, to polynitro derivatives of arenes, such as *m*-dinitro- or 1,3,5-trinitrobenzene, leading to the formation of a carbon–carbon bond at the position *ortho* to a nitro group (7). In the present paper, the ready formation of Janovsky adducts is described for reactions between a number of η^6-substituted benzene-η^5-cyclopentadienyliron cations and a carbanion derived from acetone, butanone, or 3-pentanone.

In Janovsky reactions with substituted benzenes, two or more electron-withdrawing substituents have to be present before the reaction can take place (7). Complexation to the cyclopentadienyliron (CpFe) moiety apparently has a similar effect as a second electron-withdrawing substituent, and thus the η^6-nitrobenzene-η^5-cyclopentadienyliron cation (**1***a*), prepared as its hexafluorophosphate (8), could react readily under very mild conditions with the enolate-carbanion derived from acetone to give the Janovsky adduct, (1-5-η^5-1-nitro-6-*exo*-(2-oxo-1-propyl)-cyclohexadienyl)(η^5-cyclopentadienyl)iron, a complex resulting from *exo*-addition of the acetonyl anion regioselectively at a position *ortho* to the nitro substituent (eq. [1]).

[a]The chemical shifts of the two diastereotopic protons of the methylene group were determined by a 360-MHz spectrometer. The other spectral data were obtained by a 60-MHz spectrometer. More detailed splitting patterns for the cyclohexadienyl protons obtained by the 360-MHz spectrometer will be reported later.

[b]Adduct formed from reaction with acetone-d_6.

Similar results were obtained when the nitro group in **1***a* was replaced by another electron-withdrawing substituent. Thus the CpFe complex of cyanobenzene (**1***b*), *p*-tolylsulfonylbenzene (phenyl *p*-tolyl sulfone) (**1***c*), or benzoylbenzene (benzophenone) (**1***d*) gave the same reaction with the acetonyl anion, resulting in the formation of Janovsky adducts **2***b*, **2***c*, or **2***d*, respectively (eq. [1]). In all of these cases, since C-6 is a chiral carbon, the products would be *R*,*S* pairs.

exo-Addition of nucleophiles to CpFe complexes of arenes is well known (9–13), and by analogy the acetonyl groups in these adducts are assigned the *exo*-configuration. Data from the ^{1}H nmr spectra of Janovsky adducts **2***a*–**2***d* are summarized in Table 1, and these results are consistent only with an attack by the acetonyl anion at a position *ortho* to the electron-withdrawing substituent. It may also be noted that in the reaction with **1***d*, acetone-d_6 in KOD–D_2O was employed with the resulting deuterated adduct showing a simpler spectrum. Some observations from the ir and ms spectra of these adducts, which are also consistent with the structures assigned, are given in Table 2 together with the physical appearance, yields, and analytical data.

In the Janovsky reaction with *m*-dinitrobenzene, for example, the acetonyl anion adds to the C-4 position, *ortho* to one and *para* to the other NO_2 group, and the resulting negative charge in the ring can be shown as being delocalized over both NO_2 groups (7). The present finding of regiospecific addition only to the *ortho* position and not to the *para* position may suggest that the electron-withdrawing inductive effect of substituent X in cations **1***a*–**1***d* may play a more important role than resonance delocalization in controlling the regiospecificity. In contrast to this regiospecificity, reaction of the CpFe complex of toluene (**1**, X = CH_3) with the hydride ion gave a 1:1:1 mixture of products derived from additions at the *o*-, *m*-, and *p*-positions (14). On the other hand, a similar reaction with the CpFe complex of chlorobenzene (**1***e*) or of methyl benzoate (**1**, X = $COOCH_3$), respectively, gave a 4:1:0 or 12.7:1:1.1 mixture of products derived from hydride additions at the *o*-, *m*-, and *p*-positions (14), the major product being derived from *o*-addition, and probably also indicating an important role for the inductive effect of the electron-withdrawing substituent.

It is of interest to note that in Meisenheimer or Janovsky type of adducts of nitroarenes such as 1,3,5-trinitrobenzene, from the ir spectra, it was found that there was a lowering of the asymmetric and symmetric stretching vibrational frequencies of the NO_2 group when compared with the analogous frequencies in the nitroarene, and this finding was attributed to a decrease in the N—O bond order because of the transfer of negative charge to the nitro groups in the adduct (15, 16).[3] A similar lowering in NO_2 stretching frequencies was observed in the presently prepared Janovsky adducts; for example, the ir frequencies for the NO_2 group of **2***a* are lower than the corresponding frequencies for the NO_2 group of cation **1***a* (Table 2) from which **2***a* was prepared. Apparently, such a decrease in bond order also occurred in the CN, SO_2, or CO substituent directly attached to the complexed cyclohexadienyl ligand in adduct **2***b*, **2***c*, or **2***d*, with the corresponding ir absorptions in cation **1***b*, **1***c*, or **1***d*, respectively, appearing at higher frequencies (Table 2).

When the hexafluorophosphate salts of the η^6-benzene-η^5-cyclopentadienyliron or similar CpFe complexes of substituted benzenes including toluene, cumene, anisole, *N*,*N*-dimethylaniline, (*p*-tolylthio)benzene, tetralin, and biphenyl were treated with acetone in aqueous KOH, no Janovsky adduct was obtained and the complex used as reactant was recovered unchanged. Thus a strong electron-withdrawing substituent on the complexed arene is required for the Janovsky reaction. Similar attempts to prepare the Janovsky adduct with the CpFe complex of azidobenzene or fluorobenzene resulted in a nucleophilic aromatic substitution to give a CpFe complex of phenol that in the basic medium led to the formation of a known complex, η^5-cyclohexadienone-η^5-cyclopentadienyliron (**3**) (17). When the hexafluorophosphate of the η^6-chlorobenzene-η^5-cyclopentadienyliron cation (**1***e*) was treated with acetone in aqueous KOH, a mixture of Janovsky adduct **2***e* and the cyclohexadienone complex **3** was formed and a pure sample of **2***e* was not obtained.

Although the chlorobenzene complex **1***e* failed to give a pure Janovsky adduct, CpFe complexes of dichlorobenzenes readily undergo the Janovsky reaction. With the *o*- or *p*-dichlorobenzene complex **4***a* or **6***a*, reaction with the acetonyl anion gave only one product, **5***a* or **7***a*, respectively, again derived from regioselective *exo*-addition at a position *ortho* to a chloro substituent (eqs. [2] and [3]). With the *m*-dichlorobenzene complex **8***a*, two Janovsky products, **9***a* and **10***a*, were obtained (eq. [4]), the ratio of **9***a*:**10***a* being about 9:1 based on the

relative intensities of the Cp absorptions in the ^{1}H nmr spectra. Thus the major product, **9***a*, was derived from reaction at the position *ortho* to both electron-withdrawing chloro substituents.

In a similar way, the CpFe complex of *o*- or *p*-nitrotoluene (**4***b* or **6***b*) gave only one Janovsky adduct, **5***b* or **7***b*, respectively, with the acetonyl anion reacting regioselectively at the position *ortho* to the nitro substituent. In the reaction with the *m*-nitrotoluene complex **8***b*, two Janovsky adducts, **9***b* and **10***b*, were obtained in a relative ratio of about 3:2 for **9***b*:**10***b* (eq. [4]). Both **9***b* and **10***b* are derived from regioselective reaction at a site *ortho* to the electron-withdrawing nitro group, but the reason for the somewhat higher amount of **9***b* than **10***b* is not apparent. Data from the ^{1}H nmr spectra of these Janovsky adducts obtained from CpFe complexes of disubstituted benzenes are given in Table 3, and these results are consistent with the assigned structures. The yields, analytical data, and some ir and ms results for these adducts are included in Table 2.

When the nitrobenzene complex **1***a* was treated with 3-pentanone, instead of acetone, in aqueous KOH, the Janovsky adduct obtained, (1-5-η^5-1-nitro-6-*exo*-(3-oxo-2-pentyl)-cyclohexadienyl)(η^5-cyclopentadienyl)iron (**11***a*, *b*), would have two chiral centers (C-2 of the 3-oxo-2-pentyl side chain and C-6 of the cyclohexadienyl ring), thus giving rise to two diastereomeric products, the *R*,*R* + *S*,*S* enantiomeric pair and the *R*,*S* + *S*,*R* enantiomeric pair. The 360-MHz nmr spectrum of the product mixture, as given in Table 4, confirms the formation of two diastereomeric products, **11***a* and **11***b*, present in a ratio of about 5:4. It is, however, not possible to decide whether **11***a* or **11***b* is *R*,*R*-*S*,*S* or *R*,*S*-*S*,*R*.

[4]

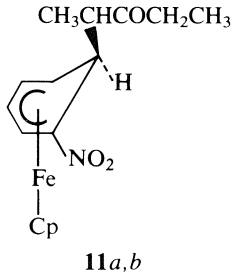
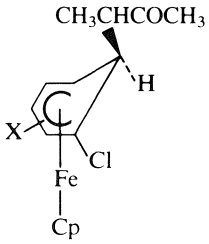
a, X = Y = Cl
b, X = NO_2, Y = CH_3

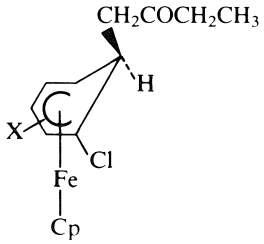


11*a*,*b*

On treatment of the chlorobenzene complex **1***e* with butanone in aqueous KOH, high resolution ^{1}H nmr (Table 4) showed that although the product mixture was contaminated with a small amount of the cyclohexadienone complex **3**, three Janovsky products were obtained from *exo*-addition at the position *ortho* to the chloro substituent of the two carbanions derived from removal of a proton from either α-position of butanone to give **12***a*, **12***b*, and **12***c*, with **12***a* and **12***b* as diastereomers. In an analogous way, reaction of *o*- or *p*-dichlorobenzene complex **4***a* or **6***a* with butanone in aqueous KOH gave Janovsky adducts **13***a*, **13***b*, and **13***c* or **14***a*, **14***b*, and **14***c*, respectively. The ^{1}H nmr data for these adducts are given in Table 4 and other relevant observations are included in Table 2.



12*a*,*b*, X = H
13*a*,*b*, X = Cl at C-2
14*a*,*b*, X = Cl at C-4



12*c*, X = H
13*c*, X = Cl at C-2
14*c*, X = Cl at C-4

It has been noted earlier that treatment of the chlorobenzene complex **1***e* with acetone in aqueous KOH gave a mixture of the Janovsky adduct **2***e* and the cyclohexadienone complex **3**. The relative amounts of these two products were found to be dependent on reaction time, increasing amounts of **3** being formed with longer reaction times. Similarly, when the nitrobenzene complex **1***a* was stirred with acetone in aqueous KOH at room temperature for about 20 min, the product obtained was the Janovsky adduct **2***a*. If the stirring was extended to 4–6 h, the major product became the cyclohexadienone complex **3**. These observations suggest that the Janovsky reaction with the chlorobenzene complex **1***e* or the nitrobenzene complex **1***a*, and nucleophilic aromatic substitution of the chloro group of **1***e* or the nitro group of **1***a* by hydroxide ion may be competing reactions and, probably, the Janovsky adduct is the kinetically controlled product, while with prolonged reaction time, more nucleophilic aromatic substituion would occur to give rise to the

[a]All spectral data were obtained by a 360-MHz spectrometer; the splitting patterns given for the cyclohexadienyl protons are rough approximations and more detailed analyses of these patterns will be reported later.
[b]Data from the spectrum of a mixture of **11***a* and **11***b*, the ratio of **11***a*:**11***b* being about 5:4 based on the relative intensities of the Cp absorptions.
[c]Data from the spectrum of a mixture of **12***a*, **12***b*, and **12***c*, the ratio of **12***a*:**12***b*:**12***c* being about 7:6:4 based on the relative intensities of the Cp absorptions.
[d]Diastereotopic C-1 methylene protons of the side chain coupled with the C-6 proton of the cyclohexadienyl ring to give two sets of AB splitting patterns.
[e]Data from the spectrum of a mixture of **13***a*, **13***b*, and **13***c*, the ratio of **13***a*:**13***b*:**13***c* being about 3:2:1 based on the relative intensities of the Cp absorptions.
[f]Data from the spectrum of a mixture of **14***a*, **14***b*, and **14***c*, the ratio of **14***a*:**14***b*:**14***c* being about 9:6:4 based on the relative intensities of the Cp absorptions.

CpFe complex of phenol, which in the basic medium would be irreversibly converted to the cyclohexadienone complex **3**.

The present work may also have potential for applications in organic synthesis. We have found that when the Janovsky adduct **7***a*, obtained from the *p*-dichlorobenzene complex **6***a*, was treated with ammonium ceric nitrate in wet acetone in the presence of NaOAc as described by Pearson *et al.* (18), demetallation together with oxidation took place to give a 50% yield of (2,5-dichlorophenyl)propanone (erroneously stated as (2,4-dichlorophenyl)propanone in ref. 1), a compound that has not been previously reported. RajanBabu *et al.* (19) have recently studied the addition of silyl enol ethers to aromatic nitro compounds, followed by oxidation to give α-nitroaryl carbonyl compounds. These workers (19) have also pointed out that "even though α-anionic complexes between aromatic polynitro compounds and enolates (Janovsky complexes) have been known for over 90 years, these have found no application in synthesis." As in the present preparation of (2,5-dichlorophenyl)propanone, it appears that similar demetallation–oxidation of Janovsky adducts of CpFe complexes of substituted arenes may provide a method for the introduction of alkyl side chains bearing a useful oxo function into the *ortho* position of substituted benzenes with an electron-withdrawing substituent such as nitrobenzene.

Experimental

η^6-Substituted benzene-η^5-cyclopentadienyliron cations

The η^6-substituted benzene-η^5-cyclopentadienyliron cations employed in the present study were prepared as their hexafluorophosphate salts utilizing known procedures. The CpFe complexes of nitrobenzene (**1***a*) and *o*-, *p*-, or *m*-nitrotoluene (**4***b*, **6***b*, or **8***b*, respectively) were obtained as described by Lee *et al.* (8). Similar complexes of chlorobenzene (**1***e*) and *o*-, *p*-, or *m*-dichlorobenzene (**4***a*, **6***a*, or **8***a*, respectively) were prepared by ligand exchange reactions as reported by Khand *et al.* (20). The cyanobenzene complex **1***b* was obtained by a nucleophilic substitution reaction between cyanide ion and the chlorobenzene complex **1***e* (21). The sulfone complex **1***c* was prepared by oxidation of the η^6-(*p*-tolylthio)benzene-η^5-cyclopentadienyliron cation, while the benzophenone complex **1***d* was obtained from the $KMnO_4$ oxidation of the η^6-diphenylmethane-η^5-cyclopentadienyliron cation (22). The CpFe complex of (*p*-tolylthio)benzene (**15**) was prepared from a nucleophilic aromatic substitution reaction between the nitrobenzene complex **1***a* and 4-methylbenzenethiol in the presence of K_2CO_3 (23). Oxidation of **15** by *m*-chloroperbenzoic acid gave the sulfone complex **1***c* as its hexafluorophosphate (24).

Besides cation **15**, which did not give the Janovsky reaction, other complexes that also failed to give the Janovsky adduct, including the CpFe complexes of benzene, toluene, cumene, anisole, *N*,*N*-dimethylaniline, tetralin, biphenyl, and fluorobenzene, were all prepared from ligand exchange reactions between the arene and ferrocene as reviewed by Sutherland (25). Finally, the azidobenzene complex, which, like the fluorobenzene complex, gave the cyclohexadienone complex **3** under the Janovsky reaction conditions, was prepared from the nucleophilic aromatic substitution reaction between chlorobenzene complex **1***e* and NaN_3 (26).

Janovsky reactions

Described below is the general procedure for the preparation of Janovsky adducts formed from reactions between the various η^6-substituted benzene-η^5-cyclopentadienyliron cations and acetone, butanone, or 3-pentanone.

To a stirred solution of 3.0 mmol of the hexafluorophosphate salt of an η^6-substituted benzene-η^5-cyclopentadienyliron cation in 15 mL of the ketone, 5.0 mL of a 20% solution of KOH in H_2O was added. An intense color developed immediately and the solution was stirred at room temperature for about 20 min. The reaction mixture was then extracted with $CHCl_3$ (3 × 25 mL) and the extract washed with H_2O (3 × 50 mL). After drying over $MgSO_4$, the $CHCl_3$ was removed in a rotary evaporator. The residue was then purified by passage through a short column (5 cm) packed with F-20 alumina (Alcoa Chemical Co.) that had been deactivated by exposure to air for 48 h. Any impurities that may have been present were first removed by elution with pentane and the Janovsky adduct was then eluted with $CHCl_3$. Upon evaporation to dryness at room temperature, the highly colored product was obtained either as an oil or recrystallized from $CHCl_3$–pentane.

2,5-Dichlorophenylpropanone

To a stirred solution of 800 mg (2.47 mmol) of Janovsky adduct **7***a* ((1-5-η^5-1,4-dichloro-6-*exo*-(2-oxo-1-propyl)-cyclohexadienyl)(η^5-cyclopentadienyl)iron) in 15 mL of acetone and 0.5 mL of H_2O containing 2.0 g of NaOAc, $(NH_4)_2Ce(NO_3)_6$ (Aldrich Chemical Co.) was added at room temperature and with stirring in ten 200-mg portions over a period of 2.5 h. Ether (200 mL) was then introduced and the resulting solution was washed with H_2O (3 × 50 mL). After drying over $MgSO_4$, removal of the solvent in a rotary evaporator gave an oil that, upon analysis by gc–ms, showed a 50% yield of 2,5-dichlorophenylpropanone; ^1H nmr ($CDCl_3$) δ: 2.33 (s, 3H, CH_3), 3.95 (s, 2H, CH_2), 7.36 (br s, 3H, Ar). Its ir spectrum showed a carbonyl absorption at 1710 cm^{-1}. In its mass spectrum, the molecular ion region showed *m*/*e* 202, 204, and 206 with relative abundances of 37.16, 23.20, and 4.05%, respectively, in agreement with the expected relative ratio of about 9:6:1 for two Cl atoms in the molecule with an approximate ^{35}Cl:^{37}Cl ratio of 3:1.

Aqueous solution interaction of the methylmercuric cation with the dinucleotides CpG and dCpdG as studied by carbon-13 nuclear magnetic resonance spectroscopy[1]

G. W. BUCHANAN AND M. J. BELL

Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received December 30, 1985

G. W. BUCHANAN and M. J. BELL. Can. J. Chem. **64**, 2038 (1986).

^{13}C nuclear magnetic resonance chemical shifts and ^{13}C–^{31}P coupling constants are reported for the self-complementary dinucleotides CpG and dCpdG in aqueous solution. The influence of methylmercuration at pH 6.0 on these spectral parameters has been examined. Results are interpreted in terms of preferential methylmercuration at the N-7 site of the guanine base of each dinucleotide with concomitant base destacking.

G. W. BUCHANAN et M. J. BELL. Can. J. Chem. **64**, 2038 (1986).

On rapporte les déplacements chimiques en rmn du ^{13}C et les constantes de couplages ^{13}C–^{31}P des dinucléotides autocomplémentaires CpG et dCpdG en solution aqueuse. On a examiné l'influence de la méthylmercuration à pH 6,0 sur ces paramètres spectraux. On interpréte les résultats en fonction d'une méthylmercuration préférentielle au niveau de l'azote en position 7 du site de la guanine de chaque nucléotide avec un désentassement concomitant de la base.

[Traduit par la revue]

Introduction

Chromosomal damage caused by some organomercurials appears to be due in part to the consequences of "secondary" interactions between the heavy metal ion and DNA constituents (1–3). A number of attempts have been made to "model" such interactions between the methylmercuric cation, CH_3Hg^+, and nucleotide components. The earliest work utilized uv difference spectra to examine CH_3Hg^+–nucleoside interactions as a function of pH (4). Subsequently, Raman difference spectroscopy was employed to probe purine and pyrimidine mononucleotide interactions with CH_3Hg^+ (5). More recently, ^1H and ^{13}C nmr were applied in this area involving complexes of the nucleosides guanosine and inosine (6).

To date, no nmr studies on these interactions have proceeded beyond the mononucleotide level. There is, therefore, a clear need to examine systems that more closely approximate the DNA and RNA structures in solution. To this end, we report herein the results of a ^{13}C nmr investigation of the interaction of CH_3Hg^+ with the self-complementary dinucleotides cytidylyl-(3′-5′)-guanosine (CpG, **1**) and its deoxy counterpart dCpdG **2**. These dinucleotides are known to form base-stacked dimers that are mini-helices in aqueous solution (7) and thus they constitute reasonable structural models for RNA and DNA respectively.

Results and discussion

^{13}C chemical shift assignments

The structure and numbering scheme for CpG, **1**, is depicted in Fig. 1. Since 13 of the 19 carbons of this molecule are protonated, our initial strategy was to check the literature ^1H assignments and then use the ^1H shifts along with selective ^1H decoupling in the ^{13}C spectrum to identify directly bonded carbons.

The published 270-MHz ^1H spectrum of **1** contains some resonance overlap, but was successfully analyzed by spectral simulation (8). In the present work the earlier assignments have been verified by 2-D spectroscopy via the ^1H–^1H COSY (9) experiment at 500 MHz.

With the ^1H assignments in hand, selective ^1H decoupling in the ^{13}C spectra readily furnished the protonated carbon assignments for CpG. In Table 1 are presented the complete ^{13}C shift data for CpG along with those for the related mononucleotide models 3′-CMP and 5′-GMP. For 3′-CMP there has been a recent report (10) of the ^{13}C–^{31}P couplings, but no ^{13}C shift data were included. Our results for 5′-GMP are in good agreement with the literature (11), with the appropriate reversal (12) of the original (11) assignments for the 2′ and 3′ carbon resonances.

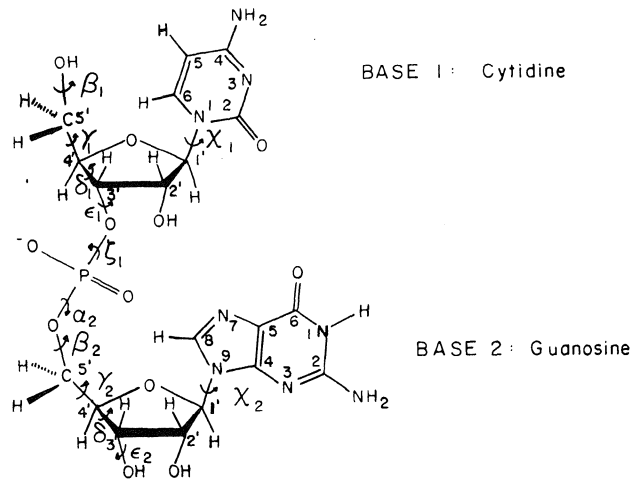

FIG. 1. Structure, numbering scheme, and some appropriate torsional angles for CpG **1**.

Several methods were used to assign the 6 quaternary carbon resonances of CpG. Examination of data in Table 1 shows that the resonance at $\delta_C = 115.82$ if CpG is separated by more than 20 ppm from any other. It can therefore, by analogy with the results for 5′ GMP, be confidently assigned to the 5 position of the guanosine residue.

The totally coupled ^{13}C spectrum of CpG revealed several $^2J_{CH}$ and $^3J_{CH}$ interactions that could be selectively removed by low power ^1H decoupling, leading to assignment of 3 quaternary carbons. Specifically, the cytidine 4 position (via $^2J_{CH}$ to H-5 of cytidine and $^3J_{CH}$ to H-6 of cytidine), the guanosine 4 position (via $^3J_{CH}$ to H-1′ of guanosine), and the cytidine 2 position (via $^3J_{CH}$ to H-6 of cytidine and $^3J_{CH}$ to H-1′ of cytidine) were assigned in this manner.

The remaining two resonances of CpG appear at $\delta_C = 153.63$

[1]Taken in part from the Ph.D. thesis of M. J. Bell, Carleton University, Ottawa, June 1985.

and 158.37 respectively and they show no appreciable splittings in the ^1H coupled ^{13}C spectrum in D_2O. This is consistent with expectations for the 2 and 6 positions of guanosine, the only 2 unassigned carbons. Specific designation of these two resonances was made using 5′-GMP as a model and the agreement is excellent.

A similar strategy was employed to assign the ^{13}C signals for the deoxy analog of **1**, namely dCpdG (**2**). Although no ^{13}C data for **2** are in the literature, the experimental 270-MHz ^1H spectrum has been published, as well as the computer simulated version. Using these available proton data (13), the protonated carbon assignments were obtained directly and the remaining carbon resonances were assigned in ways totally analogous to those for **1**. The resulting data are presented in Table 2. Included in this table are chemical shifts for the related mononucleotide models 3′-dCMP and 5′-dGMP. No ^{13}C shift data for 3′-dCMP have been reported previously, although the $^{13}C-^{31}P$ couplings have been studied (10). Our results for 5′-dGMP are in good accord with literature values (11).

TABLE 3. $^{13}C-^{31}P$ couplings (Hz) ± 0.1

$^{13}C-^{31}P$ couplings

These data for **1** and **2**, along with those for the corresponding mononucleotides, are presented in Table 3. Our data for the mononucleotides are in good agreement with published results (10, 11).

Effects of methylmercuration on ^{13}C chemical shifts

These results are depicted in graphical form in Figs. 2 and 3 for **1** and **2** respectively. Experiments were limited to 0.5 molar equivalents of added CH_3HgOH for reasons of solubility at pH 6.0. Of the ribose and deoxyribose carbons only C-1′ is affected to any extent by methylmercuration and thus data for C-2′ to C-5′ are not included. For both **1** and **2** the major result of CH_3HgOH addition in the cytidylyl region is the substantial deshielding of the C-2 and C-4 resonances. In fact the chemical shifts for these carbons of the "complexes" approach those for the mononucleotide models 3′-CMP and 3′-dCMP respectively.

Interestingly, in **1** and **2**, which are self-complementary and base-stacked (see Fig. 4), the ring current of the purine moiety will cause the carbons of the pyrimidine base to be shielded relative to the corresponding carbons of the 3′-CMP and 3′-dCMP systems, which do not base-stack. Due to the preferred conformations of **1** and **2** these effects are most pronounced at the C-2 and C-4 sites.

The ^{13}C shifts indicate no apparent mercury binding to the N-3 site of the cytidine moiety in either **1** or **2**. Such a conclusion can be made by noting that the presently observed ^{13}C shift changes are different from those previously found for the nucleoside cytosine, upon Hg coordination to N-3 (14).

The nearly identical nature of the cytidine ring carbon shifts for the methylmercuric adducts of **1** and **2** with the isolated mononucleotides 3′-CMP and 3′-dCMP suggests that a major

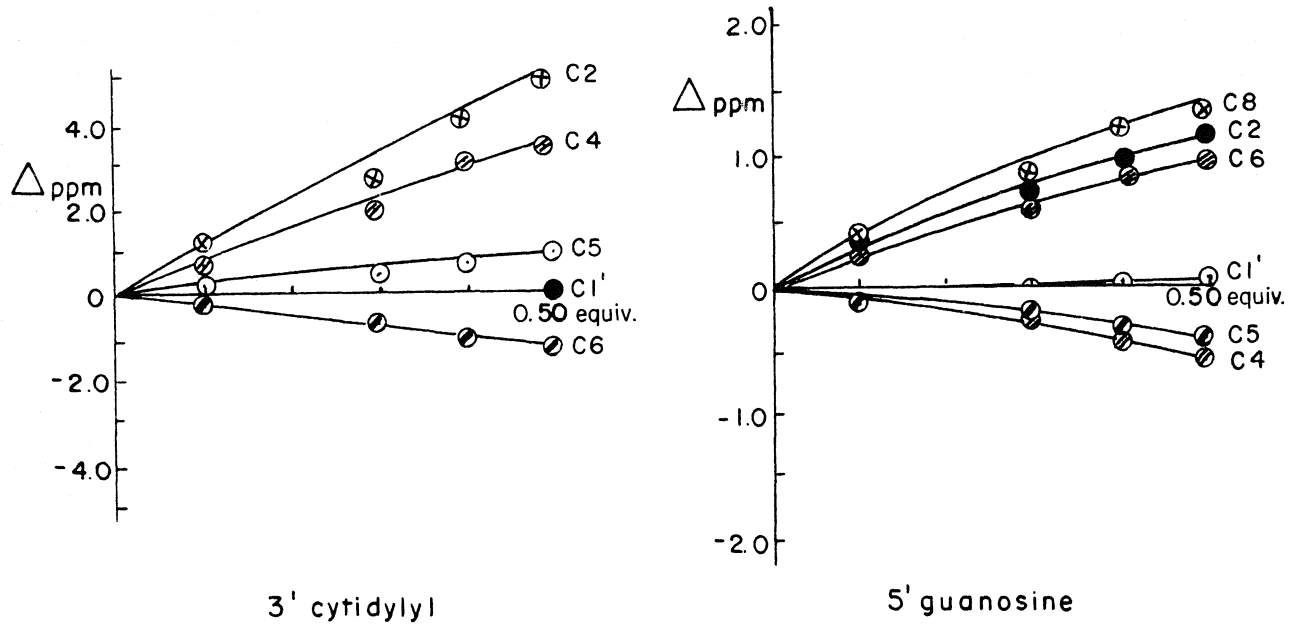

FIG. 2. Effects of methylmercuration on ^{13}C shifts of CpG **1**. Positive values denote downfield shifts.

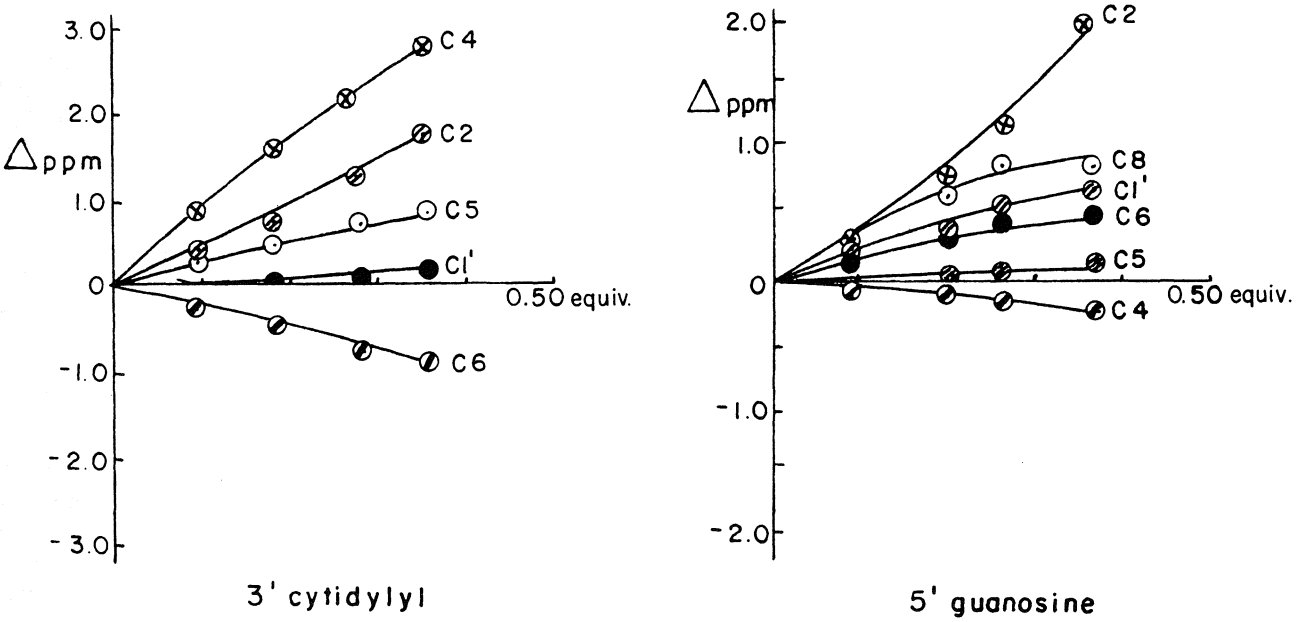

FIG. 3. Effects of methylmercuration on ^{13}C shifts of dCpdG **2**. Positive values denote downfield shifts.

result of CH_3HgOH addition is to disrupt the base-stacking phenomena.

The induced ^{13}C shifts in the guanine rings of **1** and **2** are indicative of CH_3Hg^{II} interactions at the N-7 site in rapid equilibrium with binding at the N-1 site. This conclusion is based primarily on the induced downfield shifts of the C-2 and C-8 sites of the guanine rings of **1** and **2** (6).

It is well known (4) that the nature of CH_3Hg^{II} species in solution depends greatly on the pH. At pH 6.0 (i.e., the present work) the charged $(CH_3Hg)_2\overset{+}{O}H$ species exists in an equilibrium with CH_3HgOH, in which the two moieties are almost equally prevalent (4). The cationic species can bind directly at the N-7 site of guanine while the CH_3HgOH can bind at N-1 in a two-step process involving deprotonation at N-1. This latter process becomes more likely as the pH increases. Indeed for 5′-GMP we have confirmed recently via ^{15}N nmr (15) that at pH 8.0 this N-1 binding completely dominates.

At pH 6.0, however, it is likely that N-7 is the preferred binding site for the methylmercuric ion. The consequences of this binding could be twofold in their influence on the structure of the self-complementary systems **1** and **2** in solution. Initially the hydrogen bonding possibilities at N-7 of the guanine ring are removed. This will destabilize the mini-helix and lead to destacking phenomena. An increase in the acidity of the N1-H proton should also accompany N-7 mercuration (16).

Effects of methylmercuration on ^{13}C–^{31}P coupling constants

For mononucleotides 3′-CMP, 3′-dCMP, 5′-GMP, and

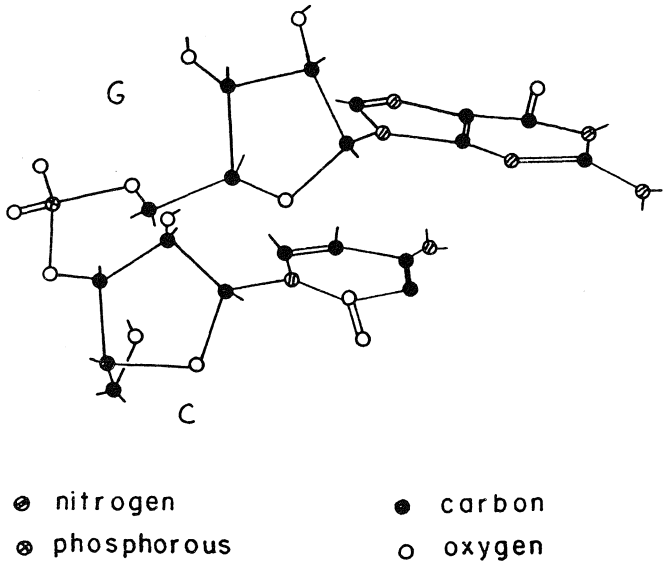

FIG. 4. Base stacked mini-helix structure of CpG **1**.

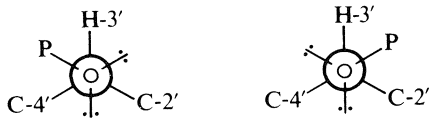
5′-dGMP no substantial change (i.e., above 0.2 Hz) was noted for any of the geminal or vicinal $^{13}C-^{31}P$ couplings upon CH_3HgOH addition.

By contrast, significant changes in two of the vicinal $^{13}C-^{31}P$ couplings were noted for **1** upon methylmercuration. Specifically, these involved 2′ and 4′ ribose carbons attached to the cytidine base. Before complexation, $^3J_{C4'-C-O-P}$ is 6.0 Hz while $^3J_{C2'-C-O-P}$ is 2.4 Hz. After complexation these couplings become nearly equal, with values of 4.6 and 4.2 Hz respectively. This result suggests a substantial increase in the amount of the ε_{tg} conformation (below) relative to the ε_{gt} conformation upon methylmercuration.



ε_{tg} ε_{gt}

Such a change in these vicinal coupling constants would be an expected consequence of the destacking process. In the base-stacked (uncomplexed) case, the ε_{gt} conformer dominates, as evidenced by the larger vicinal coupling from ^{31}P to C-4′ than to C-2′. This is consistent with expectations, by analogy with results for other cytidine polynucleotides (17) in which stacking occurs.

A further point of interest here is that $^3J_{C2'-C-O-P}$ and $^3J_{C4'-C-O-P}$ in the methylmercuric adduct of **1** are almost identical to the corresponding couplings in 3′-CMP, which also lacks base-stacking.

By contrast, complexation of CH_3HgOH with dCpdG **2** produces no significant changes in $^3J_{C4'-C-O-P}$ or $^3J_{C2'-C-O-P}$. It has been noted previously (13) that there is a much wider conformational spread for the pentose ring in deoxyriboses relative to riboses. As a result, attempts to translate time-averaged nmr coupling constants into conformer populations is much more difficult than in the ribose systems.

Thus it appears from ^{13}C chemical shift results for **2** that the methylmercuric ion does induce destacking, but that the more flexible pentose ring in **2** prevents monitoring of this destacking via vicinal $^{13}C-^{31}P$ coupling constants that necessarily invoke the pentose carbons.

Experimental

Materials

All nucleotides were purchased as their sodium salts from Sigma Chemical Company and were used without further purification. The source of methylmercury was $[(CH_3Hg)_3O]OH$, which was available from Alpha Products Ltd.

The initial pH of the sodium salts of the nucleotides in aqueous solution was 6.0. No substantial change in pH was noted after addition of 0.5 equivalents of mercuric salt. A 20-min shaking period was needed for complete dissolution of the salt.

Spectra

^{13}C spectra were obtained using 0.1 *M* solutions in D_2O with a Varian XL-200 nmr spectrometer. Normally 5-mm sample tubes were employed with spectral widths of 10 kHz and 32K data points. Pulse widths were 45° with repetition rates of 2 s. For measurement of $^{13}C-^{31}P$ couplings spectral widths of 2 kHz were commonly employed with retention of 32K data points.

The 500 MHz ^1H-COSY spectrum of **1** was obtained on a Bruker WH500 spectrometer using a sample that had been lyophilized five times from D_2O. The sweep width was 625 Hz in both dimensions and this was centered in the ribose proton region between 3.6 and 6.2 ppm. A data matrix of 256 × 512 data points was transformed to yield the final 2-D spectrum.

SAI CHENG CHOI and RUSSELL J. BOYD. Can. J. Chem. **64**, 2042 (1986).

A new method for the analysis of intramolecular hydrogen bonding is proposed and applied to the equilibrium structures of the protonated fluoroacetones. The method, based on a theory of molecular structure due to Bader, uses the topological properties of the charge density to elucidate the types of interactions within a molecule of interest. The calculations show a strong basis set dependence. In particular, the STO-3G optimized geometries exhibit intramolecular hydrogen bonding between a fluorine substituent and the carbonyl proton, whereas some calculations with geometries optimized at the 4-31G and 6-31G* levels indicate a direct bonding interaction between the fluorine and oxygen atoms. Two types of catastrophe point, namely conflict and bifurcation, are possible in protonated monofluoroacetone. Only the latter was located in the present calculations.

SAI CHENG CHOI et RUSSELL J. BOYD. Can. J. Chem. **64**, 2042 (1986).

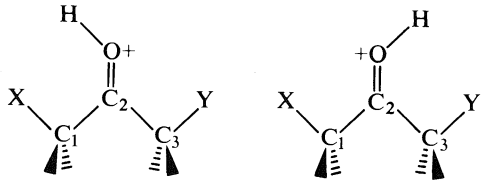
On propose une nouvelle méthode pour analyser les liaisons hydrogènes intramoléculaires et on l'applique aux structures en équilibre dans les fluoroacétones protonées. La méthode, qui est basée sur une théorie de structure moléculaire due à Bader, fait appel aux propriétés topologiques de la densité de charge pour élucider les divers types d'interactions à l'intérieur d'une molécule présentant de l'intérêt. Les calculs démontrent qu'il existe une grande dépendance sur l'ensemble de base choisi. En particulier, des calculs à l'aide de l'ensemble STO-3G avec des géométries optimisées démontre l'existence de liaisons hydrogènes moléculaires entre un substituant fluor et le proton d'un carbonyle; par ailleurs, des calculs aux niveaux 4-31G et 6-31G* avec des géométries optimisées indiquent la présence d'une interaction directe de liaison entre les atomes de fluor et d'oxygène. Les deux types de point de catastrophe, soit le conflit et la bifurcation, sont possibles dans la monofluoroacétone protonée. Seulement le dernier point a pu être localisé dans les calculs effectués jusqu'à maintenant.

[Traduit par la revue]

Introduction

Numerous experimental and theoretical methods exist for the direct investigation of intermolecular hydrogen bonding, whereas evidence for internal or intramolecular hydrogen bonding is generally obtained indirectly. For example, an ion cyclotron resonance study (1) of the gas-phase basicities of six fluorinated acetones has revealed a very regular decrease of 6.1 ± 0.4 kcal/mol in the proton affinity for each successive fluorine substituent. Furthermore, the 2–3 kcal/mol departure from linearity for acetone has been attributed to the formation of an intramolecular hydrogen bond within each of the protonated fluoroacetones.

Previous theoretical studies have used the energy difference between *syn* and *anti* conformations to estimate the intramolecular hydrogen bond energy of selected systems (2–4).



syn *anti*

This method has a number of shortcomings, not the least of which is the fact that application of the method is limited because it is not always possible to choose appropriate *syn* and *anti* conformations. For example, in the protonated form of hexafluoroacetone, positions X and Y are both occupied by fluorine atoms and, therefore, the distinction between the *syn* and *anti* conformations disappears. Moreover, where two appropriate conformations are possible, the energy difference is the net result of all interactions and not simply due to intramolecular hydrogen bonding. Such calculations provide only indirect evidence for hydrogen bonding. As an aside, we note that the two conformations have been detected in some protonated carbonyl compounds (5). In this paper we propose a direct theoretical method for the investigation of intramolecular hydrogen bonding and we apply the method to the protonated fluoroacetones.

The main focus of this paper is on analysis of intramolecular hydrogen bonding in terms of the topological properties (6, 7) of the charge density $\rho(\boldsymbol{r})$. Specifically, the sign of the Laplacian of the charge density, $\nabla^2\rho(\boldsymbol{r})$, is used to determine the existence of local concentrations of charge between two atoms within the molecule of interest. Particular attention is paid to the properties of the bond critical points and the bond paths defined in terms of the gradient of $\rho(\boldsymbol{r})$. The magnitude of the charge density at a bond critical point, $\rho(\boldsymbol{r}_c)$, provides a measure of the bond strength (8). In fact, Bader *et al.* (9) have shown that the bond-length – bond-order relationship of CC bonds in Hückel theory may be generalized to include a variety of hydrocarbons. Their conclusion is based on the observation that the value of the total charge density at a bond critical point is characteristic of a bond of a given formal order. Thus, they observed a linear relationship between $\rho(\boldsymbol{r}_c)$ and the CC bond length. Recently we have shown (10) that there exists a similar relationship between the charge density of the hydrogen-bond critical point of RCN---HF complexes and the NH internuclear distances of the complexes. Moreover, we have some additional calculations which indicate that bond-length – bond-order relationships based on the topological properties of the charge density exist for other examples of intermolecular interactions.

Method

In addition to the MO calculations described previously (11), some supplementary calculations were performed on a Perkin-Elmer 3230 by use of the GAUSSIAN 80 series of programs (12). The bond critical points and bond paths were computed by use of program EXTREM

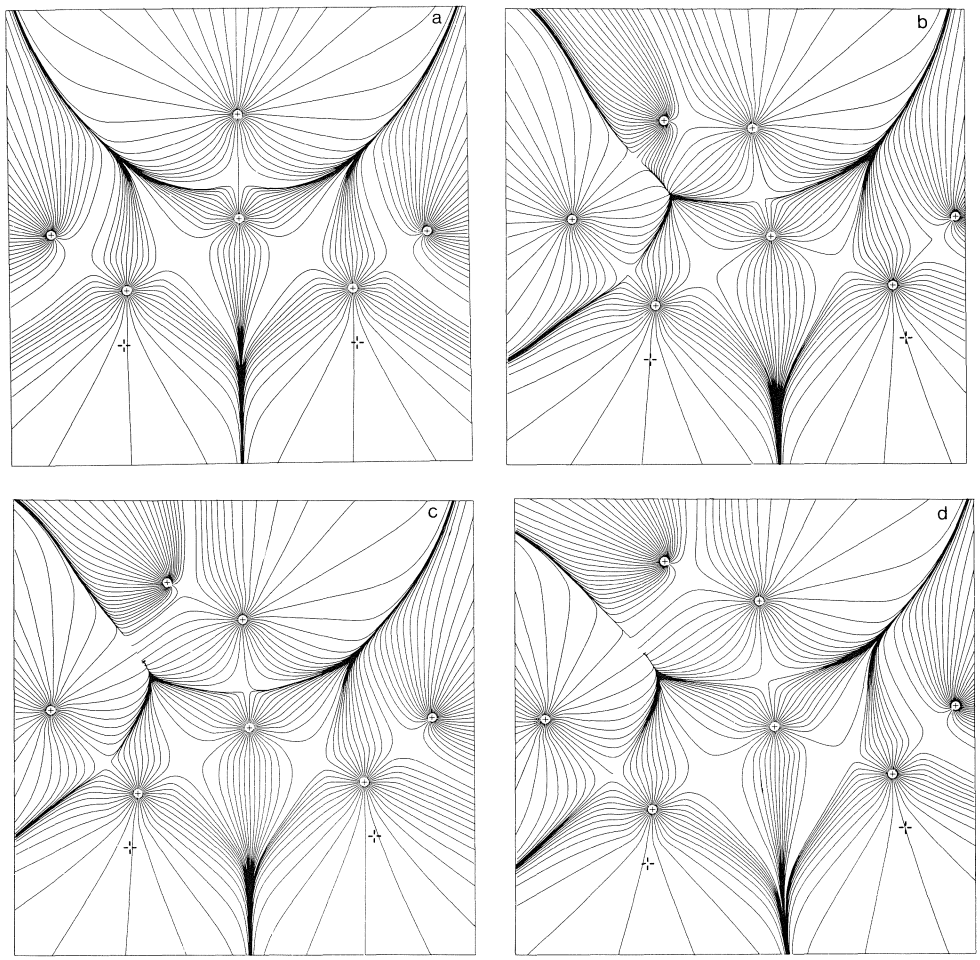

FIG. 1. Gradient vector field of the charge densities: (*a*) acetone, (*b*) $CH_2FCOHCH_3^+$, (*c*) $CH_2FCOHCH_3^+$, (*d*) bifurcation of $CH_2FCOHCH_3^+$. Both (*a*) and (*b*) are at the STO-3G equilibrium geometries while (*c*) is at the 4-31G geometry. Nuclei on the molecular plane are denoted by + while the projections of the out-of-plane nuclei are denoted by -|-.

(13), while plots of the charge density and its Laplacian were obtained by use of program PLOTDEN (13) and a Nicolet Zeta 8 plotter attached to the PE-3230. Program SCHUSS (13) was used to obtain plots of the trajectories or gradient vector field of the charge densities and the molecular graphs.

Results and discussion

Figure 1 shows the gradient vector field of the charge density in a few representative cases, while Fig. 2 displays the corresponding contour maps of the Laplacian of the charge density, $\nabla^2\rho(\boldsymbol{r})$. The cross sign (+) in a gradient vector field diagram refers to the nuclei on the molecular plane while the out-of-plane nuclei are denoted by -|-. Positive values of $\nabla^2\rho(\boldsymbol{r})$ are denoted by solid contours, negative values by dashed contours. The former indicates a depletion of charge density while the latter is just the reverse (14). The molecular graphs of many of the molecules studied are given in Fig. 3 where the bond critical points are denoted by solid circles. Properties at the critical points are listed in Table 1, where the notation A//B indicates that the properties have been calculated at the level of basis set A with the geometry optimized at the level of basis set B.

Figure 1 shows that none of the gradient paths (trajectories) cross zero-flux surfaces and that all trajectories terminate at nuclei. Each atom in a molecule is governed by an interatomic surface which separates neighbouring atoms (7). Furthermore, when two atoms are bonded to each other, a (3, −1) critical point exists between the atoms. The STO-3G calculations for $CH_2FCOHCH_3^+$, $CH_2FCOHCH_2F^+$, and $CF_3COHCH_3^+$ exhibit (3, −1) critical points between fluorine and the carbonyl proton (Fig. 3(*c*), 3(*f*), and 3(*g*), respectively). A F---H bond interaction is also observed (Fig. 3(*h*)) for $CF_3COHCH_3^+$ at the "4-31G" geometry (11). These F---H—O intramolecular hydrogen bonds are consistent with the interpretation of the gas-phase basicities of the protonated fluoroacetones (1). Further insight can be gained by examining the properties of the bond critical point. In particular, the charge density of the F---H bond critical point at the 4-31G//STO-3G level decreases as the number of F atoms increases (Table 1). This indicates a weakening of the bond, which is reflected by the increase in the F—H distance in going from the protonated mono- to trifluorinated acetones. This is similar to the relationship, noted above, between $\rho(\boldsymbol{r}_c)$ and the CC bond length (9). Note that for a X—Y bond where X ≠ Y, the bond critical point (solid circle) in a molecular graph is shifted in accord with the transfer of electrons between atoms (7). In short, the bond critical point of each bond lies nearer to the less electronegative atom of each bonded pair. The relationship between the position of the bond critical point and the polarity of bonds will be discussed in other papers from this laboratory (15, 16).

The 4-31G and 6-31G* basis sets give equilibrium geo-

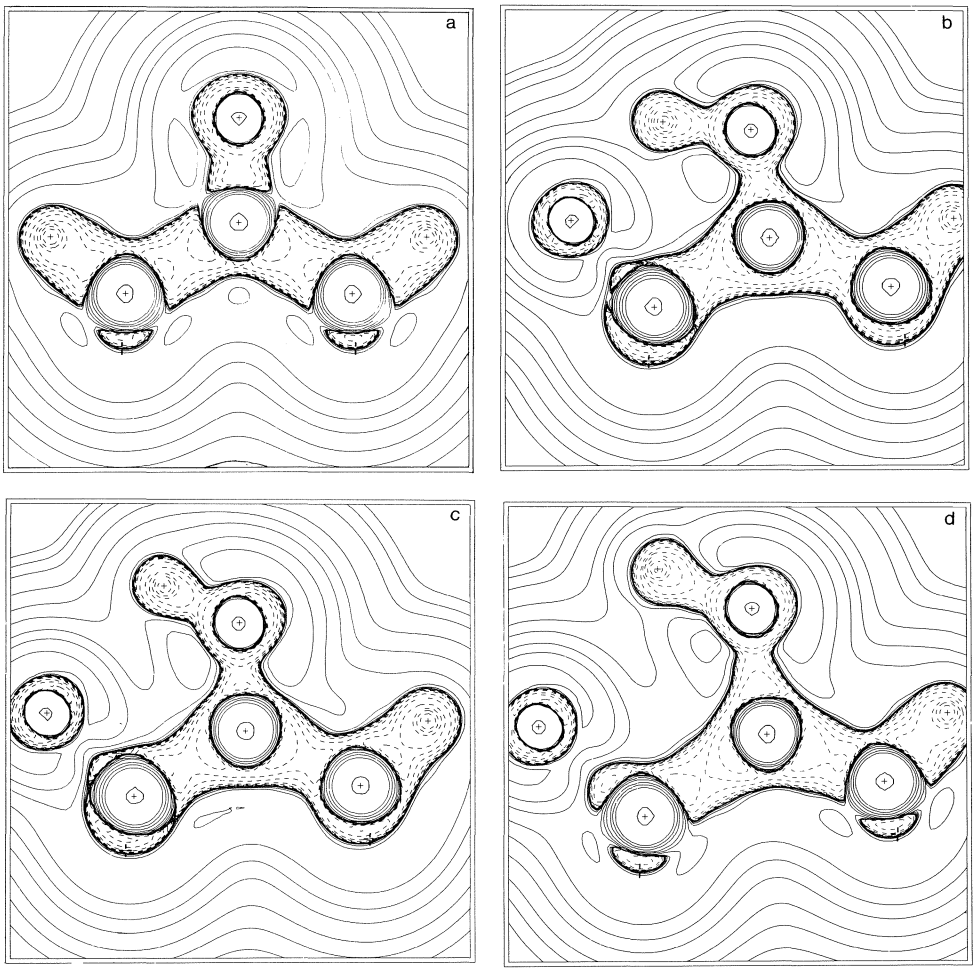

FIG. 2. Contour maps of the Laplacian of atomic densities. The molecules shown are the same as in Fig. 1. The contour values in au are ±0.002, ±0.004, and ±0.008 increasing in powers of 10. The orientations are as shown in the Introduction section. Nuclei on the molecular plane are denoted by + while the projections of the out-of-plane nuclei are denoted by -|-.

metries that show intramolecular bonding between the fluorine and the carbonyl oxygen in $CH_2FCOHCH_3^+$. In order to assess the effect of the choice of basis set on the intramolecular bonding interaction in protonated fluoroacetones, both $CH_2FCOHCH_2F^+$ and $CF_3COHCH_3^+$ were optimized at the 4-31G level. Table 2 summarizes the types of interactions and the bond distances between fluorine and oxygen, and between fluorine and the carbonyl proton. These data suggest that: (*i*) a F---H interaction is observed if the F—H separation is less than about 1.6 Å; and (*ii*) a F---O interaction is observed if the F—H separation is about 2.0 Å and the F—O separation is about 2.5 Å or less. With F—H and F—O separations of 2.1 Å and 2.5 Å, or greater, respectively, no F---H or F---O interactions are observed. To test these conclusions, we carried out STO-3G//STO-3G and 4-31G//4-31G calculations on *o*-fluorophenol. The optimized structures are shown in Fig. 4. No F---H and F---O intramolecular bonding interactions were observed. Moreover, the F---H and F---O internuclear separations are greater than the values for which intramolecular bonding interactions are observed in the protonated fluoroacetones (Table 2). Our calculations support the claim (17) that there is no hydrogen bonding in *o*-fluorophenol due to the larger internuclear separation between fluorine and the carbonyl proton. It is interesting to note that in the case of $CH_2FCOHCH_3^+$, $\rho(\boldsymbol{r}_c)$ of the F---H interaction at the 4-31G//STO-3G level is more than double that of the F---O interaction at the 4-31G//4-31G level. Clearly this indicates a significant bond interaction in the former.

The charge densities of the *syn* and *anti* conformers of $CH_2FCOHCH_3^+$ at the C=O, C_1—F, and O—H bond critical points show considerable differences (Table 1). The decrease in the C=O $\rho(\boldsymbol{r}_c)$ value of the *anti* conformer indicates a weakening of the bond relative to the *syn* conformer. In contrast both the C_1—F and O—H bonds show an increase for $\rho(\boldsymbol{r}_c)$ upon going from the *syn* to the *anti* conformation. Clearly, the substantial changes in $\rho(\boldsymbol{r}_c)$ in the above three bonds should cast doubt on the validity of evaluating the intramolecular hydrogen bond energy by the energy difference between the *syn* and *anti* conformations.

Protonation at the carbonyl oxygen results in a considerable reorganization of charges. As shown in Table 3, the carbonyl oxygen remains negatively charged, and electron transfer to the carbonyl proton decreases as the number of fluorine substituents increases. This is consistent with the inverse dependence of the proton affinity on the number of fluorine substituents (11). The contour maps for $\nabla^2\rho(\boldsymbol{r})$ exhibit noticeable changes within the carbonyl group relative to $CH_3COHCH_3^+$. In addition, replacement of the H at C_1 by F reduces the covalent nature of the C_1—H bond.

Two types of catastrophe point are possible in $CH_2FCOHCH_3^+$,

namely, the conflict and the bifuraction types (18) from the STO-3G and 4-31G geometries, respectively. A catastrophe point can be defined as a point in control space where a discontinuous change in the molecular behaviour is observed (8). The difference between conflict and bifurcation catastrophe points is that the former is one in which a bond switches from one nucleus to another nucleus, while the latter is due to the formation of a singularity in the charge density. Needless to say both types of catastrophe points are structurally unstable. A bifurcation catastrophe point can be obtained by elongation of the F—O distance of $CH_2FCOHCH_3^+$ from its 4-31G equilibrium value of 2.454 Å (see Fig. 1(*d*)). The coalescence of the bond and ring critical points occurs at an O—F distance of about 2.819 Å, as illustrated in Fig. 3(*i*). The exact location of the bifurcation point cannot be located due to the low symmetry (C_s) of the molecule. Even in water, which is a simpler molecule of higher symmetry, the position of the coalescence of the bond and ring critical points can only be determined to within ±0.03 Å (19). A conflict catastrophe point can be observed when the F—H distance is increased from the

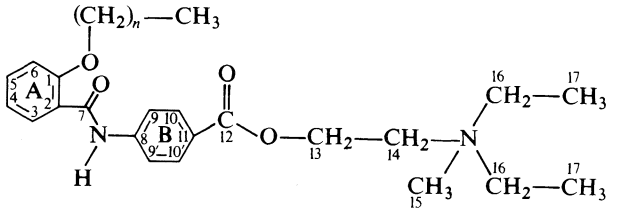
Dynamic features were investigated in a homologous series of synthesized drugs having pharmacologic activity, with particular emphasis on relative motions of the two side chains anchored to a backbone of two aromatic rings linked by an amide bridge. A general and deep insight was reached by using a model-free approach. Conformational and motional dynamics within the compound exhibiting maximum activity were delineated and the most relevant parameters for pharmacologic action were defined.

GIANNI VALENSIN, ELENA GAGGELLI, ANDREA LEPRI et ALESSANDRO SEGA. Can. J. Chem. **64**, 2048 (1986).

On a étudié les caractéristiques dynamiques d'une série homologue de médicaments synthétiques ayant une activité pharmacologique en insistant particulièrement sur les mouvements relatifs des deux chaînes latérales attachées au squelette de deux cycles aromatiques liés par un pont amide. L'utilisation de l'approche du modèle libre a permis d'avoir une connaissance générale et profonde de ces substances. On a délimité les dynamiques conformationnelles et les dynamiques du mouvement dans le composé qui a une activité maximale et on a défini les paramètres les plus significatifs de l'action pharmacologique.
[Traduit par la revue]

Introduction

p(*o*-Alkyloxybenzamido)benzoate diethyl(2-hydroxyethyl)-methylammonium halides (see formula) are synthesized drugs that exhibit a smooth muscle relaxing property (1). Investigations of their pharmacologic activities demonstrated a striking dependence upon length and position of the alkyloxy sidechain. The *ortho*-substituted compounds were by far the most effective and a sharp maximum of activity could be shown for the octyloxy (n = 7) derivative; this derivative is moreover almost completely devoid of central ocular and cardiovascular atropine-like side effects when administered in doses producing spasmolytic effects comparable with those of *N*-butylscopolammonium bromide (2, 3).



We have previously delineated the first term of the series (n = 2) for conformation and dynamics of the two aromatic moieties by exploiting ^{1}H nmr selective and nonselective relaxation rate measurements, ^{1}H–^{1}H intramolecular nOes (nOe, nuclear Overhauser effect), and ^{13}C nmr relaxation rate measurements (4, 5). The preferred conformations of the two aromatic rings were inferred by evaluating proton–proton distances, and a molecular model was built in which complete motional freedom was allowed for the two hydrocarbon side chains.

In a first attempt to correlate pharmacologic activity and conformational features, calculations were extended to other alkyloxy derivatives (n = 3, n = 7, n = 9) (6). Substantial differences in the spatial arrangement of the two aromatic moieties at increasing length of the alkyloxy chain were inferred: the most active octyloxy derivative was shown to assume a configuration in which the angles between each aromatic ring and the plane of the amide unit were almost equal (±55° and ±53°). Moreover, ^{1}H 2D-magnetization transfer experiments (6) demonstrated that, in the case of the octyloxy derivative only, an intramolecular dipolar connectivity exists between methyl groups of the two side chains. Also in agreement with these findings, X-ray analysis of single crystals suggested folding of the alkyloxy side chain towards the diethylmethylammonium moiety, but only in the case of the most active compound was a "closed" structure found (7).

We present hereafter the whole picture of nmr data for the four compounds of the series, from which a complete dilineation of motional and conformational dynamics is reached. Besides the aromatic backbone already investigated, attention is focussed on the hydrocarbon side chains in order to arrive at a thorough understanding of structural parameters relevant for biological activity.

Results and discussion

The ^{13}C spin-lattice relaxation rates (R_1's) are almost exclusively determined by dipolar interactions with directly bonded or nearby protons (8) thus allowing suitable delineation of the molecular dynamics. ^{13}C R_1 values are summarized in Table 1 for the four compounds. We first considered motional features of aromatic carbons that have fewer degrees of freedom with respect to the two side chains, as in the analysis previously carried out for compound **1** (n = 2) (4). The relaxation rate of C5 (the carbon *para* to the amide bridge) is always faster than those of the other aromatic carbons; it follows that C2—C5 is always the main rotation axis for ring A despite the increasing length and weight of the alkyloxy chain in the *ortho* position. Passing from n = 2 to n = 3 to n = 9, this motion slows down, which is very likely due to the effect of the alkyloxy chain. The

matter is, however, not simple since the motion around the C2—C5 axis reaches a relative minimum for $n = 7$ (6.02 s^{-2} against 6.71 s^{-1} for $n = 3$). The relaxation rates of the other carbons in ring A steadily increase along the series with increasing length of the alkyloxy chain, from a mean value of 2.97 s^{-1} ($n = 2$) to 3.67 s^{-1} ($n = 3$), 4.47 s^{-1} ($n = 7$), and 5.00 s^{-1} ($n = 9$). Consequently, the librational motions of ring A, accompanying the main rotational motion around the C2—C5 axis, are slowed down by the increasing size of the substituent. It should be observed that, as a consequence of the relative minimum reached in the relaxation rate of C5 for $n = 7$, this compound exhibits the lowest difference between the rates of the main rotational motion and librational motions. In fact the ratio between R_1 (*para*) and the average R_1 of the other protonated ring carbons (9) is 1.66, 1.84, 1.35, and 1.44 for $n = 2$, 3, 7, and 9 respectively.

The C8—C11 axis is naturally the main rotational axis for ring B. The relaxation rates of C9,9′ and C10,10′ steadily increase along the series from $n = 2$ to $n = 9$; the overall increment (1.0 s^{-1}) is, however, much less pronounced than that observed for ring A (2.0 s^{-1}), the former being one-half of the latter. Clearly, motions of ring B are less markedly affected by the alkyloxy chain. Librational motions of ring B therefore become faster than those of ring A: for $n = 2$, $n = 3$, and, to a lesser extent, $n = 7$, the two librational motions occur at the same or at very similar velocities, whereas dephasing is accomplished for $n = 9$. The relaxation data can be rationalized in terms of an anisotropic model made by rotational reorientation around the two molecular axes with some degrees of internal motion (8), as already done for the first term of the series (4). The values of the calculated correlation times are reported in Table 2. The most important feature to be inferred is the matching of librational motions with the main rotational motion for $n = 7$, while librational motions of the two rings are still governed by approximately the same correlation time (see Table 2).

Motional delineation of the side chains was then attempted in the light of the surprising intramolecular dipolar connectivity between protons of the terminal methyl of the octyloxy chain and protons of the methyls of the ethyl groups bonded to the quaternary nitrogen (6). When analyzing ^{13}C R_1's of the compound with $n = 2$, it was noticed that C13 was undergoing a reorientational motion very close to that of the aromatic rings while, on the contrary, the ^{13}C R_1 of C18 suggested that motions of the propyloxy chain were faster than those in the backbone.

Quantitative evaluation of motional features within the four compounds was approached in terms of the model-free approach of Lipari and Szabo (10, 11). According to these authors, dynamic information on fast internal motions in an nmr relaxation experiment on molecules in solution can be specified by a "generalized" order parameter, ζ^2, and an effective correlation time, τ_e, that can be calculated either by ^{13}C R_1's and ^{13}C–{^1H} nOes at one frequency or by ^{13}C R_1's at two frequencies. Instead of assuming any given model of molecular motion, such an approach allows immediate inference on local steric hindrances experienced by molecular motions and on the way such hindrances develop along any hydrocarbon chain. It therefore appeared to be the most suitable method for pointing out eventual differences in local order parameters for homologous compounds, where the length of one side chain exclusively determines the conformation assumed in solution.

Following the procedure presented by Lipari and Szabo we selected C6 as the carbon atom of the backbone to which motional features of carbon atoms in the side chains refer. In fact, the alkyloxy chain is motionally linked to ring A, as suggested by the strong ^1H–^1H dipolar connectivity between H6 and H18 shown by all the compounds (the ^1H–^1H H18–{H6} nOe ranges from 0.072 ($n = 2$) to 0.038 ($n = 9$)) (5, 6). Such connectivity was already explained in terms of folding of the initial segments of the alkyloxy chain towards ring A. The decreasing nOe is again a consequence of slowing down motions with increasing chain length. If the ^{13}C–{^1H} nOes of the four compounds (Table 3) are considered and compared to the R_1 values (Table 1), it is apparent that, while all the aromatic protonated carbons of ring A but C5 exhibit the same relaxation behavior, the nOe is similar for C3 and C4 but much lower for C6. The ^{13}C relaxation rates, under broadband proton decoupling and in the extreme narrowing region, are mainly determined (12, 13) by single-quantum (W_1) and double-quantum (W_2) relaxation transition probabilities among the four energy levels of the AX spin system. Thus only fast motions are relevant for spin-lattice relaxation, and slow superimposed motions, if any, cannot be detected. On the contrary the ^{13}C–{^1H} nOe also includes a contribution, to a variable extent, by the zero-quantum (W_0) relaxation transition probability and it is therefore more suited to detect eventual slow-motion components. The lower nOe for C6 was, as a consequence, thought to result from the presence of a slowly modulated ^{13}C–^1H interaction, the observed nOe being proportional to $W_2 - W_0$. To further support such an interpretation, the

spin–spin relaxation rates (R_2's) of aromatic protonated carbons of ring A (Table 4) demonstrated that (*i*) $R_1 \ll R_2$, such that a single correlation time cannot account for modulation of the whole motional features of the various ^{13}C—^{1}H vectors; (*ii*) R_2 of C6 is faster than those of C3 and C4, demonstrating that slow-motion components are much more effective for C6 than for the other two carbons.

According to one of the possible procedures, the measured ^{13}C R_1's (Table 1) and ^{13}C–{^{1}H} nOes (Table 3) at 50.3 MHz were used in the following equations whereby ζ^2 and τ_e were directly extracted:

$$\zeta^2 = \frac{R_1(2.988 - \mathrm{nOe})}{R_{1_0}(2.988 - \mathrm{nOe}_0)}$$

and

TABLE 4. ^{13}C spin–spin relaxation rates for selected carbons of *p*-(*o*-octyloxybenzamido) benzoate diethyl(2-hydroxyethyl)methylammonium bromide 0.2 mol dm^{-3} in DMSO-d_6 at 298 K

$$\frac{\hbar^2 \gamma_C^2 \gamma_H^2}{r_{CH}^6} \tau_e = \frac{\mathrm{nOe} - \mathrm{nOe}_0}{R_1^{-1}(2.988 - \mathrm{nOe}_0) - R_{1_0}^{-1}(2.988 - \mathrm{nOe})}$$

where R_{1_0} and nOe_0 are the relaxation parameters describing the main isotropic motion to which the actual internal motion is referred. This is not apparently our case; however, since the aim is the comparison among relative motions of homologous side chains, we used the isotropic expressions referring the internal motion to the slowest reorienting C—H vector, that is, to C6. The values of ζ^2 and τ_e calculated in such a way are reported in Tables 5 and 6 respectively.

According to Lipari and Szabo, ζ, the "generalized" order parameter, is a model-independent measure of the degree of spatial restriction of the motion, such that

$$0 \leq \zeta^2 \leq 1$$

If the internal motion of any particular C—H vector is isotropic, $\zeta^2 = 0$, while if the same motion is completely restricted, $\zeta^2 = 1$. Inspection of Table 5 shows that very high values of ζ^2 are found for C18, in agreement with the already mentioned motional connection between the C18 methylene and ring A, thus ratifying the interpretation of restricted motion for the first segment of the alkyloxy chain. A very interesting feature is the large value of ζ^2 for C22 within the octyloxy chain in the compound with $n = 7$ ($\zeta^2 = 0.316$). This value is much greater than that corresponding to the Woessner model ($\zeta^2 = 0.111$, for axially symmetric motion) (14). If it is considered that C22 has a middle chain position relatively far from the almost anchored C18, it may be stated that the conformational freedom of the octyloxy chain ($n = 7$) is somehow reduced with respect to the decyloxy chain ($n = 9$). This is further ratified by the fact that for the least restricted carbon atom for $n = 7$ (C21) ζ^2 is more than one order of magnitude greater than for the least restricted

TABLE 5. Comparison of the generalized order parameter ζ^2 for selected carbons of *p*-(*o*-alkyloxybenzamido)benzoate diethyl(2-hydroxyethyl)methylammonium halides 0.2 mol dm^{-3} in DMSO-d_6 at 298 K[a]

carbon atoms for $n = 9$ (C19) and C25). In general the ζ^2 values for $n = 7$ are of the same order of magnitude as those for $n = 2$ and $n = 3$ (with the remarkable exception of C22). Then only for $n = 9$ is the alkyloxy chain characterized by a certain degree of conformational freedom.

The same analysis has been extended to the quaternary nitrogen side chain, maintaining C6 as the reference carbon atom. In fact, although the activity depends on the length of the alkyloxy chain, an interaction between the terminal methyls of the two side chains was strongly suggested by ^{1}H 2D nOe measurements (6), indicating that a "loop" conformation could be the most important or, at least, one of the most important conformational features. It is therefore relevant to delineate motions within the quaternary nitrogen side chain in connection with motions within the alkyloxy side chain.

For $n = 2$, $\zeta^2 = 0.966$ was found for C13, a value that confirms what had been already interpreted on the basis of ^{13}C R_1's (R_1(C6) = 3.11 s^{-1} as compared with $\frac{1}{2}R_1$(C13) = 2.96 s^{-1}). C—H vectors within the C13 methylene are reorienting in close connection with librational motions of aromatic rings; thus selecting C6 as a motional reference brings about a value of ζ^2 close to 1 for C13. For $n = 3$ and also for $n = 7$, motions of C13 are still spatially restricted, whereas for $n = 9$ such motions are far less hindered. By considering all ζ^2 values for these side chains it is apparent that the most restricted motions belong to the $n = 7$ compound where, in particular, the alkyl substituents undergo very hindered reorientations. It is worth stating again that terms such as "spatially restricted" or "hindered" must be taken on a relative scale, the calculated order parameter being referred to the motion of the alkyloxy chain. It can be concluded that the octyloxy derivative (the most active compound) displays the lowest conformational freedom, which can explain the detection of the otherwise surprising dipolar connectivity between the terminal methyls.

The effective correlation times, τ_e (see Table 6), depend on both the microscopic diffusion constants and the spatial nature of the motion. As a consequence, the interpretation of τ_e values is more complicated than that of ζ^2 values; in fact, while ζ^2 is a model-free parameter by definition, the effective correlation times can be related to microscopic rate constants only within the framework of a particular dynamic model (14–18). Generally speaking, any such model contains at least one adjustable rate parameter that is intrinsically flexible, making it possible to reproduce the τ_e values in any model. Since simple models are not suitable for the complete analysis of our data, we preferred not to introduce any motional model and limited ourselves to a qualitative discussion of dynamic features. It should in any case be noticed that ζ^2 and τ_e values exhibit different trends such that spatial restriction of the motion does not always correspond to lengthening of effective correlation times.

By considering the ζ^2 values and the conformational features previously established, a consistent picture of motional and conformational dynamics of the four molecules can be obtained. The following results are a consequence of increasing length of the alkyloxy chain.

(*i*) The preferred conformations of the benzanilide moiety change: the angle between ring A and the plane of the amide bridge steadily increases from ±15° ($n = 2$) to ±75° ($n = 9$) while the angle between ring B and the same plane steadily decreases from ±60° ($n = 2$) to ±48° ($n = 9$) (6). In the biologically most active compound ($n = 7$), the two dihedral angles have very similar values (±55° and ±53° respectively) yielding conformations having the two rings either parallel or nearly perpendicular to each other.

(*ii*) The mean rotational correlation time of the rings increases (the motion slows down), with the exception of the $n = 7$ compound. The librational motions of the two rings follow the same trend: they increase from $n = 2$ to $n = 7$ and decrease for $n = 9$. The whole motional picture of the aromatic moieties is such that the most active compound is characterized by librational motions of the two rings still very close to each other and also close to the main rotational motion; as a consequence this compound exhibits the most limited internal motions.

(*iii*) The analysis of ζ^2 values points out the overall greater

spatial constraints presented by the two side chains in the case of $n = 7$ as compared to the other terms of the homologous series; this loss of conformational freedom could explain the ^{1}H 2D nOe between the terminal methyls (6), and it is, at the same time, in agreement with the restriction of internal motions within the aromatic moieties.

As far as the relationship between pharmacologic activity and position and length of the alkyloxy chain is concerned, the following general conclusion can be reached: intramolecular interaction between the ends of the two side chains must be important. This being the case, as strongly suggested by present and previous results, the sharp decrease of activity in the case of *meta*- or *para*-substituted molecules (whatever the length of the alkyloxy chain) could also be explained.

Experimental

The compounds investigated were synthesized as already described (1). Solutions were made in 99.96% DMSO-d_6 and were carefully deoxygenated. The nmr spectra were registered on a Varian XL-200 spectrometer in the pulse FT mode at probe temperatures of 25 ± 1°C; chemical shifts were referenced to internal TMS.

Spin-lattice relaxation rates were measured with the inversion recovery pulse sequence $(t-\pi-\tau-\pi/2)_n$; spin–spin relaxation rates were measured with the Carr–Purcell–Meiboom–Gill pulse sequence; 100 FIDs were collected in both cases. R_1 and R_2 values were calculated from exponential regression analysis of the recovery or decay curves of longitudinal or transverse magnetization components respectively by using the computer of the spectrometer.

The ^{13}C–{^{1}H} nOes were calculated by comparing peak intensities measured on fully relaxed ^{13}C spectra obtained under conditions of continuous and gated broadband decoupling.

As the initial step in the investigation of metal ion- and vitamin B_6-catalyzed, β,γ-elimination in α-amino acids, the pyridoxal- and pyridoxal 5′-phosphate-catalyzed β-deuteration of α-aminobutyric acid and homoserine in D_2O in metal-free systems has been studied by nuclear magnetic resonance. The reaction kinetics of α-H, β-H, and 4′-CH exchange rates were measured by following the rates of deuteration of these positions. The kinetic data obtained for these reactions lead to a proposed mechanism for β-deuteration. The relative rates of the deuteration reactions observed, and the order in which deuteration products were obtained are: α-H exchange > transamination (4′-CH exchange) > β-H exchange. The observed rates of β-proton exchange exhibit specific base catalysis and are dependent on the activation of the α-hydrogen of the amino acid moiety in the aldimine, and on the activation of the β-hydrogens of the amino acids in the ketimine.

Dans le cadre de la recherche sur les éliminations β,γ dans les acides α aminés, catalysées par les ions métalliques et par la vitamine B-6, on a fait appel à la rmn pour étudier la deutération β de l'acide α-aminobutyrique et de l'homosérine, catalysée par le pyridonal et le phosphate-5′ de pyridonal, dans le D_2O dans des systèmes ne contenant pas de métal. On a mesuré les cinétiques des vitesses d'échange des protons: H-α, H-β et CH-4′, en examinant les vitesses de deutération en ces positions. Les données cinétiques obtenues permettent de proposer un mécanisme réactionnel. Les vitesses relatives de deutération observées et l'ordre dans lequel on obtient les produits sont les suivants : échange du H en α > transamination (échange CH-4′) > échange H en β. Les vitesses observées pour les échanges du proton H en β montrent une catalyse basique spécifique et dépendent de l'activation de l'hydrogène en position α du fragment d'acide aminé de l'aldimine et également de l'activation des hydrogènes β de l'acide aminé de la cétimine.

[Traduit par la revue]

Introduction

The general mechanism suggested for β-proton exchange (1, 2) as a preliminary step in the elimination of electronegative groups in the γ-positions of amino acids is one of the recognized vitamin B_6-catalyzed reactions (3, 4). Somewhat earlier, β-proton exchange was observed for leucine at pH 5 in the presence of pyridoxal (5). More recently, some initial studies of the rates and mechanism of β-proton exchange of α-amino acids and α-keto acids in the presence and in the absence of metal ions have been carried out (3). The generally accepted mechanism of β-proton exchange involves the formation of ketimine Schiff base, followed by preliminary β-proton labilization to produce an intermediate ketimine-stabilized carbanion. Reprotonation at the β position regenerates the ketimine Schiff base.

The purpose of the present work is to undertake a kinetic study of the reaction sequences of β-proton exchange as an aid in elucidating the reaction mechanism, and thus to contribute to the understanding of the nature of the related enzymatic reactions. In this paper, nmr measurements are employed under β-proton exchange conditions in the presence of pyridoxal or pyridoxal 5′-phosphate. The use of these two forms of vitamin B_6 makes it possible to overcome the difficulties encountered because of limited solubilities of each catalyst at various but different pH ranges, thus greatly expanding the range of pH available for kinetic studies. The results of the present study provide a baseline for comparison with subsequent work on metal-ion catalysis of these reaction systems.

Experimental

Pyridoxal hydrochloride and pyridoxal 5′-phosphate, obtained from Sigma Chemical Company, and DL-α-aminobutyric acid and DL-homoserine from Mann Laboratories, were of sufficiently high quality to be used without further purification. NaOD and D_2O were obtained from Diaprep Corporation, and the purity of D_2O was 99.7%. NaOD (40% in D_2O) was diluted to the appropriate concentration under dry nitrogen.

The pH values of the solutions were measured by using a Corning Model 101 digital electrometer fitted with a Beckman miniature combination glass electrode and pH values were adjusted by the addition of NaOD solution in D_2O. The instrument was calibrated before and after each kinetic run by the use of standard buffers and corrected by the use of activity coefficients to read $-\log [H^+]$ directly. In D_2O solution, the deuterium ion concentration was computed by adding 0.41 (6) to the observed reading. The temperature was maintained at 25.0 ± 0.1°C and the ionic strength was maintained at 1.0 *M* (KNO_3). In the binary systems studied, the analytical concentrations of amino acid, pyridoxal, and pyridoxal phosphate were 0.10 *M*.

The nmr spectra were obtained with a Varian HA-100 nuclear magnetic resonance spectrometer. The chemical shifts (ppm) are reported relative to tetramethylsilane (Me_4Si), which was inserted in the reaction mixture in a coaxial tube. All kinetic runs were carried out on homogeneous systems. Before each spectrum was taken, the instrument was readjusted and five integrals were taken of the resonances used for following kinetics, and at least three integrals were taken for other peaks. The integral values were then averaged for further calculation and normalized relative to spectra based on unreactive protons. The fraction of Schiff base in the experimental solution was determined by taking ratios of the sums of the integrals of the 6H and $2CH_3$ resonances of the pyridoxal and pyridoxal phosphate Schiff bases and the γ-CH_3 of 2-aminobutyric acid. Since the resonances for the β-protons of the Schiff base and of the free amino acid overlap considerably, the integral values for Schiff base β-protons were obtained from the differences between the total integrals for the β-protons and the corresponding normalized values of the free amino acids. The constants were determined from the slope of the line obtained by plotting the appropriate values versus time. The reliabilities of the measurements were determined from the variations of the concentrations from the expected values based on the least-squares treatment. Since most of the kinetic runs were repeated, the results of these runs are reported with the estimated deviations.

Results and treatment of data

Nuclear magnetic resonance spectra

The pyridoxal (PL) and pyridoxal 5′-phosphate (PLP) resonances have been assigned previously (7, 8). In this study, the resonances of α-aminobutyric acid (α-ABA) at pD 7.15 consist of a triplet near 1.05 ppm (CH_3), a multiplet near 2.00 ppm (β-CH_2), and a triplet near 3.80 ppm (α-CH). At pD values less than 6 in the absence of metal ion, the nmr spectra of equimolar solutions of pyridoxal and α-aminobutyric acid consist of resonances attributable entirely to the components as shown in Fig. 1 (pD 5.40). As the pD is raised, the resonances of the Schiff base become apparent and are labelled as SB in Fig. 2 (pD 7.97). In the case of the pyridoxal 5′-phosphate system, Schiff base formation becomes apparent at pD 4.82 (15%). This indicates that at a given pD in acid solution the degree of Schiff base formation is considerably higher for PLP than for PL. This behavior is expected since PL exists predominantly in the hemiacetal form, tending to inhibit Schiff base formation, whereas for PLP, in which the phosphate group precludes hemiacetal formation, the concentration of the free aldehyde is approximately 50 times higher (9). In pH or pD ranges in which the Schiff bases are minor species, the concentration of the PLP Schiff base should be nearly two orders of magnitude higher than that of the PL Schiff base. All resonances shift to higher field with increasing pD of the solution, as would be expected from the increasing negative charge on the Schiff base anion as protons are dissociated in a stepwise fashion from the pyridine and azomethine nitrogen atoms. Figure 3 presents the 100-MHz nmr spectrum of the pyridoxal–α-aminobutyric acid Schiff base, showing the decrease of β-CH_2 resonances of α-ABA with time, and Fig. 4 is the 100-MHz nmr spectrum of pyridoxal 5′-phosphate-α-aminobutyric acid Schiff base, also

showing the decrease in β-proton resonances. The results are summarized in Table 1 for 4′-CH and α-H exchange rates.

Kinetic treatment

For the α-amino acid – PL and α-amino acid – PLP systems, the rate equations are based on the simple α- and β-proton exchange reactions:

α-Proton exchange

The removal or exchange of the α-proton is expressed by:

$$[1] \quad \alpha\text{-HSB} \xrightarrow{k'} \alpha\text{-DSB}$$

where α-HSB is α-amino acid Schiff base **1** with a hydrogen at the α-position and α-DSB is the corresponding α-deuterated Schiff base. The first-order rate equation

$$[2] \quad \frac{d[\alpha\text{-DSB}]}{dt} = k'_{obs}[\alpha\text{-HSB}]$$

may be employed directly if the concentration of α-HSB in solution can be determined, and the first-order rate constant k'_{obs} is then found from the slope of the line by plotting ln [α-HSB] vs. time.

4′-CH Exchange

The reactions controlling the rate of 4′-CH exchange in D_2O involve forward and reverse transamination steps (aldimine $\rightleftharpoons$ ketimine) and may be expressed by the following equations:

$$[3] \quad 4\text{CHSB} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 4\text{CHDSB} \xrightarrow{k_t} 4\text{CDSB}$$

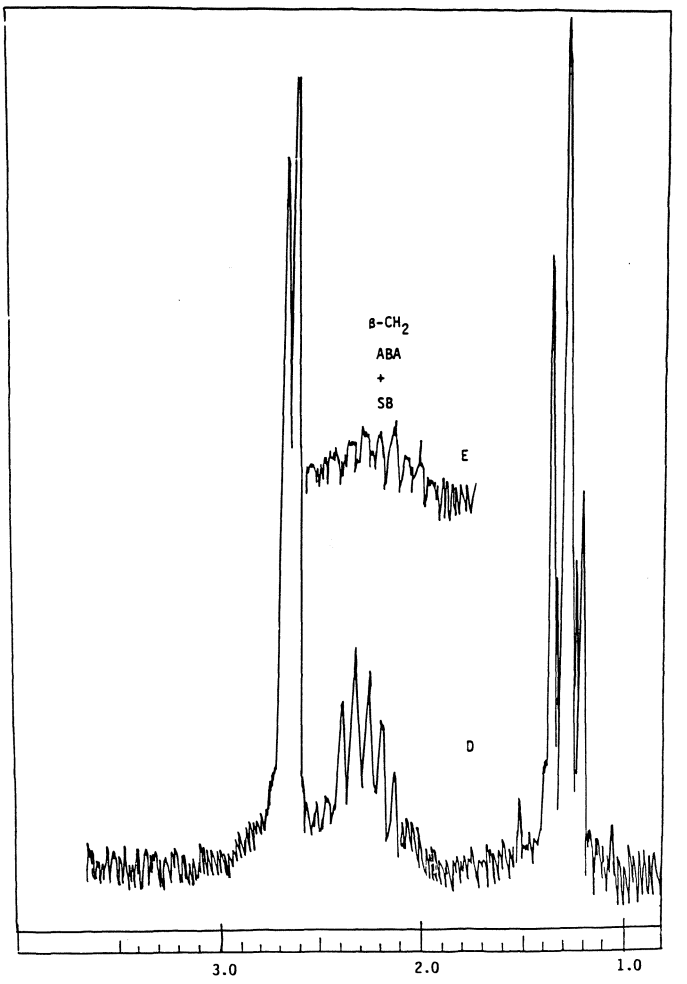

FIG. 4. The 100-MHz nmr spectrum of 0.10 *M* pyridoxal phosphate and 0.10 *M* α-aminobutyric acid at pD 8.47 showing the decrease of the β-CH_2 signal of α-ABA. PLP = pyridoxal phosphate, α-ABA = α-aminobutyric acid, and SB = Schiff base. D: after 1 h; E: 88 h. Chemical shifts are reported in ppm with respect to Me_4Si.

*Repeated measurements indicate that constants reported are reliable to ±5%.

$$[4] \quad 4\text{CDSB} \underset{k'_r}{\overset{k'_f}{\rightleftharpoons}} 4\text{CD}_2\text{SB}$$

where 4CHSB is the α-amino acid (aldimine) Schiff base **1**, with a hydrogen atom at the 4′ (α′) position of the pyridine ring, 4CDSB is the same Schiff base with a deuterium at the 4 position, and 4CHDSB is the intermediate half-deuterated ketimine, **3**.

The rate of disappearance of **1** is expressed by:

$$[5] \quad -\frac{d[4CHSB]}{dt} = k_f[4CHSB] - k_r[4CHDSB]$$

The rate of change in concentration of the intermediate ketimine, 4CHDSB, is expressed by:

$$[6] \quad \frac{d[4CHDSB]}{dt} = k_f[4CHSB] - k_r[4CHDSB] - k_t[4CHDSB]$$

The rate of change in concentration of the fully deuterated ketimine is expressed by:

$$[7] \quad \frac{d[4CD_2SB]}{dt} = k'_f[4CDSB] - k'_r[4CD_2SB]$$

The steady-state assumption is applied to the ketimine intermediate 4CHDSB, which is formed in undetectable concentrations in the experimental solution.

$$[8] \quad \frac{d[4CHDSB]}{dt} = k_f[4CHSB] - k_r[4CHDSB] - k_t[4CHDSB] = 0$$

To a first approximation, it may be assumed that $k_f = k'_f$ since these reactions both involve the transfer of D^+ from solution to α'-CH and α'-CD of the aldimine to form a C—D covalent bond. Similarly, $2k_r = k'_r$ because the reaction steps being compared both involve the breaking of a C—D covalent bond and transfer of D^+ to a base in solution, and differ only in the presence of adjacent C—H and C—D bonds, respectively. The rate constants k_t and k_r, however, should reflect a primary isotope effect resulting from the breaking of C—H and C—D bonds for the transfer of protons to a base in solution, so that $k_t = \alpha k_r$, where α is the kinetic deuterium isotope effect. Therefore:

$$[9] \quad k_r[4CHDSB] = \frac{k_f}{1+\alpha}[4CHSB]$$

and substituting the above relationship (9) into eq. [5]:

$$[10] \quad -\frac{d[4CHSB]}{dt} = \frac{\alpha}{1+\alpha}k_f[4CHSB] = k''_{obs}[4CHSB]$$

where the factor $\alpha/(1+\alpha)$ varies from $\frac{1}{2}$ for a minimal isotope effect, to nearly unity for a large isotope effect.

The only isotope effect that has been reported for pyridoxal Schiff bases in D_2O is 2.7, by Blake *et al.* (10), for the rate-determining transfer of a proton from the α-CH to the solvent. Assuming a value of similar magnitude for the α'-CH, the ratio of k_{obs} (i.e., k''_{obs}) to k_f would be about 0.74.

Thus the rate of 4′-CH exchange is also based on the concentration of Schiff base in solution, and the first-order constant k''_{obs} may be found from the slope of the plot of ln [4CHSB] vs. time.

β-CH exchange

With two hydrogen atoms in the β position, the rate of β-CH exchange is dependent on the sequential reaction steps:

$$[11] \quad \beta\text{-}CH_2SB \xrightarrow{k_1} \beta\text{-}CHDSB \xrightarrow{k_2} \beta\text{-}CD_2SB$$

where β-CH_2SB is the α-amino acid Schiff base with both hydrogens on the β position of the amino acid moiety, β-CHDSB is the same Schiff base with one hydrogen and one deuterium on the β position, and β-CD_2SB is the Schiff base with both hydrogens replaced by deuterium atoms. The following rate equations apply to this system:

$$[12] \quad \frac{d[\beta\text{-}CH_2SB]}{dt} = -k_1[\beta\text{-}CH_2SB]$$

$$[13] \quad \frac{d[\beta\text{-}CHDSB]}{dt} = k_1[\beta\text{-}CH_2SB] - k_2[\beta\text{-}CHDSB]$$

The stoichiometric relationships are:

$$[14] \quad T_c = [\beta\text{-}CH_2SB] + [\beta\text{-}CHDSB] + [\beta\text{-}CD_2SB]$$

$$[15] \quad T_p = 2[\beta\text{-}CH_2SB] + [\beta\text{-}CHDSB]$$

where T_c is total concentration of the species and T_p is total proton count. The following rate equation is obtained for total proton count.

$$[16] \quad \frac{dT_p}{dt} = 2\frac{d[\beta\text{-}CH_2SB]}{dt} + \frac{d[\beta\text{-}CHDSB]}{dt}$$

Substituting the variables from eqs. [12] and [13] into eq. [16]

$$[17] \quad \frac{dT_p}{dt} = -2k_1[\beta\text{-}CH_2SB] + k_1[\beta\text{-}CH_2SB] - k_2[\beta\text{-}CHDSB]$$

By substituting relationship [15] into eq. [17], and with the assumption $k_1 = 2k_2$ (i.e., the isotope effect here would also be minimal because both reactions involve the breaking of a C—H bond, and differ only in having adjacent C—H or C—D bonds),

$$[18] \quad \frac{dT_p}{dt} = -k_2T_p = -k'''_{obs}T_p$$

Thus the rate of proton exchange is directly proportional to the total concentration of the protonated Schiff base species in solution. This first-order rate constant k_2 is then found from the slope of the line by plotting ln $[T_p]$ vs. time.

The β-deuteration rate constants obtained for the PL and PLP Schiff bases are presented in Table 2. The values for these constants are reported to only two significant figures because of the difficulty encountered in determining precise integral values for these protons located adjacent to the intense HOD resonance. The spinning side-band encountered from the large HOD resonance complicated the integration of these resonances in some cases.

Mechanistic considerations

The proposed β-exchange mechanism is outlined in Scheme 1. The final product, assuming no side reactions, is the deuterated aldimine Schiff base species, **9**. Since no transamination reaction products (the keto acid and pyridoxamine or pyridoxamine-5′-phosphate) were found even after four half-lives of β-deuteration, the reaction is expected to go through two successive (forward and reverse) transamination steps. The first transamination involves the formation of the ketimine Schiff base **3**, which initiates the β-deuteration reaction, and the final transamination step is conversion of the ketimine to the aldimine Schiff base (**5** → **10** → **11** and **5** → **6** → **7** → **8** → **9**). Since the aldimine form is more stable than the ketimine form in these systems, it would be expected to predominate in the reaction mixture. Thus intermediates **3**, **5**, and **7** are not formed in sufficient quantities to be detected by nmr, but are essential for the sequential eliminations of the α- and β-protons.

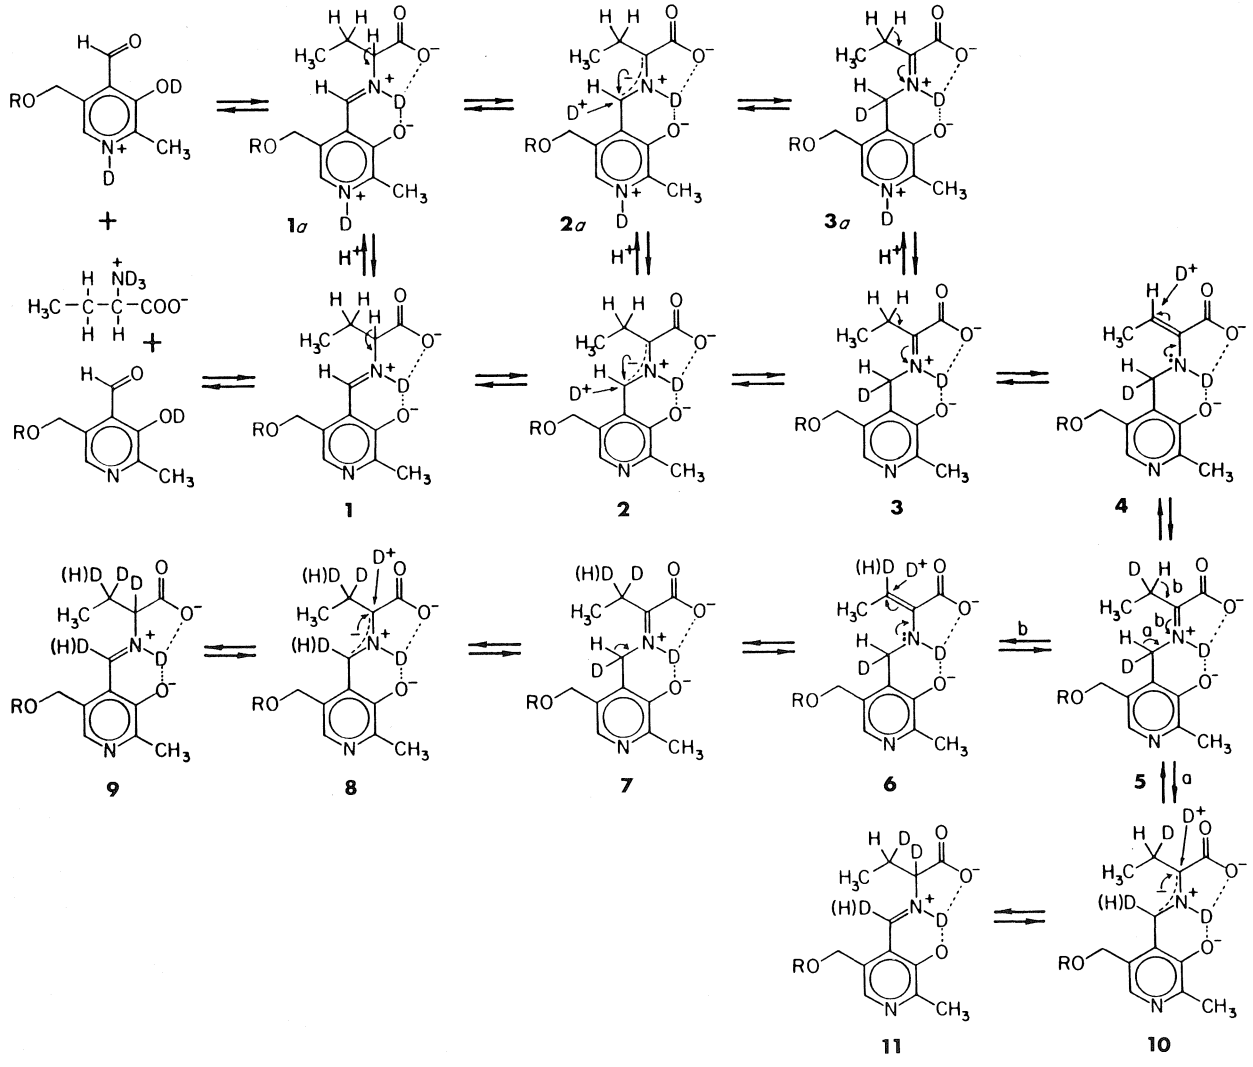

SCHEME 1. Metal free pyridoxal (R = H) or pyridoxal phosphate (R = PO_3H^-) catalyzed mechanism of β-proton exchange of α-aminobutyric acid.

Discussion

The rates of α′(4′-CH) exchange and α-H exchange of α-amino acid Schiff bases in the absence of metal ions are influenced by the ability of the Schiff base to labilize the protons at the α and α′ positions, which in turn is directly influenced by the protonation of the Schiff base at the azomethine and pyridine nitrogen atoms. The ability of the Schiff base to labilize α- and α′-protons should be greater for the doubly protonated form, since the negative charge of the active deprotonated intermediates **2** and **2***a* can then be distributed throughout the

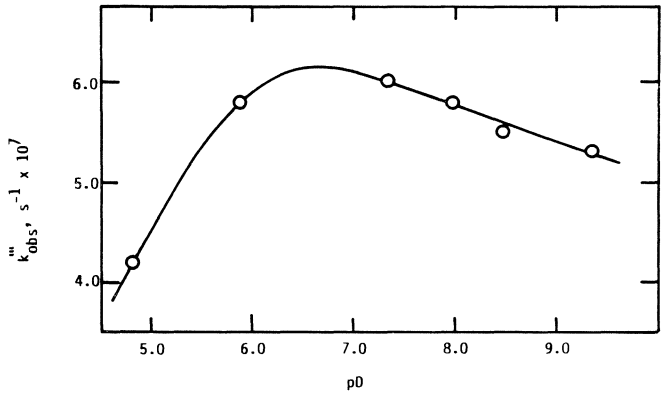

FIG. 5. The observed rate constants for the β-deuteration of α-aminobutyric acid and pyridoxal 5′-phosphate in D_2O solution at μ = 1.00 *M* (KNO_3); *t* = 25.0°C.

conjugated π-bond system of the Schiff base. Thus the electron-withdrawal effect in **2** is less than in **2***a*, and the rate of transamination would be expected to decrease with increasing pH, on the basis of these factors alone.

As pD increases, the diprotonated species **2***a* disappears first, and finally the monoprotonated species **2** becomes converted to the completely deprotonated Schiff base (not shown), which does not have an activating positive charge on the azomethine nitrogen. The lowered reactivity of this species toward α and α′ exchange would be counterbalanced by base (hydroxide ion)-catalyzed activation of the exchange process. This type of catalysis would also occur with **2**, so that the effect of its deprotonation at high pH would be balanced by increased hydroxide ion catalysis. Thus the base-catalyzed rate assigned to **2** would be kinetically indistinguishable from the exchange rate attributed to the fully deprotonated Schiff base.

In the pyridoxal – aminobutyric acid system, the values for the rate constants of α and α′ exchange, as functions of pD, show interesting trends. The α exchange shows the effect of base catalysis since the rates increase with increasing pD, while α′ exchange shows the effect of base as well as of protonation. Since the pK_a of the monoprotonated Schiff base is ≈10, the fact that the values for the rate constants are equivalent within the standard deviation range at pD 9.93 and pD 10.26 suggests that the decrease in the concentration of **2** is approximately balanced by increased hydroxide concentration.

In the pyridoxal phosphate – aminobutyric acid system, the trend of decreasing rate constants with increasing pD was observed (Fig. 5). The trend was as predicted on the basis of the factors previously mentioned for transamination, as well as by the fact that the phosphate group would be expected to sterically and electrostatically hinder base catalysis in the abstraction of a proton from the α′(4′-CH_2) position. Thus the effect of the degree of protonation of the Schiff base would predominate. The marked difference between the pyridoxal and pyridoxal phosphate trends must be due to steric and electrostatic effects on the phosphate anion and on the hydroxymethyl group. The phosphate hydroxyl group at the 5′ position may hydrogen bond with the azomethine nitrogen (11) of the pyridoxamine Schiff base, thus increasing the reactivity of the α′-hydrogen toward base catalysis. In view of these factors the observed difference between the trends for α and α′ exchange becomes reasonable.

The rate constants for β-deuteration for the α-ABA Schiff base and for D,L-homoserine – pyridoxal 5′-phosphate, presented in Table 2, also indicate interesting trends. The factors that influence the rate of the β-deuteration of the amino acid moiety in the absence of the metal ion are analogous to those suggested for the α and α′ exchange. After transamination takes place to form the ketimine Schiff base, the conjugation of π-bonds between the aromatic ring and the azomethine nitrogen is eliminated. Thus the Schiff base influences the labilization of β-protons through the positive charge on the azomethine nitrogen in the protonated form and through inductive forces exerted by the substituents on the amino acid. The effect of substituents is applicable only when comparing the rates of different amino and keto acids. Electron-withdrawing substituents are expected to increase the rate while the reverse is true for the electron-donating substituents. The influence of protonation of the imine nitrogen is restricted to the pD range below the pK_a (12–14) of the azomethine nitrogen atom (~10–11), and the effect on rate of this factor is expected to decrease above this pD. Base catalysis of β-proton exchange is expected to show an increase in rate with increase in pH. In the pyridoxal system the trends expected in the β-exchange rate constants were not so clearly discernable for the pD range studied since the accuracy of the values of the constants was somewhat limited, and the pD range was too narrow to observe the effect of the diprotonated form of the Schiff bases.

In the pyridoxal phosphate system as well as in other similar systems the following trends are expected: (*a*) if the rates were dependent on the degree of the Schiff base imine nitrogen protonation, the observed trend would be an increase or decrease depending on the relative amounts of protonated and deprotonated species present, as predicted by the pK_a of the imine nitrogen (~11). In the corresponding species distribution curve, the amount of the monoprotonated Schiff base maximizes around pD 8.5–9.0, giving a bell-shaped curve for the relative population of catalytic species. Also (*b*) if the rates were dependent on hydroxide ion catalysis, then the rate would increase with increasing pH. In the α-ABA system the values of the rate constants show a bell-shaped curve with a shallow maximum at pD 7.34. Although this is somewhat lower than the expected maximum it is not much different from the rate constant at pD ~7.97, which is much closer to the pD of the maximum degree of formation of the monoprotonated species. The increasing effect of hydroxide ion catalysis with pH is observed in the lack of a sharp decrease in the rate constants above pD 8.0. The considerable decrease in rate constants observed at pD 4.82 is probably due in part to dissociation of the Schiff base. The homoserine system also shows a bell-shaped rate curve, but with a maximum at pD ~9.0. This system shows the effect of Schiff base protonation and hydroxide ion catalysis more clearly than does the α-ABA Schiff base. Comparison of the values of the rate constants of homoserine and α-ABA indicates the effect, on the exchange rate, of the substituent on the amino acid moiety. The methoxy group has higher electron-withdrawing effect than does the methyl group, weakening the bonding of the β-hydrogen and increasing the exchange rate.

Additional studies of metal-ion catalysis of β-proton exchange and elimination of γ-electronegative substituents are now being carried out in this laboratory.

Ionic dissociation in pyridine–iodine solutions

SEYMOUR ARONSON, STUART BRYAN WILENSKY, TAUN-IUAN YEH, DARNEL DEGRAFF, AND GRACE MARILYN WIEDER

Department of Chemistry, City University of New York, Brooklyn College, Brooklyn, NY, U.S.A. 11210

Received January 28, 1986

SEYMOUR ARONSON, STUART BRYAN WILENSKY, TAUN-IUAN YEH, DARNEL DEGRAFF, and GRACE MARILYN WIEDER. Can. J. Chem. **64**, 2060 (1986).

An electrochemical technique has been employed to study the ionization of the pyridine–iodine complex in pure pyridine and in 1,2-dichloroethane. A mechanism for the ionization in accord with the experimental data is proposed. The results indicate that, for wide ranges of iodine and pyridine concentration, one quarter of the I_2 is dissociated into ionic species.

SEYMOUR ARONSON, STUART BRYAN WILENSKY, TAUN-IUAN YEH, DARNEL DEGRAFF et GRACE MARILYN WIEDER. Can. J. Chem. **64**, 2060 (1986).

Opérant dans la pyridine pure ainsi que dans le dichloro-1,2 éthane, on a utilisé une technique électrochimique pour étudier l'ionisation du complexe pyridine/iode. On propose un mécanisme pour l'ionisation qui est en accord avec les données expérimentales. Les résultats indiquent que, pour des concentrations très variables d'iode et de pyridine, 25% du I_2 est dissocié en espèces ioniques.

[Traduit par la revue]

Introduction

The pyridine–iodine system has been the subject of intensive investigation (1–10). Mulliken (4) suggested the following complexation and ionization sequence for the reaction between pyridine and iodine.

[1] $Py + I_2 = PyI_2$

[2] $PyI_2 = PyI^+I^-$

[3] $PyI^+I^- = PyI^+ + I^-$

Reaction [1], whose product Mulliken called an "outer complex", occurs in both polar and nonpolar solvents. Reaction [2] produces an "inner complex" PyI^+I^-. Reaction [3] takes place only in polar organic solvents (1, 4, 5). One evidence for the ionization process in reaction [3] is the relatively high electrical conductivity observed in pyridine–iodine solutions in polar solvents (1, 5). On the basis of experimental evidence, Mulliken (3) suggested that reactions [1] and [3] reach equilibrium rapidly. He further suggested that reaction [2] involves an activation barrier of considerable height and that equilibrium is approached slowly.

Equilibrium constants for reaction [1] have been determined in a number of solvents (10). Experimental evidence indicates that reaction [2] requires a period of days or weeks for equilibrium to be attained (3, 7). Ionization reactions which yield the I_3^- ion as well as the I^- ion formed in reaction [3] have only been studied at short reaction times during which period reaction [2] has not reached equilibrium. Ionization constants which have been determined (8, 9, 11, 12) are, therefore, of questionable value.

In the present study, an electrochemical technique (12) has been used to investigate the ionization process in the pyridine–iodine complex. Quantitative information has been obtained on solutions of iodine in pyridine and solutions of pyridine and iodine in 1,2-dichloroethane.

Experimental

Chemicals

Fisher certified ACS grade pyridine was allowed to stand over solid potassium hydroxide for several days, then refluxed over calcium hydride for several hours, and then repeatedly distilled from fresh portions of the hydride with a boiling point 115–116°C at 760 Torr. This procedure sufficed to give a highly purified and anhydrous pyridine whose specific conductivity was below 1×10^{-7} (ohm-cm)$^{-1}$. Fisher certified ACS grade 1,2-dichloroethane was dried over calcium hydride for several days, then refluxed over calcium hydride for one day and repeatedly distilled from fresh portions of this hydride. A middle fraction was collected. This gave a pure, anhydrous product with a normal boiling point of 82.9–83.1°C. Fisher laboratory grade resublimed iodine was resublimed twice and kept in a dessicator over anhydrous copper sulfate. Reagent grade sodium iodide and tetraethylammonium iodide, obtained from Alpha Products, were used as received.

Electrochemical, conductivity, and spectrophotometric measurements

The electrochemical measurements were made in a 2-compartment "H" cell in which separation of the compartments was effected by a fine-frit disk. Both compartments were filled to the same level. Pieces of platinum foil attached to platinum wire leads were inserted into each compartment to serve as electrodes. Voltage measurements were made with a Keithley Model 160B digital multimeter. All measurements were made in a constant temperature water bath regulated to 25.0 ± 0.1°C. The platinum electrodes and cells were cleaned by immersion in hot concentrated nitric acid, and then in cleaning solution for several days. The electrodes were then repeatedly rinsed with distilled water and left standing in distilled water for several days.

Conductivity measurements were made using a standard conductivity cell with platinum electrodes and a YSI Model 31 conductivity bridge. The cell constant was determined to be 0.1037 cm^{-1} using a 0.0200 *N* solution of potassium chloride at 25.0°C.

In addition to the electrical measurements, ultraviolet–visible absorption measurements were made with a Cary 17 spectrophotometer using quartz cells of 10 mm and 2 mm thickness.

All solutions of iodine and pyridine were freshly prepared just before the first measurement of a property. Subsequent measurements were then made at intervals of one day, three to four days, one week, two weeks, three weeks, etc., for a total time of one month. All stored solutions were protected by sealing stoppered flasks with Parafilm.

Mathematical treatment

Reaction mechanism

The reaction sequence we will employ utilizes reactions [1] and [2] above as proposed by Mulliken. In place of reaction [3], we employ the following reaction

[4] $2PyI^+I^- = Py_2I^+ + I_3^-$

The ionic species Py_2I^+ and PyI^+ have been postulated and observed (6, 8, 9, 13). We postulate the formation of Py_2I^+

Printed in Canada

because the experimental data presented below will be shown to be independent of pyridine concentration. This observation is in accord with the formation of Py_2I^+, as in reaction [4], but not with the formation of PyI^+. The I_3^- ion rather than the I^- ion is postulated to form because the concentrations of iodine used in this investigation are high enough to favor the stable I_3^- ion (14). Experimental verification for the presence of I_3^- are the very strong absorption bands observed at 365 nm and 295 nm which are the locations of the I_3^- peaks (14, 15).

The equilibrium constant for reaction [4] is

$$[5] \quad K_4 = \frac{[Py_2I^+][I_3^-]}{[PyI^+I^-]^2}$$

We will assume that concentration can be substituted for activity in all the equilibrium expressions. For the autoionization of PyI^+I^- in reaction [4], we can write

$$[6] \quad [Py_2I^+] = [I_3^-] = x$$

An additional assumption we make is that the ratio of pyridine to iodine is sufficiently high (>10:1) so that all the iodine is in complex form, i.e., reaction [1] goes all the way to the right. This assumption is experimentally verified by the absence of an I_2 peak in the visible region of the spectrum.

Using the symbol, b, for the nominal[1] concentration of iodine, we can write

$$[7] \quad b = [PyI_2] + [PyI^+I^-] + 2x$$

From reaction [2], we obtain

$$[8] \quad [PyI_2] = [PyI^+I^-]/K_2$$

Substituting in eq. [7], we get

$$[9] \quad b = (1 + 1/K_2)[PyI^+I^-] + 2x$$

and

$$[10] \quad [PyI^+I^-] = (b - 2x)/(1 + 1/K_2)$$

Substituting in eq. [5], we obtain

$$[11] \quad K_4 = \frac{x^2}{\left(\frac{b - 2x}{1 + 1/K_2}\right)^2}$$

and finally

$$[12] \quad \frac{[Py_2I^+]}{[PyI_2] + [PyI^+I^-]} = \frac{K_2}{K_2 + 1}(K_4)^{1/2} = K$$

Thus, the ratio of the concentrations of charged complex, Py_2I^+, to neutral complexes, PyI_2 and PyI^+I^-, should be independent of the nominal iodine and pyridine concentrations.

Electrochemical equations

We have employed electrochemical cells of the following types

$$[13] \quad Pt|I_2, NaI(c) \text{ in } Py\|I_2, NaI(c') \text{ in } Py|Pt$$

and

$$[14] \quad Pt|I_2, Py, TEAI(c) \text{ in DCE}\|I_2, Py \text{ in DCE}|Pt$$

where TEAI and DCE refer to tetraethylammonium iodide and 1,2-dichloroethane, respectively. The c and c' values represent nominal concentrations. The nominal I_2 and Py concentrations are the same in both half-cells.

We will assume that added NaI or TEAI, represented by the term MI, is completely ionized according to the reactions

$$[15] \quad MI + PyI^+I^- \rightarrow I_3^- + Py + M^+$$

and

$$[16] \quad MI + Py_2I^+ \rightarrow PyI^+I^- + Py + M^+$$

complete ionization of MI appears reasonable on the basis of the known information about the ionization of NaI and TEAI and the stability of I_3^- (11, 14). The species PyI^+I^-, Py_2I^+, and I_3^- rapidly resume thermodynamic equilibrium on the basis of reaction [4]. We assume the following virtual electrode reactions corresponding to Line-diagrams 13 and 14.

$$[17] \quad 3Py(1) + PyI^+I^-(1) - 2e = 2Py_2I^+(1)$$

$$[18] \quad 2Py_2I^+(2) + 2e = 3Py(2) + PyI^+I^-(2)$$

Half-cell 1 in Line-diagram 13 has more NaI than half-cell 2. Half-cell 1 in Line-diagram 14 contains TEAI while half-cell 2 contains no TEAI.

We will make the reasonable assumption that, for small additions of MI, the concentration of PyI^+I^- does not depend significantly on the quantity of added MI. We can then write for the emf, E, of the cell at room temperature

$$[19] \quad E = -0.0591 \log \frac{[Py_2I^+(2)]}{[Py_2I^+(1)]}$$

We have already used the symbol, x, for $[Py_2I^+]$ in a solution without added MI. In the presence of nominal concentration of MI designated as c, the concentration of Py_2I^+ is designated as y. The equilibrium expression corresponding to Line-diagram 14 is

$$[20] \quad y(y + c) = x^2$$

We can solve for x and y using eqs. [19] and [20].

When MI is present in the half-cell on the right in concentration, c', as well as on the left in concentration, c, which corresponds to Line-diagram 13, we can use the equation

$$[21] \quad y(y + c) = y'(y' + c') = x^2$$

y, y', and x can be determined.

The value of x and the nominal concentration of iodine, b, yield the constant K in eq. [12] corresponding to the ratio of the concentrations of charged to neutral complexes.

Results and discussion

The acquisition of equilibrium data for the ionization process in reaction [4] requires that reactions [1], [2], and [4] all be at equilibrium. Reaction [1] reaches equilibrium rapidly (3, 10). On the basis of the electrochemical data presented below, reaction [4] also approaches equilibrium rapidly. The slow approach to equilibrium of reaction [2] is indicated in Fig. 1. In the upper graph, the conductivity of a pyridine–iodine solution in dichloroethane reaches a plateau in about one week. The absorptivity of a pyridine–iodine solution in dichloroethane, shown in the lower graph in Fig. 1 also reaches a plateau in about one week. The explanation for these phenomena is that the concentrations of Py_2I^+ and I_3^- continue to increase until reaction [2] reaches equilibrium. The absorption maximum at 365 nm is primarily due to the presence of the I_3^- ion with a

[1]The nominal concentration of iodine is the number of moles of I_2 dissolved in a litre of solution. The value is not effected by the dissociation and interaction of iodine in solution which yields new iodine species.

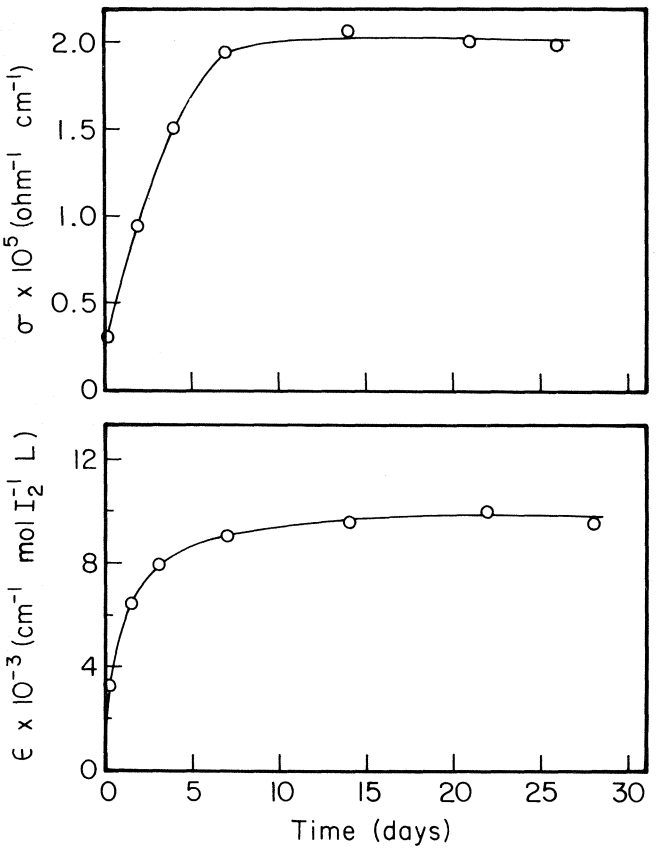

FIG. 1. The upper curve shows the variation of conductivity with time for nominal concentrations of 0.0903 *M* Py and 0.00101 *M* I_2. The lower curve shows the variation of absorptivity at 365 nm with time for nominal concentrations of 0.0496 *M* Py and 0.000492 *M* I_2.

small contribution from the PyI_2 "outer complex" (10). PyI^+I^- does not absorb in this region of the spectrum (4). Conductivity and absorptivity data on samples with other pyridine–iodine concentrations gave similar results.

We used the electrochemical cell, in dichloroethane,

$$\text{Pt}|\text{I}_2\ (2.98 \times 10^{-3}\ M),\ \text{Py}\ (0.297),$$
$$\text{TEAI}\ (3.12 \times 10^{-5}\ M)\|\text{I}_2\ (2.98 \times 10^{-3}\ M),\ \text{Py}\ (0.297\ M)|\text{Pt}$$

to determine the value of x, the concentration of Py_2I^+, as a function of time on the basis of eqs. [19] and [20]. The data obtained, shown in Fig. 2, confirm the approach to equilibrium in about one week.

Electrochemical data were obtained at 25°C for solutions of pyridine and iodine in dichloroethane. The solutions were stored for two weeks prior to measurement. The electrochemical cells used were of the type shown in Line-diagram 14. Data obtained on a typical cell are presented in Table 1. The nominal iodine concentration in both half-cells was 2.00×10^{-3} *M*. One half-cell contained a nominal concentration of TEAI of 2.20×10^{-5} *M*. The emf was measured over a period of 1 h and was found to have a steady value of 1.25 ± 0.05 mV. The TEAI concentration was increased in steps four times and emf measurements were made. The calculated value of x was constant to within experimental error.

Values of the ionization constant, K, in eq. [12], were calculated from electrochemical data on solutions with nominal I_2 concentrations ranging from 2.56×10^{-4} *M* to 2.98×10^{-3} *M*. In each case, the nominal Py concentration was 100 times higher than the nominal I_2 concentration. The values

of x and K are shown in Table 2. For the ten-fold range of iodine and pyridine concentrations, the value of K is reasonably constant, 0.158 ± 0.014.

Solutions of iodine in pure pyridine were also investigated. Spectrophotometric and Py_2I^+ concentration data of the type shown in Figs. 1 and 2 again indicated the attainment of equilibrium in about one week. Electrochemical data were obtained at 25°C for solutions of iodine in pyridine stored for two weeks. The electrochemical cells were of the type shown in Line-diagram 13. Data obtained on a typical cell are shown in Table 3. In this case, NaI was added to both half-cells as indicated by the initial values of c and c'. Additional aliquots

of NaI in pyridine–iodine solution were added in increments to one half-cell. Equal aliquots of pyridine–iodine solution were added in increments to the other side to avoid hydrostatic pressure. The calculated value of x was constant to within experimental error.

Values of the ionization constant, K, were calculated from data on solutions with nominal I_2 concentrations ranging from 0.0411 to 1.26 *M*. A value of K of 0.158 ± 0.008 was obtained for the thirty-fold variation in iodine concentration.

It is interesting that the interaction of iodine with pyridine is the same over wide ranges of iodine concentration in pure pyridine and in solutions in dichloroethane. The difference in dielectric constant between pyridine, 12.3, and dichloroethane, 10.4, is apparently not sufficient to effect the degree of ionization of the pyridine–iodine complexes. In nonpolar solvents such as heptane and benzene, with dielectric constants in the range of 2, no ionization is expected to occur (4).

When the concentration ratio of pyridine to iodine in dichloroethane is close to unity, the behavior of the system is more complex. Uncomplexed I_2 is observed spectrophotometrically and the I_3^- concentration continues to increase for more than 4 weeks.[2] This behavior can be qualitatively explained on the assumption that, in this case, reaction [1] does not proceed all the way to the right.

Received January 10, 1986

MIROSLAW CYGLER, CAROL P. HUBER, JAMES R. P. GODIN, and DAVID J. PHELPS. Can. J. Chem. **64**, 2064 (1986).

The crystal structure of 4-(2,4,6-trimethyl)benzylidene-2-phenyloxazolin-5-one has been determined. Crystals of $C_{19}H_{17}NO_2$, fw 291.35, are monoclinic, $P2_1/c$, a = 10.207(2), b = 8.977(2), c = 17.123(4) Å, β = 92.66(1)°. For 2435 observed independent reflections the final R = 0.039 and R_w = 0.042. The molecule has Z configuration about the exocyclic double bond, and the benzylidene ring is twisted 61.3° out of the oxazoline ring plane, thus relieving the overcrowding caused by the two *ortho*-methyl substituents. The reaction of this compound with benzylamine in acetonitrile occurs almost four times as fast as predicted using model reactions.

MIROSLAW CYGLER, CAROL P. HUBER, JAMES R. P. GODIN et DAVID J. PHELPS. Can. J. Chem. **64**, 2064 (1986).

On a déterminé la structure cristalline de la triméthyl-2,4,6 benzylidène-4 phényl-2 oxazolinone-5. Les cristaux de $C_{19}H_{17}NO_2$, m.f. 291.35, sont monocliniques, $P2_1/c$, avec a = 10,207(2), b = 8,977(2) et c = 17,123(4) Å et β = 92,66(1)°. En se basant sur 2435 réflexions indépendantes observées, les valeurs finales de R et R_w sont respectivement de 0,039 et 0,042. La molécule adopte une configuration Z autour de la double liaison exocyclique et le cycle benzylidène forme un angle de 61,3° avec le plan du cycle oxazoline; cette déviation élimine l'encombrement stérique causé par les deux substituants méthyles en positions *ortho*. La vitesse de la réaction de ce composé avec la benzylamine dans l'acétonitrile est pratiquement quatre fois plus rapide que celle qui pourrait être prédite en utilisant des réactions modèles.

[Traduit par la revue]

Introduction

The 4-benzylidene-2-phenyloxazolin-5-one molecule (**1**) and its substituted analogues[3] can exist in two configurations, *E* and *Z*, about the exocyclic double bond. In the cases studied to date (1–5) the Plöchl azlactone synthesis (6), or modifications of it (7) used in the synthesis of oxazolinones, gave the *Z* isomer, obviously the more thermodynamically stable form. It is, however, possible to effect *Z* to *E* isomerization (8). Infrared, Raman, and absorption spectra of the two isomers are quite similar (4), but more fine structure has been noted (1, 4) in the absorption spectrum of the *Z* isomer. A study of fifteen methyl- and dimethyloxazolinones, all in the *Z* form (7), found no significant changes in absorption maximum, extinction coefficient, or fine structure over the series, even for the relatively hindered di-*ortho* derivative, **2**. But in the reaction of benzylamine with *ortho*-substituted oxazolinones, a quantitative effect is exerted by *ortho* substituents (9). *Ortho* substitution in the benzylidene ring, e.g. **3**, leads to acceleration of the ring-opening reaction by a factor of ca. 2, while *ortho* substitution in the phenyl ring, e.g. **4**, retards the reaction by a factor of ca. 2. A possible explanation for this is that steric strain is released if **3** is ring-opened, whereas **4** presents steric hindrance to the approach of the nucleophile. In order to investigate further the effects of *ortho* substitution on the absorption spectra and reactivity of oxazolinones, compounds **5**–**7** were synthesized. In this paper, the physical properties and reactivity of **5**–**7** and the crystal structure of **5**, 4-(2,4,6-trimethyl)benzylidene-2-phenyloxazolin-5-one, will be discussed.

Experimental

All oxazolinones were synthesized by a previously described method (7). Kinetic studies of the reaction with benzylamine were carried out as before (9). Compounds **5**, **6**, and **7** were prepared for the first time for this study. Their physical properties are reported in Table 1. Yields are based on recrystallized (ethanol/water), analytically pure material. Melting points are uncorrected. Elemental analyses were performed by Mr. Hector Seguin, NRCC.

Crystals of **5** were obtained from 95% ethanol as yellow prisms. The specimen used for data collection had maximum dimensions 0.30 × 0.35 × 0.25 mm. Crystal data are as follows:

$C_{19}H_{17}NO_2$ fw = 291.35

Monoclinic, $P2_1/c$, a = 10.207(2), b = 8.977(2), c = 17.123(4) Å, β = 92.66(1)°, V = 1567.3 Å^3, (based on λ(Cu Kα_1) = 1.54056 Å), Z = 4, D_x = 1.235 Mg m^{-3}, μ(Cu) = 0.65 mm^{-1}, F(000) = 616, T = 293 K.

Measurements were made on a CAD-4 diffractometer. The cell dimensions were determined from the angular settings of 22 carefully centered reflections with 45° < θ < 58°. Relative intensities were measured using $\omega/2\theta$ scans for ω ranges of 1.50 (0.85 + 0.20 tan θ) at scan speeds of 0.65–5.0°/min in ω. All 3219 independent reflections in the hkl and $\bar{h}kl$ octants with θ = 0–75° were recorded, and 2435 of these were considered observed at the 1.0$\sigma(I)$ level. The others were assigned zero weights during least-squares refinement. Three standard reflections were monitored after every 6000 s exposure time. Their intensities showed only minor fluctuations, within ±2% of their respective means. Lorentz and polarization corrections were applied, and a correction for secondary extinction ($g/\mu = 0.185 \times 10^{-6}$) was made during the refinement stage. Absorption corrections were considered unnecessary because of the small value of μR and the nearly equidimensional specimen.

The structure was solved by direct methods, using the MULTAN 78 program (10). Refinement was by block-diagonal least-squares calculations, minimizing $\Sigma w(\Delta F)^2$. All hydrogen atoms were located on a difference map, and were refined isotropically while non-hydrogen atoms were refined anisotropically. The weighting scheme was of the form $w = P_1/|F_o|$ if $|F_o| > P_1$, and $w = 1$ otherwise, with P_1 = 25.0 e. Scattering factor values for O, N, C, and H were taken from International tables for X-ray crystallography (11). Convergence was attained at R = 0.039, R_w = 0.042 (for all observed reflections). During the final cycle of refinement the mean (shift/esd) was 0.057 and $(\Delta/\sigma)_{max}$ was 0.27. A difference map was calculated from the

final structure factors[4] and showed no residual density outside the limits −0.12 to 0.12 e Å^{-3}. Computer programs of Ahmed *et al.* (12), Main *et al.* (10), and Johnson (13) were used.

Results and discussion

Final coordinates for the non-hydrogen atoms obtained from the X-ray analysis are listed in Table 2. A perspective view of the molecule with the numbering scheme used in this analysis is shown in Fig. 1 and bond distances and angles are given in Fig. 2. The X-ray analysis has established that the molecule has the *Z* configuration, with C(8) *cis* to N(3).

Comparison of the bond lengths found here with those in a closely-related dinitro oxazolinone, **8** (3), suggests that there is less conjugation in the present compound. Bonds C(2)—N(3) and C(4)—C(7) are slightly shorter and N(3)—C(4) and C(7)—C(8) slightly longer here. While the individual differences are not significant, the overall pattern is consistent with the fact that the trisubstituted benzylidene ring is twisted 61.3° out of the oxazoline ring plane, whereas in the dinitro compound the rings are approximately coplanar. The large twist in the present compound avoids too-close contact of C(14) and N(3), here 3.180(2) Å, and of C(16) and H(7), 2.81(2) Å.

Each of the three rings separately is planar within ±0.011 Å, although the deviations from planarity are statistically significant for each ring. Substituents on the rings show displacements from the mean planes of up to 0.089(2) Å; interestingly, the two *ortho*-methyl carbon atoms do not show the largest deviations. The unsubstituted phenyl ring is twisted 15.0° out of the plane of the oxazoline ring. Agreement of the bond angles in this structure with those in the dinitro compound is very good, especially for the oxazolinone system. Few other crystal structures containing an oxazolin-5-one group have been reported (14–17), and because they each show important differences in the immediately adjacent bonding, detailed comparisons would be meaningless.

The packing arrangement is shown in Fig. 3. The pair of

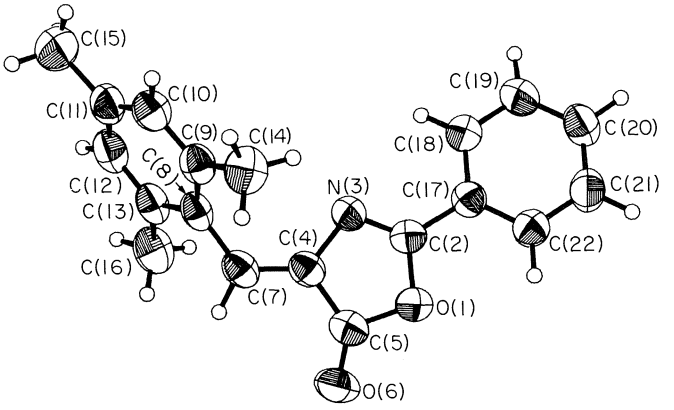

FIG. 1. A perspective view of the molecule showing the numbering scheme. Hydrogen atoms are shown as spheres of 0.1 Å radius, while the anisotropic ellipsoids enclose 50% probability.

lactone groups related by the centre of symmetry at $\frac{1}{2}$, $\frac{1}{2}$, 0 show C···C and C···O contacts of about 3.3 Å; however, stacking of the oxazoline rings is only marginal. A distance of about 5.6 Å along *b* separates such pairs of lactone groups. The pair of head-to-tail trimethylbenzene groups related by a centre of symmetry at 0, $\frac{1}{2}$, 0 show a ring spacing of about 3.64 Å. Overlap is at the C(8) end of the rings, such that the C(8)—C(7) bond of one molecule is superimposed on the benzene ring of the other molecule, and there is considerable overlap of the C(14)—C(9), C(9)—C(8), C(8)—C(13), C(13)—C(16) bonds of one molecule with the opposite sequence of bonds in the other molecule.

The absorption spectra of **5**, **6**, and **7** are shown in Fig. 4. The absorption maximum is shifted significantly for **5**, while its extinction coefficient is less by a factor of ca. 2, and no fine structure can be seen in its spectrum. Such fine structure *is* evident in the spectra of **6** and **7** and in other published examples (4, 5).

Second order rate constants for the reaction of benzylamine with compounds **5**–**7** are reported in Table 3. Each is an average of three determinations. For comparison, and to obtain "calculated" rate constants for **5**, **6**, and **7**, data for **1**-Z, **3**, 4-(3-methyl)benzylidene-2-phenyloxazolin-5-one, and 4-(4-

methyl substituent allows an estimate of the rate constants for compounds **5**, **6**, and **7**. From Table 3 the experimentally obtained values for **6** and **7** are in reasonable agreement with the calculated values while the respective rate constants for **5** are very different.

Compound **5** differs from the two isomeric dimethylated oxazolinones **6** and **7** in four major regards: (*1*) There is no fine structure in the absorption spectrum of **5** while there is such structure in other alkyl- or unsubstituted *Z*-oxazolinones (4, 7, Fig. 4). (*2*) The λ_{max} value of **5** is about 30 nm lower than those of **6** and **7**. (*3*) The molar extinction coefficient is reduced about two-fold for **5**. (*4*) The reaction of **5** with benzylamine in acetonitrile occurs about four times as fast as predicted using model reactions.

The lack of fine structure might be consistent with an isomerization of the usual *Z* isomer to the *E* form. The other points, however, are consistent with a lack of resonance between π electrons of the benzylidene ring and the remainder of the 2-phenyloxazolin-5-one structure. The finding that the benzylidene ring conformation is greatly removed from co-planarity with the oxazolinone portion satisfactorily explains the absorption spectrum and the reduced inductive effect of the methyl groups in **5**. An earlier study of oxazolinone ring opening by benzylamine concluded that *o*-substitution in the 4-benzylidene ring actually enhanced reactivity, probably by release of strain upon ring opening (9). In the present case, due to non-planarity, this argument need not be called upon. It is interesting, and yet another indication that the *Z* isomer is the preferred form, that the di-*ortho*-substituted compound **5** takes up this configuration.

Synthesis of 9- and 10-membered rings by the intramolecular Michael addition of malonate on enone and ynone

PIERRE DESLONGCHAMPS AND BERNARD L. ROY[1]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 29, 1986

PIERRE DESLONGCHAMPS and BERNARD L. ROY. Can. J. Chem. **64**, 2068 (1986).

The base-catalyzed (Cs_2CO_3 in THF/DMF) intramolecular Michael addition of β-ketoester-ynones **7**–**10** and -enone **11** is reported. Macrocyclization (Table 1), which produces the corresponding medium rings, was observed in 25–50% yield.

PIERRE DESLONGCHAMPS et BERNARD L. ROY. Can. J. Chem. **64**, 2068 (1986).

On rapporte l'addition Michael intramoléculaire baso-catalysée (Cs_2CO_3, THF/DMF) des β-cétoesters-ynones **7**–**10** et -énone **11**. La réaction conduit aux cycles moyens correspondants avec des rendements de 25–50% (Tableau 1).

The study of medium and large carbocyclic rings containing several substituents and functional groups has not yet received much attention (1) and one of the main reasons is the lack of direct reliable synthetic methods. Our laboratory has recently reported (2) that 10-membered rings were accessible by using a simple irreversible process, i.e., the SN_2 displacement of a leaving group by malonate anion under medium diluted conditions. The success of this approach relied upon the choice of aliphatic precursors that have two unsaturations (*cis* and *trans* double or triple bonds) in the chain. These unsaturations eliminate most of the transannular steric interactions and diminish, at the same time, the number of degrees of freedom in the chain. More recently, we have also shown that 11-, 12-, 13-, and 14-membered rings can also be successfully constructed by this approach, and in very good yield (13).

In principle, any factor that will appropriately restrict the conformational mobility of a chain and lower transannular steric interactions should favor macrocyclization reaction. For instance, conjugation between sp_2 type functional groups and use of reactions that have a high degree of stereochemical control at the transition state level should promote these cyclizations. For these reasons, the internal Michael reaction of a nucleophile on enone and ynone appears to be an attractive route, because stereoelectronic effects predict a high degree of conformational restriction at the transition state level in the first step of these reactions (4). Indeed, it is expected that the intramolecular addition of a nucleophile on enone **1** and ynone **4** (Scheme 1) will produce an enolate intermediate having a structure and conformation close to **2** and **5** respectively, which by protonation will then lead to the reaction products, i.e., the cyclic ketone **3** and conjugated ketone **6**. Our previous studies (2, 3) indicated that two unsaturations in the chain are necessary for a successful macrocyclization; it was therefore planned to study the cyclization of enone and ynone of types **1** and **4**, which possess a second unsaturation site in the chain. Following this idea, we wish to report a study on the cyclization of ynones **7**–**10** and enone **11** (Scheme 2). Compound **7** can theoretically give a nine-membered ring while the others can lead to a ten-membered ring.

Results and discussion

Compounds **7**–**11** were prepared following standard procedures of known reactions. The synthesis of compound **7** is illustrated in Scheme 3, and syntheses of compounds **8**–**11** are shown in Scheme 4. Both schemes are self-explanatory. One element that is worth mentioning is the temporary transformation of the malonate group into a triester (cf. **18** → **19** and **25** → **26**) and, at a later stage, the reconversion of the triester into the malonate group (**20** → **21**, **28** → **29**, **28** → **30**, **32** → **33**, **32** → **34**) by reactions with organometallic reagents (5).

The cyclization of the acyclic precursors **7**–**11** was carried out with cesium carbonate in a 1:1 mixture of tetrahydrofuran and *N*,*N*-dimethylformamide at room temperature. The results are summarized in Table 1 and the structure of the cyclic monomers and (or) dimers obtained are shown in Scheme 5. The cyclizations were carried out at 2×10^{-3} *M*. In some cases, a pseudo high dilution technique (slow addition of the substrate in the medium with a syringe pump (6, 7)) was used to increase the quantity of cyclic monomer and (or) dimer.

The structures of the monomers and dimers were established spectroscopically (ir, ^1H and ^{13}C nmr, and ms). The configuration of the olefin of the conjugated enones was assigned *cis* for the monomers **35**, **36**, and **38** and *trans* for the dimer **39**. This assignment is based on the coupling constant ($J_{H,H}$(*cis*) ≅ 13 Hz and $J_{H,H}$(*trans*) ≅ 17 Hz) observed for the olefinic hydrogens of the enone.

Compound **37** with an exocyclic olefin must be formed via the isomerization of conjugated enone **42** under basic conditions. Such deconjugation of a 10-membered ring enone has literature precedent (8). The structure of enone **38** was further established by its conversion into bicyclic dienone **43** under acidic conditions. This type of transannular reaction between a ketone and an acetylene in a 10-membered ring yielding a bicyclic enone has been previously observed by Weiler and co-workers (9).

The aliphatic precursors **7**, **8**, and **9**, which contain a *cis* olefin, gave the corresponding cyclic monomers **35**, **36**, and **37** respectively in moderate yield, but no dimer was observed. Cyclization of enone **10**, which contains an isolated triple bond, gave a mixture of monomer **38** and dimer **39** at medium dilution, and only monomer **38**, in 50% yield, at pseudo high dilution. The enone **11** gave at medium dilution a low yield of dimer **41** and no monomer. At pseudo high dilution, both monomer **40** and dimer **41** were observed.

Nine and ten-membered rings are the most difficult ones to be produced by a direct cyclization method. For instance, the internal displacement of bromide by malonate anion in C-9 and C-10 saturated chains gave the corresponding cyclic monomer under high dilution in 3 and 0.1% yield respectively (10). It can therefore be concluded that, although the yields are moderate

(25–50%), the intramolecular addition of malonate on enone and ynone is an interesting method to produce medium rings directly. This synthetic strategy may eventually lead to excellent yield (≥80%) in macrocyclization provided that transannular steric interactions and conformational mobility can be further decreased. Work in this direction is in progress in our laboratory.

Experimental

The infrared (ir) spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nmr spectra were recorded on a Bruker WP-60, WP-80, or a Bruker WM-250 instrument. Carbon-13 nmr spectra were recorded on a Bruker WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; t, triplet; q, quadruplet; m, multiplet; b, broad. Deuterated chloroform was used as the solvent and internal standard unless indicated otherwise. The mass spectra (ms) were recorded on a VG Micromass ZAB-1F mass spectrometer.

Reactions were carried out under argon. Anhydrous magnesium sulfate was used as the drying agent in work-up of reactions.

Dioloxane ***14***

n-Butyllithium (3.7 mL of 1.7 *M* in hexane, 6.3 mmol) was added to a solution of acetylene **13** (850 mg, 6.1 mmol) in dimethoxyethane (10 mL) at −78°C. The solution was stirred for 15 min, after which hexamethylphosphoramide (3 mL) was added. The mixture was stirred at −78°C for an additional 5 min, then warmed to 0°C. The bromide **12** (1.0 g, 5.52 mmol) was then added, the mixture was stirred at 0°C for 1 h, and the reaction was quenched with a saturated solution of ammonium chloride (4 mL). The resulting mixture was extracted with ether–hexane ((1:1, 3 × 50 mL). The organic layer was washed with a solution of lithium chloride (10% weight/vol, 2 × 100 mL) and the solvent was evaporated. The residue was purified by flash chromatog-

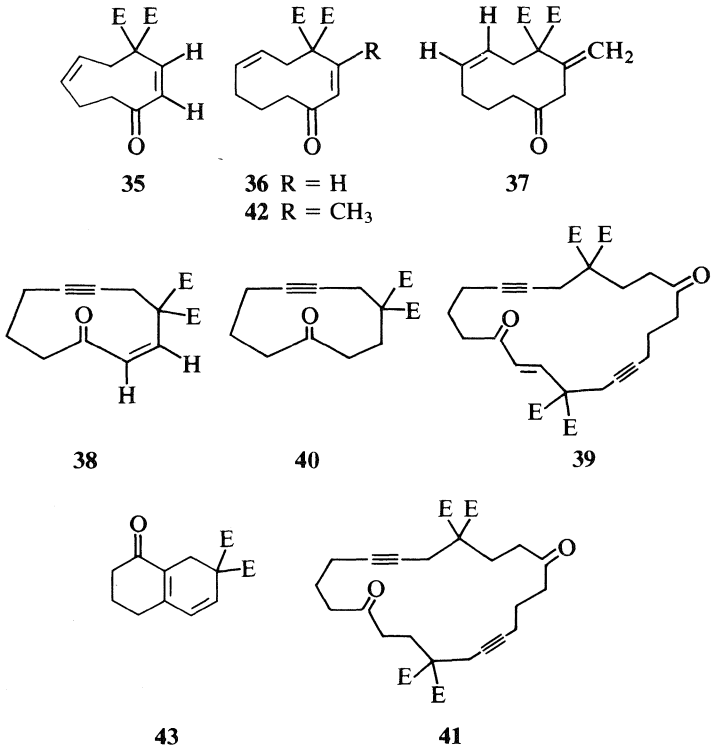

SCHEME 5

benzene (1 mL) and quinoline (50 μL). The mixture was shaken under a hydrogen atmosphere until all uptake of hydrogen had ceased. The mixture was then filtered on Celite and the solution was washed with a solution of hydrochloric acid (10 mL, 1 *N*). The organic layer was dried and evaporated, affording pure olefin diester **18** (558 mg, 99%); ir: 1740 (C=O); nmr δ: 5.37 (2H, m, —*H*C=C*H*—), 4.76 (1H, t, *J* = 4.5 Hz, CH of the dioxolane), 3.83 (2H, s, —CH_2O—), 3.80 (2H, s, —CH_2O—), 3.64 (6H, s, 2 × —COOCH_3), 3.31 (1H, t, *J* = 6.9 Hz, —C*H*—(COOCH_3)$_2$), 2.60 (2H, m, —CH=CH—CH_2—CH—), 2.06 (2H, m, —CH_2—CH=CH—), 1.68 (2H, m, —CH_2—CH_2—CH=CH—); ms *m/e*: 272 (M^+), 241 ($M^+ - OCH_3$).

*Triester **19***

Sodium hydride (90 mg, 3.73 mmol) was added to a solution of olefin diester **18** (562 mg, 2.07 mmol) in tetrahydrofuran (1.6 mL) at 0°C. The solution was stirred at room temperature for 45 min, methyl chloroformate (293 mg, 3.10 mmol) was then added, and the solution was stirred for one extra hour. A saturated solution of ammonium chloride (5 mL) was then added to the cooled solution (0°C). The mixture was extracted with ether (3 × 20 mL), and the organic layer was dried and evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (2:1) as the eluent to afford pure triester **19** (600 mg, 88%); ir: 1740 (C=O); nmr δ: 5.52 (2H, m, —C*H*=C*H*—), 4.85 (1H, t, *J* = 4.5 Hz, CH of the dioxolane), 3.91 (2H, s, —CH_2O—), 3.89 (2H, s, —CH_2O—), 3.76 (9H, s, 3 × —COOCH_3), 2.90 (2H, d, *J* = 4.9 Hz, —CH_2—C—(COOCH_3)$_3$), 2.12 (2H, m, —CH_2—CH=CH—), 1.67 (2H, m, —CH_2—CH_2—CH=CH—).

*Aldehyde triester **20***

To a solution of ketal **19** (322 mg, 0.976 mmol) in acetone (10 mL) was added water (20 μL) and *p*-toluenesulfonic acid (50 mg). The solution was refluxed for 48 h, after which the acetone was evaporated and the residue was taken up in methylene chloride (20 mL). The solution was then washed with a saturated solution of sodium bicarbonate (10 mL), the organic layer was dried, and the solvent was evaporated to afford pure aldehyde **20** (230 mg, 83%); ir: 1730 (C=O); nmr δ: 9.75 (1H, bs, *H*C=O), 5.50 (2H, m, —C*H*=C*H*—), 3.75 (9H, s, 3 × —COOCH_3), 2.90 (2H, d, *J* = 5.0 Hz, —CH_2—C—(COOCH_3)$_3$), 2.40 (2H, m, —CH_2—CH_2—CH=CH—), 2.12 (2H, m, —CH_2—CH=CH—).

Ethynylmagnesium bromide

Ethyl bromide (1.27 g, 11.6 mmol) was added in 100-μL portions to a suspension of magnesium (310 mg, 12.8 at.-g) in tetrahydrofuran (12 mL). The internal temperature was monitored to maintain a maximum of 45°C. After the addition of ethyl bromide was completed the solution was stirred at room temperature for 20 min. Acetylene was purified by flowing the gas through two cold traps (−78°C), concentrated sulfuric acid, and potassium hydroxide and copper sulfate. The purified acetylene was then bubbled into the ethyl magnesium bromide solution at such a rate as to maintain a maximum internal temperature of 36°C. After the exothermic reactions had subsided, the acetylene was bubbled another 5 min. The solution was used as such.

*Alcohol diester **21***

Ethynylmagnesium bromide (2.58 mL of a 0.95 *M* solution in tetrahydrofuran, 2.45 mmol) was added to a solution of aldehyde triester **20** (139 mg, 0.49 mmol) in tetrahydrofuran (3 mL) maintained at −35°C. The solution was stirred at −35°C for an additional 30 min and then quenched with a saturated solution of ammonium chloride (10 mL). The mixture was extracted with ether (3 × 30 mL), the organic layer was dried, and the solvent was evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (2:1) as the eluent to afford pure alcohol diester **21** (43 mg, 34%); ir: 3610, 3480 (OH), 3310 (—C≡C—H), 1730 (C=O); nmr δ: 5.45 (2H, m, —C*H*=C*H*), 4.37 (1H, m, —C*H*OH), 3.74 (6H, s, 2 × —COOCH_3), 3.42 (1H, t, *J* = 7.4 Hz, —C*H*—(COOCH_3)$_2$), 2.45 (1H, d, *J* = 2.1 Hz, —C≡C—*H*), 2.68 (2H, m, —CH_2—CH—(COOCH_3)$_2$), 2.20 (3H, m, —CH$_2$—CH_2—CH=CH—, O*H*), 1.82 (2H, m, —CH_2—CH$_2$—CH=CH—); ms *m/e*: 255 (MH^+), *m/e*: 237 (M^+ − OH), and *m/e*: 223 ($M^+ - OCH_3$).

*Ynone **7***

To a solution of alcohol diester **21** (14.7 mg, 0.057 mmol) in acetone (2 mL) was added dropwise a solution of Jones reagent until persistence of a reddish colour. Ethanol (3 mL) was then added to the solution, which was thereafter neutralized with solid sodium bicarbonate, filtered, and the solvent evaporated. The residue was taken up in a saturated solution of sodium bicarbonate (3 mL) and the mixture was extracted with ether (3 × 20 mL). The organic layer was then washed with brine (30 mL), dried, and the solvent evaporated to afford pure ynone **7** (14 mg, 95%); ir: 3310 (C≡CH), 2110 (C≡C), 1730 (C=O, ester), 1680 (C=O, ynone); nmr δ: 5.41 (2H, m, —C*H*=C*H*—), 3.74 (6H, s, 2 × —COOCH_3), 3.41 (1H, t, *J* = 7.1 Hz, —C*H*—(COOCH_3)$_2$), 3.22 (1H, s, C≡C—*H*), 2.75–2.40 (6H, m, 3 × CH$_2$); ms *m/e* 253 (MH^+) and *m/e*: 221 ($M^+ - OCH_3$).

*Monomer **35***

Cesium carbonate was added to a solution of ynone **7** (7.5 mg, 0.030 mmol) in tetrahydrofuran (11 mL) and *N*,*N*-dimethylformamide (4 mL). The solution was stirred for 48 h at room temperature. The solution was then filtered, and the solvents were removed by distillation under reduced pressure. The residue was purified on a small column of silica gel with hexane – ethyl acetate (3:1) as the eluent to afford pure monomer **35** (2.6 mg, 35%); ir: 1735 (C=O, ester), 1690 (C=O, enone), 1650 (C=C); nmr δ: 6.36 (1H, d, J_{AB} = 15 Hz, —C*H*=CH—C(O)—), 6.09 (1H, d, J_{AB} = 15 Hz, —CH=C*H*—C(O)—), 5.36 (2H, m, —C*H*=C*H*—), 3.79 (6H, s, 2 × —COOCH_3), 2.90 (2H, d, *J* = 8.6 Hz, —CH_2—C—(COOCH_3)$_2$), 2.45 (2H, s, —CH_2—), 2.41 (2H, s, —CH_2—); ms *m/e*: 252 (M^+), *m/e*: 224 (M^+ − C=O), *m/e*: 221 ($M^+ - OCH_3$). *Exact Mass* calcd. for $C_{13}H_{16}O_5$: 252.0998; found: 252.0993.

*Alcohol **23***

A solution of ketal acetylene **22** (10 g, 59 mmol) and triphenylmethane (25 mg) in tetrahydrofuran (125 mL) and ether (125 mL) was treated with *n*-butyllithium (44 mL of 1.6 *M* in hexane, 70 mmol) at

−30°C. The reddish solution was then treated with dry paraformaldehyde (6.2 g, 206 mmol), warmed to room temperature (the reddish colour disappeared), and stirred for 16 h. Water (250 mL) was then added and the layers were separated. The aqueous layer was extracted with water (3 × 250 mL). The combined organic layers were dried and evaporated. The residue was then purified by flash chromatography with hexane – ethyl acetate (3:1) as the eluent to afford pure alcohol **23** (5.4 g, 46%); ir: 3610, 3450 (OH); nmr δ: 4.67 (1H, q, J = 5.1 Hz, CH of the ketal), 4.21 (2H, s, —C≡C—CH_2O—), 3.53 (4H, m, 2 × —CH_2O—), 2.23 (3H, m, —CH_2—C≡C—, OH), 1.67 (4H, m, —CH_2—CH_2—), 1.28 (3H, d, J = 5.3 Hz, CH_3—CH—), 1.18 (3H, t, J = 7.0 Hz, CH_3—CH$_2$—); ms m/e: 199 (M^+ − H), m/e: 183 (M^+ − OH). *Exact Mass* calcd. for $C_{11}H_{20}O_3$: 199.1334; found: 199.1331.

Chloride ***24***

To a solution of alcohol **23** (11 g, 55 mmol), lithium chloride (4.66 g, 110 mmol), and s-collidine (10.6 g, 88 mmol) in *N,N*-dimethylformamide (600 mL) maintained at 0°C was added mesyl chloride (9.4 g, 82 mmol). The solution was stirred for 20 min at 0°C, warmed to room temperature, and stirred for an additional 3 h. A saturated solution of sodium bicarbonate (600 mL) was then added and the mixture was extracted with ether–hexane ((1:1), 3 × 500 mL). The organic layer was dried and evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (4:1) to afford pure chloride **24** (10.4 g, 87%); ir: 2240 (C≡C); nmr δ: 4.53 (1H, q, J = 5.1 Hz, CH of the ketal), 4.14 (2H, t, J = 2.3 Hz, —C≡C—CH_2Cl), 3.54 (4H, m, 2 × —CH_2O—), 2.27 (2H, m, —CH_2—C≡C—), 1.63 (4H, m, —CH_2—CH_2—), 1.30 (3H, d, J = 5.3 Hz, CH_3—CH—), 1.20 (3H, t, J = 6.9 Hz, CH_3—CH$_2$—); ms m/e: 203, 205 (M^+ − OCH_3). *Exact Mass* calcd. for $C_{11}H_{19}O_2Cl$: 203.0838; found: 203.0832.

Diester ***25***

A solution of chloride **24** (217 mg, 1.0 mmol), dimethylmalonate (661 mg, 5.0 mmol), and potassium carbonate (690 mg, 5.0 mmol) in tetrahydrofuran (5 mL) and *N,N*-dimethylformamide (5 mL) was refluxed for 18 h. The mixture was then cooled to room temperature, filtered, and the solvents were removed under reduced pressure. The residue was purified by flash chromatography with hexane – ethyl acetate (3:1) as the eluent to afford pure diester **25** (310 mg, 99%); ir: 1740 (C=O); nmr δ: 4.66 (1H, q, J = 5.3 Hz, CH of the ketal), 3.75 (6H, s, 2 × —COOCH_3), 3.53 (5H, m, 2 × —CH_2O—, —CH—(CO_2CH_3)$_2$), 2.73 (2H, d of t, J = 7.8 Hz, 2.3 Hz, —CH_2—CH—(CO_2CH_3)$_2$), 2.13 (2H, m, —CH_2—C≡C—), 1.62 (4H, m, —CH_2—CH_2—), 1.29 (3H, d, J = 5.1 Hz, CH_3—CH—), 1.19 (3H, t, J = 7.0 Hz, CH_3—CH$_2$—); ms m/e: 299 (M^+ − CH_3), m/e: 269 (M^+ − OCH_2CH_3). *Exact Mass* calcd. for $C_{16}H_{26}O_6$: 299.1494; found: 299.1494.

Triester ***26***

Sodium hydride (96.6 mg, 4.0 mmol) was added to a solution of diester **25** (812 mg, 2.6 mmol) in tetrahydrofuran (2.0 mL) at 0°C. The solution was stirred at room temperature for 1 h, methyl chloroformate (368 mg, 3.9 mmol) was then added, and the solution was stirred for an extra hour. A saturated solution of ammonium chloride (10 mL) was then added to the cooled solution (0°C). The mixture was extracted with ether (3 × 20 mL), and the organic layer was dried and evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (3:1) as the eluent to afford pure triester **26** (962 mg, 99%); ir: 2300 (C≡C), 1745 (C=O); nmr δ: 4.65 (1H, q, J = 5.3 Hz, CH of the ketal), 3.80 (9H, s, 3 × —COOCH_3), 3.52 (4H, m, 2 × —CH_2O—), 2.97 (2H, t, J = 2.5 Hz, —CH_2—($COOCH_3$)$_3$), 2.15 (2H, m, —CH_2—C≡C—), 1.62 (4H, m, —CH_2—CH_2—), 1.31 (3H, d, J = 5.3 Hz, CH_3—CH—), 1.18 (3H, t, J = 6.9 Hz, CH_3—CH$_2$—).

Alcohol triester ***27***

Trifluoroacetic acid (2 drops) was added to a solution of triester **26** (962 mg, 2.6 mmol) in methanol (8 mL). The solution was stirred at room temperature for 2.5 h. The methanol was evaporated and the residue was taken up in methylene chloride (5 mL), which was then evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (1:1) as the eluent to afford pure alcohol triester **27** (769 mg, 99%); ir: 3610, 3560 (OH), 1745 (C=O); nmr δ: 3.81 (9H, s, 3 × —COOCH_3), 3.64 (2H, m, —CH_3OH), 2.98 (2H, t, J = 2.7 Hz, —CH_2—C—($COOCH_3$)$_3$), 2.28 (3H, m, —CH_2—C≡C—, —OH), 1.53 (4H, m, —CH_2—CH_2); ms m/e: 301 (MH^+), m/e: 283 (M^+ − OH), and m/e: 269 (M^+ − OCH_3). *Exact Mass* calcd. for $C_{14}H_{20}O_7$: 283.1181; found: 283.1181.

Aldehyde triester ***28***

Pyridinium chlorochromate (453 mg, 2.1 mmol) was added to a solution of alcohol **27** (208 mg, 0.70 mmol) in methylene chloride (5 mL) containing crushed 3 Å molecular sieves (400 mg). The solution was stirred for 10 min at room temperature, and ether (20 mL) was then added to precipitate the chromium salts. The solution was then filtered on silica gel with ether as the eluent. The solvents were evaporated to afford pure aldehyde **28** (175 mg, 85%); ir: 2840, 2720 (CHO), 1740 (C=O); nmr δ: 9.76 (1H, t, J = 2.0 Hz, HC=O), 3.78 (9H, s, 3 × —COOCH_3), 2.96 (2H, t, J = 2.5 Hz, —CH_2—C—($COOCH_3$)$_3$), 2.55 (2H, t, J = 6.7 Hz, —CH_2—CHO), 2.20 (2H, d of t, J = 7.0 Hz, 2.5 Hz, —CH_2—C≡C—), 1.80 (2H, bq, J = 6.7 Hz, —CH$_2$—CH_2—CH$_2$—).

Alcohol diester ***29***

Alcohol diester **29** was prepared in the same manner as alcohol diester **20**, from aldehyde **28** (96 mg, 0.32 mmol), to afford after purification pure alcohol **29** (50 mg, 59%); ir: 3600, 3520 (OH), 3310 (C≡CH), 1740 (C=O); nmr δ: 4.40 (1H, m, —CH≡C—CHOH—), 3.68 (6H, s, 2 × —COOCH_3), 3.43 (1H, t, J = 7.2 Hz, —CH—($COOCH_3$)$_2$), 2.72 (2H, d of t, J = 7.0 Hz, 1.9 Hz, —CH_2—CH—($COOCH_3$)$_2$), 2.45 (1H, d, J = 2.1 Hz, —C≡CH), 2.17 (2H, m, —CH_2—C≡C—), 1.73 (4H, m, —CH_2—CH_2—).

Ynone ***10***

Pyridinium chlorochromate (215 mg, 1.0 mmol) was added to a solution of alcohol **29** (67 mg, 0.25 mmol) in methylene chloride (5 mL) containing crushed 3 Å molecular sieves (125 mg). The solution was stirred for 60 min at room temperature, and ether (10 mL) was then added to precipitate the chromium salts. The solution was then filtered on silica gel with ether as the eluent. The solvents were evaporated to afford pure ynone **10** (59 mg, 89%); ir: 3295 (C≡CH), 2100 (C≡C), 1740 (C=O, ester), 1685 (C=O, ynone); nmr δ: 3.74 (6H, s, 2 × —COOCH_3), 3.43 (1H, t, J = 7.2 Hz, —CH—($COOCH_3$)$_2$), 3.24 (1H, s, —C≡C—H), 2.73 (2H, d of t, J = 6.6 Hz, 2.0 Hz, —CH_2—CH(CO_2CH_3)$_2$), 2.57 (2H, t, J = 5.0 Hz, —CH_2—C(O)—C≡C—H), 2.11 (2H, m, —CH_2—C≡C—), 1.77 (2H, m, —CH$_2$—CH_2—CH$_2$—); ms m/e: 264 (M^+), m/e: 265 (MH^+), and m/e: 233 (M^+ − OCH_3). *Exact Mass* calcd. for $C_{14}H_{16}O_5$: 264.0998; found: 264.0991.

Monomer ***38*** *and dimer* ***39****:* direct cyclization

Cyclization of ynone **10** (27 mg, 0.103 mmol) was done in the same manner as for ynone **7** to afford, after purification, pure monomer **38** (8.2 mg, 31%) and dimer **39** (3.5 mg, 13%).

Monomer ***38****:* "pseudo" high dilution

To a solution of cesium carbonate (2 mg, 0.009 mmol) in tetrahydrofuran (50 mL) and *N*,*N*-dimethylformamide (50 mL) was added, via a syringe pump, a solution of ynone **10** (54 mg, 0.21 mmol) in tetrahydrofuran (5 mL) and *N*,*N*-dimethylformamide (5 mL) at room temperature over a period of 10 h. The mixture was stirred for an additional 2 h, after which the mixture was filtered and the solvents were removed by distillation under reduced pressure. The residue was purified on a small column of silica gel with hexane – ethyl acetate (3:1) as the eluent to afford pure monomer **38** (27 mg, 50%).

Triester ***31***

A solution of alcohol triester **27** (600 mg, 2.0 mmol) and quinoline (45 μL) in benzene (5 mL) was added to a suspension of palladium 5% on barium sulfate (130 mg) in benzene (2 mL). The solution was stirred under a hydrogen atmosphere until the hydrogen uptake had ceased (8 h). The solution was filtered and the solvent evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (2:1) to afford starting material (187 mg) and triester **31** (387 mg, 86% based on recovered starting material); ir: 3610, 3500 (OH), 1740 (C=O); nmr δ: 5.52 (2H, m, —C*H*=C*H*—), 3.78 (9H, s, 3 × —COOCH_3), 3.65 (2H, m, —CH_2OH), 2.90 (2H, d, *J* = 8.0 Hz, —CH_2—C—(COOCH_3)$_3$), 2.04 (2H, m, —CH_2—CH=CH—), 1.51 (5H, m, —CH_2—CH_2—, OH); ms *m/e*: 303 (MH^+), *m/e*: 285 ($M^+ - OH$).

Aldehyde ***32***

Oxidation of alcohol **31** (115 mg, 0.38 mmol) was done in the same manner as for alcohol **27** to afford pure aldehyde **32** (101 mg, 88%); ir: 2720 (HC=O), 1740 (C=O); nmr δ: 9.76 (1H, m, *H*C=O), 5.52 (2H, m, —C*H*=C*H*—), 3.78 (9H, s, 3 × —COOCH_3), 2.85 (2H, m, —CH_2—C—(COOCH_3)$_3$), 2.43 (2H, m, —CH_2—CHO), 2.20 (2H, m, —CH_2—CH=CH—), 1.66 (2H, m, —CH$_2$—CH_2—CH$_2$—).

Alcohol diester ***33***

Alcohol diester **33** was prepared in the same manner as alcohol diester **21** from aldehyde **32** (101 mg, 0.34 mmol) to afford after purification pure alcohol **33** (28 mg, 31%); ir: 3600, 3500 (OH), 3310 (C≡CH), 1740 (C=O); nmr δ: 5.44 (2H, m, —C*H*=C*H*—), 4.36 (1H, m, —C*H*OH), 3.73 (6H, s, 2 × —COOCH_3), 3.40 (1H, t, *J* = 8.2 Hz, —C*H*—(COOCH_3)$_2$), 2.78 (2H, m, —CH_2—CH—(COOCH_3)$_2$), 2.47 (1H, d, *J* = 2.0 Hz, —C≡C*H*), 2.03 (2H, m, —CH_2—CH=CH—), 1.64 (3H, m, —CH_2—CHOH, —O*H*), 1.32 (2H, m, —CH$_2$—CH_2—CH$_2$); ms *m/e*: 268 (M^+), *m/e*: 237 ($M^+ - OCH_3$).

Ynone ***8***

Ynone **8** was prepared in the same manner as ynone **10** from alcohol **33** (28 mg, 0.104 mmol) to afford pure ynone **8** (24 mg, 86%); ir: 3300 (C≡CH), 2100 (C≡C), 1735 (C=O, ester), 1670 (C=O ynone); nmr δ: 5.44 (2H, m, —C*H*=C*H*—), 3.73 (6H, s, 2 × —COOCH_3), 3.41 (1H, t, *J* = 6.0 Hz, —C*H*—(COOCH_3)$_2$), 3.21 (1H, s, —C≡C—*H*), 2.80 (4H, m, —CH_2—C(O)—, —CH_2—CH—(COOCH_3)$_2$), 2.03 (2H, m, —CH_2—CH=CH—), 1.60 (2H, m, —CH$_2$—CH_2—CH$_2$—); ms *m/e*: 266 (M^+), *m/e*: 235 ($M^+ - OCH_3$).

Monomer ***36***

Cyclization of ynone **8** (21 mg, 0.079 mmol) was done in the same manner as for ynone **7** to afford after purification pure monomer **36** (6 mg, 29%); ir: 1735 (C=O, ester), 1680 (C=O, enone), 1650 (C=C, enone); uv λ_{max} (CH_3CN): 227 nm (ε 3000); nmr δ: 6.35 (1H, d, J_{AB} = 13 Hz, —C*H*=CH—C(O)—), 6.05 (1H, d, J_{AB} = 13 Hz, —CH=C*H*—C(O)—), 5.48 (1H, m, —CH=C*H*—), 5.12 (1H, m, —C*H*=CH—), 3.78 (6H, s, 2 × —COOCH_3), 2.60 (4H, m, —CH_2—C—(COOCH_3)$_2$), —CH_2—C(O)—), 2.16 (2H, m, —CH_2—CH=CH—), 1.93 (2H, m, —CH$_2$—CH_2—CH$_2$—); nmr (^{13}C) δ: 205 (C=O, enone), 134 (C=C, β of enone), 132 (C=C, α of enone), 130, 125 (C=C), 58 (C, α of esters), 53 (CH_3 of esters), 39 (CH_2, α of enone), 29 (CH_2, β of esters), 23 (—CH_2—C≡C—), 22 (CH_2, β of enone); ms *m/e*: 266 (M^+), 231 ($M^+ - OCH_3$). *Exact Mass* calcd. for $C_{14}H_{18}O_5$: 266.1154; found: 266.1154.

Propynylmagnesium bromide

A solution of propyne (6.3 g, 158 mmol) in tetrahydrofuran (9.3 g) was prepared by distilling liquified propyne over calcium hydride. The distillate was collected in a round-bottom flask containing dry tetrahydrofuran at −78°C. This solution was then added via a cannula to a solution of ethylmagnesium bromide (50 mL of 1.2 *M* in tetrahydrofuran, 60 mmol) at −78°C. The solution was warmed to 0°C and kept at this temperature until the evolution of ethane had ceased; the solution was then heated to 40°C to get rid of any excess gas. A concentration of 0.55 *M* was estimated by gas-volume displacement.

Alcohol diester ***24***

To a solution of aldehyde triester **32** (32 mg, 0.106 mmol) in tetrahydrofuran (2 mL) was added a solution of propargylmagnesium bromide (1.16 mL of 0.55 *M* in tetrahydrofuran, 0.64 mmol). The mixture was stirred for 1 h at −30°C, after which a saturated solution of ammonium chloride (5 mL) was added. The mixture was then extracted with ether (3 × 15 mL), and the organic layer was dried and evaporated. The residue was purified by flash chromatography with hexane – ethyl acetate (3:1) as the eluent to afford pure alcohol **34** (17.4 mg, 58%); ir: 3600 (OH), 1735 (C=O); nmr δ: 5.36 (2H, m, —C*H*=C*H*—), 4.34 (1H, m, —C*H*OH), 3.73 (6H, s, 2 × —COOCH_3), 3.41 (1H, t, *J* = 7.4 Hz, —C*H*—(COOCH_3)$_2$), 2.65 (2H, m, —CH_2—CH—(COOCH_3)$_2$), 2.11 (2H, m, —CH_2—CH=CH—), 1.80 (2H, m, —CH_2—CH(OH)—), 1.90 (3H, d, *J* = 2.1 Hz, CH_3—C≡C—), 1.61 (2H, m, —CH$_2$—CH_2—).

Ynone ***9***

Pyridinium chlorochromate (247 mg, 1.15 mmol) was added to a solution of alcohol **34** (69 mg, 0.24 mmol) in methylene chloride (5 mL) containing sodium acetate (94 mg, 1.15 mmol) and crushed 3 Å molecular sieves (150 mg). The mixture was stirred for 1 h at room temperature, after which ether (20 mL) was added; the mixture was then filtered over silica gel with ether as the eluent to afford pure ynone **9** (59 mg, 89%); ir: 2210 (C≡C), 1735 (C=O, ester), 1660 (C=O, ynone); nmr δ: 5.42 (2H, m, —C*H*=C*H*—), 3.74 (6H, s, 2 × —COOCH_3), 3.42 (1H, t, *J* = 7.0 Hz, —C*H*—(COOCH_3)$_2$, 2.65 (2H, m, —CH_2—CH—(COOCH_3)$_2$), 2.53 (2H, t, *J* = 6.6 Hz, —CH_2—C(O)—), 2.10 (2H, m, —CH_2—CH=CH—), 2.02 (3H, s, CH_3—C≡C—), 1.70 (2H, m, —CH$_2$—CH_2—CH$_2$—); ms *m/e*: 281 (MH^+), *m/e*: 249 ($M^+ - OCH_3$).

Monomer ***37****:* "pseudo" high dilution

Cyclization of ynone **9** (7 mg, 0.021 mmol) was done in the same manner as for ynone **10** at "pseudo" high dilution to afford after purification pure monomer **37** (4 mg, 27%); ir: 1735 (C=O), 1680 (C=C); nmr δ: 5.50 (2H, m, —C*H*=C*H*—), 5.33 (1H, bs, *exo* olefin), 5.28 (1H, bs, *exo* olefin), 3.78 (6H, s, 2 × —COOCH_3), 3.25 (2H, CH$_2$=C—CH_2), 2.72 (2H, d, *J* = 6 Hz, —CH_2—C—(COOCH_3)$_2$), 2.49 (2H, m, —CH$_2$—CH_2—C(O)—), 2.10 (2H, m, —CH_2—

CH=CH—), 1.80 (2H, m, —CH_2—CH_2—CH_2—); ms *m/e*: 280 (M^+), *m/e*: 249 ($M^+ - OCH_3$). *Exact Mass* calcd. for $C_{15}H_{20}O_5$: 280.1311; found: 280.1319.

Allylic alcohol ***30***

To a solution of aldehyde **28** (65.6 mg, 0.22 mmol) in tetrahydrofuran (4 mL) was added a solution of vinylmagnesium bromide (412 μL of 1.6 *M* in tetrahydrofuran, 0.66 mmol) at −30°C. The solution was stirred for 15 min, after which a saturated solution of ammonium chloride (10 mL) was added. The mixture was extracted with ether (3 × 20 mL), the organic layer was then dried and evaporated, and the residue was purified by flash chromatography with hexane – ethyl acetate (3:1) as the eluent to afford pure alcohol **30** (34 mg, 58%); ir: 3600–3500 (OH), 1740 (C=O); nmr δ: 5.75 (1H, ddd, *J* = 9.8 Hz, 5.9 Hz, 1.0 Hz, CH_2=C*H*—), 5.20 (2H, ddd, *J* = 10.0 Hz, 4.0 Hz, 1.0 Hz, CH_2=CH—), 4.15 (1H, m, —C*H*OH), 3.75 (6H, s, 2 × —COOCH_3), 3.56 (1H, t, *J* = 7.2 Hz, —C*H*—$(COOCH_3)_2$), 2.70 (2H, d of t, *J* = 7.8 Hz, 2.5 Hz, —CH_2—CH—$(COOCH_3)_2$), 2.23 (2H, m, —CH_2—C≡C—), 1.81 (1H, s, —O*H*), 1.60 (4H, m, —CH_2—CH_2—).

Enone ***11***

Manganese dioxide (220 mg, 2.54 mmol) was added to a solution of allylic alcohol **30** (34 mg, 0.127 mmol) in chloroform (1 mL) and hexane (1 mL). The mixture was stirred at room temperature for 1 h, after which ether (20 mL) was added and the solution was filtered over silica gel with ether as the eluent. The solvents were evaporated to afford pure enone **11** (25 mg, 73%); ir: 1740 (C=O, ester), 1660 (C=O, enone), 1620 (C=C); nmr δ: 6.35 (2H, dd, *J* = 7.0 Hz, 4.5 Hz, CH_2=CH—), 5.85 (1H, dd, *J* = 7.0 Hz, 4.5 Hz, CH_2=C*H*—), 3.75 (6H, s, 2 × —COOCH_3), 3.54 (1H, t, *J* = 7.0 Hz, —C*H*—$(COOCH_3)_2$), 2.75 (2H, d of t, *J* = 7.0 Hz, 2.0 Hz, —CH_2—CH—$(COOCH_3)_2$), 2.59 (2H, t, *J* = 3.0 Hz, —CH_2—C(O)—), 2.18 (2H, m, —CH_2—C≡C—), 1.75 (2H, m, —CH_2—CH_2—CH_2—); ms *m/e*: 266 (M^+), *m/e*: 235 ($M^+ - OCH_3$). *Exact Mass* calcd. for $C_{14}H_{18}O_5$: 266.1154; found: 266.1159.

Dimer ***41****: direct cyclization*

Cyclization of enone **11** (25 mg, 0.094 mmol) was done in the same manner as for ynone **7** (*vide supra* monomer **35**) to afford, after purification, pure dimer **41** (5.2 mg, 20%).

Monomer ***40*** *and dimer* ***41****:* "pseudo" high dilution

To a solution of cesium carbonate (10 mg, 0.032 mmol) in tetrahydrofuran (18 mL) and *N*,*N*-dimethylformamide (18 mL) was added, via a syringe pump, a solution of enone **11** (19 mg, 0.071 mmol) in tetrahydrofuran (2 mL) and *N*,*N*-dimethylformamide (2 mL) at room temperature over a period of 10 h. The mixture was stirred for an additional 3 h, after which it was filtered and the solvents were removed by distillation under reduced pressure. The residue was purified on a small column of silica gel with hexane – ethyl acetate (3:1) as the eluent to afford pure monomer **40** (5.1 mg, 27%) and dimer **41** (10.7 mg, 56%).

Monomer ***40****:* ir: 1735 (C=, ester), 1710 (C=O, ketone); nmr δ: 3.75 (6H, s, 2 × —COOCH_3), 2.89 (2H, m, —C(O)—CH_2—CH_2—), 2.77 (2H, t, *J* = 2.0 Hz, —CH_2—C—$(COOCH_3)_2$), 2.50 (2H, m, —C(O)—CH_2—CH_2—C—$(COOCH_3)_2$), 2.35 (2H, m, —CH_2—CH_2—CH_2—C(O)—), 2.16 (2H, m, —CH_2—C≡C—), 2.11 (2H, m, —CH_2—CH_2—CH_2—); ms *m/e*: 266 (M^+), *m/e*: 235 ($M^+ - OCH_3$). *Exact Mass* calcd. for $C_{14}H_{18}O_5$: 266.1154; found: 266.1156.

Dimer ***41****:* ir: 1735 (C=O, ester), 1715 (C=O, ketone); nmr δ: 3.73 (12H, s, 4 × —COOCH_3), 2.80 (4H, t, *J* = 2.4 Hz, 2 × —CH_2—$(COOCH_3)_2$), 2.59 (4H, t, *J* = 7.1 Hz, 2 × —CH_2—CH_2—CH_2—C(O)—), 2.50 (4H, m, 2 × —C(O)—CH_2—CH_2—$(COOCH_3)_2$, 2.35 (4H, m, 2 × —C(O)—CH_2—CH_2—C$(COOCH_3)_2$), 2.21 (4H, m, 2 × —CH_2—C≡C—), 1.74 (4H, quintuplet, *J* = 6.9 Hz, 2 × —CH_2—CH_2—CH_2—); ms *m/e*: 532 (M^+), *m/e*: 501 ($M^+ - OCH_3$). *Exact Mass* calcd. for $C_{28}H_{36}O_{10}$: 532.2309; found: 532.2306.

Dienone ***43***

Two drops of hydrochloric acid (12 *N*) were added to a solution of cyclic monomer **38** (10 mg, 0.038 mmol) in *tert*-butanol. The mixture was left under argon for 30 h at room temperature. Solvent was evaporated and the residual material was purified by column chromatography with silica gel and a mixture of ethyl acetate – hexane (1:2) to give pure dienone **43** (4.2 mg, 42%); ir: 1735 (C=O, ester), 1660 (C=O, enone), 1590 (C=C), 1150 (C—O); nmr δ: 6.35 (1H, d, *J* = 9.7 Hz, CH=C*H*—C$(COOCH_3)_2$, 6.15 (1H, d, *J* = 9.7 Hz, C*H*=CH—C$(COOCH_3)_2$), 3.74 (6H, s, 2 × $COOCH_3$), 3.09 (2H, m, CH_2—C$(COOCH_3)_2$, 2.45 (2H, m, —CH_2—CO—), 2.06 (2H, q, *J* = 6.8 Hz, —CH_2—CH=C—), 1.64 (2H, m, CH_2—CH_2—CH_2); ms *m/e*: 265 (MH^+) and *m/e*: 205 ($M^+ - COOCH_3$). *Exact Mass* calcd. for $C_{14}H_{16}O_5$: 265.1076; found: 265.1076.

PETER WAN and KEITH YATES. Can. J. Chem. **64**, 2076 (1986).

The photochemistry of several *m*- and *p*-nitrobenzyl alcohols (**1**–**5**) has been studied in aqueous solution. These compounds react via an intramolecular photoredox pathway to give reduced and oxidized moieties of the substituent groups. The reaction is an example of a new type of photoreaction of nitro-substituted aromatic derivatives that is not observed in organic solvents, the presence of water being essential. This effect is exemplified by measuring the quantum efficiency as a function of mol% water in aqueous acetonitrile, methanol, and formamide: the reaction efficiency decreases rapidly as water is depleted in the mixture. Catalytic effects due to the hydronium and hydroxide ions were studied: the *para* derivatives exhibited hydroxide ion catalysis; the *meta* derivatives exhibited hydronium ion catalysis. Quantum yields, solvent isotope effects, and α-deuterium isotope effects are reported for the parent derivatives.

PETER WAN et KEITH YATES. Can. J. Chem. **64**, 2076 (1986).

On a étudié la photochimie de plusieurs alcools *m*- et *p*-nitro benzyliques (**1**–**5**) en solution aqueuse. Ces composés réagissent selon un processus photoredox intermédiaire pour donner des fragments de groupes substitués oxydés et réduits. C'est un exemple d'un nouveau type de réactions photochimiques des dérivés aromatiques nitrés que l'on n'observe pas dans des solvants organiques. L'eau est donc indispensable. On a mis en évidence le rôle de l'eau en mesurant le rendement quantique de la réaction en fonction du pourcentage molaire d'eau dans des solutions aqueuses d'acétonitrile, de méthanol et de formamide. Le rendement de la réaction diminue rapidement lorsque la teneur en eau du mélange diminue. On a étudié les effets catalytiques dus aux ions hydronium et hydroxydes. Les réactions des dérivés *para* sont catalysés par les ions hydroxydes tandis que celles des dérivés substitués en *méta* sont catalysées par les ions hydroniums. On rapporte les rendements quantiques, les effets isotopiques du solvant et les effets isotopiques du deutérium en α des dérivés apparentés.

Introduction

The photochemistry of the nitro group has been a topic of continued interest although it has not been as extensively studied as the carbonyl group. Four reviews (1–4) summarize the present understanding of the photochemistry of the nitro group in solution. Aromatic nitro compounds undergo a variety of intriguing photoreactions that are initiated by five known primary photochemical processes (1–4). The vast majority of these reactions are known to proceed via the triplet excited state, of either π,π^* or n,π^* configuration. The intramolecular photoredox reactions of nitrobenzenes comprise a class of reactions of interest in this work since the reactions to be reported here can be classified under this category. The intramolecular photoredox reaction of a nitroaromatic compound may be defined as a reaction resulting in the overall reduction of the nitro group (usually to nitroso) concurrent with the oxidation of another functional group in the same molecule (eq. [1]).

[1] 
(X $\xrightarrow{[O]}$ Y)

All the known intramolecular redox reactions (1–5) (with one exception, *vide infra*) involve *ortho*-substituted nitrobenzenes. Mechanistically related to these reactions is the photochromic behaviour exhibited by some *ortho*-substituted alkyl nitrobenzenes (6). The primary photochemical event in all the above intramolecular reactions is believed to be hydrogen atom abstraction by the excited nitro group (usually triplet n,π^*, but not restricted to this reactive state (5)), to give a biradical. Subsequent transformation of the biradical results in overall reduction of the nitro group and oxidation of the other substituent (eq. [1]). An example of this type of mechanism is shown in eq. [2] for the well-known reaction of *o*-nitrobenzaldehyde, to give *o*-nitrosobenzoic acid (1–4, 7). Prior to our investigations, the only known example of a nitroaromatic compound reacting via an intramolecular redox-type pathway that was not *ortho*-substituted is that of *p*-nitrobenzaldehyde, to give *p*-nitrosobenzoic acid (8–10). We report in this paper a new class of intramolecular redox-type reactions of *meta*- and *para*-substituted nitroaromatic compounds discovered by us recently (11, 12), which exhibit novel pH effects. These reactions appear to be general for appropriately substituted nitrobenzene derivatives.

Results

Materials

para-Substituted nitrobenzyl alcohols **1** and **2** and *meta*-substituted nitrobenzyl alcohols **3–5** were studied in this work. *o*-Nitrobenzyl alcohol **6** was used as the model for the photochemical behaviour of the *ortho*-substituted isomers. These materials were either purchased or obtained via $NaBH_4$ reduction of the corresponding ketones or aldehydes.

Product studies

Irradiation of argon-purged 10^{-4} *M* quartz cuvette solutions of *meta*-substituted alcohols **3–5** in neutral water (1% CH_3CN as cosolvent) at 254, 300, or 350 nm in a Rayonet photochemical reactor (merry-go-round apparatus) resulted in large changes in the uv spectrum (see Fig. 1 for *m*-nitrobenzyl alcohol **3**). Loss of the substrate absorption band at 268 nm is accompanied by growing bands at 233 nm and at 330 nm. Photolysis under identical conditions as above, but in MeOH, CH_3CN, 95% EtOH, and cyclohexane, resulted in no observable change in the uv spectrum. Irradiation of **1** and **2** at pH's > 11 resulted in loss of the absorption band at 278 nm accompanied by an increasing absorption band at 340 nm. These absorption changes are not observed when the alcohol is photolyzed in organic solvents or at pH's < 11. *o*-Nitrobenzyl alcohol **6** is known to react to give *o*-nitrobenzaldehyde (13) on photolysis, neat or in organic solvents. Using uv spectrophotometry to monitor the reaction, we found no observable differences in efficiency of photoreaction of **6** in a variety of solvents (neutral water, aqueous H_2SO_4, MeOH, and CH_3CN). Thus the *ortho* isomer **6** reacts according to the known intramolecular pathway regardless of solvent, while significant photochemistry is observed for the *meta* and *para* isomers only when photolysis is carried out in aqueous solution.

Product studies were carried out using 10^{-3} *M* solutions. In a typical run for the *para* isomers, 100 mg of the alcohol was dissolved in 200 mL of aqueous CH_3CN (80% H_2O; pH of the aqueous portion > 11) and photolyzed at 254 or 300 nm after saturating the solution with argon. The *para*-substituted alcohols **1** and **2** gave the corresponding nitrosocarbonyl compounds (dimeric form, see Experimental) as the only product in conversions of up to 40% (eq. [3]). When the solutions were

[3] 
1 R = H
2 R = CH_3

1*a* R = H (nitroso dimer)
2*a* R = CH_3 (nitroso dimer)

photolyzed for extended periods, highly colored material was formed, in addition to the nitrosocarbonyl products. After chromatographic separation, the structures of all the products were fully characterized by standard spectroscopic techniques. In solutions of pH < 11 or in strongly acidic medium

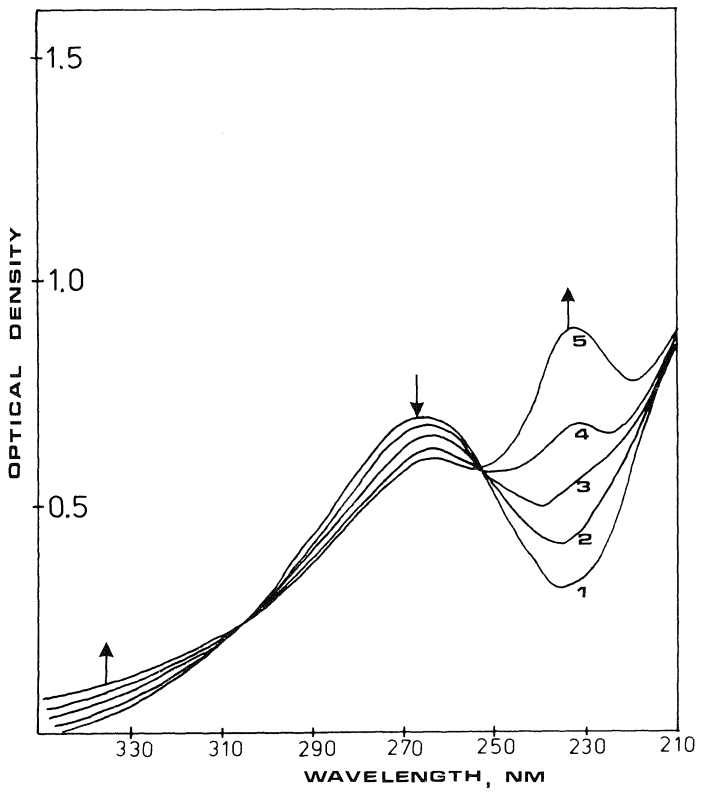

FIG. 1. Photochemical uv traces for *m*-nitrobenzyl alcohol **3** in neutral water (λ_{excit} = 254 nm; 3 min irradiation time per trace).

($H_0 \simeq -2$), complete recovery of the substrate was possible after photolysis. Additionally, no photoreaction was observed when photolysis was carried out in a number of organic solvents (pure CH_3CN, 0.1 *M* NaOMe/MeOH, pure MeOH, EtOH, and diethyl ether). The *meta*-substituted alcohols **3–5** gave two products (10–100% conversion) in basic (pH 12), neutral, or acidic medium (up to $H_0 = -4$): nitroketones (or aldehyde) **7** and azoxyketones (or azoxyaldehyde) **8** in the quoted isolated weight ratios (eq. [4]). The total yield of **7** and **8** is about 50%.

resulted in no observable reaction and hence demonstrates that **8** does not arise via secondary photochemistry of **7**. The fact that both **7** and **8** are observed as products at low conversions (down to 5%) suggests that they are either primary products or are formed via a number of very fast dark reactions after the primary photochemical step.

Product quantum yields and pH effects

Relative quantum yields (Φ_p/Φ_p^0) for reaction of **1**, where Φ_p^0 is the quantum yield of product formation in 1.0 *M* NaOH, were measured as a function of pH via preparative photolysis and also via uv spectrophotometry (λ_{excit} = 254 nm). The results are shown in Fig. 2. The efficiency of the photoreaction was found to depend strongly on the hydroxide ion concentration. Nearly identical results were observed for **2**. The absolute quantum yield for reaction at pH 14 was below 0.01 and an accurate measurement was not obtainable using the apparatus available. The photoredox chemistry of the *meta* isomers **3–5** was also subject to pH effects. The effect of medium acidity (aqueous H_2SO_4) on the total quantum yield for formation of **7** and **8** (Φ_m, defined as $\Phi_m = \Phi(\mathbf{7}) + \Phi(\mathbf{8})$, *vide infra*) was determined by monitoring for the increase in absorbance at 233 nm (λ_{max}) due to both **7** and **8** (Fig. 1), using a merry-go-round apparatus at 254 nm. The results are shown in Fig. 3. The efficiency of the photoreaction was found to depend strongly on the acidity of the medium, reaching a maximum efficiency at $H_0 \simeq -2$, and decreases significantly on going to higher acidity. There is no base catalysis of reaction since photolysis at pH 9 and 12 resulted in no observable increase in reaction efficiency, compared to a solution at pH 7. However, in contrast to the *para* isomers, the *meta* isomers react in neutral solution with moderate efficiencies.

The absolute quantum yields for formation of **7** ($\Phi(\mathbf{7})$) and of **8** ($\Phi(\mathbf{8})$) were calculated by partitioning the total quantum yield for these derivatives (Φ_m) into a $\Phi(\mathbf{7})$ and a $\Phi(\mathbf{8})$ component, using eq. [5], where the ratio 0.76:0.24 is the isolated mole ratio

$$[5] \quad \Phi_m = 0.76\Phi(\mathbf{7}) + 0.24\Phi(\mathbf{8})$$

(averaged) of products **7** and **8**, respectively. The results are given in Table 1.

[a]Determined spectrophotometrically. Estimated error 10%.

The effect of substrate concentration on the efficiency of the photoredox reaction of **3** was studied via uv spectrophotometry in the $10^{-3} - 10^{-5}$ *M* concentration range. The total quantum efficiency (Φ_m) for formation of **7** and **8** as a function of initial substrate concentration is given in Table 2. The observation of no change in reaction efficiency over a tenfold change in initial substrate concentration suggests that the mechanism for reaction involves a single substrate molecule in the primary photochemical step. Due to the relative inefficiency of the reaction for the *para* isomers (**1** and **2**), a study of the variation of quantum efficiency with substrate concentration has not been carried out. However, studies at 10^{-5} *M* initial substrate

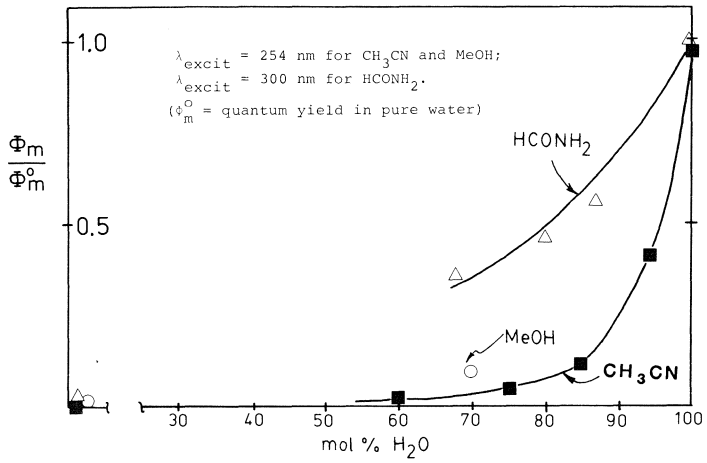

FIG. 4. Effect of added H_2O to CH_3CN, CH_3OH, and $HCONH_2$ on the photoredox efficiency of *m*-nitrobenzyl alcohol **3** (λ_{excit} = 254 nm; results determined spectrophotometrically). The quantum yield (Φ^0_m) in 100 mol% water was normalized to unity.

concentration (via uv spectrophotometry, monitoring for the product λ_{max} at 340 nm) indicates that the reaction proceeds with comparable efficiency to that carried out with uv studies at 10^{-3} *M*. Additional evidence for a unimolecular primary photochemical step in these reactions is the finding that irradiation of an equimolar (10^{-4} *M*) mixture of nitrobenzene and benzyl alcohol (20% H_2SO_4 or pH 12) results in no observable reaction, as indicated by uv spectrophotometry and via preparative photolysis.

Medium and isotope effects

The requirement of water in the photoreaction of these substrates is exemplified by the effect of added H_2O to CH_3CN, MeOH, and $HCONH_2$ on the photoredox efficiency of *m*-nitrobenzyl alcohol **3** (Fig. 4). In this plot, the ratio Φ_m/Φ^0_m represents the relative reaction efficiency of **3**, as organic solvent is added to the pure water solution (pH 7). Φ^0_m is the total quantum yield for formation of **7***a* and **8***a* in pure water (at pH 7), normalized to unity at 100 mol% water. In CH_3CN and MeOH, the reaction is not observed below 60 mol% water. In $HCONH_2$, the decrease in reaction efficiency is more gradual. The reaction efficiency is also sensitive to added electrolytes (Fig. 5). In the solvent system 30% CH_3CN/H_2O (v/v), the efficiency of the reaction nearly doubles on the addition of 0.6 *M* LiCl (or $NaClO_4$), relative to a solution without added salt (at pH 7). In pure water, much higher salt concentrations are required ($\simeq$2 *M*) to give an observable salt effect. For the *para* isomer **1**, the presence of 1.0 *M* NaCl in pH 13 failed to enhance the efficiency. However, since the medium at pH 13 is already quite polar, the amount of enhancement may be insignificant. The observation of a salt effect for the *meta* isomers would favour a mechanism involving polarized or ionic species.

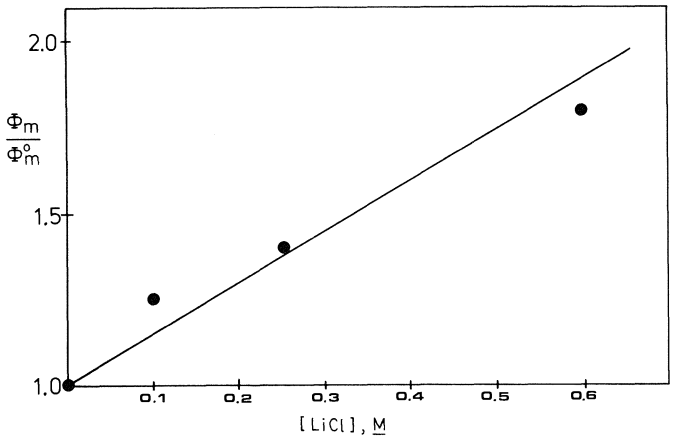

FIG. 5. Effect of added LiCl in 30% CH_3CN/H_2O (pH 7) on the photoredox efficiency of *m*-nitrobenzyl alcohol **3** (λ_{excit} = 254 nm; results determined spectrophotometrically). The quantum yield (Φ^0_m) in the absence of LiCl was normalized to unity.

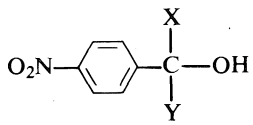
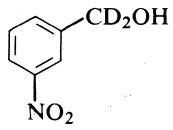
Solvent isotope effects on the efficiency of the photoredox reaction were measured for **1** and **3**. For the *meta* isomer **3**, the experiment was performed using pure H_2O vs. pure D_2O, and the relative quantum efficiency (as monitored by uv spectrophotometry at 233 nm) in these two solvents (Φ_H/Φ_D) was 1.40 ± 0.05. For **1**, 0.1 *M* NaOH/H_2O and 0.1 *M* NaOD/D_2O solutions were used, and the relative efficiency (Φ_H/Φ_D) was 1.09 ± 0.05. These observations suggest that the solvent is involved chemically in the reaction, perhaps providing a source of available protons to mediate these reactions, as suggested by the values (greater than unity) of the solvent isotope effects.

α-Deuterium isotope effects were studied using compounds **9–11** under several different medium basicities or acidities.



9 X = H; Y = D
10 X = Y = D



11

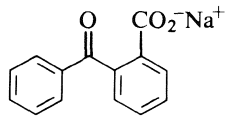
Compound **9** (mono-α-deuterated analog of **1**) can be studied by noting the relative amounts of *p*-nitrosobenzaldehyde-α-H vs. α-D product formed in the ^1H nmr spectrum of the product mixture. The amount of α-D product formed was deduced by noting the ratio of the integrated areas of the formyl proton of the α-H product vs. total aromatic protons. A preference for abstracting the proton over the deuteron in **9** would give more *p*-nitrosobenzaldehyde-α-D product vs. the α-H product. This was in fact observed, and the isotope effect (Φ_H/Φ_D), which measures the preference for α-H vs. α-D, was 6.1 ± 0.6 at pH 14 and 4.6 ± 0.7 in 0.25 *M* NaOH. A different approach for measuring this type of isotope effect is to compare the relative reaction efficiencies of **10** vs. the parent compound **1**, under

identical reaction conditions. Surprisingly, however, **10** failed to react in pH 14, whereas **1** gave 54% conversion, both under identical photolysis conditions. This would give an estimated isotope effect of about 10, by assuming an upper limit of 5% conversion for **10**.

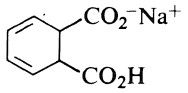
The corresponding isotope effect for the *meta* isomer **3** was studied by comparing the difference in reaction efficiency between **3** and **11** under identical conditions, using uv spectrophotometry to monitor the reaction. As was observed for the *para* isomer, there is again a preference for the undeuterated compound, and the isotope effects Φ_H/Φ_D (as defined above) were 2.4 ± 0.2 in pH 7, 1.4 ± 0.1 in $H_0 = -0.60$, and 1.3 ± 0.1 in $H_0 = -1.3$. These observations suggest that deprotonation (or removal in the form of hydrogen atom) of the α-proton is involved in the primary step of the reaction mechanism. To test whether the α-hydrogens of **1–5** are exchangeable in recovered starting material, a number of exchange experiments were performed using labelled **11** in H_2O (model for the *meta* isomers) and *p*-nitrobenzyl alcohol **1** in 0.10 *M* NaOD/D_2O (model for the *para* isomers). At conversions of 8–62%, no exchange of α-D or α-H in **11** and **1**, respectively, was detected, as indicated by ^1H nmr and mass spectrometry. Since these two techniques can detect a minimum of ≃3% exchange, we conclude that at most 3% of the "deprotonated" substrate molecules returns to starting material without going on to form product.

Triplet sensitization and quenching studies

The photoredox reactions of **1** and **3** can be sensitized by sodium benzophenone-2-carboxylate **12** ($E_T \simeq 69$ kcal mol^{-1}) (14) in 0.1 *M* NaOH and neutral water, respectively, using 350 nm irradiation. Both reactions can be quenched by 2,4-cyclohexadiene-1,6-dicarboxylic acid (monosodium salt) **13**



12



13

($E_T \simeq 50$ kcal mol^{-1}, based on the known value for 1,3-cyclohexadiene (14)). At a quencher concentration of 0.02 *M*, the photoreaction was quenched to the extent of ≃70%, compared to a sample without added quencher, in neutral water for **3** and in 0.1 *M* NaOH for **1**. These results imply that the major part of the reaction proceeds from the triplet state.

The quantum efficiency via S_1 (Φ_S) was estimated via the following analysis for "bracketing" Φ_S (15). The quantum yield for reaction on direct irradiation (Φ_D) is given by eq. [6], where

$$[6] \quad \Phi_D = \Phi_S + \Phi_{ST}\Phi_T$$

$$[7] \quad \Phi_{sens} = \Phi_{ET}\Phi_T$$

Φ_{ST} is the quantum yield for intersystem crossing from the singlet to the triplet state, and Φ_T is the fractional efficiency of triplets undergoing reaction. The sensitized quantum yield (Φ_{sens}) is given by eq. [7], where Φ_{ET} is the quantum efficiency of energy transfer between the sensitizer and the substrate. Assuming 100% efficient energy transfer, we have $\Phi_{sens} = \Phi_T$. This condition is met if E_T(sens) > E_T(substrate), and the substrate concentration is sufficiently high to intercept all the excited sensitizer triplets. Employing compound **12** as the sensitizer in 0.1 *M* NaOH and a substrate (compound **1**) concentration of 10^{-3} *M*, it was found that $\Phi_{sens}/\Phi_D = 1.5 \pm 0.3$. Since E_T(**12**) ≃ 69 kcal mol^{-1} (14) and the triplet energy of **1** ≃ 60 kcal mol^{-1} (3, 16), and because the triplet lifetime of **12** is ≃10^{-6} s (14), we have $\Phi_{sens} = \Phi_T$ (i.e., $\Phi_{ET} \simeq 1$; every excited triplet of **12** is intercepted by **1**). Therefore, we can write $\Phi_T/\Phi_D = 1.5 \pm 0.2$. Equation [6] can be rearranged as eq. [8]. Substituting the inverse value of Φ_T/Φ_D in eq. [7] and

$$[8] \quad \Phi_D/\Phi_T = (\Phi_S/\Phi_T) + \Phi_{ST}$$

$$[9] \quad \Phi_S/\Phi_T = (0.69 \pm 0.09) - \Phi_{ST}$$

rearranging, we obtain eq. [9]. Since Φ_{ST} for simple nitrobenzenes is ≃0.7 (3, 16, 17), we find that $\Phi_T \gg \Phi_S$. That is, reaction via Φ_S is insignificant, if not completely absent. Although Φ_{sens}/Φ_D for the *meta* isomer **3** has not been measured as accurately as for **1**, a value of ca. 1.6 has been observed, and a similar conclusion regarding the insignificance of the S_1 pathway can be made.

Discussion

The proposed mechanism for the photoredox reaction of the *para* isomers (**1** and **2**) is shown in Scheme 1 for *p*-nitrobenzyl alcohol **1**, which is consistent with all the available experimental data. The k_{OH} step is presumed to involve hydroxide ion deprotonation of the benzylic proton concerted with proton transfer from solvent water to the nitro group oxygen. Although a two-step sequence would be kinetically distinguishable from this concerted step, the one-step process was chosen based on its kinetic simplicity. The mechanism involves a highly polarized intermediate in **14**, consistent with the observed solvent effect and base catalysis of reaction. The triplet reactive state is also presumed to be highly polarized, to facilitate the α-deprotonation (*vide infra*). The expression for product quantum yield can be derived by assuming a steady state for intermediate **14** and the singlet and triplet excited states of the substrate. The resulting expression is given by eq. [10],

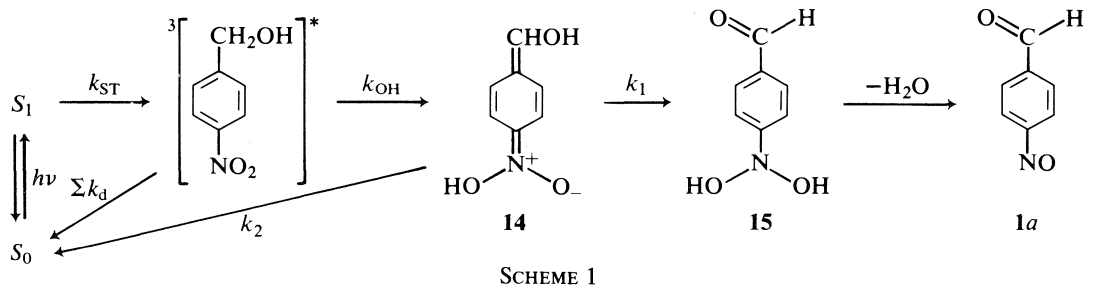
$$[10] \quad \Phi_p = \Phi_{ST}\left(\frac{k_1}{k_1 + k_2}\right)\left(\frac{k_{OH}[OH^-] + k_{H_2O}[H_2O]}{\Sigma k_d + k_{OH}[OH^-] + k_{H_2O}[H_2O]}\right)$$

$$[11] \quad \Phi_p = \Phi_{ST}\left(\frac{k_{OH}[OH^-]}{\Sigma k_d + k_{OH}[OH^-]}\right)$$

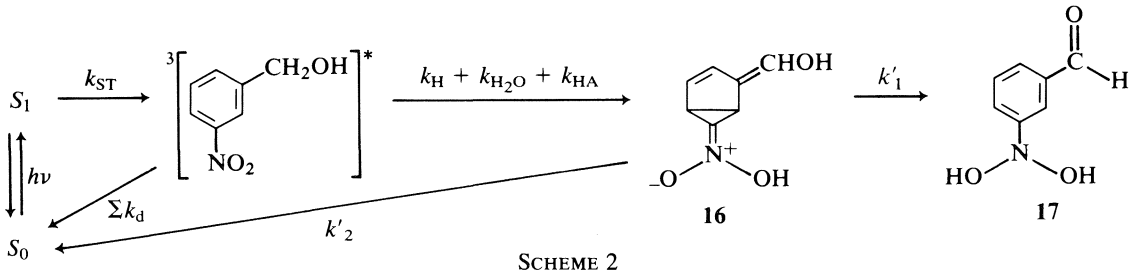
$$[12] \quad \Phi_p^0 = \Phi_{ST}\left(\frac{k_{OH}}{\Sigma k_d + k_{OH}}\right)$$

$$[13] \quad \Phi^0/\Phi_p = \left(\frac{1}{\Sigma k_d + k_{OH}}\right)k_{OH} + \left(\frac{\Sigma k_d}{\Sigma k_d + k_{OH}}\right)[OH^-]^{-1} = \tau_p^0 k_{OH} + (\tau_p^0/\tau_p')[OH^-]^{-1}$$

where Σk_d represents all triplet decay processes that do not lead to product and k_{H_2O} and k_{OH} are the water and hydroxide ion catalyzed rate constants for the primary photochemical step (leading to intermediate **14**). However, since it was observed that water is ineffective as a catalyzing base (no reaction in neutral solution), we have $k_{H_2O}[H_2O] \ll k_{OH}[OH^-]$. In addition, based on the exchange experiments, we know that intermediate **14** does not return to starting material efficiently. Kinetically this implies that $k_1 \gg k_2$. Therefore, eq. [10] simplifies to eq. [11]. We define the quantity Φ_p^0 as the quantum yield of reaction in 1.0 *M* NaOH, which can be written as eq. [12]. A simple division of eq. [12] by eq. [11] results in an expression for Φ_p^0/Φ_p, which after simplification is given by eq. [13], where τ_p^0 and τ_p' are the triplet lifetimes of the molecule in 1.0 *M* NaOH and in neutral water, respectively.



SCHEME 1



SCHEME 2

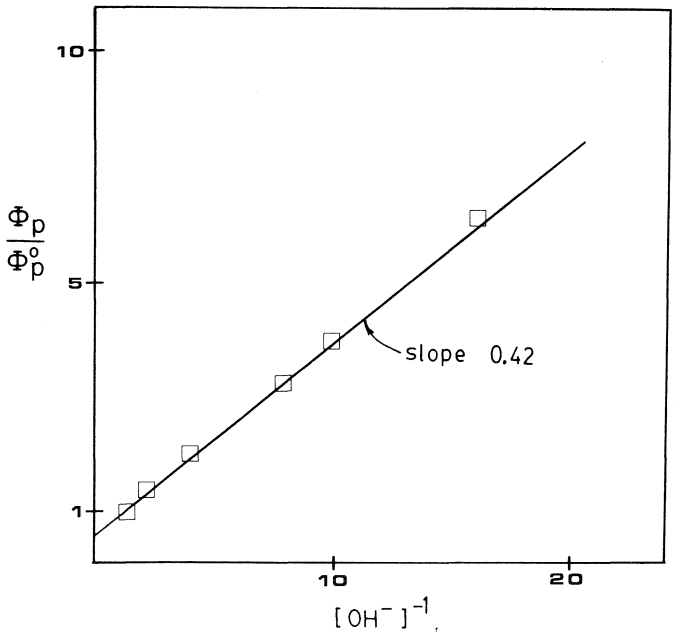


FIG. 6. Plot of Φ_p^0/Φ_p vs. $[OH^-]^{-1}$ for the photoredox reaction of *p*-nitrobenzyl alcohol **1** (Φ_p^0 = quantum yield at pH 14).

In this way, the kinetic equation presented by eq. [10] can be linearized. Using data presented in Fig. 2, a plot of Φ_p^0/Φ_p^0 vs. $[OH^-]^{-1}$ (Fig. 6) gave a good straight line, with a slope of 0.42 and an intercept of 0.6. This result gives kinetic support to the proposed mechanism presented in Scheme 1. Simple nitrobenzenes are known to have characteristically short triplet lifetimes of $\simeq$1 ns (3, 16, 17), which has been attributed to rapid radiationless decay to S_0. Assuming that $\tau'_p = 1 \times 10^{-9}$ s, then we calculate $\tau_p^0 = 0.42 \times 10^{-9}$ s and $k_{OH} = 1 \times 10^9\ M^{-1}\ s^{-1}$. However, as the triplet lifetimes of the molecules studied in this work are not available, we can calculate that intercept/slope = $k_{OH}/\Sigma k_d \simeq 1.4$, indicating that k_{OH} and Σk_d are similar in magnitude.

The mechanism for the photoredox reaction of the *meta* isomers appears to be somewhat more complicated: the *meta* isomers do not react via an overall simple intramolecular reduction–oxidation process. However, it seems clear that the initial steps should be similar to the mechanism proposed for the *para* isomers (Scheme 1), since the evidence accumulated does not require a completely different mechanism. By analogy with Scheme 1, the proposed sequence of events for the *meta* isomers is shown in Scheme 2 for *m*-nitrobenzyl alcohol **3**. The "$k_H + k_{H_2O} + k_{HA}$" step in Scheme 2 involves abstraction of the benzylic proton by solvent water concerted with protonation at the nitro group by protonating agents H_2O, H_3O^+, and general acid HA, respectively. The proposed highly polarized nature of the reactive triplet state facilitates protonation at the nitro group. Acid catalysis due to initial protonation of the nitro group in the ground state can be ruled out since the nitro group is an extremely weak base in S_0 ($pK_{SH^+} < -10$) (18). The quantum yield expression for loss of substrate (Φ_L) or formation of **17** is given by eq. [14]. However, experimentally the quantum yields for formation of **7** and **8** (i.e., Φ_m) were measured, where these products are believed to be derived from **17** via secondary dark reactions (*vide infra*). Therefore, we can write eq. [15], which gives the relationship between Φ_L and Φ_m, where $\beta < 1$. The value of β is not unity since the reaction is not 100% clean. Intermediate **16** does not return to starting material to any significant extent, based on the results of the exchange experiments (*vide supra*). Kinetically this implies that $k'_1 \gg k'_2$. In the pH region and in the absence of general acids, eqs. [14] and [15] can be simplified to give eq. [16].

$$[14]\quad \Phi_L = \Phi_{ST}\left(\frac{k'_1}{k'_1 + k'_2}\right) \times \left(\frac{k_H[H^+] + k_{H_2O}[H_2O] + k_{HA}[HA]}{\Sigma k_d + k_H[H^+] + k_{H_2O}[H_2O] + k_{HA}[HA]}\right)$$

$$[15]\quad \Phi_m = \beta \times \Phi_L$$

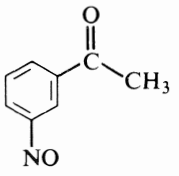
$$[16]\quad \Phi_m = \beta\Phi_{ST}\left(\frac{k_{H_2O}[H_2O]}{\Sigma k_d + k_{H_2O}[H_2O]}\right)$$

In stronger acids (pH < 1), the proton-catalyzed reaction dominates ($k_H[H^+] \gg k_{H_2O}[H_2O]$), resulting in a rapid increase in Φ_m with increasing medium acidity. The maximum in reaction

efficiency is observed at $H_0 \simeq -2$, followed by a decrease in reaction efficiency at higher acidities. It is proposed that this decrease at higher acidities is due to static quenching effects by hydronium ion, as the hydroxyl group can be protonated significantly at these acidities (estimated $pK_{SH^+} \simeq -2$ to -4). The exact nature of this quenching mechanism has not been delineated and is a topic for future studies.

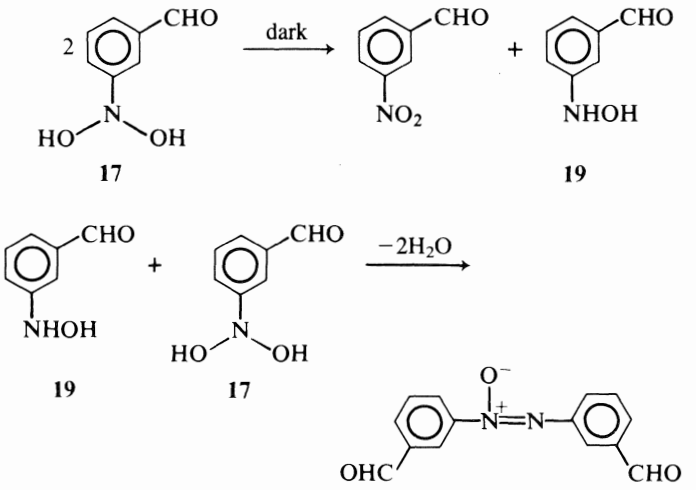
The proposed mechanism in Scheme 2 predicts general acid catalysis of photoreaction. We have observed general acid catalysis of reaction for compound **3** at pH 1.5 using H_3PO_4/NaH_2PO_4 as the buffer, at pH 4.2 using NaH_2PO_4/K_2HPO_4 as the buffer. These experiments were carried out relative to a solution of the same pH and ionic strength, but without added general acid. Typically, $\Phi(0.44\ M\ [HA])/\Phi(0\ M[HA]) = 1.22 \pm 0.05$ at pH 4.2, where NaH_2PO_4 is the general acid, and a value of 1.5 ± 0.01 at pH 1.5, where H_3PO_4 is the general acid. These results corroborate the proposed mechanism requiring proton assistance in the primary photochemical step.

The problem of proposing a viable route from intermediate **17** (Scheme 2) to the observed reaction products **7** and **8** (eq. [4]) will now be addressed. Compound **17**, on dehydration, gives *m*-nitrosobenzaldehyde. However, this compound is not observed in the photoreaction. To examine the possibility that the observed photoproducts are due to a secondary photoreaction (or dark reaction) of *m*-nitrosobenzaldehyde, attempts were made to synthesize this compound independently and study its chemical and photochemical behaviour. After a number of unsuccessful attempts at preparing *m*-nitrosobenzaldehyde, we decided to make *m*-nitrosoacetophenone **18** instead, since it is the analogous product for reaction of alcohol **4**. Compound **18** (in the dimeric form) was readily prepared via *m*-chloroperoxybenzoic acid oxidation of *m*-aminoacetophenone. The results for **18** should be equally valid for the other *meta* alcohols



18

(**3** and **5**). Compound **18** was found to be stable in the dark indefinitely in aqueous solution (pH 7–0). It could be recovered unchanged as the dimeric form. Since the color remained yellow in solution, there is no evidence to suggest that significant amounts of monomeric **18** are formed on dissolution. Photolysis of **18** in aqueous solution (neutral or acidic) failed to give rise to the observed photoproducts, and only resulted in decomposition to give highly colored material that was not characterized. These observations rule out **18**, at least in the dimer form, as a discrete intermediate in the reaction pathway. We present two possible reaction schemes to account for the reaction products. The first involves a dark disproportionation reaction of two molecules of **17** (or some structurally equivalent species, which may be in a hot ground state), to give *m*-nitrobenzaldehyde and hydroxylamine derivative **19**. Subsequent reaction of **19** with **17** results in *m*-azoxybenzaldehyde, via the known condensation reaction of hydroxylamines and nitroso groups, to give azoxy compounds (19). However, it is not clear at this time why the primary nitroso carbonyl products (eq. [3]) are isolable for the *para* isomers and not so for the *meta* isomers. It would appear that this difference in reaction products observed between the



SCHEME 3

meta and *para* alcohols, which otherwise complement each other, reflects a fundamental difference in their photochemical behaviour.

An alternative explanation[2] to account for the fact that the primary nitroso products are not observed for the *meta* alcohols is that the initially formed *m*-nitrosobenzaldehyde *monomer* (from reaction of **3**) may react with a molecule of starting material in a redox fashion, to give *m*-nitrobenzaldehyde and **19**. Subsequent reaction of **19** with *m*-nitrosobenzaldehyde leads to azoxy compound **8***a*. This alternative pathway seems plausible considering the fact that nitrosobenzene monomer itself is known to oxidize certain benzylic amines (20), to give azoxybenzene and the corresponding carbonyl compound derived from the benzyl amine. As we have no viable way of making monomeric **18**, this possible pathway remains to be explored.

The isolated mole ratios of **7** and **8** (average ratio 1:0.33) do not represent redox material balance. For redox balance, one requires a 1:1 mole ratio of **7** to **8**. In other words, 0.67 equivalents of oxidized material is missing, or an excess of 0.67 equivalents of oxidized material is formed. Such a large discrepancy cannot adequately be accounted for by the presence of adventitious oxygen since >90% of dissolved oxygen can be removed by saturating the solution with argon. A reasonable explanation to account for this discrepancy is the observation that products **7***a–c* are photostable, while products **8***a–c* are photolabile under the photolysis conditions. For example, photolysis of **8***a* in aqueous solution quickly results in decomposition of the azoxy compound, as followed by tlc. The products are highly colored materials that failed to elute on preparative tlc and are believed to be phenolic dyes (see Experimental).

The proposed initial sequence of events (Schemes 1 and 2) represents a new type of photoreaction of nitroaromatic compounds. The overall result is a redox reaction. The reaction mechanism proposed has as its key step the substrate acting as a carbon acid. It is known that the pK_a values of common carbon acids are generally much greater than 20, particularly for those compounds without adjacent groups that can stabilize the negative charge of the conjugate base. For example, the ground state pK_a of toluene has been estimated to be about 41 (21). The introduction of two nitro groups at the *ortho* and *para* positions increases the acidity by 24 log units, to give a pK_a value of 17

[2]We thank Prof. D. Gravel for suggesting this possibility to us.

(22). The pK_a of *p*-nitrotoluene (23) and that of the α-cyano derivative (22) have been estimated to be 20 and 13, respectively. Based on these values, the pK_a of *p*-nitrobenzyl alcohol **1** for deprotonation of the benzylic proton should be in the range 17–19 in the ground state since the α-hydroxyl group can stabilize the anion to some extent by an inductive effect. The pK_a of the *meta* isomer (*m*-nitrobenzyl alcohol **3**) should be greater than the range 17–19 since resonance stabilization of the α-anion is not available. A reasonable pK_a range for **3** in the ground state is 19–22. On excitation to the triplet state, it would appear that the acidities of the α-protons of **1–5** increase dramatically. For the *para* isomers (**1** and **2**), it is estimated that $pK_a(T_1) \simeq 13$–15, as suggested by Fig. 2, an increase in acidity of 3–6 log units. For the *meta* isomers, the increase in acidity appears to be more dramatic; the $\Delta pK = pK(S_0) - pK(T_1)$ is probably greater than 20 log units since even water can deprotonate the molecule in T_1. The observed increase in acidity of the α-proton of these compounds can be interpreted as being due to the enhanced electron-withdrawing effect of aromatic nitro groups in T_1. This phenomenon has been well documented by Zimmerman and Somasekhara (24) and Cornelisse and Havinga (25) in their studies of nucleophilic aromatic substitutions of nitroaromatic derivatives. That the *meta* nitro group has a better electron-withdrawing effect has also been observed previously (24, 25) and lends support to the interpretation offered above.

A comment regarding the configuration of the T_1 reactive state is warranted. Simple nitrobenzenes, without strongly electron-donating groups, are believed to have n,π^* lowest triplets (1–4, 16, 17) in the commonly employed organic solvents. This is consistent with the observation that simple nitrobenzenes react via characteristic n,π^* triplet state reactions, in close analogy with many carbonyl n,π^* triplets. However, the photoredox reactions reported in this work do not take place in organic solvents and appear to be inconsistent with the assumption that these molecules have n,π^* lowest triplet reactive states, since the redox reactions clearly must involve activation of the benzene ring. n,π^* Triplets are not known to activate the benzene ring in photochemical reactions (1–4). It is well known that solvents of high dielectric constant stabilize π,π^* and destabilize n,π^* configurations (26). It is proposed that in water ($\varepsilon = 80$), either the lowest triplet is π,π^* or that the two configurations are very close in energy, thus allowing for a significant thermal population of π,π^* triplets and hence the observed reaction. In the commonly employed organic solvents (typically $\varepsilon < 40$), the lowest triplet configuration is n,π^* in character and no reaction is observed. In pure formamide ($\varepsilon = 110$) these reactions are also not observed. This can be explained by noting that formamide cannot catalyze the reactions as can water, that is, functioning as a weak base and also as a source of protons.

The only other photoredox reaction of a nitroaromatic compound that does not involve an *ortho*-substituted nitro group, known prior to this work, is that of the water-catalyzed reaction of *p*-nitrobenzaldehyde, to give *p*-nitrosobenzoic acid, reported by Wubbels *et al.* (8, 9). The primary photochemical event proposed by Wubbels for this reaction involves electron transfer from water to the n,π^* triplet of the nitro group. The results of our work suggest that the reaction reported by Wubbels (8, 9), although chemically similar, is fundamentally different from the reactions reported in this work with respect to the nature of the primary photochemical event. For example, *m*-nitrobenzaldehyde does not react at any pH. Interestingly, no additional examples of the reaction reported by Wubbels (8, 9) have been discovered whereas the photoredox reactions of **1–5** appear to be quite general for structurally related systems. However, additional work is required to fully delineate the difference between the above two types of photoredox reactions with respect to the primary photochemical event.

In summary, the photochemistry of a number of *meta* and *para* nitro-substituted benzyl alcohols, previously believed to be photochemically unreactive, has been investigated in some detail. Interesting catalytic effects due to hydronium and hydroxide ions were observed. The *para* isomers react via a simple photoredox mechanism whereas the *meta* isomers give rise to products that are believed to be due to secondary dark reactions of the initially photogenerated intermediate.

Experimental

General

Ultraviolet spectra were recorded in 95% EtOH (unless otherwise noted) on either a Cary 14 or a Unicam SP 1800 instrument. The ^{1}H nmr spectra were recorded on a Varian T60 spectrometer in $CDCl_3$. The ir spectra were obtained on a Unicam SP 1025 instrument in chloroform solution. Mass spectra were taken on a CEC 21-490 single-focussing magnetic sector instrument operating at 70 eV. Preparative photolyses were carried out using a Rayonet RPR 100 photochemical reactor.

Materials

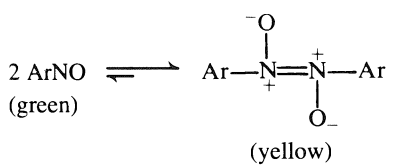
Nitrobenzyl alcohols **1**, **3**, and **6** were purchased from Aldrich, while **2** and **4** were prepared via $NaBH_4$ reduction of the corresponding ketones in MeOH. These were either distilled or recrystallized prior to use. Compound **12** was purchased from Aldrich and **13** was a gift from BASF Wyandotte.

m-*Nitrosoacetophenone* ***18*** *(dimer)*

A solution of 3.1 g (18 mmol) of *m*-chloroperoxybenzoic acid in 50 mL CH_2Cl_2 was added dropwise over a 20-min period to a boiling solution of 1.0 g (7.4 mmol) of *m*-aminoacetophenone (Aldrich) in 100 mL CH_2Cl_2. After one minute the solution turned green, indicative of the formation of a monomeric nitroso compound. After refluxing for an additional 15 min, the solution was quenched by adding 200 mL 3% NaOH. The CH_2Cl_2 layer was separated (the solution was now yellow rather than green) and washed with additional aliquots of 3% NaOH, and finally with 5% HCl. Evaporation of the solvent gave 300 mg of a yellow solid, which was recrystallized twice from pentane/CH_2Cl_2, mp 134–135°C; ir ($CHCl_3$): 1275 (s), 1360 (s), 1465 (s), 1490 (m), 1695 (vs); uv (80% H_2O/EtOH): 238 nm (ε 20 000), 310 nm (ε 10 000), no absorption >400 nm; ^{1}H nmr δ: 2.6 (s, 3H, $COCH_3$), 2.65 (s, 3H, $COCH_3$), 7.2–9 (m, 8H, arom.); mass spectrum (*m/e*): 119 (100), 163 (10), 264 (15) ($M^+ - 32$), 282 (40) ($M^+ - 16$). *Anal.* calcd. for $C_8H_7NO_2$: C 64.42, H 4.73, N 9.93%; found: C 64.23, H 4.62, N 9.21%.

p-*Nitrosoacetophenone* ***2a*** *(dimer)*

In a similar procedure as described for *m*-nitrosoacetophenone, use of *p*-aminoacetophenone gave a yellow solid that on recrystallization from acetone gave mp 190–191°C; ir ($CHCl_3$): 955 (m), 1010 (w), 1270 (s), 1310 (m), 1355 (s), 1410 (m), 1465 (s), 1600 (w), 1690 (s); uv (95% EtOH): 340 nm (ε 10 000); ^{1}H nmr δ: 2.7 (s, 3H, $COCH_3$), 2.75 (s, 3H, $COCH_3$), 8.1–8.8 (m, 8H, arom.); mass spectrum (*m/e*): 91 (59), 119 (100), 126 (13), 135 (12), 147 (13), 169 (13), 211 (10), 267 (10), 168 (13) ($M^+ - 32$), 282 (65) ($M^+ - 16$). *Anal.* calcd. for $C_8H_7NO_2$: C 64.42, H 4.73, N 9.39%; found: C 64.62, H 4.81, N 9.42%. The spectral data (uv, mass spectra, and ^{1}H nmr) indicate that both **18** and ***2a*** exist in the dimeric form:



A large number of nitroso compounds are known to exist in the form of the dimer (27). Doubling-up of the ^{1}H nmr peaks due to restricted rotation about the Ar—N bond has been reported for aromatic nitroso compounds with electron-donating groups (28), which are known to be monomeric in solution. We believe the nitroso dimers reported here also have restricted rotation about the Ar—N bond in solution, although this phenomenon to our knowledge has not been documented for these types of nitroso dimers.

α-Deuterio-*p*- and *m*-nitrobenzyl alcohols (**9** and **11**) were prepared via $NaBD_4$ reduction of the corresponding aldehydes. α,α-Dideuterio-*p*-nitrobenzyl alcohol **10** was prepared via LAD reduction of methyl *p*-nitrobenzoate in THF. The deuterated alcohols were spectroscopically identical (except for the absence or reduced absorption of the α-H in the ^{1}H nmr) with the parent compounds.

Preparative photolyses

Dark reactions of ***1–6***

Alcohols **1–6** are stable in the dark in pure H_2O, 10% H_2SO_4, 40% H_2SO_4, and at pH 14, with or without argon saturation, for an indefinite period at room temperature. A typical experiment involves dissolving 100 mg of the substrate in 250 mL solution (no cosolvent required for **1–4** and **6** since these are sufficiently water soluble) and leaving it for the required time in the dark.

Preparative photolysis of m-*nitrobenzyl alcohol* ***3***

A solution of 100 mg of **3** in 500 mL distilled water was placed in a 0.67-L quartz vessel and saturated with argon for 30 min using a fritted-glass dispersion tube. A cold finger was placed inside the vessel along with a long syringe needle connected to the argon line. A stream of argon was allowed to enter the vessel continuously. The solution was then irradiated for 2 h at 254 nm (Rayonet reactor; 300- or 350-nm lamps were also used and gave the same result). The standard work-up procedure involves saturating the aqueous solution with NaCl and extracting with 2 × 100 mL CH_2Cl_2. The above photolysis was repeated four times, the crude isolated materials combined, and the products separated on preparative tlc plates (silica gel; CH_2Cl_2). An ^{1}H nmr spectrum was recorded of the product mixture before separation was carried out, to ensure that no new products were formed during the preparative tlc procedure. In this way, it was shown that the products recovered from prep. tlc were the primary products observed after photolysis. There was isolated 120 mg (40% isolated yield; R_f 0.45) of *m*-nitrobenzaldehyde **7***a* as identified by spectroscopic comparison with the authentic material, and 50 mg (17% isolated yield; R_f 0.30) of a yellow solid identified as *m*-azoxybenzaldehyde **8***a*, mp 103–106°C; ir ($CHCl_3$): 1140 (m), 1320 (w), 1470 (w), 1490 (w), 1590 (w), 1620 (w), 1710 (s); uv (95% EtOH): 235 nm (ε 22 000), 320 nm (ε 9 800); ^{1}H nmr δ: 7–9 (8H, arom.), 10.1 and 10.15 (2s, 2H, non-equiv. CHO); mass spectrum (*m*/*e*): 254 (M^+). *Anal.* calcd. for $C_{14}N_{10}N_2O_3$: C 66.14, H 3.96, N 11.02%; found: C 66.22, H 4.16, N 10.96%. Relative yield experiments (prep. scale) were performed in H_2O (pH 7, pH 9, pH 13), 10% and 20% H_2SO_4 with 100-mg samples in 400 mL of the appropriate solvent. The irradiation time was 20 min at 254 nm, which gave a conversion of 20% at pH 7, as calculated by ^{1}H nmr integration (C*H*O vs. CH_2OH peaks). An increase in conversion was observed only in the 10% and 20% H_2SO_4 samples, and the relative increase calculated agrees with those reported in Fig. 3, which were calculated via uv spectrophotometry.

Preparative photolysis of α-*methyl*-m-*nitrobenzyl alcohol* ***4***

The procedure for **4** is identical to that described for **3**. The products were isolated via preparative tlc (silica gel; CH_2Cl_2) and were *m*-nitroacetophenone **7***b* and *m*-azoxyacetophenone **8***b* in the quoted isolated weight ratios (eq. [4]). *m*-Azoxyacetophenone **8***b*: mp 100–103°C; ir ($CHCl_3$): 900 (m), 960 (m), 1080 (m), 1115 (m), 1165 (m), 1290 (s), 1360 (s), 1465 (s), 1545 (m), 1620 (s), 1700 (s), 2940 (s); uv (95% EtOH): 227 nm (ε 23 000), 315 nm (ε 10 000); ^{1}H nmr δ: 2.7 and 2.8 (2s, 6H, non-equiv. $COCH_3$), 7–9 (8H, arom.); mass spectrum (*m*/*e*): 282 (M^+). *Anal.* calcd. for $C_{16}H_{14}N_2O_3$: C 68.08, H 4.99, N 9.92%; found: C 67.89, H 4.89, N 9.88%.

Preparative photolysis of α-*phenyl*-m-*nitrobenzyl alcohol* ***5***

Employing the above procedure, *m*-nitrobenzophenone **7***c* and *m*-azoxybenzophenone **8***c* were isolated. The former was identified by comparison with the authentic material. *m*-Azoxybenzophenone **8***c*: mp 170–171°C; ir ($CHCl_3$): 1120 (m), 1290 (s), 1320 (s), 1450 (m), 1600 (s), 1660 (s); uv (95% EtOH): 253 nm (ε *25 000), 320 (*ε 10 000); ^{1}H nmr δ: 7–9 (arom.); mass spectrum (*m*/*e*): 406 (M^+). *Anal.* calcd. for $C_{26}H_{18}N_2O_3$: C 76.83, H 4.46, N 6.89%; found: C 77.04, H 4.62, N 6.64%.

Photolysis of m-*azoxybenzaldehyde* ***8***a

m-Azoxybenzaldehyde **8***a* is photochemically labile when irradiated at 254 nm in aqueous solution, as exemplified by the following experiment. A solution of 50 mg of **8***a* (100 mL CH_3CN and 400 mL H_2O) was irradiated in a quartz vessel for 45 min at 254 nm in a Rayonet reactor. The color of the solution changes from light yellow to deep yellow. Upon basification to pH 10, the solution turns to a deep orange, indicative of the presence of phenolic material. The ^{1}H nmr of the recovered material showed broad absorption peaks and could not be characterized. We presume **8***a* (and also **8***b* and **8***c*) photodecomposes to give azophenols, which is a known reaction pathway of aromatic azoxy compound (the photo-Wallach rearrangement) (29).

Preparative photolysis of p-*nitrobenzyl alcohol* ***1***

A solution of 200 mg of **1** in 25 mL CH_3CN and 300 mL pH 13 (NaOH) was prepared in a 0.67-L quartz vessel and saturated with argon. The solution was photolyzed at 254 nm for 10 h in a Rayonet reactor. After irradiation, the solution was neutralized with concentrated HCl, saturated with NaCl, and extracted with 2 × 100 mL CH_2Cl_2. Evaporation of the solvent gave 170 mg of a yellow solid. The tlc of this material showed two spots (silica gel, CH_2Cl_2): R_f 0.2 (substrate) and R_f 0.3 (product; yellow in color). The above photolysis was done in triplicate and the crude materials combined and separated via prep. tlc. There was obtained 180 mg (30% overall isolated yield) of fraction #2 (R_f 0.3), identified as *p*-nitrosobenzaldehyde **1***a* (dimer): mp 185–187°C; ir ($CHCl_3$): 1180 (s), 1460 (m), 1600 (m), 1710 (s), 2740 (w), 2840 (w); uv (95% EtOH): 340 nm (ε 12 000); ^{1}H nmr δ: 10.1 and 10.15 (2s, 2H, non-equiv. CHO), 7.8–8.7 (8H, arom.); mass spectrum (*m*/*e*): 254 (M^+ − 16). *Anal.* calcd. for $C_7H_5NO_2$: C 62.22, H 3.73, N 10.36%; found: C 62.10, H 3.80, N 10.21%. As was observed for **2***a*, **1***a* also exists as a dimer.

Preparative photolysis of α-*methyl*-p-*nitrobenzyl alcohol* ***2***a

The procedure employed for **2** is identical to that for **1** described above. The isolated product was identified as *p*-nitrosoacetophenone **2***a* (dimer), by comparison with the authentic material synthesized in a previous section above.

Relative quantum yields for reaction of ***1*** *and* ***2*** *via preparative photolyses*

The general procedure is described as follows: A solution of 100 mg of the substrate is dissolved in 140 mL aqueous NaOH (6% CH_3CN) and irradiated in a Rayonet reactor for 6 h at 254 nm. After work-up (described above), the extent of reaction was calculated by integrating the aldehyde resonance of **1***a* (or $COCH_3$ resonance of **2***a*) relative to the methylene signal of the substrate at δ 4.8.

Reactions of m-*nitrosoacetophenone* ***18*** *(dimer)*

A solution of 100 mg of **18** was prepared in 50 mL CH_3CN and 200 mL H_2O (pH 7) and left in the dark overnight. The color of the solution was a light yellow during the whole period and therefore suggests that little, if any, monomeric nitroso compound exists in solution. After work-up, **18** was recovered unchanged (as the dimer). When an identical solution was photolyzed at 254 nm for 1 h, an intense orange color developed. After work-up, the tlc (CH_2Cl_2; silica gel) of this material showed a single orange spot at R_f 0.25; no trace of *m*-nitroacetophenone or *m*-azoxyacetophenone was observed. The ^{1}H nmr of the reaction mixture showed a new singlet at δ 2.7, along with the "doublet" at δ 2.6 and 2.65 characteristic of **18** (ratio of product to **18** is about 2:1). We have tentatively identified this product as the corresponding nitroxide of **18**, a known photoproduct of aromatic nitroso compounds (30).

Spectrophotometric studies

Solutions for spectrophotometric studies were prepared in 1.00-cm quartz cuvettes (3.0 mL) by injecting a solution of the substrate (dissolved in CH_3CN) into the solution of appropriate pH via a

microlitre syringe. After purging with argon for 5 min, the cuvette was photolyzed in a merry-go-round apparatus placed inside a Rayonet reactor. The pH solutions were made from aqueous NaOH or phosphate buffer; neither of these absorb significantly above 230 nm. After photolysis, uv spectra were recorded and the increase in OD at λ_{max} of the product was measured. The λ_{max} of the products are given in the above sections dealing with product isolation. An example of a typical uv trace of the photochemical reaction is given in Fig. 1 for *m*-nitrobenzyl alcohol **3**. For relative quantum determinations, care was taken not to irradiate beyond 20% conversion.

Absolute quauntum yield measurements

Malachite green leucocyanide (MGL) in acidic ethanol was employed for chemical actinometry (31). The material was synthesized according to the method of Calvert and Rechen (32), mp 174–176°C (lit. (32) mp 176–177°C). The actinometer is best suited for low light intensities ($\simeq 10^{-9}$ einsteins min^{-1}), which was the situation encountered in these measurements. The actinometer solution was prepared by mixing 0.50 mL acidic aqueous ethanol ($\simeq 10^{-3}$ *M* HCl) with 2.50 mL of a 10^{-3} *M* stock of MGL in 95% EtOH in a quartz cuvette (1.00 cm). The OD at 622 nm was measured prior to and after photolysis (typical irradiation time 3–10 min), and the change in OD (ΔA) at 622 nm was then used to calculate the light intensity of the source via the equation:

$$I(\text{einsteins min}^{-1}\text{ cm}^{-3}) = 10^{-3}\,\Delta A/(\varepsilon_{622}\Phi_{MGL}\Delta t)$$

where ε_{622} is the extinction coefficient of the blue dye produced at 622 nm (1.063×10^5 cm M^{-1}) (31), Φ_{MGL} is the quantum yield for dye formation (0.91) (31), and Δt the elapsed irradiation time in minutes. The light source employed was a 200-W Hg lamp filtered through a Bausch and Lomb monochromator and a 240–420 nm bandpass (Corning 7–54). Ultraviolet spectrophotometry was also employed to monitor the extent of conversion of photoreaction of the substrates. In this method, the product quantum yield (Φ_m), under low conversions, is given by the equation:

$$\Phi_m = \Delta A_\lambda/(10^3\,\varepsilon_\lambda \Delta I_a)$$

where ΔA_λ is the change in OD at the monitored wavelength (λ_{max} of the product) and ε_λ is the corresponding extinction coefficient, and ΔI_a the number of quanta absorbed by the compound during the photolysis time. For compounds **3–5**, the excitation wavelength was 254 nm. The λ_{max} of **7** and **8** (the products) are the same and the extinction coefficients differ by less than 5% at this wavelength. Therefore the above equation can be employed to calculate the total quantum yield for formation of **7** and **8**. Since the mole ratio of **7** and **8** could be determined experimentally (0.76:0.24, respectively; averaged value), we have:

$$\Phi_m = 0.76\Phi(\mathbf{7}) + 0.24\Phi(\mathbf{8})$$

where $\Phi(\mathbf{7})$ and $\Phi(\mathbf{8})$ represent the quantum yield for formation of **7** and **8**, respectively. Individual values for $\Phi(\mathbf{7})$ and $\Phi(\mathbf{8})$ determined via the above method are tabulated in Table 1.

Triplet sensitization

Sodium benzophenone-2-carboxylate **12** was employed as the water-soluble triplet sensitizer. A typical experiment is described as follows. A 10-g solution of **12** was first prepared in the appropriate pH and 100 mg of the substrate dissolved in 50 mL CH_3CN was added with vigorous stirring. The solution was photolyzed at 350 nm, where **12** absorbs >95% of the exciting light. The solution was worked up by first extracting with 2 × 100 mL ether and then back-washing several times with bicarbonate solution to remove residual sensitizer. The extent of reaction could be determined by ^{1}H nmr spectroscopy, by integrating the CHO resonance of the products (for **3**) vs. the methylene protons of the substrate.

Triplet quenching experiments

Diene **13** was used as the water-soluble triplet quencher. A typical experiment is described as follows. A 250-mg solution of **1** and **2** was first prepared in the appropriate pH (100 mL) and a sufficient amount of **13** was added to give a quencher concentration of 0.02 *M*. An identical sample of **1** or **2** was prepared but without added quencher. These two solutions were photolyzed at 350 nm (where the quencher absorbs negligibly) under identical conditions (typically 20–40 min). Both solutions were worked up and the extent of reaction compared via ^{1}H nmr.

General acid catalysis experiments

Two solutions (200 mL) each of 100 mg of **3** were prepared. One solution was made up in 1.0 *M* NaH_2PO_4 and the pH adjusted to 4.2 with dilute $HClO_4$, while the other, of 1.0 *M* NaCl, was also adjusted to pH 4.2. After the photolysis, the percentage conversion was determined via ^{1}H nmr integration as described above. By this method, it was found that $\Phi(1.0\ M\ [HA])/\Phi(1.0\ M\ NaCl) = 1.22 \pm 0.05$ (error is standard deviation), which is indicative of general acid catalysis. The same result was obtained by monitoring the reaction spectrophotometrically at λ_{max} of the product. Using H_3PO_4 (a stronger general acid), at pH 1.5, a value of 1.5 ± 0.1 was obtained and suggests that additional studies are warranted to delineate this effect, which is suggestive of a Brønsted catalysis law of photochemical reaction.

A C-13 nuclear magnetic resonance study of the pyrimidine synthesis by the reactions of 1,3-dicarbonyl compounds with amidines and ureas

ALAN R. KATRITZKY[1] AND TAHER I. YOUSAF
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

Received April 14, 1986

ALAN R. KATRITZKY and TAHER I. YOUSAF. Can. J. Chem. **64**, 2087 (1986).

The detailed mechanistic pathways are elucidated for the reactions of acetylacetone, methyl acetoacetate, and dimethyl malonate with a variety of amidines and ureas. In many cases the identification of a single intermediate allows the definition of the reaction path and identification of two slow steps. Intermediates characterized include ring-closed dihydroxytetrahydropyrimidines, dihydrohydroxypyrimidinones, open-chain enamides, and carbonyl addition compounds.

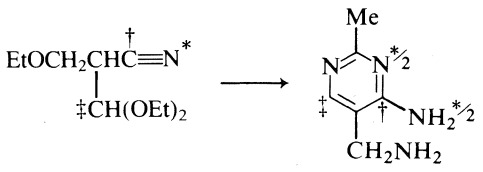
ALAN R. KATRITZKY et TAHER I. YOUSAF. Can. J. Chem. **64**, 2087 (1986).

On a élucidé le mécanisme détaillé des réactions de l'acétylacétone, de l'acétoacétate de méthyle et du malonate de méthyle avec diverses amidines et urées. Dans plusieurs cas, l'identification d'un seul intermédiaire permet de définir le chemin réactionnel et l'identification de deux étapes lentes. Les intermédiaires caractérisés comprennent les dihydroxytétrahydropyrimidines et les dihydrohydroxypyrimidinones cycliques ainsi que les énamides en chaîne ouverte et les composés provenant d'une addition sur le groupement carbonyle.

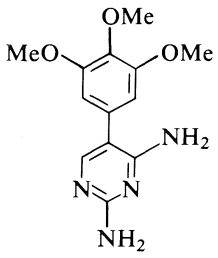
[Traduit par la revue]

Introduction

Pyrimidines are widely distributed in nature (1*a*), and include many synthetic drugs (1*b*). An important principal synthesis of pyrimidines is the reaction of a 1,3-dicarbonyl compound with amidines or ureas, the Traube synthesis (2*a*,*b*, 3*a*,*b*). The older (4*a*,*b*,*c*) and the more recent (5*a*,*b*,*c*) literature on this reaction give preparative details for the synthesis of literally thousands of pyrimidines, but surprisingly little is known of its mechanism. Thus, neither of the two definitive monographs on the subject (6*a*,*b*), nor a recent review by Brown (1*c*), discuss the mechanism. Just two papers published in the last decade have dealt with limited aspects of this question: a ^{14}C and ^{15}N labeling study (7) of the formation of 4-amino-5-aminomethyl-2-methylpyrimidine **2** from two specifically labeled 2-(diethoxymethyl)-3-ethoxypropionitriles **1** and acetamidine showed that the labels were incorporated as indicated: two alternative reaction pathways via a bicyclic intermediate were postulated. An ^1H nmr kinetic study (8) of the formation of trimethroprim **3**



1 **2**



3

from the reaction of various precursor α,β-unsaturated nitriles with guanidine disclosed no intermediates, and was interpreted to show that the initial, and rate-determining, step was attack of the guanidine nitrogen on the nitrile carbon, followed by a fast intramolecular Michael addition to give product.

The present work examines the reactions of acetylacetone **4** (Schemes 1 and 2), methyl acetoacetate **18** (Schemes 3 and 4), and dimethyl malonate **27** (Schemes 5 and 6) with the amidines **5** and ureas **11** by ^{13}C nmr spectroscopy. It was undertaken with a view to identify the intermediates on the reaction pathways, and represents a continuation of our earlier studies of the mechanisms of heterocyclic ring formation (9, 31).[2]

Results and discussion

Basis of investigation

The reactions were carried out in the spectrometer cavity in 5-mm nmr tubes using deuterated solvents. They were all followed by observing in the nmr spectrum the decay of peaks due to starting material, the formation and decay of peaks due to an intermediate, and the concomitant formation of product peaks. The assignments of all starting materials and some product pyrimidines were in accord with the literature. Authentic values for chemical shifts of those pyrimidines not reported in the literature were obtained by appropriate syntheses using literature procedures (6*a*,*b*) and subsequent ^{13}C nmr characterization. Intermediate peaks were assigned by reference to tables of published values for the appropriate open chain compounds (10–13, 14, 15). All assignments were supported using the two INEPT(D) pulse sequences previously described (9).

C-13 assignments and identification of intermediates

Table 1 gives the chemical shifts and assignments of the 1,3-dicarbonyl compounds used in the present study; similar data for amidines **5** (*a*–*d*) are given in the Experimental; they are in broad agreement with the literature values (12, 13), as are the chemical shifts and assignments of the pyrimidines **9** (Table 2), formed from the reactions of the amidines **5** (*a*–*c*) with acetylacetone **4** (Scheme 1) (16).

A maximum of one intermediate was observed in each of the reactions studied, and this was identified on the basis of the evidence discussed below as either the diol **7** (Table 3, Scheme 1) (in reactions with amidines) or as the enamide **17** (Scheme 2) (in reactions with ureas).

[a]Chemical shifts in ppm relative to DMSO-d_6 at 39.5 ppm.
[b]2-Me s at 26.3 ppm.

The peak most characteristic of the diols **7** is that due to the two equivalent sp^3 carbons, C(4,6), at ca. 80 ppm (Table 3). Given that an sp^3 carbon attached to one oxygen resonates at ca. 50–56 ppm (11*a*), and when attached to a nitrogen at ca. 27–45 ppm (11*b*), and assuming the additivity of substituent effects (11*c*), it follows that the hemiaminal carbons C(4,6) should resonate in the region 77–110 ppm, as observed above and in the literature (15*b*). A similar approach rationalizes the chemical shifts of the methylene (5-CH_2) and methyl (4,6-CCH_3) carbons, which resonate characteristically at ca. 44 ppm and 28–29 ppm, respectively (Table 3). The C=N carbons (C2) resonate in the intermediate ca. 7–8 ppm upfield of the corresponding carbons in the parent amidine (cf. C2, Table 3 and Experimental) with the exception of R = NH_2, where the value in the intermediate is ca. 2 ppm downfield of that in the amidine. Notably, replacement of hydrogen by methyl at C2 has a *deshielding* effect: thus, C2 (R = Me) is ca. 10 ppm downfield of C2 (R = H) in the intermediates **7** (Table 3), products **9** (Table 2), and amidines **5** (cf. Experimental). A similar effect is observed at carbons 4 and 6 of the product: in the dimethyl derivatives these carbons resonate at ca. 167–170 ppm (Table 2), whereas in the parent compounds (16, 17) they resonate in the region 157–162 ppm.

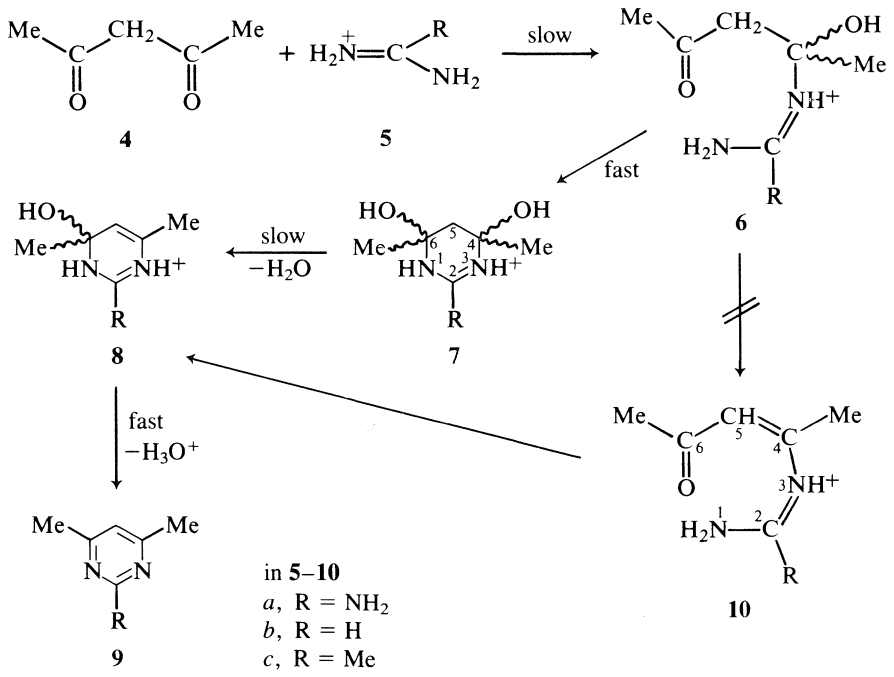
The diols **7** (Scheme 1) may, in principle, be formed as mixtures of three enantiomers, having the configurations *RR*, *SS*, or *RS* at C4 and C6. As the first two enantiomers are diastereomerically related to the third, *two* peaks may, in principle, be observed for the atoms C(4,6) (which are otherwise identical due to rapid proton exchange between the two nitrogens at the medium pH of 10–12). In practice, only one peak was observed (Table 3; C4,6).

No intermediate was observed in the reaction of benzamidine **5***d* with acetylacetone **4**; this reaction goes smoothly to product **9***d* (Table 2). Lowering of the reaction temperature merely slowed the rate of product formation and led, ultimately, to precipitation of the amidine.

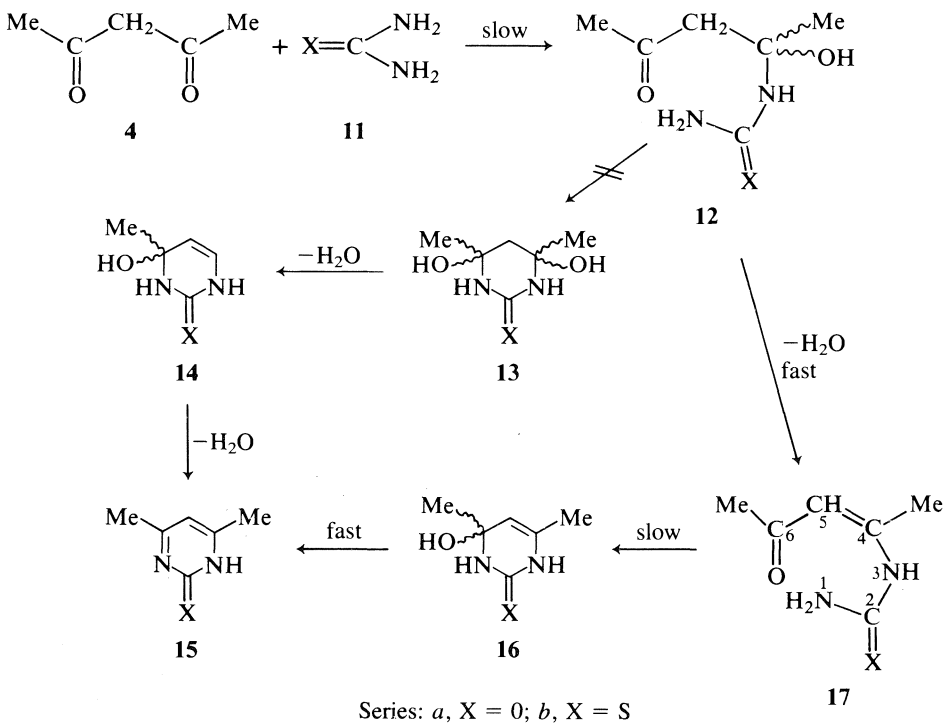
In none of the above reactions was the intermediate enamide **10** (Scheme 1) observed. In particular, none of the three characteristic peaks (the key enamine carbon C4 (expected in the range 135–165 ppm) (15*a*), the methine carbon C5 (92–110 ppm) (15*a*), and the conjugated carbonyl C6 (190–200 ppm) (12*a*)) were observed in reactions of the amidines **5** (*a*–*d*) with acetylacetone **4**.

In stark contrast, in reactions of urea **11***a* and thiourea **11***b* with acetylacetone **4** in acidic media (pH 1–2) the enamide **17** (Scheme 2) is the *only* intermediate seen; it is formed immediately upon mixing and slowly decays to give product **15** (Table 2). All three key enamide **17** carbons, C4 (δ 148.7), C5 (δ 102.7), and C6 (δ 198.2) of **17***a* and C4 (149.0), C5 (101.5), and C6 (197.1) of **17***b*, resonate in the expected regions (see above). Only the (*Z*) isomer is seen in both reactions, although in principle, both the (*E*) and the (*Z*) isomers could be formed. The C2 carbons resonate at 157.0 and 183.9 ppm for **17***a* and **17***b*, respectively, differing little from the resonances of the starting materials (cf. Experimental); the chemical shifts of the methyls C4-Me (21.3) and C6-Me (29.8) of **17***a* and C4-Me (22.8) and C6-Me (29.4) of **17***b* parallel those of the atoms C4 and C6 to which they are attached: the mechanistic interpretations of these observations are discussed later.

Table 4 gives the chemical shifts and assignments of the pyrimidin-ones **21** and -diones **25** formed in the reactions of methyl acetoacetate **18** with the amidines **5** (*a*–*d*) (Scheme 3) and with the ureas **11***a* and **11***b* (Scheme 4). Their values are not recorded in the pyrimidine nmr literature (1*d*, 12*e*), although those of the parent compounds are known (12*f*, 14). Again, replacement of hydrogen by methyl or phenyl at C2 has a



SCHEME 1. Mechanism of reaction of acetylacetone **4** with the amidines **5**.



SCHEME 2. Mechanism of reaction of acetylacetone with urea **11***a* and thiourea **11***b*.

deshielding effect: thus, for R = Me or Ph, C2 resonates ca. 14 ppm downfield of R = H (Table 4). Substitution at C2 has a small effect on the chemical shifts of carbons 4 and 6, which resonate in the regions 161–171 ppm and 153–162 ppm, respectively (Table 4), and a somewhat larger effect on the chemical shift of the methine carbon C5, which resonates at ca. 99–113 ppm (Table 4).

Table 5 gives the chemical shifts and assignments of the intermediates **19** and **20**, seen in the reactions of the amidines **5** (*a*–*d*) with methyl acetoacetate **18** (Scheme 3); for guanidine **5***a* and formamidine **5***b*, the peaks were assigned to the intermediate ester **19**, and for acetamidine **5***c* and benzamidine **5***d*, they were assigned to the hydroxydihydropyrimidinone **20**. In all cases, the characteristic HN—C—OH sp^3 carbons (C-4) (Scheme 3) resonate in the region 80–84 ppm (Table 5), ca. 2–4 ppm downfield of the analogous carbons in the intermediate diol **7** (Scheme 1, Table 3). Both the ester and lactam carbonyls of the intermediates **19** and **20**, respectively (Scheme 3), resonate in the region 172–176 ppm (Table 5), within the literature values (12*b*, *c*). No difference is observed between the

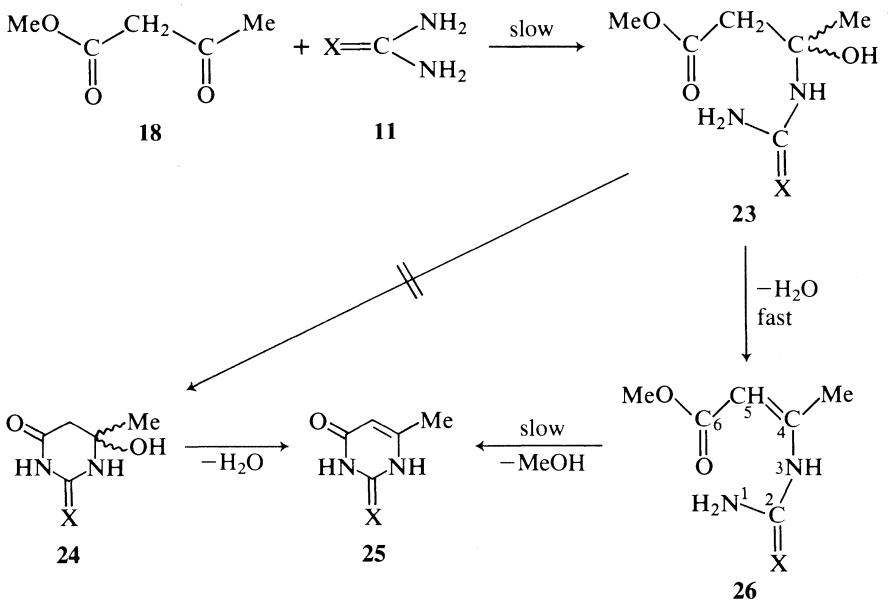
[e]Phenyl carbons of intermediate overlapping with those of starting material and product.

chemical shifts of the methylene carbons C5 in the intermediates **19** and **20** (Table 5) and those in the diol **7** (C5, Table 3), all resonating at ca. 43–45 ppm (with the exception of C5 in **19***b*, which resonates at 48.0 ppm). The amidine-like carbons C2 in the intermediates **19** and **20** resonate in the region 158–166 ppm (Table 5), downfield of the corresponding carbons in the diol **7**, which resonate in the region 151–162 ppm (C2; Table 3).

The only intermediate observed in the reaction of methyl acetoacetate **18** with urea **11***a* is the enamide **26***a* (Scheme 4). Both the (*E*) and (*Z*) isomers are seen, with the latter predominating (*Z*:*E* ca. 10:1 as determined from ^{13}C peak heights). This is in contrast to the reaction of acetylacetone **4** with the ureas **11***a* and **11***b* (Scheme 2), where only the (*Z*) isomer was observed. The key enamide **26***a* carbons C4 and C5 (Scheme 4) resonate at δ 154.2 and 91.5, respectively, for the (*Z*) isomer, and at δ 152.4 and 94.5, respectively, for the (*E*) isomer, and are within the literature range (15*a*). Little change occurs in the chemical shifts of the methoxy carbonyl group in going from starting material **18***a* (C3 and OMe; Table 1) to the intermediate **26***a* (C6 (δ 168.6) and C7 (δ 50.4) for both (*E*) and (*Z*) isomers). A small upfield shift (ca. 5 ppm) is observed in the carbonyl carbon of urea in going from starting material **11***a* (δ 160.7) to the intermediate **26***a* ((*Z*), (δ 156.9); (*E*), (δ 152.4)). A much larger shift (ca. 10 ppm) is observed in the C4 methyl carbon, which resonates at 30.3 ppm in the starting material (Table 1; **18***a*; Me) and at 21.6 ppm ((*Z*) isomer) and 18.1 ppm ((*E*) isomer) in the intermediate **24***a*; this is due to conversion of the ketone carbonyl (C1) of starting material to the enamide carbon C4 of intermediate (Scheme 4).

Table 6 gives the chemical shifts and assignments of the pyrimidinones **29** and **31** formed from the reactions of dimethyl malonate **27** with the amidines **5***a* and **5***d* (Scheme 5) and the ureas **11***a* and **11***b* (Scheme 6).

The chemical shifts of the barbituric acids **31***a* and **31***b* (Scheme 6; Table 6) are in broad agreement with the literature values (12*e*), but those of the pyrimidinones **29***a* and **29***d* (Scheme 5; Table 6) have not been previously reported (10–14, 16, 17). No intermediates were observed in these four reactions, the starting materials going smoothly to product. The mechanistic interpretations of this result are discussed below.



Series: *a*, X = O; *b*, X = S

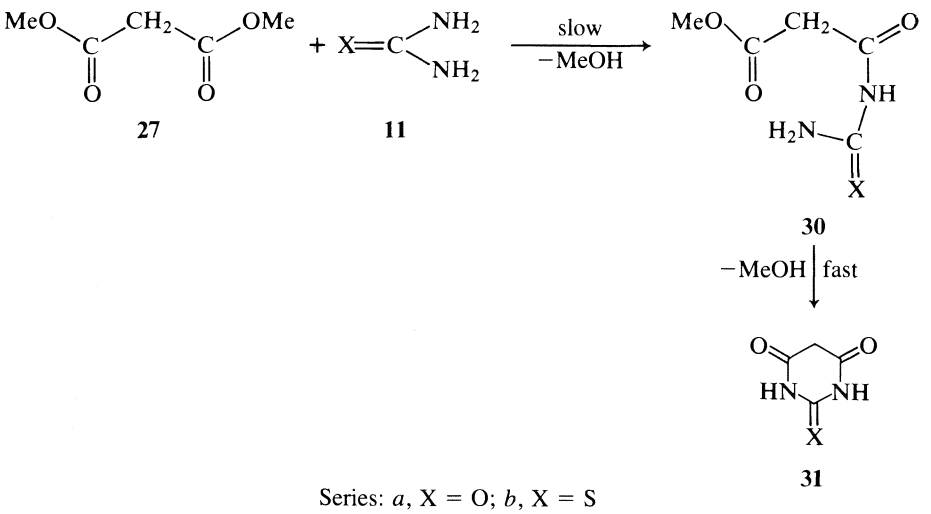
SCHEME 5. Mechanism of reaction of dimethyl malonate **27** with the amidines **5**.

Discussion of mechanistic pathways

The observation of the diol **7** (Scheme 1) as the only intermediate in the reaction of acetylacetone **4** with amidines **5** implies: (*i*) that there are two slow steps in the reaction, one preceding diol **7** formation, and the other succeeding it; (*ii*) that elimination from the intermediate **6** to form the enamide **10** is much slower than ring closure of **6** to the diol **7**. This implies that the initial nucleophilic attack, **4** + **5** → **6**, is the first slow step of the reaction, confirming Todd's earlier speculations (5*b*). Further support for this comes from the fact that the rate of diol **7** formation increases with the pK_a of the amidine (18): thus, guanidine is the most reactive nucleophile, and benzamidine the least reactive. The second slow step of the reaction *must* be the elimination, **7** → **8**, for otherwise the intermediate **7** could not accumulate. The elimination, **8** → **9**, is therefore fast, consistent with the fact that it leads to aromatization (1*e*).

The above mechanism, i.e. **4** —(slow)→ **6** —(fast)→ **7** —(slow)→ **9** is directly analogous to the mechanism of pyrazole formation from 1,3-diketones and hydrazine (19*a*,*b*,*c*), in which the diol **32** and not the hydrazone **33** was observed. It is also analogous to the mechanism of reaction of acetylacetone **4** with hydroxylamine (20) in which the diol **34** (and not the oxime **35**) was the only intermediate observed. However, it is in contrast with the mechanism of pyrrole formation from acetonylacetone and amines (9), where the imine **37** and *not* the diol **36** was the only intermediate observed, and also contrasts with the reaction of hydroxylamine with ethyl acetoacetate (21) in which the oxime **39** and not the isoxazolone **38** was observed. All the above reactions were carried out in basic media and thus these mechanistic differences cannot be ascribed to differences in reaction pH. In reactions of β-dicarbonyl compounds that proceed *via* diols (19, 20), ring closure of the initially formed carbinolamines is faster than elimination; the reverse is true in reactions of β-ketoesters (32), and this difference may be attributed to the greater electrophilicity of a ketone carbonyl vis-à-vis an ester carbonyl: thus Cocivera *et al.* have shown that



Series: *a*, X = O; *b*, X = S

intramolecular nucleophilic attack at a ketone carbonyl is ca. 10^6 times faster than at an ester carbonyl (21).

The observation of the enamide **17** (Scheme 2) as the *only* intermediate in the reactions of the ureas **11** with acetylacetone **4** under acidic conditions (pH ca. 1–2; no reaction occured at alkaline pH) implies that the elimination **12** → **17** (Scheme 2) is fast compared to the ring closure **12** → **13**, and that the second slow and rate-determining step is ring closure of the enamide **17**, to the hydroxypyrimidinone **16**. The overall mechanistic pathway therefore is **4** —(slow)→ **12** —(fast)→ **17** —(slow)→ **15**, paralleling the mechanism of the Paal–Knorr reaction (9), and the reaction of β-ketoesters with hydroxylamine (21, 32).

39

In the reactions of methyl acetoacetate **18** with four different amidines **5** (Scheme 3), in each case just one intermediate is seen. However, the nature of this intermediate depends on the structure of the amidine: it is the open chain ester **19** with formamidine **5***b* and guanidine **5***a* and the hydroxypyrimidinone **20** with acetamidine **5***c* and benzamidine **5***d*. In all cases, the initial nucleophilic attack is the first slow step of the reaction as the intermediates are seen in the presence of starting material (paralleling reactions with acetylacetone **4**), but, in the former, the *second* slow step must be the ring closure **19** → **20**, followed by the fast elimination to give product **21**, whereas in the latter it must be the elimination **20** → **21** (with the ring closure **19** → **20** being fast). There appears to be a clear changeover in rate-determining step with the nature of the R group, a result that might be due to the conformational effect of R. The overall mechanistic pathways therefore are **18** —(slow)→ **19** —(fast)→ **20** —(slow)→ **21** for R = Me, Ph; and **18** —(slow)→ **19** —(slower)→ **20** —(fast)→ **21** for R = NH_2, H.

In the reaction of methyl acetoacetate **18** with urea **11***a*, however, only the enamide **26** (Scheme 4) was observed as intermediate, paralleling reactions of acetylacetone **4** with the ureas **11** (Scheme 2), and in accord with earlier isolation of the corresponding enamide from the reaction of ethyl acetoacetate with urea (22). The observation of **26** (Scheme 4) as the only intermediate on the pathway to **25** implies that elimination from the open-chain ester **23** is much faster than ring closure of **23** to **24**; it also implies that the second slow step of the reaction must be the ring closure **26** → **25**, the first slow step being the initial nucleophilic addition, as the intermediate **26** is seen in the presence of starting materials. The overall mechanistic pathway therefore is **18** —(slow)→ **23** —(fast)→ **26** —(slow)→ **25** (Scheme 4) and is analogous to the mechanism in Scheme 2.

No intermediates were observed in reactions of dimethyl malonate **27** with either guanidine **5***a* and benzamidine **5***d* (Scheme 5) or urea **11***a* and thiourea **11***b* (Scheme 6) and this implies that ring closure of the open-chain esters **28** (Scheme 5) and **30** (Scheme 6) is faster than initial nucleophilic attack. This is to be expected when both functional groups have the same reactivity, as was observed previously in reactions with acetyl-

acetone (Scheme 1) where the *intra*molecular nucleophilic attack **6** → **7** was faster than the *inter*molecular nucleophilic attack **4** → **6**.

Experimental

All melting points were determined on a Kofler hot-stage and are uncorrected. Combustion analyses were carried out on a Carlo Erba elemental analyser 1106. All reagents were obtained from Aldrich and characterized by their ^{13}C nmr spectra: guanidine **5***a* (δ 159.8); formamidine **5***b* (δ 158.6); acetamidine **5***c* (δ 169.0) (13*c*); benzamidine **5***d* (δ 163.9) (13*d*); urea, **11***a* (δ 160.7) (12*d*); thiourea, **11***b* (δ 183.7) (12*d*).

General method

Reactions were started by the addition of a concentrated DMSO-d_6 solution of the appropriate amidine or urea (0.01 mol) from a hypodermic syringe to a 5-mm nmr tube containing the β-dicarbonyl compound (0.01 mol); the total volume of the resultant solution was ca. 0.3 mL, giving an initial concentration of reactants of ca. 25–30 mol L^{-1}.

Spectra

C-13 spectra were recorded in the temperature range 22–28°C (unless otherwise stated) on a JEOL FX-100 spectrometer at 25.1 MHz; DMSO-d_6 and methanol-d_4 were both used as internal lock and internal reference. The spectral window was 6 kHz with 8K data points giving a digital resolution greater than 1.5 Hz per point. A pulse width of 19 μs (90°) was used with a 0.5–2.0 s pulse delay (depending upon reaction rates) and an acquisition time of 0.68 s; longer pulse delays (4–6 s) were occasionally used to assign the quaternary carbons of reaction intermediates. Accumulations varied from 500 to 2000 giving a typical signal : noise ratio > 10^2:1.

Syntheses

The following compounds were prepared by literature methods: 2,4,6-trimethylpyrimidine **9***c* (23); 2-phenyl-4,6-dimethylpyrimidine **9***d* (24), mp 83.5–84°C (lit. (24) mp 81–83°C. *Anal.* calcd.: C 78.2, H 6.6, N 15.2; found: C 78.4, H 6.7, N 15.0); 2-amino-4,6-dimethylpyrimidine **9***a* (24), mp 152–153.5°C (lit. (24) mp 152–154°C. *Anal.* calcd.: C 58.5, H 7.4, N 34.1; found: C 58.7, H 7.5, N 33.9); 4,6-dimethylpyrimidin-2-one **15***a* (25), mp 198–199°C (lit. (25) mp 197°C. *Anal.* calcd.: C 58.1, H 6.5, N 22.6; found: C 57.9, N 6.5, H 22.4); 4,6-dimethylpyrimidin-2-thione **15***b* (26), mp 211–211.5°C (lit. (26) mp 210°C. *Anal.* calcd.: C 51.4, H 5.8, N 20.0; found: C 51.6, H 5.9, N 19.8); 6-methylpyrimidin-4-one **21***b* (27), mp 147–148.5°C (lit. (27) mp 148–149°C. *Anal.* calcd.: C 54.4, H 5.5, N 25.5; found: C 54.7, H 5.5, N 25.3); 2-amino-6-methylpyrimidin-4-one **21***a* (28), mp 268–269°C (lit. (28) mp 270°C (dec.). *Anal.* calcd.: C 48.0, H 5.6, N 33.6; found: C 48.3, H 5.6, N 33.4); 2,6-dimethylpyrimidin-4-one **21***c* (29), mp 194.5–195°C (lit. (29) mp 195.5–196.5°C. *Anal.* calcd.: C 58.1, H 6.5, N 22.6; found: C 58.0, H 6.5, N 22.5); 6-methylpyrimidin-2,4-dione **25***a* (22), mp >300°C (lit. (22) mp >300°C. *Anal.* calcd.: C 47.6, H 4.8, N 22.2; found: C 47.3, H 4.6, N 22.1); 2-phenylpyrimidin-4,6-dione **29***d* (30), mp >300°C (lit. (30) mp 325–330°C. *Anal.* calcd.: C 63.8, H 4.3, N 14.9; found: C 63.8, H 4.3, N 14.7).

COMMUNICATION

Ring inversion in solid fluorocyclohexane

RODERICK E. WASYLISHEN
Department of Chemistry, Dalhousie Univrsity, Halifax, N.S., Canada B3H 4J3

Received March 17, 1986

RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 2094 (1986).

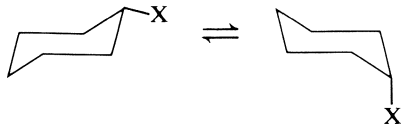
Inversion of the cyclohexane ring system in the solid state has been directly observed in a ^{19}F nmr study of solid fluorocyclohexane. The barrier to ring inversion in the orientationally disordered solid phase, $\Delta G^{\ddagger}_{e\rightarrow a} = 44.1 \pm 0.9$ kJ mol^{-1} at 263 K is found to be only slightly larger than the value previously reported for a $CFCl_3$ solution of fluorocyclohexane. The population of the equatorial conformation is slightly favored over the axial conformation with $K = P_e/P_a = 1.56$ at 281 K; similar values have been obtained in $CFCl_3$ and in the gas phase.

RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 2094 (1986).

Une étude par rmn du ^{19}F du fluorocyclohexane à l'état solide a permis d'observer directement l'inversion du noyau cyclohexane à l'état solide. On a trouvé que, à 263 K, la barrière à l'inversion de cycle, dans le phase solide désordonnée du point de vue de l'orientation, $\Delta G^{\ddagger}_{e\rightarrow a} = 44{,}1 \pm 0{,}9$ kJ mol^{-1}, n'est que légèrement supérieure à la valeur rapportée antérieurement pour une solution de fluorocyclohexane dans le $CFCl_3$. La population de la conformation équatoriale est légèrement favorisée par rapport à la conformation axiale et $K = P_e/P_a = 1{,}56$, à 281 K; des valeurs semblables ont été obtenues pour des solutions dans le $CFCl_3$ ainsi qu'en phase gazeuse.

[Traduit par la revue]

In the gas phase (1, 2) and in solution (3–8) the cyclohexane ring of monosubstituted cyclohexanes is known to undergo rapid ring inversion (**I**). The transition state for this process is



I

thought to involve a half-chair structure with boat and twist-boat forms existing as intermediates along the reaction path (Fig. 1) (3, 8–12). Typical barriers for ring inversion are 40–45 kJ mol^{-1} while the energy differences between the equatorial and axial conformers are generally 0–4 kJ mol^{-1} (3, 7, 8, 13). Although some infrared and Raman evidence exists for ring inversion in solid cyclohexane (11), fluorocyclohexane, and chlorocyclohexane (14, 15), the rates of inversion have not been determined. Here we present preliminary results of a ^{19}F nmr study of *solid* fluorocyclohexane, which clearly demonstrate that the inversion process takes place in the solid state at rates comparable to those reported in $CFCl_3$ solutions (3).

Representative variable temperature ^{19}F nmr spectra of solid fluorocyclohexane are shown in Fig. 2. The spectra were obtained on a commercial sample (Cationics, Inc.) at 339.6736 MHz with ^1H decoupling ($\gamma B_2 \simeq 2$ kHz) using a Nicolet 360 nmr spectrometer. The sample (mp $\simeq$ 285 K) was degassed and sealed under vacuum at 77 K in a 5-mm nmr tube. The relatively narrow ^{19}F nmr lines observed for solid fluorocyclohexane imply that it exists as an orientationally disordered solid between the mp and 183 ± 3 K. Below 183 ± 3 K we were unable to detect a ^{19}F resonance because of dipolar broadening. A similar orientationally disordered solid phase is known to exist for cyclohexane between the mp (279.8 K) and 186.0 (16).

The spectra in Fig. 2 represent a typical example of decoupled two-site exchange between unequally populated sites. In the region of fast exchange ($T > 280$ K) the observed chemical

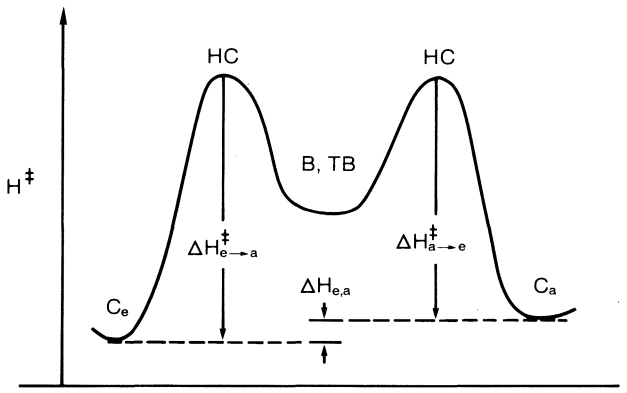


FIG. 1. Energy diagram for ring inversion in a monosubstituted cyclohexane showing the relative energies of the chair (C), half-chair (HC), and twist-boat (TB) conformations.

shift, δ_{obs}, is given by eq. [1],

$$[1] \quad \delta_{obs} = p_e\delta_e + p_a\delta_a$$

where p_e and p_a are the relative populations of the equatorial and axial conformers ($p_e + p_a = 1$) and δ_e and δ_a are the ^{19}F chemical shifts of the two respective conformers. From our data we calculate $p_e = 0.61$ and $p_a = 0.39$ at 281 K, hence $\Delta G^0_{e,a} = 1.045 \pm 0.10$ kJ mol^{-1} (250 ± 25 cal mol^{-1}). This value is within experimental error of the value measured in $CFCl_3$ solution, 242 cal mol^{-1} at 218 K (3), and the value measured in the gas phase, 400 ± 300 cal mol^{-1} (1).

The average lifetime, τ, that the fluorine spends in the equatorial and axial sites can be obtained by visually comparing observed spectra with those calculated for different τ values using standard line-shape computer programs (8, 17). Using this procedure we obtain $\tau = 40 \pm 5$ μs at 263 K, the approximate coalescence temperature. The free energy changes for $\Delta G^{\ddagger}_{e\rightarrow a}$ and $\Delta G^{\ddagger}_{a\rightarrow e}$ were calculated using eq. [2],

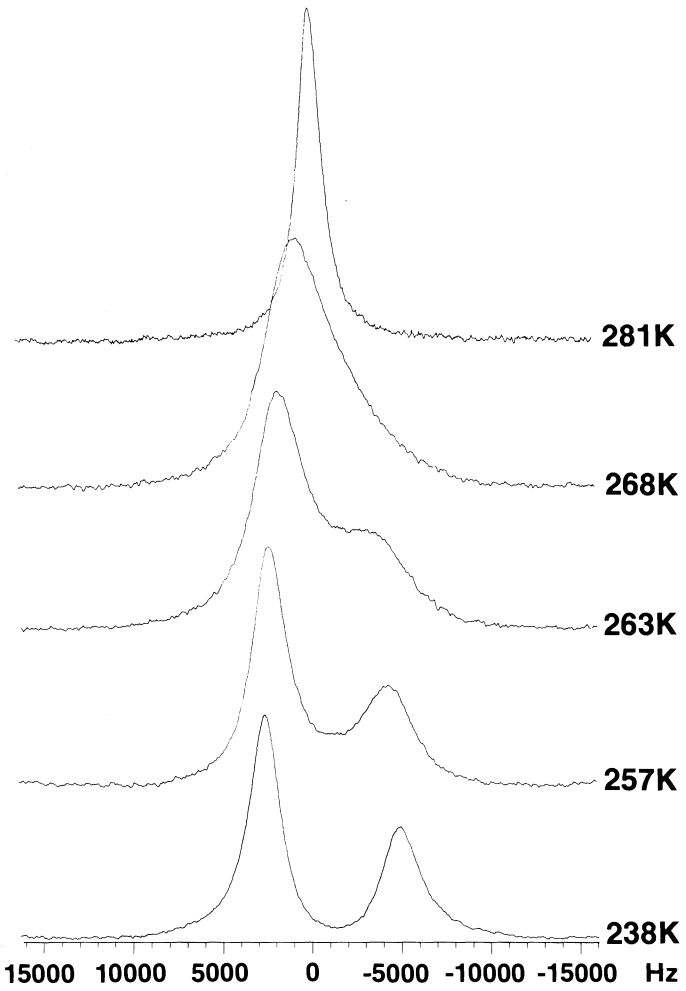

FIG. 2. Fluorine-19 nmr spectra of solid fluorocyclohexane at 339.67 MHz.

$$[2] \quad \Delta G^{\ddagger} = -RT \ln \frac{k_B T}{hk}$$

where k is either $k_{e\to a}$ or $k_{a\to e}$ ($\tau = p_a/k_{e\to a} = p_e/k_{a\to e}$) and all other symbols are standard (8, 15). We obtain $\Delta G^{\ddagger}_{e\to a} = 44.1 \pm 0.9$ kJ mol^{-1} (10.5 ± 0.2 kcal mol^{-1}) and $\Delta G^{\ddagger}_{a\to e} = 43.1 \pm 0.9$ kJ mol^{-1} (10.3 ± 0.2 kcal mol^{-1}). Similar results were obtained using the approximate procedure of Shanan-Atidi and Bar-Eli (18). It is interesting to compare these results with the accurate values obtained in a solution study by Bovey *et al.* (3). In a $CFCl_3$ solution at 218 K they obtained $\Delta G^{\ddagger}_{e\to a} = 10.14 \pm 0.05$ kcal mol^{-1} and $\Delta G^{\ddagger}_{a\to e} = 9.90 \pm 0.05$ kcal mol^{-1}; at 264 K, $\tau = 21.3$ μs. These results indicate that in the case of fluorocyclohexane the barrier to inversion in the high-temperature solid phase is only slightly more hindered than in solution. In fact, the barrier to ring inversion observed here is within experimental error of the value recently measured in the gas phase (19).

Previously Ellett *et al.* (20) found evidence for ring inversion in the plastic crystalline phase of perfluorocyclohexane; however, the barrier to ring inversion was not measured. Further dynamic studies on fluorocyclohexane and related compounds in the solid state are in progress.

Acknowledgement

I wish to thank Mr. J. B. Macdonald for helping obtain some of the preliminary nmr spectra, Mr. Ross Dickson and Dr. T. B. Grindley for assistance with the line-shape calculations, and NSERC for financial support.

GEORGE R. PETTIT and PAUL S. NELSON. Can. J. Chem. **64**, 2097 (1986).

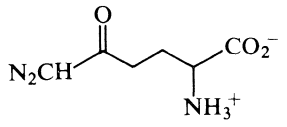
A study of carboxylic acid → diazoketone conversion was pursued employing the γ-carboxyl group of otherwise protected L-glutamic acids. The Arndt–Eistert route employing carboxylic acid chloride intermediates was found best (52% yield, **5***b*), performed at very low temperatures employing oxalyl chloride in dimethylformamide–tetrahydrofuran followed by diazomethane at −23°C. Alternatively, substitution of a mixed carbonic anhydride for the acyl chloride led to very similar yields (57% of **5***b*) of diazoketones (**5**). Among a series of active ester intermediates (**7**) examined, only the ODnp (**7***d*) and SPfp (**7***f*) esters were found to react (23–26% yield), at least partially, with diazomethane. The latter two reactions appear to represent the first such examples employing active esters.

GEORGE R. PETTIT et PAUL S. NELSON. Can. J. Chem. **64**, 2097 (1986).

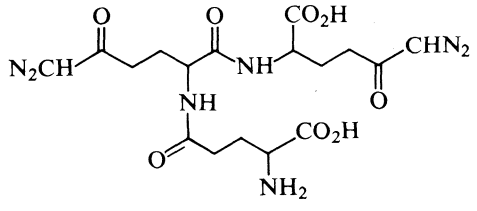
On a effectué une étude sur la transformation acide carboxylique → diazocétone d'un groupement carboxyle γ d'acides L-glutamiques qui sont par ailleurs protégés. On a trouvé que la réaction de Arndt–Eistert, impliquant un chlorure d'acide comme intermédiaire, conduit aux meilleurs résultats (rendement de 52% en **5***b*) lorsque l'on opère à de très basses températures, avec du chlorure d'oxalyle dans un mélange diméthylformamide et tétrahydrofuranne et que l'on ajoute ensuite le diazométhane à −23°C. Par ailleurs, si l'on substitue un anhydride carbonique mixte pour le chlorure d'acide, on obtient des rendements très semblables (57% de **5***b*) de diazocétones (**5**). Parmi la série d'esters actifs intermédiaires (**7**) qui a été étudiée, on a trouvé que seuls les esters ODnp (**7***d*) et SPfp (**7***f*) réagissent relativement bien (23–26% de rendement) avec le diazométhane. Ces deux dernières réactions semblent représenter les premiers exemples de réactions impliquant des esters actifs.

[Traduit par la revue]

The Streptomyces anticancer antibiotics 6-diazo-5-oxo-L-norleucine (**1**, DON) and azotomycin (**2**) display a broad spectrum of activity against experimental neoplastic diseases and have given evidence of potential clinical utility (2). In 1983 we summarized a new synthesis of DON (3) and more recently completed the first total synthesis of azotomycin (1). For the latter investigation it became necessary to carefully define suitable (very mild) experimental conditions for converting the γ-carboxyl group of glutamic acid to a diazoketone. For that purpose we conducted the present study of carboxylic acid chloride, anhydride, and active ester reactions with diazomethane.



1, DON



2, Azotomycin

The most common route to α-diazoketones is the Arndt–Eistert method (4) involving reaction of an acid chloride with diazomethane. In early transformations of amino acids to diazoketone derivatives, *N*-monosubstituted glycyl chlorides were found to react with diazomethane to give oxazolones (5) instead of the diazoketones. Later, diazoketone derivatives of *N*-phthaloyl (6) and tosyl (7) protected amino acids were prepared via the Arndt–Eistert method. In respect to diazoketones derived from dicarboxyl amino acids, early studies showed that the γ-carboxyl diazoketone derivative of *N*-Z-Glu-OBzl could be prepared (but not characterized), albeit in low yield (20% based on the α-chloroketone derivative (7*a*)), from its corresponding acid chloride. Later Rudinger and Farkasova (8) showed that a diazoketone could be prepared from an *N*-tosyl oxazolidone protected L-glutamic acid. The β-carboxyl diazoketone derivative of *N*-Tfa-L-Asp-OEt was generated in 82% yield. More recently, using typical Arndt–Eistert conditions, *N*-tosyl-L-glutamic acid was found to give, instead of the expected bisdiazoketone, 5-oxo-1-tosyl-2-(diazoacetyl)pyrrolidine (7*c*). Results of such experiments suggested that synthesis of azotomycin (**2**) would require carefully defined experimental conditions for generating and maintaining the diazoketone groups. Thus we were encouraged to consider alternatives to the acyl halide intermediates, such as carboxylic acid anhydrides, and the previously unexplored possibility of using carboxylic acid active esters.

Previous efforts to employ carboxylic acid anhydrides (9) have included reaction between benzoic acid anhydride and diazomethane to form diazoacetophenone (9*e*) and with cyclic anhydrides to yield mono-diazoketones (9*c*). A more useful diazoketone synthesis has utilized the mixed carbonic anhydride activation of a carboxylic acid (10). And diazoketone derivatives of *N*-phthaloyl, *N*-Boc, and *N*-Z protected amino acids have been obtained from isobutyl- and ethyl-type mixed carbonic anhydrides in 30–70% yields (10).

In the present evaluation of diazoketone formation via an acyl chloride, oxalyl chloride was selected for acid chloride formation in place of, e.g., the more side-reaction-promoting (7*c*) thionyl chloride or phosphorus pentachloride reagents. Three of the most important criteria considered when subjecting the γ-carboxyl group of Glu derivative **3***a* to reaction with oxalyl chloride were low temperature to avoid cyclization, catalytic-type assistance by dimethylformamide, and removal of hydro-

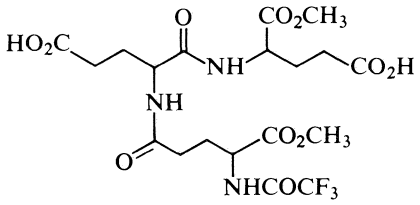
gen chloride with triethylamine. Best results (86% yield of the purified methyl ester derivative **4**, Method A) were obtained employing oxalyl chloride (1 equiv.) in tetrahydrofuran containing triethylamine (1 equiv.) and 2 drops of dimethylformamide near 0°C for 30 min. Application of this procedure to γ-carboxylic acid **3***a* followed by reaction with diazomethane afforded diazoketone **5***b* in 52% yield, as yellow crystals displaying significant antineoplastic activity (1) (e.g., with the MX-3 breast xenograft, 58–84% tumor regression at 150–600 mg/kg). Extension of this diazoketone route to preparation (**3***b* → **5***c*) of the key intermediate, diazoketone **5***c*, used in our synthesis of DON (3, 11) consistently afforded a yield improvement (20% vs. 16% following purification). Earlier we employed oxalyl chloride in methylene chloride for generating the acid chloride.

To ascertain if the yield of diazoketone **5** could be increased by utilizing anhydride or active ester (12) intermediates, attention was redirected to glutamic acid derivatives **6** and **7**. Except for γ-ONp ester **7***c*, all of the active esters are new substances and were obtained (excluding **7***g* prepared using a mixed carbonic anhydride) by condensing acid **3***a*, using dicyclohexylcarbodiimide, with the respective phenol (**7***a–d*), hydroxylamine (**7***e*), or thiophenyl (**7***f*; ref. 12).

Reaction of anhydride **6***a* with diazomethane selectively attacked the γ-carbonyl to afford diazoketone **5***a* in 18% yield. Structure of the product was confirmed by an unambiguous synthesis. For this purpose *N*-Z-L-Glu-α-OMe γ-Dcha salt (13) was converted to the acid chloride, followed by treatment with diazomethane to afford diazoketone **5***a*. Unfortunately, *N*-Tfa-L-Glu-anhydride (**6***b*) proved inert to diazomethane treatment. However, the mixed carbonic anhydride (MCA) approach proved more rewarding. The reactive mixed carbonic anhydride generated *in situ* (at −23°C) from *N*-Z-L-Glu-OBzl (13) or the corresponding dicyclohexylammonium salt (3, 13) and isobutyl chloroformate was allowed to react with diazomethane and warmed to room temperature for 1 h. By this means diazoketone **5***b* was isolated in 55 and 57% yields respectively. This method also proved quite competitive with the improved (see above) acid chloride pathway.

Active esters **7***a–g* proved sluggish or refractory toward reaction with 2 equivalents of diazomethane at room temperature for 1 day. When a significant amount of diazoketone **5***b* was not detectable by tlc analysis, the reaction was terminated. Otherwise the reaction was continued for another day with periodic additions of diazomethane. In only two cases, 2,4-dinitrophenyl ester **7***d* and pentafluorothiophenyl ester **7***f*, were practical amounts (23 and 25% yield respectively) of diazoketone **5***b* isolated. To our knowledge these are the first examples of diazoketones being generated from active esters. Apparently, an even more electron-withdrawing ester than ODnp or SPfp will be required to allow this method of diazoketone formation to more favorably compete with the acyl halide or MCA routes.

A comparison of the acyl chloride and MCA procedures was obtained by parallel syntheses of DON (**1**) precursor diazoketone **5***c*. Reaction of γ-carboxylic acid **3***b* with oxalyl chloride, triethylamine, and dimethylformamide (catalytic amount) at 0°C followed by diazomethane afforded diazoketone **5***c* in 20% yield. Alternatively, reaction of acid **3***b* or its dicyclohexylamine salt (3) with isobutyl chloroformate followed by diazomethane afforded slightly better yields of diazoketone **5***c*, i.e., 21 and 22% respectively. Interestingly, when the acid chloride procedure developed here was employed (dimethoxyethane was substituted for tetrahydrofuran) in our (1) synthesis of azotomycin (**2**), diacid **8** was transformed to the corresponding



8

bis-diazoketone in 38% yield. Presumably, synthesis of diazoketone **5***c*, the DON precursor, is a quite stringent test of the herein developed acyl chloride and MCA routes to amino acid diazoketones and, under other structural circumstances, should lead to markedly improved yields.

Experimental

Dimethoxyethane and tetrahydrofuran were redistilled from lithium aluminum hydride. Solvent extracts of aqueous solution were dried over sodium sulfate. Analtech Silica Gel GF (0.25 mm) plates were used for thin-layer chromatography (tlc) and viewed with uv light. The thin-layer plates were also developed with concentrated sulfuric acid or a 1% ninhydrin spray. Column chromatography was based on silica gel (70–230 mesh) or neutral alumina supplied by E. Merck (Darmstadt). Ethereal diazomethane solutions (and standardization) used for synthesizing diazoketones were prepared from *N*-nitrosomethylurea by the procedure of Arndt (14). The instrumental methods used in this study have been summarized in the introduction to the experimental of ref. 1.

γ-OMe-N-*Z*-L-*Glu-OBzl* (**4**)

Method A

A solution composed of *N*-Z-L-Glu-OBzl (13) (1.0 g, 2.7 mmol), tetrahydrofuran (25 mL), triethylamine (0.38 mL, 2.7 mmol), and dimethylformamide (2 drops) was cooled (under nitrogen) to −78°C. Oxalyl chloride (0.26 mL, 2.8 mmol) was added and the reaction mixture was warmed to 0°C. After stirring 30 min, absolute methanol (10 mL) was added and the solvent evaporated. The residue was dissolved in chloroform (80 mL) and washed with water (2 × 25 mL), brine (1 × 25 mL), and dried. After evaporating solvent, the oily residue was chromatographed on a column of silica gel (75 g) and the ester was eluted with ethyl acetate – methylene chloride (1:19). The fractions with tlc R_f 0.54 (ethyl acetate – methylene chloride, 1:19) were collected and solvent evaporated to give 0.89 g (86%) of a colorless oil that crystallized on standing (all attempts to recrystallize failed): mp 51–52°C; $[\alpha]_D^{25}$ +1.2 (*c* 1.5, $CHCl_3$); ir (KBr): 3345, 1750, 1732, 1700, 1530, 1457, 1210, 1059, 740, 698 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.86–2.58 (m, 4H), 3.74 (s, 3H, -OMe), 4.30–4.68 (m, 1H, asymmetric hydrogen), 5.22 (s, 2H, $-CH_2Ph$), 5.28 (s, 2H, $-CH_2Ph$), 5.59 (d, J = 8 Hz, 1H, -NH-), 7.49[4] (s, 10H, aromatic); and SP-SIMS (15) (solution phase secondary ion mass spectrometry) ms, *m/e*: 406 $(M + Na)^+$ and 386 $(M + H)^+$. *Anal.* calcd. for $C_{21}H_{23}NO_6$: C 65.44, H 6.02, N 3.63; found: C 65.38, H 6.10, N 3.61.

Method B

The preceding reaction was repeated using the exact quantities of reagents except that the dimethylformamide was deleted. Solvent was removed (rotary evaporation) and the resultant oil was purified in the same manner as described in Method A to give 0.85 g (82%) of colorless crystals that melted at 49–51°C, and showed $[\alpha]_D^{25}$ +1.2° ($CHCl_3$).[5]

Method C

A solution of *N*-Z-L-Glu-OBzl-γ-Dcha (13) (1.5 g, 2.7 mmol) in dry methylene chloride (25 mL) – dimethylformamide (2 drops) was cooled to −78°C under nitrogen. Oxalyl chloride (0.26 mL, 2.8 mmol) was added and the reaction mixture was warmed to 0°C. After 30 min of stirring at 0°C, absolute methanol (10 mL) was added and the solvent evaporated. The residue in chloroform (80 mL) was washed with water (2 × 25 mL) and dried. Solvent was removed (rotary evaporation) and the oily residue was purified as described in Method A to give 0.55 g (53%) of colorless crystals that melted at 49–51°C with $[\alpha]_D^{25}$ +1.2° ($CHCl_3$).[5] When this reaction was repeated with omission of the dimethylformamide, the yield of product, mp 49–51°C with $[\alpha]_D^{25}$ 1.2° ($CHCl_3$), rose to 77%.

Method D

In this procedure Method C was repeated employing dry dimethoxyethane (25 mL in place of methylene chloride) and dimethylformamide (2 drops). The yield was 0.70 g (67%) of colorless crystals that melted at 49–51°C and displayed $[\alpha]_D^{25}$ +1.2° ($CHCl_3$).[5]

Method E

To a mixture of sodium hydride (0.12 g of a 53.4% mineral oil dispersion, 2.7 mmol) in dry tetrahydrofuran (10 mL at −78°C), *N*-Z-L-Glu-OBzl (1.0 g, 2.7 mmol) in dry tetrahydrofuran (12 mL) was added (dropwise, under nitrogen). Oxalyl chloride (0.26 mL, 2.8 mmol) was added and the mixture warmed to 0°C for 30 min with stirring. Absolute methanol (10 mL) was added and solvent evaporated. The residue in chloroform (80 mL) was washed with water (2 × 25 mL), dried, and the solvent was removed (rotary evaporation). The resultant oil was purified as summarized in Method A to provide 0.80 g (77%) of colorless crystals that melted at 49–51°C and showed $[\alpha]_D^{25}$ +0.8° ($CHCl_3$).[5]

Method F

A solution of *N*-Z-L-Glu-OBzl (1.0 g, 2.7 mmol) in 0.2 *N* sodium hydroxide (13.5 mL, 2.7 mmol) and tetrahydrofuran (5 mL) was freeze-dried. The solid sodium salt was suspended in dry tetrahydrofuran (25 mL) and dimethylformamide (2 drops) and cooled to −78°C (under nitrogen). Oxalyl chloride (0.27 mL, 2.8 mmol) was added and the reaction performed as described in Method E. The oily product was purified as noted in Method A to afford 0.49 g (47%) of colorless crystals melting at 49–51°C; $[\alpha]_D^{25}$ +1.3° ($CHCl_3$).[5]

γ-Pfp-N-*Z*-L-*Glu-OBzl* (**7**a)

To a solution of *N*-Z-L-Glu-OBzl (13) (2.09 g, 5.6 mmol) and ethyl acetate (35 mL) was added pentafluorophenyl (1.04 g, 5.6 mmol) and dicyclohexylcarbodiimide (1.16 g, 5.6 mmol) at 0°C. The reaction mixture was stirred (magnetically) at 0°C for 1 h, the ice bath was removed, and the mixture was allowed to warm to room temperature overnight (16 h). Dicyclohexylurea was collected and solvent evaporated to a white solid that was dissolved in ethyl acetate (50 mL). The solution was filtered (to remove remaining dicyclohexylurea), and pentane (200 mL) added. After standing 3 h at 0°C, 2.44 g (81%) of the pentafluorophenyl ester was obtained as colorless crystals: mp 60–70°C: $[\alpha]_D^{25}$ +2.8° ($CHCl_3$); ir (KBr): 3355, 1787, 1753, 1697, 1523, 1304, 1295, 1190, 1123, 1095, 996, 751, 738, 700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.90–2.90 (m, 4H), 4.39–4.81 (m, 1H, asymmetric α-H), 5.18 (s, 2H, $-CH_2Ph$), 5.27 (s, 2H, $-CH_2Ph$), 5.33–5.60 (m, 1H, -NH-), 7.43 (12) (s, 10H, aromatic); and SP-SIMS (15) ms, *m/e*: 560 $(M + Na)^+$ and 538 $(M + H)^+$. *Anal.* calcd. for $C_{26}H_{20}F_5NO_6$: C 58.11, H 3.75, N 2.56; found: C 58.27, H 3.75, N 2.53.

γ-OTcp-N-*Z*-L-*Glu-OBzl* (**7**b)

A mixture of *N*-Z-L-Glu-OBzl-γ-Dcha (13) (5.0 g, 9.06 mmol), ethyl acetate (50 mL), and 0.5 *N* citric acid (25 mL) was shaken until only two liquid phases were obtained. The organic phase was separated and washed with water (1 × 25 mL), brine (1 × 25 mL), and dried. The solution was cooled to 0°C and 2,4,5-trichlorophenol (1.79 g, 9.06 mmol) was added, followed by dicyclohexylcarbodiimide (1.87 g, 9.06 mmol). The reaction mixture was stirred for 1 h at 0°C and for 18 h at room temperature. After collecting the dicyclohexylurea, the solution was washed with 5% sodium bicarbonate (1 × 25 mL), brine (1 × 25 mL), and dried. Solvent was evaporated and crystallization induced by addition of ethyl ether followed by hexane. The solid was washed with ethyl ether and recrystallized from ethyl acetate – ethyl ether – hexane to afford 2.03 g (41%) of colorless crystals: mp 118–119°C; $[\alpha]_D^{25}$ +0.3° ($CHCl_3$); ir (KBr): 3335, 1776, 1732, 1695, 1543, 1268, 1280, 1120, 749, 700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.80–2.82 (m, 4H), 4.40–4.94 (m, 1H, asymmetric α-H), 5.17 (s, 2H, $-CH_2Ph$), 5.24 (s, 2H, $-CH_2Ph$), 5.34–5.74 (br m, 1H, -NH-), 7.42[4] (s, 11H, aromatic), 7.60 (s, 1H, aromatic); and SP-SIMS (15) ms, *m/e*: 572 $(M + Na)^+$ and 574 $(M + Na)^+$. *Anal.* calcd. for $C_{26}H_{22}Cl_3NO_6$: C 56.69, H 4.03, N 2.54, Cl 19.31; found: C 56.96, H 4.06, N 2.51, Cl 19.34.

γ-ONp-N-*Z*-L-*Glu-OBzl* (**7**c)

From *N*-Z-L-Glu-α-OBzl-γ-Dcha (13) (5.0 g, 9.06 mmol), *p*-nitrophenol (1.26 g, 9.06 mmol), and dicyclohexylcarbodiimide (1.87 g, 9.06 mmol) ester **7***c* was prepared essentially as described for obtaining ester **7***b* above. Evaporation of solvent yielded a yellow oil, which was chromatographed on a column of silica gel (45 g). The ester was eluted with methylene chloride – ethyl acetate (99:1) as a yellow-green oil (4.0 g, tlc showed only one spot, R_f 0.25, ethyl acetate – methylene chloride, 1:50). Solidification occurred after standing for 2 weeks and recrystallization was accomplished with ethyl ether – hexane to give light yellow crystals melting at 65–67°C; $[\alpha]_D^{25}$ −21.3° (CH_3OH) (lit. (16) mp 64–66°C and $[\alpha]_D^{25}$ −21° in CH_3OH).

γ-ODnp-N-*Z*-L-*Glu-OBzl* (**7**d)

The procedure used for converting *N*-Z-L-Glu-α-OBzl-γ-Dcha (13) (5.0 g, 9.06 mmol) to ester **7***b* was repeated with 2,4-dinitrophenol (1.67 g, 9.06 mmol) and dicyclohexylcarbodiimide (1.87 g, 9.06 mmol). After collecting the dicyclohexylurea the solution was washed with 5% sodium bicarbonate (2 × 25 mL), water (2 × 25 mL), and brine (1 × 25 mL). Solvent was evaporated and the residue dissolved in methanol (25 mL). No precipitation occurred upon addition of ether

[4]Proton resonances superimposed as evidenced by area integration.

[5]Identity was determined by comparison of ^1H nmr and ir spectra and tlc mobilities. Melting points and optical rotations were compared when necessary.

and hexane but addition of acetone caused immediate precipitation. The light yellow solid was recrystallized from acetone–methanol–hexane to yield 2.08 g (43%) of pale yellow crystals: mp 102.5–103.5°C; $[\alpha]_D^{25}$ −2.6° ($CHCl_3$); ir (KBr): 3335, 1780, 1733, 1700, 1615, 1547, 1350, 1280, 1111, 747, 700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.88–2.92 (m, 4H), 4.42–4.90 (m, 1H, asymmetric α-H), 5.18 (s, 2H, -CH_2Ph), 5.25 (s, 2H, -CH_2Ph), 5.36–5.72 (m, 1H, -NH-), 7.43[4] (s, 10H, aromatic), 7.50 (d, J = 9 Hz, 1H, aromatic), 8.50 (dd, J = 9 Hz and J = 1.5 Hz, 1H, aromatic), 9.20 (d, J = 1.5 Hz, 1H, aromatic); and SP-SIMS (15) ms, m/e: 560 $(M + Na)^+$. *Anal.* calcd. for $C_{26}H_{23}N_3O_{10}$: C 58.10, H 4.31, N 7.82; found: C 58.15, H 4.32, N 7.68.

*γ-OSu-*N*-Z-*L*-Glu-OBzl (**7**e)*

By the technique employed with OTcp ester **7***b* (see above), *N*-Z-L-Glu-OBzl-γ-Dcha (13) (5.0 g, 9.06 mmol) was converted to the corresponding carboxylic acid and allowed to react with *N*-hydroxysuccinimide (1.04 g, 9.06 mmol) and dicyclohexylcarbodiimide (1.87 g, 9.06 mmol) for 1 h at 0°C and for 15 h at ambient temperature. Recrystallization was accomplished from methylene chloride – ethyl ether (allowing to stand for 3 h at 0°C) to give 2.5 g (60%) of colorless crystals: mp 105–107°C; $[\alpha]_D^{25}$ +4.7° ($CHCl_3$); ir (KBr): 3325, 1818, 1747 (shoulder), 1698, 1540, 1460, 1288, 1260, 1213, 1083, 732, 696 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.94–2.76 (m, 4H), 2.78 (s, 4H, -OSu), 4.35–4.70 (m, 1H, asymmetric α-H), 5.17 (s, 2H, -CH_2Ph), 5.24 (s, 2H, -CH_2Ph), 5.69 (br d, J = 8 Hz, 1H), 7.43[4] (s, 10H, aromatic); and SP-SIMS (15) ms, m/e: 491 $(M + Na)^+$ and 469 $(M + H)^+$. *Anal.* calcd. for $C_{24}H_{24}N_2O_8$: C 61.53, H 5.16, N 5.98; found: C 61.61, H 5.24, N 5.99.

*γ-SPfp-*N*-Z-*L*-Glu-OBzl (**7**f)*

Except for a 7-h period at room temperature, reaction between *N*-Z-L-Glu-OBzl (13) (2.0 g, 5.4 mmol), pentafluorothiophenol (0.72 mL, 5.4 mmol), and dicyclohexylcarbodiimide (1.11 g, 5.4 mmol) in ethyl acetate (35 mL) was conducted as summarized for obtaining OPfp ester **7***a*. The clear oily product solidified on standing overnight (at 5°C) and was dissolved in ethyl ether (40 mL). After filtering the solution, pentane was added until opalescence and the mixture was allowed to stand at 0°C for 2 h. Upon filtration, 1.52 g (51%) of pentafluorothiophenol ester **7***f* was obtained as colorless crystals: mp 58–61°C; $[\alpha]_D^{25}$ +7.6° ($CHCl_3$); ir (KBr): 3330, 1738 br, 1701, 1520, 1500, 1097, 986, 868, 747, 696 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.84–2.94 (m, 4H), 4.36–4.76 (m, 1H, asymmetric α-H), 5.18 (s, 2H, -CH_2Ph), 5.25 (s, 2H, -CH_2Ph), 5.32–5.55 (m, 1H, -NH-), 7.44[4] (s, 10H, aromatic); and SP-SIMS (15) ms, m/e: 576 $(M + Na)^+$. *Anal.* calcd. for $C_{26}H_{20}FN_5O_5S \cdot 1/2H_2O$: C 55.52, H 3.58, N 2.49; found: C 55.39, H 3.37, N 2.44.

*γ-SPy-*N*-Z-*L*-Glu-OBzl (**7**g)*

To a solution of *N*-Z-L-Glu-OBzl (13) (1.0 g, 2.7 mmol) in dry tetrahydrofuran (20 mL, with magnetic stirring, under nitrogen at −23°C maintained by Dry Ice/carbon tetrachloride) was added *N*-methylmorpholine (0.30 mL, 2.7 mmol) and isobutyl chloroformate (0.35 mL, 2.7 mmol) by syringe while maintaining the temperature at −23°C. After stirring for 15 min at −23°C, 2-pyridine thiol (0.34 g, 3.1 mmol) in dry tetrahydrofuran (5 mL) was added (addition funnel). The reaction flask was transferred to an ice bath and stirred for 2 h at 0°C followed by 2 h at room temperature. The mixture was filtered (solid rinsed with tetrahydrofuran) and the filtrate evaporated. A solution of the residue in ethyl acetate (80 mL) was washed with brine (1 × 25 mL), 5% sodium bicarbonate (3 × 25 mL), brine (1 × 25 mL), and dried. Solvent was evaporated and the residue allowed to stand overnight at 0°C (no solidification) and dissolved in carbon tetrachloride. Ester **7***g* was induced to crystallize by adding hexane to opalescence, followed by a small amount of acetone. After standing for 2 h at −10°C (freezer), the solid was collected to yield 0.94 g (75%) of pale yellow crystals; mp 84–85°C; $[\alpha]_D^{25}$ +6.3° ($CHCl_3$); ir (KBr): 3345, 1760, 1702, 1533, 1288, 1227, 1174, 1065, 971, 778, 736, 698 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.00–2.53 (m, 2H), 2.53–2.93 (m, 2H), 4.31–4.64 (m, 1H, asymmetric α-H), 5.17 (s, 2H, -CH_2Ph), 5.23 (s, 2H, -CH_2Ph), 5.37–5.72 (m, 1H, -NH-), 7.26–7.91[4] (m, 13H; singlet at 7.43, 10H, aromatic), 8.69 (d, J = 5 Hz, 1H aromatic); and SP-SIMS (15) ms, m/e: 487 $(M + Na)^+$. *Anal.* calcd. for $C_{25}H_{24}N_2O_5S$: C 64.64, H 5.21, N 6.03; found: C 64.81, H 5.30, N 6.00.

*6-Diazo-5-oxo-*N*-Z-*L*-norleucine-OMe (**5**a)*

Method A

To a cold (ice bath) solution of *N*-Z-L-Glu-α-OMe-γ-Dcha salt (2.0 g, 4.2 mmol) in dry methylene chloride (30 mL) and pyridine (4 drops) was added (dropwise over 10 min with stirring) oxalyl chloride (4 mL, 47 mmol) in dry methylene chloride (9 mL). Fifteen minutes later the ice bath was removed and the mixture stirred for an additional 5 min. Solvent was evaporated (below 10°C) and cold (and dry) chloroform (10 mL) was added (3 ×) and evaporated. A mixture of dry chloroform (10 mL) and ethyl ether (15 mL, anhydrous) was added, the solution filtered, and the filtrate added dropwise (over 10 min) to an ethereal solution of diazomethane (from 5 g of *N*-nitrosomethylurea) at 0°C. After stirring 0.5 h at 0°C and 1.5 h at room temperature, the solvent was evaporated to give a brown oil (2.5 g). The crude product was purified on a column of silica gel (100 g) using a gradient of 9:1 to 0:1 hexane – ethyl acetate. Fractions with R_f 0.18 (1:2 hexane – ethyl acetate) were collected and solvent evaporated to give 0.5 g (40%) of a yellow oil that crystallized from ether – petroleum ether as light yellow crystals (0.15 g, 12% yield): mp 117–119°C; $[\alpha]_D^{25}$ −14.4° ($CHCl_3$); ir: 3280, 2110, 1746, 1708, 1597, 1535, 1256, 1044, 695 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.60–2.20 (m, 4H), 3.65 (s, 3H, -OMe), 4.00–4.61 (m, 1H, asymmetric α-H), 5.10 (s, 2H, -CH_2Ph), 5.50 (s, 1H, -CHN_2), 5.75 (d, 7 Hz, 1H, -NH-), 7.35 (s, 5H, aromatic); SP-SIMS ms, m/e: 326 $(M + Li)^+$, 298 $(M + Li - N_2)^+$. *Anal.* calcd. for $C_{15}H_{17}O_5N_3$: C 56.42, H 5.37, N 13.16; found: C 56.56, H 5.50, N 12.80.

Method B

A solution of *N*-Z-L-Glu anhydride (17) (**6***a*, 1.5 g, 5.3 mmol) in dry tetrahydrofuran (10 mL) was added to a stirred (magnet) ethereal solution of diazomethane (from 5 g of *N*-nitrosomethylurea) cooled in an ice bath. The mixture was stirred at 0°C for 1.5 h and for an additional 2 h at room temperature. Solvent was evaporated to give a yellow oil, which was chromatographed on a column of silica gel (40 g). The fractions with R_f 0.45 and 0.38 (ethyl acetate – methylene chloride, 1:3) eluted with ethyl acetate – methylene chloride (1:6) were combined and solvent removed to give a yellow oil. Crystallization was induced by addition of ethyl ether to yield 0.32 g (18%) of diazoketone **5***a* as light yellow crystals melting at 117°C.

When the reaction was repeated with *N*-Tfa-L-Glu anhydride (17, 18) (**6***b*, 2.0 g) no evidence (ir) was obtained, even following a 24-h reaction period, for production of diazoketone **5***c*.

*6-Diazo-5-oxo-*N*-Z-*L*-norleucine-OBzl (**5**b)*

The acid chloride procedure

A solution of *N*-Z-L-Glu-α-OBzl (13) (1.00 g, 2.7 mmol), dry tetrahydrofuran (25 mL), triethylamine (0.38 mL, 2.7 mmol), and dimethylformamide (2 drops) was cooled to −30°C under argon with mechanical stirring. Oxalyl chloride (0.26 mL, 2.8 mmol) was added (syringe) and the reaction mixture was warmed to 0°C. After stirring for 30 min at 0°C, the mixture was cooled to −78°C and added slowly (over 1 h through a sintered glass filter) into an ethereal solution of diazomethane (0.59 *N*, 15 mL) cooled to −23°C. The temperature was raised to 0°C for 30 min while continuing stirring. Solvent was evaporated (passing through a stream of argon) and the residue was chromatographed on a column of silica gel (65 g). Elution with ethyl acetate – hexane (1:5) and collection of fractions with R_f 0.30 (acetone–hexane, 1:2) gave, upon evaporation of solvent, 0.55 g (52%) of a yellow solid that was recrystallized from methylene chloride – hexane: mp 85–86°C; $[\alpha]_D^{25}$ +0.7° ($CHCl_3$). The product (**5***b*) was found identical[5] to an authentic sample (3).

The mixed carbonic anhydride procedure

A solution of *N*-Z-L-Glu-OBzl-γ-Dcha (13) (2.12 g, 3.84 mmol) in dry methylene chloride (40 mL) was cooled to −23°C, isobutyl

chloroformate (0.50 mL, 3.85 mmol) was added, and stirring was continued for 25 min at −23°C. Ethereal diazomethane (25 mL, 0.4 *M*) was added (dropwise) and immediate precipitation occurred. The mixture was stirred 1 h at 0°C, the solution was filtered (hood), and solvent removed by a stream of nitrogen. The solid yellow residue was chromatographed (attempts to recrystallize failed) on a column of silica gel (45 g) in acetone–hexane (1:5). Elution with acetone–hexane (1:3) and collection of the fractions with tlc R_f 0.30 (1:2 acetone – hexane) followed by crystallization from ethyl ether led to 0.70 g of yellow solid. Hexane was added to the filtrate and, upon standing overnight at −10°C (freezer), an additional 0.14 g was recovered to give an overall yield of 0.85 g (57%) of light yellow crystals that melted at 85–86°C. The specimen of diazoketone **5***b* was identical to an authentic sample (3; see also footnote 5).

The preceding reaction was repeated using *N*-Z-L-Glu-OBzl (13) (1.07 g, 2.88 mmol) in dry methylene chloride (30 mL) – *N*-methylmorpholine (0.32 mL, 2.88 mmol) at −23°C. The isobutyl chloroformate (0.37 mL, 2.88 mmol) and ethereal diazomethane (25 mL, 0.4 *M*) were again added through an addition funnel. Following chromatographic purification (see above) on a column of silica gel, 0.63 g (55%) of light yellow crystals were isolated, melting at 85–86°C and found identical[5] with an authentic sample (3).

The active ester procedure

Each active ester, **7***a–g*, (1.0 g) in dry methylene chloride (30 mL) was cooled to 0°C with magnetic stirring. Two equivalents of diazomethane were added and stirring at 0°C was continued. After 1 h, the reaction was warmed to room temperature and allowed to stir for 16 h. If no significant amount of diazoketone **5***b* was in evidence by tlc, the reaction was terminated. When a promising amount of product was present the reaction was continued for another 24 h with periodic additions of diazomethane. Product isolation and purification were accomplished in the same fashion as described above for the acid chloride procedure. By this means the ODnp (**7***d*) and SPfp (**7***f*) active esters afforded diazoketone **5***b* in 23 and 26% yields respectively. And trace amounts of diazoketone **5***b* were detected (tlc) using esters **7***a*, *e*, and *g*.

N-*Tfa-L-Glu-α-OMe* (**3**b)

To a solution of γ-OBzl-*N*-Tfa-L-Glu-OMe (2.5 g) in 95% ethanol (360 mL) was added 5% palladium-on-carbon (2.0 g). While the mixture was vigorously stirred, a stream of hydrogen was passed through the solution for 1 h. The catalyst was collected and solvent evaporated (*in vacuo*) to give 2.0 g of a pinkish oil (tlc showed only 1 spot at R_f 0.29 using ethyl acetate), which was finally purified by column chromatography (silica gel) with ethyl acetate – methylene chloride (1:1) as eluent to give 1.61 g (88%) of *N*-Tfa-L-Glu-OMe as a colorless oil: $[\alpha]_D^{25}$ +21.0° ($CHCl_3$); ir: 3310 br, 3700–2500, 1720 br, 1557, 1445, 1217, 1180 br cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.83–2.67 (m, 4H), 3.80 (s, 3H, -OMe), 4.43–4.87 (m, 1H, asymmetric α-H), 7.60 (d, J = 8 Hz, 1H, -NH-), 10.20 (s, 1H, -COOH); ^{13}C nmr ($CDCl_3$) δ: 26.4, 29.7, 52.1, 53.1, 115.7 (q, J = 287.5 Hz, F-coupling), 157.3 (q, J = 38 Hz, F-coupling), 170.9, 177.7; and EI ms, *m/e*: 258 $(M + H)^+$ and 257 M^+.

To a solution of *N*-Tfa-L-Glu-OMe (1.5 g, 5.8 mmol) in tetrahydrofuran (50 mL) was added dicyclohexylamine (1.16 mL, 5.9 mmol). After stirring for 2 h at ambient temperature, and overnight (15 h) in a refrigerator (5°C), the precipitate was collected and washed with tetrahydrofuran to provide 2.4 g (94%) of the Dcha salt[5] as colorless crystals melting at 165–167°C, as we previously reported (3).

6-Diazo 5-oxo-N-*Tfa-L-norleucine-OMe* (**5**c)

Method A

A solution of *N*-Tfa-L-Glu-α-OMe (**3***b*, 1.26 g, 4.9 mmol) prepared as described in the preceding experiment, in dry tetrahydrofuran (25 mL) containing triethylamine (0.68 mL, 4.9 mmol), was cooled (Dry Ice – isopropyl alcohol) to −30°C under argon with mechanical stirring. Oxalyl chloride (0.44 mL, 4.9 mmol) and dimethylformamide (2 drops) were added (syringe). The reaction mixture was warmed to 0°C for 30 min and cooled to −78°C while slowly (30 min) adding it through a sintered glass filter to an ethereal solution of diazomethane (30 mL, 0.51 *M*) cooled to −23°C (Dry Ice – carbon tetrachloride). Following 30 min of stirring at 0°C, solvent was evaporated (by passing through a stream of argon) and the residue was purified as described earlier (3) to yield 0.27 g (20%) of a yellow oil identical[5] to an authentic sample (3) of daizoketone **5***c*.

Method B

A solution of *N*-Tfa-L-Glu-OMe-γ-Dcha salt (2.5 g, 5.7 mmol) prepared in the experiment above, in dry methylene chloride (60 mL), was cooled to −23°C. Isobutyl chloroformate (0.74 mL, 5.7 mmol) was added and the solution stirred for 25 min at −23°C. Ethereal diazomethane (25 mL, 0.4 *M*) was added (dropwise) to the solution and precipitation was immediate. The reaction flask was transferred to an ice bath, the mixture was stirred for 30 min at 0°C, and the solution filtered (hood). Solvent was removed by passing nitrogen above the solution surface. The resulting yellow residue was purified by chromatography as reported (3) to yield 0.35 g (22%) of the diazoketone **5***c* (3; see also footnote 5) as a yellow oil.

When the synthesis was repeated using *N*-Tfa-L-Glu-α-Ome (1.46 g, 5.67 mmol) in dry tetrahydrofuran (30 mL) containing *N*-methylmorpholine (0.63 mL, 5.67 mmol) with isobutyl chloroformate (0.74 mL, 5.67 mmol) and ethereal diazomethane (16.5 mL, 0.52 *M*), the product was again purified by chromatography as described (3) and 0.34 g (21%) of the diazoketone (**5***c*) was isolated as a yellow oil (ref. 3, and footnote 5).

Acknowledgments

With pleasure we thank the following for the financial support necessary to this investigation: Eleanor W. Libby, the Waddell Foundation (Donald Ware), Mary Dell Pritzlaff, the Olin Foundation (Spencer T. and Ann W.), the Fannie E. Rippel Foundation, the Robert B. Dalton Endowment Fund, Virginia L. Bayless, Jack W. Whiteman, Lotte Flugel, Elias M. Romley, and Grants CA-16049-07-09 awarded by the National Cancer Institute, DHHS.

Autoxidation of phosphatidylcholines initiated with dicumylhyponitrite in solution and in bilayers

LAWRENCE ROSS COATES BARCLAY,[1] DAVID KONG, AND JOANN VANKESSEL
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received March 19, 1986

LAWRENCE ROSS COATES BARCLAY, DAVID KONG, and JOANN VANKESSEL. Can. J. Chem. **64**, 2103 (1986).

Dicumylhyponitrite (DCHN) was used as a thermal initiator of autoxidation of unsaturated phosphatidylcholines in *o*-dichlorobenzene and in mixed bilayers of dilinoleoylphosphatidylcholine (DLPC) with dimyristoylphosphatidylcholine (DMPC). Quantitative studies were made of the products, α,α-dimethylbenzyl alcohol (DMBA), acetophenone (AP), and dicumylperoxide (DCP) from DCHN. The ratio DMBA/Δ2DCHN (37 ± 6%) indicates the effectiveness of cumyloxy in hydrogen abstraction from the phospholipid in solution. The *overall* efficiency (*e*) of DCHN determined by the inhibitor method with α-tocopherol (α-T) was 84 ± 5%, close to the overall ratio (DMBA + AP)/Δ2DCHN (90 ± 6%), and indicates either significant initiation through the methylperoxy radical in *o*-dichlorobenzene solution or that α-tocopherol traps cumyloxy radical before β-scission occurs. The thermal decomposition rate constant of DCHN is greatly reduced in a medium of high viscosity; in DLPC to one-quarter, in Nujol to one-sixth that in isooctane and this is interpreted in terms of a one-bond scission of DCHN. In DLPC + DMPC mixed bilayers the effectiveness of the cumyloxy radical to initiate reaction varied from 30 to 19% depending on the amount of DLPC and in this medium there is little or no initiation by methylperoxy according to product analysis and α-T inhibition studies. In mixed bilayers, the rate of oxidation was directly related to the [DLPC] indicating that the classical rate law applies. The oxidizability of DLPC in mixed bilayers (0.046 $M^{-1/2}$ $s^{-1/2}$) is comparable to that of neat DLPC.

LAWRENCE ROSS COATES BARCLAY, DAVID KONG et JOANN VANKESSEL. Can. J. Chem. **64**, 2103 (1986).

On a utilisé l'hyponitrite de dicumyle (HNDC) comme initiateur thermique pour l'autooxydation de phosphatidylcholines non-saturés dans le *o*-dichlorobenzène et dans des doubles couches mixtes de dilinoléylphosphatidylcholine (DLPC) et de dimyristoylphosphatidylcholine (DMPC). On a réalisé des études quantitatives des produits : l'alcool α,α-diméthylbenzylique (ADMB), l'acétophénone (AP) et le peroxyde de dicumyle provenant du HNDC. Le rapport ADMB/Δ2HNDC (37 ± 6%) est un indicateur de l'efficacité du radical cumyloxy à faire l'abstraction d'un hydrogène du phospholipide en solution. L'efficacité *globale* (*e*) du HNDC, telle que déterminée par la méthode de l'inhibiteur à l'aide de α-tocophérol (α-T), est égale à 84 ± 5%; cette valeur est proche du rapport global (ADMB + AP)/Δ2HNDC (90 ± 6%) et elle indique soit qu'il se produit une initiation importante par le biais du radical méthylperoxy en solution dans le *o*-dichlorobenzène soit que l'α-tocophérol piège le radical cumyloxy avant que la scission β puisse se produire. La constante de vitesse de décomposition du HNDC est grandement réduite dans des milieux de haute densité; dans le DLPC elle est réduite au quart de sa valeur alors que dans le Nujol elle est réduite au sixième et l'on interprète ces résultats en fonction d'une scission d'une liaison du HNDC. Dans des doubles couches de DLPC + DMPC, l'efficacité du radical cumyloxy à initier la réaction varie de 30 à 19% dépendant de la quantité de DLPC et, sur la base d'une analyse des produits ainsi que d'études d'inhibition par α-T, on peut conclure que, dans ce milieu, il ne se produit que peu ou pas d'initiation par le radical méthylperoxy. Dans les doubles couches mixtes, la vitesse d'oxydation peut être reliée directement à la concentration en DLPC et ceci indique que la loi de vitesse classique s'applique. La facilité d'oxyder le DLPC dans des doubles couches mixtes (0,046 $M^{-1/2}$ $s^{-1/2}$ est comparable à celle observée à l'état pur.

[Traduit par la revue]

Introduction

The autoxidation of biological molecules such as phosphatidylcholines organized into bilayers as model biomembranes is relevant to autoxidative disruption of the functions of natural biomembranes leading to important pathological events (1–3). Several groups have recently developed an increased interest in autoxidation of such biologically important molecules. Of particular significance are the application of quantitative kinetic methods (4–8), the mechanism of action and activity of antioxidants (9–21), quantitative product studies (22–25), and the dynamics of free radical initiation, especially in microenvironments (26–29).

Autoxidation of organic substrates in homogenous solution is well known to be a free-radical chain process which follows the classical rate law given by eq. [1] (30–32):

$$[1] \quad -\frac{d[O_2]}{dt} = \frac{k_p}{2k_t^{1/2}}[RH]R_i^{1/2}$$

where RH is the substrate, R_i the rate of chain initiation, k_p the propagation rate constant, and $2k_t$ the termination rate constant. The R_i may be controlled by using a thermal initiator with a known decomposition rate constant, k_i. Because not all of the radicals escape the solvent cage where they are formed, the real R_i must be measured, for example, by the inhibitor method (33) using a phenolic antioxidant such as α-tocopherol (α-T) known to trap two peroxyl radicals (15) so that R_i is given by eq. [2], where τ is the period during which oxidation is suppressed.

$$[2] \quad R_i = 2[ArOH]/\tau$$

Under these conditions, the efficiency (*e*) of chain initiation by a thermal azo initiator, $In \xrightarrow{k_i} 2R\cdot + N_2$, is given by eq. [3].

$$[3] \quad e = R_i/2k_i[In]$$

If the kinetics follows the classical equation [1], the susceptibility of a substrate to undergo autoxidation, the "oxidizability", is given by eq. [4].

$$[4] \quad \frac{k_p}{(2k_t)^{1/2}} = \frac{-d[O_2]/dt}{[RH]R_i^{1/2}}$$

Of the initiators investigated so far for kinetic studies in bilayers, di-*tert*- butylhyponitrite (**1***a*) appeared to be the most useful (5).

[1] Author to whom all correspondence to be addressed.

The diazene, **1***a*, however, has several disadvantages: (*1*) Its low efficiency, *e*, or high cage recombination in bilayer autoxidation (e = 9.1% (5)), means that a relatively high concentration of **1***a* is needed in the bilayer. (*2*) The volatility of the products from **1***a* made it impossible to determine accurately the efficiency of **1***a* by product analyses (5) as a check on the *e* determined by the induction period method with a phenolic inhibitor (33). (*3*) The question of the exact location of **1***a* within the bilayer (5) is further complicated by its partial water solubility (*vide infra*) and this complicates the assessment of the bilayer cage effect on this initiator.

With the above points in mind, we have selected dicumylhyponitrite (DCHN, **1***b*) as a thermal initiator in bilayer autoxidation, anticipating that this more hydrophobic molecule would be wholly sequestered within the bilayer and would also obviate the other limitations of **1***a*. Although the cumyloxy radical (from DCHN) undergoes very rapid cleavage to acetophenone and methyl radical in aqueous solution (34), it is reported to have a higher reactivity in hydrogen abstraction than *t*-BuȮ (34, 35). This current study reports on (*1*) An analysis of the **1***b* decomposition products, α,α-dimethylbenzyl alcohol (DMBA), acetophenone (AP), and dicumylperoxide (DCP) in *o*-dichlorobenzene containing unsaturated phospholipids, and a comparison of the initiator efficiency, *e*, from these product data with the overall *e* measured by a phenolic inhibitor, α-tocopherol (α-T). (*2*) Rate constants for thermal decomposition of **1***b* in bilayers compared to decomposition in organic solvents. (*3*) Analysis of the **1***b* products, DMBA, AP, and DCP in mixed bilayers containing dilinoleoylphosphatidylcholine (DLPC) and comparison of initiator *e* values so obtained with those from inhibition studies with α-T in the bilayer phase and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxyl (Trolox) in the aqueous phase. (*4*) The kinetics of DCHN-initiated autoxidation and oxidizability of DLPC in mixed bilayers.

Experimental

1. Materials and preparations

Solvents

ortho-Dichlorobenzene, reagent grade, was dried over calcium chloride and distilled. Other solutions were hplc grade.

Phospholipids

The egg phosphatidylcholine (EPC), dilinoleoylphosphatidylcholine (DLPC), and dimyristoylphosphatidylcholine (DMPC) were obtained from Avanti Polar Lipids. 1-Palmitoyl-2-linoleoylphosphatidylcholine was synthesized in the laboratory of N. A. Porter by known methods (36). The phospholipids were stored in sealed vials in the dark at −30°C.

Inhibitors

α-Tocopherol (α-T) (Eastman-Kodak) was stored in known concentrations in hexane under argon at −30°C. The water-soluble Trolox, a gift from Hoffmann-LaRoche, Nutley, New Jersey, was used in freshly prepared aqueous solutions.

Dicumylhyponitrite (DCHN) was prepared by the procedure of Mendenhall (37) and recrystallized from methanol at low temperatures before use. Commercially available samples of α,α-dimethylbenzyl alcohol, acetophenone, and cumylperoxide were used to prepare standards for hplc analyses.

Bilayers

The multilamellar bilayer dispersions were prepared in 0.1 *M* sodium chloride (Ventron Ultrapure) by vortex stirring as described previously (5). Additives such as DCHN and α-T were introduced with the phospholipids in methylene chloride followed by evaporation of the solvent under reduced pressure. Trolox was added in aqueous solution as inhibitor after initiation of the autoxidations. The amount of DCHN remaining in the bilayer was determined by hplc analysis (*vide infra*).

2. Analyses

The amount of DCHN in each run in *ortho*-dichlorobenzene and incorporated into the phospholipids for the runs in bilayers was determined by hplc analysis. In addition autoxidation runs were continued until the DCHN had decomposed nearly completely into the products: α,α-dimethylbenzyl alcohol (DMBA), acetophenone (AP), and dicumylperoxide (DCP). These compounds were all determined quantitatively by hplc on small aliquots removed from the reactions for purposes of calculating the rate constant for DCHN decomposition and the initiator efficiency. The analyses were carried out on a SP-8000 hplc using a Brownlee RP-8 column operating at 15°C eluted with acetonitrile:water (40:60 for 25 min at 0.5 mL/min and 70:30 at 1.0 mL/min to 45 min). This procedure separated the desired products from solvent and phospholipids and gave the retention times: acetanilide (internal standard) 11.2 min, DMBA (15.7 min), AP (18.3 min), DCHN (38.7 min), and DCP (40.5 min). Three such measurements were made on each sample, the deviations being less than 5% for each compound.

The solubilities of di-*tert*-butylhyponitrite (DBHN) (7) and of DCHN in water were determined by shaking films (from methylene chloride) of these initiators with 2.00 mL of aqueous phase for 2 h at 30°C. The concentration in the filtered aqueous phase was measured by hplc (DBHN) or by ultraviolet analysis (DCHN) (38).

3. Autoxidation procedure

The autoxidations were carried out at 30°C and 760 Torr of O_2 using the sensitive automatic recording gas absorption apparatus and the procedures described earlier (5, 8).

Results and discussion

1. The initiator efficiency of DCHN

(a) In solution in ortho-dichlorobenzene

Results for the analysis of decomposition products from DCHN in the presence of oxygen and oxidizable phospholipids in solution in *o*-dichlorobenzene are summarized in Table 1. The proportion of α,α-dimethylbenzyl alcohol formed as measured by the ratio DMBA/2DCHN varies somewhat with DLPC concentration but the overall number (37 ± 6%) may be taken as an indicator of the effectiveness of the cumyloxy radical to initiate reaction by hydrogen abstraction in this system.

The significant amounts of acetophenone (AP) formed reflects the tendency of cumyloxy to readily undergo β-scission to produce the methyl radical, especially in the absence of an effective hydrogen atom donor (38). This raises the interesting question as to whether the derived methyl peroxy ($CH_3OO\cdot$) radical can also act as an initiator under these conditions. In order to test for this, we carried out some inhibition experiments using α-tocopherol to measure the efficiency of DCHN by the induction period method. The results of these experiments are given in Table 2. The efficiency so determined (e = 84 ± 5%)[2] is much higher than that accounted for by initiation via the cumyloxy radical alone. The *e* determined by product studies agrees with this value by the inhibitor method, within experimental error, if one includes the amount of acetophenone in the ratio and calculates *e* from the ratio: (DMBA + AP)/2DCHN (90 ± 6%). This indicates that the eliminated methyl radical, through the formation of $CH_3OO\cdot$, could play a significant role in initiating these autoxidations in homogeneous solutions. (Compare last columns of Tables 1 and 2.)[3]

[2]The "radical yield" from DCHN is reported to be 84% based on the DMBA yield in the presence of excess hydroquinone (39).

[3]A referee offers an alternative explanation; namely, that α-tocopherol could trap *all* of the cumyloxy radicals before they undergo β-scission.

[c]$k_i = 2.80 \times 10^{-5}\ s^{-1}$ was used in the calculations (38), see Table 3, footnote *a*.

(b) Effect of phospholipid bilayers on initiator decomposition and efficiency of DCHN

In the course of product analysis from DCHN decomposition in DLPC bilayers, we discovered that nearly half of the DCHN remained after 20 h at 30°C although the rate constant *in solution* at 30°C ($k_i = 2.80 \times 10^{-5}\ s^{-1}$) (38) gives a half-life of only 7 h. This is a completely unexpected result, since the rate of decomposition of di-*tert*-butylhyponitrite was essentially independent of the medium (5), and it prompted us to explore the effect of the medium on the decomposition of DCHN. Some exploratory data are given in Table 3. We find that the k_i for DCHN in a bilayer (DLPC) is substantially less, approximately one-quarter of that in homogeneous solution in organic solvents. There is a similar lowering of the k_i in a viscous homogeneous medium (Nujol) to one-sixth of that in isooctane.

The effect of these media (Nujol and bilayers) on the decomposition rate of DCHN is very surprising. Despite the considerable evidence on the decomposition of organic hyponitrites as a convenient source of alkoxy radicals (40–48), there is no literature report that the decomposition of organic hyponitrites is retarded by high viscosity media. On the contrary, di-*tert*-butylhyponitrite (DBHN), which has been studied extensively, showed a 25% *increase* in k_i in a viscous solvent (Nujol) compared to that in isooctane, and this effect was attributed to "solvent stabilization" of DBHN by isooctane (40). A viscosity effect is more difficult to define when one considers the behaviour of solutes in bilayers. These have a gradation of fluidity as one moves from a region near the head group towards the terminal methyl groups (49). Thus the concept of a *microviscosity* of bilayers has been questioned (50), although there is no doubt that there is restriction of motion of molecules, and presumably of smaller solubilized compounds, when aggregated into bilayers.[4]

We interpret the viscosity effects of Nujol and DLPC bilayers on the rate of decomposition of DCHN in terms of a *one-bond scission* mechanism

$$R{-}O{-}N{=}N{-}OR \rightarrow R{-}O{-}N{=}N\cdot + \cdot OR.$$

Although evidence has been given for a two-bond concerted mechanism for scission of dialkylhyponitrites (42), the matter is not closed, even for di-*tert*-butylhyponitrite (45). It is known that the rate of a one-bond scission may depend on the solvent viscosity whereas two-bond concerted decompositions do not (51). The viscosity effect, found here for DCHN, is presumably due to the effect of high viscosity which retards the diffusion apart of the initially formed radical pair (above).[5] Our findings

[4]DPPC bilayers are reported to exert a "kinetic differentiation" in the k_i between *meso* and ± amphipathic diazenes resulting in a very significant rate ratio of decomposition of over 6 (27). It is possible that DLPC bilayers exert a specific effect on the DCHN decomposition rate; for example, if the two terminal phenyls are in regions of different microviscosities.

[5]The fraction of cage collapse as measured by the ratio DCP/ΔDCHN changed from 0.146 ± 0.035 in *ortho*-dichlorobenzene to 0.781 ± 0.058 in bilayers. The value in Nujol was 0.67, the same as reported for di-*tert*-butylhyponitrite (40).

TABLE 3. Rate constants for the thermal decomposition of DCHN at 30°C

Medium	Viscosity (cP)	[DCHN] (L^{-1})	$10^5 k_i$ (s^{-1})	Method[a]
Isooctane	0.475	—	2.80	Ref. 38
o-Dichlorobenzene	1.324	5.20×10^{-3}	2.21	hplc
DLPC bilayer	—[b]	0.268	0.604	N_2 evolution
DLPC bilayer		0.381	0.843	hplc
		0.193	0.737	hplc
Nujol[d]	79.9 (45°C)	1.80×10^{-2}	0.474[c]	N_2 evolution

[a]Rate constants by N_2 evolution were measured under nitrogen; measurements by hplc were determined on aliquots and are not corrected for DCHN lost during analyses.

[b]Microviscosity values for bilayers vary (e.g. egg lecithin 58–96 cP), according to the probe used for measurement, see ref. 5.

[c]The average of two measurements, 0.486×10^{-5} and 0.461×10^{-5} s^{-1}.

[d]High pressure liquid chromatographic analysis of products from the decomposition of DCHN (3.53×10^{-5} mol) gave DMBA (1.90×10^{-5} mol), AP (0.019×10^{-5} mol), and DCP (2.35×10^{-5} mol). See footnote 4 in text.

[a]All runs carried out in 0.1 *M* NaCl, 760 Torr O_2.

[b]Bilayers were prepared from DLPC + dimyristoylphosphatidycholine giving a total 20 mg sample in each run. DLPC concentrations are in *M* of total bilayer using a density of 0.8 (5).

[c]DCP was not completely resolved from bilayer material on hplc.

are fortuitous, especially in view of the various requirements before the viscosity test can be applied (51), and independent evidence is needed on the mechanism of decomposition of DCHN. In any event, this viscosity effect has important practical results; namely, this initiator has a convenient half-life in the hydrophobic phrase of bilayers to be a useful free radical initiator for quantitative autoxidation studies.

Our previous estimate of the solubility of DBHN in water (5) was based on an incorrect molar absorptivity. Therefore, we repeated this measurement here and find the solubility to be significantly higher (2.87×10^{-3} *M*) using a corrected $\epsilon = 5954$ at 227 nm (7). On the other hand, DCHN was found to be insoluble in water,[6] and we assume that it is completely solubilized in the hydrophobic bilayer phase.

Results for the analysis of decomposition products from DCHN in mixed bilayers are given in Table 4. The effectiveness of the cumyloxy radical to initiate reaction by hydrogen abstraction varied from 30 ± 1% to approximately 19% as the amount of readily abstractable hydrogen (e.g. DLPC) decreases. The overall efficiency *e* as determined by the ratio (DMBA + AP)/Δ2DCHN, with DLPC present, is consistently a few percent higher but *generally comparable to the efficiency of cumyloxy alone*. This behaviour is in marked contrast with that in homogeneous solution (Table 1, last column) and indicates that the methylperoxy radical does not contribute significantly to initiation in these bilayer experiments, probably because this small methylperoxy radical could diffuse rapidly out of the bilayer and decompose in the water. To test this idea we carried out some experiments to measure the *e* for DCHN in these bilayers by the inhibitor method with α-tocopherol (in the bilayer phase). These results are shown in Table 5. Now the overall *e* (26–30%) is comparable, within experimental error to the value obtained from products(s) of hydrogen abstraction alone at higher DLPC concentration, DMBA/2DCHN (Table 4), in contrast to the results from the use of α-tocopherol in solution (Table 2).

Some experiments were conducted using the water-soluble inhibitor 6-hydroxy-2,5,7,8-tetramethyl-chroman-2-carboxylate (Trolox) to compare its effectiveness with that of α-tocopherol, to inhibit autoxidation initiated in the hydrophobic bilayer phase by DCHN. We find that Trolox is *not* as effective at stopping the chain reaction as α-tocopherol. The initial rate during the inhibition period with Trolox typically was at least 5% of the uninhibited rate compared to only 2–3% when α-tocopherol was used. This difference in behavior is attributed to the nature of the multilamellar system used. With both DCHN and α-tocopherol uniformly distributed in these bilayers, there is efficient inhibition in all layers. On the other hand, Trolox

[6]Within the detection limit estimated to be $\leq 1.0 \times 10^{-6}$ *M*.

[a]The same as footnote a, Table 4.
[b]See footnote b, Table 4. In runs 5–8 42 mg (5.25×10^{-5} mol) DLPC was used.
[c]An average $e = 0.276$ was used to calculate R_i.
[d]The $e = 0.264$ determined with α-Toc (Run 5) was used to calculate R_i.
[e]The k_i determined by N_2 evolution ($0.604 \times 10^{-5}\ s^{-1}$) was used (see Table 3 and Text).
[f]Rates are corrected for nitrogen evolution from the initiator, oxygen absorbed by the initiating radicals and evolved in chain termination by adding $(1 - e)k_i$[In] to the measured rate. Experimental errors in the rate measurements are estimated as ≤20%.

apparently can only effectively access the outer layers while some oxidation continues in the inner layers (52). Thus the apparent efficiency of DCHN as measured by Trolox *appears* to be higher than that measured by α-tocopherol.

2. The kinetics of autoxidation in mixed bilayers

The earlier conclusion that the classical rate law (eq. [1]) applied to the kinetics of autoxidation in bilayers was based only on the variation of the rate of oxygen uptake with the initiator (DBHN) concentration in egg lecithin bilayers and the near constancy of the resulting oxidizability. Results shown in Table 5 now provide important evidence on *the effect of oxidizable (DLPC) bilayer concentration* in mixed bilayers on the rate of oxygen uptake. Thus for approximately the same DCHN concentration in the bilayers, the rates are directly proportional to the DLPC concentration (Runs 1–4). This provides confirmation that the classical rate law is applicable to mixed bilayers. The oxidizability of DLPC in mixed bilayers ($0.046 \pm 0.002\ M^{-1/2}\ s^{-1/2}$) is the same, within experimental error, to that of neat DLPC ($0.051 \pm 0.005\ M^{-1/2}\ s^{-1/2}$), and the value is in agreement with previous reported results (6). A more detailed kinetic analysis and product studies on mixed bilayers for reactions initiated in either the aqueous phases or the bilayer phase is in progress.

Acyl migration from N^6 to $N7$ of a 2′,3′-*O*-isopropylideneadenosine derivative accompanied by cyclonucleoside formation

KENTARO ANZAI[1] AND JUN UZAWA

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351, Japan

Received December 24, 1985

KENTARO ANZAI and JUN UZAWA. Can. J. Chem. **64**, 2109 (1986).

Reaction of 2′,3′-*O*-isopropylideneadenosine (**1**) with *p*-NCC_6H_4COCl in 1:6 Et_3N–CH_2Cl_2 afforded the cyanoimidazole nucleoside **8** (53%) and the 8,5′-*O*-cycloadenosine derivative **7** (29%). Treatment of N^6,N^6-di-*p*-toluyl-2′,3′-*O*-isopropylideneadenosine (**23**) with $ZnBr_2$ in *p*-dioxane resulted in acyl migration from N^6 to $N7$ to give the cycloadenosine derivative **4**. The coordination site of the zinc cation on the base moiety of adenosine derivatives was determined by ^{15}N nmr spectra.

KENTARO ANZAI et JUN UZAWA. Can. J. Chem. **64**, 2109 (1986).

La réaction, dans un mélange 1:6 de Et_3N–CH_2Cl_2, du *O*-isopropylidène-2′,3′ adénosine (**1**) avec le *p*-NCC_6H_4COCl conduit au nucléoside du cyanoimidazole (**8**) (53%) ainsi qu'au dérivé *O*-cycloadénoside-8,5′ (**7**) (29%). Si l'on traite le N^6,N^6-di-*p*-toluyl *O*-isopropylidène-2′,3′ adénosine (**23**) par du $ZnBr_2$ dans du *p*-dioxanne, il en résulte une migration de l'acyle du N^6 vers le $N7$ ainsi que la formation du dérivé cycloadénosine **4**. On a fait appel à la rmn du ^{15}N pour déterminer le site de coordination du zinc sur la portion basique des dérivés de l'adénosine.

[Traduit par la revue]

Introduction

We reported previously (1) that reaction of 2′,3′-*O*-isopropylideneadenosine (**1**) with *p*-toluyl chloride in pyridine afforded 2′,3′-*O*-isopropylidene-N^6,N^6,5′-*O*-tri-*p*-toluyladenosine (**2**) as the main product (70%), as well as the tri-*p*-toluyl-8,5′-*O*-cycloadenosine derivative **3** as the minor one (6%). On the other hand, when the reaction was carried out in a mixture of methylene chloride and triethylamine (6:1), cyclonucleoside formation was the main reaction path, thus giving **2** (30%), **3** (34%), the di-*p*-toluyl-8,5′-*O*-cycloadenosine derivative **4** (11%), and the cyanoimidazole nucleoside **5** (12%), the formation of which was explained by initial acylation at $N1$ followed by $N1$—$C2$ elimination.

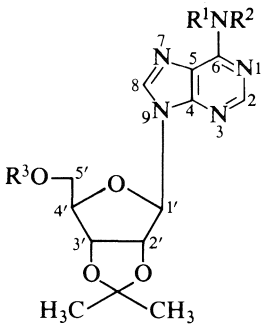
The present paper is an extension of the study on acylation of adenosine derivatives, which has led to the finding of acyl migration from N^6 to $N7$.

Results and discussion

Several *p*-substituted derivatives of benzoyl chloride were used in acylation of **1** in a mixture of methylene chloride and triethylamine (6:1), and the reaction products are listed in Table 1. The results showed that, in the methylene chloride – triethylamine solvent, cyclonucleoside formation predominated over the conventional acylation reaction and, in the case of reaction with *p*-cyanobenzoyl chloride (Entry 2), production of the cyanoimidazole nucleoside **8**, i.e. acylation at $N1$ of **1**, was the main reaction course. The ester bond in **8** was selectively cleaved to give **6**.

Reaction of **1** with excess *p*-toluyl chloride in a mixture of methylene chloride and pyridine (3:1) gave **2** (32%) and **3** (41%) without formation of **5** and, with a limited amount of the acid chloride in the same solvent, **1** was converted to **4** as the main reaction path as well as **21** as the minor one.

These results showed that, in the reaction of **1** with the substituted derivatives of benzoyl chloride, the product distribution, i.e. the position of attack on the base moiety of **1** by acyl groups (N^6, $N7$ or $N1$), seemed to be determined by several factors, i.e. solvent polarities, base species, and acylating reagents.



1 R^1,R^2,R^3 = H
2 R^1,R^2,R^3 = *p*-$CH_3C_6H_4CO$
9 R^1,R^2,R^3 = *p*-$CH_3OC_6H_4CO$
13 R^1,R^2,R^3 = *p*-BrC_6H_4CO
17 R^1,R^2,R^3 = *p*-ClC_6H_4CO
21 R^1 = H, R^2,R^3 = *p*-$CH_3C_6H_4CO$
23 R^1, R^2 = *p*-$CH_3C_6H_4CO$, R^3 = H
24 R^1, R^2 = *p*-$CH_3C_6H_4CO$
R^3 = $(p\text{-}CH_3OC_6H_4)_2C_6H_5C$
25 R^1, R^2 = *p*-$CH_3C_6H_4CO$, R^3 = CH_3COO
26 R^1 = *p*-$CH_3C_6H_4CO$, R^2, R^3 = H
27 R^1, R^2 = H, R^3 = *p*-$CH_3C_6H_4CO$
28 R^1, R^2 = H, R^3 = $(p\text{-}CH_3OC_6H_4)_2C_6H_5C$

Rearrangement of the N^6,N^6,5′-*O*-triacyladenosine compound **2** to its 8,5′-*O*-cycloadenosine isomer **3** was investigated under both acid and alkaline conditions. With zinc bromide as the acid catalyst, **2** was converted to **3** in low yield (18%), the main reaction path being hydrolysis to give **21** (54%). Another minor product (10%) was identified as the 4,5,6-triaminopyrimidine nucleoside **22**, based on the fact that the H-8 and C-8 signals of adenosine were missing on the ^1H nmr and ^{13}C nmr spectra of **22**. The assignment of the three carbonyl groups in the ^{13}C nmr spectrum was accomplished with help of selective $^{13}C\{^1H\}$ nOe (nuclear Overhauser enhancement) (2): δ 165.0 ($^{13}COOCH_2$, $^{13}C\{CH_2\}$ 50%), δ 164.5 ($^{13}CONH$, $^{13}C\{NH\}$ 50%), δ 166.0 ($^{13}CONH$, $^{13}C\{NH\}$ 60%).

Acyl migration from N^6 to $N7$ accompanied by cyclonucleoside formation as the sole reaction path was achieved using, as the starting material, N^6,N^6-di-*p*-toluyl-2′,3′-*O*-isopropyli-

deneadenosine (**23**), which was prepared by three different routes: (*1*) hydrolysis of the dimethoxytrityl derivative **24** in aqueous acetic acid, (*2*) hydrolysis of the acetyl derivative **25** in aqueous sodium hydrogen carbonate, and (*3*) hydrolysis attending rearrangement of the cyclonucleoside **3** in aqueous sodium hydrogen carbonate. Thus, reaction of **23** with zinc bromide in *p*-dioxane proceeded without hydrolysis to give the N^6,7-diacyl-8,5′-*O*-cycloadenosine derivative **4**.

The necessity of the N^6,N^6-diacyl structure in **23** for this

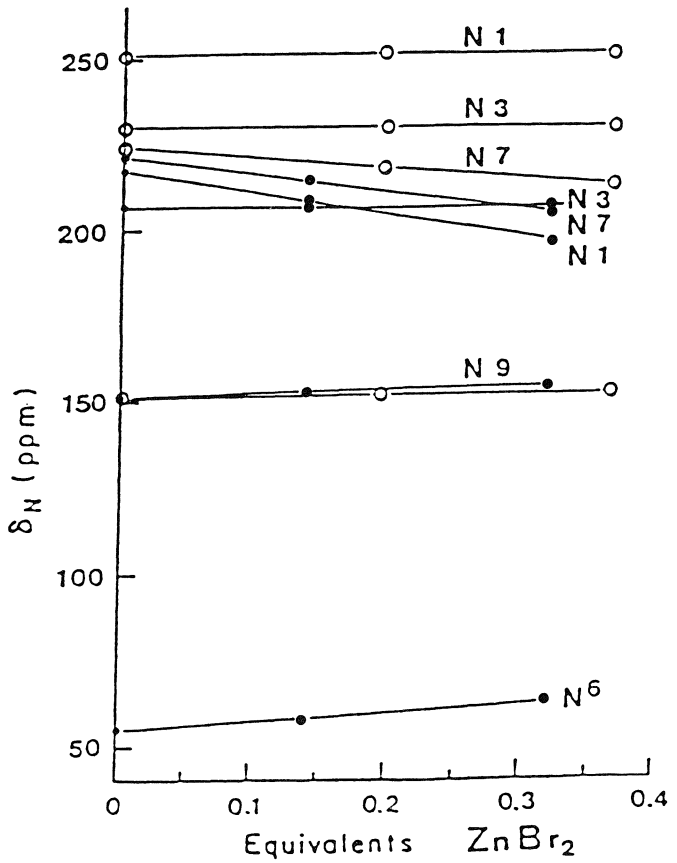

FIG. 1. The ^{15}N nmr chemical shifts of compound **2** (—○—) and compound **27** (—●—) in the presence of $ZnBr_2$.

rearrangement reaction was shown by the fact that 2′,3′-*O*-isopropylidene-N^6-*p*-toluyladenosine (**26**) was stable under the same conditions. The N^6-acyl compound **26** for this experiment was prepared by treatment with 2,4,5-trichlorophenyl-*p*-toluate (**29**). 2,4,5-Trichlorophenyl benzoate (**30**) had been used to acylate N^4 of cytidine selectively (3). In the present case the N^6,5′-*O*-di-*p*-toluyl compound **21** was also obtained as the minor product. Ammonium hydrolysis of **25** also gave **26**.

To learn something about the mechanism of the zinc bromide catalyzed conversion of **2** to **3** or **23** to **4**, we investigated how zinc bromide coordinated to the adenine ring. The ^{15}N nmr spectrum of the N^6,N^6,5′-*O*-tri-*p*-toluyl compound **2**[2] as well as that of 2′,3′-*O*-isopropylidene-5′-*O*-*p*-toluyladenosine (**27**) (1) were taken at the natural abundance level based on INEPT (4–6) in the presence and absence of zinc bromide (Fig. 1).[3] We found that the coordination site was *N*7 in the case of **2** and both *N*1 and *N*7 in the case of **27**, being shown by upfield shifts of the ^{15}N nmr signals on addition of zinc bromide (Δ 3 ppm for 0.1 equiv. of $ZnBr_2$). The coordination site of zinc cation on guanosine had been investigated using the ^{15}N nmr chemical shift (7).

In the ^1H nmr spectrum of **2** only the *H*-8 signal suffered a downfield shift to a considerable extent (Δ 0.2 ppm for 0.5 equiv. $ZnBr_2$). Coordination of zinc cation at *N*7 in **23**

[2]Determination of the coordination site of $ZnBr_2$ on the adenine ring of **23** using ^{15}H nmr spectra could not be accomplished, because cyclonucleoside formation proceeded during the period of taking the spectrum.

[3]The same experiment was run with the N^6-*p*-toluyladenosine compound **21**. The result was almost the same as was obtained for **2**.

TABLE 1. The reaction products from 2′,3′-*O*-isopropylideneadenosine and some *p*-substituted derivatives of benzoyl chloride in 1:6 Et_3N–CH_2Cl_2[a]

[a]Reaction conditions: room temperature, overnight. See also Experimental.
[b]Non-cyclo: conventional acylating reaction; cyclo: cyclonucleoside formation; ring cleavage: formation of cyanoimidazole nucleoside.

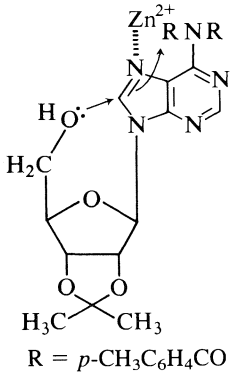

FIG. 2. Mechanistic drawing of the conversion of **23** to **4**.

would result in the decrease of π-electron density at *C*8, thus rendering possible attack of 5′-*O* at *C*8, accompanying acyl migration from N^6 to *N*7 (Fig. 2).

The mechanism of the conversion of **2** to **3** in the presence of zinc bromide is presumably a variation of that depicted in Fig. 2. The same conversion under alkaline conditions was also observed: i.e. **2** was treated in a mixture of propanol and 0.25 *M* $NaHCO_3$ (2:1) for 10 days, giving 30% of **3** with a 50% recovery of the starting material. To the best of our knowledge, acyl migration onto the basic moiety of adenosine compounds has not been reported previously.

Experimental

Measurement of ^{15}N nmr spectra

The ^{15}N nmr spectra were recorded using a JEOL FX-100 spectrometer with multinuclear observed system and PG-200 pulse programmer based on INEPT. Chemical shifts were measured relative to external aqueous NH_4NO_3 ($\delta_{NH_4^+}$ = 0). As the refocussed INEPT sequence (8, 9) gave a poor S/N ratio because of the presence of zinc bromide, which caused shortening of T_2, the measurement was carried out based on the non-refocussed INEPT sequence (4, 5). It was also useful to observe $^2J_{N,H}$, thus making it possible to establish the chemical shift assignment, i.e. selective low power irradiation ($\gamma B_2/2\pi$ = 25 Hz) on proton signals resulted in enhancement of nitrogen signals: τ = 16 ms ($1/4J$); ^1H 90° pulse, 11 ms; repetition time, 1.8 s.

General procedure for acylation of 2′,3′-O-isopropylideneadenosine (1)

To an ice-cooled solution of **1** in pyridine or a mixture of CH_2Cl_2 and an organic base (pyridine or Et_3N) was added an acyl chloride and, after the mixture was stirred at room temperature overnight, it was evaporated to dryness. The pyridine was removed as the toluene azeotrope. The residue was distributed between aqueous $NaHCO_3$ and $CHCl_3$ and, after the organic layer was washed with water and concentrated, it was applied to a silica gel column. Eluting solvents were, in most cases, mixtures of C_6H_6 and EtOAc, gradually increasing the latter content.

7,8-Dihydro-2′,3′-O-isopropylidene-N^6,N^6,7-tri-p-toluyl-8,5′-O-cycloadenosine (3)

The previous method (1) was modified to increase the yield of **3** and avoid the ring-cleavage reaction. Thus, **1** (921 mg, 3 mmol) was treated with *p*-toluyl chloride (4 g, 26 mmol) in a mixture of CH_2Cl_2 (30 mL) and pyridine (10 mL) following the general procedure for acylation. Silica gel chromatography (4:1 C_6H_6–EtOAc) afforded two compounds, the less polar one being **3**, mp 205–208°C (MeOH) (lit. (1) mp 182–185°C (toluene–hexane)); uv λ_{max} (MeOH): 253 nm (ε 47 000), 310 nm (sh) (ε 12 600). The more polar one was *2′,3′-O-isopropylidene-N^6,N^6,5′-O-p-toluyladenosine* (**2**), yield 630 mg (32%), mp 188–189°C (MeOH) (lit. (1) mp 189–190°C (MeOH)); uv λ_{max} (MeOH): 243 nm (ε 35 000), 275 nm (sh) (ε 27 000).

7,8-Dihydro-N^6,7-di-p-toluyl-2′,3′-O-isopropylidene-8,5′-O-cycloadenosine (4)

Treatment of **1** (921 mg, 3 mmol) with *p*-toluyl chloride (1.8 g, 11.8 mmol) in a mixture of CH_2Cl_2 (30 mL) and pyridine (2 mL) afforded, as was shown on tlc, four products, which were separated on

a silica gel column by eluting with a mixture of C_6H_6 and EtOAc (4:1), gradually increasing the latter content. Thus, **3** (120 mg, 6%) and **2** (70 mg, 4%) were eluted with 4:1 to 2:1 C_6H_6–EtOAc, **4** (810 mg, 50%) with 2:1 to 1:1 C_6H_6–EtOAc, and **21** (280 mg, 17%) with EtOAc; **4**: mp 229–230°C (C_6H_6) (lit. (1) mp 229–230°C (C_6H_6)); uv λ_{max} (MeOH): 240 nm (ε 28 800), 285 nm (ε 15 200); **21**, glassy solid from toluene–ligroin (1).

*4-Cyano-1-(2,3-O-isopropylidene-β-D-ribofuranosyl)-5-(*p*-cyanobenzoylamino)imidazole (**6**)*

(*a*) A solution of **8** (1) (1 g, 1.86 mmol) in a mixture of MeOH (20 mL) and 1 *M* NaOH (5 mL) was left standing at room temperature overnight and neutralized with AcOH to pH 5. The product was, after the methanol was removed by evaporation, extracted with $CHCl_3$ and separated by silica gel chromatography (EtOAc), yield 680 mg (89%), mp 191–192°C (BuOAc); ir ν_{max} (KBr) cm^{-1}; 2250 (m, CN), 1670 (s, NH_2CO); uv λ_{max} (MeOH): 235 nm (ε 25 400), 285 (sh) (ε 4100); ^1H nmr data (100 MHz, $CDCl_3$) δ: 5.78 (s, 1H, H-1′, $J_{1',2'}$ = 2 Hz), 7.76 (s, 1H, H-2), 7.81 and 8.10 (2d, 4H, *p*-cyanobenzoyl, J_o = 7 Hz). *Anal.* calcd. for $C_{20}H_{19}O_5N_5$: C 58.67, H 4.68, N 17.11; found: C 58.90, H 4.57, N 17.25.

(*b*) A solution of **8** (269 mg, 0.5 mmol) in a mixture of EtOH (10 mL) and concentrated NH_4OH (1 mL) was left standing at room temperature for one week. After ammonia was removed by evaporation, the product was isolated as mentioned in (*a*), yield 190 mg (93%).

*Reaction of **1** with* p*-cyanobenzoyl chloride*

Compound **1** (3.07 g, 10 mmol) was treated with *p*-cyanobenzoyl chloride (7.8 g, 47 mmol) in a mixture of CH_2Cl_2 (150 mL) and Et_3N (25 mL). *7,8-Dihydro-2′,3′-*O*-isopropylidene-*N^6,N^6,*7-tri-*p*-cyanobenzoyl-8,5′-*O*-cycloadenosine (**7**)* was eluted from a silica gel column with 4:1 C_6H_6–EtOAc, yield 2.04 g (29%), mp 236.5–237.5° (MeOH); uv λ_{max} (MeOH): 243 nm (ε 47 900); ^1H nmr data (100 MHz, $CDCl_3$) δ: 3.30 (dd, 1H, H-5′a, J_{gem} = 12 Hz, $J_{4,5'a}$ = 2 Hz), 3.94 (d, 1H, H-5′b, J_{gem} = 12 Hz), 5.81 (s, 1H, H-1′), 6.08 (s, 1H, H-8), 8.16 (s, 1H, H-2). *Anal.* calcd. for $C_{37}H_{26}O_7N_8 \cdot 1/2\ H_2O$: C 63.16, H 3.74, N 15.93; found: C 63.14, H 3.74, N 15.79.

*4-Cyano-5-*p*-cyanobenzoylamino-1-(5-*O*-*p*-cyanobenzoyl-2,3-*O*-isopropylidene-β-D-ribofuranosyl)imidazole (**8**)* was eluted with 1:1 C_6H_6–EtOAc, yield 2.87 g (53%), mp 139–143°C (toluene); ir ν_{max} (KBr): 2250 cm^{-1} (m, CN); uv λ_{max} (MeOH): 247 nm (ε 37 800); ^1H nmr data (100 MHz, $CDCl_3$) δ: 5.88 (d, 1H, H-1′, $J_{1',2'}$ = 2 Hz), 7.68 (s, 1H, H-2); ms *m/e*: 538 (M^+). *Anal.* calcd. for $C_{28}H_{22}O_6N_6$: C 62.45, H 4.12, N 15.61; found: C 62.43, H 4.26, N 15.39.

*Reaction of **1** with* p*-anisoyl chloride*

Compound **1** (1.54 g, 5 mmol) was treated with *p*-anisoyl chloride (5 g, 29 mmol) in a mixture of CH_2Cl_2 (150 mL) and Et_3N (25 mL). *7,8-Dihydro-2′,3′-*O*-isopropylidene-*N^6,N^6,*7-tri-*p*-anisoyl-8,5′-*O*-cycloadenosine (**10**)* was eluted from a silica gel column with 4:1 C_6H_6–EtOAc, yield 1.04 g (29%), mp 167–170°C (MeOH); uv λ_{max} (MeOH): 278 nm (ε 45 000); ^1H nmr data (100 MHz, $CDCl_3$) δ: 3.42 (dd, 1H, H-5′a, J_{gem} = 14 Hz, $J_{4,5'a}$ = 2 Hz), 3.94 (d, 1H, H-5′b, J_{gem} = 14 Hz), 5.80 (s, 1H, H-1′), 6.08 (s, 1H, H-8), 8.21 (s, 1H, H-2). *Anal.* calcd. for $C_{37}H_{35}O_{10}N_5$: C 62.61, H 4.97, N 9.87; found: C 62.38, H 4.92, N 9.64.

*2′,3′-*O*-Isopropylidene-*N^6,N^6,*5′-*O*-tri-*p*-anisoyladenosine (**9**)* was eluted with 2:1 to 1:1 C_6H_6–EtOAc, yield 540 mg (15%), mp 144.5–145.5°C (MeOH). **Notice**: the solubility of this compound in MeOH at room temperature is lower than that in a refrigerator; uv λ_{max} (MeOH): 260 nm (sh) (ε 39 000), 272 nm (ε 41 100), 290 nm (ε 37 600); ^1H nmr data (100 MHz, $CDCl_3$) δ: 4.56 (br, 3H, H-4′ and H-5′), 6.14 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 8.16 (s, 1H, H-8), 8.64 (s, 1H, H-2). *Anal.* calcd. for $C_{37}H_{35}O_{10}N_5$: C 62.61, H 4.97, N 9.87; found: C 62.64, H 4.94, N 9.90.

*5-*p*-Anisoylamino-1-(5-*O*-*p*-anisoyl-2,3-*O*-isopropylidene-β-D-ribofuranosyl)-4-cyanoimidazole (**12**)* was eluted with 1:1 C_6H_6–EtOAc and obtained as a glassy solid from toluene, yield 630 mg (23%); ir ν_{max} (KBr): 2250 cm^{-1} (m, CN); uv λ_{max} (MeOH): 259 (ε 34 400); ^1H nmr data (100 MHz, $CDCl_3$) δ: 5.84 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 7.64 (s, 1H, H-2); ms *m/e*: 548 (M^+). *Anal.* calcd. for $C_{28}H_{28}O_8N_4$: C 61.31, H 5.15, N 10.21; found: C 61.16, H 5.10, N 10.35.

*N^6,7-di-*p*-Anisoyl-7,8-dihydro-2′,3′-*O*-isopropylidene-8,5′-*O*-cy*cloadenosine (**11**) was eluted with EtOAc and obtained as a glassy solid from toluene, yield 610 mg (21%); uv λ_{max} (MeOH): 266 nm (ε 39 100); ^1H nmr data (100 MHz, $CDCl_3$) δ: 3.48 (dd, 1H, H-5′a, J_{gem} = 14 Hz, $J_{4',5'a}$ = 2 Hz), 3.92 (d, 1H, H-5′b, J_{gem} = 14 Hz), 5.83 (s, 1H, H-1′), 6.07 (s, 1H, H-8), 8.52 (s, 1H, H-2). *Anal.* calcd. for $C_{29}H_{29}O_8N_5$: C 60.51, H 5.08, N 12.17; found: C 60.50, H 5.12, N 11.96.

*Reaction of **1** with* p*-bromobenzoyl chloride*

Compound **1** (1.54 g, 5 mmol) was treated with *p*-bromobenzoyl chloride (8 g, 36.4 mmol) in a mixture of CH_2Cl_2 (150 mL) and Et_3N (25 mL). *7,8-Dihydro-2′,3′-*O*-isopropylidene-*N^6,N^6,*5′-*O*-tri-*p*-bromobenzoyl-8,5′-*O*-cycloadenosine (**14**)* was eluted first from a silica gel column with 4:1 C_6H_6–EtOAc, yield 1.41 g (33%), mp 197–199°C (EtOH); uv λ_{max} (MeOH): 254 nm (ε 41 900), 315 nm (sh) (ε 6800); ^1H nmr data (100 MHz, $CDCl_3$) δ: 3.37 (dd, 1H, H-5′a, J_{gem} = 13 Hz, $J_{4',5'a}$ = 2 Hz), 3.94 (d, 1H, H-4, J_{gem} = 13 Hz), 5.80 (s, 1H, H-1′), 6.07 (s, 1H, H-8), 8.20 (s, 1H, H-2). *Anal.* calcd. for $C_{34}H_{26}O_7N_5Br_3$: C 47.68, H 3.06, N 8.18, Br 28.00; found: C 47.57, H 2.97, N 8.03, Br 27.90.

*2′,3′-*O*-Isopropylidene-*N^6,N^6,*5′-*O*-tri-*p*-bromobenzoyladenosine (**13**)* was eluted with 4:1 C_6H_6–EtOAc contaminated by **14**. However, an analytically pure sample of **13** was obtained by crystallization from BuOH, yield 360 mg (7%), mp 214–215°C; uv λ_{max} (MeOH): 242 nm (ε 67 600), 275 nm (sh) (ε 18 500); ^1H nmr data (100 MHz, $CDCl_3$) δ: 6.16 (d, 1H, H-1′, $J_{1',2'}$ = 2 Hz), 8.16 (s, 1H, H-8), 8.61 (s, 1H, H-2). The isolated sample was found to be a *p*-bromobenzoic acid adduct. *Anal.* calcd. for $C_{34}H_{26}O_7N_5Br_3 \cdot BrC_6H_4CO_2H$: C 46.57, H 2.96, N 6.62, Br 30.23; found: C 46.80, H 2.84, N 6.55, Br 30.54.

*1-(5-*O*-p-bromobenzoyl-2,3-*O*-isopropylidene-β-D-ribofuranosyl)-4-cyano-5-di-*p*-bromobenzoylaminoimidazole (**15**)* was eluted with 4:1 to 2:1 C_6H_6–EtOAc and obtained as a glassy solid from toluene–ligroin, yield 450 mg (11%); ir ν_{max} (KBr): 2250 cm^{-1} (m, CN); uv λ_{max} (MeOH): 248 nm (ε 35 900); ^1H nmr data (100 MHz, $CDCl_3$) δ: 1.32 and 1.44 (2s, 6H, 2 isopropylidene methyls), 4.5 (br, 2H, H-5′), 4.68 (complex, 1H, H-4′), 4.84 (dd, 1H, H-3′, $J_{3',4'}$ = 2 Hz, $J_{2',3'}$ = 6 Hz), 5.02 (dd, 1H, H-2′, $J_{2',3'}$ = 6 Hz, $J_{1',2'}$ = 3 Hz), 5.78 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 7.3–7.8 (aromatic protons and H-2). *Anal.* calcd. for $C_{33}H_{25}O_7N_4Br_3$: C 47.79, H 3.04, N 6.76, Br 28.91; found: C 48.09, H 3.07, N 6.78, Br 28.79.

*5-*p*-Bromobenzoylamino-1-(5-*O*-*p*-bromobenzoyl-2,3-*O*-isopropylidene-β-D-ribofuranosyl)-4-cyanoimidazole (**16**)* was eluted with 1:1 C_6H_6–EtOAc, yield 1.17 g (36%), mp 114–115°C (toluene); uv λ_{max} (MeOH): 244 nm (ε 36 100); ^1H nmr data (100 MHz, $CDCl_3$) δ: 1.32 and 1.44 (2s, 6H, 2 isopropylidene methyls), 4.5 (br, 2H, H-5′), 4.68 (complex, 1H, H-4′), 4.76 (dd, 1H, H-3′, $J_{3',4'}$ = 2 Hz, $J_{2',3'}$ = 6 Hz), 4.92 (dd, 1H, H-2′, $J_{2',3'}$ = 6 Hz, $J_{1',2'}$ = 3 Hz), 5.85 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 7.64 (s, 1H, H-2), 8.84 (br s, 1H, NH). *Anal.* calcd. for $C_{26}H_{22}O_6N_4Br_2$: C 48.31, H 3.43, N 8.67, Br 24.73; found: C 48.14, H 3.36, N 8.57, Br 24.73.

*Reaction of **1** with* p*-chlorobenzoyl chloride*

Compound **1** (3.07 g, 10 mmol) was treated with *p*-chlorobenzoyl chloride (14 g, 80 mmol) in a mixture of CH_2Cl_2 (300 mL) and Et_3N (50 mL). *7,8-Dihydro-2′,3′-*O*-isopropylidene-*N^6,N^6,*7-tri-*p*-chlorobenzoyl-8,5′-*O*-cycloadenosine (**18**)* was eluted from a silica gel column with 9:1 to 4:1 C_6H_6–EtOAc, yield 2.5 g (35%), mp 184–186°C (EtOH); uv λ_{max} (MeOH): 248 nm (ε 39 700), 310 nm (sh) (ε 7900); ^1H nmr data (100 MHz, $CDCl_3$) δ: 3.37 (dd, 1H, H-5′a, J_{gem} = 13 Hz, $J_{4',5'a}$ = 2 Hz), 3.96 (d, 1H, H-5′b, J_{gem} = 13 Hz), 5.82 (s, 1H, H-1′), 6.07 (s, 1H, H-8), 8.19 (s, 1H, H-2); ms *m/e*: 727, 725, 723 (a cluster of parent ions). *Anal.* calcd. for $C_{34}H_{26}O_7N_5Cl_3$: C 56.48, H 3.63, N 9.69, Cl 14.71; found: C 56.37, H 3.62, N 9.64, Cl 14.85.

*2′,3′-*O*-Isopropylidene-*N^6,N^6,*5′-*O*-tri-*p*-chlorobenzoyladenosine (**17**)* was eluted with 4:1 C_6H_6–EtOAc, yield 1.6 g (15%), mp 180–181°C (toluene); uv λ_{max} (MeOH): 237 nm (ε 80 800), 275 nm (sh)

(ε 41 400); ^{1}H nmr (100 MHz, $CDCl_3$) δ: 6.19 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 8.21 (s, 1H, H-8), 8.64 (s, 1H, H-2); ms *m/e*: 727, 725, 723 (a cluster of parent ions). The isolated sample was found to contain two moles of *p*-chlorobenzoic acid as the adduct. *Anal.* calcd. for $C_{34}H_{26}O_7N_5Cl_3 \cdot 2ClC_6H_4CO_2H$: C 55.64, H 3.50, N 6.76, Cl 17.11; found: C 55.49, H 3.49, N 6.64, Cl 17.10.

N^6,*7-Dichlorobenzoyl-7,8-dihydro-2′,3′-*O*-isopropylidene-8,5′-*O*-cycloadenosine (**19**)* was eluted with 4:1 C_6H_6–EtOAc and obtained as a glassy solid from toluene–hexane, yield 370 mg (6%); uv λ_{max} (MeOH): 242 nm (ε 31 800), 265 nm (ε 30 000); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 3.36 (dd, 1H, H-5′a, J_{gem} = 13 Hz, $J_{4',5'a}$ = 3 Hz), 3.88 (d, 1H, H-5′b, J_{gem} = 13 Hz), 5.80 (s, 1H, H-1′), 6.04 (s, 1H, H-8), 8.02 (s, 1H, H-2). *Anal.* calcd. for $C_{27}H_{23}O_6N_5Cl_2$: C 55.48, H 3.97, N 11.99, Cl 12.14; found: C 55.59, H 4.05, N 11.62, Cl 11.93.

*5-*p*-Chlorobenzoylamino-1-(5-*O*-*p*-chlorobenzoyl-2,3-*O*-isopropylidene-β-*D*-ribofuranosyl)-4-cyanoimidazole (**20**)* was eluted with 2:1 C_6H_6–EtOAc, yield 1.1 g (20%), mp 118–120°C (toluene); ir ν_{max} (KBr): 2250 cm^{-1} (m, CN); uv λ_{max} (MeOH): 239 nm (ε 32 400); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 5.83 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 7.83 (s, 1H, H-2), 9.90 (br s, 1H, NH); ms *m/e*: 560, 558, 556 (a cluster of parent ions). *Anal.* calcd. for $C_{26}H_{22}O_6N_4Cl_2$: C 56.02, H 3.98, N 10.05, Cl 12.72; found: C 56.22, H 4.02, N 9.92, Cl 12.66.

*Treatment of **2** with $ZnBr_2$ in* p*-dioxane*

A solution of **2** (935 mg, 1.41 mmol) and $ZnBr_2$ (10 g) in *p*-dioxane (100 mL) was left standing at room temperature for 4 days. Aqueous $NaHCO_3$ was added and, after the precipitate of $Zn(OH)_2$, was removed by centrifugation; the products were extracted with $CHCl_3$. Thin-layer chromatography (1:1 C_6H_6–EtOAc) showed the presence of three uv-absorbing compounds, which were separated by silica gel chromatography. Compound **3** was eluted with 2:1 C_6H_6–EtOAc, yield 170 mg (18%).

N^5,N^6-*di*-*p*-*toluylamino*-N^4-*(2,3-*O*-isopropylidene-5-*O*-*p*-toluyl-β-*D*-ribofuranosyl)-4,5,6-triaminopyrimidine (**22**)* was eluted with 1:1 C_6H_6–EtOAc and obtained as a glassy solid from toluene, yield 90 mg (10%); uv λ_{max} (MeOH): 240 nm (ε 39 400); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.36 and 1.58 (2s, 6H, 2 isopropylidene methyls), 2.32, 2.36, and 2.40 (3s, 9H, *p*-toluyl methyls), 6.73 (s, 1H, H-1′, $J_{1',2'}$ = 4 Hz), 8.16 (s, 1H, H-1′), 9.00 and 9.60 (2s, 2H, 2NH, collapsed on addition of D_2O); ^{13}C nmr data ($CDCl_3$, TMS) δ: 159.6 (C4), 155.1 (C2, ^1J = 201.4 Hz), 153.1 (C6), 108.9 (C5), 87.6 (C1′), 83.6 (C2′), 81.6 (C4′), 81.2 (C3′), 64.6 (C5′); ms *m/e*: 651 (M^+), 636 ($M^+ - CH_3$), 532 ($M^+ - CH_3C_6H_4CO$), 516 ($M^+ - CH_3C_6H_4CONH_2$). *Anal.* calcd. for $C_{36}H_{37}O_7N_5 \cdot 1/4H_2O$: C 65.89, H 5.76, N 10.67; found: C 65.91, H 5.78, N 10.66.

N^6,*5′-*O*-Di-*p*-toluyl-2′,3′-*O*-isopropylideneadenosine (**21**)* was eluted with EtOAc, yield 380 mg (54%).

*Treatment of **2** with aqueous $NaHCO_3$*

A solution of **2** (500 mg, 0.76 mmol) in a mixture of PrOH (100 mL) and 0.25 *M* $NaHCO_3$ (50 mL) was left standing at room temperature for 10 days. The propanol was removed by evaporation and the products were extracted with EtOAc. Thin-layer chromatography (4:1 C_6H_6–EtOAc) showed the presence of two uv-absorbing compounds, which were separated by silica gel chromatography eluting with 4:1 C_6H_6–EtOAc. The less polar compound was **3**, yield 150 mg (30%). The more polar compound was the starting material with a recovery of 250 mg (50%).

N^6,N^6-*di*-*p*-*toluyl-2′,3′-*O*-isopropylideneadenosine (**23**)*

(*1*) A solution of **24** (350 mg, 0.41 mmol) in 70% AcOH (10 mL) was left standing at room temperature for 1 h and concentrated to dryness keeping the temperature below 40°C. After the residue was distributed between EtOAc and aqueous $NaHCO_3$, the organic layer was applied to silica gel chromatography (1:1 C_6H_6–EtOAc followed by EtOAc) to obtain a glassy solid (C_6H_6–ligroin), yield 160 mg (72%); uv λ_{max} (MeOH): 260 nm (ε 27 700), 275 nm (sh) (ε 25 500); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.42 and 1.68 (2s, 6H, 2 isopropylidene methyls), 2.40 (s, 6H, 2 *p*-toluyl methyls), 5.96 (d, 1H, H-1′, $J_{1',2'}$ = 4 Hz), 8.18 (s, 1H, H-8), 8.66 (s, 1H, H-2). *Anal.* calcd. for $C_{29}H_{29}O_6N_5$: C 64.08, H 5.38, N 12.89; found: C 63.99, H 5.45, N 12.75.

(*2*) A solution of **25** (7.5 g, 12.8 mmol) in a mixture of 0.25 *M* $NaHCO_3$ (1 L) and EtOH (1 L) was left standing for 6 days. After the ethanol was removed by evaporation, the product was extracted with $CHCl_3$. Silica gel chromatography (1:1 C_6H_6–EtOAc) afforded 5.95 g (86%) of **23**.

(*3*) A solution of **3** (1.32 g, 2 mmol) in a mixture of acetone (100 mL), MeOH (80 mL), and 0.25 *M* $NaHCO_3$ (20 mL) was refluxed for 3 h. The organic solvent was removed by evaporation and the product was extracted with $CHCl_3$. Silica gel chromatography (1:1 C_6H_6–EtOAc) afforded 770 mg (71%) of **23**.

*5′-*O*-(4,4′-dimethoxytrityl)-*N^6,N^6-*di*-*p*-*toluyl-2′,3′-*O*-isopropylideneadenosine (**24**)*

Compound **28** (981 mg, 1.61 mmol) was treated with *p*-toluyl chloride (800 mg, 5.18 mmol) in pyridine (10 mL). Silica gel chromatography (4:1 C_6H_6–EtOAc) afforded 860 mg (63%) of a glassy solid (ligroin); uv λ_{max} (MeOH): 234 nm (ε 33 800), 260 nm (ε 29 600), 275 nm (sh) (ε 27 000); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.39 and 1.63 (2s, 6H, 2 isopropylidene methyls), 2.32 (s, 6H, 2 *p*-toluyl methyls), 3.74 (s, 6H, $2CH_3O$), 6.14 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 8.16 and 8.49 (2s, 2H, H-8 and H-2). *Anal.* calcd. for $C_{50}H_{47}O_8N_5$: C 70.99, H 5.60, N 8.28; found: C 71.10, H 5.68, N 8.08.

*5′-*O*-acetyl-*N^6,N^6-*di*-*p*-*toluyl-2′,3′-*O*-isopropylideneadenosine (**25**)*

5′-O-Acetyl-2′,3′-*O*-isopropylideneadenosine (1.745 g, 5 mmol) was treated with *p*-toluyl chloride (3 g, 19 mmol) in pyridine (50 mL). Silica gel chromatography (2:1 C_6H_6–EtOAc) afforded 2.75 g (94%) of a glassy solid (C_6H_6–ligroin); uv λ_{max} (MeOH): 260 nm (ε 29 000), 275 nm (sh) (ε 27 000); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.40 and 1.63 (2s, 6H, 2 isopropylidene methyls), 1.98 (s, 3H, acetyl), 2.36 (s, 6H, 2 *p*-toluyl methyls), 6.16 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 8.17 (s, 1H, H-8), 8.68 (s, 1H, H-2). *Anal.* calcd. for $C_{31}H_{31}O_7N_5$: C 63.58, H 5.34, N 11.96; found: C 63.63, H 5.39, N 11.71.

*2′,3′-*O*-isopropylidene-*N^6-*p*-*toluyladenosine (**26**)*

(*1*) A solution of **1** (767.5 mg, 2.5 mmol) and 2,4,5-trichlorophenyl *p*-toluate (945 mg, 3 mmol) in pyridine (30 mL) was refluxed for one week. Thin-layer chromatography (EtOAc) showed the presence of two products as well as the starting material in the reaction mixture. The solution was concentrated to dryness and the residue was applied to a silica gel column. Elution with EtOAc afforded 220 mg (16%) of **21**. Compound **26** was eluted with 9:1 EtOAc–MeOH, yield 510 mg (48%), mp 170–171°C (toluene); uv λ_{max} (MeOH): 255 nm (ε 15 700), 279 nm (ε 21 900); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.40 and 1.66 (2s, 6H, 2 isopropylidene methyls), 2.44 (s, 3H, *p*-toluyl methyl), 6.06 (d, 1H, H-1′, $J_{1',2'}$ = 4 Hz), 8.19 (s, 1H, H-8), 8.76 (s, 1H, H-2). *Anal.* calcd. for $C_{21}H_{23}O_5N_5$: C 59.28, H 5.45, N 16.46; found: C 59.26, H 5.40, N 16.33.

(*2*) A solution of **25** (500 mg, 0.85 mmol) in a mixture of EtOH (40 mL) and concentrated NH_4OH (20 mL) was left standing at room temperature for 1.5 h. The main product was isolated by silica gel chromatography (EtOAc), yield 210 mg (58%). Other minor products, which were eluted with 19:1 to 9:1 EtOAc–MeOH, were 5′-*O*-acetyl-2′,3′-*O*-isopropylideneadenosine (30 mg, 10%) and **1** (20 mg, 8%).

*5′-*O*-(4,4′-dimethoxytrityl)-2′,3′-*O*-isopropylideneadenosine (**28**)*

To an ice-cooled solution of **1** (1.04 g, 5 mmol) in pyridine (50 mL) was added 4,4′-dimethoxytrityl chloride (1.8 g, 5.3 mmol) portionwise during a period of 5 h, and the reaction mixture was left standing at 0°C overnight. An ice-cooled aqueous solution of $NaHCO_3$ was added and the products were extracted with $CHCl_3$.

Thin-layer chromatography showed the formation of one main product, which was separated by silica gel chromatography (19:1 EtOAc–MeOH), and obtained as a glassy solid from C_6H_6–ligroin, yield 1.6 g (53%), uv λ_{max} (MeOH): 234 nm (ε 25 000), 257 nm (ε 15 800); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.41 and 1.63 (2s, 6H, 2 isopropylidene methyls), 3.78 (s, 6H, $2CH_3O$), 6.11 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 7.90 (s, 1H, H-8), 8.23 (s, 1H, H-2). *Anal.* calcd. for

$C_{34}H_{35}O_6N_5$: C 66.98, H 5.79, N 11.49; found: C 66.61, H 5.77, N 11.36.

Reaction of ***23*** *with* $ZnBr_2$ *in* p-*dioxane*

A solution of **23** (1.63 g, 3 mmol) and $ZnBr_2$ (6.75 mmol, 30 mmol) in *p*-dioxane (75 mL) was left standing at room temperature overnight. Aqueous $NaHCO_3$ was added and, after the precipitate of $Zn(OH)_2$ was removed by centrifugation, the product was extracted with $CHCl_3$. The solution was concentrated to dryness and the residual material was crystallized from *p*-dioxane and ligroin to give 1.15 g (71%) of **4**.

2,4,5-Trichlorophenyl p-*toluate* (***29***)

To a solution of 2,4,5-trichlorophenol (3.95 g, 20 mmol) in pyridine (50 mL) cooled at −15°C was added *p*-toluyl chloride (3.5 g, 23 mmol) and the mixture was stirred at room temperature overnight. The pyridine was removed by evaporation and the residue was distributed between aqueous $NaHCO_3$ and EtOAc. After the organic layer was washed with water, it was concentrated to dryness. From EtOH 6 g (95%) of **29** melting at 120–121°C was obtained. *Anal.* calcd. for $C_{14}H_9O_2Cl_3$: C 53.28, H 2.87, Cl 33.71; found: C 53.10, H 2.85, Cl 33.69.

ERWIN BUNCEL and IKENNA ONYIDO. Can. J. Chem. **64**, 2115 (1986).

The kinetics of hydrolysis of 4-(*p'*-methoxyphenylazo)pyridine, **1**, and its 3-isomer, **2**, have been studied in moderately concentrated sulfuric acid media at 25°C. In all the acid solutions investigated, **1** reacted faster than **2**; rate differences between the two compounds varied from ca. 1000-fold in the dilute region of acidity to ca. 250-fold in the more concentrated acid solutions. The observed first-order rate constants, k_ψ, for both substrates exhibit a maximum, at ca. 42% H_2SO_4 and 47% H_2SO_4 for **1** and **2** respectively. Activation parameters have also been determined. The pK_a values for the second protonation equilibria of **1** and **2** have been evaluated and structures of the diprotonated species are discussed. Hydrolysis is shown to occur from the diprotonated substrates and two main mechanisms are operative. The first is an A-2 type mechanism, which involves rate-limiting attack of H_2O on the aryl carbon center giving delocalized transition states and intermediates in which the pyridinium and azonium functions are involved in charge delocalization. Subsequent transfer of a proton and detachment of the leaving group are fast processes. In the second A-S_E2 type mechanism, nucleophilic attack and transfer of the proton are fast steps preceding the slow general acid catalyzed separation of the leaving group. The difference in reactivity of the two compounds is attributed to differences in extent of charge delocalization in the transition states of the reactions: for **1** both the pyridinium and protonated azonium functions are involved whereas for **2** only the azonium function participates in charge delocalization.

ERWIN BUNCEL et IKENNA ONYIDO. Can. J. Chem. **64**, 2115 (1986).

Opérant à 25°C, dans un milieu modérément concentré en acide sulfurique, on a mesuré la cinétique de l'hydrolyse du (*p*-méthoxyphénylazo)-4 pyridine (**1**) et de son isomère en position 3 (**2**). Dans tous les milieux acides étudiés, le composé **1** réagit plus rapidement que le composé **2**; les vitesses de réaction des deux composés sont dans un rapport d'environ 1000 en milieu acide dilué et d'environ 250 dans des solutions acides plus concentrées. Les constantes de vitesse du premier ordre qui sont observées pour chacun des deux substrats (**1** et **2**) présentent respectivement un maximum à environ 42% et 47% en H_2SO_4. On a aussi déterminé les paramètres d'activation. On a évalué les valeurs de pK_a pour le deuxième équilibre de protonation des espèces **1** et **2** et on discute de la nature des espèces diprotonées. On démontre que l'hydrolyse se produit à partir des substrats diprotonés et que deux mécanismes principaux sont en opération. Le premier est un mécanisme principaux sont en opération. Le premier est un mécanisme du type A-2 impliquant une attaque, qui détermine la vitesse de la réaction, de H_2O sur le carbone de l'aryle conduisant à des états de transition délocalisés et à des intermédiaires dans lesquels les fonctions pyridinium et azonium sont impliquées dans la délocalisation de la charge. Un transfert subséquent d'un proton ainsi que le détachement du groupement nucléofuge sont des processus rapides. Dans le deuxième mécanisme de type A-S_E2, une attaque nucléophile et un transfert de proton sont deux étapes rapides précédant la séparation lente, soumise à une catalyse acide générale, du groupement nucléofuge. On attribue les différences de réactivité des deux composés à des différences dans l'étendue de la délocalisation de la charge dans les états de transition des réactions : dans le cas du composé **1**, tant le pyridinium que l'azonium protoné sont impliqués dans cette délocalisation alors que, dans le cas du composé **2**, seule la fonction azonium participe à la délocalisation de la charge.

[Traduit par la revue]

The relative insensitivity of alkyl aryl ethers towards hydrolysis in acid media is well known. Interestingly, however, when the aromatic ring is activated through phenylazo substitution, these ethers become susceptible to hydrolysis in acidic media. Following earlier observations of this phenomenon (2–4), Bunnett *et al.* (5–7) reported kinetic and mechanistic studies of such cleavages for several azo aryl ethers. There have been no studies reported so far in which the effect of pyridyl substitution on these processes has been examined, which is the subject of the present paper.

Our original interest was the investigation of the spectroscopic properties and protonation equilibria of some phenylazopyridines, in connection with studies of the mechanism of the acid catalyzed Wallach rearrangement of azoxyarene compounds (8). We observed, as part of another study (8*e*), that 4-(*p'*-methoxyphenylazo)pyridine, **1**, underwent hydrolysis even in mild acid at room temperature. We thought that a more detailed study of this system would add to information available regarding the mechanism of such ether cleavages. As well, it was of interest to evaluate the effect of an additional protonation equilibrium, which could be anticipated in this and related processes. Accordingly we undertook a kinetic study of **1** in aqueous sulfuric acid media, as well as that of its isomer, 3-(*p'*-methoxyphenylazo)pyridine, **2**, which we report herein.

[1]Part 17: ref. 1.

Results

Kinetics

The kinetics of the hydrolysis of **1** and **2** were followed by monitoring spectrophotometrically the appearance of the products, 4- and 3-(*p*-hydroxyphenylazo)pyridines. These products were formed quantitatively. The kinetic data, along with other relevant information, are assembled in Table 1 and presented graphically in Fig. 1. The pseudo first-order rate constants, k_ψ, for both substrates pass through a maximum, at ca. 42 wt.% and 47 wt.% H_2SO_4 for **1** and **2** respectively.

[e]Values taken from the data of ref. 21.

Similar maxima in moderately concentrated acid solutions were reported by Bunnett and Buncel (6) in their study of the acid catalyzed hydrolysis of 4-(*p'*-sulfophenylazo)-1-naphthyl methyl ether, **3**, and 4-(*p'*-sulfophenylazo)anisole, **4**, in hydrochloric and perchloric acid solutions. In all the acid solutions investigated, **1** reacted faster than **2**. A rate difference of ca. 10^3-fold was observed in the more dilute acid solutions but this difference decreased as the acidity of the medium increased. Activation parameters were also determined for some of the acid solutions. Rate data at various temperatures as well as the corresponding activation parameters are given in Table 2.

*p*K$_{SH_2^{2+}}$ *Determination*

The basicity of the ring nitrogen in **1** and **2** ensures that these substrates are already fully monoprotonated in the pH range of acidity and hence the pK determination of interest in the present study was for the second protonation equilibrium:

$$SH^+ + H^+ \underset{}{\overset{K_{SH_2}^{2+}}{\rightleftharpoons}} SH_2^{2+}$$

where SH^+ and SH_2^{2+} represent the mono- and diprotonated forms of the substrates.

A study of the protonation behaviour of the conjugate acid of **2** gave the following results. Compound **2** has an absorption maximum (λ_{max}) at 351 nm in ethanol. In dilute aqueous acid, e.g. 2 wt.% H_2SO_4, this maximum shifts to 367 nm and we ascribe this λ_{max} to the species **7**. Between 2.0 and 28.4 wt.% H_2SO_4 there were small changes in absorbance and in λ_{max} that

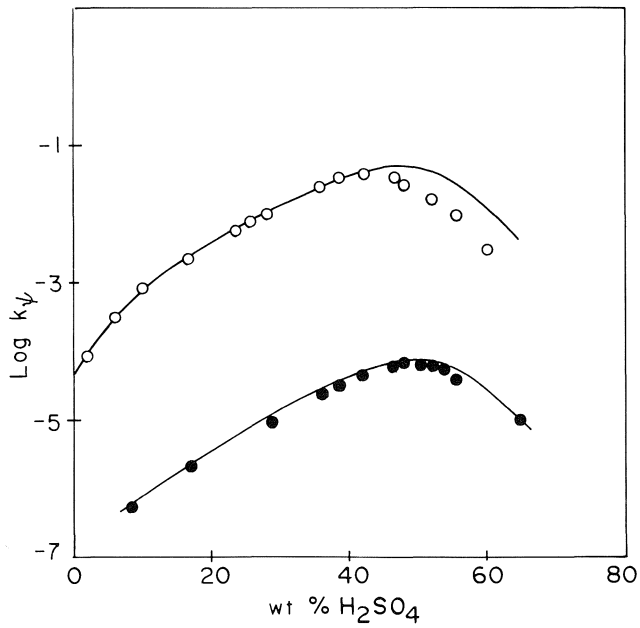

FIG. 1. Plots of log k_ψ versus % H_2SO_4 for the hydrolysis of **1** (○) and **2** (●) at 25°C. Points are experimental; lines are calculated from eq. [7] with $r = 3$ using log k_2 values derived from plots in Fig. 5.

could not readily be correlated with the acidity of the medium. This may be due to a medium effect, as such effects have been noted previously (6, 9, 10). In the region 36.4–65.2 wt.% H_2SO_4, the spectra (not shown) showed regular behaviour consistent with decreasing concentration of the species with λ_{max} at 367 nm and increasing concentration of a new species with λ_{max} 465 nm. The peak at 465 nm is attributed to the diprotonated substrate, **8**. The $pK_{SH_2^{2+}}$ was evaluated using the Davis–Geissman method (12). The relevant data are presented in Table 3. A plot of $A_{465} - A_{367}$ versus H_0 (not shown) gives the usual sigmoid curve from which the $pK_{SH_2^{2+}}$ value of −3.38 was obtained. It is interesting to note that this value is similar to the value of −3.35 obtained by the same procedure for 3-(*p'*-hydroxyphenylazo)pyridine (11), the hydrolysis product of **2**. It should also be noted, however, that the H_0 function may

not strictly be applicable to this protonation equilibrium (*vide infra*), although its use is not expected to lead to a significant error while facilitating comparison with previous studies.

The $pK_{SH_2^{2+}}$ of **1** was not measured as it hydrolysed much more rapidly than **2** in acidic solutions. Although an extrapolation procedure could perhaps be used to estimate its $pK_{SH_2^{2+}}$ value, this was not attempted; rather the close similarity between the $pK_{SH_2^{2+}}$ value of **2** and that of its phenolic product led us to assume that the $pK_{SH_2^{2+}}$ of **1** would be very similar to that of 4-(*p'*-hydroxyphenylazo)pyridine, i.e. −3.20 (11). Such an assumption seemed quite reasonable, as the replacement of H by a CH_3 group would not be expected to have a profound effect on the second protonation equilibrium of 4-(*p'*-hydroxyphenylazo)pyridine.

The $pK_{SH_2^{+}}$ of **1** was measured to be 4.53 (8*e*), and the $pK_{SH_2^{+}}$ of **2** was estimated to be 3.88 by analogy with the $pK_{SH_2^{+}}$ of 3-(*p'*-hydroxyphenylazo)pyridine (11).

Discussion

In this study, the rate of hydrolysis of **1** was determined in the region 1.80–60.09 wt.% H_2SO_4, while **2** was studied in the range 8.27–65.17 wt.% H_2SO_4. The $pK_{SH_2^{2+}}$ values of these

[1] 
[2] 
substrates indicate that in this region of acidity, substantial amounts of the substrates exist in their diprotonated forms. Any mechanism that is proposed for the hydrolysis must therefore include consideration of such diprotonated species.

Protonation equilibria

The equilibria for the second protonation of **1** and **2** are given in eqs. [1] and [2], which include the principal resonance structures of the various species involved for purposes of subsequent discussion. It is noted that in principle the second protonation could occur on either nitrogen of the azo function and hence **9** and **10** may be envisaged as alternatives to the structures of the diprotonated species of the substrates represented as **6** and **8**. However, the resonance forms **9***b* and **10***a*, corresponding to **6***b* and **8***a* respectively, are deemed to be destabilizing due to accumulation of charges, and hence **6** and **8** are preferred. The ensuing discussion will thus consider the involvement of the latter species in the various mechanistic schemes.

The pK values for the protonation of the azo nitrogen in **1**–**4** are listed in Table 4, with the value for *p*-hydroxyazobenzene, **11**, (eq. [3]) being given for comparison. One would not expect a large effect on the basicity of the azo function when a CH_3 group replaces H; thus introduction of the pyridinium function

[3] 
11 12 12*a*

into **11** lowers the basicity of the azo nitrogen by ca. 2.5 pK units. This difference, representing a $\Delta\Delta G^0$ value of 3.4 kcal, reflects the effect of protonation of an azo nitrogen when this is linked to an aromatic ring that already bears a positive charge.

Mechanism of hydrolysis

Hydrolysis of diverse substrates in acid solutions has generally been discussed in terms of three mechanisms, as follows. 1. The A-1 mechanism involves equilibrium protonation of the substrate S to give the protonated substrate SH^+, which decomposes unimolecularly in the rate-limiting step to give an intermediate X^+; this intermediate reacts rapidly with water to give the products. 2. The A-2 mechanism involves again a rapid pre-equilibrium to give SH^+ but this is attacked by water in the rate-limiting step. 3. In the A-S_E2 mechanism, transfer of the proton either to the substrate or from the protonated substrate constitutes the rate-determining step.

In the systems under investigation, some of these mechanisms can be rejected or favoured on theoretical grounds and (or) other considerations. Thus the A-1 mechanism of hydrolysis is untenable for our substrates on energetic grounds in view of the fact that the CH_3^+ cation that would result in the rate-limiting step is a very high energy species. This leaves the A-2 and A-S_E2 mechanisms for further consideration.

Secondly, the reactive species could in theory be the monoprotonated substrates **5** and **7**, the diprotonated substrates **6** and **8**, or even triprotonated species involving O-protonation as well. Reaction from the monoprotonated substrates cannot account for the increase in rate observed with increasing acidity, since the substrates are already fully monoprotonated in the pH region. On the other hand, reaction from a triprotonated species is unlikely on the following grounds. (*i*) Normal ether hydrolysis proceeds by way of a pre-equilibrium oxygen protonation and one might reasonably assume that the substrates **1** and **2** would hydrolyse in a similar way. The $pK_{SH_2^{2+}}$ measurements discussed above provide experimental evidence for the existence of diprotonated species in which the two protons are attached to the pyridine and azo nitrogens. The structures contributing to the diprotonated species for the two substrates are shown in eqs. [1] and [2] and it is evident that the ether oxygen is depleted of charge density through resonance so that further protonation on oxygen is unlikely. (*ii*) A three-proton mechanism would demand rates of reaction that would increase throughout the entire range of acidity studied; this is contrary to the kinetic results, which actually show a downturn in k_ψ in the higher acid concentration range.

A third question that should be addressed is whether attack by water as the nucleophile occurs on the alkyl or on the aromatic carbon center. We favour attack on the aromatic carbon on the following grounds. (*i*) There is experimental evidence from ^{18}O studies that the aryl-oxygen bond is the one broken in the hydrolysis of **4** in HCl solutions (7), and since **1** and **2** are structurally similar to **4**, it is reasonable to assume that they undergo the same kind of bond rupture. (*ii*) Attack on the aryl carbon is actually an activated aromatic nucleophilic substitution (S_NAr) reaction and would involve structurally favoured intermediates (as shown in Schemes 1 and 2) with the azonium and pyridinium functions providing the activation by serving as electron sinks. Our discussion of mechanism will therefore focus on A-2 and A-S_E2 mechanisms of the S_NAr type involving diprotonated substrates. These mechanisms are given in Schemes 1 and 2 and are considered in detail below in terms of rate correlations that can be derived using established criteria of mechanism.[2]

Rate correlations

(a) Edward–Meacock acidity function correlations

Rate maxima of the type observed in the present study have been reported in the acid hydrolysis of amides, for which the mechanism is believed to be of the A-2 type (14). Edward and Meacock (14*c*) utilized the expression of eq. [4] to draw theoretical curves correlating rates with acidities and these showed satisfactory fit with experimental data for the hydrolysis of benzamide, *p*-methoxybenzamide, and *p*-nitrobenzamide.

$$[4] \quad k_\psi = k_2K[H_3O^+]/(K + h_0)$$

They also found that the acid concentrations corresponding to the maximum rates were in accord with the pK_a values of the amides. However, our attempts to employ this method to test for the A-2 mechanism with our substrates led to theoretical curves that deviated considerably from experimental data, although the acid concentrations corresponding to the maximum rates were coincident for the experimental and theoretical curves. The Hammett acidity function is included in eq. [4] and it is possible that the inherent assumption about the activity coefficient behaviour of the monoprotonated substrates and transition states (15) does not hold in our system, which involves attack by H_2O on diprotonated species.

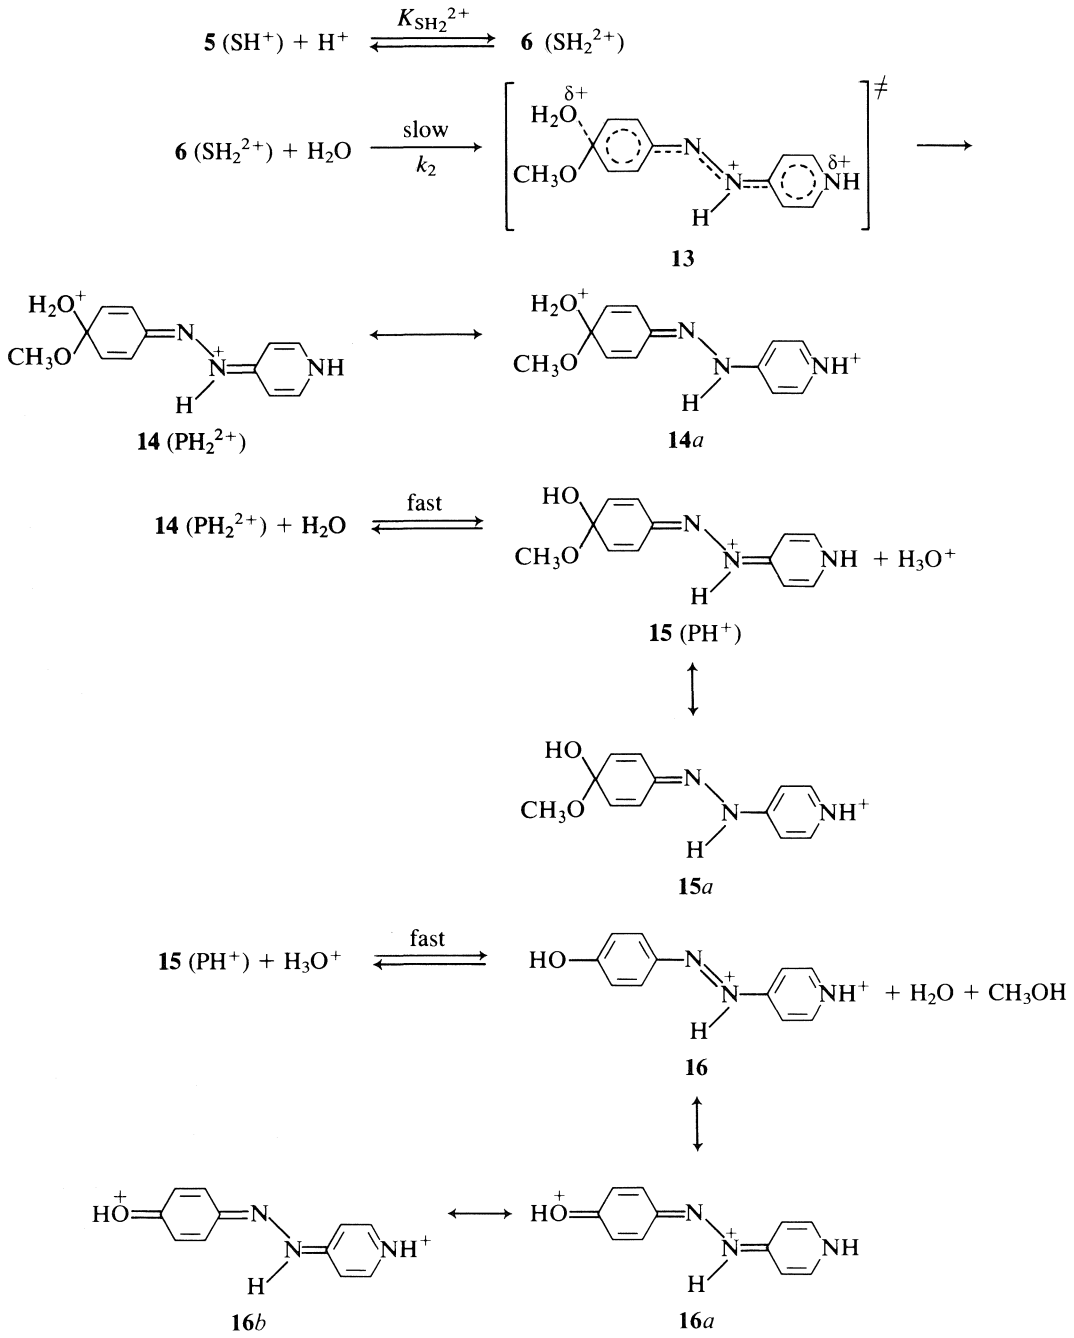
[a]This is an estimate of the $pK_{SH_2^{2+}}$ of **1**, based on an analogy with the $pK_{SH_2^{2+}}$ of 4-(*p*′-hydroxyphenylazo)pyridine, taken from ref. 11.

[b]Value for the hydrolysis product of **2**, taken from ref. 11.

[c]Values taken from ref. 6.

[d]Values taken from ref. 13.

[2]It has been pointed out by a referee that, in Scheme 2, the addition of H_2O to **6** might be subject to general base catalysis, analogous to the general acid catalyzed detachment of CH_3OH from **15**. This has not been included in Scheme 2 owing to the difficulty of establishing satisfactory criteria for such a process in moderately concentrated acid solutions. We thank the referee for drawing attention to this possible ambiguity.



SCHEME 1. A-2 mechanism for azo ether hydrolysis.

(b) Bunnett–Olsen ϕ parameter treatment

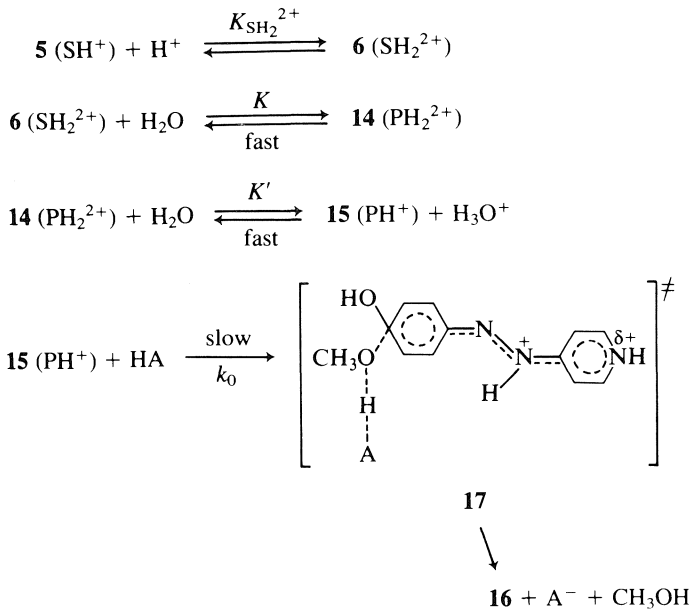
The Bunnett–Olsen linear free energy relationship (LFER) method for correlating rates in moderately concentrated mineral acids (16–18) has been used successfully by various workers, although the method was subsequently modified by Lucchini *et al.* (19). In its original form, for moderately basic substrates the relevant expression for an A-2 reaction is given by eq. [5].

$$[5] \quad \log k_\psi - \log \frac{C_{SH_2^{2+}}}{C_{SH^+} + C_{SH_2^{2+}}} = \log k_2 + \phi(H_0 + \log C_{H^+})$$

Plots according to eq. [5] shown in Fig. 2 are curved, with initial slopes of 0.2 for both substrates increasing to 1.1 and 0.7 for **1** and **2** respectively. These plots deserve further consideration. It has been pointed out by Lucchini *et al.* (19) that eq. [5] does not include the nucleophile activity, as would be required in an A-2 type reaction. However, the plot involving one molecule of water is also curved, as shown in Fig. 3. Cox and Yates (20) have pointed out that such a modification of the Bunnett–Olsen LFER as suggested by Lucchini *et al.* (19) closely resembles their excess acidity method, and further showed that $H_0 + \log C_{H^+} \approx -X$. This is considered further below.

(c) The Cox–Yates excess acidity method

The Cox–Yates method for correlating rates using the concept of "excess acidity" or X-functions (21) has been employed to establish the mechanisms of the acid hydrolysis of diverse substrates (20–22). This method has not so far been



SCHEME 2. A-S_E2 mechanism for azo ether hydrolysis.

extended to the hydrolysis of alkyl aryl ethers and it is of interest to employ the method for our substrates **1** and **2** and also to check its validity for the substrates **3** and **4** whose mechanism of hydrolysis has been established by Bunnett and Buncel (6, 7).

For the A-2 mechanism of Scheme 1, eq. [6] is derived. One would expect that on plotting the LHS of [6] against X for an A-2 process, a downward curve would result (20). Such curves are indeed obtained for **1** and **2**, as shown in Fig. 4. Different r log a_{H_2O} values are then subtracted from the LHS until linearity is achieved, such that eq. [6] transforms to [7].

$$[6]\quad \log k_\psi - \log \frac{C_{SH_2^{2+}}}{C_{SH^+} + C_{SH_2^{2+}}} = (m^\ddagger - 1)m^*X + r \log a_{H_2O} + \log k_2$$

$$[7]\quad \log k_\psi - \log \frac{C_{SH_2^{2+}}}{C_{SH^+} + C_{SH_2^{2+}}} - r \log a_{H_2O} = (m^\ddagger - 1)m^*X + \log k_2$$

The resulting plots are shown in Fig. 5. Linearity is achieved with $r = 3$ over the entire range of acidity for **2**, while a break occurs at ca. 42 wt.% H_2SO_4 for **1**. The magnitude of the slope parameter $m^\ddagger$ offers mechanistic information; in particular, for the A-2 mechanism presently under consideration, $m^\ddagger \approx 1$ is expected (20). Values of $m^\ddagger$ calculated from the slopes by using m^* values obtained from protonation data indicate that **2** ($m^\ddagger = 1.3$) reacts by the A-2 mechanism over the entire range of acidity, whereas **1** ($m^\ddagger = 1.1$) reacts by the same mechanism up to ca. 42 wt.% H_2SO_4 where there is a break in the plot. Using the values of log k_2 derived from the plots in Fig. 5, log k_ψ can be calculated for both substrates. The theoretical curves obtained from such calculations are shown in Fig. 1 and it is clear that there is agreement between the theoretical and experimental curves for **2** over the entire range of acidity studied. The deviation of the theoretical curve from the experimental for **1** in the more concentrated acid solutions suggests that this substrate reacts by a different mechanism in this region of acidity.

In their study of the hydrolysis of **3** and **4**, Bunnett and Buncel (6, 7) showed that attack by water occurs on the aromatic carbon and that the substrates react by an A-S_E2 mechanism involving general acid catalysis of leaving group departure. The reaction sequence for compounds **3** and **4** differs from the mechanism of Scheme 2 applicable to **1** and **2** in the sense that reaction occurs from the monoprotonated forms of these substrates. For the mechanism of Scheme 2, eq. [8] is derived for **3** and **4**. Since $a_{SH^+} = a_S a_{H^+}/K_{SH^+}$, eqs. [9] and [10] result and hence a plot of the LHS against X should be linear with slope $= m^\ddagger m^*$. Values of m^* have been calculated from the original data (6, 7) of these workers to be ca. 0.9.

$$[8]\quad k_\psi(C_S + C_{SH^+}) = k_0 \cdot a_{PH^+} \cdot a_{H_3O^+}/f^\ddagger = k_0 K K' a_{SH^+} \cdot a_{H_2O^+}{}^2/f^\ddagger$$

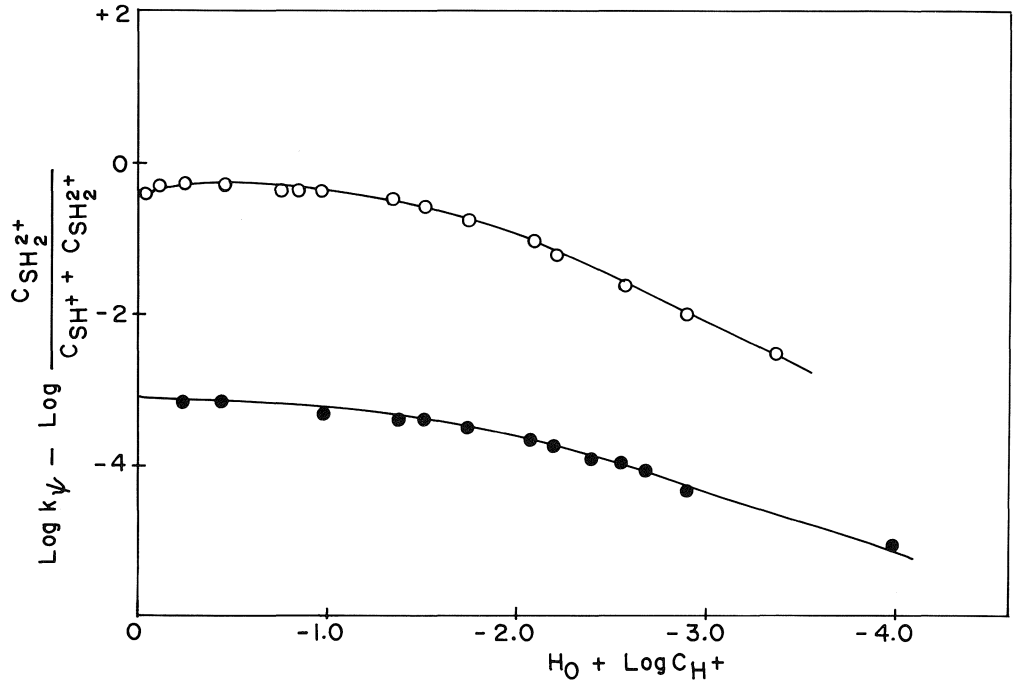


FIG. 2. Bunnett–Olsen plots for the hydrolysis of **1** (○) and **2** (●).

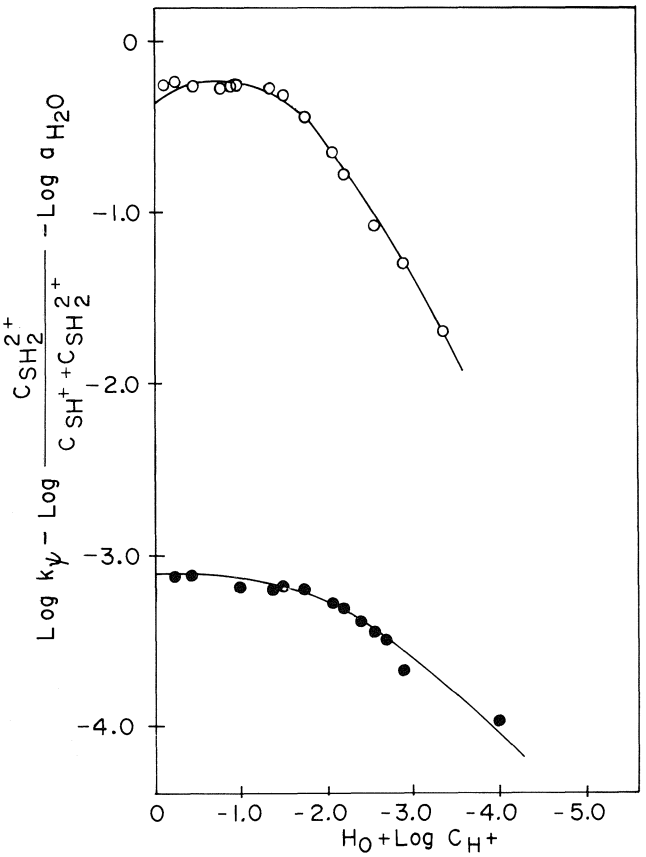

FIG. 3. Bunnett–Olsen plots for the hydrolysis of **1** (○) and **2** (●) assuming an A-2 mechanism involving one H_2O molecule.

$$[9] \quad k_\psi(C_S + C_{SH^+}) = \frac{k_0 KK'}{K_{SH^+}} \cdot a_S \cdot a_{H^+} \cdot a_{H_2O^+}{}^2/f^{\neq} = k' \cdot C_S \cdot C_{H^+} \cdot a^2{}_{H_2O} f_S f_{H^+}/f^{\neq}$$

$$[10] \quad \log k_\psi - \log \frac{C_S}{C_S + C_{SH^+}} - \log C_{H^+} - 2\log a_{H_2O} = \log k' + m^{\neq} m^* X$$

Application of eq. [10] to the data for **3** and **4** gives reasonably good straight lines, as shown in Fig. 6, and values of $m^{\neq}$ of 0.5 and 0.8 for **3** and **4**, respectively, lie within the limits of 0 and 1 expected for rate-limiting proton transfer (20). The agreement of the conclusions obtained from these plots with the mechanism proposed by Bunnett and Buncel (6, 7) based on ω-values gives further confidence to the conclusion that the Cox–Yates method is a valid criterion of mechanism in azoether hydrolysis.

Similar plots for the A-S_E2 mechanism can be made for our substrates **1** and **2** allowing for a second protonation equilibrium, and hence eq. [10] transforms to [11].

$$[11] \quad \log k_\psi - \log \frac{C_{SH^+}}{C_{SH^+} + C_{SH_2^{2+}}} - \log C_{H^+} - 2\log a_{H_2O} = \log k' + m^{\neq} m^* X$$

The plots are displayed in Fig. 7. The plot for **2** is linear over the entire range of acidity with $m^{\neq} = 1.1$. For **1** there is a break in the plot with an initial value of $m^{\neq} = 1.1$, which then changes to 0.6. These values of $m^{\neq}$ suggest that **2** does not react by an A-S_E2 mechanism over the entire range of acidity, whereas **1** reacts by this mechanism beyond 42 wt%. H_2SO_4.

The M_c function of Marziano, Passerini, and co-workers (23) is analogous to the X function of Cox and Yates (20) and the same mechanistic conclusions as drawn by use of X can also be reached using M_c values.

Evaluation of mechanisms

Having applied several mechanistic criteria in relation to the present study, we can now evaluate the results of these treatments. In the A-2 mechanism, if the involvement of 3 water molecules as indicated by the Cox–Yates excess acidity method is assumed, then the Bunnett–Olsen LFER method leads to eq. [12] as the relevant expression. Plots (not shown) according to eq. [12] closely parallel the plots of Fig. 5 and the same mechanistic conclusions can be reached. If an A-S_E2 mechanism is assumed, the relevant expression is eq. [13] and once again the plots (not shown) obtained according to these

$$[12] \quad \log k_\psi - \log \frac{C_{SH_2^{2+}}}{C_{SH^+} + C_{SH_2^{2+}}} - 3\log a_{H_2O} = (\phi_{\neq} - \phi_e)(H_0 + \log C_{H^+}) + \log k_2$$

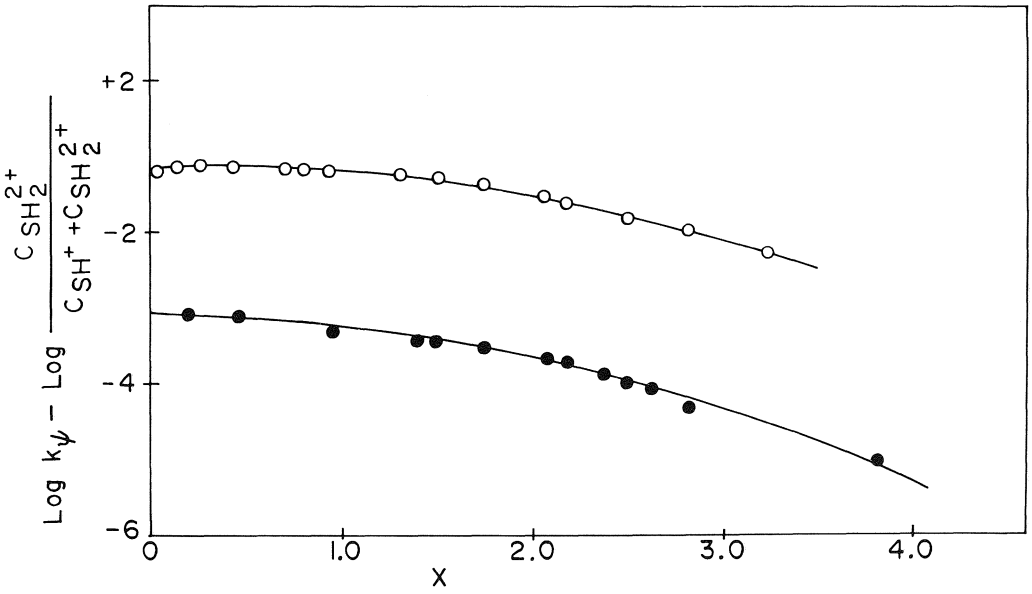

FIG. 4. Cox–Yates plots for the A-2 mechanism of hydrolysis for **1** (○) and **2** (●).

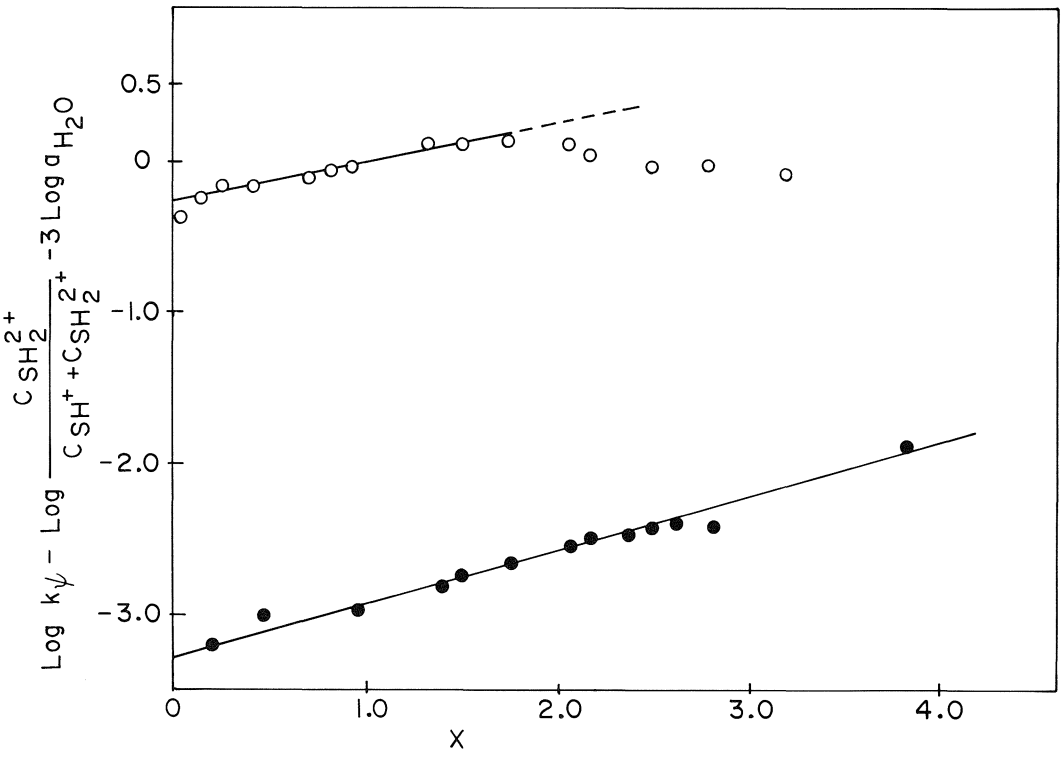

FIG. 5. Cox–Yates plots for the A-2 mechanism of hydrolysis involving 3 H_2O molecules for **1** (○) and **2** (●).

$$[13]\quad \log k_\psi - \log \frac{C_{SH^+}}{C_{SH^+} + C_{SH_2^{2+}}} - \log C_{H^+} - 2\log a_{H_2O} = (\phi_\pm - \phi_e)(H_0 + \log C_{H^+}) + \log k'$$

equations are similar to the plots of Fig. 7 (eq. [11]). We infer that the breaks in the plots for **1** imply a change of mechanism in the reaction of this substrate, from A-2 to A-S_E2.

Values of the slope parameters ($\phi_\pm - \phi_e$) for both substrates are set out in Table 5, along with those for **3** and **4**, whose reactions are known to proceed by the A-S_E2 mechanism. According to Arnett and Scorrano (24) and Modena and co-workers (25), ϕ_e values range from +1.0 to −1.6 depending on the type of cationic species formed on protonation and the degree of interaction with the solvent, particularly when the cation is small and the positive charge is localized. The negative values of the slope parameters ($\phi_\pm - \phi_e$) for all the substrates indicate that the transition states are in all cases less solvated than the initial states.

The detailed mechanism for the A-2 reaction as set out in Scheme 1 would involve 3 molecules of water as indicated by the Cox–Yates excess acidity method demonstrated above. This is best represented by the transition states, **18** and **19**, for the reactions of **1** and **2**, respectively. In **18**, the electrons from the incoming nucleophile are delocalized into the pyridinium moiety. As this is not possible in **19**, the transition state for the reaction of **1** is better stabilized than that for **2**. The requirement for three water molecules stems from the need for one to act as nucleophile and two to provide solvation as the nucleophilic water acquires a positive charge. It can be pointed out that the idea of 3 H_2O molecules being involved in hydrolysis reactions has precedent. Thus Cox and Yates have shown that the A-2 reaction of benzamide and some benzimidium ions in dilute acid involves 3 H_2O molecules (14*d*). Similarly, an A-2 mechanism involving 3 H_2O molecules has also been implicated in the hydrolysis of thioacids (21).

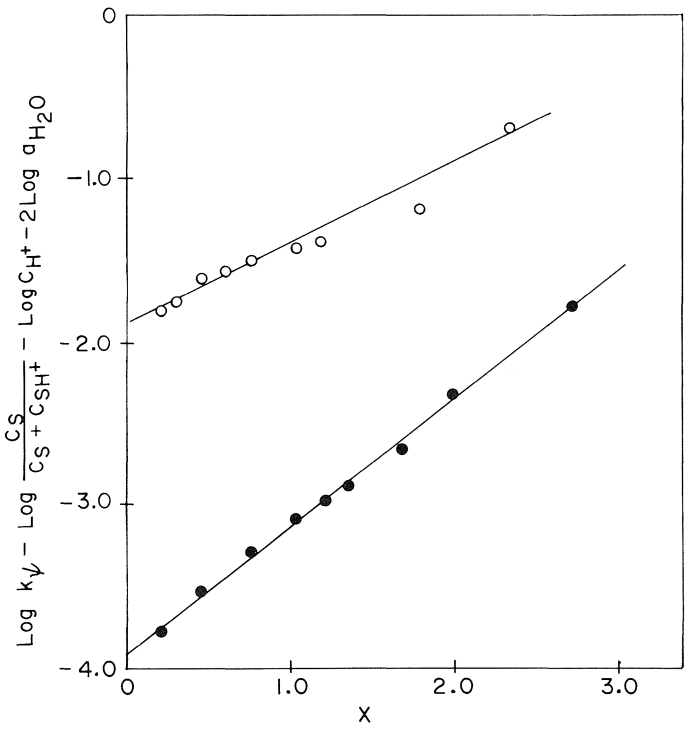

FIG. 6. Cox–Yates plots for the A-S_E2 mechanism of hydrolysis of **3** (○) and **4** (●).

Scheme 2 gives the A-S_E2 mechanism that is believed to hold for **1** in media >42 wt.% H_2SO_4. This is essentially a general acid catalyzed detachment of the leaving group in which the catalytic entities are the various acidic species present in solution.

The activation parameters displayed in Table 2 show that in all cases $\Delta H^\ddagger$ for **1** is less than that for **2**. This reflects the lower

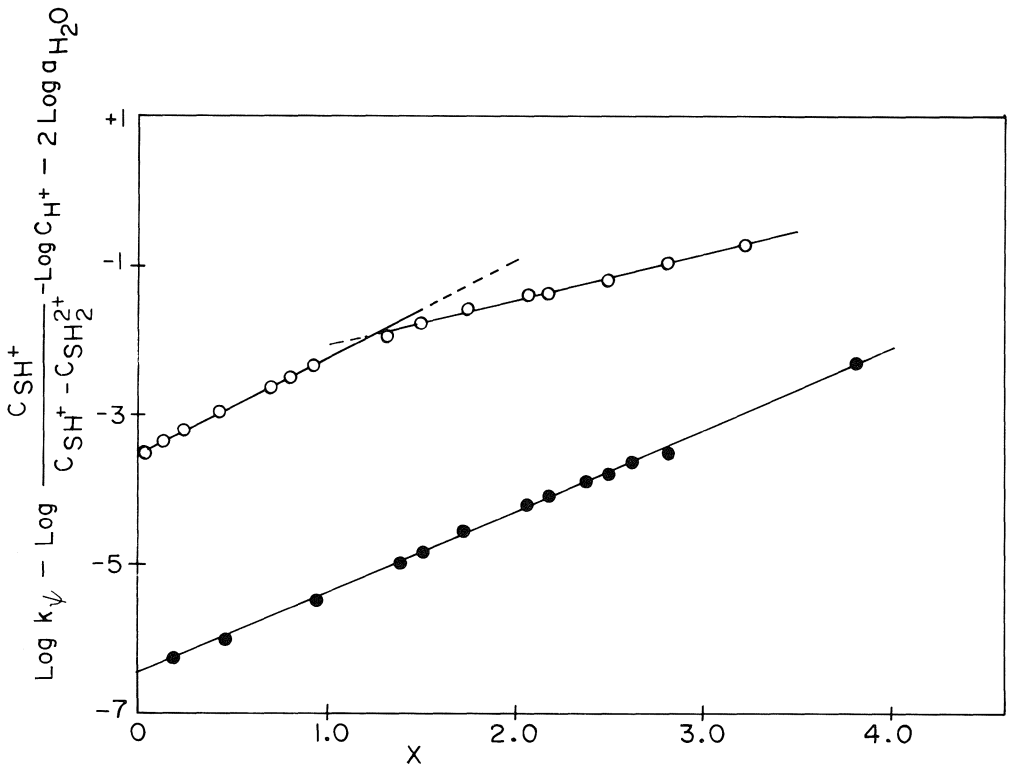

FIG. 7. Cox–Yates plots for the A-S_E2 mechanism of hydrolysis of **1** (○) and **2** (●).

TABLE 5. Summary of the slope parameters ($\phi_{\neq} - \phi_e$) for hydrolysis of the azoaryl ethers **1**–**4**

	Substrate			
Parameter	**1**	**2**	**3**[a]	**4**[a]
($\phi_{\neq} - \phi_e$)	−0.25[b] −0.56[c]	−0.34[b]	−0.54[c,d]	−0.84[c,d]

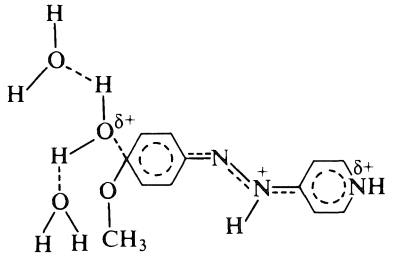
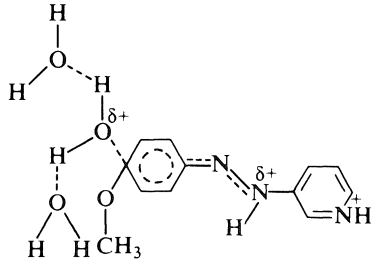
[c]Values for A-S_E2 mechanism.
[d]In aqueous HCl media.

activation provided by a 3-azopyridinium function compared with a 4-azopyridinium group. Comparison of the contributing resonance structures of **8** for the 3-isomer with those for **6** for the 4-isomer clearly shows that there is charge delocalization into the pyridinium moiety for the 4-isomer that is not readily available for the 3-isomer. Both $\Delta H^{\neq}$ and $\Delta S^{\neq}$ vary in a more or less compensating manner. The large negative values of $\Delta S^{\neq}$ indicate ordered transition structures for the reactions of both substrates in accord with charge development in the transition state and the consequent electrostriction of solvent molecules.

Finally, it would be of interest to compare reactivity in the pyridinylazo and phenylazo series. Such comparison should be meaningfully restricted to **1** and **2** versus **4** since replacement of a phenyl group by naphthyl is known to have a large effect on reactivity (6). A strict comparison is difficult since reactions in the two series were studied in different acid media and at widely different temperatures, and in all cases reaction rates vary with medium acidity. These restrictions are further heightened by sulfo substitution in **4**, which is absent in the pyridinylazo compounds. However, an estimate of reactivity differences can be made after extrapolation of data to $C_{H^+} = 1\,M$



18



19

and a common temperature. Under these conditions, **1** reacts ca. 10^4 times faster than **4** while **2** reacts only 20 times faster, thereby highlighting the powerful activating influence of an aza substituent when situated in a position where it can conjugatively interact with the reaction centre.

Conclusions

The main conclusions that can be drawn from the above discussion are as follows:

1. Compound **1** reacts by the A-2 mechanism (Scheme 1) in acidities less than 42% H_2SO_4, while at higher acidities the mechanism changes to A-S_E2 involving general acid catalysis of leaving group departure (Scheme 2). Compound **2**, on the other hand, reacts by the A-2 mechanism over the entire range of acidity studied.

2. The A-2 reactions of these substrates involve 3 H_2O molecules in the transition state.

3. Introduction of a protonated azopyridinyl moiety decreases the basicity of the azo nitrogen relative to an azophenyl group by ca. 2.5 pK units.

4. An estimate of reactivity differences indicates that **1** reacts ca. 10^4 times faster than **4** while **2** reacts only 20 times faster.

Experimental

p$K_{SH_2^{2+}}$ Determination

The p$K_{SH_2^{2+}}$ of **2** was determined as follows. Aliquots of 3 μL of a stock solution of **2** in ethanol (2.89×10^{-2} M) were injected into 2.5 mL of the different acid solutions contained in a 1-cm cuvette and the spectra were recorded with distilled water as the reference on a Perkin–Elmer Lambda-5 spectrophotometer. Results are given in Table 3. An estimate of the p$K_{SH_2^{2+}}$ of **1** was made by analogy with the close similarity of the p$K_{SH_2^{2+}}$ of **2** and its hydrolysis product.

Materials

Sulfuric acid solutions were made up with distilled water and concentrated sulfuric acid (Fisher Reagent Grade) and standardized by titration.

Compound **2** was prepared by diazotization of 3-aminopyridine and coupling with phenol. The yellow precipitate of 3-(*p'*-hydroxyphenylazo)pyridine was washed thoroughly with water and recrystallized from ethanol, mp 220°C (lit. (11) mp 222°C). The compound was methylated by dissolving 0.65 g in 60 mL of 2 M methanolic H_2SO_4 and refluxing under N_2 for 30 h. Progress of methylation was followed through uv–visible spectroscopy by withdrawing samples of the reaction mixture at various intervals, quenching in excess NaOH, and observing the disappearance of the peak at 443 nm (λ_{max} of the conjugate base of the azophenol) and the growth of the peak at 353 nm (λ_{max} of **2** in basic solution). The reaction mixture was neutralized by addition of 120 mL of ice-cold 10% NaOH solution and extracted with three 100-mL portions of ether. The ether was distilled off and the resulting material purified by preparative tlc (benzene:acetonitrile 24:1). The orange solid was recrystallized from methanol and dried *in vacuo*, mp 69–70°C, yield 0.40 g (62%); $\lambda_{max}(\varepsilon)$ in EtOH: 351 nm (27 600 M^{-1} cm^{-1}). *Anal.* calcd. for $C_9H_{11}ON_3$: C 67.59, H 5.20, N 19.27%; found: C 67.20, H 5.21, N 19.40%.

Although **1** was previously prepared in low (5%) yield from *p*-nitroanisole and 4-aminopyridine (8*a*), we have since found that by employing the method given for **2** above, with the modifications of keeping the reaction mixture at 60°C and using 0.1 M methanolic H_2SO_4 as the methylating medium, the reaction was complete in 4 h with 67% yield.

Kinetics

The rates of formation of products were monitored spectrophotometrically. Slow reactions were followed mainly by the "indirect method," as follows. The substrate (ca. 1.5–2 mg) was weighed into a 25-mL volumetric flask and 50 μL of ethanol was added to aid solubility. Both the acid solution and the volumetric flask were placed in a thermostat to attain temperature equilibrium. Reaction was initiated by introducing 25 mL of the acid solution by means of a rapid delivery pipette. Aliquots (1 mL) were withdrawn at various intervals by means of a rapid delivery pipette and quenched in 20 mL of ca. 3 M NaOH solution containing ethanol in a 25-mL volumetric flask previously cooled in ice. At the end of the kinetic run the flasks were made up to mark and spectra of the quenched solutions were recorded by the overlay method on a Beckman DU-8 spectrophotometer.

For faster reactions the "direct method" of following the reaction was employed. A sample of the acid solution was placed in a 1-cm cuvette and thermostatted in the cell compartment of either a Beckman DU-8 or Beckman Acta IV spectrophotometer. Reaction was initiated by injecting 3–6 μL of the stock solution of the substrate (ca. $(2.75–3.0) \times 10^{-2}$ M in ethanol) into the acid solution, and the cuvette was shaken to ensure homogeneity. Depending on the rate of the reaction, data were collected either by the overlay method or at a fixed wavelength.

All rate constants were calculated by plotting $\ln(A_\infty - A_t)$ versus time. Excellent linearity was obtained in all cases.

Dissolution enthalpy of NaCl in aqueous nonelectrolyte solutions at 298.15 K. Analysis of electrolyte–nonelectrolyte enthalpic pair interaction coefficients in aqueous solution

HENRYK PIEKARSKI

Department of Physical Chemistry, University of Lódź, ul. Nowotki 18, Lódź, 91-416 Poland

Received January 20, 1986

HENRYK PIEKARSKI. Can. J. Chem. **64**, 2127 (1986).

Enthalpies of solution of NaCl in aqueous solutions of isopropanol, *s*-butanol, 2-methoxyethanol, 2-ethoxyethanol, acetone, and *N*,*N*-dimethylformamide were measured. The results of enthalpy measurements were analyzed from the point of view of the effect of added nonelectrolyte on water structure, and enthalpic pair interaction coefficients $h_{xy}\{(Na^+ + Cl^-)$–nonelectrolyte$\}$ were calculated and compared with appropriate data for $(Na^+ + I^-)$–nonelectrolyte pairs. The group additivity concept appeared to be useful for the analysis of calculated h_{xy} coefficients. The correlations between h_{xy} and the functions characterizing different properties of the solutes under study were examined. It was shown that the correlation with the heat capacity of transfer of the nonelectrolyte molecule from the vapour phase to high dilution in water was the most promising. The interpretation of observed correlations was proposed.

HENRYK PIEKARSKI. Can. J. Chem. **64**, 2127 (1986).

On a mesuré les enthalpies de solution du NaCl dans des solutions aqueuses d'isopropanol, de *s*-butanol, de méthoxy-2 éthanol, d'éthoxy-2 éthanol, d'acétone et de *N*,*N*-diméthylformamide. On a analysé les résultats des mesures d'enthalpies en fonction de l'effet de l'addition d'électrolytes sur le structure de l'eau; de plus, on a calculé les coefficients d'interaction entre les paires enthalpiques $[h_{xy}\{(Na^+ + Cl^-)$–nonelectrolyte$\}]$ et on les a comparés avec les données appropriées relatives aux paires $(Na^+ + I^-)$–nonelectrolyte. Le concept d'additivité de groupe semble utile pour l'analyse des coefficients h_{xy} calculés. On a examiné les corrélations qui existent entre h_{xy} et les fonctions qui caractérisent les diverses propriétés des solutés étudiés. On a démontré que la corrélation avec la capacité calorifique de transfert de la molécule nonélectrolyte de la phase vapeur à une grande dilution dans l'eau est celle qui offre le plus de promesses. On propose une interprétation des corrélations observées.

[Traduit par la revue]

Introduction

Thermochemical properties of electrolyte solutions in the mixtures of water with nonelectrolytes are frequently studied in many scientific centres. The obtained results are explained from the point of view of mixed solvent structure as well as solute – mixed solvent interactions. Enthalpic pair interaction coefficients between the solute and cosolvent in solvent water are often regarded as a measure of the interactions that can appear in these systems (1). As it is known the above mentioned coefficients can be calculated among others from experimentally determined enthalpy of transfer of the solute from water to water–cosolvent mixture (2, 3). From the numerous papers devoted to the analysis of the pair interaction coefficients, the most refer to the nonelectrolyte–nonelectrolyte pairs. Only a few papers concern the interactions between an electrolyte and a nonelectrolyte. One of them is a previous publication, prepared in our laboratory, that presents the systematic investigations of enthalpic pair interaction coefficients between NaI and different nonelectrolytes (4). The data related to other electrolytes (e.g. NaCl (5), Bu_4NBr (6), $CaCl_2$ (7)) are only fragmentary. Such situation hampers explicit interpretation of discussed coefficients and drawing of more general conclusions concerning the impact of different factors on h_{xy} values.

In order to fill this gap at least partly, there were performed thermochemical investigations of NaCl solution in mixtures of water with isopropanol, *s*-butanol, 2-methoxyethanol, 2-ethoxyethanol, acetone, and *N*,*N*-dimethylformamide, within the range of small organic component content. The above mentioned systems have not been examined calorimetrically till now. This set of water–organic mixtures together with data concerning dissolution enthalpy of NaCl in other nonelectrolyte–water mixtures, taken from the literature, made it possible to carry out more complete analysis of interactions occurring in NaCl–nonelectrolyte–water system and their comparison with interactions observed in the NaI–nonelectrolyte–water system.

Experimental

Materials

Sodium chloride, suprapur (Merck, FRG), was dried for several days at 393 K. Isopropanol and acetone, both analytically pure (POCh Gliwice, Poland), *s*-butanol A.R. (Reanal, Hungary), and *N*,*N*-dimethylformamide for spectroscopy (Fluka, FRG) were purified and dried using standard procedures (8). 2-Methoxyethanol and 2-ethoxyethanol, pure (Loba Chemie), were fractionally distilled. All solvents were stored over 4A molecular sieves. The water–organic mixtures were prepared by weight.

Apparatus and method of measurements

The measurements of solution enthalpies were made up using an "isoperibol" calorimeter. The calorimeter and the method of measurements were described in an earlier paper (9).

Results

The measured enthalpies of NaCl solution in the mixtures of water with isopropanol, *s*-butanol, 2-methoxyethanol, 2-ethoxyethanol, acetone, and *N*,*N*-dimethylformamide were extrapolated to an infinitely dilute solution, using the method introduced by Criss and Cobble (10). The standard enthalpies of NaCl solution in all investigated mixtures determined in this way are presented in Table 1 and Fig. 1. The complete set of experimental data is available elsewhere upon request.[1]

The standard solution enthalpy of NaCl in water at 298.15 K

[1]Values of $\Delta_{sol}H$ of NaCl in all investigated mixtures may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

0.35	10420	—	—	5120	3975	—

[a]Mass fraction of the nonelectrolyte. Estimated uncertainty is ±20 J mol^{-1}.

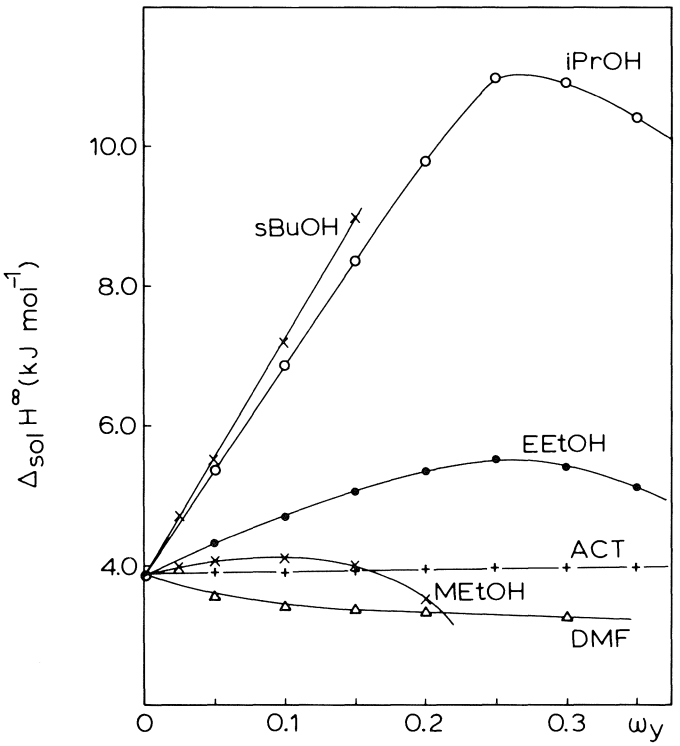

FIG. 1. Standard enthalpies of solution of NaCl in mixtures of water with isopropanol (*i*-PrOH), *s*-butanol (*s*-BuOH), 2-methoxyethanol (MEtOH), 2-ethoxyethanol (EEtOH), acetone (ACT), and *N*,*N*-dimethylformamide (DMF) vs. mass fraction of the organic component ω_y.

found in this work $\Delta_{sol}H^{\infty} = 3875$ J mol^{-1} is fully compatible with literature data (e.g. 3.82 kJ mol^{-1} (10), 3.88 kJ mol^{-1} (11)).

Discussion

Enthalpy of solution

As it can be seen in Fig. 1 enthalpy of NaCl solution in water mixtures of isopropanol, 2-methoxyethanol, 2-ethoxyethanol shows a maximum analogous to that observed in other water–alcohol mixtures hitherto analyzed (4, 12–23). It is generally accepted that this maximum is connected with the structure-making or -stabilizing effect of the added alcohol on water (24–28). In the case of *s*-butanol, the maximum is nonvisible, most probably due to limited solubility of this alcohol in water. The enthalpy of solution of NaCl in the mixtures of water with acetone grows quite insignificantly along with growing acetone content, without showing any maximum within the examined area of the mixed solvent composition. In the mixtures of DMF with water, unlike the previously discussed systems a drop of dissolution enthalpy of NaCl with growth of DMF content can be observed.

Enthalpic pair interaction coefficients

Enthalpic pair interaction coefficients $h_{xy}\{(Na^+ + Cl^-)$–nonelectrolyte$\}$ in water were estimated on the basis of dissolution enthalpy of NaCl in water–organic mixtures measured in this work. In order to calculate the h_{xy} coefficients, the method similar to that described by Heuvelsland *et al.* (6) was used. The standard enthalpy of solution $\Delta_{sol}H^{\infty}$ of NaCl in water–organic mixtures was presented as a function:

$$[1]\quad \Delta_{sol}H^{\infty}(\text{NaCl in W} + \text{Y}) = \Delta_{sol}H^{\infty}(\text{NaCl in W}) + b\omega_y + c\omega_y^2$$

where $\Delta_{sol}H^{\infty}$(NaCl in W) denotes standard enthalpy of solution of NaCl in pure water, ω_y is mass fraction of cosolvent Y, and b and c are coefficients that can be determined by the least-squares method. Parameter b in eq. [1], which represents limiting slope of function $\Delta_{sol}H$(NaCl in W + Y) is connected with McMillan–Mayer interaction coefficient h_{xy}:

$$[2]\quad b = 2\nu h_{xy}(\delta m_y/\delta\omega_y)_{\omega_y\to 0}$$

Denoting the molecular mass of cosolvent by M_y, we have for dilute solutions:

$$[3]\quad (\delta m_y/\delta\omega_y)_{\omega_y\to 0} = 1/M_y$$

where m_y is in mol kg^{-1}, M_y in kg mol^{-1}. Hence:

$$[4]\quad h_{xy} = bM_y/2\nu$$

where ν is the number of ions. The pair interaction coefficients defined as above constitute, for the systems containing an electrolyte of the 1–1 type, a half of the sum of the enthalpic effect of the interaction between molecule of a given nonelectrolyte and cation C^+ and anion A^-:

$$[5]\quad h_{xy} = \tfrac{1}{2}h\{(C^+ + A^-)\text{–nonelectrolyte}\} = \tfrac{1}{2}\{h(C^+\text{–nonelectrolyte}) + h(A^-\text{–nonelectrolyte})\}$$

The values of h_{xy} obtained this way can be found in Table 2. The same table shows also the $h_{xy}\{(Na^+ + Cl^-)$ – nonelectrolyte$\}$ values referring to other nonelectrolytes not examined in this work. These values were taken from literature (5), or estimated on the basis of enthalpies of NaCl solution found in the literature (29–35). Moreover, for comparison, Table 2 gives h_{xy} values for interactions $(Na^+ + I^-)$–nonelectrolyte determined in earlier work (4) as well as estimated on the basis of literature data (29, 31, 34–38).

The data presented in Table 2 show that the enthalpic pair interaction coefficients assume different values according to the kind of nonelectrolyte: positive for aliphatic alcohols, cellosolves, and THF and negative for the others. It is worth noting here that h_{xy} coefficients concerning the interactions of $(Na^+ + I^-)$ with aprotic nonelectrolyte have more negative (for DMF, DMSO, acetone, dioxane, sulfolane, acetonitrile) or less positive (for THF) values than analogous coefficients for $(Na^+ + Cl^-)$ interactions with the same nonelectrolytes. The cause of the observed differences should be sought in a different interaction of both anions with molecules of the above mentioned nonelectrolytes. In the case of the remaining nonelectro-

lytes (apart from *t*-butanol) h_{xy} coefficients referring to NaCl and NaI have similar values.

Having at our disposal the values of enthalpic pair interaction coefficients for $(Na^+ + Cl^-)$–nonelectrolyte pairs it seemed interesting to check whether the group additivity concept can be applied for analysis of the system examined in this work. As it is known the group additivity concept was introduced by Savage and Wood (40) to correlate the pair interaction coefficients for a number of nonelectrolyte pairs, mainly alcohols, polyols, and amides in aqueous solutions. This concept was applied successfully to the systems containing both organic $\{(R_4N^+ + Br^-)$–DMF in water (41)$\}$ and inorganic $\{(Na^+ + I^-)$–alkanols in water (4)$\}$. Basing on the model described in the work already mentioned (4) three interaction types in the system analyzed can be distinguished here: $\frac{1}{2}\{(Na^+ + Cl^-)$–$CH_2\}$, $\frac{1}{2}\{(Na^+ + Cl^-)$–OH$\}$, and $\frac{1}{2}\{(Na^+ + Cl^-)$–O$\}$. In this case h_{xy} may be denoted as a sum:

$$[6] \quad h_{xy} = \sum^{i} n_{yi} h_{yi}$$

where n_{yi} is the number of group "*i*" in molecule Y, and h_{yi} is a characteristic contribution to h_{xy} of an average ionic interaction with a selected "*i*" type group in molecule Y. Following other authors it can be accepted that CH_3 group corresponds to $1.5CH_2$ while CH corresponds to $\frac{1}{2}CH_2$ (40, 41). Applying the method of multiple linear regression to solve eq. [6] for h_{xy} values for nine nonelectrolytes having in their molecule the distinguished groups (methanol, ethanol, propanol, isopropanol, *s*-butanol, 2-methoxyethanol, 2-ethoxyethanol, THF, dioxane) the group contributions collected in Table 3 were calculated. Table 3 also shows analogous group contributions referring to $(Na^+ + I^-)$–nonelectrolyte systems described in a previously cited work (4). In order to compare both data series, values concerning the $(Na^+ + I^-)$–nonelectrolyte systems were recalculated taking additional h_{xy} coefficients for $(Na^+ + I^-)$–THF and $(Na^+ + I^-)$–2-ethoxyethanol (36) pairs. The enthalpic pair interaction coefficients $h_{xy}\{(Na^+ + Cl^-)$–nonelectrolyte$\}$ calculated on the basis of the group additivity concept and determined experimentally are compared in Fig. 2. The slope and the regression coefficient for the function:

$$[7] \quad h_{xy}^{exp} = \alpha h_{xy}^{calc} + \beta$$

are equal to 1.003 ± 0.007 and 0.9933, respectively.[2]

This correlation visualised in Fig. 2 shows, that despite simplicity of the model its application both for nonelectrolytes with linear (alcohols) and cyclic (THF, dioxane) structure of molecule yields fully satisfactory results.

TABLE 3. Functional group interaction parameters h_{yi} with their standard deviations in water at 298.15 K

Functional group combinations "i"	h_{yi} (J kg mol^{-2}) $(Na^+ + Cl^-)$	$(Na^+ + I^-)$
$\frac{1}{2}\{(C^+ + A^-)$–$CH_2\}$	+138 ± 8	+145 ± 11
$\frac{1}{2}\{(C^+ + A^-)$–OH$\}$	−55 ± 25	−48 ± 36
$\frac{1}{2}\{(C^+ + A^-)$–O$\}$	−347 ± 20	−394 ± 34
Standard error of fit	28.0	40.7
Regression coefficient r^2	0.9948	0.9928

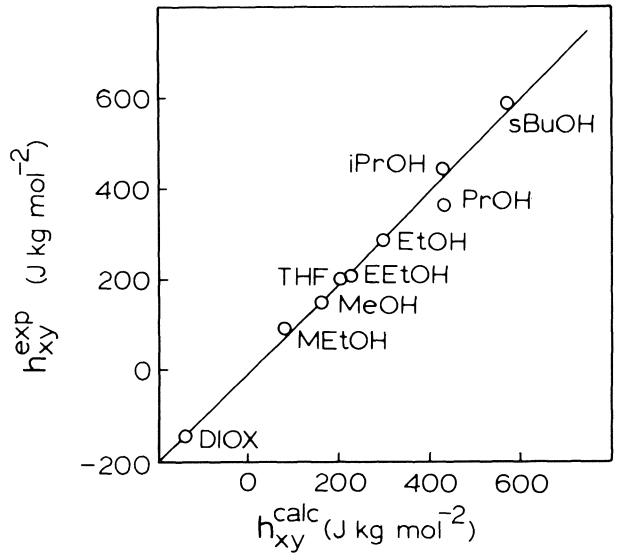

FIG. 2. A comparison of the enthalpic pair interaction coefficients $(Na^+ + Cl^-)$–nonelectrolyte determined experimentally (h_{xy}^{exp}) and calculated from group contributions (h_{xy}^{calc}). DIOX = dioxane, THF = tetrahydrofurane.

[2]Analogous data for the pairs containing NaI as an electrolyte are $\alpha = 1.016 \pm 0.007$, $r^2 = 0.9908$.

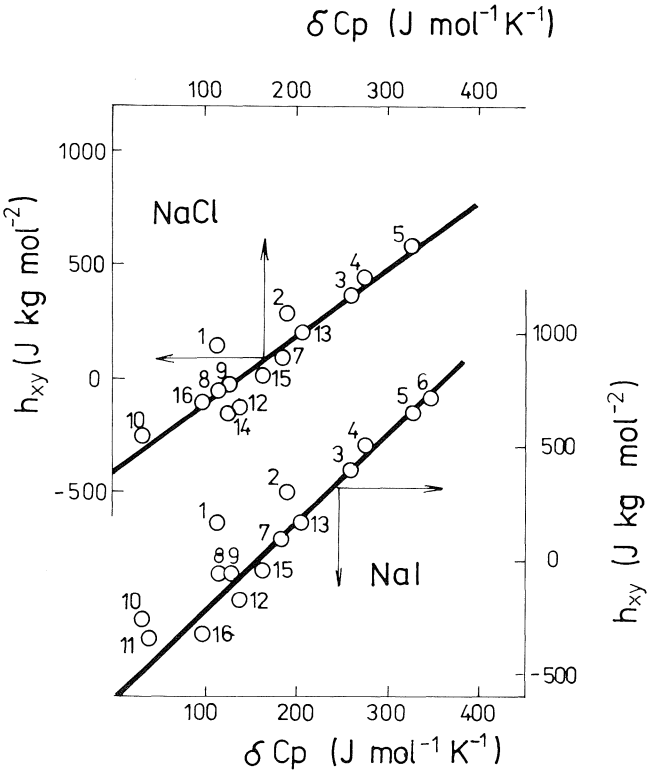

FIG. 3. The dependence of the enthalpic pair interaction coefficients h_{xy} for $(Na^+ + Cl^-)$–nonelectrolyte and $(Na^+ + I^-)$–nonelectrolyte interactions on the heat capacity of transfer of the nonelectrolyte from gas phase to high dilution in water: $\delta C_p = (\bar{C}^{\infty}_{p,2} - C^{g}_{p,m})$ at 298.15 K. The numbers denote the following: *1*, methanol; *2*, ethanol; *3*, propanol; *4*, isopropanol; *5*, *s*-butanol; *6*, *tert*-butanol; *7*, 2-methoxyethanol; *8*, ethylene glycol; *9*, glycerol; *10*, urea; *11*, formamide; *12*, *N*,*N*-dimethylformamide; *13*, tetrahydrofurane; *14*, dioxane; *15*, acetone; *16*, dimethylsulfoxide.

Comparison of h_{yi} group contributions concerning NaCl and NaI indicates that interaction of both electrolytes with CH_2 as well as OH group is similar. In the case of their interaction with aprotic ether group the value h_{yi} for NaI is more negative than h_{yi} for NaCl. This confirms an earlier observation concerning more negative interaction coefficients of aprotic nonelectrolytes with NaI than with NaCl (Table 2).

The enthalpy effect of the interaction between the ions and CH_2 group is positive due to the breaking of the structured water around the methylene group. The interactions of the ions with the polar group in a nonelectrolyte molecule is negative. A comparison of these results with the analogical data concerning the nonelectrolyte–nonelectrolyte interactions (42) indicates that the ion behaves similarly to polar group in the nonelectrolyte molecule, when it interacts with any distinguished group in other nonelectrolyte molecule. The functional group interaction parameters have respectively the same signs. These observations confirm the conclusions presented in the paper of Okamoto *et al.* that "... an exothermic enthalpy of interaction does not necessarily depend on hydrogen bonding between polar group" (42).

Very recently it has been found that enthalpic pair interaction coefficients h_{xy}(DMF–nonelectrolyte) for 16 nonelectrolytes of different type, depended linearly on heat capacity of transfer of the nonelectrolyte molecule from gas phase to high dilution in water (9).

[8] $\delta C_p = \bar{C}^{\infty}_{p,2} - C^{g}_{r,m}$

The h_{xy} values for interactions of 13 nonelectrolytes with urea gave similar correlation (9). It seemed interesting to verify whether a similar relation could be found also in the case of electrolyte–nonelectrolyte interactions in water solution. Figure 3 presents the dependence of h_{xy} for $(Na^+ + Cl^-)$–nonelectrolyte and $(Na^+ + I^-)$–nonelectrolyte pairs on δC_p of the nonelectrolyte in water. The values of $\bar{C}^{\infty}_{p,2}$ and $C^{g}_{p,m}$ are taken from compilation of Cabani *et al.* (43). As it can be seen from the Fig. 3 the analyzed functions correlate well with each other. The slope of the line correlating δC_p with h_{xy} values for pairs $(Na^+ + Cl^-)$–nonelectrolyte is 2.99 ± 0.25 kg mol^{-1} K^{-1}; that for pairs $(Na^+ + I^-)$–nonelectrolyte amounts to 3.28 ± 0.21 kg mol^{-1} K^{-1}. It is worth noting that neither $\bar{C}^{\infty}_{p,2}$ (partial molal heat capacity of nonelectrolyte in infinitely diluted aqueous solution) nor $C^{g}_{p,m}$ (molal heat capacity of nonelectrolyte in gas phase) correlate with h_{xy}.

The observed dependences strongly suggest that for a given X (NaCl or NaI, respectively), the effect of hydration of nonelectrolyte Y is more important than the direct interaction between particles X and Y when they approach each other (see also ref. 9). However, in some cases the latter effect can be more significant and then the deviations of the h_{xy} values from linear relation are observed — just as it happens for $(Na^+ + Cl^-)$–methanol and $(Na^+ + I^-)$–methanol pairs (Fig. 3).

The above observations together with conclusions provided by earlier work concerning the nonelectrolyte–nonelectrolyte–water systems (9) allowed us to suppose that the correlation of enthalpic pair interaction coefficients in water and δC_p can be of a general character. Now it seems interesting to check whether this correlation can find its application also in the case of solution in nonaqueous media. Appropriate studies are under way at the present time.

A ^{1}H and ^{13}C nuclear magnetic resonance study of carnosine

JAN O. FRIEDRICH[1] AND RODERICK E. WASYLISHEN[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 10, 1986

JAN O. FRIEDRICH and RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 2132 (1986).

The proton and carbon-13 resonance signals of carnosine (β-alanyl-L-histidine) were unambiguously assigned using a variety of nmr techniques including proton–carbon chemical shift correlations, titrations of nmr chemical shifts, coupling constants, and isotope shifts. From the ^{13}C nmr titration, carnosine's three pK_a values were estimated to be 2.7, 7.1, and 10.6, and it was found that the imidazole ring existed predominantly as the 3-H tautomer in basic solution. Conformational information about the C_α—C_β bond and about the N—C_α bond was deduced from observed ^3J(C,H) and ^3J(H,H) values. The ^{13}C nmr spectrum of carnosine in solution is also compared with that obtained for a solid sample.

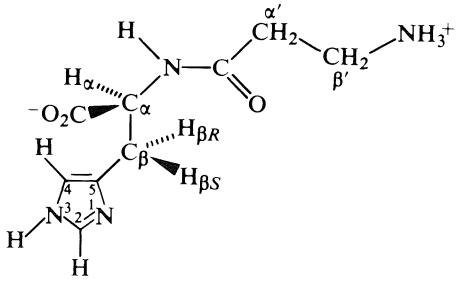
JAN O. FRIEDRICH et RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 2132 (1986).

Faisant appel à diverses techniques de rmn, incluant les corrélations de déplacements chimiques proton–carbone, les titrations des déplacements chimiques en rmn, les constantes de couplage ainsi que les déplacements dus aux isotopes, on a attribué sans ambiguïtés les signaux observés dans les spectres rmn du ^{1}H et du ^{13}C de la carnosine (β-alanyl L-histidine). En se basant sur la titration en rmn du ^{13}C, on a évalué que les trois constantes de pK_a de la carnosine sont respectivement égales à 2,7, 7,1 et 10,6; de plus, on a aussi trouvé que, en solution aicaline, le cycle imidazole existe principalement sous le forme du tautomère 3-H. À l'aide des valeurs observées pour les constantes de couplage ^3J(C,H) et ^3J(H,H), on a déduit des informations relatives à la conformation autour des liaisons C_α—C_β et N—C_α. On a aussi comparé le spectre rmn du ^{13}C de la carnosine en solution avec celui obtenu à l'aide d'un échantillon à l'état solide.

[Traduit par la revue]

Introduction

Carnosine (**1**), a dipeptide consisting of L-histidine and β-alanine, was discovered at about the beginning of the century (1). Although it is present in relatively high concentrations in skeletal muscle it can be found in a variety of other animal tissues as well. Various suggestions have been made (2) as to its role in living organisms but its precise function is not well understood. Carnosine has been the subject of numerous ^{1}H and ^{13}C nmr investigations, even being detected with ^{1}H nmr in intact muscle (3–5). However, there still seems to be ambiguity over some of the proton and carbon-13 assignments. For example, the ^{1}H nmr signals of the two pairs of methylene protons of the β-alanine group, which have similar chemical shifts, have been assigned in both possible ways (6–9). In this paper the proton and carbon resonance signals were unambiguously assigned using a variety of nmr techniques. These techniques involved a ^{13}C nmr titration, which also yielded estimates of carnosine's pK_a values and the site of protonation on the imidazole ring. Conclusions regarding the conformation of carnosine in aqueous solution were deduced from measured three-bond ^{1}H–^{1}H and ^{13}C–^{1}H spin–spin coupling constants. Finally, carbon-13 chemical shifts of solid carnosine were measured using cross-polarization and magic-angle spinning techniques and the solid (10, 11) and solution structures were compared.



1

Experimental

L-carnosine (β-alanyl-L-histidine) was obtained from Sigma Chemical Company and used without further purification. The concentrations of carbon-13 and proton nmr samples were approximately 0.5 *M* and 0.1 *M* respectively in D_2O or H_2O. The values of pH (uncorrected for deuterium) were obtained at 25 ± 1°C with an Orion model 601A digital Ionalyzer pH meter. The meter was calibrated with two buffers: a 0.05 *M* phosphate buffer (pH 6.865) and a 0.05 *M* phthalate buffer (pH 4.008) at pH readings below pH 7; the phosphate buffer and a 0.01 *M* borax buffer (pH 9.18) were used at pH readings above 7.

Proton-decoupled carbon-13 nmr spectra were recorded on a Varian CFT-20 with data acquisition times of at least 1.023 s (1 data point every 0.98 Hz). Sensitivity enhancements were always 0.3 s thus ensuring that the line widths were not broadened by more than about 1 Hz. All chemical shifts are reported with respect to external TMS and are accurate to 0.05 ppm except where noted. Proton spectra and proton coupled ^{13}C nmr spectra were obtained at 21°C on a Nicolet 360 NB operating at 361.06 MHz and 90.81 MHz, respectively. The 1331 sequence (12) was used to suppress the solvent signal for spectra obtained in H_2O.

The ^{1}H–^{13}C chemical shift correlations (13) were obtained on a Bruker MSL-300, where ^{1}H and ^{13}C resonated at 300.13 and 75.47 MHz, respectively.

Carbon-13 spectra of solid samples were obtained on a Bruker MSL-200 using ^{1}H cross-polarization (CP) and magic-angle spinning (MAS) techniques (14–16). The contact and recycle times were 1 ms and 5 s, respectively, and the MAS spinning rates were 5.0 kHz. An aluminum oxide rotor of volume 0.35 cm^3 was used. The quaternary carbon resonances were assigned using the pulse sequence of Opella and Frey (17). Chemical shifts were referenced to external adamantane (18).

Results and discussion

^{1}H and ^{13}C nuclear magnetic resonance spectra of carnosine in solution

^{13}C chemical shifts as a function of pH

As mentioned above, some ambiguity existed over the

assignment of the $C_{\alpha'}$ and $C_{\beta'}$ signals in the carbon-13 spectrum and their respective pairs of attached protons in the ^1H spectrum. To determine whether any carbon-13 resonance signals cross over the entire pH range, a ^{13}C nmr titration of carnosine was carried out in which the resonance signals were recorded at increments of 0.5 pH units. As expected, the ^{13}C chemical shifts exhibited typical titration curves as an amino, imidazole, or carboxyl group in the vicinity was titrated (for example, see Fig. 1). From these titration curves it is possible to calculate acid dissociation constants (19, 20). The average values for the three acid dissociation constants of carnosine obtained from the ^{13}C chemical shifts are shown in Table 1, as are values obtained from previous ^1H nmr titrations (9, 20, 21). Although these experiments were all carried out in deuterium oxide, the pK_a values obtained in this study are within 0.2 units of the values in H_2O (22).

Assignment of ^{13}C and ^1H resonances of the β-alanyl group

Table 2 lists the chemical shifts of the carbon signals for the various species obtained from the nmr titration while Table 3 lists the corresponding proton chemical shifts. From the ^{13}C data it appears that the signals for $C_{\alpha'}$ and $C_{\beta'}$ do indeed cross around pH 11.5 (see Fig. 2). This was verified using proton–carbon correlation two-dimensional nmr (13) and using isotope effects as explained below.

At pH 7.0, the proton–carbon correlation spectra indicated that the protons at 2.5 ppm were bonded to the carbon resonating at 33.5 ppm, and the protons at 3.0 ppm were bonded to the carbon resonating at 37.2 ppm. At pH 13.4, the 2D spectra also indicated that the low frequency (upfield) protons were bonded to the carbon resonating at 40.3 ppm and the high frequency (lowfield) protons to the carbon resonating at 39.0 ppm. Thus, since the chemical shift difference between the corresponding proton triplets remains fairly constant over the pH range (i.e., they do not cross), the carbon signals must have crossed.

Another method for confirming that the two carbon resonance signals crossed and also to unambiguously assign them is to use H/D isotope effects (23–25). It has been demonstrated (25) that carbons directly bonded to an amino group (that is, a two-bond isotope effect) experience a low frequency shift of approximately 0.055–0.097 ppm/deuteron while carbons two bonds from an amino group (a three-bond isotope effect) experience a low frequency shift of approximately 0.025–0.051 ppm/deuteron. The results obtained for two 0.5 *M* samples of carnosine, one dissolved in H_2O and the other in D_2O, are summarized in Table 4. The isotope shift data confirm that the $C_{\alpha'}$ and $C_{\beta'}$ signals cross because at low pH the high frequency ^{13}C resonance signal has the larger isotope shift while at high pH the low frequency peak has the larger shift. The isotope shift data also allow one to assign the two resonance signals since $C_{\beta'}$, which is directly bonded to the nitrogen atom, should experience a larger isotope shift than the more distant $C_{\alpha'}$. Finally returning to the proton–carbon chemical shift correlation spectra, it is possible to assign the proton signals as well. These assignments can be found in Tables 2 and 3.

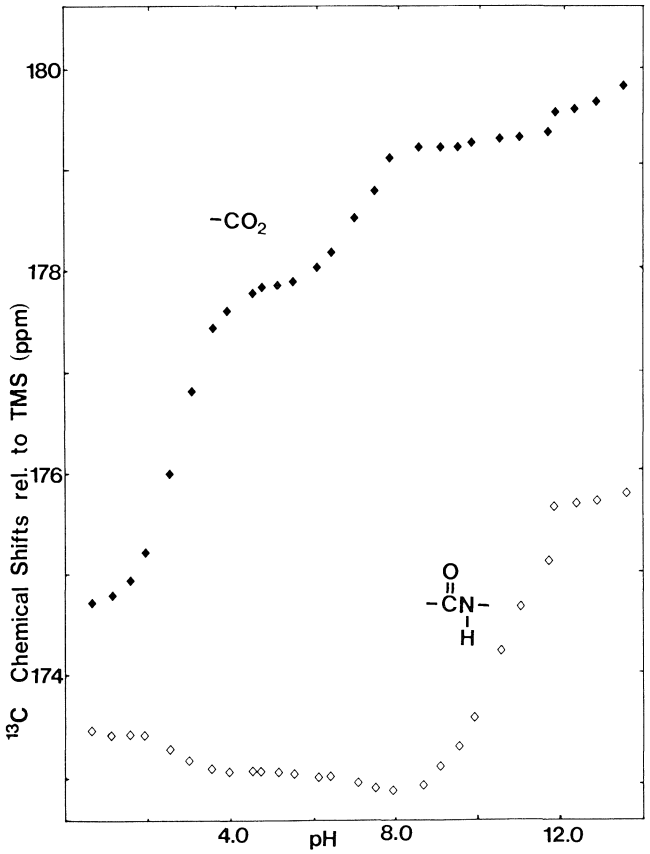

FIG. 1. Chemical shifts of the carbonyl and carboxyl ^{13}C nuclei as a function of pH.

Further support for this carbon-13 assignment comes from the

TABLE 2. Carbon-13 chemical shifts relative to external TMS[a]

[a]Shifts are accurate to ±0.01 ppm; shifts were also measured with respect to internal 0.01 *M* DSS (add 0.28 ppm to each of the above values to obtain the chemical shift with respect to internal DSS).
[b]pH meter readings are accurate to ±0.1 pH units.

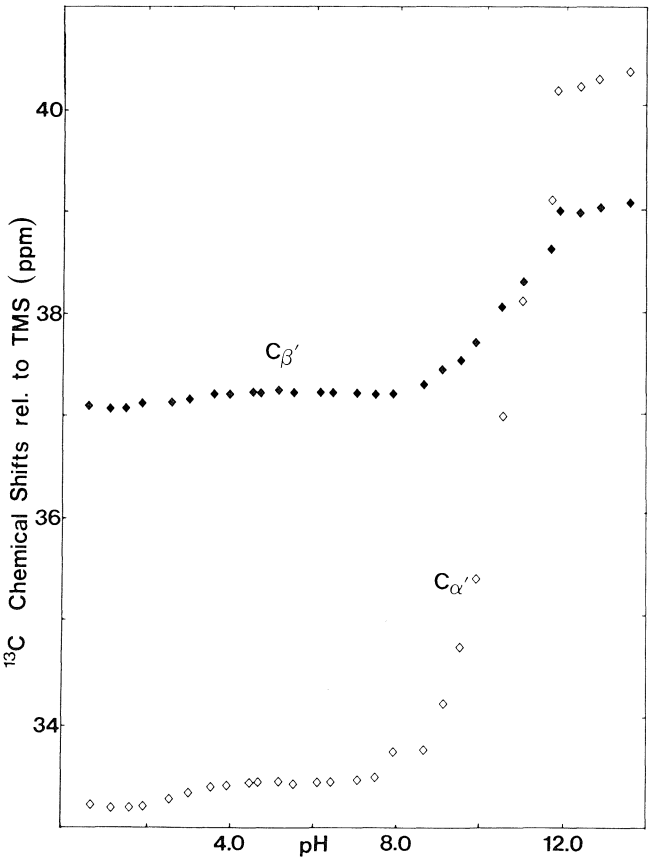

FIG. 2. Chemical shifts of $^{13}C_{\alpha'}$ and $^{13}C_{\beta'}$ as a function of pH.

changes in the chemical shifts of $C_{\alpha'}$ and $C_{\beta'}$ upon amino protonation (26, 27). Also, the smaller value of $^1J(C_{\alpha'},H_{\alpha'})$, 129.6 Hz, compared to $^1J(C_{\beta'},H_{\beta'})$, 145.5 Hz, is consistent with our assignment since $CH_3NH_3^+$, $^1J(C,H) = 145$ Hz (28), and in CH_3CONH_2, $^1J(C,H) = 129$ Hz (29).

Site of imidazole ring protonation

The behavior of the chemical shifts of the three carbon atoms C2, C4, and C5 upon protonation of the imidazole ring can provide some information on which of the two nitrogen atoms is protonated and hence which tautomer predominates in basic solution. Comparing previous results (26, 30) on histidine and methylhistidines to the carnosine results (Table 5), one comes to the same conclusion for carnosine as Reynolds *et al.* (26, 30) did for histidine. That is, protonation occurs predominantly at the N1 position because the change in chemical shift of C4 is relatively small and close to zero while that of C5 is larger in magnitude and to lower frequency. These shifts are similar to those in 3-methylhistidine, which must of course protonate at the N1 position. Therefore the neutral ring exists predominantly as the N3—H tautomer. However, this does not rule out the presence of some of the N1—H tautomer since the carbon shifts are intermediate between those of the two methylhistidines. In fact if one assumes that the shifts of the N1—H and N3—H forms of carnosine are similar to the 1-methyl- and 3-methylhistidines one obtains a 2:1 ratio of the N3—H:N1—H tautomers. This estimate is only approximate in view of the above assumption.

Application of coupling constants to determine the conformations about the C_α—C_β bond and assign $H_{\beta R}$ and $H_{\beta S}$

Because of the chiral centre at C_α the two H_β protons are nonequivalent in carnosine, thus, the methine and methylene protons attached to C_α and C_β respectively form an approximate AMX spin system (see Fig. 3). The assignment of $H_{\beta R}$ and $H_{\beta S}$ is not immediately obvious; however, from observed $^3J(H,H)$ and $^3J(^{13}C,H)$ values this assignment can be made (31–33). The conformation about the C_α—C_β bond axis is generally described in terms of the fractional populations P_I, P_{II}, and P_{III} of the rotamers I–III (34). Assuming that the vicinal coupling constants are functions only of dihedral angle, $^3J(H_\alpha,H_{\beta R})$ and $^3J(H_\alpha,H_{\beta S})$ can be expressed in terms of the *gauche* ($J_g(H,H)$) and *trans* ($J_t(H,H)$) coupling constants (31–34). Of particular interest is the difference and sum of the two observed vicinal proton–proton coupling constants

[c]This work.

(eqs. [1] and [2]) (31, 32, 35).

$$[1]\quad {}^3J(H_\alpha,H_{\beta R}) - {}^3J(H_\alpha,H_{\beta S}) = (P_I - P_{II})(J_t(H,H) - J_g(H,H))$$

$$[2]\quad {}^3J(H_\alpha,H_{\beta R}) + {}^3J(H_\alpha,H_{\beta S}) = J_g(H,H)(1 + P_{III}) + J_t(H,H)(1 - P_{III})$$

Although P_{III} can be determined from eq. [2] it is impossible to determine P_I and P_{II} from eq. [1] unless $H_{\beta R}$ and $H_{\beta S}$ are correctly assigned. Further information about P_I and P_{II} can be obtained from the observed values of ${}^3J({}^{13}CO_2^-,H_\beta)$. Again averaging the observed coupling constants over the fractional populations one obtains, after rearrangement,

$$[3]\quad {}^3J({}^{13}CO_2^-,H_{\beta R}) - {}^3J({}^{13}CO_2^-,H_{\beta S}) = (P_{II} - P_{III})(J_t(C,H) - J_g(C,H))$$

$$[4]\quad {}^3J({}^{13}CO_2^-,H_{\beta R}) + {}^3J({}^{13}CO_2^-,H_{\beta S}) = J_g(C,H)(1 + P_I) + J_t(C,H)(1 - P_I)$$

Given the *trans* and *gauche* proton–carbon coupling constants, one can uniquely determine P_I from eq. [4], which can then be used to unambiguously determine ${}^3J(H_\alpha,H_{\beta R})$ and ${}^3J(H_\alpha,H_{\beta S})$.

Using eqs. [2] and [4] and taking $J_g(H,H)$ = 2.4 ± 0.3 Hz, $J_t(H,H)$ = 13.3 ± 0.3 Hz, $J_g(C,H)$ = 1.2 ± 0.2 Hz, and $J_t(C,H)$ = 10.0 ± 0.2 Hz (35),[3] and our measured coupling constants (see Table 6), gives P_{III} = 0.20 ± 0.06, and P_I = 0.68 ± 0.08. Since $P_I > P_{II}$ it is apparent from eq. [1] that ${}^3J(H_\alpha,H_{\beta R})$ = 8.7 ± 0.3 Hz and ${}^3J(H_\alpha,H_{\beta S})$ = 4.8 ± 0.3 Hz, thus the signal at 2.82 ppm (see Table 1) corresponds to $H_{\beta S}$ while the lower frequency signal corresponds to $H_{\beta R}$. Similar observations on the relative chemical shifts of the two β protons have been observed for several amino acids (33, 34*b*, and 35). From the ${}^3J(H,H)$ values, P_I = 0.58 ± 0.04 and P_{II} = 0.22 ± 0.04.

Our conclusion that $P_I \cong 0.6 > P_{II} = P_{III}$ for carnosine is in excellent agreement with results obtained in two independent studies of the related dipeptide Gly-L-His (31, 37). It is interesting to note that the conformation about the C_α—C_β bond of carnosine in the solid state is best described by rotamer II (10, 11).

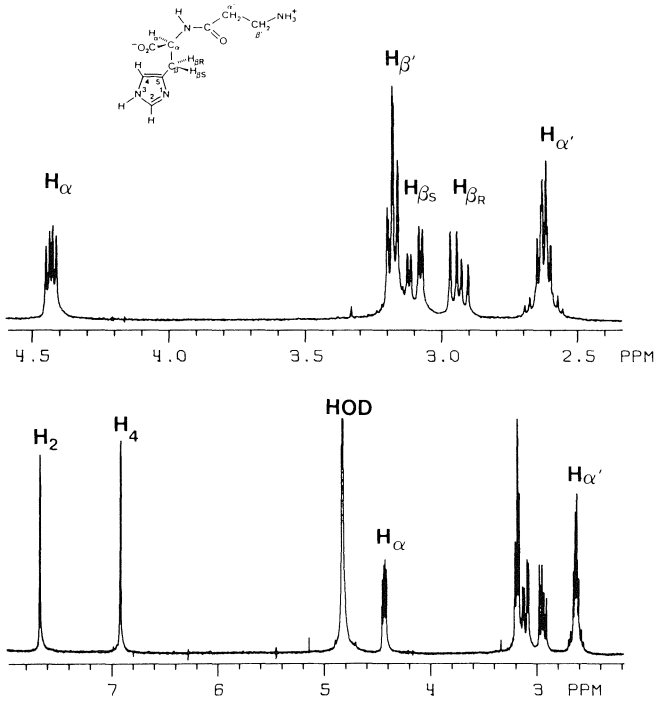

FIG. 3. Proton nmr spectrum of 0.1 *M* carnosine in D_2O at pH 8.0. Chemical shifts are relative to internal DSS. The upper spectrum is an expansion of the region between δ = 2.4 and 4.5 ppm.

[3]Using different *gauche* and *trans* proton–proton coupling constants (determined using cyclic amines) that are rotamer dependent (36) gives almost identical results for ${}^3J(H_\alpha,H_{\beta R}) > {}^3J(H_\alpha,H_{\beta S})$: P_I = 0.63, P_{II} = 0.23, P_{III} = 0.14.

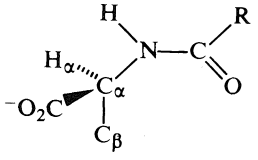
[c] Sign not determined.

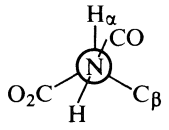
Dihedral analysis of the N—C_α bond

It is well known that the peptide fragment (**2**), is essentially

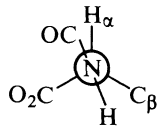


2

planar and that the barrier to internal rotation about the N—C amide bond exceeds 80 kJ mol^{-1} (38). Information concerning the conformation about the N—C_α bond is potentially available from observed values of $^3J(^1H–N—C_\alpha–^1H_\alpha)$, $^3J(^1H–N—C_\alpha–^{13}CO_2^-)$, $^3J(^1H–N—C_\alpha–^{13}C_\beta)$, and $^3J(^{13}C(O)–N—C_\alpha–^1H_\alpha)$. The dependencies of these coupling constants on the torsional angle (the torsional angle, ϕ, is defined using IUPAC rules (39)) have been extensively investigated using empirical (40–44) and theoretical (45, 46) data, which are summarized in ref. 47. Our measured value of $^3J(^1H–N—C_\alpha–^1H)$ = 7.5 Hz at pH 4.3 and at pH 0.2 is similar to $^3J(^1H–N—C_\alpha–^1H)$ = 8 Hz observed from pH 1.0 to 4.5 (10) and gives possible dihedral angles, ϕ, of −150°, −80°, and 30–90° (47). The measured value of $^3J(^{13}C(O)–N—C_\alpha–H_\alpha)$ = 3.4 Hz at pH 4.3 gives dihedral angles of −150°, −80°, 0°, and 120° (47). Thus the two dihedral angles of −150° (**3**) and −80° (**4**) are both consistent with the observed coupling constants $^3J(^1H–N—C_\alpha–^1H_\alpha)$ and $^3J(^{13}C(O)–N—C_\alpha–^1H_\alpha)$. It is interesting to note that the X-ray diffraction data indicate that the torsional angles about the N—C_α bonds of various histidine residues may be classified into two groups of about −80° and −150°. Our inability to observe $^3J(^1H–N—C_\alpha–^{13}CO_2^-)$ and $^3J(^1H–N—C_\alpha–^{13}C_\beta)$ in aqueous solution suggests that the relative energies of **3** and **4** are comparable to or less that *kT*; hence one is measuring an average coupling constant, which to a first approximation can be described as a weighted average of **3** and **4**. If either rotamer existed alone in solution it should be possible to measure $^3J(^1H–N—C_\alpha–^{13}CO_2^-)$ for **3** and $^3J(^1H–N—C_\alpha–^{13}C_\beta)$ for **4** since the relevant Karplus angles are 30° and −20° respectively. In the solid state the conformation about the N—C_α bond is best described by **4** with ϕ = −93° (10, 11).



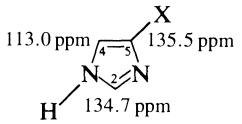
3



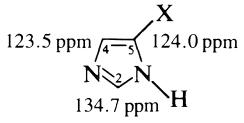
4

Solid ^{13}C spectrum of carnosine

In Fig. 4, the CP/MAS ^{13}C nmr spectrum of solid carnosine is compared with the spectrum obtained in aqueous solution (pH = 8). The three carbon nuclei not directly bonded to protons (C(O)N, C5, and CO_2^-) were distinguished from the other carbons by turning the ^1H rf power off for 40 μs just prior to data acquisition (17). Other assignments in the solid spectrum were made by assuming that the chemical shifts are similar in the solid and in aqueous solution (see Table 7). In contrast to the solution spectrum, the chemical shifts of C2 and C5 coincide in the solid spectrum; this can be qualitatively explained as follows. Using ^{13}C solution chemical shift data for pyrrole and 2-methylpyrrole (48), one calculates an α-effect of +8.7 ppm, a β-effect of −2.3 ppm, and a γ-effect (across the nitrogen) of −1.8 ppm upon methyl substitution. Assuming these methyl group substituent effects are valid for the imidazole ring and using the ^{13}C chemical shifts for imidazole in the solid state (49), one calculates the ^{13}C chemical shifts depicted below for the N3—H (**5**) and N1—H (**6**) tautomers. The observed ^{13}C



5



6

chemical shifts for C2, C4, and C5 in the solid state are in good agreement with those calculated assuming N3 is protonated (which is the nitrogen protonated in the solid state (10, 11)). Notice that while the C4 and C5 resonances differ by more than 20 ppm in the solid state, in aqueous solution (pH = 8) their resonances move closer together (separation 15.8 ppm) indicating the presence of some of the N1—H tautomer (**6**). Carbon-13 nmr spectra of solid histidine and histamine appear to support this qualitative explanation; the resonance signals for C2 and C5 of histidine, which also crystallizes as the N3—H tautomer in the solid (50), were found to almost overlap while those of histamine, which crystallizes as the N1—H tautomer (51), were found to be separated by 8 ppm.

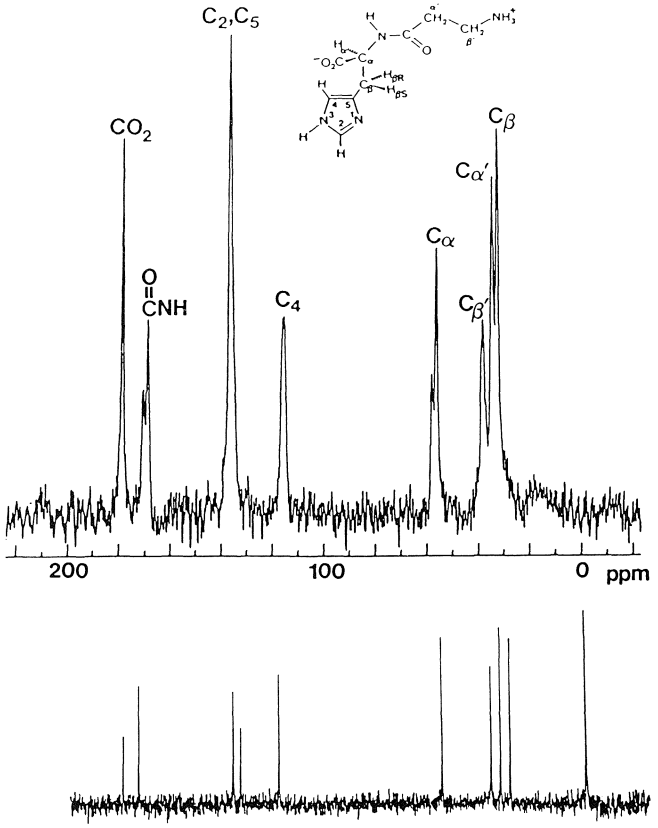


FIG. 4. Solid-state carbon-13 spectrum of carnosine using ^1H cross-polarization and magic angle spinning compared to solution spectrum at pH 8.

TABLE 7. Comparison of solution and solid carbon-13 chemical shifts in carnosine

	Chemical shifts (ppm)		
Carbon	Solution (pH = 8)	Solid state	Difference
CO_2^-	179.1	178.7	0.4
CONH	172.9	169.4	3.5
C2	137.0	136.5	0.5
C5	134.5	136.5	−2.0
C4	118.7	116.0	2.7
C_α	56.5	57.0	−0.5
$C_{\beta'}$	37.2	38.0	−0.8
$C_{\alpha'}$	33.7	34.6	−0.9
C_β	30.2	32.6	−2.4

In contrast to the solution spectra, the resonances due to C(O)NH and C_α were split into unsymmetrical doublets and the C4 resonance was significantly broadened. Brown (52) was unable to resolve these splittings in his reported ^{13}C nmr spectra of solid carnosine. In two independent X-ray crystallography studies (10, 11) it was determined that carnosine crystallizes in the monoclinic *C*2 space group which indicates that all carnosine molecules are equivalent in the solid. We attribute the doublets to ^{14}N–^{13}C dipolar coupling, which is not averaged to zero because the ^{14}N quadrupolar interaction is comparable in magnitude to the ^{14}N Zeeman interaction (53–56). The magnitude of the apparent splitting is proportional to the dipolar interaction, $\gamma_C\gamma_N h/4\pi^2(r_{CN})^3$, the quadrupolar interaction, e^2qQ/h, its orientation with respect to r_{CN}, and the magnitude of the Zeeman interaction, B_o. No attempt will be made to analyze these line shapes at this time; details for related compounds are presented in refs. 54–57.

One final point: the spectrum of solid carnosine in Fig. 4 was obtained using only 148 acquisitions; clearly paramagnetic doping is unnecessary (52).

Conclusions

The results of this nmr study of carnosine may be summarized as follows:

1. All ^1H and ^{13}C nmr resonances of carnosine have been unambiguously assigned as a function of pH, and the following pK_a's have been measured: 2.7, 7.1, and 10.6.
2. The N3—H tautomer predominates in aqueous solution.
3. The conformation about the C_α—C_β bond in aqueous solution can be described in terms of three rotamers with relative populations, $P_I = 0.58 \pm 0.04$, $P_{II} = 0.22 \pm 0.04$, and $P_{III} = 0.20 \pm 0.06$. Interestingly, in the solid state the conformation about C_α—C_β corresponds to rotamer II.
4. The conformation about the N—C_α bond in solution is best described by an average of at least two rotamers with potential minima near $\phi = -150°$ (**3**) and $\phi = -80°$ (**4**), whereas in the solid state $\phi = -93°$.
5. In spite of the conformational differences in solution and the solid state, all ^{13}C nmr chemical shifts in these two phases differ by less than 4 ppm. This suggests that it may be dangerous to assume that similar ^{13}C shifts in the solid and solution states imply identical conformations in these phases.

Acknowledgements

We wish to thank Dr. J. A. Walter, Dr. S. Peris, and Mr. B. J. Macdonald for their assistance in obtaining some of the nmr spectra, and Professor T. P. Forrest and Dr. Martin Nicholas for several helpful suggestions. Proton measurements with respect to internal DSS were carried out by Mr. Bill Power. This research was supported by generous NSERC operating and equipment grants.

Heat capacities of binary mixtures of *n*-octane with each of the hexane isomers at 298.15 K[1]

GEORGE C. BENSON[2] AND PATRICK J. D'ARCY
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 17, 1986

GEORGE C. BENSON and PATRICK J. D'ARCY. Can. J. Chem. **64**, 2139 (1986).

Volumetric heat capacities for binary mixtures of *n*-octane with *n*-hexane, 2-methylpentane, 3-methylpentane, 2,2-dimethylbutane, and 2,3-dimethylbutane were measured at 298.15 K in a Picker flow microcalorimeter. The results were combined with previously published excess molar volumes to obtain excess molar isobaric heat capacities. Interpretation of the results in terms of the Flory theory of mixtures is discussed.

GEORGE C. BENSON et PATRICK J. D'ARCY. Can. J. Chem. **64**, 2139 (1986).

Opérant à 298,15 K et utilisant un microcalorimètre à écoulement de Picker, on a mesuré les capacités calorifiques volumétriques des mélanges binaires du *n*-octane avec le *n*-hexane, le méthyl-2 pentane, le méthyl-3 pentane, le diméthyl-2,2 butane et le diméthyl-2,3 butane. En combinant les résultats obtenus avec ceux publiés antérieurement pour les volumes molaires en excès, on a pu déterminer les capacités molaires calorifiques isobariques en excès. On discute de l'interprétation de nos résultats en fonction de la théorie de Flory des mélanges.

[Traduit par la revue]

Recent papers from our laboratory reported excess molar enthalpies (1) and excess molar volumes (2) for binary mixtures of *n*-octane with the five isomeric hexanes: *n*-hexane (*n*-C_6), 2-methylpentane (2-MP), 3-methylpentane (3-MP), 2,2-dimethylbutane (2,2-DMB), and 2,3-dimethylbutane (2,3-DMB). As an extension of those investigations, we have determined the excess molar isobaric heat capacities of the same set of mixtures.

Experimental

Component liquids

The *n*-octane was Aldrich Chemical Co. Gold Label reagent with a specified purity of 99+ mol%. The isomeric hexanes were Phillips Research Grade reagents with purities of 99.88 mol% or greater. The component liquids were stored over molecular sieve pellets (BDH Type 4A) and partially degassed prior to their use. Densities of the liquids, determined at 298.15 K in an Anton-Paar densimeter (Model DMA 02C) are listed in Table 1, where the values compiled by the TRC (3) are given for comparison.

Calorimetric measurements

Heat capacities per unit volume were obtained from comparisons between pairs of liquids flowing in the test and reference cell of a Picker microcalorimeter (4, 5). A temperature interval of 1.5 K centred on 298.15 K was used.

The initial reference liquid was Pure Grade *n*-heptane from the Phillips Petroleum Co., and a value of 226.764 J K^{-1} mol^{-1} was adopted for its molar isobaric heat capacity at 298.15 K (6). The molar isobaric heat capacity of *n*-octane was then determined to be 254.11 J K^{-1} mol^{-1} by comparison with *n*-heptane.

Mixtures were prepared by weighing, and corrections for the effect of buoyancy were included in calculating their mole fractions. The error of the mole fractions is estimated to be less than 5×10^{-5}. Starting with *n*-octane as the reference liquid, the volumetric heat capacities of the mixtures were determined by the stepwise procedure (5). Molar isobaric heat capacities, $C_{p,m}$, were obtained from the volumetric heat capacities, $C_{p,m}/V_m$, using molar volumes, V_m, estimated from the densities of the components and the excess molar volumes, V_m^E, of their mixtures (2). Excess molar isobaric heat capacities, $C_{p,m}^E$, were then calculated from the relation:

$$[1] \quad C_{p,m}^E = C_{p,m} - xC_{p,1}^* - (1 - x)C_{p,2}^*$$

where x is the mole fraction of *n*-octane, and $C_{p,1}^*$ and $C_{p,2}^*$ are the molar isobaric heat capacities of the pure liquids, *n*-octane and hexane isomer, respectively. The error of $C_{p,m}^E$ is estimated to be less than 0.05 J K^{-1} mol^{-1}.

Results and discussion

The molar isobaric heat capacities of the component liquids are listed in Table 1. The results for each of the hexane isomers are averages of the values obtained from three or more stepwise runs involving an indirect comparison of the isomer with *n*-octane. In most cases, these agree reasonably (within 0.2%) with the literature values (3) given in the last column of the table.

Values of $C_{p,m}^E$ measured for $\{xn\text{-}C_8H_{18} + (1 - x)C_6H_{14}\}$ mixtures are summarized in Table 2. The smoothing equation:

$$[2] \quad C_{p,m}^E/(\text{J K}^{-1}\,\text{mol}^{-1}) = x(1 - x)\sum_{j=1}^{n} c_j(1 - 2x)^{j-1}$$

was fitted to each set of results by the method of least-squares with all points weighted equally. Values of the coefficients c_j are listed in Table 3 together with the standard deviations s of the representations.

The experimental results and their representations by eq. [2] are plotted in Fig. 1. In all cases, $C_{p,m}^E$ is negative and nearly symmetric about $x = 0.5$. We are not aware of any directly

[1]NRC No. 26086.

[a]Values of p^*, V^*, T^*, and X_{12} are taken from ref. 2.

comparable studies of these mixtures. However, in previous papers, we have reported $C^E_{p,m}$ for (*n*-heptane + hexane isomer) mixtures (7) and for (*n*-dodecane + hexane isomer) mixtures (8). Comparison of the results for the three sets of mixtures shows that at a fixed value of x, $|C^E_{p,m}|$ increases in the order:

$$n\text{-}C_6 < \text{2-MP} < \text{3-MP} < \text{2,3-DMB} < \text{2,2-DMB}$$

and that for the same hexane isomer $|C^E_{p,m}|$ increases with increasing size of the *n*-alkane.

Previous work (2) has shown that the excess enthalpies and excess volumes of (*n*-octane + hexane isomer) mixtures can be correlated satisfactorily by means of the Flory theory (9, 10). Analysis of $C^E_{p,m}$ in terms of the Flory theory follows the treatment described for other (*n*-alkane + hexane isomer) mixtures (7, 8). Differentiation of the Flory expression for the excess molar enthalpy (9) with respect to the temperature, T, leads to the relation[3]:

$$[3]\quad C^E_{p,m} = -(x_1p_1^*V_1^*/\tilde{v}_1^2)(\partial\tilde{v}_1/\partial T)_p - (x_2p_2^*V_2^*/\tilde{v}_2^2)(\partial\tilde{v}_2/\partial T)_p + \tilde{v}^{-2}(x_1p_1^*V_1^* + x_2p_2^*V_2^* - x_1V_1^*\theta_2X_{12})(\partial\tilde{v}/\partial T)_p + (x_1V_1^*\theta_2/\tilde{v})(\partial X_{12}/\partial T)_p$$

where, in the present application, the subscripts 1 and 2 refer to *n*-octane and a hexane isomer, respectively. The characteristic pressures p^*, molar volumes V^*, and temperatures T^* for

[3]In refs. 7 and 8, the term in $(\partial X_{12}/\partial T)_p$ is misprinted. The correct formula was used in all of the calculations.

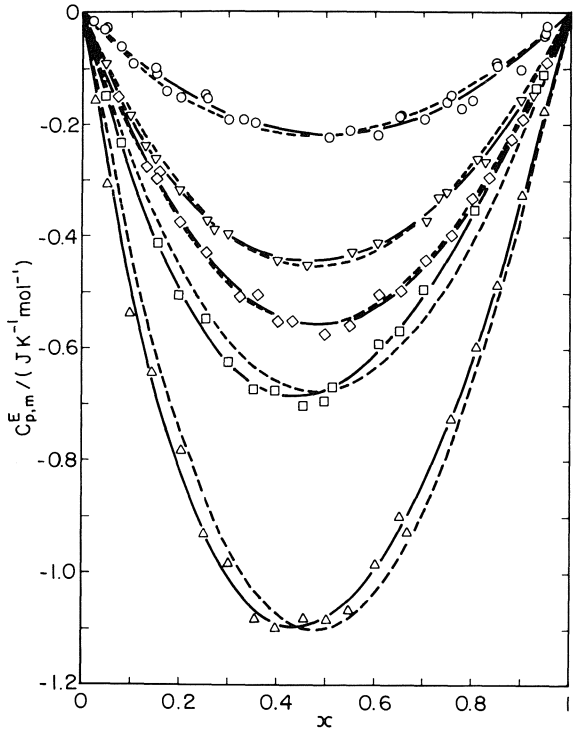

FIG. 1. Excess molar isobaric heat capacities, $C^E_{p,m}$, for $\{xn\text{-}C_8H_{18} + (1 - x)C_6H_{14}\}$ at 298.15 K. Experimental results: ○, n-C_6; ▽, 2-MP; ◇, 3-MP; △, 2,2-DMB; □, 2,3-DMB. Curves: —, calculated from eq. [2] with coefficients from Table 3; ----, calculated from the Flory theory.

the components, and the interchange energy parameters X_{12} have already been evaluated (2), and are summarized for convenience in Table 4. In eq. [3], $\tilde{v}$ denotes the reduced volume (V_m/V^*), and the derivatives $(\partial\tilde{v}/\partial T)_p$ can be calculated from Flory's equation of state (9). As in our previous work, it is assumed that the site fraction, θ_2, for species 2 can be approximated by the relation:

$$[4] \quad \theta_2 = x_2/[x_2 + x_1(V_1^*/V_2^*)^{2/3}]$$

In Flory's original formulation, X_{12} was considered to be independent of T. However, our previous work (7, 8) has shown that the magnitude of $C^E_{p,m}$ is underestimated if the last term in eq. [3] is neglected, and that it is necessary to treat $(\partial X_{12}/\partial T)_p$ as an adjustable parameter. Values of $(\partial X_{12}/\partial T)_p$, determined by a least-squares procedure in which eq. [3] was fitted to the representations of the $C^E_{p,m}$ results by eq. [2], are given in Table 4. The broken curves in Fig. 1 were calculated from eq. [3] with the parameters from Table 4 and agree well with the curves representing the smoothed experimental results. If the term in $(\partial X_{12}/\partial T)_p$ is omitted, the curves calculated for the five systems fall above the experimental curve for the (n-octane + n-C_6) mixtures and the estimates of $C^E_{p,m}$ at $x = 0.5$ are limited to the narrow range between -0.11 and -0.19 J K^{-1} mol^{-1}. Thus the calculations again indicate the importance of the last term in eq. [3].

Received June 4, 1986

D. MÉNARD and M. ST-JACQUES. Can. J. Chem. **64**, 2142 (1986).

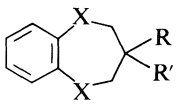
The conformational and dynamic properties of 1,5-benzodithiepin (**1**), its 3,3-dimethyl (**2**), 3-methyl (**3**), and 3-methoxy (**4**) derivatives have been investigated by high-field ^1H and ^{13}C dynamic nuclear magnetic resonance methods. Analyses of the spectra at low temperatures indicate that, in CS_2, both **1** and **2** exist as a mixture of C and TB forms (97:3 for **1**; 63:37 for **2**). In contrast, both **3** and **4** exist as a mixture of three equilibrating conformations C_e, C_a, and TB in ratios of 55:25:20 and 88:8:4 respectively. Comparison with analogues derived from 1,5-benzodioxepins (**1***a*–**4***a*) indicates that the replacement of O by S decreases the amount of the TB form for all four compounds studied. The observation that C_e is the most abundant form for **4** while it is not observed for **4***a* can be explained by a repulsive S/O *gauche* interaction in **4** compared to an attractive O/O interaction in **4***a*.

D. MÉNARD et M. ST-JACQUES. Can. J. Chem. **64**, 2142 (1986).

Faisant appel à des méthodes de rmn du ^1H et du ^{13}C à hauts champs, on a étudié les propriétés dynamiques et conformationelles de la benzodithiépine-1,5 (**1**) et de ses dérivés diméthyl-3,3 (**2**), méthyl-3 (**3**) et méthoxy-3 (**4**). L'analyse des spectres mesurés dans le CS_2, à basse température, indiquent que les composés **1** ainsi que **2** existent à l'état de mélange des formes C et TB (97:3 dans le cas du composé **1** et 63:37 dans le cas du composé **2**). Par ailleurs, les composés **3** and **4** existent tous les deux à l'état de mélange des trois conformations à l'équilibre, C_e, C_a et TB dans des proportions respectives de 55:25:20 et 88:8:4. Une comparaison avec des analogues provenant des benzodioxépines (**1***a*–**4***a*) indique que, dans chacun des composés étudiés, le remplacement d'un oxygène par un soufre diminue la proportion de la forme TB. Le fait que la forme C_e soit la forme la plus abondante dans le composé **4** alors que l'on n'observe pas sa présence dans le cas du composé **4***a* pourrait être expliqué par la présence d'un interaction *gauche* S/O répulsive dans le composé **4** alors que, dans le composé **4***a*, il existerait une interaction O/O attractive.

[Traduit par la revue]

Pursuing our study of seven-membered heterocyclic compounds related to the 1,5-benzodioxepin (**1***a*) family, which recently revealed novel and diversified conformational features for some 3-substituted derivatives (1, 2), we have sought to identify the conformational preferences of analogous compounds derived from 1,5-benzodithiepin (**1**). Comparison of the results from the two series should provide valuable information on the origin of the underlying forces, which appear to involve strong electrostatic interactions in addition to steric ones. Indeed, it has been pointed out that the substitution of oxygen by sulfur significantly modifies the *gauche* effect in six-membered heterocycles so that the O/O *gauche* interaction present in **4***a* should be attractive (2) while the O/S interaction that would exist in **4** should be repulsive (3).



1: X = S; R = R′ = H
1*a*: X = O; R = R′ = H
2: X = S; R = R′ = CH_3
3: X = S; R = CH_3, R′ = H
4: X = S; R = OCH_3, R′ = H

We therefore wish to report the results of a high-field ^1H and ^{13}C dynamic nmr study of 1,5-benzodithiepin together with its 3,3-dimethyl (**2**), 3-methyl (**3**), and 3-methoxy (**4**) derivatives. The significant conformational differences brought about by sulfur shed more light on the many forces governing the conformational features of seven-membered heterocycles.

Results

All four compounds investigated (**1**–**4**) gave dynamic ^1H and ^{13}C spectral changes at low temperatures. Spectral parameters for these compounds are listed in Tables 1 and 2.

The three aromatic signals observed in the 100.62-MHz ^{13}C spectrum of **1** in THF-d_8 at 22°C (Fig. 1) (142.72, 134.47, and 128.88 ppm) broaden noticeably near −10°C to sharpen again at lower temperatures with the appearance of two additional smaller signals at 131.6 and 126.6 ppm at −90°C. These minor signals (labelled TB) have intensities of 3–4% relative to the intensity of the larger signals (labelled C). The three aliphatic carbons show one signal at 34.02 ppm at +22°C, because of accidental equivalence. It has separated into two signals (34.53 and 33.95 ppm) at −90°C with relative intensities of 1:2 assigned to C-3 and C-2,4 respectively. Minor peaks in the aliphatic region are not observed clearly in the low temperature spectrum owing to the solvent and impurity signals nearby. The quaternary carbon line C-6,7 is also assigned on the basis of reduced intensity, as was C-3 above.

The lines belonging to the four protonated C-8 to C-11 aromatic carbons are assigned tentatively on the basis of analogies with chemical shifts determined for benzocycloheptene (4) and other related compounds (5). For all the compounds studied, the equivalent C-8 and C-11 carbons (referred to as C-8,11) appear at lower field than the C-9,10 carbons. Furthermore, a comparison of the substituent effects of the methyl and the thiomethyl groups, as in toluene and thioanisole, show relatively small differences (**5***b*). Unfortunately the AA′XX′ pattern of the ^1H aromatic signals precludes correlations of ^{13}C signals with ^1H assignments. The above tentative assignment is adequate for our purpose since a reversal

[a]Chemical shifts are in ppm downfield from TMS. Solvent: CS_2 with 19% CD_2Cl_2 added for field locking purpose.
[b]The meaning of the symbols used is: a: axial; e: equatorial; s = singlet; d = doublet; t = triplet; quint = quintuplet; m = multiplet; sep. = separation.
[c]At high temperature the various conformations are averaged.
[d]This line is very broad.

does not alter the conformational conclusions formulated later in the text.

The aliphatic proton signals in the 400.13-MHz ^{1}H nmr spectrum of the same compound in CS_2 (Fig. 2) undergo important changes when the temperature is lowered from 25 to −100°C. At 25°C, the spectrum shows two slightly broadened signals at 2.83 ppm (H-2,4) and 2.26 ppm (H-3). Maximum broadening occurs near −20°C, below which three intense signals are observed at 2.98, 2.47, and 2.15 ppm while, below −50°C, another small signal (4%; labelled TB) appears at 3.47 ppm.

At −100°C, the three intense signals are better resolved and proton decoupling experiments were carried out at that temperature. The doublet at 2.98 ppm (separation = 13 Hz) collapses into a singlet when the quartet (separation ~ 13 Hz) at 2.15 ppm is selectively irradiated. This decoupling also causes the triplet (separation = 13 Hz) at 2.47 ppm to become a large singlet overlapping a smaller signal. Homonuclear decoupling of the doublet at 2.98 also perturbs the central peaks while selective irradiation of the signals at 2.47 ppm collapses both signals at 2.98 ppm and 2.15 ppm into broad singlets. These experiments therefore show that the H-3e signal is actually a broadened doublet superimposed on that of H-2,4a, which is a broadened triplet. Finally, irradiation at 3.47 ppm produces no change in the other three signals. These experiments lead to the assignments shown in Fig. 2 and summarized in Table 1. The aromatic ^{1}H spectral region of **1** also shows a change whereby weak additional signals appear slightly above 7.0 ppm as summarized in Table 1.

The 100.62-MHz ^{13}C nmr spectrum of **2** (dimethyl derivatives) in CHF_2Cl (Fig. 3) shows broadening at 20°C arising from an appreciable slowing down of a conformational process. Maximum broadening occurs near 10°C and, at −100°C, the spectrum consists of 7 well-resolved lines in the aliphatic region and 5 lines in the aromatic region. Figure 3 shows that the C-2,4 signal (46.05 ppm at 20°C) has split into two components

[a]Solutions containing internal Me_4Si and CD_2Cl_2 (20%) for field lock purpose.
[b]The letters C_a, C_e, and TB refer to the conformations described in the text.
[c]Tentative assignment only; see text for details.
[d]These letters identify the equatorial and axial methyl signals.

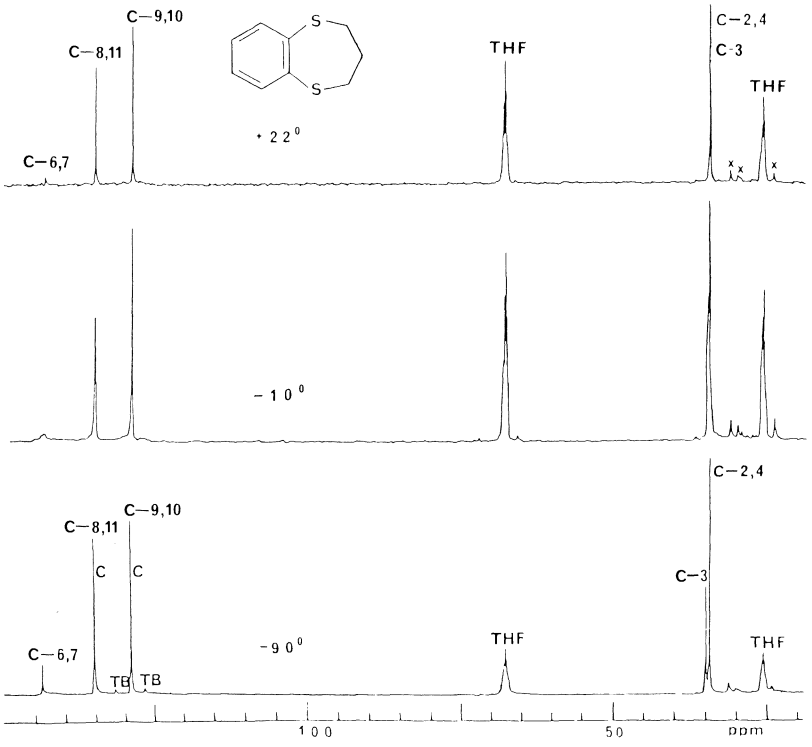

FIG. 1. 100.62-MHz ^{13}C nmr spectrum of **1** in THF-d_8 at several temperatures. The small signals denoted by X arise from impurities. The symbols C and TB refer to conformations described in the text.

at 46.10 and 43.11 ppm (labelled C and TB) with relative intensities of 82:18 respectively. The line labels C and TB in this figure (and in others) indicate the conformations (to be identified later) responsible for the various signals. The methyl signal (~28 ppm at 20°C) splits into three components at 31.34, 26.43, and 23.82 ppm (labelled CH_{3e}, TB, and CH_{3a}) with relative intensities of 41:18:41 at −100°C. At this temperature, the quaternary C-3 carbon appears as two small and close signals at 35.47 (C) and 35.18 ppm (TB). The aromatic region of the spectrum undergoes similar changes whereby the two intense C-8,11 and C-9,11 signals at 133.94 and 128.40 ppm split into intense components at 135.15 and 129.67 ppm (labelled C) and minor ones at 131.61 and 126.93 ppm (labelled TB). The C-6,7 signal shows no visible evidence of splitting.

The partial 400.13-MHz ^1H nmr spectrum of **2** in CS_2 (Fig. 4) is similar to that reported earlier (6) at 60 MHz. The

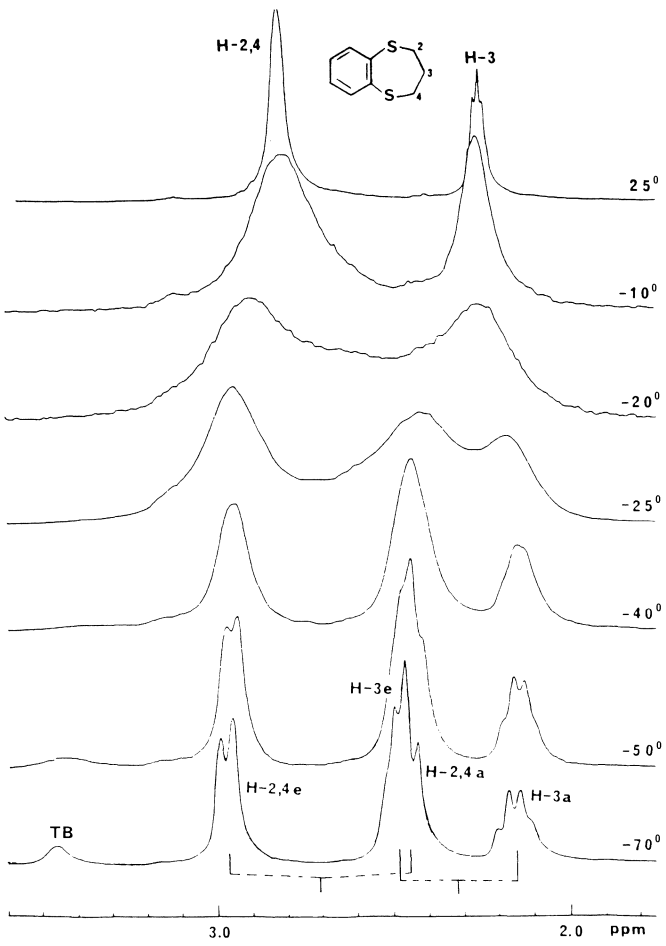

FIG. 2. Partial 400.13-MHz ^{1}H nmr spectrum of **1** in CS_2 at several temperatures.

methyl signal (1.15 ppm), already broadened at about 18°C, splits into a triplet below −10°C with components at 1.31, 1.14, and 1.02 ppm having relative intensities 31:37:32 at −60°C. The H-2,4 signal (2.74 ppm) experiences maximum broadening near 0°C and splits into two components consisting of a quartet at 2.4 ppm, arising from nonequivalent H-2,4 methylene protons in the C form, and a broad singlet at 3.1 ppm attributed to TB. The intensities of these two signals are in a 62:38 ratio at −40°C. When the temperature is further lowered, the lower field singlet (3.1 ppm) broadens further, possibly indicating the slowing down of a second conformational process. At −125°C, the lowest temperature reached, this signal is very broad and does not show resolved lines as would be expected from the nonequivalent H-2,4 methylene protons of the TB form. Additional aromatic signals also appeared at low temperature, as summarized in Table 1.

The 100.62-MHz ^{13}C nmr spectrum of the methyl derivative **3** in CS_2 is illustrated in Fig. 5 with the exception of the C-6,7 signal, which is not detected at 0°C under the conditions used at the higher temperatures. At 0°C the C-8,11 and C-9,10 signals are observed at 133.08 and 127.05 ppm while the C-6,7 signal was found at 140.13 ppm using a longer pulse delay. In the upfield region, the intense signal at 39.57 ppm is attributed to C-2,4 while two smaller and already broad signals at 36.92 and 20.45 ppm are assigned to C-3 and the CH_3 carbon respectively. All these lines split at lower temperature: the C-3 and the methyl signals each show three well-resolved components (labelled C_e, TB, and C_a) at −40°C with intensities in a 55:20:25 ratio. The other 4 signals each give rise to only two components with intensities in an 80:20 ratio (labelled C and TB). In THF-d_8 the ratio of the three conformations is found to be similar to CS_2 (i.e. 54:23:23) whereas in the more polar solvent CHF_2Cl, the intensities of the three components of the C-3 and CH_3 signals are in a 60:11:20 ratio while those for the two-component signals are 88:12.

Figure 6(*a*) shows the changes observed in the upfield part of the 400.13-MHz ^{1}H nmr spectrum of **3** in CS_2. Again all the lines show broadening at 20°C. Maximum broadening occurs near −10°C for the methyl signal and the high-field component of the H-2,4 signal (2.57 ppm) and near −20°C for the H-3 signal and the low-field component of H-2,4. At −60°C the methyl signal shows three components (labelled C_a, TB, and C_e). Additional aromatic signals also appeared, as summarized in Table 1. At −100°C (Fig. 6*b*) most lines in the spectrum are better resolved. The three components of the methyl signal now appear as doublets with coupling constants reported in Table 1. The high-field portion of the major component of the H-2,4 signal is a doublet (separation = 12.9 Hz) that appears to overlap a smaller signal seen as a shoulder while the low-field portion appears as a triplet (separation ≈ 14 Hz). Smaller signals with various multiplicities are seen at 3.48, 3.12, 2.4, and 2.3 ppm. Figure 6(*b*) also shows the results of selective homonuclear decoupling experiments performed at −100°C. These will be discussed in the next section of this text.

Figure 7 illustrates that 100.62-MHz ^{13}C nmr spectral modifications observed for the methoxy derivative **4** in CHF_2Cl. As was the case for the methyl derivative, all lines observed in the spectrum at 0°C have split into two or three components at lower temperatures. The relative intensities of the three components (labelled C_e, C_a, and TB) of the C-3 and methoxy signals are 61:33:6 while the two components (labelled C and TB) of the remaining signals give a 94:6 intensity ratio.

The 400.13-MHz ^{1}H nmr spectrum of **4** in CF_2Cl_2 is partially illustrated in Fig. 8. Here, as in the case of the methyl derivative **3**, complex changes are observed as the temperature is lowered. The H-2,4 signal, which appears as a doublet at 3.1 ppm (separation = 12.9 Hz) and a broad line at 2.55 ppm, experiences maximum broadening near −9°C. Below this temperature, two intense signals (88%) sharpen into a triplet (separation = 12–13 Hz) at 2.18 ppm (C_e) and a doublet (separation = 12–13 Hz) at 3.02 ppm (C_e). Smaller doublets also appear at 2.62 ppm (8%; C_a) and 2.75 ppm (4%; TB). Additional aromatic signals have also appeared at low temperature as summarized in Table 1. Homonuclear selective decoupling of the triplet at 2.18 ppm collapses both the intense doublet at 3.02 ppm and the H-3 triplet at 3.62 ppm into singlets while irradiation of the small C_a doublet at 2.62 ppm has a similar effect on the other small doublet of doublets at 3.14 ppm, also assigned C_a. Such decouplings help assigning the signals belonging to each of the C_e and C_a forms whose geometries will be defined in the next section.

Discussion

Spectral interpretation and the conformations of the seven-membered rings

The spectral modifications observed in the ^{1}H and ^{13}C nmr spectra of compound **1** (Figs. 1 and 2) reveal that this compound exists predominantly in one conformation in both CS_2 and THF-d_8. The presence of weak aromatic signals noted in both of the ^{1}H (Table 1) and ^{13}C (Fig. 1) low temperature spectra,

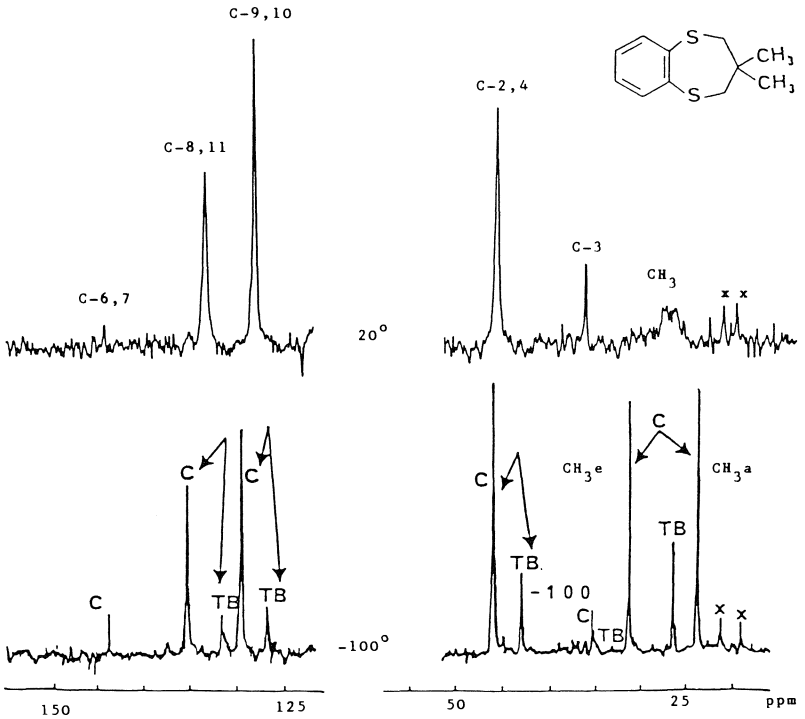

FIG. 3. 100.62-MHz ^{13}C nmr spectrum of **2** in CHF_2Cl at several temperatures.

however, shows that a minor conformer (about 3%) is also present.

The nature of the major conformation is identified as a chair form (C) from the chemical nonequivalence of the two H-3 protons observed in the ^1H spectrum at $-70°C$ and below (Fig. 2). The nature of the minor conformation is thought to be the twist-boat (TB) for energetic reasons discussed previously (1, 2) and by analogy with **1***a*.

The splitting of signals in the ^{13}C nmr spectrum of **2** in CHF_2Cl (Fig. 3) indicates that this compound exists in a mixture of two conformers in an 82:18 ratio at $-100°C$. The nature of these two conformers is easily deduced from the three-line pattern of the methyl carbon signals for which the two intense components of equal intensity at 31.34 and 23.82 ppm are assigned to the equatorial and axial methyl group of the C form while the third line identifies a second less intense component that is characterized by the two equivalent methyl positions of the TB conformation. This conclusion is confirmed by the ^1H spectrum of **3** in CS_2 at $-60°C$ (Fig. 4). The methyl proton signal shows a similar pattern to that just described for the methyl carbons with the exception that, because of the solvent change, the total relative intensity of the two components of the C form is 63% with respect to the single component of the TB form. The identification of the minor conformer as the TB form is compatible with the broadening of the H-2,4 signal at 3.1 ppm below $-40°C$, resulting from the slowing down of the TB inversion on the nmr time scale.

The analysis of the ^{13}C spectrum of **3** at $-40°C$ in CS_2 (Fig. 5) clearly reveals, as was the case in the benzodioxepin analog (**3***a*), the presence of three stable conformers. The pattern observed in the methyl region indicates that these conformers are the chair with equatorial methyl group (C_e, 55% in CS_2; 69% in CHF_2Cl), the chair with an axial methyl group (C_a, 25%; 20% in CHF_2Cl), and the TB form (20%; 11% in CHF_2Cl). This assignment is suggested by the fact that in the dithiane-1,3 system the signal of an axial methyl group appears at higher field than an equatorial one (7).

Confirmation is provided by the analysis of the ^1H spectrum at $-100°C$ (Fig. 6(*b*)), which shows that one of the two components of the H-2,4 signal of the major conformation (labelled H-2,4a) appears as a triplet. This pattern can only arise from large coupling of the axial H-2,4 protons with the axial H-3 proton and with the geminal H-2,4 equatorial protons. The H-2,4e protons, on the other hand, appear as a doublet due to the effect of the large geminal coupling with H-2,4a. It is pertinent to point out that, as was observed for some derivatives of 1,3-dithiane (8), the axial H-2,4 protons appear at lower field than the equatorial ones.

Having established that C_e is the major form for **3**, it now remains to confirm that C_a exists in a larger amount than TB. Because the C-8,11 and C-9,10 signals are very distant from the site of substitution, chemical shifts are not expected to be appreciably influenced by the axial or equatorial nature of the substituent and hence both C_e and C_a signals should coincide. On the other hand, changing the ring conformation from C to TB is expected to produce a significant change in these chemical shifts. Integration of the two lines for each of the C-8,11 and C-9,10 signals at $-40°C$ (Fig. 5) shows an 80:20 ratio, indicating that the weaker signals belong to the TB form. Thus observations for **1**, **2**, and **3** in Table 2 show that the presence or not of a 3-substituent does not significantly perturb the chemical shifts of these aromatic carbons, so that their signals constitute convenient conformational probes.

Finally, the three components observed for most signals of the ^{13}C spectrum of **4** at $-120°C$ indicate that this compound also exists as a mixture of three stable conformations at this temperature. Comparing the chemical shifts of the components of the C-3 signal with those observed for **3** suggests that these three conformations are C_e (61%), C_a (33%), and TB (6%). This suggestion is confirmed by the triplet multiplicity of the

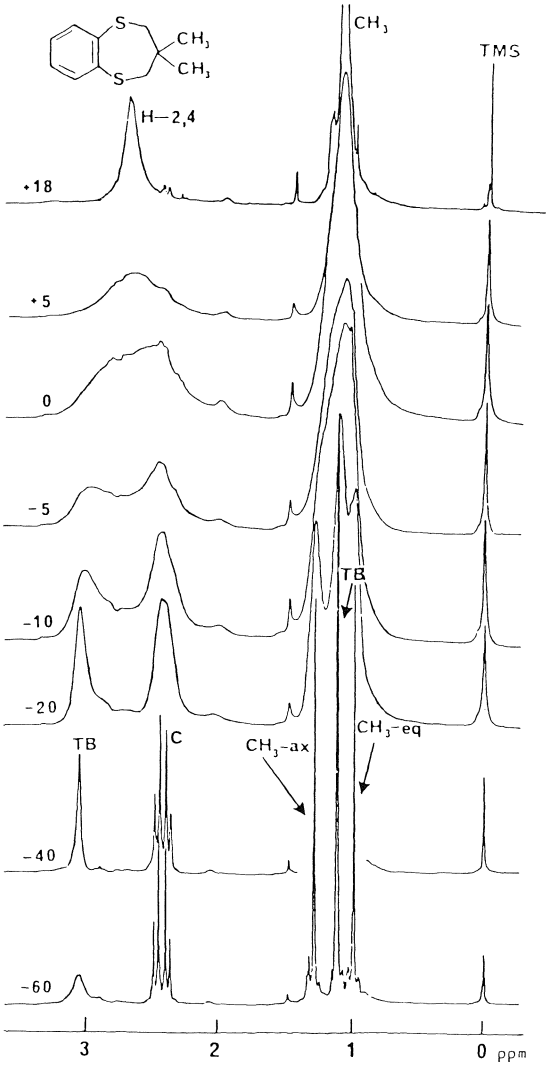

FIG. 4. Partial 400.13-MHz ^{1}H nmr spectrum of **2** in CS_2 at several temperatures.

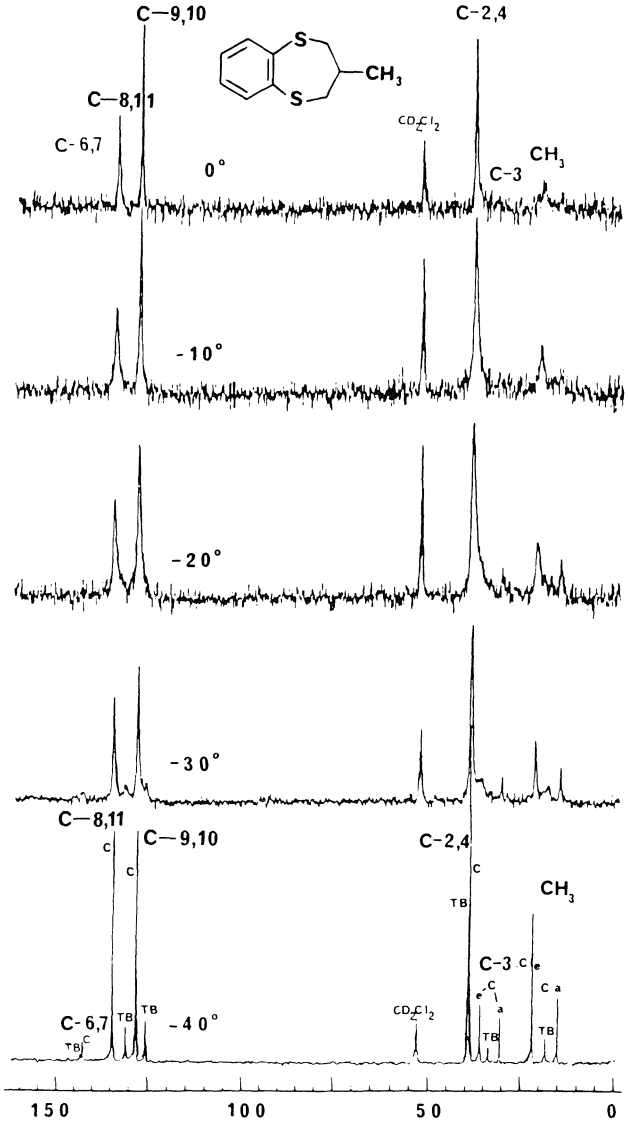

FIG. 5. 100.62-MHz ^{13}C nmr spectrum of **3** in CS_2 at several temperatures.

most intense H-2,4 signal at 2.18 ppm (Fig. 7), which, as in **3**, is assigned to the axial H-2,4 protons. Finally, analysis of the C8–C11 region of the low temperature ^{13}C spectrum shows that TB is the least abundant form.

Table 3 summarizes the relative populations of the various conformers adopted by compounds **1**–**4** and the corresponding dynamic parameters characterizing the conformation equilibria exhibited by each of these compounds.

Conformational averaging processes

Although Friebolin and co-workers (6) studied the parent compound 1,5-benzodithiepin (**1**), they were not able to determine the nature of its stable conformation nor its kinetic parameters.

The information derived from the ^{1}H nmr spectra of **1**, namely T_c = 20°C, $\Delta\nu$ = 204 Hz, and $^2J_{HH}$ = −13.2 Hz for the H-2,4 protons of the major conformation, enables us to calculate a free energy of activation ($\Delta G^{\ddagger}$) of 11.3 ± 0.3 kcal/mol for the chair inversion process using a transmission coefficient of one-half. No detailed information can be deduced for the pseudorotation process of the minor TB conformation.

An average $\Delta G^{\ddagger}$ of 12.9 ± 0.5 kcal/mol is estimated for the C → TB interconversion of the dimethyl derivative **2** from the coalescence temperature of +10°C observed for the ^{13}C nmr signals of the C-2,4 and C-8,11 carbons, using a two-site approximation (9) and a transmission coefficient of one. A slightly lower value of 12.4 ± 0.5 kcal/mol is obtained when using the ^{1}H coalescence temperature of 0°C and $\Delta\nu$ = 280 Hz for the H-2,4 proton signals of both conformers at −20°C. Finally, a value of 12.1 ± 0.5 kcal/mol is obtained for the chair inversion process when using a T_c = −10°C and $\Delta\nu$ = 116 Hz for the methyl protons of the chair form or T_c = +10°C and $\Delta\nu$ = 762 Hz for the methyl carbons and a transmission coefficient of one-half. These values are similar to that of 12.6 kcal/mol reported by Friebolin (6).

The free energy of activation of the C → TB transformation in the monomethyl derivative **3**, is estimated from the ^{13}C coalescence temperature of −20°C observed for the two components of the C-8,11 and C-9,10 carbons. A value of 11.4 ± 0.5 kcal/mol is obtained. The coalescence of the methyl carbon signals of the chair form of this compound (−10°C) yields a value of 12.1 ± 0.5 kcal/mol for the chair inversion process.

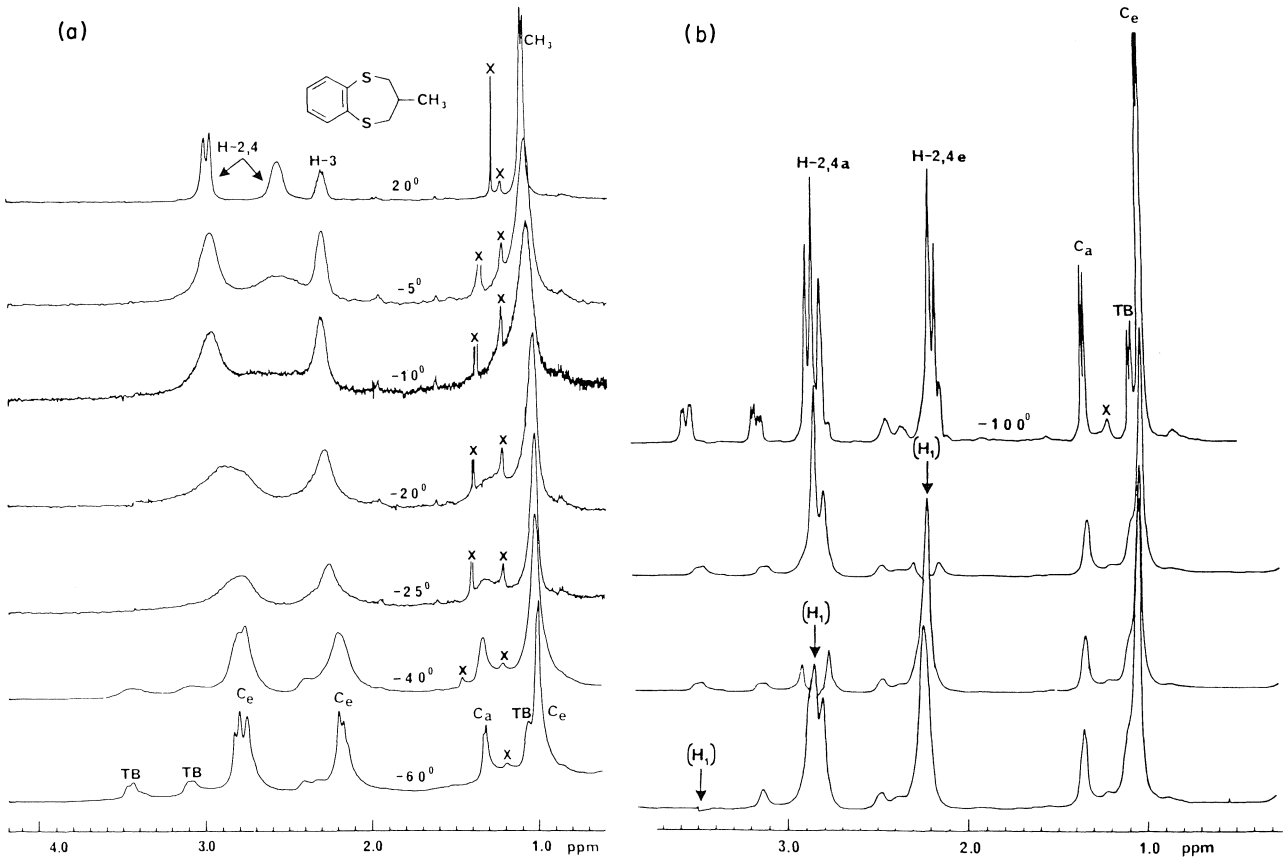

FIG. 6. (*a*) Partial 400.13-MHz ^{1}H nmr spectrum of **3** in CS_2 at several temperatures (X denotes impurities). (*b*) Homonuclear selective decoupling experiments on the 400.13-MHz ^{1}H nmr spectrum of **2** in CS_2 at −100°C.

Finally, a value of 10.9 ± 0.5 kcal/mol is derived for the C → TB interconversion of **4** using a ^{13}C coalescence temperature of −30°C and a $\Delta\nu$ = 332 Hz between the signals of the C-1,4 carbons of both forms. The chair inversion process involves a $\Delta G^{\ddagger}$ of 11.4 ± 0.5 kcal/mol as calculated from the following parameters: T_c = 0°C, $\Delta\nu$ = 1001 Hz for C-3 or T_c = −30°C, $\Delta\nu$ = 82.5 Hz for the methoxy carbon.

These results, summarized in Table 3, indicate that the presence of substituents at the 3-position of the seven-membered ring has little influence on the energy barrier for chair inversion, somewhat like analogous results for 1,3-dithianes substituted at the 5-position (10).

Origin of the conformation preferences

We have previously (2, 11) explained the conformational behavior of seven-membered carbocyclic and heterocyclic molecules in a framework combining such effects as steric, electrostatic (12), and bond–antibond interactions (13–15).

Because it has been estimated that the chair–TB energy difference is less for 1,3-dithiane than for 1,3-dioxane (16), it is most surprising to observe the opposite with regard to the conformation preferences of 1,5-benzodioxepin and 1,5-benzodithiepin. Indeed, the replacement of the ring oxygens in 1,5-benzodioxepins by sulfur leads to a larger amount of the C form(s) for all four compounds studied. A brief explanation of the results for each compound is given next in light of the above broadly applicable generalization, together with refinements arising from specific effects associated with each of the substituents.

The parent compound, 1,5-benzodithiepin (**1**), exists predominantly in the chair conformation and the free energy difference ($-\Delta G^0$) between this form and the TB conformation at −90°C is 1.1 kcal/mol. It would then appear that the stabilization of the TB form through electronic factors, as noted for the oxygen analog **1***a*, is attenuated when sulfur has replaced oxygen (2). Possibly the two-electron stabilizing interactions (17) stabilizing the TB arrangement becomes less important when oxygen is replaced by sulfur.

The shift in population observed for **1** by changing the solvent from CS_2 to THF is negligible, as would be expected from the similarly weakly polar nature of both solvents. The effect of CHF_2Cl was not investigated because the anticipated reduction of the already small amount of TB would not have permitted detection.

Dimethyl substitution in **2** causes a shift favoring TB, as similarly observed (2) for **1***a* and **2***a*. Table 3 shows that an increase in solvent polarity favors the C form, probably because of better solvation of the more polar chair form (2).

The data in Table 3 show that, in CS_2, the C_a form of **3** is more abundant (C_e:C_a:TB = 55:25:20) than for **3***a* in CH_3OCH_3 (C_e:C_a:TB = 42:9:49) (2), most probably because of reduced steric interaction between the axial methyl group and the sulfur lone pair owing, in part, to the larger C—S bond length. An increase in solvent polarity (CS_2 to CHF_2Cl) favors the C_e form of **3** at the expensve of C_a, whereas for **3***a*, C_e is also favored but at the expense of TB, since the amount of C_a is rather small for **3***a*.

Furthermore, the $-\Delta G^0$ value[1] between the axial and equatorial methyl groups of **3** in both solvents (0.27 kcal/mol in

[1]The use of ΔG^0 implies the equilibrium between the two conformers is viewed as axial conformer ⇌ equatorial conformer.

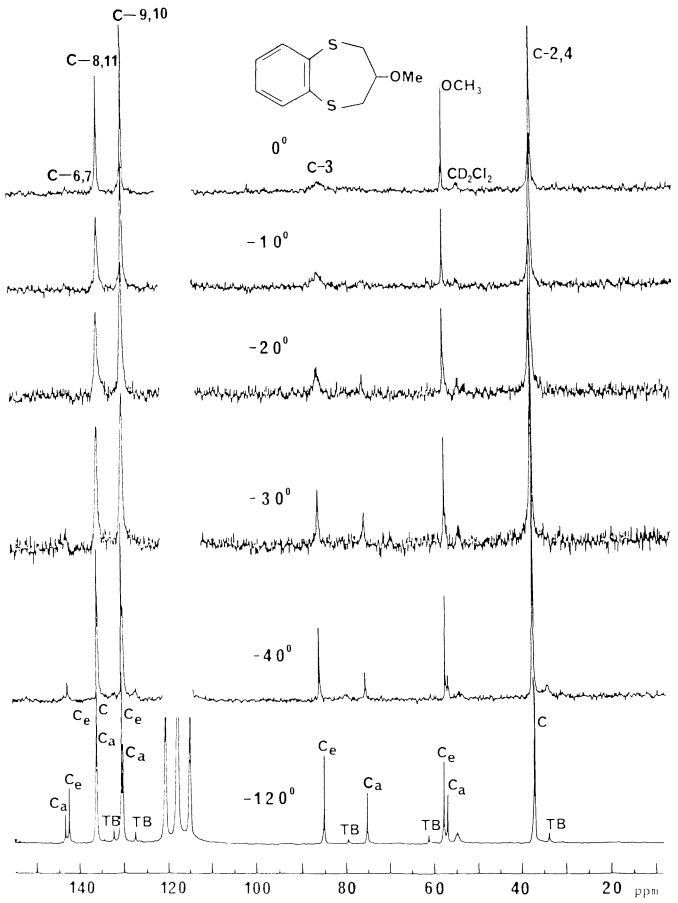

FIG. 7. 100.62-MHz ^{13}C nmr spectrum of **4** in CHF_2Cl at several temperatures.

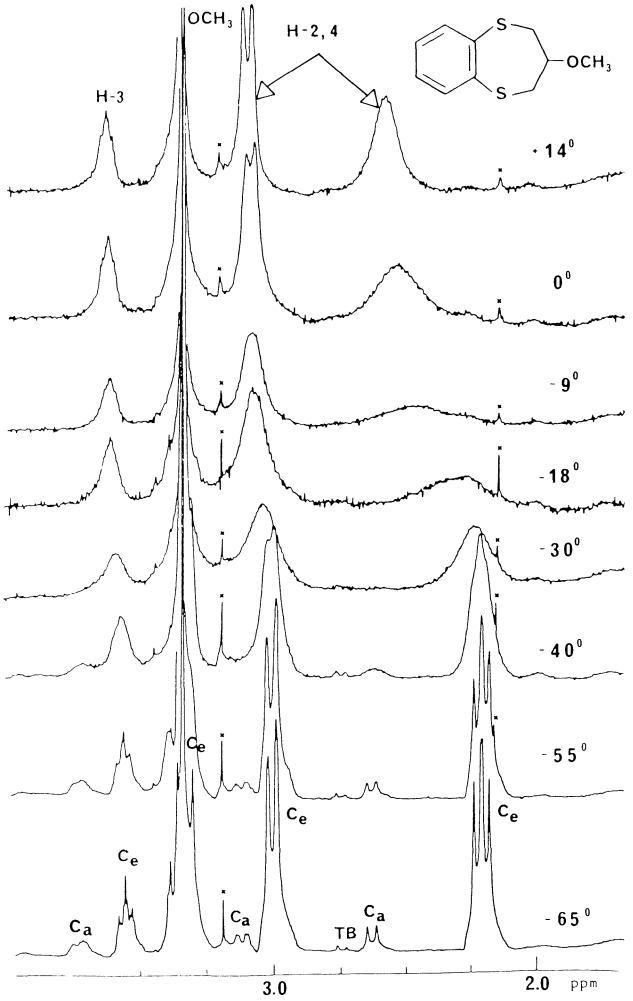

FIG. 8. Partial 400.13-MHz ^1H nmr spectrum of **4** in CHF_2Cl at several temperatures.

CS_2 and 0.63 kcal/mol in CHF_2Cl) is lower than that reported for 5-methyl-1,3-dithiane in $CHCl_3$ (1.05 kcal/mol) (16). This suggests that steric interactions are indeed weaker in the present seven-membered ring, as is also the case in the analogous oxa-pair (2).

Finally, the methoxy derivative **4** exists predominantly in the C_e form in CS_2. The great importance of the C_e form for **4**, contrary to **4***a*, can be explained in terms of bond–antibond interactions (13–15) that act in a totally reverse manner when oxygen is replaced by sulfur. Indeed, it has been reported that the O/S *gauche* "conformation effect" is repulsive whereas the O/O *gauche* effect is attractive (3, 15). Thus, the C_a conformer of **4**, possessing the largest number of *gauche* arrangements for the $S—CH_2CH—OCH_3$ fragments, should be destabilized relative to C_e. On the other hand, the absence of the C_e form noted for **4***a* would then result from the fact that the O/O *gauche* interaction is attractive.

An increase in solvent polarity (as in CHF_2Cl) increases the amount of the C_a conformer of **4** at the expense of C_e, keeping the amount of TB essentially unchanged. In contrast, only the TB conformation of **4***a* is observed in the less polar solvent (2) (CH_3OCH_3 or CS_2) while the increase in polarity leads to a mixture of TB and C_a. If we consider that the TB preference is stronger in the oxa family because of electronic factors (17), then the solvent effect, increasing the amount of the more polar C_a conformation through better solvation in the more polar solvent (12), is similar for both **4** and **4***a*.

Experimental

The vapor phase chromatographic (vpc) analyses and separations were carried out on a Varian-Aerograph Model 920 instrument using helium as carrier gas.

The variable temperature ^1H and ^{13}C nmr spectra were recorded in the FT mode with a Bruker WH-400 instrument operating at 400.13 and 100.62 MHz respectively and equipped with a standard Bruker variable temperature accessory. Temperatures were read off the B-VT-1000 control unit and compared to a calibration curve previously established by using a Fluka Model 2165A digital display thermometer, equipped with a copper constantan thermocouple placed inside a solvent containing a dummy nmr tube inserted in the probe. A precision of ±3°C is expected.

All ^{13}C nmr spectra were recorded with broad-band proton decoupling and the following instrumental parameters are typical: SW = 52 215 Hz; flip angle = 15 μs; data size = 16 K; AQ = 0.4 s; pulse delay = 0.2 s. For proton spectra, the typical instrumental parameters used are as follows: flip angle = 50 μs; SW = 20 000 Hz; data size = 8 K; AQ = 0.2 s; pulse delay = 0.3 s. The ^1H spectra were resolution enhanced by exponential and (or) gaussians multiplication.

All variable temperature studies were performed on CHF_2Cl and CS_2 or THF-d_8 solutions of the sample containing Me_4Si and about 18% of CD_2Cl_2 (for field locking purposes) in standard 5-mm (^1H) and 10-mm (^{13}C) nmr tubes that had been degassed and sealed. The ^1H nmr tubes contained 5–10 mg of the sample in 0.5 mL of solvent while the ^{13}C nmr tubes contained 60–120 mg of the sample in 2.2 mL of the solvent.

Some rate constants were estimated at the coalescence temperature with the equations $k = \pi\Delta\nu/2^{1/2}$ for singlet to doublet splitting and $k = \pi(\Delta\nu^2 + J^2)^{1/2}/2^{1/2}$ for singlet to AB quartet splitting (9). The free energies of activation values ($\Delta G^{\pm}$) were calculated from standard

TABLE 3. Thermodynamic and kinetic parameters characterizing compounds **1**–**4**

[a]The uncertainty in the integration results is about ±2%.

[b]The identity of nucleus and signal whose parameters are used to calculate $\Delta G^{\ddagger}$ is given in brackets next to the coalescence temperature. For the methyl group, CH_3 refers to the ^{13}C spectra whereas H_3C refers to the ^1H data.

[c]The ΔG^0 values referring to the TB form are corrected (2) for statistical effects owing to the existence of two equivalent TB forms for **3** and **4**.

equations using a transmission coefficient of 1 (for chair to twist-boat transformation) and of ½ (for chair inversion and TB inversion) (18).

o-*Benzenedithiol*

This compound was prepared by a three-step procedure described in the literature (19, 20) starting from butanethiol and *o*-dibromobenzene. Quantities of this compound were also purchased from Aldrich.

1,5-Benzodithiepin (ref. 6)

A suspension of 0.80 g of K_2CO_3 in 3 mL of *n*-pentanol was refluxed under vigorous stirring and a solution of 218 mg (1 mmol) of 1,3-dibromopropane and 142 mg (1 mmol) of *o*-benzenedithiol in 3 mL of *n*-pentanol was added dropwise. The mixture was refluxed for 10 h, then cooled and filtered. The filtrate was washed with water, dried over $MgSO_4$, and the solvent was evaporated. The residue was dissolved in benzene, treated with activated charcoal, and distilled. The colorless liquid obtained was purified by gas chromatography on a SE-30 5% column (150 cm × 6.4 mm, T = 140°C) yielding 85 g (47%) of 1,5-benzodithiepene, characterized by its ^1H nmr spectrum described in Table 1 and its comparison with that reported in the literature (6).

3-Methyl-1,5-benzodithiepene

A solution of 145 mg of *o*-benzenedithiol (1 mmol) and 342 mg of ditosylate of 2-methyl-1,3-propanediol (described elsewhere (2)) was added to a suspension of 0.78 g of K_2CO_3 in 3 mL of DMSO. The mixture was heated at 110°C for 20 h. After cooling at room temperature, water and benzene were added and the phases were separated. The aqueous layer was extracted with benzene (2 × 20 mL) and the combined organic fractions were washed with water and dried over $MgSO_4$. The solvent was evaporated and the residue purified by gas chromatography on a SE-30, 5% column (150 cm × 6.4 mm, T = 140°C). Thus 107 mg (64%) of a colorless liquid was obtained. *Exact Mass* calcd. for $C_{10}H_{12}S_2$: 196.0380; found (ms, m/e): 196.0365 $(M)^+$, 180 $(M - CH_4)^+$, 153 $(C_7H_5S_2)^+$, 140 $(C_6H_4S_2)^+$.

3,3-Dimethyl-1,5-benzodithiepene

This compound was prepared from 0.28 g (2 mmol) of *o*-benzenedithiol and 0.51 g of 1,3-dibromo-2,2-dimethylpropane according to a procedure already described (3). Distillation yielded 105 g (25%) of a colorless liquid whose ^1H nmr spectrum was identical to that already known (6).

3-Methoxy-1,5-benzodithiepene

A solution of 190 mg (1.3 mmol) of *o*-benzenedithiol and 392 mg (1.8 mmol) of 1,3-dibromo-2-propanol in 4 mL of pentanol was slowly added to a refluxing and vigorously stirred mixture of 1.11 g of K_2CO_3 in 4 mL of pentanol. After refluxing overnight, the mixture was cooled and filtered. The filtrate was washed with water and dried over $MgSO_4$. The solvent was evaporated and the remaining yellow oily product was dissolved in 3 mL of diglyme and cooled in an ice bath. CH_3I (12.15 g, 15 mmol) was added and then slowly 0.375 g (16 mmol) of NaH suspended in 3 mL of diglyme. The mixture was stirred at room temperature overnight and the excess of hydride was destroyed by slowly adding 2 mL of methanol. Water and ether were added, the phases were then separated, and the aqueous layer was extracted with ether (3 × 20 mL). The combined organic fractions were washed with water (3 × 20 mL) and dried over $MgSO_4$. The solvent was evaporated and the resulting yellow oil was purified by gas chromatography using a SE-30, 5% column (150 cm × 6.4 mm, T = 140°C). A colorless liquid (98 mg, 36%) was recovered. *Exact Mass* calcd. for $C_{10}H_{12}S_2O$: 212.0330; found (ms, m/e): 212.0316 $(M)^+$, 180 $(M - CH_3OH)^+$, 153 $(M - C_3H_3O)^+$.

The visible absorption spectrum of 1,2-cyclobutanedione in the gas phase[1]

R. A. Back and J. M. Parsons

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa., Ont., Canada K1A 0R6

Received February 27, 1986

R. A. Back and J. M. Parsons. Can. J. Chem. **64**, 2152 (1986).

The visible absorption spectrum of 1,2-cyclobutanedione has been measured in the gas phase at wavelengths between 4000 and 5100 Å. The absorption is attributed to the allowed $\pi^* \leftarrow n_+$, $^1B_1 \leftarrow {}^1A_1$ transition corresponding to the first excited singlet state. The spectrum shows a complex well-resolved vibrational structure which has been analysed, with some 125 bands measured and assigned. The bands at the longer wavelengths show sharp rotational fine structure, not yet analysed. The strongest band in the spectrum at 4933 Å has been assigned as the 0–0 band, while a band almost as strong at 4820 Å is attributed to excitation of one quantum of ν'_{12}, the a_2 out-of-plane carbonyl bending vibration, and it is suggested that this band owes its intensity to vibronic coupling. A number of symmetric vibrations are also excited in the spectrum, but with no long progressions. Sequence bands running to the blue with an interval of about 72 cm^{-1} are prominent throughout the spectrum, and are assigned to ν_{13}, the a_2 ring-twisting vibration. Other hot bands were also observed involving ν_{13} which permitted estimation of energy levels for this vibration both in the ground state and the excited state. The infrared spectrum was also measured and analysed in the gas phase between 600 and 4000 cm^{-1}, and 14 bands were assigned to fundamental vibrations; some of these assignments, at the lower frequencies, are uncertain.

R. A. Back et J. M. Parsons. Can. J. Chem. **64**, 2152 (1986).

Opérant en phase gazeuse, on a mesuré le spectre d'absorption visible de la cyclobutanedione-1,2 à des longueurs d'onde allant de 4000 à 5100 Å. L'absorption est attribuée à une transition $\pi^* \leftarrow n_+$, $^1B_1 \leftarrow {}^1A_1$ qui est permise et qui correspond au premier état singulet excité. Le spectre présente une structure vibrationnelle complexe et bien résolue que l'on a analysé; on a mesuré et attribué quelques 125 bandes. Les bandes aux longueurs d'onde les plus élevées présentent une structure fine rotationnelle qui est bien définie; on ne les a toutefois pas analysées. La bande la plus intense du spectre apparaît à 4933 Å et on l'a attribuée à la bande 0–0; par ailleurs, une bande qui est pratiquement aussi intense et qui apparaît à 4820 Å est attribuée à l'excitation d'un quantum de ν'_{12}, la vibration a_2 de déformation angulaire hors-plan du carbonyle; on suggère que cette bande doit son intensité à un couplage vibronique. Un certain nombre de vibrations symétriques sont aussi excitées dans ce spectre; elles ne présentent toutefois pas de longues progressions. Des séquences de bandes allant jusqu'au bleu, avec un intervalle d'environ 72 cm^{-1}, sont en évidence dans tout le spectre et on les attribue à ν_{13}, la vibration a_2 de déformation du cycle. On a aussi observé d'autres bandes chaudes impliquant ν_{13} qui permettent d'évaluer les niveaux d'énergie de cette vibration tant à l'état fondamentale qu'à l'état excité. On a aussi mesuré le spectre infrarouge en phase gazeuse entre 600 et 4000 cm^{-1}, on l'a analysé et on a attribué 14 bandes à des vibrations fondamentales; toutefois quelques-unes de ces attributions, aux fréquences les plus basses, sont incertaines.

[Traduit par la revue]

Introduction

The spectroscopy of α-dicarbonyl compounds shows many interesting features. The two lone-pair orbitals interact strongly, splitting into n_+ and n_- components, raising the energy of the former enough to shift the $\pi^* \leftarrow n_+$ transition into the near ultraviolet or visible region. The spectroscopy of glyoxal, the prototype α-dicarbonyl compound, has been very thoroughly studied (1). The ultraviolet spectrum of oxalic acid has recently been analysed in this laboratory (2), and those of pyruvic (3) and glyoxylic acid (4) briefly reported. All these compounds exist almost entirely as the *trans* isomer; only with glyoxal has the *cis* isomer been detected and its absorption spectrum observed, and this only with difficulty because of overlapping absorption by the *trans* isomer which is present in about a thousand-fold excess (5). With 1,2-cyclobutanedione (hereafter CBD), in contrast, the molecule is locked in a *cis* configuration. It is a yellow solid, and visible absorption bands have been observed in solution (6), but no gas-phase spectra appear to have been measured. In conjunction with photochemical studies of CBD (7), we have measured the visible absorption spectrum, which we now report in detail in the present paper. To aid in the vibrational analysis, the infrared absorption spectrum, not previously reported, was also measured.

Experimental

Absorption spectra were first measured in a 1-m single-pass quartz cell, heated to temperatures up to about 50°C, using a Spex 1-m grating spectrometer with a resolution of about 0.1 Å. Spectra were also photographed at medium resolution using an Eagle spectrograph in the 1st and 2nd order, using a multi-pass 2-m White cell at room temperature. High resolution spectra of some bands were photographed using the 12th order of an Ebert spectrograph.

The infrared spectrum of the vapor was measured from 600 to 4000 cm^{-1} with a path length of about 60 cm and a pressure of 0.5 Torr, using a Bomem F.T. spectrometer at a resolution of about 1 cm^{-1}.

Cyclobutanedione was prepared by M. Hrytsak and his colleagues at the University of Ottawa, using methods in the literature (8, 9). The vapor was admitted to the absorption cell after simple degassing, keeping exposure to visible light and to water vapor at a minimum. The sample was replaced frequently as some loss by photolysis was observed, but the products, chiefly C_2H_4 and CO, are transparent in the region of interest.

Results

The absorption spectrum between 5100 and 4000 Å, measured in the Spex spectrometer, is shown in Fig. 1. No absorption could be observed at longer wavelengths or at wavelengths between 3900 and 2200 Å. Medium-resolution photographic spectra from 5100 to 4780 Å are shown in Fig. 2. In Table 1 are listed the vibrational bands observed, their wavelengths in air, and their wavenumbers *in vacuo*. Bands evident in the spectrometer trace (Fig. 1) are designated by upper-case letters, while other bands seen only in photographs are labelled with lower-case letters. Numerical subscripts refer to members of ν_{13} sequences, discussed below. The wavelengths and wavenumbers shown were measured from the photographic spectra using iron-arc lines as references in the usual way, and refer to

[1]NRC No. 25309.

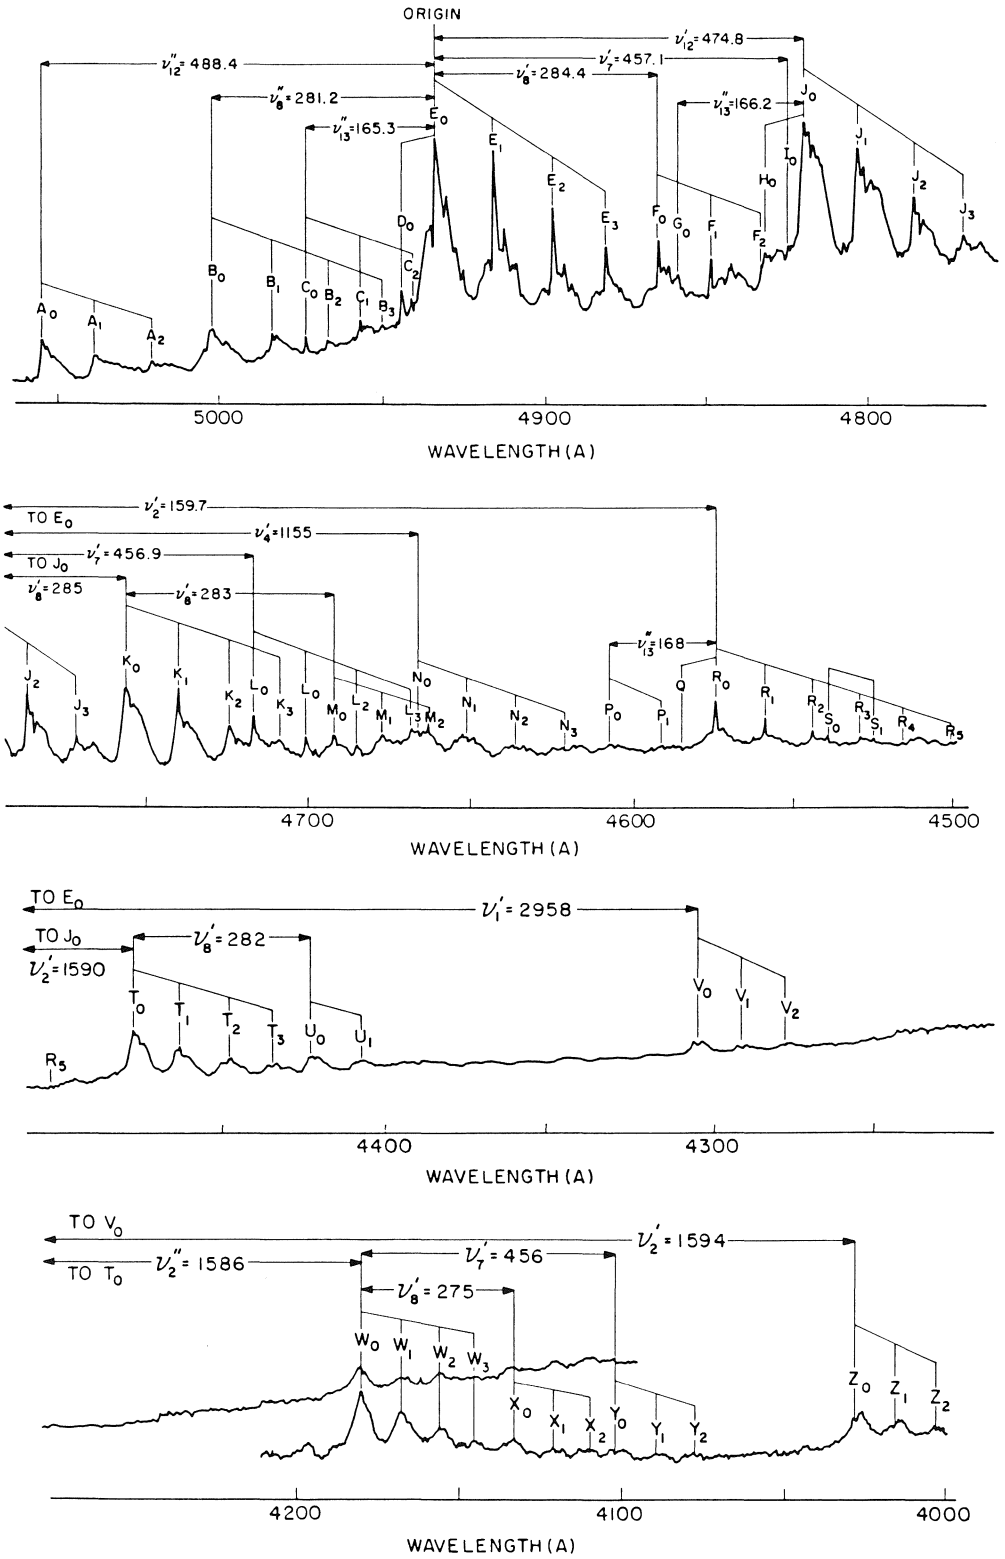

FIG. 1. Low-resolution absorption spectrum of 1,2-cyclobutanedione, measured with a Spex 1-m grating spectrometer. No correction was made for the wavelength response of the photomultiplier. See text and Table 1 for band assignments, wavelengths, and meaning of symbols.

the band heads, degraded to the blue, evident in the spectrum (Fig. 2). At the lower wavelengths, these band heads are very sharp, and measurements were made from these sharp edges (e.g. bands labelled A_0, B_0, E_0, E_1, E_2, J_0, J_1 in Fig. 2). With decreasing wavelength generally, and within ν_{13} sequences, band heads tend to become more diffuse, and measurements were made from estimated points of maximum intensity. At the shortest wavelengths, the band heads become quite diffuse, and some bands become distinctly double (e.g., V_0, Y_0, and Z_0 in Fig. 1), and in these cases measurements refer to the intensity maximum of the longest-wavelength member of each pair. Frequencies are reported to the nearest cm^{-1} or the nearest $0.1\,cm^{-1}$, depending on the sharpness of the band. The accuracy of the measurements varies considerably from band to

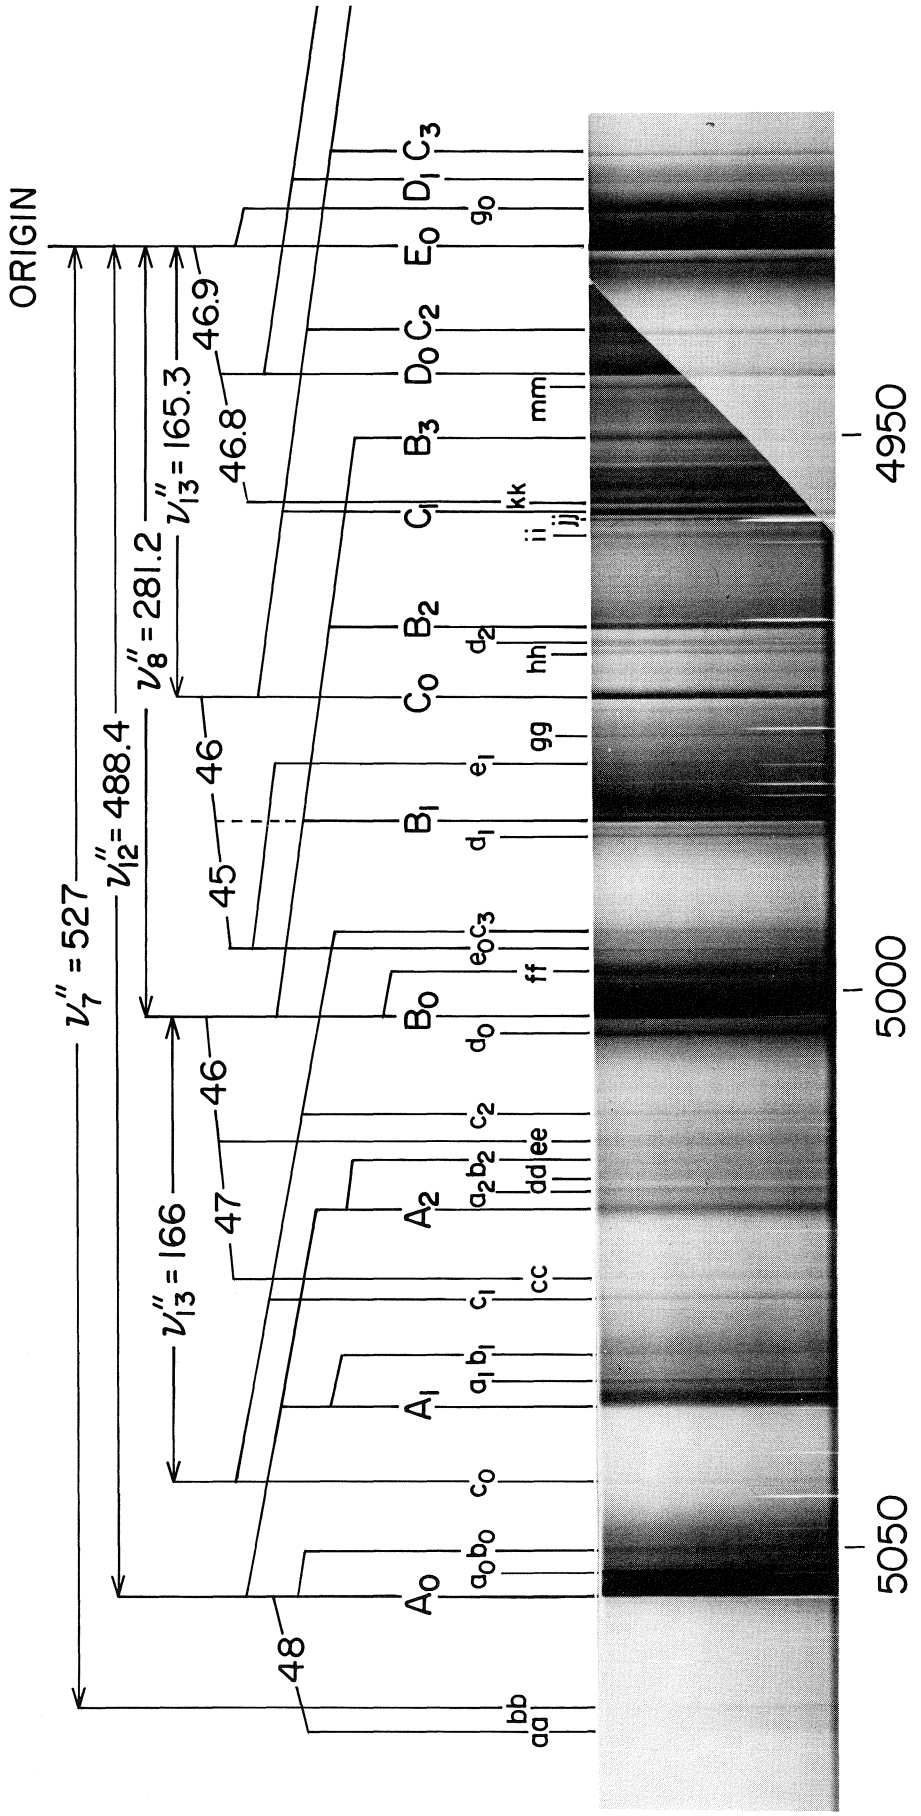

FIG. 2. Medium-resolution absorption spectrum of 1,2-cyclobutanedione photographed in the 1st order of an Eagle 6.65-m grating spectrograph. See text and Table 1 for band assignments, wavelengths and meaning of symbols.

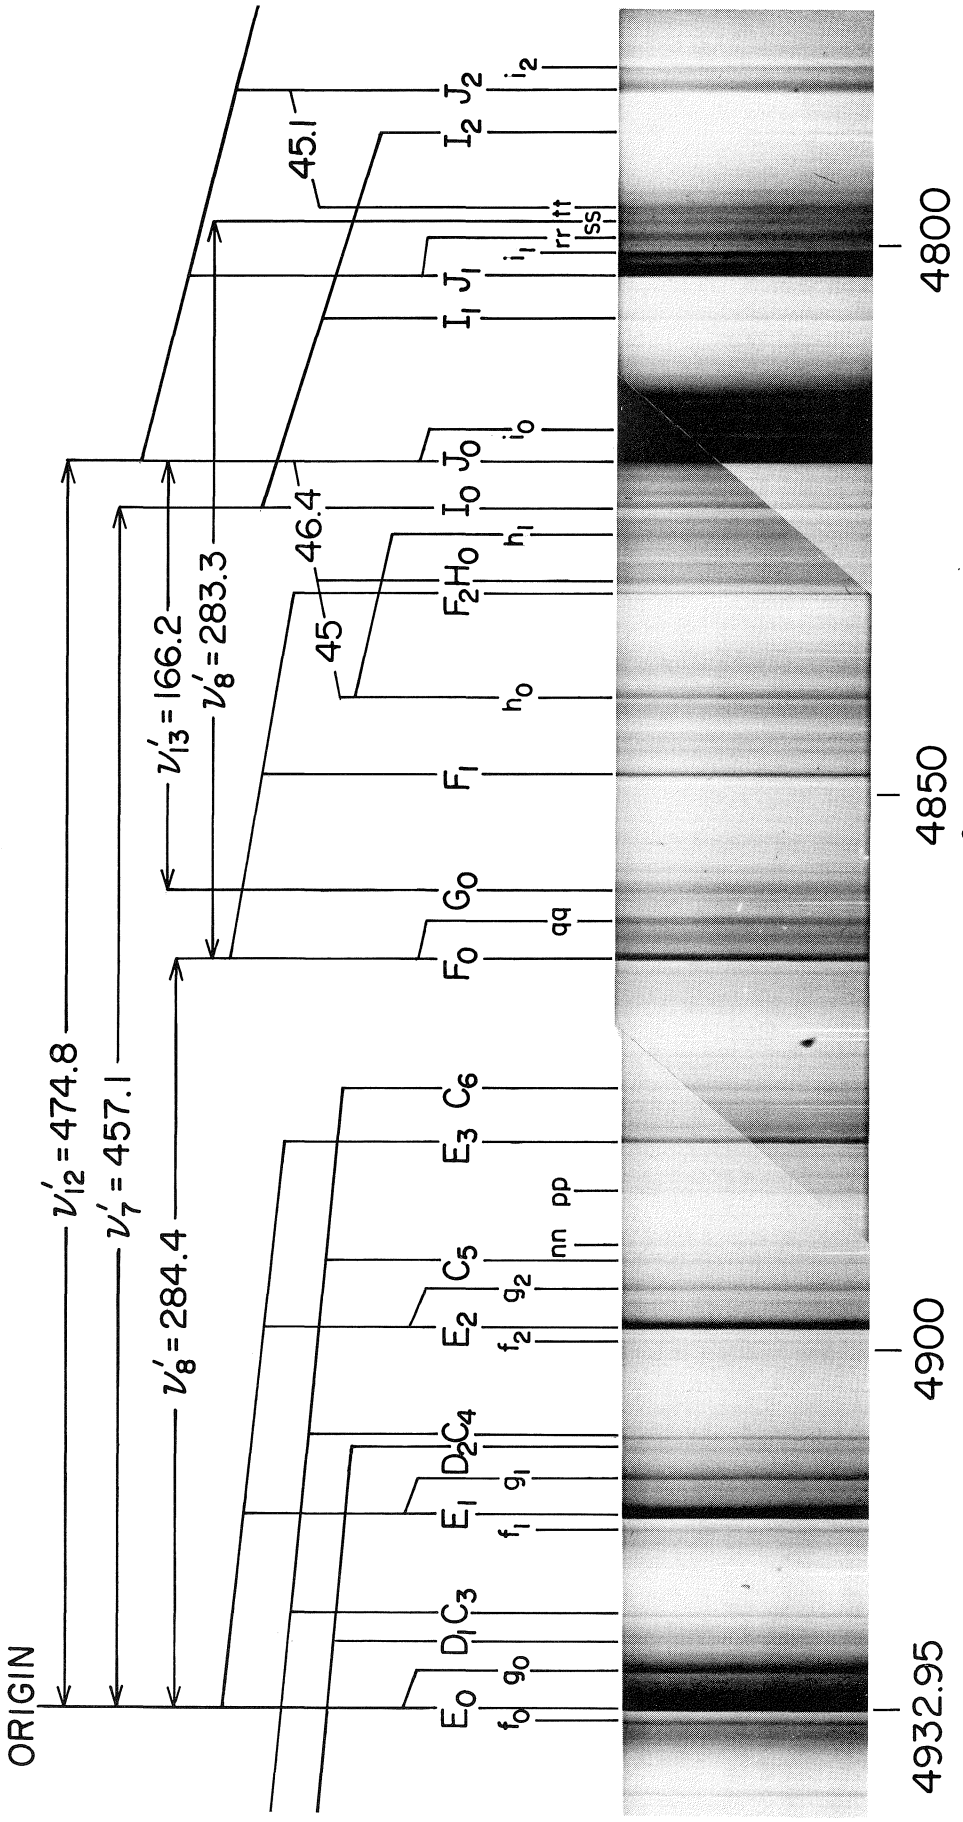

FIG. 2. (*concluded*)

TABLE 1. Band heads in the absorption spectrum of 1,2-cyclobutanedione (all frequencies and frequency differences in cm^{-1} *in vacuo*)*

*sh = sharp, df = diffuse, st = strong, wk = weak, rf = rotational feature, db = double.

band, but should be adequate for vibrational analysis. High-resolution spectra show sharp, partially resolved rotational structure in most bands at longer wavelengths. This structure is complex and overlapped and has not yet been analysed, but it appears that the true vibronic band origins probably lie from 5 to 10 cm^{-1} to the blue of the values listed in Table 1.

Table 2 lists and describes the bands observed in the infrared spectrum between 600 and 4000 cm^{-1}, and their assignments; some of the latter are obviously uncertain, especially some of the weaker bands and those at the lower frequencies. Where the band types are clear, they are all in accord with the vibrational assignment, with consideration of the permanent dipoles associated with the C—O and C—H bonds. Of the 24 fundamentals, 14 are assigned to observed bands, 4 should be infrared inactive or very weakly active (ν_4, ν_9, ν_{10}, ν_{11}), and the other 6 are expected to lie below 600 cm^{-1}. This spectrum will not be discussed further.

Discussion

The electronic transition

The microwave spectrum (10) and electron diffraction measurements (11) have shown that the carbon—oxygen skeleton of CBD is planar in the ground state, with C_{2v} geometry; like glyoxal, it probably also remains planar in the excited state. From the photoelectron spectrum (12) and by analogy with other α-dicarbonyl compounds, the highest occupied molecular orbital is the $a_1(n_+)$ component of the n_+–n_- pair formed by interaction of the two carbonyl lone-pair orbitals. The observed spectrum is undoubtedly due to the allowed $\pi^* \leftarrow n_+$, $^1B_1 \leftarrow {}^1A_1$ transition, entirely analogous to the similar visible absorption spectrum of *cis*-glyoxal (5). The O–O bands are quite close (4933 vs. 4875 Å in *cis*-glyoxal) and the value (7) of $\epsilon_{max} \approx 20\ M^{-1}\ cm^{-1}$ is about that expected for a $\pi^* \leftarrow n_+$ transition.

Vibrational analysis

The 24 normal-mode vibrations of CBD are listed and approximately described in Table 3. Lacking well-established ground-state frequencies, the numbering of several of these is uncertain. Ground-state values for ν_1'', ν_8'', ν_{12}'', and ν_{13}'' have been obtained from hot-bands in the visible absorption spectrum and from the fluorescence spectrum (13), while other values are taken from the ir spectrum, or estimated.

The strongest band in the spectrum at 4933 Å, labelled E_0, has been assigned as the 0—0 band. Obvious sequence bands, labelled E_1, E_2, and E_3 run towards shorter wavelengths with an interval of about 70 cm^{-1}. Similar sequences can be seen throughout the spectrum (denoted by subscripts) and are all assigned as $\Delta v = 0$ sequences in ν_{13}. Similar sequences, running to the blue, are prominent in the spectra of glyoxal (1) and oxalic acid (2), where they involve the torsional vibration around the C—C bond, which becomes shorter and stronger in the excited state. The analogous vibration in CBD is the a_2 out-of-plane ring-twisting mode, ν_{13}, which is also expected to have the lowest frequency in the molecule, and has been observed in the form of vibrational satellites in the microwave spectrum (10). The role of ν_{13} in the spectrum will be discussed further at a later stage.

The second strongest band in the spectrum, J_0, 475 cm^{-1} above E_0 at 4820 Å, is assigned to excitation of one quantum of ν_{12}', the a_2 out-of-plane C=O bending vibration. We suggest that this band owes its strength to Herzberg–Teller intensity borrowing through vibronic coupling to a strong, higher-energy electronic transition. The lowest π^*–π state, which probably corresponds to the next allowed transition of CBD and can be expected to lie around 2000 Å, is a likely candidate for such coupling, and a consideration of the orbitals involved shows that this will be a $^1B_2$ state. Vibronic coupling with this state requires an a_2 vibration which combines with the $^1B_1$ upper state of the π^*–n_+ transition to give a vibronic state of the same B_2 symmetry species. The only a_2 vibrational mode of the right frequency for the J_0 band appears to be ν_{12}'.

Support for this assignment for J_0 comes from the absence of

strong bands corresponding to $v'_{12} = 2$, 3, etc., expected if J_0 were simply the first member of a progression in a symmetric mode. (A weak band, P_0, may correspond to $v'_{12} = 3$, in which ν_{12} would again act as an inducing mode; there is no band at the wavelength expected for $v'_{12} = 2$, where it would not.) Further evidence that J_0 is induced by vibronic coupling is the distinctly different band profile, compared to E_0, which is expected from the different vibronic symmetry of the excited state (Figs. 1, 2). It is interesting that the spectrum of *trans*-glyoxal (1) and probably of *cis*-glyoxal (5, 14) also show strong bands induced by vibronic coupling involving an out-of-plane bending vibration.

The band designated F_0 at 4865 Å, 284.4 cm^{-1} above the origin, has been assigned to ν'_8, the symmetric, in-plane carbonyl bending mode; in *cis*-glyoxal the corresponding ν''_5 is 284.5 cm^{-1} in the ground state (5). The same vibration is also active in a number of combination bands, K_0, M_0, j_0, U_0, p_0, X_0, and s_0, and in the band *ss* assigned as 8_0^2.

The band I_0, 457.1 cm^{-1} above the origin, is attributed to ν'_7, an in-plane ring distortion that might be expected to be excited by a change in the C_1—C_2 bond length. The same vibration shows up more clearly in L_0 in combination with ν'_{12}, and in the other combination bands k_0, n_0, q_0, and Y_0. A weak broad band, N_0, 1155 cm^{-1} above the origin, has been assigned to a second in-plane ring vibration, ν'_4, the symmetric breathing mode.

The band R_0, 1592.7 cm^{-1} above the origin, is assigned to ν'_2, the symmetric C=O stretching vibration, which is also excited in the combination bands T_0, W_0, and Z_0 and is a common feature of most $\pi^* \leftarrow$ n transitions. The band V_0 is assigned to ν'_1, the symmetric C—H stretching vibration, with a frequency of 2958 cm^{-1}.

It remains to discuss the bands observed to the red of the origin, and related bands throughout the spectrum. The band A_0, 488.4 cm^{-1} from the origin, has been assigned to absorption from the $v''_{12} = 1$ level in the ground state. This is supported by the frequency (close to ν'_{12}), by the band profile, which resembles that of J_0, and by its strength, which is greater than predicted from the Boltzmann factor but can be explained by the action of ν_{12} as a vibronic coupling mode as discussed earlier.

The band B_0 is assigned to ν''_8, a symmetric vibration also actively excited in the upper state. The band m_0, lying 280 cm^{-1} to red of V_0, is also assigned to ν''_8. The band C_0 has been assigned to ν''_{13} (165.3 cm^{-1}), the ring-twisting vibration so prominent in many sequences throughout the spectrum, while it is also involved in the combination bands c_0, G_0, and P_0. The band D_0, 46.9 cm^{-1} from the origin, has been assigned as a 1,1 sequence band of ν_{24}, the asymmetric in-plane carbonyl bend, chosen chiefly because of its probable low frequency, but a sequence in some other vibration is almost equally possible. The same sequence seems to be involved in a dozen other combination bands listed in Table 1. The band g_0, 14.3 cm^{-1} to the blue of E_0, has been assigned as a sequence band of an unknown vibration X, and a number of similar bands lying about the same distance to the blue of other strong features have been given similar assignments. A number of other features even closer to several of the stronger bands are probably rotational structure. Finally, a very weak band, *bb*, 527 cm^{-1} to the red of E_0, is assigned to ν''_7, a ring-distortion vibration; the

same band has also been observed in the emission spectrum of CBD (13) where it is much stronger. Many of the other bands to the red of the origin have also been seen in emission.

The role of the ν_{13} ring-twisting vibration in the spectrum requires some further comment. There is little doubt about the assignment of the many regular sequences throughout the spectrum to this vibration. There is some doubt, however, about the assignment of C_0 as 13_1^0, with $\nu''_{13} = 165.3\,cm^{-1}$, and the alternative assignment of D_0 as 13_1^0, with $\nu''_{13} = 46.9\,cm^{-1}$, was given serious consideration. In favour of the D_0 assignment was the approximate agreement with a value of about $50\,cm^{-1}$ for ν''_{13} that can be obtained from a Boltzmann factor estimated from the ratio of intensities E_1/E_0 or J_1/J_0, and with a value of 68 (±30) estimated in a similar way from microwave "satellite" bands (10). On the other hand, 46.9 cm^{-1} seems very low for the observed sequence interval of 72 cm^{-1}, which would lead to an exceptionally large percentage change in frequency between the ground and excited states. This frequency also seems low for the relatively stiff ring expected in CBD, planar in both states, not much higher than the frequency of 36 cm^{-1} found in the

much less rigid ring in cyclobutanone (15). A more convincing piece of evidence favoring the C_0 assignment for 13_1^0 is the significantly lower sequence interval in the C_0–C_5 sequence, compared with the E_0–E_3 sequence; the former sequence would then be 0,1, 1,2, etc., rather than 0,0, 1,1, etc., and a different interval is not unexpected. The D_0–D_2 sequence, on the other hand, shows the same sequence interval as the E_0–E_3 sequence. A second sequence, based on c_0, which we have assigned as $8_1^0 13_1^0$, also shows a reduced interval, close to that of the C_0–C_5 sequence, as expected from this assignment. From these observations, and the fact that frequencies based on Boltzmann factors can be notoriously unreliable, we have chosen to assign C_0 as 13_1^0 and D_0 as a 1,1 sequence band of ν_{24}. A low-frequency infrared spectrum would obviously be useful to confirm this assignment. From the two sequences, E_0–E_3 and C_0–C_5, energy levels for ν_{13} for both excited and ground states can be calculated and are shown in Table 4. Both states showed a modest regular negative anharmonicity, compatible with a relatively stiff ring structure in CBD, probably planar rather than quasi-planar in both states.

Finally, in Table 5 are summarized the fundamental vibrational frequencies of both excited and ground states determined in this study and in the recent measurement of the emission spectrum in this laboratory (13).

$^{13}C,^{19}F$ and $^{19}F,^{19}F$ nuclear spin–spin coupling constants over n formal bonds, n = 1–9, are reported for 4-fluorobiphenyl, 4,4′-difluorobiphenyl, 4,4′-difluoro-2,2′,6,6′-tetramethylbiphenyl, 2,7-difluorofluorene, 2-fluoro-9-fluorenone, and 2,7-difluoro-9-fluorenone in acetone solutions. The signs of many of the coupling constants are deduced from second-order spectral phenomena caused by differential ^{13}C isotope effects on the ^{19}F nmr chemical shifts. Theoretical potentials, based on geometry-optimized STO 3G MO computations for 4-fluorobiphenyl and 4,4′-difluorobiphenyl, yield expectation values for the torsion angles about the exocyclic C—C linkage that are very close to those deduced from electron diffraction patterns. These potentials and INDO MO FPT computations of the long-range coupling constants allow a discussion of the coupling mechanisms. In Hz, $^9J(F,F) = 1.3(1)\cos^2\theta$, where θ is zero for a planar biphenyl, while $^8J(C,F) = 0.8(1)\cos^2\theta$ and $^7J(C,F) = -0.43(5)\cos^2\theta$. $^6J(C,F)$ is a composite of $\sigma-\pi$ and π electron coupling components and is written in Hz as $0.57(1) + 0.29(1)\sin^2\theta$. The corresponding coupling constants in the fluorene and 9-fluorenone derivatives are enhanced in magnitude relative to a hypothetical planar biphenyl derivative. It is tentatively suggested that $^5J(C,F)$ consists of three coupling components, one negative and proportional to $\cos^2\theta$, the other two positive and independent of θ. $^4J(C,F)$ is suggested to consist of a σ component of -1.0 Hz and a π component proportional to the atom–atom polarizability for the parent hydrocarbon.

TED SCHAEFER, JAMES PEELING et GLENN H. PENNER. Can. J. Chem. **64**, 2162 (1986).

Opérant dans des solutions dans l'acétone, on a mesuré les constantes de couplage nucléaires $^{13}C,^{19}F$ et $^{19}F,^{19}F$ à travers n liaisons (n = 1–9) dans le fluoro-4 biphényle, le difluoro-4,4′ biphényle, le difluoro-4,4′ tétraméthyl-2,2′,6,6′ biphényle, le difluoro-2,7 fluorène, la fluoro-2 fluorénone-9 et la difluoro-2,7 fluorénone-9. On a déduit les signes de plusieurs des constantes de couplage à partir d'un phénomène spectral du deuxième ordre qui est causé par des effets isotopiques ^{13}C différentiels sur les déplacements chimiques rmn du ^{19}F. Les potentiels théoriques, basés sur des calculs d'orbitales molécules STO 3G optimisés pour la géométrie, conduisent à des valeurs attendues pour les angles de torsion autour de la liaison C—C exocyclique qui sont en accord avec celles que l'on peut déduire à partir de données de diffraction des rayons-X. Sur la base de ces potentiels ainsi que sur la base de calculs d'orbitales moléculaires INDO FPT des constantes de couplage à longue distance, on peut discuter des mécanismes de couplage. Si l'on exprime les constantes de couplage en Hz, $^9J(F,F) = 1{,}3(1)\cos^2\theta$ (θ est égal à zéro dans un biphényle plan) alors que $^8J(C,F) = 0{,}8(1)\cos^2\theta$ et $^7J(C,F) = -0{,}43(5)\cos^2\theta$. Le couplage $^6J(C,F)$ est composé de couplages $\sigma-\pi$ ainsi que de couplages d'électrons π et il est égal à $0{,}57(1) + 0{,}29(1)\sin^2\theta$. Les amplitudes des constantes de couplage correspondantes dans les dérivés du fluorène et de la fluorénone-9 sont plus grandes que celles qui sont prévues en faisant l'hypothèse qu'il s'agit de dérivés biphénylés plans. On suggère que le couplage $^5J(C,F)$ comporte trois composantes : une serait négative et proportionnelle à $\cos^2\theta$ alors que les deux autres seraient positives et indépendantes de θ. On suggère que $^6J(C,F)$ comporte une composante σ de $-1{,}0$ Hz et une composante π qui est proportionnelle à la polarisabilité atome–atome de l'hydrocarbure de base.

[Traduit par la revue]

Introduction

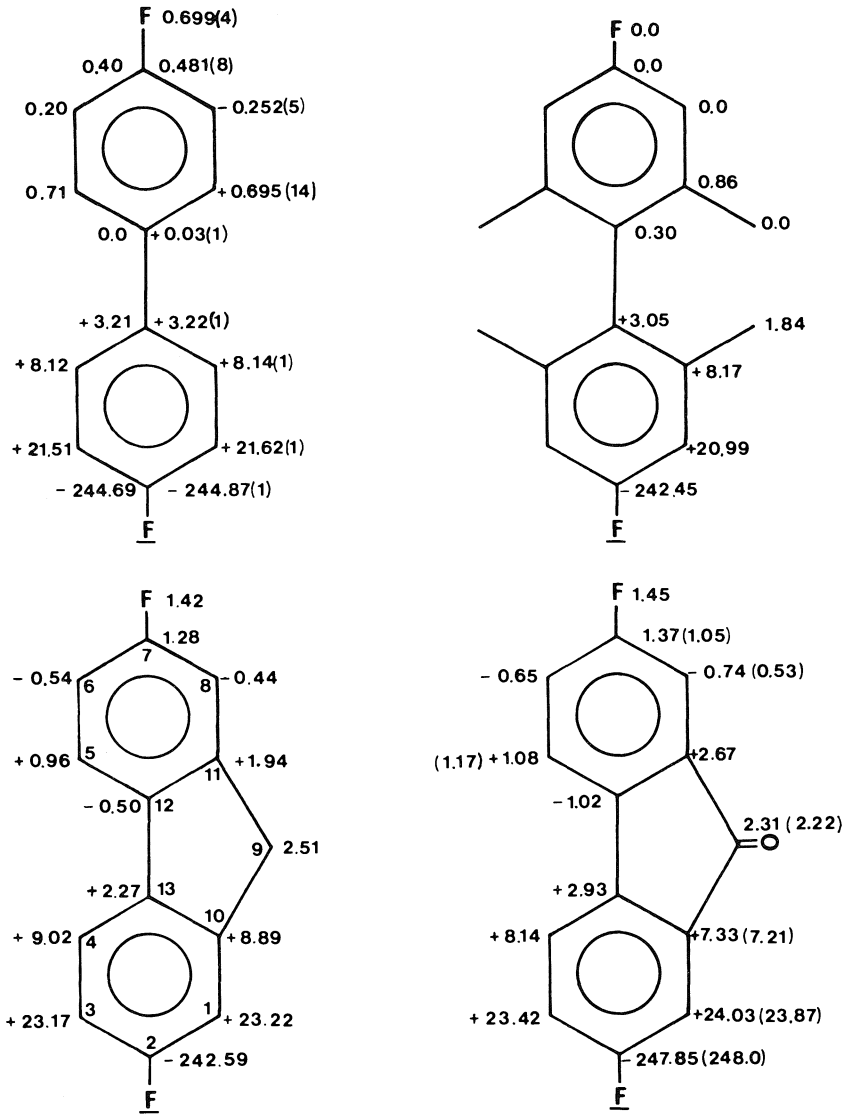
The form of the potential governing the hindered rotation about the carbon–carbon bond linking the benzene rings in biphenyl has been investigated extensively by theory and experiment. Recent reviews are available (1, 2), so that a compilation of references is unnecessary here. Briefly, biphenyl is nearly planar in the crystal below 40 K and twists about the linking C—C bond by about 44° in the vapor phase. The hindering potential certainly contains twofold and fourfold components, but sixfold and eightfold components may also be present (3). In the presence of substituents *ortho* to the linking C—C bonds, the angle of twist increases. Sufficiently bulky substituents lead to a perpendicular arrangement of the two phenyl planes (4–11).

Although ^1H and ^{13}C nmr chemical shifts (12–20), dipolar couplings in ordered solvents (8, 9, 21), and multiple quantum nmr spectra (22) have been studied as indicators of the conformations of biphenyl and its derivatives in solution, little or no use has been made of long-range spin–spin couplings as conformational indicators in such compounds. Long-range $^{13}C,^{19}F$ couplings are informative about the conformational preferences of 4-fluorophenyl derivatives of methane, ethene, and other compounds (23). Their precise measurement is relatively easy.

In this study, the long-range couplings $^nJ(C,F)$ over six to eight bonds (n = 6, 7, 8) in 4-fluorobiphenyl, 4,4′-difluorobiphenyl, and in 4,4′-difluoro-2,2′,6,6′-tetramethylbiphenyl are investigated as to their dependence on the twist angle, θ, about the linking C—C bond. Because the θ dependence of the hindering potential is not simple, the measurement of $J(C,F)$ is combined with extensive geometry-optimized STO 3G MO calculations. These yield potential functions that can be used to compute average or expectation values of θ and of functions of θ. INDO MO FPT computations of the long-range $J(C,F)$ values, and of $^9J(F,F)$ in 4,4-difluorobiphenyl, indicate the form of their θ dependence, if not their correct extrema. A combination of the experimental and theoretical data allows reasonable semiquantitative deductions about the coupling mechanisms.

Measurements of chemical shifts in fluorene have been taken to mimic those in planar biphenyl (12, 15). We report values for $^nJ(C,F)$ in 2,7-difluorofluorene, the corresponding

[1]University of Petroleum and Minerals, Dhahran, Saudi Arabia.



SCHEME 1. The coupling constants to ^{13}C and ^{19}F in Hz are given for the underlined ^{19}F nucleus. The signs are given when known. For the 4,4′-difluorobiphenyl the coupling constants are given on the right and, on the same structure, are given on the left for 4-fluorobiphenyl. The atoms in 2,7-difluorofluorene are numbered in the same way as for 2-fluorofluorene (29). The coupling constants in the latter (29) differ very little from those in the difluoro derivative. One significant difference is that to C-7, being 1.01 Hz in the former. Similarly, in the 2-fluoro-9-fluorenone, this coupling is 1.05 Hz and that to C-8 is 0.53 Hz. For the latter, the coupling constants are given in parentheses if they differ by more than 0.03 Hz from those in the difluoro derivative.

9-fluorenone, and in 2-fluoro-9-fluorenone. The presence of differential ^{13}C isotope effects on ^{19}F chemical shifts allows the determination of the signs of many of the $^{n}J(C,F)$.

Experimental

4-Fluorobiphenyl, 4,4′-difluorobiphenyl, 2,7-difluorofluorene, and 2-fluoro-9-fluorenone came from Aldrich. The 2,7-difluoro-9-fluorenone was prepared from the fluorene derivative, of which 2 g in 10 mL of benzene were stirred at room temperature for 36 h with 10 mL of a 50 wt.% aqueous NaOH solution containing 0.1 g of benzyltriethylammonium chloride. A green precipitate formed, which was extracted with CH_2Cl_2 and evaporated to dryness, yielding 1.7 g of a yellowish green, fluffy powder. The ^{13}C nmr spectrum was consistent with the desired product. The 4,4′-difluoro-2,2′,6,6′-tetramethylbiphenyl was prepared (24) via the 3,3′,5,5′-tetramethylhydrazobenzene (obtained from 5-nitro-*m*-xylene) by rearrangement to 4,4-diamino-2,2′,6,6′-tetramethylbiphenyl, followed by the usual diazotization procedures.

Because of limited solubility the nmr samples were prepared as saturated solutions in acetone-d_6.

The ^{13}C and ^{19}F spectra were accumulated on WH-90 and AM-300 FFT Bruker spectrometers at a probe temperature of 300 K in a manner described previously (23).

Geometry-optimized STO 3G MO (25) computations employed the program MONSTERGAUSS (26) on an Amdahl 470/V8 system. This computer was also used for the INDO MO FPT computations (27, 28) of $^{n}J(C,F)$ and $J(F,F)$.

Results and discussion

The $^{n}J(C,F)$ values and $^{9}J(F,F)$ are given in Scheme 1, which presents the data in the most easily comprehensible form (note that n is determined by counting via the C_{sp^2}—C_{sp^2} linkage). The coupling magnitudes for 2-fluorofluorene were determined elsewhere (29). The signs of $^{5,6,7}J(C,F)$ were determined for the difluoro derivatives relative to $^{2,3,4}J(C,F)$, the latter being positive (29). The sign determination depended on $^{13}C/^{12}C$ isotope shifts for ^{19}F, $^{n}\Delta$. From the ^{19}F spectra, $^{n}\Delta$ (n = 1, 2, 3) were typically obtained as 80, 25, and 5 ppb, respectively. In

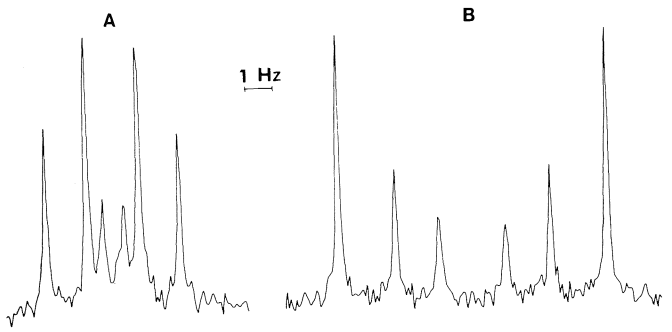


FIG. 1. In (A) is shown the $^{13}C\{^1H\}$ nmr spectrum of C-12 and C-13 in 2,7-difluoro-9-fluorenone as a saturated solution in acetone-d_6. The spectrometer frequency is 75.477 MHz and the probe temperature is 300 K. The difference in resonance frequencies of the ^{19}F nuclei is 0.478 Hz (1.69 ppb); $^9J(F,F)$ is $\pm 1.45(3)$ Hz. The six peaks of the ^{13}C nmr spectrum show that $^4J(C,F)$ and $^5J(C,F)$ are of opposite sign, as given in Scheme 1. Similarly, in (B) the six peaks of the ^{13}C nmr spectrum of C-10 and C-11 are consistent with equal signs of $^3J(C,F)$ and $^6J(C,F)$, the difference in resonance frequencies of the ^{19}F nuclei (differential isotope shift) being 1.55_6 Hz (5.51 ppb). The relative signs follow from an ABX analysis (52). Note also that the separation between the most intense peaks is equal to $^4J(C,F) + {}^5J(C,F)$ in (A) and $^3J(C,F) + {}^6J(C,F)$ in (B). $^4J(C,F)$ and $^3J(C,F)$ are of known sign and their magnitudes in the monofluoro derivative must be almost the same as in the difluoro derivative. Therefore the relative signs here follow by inspection.

the difluoro derivatives, a differential isotope shift gives rise to an ABX spectrum, the ^{19}F nuclei being represented as AB with an AB spin–spin coupling constant. If J_{AB}/ν_{AB} has the appropriate value, six peaks appear in the $^{13}C(X)$ nmr spectrum. The relative signs of J_{AX} and J_{BX}, that is, of the $^nJ(C,F)$ values, follow in a straightforward analysis. Their magnitudes can also be checked against the first-order splittings observed in the monofluoro derivatives. Figure 1 displays two typical ^{13}C nmr spectral patterns, from which relative signs can be deduced. The sign of $^8J(C,F)$ could not be determined in this way, nor could that of the coupling to ^{13}C in the CH_2 or C=O groups (symmetry).

The signs of the coupling constants are useful in the discussion of coupling mechanisms below. In addition, computations of the internal rotational potential in biphenyl and its derivatives, as well as of long-range $^nJ(C,F)$ values, are helpful and these are given next.

Theoretical internal barriers and $^{6,7,8}J(C,F)$

Geometry-optimized STO-3G MO computations of the internal rotational potential in biphenyl (3) yield $V(\theta) = \sum_{i=1}^{n} V_{2i} \sin^2 i\theta$ where n is the foldedness of the barrier component. A best fit (3) to the computed energies gave V_2, V_4, V_6, and V_8 as $-1.60(4)$, $-10.93(4)$, $-2.25(4)$, and $-0.43(4)$ kJ/mol, respectively. $\theta = 0$ corresponds to a planar molecule. For this potential, the classical expectation value, $\langle\theta\rangle$, is 43.8° at 300 K and $\langle\sin^2\theta\rangle$ is 0.447_5. As it happens, the latter is nearly the same as $\sin^2\langle\theta\rangle$ in this instance. In the gas phase, the best value of θ deduced from electron diffraction patterns is 44.4°, apparently the angle of maximum probability (1, 2).

A similar computation for 4-fluorobiphenyl, done at 15° intervals of the torsion angle, θ, gave a set of energies that could be best fit (judging by standard errors at the 95% confidence level) to a potential consisting of $-1.14(13)$, $-10.93(13)$, and $-2.34(13)$ kJ/mol for V_2, V_4, and V_6, respectively. Similarly, V_2, V_4, and V_6 were -0.62, -10.82, and -2.29 kJ/mol for 4,4′-difluorobiphenyl, again with an error of 0.13 kJ/mol. For 4-fluorobiphenyl the potential yields $\langle\sin^2\theta\rangle$ as 0.471 at 300 K, while it is 0.464 for the difluoro derivative. These potentials correspond to $\langle\theta\rangle$ values of 43°, compared to 45° from electron diffraction studies (2).

The INDO MO FPT numbers for $^{6,7,8}J(C,F)$ are given in Table 1, computed for the optimized STO 3G MO geometries. In view of previous experience with computed long-range H,F and C,F coupling constants (23, 30), it is anticipated that the form of their θ dependence will be reproduced by the theory, but that their magnitudes will be underestimated. The variation with θ of $^{6,8}J(C,F)$ appears to go roughly as $\sin^2\theta$ or $\cos^2\theta$ in Table 1.

The conformational implications of $^9J(F,F)$

In the difluorofluorene, $^9J(F,F)$ is $\pm 1.42(1)$ Hz and is $\pm 1.45(1)$ Hz in the corresponding fluorenone derivative, consistent with a coupling pathway over nine bonds via the C_{sp^2}—C_{sp^2} bond, unless the CH_2 and C=O groups are equally efficient as transmitters of spin-state information.

For 4-fluorobiphenyl, INDO MO FPT computations give $^9J(F,F)$ as positive, decreasing to zero as θ goes to 90° and varying approximately as $\cos^2\theta$ (footnote in Table 1). The theoretical values are much too small, as is often found for long-range couplings involving a C_{sp^2}—F bond (23, 30), but their qualitative θ dependence is indicative of an electron mechanism depending on $2p\pi$ overlap at the exocyclic C—C bond. This indication is confirmed by the vanishing $^9J(F,F)$ in 4,4′-difluoro-2,2′,6,6′-tetramethylbiphenyl, for which all available evidence suggests a θ of very near 90° and a large barrier to internal rotation, that is, that $\langle\cos^2\theta\rangle \sim 0$ (4, 8, 9, 11, 17, 31, 32).

Now, in 4,4′-difluorobiphenyl, $^9J(F,F)$ is 0.699(4) Hz. The theoretical potential implies a $\langle\cos^2\theta\rangle$ of 0.536 and therefore that $^9J(F,F)$ can be written as $^9J_0\langle\cos^2\theta\rangle$, where $^9J_0$ is ± 1.30 Hz. The $^9J(F,F)$ values for the fluorene derivatives imply $^9J_0$ as $\pm 1.4_3$ Hz. The magnitudes of $^9J_0$ in these compounds will presumably depend on the mobile bond orders ($2p\pi$ overlap) of the exocyclic C_{sp^2}—C_{sp^2} bonds and these need not be identical in biphenyl and fluorene.

The observed $^9J(F,F)$ values are consistent with $\langle\theta\rangle$ of 43–45° in 4,4′-difluorobiphenyl. Of course, the measurements are for acetone solutions.[2] Nevertheless, it appears that $^9J(F,F)$ is a π-electron transmitted coupling constant, going as $\cos^2\theta$, and that it is therefore a convenient conformational indicator. $^9J(F,F)$ is obtainable by procedures much less tedious than those presently employed in solution.

The mechanisms of $^nJ(C,F)$ for n = 6–8

For a π-electron mechanism the signs of $^{6,7,8}J(C,F)$ are expected to alternate. Then (Scheme 1) $^8J(C,F)$ is positive, as also indicated by the INDO MO results in Table 1. It follows that $^9J(F,F)$ is also positive because the hyperfine coupling parameter, which measures the spin polarization transfer from π to σ electrons, is positive (30, 35), in agreement with the theoretical sign. If $^9J(F,F)$ is proportional to $\cos^2\theta$, then

[2]A series of 4,4′-disubstituted biphenyls have θ values between 39.4 and 42.4° in their crystals (33), but θ cannot be determined accurately for 4,4-difluorobiphenyl (33, 34) because of disorder. The electron diffraction data (2) for the latter suggest about 45°, as noted above.

TABLE 1. INDO MO FPT values for $^{6,7,8}J$(C,F) in 4-fluoro- and 4,4′-difluorobiphenyl[a]

	^6J(C,F)/Hz		^7J(C,F)/Hz		^8J(C,F)/Hz	
θ/deg	4-F		4-F		4-F	
0	0.395	0.410	−0.297	−0.322	0.382	0.410
15	0.401	0.417	−0.268	−0.292	0.350	0.374
30	0.419	0.435	−0.196	−0.213	0.274	0.291
45	0.449	0.466	−0.101	−0.111	0.177	0.186
60	0.479	0.497	−0.006	−0.008	0.082	0.086
75	0.499	0.521	−0.066	−0.070	0.013	0.013
90	0.506	—	0.093	—	−0.013	—

[a] ^9J(F,F) varies from 0.12 to 0.00 Hz, approximately as $\cos^2\theta$ between 0 and 90°; θ = 0 for the planar form.

$^{7,8}J$(C,F) should also depend on $\cos^2\theta$.

Indeed, $^{7,8}J$(C,F) vanish in 4,4′-difluoro-2,2′,6,6′-tetramethylbiphenyl. In terms of the theoretical potentials, $^7J_0$ and $^8J_0$ are then −0.38 and 0.75 Hz in 4-fluorobiphenyl, respectively, and −0.48 and 0.90 Hz in 4,4′-difluorobiphenyl. The larger magnitudes in the latter compound can be attributed to the perturbation caused by a fluorine substituent near the end of the coupling path.[3]

However, these $^{7,8}J_0$ numbers are smaller in magnitude than those in the fluorene derivatives. If the latter are taken as correct for planar biphenyl, then $\langle\theta\rangle$ becomes about 39° for the biphenyl derivatives. That the presence of the CH_2 and C=O groups does alter the observed couplings, is clear from their values in Scheme 1. The idea that fluorene and perhaps fluorenone mimic a planar biphenyl is not quantitative. Nevertheless, it is very probable that $^{7,8}J$(C,F) are π-electron coupling constants and vary as $\cos^2\theta$ in biphenyl derivatives.

Turning to ^6J(C,F), it is known that, for sp^3 carbon atoms in the sidechain containing the coupled ^{13}C nucleus, ^6J(C,F) arises from a σ−π mechanism, proportional to $\sin^2\theta$ and involving hyperconjugation with the electron system of the aromatic moiety (23). If the sidechain carbon atom is sp^2 hybridized, then a π-electron mechanism can exist, depending on $2p\ldots2p\pi$ electron conjugation across the exocyclic bond, and proportional to $\cos^2\theta$. Accordingly, write eq. [1].

$$[1]\quad {}^6J(\mathrm{C,F})/\mathrm{Hz} = {}^6J_{90}^{\sigma,\pi}\langle\sin^2\theta\rangle + {}^6J_0^{\pi}\langle 1-\sin^2\theta\rangle = {}^6J_0^{\pi} + ({}^6J_{90}^{\sigma,\pi} - {}^6J_0^{\pi})\langle\sin^2\theta\rangle$$

If the numbers in Table 1 for 4,4′-difluorobiphenyl were correct, then $^6J_0^{\pi}$ would be 0.41 Hz and $^6J_{90}^{\sigma,\pi}$ would be 0.52 Hz. As noted above, their magnitudes are most likely too small.

Now, in the tetramethyl compound, ^6J(C,F) is 0.856(2) Hz. Because $\langle\sin^2\theta\rangle$ must be near unity, $^6J_{90}^{\sigma,\pi}$ is near 0.86 Hz in eq. [1]. Further, if the computed internal rotational potential holds for 4,4′-difluorobiphenyl, then the observed ^6J(C,F) of 0.70 Hz and the $\langle\sin^2\theta\rangle$ of 0.464 imply a $^6J^{\pi}$ of 0.56 Hz, yielding eq. [2] for ^6J(C,F).

$$[2]\quad {}^6J(\mathrm{C,F})/\mathrm{Hz} = 0.86\langle\sin^2\theta\rangle + 0.56\langle\cos^2\theta\rangle = 0.56 + 0.30\langle\sin^2\theta\rangle$$

[3] For ^8J(C,F) the attached fluorine atom contracts the 2*s* orbital on the carbon, increasing the contact contribution to the coupling constant, while for ^7J(C,F) the π donation by fluorine increases the π-electron density at carbon.

For 4-fluorobiphenyl the same reasoning yields eq. [3].

$$[3]\quad {}^6J(\mathrm{C,F})/\mathrm{Hz} = 0.86\langle\sin^2\theta\rangle + 0.58\langle\cos^2\theta\rangle = 0.58 + 0.28\langle\sin^2\theta\rangle$$

It seems certain that $^6J_{90}^{\sigma,\pi} > {}^6J_0^{\pi}$, the reverse of the situation in styrene (23) and probably sensible because, in contrast to biphenyl, in styrene the pathway for $^6J^{\pi}$ involves a sidechain C=C bond with a mobile bond order of very near unity. The ratio of the computed $^6J_{90}^{\sigma,\pi}$ in Table 1 to that in eq. [3] is 0.59, almost exactly that for the corresponding numbers for 4-fluorophenylethane (23). Because of the interference between the two coupling mechanisms, the change in ^6J(C,F) caused by rotation about the exocyclic C—C bond is small, varying between 0.6 and 0.9 Hz as θ goes from 0 to 90°.

^nJ(C,F) in the fluorene derivative

While the θ dependence of $^{6,7,8}J$(C,F) and ^9J(F,F) in the biphenyl derivatives is rather simple and the magnitudes of these couplings at 90° can be reasonably inferred from the tetramethyl derivative, their magnitudes at 0° are somewhat uncertain. The latter are estimated above from the theoretical potentials. Suppose, however, that in acetone solution $\langle\theta\rangle$ is rather less than in the gas phase. Intramolecular magnetic dipolar splittings for 4,4′-dichlorobiphenyl dissolved in anisotropic media (8) imply a θ of 31.8°, actually smaller than the 39.4° found in the solid (33). The vibrational spectra of 4,4′-difluorobiphenyl indicate that θ is much the same as in biphenyl, 35–40°, both in solution (36).

Suppose now that $\langle\theta\rangle$ is as low as 30° for the two fluorine derivatives of biphenyl in solution and suppose that $\langle\cos^2\theta\rangle$ is near 0.75. Then ^9J(F,F) at 0° is 0.93 Hz while ^6J(C,F), ^7J(C,F), and ^8J(C,F) become 0.65, −0.27, and 0.53 Hz, respectively, at 0° for 4-fluorobiphenyl. These numbers deviate markedly from those measured in 2-fluorofluorene and 2,7-difluorofluorene (Scheme 1). The deviations are larger than those obtained with the theoretical internal rotational potentials.

Indeed, if the fluorene derivatives are taken as planar biphenyls, then the mechanism for ^6J(C,F) as given by eqs. [1]–[3] is incorrect; yielding $\langle\sin^2\theta\rangle$ as greater than unity in 4-fluorobiphenyl, for example, when the coupling constant to C-5 is employed.

This discussion implies that, for C,F coupling constants, the fluorene derivatives do not mimic planar biphenyl. The exocyclic C_{sp^2}—C_{sp^2} bond lengths in biphenyl, fluorene, and 9-fluorenone are 1.494(3), 1.486(6), and 1.475(5) Å, respectively (4, 37–39), in the solid state. If the $^{6,7,8}J$(C,F) depend on the mobile bond order of this linkage, then their apparent increase in magnitude in going from "planar" biphenyl to fluorene and 9-fluorenone is rationalized. Of course, this rationalization does not prove that the CH_2 and C=O groups are non-transmitters of π-electron spin-state information in these molecules (see below). Note, however, that coupling to C-5, formally a ^6J(C,F) if considered as transmitted via the C_{sp^2}—C_{sp^2} linkage, becomes a ^7J(C,F) or a ^9J(C,F) if the π-electron coupling goes via the C=O or CH_2 moieties. Presumably these pathways should provide a negative contribution to this coupling constant. Yet the coupling is large and positive. Similar remarks apply to the coupling constants involving C-6 and C-7.

Turning to the coupling constants involving the nonprotonated carbon atoms, note first that ^4J(C,F) in fluorobenzene is 3.20 Hz and has a large positive π-electron component (40). ^4J(C,F) has the same values in the two biphenyl derivatives

TABLE 2. Differential isotope shifts for ^{19}F caused by ^{13}C, in Hz at 282.363 MHz

Compound	$^1\Delta \pm {}^8\Delta$[a]	$^2\Delta \pm {}^7\Delta$	$^3\Delta \pm {}^6\Delta$		$^4\Delta \pm {}^5\Delta$
4,4′-DiF-biphenyl	23.77	6.62	1.309		0.679
2,7-DiF-fluorene	23.03	6.14[d]	1.134[b]	1.484[c]	0.698
2,7-Di-F-9-fluorenone	24.47	7.63[d]	1.002[b]	1.556[c]	0.478

[a] $^n\Delta$ is the shift to low frequency (high field) cause by ^{13}C situated n bonds away from ^{19}F counting via the C_{sp^2}—C_{sp^2} linkage. If all $^n\Delta$ have the same sign as $^1\Delta$, then the negative sign applies.
[b] For C-4 in Scheme 1.
[c] For C-10 in Scheme 1.
[d] These are the averages for C-1 and C-3. $^1\Delta \pm {}^8\Delta$ and $^2\Delta \pm {}^7\Delta$ are determined from the ^{19}F nmr spectra. The other shifts are obtained from the analysis of the ^{13}C nmr spectra.

above and in derivatives of 4-fluorotoluene (23), and changes by less than 0.1 Hz in 4-fluorostyrene (23). Yet in the fluorene derivatives ^4J(C,F) drops to 2.3 Hz. In the tetramethylfluorene compound, ^4J(C,F) is 3.05 Hz.

It is interesting, therefore, that 13 values of ^4J(C,F) in alternant and nonalternant hydrocarbon derivatives (29) correlate significantly with the mutual atom–atom polarizabilities computed (41) for the parent hydrocarbons, as in eq. [4]. A

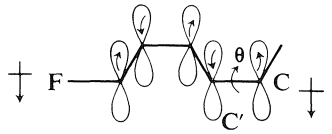
$$[4] \quad {}^4J(\mathrm{C,F}) = -0.98 + 40.24\,\pi_{pp'} \quad (r = 0.922)$$

precedent for such a correlation between the π-electron contribution to a coupling constant and the atom–atom polarizability, $\pi_{pp'}$, exists for the orthobenzylic coupling constant, $^4J(\mathrm{H,CH_3})$, in toluene derivatives (42). Equation [4] includes the diphenyl derivatives in this paper. The value of −0.98 Hz is then an estimate of the σ-electron contribution to ^4J(C,F). Now, if fluorene is conceived as an analog of the nonalternant hydrocarbon, dibenzofulvene (take the carbon atom of the methylene group as sp^2 hydridized and take appropriate linear combinations of the hydrogen orbitals to simulate a π-type orbital on the exocyclic methylene carbon atom of fulvene), then $\pi_{pp'}$ is 0.083 (41). Equation [4] yields ^4J(C,F) as 2.36 Hz compared with the observed value of 2.27 Hz (29).

In terms of this model, the methylene moiety in fluorene hyperconjugates with the aromatic π-electron system[4] and is therefore not a good mimic of planar biphenyl.

Unpublished work in this laboratory on long-range ^nJ(C,F) in derivatives of 4-fluoroacetophenone strongly implies that the carbonyl group is a relatively weak transmitter of π-electron spin-state information. In that event the ^4J(C,F) of 2.92 Hz in the 9-fluorenone derivatives is reasonable. On the other hand, the carbonyl moiety definitely enhances σ-electron coupling magnitudes and hence the ^5J(C,F) of 2.65 Hz to C-11 in these compounds is expected and observed to be larger than the corresponding ^5J(C,F) of 1.99 Hz in the fluorene compounds in Scheme 1. These ^5J(C,F) values, of course, also contain positive six-bond π-electron contributions via the C_{sp^2}—C_{sp^2} linkage. The notation, ^5J(C,F), used for C-11 coupling constants, forms an exception to the notation used elsewhere in this paper and is meant to emphasize the likelihood of a large positive σ-electron component.

The ^5J(C,F) values for the carbon-13 nucleus in the C_{sp^2}—C_{sp^2} linkage can be discussed as follows. The π-electron contribution to ^5J(C,F) is negative, being positive for ^4J(C,F) above. Schematically, as in **1**, it is known that the signs of the hyperfine interaction constants are $Q^F_{CF} > 0$, $Q^C_{CC} > 0$, and $Q^C_{C'C} < 0$ (44). Hence the indicated π-electron spin polarizations caused by



1

the ^{19}F magnetic moment all result in a negative $^5J^\pi$. The σ-electron contribution to ^5J(C,F) will be positive, as, for example, for ^5J(H,F) in fluorobenzene (29, 45). In the fluorene and fluorenone derivatives, ^5J(C,F) is indeed negative, implying that $|^5J^\pi| > |^5J^\sigma|$ when $\theta = 0°$. Assume that this relationship holds for biphenyl derivatives.

Now, as θ increases, the $2p\ldots2p\pi$ overlap decreases. The π-electron contribution originating in Q^C_{CC} will diminish, probably as $\cos^2\theta$. If $^5J^\sigma$ does not change, then ^5J(C,F) will decrease in magnitude. Indeed, ^5J(C,F) is +0.03 Hz in 4,4′-difluorobiphenyl, implying a near cancellation of the composite $^5J^\pi$ and the $^5J^\sigma$ near 45°. In the tetramethyl derivative, ^5J(C,F) is ±0.30 Hz. Unfortunately its sign is unknown and cannot be determined via differential isotope shifts because ^9J(F,F) vanishes in this compound. The model implies that ^5J(C,F) is positive, assuming that the methyl substituents do not alter the individual components except via their determination of θ as near 90°.

The model implies eq. [5]

$$[5] \quad {}^5J(\mathrm{C,F}) = {}^5J^\pi_0\langle\cos^2\theta\rangle + {}^5J^\pi_0 + {}^5J^\sigma$$

in which $^5J^\pi_0$ is the coupling constant arising from Q^C_{CC}, that is, from the π-electron density centered on the atom containing the coupled nucleus (see **1**). $^5J^\pi_1$ arises from $Q^C_{C'C}$. In the fluorene derivative $\langle\cos^2\theta\rangle$ is unity, whereas it is near zero in the tetramethyl compound. Taking $^5J^\pi_1 + {}^5J^\sigma$ as +0.30 Hz, yields $^5J^\pi_0$ as −0.80 Hz. Application of eq. [5] to 4,4′-difluorobiphenyl implies a $\langle\cos^2\theta\rangle$ of 0.41 or a $\langle\theta\rangle$ of 50°, instead of the 43° derived from the STO 3G MO computations.

Alternatively, the theoretical potential for 4,4′-difluorobiphenyl implies $^5J^\pi_0$ as −0.50 Hz and ^5J(C,F) in the planar form as −0.20 Hz. A plot of ^5J(C,F) versus the length of the C_{sp^2}—C_{sp^2} linkage in biphenyl, fluorene, and 9-fluorenone, assuming linearity over such a small change in length (see values above), yields ^5J(C,F) as −0.10 to −0.20 Hz, depending on how near planarity biphenyl is in the crystal (46). This rationalization is consistent with the apparently enhanced magnitudes of the long-range ^nJ(C,F) and J(F,F) values in the fluorene and 9-fluorenone derivatives, as discussed above. Clearly, the available structural information is insufficient to settle the coupling mechanism and eq. [5] remains tentative. Ideally, a series of 4,4-difluorobiphenyl derivatives with a range of θ values are needed.

[4] See a similar treatment of cyclopentadiene by Mulliken (43).

Finally, ^4J(C,F) for the methyl groups is ± 1.84 Hz. Because of the zigzag or omega (ω) arrangement of the intervening bonds, this coupling is probably dominated by a σ-electron mechanism. This could also be true for the ^4J(C,F) of 2.51 Hz in the fluorene derivative. The vanishing ^7J(C,F) in the tetramethyl derivative reflects a θ near 90° and a $\sigma-\pi$ (hyperconjugative) coupling interaction with the contiguous ^{13}C nucleus in the benzene ring as described in eq. [3]. Hence no ^7J(C,F) is expected, just as in 4-fluoro-*n*-propylbenzene, for example (23), and its absence can be taken as confirmation of the model represented by eq. [3].

Differential isotope shifts

$^1\Delta$ lies between 81 and 93 ppb in the mono and poly fluorobenzenes (47–51) and $^1\Delta \pm {}^8\Delta$ in Table 2 falls into this range, as expected. $^2\Delta \pm {}^7\Delta$ in Table 2 varies from 21.7 to 27.0 ppb, also within the reported range of the seven values found for $^2\Delta$ in the fluorobenzenes. Again, $^3\Delta$ in the difluorobenzenes samples values between 1.4 and 6 ppb, whereas $^3\Delta \pm {}^6\Delta$ brackets 3.5 and 5.5 ppb in Table 2. In 1,3-difluorobenzene, $^4\Delta$ is 4 ppb and is as large as 8 ppb in 1,3,5-trifluorobenzene. $^4\Delta \pm {}^5\Delta$ in Table 2, however, ranges from only 1.7 to 2.5 ppb, suggesting a $^5\Delta$ of the same sign as $^4\Delta$. No $^5\Delta$ numbers appear to be available. Finally, the differential isotope shifts in Table 2 appear not to depend on θ.

Acknowledgements

We thank Dr. Alberta Lemire for the synthesis of 4,4′-difluoro-2,2′,6,6′-tetramethylbiphenyl and the Natural Sciences and Engineering Research Council of Canada for financial assistance.

The pressure dependence of rates of homolytic fission of metal–ligand bonds in aqueous solution

KOJI ISHIHARA AND THOMAS WILSON SWADDLE
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 13, 1986

KOJI ISHIHARA and THOMAS WILSON SWADDLE. Can. J. Chem. **64**, 2168 (1986).

The volume of activation for the exclusively homolytic decomposition of protonated 4-pyridylmethylchromium(III) ion in aqueous $HClO_4$ at 63.4°C is $+19\ cm^3\ mol^{-1}$, with negligible dependence on pressure up to 350 MPa at least. The origins of the strongly positive volumes of activation that characterize homolysis of complex cations in aqueous solution are examined.

KOJI ISHIHARA et THOMAS WILSON SWADDLE. Can. J. Chem. **64**, 2168 (1986).

Le volume d'activation uniquement de la décomposition homolytique de l'ion méthyl-4 pyridyl chrome(III) protoné, à 63,4°C et en solution dans du $HClO_4$ aqueux, est égal à $+19\ cm^3\ mol^{-1}$; cette valeur ne varie pratiquement pas avec la pression jusqu'à 350 MPa. On discute des origines des valeurs extrèmement positives des volumes d'activation qui caractérisent l'homolyse des cations complexes, en solutions aqueuses.

[Traduit par la revue]

Introduction

There are relatively few authenticated cases of homolytic fission of metal–ligand bonds in aqueous coordination chemistry, and most of them involve Cr—C σ-bonds in organochromium complexes of the type $(H_2O)_5CrR^{2+}$, the chemistry of which has been reviewed by Espenson (1). There are two primary mechanisms for the decomposition of these complexes in acidic aqueous solution: heterolysis, which would in principle give initially $Cr^{3+}(aq)$ and the carbanion R^- but actually seems to produce RH together with the conjugate base of $Cr^{III}(aq)$:

$$[1]\quad (H_2O)_5CrR^{2+} + H_2O \xrightarrow{k_A} Cr(H_2O)_5OH^{2+} + RH,$$

and homolysis which gives initially chromium(II) and the organic free radical R•:

$$[2]\ (H_2O)_5CrR^{2+} + H_2O \underset{k_{-H}}{\overset{k_H}{\rightleftharpoons}} Cr(H_2O)_6^{2+} + R^\bullet \rightarrow \text{etc.}$$

Homolytic decomposition can be suppressed by addition of sufficient chromium(II) ion, or it can be driven at the limiting rate set by the first-order rate constant k_H by adding a scavenger such as O_2 or Cu^{2+} to eliminate $Cr^{2+}(aq)$ and (or) R• (2, 3). Reaction [1], however, cannot be suppressed, and turns out to be important in the decompositions of most CrR^{2+} species in acidic aqueous solution (indeed, it is usually acid-catalyzed).

In two suitable cases (R = $CH(CH_3)_2$ and $C(CH_3)_2OH$) in which k_H and the rate constant k_A for reaction [1] are similar under ambient conditions, it proved to be possible to measure the pressure dependence of the rate constants to obtain the corresponding volumes of activation ΔV_H^* and ΔV_A^* (Table 1) (4). This is intriguing inasmuch as ΔV_H^* and ΔV_A^* refer to isomeric transition states (in essence, $\{(H_2O)_6Cr^{2+}\ldots R^\bullet\}^*$ and $\{(H_2O)_5CrOH^{2+}\ldots HR\}^*$) for the decomposition of a given species. As Table 1 shows, activation via the homolytic pathway involves a remarkable expansion whereas heterolysis does not, and this was attributed (4) to the necessity of breaking up the solvent cage in homolysis to separate Cr^{2+} from R• if recombination is to be avoided and net reaction observed — a restriction that is irrelevant to heterolysis, which forms the product RH directly and irreversibly.

The measured volume of activation for homolytic decomposition of $(H_2O)_5CrCH(CH_3)_2^{2+}$, however, decreased significantly with increasing pressure beyond 100 MPa (4), i.e., the plot of ln k_H against pressure was curved. Such curvature is a common phenomenon, and is often associated with solvational change in the activation process (5), which in this case could be related to break-up of the solvent cage (4). Nevertheless, data from the 100–300 MPa region which defined this curvature were susceptible to systematic errors because the fraction $k_H/(k_H + k_A)$ of the total rate constant for decomposition that was due to homolysis became small at high pressures.

We have therefore measured k_H over a wide range of pressure for a reaction for which k_A is negligible (i.e., for which homolysis is the only detectable reaction pathway), namely, the decomposition of the protonated 4-pyridylmethylchromium(III) aqua-ion, $(H_2O)_5CrCH_2C_5H_4NH^{3+}$, in oxygenated aqueous $HClO_4$ (2, 3, 6).

Experimental

The general preparative and kinetic procedures have been described elsewhere (2, 3, 6). Rate constants were measured *in situ* with a Cary Model 17H spectrophotometer at 308 nm and 63.4°C; the light beam was allowed to pass through the sample only long enough to make intermittent absorbance measurements, so as to avoid possible photolysis of the organochromium complex (although there was no indication that this was ever significant). Samples were saturated with pure oxygen gas at 0°C before each kinetic run. For runs at high pressure, the samples were contained in a le Noble-Schlott cell (7) and pressurized with water in an Aminco high-pressure optical cell.

Because the reactions were slow, especially at the higher pressures, the first-order rate constants k_H were calculated by the Kedzy–Swinbourne method (8) from optical absorbance data collected over the first four half-lives; standard deviations were typically about 0.3%, and values of k_H obtained at atmospheric pressure were in excellent agreement with published data (2, 3).

Results

Two to four measurements of k_H were made at each of ten pressures P ranging from 0.1 to 350 MPa. The results are summarized in the semilogarithmic plot (Fig. 1) in which the error bars show the *range* in ln k_H values. Clearly, ln k_H is quite adequately represented by the linear relationship

$$[3]\quad \ln k_H = \ln k_H^0 - (\Delta V_H^*/RT)P$$

which gives $\Delta V_H^* = +18.9 \pm 0.3\ cm^3\ mol^{-1}$ and the zero-pressure rate constant $k_H^0 = 1.50 \times 10^{-4}\ s^{-1}$ (±1.6%), with a

[d]This work; $[Cr] = 5.2 \times 10^{-5}\ mol\ L^{-1}$; $[HClO_4] = 0.026\ mol\ L^{-1}$; 63.4°C.

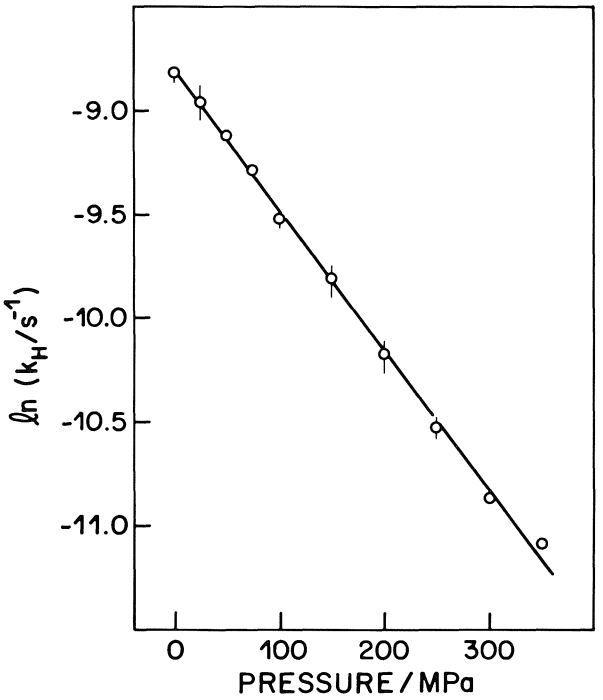

FIG. 1. Pressure dependence of ln k_H for the decomposition of 4-pyridylmethylchromium(III) ion in aqueous $HClO_4$ (0.026 mol L^{-1} at ambient conditions) at 63.4°C. Line represents linear fit of data (eq. [3]).

residual sum of squares of 0.0954. Only a minor improvement in fit (residual sum of squares = 0.0905) is achieved by going to a quadratic in pressure

$$[4] \quad \ln k_H = \ln k_H^0 - (\Delta V_H^{0*}/RT)P + (\Delta\beta_H^*/2RT)P^2$$

in which the zero-pressure volume of activation $\Delta V_H^{0*} = +20.0 \pm 0.9\ cm^3\ mol^{-1}$ and the mean compressibility coefficient of activation $\Delta\beta_H^* = -(\partial\Delta V_H^*/\partial P)_T$ for this pressure range is $(6.8 \pm 5.6) \times 10^{-3}\ cm^3\ mol^{-1}\ MPa^{-1}$. These uncertainty limits are standard deviations, so $\Delta\beta_H^*$ is not really significant at the 95% confidence level, but in any event it is only about one-tenth of that reported (4) for the 2-propylchromium(III) ion ($+(5.9 \pm 1.4) \times 10^{-2}\ cm^3\ mol^{-1}\ MPa^{-1}$).

Discussion

Table 1 shows that a large, positive volume of activation is characteristic of the homolytic pathway for decomposition of aqueous organochromium(III) complexes, regardless of the charge on the leaving organic radical, R•.

The $\Delta\beta_H^*$ data, however, raise the question as to whether ΔV_H^* is, in the general case, significantly pressure-dependent. When $^\bullet CH(CH_3)_2$ is the leaving group, the measured $\Delta\beta_H^*$ is large, but is derived from rate data at the higher pressures where k_H makes only a minor contribution and may therefore be subject to large systematic errors. For cationic $^\bullet CH_2C_5H_4NH^+$ as the leaving-group, k_H values at the higher pressures are more reliable than for the 2-propyl analogue because heterolysis is absent, and here $\Delta\beta_H^*$ is negligible. It is likely, however, that the marked curvature of the plot of ln k_H vs. P for the 2-propylchromium(III) case is real, and originates in a desolvation effect associated with neutral hydrocarbon radical release that may be minimized when *both* of the separating fragments (Cr^{2+} and $R^{+\bullet}$) are cations. In other words, solvent cage break-up need not imply desolvation, at least not when the escaping fragments are both cationic.

It is not feasible at present to attempt to account in a quantitative, absolute way for the large, positive values that are found for ΔV_H^*, but a crude estimate of $\Delta\Delta V^* = (\Delta V_H^* - \Delta V_A^*)$, i.e., the volume of activation for homolysis relative to heterolysis for the decomposition of a given aqueous organochromium(III) complex, can be made. A model introduced previously (9, 10) allows us to estimate that the (presently unmeasured) absolute molar volume of $Cr(H_2O)_6^{2+}(aq)$ is 20.7 $cm^3\ mol^{-1}$ larger than that of $Cr(H_2O)_6^{3+}(aq)$, and so, from the known volume of hydrolysis of the latter ion (11), 19.1 $cm^3\ mol^{-1}$ larger than that of $Cr(H_2O)_5OH^{2+}(aq)$. The contribution of a covalent hydrogen atom to the molar volume of an alkyl group is about 5.5 $cm^3\ mol^{-1}$ (12), and so, *solvation apart*, the radical R• should occupy that much less volume than RH. Thus, if the activation processes of heterolysis and homolysis can be approximated to the generation of the intermediates shown in reactions [1] and [2], $\Delta\Delta V^*$ should be about 14 $cm^3\ mol^{-1}$ if solvation of R and RH is ignored (solvation of the chromium ions is already taken into account). Table 1 indicates that this is a reasonable estimate; the excess in the experimental $\Delta\Delta V^*$ values probably reflects contributions from desolvation, and indeed is largest where $\Delta\beta_H^*$ is significant.

Finally, we consider other possible homolyses involving inorganic complexes in aqueous solution for which volumes of activation are available. It has been proposed (13) that the internal redox decomposition of the O-bonded sulfitopentaamminecobalt(III) ion in water involves a rate-determining initial step in which the $SO_3^{\bullet-}$ radical is created along with cobalt(II) — i.e., that the Co—OSO_2 bond undergoes homolysis:

$$[5] \quad Co(NH_3)_5OSO_2^+ \xrightarrow{\text{slow}} Co(NH_3)_5^{2+} + SO_3^{\bullet-} \rightarrow \text{etc.}$$

Our present study lends support to this interpretation, since the volume of activation is strongly positive ($+35\ cm^3\ mol^{-1}$ (13);

the pressure range was only 100 MPa, so experimental uncertainty may have obscured any curvature of the ln k vs. P plot). This volume of activation is unusually large by the standards set by Table 1, and may reflect homolysis with a change of spin state on going from cobalt(III) (singlet) to cobalt(II) (quartet), as this would be accompanied by substantial changes in metal–ligand bond lengths (14).

It might be thought that the markedly positive and pressure-dependent volume of activation ($\Delta V^{0*} = +16.0\,cm^3\,mol^{-1}$, $\Delta\beta^* = +2.1 \times 10^{-2}\,cm^3\,mol^{-1}\,MPa^{-1}$) for the acid-independent pathway for hydrolysis of azidopentaamminecobalt(III) ion (15) is indicative of a very plausible homolytic mechanism producing initially $Co(NH_3)_5^{2+}$ and the familiar $N_3^{\bullet}$ radical, with $Co^{2+}(aq)$ and gaseous nitrogen among the final products. The products of hydrolysis in dilute aqueous acid, however, appear to be exclusively $Co(NH_3)_5OH_2^{3+}$ and HN_3 (16), and certainly the reverse reaction in azide/hydrazoic acid buffer goes to at least 99% completion with very little reduction of cobalt(III) (17). The heterolytic interpretation advanced previously (15, 17) therefore remains appropriate.

We therefore conclude that a strongly positive volume of activation provides a valuable piece of confirmatory evidence in the assignment of homolytic mechanisms of decomposition of metal complexes in aqueous solution. Caution, however, must be exercised in the use of ΔV^* as a *prima facie* criterion of a homolysis mechanism, however plausible such a process may seem, unless there is supporting chemical evidence.

Influence of alkene structure on the formation constants of alkene–ICl molecular complexes

GEORGE H. SCHMID AND JAMES W. GORDON
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 14, 1986

GEORGE H. SCHMID and JAMES W. GORDON. Can. J. Chem. **64**, 2171 (1986).

The experimentally determined rate law for the addition of ICl to 22 alkenes in CCl_4 at 25°C under conditions of $(alkene)_0 \gg (ICl)_0$ is $-d(ICl)/dt = k_{exp}(alkene)_0(ICl)^3/\{1 + C_2(alkene)_0\}^3$. The constant C_2 is shown to be equal to K_{app} which is a measure of the formation constant or constants of the molecular complexes in this system. Under the experimental conditions used, C_2 is a good approximation of the formation constant of the 1:1 alkene–ICl molecular complex. Thus the values of C_2 obtained allow an estimate of the effect of alkene structure on the formation constant of the first molecular complex involved in this addition reaction. The contribution of the effect of substituents on C_2 is estimated to be approximately 24% of the overall change in rate due to change in the alkene structure.

GEORGE H. SCHMID et JAMES W. GORDON. Can. J. Chem. **64**, 2171 (1986).

Opérant dans le CCl_4, à 25°C et dans des conditions où la $(alcène)_0 \gg (ICl)_0$, on a déterminé expérimentalement que la loi de vitesse pour l'addition du ICl sur 22 alcènes est définie par l'équation $-d(ICl)/dt = k_{exp}(alcène)_0(ICl)^3/\{1 + C_2(alcène)_0\}^3$. On démontre que la constante C_2 est égale à K_{app} qui est une mesure de la constante de formation ou des constantes des complexes moléculaires impliqués dans ce système. Dans les conditions expérimentales utilisées, C_2 est une bonne approximation de la constante de formation du complexe moléculaire 1:1 alcène/ICl. Les valeurs de C_2 obtenues permettent donc d'évaluer l'effet de la structure de l'alcène sur la constante de formation du premier complexe moléculaire impliqué dans cette réaction d'addition. On a évalué que la contribution de l'effet des substituants sur C_2 est égale à environ 24% du changement global dans la vitesse du à un changement dans la structure de l'alcène.

[Traduit par la revue]

There is ample evidence in the literature (1–3) that molecular complexes or charge transfer complexes (CTC) as they are also called are involved on the reaction pathway prior to the rate determining step in electrophilic additions of bromine, chlorine, and iodine monochloride to alkenes. These complexes are defined according to Mulliken as σ–π CTC (4).

The existence of one or more complexes prior to the rate determining step introduces a complication in the interpretation of linear free energy relationships in electrophilic additions of bromine to alkenes because a change in alkene structure affects not only the rate determining step but also the value of the formation constant of the CTC. Thus the value of ρ obtained from such rate data is the sum of ρ for the formation of the complex or complexes and ρ for the rate determining step.

Based upon data from CTC formed between ketones and bromine, it was concluded that the effect of structure on the formation constants of the CTC is much smaller than the kinetic substituent effect. Consequently, it was assumed that ρ for the formation constant of the CTC is negligible as compared to ρ for the rate determining step (5). While values of formation constants have been measured for complexes of alkenes with bromine (6), ICl (7), and chlorine (8), the variation of alkene structure has not been sufficiently large to be able to verify this conclusion.

We have previously studied the rate of addition of ICl to a limited number of alkenes in CCl_4 at 25°C and have determined the experimental rate law (9). In this paper, we wish to show that from this rate law it is possible to extract a value of the formation constant of the ICl–alkene complex. In this way, we can for the first time determine the effect of substituents on this formation constant. We report these data in this paper.

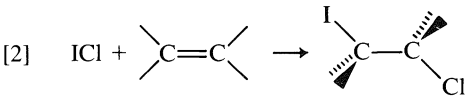
Results and discussion

The rates of addition of ICl to the 22 alkenes listed in Table 1 were measured by monitoring the disappearance with time of the ICl absorption at 460 nm by means of a Durrum–Gibson stopped-flow spectrometer. The rate measurements were made with $(alkene)_0 \gg (ICl)_0$. All data were treated in the same way as previously described (9) for addition to 2,3-dimethyl-2-butene. Treatment of the data in this way allows the reactivity of all alkenes to be described by the experimental rate law given in eq. [1].

$$[1] \quad -d(ICl)/dt = k_{exp}(alk)_0(ICl)^3/[1 + C_2(alk)_0]^3$$

The values of k_{exp} and C_2 from analysis of the rate law for all the alkenes are summarized in Table 1.

The addition of ICl to alkenes is a simple irreversible addition reaction (10) whose stoichiometry is shown in eq. [2].



From the rate data in Table 1, it is clear that this reaction is a typical electrophilic addition reaction.

While the stoichiometry of this reaction is simple, the experimental rate law, as given in eq. [1], is not. Furthermore, immediately upon mixing ICl and an alkene in CCl_4 at 25°C a new absorption band, absent in either reactant or product, appears in the ultraviolet region of the spectrum and decreases with time. This new band is assigned to the presence of an intermediate ICl-alkene molecular complex (9).

Based on evidence of a CTC, the rate law, and the experimentally determined enthalpy change during the reaction, the mechanism shown in Scheme 1 was proposed in a previous publication (9). This mechanism involves both 1:1 and 2:1 ICl–alkene complexes.

The value of formation constants of donor–acceptor complexes can be determined by a number of standard techniques (11). In our previous publication (9), we applied the Benesi–Hildebrand method to the variation of the initial absorbance values at 300 nm with varying initial concentrations of alkene where $(alkene)_0 \gg (ICl)_0$ in order to determine the value of

the formation constant for the ICl–alkene complex. Linear plots of $1/(\text{alkene})_0$ against the apparent extinction coefficient were obtained.

A major problem with this and other methods of determining values of the formation constants of donor–acceptor complexes is that it is difficult to establish the stoichiometry of the complex. The Benesi–Hildebrand method assumes a 1:1 stoichiometry for the complex. In theory, if a 2:1 complex is present in the system in appreciable amounts, nonlinearity of the Benesi–Hildebrand plot is predicted. However, in practice a linear plot can be obtained even in systems where both 1:1 and 2:1 complexes are present. This occurs under the following circumstances. Firstly, if the range of saturation fraction is low, a linear plot can be obtained.[1] Secondly, in the particular case where $K_1 = 4K_2$ (K_1 and K_2 are the formation constants for 1:1 and 2:1 complexes, respectively), a Benesi–Hildebrand plot will be exactly linear over the entire saturation range.

In our previous work (9), we found that the absorbance values at 300 nm disappear rapidly with time and follow a third order rate law. In order to obtain initial absorbance values, it was necessary to extrapolate back to zero time. This was possible as long as the rates of disappearance of the band at 300 nm could be measured by stopped-flow technique. At saturation fractions above 0.29, it was impossible to follow the rate and consequently, no initial absorbance values could be obtained. This means that our Benesi–Hildebrand plots are linear only at the low saturation fraction and no conclusion can be reached about the stoichiometry of the CTC observed in the reaction.

Deranleau (13, 14) has shown that the value of the formation constant obtained from the slope and intercept of the Benesi–Hildebrand plot at low saturation fraction is given by eq. [3].

$$\text{A} + \text{D} \underset{}{\overset{K_1}{\rightleftharpoons}} \text{AD}$$

$$\text{AD} + \text{A} \overset{K_2}{\rightleftharpoons} \text{A}_2\text{D}$$

$$\text{A}_2\text{D} + \text{A} \xrightarrow{k} \text{product}$$

A = ICl

D = 
SCHEME 1

[3] $$K_{app} = K_1\{1 - [(K_2)(E_2)/(K_1)(E_1)]\}$$

The quantities E_1 and E_2 are the extinction coefficients of the 1:1 and 2:1 complexes, respectively. We have followed the proposal of Deranleau and have given this formation constant the designation K_{app} (14). A K_{app} value of 19 ± 6 M^{-1} was obtained by this method for the addition of ICl to 2,3-dimethyl-2-butene (9).

A value of the formation constant of the complex or complexes can be obtained independently from the rate law derived from the mechanism in Scheme 1. For convenience, the following abbreviations are used. A = ICl; D = alkene. When $(\text{alkene})_0 \gg (\text{ICl})_0$, the following mass balance equations can be written.

$$(\text{A})_t = [\text{A}]_t + [\text{AD}]_t + [\text{A}_2\text{D}]_t$$

$$(\text{D})_0 = [\text{D}]_t$$

where $(\text{X})_t$ equals total concentration and $[\text{X}]_t$ equals free concentration of a reagent at time t. From these equations and

[1]The saturation fraction is defined according to ref. 13 as $s = K[\text{alkene}]/(1 + K[\text{alkene}])$, $0 < s < 1$.

the equilibrium constant expression, eq. [4] can be derived.

[4] $[AD] + K_1(D)[AD] + K_2[AD]^2 = K_1(A)(D)$

If we make the reasonable assumption,[2] that $K_2[AD]^2 \ll K_1(D)[AD] + [AD]$, then

[5] $[AD] = K_1(D)(A)/[1 + K_1(D)]$

and

[6] $[A_2D] = K_1K_2(D)(A)[A]/[1 + K_1(D)]$

From the mass balance equation, we can obtain the following equation for [A].

[7] $[A] = (A)/[1 + K_1(D) + K_1K_2(D)(A)]$

Since $-d(A)/dt = kK_1K_2[D][A]^3$, it follows that

[8] $$\frac{-d(ICl)}{dt} = \frac{kK_1K_2(alkene)_0(ICl)^3}{\{1 + K_1[1 + K_2(ICl)](alkene)_0\}^3}$$

Comparing eqs. [1] and [8], it follows that $kK_1K_2 = k_{exp}$ and $C_2 = K_1[1 + K_2(ICl)]$.

We know that for the addition of ICl to 2,3-dimethyl-2-butene $C_2 \approx K_{app}$. For this to be true, $K_2(ICl) < 1$ and $K_2E_2/K_1E_1 < 1$. Therefore C_2, obtained from the kinetic data, or K_{app}, obtained from data extrapolated to time zero, *while not exactly equal to* K_1, are both a good approximation of the formation constant of the first molecular complex involved in this reaction. Thus, it is possible to estimate the effect of alkene structure on K_1 from the value of C_2 obtained from the rate of addition of ICl to a series of alkenes.

It is clear from the values of C_2 given in Table 1 that the alkene–ICl complex stability increases as the hydrogen atoms on ethylene are successively replaced by alkyl groups. In two of the four series of alkenes, the nature of the alkyl substituent has little effect on the value of C_2. Thus the values of C_2 for propene, 1-butene, 3-methyl-1-butene, and 3,3-dimethyl-1-butene are the same within experimental error. In the other series the introduction of bulky substituents such as isopropyl and *tert*-butyl groups decreases the stability of the complex. These data are in accord with previous work by Dubois (16) who established a spectroscopic measure of CTC stability called Γ. Values of Γ determined in Freon 112 show a similar variation with alkyl substituents within a particular alkene type.

One way to estimate the steric effects within the ICl–alkene CTC is to compare their values of C_2 with a series of complexes in which there is little or no steric hindrance. Such a system is a series of phenol–alkene complexes whose stabilities have been determined by the frequency shift, $\Delta\nu$, of the OH stretching frequency of the complexes in CCl_4 (17). ICl and phenol are similar in that both are σ acceptors but they differ greatly in their steric requirements for complex formation. Since phenol has a low steric requirement for complex formation, it is assumed that in the reaction of phenol and alkenes the only change in entropy is the loss of translational entropy which is constant for the series. Therefore it is possible to compare $\Delta\nu$, a measure of enthalpy change, with C_2, a measure of the free energy change in the system. The plot of ΔG (which is equal to $RT \ln C_2$) vs. $\Delta\nu$ is given in Fig. 1.

[2]When concentrations of [ICl] and $(D)_0$ in the range used experimentally and reasonable values of K_1 and K_2 are chosen, this condition is fulfilled. For example: if $[ICl] = [AD] = 10^{-3}$; $K_1 = K_2 = 20$; and $(D)_0 = 10^{-2}$, then $K_2[AD]^2 = 2 \times 10^{-5}$ and $K_1(D)_0[AD] + [AD] = 10^{-3}$.

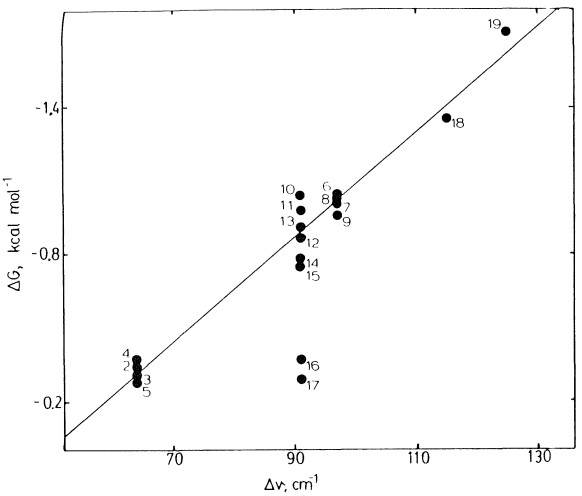

FIG. 1. Correlation of alkene–ICl complex stability, ΔG, with the numbers and the corresponding alkenes are **2**, propene; **3**, butene-1; **4**, 3-methylbutene-1; **5**, 3,3-dimethylbutene-1; **6**, methylpropene; **7**, 2-methylbutene-1; **8**, 2,3-dimethylbutene-1; **9**, 2,3,3-trimethylbutene-1; **10**, *Z*-butene-2; **11**, *Z*-pentene-2; **12**, *Z*-4-methylpentene-2; **13**, *Z*-4,4-dimethylpentene-2; **14**, *E*-butene-2; **15**, *E*-pentene-2; **16**, *E*-4-methylpentene-2; **17**, *E*-4,4-dimethylpentene-2; **18**, 2-methylbutene-2; **19**, 2,3-dimethylbutene-2.

The values of $\Delta\nu$ are insensitive to the steric bulk of the substituent within a given alkene type. This is shown in the value of $\Delta\nu$ which is the same for compounds **2**, **3**, **4**, and **5**, all monsubstituted terminal alkenes.

If there were no steric effects in the ICl–alkene complexes, a good linear correlation between log C_2 and $\Delta\nu$ would be expected. The points in Fig. 1 do follow a general linear trend with a few notable exceptions. The points for all the alkenes except the 1,2-disubstituted alkenes fit reasonably well on the line. The two alkenes *E*-4-methylpentene-2 (**16**) and *E*-4,4-dimethylpentene-2 (**17**) deviate markedly from the line. Furthermore, while there is no difference in the stability of complexes formed between isomeric *E*- and *Z*-alkenes and phenol, a *Z*-alkene complexes more strongly with ICl than does the isomeric *E*-alkene. This difference between *E*- and *Z*-isomeric alkenes is also found in their rates of addition of Br_2 (18), arenesulfenyl chlorides (19), Cl_2 (20), and areneselenenyl chlorides (21). From our data, we can conclude that the cause of this difference in rates of additions to isomeric *Z*- and *E*-alkenes is present also in their molecular complexes prior to the rate determining step.

Several explanations have been advanced to explain this reactivity difference. Dubois originally postulated that relief of some of the ground state steric strain present in the *Z*-alkene was occurring in the transition state (22). However, the lack of correlation of *E*/*Z* reactivity with the difference in ground state strain of isomeric alkenes has been cited as evidence against such an explanation (23). Steric interaction between electrophile and alkene in which approach to the *Z*-alkene is less sterically hindered relative to the corresponding *E*-alkene has been postulated to explain the large rate difference in the addition to *E*- and *Z*-1,2-di-*tert*-butylethylenes (24).

A more likely general explanation is that there is less entropy loss on activation of the *Z*-alkene. Since there is more rotational entropy available in the *E*-alkene than in the corresponding *Z*-alkene, there will be a greater loss of entropy in the *E*-alkene

upon complex formation and subsequent reaction. This results in a lower complex stability and a slower rate. The effect is more marked as the alkyl group becomes more complex in the 1,2-disubstituted series as shown by the $C_2(Z)/C_2(E)$ ratios for the series $CH_3CH{=}CHR$: CH_3, 1.6; C_2H_5, 1.5; $CH(CH_3)_2$, 2.3; $C(CH_3)_3$, 2.9.

While it is possible to determine how substituents affect C_2, the effect of such substitution on the rate of addition of ICl to alkenes cannot be exactly determined from our data in Table 1. The reason for this is clear from the rate law (eq. [8]) derived from Scheme 1. The experimentally obtained rate constant k_{exp} is the product of the rate constant of the slow step, k, and two equilibrium constants, $C_2 \approx K_1$ and K_2. The quantity k_{res}, obtained by dividing k_{exp} by C_2 is equal to kK_2. It is impossible from our data to determine values of K_2 and consequently the effect of alkene structure on values of K_2.Thus it is impossible to obtain values of k from kK_2.

However, it is possible to estimate the contribution of the effect of substituents on C_2 to the overall value of ρ simply by considering the effect on C_2, k_{exp}, and k_{res} of replacing the hydrogens of propene by methyl groups. Plots of log C_2, log k_{exp}, and log k_{res} vs. the number of methyl groups are all linear giving the following Taft ρ values. For C_2, -0.67 ± 0.09; k_{exp}, -2.8 ± 0.2; k_{res}, -2.0 ± 0.3. Thus the effect of alkene structure on the value of C_2 contributes approximately 24% of the overall change in rate due to changes in the alkene structure. This is a substantial amount even without considering structural effects on the value of K_2. While we do not have the data, we can make an estimate from data in the literature. In cases where both 1:1 and 1:2 molecular complexes have been shown to exist and their values have been determined, K_2 is usually less than K_1 (15). In addition it would be expected that due to saturation, the effect of substituents on K_2 would be smaller. If we assume that as a maximum, the value of ρ for K_2 would be equal to that for K_1, then almost half of the overall change in rate would be due to substituent effects in the equilibrium reaction occurring prior to the rate determining step.

From this analysis of our data, we caution that comparing ρ values of even similar kinds of reactions may lead to erroneous mechanistic conclusions. For example, the first step is rate determining in the mechanism of the addition of arenesulfenyl chlorides with alkenes in nonpolar solvents (12). Thus a value of ρ obtained from these rate data is a true measure of substituent effects on an elementary reaction. This value of ρ cannot be compared with that obtained from experimental rate constants for the addition of ICl to alkenes in nonpolar solvents because the latter value of ρ measures the effect of substituents not on a single elementary reaction but on the sum of three consecutive reactions.

Experimental

All of the liquid alkenes were commercially available from Chemical Samples Co. Gaseous alkenes were obtained from Matheson Co. Iodine monochloride (Sargent-Welch) was purified by fractional crystallization from the melt, discarding the remaining liquid portion. ACS grade carbon tetrachloride was found to be satisfactory without further purification. Use of dried and carefully fractionated carbon tetrachloride did not affect the rates of addition. Solutions were prepared by weight. The concentration of propene in solution was determined by titration with bromine. The concentration of ethylene in solution was determined by titration with iodine monochloride. In both cases the amount of excess halogen was determined spectrophotometrically. All solutions were prepared at room temperature.

The rate of addition of iodine monochloride to the alkenes was determined by monitoring the disappearance with time of the iodine monochloride absorption at 460 nm by means of a Durrum–Gibson stopped-flow spectrometer. The rate measurements were made with $(\text{alkene})_0 \gg (\text{ICl})_0$.

The high reactivity of *E*-1-(4-methoxyphenyl)propene limited the concentration of alkene to the range 0.002 *M* to 0.015 *M* with an iodine monochloride concentration of about 3×10^{-4} *M*. Under these dilute conditions, k_{app}, when plotted against $(\text{alkene})_0$, gave a straight line described by a zero intercept and slope equal to k_{exp}.[3] With ethylene, the highest concentration obtainable was only 0.055 *M*. The low reactivity did not permit working with dilute solutions as in the case of *E*-1-(4-methoxyphenyl)propene. The initial absorbance readings agreed with the values predicted by assuming that none of the iodine monochloride was complexed. Thus k_{exp} was obtained as the average value of $k_{app}/(\text{ethylene})_0$.

Thermolysis of *N*-alkylated ethylenediamines: an ultraviolet photoelectron spectroscopy study

N. H. WERSTIUK

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 8, 1986

N. H. WERSTIUK. Can. J. Chem. **64**, 2175 (1986).

Thermolyses of *N,N,N',N'*-tetramethylethylenediamine (**1***a*), *N,N,N',N'*-tetraethylethylenediamine (**1***b*) and *sym-N,N'*-dimethylethylenediamine (**1***c*) at 760–825°C have been studied by ultraviolet photoelectron spectroscopy. Although the corresponding *N*-alkylated aminomethylene radicals were not observed, this study establishes that thermolysis of **1***a* is an efficient route to *N*-methylenimine (**3***a*); methane, ethane, and ethene are the other major products. Diamine **1***b* yields, besides ethane, ethene, and propane, heretofore unreported *N*-ethylmethylenimine (**3***b*). Diamine **1***c* yields imine **3***a* and methylenimine (**3***c*), as well as hydrogen, methane, ethane, and ethene. Molecular orbital eigenvalues of the imines are calculated using HAM/3, MNDO, HF/STO-3G, HF/3-21G, and HF/6-31G* methods.

N. H. WERSTIUK. Can. J. Chem. **64**, 2175 (1986).

Faisant appel à la spectroscopie photoélectronique ultraviolette et opérant entre 760 et 825°C, on a étudié la thermolyse de la *N,N,N',N'*-tétraméthylènediame (**1***a*), de la *N,N,N',N'*-tétraéthylènediamine (**1***b*) et de la *N,N'*-diméthylènediamine symétrique (**1***c*). Même si l'on n'observe pas la formation des radicaux aminométhylènes *N*-alkylés correspondants, cette étude a permis d'établir que la thermolyse du composé **1***a* est une méthode efficace d'obtenir la *N*-méthylèneimine (**3***a*); le méthane, l'éthane et l'éthylène sont les autres produits majeurs. La diamine **1***b* conduit, aux côtés de l'éthane, de l'éthylène et du propane, à la *N*-éthylméthylèneimine (**3***b*) qui n'avait pas été décrite jusqu'à maintenant. La diamine **1***c* conduit à l'imine **3***a* et à la méthylèneimine (**3***c*) ainsi qu'à de l'hydrogène, du méthane, de l'éthane et de l'éthylène. On a calculé les valeurs de eigen des orbitales moléculaires des imines en faisant appel à des méthodes HAM/3, MNDO, HF/STO-3G, HF/3-21G et HF/6-31G*.

[Traduit par la revue]

Introduction

Over the last decade uv photoelectron spectroscopy has been used extensively to study transient species in the gas phase. A variety of highly reactive molecules and free radicals have been generated and their p.e. spectra recorded for identification and to study bonding. This unconventional use of p.e. spectroscopy yields information about electronic structure of transients which can be obtained by no other technique. To assist in the identification of species and to assign the ionization energies (IEs) to specific molecular orbitals these studies are usually accompanied by calculations of molecular orbital eigenvalues (MOEs).

This publication documents an attempt to determine the IEs of the *N,N*-dimethylaminomethylene radical ($(CH_3)_2NCH_2\cdot$) — two different values (5.7 and 5.35 eV) have been reported (1, 2) — by using gas phase thermolysis of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) (**1***a*) at 790°C as its source. Accounts of the thermolyses of *N,N,N',N'*-tetraethylethylenediamine (TEEDA) (**1***b*) and *sym-N,N'*-dimethylethylenediamine (*s*-DMEDA) (**1***c*) are given as well, along with the MOEs calculated for *N*-methylmethylenimine (**3***a*), *N*-ethylmethylenimine (**3***b*), and methylenimine (**3***c*) using HAM/3 (3), MNDO (4), HF/STO-3G (5), HF/3-21G (5), and HF/6-31G* (5) methods.

Experimental

The spectrometer used in this study is described elsewhere (6). Spectra were calibrated by N_2 or Ar. Temperature was measured by a digital thermometer using a type-K thermocouple located mid-way along the hot zone of the furnace. Thermolyses were carried out at $>1 \times 10^{-5}$ Torr[1] in a silica tube heated to 760–825°C depending on the substrate used. Two furnaces were used for thermolyzing TMEDA. For thermolysis of TMEDA, TEEDA, and *s*-DMEDA, a 40-cm furnace with a hot zone of approximately 20 cm was used with a 10-cm "U"-trap located between the pyrolysis tube and the spectrometer. That the furnace had no effect on the count rate and resolution was established by comparing the spectra of air obtained with the furnace off and with the furnace on. To maximize the probability of detecting the *N,N*-dimethylaminomethylene radical, several thermolyses of TMEDA were also carried out by a 3-cm non-inductively wound furnace located in a housing 2 cm above the ionization cup of the spectrometer and the system was fast-pumped. To calibrate the spectrometer with respect to the detection of radicals with this furnace, azohydroperoxide **2**, a source of *t*-butyl radicals,[2] was thermolyzed at 350°C. To separate the products of the diamines, the "U"-trap was cooled with liquid nitrogen and the thermolysis was carried out for 1–2 h as 200–300 scans were accumulated. The flow of substrate was stopped, most of the liquid nitrogen was blown away with a stream of air, and, as the trap was allowed to warm up gradually, the low-temperature distillation was monitored by recording p.e. spectra. Bock *et al.* (7) have used this method to detect 2*H*-azirine. When possible, at least 20 scans were accumulated for each species obtained from the distillation. In all cases, the products exhibited sufficiently different volatilities making analysis of the products an easy matter. In the case of TEEDA, the yield of highly reactive **3***b* was reduced because it was necessary to warm the trap more than in the case of

[1] The pressure was measured below the analyzer. The pressure in the thermolysis tube is expected to be substantially higher.

[2] The author thanks Professor J. Warkentin for a sample of **2**. Studies of other azohydroperoxides are planned.

TMEDA and *s*-DMEDA. Where spectrum stripping was necessary, VISICHARTAD, a program for the APPLE II+ available from Interactive Microware was used. Spectra of methane, ethane, propane, butane, and ethene were obtained and used as standards.

Results

Thermolysis of N,N,N′,N′-*tetramethylethylenediamine (TMEDA)* (*1*a)

The p.e. spectra of TMEDA and its thermolysate produced at 790°C are given in Fig. 1 as 1*A* and 1*B*, respectively. From 1*B* it is seen that thermolysis is essentially complete at a pressure $>1 \times 10^{-5}$ Torr and that the spectrum is dominated by four peaks; at 9.8, 11.3, 13.4, and 15.9 eV.[3] During the trapping with liquid nitrogen, spectrum 1*C* was obtained. After 2 h, the flow of TMEDA was stopped, the trap was allowed to warm up slowly and p.e. spectra were obtained as the pressure was maintained roughly constant by opening and closing the fast-pumping valve. Spectrum 1*D* was obtained first, followed by spectra 1*E* and 1*F*. Spectrum 1*C* collected during the thermolysis identifies methane as one of the products, in keeping with the fact that it is not trapped at −196°C. It is established from the bands of spectrum 1*D*, a composite of ethene and ethane, that ethene is a minor product. This result identifies the small peaks at 10.5–10.7 eV of spectrum 1*B*. This is also in accord with the fact that this product distills after a slight warming of the trap. Spectrum 1*E* identifies ethane as a major product of thermolysis and spectrum 1*F* corresponds to the p.e. spectrum of *N*-methylmethylenimine (**3***a*) reported previously (8). When the trap was warmed to ambient temperature a spectrum of TMEDA was obtained. By warming the viscous liquid remaining in the trap, a spectrum corresponding to the trimer of *N*-methylmethylenimine was obtained (8). Analysis of this residue by ^{1}H nmr yielded a spectrum consistent with assignment of the p.e. spectrum.

When TMEDA was thermolyzed by the 3-cm furnace with fast pumping and with scanning beginning 4 eV below the lowest IE of TMEDA, no peak was detected in the region where the radical was expected. To "calibrate" the system with respect to the detection of radicals, azohydroperoxide **2** was thermolyzed at 350°C with fast pumping and the *t*-butyl radical was detected by its IE at 7 eV (9).

Thermolysis of N,N,N′,N′-*tetraethylethylenediamine (TEEDA)* (*1*b)

The p.e. spectra of TEEDA and its thermolysate, obtained at 760°C, are given in Fig. 2 as 2*A* and 2*B*, respectively. Spectrum 2*B* is dominated by peaks at 9.7, 11.1, 12.3, 13.3, 14.0, 15.0, and 16.0 eV.[3] When the products were trapped by liquid nitrogen and a spectrum acquired over the 2-h period, no significant features above background were evident. This indicates that unlike the case of TMEDA, methane is not a major product of thermolysis. When the trap was warmed slowly, a spectrum of ethene shown as 2*C* is obtained indicating that it is a major product of thermolysis. In fact, the peak of lowest binding energy of ethene is seen at 10.4 eV of 2*B*. As the trap was warmed slowly a "transition" spectrum was obtained that appeared to be predominately due to ethane. Furthermore, the broad peak with an on-set at approximately 10.5 eV of 2*C* is consistent with the presence of a small amount of ethane. As the trap was warmed further, spectrum 2*D* corresponding to propane was obtained. In several runs, a "transition" spectrum that appeared to be *N*-methylmethylenimine (**3***a*) was observed as well. Finally spectrum 2*E* was obtained. Some difficulty was experienced in obtaining a good spectrum of this product even though it is clear, by comparison to 2*B*, that it is one of the major products of thermolysis. When the trap was allowed to warm to ambient temperature, a viscous film remained. Further warming of the trap to 30°C yielded a spectrum of TEEDA, in keeping with the fact that thermolysis is incomplete.

Thermolysis of sym-N,N′-*dimethylethylenediamine (s-DMEDA)* (*1*c)

Unlike the thermolyses of TMEDA and TEEDA, a temperature of 825°C was required to achieve significant conversion of *s*-DMEDA to products. The spectra of *s*-DMEDA and its thermolysate are given in Fig. 3 as 3*A* and 3*B*(1), respectively. Although spectrum 3*B*(1) is rather featureless except for the band between 8–9 eV, considered to be due to *s*-DMEDA, this component was selectively trapped by solid Dry Ice, yielding 3*B*(2). The peaks at 13.7–14 eV of 3*B*(2) are due to HCN (10, 11) and the peaks at 15.6–17 eV are due to N_2 used as the calibrant. Application of the method — trapping followed by low temperature distillation — used successfully in this study yields a remarkable resolution of the spectrum. Spectrum 3*C*, acquired as the products were trapped by liquid nitrogen, establishes that methane, and hydrogen — identified by the group of sharp peaks at 15.5–18 eV — are products of thermolysis. When the trap was allowed to warm up slowly over a period of 1.5 h, 3*C*, 3*D*, 3*E*, and 3*F* as well as several "transition" spectra were obtained, one of which, after spectrum stripping, established that propane is a minor product. Spectra 3*D* — the shoulder at 11.5 eV is due to ethane — and 3*E* identify ethene and ethane as major products. Aside from including a small amount 3*G* that was stripped to yield 3*F*(2), 3*F*(1) is the spectrum of *N*-methylmethylenimine (**3***a*). The low-intensity, sharp peaks at 10.5 of 3*F*(1) and 3*F*(2) could be due to ammonia (10). Spectrum 3*G*(2), obtained after 3*G*(1) was stripped of 3*F*(2), is the best spectrum of methylenimine (**3***c*) reported to date (11, 12). The distillation also established that *N*-methylmethylenimine has a lower boiling point than methylenimine.

Discussion

It is clear from this study that thermolysis of TMEDA in a silica tube at 790°C provides a simple, one-step, high-yield route to highly reactive *N*-methylmethylenimine (**3***a*). In Table 1 are listed the experimental IEs as well as the molecular orbital eigenvalues (MOEs) calculated using MNDO, HF/3-21G, and HF/6-31G* methods. The results complement the calculations already carried out on this molecule (13). That **3***a* is one of the major products is consistent with cleavage of the C—C bond to form the dimethylaminomethylene radical (pathway *a*, Scheme 1). However, under the conditions required to cleave the bond, the life-time of the radical is expected to be short because β-scission to **3***a* and a methyl radical is fast. Subsequently, the methyl radical abstracts hydrogen to form methane and dimerizes to ethane. Although it is possible that ethene is formed by dehydrogenation of ethane at 790°C, an alternative route to this product, along with **3***a* and a methyl radical, is shown as pathway *b*. It will be of interest to carry out the thermolysis of TMEDA on a larger scale and establish by suitable experiments whether or not **3***a* is a useful synthon.

From the products, it appears that thermolysis if TEEDA proceeds via a mechanism (pathway *a*, Scheme 2) similar to the one proposed for TMEDA, and, *N*-ethylmethyleneimine (**3***b*),

[3]Due to the broadness of the bonds the errors in the IEs are estimated to be in the region of ±0.1 eV.

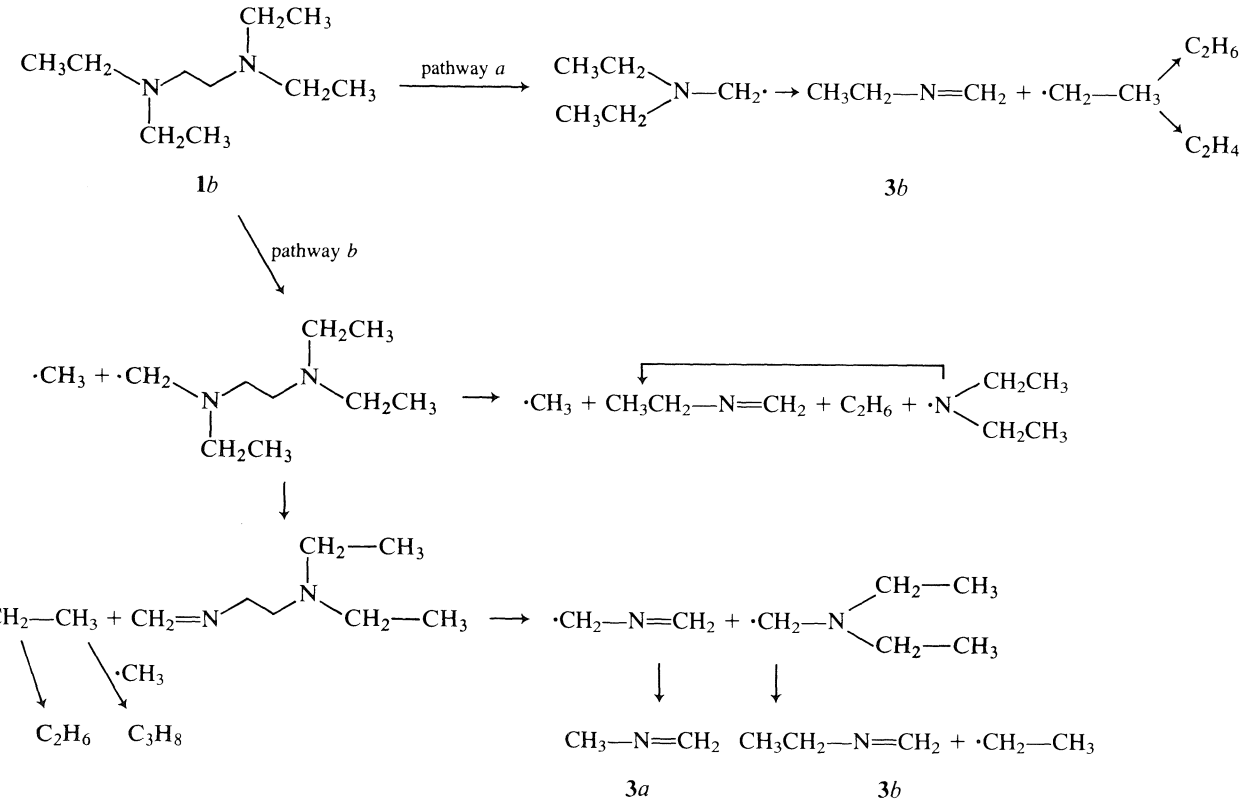

SCHEME 2

heretofore unreported, is a major product. Ethene, also a major product, could result from loss of a hydrogen atom from the ethyl radical formed by β-scission of the *N*,*N*-diethylaminomethylene radical. Unlike the case of TMEDA where R· dimerizes, the dimer of $CH_3—CH_2·$ is not observed presumably because loss of a hydrogen atom is fast. However, this mechanism does not account for the formation of propane, also a major product. An attractive alternative is shown as pathway *b*. Cleavage of a C—C bond of an ethyl group followed by further bond cleavages yields **3***a*, ethene, methyl radicals, and ethyl radicals which lead to the other products. That methane is not formed in significant amount may be a consequence of the

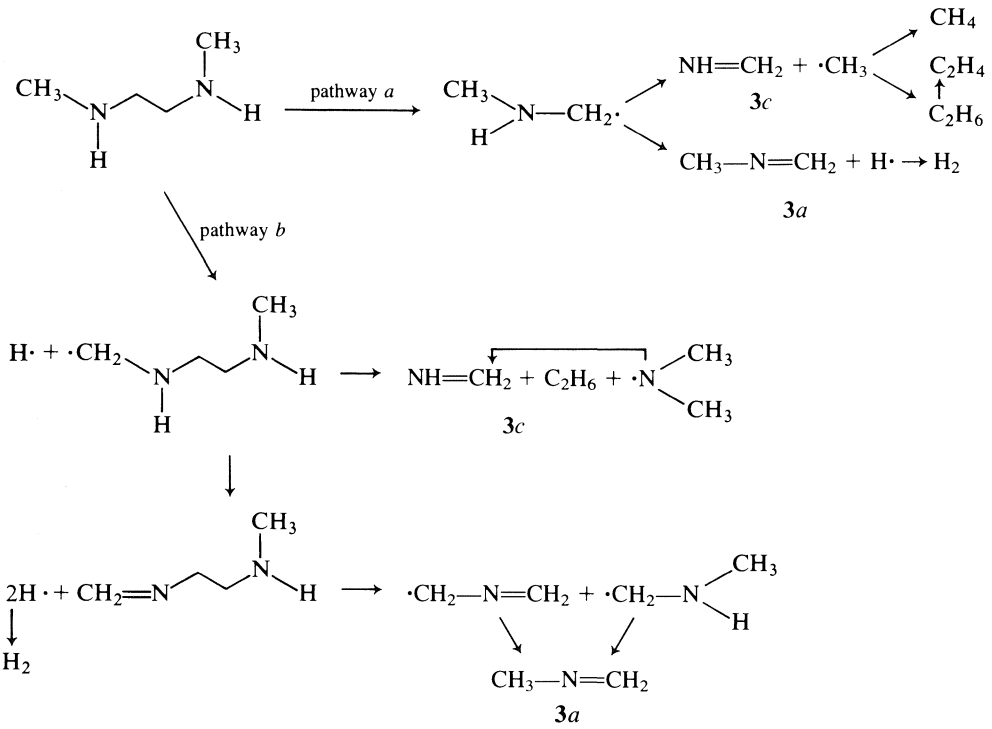

SCHEME 3

fact that methyl radicals are scavenged by ethyl radicals. The small amount of **3***a* observed in "transition" spectra in several thermolyses could result from decomposition of **3***b* to the 2-azaallyl radical (CH_2=N—CH_2·) or from decomposition of the intermediate CH_2=N—CH_2—CH_2R shown in pathway *b*. Whatever the route to propane and **3***a*, thermolysis of TEEDA appears to be more complex than thermolysis of TMEDA. Nevertheless, that **3***b* is a major product is clear from spectra 2*B* and 2*E*, the nature of the other products, its volatility in the low temperature distillation — it distilled after propane — and by the fact the IEs of the "lone-pair" and the "π-system" are slightly lower (~0.1 eV) than the IEs of **3***a*. These differences are comparable to the small differences in IEs reported for *N*-methyl- and *N*-ethylimines **5** (14) and **6** (15). The results of calculations listed in Table 2 also support the assignment of spectrum 2*E* to **3***b*.

Thermolysis of *s*-DMEDA can also be rationalized on the basis of a mechanism (Scheme 3) that is identical to the one suggested for TMEDA (Scheme 1). That a higher temperature is required to achieve significant conversion of *s*-DMEDA is in keeping with an expected lower stability of the *N*-methylaminomethylene radical — relative to its fully alkylated analogue — which is reflected in the C—C dissociation energy. That imines **3***a* and **3***c* are obtained in roughly equal yields, based on the number of scans which were acquired at the same pressure, indicates that cleavage of the C—H and C—C bonds is equally likely. However, this pathway does not account for the formation of ethene, a major product, unless it is formed by dehydrogenation of ethane. An alternative mehanism, shown as pathway *b*, which leads to ethene, **3***c* and H_2 involves initial cleavage of a C—H bond to yield an *N*-alkylaminomethylene radical that undergoes further decomposition.

Calculation of molecular orbital eigenvalues (MOEs)

The geometry used in the calculations on **3***a*, shown as **3***a*Cl (Fig. 4), was obtained by microwave spectroscopy (16, 17). It is seen in Table 1 that MNDO yields MOEs which closely parallel the experimental IEs although the binding energy of the "lone-pair" is somewhat high. That the calculations yield MOEs — especially those obtained by MNDO optimization of the experimental geometry — which closely approximate the IEs, indicates that this method can be used to identify simple imines with some degree of confidence. Hence the data in Table 2 provide support that **3***b* is indeed a product of thermolysis of TEEDA. Although the geometry of **3***b* is unknown, calculations were initially carried out on a geometry based on **3***a*Cl, a NCC bond angle of 109.3°, CCH angles of 109.3°, and C—C and C—H bond lengths of 1.540 and 1.091 Å, respectively. The good correlation between the experimental IEs and the calculated MOEs (column 2, Table 2) validates this assumption and supports the conclusion that **3***b* is a product of thermolysis of TEEDA. MNDO optimization (see **3***b*Cl, Fig. 4) of the trial geometry yields a better fit of the MOEs (column 3, Table 2) and the experimental IEs. The same general trends in the MOEs are observed for **3***b* as are observed for **3***a*. Both 3-21G and 6-31G* bases yield MOEs which are reasonably close to the IEs although the fit is not quite as good at higher energies. However, if 92% of the Koopmans' values are used (18), the fit is improved. Although the fit at higher IEs is reasonably good when the STO-3G basis is used, the MOEs for the "lone pair" and the "π-system" are somewhat low. Optimizations using 3-21G and 6-31G* bases was not carried out because of the cpu time required relative to MNDO.

MOEs were also obtained for two other conformations of **3***a*: **3***a*C2 (MNDO opt.; 10.62, 11.43, 13.47, 14.95, 15.87, and 16.69) and **3***a*C3 (MNDO; 10.84, 11.37, 13.76, 15.13, 16.09, and 16.58). MOEs (10.60, 11.40, 13.07, 13.09, 13.47, 15.63, 15.64, 16.80) were also calculated for the zig–zag conformation of **3***b* shown as **3***b*C2 (Fig. 4) using MNDO with optimization.

Calculations carried on the experimental geometry[4] (19) of **3***c* complement the calculations carried out previously (10). In this connection it is useful to point out, once again, the utility of MNDO. The experimental geometry of the CH_2=N— fragment of **3***a* (see **3***a*Cl, Fig. 4), was used with an assumed =N—H bond length of 0.99 Å (20) and the parameters optimized using MNDO (see **3***c*C, Fig. 4) to calculate the MOEs (column 1, Table 3). The correlation between the parameters obtained by optimization and the experimental values is good. The MOEs obtained by optimizing the experimental geometry[4] (column 2, Table 3) are identical to the values obtained by optimizing the trial geometry. This indicates that accurate experimentally-obtained geometries will not be required to obtain MOEs which will be useful for identifying other, as yet unknown, imines.

[4]Geometry: *r*CN = 1.273, *r*NH = 1.021, *r*CH = 1.09 Å, ∠HNC = 110.4, ∠HCH = 117.0, and ∠NCH(*cis*) = 125.1, ∠NCH(*trans*) = 117.9°.

Synthesis and in vitro activity of several new carbapenems

YASUTSUGU UEDA[1] AND VIVIANE VINET

Antiinfective Chemistry Department, Pharmaceutical Research and Development Division, Bristol-Myers Co., 100 Industrial Blvd., Candiac (Qué.), Canada J5R 1J1

Received March 12, 1986

YASUTSUGU UEDA and VIVIANE VINET. Can. J. Chem. **64**, 2184 (1986).

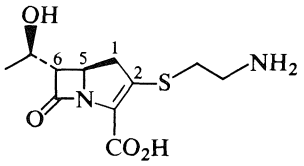
The synthesis and in vitro activity of several new carbapenems, 2-(3-*cis*-substituted cyclopentylthio)- and 2-(4-*cis*-substituted cyclohexylthio)-(6*S*)-[(1′*R*)-hydroxyethyl]-(5*R*)-carbapen-2-em-3-carboxylic acids **7** and **8**, are described. The synthesis involves the stereospecific preparation of *cis*-substituted cyclopentyl- and cyclohexylthiols **2** and **3** by the hetero Diels–Alder reaction followed by some chemical manipulations.

YASUTSUGU UEDA et VIVIANE VINET. Can. J. Chem. **64**, 2184 (1986).

On décrit la synthèse et l'activité in vitro de plusieurs nouveaux carbapénèmes, soit les acides (X-3-*cis* cyclopentylthio)-2 et (X-4-*cis* cyclohexylthio)-2 [hydroxy-1′*R* éthyl]-6*S* carbapène-2 ème-2 carboxyliques-3 (**7** et **8**). La synthèse implique la préparation stéréospécifique des cyclopentyl- et cyclohexylthiols, **2** et **3**, portant des substituants en position *cis*; cette synthèse implique une réaction hétérocyclique de Diels–Alder qui est suivie de quelques manipulations chimiques.

[Traduit par la revue]

Since the discovery of thienamycin (**1**), a potent and broad spectrum antibiotic, extensive efforts have been directed toward the chemical modification at the 2-position of the carbapenem ring system, to improve the undesirable characteristics associated with this antibiotic, that is, chemical and metabolic instability (1). The 6*S*-(1*R*-hydroxyethyl) group has been left unchanged, since it was reported to be responsible for the β-lactamase stability of thienamycin (2).

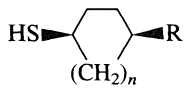


1

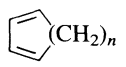
As part of our program directed toward the synthesis of thienamycin analogs, we designed novel side chains, 3-substituted cyclopentylthio- and 4-substituted cyclohexylthio groups, at the 2-position of the carbapenem ring system. Unlike the thioethyl chain in thienamycin, these cyclic rings will provide a more rigid spacing between the terminal functionality (e.g., amino group in thienamycin) and the nucleus. Thus the effect of the ring vs. the flexible ethyl chain on the antibacterial potency might be observed.

In this paper, we wish to describe (*1*) the stereospecific preparation of 3-*cis*-substituted cyclopentylthiols **2** and 4-*cis*-substituted cyclohexylthiols **3** by applying an hetero Diels–Alder reaction of cyclic dienes **4**, and **5**, with 1,1′-thiocarbonylbis(1,2,4-triazole), **6**, which was recently developed by Larsen and Harpp (3) and (*2*) the subsequent synthesis and the in vitro antibacterial activity of 2-(3-*cis*-substituted cyclopentylthio)- and 2-(4-*cis*-substituted cyclohexylthio)carbapenems, **7** and **8**.

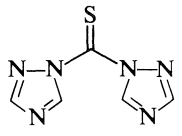
Thiabicyclo compounds **9** and **10**, prepared by the method of Larsen and Harpp (3) from cyclopentadiene (**4**) and 1,3-cyclohexadiene (**5**) respectively, with thiocarbonylbis-triazole **6** were hydrogenated in the presence of 10% Pd–carbon in ethyl acetate to give thiabicycloheptane **11** and thiabicyclooctane **12**



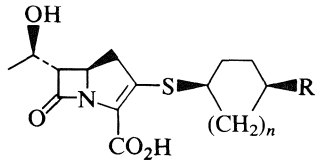
2, $n = 1$
3, $n = 2$



4, $n = 1$
5, $n = 2$



6



7, $n = 1$
8, $n = 2$

in 84.7 and 86.8% yield respectively. The partial hydrolysis of the bis-triazolyl moiety was successfully achieved by treatment with two equivalents of *p*-toluenesulfonic acid monohydrate in acetone to produce bicyclic thiolactones **13** and **14**[2] in 66.3 and 89.8% yield respectively (Scheme 1). These bicyclic thiolactones served as our common synthetic intermediates for the stereospecific preparation of several 3-*cis*-substituted cyclopentylthiols **2** and 4-*cis*-substituted cyclohexylthiols **3**.

It has been recognized that a strongly basic functionality, such as an amino or a formimidoyl group, in the side chain at the 2-position of the carbapenem ring system confers antibacterial activity, particularly antipseudomonal activity (2*b*). Therefore we were primarily interested in introducing a strongly basic group in the cyclopentyl- and cyclohexylthiols.

The stereospecific preparation of *cis*-3-(*p*-nitrobenzyloxycarbonylamino)cyclopentylthiol **2***a* and *cis*-4-(*p*-nitrobenzyloxycarbonylamino)cyclohexylthiol **3***a* from bicyclic thiolactones **13** and **14** is outlined in Scheme 2.

Bicyclic thiolactone **13** was hydrolyzed in refluxing 4 *N* HCl to produce *cis*-3-mercaptocyclopentyl carboxylic acid (**15**) in quantitative yield. *cis*-4-Mercaptocyclohexyl carboxylic acid (**16**) was more conveniently prepared, in 70.3% yield, from bis-triazolylthiabicyclooctane **12** by refluxing in 6 *N* HCl. However, this same treatment on thiabicyclopentane **11** often

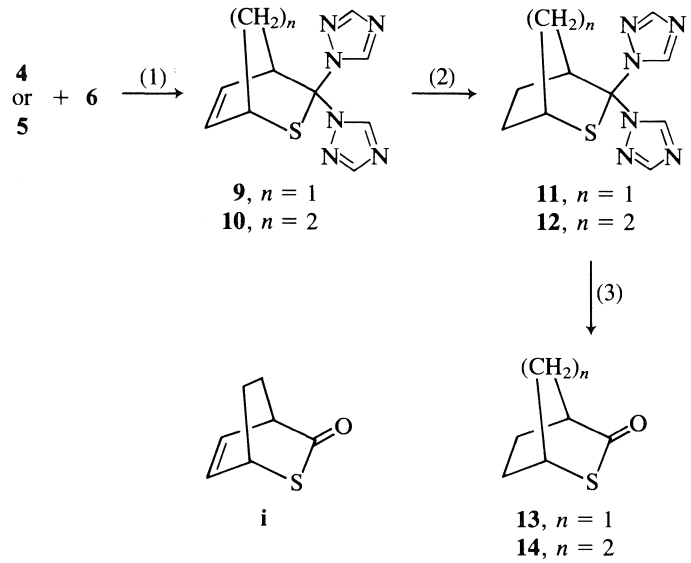
[2]Bicyclic thiolactone **14** was also prepared by a partial hydrolysis of **10** to thiolactone **i** followed by hydrogenation. However, the hydrogenation was much slower than that on **12**, requiring a large amount of the catalyst (10% Pd–C, three times by weight).



(1) Δ, CH_2Cl_2 or benzene
(2) H_2/Pd–C, EtOAc
(3) *p*-TsOH·H_2O, acetone

SCHEME 1

produced a mixture of thiolactone **13** and carboxylic acid **15**. The thiol group was readily protected by treatment with triphenylmethyl chloride (trityl chloride) and pyridine in $CHCl_3$, which produced tritylthio derivatives **17** and **18** in 72 and 63% yield respectively. These carboxylic acids were converted to acyl azides **19** and **20** in 98 and 90% yield respectively by activation with ethyl chloroformate followed by reaction with NaN_3. Refluxing with *p*-nitrobenzyl alcohol in toluene furnished bis-protected *cis*-amino cyclic thiols **21** and **22** in 63 and 84% yield respectively. The *cis* stereochemistry was maintained, since the Curtius rearrangement is known to proceed with retention of configuration. Finally the trityl group was removed (4) by treatment with mercuric acetate followed by reaction with H_2S, yielding the desired N-protected *cis*-3-aminocyclopentylthiol **2***a* as an oil and *cis*-4-aminocyclohexylthiol **2***b* as white crystals in quantitative yields.

The preparation of a few other *cis*-substituted cyclopentyl- and cyclohexylthiols, **2***b* and **3***b*–**3***e*, is outlined in Scheme 3. The nonbasic carbamyl and cyano groups were introduced into the ring for comparison of the antibacterial activity. The ring opening of bicyclic thiolactones **13** and **14** by ammonium hydroxide in methanol cleanly produced *cis*-carbamylcyclopentylthiol **2***b* and *cis*-carbamylcyclohexylthiol **3***b* in 88 and 90% yield respectively. The carbamyl derivative **3***b* was converted to 4-cyanocyclohexylthiol **3***c* in 52.5% yield by reaction with titanium tetrachloride in the presence of *N*-methylmorpholine (5). *cis*-Aminomethyl cyclohexylthiol hydrochloride (**3***d*) was prepared in 77% yield from **3***b* by lithium aluminum hydride reduction. Treatment with trimethylsilyl chloride followed by reaction with *p*-nitrobenzyl chloroformate (6) furnished N-protected *cis*-4-(aminomethyl)cyclohexylthiol **3***e*, which is a homolog of **3***a*, as white crystals in 57% yield.

The 2-(*cis*-substituted cyclopentylthiol and *cis*-substituted cyclohexylthiol)carbapenems **7***a*, **7***b* and **8***a*–**8***e* were prepared from the thiols described above, following essentially the same method developed by Salzmann *et al.* (7*a*) and Sletzinger *et al.* (7*b*) (Scheme 4).

Thus, the chiral 2-ketocarbapenam ester **23**, derived from diazoazetidinone **24** (7*a*, 8) was reacted with diphenyl chlorophosphate in the presence of diisopropylethylamine, then with *cis*-cyclopentyl- and cyclohexylthiols **2***a*, **2***b*, **3***a*, **3***b*, **3***c*, and **3***e* to furnish carbapenem esters **25***a*, **25***b*, and **26***a*–**26***d*. The hydrogenolysis over 10% Pd–C in the presence of pH 7.0 phosphate buffer produced *cis*-substituted cyclopentylthiol- and cyclohexylthiocarbapenem carboxylic acids or their salts **7***a*, **7***c*, **8***a*, and **8***c*–**8***e*. At this stage, two diastereomers in the cyclopentyl series **7***a* and **7***c* were successfully separated by hplc (high pressure liquid chromatography) on a reverse phase silica gel. No attempt was made to determine the absolute configuration of each diastereomer. The *N*-formimidolyl derivatives **7***b* and **8***b* were also prepared from the corresponding amino compounds **7***a* and **8***a* by treatment with benzyl formimidate hydrochloride in water at pH 8.5 (9).

In vitro antibacterial activities of the new carbapenems were tested and the minimum inhibitory concentrations (MIC) against a variety of Gram-positive and Gram-negative bacteria are listed in Table 1, which includes those of imipenem (*N*-formimidoyl thienamycin) for comparison.

The carbapenems having a strongly basic group, **7***a*, **7***b*, **8***a*, **8***b*, and **8***c*, generally exhibited better antibacterial activity than those having a nonbasic group, **7***c*, **8***c*, and **8***d*, although the latter also had good activity against Gram-positive and Gram-negative organisms. In the cyclopentyl series, two diastereomers did not show a significant difference in their antimicrobial potency. The aminomethyl derivative **8***d*, a homolog of **8***a*, was found to be less active against Gram-positive organisms than **8***a*. Among them, the most active carbapenem was one of the diastereomers of the *cis*-aminocyclopentylthio derivative **7***a*,

which had comparable activities to imipenem, except against pseudomonas aeruginosa. Overall, the introduction of the rigid ring system between the nucleus and the strongly basic functionality did not significantly change the antibacterial potency.

Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are not corrected. The infrared spectra were recorded on a Perkin–Elmer 267 grating infrared spectrometer. The ^1H nuclear magnetic resonance spectra were taken with either a Varian EM-360 (60 MHz), unless specified, or a Varian CFT-20 (80 MHz) nmr spectrometer. Tetramethylsilane was used as an internal standard and chemical shifts were reported in parts per million (δ) relative to the internal standard. The ultraviolet spectra were recorded on an Unicam SP8-100 uv spectrophotometer. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. Tetrahydrofuran was freshly distilled from lithium aluminum hydride. All other solvents, with the exception of absolute EtOH, were reagent grade and had been stored over molecular sieves before use. Triethylamine, pyridine, and diisopropylethylamine were distilled from CaH_2 and stored over NaOH. Compounds **9** and **10** were prepared from cyclopentadiene and 1,3-cyclohexadiene respectively by the method of Larsen and Harpp (3). Compound **23** was obtained by the rhodium acetate catalyzed cyclization (7*a*) of diazoazetidinone **24**, which was in turn prepared as described in ref. 8. Analytical thin-layer chromatography (tlc) was conducted on either precoated plates (Silica Gel 60F-254, E. Merck) unless specified or reverse phase silica plates (Analtech), to obtain R_f values. High pressure column chromatography (hplc) was conducted on reverse phase silica gel, C_{18} μ Bondapak (Waters Associate). Column chromatography was carried out on Silica Gel 60 (70–230 mesh, E. Merck) unless specified. For purification of carbapenem esters **25** and **26**, Silica Gel 60 pure (70–230 mesh, E. Merck #7754) was used. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois, U.S.A.

*3,3-Bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.1]heptane (**11**)*

A solution of 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.1]hept-5-ene (**9**) (3) (30.0 g, 0.122 mol; material recrystallized from *i*-PrOH/hexanes; mp 126–128°C) in EtOAc (800 mL) was mixed with 10% Pd–C (22.5 g, Engelhard). This mixture was hydrogenated in a Parr hydrogenation apparatus (H_2, 50 psi) at room temperature for 20 h. After filtration of the catalyst over Celite, the filtrate was evaporated to obtain 30.0 g of a green oil. This oil was purified by column chromatography (900 g, EtOAc:acetone 1:1) to obtain 25.6 g (0.103 mol, yield 84.4%) of the title compound **11** as a light yellow oil: R_f 0.49 (50% EtOAc/acetone); ir (neat) ν_{max}: 3130 (triazole-CH) and 1500 (C=N) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.08 (6H, m, CH_2), 3.85 (1H, m, 4-H), 4.12 (1H, m, 1-H), 7.93 (2H, s, N=CH), 8.63 (1H, s, N=CH), and 8.67 (1H, s, N=CH) ppm.

*2-Thiabicyclo[2.2.1]heptan-3-one (**13**)*

A solution of 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.1]heptane (**11**) (4.30 g, 17.3 mmol) in acetone (105 mL) was treated at room temperature with *p*-toluenesulfonic acid monohydrate (6.57 g, 34.6 mmol) for 1 h. After filtration of the precipitate, the filtrate was evaporated to yield 2.40 g of an oily solid, which was purified by column chromatography (72 g, 20% Et_2O/hexanes) to obtain 1.459 g (11.4 mmol, yield 65.9%) of the title compound **13** as a white solid: mp 88–89°C (sublime); R_f 0.40 (20% Et_2O/hexanes); ir (film) ν_{max}: 1710 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.5–2.4 (6H, m, CH_2), 3.00 (1H, m, 4-H), and 3.97 (1H, m, 1-H) ppm.

*2-Thiabicyclo[2.2.2]oct-5-en-3-one (**i**)*

The title compound **i** was prepared in 91.0% yield as white crystals from 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.2]oct-5-ene (**10**) by the method described for the preparation of **13**: mp 61–63°C (lit. (10) mp 65–67°C, lit. (11) mp 73–74°C); R_f 0.31 (20% Et_2O/hexanes); ir (film) ν_{max}: 1680 (C=O) and 1615 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.5–2.4 (4H, m, CH_2), 3.63 (1H, m, 4-H), 4.20 (1H, m, 1-H), 6.32 (1H, td, J = 8 Hz, J = 2 Hz, 5-H), and 6.68 (1H, td, J = 8 Hz, J = 2 Hz, 6-H) ppm.

cis-*3-Mercaptocyclopentanecarboxylic acid (**15**)*

A suspension of 2-thiabicyclo[2.2.1]heptan-3-one (**13**) (4.50 g, 35.1 mmol) in 4 *N* HCl (22 mL) was heated at reflux under a nitrogen atmosphere for 4.5 h. This was extracted with EtOAc and the ethyl acetate extracts were washed with brine, dried ($MgSO_4$), and then evaporated to yield 5.09 g (34.8 mmol, yield 99.3%) of the title compound **15** as a colourless oil: R_f 0.20 (20% Et_2O/toluene). An analytical sample was obtained by purification on preparative silica gel plate (Schleicher and Schnell) eluting with 40% Et_2O in toluene to obtain the title compound as an oil: ir (neat) ν_{max}: 1700 (CO_2H) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.70 (1H, d, J = 6.5 Hz, SH), 1.7–3.2 (8H, m, CH_2), and 9.2 (1H, br, CO_2H) ppm. *Anal.* calcd. for $C_6H_{10}O_2S$: C 49.29, H 6.89, S 21.93; found: C 49.49, H 6.89, S 22.04.

cis-*4-Mercaptocyclohexanecarboxylic acid (**16**)*

A suspension of 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.2]octane (**12**) (1.04 g, 3.96 mmol) in 6 *N* HCl (10 mL) was heated at reflux under a nitrogen atmosphere for 2 h. This was extracted with EtOAc and the ethyl acetate extracts were washed with brine, dried ($MgSO_4$), and then evaporated to yield 580 mg of off-white solid. This was crystallized from boiling water (12 mL) to obtain 446 mg (2.79 mmol, yield 70.4%) of the title compound **16** as white crystals: mp 58–60°C; ir (film) ν_{max}: 1690 (CO_2H) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.51 (1H, d, J = 6.7 Hz, SH), 1.5–2.4 (8H, m, CH_2), 2.5 (1H, m, $CHCO_2$), 3.1 (1H, m, CHS), and 8.0 (br, CO_2H) ppm. *Anal.* calcd. for $C_7H_{12}O_2S$: C 52.47, H 7.55; found: C 52.33, H 7.54.

It should be noted that when less concentrated hydrochloric acid (4 *N* or 1 *N*) was used, the reaction was slower and, in some cases, produced bicyclothiolactone **14** as a by-product.

cis-*3-(Triphenylmethylthio)cyclopentanecarboxylic acid (**17**)*

To a solution of *cis*-3-mercaptocyclopentanecarboxylic acid (**15**) (4.94 g, 33.8 mmol) in $CHCl_3$ (156 mL; purified by passing through

*Determined by 2-fold serial broth dilution assay (data from Microbiology Dept., Bristol-Myers, Syracuse, N.Y. U.S.A.). Str. = Streptococcus, Staph. = Staphylococcus, K. = Klebsiella, Pr. = Proteus, Ps. = Pseudomonas.
†MIC of two diastereomers (A and B) in this series is shown.

Merck Silica Gel 60) were added triphenylmethyl chloride (10.4 g, 37.3 mol) and pyridine (5.45 mL, 67.7 mmol) and the mixture stirred at room temperature under a nitrogen atmosphere for 72 h. This was washed with 1 *N* HCl (34 mL), then with brine, dried (Na_2SO_4), and evaporated, yielding yellow oil that was purified by column chromatography (580 g, 20% Et_2O/toluene) to obtain 9.77 g of white solid. This was crystallized from Et_2O–hexanes, yielding 9.17 g (23.6 mmol, yield 69.8%) of the title compound **17** as white crystals: mp 153–154°C; R_f 0.55 (20% Et_2O/toluene); ir (film) ν_{max}: 1700 (CO_2H) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.5–2.1 (6H, m, CH_2), 2.3–2.8 (2H, m, CH), and 7.1–7.6 (15H, m, ArH's) ppm. *Anal.* calcd. for $C_{25}H_{24}O_2S$: C 77.28, H 6.23, S 8.25; found: C 77.16, H 6.24, S 8.27.

cis-*3-(Triphenylmethylthio)cyclopentanecarbonyl azide (**19**)*

To a solution of *cis*-3-(triphenylmethylthio)cyclopentanecarboxylic acid (**17**) (28.0 g, 72.1 mmol) in acetone (1.5 L) and H_2O (237 mL) was added triethylamine (12.2 mL, 87.7 mmol) followed by ethyl chloroformate (9.09 mL, 95.1 mmol). The mixture was stirred for 2 min and then to this mixture was added a solution of sodium azide (7.42 g, 0.114 mol) in H_2O (237 mL) at 0–5°C. This was stirred for 4 min and then poured into cold water (1.5 L) and extracted with Et_2O (700 mL × 3). The ether extracts were washed with water, dried ($MgSO_4$), and evaporated to yield 29.5 g (71.3 mmol, crude yield 98.9%) of the title compound **19** as a crude oil: R_f 0.70 (Et_2O); ir (neat) ν_{max}: 2270 (NCO), 2140 (N_3), and 1710 (C=O) cm^{-1}. The ir spectrum indicated the presence of the isocyanate as an impurity. This crude material was immediately used in the subsequent reaction.

cis-*3-(Triphenylmethylthio)-1-(*p*-nitrobenzyloxycarbonylamino)cyclopentane (**21**)*

A mixture of *cis*-3-(triphenylmethylthio)cyclopentylcarbonyl azide (**19**) (10.89 g, 26.3 mmol; crude) and *p*-nitrobenzylalcohol (19.8 g, 120 mmol; the material purchased from Aldrich Chem. Co. was triturated with Et_2O) in toluene (270 mL) was heated at gentle reflux for 20 h, by which time the ir spectrum indicated the absence of the peaks at 2140 and 2270 cm^{-1}. After evaporation of the solvent, the residual solid was purified by column chromatography (700 g, 10% Et_2O/CH_2Cl_2) to obtain 13.0 g of foam, which was crystallized from Et_2O to yield 9.22 g (17.1 mmol, yield 65.1% of the title compound **21** as off-white crystals. An analytical sample was obtained by recrystallization from Et_2O–EtOAc: mp 128–130°C; R_f 0.62 (Et_2O); ir (film) ν_{max}: 3320 (NH), 1715, 1695 (C=O), 1515 and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.0–2.2 (6H, m, CH_2), 2.69 (1H, m, CHS), 3.7 (1H, m, CHN), 4.7 (1H, br, NH), 5.15 (2H, s, CH_2CO_2), 7.1–7.5 (17H, m, ArH's), and 8.20 (2H, "d", J = 8.7 Hz, ArH's) ppm. *Anal.* calcd. for $C_{32}H_{30}N_2O_4S$: C 71.35, H 5.61, N 5.20; found: C 71.35, H 5.56, N 5.32.

cis-*3-Mercapto-1-(*p*-nitrobenzyloxycarboxylamino)cyclopentane (**2**a)*

A solution of *cis*-3-(triphenylmethylthio)-1-(*p*-nitrobenzyloxycarbonylamino)cyclopentane (**21**) (27.2 g, 50.5 mmol) in CH_2Cl_2 (715 mL) was diluted with absolute EtOH (715 mL). To this solution was added mercuric acetate (16.1 g, 50.5 mmol) at once and the mixture stirred at room temperature for 15 min, by which time the tlc (Et_2O) indicated the reaction was complete. The resulting clear solution was evaporated and the solid residue was triturated with Et_2O (300 mL × 2), yielding 30.0 g of the intermediate, mercuric salt, as a white solid: ir (film) ν_{max}: 1720 cm^{-1}.

This solid (30.0 g) was dissolved in CH_2Cl_2 (250 mL) and the solution was saturated with H_2S by bubbling through at 0–5°C for 1 h. The resulting black precipitate was filtered over Celite and the clear filtrate was treated with Norite (activated carbon). Evaporation of the filtrate and trituration of the residue with Et_2O gave 15.34 g (51.8 mmol, crude yield >100%) of the title compound (**2***a*) as white crystals. This crude material was used in the subsequent reaction without further purification. An analytical sample was obtained by recrystallization from EtOAc–Et_2O–hexanes: mp 87–88°C; R_f 0.68 (Et_2O); ir (film) ν_{max}: 3320 (NH) and 1685 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.4–2.8 (7H, m, CH_2, SH), 3.3 (1H, m, CHS), 4.1 (1H, m, CHN), 5.18 (2H, s, CH_2CO_2), 7.50 (2H, "d", J = 8.7 Hz, ArH's), and 8.20 (2H, "d", J = 8.8 Hz, ArH's) ppm. *Anal.* calcd. for $C_{18}H_{16}N_2O_4S$: C 52.69, H 5.44, N 9.45; found: C 52.38, H 5.32, N 9.21.

cis-*3-Mercaptocyclopentanecarboxamide (**2**b)*

A solution of 2-thiabicyclo[2.2.1]heptan-3-one (**13**) (2.56 g, 20.0 mmol) in MeOH (80 mL; deoxygenated by bubbling through nitrogen gas) was mixed with concentrated ammonium hydroxide (39.94 mL), and stirred at room temperature under a nitrogen atmosphere for 20 h. The solvent was evaporated to dryness and the solid residue was triturated with Et_2O to obtain 2.55 g (17.6 mmol, yield 88.2%) of the title compound **2***b* as a white solid. An analytical sample was obtained by crystallization from *iso*-propanol–hexanes: mp 138–140°C; ir (Nujol) ν_{max}: 3360, 3190 (NH), 2550 (SH), 1660 (sh), and 1635 ($CONH_2$) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.5–2.9 (8H, m, CH_2, CHCO, SH), 3.2 (1H, m, CHS), and 5.4 (br, NH_2) ppm. *Anal.* calcd. for $C_6H_{11}NOS$: C 49.62, H 7.63, N 9.65; found: C 49.52, H 7.43, N 9.57.

cis-*1-Cyano-4-mercaptocyclohexane (**3**c)*

A solution of $TiCl_4$ (1.1 mL, 10 mmol) in CCl_4 (2.5 mL) was injected, at 0–5°C under a nitrogen atmosphere, into THF (20 mL). To the resulting yellow mixture was added a suspension of *cis*-4-mercaptocyclohexanecarboxamide (**3***b*) (800 mg, 5.02 mmol) in THF (20 mL), followed by a solution of *N*-methylmorpholine (2.2 mL) in THF (2.0 mL). After stirring at 0–5°C under a nitrogen atmosphere for 1 h, to this mixture was added H_2O (30 mL) and EtOAc (30 mL). The ethyl acetate extract was washed with H_2O, brine, and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave 623 mg of an oily solid, which was purified by column chromatography (30 g, EtOAc) to collect 495 mg of an oil. The corresponding disulfide, 4-cyanocyclohexyl disulfide (125 mg), crystallized out by addition of Et_2O–hexanes to this oil: mp 103–115°C; R_f 0.39 (Et_2O). The filtrate was evaporated to yield 370 mg (2.62 mmol, yield 52.2%) of the title compound **3***c* as a clear oil that crystallized on standing: mp 42–44°C; R_f 0.58 (Et_2O); ir (film) ν_{max}: 2560 (SH) and 2240 (CN) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.63 (1H, d, J = 7 Hz, SH), 1.5–2.3 (8H, m, CH_2), and 2.85 (2H, br, CH) ppm.

cis-*4-Aminomethylcyclohexylthiol hydrochloride (**3**d)*

A suspension of lithium aluminum hydride (800 mg, 21.1 mmol) in THF (100 mL) was heated at reflux through a pressure-equalized dropping funnel where *cis*-4-mercaptocyclohexanecarboxamide (**3***b*) (795 mg, 5 mmol) was placed with a cotton plug. After 24 h, all of the amide **3***b* dissolved into the reaction flask and tlc (acetone:EtOAc 1:1) indicated the completion of the reaction. After cooling, the excess lithium aluminum hydride was destroyed by slow addition of H_2O (3 mL). This was slowly diluted with EtOAc (150 mL), and the precipitate was filtered over Celite and washed with hot EtOH (150 mL × 2). The filtrate and washings were combined and evaporated to yield 664 mg of a crude oil. This was dissolved in absolute EtOH (20 mL) and treated with HCl gas. The solvent was evaporated to yield white solid, which was rinsed with Et_2O to obtain 699 mg (3.85 mmol, yield 77.0%) of the title compound (**3***d*) as white solid: R_f 0.43 (CH_2Cl_2:1 *M* NH_4OH/MeOH 4:1); ir (Nujol) ν_{max}: 2550 (SH) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.54 (1H, d, J = 6.4 Hz, SH), 1.73 (9H, br, CH_2, CH), 2.95 (2H, br, CH_2N), 3.35 (1H, br, CHS), and 8.35 (br, $^+NH_3$) ppm.

cis-*4-(*p*-Nitrobenzyloxycarbonylaminomethyl)cyclohexylthiol (**3**e)*

To a suspension of *cis*-4-aminomethylcyclohexylthiol hydrochloride (**3***d*) (190 mg, 1.05 mmol) in CH_3CN (10 mL) was added at 0–5°C, trimethylsilyl chloride (0.15 mL, 1.18 mmol) followed by diisopropylamine (0.42 mL, 2.42 mmol), under a dry nitrogen atmosphere. The mixture was stirred (0–5°C, N_2) for 30 min, and to this cloudy solution was added *p*-nitrobenzyl chloroformate (226 mg, 1.05 mmol) in CH_3CN (3 mL), followed by diisopropylethylamine (0.18 mL, 1.05 mmol). The mixture was stirred at 0–5°C for 3 h and diluted with EtOAc (30 mL). This was washed with brine, with 1 *N* HCl, and then with brine again, dried (Na_2SO_4), and evaporated to yield 341 mg of a crude oil. This oil was purified by column chromatography (20 g, CH_2Cl_2) to obtain 194 mg (0.60 mmol, yield 57%) of the title

compound **3***e* as an oil that crystallized on standing: mp 61–63°C; R_f 0.29 (CH_2Cl_2); ir (neat) ν_{max}: 3420, 3350 (CONH), 1720 (C=O), 1520 and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.50 (1H, d, J = 5 Hz, SH), 1.56 (9H, br, CH_2, CH), 3–3.5 (3H, m, CH_2N, CHS), 5.17 (2H, s, CO_2CH_2), 5.35 (br, NH), 7.43 (2H, "d", J = 9 Hz, ArH's), and 8.13 (2H, "d", J = 9 Hz, ArH's) ppm.

Thiabicyclo[2.2.2]octane series **12** and **14**, and cyclohexyl series **18**, **20**, **22**, **3***a*, and **3***b* were prepared by the method described for the preparation of the corresponding 2-thiabicyclo[2.2.1]heptane series and cyclopentyl series respectively.

*3,3-Bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.2.]octane (**12**):* yield 86.8%; mp 139–141°C; R_f 0.67 (20% EtOAc/acetone); ir (film) ν_{max}: 3130 (triazole-CH) and 1500 (C=N) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.2–2.2 (8H, m, CH_2), 3.22 (1H, br s, 4-H), 3.58 (1H, br s, 1-H), 7.92 (2H, s, N=CH), and 8.77 (2H, s, N=CH) ppm. *Anal.* calcd. for $C_{11}H_{14}N_6S$: C 50.36, H 5.38, N 32.04, S 12.22; found: C 50.54, H 5.48, N 32.41, S 12.19.

*2-Thiabicyclo[2.2.2.]octan-3-one (**14**):* yield 89.8%; mp 174–175°C (Et_2O–hexanes); R_f 0.31 (20% Et_2O/hexanes); ir (film) ν_{max}: 1675 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.0 (8H, m, CH_2), 2.37 (1H, m, 4-H), and 3.50 (1H, m, 1-H) ppm. *Anal.* calcd. for $C_7H_{10}OS$: C 59.12, H 7.09, S 22.55; found: C 59.23, H 6.99, S 22.37.

cis-*4-(Triphenylmethylthio)cyclohexanecarboxylic acid (**18**):* yield 62.9%; mp 172–174°C (EtOAc/hexane); R_f 0.44 (20% Et_2O/toluene); ir (film) ν_{max}: 1705 (CO_2H) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.2–2.5 (10H, m, CH, CH_2) and 7.1–7.6 (15H, m, ArH's) ppm. *Anal.* calcd. for $C_{26}H_{26}O_2S$: C 77.58, H 6.51, S 7.97; found: C 77.61, H 6.57, S 7.94.

cis-*4-(Triphenylmethylthio)cyclohexanecarbonyl azide (**20**):* crude yield 89.4%; oil R_f 0.7 (Et_2O); ir (neat) ν_{max}: 2260 (NCO), 2140 (N_3), and 1720 (C=O) cm^{-1}.

cis-*4-(Triphenylmethylthio)-1-(*p*-nitrobenzyloxycarbonylamino)cyclohexane (**22**):* yield 84.2%; mp 184–186°C (CH_2Cl_2–pentane); R_f 0.72 (10% Et_2O/CH_2Cl_2); ir (film) ν_{max}: 3340 (NH), 1720, 1695 (C=O), 1520, and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.2–1.8 (8H, m, CH_2), 2.49 (1H, q, J = 4.5 Hz, CHS), 3.45 (1H, br, $W_{1/2}$ = 20 Hz, CHN), 4.65 (1H, d, J = 8 Hz, NH), 5.16 (2H, s, CH_2CO_2), 7.1–7.6 (17H, m, ArH's), and 8.19 (2H, "d", J = 8.8 Hz, ArH's) ppm. *Anal.* calcd. for $C_{33}H_{32}N_2O_4S$: C 71.71, H 5.84, N 5.07, S 5.80; found: C 71.80, H 5.85, N 5.03, S 5.82.

cis-*4-Mercapto-1-(*p*-nitrobenzyloxycarbonylamino)cyclohexane (**3**a):* R_f 0.45 (Et_2O); ir (film) ν_{max}: 3400, 3340 (NH), and 1710 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.49 (1H, d, J = 6.1 Hz, SH), 1.5–2.0 (8H, m, CH_2), 3.15 (1H, m, $W_{1/2}$ = 16 Hz, CHS), 3.61 (1H, m, $W_{1/2}$ = 19 Hz, CHN), 4.76 (1H, br, NH), 5.18 (2H, s, CH_2CO_2), 7.49 (2H, "d", J = 8.8 Hz, ArH's), and 8.21 (2H, "d", J = 8.8 Hz, ArH's) ppm.

cis-*4-Mercaptocyclohexanecarboxamide (**3**b):* yield 90.1%; mp 198–200°C (*i*-PrOH–hexanes); R_f 0.46 (acetone:EtOAc 1:1); ir (Nujol) ν_{max}: 3370, 3200 (NH), 1665 and 1625 ($CONH_2$) cm^{-1}; ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.53 (1H, d, J = 6.8 Hz, SH), 1.5–2.2 (8H, m, CH_2), 2.17 (1H, m, CHCO), 3.23 (1H, br, CHS), and 5.3 (2H, br, NH_2) ppm. *Anal.* calcd. for $C_7H_{13}NOS$: C 52.79, H 8.23, N 8.80, S 20.13; found: C 52.75, H 8.13, N 8.57, S 20.17.

*General procedure for the preparation of carbapenem esters **25** and **26***

To a solution of *p*-nitrobenzyl (6*S*)-[(1*R*)-hydroxyethyl]-2-oxo-(5*R*)-carbapenam-(3*R*)-carboxylate (**23**) (1 mmol) and diisopropylethylamine (1.1 mmol) in CH_3CN (20 mL) was added at 0–5°C under a dry nitrogen atmosphere diphenyl chlorophosphate (1.1 mmol). The mixture was stirred for 1 h and to this was added at 0–5°C a solution of thiol **2** or **3** (1 mmol) in CH_3CN (5 mL), followed by diisopropylethylamine (1 mmol). For thiols **2***b* and **3***b*, the solution was made in DMF (5 mL). The mixture was stirred at room temperature under a nitrogen atmosphere; reaction time: 20 h for **25***a* and **26***c*, 3 days for **25***b* and **26***b*, 6 days for **26***a* and **26***d*. For **25***a*, the mixture was cooled to 0–5°C, and the crystals were collected. For others, the mixture was diluted with EtOAc, washed with H_2O (×2), then with brine, dried (Na_2SO_4), and evaporated. The crude material was purified by column chromatography (50% acetone/EtOAc for **25***b* and **26***b*; EtOAc for others).

p-*Nitrobenzyl(6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-3-(*p*-nitrobenzyloxycarbonylamino)cyclopentylthio]-(5*R*)-carbapen-2-em-3-carboxylates (diastereomeric mixture) (**25**a):* yield 78.3%; mp 159–161°C (Et_2O–MeOH); R_f 0.35 (EtOAc); $[\alpha]_D^{22°}$ +29.7° (*c* 0.50, MeOH); ir (Nujol) ν_{max}: 3500, 3340, 1775 (β-lactam), 1700 (ester), 1520 and 1345 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 324 (ε 15 300) and 267 nm (ε 22 900); ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.37 (3H, d, J = 6.3 Hz, 1′-Me), 1.5–2.9 (6H, m, CH_2), 3.1–3.3 (3H, m, 1-H_2, 6-H), 3.5 (1H, m, CHS), 3.9–4.4 (3H, m, 1′-H, 5-H, CHN), 4.85 (1H, br, NH), 5.12–5.29–5.43–5.61 (2H, Abq, CH_2CO_2), 5.18 (2H, s, CH_2CO_2), 7.50 (2H, "d", J = 8.8 Hz, ArH's), 7.65 (2H, "d", J = 8.8 Hz, ArH's), and 8.22 (4H, "d", J = 8.8 Hz, ArH's) ppm. *Anal.* calcd. for $C_{29}H_{30}N_4O_{10}S$: C 55.58, H 4.83, N 8.94; found: C 54.86, H 4.84, N 8.90.

p-*Nitrobenzyl(6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-3-carbamylcyclopentylthio]-(5*R*)-carbapen-2-em-3-carboxylates (diastereomeric mixture) (**25**b):* yield 31.7%; mp 164–166°C (isopropanol–hexanes); R_f 0.17 (EtOAc:acetone 1:1); $[\alpha]_D^{22°}$ +2.4° (*c* 0.6, MeOH); ir (Nujol) ν_{max}: 3490, 3450, 3430, 3210, 1765 (β-lactam), 1700 (ester), and 1665 ($CONH_2$) cm^{-1}; uv (EtOH) λ_{max}: 322 (ε 13 100) and 267 nm (ε 11 200); ^{1}Hmr (acetone-d_6, CFT-20) δ: 1.28 (3H, d, J = 6.1 Hz), 1.5–3.0 (7H, m), 3.1–3.8 (4H, m), 3.9–4.4 (2H, m), 5.15–5.34–5.44–5.63 (2H, ABq), 7.80 (2H, "d", J = 8.8 Hz), and 8.25 (2H, "d", J = 8.8 Hz) ppm.

p-*Nitrobenzyl(6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-4-(*p*-nitrobenzyloxycarbonylamino)cyclohexylthio]-(5*R*)-carbapen-2-em-3-carboxylate (**26**a):* yield 30.3%; oil; R_f 0.23 (EtOAc); $[\alpha]_D^{22°}$ +51.8° (*c* 0.875, CH_2Cl_2); ir (film) ν_{max}: 3400 (OH), 1775 (β-lactam), 1705 (ester), 1525 and 1350 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 267 (ε 23 300) and 323 nm (ε 15 300); ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.35 (3H, d, J = 6.2 Hz, 1′-Me), 1.81 (8H, br s, CH_2), 3.04 (1H, dd, J = 17.5 Hz, J = 7.5, 1-H), 3.19 (1H, dd, J = 4.7 Hz, J = 2 Hz, 6-H), 3.3 (1H, m, CHS), 3.44 (1H, dd, J = 17.5 Hz, J = 7.6 Hz, 1-H), 3.7 (1H, m, CHN), 4–4.4 (2H, m, 5-H, 1′-H), 4.75 (1H, br, NH), 5.11–5.28–5.42–5.60 (2H, ABq, 3-CH_2CO_2), 5.17 (2H, s, CH_2CO_2), 7.49 (2H, "d", J = 8.8 Hz, ArH's), 7.64 (2H, "d", J = 8.8 Hz, ArH's), and 8.20 (4H, "d", J = 8.8 Hz, ArH's) ppm.

p-*Nitrobenzyl(6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-4-(carbamyl)-cyclohexylthio]-(5*R*)-carbapen-2-em-3-carboxylate (**26**b):* yield 30%; mp 172–174°C; R_f 0.24 (EtOAc:acetone 1:1); ir (Nujol) ν_{max}: 3460 (OH), 3370, 3200 (NH), 1740 (β-lactam) 1700 (ester), and 1650 ($CONH_2$) cm^{-1}; uv (EtOH) λ_{max}: 324 (ε 12 800) and 267 nm (ε 10 600) nm; ^{1}Hmr (acetone-d_6, CFT-20) δ: 1.27 (3H, d, J = 6.2 Hz, 1′-Me), 1.6–2.1 (8H, m, CH_2), 2.35 (1H, m, CHCO), 3.2–3.6 (3H, m, 1-H, 6-H), 3.55 (1H, m, CHS), 4–4.5 (2H, m, 5-H, 1′-H), 5.16–5.34–5.44–5.62 (2H, ABq, CH_2CO_2), 7.81 (2H, "d", J = 8.8 Hz, ArH's), and 8.26 (2H, "d", J = 8.8 Hz, ArH's) ppm.

p-*Nitrobenzyl(6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-4-cyanocyclohexylthio]-(5*R*)-carbapen-2-em-3-carboxylate (**26**c):* yield 43.5%; mp 167–169°C (CH_2Cl_2–EtOAc); $[\alpha]_D^{22°}$ +61.8° (*c* 0.57, CH_2Cl_2); ir (film) ν_{max}: 3400 (OH), 2240 (w, CN), 1770 (β-lactam), and 1700 (ester) cm^{-1}; uv (EtOH) λ_{max}: 267 (ε 11 000) and 322 nm (ε 13 000); ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.37 (3H, d, J = 6.3 Hz), 1.5–2.2 (8H, m), 2.8 (2H, m), 2.8–3.5 (4H, m), 4–4.4 (2H, m), 5.12–5.31–5.44–5.61 (2H, ABq), 7.65 (2H, "d", J = 8.8 Hz), and 8.22 (2H, "d", J = 8.8 Hz) ppm.

p-*Nitrobenzyl(6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-4-(*p*-nitrobenzyloxycarbonylaminomethyl)cyclohexylthio]-(5*R*)-carbapen-2-em-3-carboxylate (**26**d):* yield 54%; yellow foam; R_f 0.37 (EtOAc); $[\alpha]_D^{21°}$ +51° (*c* 0.71, CH_2Cl_2); ir (film) ν_{max}: 3400 (OH), 1770 (β-lactam), 1720, 1700 (C=O), 1520 and 1350 (NO_2) cm^{-1}; uv (EtOH) λ_{max}: 268 (ε 21 100) and 323 nm (ε 12 900); ^{1}Hmr ($CDCl_3$, CFT-20) δ: 1.38 (3H, d, J = 6.2 Hz), 1.5–2.0 (9H, m), 3–3.4 (4H, m), 3.18 (1H, dd, J = 6.9 Hz, J = 2.5 Hz, 6-H), 3.47 (1H, m, CHS), 4–4.5 (2H, m), 4.9 (br), 5.12–5.29–5.45–5.62 (2H, ABq), 5.18 (2H, s), 7.50 (2H, "d", J = 8.8 Hz), 7.65 (2H, "d", J = 8.8 Hz), and 8.22 (4H, "d", J = 8.8 Hz) ppm.

*(6S)-[(1R)-Hydroxyethyl]-2-(*cis*-3-aminocyclopentylthio)-(5R)-carbapen-2-em-3-carboxylic acid (diastereomers A and B) (7a)* (Procedure A)

A solution of *p*-nitrobenzyl (6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-3-(*p*-nitrobenzyloxycarbonylamino)cyclopentylthio]-(5*R*)-carbapen-2-em-3-carboxylates (**25***a*) (1.00 g, 1.60 mmol; diastereomeric mixture) in THF (173 mL) was mixed with Et_2O (173 mL), H_2O (173 mL), phosphate buffer (64 mL, pH 7.0, 0.05 *M*), and 10% Pd–C (1.00 g, Engelhard). The mixture was hydrogenated in a Parr apparatus (H_2, 50 psi) at room temperature for 5 h. The aqueous layer was filtered over Celite to remove the catalyst and the filtrate washed with Et_2O. This aqueous layer was lyophilized to obtain 1.08 g of yellow solid, which was purified by hplc (3% CH_3CN/H_2O) to yield 108 mg (0.343 mmol, yield 21.5%) of the title compound **7***a* (diastereomer A) as a yellowish powder; hplc, fast moving peak; $[\alpha]_D^{22°}$ +48.5° (*c* 0.3, H_2O); ir (KBr disc) ν_{max}: 3400 (OH), 1770 (β-lactam), and 1580 (CO_2) cm^{-1}; uv (H_2O) λ_{max}: 300 nm (ε 7400); ^{1}Hmr (D_2O, CFT-20) δ: 1.47 (3H, d, *J* = 6.4 Hz, 1′-Me), 1.5–3.0 (6H, m, CH_2), 3.4 (2H, m, 1-H), 3.57 (1H, dd, *J* = 6.1 Hz, *J* = 2.6 Hz, 6-H), 3.8 (2H, m, CHN, CHS), and 4.2–4.5 (2H, m, 1′-H, 5-H) ppm; and 83 mg (0.27 mmol, yield 16.7%) of the title compound **7***a* (diastereomer B) as a yellowish powder; hplc, slow moving peak; $[\alpha]_D^{22°}$ +46.9° (*c* 0.30, H_2O); ir (KBr disc) ν_{max}: 3400, 1750, and 1550 cm^{-1}; uv (H_2O) λ_{max}: 300 nm (ε 6800); ^{1}Hmr (D_2O, CFT-20) δ: 1.48 (3H, d, *J* = 6.3 Hz), 1.6–3.0 (6H, m), 3.27 (1H, dd, *J* = 17 Hz, *J* = 9.3 Hz, 1-H), 3.49 (1H, dd, *J* = 17 Hz, *J* = 8.8 Hz, 1-H), 3.58 (1H, dd, *J* = 6.1 Hz, *J* = 2.6 Hz), 3.85 (2H, m), and 4.3–4.5 (2H, m) ppm.

*(6S)-[(1R)-Hydroxyethyl]-1-[*cis*-3-(formimidoylamino)cyclopentylthio]-(5R)-carbapen-2-em-3-carboxylic acid (diastereomers A and B) (7b)* (Procedure B)

A solution of (6*S*)-[(1*R*)-hydroeyethyl]-1-(*cis*-3-aminocyclopentylthio)-(5*R*)-carbapen-2-em-3-carboxylic acid (**7***a*) (60 mg, 0.19 mmol; diastereomer A or B) in H_2O (140 mL) was cooled to 0–5°C and the pH was adjusted to 8.5 by the addition of a 0.06 *N* KOH solution. To this mixture was added at 0–5°C, portionwise and alternately, benzylformimidate hydrochloride (182 mg, 1.15 mmol) and a 0.06 *N* KOH solution, while maintaining the pH of the reaction mixture at 8.5 ± 0.3. After 15 min, the pH was adjusted to 7.0 by the dropwise addition of a 1 *N* HCl solution. The mixture was washed with Et_2O (150 mL × 2) and the aqueous layer was purified by column chromatography (10 g, Waters Assoc. $C_{18}\mu$ Bondapak reverse phase, 5% CH_3CN/H_2O) to obtain a yellow solid after lyophilization. This was purified by hplc (5% CH_3CN/H_2O) to yield the title compound **7***b* as off-white powder. Diastereomer A: yield 61 mg (0.18 mmol, yield 93%); R_f 0.45 (RP silica plate, 5% CH_3CH; H_2O); $[\alpha]_D^{22°}$ −31.0° (*c* 0.55, H_2O); ir (KBr disc) ν_{max}: 3000–3400 (br, OH, NH), 1750 (β-lactam), 1700 (C=N), and 1580 (CO_2) cm^{-1}; uv (H_2O) λ_{max}: 303 nm (ε 9500); ^{1}Hmr (D_2O, CFT-20) δ: 1.25 (3H, d, *J* = 6.4 Hz, 1′-Me), 1.5–2.3 (4H, m, CH_2), 2.3–2.8 (2H, m, CH_2), 3.04 (1H, dd, *J* = 19 Hz, *J* = 9 Hz, 1-H), 3.31 (1H, dd, *J* = 19 Hz, *J* = 9 Hz, 1-H), 3.35 (1H, dd, *J* = 6.1 Hz, *J* = 2.6 Hz, 6-H), 3.4–3.8 (2H, m, CHN, CHS), 4–4.3 (2H, m, 1′-H, 5-H), and 7.66–7.67–7.78 (1H, 3s, HC=N) ppm. Diastereomer B: yield 57 mg (0.17 mmol, yield 88%); R_f 0.40 (RP silica plate, 5% CH_3CH/H_2O); $[\alpha]_D^{22°}$ +100° (*c* 0.55, H_2O); ir (KBr disc) ν_{max}: 3000–3400 (br), 1750, 1700, and 1565 cm^{-1}; uv (H_2O) λ_{max}: 302 nm (ε 8300); ^{1}Hmr (D_2O, CFT-20) δ: 1.25 (3H, d, *J* = 6.4 Hz), 1.5–2.3 (4H, m), 2.3–2.8 (2H, m), 3.04 (1H, dd, *J* = 17.5 Hz, *J* = 9.6 Hz), 3.30 (1H, dd, *J* = 17.5 Hz, *J* = 8.8 Hz), 3.36 (1H, dd, *J* = 6.0 Hz, *J* = 2.7 Hz), 3.4–3.8 (2H, m), 3.9–4.3 (2H, m), and 7.64–7.65–7.78 (1H, 3s) ppm.

*Sodium (6S)-[(1R)-hydroxyethyl]-2-[*cis*-3-carbamylcyclopentylthio]-(5R)-carbapen-2-em-3-carboxylates (diastereomers A and B) (7c)* (Procedure C)

A suspension of *p*-nitrobenzyl (6*S*)-[(1*R*)-hydroxyethyl]-2-[*cis*-3-carbamylcyclopentylthio]-(5*R*)-carbapen-2-em-3-carboxylate (**25***b*) (235 mg, 0.494 mmol) in THF (60 mL) was mixed with Et_2O (60 mL), phosphate buffer (9.90 mL, pH 7.0, 0.05 *M*), a solution of $NaHCO_3$ (41.9 mg, 0.494 mmol) in H_2O (60 mL), and 10% Pd–C (235 mg, Engelhard). The mixture was hydrogenated (H_2, 32 psi) in a Parr apparatus at room temperature for 1 h. The same work-up and purification procedure as described for **7***a* gave 17.3 mg (0.048 mmol, yield 9.7%) of the title compound **7***c* (diastereomer A) as an orange powder; hplc, fast moving peak; ir (KBr disc) ν_{max}: 3300 (br, OH, NH_2), 1740 (β-lactam), 1660 ($CONH_2$), and 1580 (CO_2) cm^{-1}; uv (H_2O) λ_{max}: 300 nm (ε 8300); ^{1}Hmr (D_2O, CFT-20) δ: 1.44 (3H, d, *J* = 6.4 Hz, 1′-Me), 1.5–3.2 (7H, m), 3.4 (2H, 2dd, 1-H), 3.57 (1H, dd, *J* = 6.2 Hz, *J* = 2.6 Hz, 6-H), 3.7 (1H, CHS), and 4.2–4.5 (2H, m, 1′-H, 5-H) ppm; and 43.3 mg (0.119 mmol, yield 24.4%) of the title compound **7***c* (diastereomer B) as an orange powder; hplc, slow moving peak; ir (Nujol) ν_{max}: 3400 (br), 1750, 1670, and 1590 cm^{-1}; uv (H_2O) λ_{max}: 300 nm (ε 8000); ^{1}Hmr (D_2O, CFT-20) δ: 1.49 (3H, d, *J* = 6.3 Hz), 1.5–3.2 (7H, m), 3.42 (2H, 2dd), 3.57 (1H, dd, *J* = 6.1 Hz, *J* = 2.6 Hz), 3.75 (1H, m), and 4.2–4.6 (2H, m) ppm.

The cyclohexyl series, compounds **8**, were prepared by one of the procedures described above for the preparation of the cyclopentyl series, **7**.

*(6S)-[(1R)-Hydroxyethyl]-2-(*cis*-4-aminocyclohexylthio)-(5R)-carbapen-2-em-3-carboxylic acid (8a)* (Procedure A): yield 11%; ir (KBr disc) ν_{max}: 3420 (OH), 1755 (β-lactam), and 1580 (CO_2) cm^{-1}; uv (H_2O) λ_{max}: 303 nm (ε 6750); ^{1}Hmr (D_2O, CFT-20) δ: 1.45 (3H, d, *J* = 6.3 Hz, 1′-Me), 2.06 (8H, br s, CH_2), 3.20 (1H, dd, *J* = 17.3 Hz, *J* = 9.1 Hz, 1-H), 3.48 (1H, dd, *J* = 17.3 Hz, *J* = 9.1 Hz, 1-H), 3.55 (1H, dd, *J* = 6.1 Hz, *J* = 2.6 Hz, 6-H), 3.75 (1H, m), and 4.2–4.6 (2H, m, 1′-H, 5-H) ppm.

*(6S)-[(1R)-Hydroxyethyl]-2-[*cis*-4-(formimidoylamino)cyclohexylthio]-(5R)-carbapen-2-em-3-carboxylic acid (8b)* (Procedure B): yield 82%; R_f 0.13 (RP silica plate, 5% CH_3CN/H_2O); ir (KBr disc) ν_{max}: 3100–3400 (br), 1750, 1710, and 1580 cm^{-1}; uv (H_2O) λ_{max}: 307 nm (ε 9000); ^{1}Hmr (D_2O, CFT-20) δ: 1.25 (3H, d, *J* = 6.4 Hz), 1.81 (8H, br s, CH_2), 3.02 (1H, dd, *J* = 17.5 Hz, *J* = 9.5 Hz, 1-H), 3.29 (1H, dd, *J* = 17.5 Hz, *J* = 9.0 Hz, 1-H), 3.35 (1H, dd, *J* = 6.0 Hz, *J* = 2.5 Hz, 6-H), 3.65 (1H, m), 4.0–4.4 (2H, m, 1′-H, 5-H), and 7.66–7.77–7.80 (1H, 3s, HC=N) ppm.

*Sodium (6S)-[(1R)-hydroxyethyl]-2-[*cis*-4-(carbamyl)cyclohexyl]-(5R)-carbapen-2-em-3-carboxylate (8c)* (Procedure C): yield 57%; R_f 0.63 (RP silica plate, 10% CH_3CN/H_2O); ir (KBr disc) ν_{max}: 3400, 1750, 1650, and 1590 cm^{-1}; uv (H_2O) λ_{max}: 303 nm (ε 8700); ^{1}Hmr (D_2O, CFT-20) δ: 1.44 (3H, d, *J* = 6.8 Hz), 2.0 (8H, br s), 2.5 (1H, m, CHCO), 3.20 (1H, dd, *J* = 17.5 Hz, *J* = 9.2 Hz, 1-H), 3.48 (1H, dd, *J* = 17.5 Hz, *J* = 9.0 Hz, 1-H), 3.53 (1H, dd, *J* = 6.1 Hz, *J* = 2.5 Hz, 6-H), 3.65 (1H, m, CHS), and 4.15–4.5 (1H, m) ppm.

*Sodium (6S)-[(1R)-hydroxyethyl]-2-(*cis*-4-cyanocyclohexylthio)-(5R)-carbapen-2-em-3-carboxylate (8d)* (Procedure C): yield 14%; R_f 0.37 (RP silica plate, 5% CH_3CN/H_2O); ir (KBr disc) ν_{max}: 3400, 1745, and 1570 cm^{-1}; uv (H_2O) λ_{max}: 305 nm (ε 8000); ^{1}Hmr (D_2O, CFT-20) δ: 1.47 (3H, d, *J* = 6.3 Hz), 1.6–2.3 (8H, m, CH_2), 3.1–3.5 (2H, m, CHS, CHCN), 3.23 (1H, dd, *J* = 17.2 Hz, *J* = 9.2 Hz, 1-H), 3.49 (1H, dd, *J* = 17.2 Hz, *J* = 9.0 Hz, 1-H), 3.55 (1H, dd, *J* = 6.2 Hz, 6-H), and 4.1–4.5 (2H, m) ppm.

*(6S)-[(1R)-Hydroxyethyl]-2-[*cis*-4-(aminomethyl)cyclohexylthio]-(5R)-carbapem-2-em-3-carboxylic acid (8e)* (Procedure A): yield 44%; $[\alpha]_D^{22°}$ +29° (*c* 0.11, H_2O); ir (KBr disc) ν_{max}: 3450, 1735, and 1565 cm^{-1}; uv (H_2O) λ_{max}: 303 nm (ε 5400); ^{1}Hmr (D_2O, CFT-20) δ: 1.26 (3H, d, *J* = 6.4 Hz), 1.5–1.9 (9H, m, CH_2, CH), 2.92 (2H, d, *J* = 5.9 Hz, CH_2N), 3.03 (1H, dd, *J* = 17.5 Hz, *J* = 9.0 Hz, 1-H), 3.31 (1H, dd, *J* = 17.5 Hz, *J* = 9.0 Hz, 1-H), 3.36 (1H, dd, *J* = 6.1 Hz, *J* = 2.6 Hz, 6-H), 3.5 (1H, m, CHS), and 4.0–4.4 (2H, m, 1′-H, 5-H) ppm.

An electron spin resonance study of the reactions of hydrogen atoms with halocarbons

WILLIAM E. JONES AND JOSEPH L. MA
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 26, 1986

WILLIAM E. JONES and JOSEPH L. MA. Can. J. Chem. **64**, 2192 (1986).

The absolute rate constants for the reaction of H atoms with methyl- and vinyl-halides have been determined using esr spectroscopy and a conventional gas flow system. The rate constants determined at 298 ± 2 K at a pressure of 0.55 Torr are methane, $(1.7 \pm 0.3) \times 10^{-17}$; ethane, $(2.3 \pm 0.5) \times 10^{-17}$; methylfluoride, $(4 \pm 3) \times 10^{-15}$; methylchloride, $(8 \pm 2) \times 10^{-16}$; methylbromide, $(2.1 \pm 0.6) \times 10^{-14}$; vinylfluoride, $(1.47 \pm 0.02) \times 10^{-13}$; vinylchloride, $(1.66 \pm 0.08) \times 10^{-13}$; and vinylbromide $(4.07 \pm 0.73) \times 10^{-13}$ in units of cm^3 $molecule^{-1}$ s^{-1}.

WILLIAM E. JONES et JOSEPH L. MA. Can. J. Chem. **64**, 2192 (1986).

Faisant appel à la rpe et un système conventionnel d'écoulement des gaz, on a mesuré les constantes absolues des vitesses de réaction des atomes H avec les halogénures de méthyle et de vinyle. On a déterminé que, à 298 ± 2 K et à une pression de 0,55 Torr, les constantes sont les suivantes (en cm^3 $molécule^{-1}$ s^{-1}) : méthane, $(1,7 \pm 0,3) \times 10^{-17}$; éthane, $(2,3 \pm 0,5) \times 10^{-17}$; fluorométhane, $(4 \pm 3) \times 10^{-15}$; chlorométhane, $(8 \pm 2) \times 10^{-16}$; bromométhane, $(2,1 \pm 0,6) \times 10^{-14}$; fluorure de vinyle, $(1,47 \pm 0,02) \times 10^{-13}$; chlorure de vinyle, $(1,66 \pm 0,08) \times 10^{-13}$ et bromure de vinyle, $(4,07 \pm 0,73) \times 10^{-13}$.

[Traduit par la revue]

Introduction

While much work has been reported on the reactions of H atoms with the hydrocarbons; methane, ethane, and ethylene (1, 2), there have been few reports of studies of the reactions of H atoms with halo-substituted hydrocarbons (1, 3).

The reactions with saturated hydrocarbons are very slow and approach the limit of measurement in the normal vacuum flow system. The initial step in the reaction is the abstraction of a hydrogen atom, or in halo-substituted hydrocarbons a halogen atom. This initial reaction would be followed by a series of radical reactions. Since the reactions with methane and ethane are so slow, measurements have been usually made at elevated temperatures (4–14). However, these measurements provide Arrhenius parameters from which estimates of rate constants at room temperature may be predicted.

The reactions with CH_3F, CH_3Cl, and CH_3Br were first studied by Chadwell and Titani (15) and by Cremer, Curry, and Polanyi (16) in 1933. No further measurements were reported on these reactions until 1967, when Parsamyan *et al.* (17) reported their results on the reaction with CH_3F. In 1969, Seidel (18) reported results from a crossed molecular beam study on the reaction with CH_3Cl and CH_3Br. In 1970, Davis *et al.* (19) also gave values for the Arrhenius parameters for the reaction with CH_3Br.

The recent paper by Ahmed and Jones (3) summarizes the previous work (20–24) on the reactions of hydrogen atoms with the mono-halo-substituted ethylenes.

In this article we report on a study of the kinetics of the reaction of hydrogen atoms with mono-halo-substituted methanes and ethylenes using esr spectrometry as a detector for H atoms. In the course of this work, we also measured the kinetics of the reactions with methane and ethane for comparison purposes.

Experimental

The reactions were studied in a conventional fast flow vacuum system coupled to a Varian E109-B electron spin resonance spectrometer. The design of the reaction zone was similar to that described by Westenberg and DE Haas (25). The reaction tube which passed through the esr cavity was made of 19 mm i.d. quartz tubing having a low dielectric constant. The main reaction tube was 1 m long and 20 mm i.d. Mixtures of hydrogen and helium could be admitted to the reaction tube through three side tubes situated at varying distances from the esr cavity. Each of these entry tubes was made of quartz to allow production of H atoms by a microwave discharge sustained by a 2450 MHz (200 W) microwave generator. The reactant gas was admitted to the stream of H atoms through a gas inlet tube which could be moved axially within the reaction tube. This allowed admittance of the reactant to the H atom stream at various distances (various reaction times) from the esr cavity. The flow system was connected to two large mechanical vacuum pumps which maintained a pumping speed of 450 L min^{-1} at a pressure of 1 Torr, giving a linear velocity of 40 m s^{-1} in the reaction zone.

Hydrogen atoms were produced by passing a mixture of molecular hydrogen and helium through a 2450 MHz electrodeless discharge. Typical flow conditions were He, 8.7×10^{-5} mol s^{-1}; H_2, 3.1×10^{-7} mol s^{-1}. The surface of the reaction tube and the moveable inlet probe were coated with phosphoric acid to inhibit recombination of H atoms.

Helium and molecular hydrogen were obtained from Linde. Methane, ethane, halo-substituted methanes and ethylenes and nitrogen dioxide were obtained from Matheson of Canada Ltd. All condensable gases were purified by bulb-to-bulb distillation. Nitrogen dioxide was treated with molecular oxygen and purified by trap-to-trap distillation *in vacuo*.

The concentration of atomic hydrogen was determined by titration with NO_2. This determination was made by observation of the H atom signal as the flow rate of NO_2 was gradually increased. A plot of a typical result is shown in Fig. 1. In this figure the end point was located at a NO_2 flow rate of 2.1×10^{-6} mol s^{-1}. The flow rate of H atoms was thus determined on the assumption that $[H]/[NO_2] = 1/1.5$ at the end point (26). The usual correction for the NO_2/N_2O_4 equilibrium was applied to the calculation of the flow rate of NO_2.

All experiments were performed at room temperature, 298 ± 2 K, and a pressure of 0.55 Torr as measured by a mercury McLeod gauge. The axial pressure gradient in the reactor was less than 2% of the total pressure. The reaction time was calculated from the distance between the point of mixing of the reactants and the centre of the esr cavity. Under the experimental conditions used, a plug flow condition could be assumed and the time was calculated as $t = d/v$, where d is the distance from the point of mixing and the centre of the esr cavity and v is the linear flow velocity of reactant gases. The progress of the reaction was monitored by esr detection of the remaining H atoms

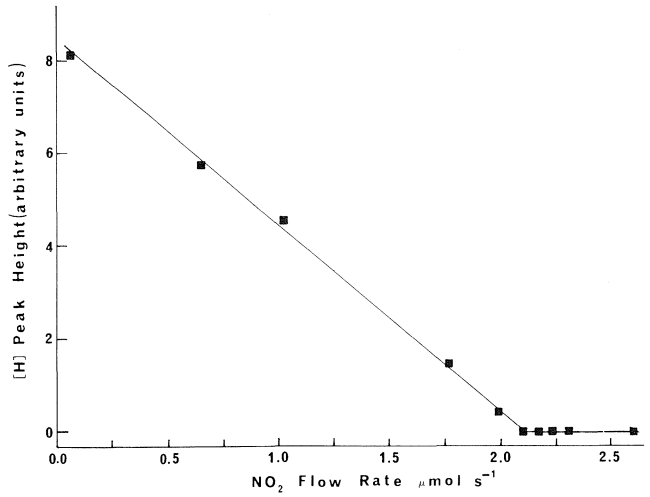

FIG. 1. A typical titration curve for the determination of the concentration of atomic hydrogen with NO_2. The curve indicates the decay of the H atom signal as the flow of NO_2 is increased.

after the specified reaction time. The concentration of the reactant gas was maintained at least 100-fold greater than the atomic hydrogen concentration allowing calculation of the rate constants to be made on the basis of pseudo-first order conditions.

Results

A simplified scheme for the bimolecular reaction between hydrogen atoms and reactants, RX, may be represented as

[1] $H + RX = \text{products}$

On the assumption that the concentration of the reactant is constant, the integrated rate expression for this reaction is given by

[2] $\ln [H]_t = -k[RX]t + \ln [H]_0$

where k is the apparent bimolecular rate constant, and $[H]_t$ and $[H]_0$ are the concentrations of H atoms at time t and 0, respectively, and [RX] is the concentration of reactant which is assumed to remain constant. Under pseudo-first-order conditions, i.e., $[RX] \gg [H]$, the integrated equation becomes

[3] $\ln [H]_t = -k_{obs}t + \ln [H]_0$

where k_{obs} is the pseudo-first-order rate constant. For the present study, it has been assumed that the reduction of H atom concentration is entirely due to reaction with the hydrocarbon or halo-hydrocarbon reactant and that homogeneous and heterogeneous recombination of H atoms are negligible. It has been also assumed that reaction of H atoms with radicals are not significant. These reactions would not be expected to be important relative to the primary step since the concentration of H atoms and radicals are extremely low compared to the concentration of major reactant.

The slope of a plot of $-\ln [H]$ vs. time t gives the pseudo-first-order rate constant k_{obs}. The value of the bimolecular rate constant k is then calculated from the value of [RX].

Methane and ethane

Although the reaction of H atoms with methane and ethane have been well studied and the rate constants determined many times, it was decided to measure these rates with the present system as a test for the apparatus and the overall procedure. As

can be seen in Table 1, the values obtained are in reasonable agreement with those of previous studies. These reactions are extremely slow at room temperature and represent a lower limit for determination by the flow technique used here. In fact, the reaction with methane may be too slow to provide reliable data (27). The main reason for measuring the kinetics of the reactions with methane was to assure that the apparatus could provide information that was in agreement with previous measurements. In so far as the previous measurements (4–14) are comparable, the current values are satisfactory.

Methylfluoride, methylchloride, and methylbromide

These reactions have received very little attention to date (1), and with the exception of the work by Chadwell and Titani (15), studies have been reported only at high temperature. However, it is possible using the Arrhenius parameters given by Parsamyan *et al.* (17) for methylfluoride and Seidel (28) for methylchloride and methylbromide, to predict the rate constants at room temperature as given in Table 2. It may be seen that the values for CH_3F and CH_3Cl in the present study are in reasonable agreement with the calculated values while the value determined here for CH_3Br is greater than the calculated value by a factor of four.

Vinylfluoride, vinylchloride, and vinylbromide

Several studies have reported values for the rate constants for the reaction of H atoms with C_2H_3F and C_2H_3Cl, the most recent by Ahmed and Jones (3), in which they followed the reactions by mass spectroscopy. They also reported the rate constant for the reaction of H atoms with C_2H_3Br for the first time. Table 3 presents the values obtained in the present work and compares them with values determined by other methods.

Discussion

Two quite different types of reaction have been studied in this work. The first is the reaction of H atoms with saturated hydrocarbons and saturated mono-halo-substituted hydrocarbons. These reactions are extremely slow and difficult to measure by normal flow techniques. However, we have been able to obtain values of the room temperature rate constants which are in reasonable agreement with previously reported values or those calculated from previously reported Arrhenius data. These measurements give us reasonable confidence in both the present apparatus and procedures.

For the reaction H + CH_3X = products, where X may be H, F, Cl, or Br, the rate constants k_X follow the order $k_H < k_{Cl} < k_F < k_{Br}$. Two reactions have been proposed as possible initial steps in these reactions. Chadwell and Titani (15) suggested the abstraction of the halogen atom by H as in the reaction:

[4] $H + CH_3X = HX + CH_3$

while Cremer *et al.* (16) proposed the abstraction of an H atoms by H as in the reaction:

[5] $H + CH_3X = H_2 + CH_2X$

If we estimate the enthalpy for the reaction [4] from available bond energies (29), we obtain the values $\Delta H^0 = -9$, -92, -113, and -153 kJ mol^{-1} for H, Cl, F, Br, respectively. Thus the relative values obtained for the rate constants appear to fit well with the relative order of the enthalpies of reaction [4], i.e., $k_H = 1.7 \times 10^{-17}$, $k_{Cl} = 8 \times 10^{-16}$, $k_F = 4 \times 10^{-15}$, and $k_{Br} = 2 \times 10^{-14}$ cm^3 molecule^{-1} s^{-1}.

Since reaction [5] involves the breaking of a C—H bond and formation of H—H bond for each of the halo-substituted hydrocarbons, the enthalpies would not differ as significantly as in reaction [4]. Further, based on the fact that the rate constant for the reaction with methane is extremely small, reaction [5] would be expected to be unimportant relative to reaction [4].

The second type of reaction, that of H atoms with the vinyl-halides, have a larger rate constant than those of reactions with the methyl halides by at least an order of magnitude. In these reactions, the initial step is the addition of H atoms to the double bond of the vinyl-halide;

[6] $H + RX = RHX^*$

The values determined for the rate constants in the present study are in good agreement with the values determined by Ahmed and Jones (3), for H + C_2H_3Cl, but are about a factor of two greater for the reactions with C_2H_3F and C_2H_3Br. Ahmed and Jones (3) found a slight dependence on pressure and a gradual increase in the value of the rate constants from H + C_2H_3F through H + C_2H_3Cl to H + C_2H_3Br. They explained this dependence on halogen by considering two opposing influences created by the substituted halogen atom on the reactivity of the olefin. The influences were the strong negative inductive effect (−I) due to the electronegativity of the halogen, and the positive inductive effect (+I) as a result of the repulsion of electrons present in the p orbitals of the halogen atom and the mesomeric (+M) effect. The results presented here confirm the earlier results obtained by a different method of measurement (mass spectroscopy).

WIESLAW P. GESSNER, BINDUMADHAVAN VENUGOPALAN, ARNOLD BROSSI, ALEX R. JURGENS, and CHARLES D. HUFFORD. Can. J. Chem. **64**, 2196 (1986).

Irradiation of N-acylated primaquines **1***b–d* in chloroform solution with ultraviolet light afforded blue diquinolinyl methine dyes **3***b–d*. The structures of compounds **3***b–d* are supported by spectral data, synthesis of **3***c* from **1***c* with orthoformate, and chemical reduction of **3***d* affording known dimer **5***d*.

WIESLAW P. GESSNER, BINDUMADHAVAN VENUGOPALAN, ARNOLD BROSSI, ALEX R. JURGENS et CHARLES D. HUFFORD. Can. J. Chem. **64**, 2196 (1986).

Lorsqu'on soumet des solutions chloroformiques de primaquines N-acétylées (**1***b–d*) à une irradiation par de la lumière ultraviolette, on obtient les colorants bleus (**3***b–d*) de la famille des diquinolinylméthines. On a déduit les structures des composés **3***b–d* de leurs données spectrales, de la synthèse du composé **3***c* à partir du composé **1***c* et de l'orthoformiate ainsi que de la réduction chimique de **3***d* qui conduit au dimère **5***d* qui est connu.

[Traduit par la revue]

The antimalarial primaquine (**1***a*) is the most widely used tissue schizonticide and the drug of choice in the treatment of vivax malaria (1). *N*-Ethoxyacetylprimaquine (**1***b*), prepared from primaquine base and ethoxyacetic anhydride, and chosen to study the importance of the primary amino group for antimalarial activity, formed a blue color on tlc plates upon irradiation with ultraviolet light of 254 nm while still wet after development with chloroform–methanol. Formation of this blue color was also observed when **1***b* was irradiated with uv light in chloroform solution, but not in dichloromethane or carbon tetrachloride solution, suggesting that chloroform played a role in this reaction. The blue dye, when extracted from tlc plates and rechromatographed with **1***b*, was found to be more polar, and its uv maximum of 618 nm (MeOH) was different from that of 589 nm (MeOH) of a blue dye obtained by Strother *et al.* by base-catalyzed air oxidation of primaquine and 5-hydroxyprimaquine in aqueous solution (2).

The structure of the blue dye formed from **1***b* was of interest, and the results of the investigation which led to the diquinolinyl methine structure **3***b* will be reported. The molecular ion at *m/z* 701 for **3***b* as determined by the Californium plasma desorption ms, the uv maximum at 618 nm, and the involvement of chloroform in its formation suggested the diquinolinyl methine dye **3***b*, formed probably by dichlorocarbene (or dichloromethyl radical) addition to **1***b*, and further reaction of the hypothetical adduct **2** with another molecule of **1***b*. Blue dye **3***b* was a gum that was difficult to handle and for this reason did not give a good elemental analysis. The *p*-nitrobenzoyl analog **1***c*, prepared from primaquine and *p*-nitrobenzoyl chloride, seemed a better compound and its photoreaction afforded the blue dye **3***c* as an amorphous solid. Blue dye **3***c* gave good spectral data, and the results of its combustion analysis supported the structure of an imine hydrochloride salt. The compound **3***c* could alternatively be obtained by treating the hydrochloride of **1***c* with trimethylorthoformate in refluxing methanol.

Photoreaction of known *N*-acetylprimaquine (3) **1***d* in chloroform solution yielded the blue dye **3***d*, fully characterized by ms, uv, ^{1}H nmr, and ^{13}C nmr spectral data. Good support for the diquinolinylmethine structure **3***d* was obtained by chemical reduction with zinc dust in dilute hydrochloric acid, leading to the known microbial metabolite **5***d*, obtained also by synthesis (4). Oxidation of **5***d* in chloroform solution by air under uv light led to the blue dye **3***d*.

Compounds **3***b–d* can in principle exist as two geometrical isomers, convertible throughout deprotonation and reprotonation, but they are most likely present as *E*-isomers (twisted around the C5=CH—C5′ axis) to avoid interaction of the two bulky 6,6′-positioned methoxy groups (based on the inspection of Dreiding models). Blue dyes **3***b–d* behave as indicators, undergoing color change from blue to colorless at pH 11.2, a behavior best explained with the formation of carbinol bases **4***b–d* and reminiscent of properties of polymethine and triphenylmethane dyes (5).

Experimental

Melting points were determined on a Fisher–Johns apparatus and are corrected. The ^{1}H nmr spectra were recorded using a Varian XL-300, JEOL FX-100, or Varian EM-390 spectrometer with TMS as the internal reference. The ^{13}C nmr spectra were recorded using a JEOL FX-100 or JEOL FX-60 spectrometer with TMS as the internal reference. Chemical ionization mass spectra (cims) were obtained on a Finnigan 1015D spectrometer with ammonia as the reagent gas and a Model 6000 data collection system. Californium-252 plasma desorption mass spectra were recorded as described previously (6), at an acceleration voltage of 10 kV. Ultraviolet–visible spectra were measured using a Hewlett–Packard 8450A uv–vis spectrometer. Elemental analyses were performed by the Instrumentation Section, Laboratory of Analytical Chemistry, NIDDK, National Institutes of Health, Bethesda, Maryland or by the Atlantic Microlab Inc., Atlanta, Georgia.

Thin-layer chromatography (tlc) plates (silica gel GHLF analytical and GF preparative) were purchased from Analtech, Inc. and silica gel 60 for short column flash chromatography (0.015–0.040 mm) was from E.M. Reagents.

N-*Ethoxyacetylprimaquine (**1**b)*

Primaquine diphosphate (4.55 g, 10 mmol) was converted to the free base by dissolving in 2 *N* NaOH and extracting with ethyl ether. The ether extract was evaporated to dryness, the residue was dissolved in 50 mL of dry pyridine, then 2.0 g (11 mmol) of ethoxyacetic anhydride and 100 mg of 4-(*N*,*N*-dimethylamino)pyridine were added, and the reaction mixture was kept at room temperature overnight. It was evaporated to dryness, dissolved in methylene chloride, washed with dilute HCl and water, dried with Na_2SO_4, and evaporated to dryness to yield 3.25 g (94%) of *N*-ethoxyacetylprimaquine as a yellow gum. This product was used in the next step without further purification.

An analytical sample was prepared as the phosphate salt and crystallized from 90% ethanol in the form of yellow crystals, mp 145–147°C; uv (free base, $CHCl_3$), λ_{max}: 364 nm; ^{1}H nmr (free base, $CDCl_3$, 100 MHz), δ: 1.20 (m, 6H, C5′CH_3-H, OCH_2CH_3), 1.64 (m, 4H, C2′-H, C3′-H), 3.10–3.70 (m, 4H, C1′-H, C4′-H, NH), 3.48 (q, J = 7.0 Hz, 2H, OCH_2CH_3), 3.84 and 3.86 (2s, 5H, OCH_3, OCH_2CO), 6.28 and 6.22 (2d, J_{5-7} = 3.0 Hz, 2H, C5-H, C7-H), 6.55 (br s, 1H, NHCO), 7.24 (dd, J_{2-3} = 5.0 Hz, J_{3-4} = 8.0 Hz, 1H, C3-H), 7.86 (dd, J_{2-4} = 1.5 Hz, J_{3-4} = 8.0 Hz, 1H, C4-H), 8.46 (dd, J_{2-3} = 5.0 Hz, J_{2-4} = 1.5 Hz, 1H, C2-H); ^{13}C nmr, see Table 1; cims (free base) m/z: 346 (M^+ + 1). *Anal.* calcd. for $C_{19}H_{30}N_3O_7P$: C 51.46, H 6.82, N 9.48, P 6.98; found: C 51.56, H 7.12, N 9.32, P 6.68.

*Photosynthesis of **3**b*

Ethoxyacetylprimaquine (1.5 g) was dissolved in 80 mL of chloroform, placed in a quartz photoreactor, and irradiated at 254 nm (model UVG-11 Mineralight lamp, Ultra-violet Products, Inc.) for 3 h, with stirring, under an argon atmosphere. The deep-green reaction mixture was then evaporated to dryness and chromatographed over a SiO_2 column (CH_2Cl_2, then CH_2Cl_2–MeOH 9:1) to yield first the unchanged starting material, then the deep-blue compound (150 mg). This was rechromatographed on a preparative SiO_2 tlc plate to yield 75 mg of blue compound **3***b* as an amorphous solid, which was homogeneous on tlc (R_f 0.35, CH_2Cl_2–MeOH 9:1); uv–vis ($CHCl_3$, MeOH, H_2O), λ_{max}: 618 nm; uv (MeOH + KOH), λ_{max}: 385 nm; ^{1}H nmr (CD_3OD, 100 MHz), δ: 1.18 (2t, J = 6.5 Hz, 6H, CH_3CH_2O), 1.40 (d, J = 7 Hz, 6H, C5′-H), 1.74 (m, 8H, C2′-H, C3′-H), 3.50 (m, 4H, CH_3CH_2O), 3.85 (2s, 4H, $COCH_2O$), 4.00 (s, 6H, OCH_3), 4.20 (m, 2H, C1′-H), 6.56 (s, 2H, C7-H), 7.32 (dd, J_{2-3} = 4.5 Hz,

[a]All spectra taken in CD_3OD solution using 15 MHz (compounds **3***b* and **3***d*) or 25 MHz (compound **1***b*) ^{13}C nmr instruments. Multiplicities were confirmed by SFORD. Assignments were based on previously reported ^{13}C nmr assignments for primaquine and derivatives (7–10).

[b]Selective SFORD irradiation was used to confirm these assignments.

J_{3-4} = 9.0 Hz, 2H, C3-H), 7.90 (br d, J_{3-4} = 9.0 Hz, 2H, C4-H), 8.58 (br d, J_{2-3} = 4.5 Hz, 2H, C2-H), 8.90 (s, 1H, =CH—); ^{13}C nmr, see Table 1; Californium plasma desorption ms, *m/z*: 701 (positive molecular ion).

N-p-*Nitrobenzoyl primaquine* (**1***c*)

The free base was generated from primaquine diphosphate (9.10 g, 20 mmol) using 50 mL of 2 *N* NaOH followed by extraction with $CHCl_3$. The organic layer was washed with water, dried, and evaporated to dryness. The free base was dissolved in 100 mL of dry benzene, then triethylamine (3.5 mL) was added, followed by *p*-nitrobenzoyl chloride (4.0 g) while keeping the reaction mixture at 0–5°C. The reaction mixture was brought to room temperature and stirred for 3 h, then the solvent was removed and the reaction product extracted with methylene chloride. The organic layer was washed with aqueous $NaHCO_3$ and water, dried, and concentrated to furnish a viscous gum. The product was converted into a hydrochloride salt and crystallized from methanol–ether to yield 7.0 g (86%) of **1***c*·HCl, mp 143–145°C; uv (MeOH), λ_{max}: 206 nm, 266 nm, 360 nm; ^{1}H nmr (CD_3OD, 300 MHz), δ: 1.37 (d, 3H, C5′-H), 1.70–1.90 (m, 4H, C2′-H, C3′-H), 3.45 (m, 2H, C4′-H), 3.85 (m, 1H, C1′-H), 3.95 (s, 3H, OCH_3), 6.95 and 7.01 (2d, J_{5-7} = 2.5 Hz, 2H, C5-H, C7-H), 7.85 (dd, J_{2-3} = 5.0 Hz, J_{3-4} = 8.0 Hz, 1H, C3-H), 7.95 (dd, J_1 = 9.0 Hz, J_2 = 1.5 Hz, 2H, ar.), 8.30 (dd, J_1 = 9.0 Hz, J_2 = 1.5 Hz, 2H, ar.), 8.72 (d, J_{3-4} = 8.0 Hz, C4-H), 8.78 (dd, J_{2-3} = 5.0 Hz, J_{2-4} = 1.5 Hz, C2-H); cims *m/z*: 409 (M^+ + 1). *Anal.* calcd. for $C_{22}H_{25}N_4O_4Cl$: C 59.38, H 5.66, N 12.59, Cl 7.97; found C 59.30, H 5.67, N 12.54, Cl 8.00.

Photosynthesis of **3**c

To a suspension of **1***c*·HCl in 300 mL of $CHCl_3$ was added aqueous NH_3 to adjust the pH to 7.0. The organic layer was washed with water and dried. The solution of the free base **1***c* in $CHCl_3$ was then photolysed as described for the preparation of **3***b*. The crude material was chromatographed on a silica gel column. Elution with methylene chloride gave the starting material first, while further elution with methylene chloride – methanol (9:1) gave the blue material (600 mg), which was again chromatographed on a silica gel column using methylene chloride – methanol (9:1) to yield a blue solid (500 mg). Attempted recrystallization from chloroform–ether gave an amorphous blue solid of mp 140–143°C (dec.); uv–vis (MeOH), λ_{max}: 620 nm; uv (MeOH + NaOH, pH 11.2), λ_{max}: 388 nm; ^{1}H nmr ($CDCl_3$, 300 MHz), δ: 1.45 (d, 6H, C5′-H), 1.95 (m, 8H, C2′-H, C3′-H), 3.55 (m, 4H, C4′-H), 4.05 (s, 6H, OCH_3), 4.30 (m, 3H, C1′-H, NH), 6.50 (2s, 2H, C7-H), 7.29 (m, 2H, C3-H), 7.80 (2d, *J* = 9.0 Hz, 2H, C4-H), 8.05–8.25 (m, 10H, ar., NHCO), 8.53 (m, 2H, C2-H), 8.90 (s, 1H, —CH=); Californium plasma desorption ms, *m/z*: 828.0 (positive molecular ion), calcd. 827.9. *Anal.* calcd. for $C_{45}H_{46}N_8O_8$·1.3 HCl: C 61.82, H 5.45, N 12.81, Cl 5.27; found: C 62.00, H 5.97, N 12.32, Cl 5.27.

Preparation of blue dye **3** d *from methylene dimer* **5** d

The solution of methylene dimer **5***d* (0.51 g), prepared as described previously (6), in 150 mL of chloroform was placed in a 250-mL round bottom flask equipped with a magnetic stirrer. The yellow nondegassed solution was irradiated externally at a distance of 6 in. with a Pyrex-filtered Hanovia mercury lamp.

After 3.5 h of irradiation the solution was evaporated to dryness and the dark green-blue residue was subjected to column chromatography on silica gel 60 (6 g), eluting wih methanol–chloroform mixtures of increasing polarity ($CHCl_3$ to 4:1 $CHCl_3$–MeOH). The "blue band" that eluted last was collected and evaporated to dryness, affording a deep blue-mauve residue (63 mg). Thin-layer chromatography of this material (silica gel 60; $CHCl_3$–MeOH 85:15) and ^{13}C nmr (CD_3OD) showed the presence of minor impurities. The material was once again subjected to column chromatography as before, this time yielding an intense blue solid (25 mg), pure by tlc and hplc. The material was stored in a desiccator where it remained as a solid residue. It quickly became a gummy residue upon exposure to moisture; uv–vis (MeOH), λ_{max}: 618 nm; ^{1}H nmr (CD_3OD, 90 MHz), δ: 1.53 (d, *J* = 6.0 Hz, 6H, C5′-H), 2.03 (s, 6H, $COCH_3$), 4.13 (s, 6H, OCH_3), 6.70 (s, 2H, C7-H), 7.39 (dd, J_{2-3} = 4.5 Hz, J_{3-4} = 9.0 Hz, C3-H), 8.10 (br d, *J* = 9.0 Hz, 2H, C4-H), 8.73 (br d, *J* = 4.5 Hz, 2H, C2-H), 9.07 (s, 1H, —CH=); ^{13}C nmr, see Table 1; Californium plasma desorption ms, *m/z*: 613 (positive molecular ion).

Preparation of blue dye **3** d *from* N-*acetylprimaquine* **1** d

The solution of *N*-acetylprimaquine (1.0 g), prepared as described previously (2), in chloroform (250 mL) was placed in a 500-mL round bottom flask equipped with a magnetic stirrer. Photolysis of the solution was carried out as above. After a total of 5.5 h of irradiation the solution was evaporated to dryness. Chromatography as above gave pure blue dye **3***d* (67.5 mg), which was identical (^{1}H and ^{13}C nmr, tlc, hplc) to that prepared above.

Reduction of blue dye **3** d *to methylene dimer* **5** d

Zinc dust (200 mg) was added to a stirring solution of blue dye **3***d* (30 mg) in 20 mL of methanol–water 1:1. To this deep blue solution was added 50 drops of 10% HCl. (**Note**: the solution must at no time be allowed to become basic.) After 10 min the green solution was filtered and concentrated to ca. 10 mL on the rotary evaporator. This solution was transferred to a separatory funnel and extracted with diethyl ether (4 × 30 mL). The organic layer was dried ($MgSO_4$) and evaporated to dryness, affording a yellow material (5 mg) that was shown to be *N*-acetylprimaquine (^{1}H nmr, tlc).

The aqueous layer was reextracted with chloroform (3 × 20 mL), the organic layer was dried ($MgSO_4$) and evaporated to dryness, affording a yellow material (15 mg) that was shown by ^{1}H nmr and tlc to consist mainly of methylene dimer **5***d* with a trace of *N*-acetylprimaquine. Preparative tlc (silica gel G-200, 2.0 mm, double run with $CHCl_3$–MeOH 95:5) gave a band (R_f ca. 0.2) that, after extraction with methanol–chloroform 1:1, afforded a residue (7 mg). This residue was shown (^{1}H nmr, ir, tlc, hplc) to be identical to the authentic methylene dimer **5***d*.

Preparation of blue dye **3**c *from* **1**c

To a solution of **1***c*·HCl (150 mg) in 5 mL of methanol was added 1 mL of trimethylorthoformate, and the reaction mixture was refluxed for 18 h. During this period the color of the reaction mixture changed from yellow to blue-green. The solvent was then removed and the crude product was passed down a column of silica gel. Elution with $CHCl_3$–MeOH (99:1) gave the starting material first, while further elution with $CHCl_3$–MeOH (97:3) gave the blue dimer **3***c* (30 mg), which was found to be identical (tlc, uv–vis, ms) with that obtained from the direct photolysis of **1***c*.

An analysis of the kinetic rate constants for ion/molecule reactions of allene by use of the Laplace–Carson transform is performed and the results are compared with experimental data.

FRANÇOIS HAMON, DANIELLE CARRIER et JAN A. HERMAN. Can. J. Chem. **64**, 2199 (1986).

On a effectué une analyse des constantes de vitesse des réactions ion/molécule de l'allène en faisant appel à la transformation de Laplace–Carson; on compare les résultats avec les données expérimentales.

[Traduit par la revue]

Introduction

In a previous paper we presented a mechanism for ion/molecule reactions of gaseous allene in the pressure range 0.02 to 3.5 Torr (1). This reaction mechanism was deduced from results obtained in a high pressure mass-spectrometer equipped with a photoionization source operating at 10 eV (krypton resonance line). At this energy only parent ions of allene are formed, therefore all daughter and subsequent generations of ions must be traced to the $C_3H_4^+$ primary species. At that time no attempt was made to calculate rate constants of the successive reaction steps. In another paper we considered the collisional stabilization by non-polar gases of the dimer-ion species, $C_6H_8^+$, which was assumed to play an important role in the overall reaction scheme (2). Other studies of the ion/molecule reaction of allene at low pressure (<0.01 Torr) have not indicated the presence of the $C_6H_8^+$ ion species, but the formation of $C_6H_7^+$ and of $C_7H_7^+$ species have been observed (3–6). Obviously, the presence of the $C_6H_8^+$ ion species at high pressure, even at low fractional intensity (<1%), is an indication that this species has to be stabilized by collision in order to be observed.

The reaction scheme for ion/molecule reactions in allene is shown below in which only the two most important reaction channels are considered.

[1] $C_3H_4^+ + C_3H_4 \xrightarrow{k_1} C_6H_7^+ + H^\cdot$

[2] $C_3H_4^+ + 2C_3H_4 \xrightarrow{k_2} C_7H_7^+ + C_2H_5^\cdot$

[3] $C_6H_7^+ + C_3H_4 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} C_6H_7^+\cdot C_3H_4$

[4] $C_6H_7^+\cdot C_3H_4 + C_3H_4 \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} C_6H_7^+(C_3H_4)_2$

[5] $C_6H_7^+(C_3H_4)_2 + C_3H_4 \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} C_6H_7^+(C_3H_4)_3$

[6] $C_7H_7^+ + C_3H_4 \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} \alpha\text{-}C_{10}H_{11}^+$

[7] $C_6H_7^+\cdot C_3H_4 + C_3H_4 \xrightarrow{k_7} \beta\text{-}C_{10}H_{11}^+ + C_2H_4$

[8] $\beta'\text{-}C_{10}H_{11}^+ + C_3H_4 \xrightarrow{k_8} \beta\text{-}C_7H_7^+ + 2C_3H_4$

These species account for around 90% of the total ion intensities (1). The question which could not have been answered at that time concerned the mechanism of formation of the $C_6H_7^+$ species at high pressure, either through the long-lived ion complex ($C_3H_4^+\cdot C_3H_4$) requiring a reactive collision with a neutral allene molecule, or simply through an unimolecular fragmentation of the excited collisional complex: $(C_3H_4)_2^+ * \rightarrow C_6H_7^+ + H\cdot$ (6, 7). In both cases the reaction processes are exothermic. Another problem which could not be settled was the unexpected behaviour at high pressure (>0.1 Torr) of the $C_{10}H_{11}^+$ and $C_7H_7^+$ ion species (1). We assumed that at least two isomeric $C_7H_7^+$ and $C_{10}H_{11}^+$ ion species have to be formed through different reaction channels accounting for the steady build up of the concentrations of these species with increasing pressure.

In order to test the proposed reaction scheme and to get a better insight we present the calculation of the rate constants of the various steps of the ion/molecule reactions and we compare the numerical results with the experimental data published in ref. 1.

Kinetic model

In order to calculate the rate coefficients of the elementary steps in the sequence of ion/molecule reactions of allene, one has to know the mean residence time, t_R, of ion species in the collision cell. The cylindrical ion source of our experimental setup is not equipped for residence time or ion mobility measurements (1). However, for the present purposes it may be assumed on the basis of ion mobility theory (8) and some experimental data (9–13) that the residence time at pressures above a few tenths of a Torr is proportional to the pressure and to the length of the path between the site of formation of the ion and the exit slit. Under vanishing electric field conditions the diffusion of ions is isotropic and one can show that the average path length of ions can be correlated to the distance, l, between the plane of ion formation by incident photons, and the exit slit. In the case of a cylindrical cavity of radius r_0 and length l the residence time is given by (14):

$$t_R = D[(2.045/r_0)^2 + (\pi/2l)^2]$$

where D is the diffusion coefficient which can be calculated from the Einstein relation, $D = KT \times 8.6 \times 10^{-5}$. The ion mobility, K, can be evaluated at the temperature and the pressure of the experiments from the reduced mobility, $K_0 = 35.9\,(\alpha\mu)^{-1/2}$, where α is the polarizability and μ is the reduced mass of the system, both expressed in atomic units. This expression of the reduced mobility applies only to an ion diffusing in a bath gas of different nature, in order to avoid resonant charge transfer, and in a vanishing field. Both conditions are met in the present case. Strictly speaking, one

should use the ambipolar coefficient of diffusion to calculate the residence time of ions, but this is very difficult to take into account in a simple manner. In any case the dominant effect of the ambipolar diffusion will involve the velocity distribution of ions rather than the average drift velocity (15).

Following these expressions, the average residence time is calculated to be $t_R = 80$ μs at 0.1 Torr and at the distance $l = 2.2$ mm for the cylindrical source used in the present experiments ($r_0 = 9.52$ mm). The average reduced mass $\mu = 30.9$ amu was used which gives a difference of 10% between the average residence time and the individual residence time values for each ion/molecule system.

The ion source used in this study (16) is not suited to residence time measurements, therefore it was difficult to verify experimentally the above calculated relation of t_R. However, at the lowest pressure ($P < 0.015$ Torr) and at the shortest path length[1] ($l = 2.2$ mm) we could roughly estimate the variation of the fractional intensities of the $C_6H_7^+$ species, which is the most important abundant ion (~60%) in this pressure range. From these data we found a residence time, $t_R = 87 \pm 17$ μs at $P = 0.1$ Torr, which compares reasonably well with the residence time calculated from the simplified model using the transport properties of gases (8). Therefore, in all subsequent calculations we used the pressure-dependent average residence time, $t_R = 0.80 \times 10^{-3} P$ (s Torr^{-1}) for all experimental data obtained for the length 2.2 mm in the collision cell.

In the kinetic model discussed below we assume that the disappearance of the primary ion species, $C_3H_4^+$, proceeds through two channels leading to $C_6H_7^+ \cdot (C_3H_4)_n$ (with $n = 0$–3) and $C_7H_7^+ \cdot (C_3H_4)_m$ (with $m = 0$, 1) ion species, respectively. We also assume that the rate constant for disappearance of the primary ion species, $C_3H_4^+$, is given by $k = (6.4 \pm 0.5) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} as measured by Lifshitz in a trapped-ion mass spectrometer (5). Moreover, we will neglect in our calculations the very weak reaction channel (around 2%) leading to $C_6H_9^+$ ion species.

In order to fit the calculated fractional intensities of ion species with experimental data, we have to assume two additional processes besides the reactions [1]–[8]:

$$[9] \quad \beta'\text{-}C_{10}H_{11}^+ + C_3H_4 \xrightarrow{k_9} \beta\text{-}C_7H_7^+ + 2C_3H_4$$

$$[10] \quad \alpha\text{-}C_{10}H_{11}^+ + C_3H_4 \xrightarrow{k_{10}} \text{unidentified products}$$

Reaction [9] might be an isomerization process or a stabilization reaction giving unreactive $C_{10}H_{11}^+$ species toward allene molecule. The relative positions of processes [9] and [10] in the sequence of ion/molecule reactions of allene are shown in Fig. 1.

For the sake of clarity we will present first the kinetics of the $C_6H_7^+ \cdot (C_3H_4)_n$ formation channel, and then the kinetics of $C_7H_7^+ \cdot (C_3H_4)_m$ channel.

The $C_6H_7^+ \cdot (C_3H_4)_n$ species formation channel

The following rate equations describe the formation of the above mentioned species

$$[11] \quad d[C_3H_4^+]/dt = -(k_1 + k_2)[C_3H_4^+]P$$

$$[12] \quad d[C_6H_7^+]/dt = k_1[C_3H_4^+]P - k_3[C_6H_7^+]P^2 + k_{-3}[C_6H_7^+ \cdot C_3H_4]P$$

[1]The photoionization collision cell is equipped with several slits whose distances vary from 2.2 to 13.2 mm from the site of primary ion formation to the exit orifice (16).

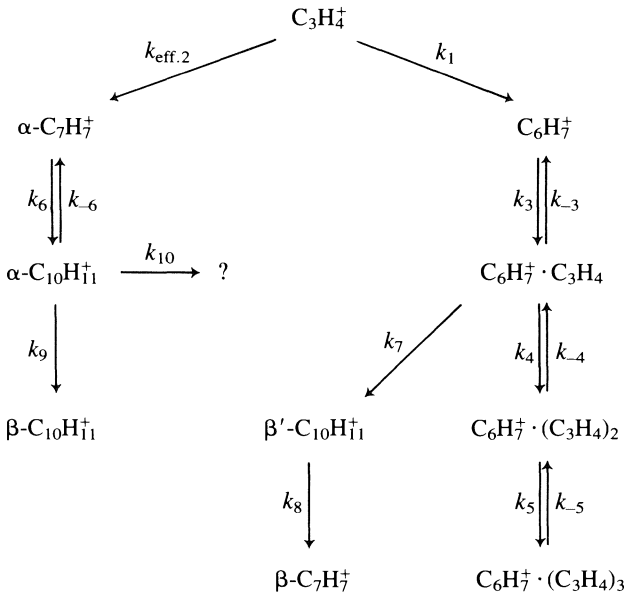

FIG. 1. The proposed reaction scheme for ion/molecule reactions in allene.

$$[13] \quad d[C_6H_7^+ \cdot C_3H_4]/dt = k_3[C_6H_7^+]P^2 + k_{-4}[C_6H_7^+ \cdot (C_3H_4)_2]P - (k_4P + k_8 + k_{-3})[C_6H_7^+ \cdot (C_3H_4)]P$$

$$[14] \quad d[C_6H_7^+ \cdot (C_3H_4)_2]/dt = k_4[C_6H_7^+ \cdot C_3H_4]P^2 + k_{-5}[C_6H_7^+ \cdot (C_3H_4)_3]P - (k_{-4} + k_5P)[C_6H_7^+ \cdot (C_3H_4)_2]P$$

$$[15] \quad d[C_6H_7^+ \cdot (C_3H_4)_3]/dt = k_5[C_6H_7^+ \cdot (C_3H_4)_2]P^2 - k_{-5}[C_6H_7^+ \cdot (C_3H_4)_3]P$$

In these equations P (Torr) stands for the concentration of the neutral allene.

The additional reaction channel characterised by rate coefficient k_8 in eq. [13] relates the experimentally established absence of thermodynamic equilibrium between the $C_6H_7^+ \cdot C_3H_4$ species and the $C_6H_7^+$ precursor ion on one side and the $C_6H_7^+ \cdot (C_3H_4)_2$ species on the other side (1). However, starting from the $C_6H_7^+ \cdot (C_3H_4)_2$ species and higher order clusters the chemical equilibrium is achieved as shown experimentally by varying the residence time of these species in the collision cell (1).

Within this kinetic scheme we assumed the generally accepted mechanisms of solvation processes, namely, that the forward reaction requires a stabilization collision and the backward or declustering reaction an activation step (17). This introduces a third order forward reaction step and a reverse bimolecular dissociation process.

Another important comment concerns the formation of $C_7H_7^+$ species in reaction [2]. The best fit of the rate coefficients with experimental data requires that $C_7H_7^+$ species to be formed in an *apparent second order reaction*. Any attempt to introduce a third order formation process of $C_7H_7^+$ species from primary $C_3H_4^+$ ions and allene neutrals leads to rate coefficients for both channels, $C_6H_7^+$ and $C_7H_7^+$, which is experimentally not supported. In the next section we will discuss this behaviour in more detail.

Keeping these remarks in mind we used the Laplace–Carson transform method for the solution of these simultaneous

TABLE 1. List of rate constants

Reaction	Rate coefficient
$C_3H_4^+[C_3H_4, H^\cdot]C_6H_7^+$	$k_1 = 4.33 \times 10^{-10}$ [a]
$C_3H_4^+[2C_3H_4, C_2H_5']\alpha\text{-}C_7H_7^+$	$k_{2,\text{eff}} = 2.16 \times 10^{-10}$ [a]
$C_6H_7^+[2C_3H_4, C_3H_4]C_6H_7^+C_3H_4$	$k_3 = 1.1 \times 10^{-27}$ [b]
$C_6H_7^+C_3H_4[C_3H_4, 2C_3H_4]C_6H_7^+$	$k_{-3} = 1.5 \times 10^{-12}$ [a]
$C_6H_7^+C_3H_4[2C_3H_4, C_3H_4]C_6H_7^+(C_3H_4)_2$	$k_4 = 9.6 \times 10^{-29}$ [b]
$C_6H_7^+(C_3H_4)_2[C_3H_4, 2C_3H_4]C_6H_7^+C_3H_4$	$k_{-4} = 1.2 \times 10^{-11}$ [a]
$C_6H_7^+(C_3H_4)_2[2C_3H_4, C_3H_4]C_6H_7^+(C_3H_4)_3$	$k_5 = 9.6 \times 10^{-30}$ [b]
$C_6H_7^+(C_3H_4)_3[C_3H_4, 2C_3H_4]C_6H_7^+(C_3H_4)_2$	$k_{-5} = 4.6 \times 10^{-13}$ [a]
$\alpha\text{-}C_7H_7^+[2C_3H_4, C_3H_4]\alpha\text{-}C_{10}H_{11}^+$	$k_6 = 1.9 \times 10^{-27}$ [b]
$\alpha\text{-}C_{10}H_{11}^+[C_3H_4, 2C_3H_4]\alpha\text{-}C_7H_7^+$	$k_{-6} = 1.9 \times 10^{-12}$ [a]
$C_6H_7^+\cdot C_3H_4[C_3H_4, C_2H_4]\beta'\text{-}C_{10}H_{11}^+$	$k_7 = 3.1 \times 10^{-15}$ [a]
$\beta'\text{-}C_{10}H_{11}^+[C_3H_4, 2C_3H_4]\beta\text{-}C_7H_7^+$	$k_8 = 6.2 \times 10^{-15}$ [a]
$\alpha\text{-}C_{10}H_{11}^+[C_3H_4, C_3H_4]\beta\text{-}C_{10}H_{11}^+$	$k_9 = 9.3 \times 10^{-13}$ [a]
$\alpha\text{-}C_{10}H_{11}^+[C_3H_4, ?]I^+$ [c]	$k_{10} = 2.2 \times 10^{-12}$ [a]

[a] Units: cm^3 $molecule^{-1}$ s^{-1}.
[b] Units: cm^6 $molecule^{-2}$ s^{-1}.
[c] Unidentified ion products.

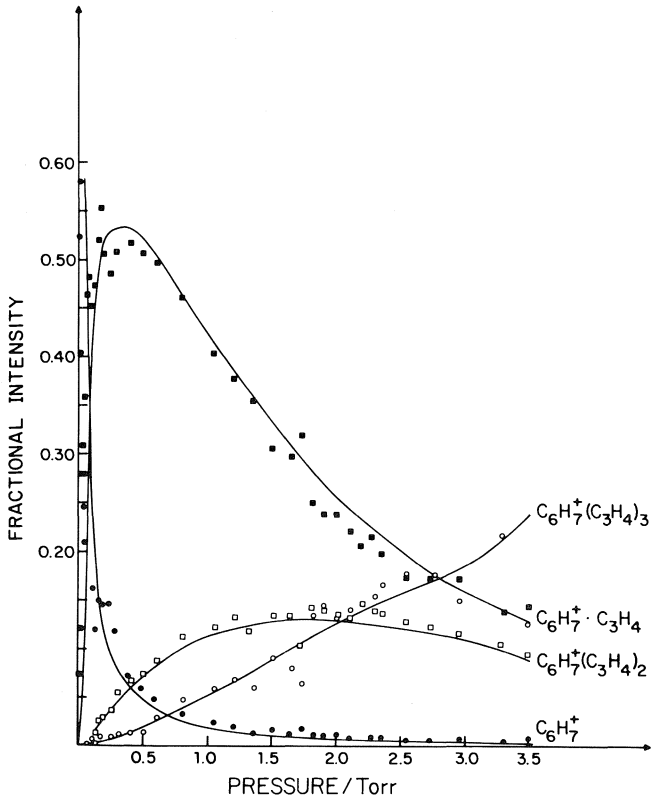

FIG. 2. Calculated fractional intensity curves (solid lines) as a function of the pressure for the $C_6H_7^+\cdot(C_3H_4)_n$ family of ions.

differential equations as a function of time. Some details of the solutions are presented in Appendix 1. The rate coefficients for the $C_6H_7^+(C_3H_4)_n$ species channel formation are presented in Table 1, and in Fig. 2 the calculated corresponding fractional intensities curves are shown.

The $C_7H_7^+$ and $C_{10}H_{11}^+$ species formation channel

First, let us look into the apparent anomaly, mentioned in the previous section, of the experimental second order rate of formation of the $C_7H_7^+$ ion species instead of a third order process which would normally be expected. Indeed, if one tries to fit the $C_7H_7^+$ ion formation to a third order process, the best calculated rate coefficient is around 10^{-25} cm^6 $molecule^{-2}$ s^{-1}, which is physically not acceptable and, moreover, the rate of formation of $C_6H_7^+$ species has to be compensated also by a third order contribution also having an unlikely high rate coefficient of the order of 10^{-24} cm^6 $molecule^{-2}$ s^{-1}. However, the *pseudo second order* mechanism of $C_7H_7^+$ formation is explained by assuming the formation of a $C_4H_4^+$ intermediate ion species, which reacts very efficiently with neutral allene to form the $C_7H_7^+$ species:

$$[16]\quad C_3H_4^+ + C_3H_4 \underset{k_r}{\overset{k_f}{\rightleftharpoons}} (C_3H_4)_2^+{}^*$$

$$[17]\quad (C_3H_4)_2^+{}^* \xrightarrow{k_1} C_6H_7^+ + H^\cdot$$

$$[18]\quad (C_3H_4)_2^+{}^* \xrightarrow{k_d} C_4H_4^+ + C_2H_4$$

$$[19]\quad (C_3H_4)_2^+{}^* + C_3H_4 \xrightarrow{k_s} C_6H_8^+ + C_3H_4$$

$$[20]\quad C_4H_4^+ + C_3H_4 \xrightarrow{k_2'} \alpha\text{-}C_7H_7^+ + H^\cdot$$

In our experiments the pressure is too high to allow the detection of the $C_4H_4^+$ species, but at lower pressure ($P < 10^{-3}$ Torr) it was observed experimentally (3), and reaction [20] was definitely established in double resonance I.C.R. experiments (4, 5). We assume that the $C_4H_4^+$ species is very reactive and reacts at almost every collision with neutral allene in process [20], which might explain its absence in the mass spectrum, even at the lowest pressure of our experiments. Applying the steady state assumption to the collisional complex, $(C_3H_4)_2^+$, and to the $C_4H_4^+$ species, one gets the following order dependence for the formation of $C_7H_7^+$

$$[21]\quad d[C_7H_7^+]/dt = \left(\frac{k_f k_d}{k_r + k_1 + k_d + k_s P}\right)[C_3H_4^+]P$$

The relative stabilization rate coefficient, k_s, was measured by Nagase *et al.* (18), and is at least two orders of magnitude smaller than the sum $(k_r + k_1 + k_d) \simeq k_f$, and at low pressure it can be neglected in eq. [21]. Consequently, eq. [21] takes

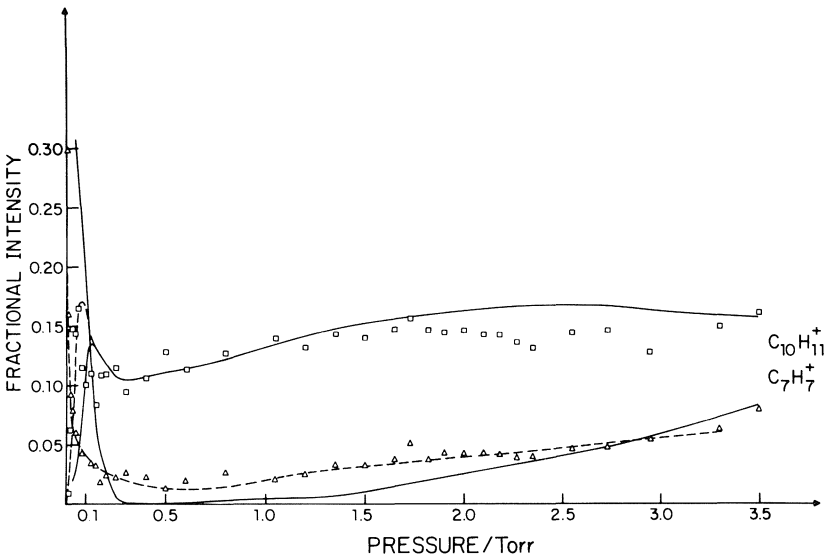

FIG. 3. Calculated fractional intensity curves (solid lines) as a function of the pressure for the $C_7H_7^+$ and $C_{10}H_{11}^+$ species. The broken lines are the experimental curves.

the experimentally required kinetic order dependence:

$$[22]\quad d[C_7H_7^+]/dt \simeq \left(\frac{k_f k_d}{k_r + k_1 + k_d}\right)[C_3H_4^+]P = k_{2,\text{eff}}[C_3H_4^+]P$$

Assuming that the rate coefficient, k_f, can be calculated from the "average dipole orientation" collision rate theory (ADO), and is equal to $k_f = k_{ADO} = 12.9 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} [7], one can use this value to estimate the ratio $(k_r + k_1)/k_d$ in eq. [22]. Substituting the experimental value for $k_{2,\text{eff}} = 2.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} (Table 1) one finds $(k_r + k_1)/k_d \simeq 5.9$.

As shown previously the $C_7H_7^+$ and $C_{10}H_{11}^+$ ion formation channel displays a complex behaviour (1). At low pressure and short residence time the fractional intensity of $C_{10}H_{11}^+$ species reaches a sharp maximum at $P \sim 0.05$ Torr, passes through a minimum at $P = 0.2$ Torr, and then rises slowly with pressure to a plateau. Concurrently the fractional intensity of the $C_7H_7^+$ species drops to 0.03 at low pressure <0.4 Torr, and then slowly rises with increasing pressure to around 0.06 at 3.5 Torr. At longer residence time of ion species in the collision cell this behaviour is enhanced. In order to explain this complex behaviour we have assumed that the $C_7H_7^+$ and $C_{10}H_{11}^+$ ion species are formed in at least two different reaction channels leading to isomer species of different structures, as shown by their different reactivities toward the neutral allene. There is also the possibility that these isomeric species of $C_7H_7^+$ and $C_{10}H_{11}^+$ general formula, are converted through collisionally induced isomerization processes.

Several kinetic schemes were tested and the best results were obtained for the reaction sequence:

$$[23]\quad d[\alpha\text{-}C_7H_7^+]/dt = k_{2,\text{eff}}[C_3H_4^+]P + k_{-6}[\alpha\text{-}C_{10}H_{11}^+]P - k_6[\alpha\text{-}C_7H_7^+]P^2$$

$$[24]\quad d[\beta\text{-}C_7H_7^+]/dt = k_9[\beta'\text{-}C_{10}H_{11}^+]P$$

$$[25]\quad d[\alpha\text{-}C_{10}H_{11}^+]/dt = k_6[\alpha\text{-}C_7H_7^+]P^2 - (k_{-6} + k_7 + k_{10})[\alpha\text{-}C_{10}H_{11}^+]P$$

$$[26]\quad d[\beta'\text{-}C_{10}H_{11}^+]/dt = k_8[C_6H_7^+\cdot C_3H_4]P - k_9[\beta'\text{-}C_{10}H_{11}^+]P$$

In the expressions [23]–[26] the reaction processes and the corresponding rate coefficients are numbered according to the overall reaction scheme in Fig. 1.

The α-, β-, and β′- species are identified in Fig. 1. The α-$C_7H_7^+$ and α-$C_{10}H_{11}^+$ ion species seems to be related by a solvation process and are formed preferentially at low pressure. The β-$C_7H_7^+$, β-$C_{10}H_{11}^+$, and β′-$C_{10}H_{11}^+$ species are most probably a mixture of unreactive isomers formed at high pressure which accumulate in the system. The experimental fractional intensities of $C_7H_7^+$ and $C_{10}H_{11}^+$ as a function of the pressure are, of course, the sum of these processes and the solutions of corresponding differential equations are shown in the Appendix (eqs. [34], [35]). The numerical solutions are presented in Table 1 and the calculated curves are shown in Fig. 3.

Discussion

The Laplace–Carson transform method applied to a scheme of elementary reactions such as shown in Fig. 1, is sensitive to the assumed order of the reactions and to the number of elementary steps involved in the formation of each species. In such a way a number of kinetically plausible combinations of elementary reactions can be eliminated, because they do not fit the experimental intensities. However, it should be pointed out that the rate coefficient values of the first steps are critical, allowing only a small variation in order to reproduce the experimental curves. On the other hand, the rate coefficient values of the last steps are less sensitive.

The calculated curves of fractional intensities as a function of the pressure using the rate coefficients obtained by the Laplace–Carson transform method fit the experimental data satisfactorily (Figs. 2, 3). The precision expected in these calculations for the $C_6H_7^+\cdot(C_3H_4)_n$ ion formation channel is estimated to be around 30% if one takes into account the approximate values of the mean residence time of ions in the collision cell and the use of an average value for the reduced mass of all ions in the system. In the case of this reaction channel the thermodynamic equilibrium relations impose supplementary constraints on the choice of possible combinations of rate coefficient values describing the experimental curves. The value of the third-order rate coefficient for the forward reaction forming the $C_6H_7^+\cdot C_3H_4$

species (reaction [3]) of approximately 10^{-27} cm^6 molecule^{-2} s^{-1} is a fairly large value. However, the value for a third-order rate coefficient depends primarily on the lifetime of the excited complex which must be collisionally deactivated. The further solvation processes (reactions [4] and [5] proceed much slower, as indicated by the corresponding rate coefficients, and this may be due to a decrease in the energy of association as the size of the cluster increases.

The overall precision in the calculations of the $C_7H_7^+$ and $C_{10}H_{11}^+$ formation channel is lower than that for the $C_6H_7^+ \cdot (C_3H_4)_n$ reactions sequence. Especially in the case of $C_7H_7^+$ the precision seems to be poor.

The calculated curves for the $C_7H_7^+$ and $C_{10}H_{11}^+$ species formation involve several contributions from different sources (Fig. 1), therefore their fit to experimental data is more complex. At low pressure both calculated curves diverge from the experimental points. In the case of $C_7H_7^+$ species the disagreement is sufficiently pronounced to consider the existence of another process consuming the precursor of the $C_7H_7^+$ species. However, we have not succeeded in reproducing such a reaction channel in our calculations. Moreover, we have to assume an additional second order reaction channel consuming the α-$C_{10}H_{11}^+$ species (reaction [10]) in order to account for the shape of the curve. In fact, this second order reaction is relatively slow ($k_{10} = 2.2 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}) and it could also be responsible for the formation of minor ion species, i.e. $C_9H_9^+$ whose origin is difficult to assess with certainty.

The contribution to the β-$C_{10}H_{11}^+$ and β'-$C_7H_7^+$ formation through reactions [7] and [8] accounts for >50% at high pressure. It seems that the slow decomposition reaction [7] with a rate coefficient $k_7 \sim 10^{-15}$ cm^3 molecule^{-1} s^{-1} is the rate-determining step at pressures above 1 Torr. For the olefin systems studies in this laboratory we have found that there are slow ion/molecule reactions which take place at high pressure. The origin of these reactions is not very clear owing to the numerous steps preceding the formation process of the species accumulated in the gas phase.[2] This may also be the case for reactions [7] and [8], which albeit slow are determinant for the formation of the unreactive $C_7H_7^+$ and $C_{10}H_{11}^+$ species.

The kinetic analysis of ion/molecule reactions of allene suggests two mechanisms for the disappearance of $C_3H_4^+$ primary ions through an excited complex $(C_3H_4^+)^{2*}$: (*a*) dissociating into $C_6H_7^+$ and a hydrogen atom, which is the main reaction channel [7], and (*b*) dissociating into $C_4H_4^+$ ion species, which on collision with neutral allene form the $C_7H_7^+$ species (reaction [20]). It is possible that the long-lived dimer-ion is formed by a partial deactivation of the excited loose complex $(C_3H_4^+)^{2*}$ preventing further dissociation into $C_6H_7^+$, but transforming it into a tighter configuration.

The discrepancy between the rate coefficients for the disappearance of the primary ion species, $C_3H_4^+$, measured by ICR mass-spectrometry (19) and in photoionization high-pressure mass-spectrometry (5–7) is probably due to the differences of internal energies in the primary ion species. The ion–molecule reaction cross-section of allene decreases with increasing photon energy and was observed to decrease by ~70% of the initial value for $C_6H_7^+$ production upon increasing the internal vibrational energy by 1.0 eV, [7]. In the ICR mass-spectrometry experiments the rate coefficient for $C_6H_7^+$ formation was measured to be 9.6×10^{-10} cm^3 molecule^{-1} s^{-1} (19), which is 2.2 times higher than the calculated rate constant for the same reaction in the present experiments (Table 1). For the time being we have no explanation for this apparently contradictory result, unless some deactivation and stabilization processes have to be accounted for in experiments at high pressure ($>10^{-3}$ Torr).

Appendix

The system of linear differential equations for the rates of consecutive, reverse, or parallel reactions can be solved using the Laplace–Carson method

$$F(L) = L\int_0^\infty e^{-Lt} f(t)dt$$

as described by Rodiguin and Rodiguina (20). In the present case of a complex ion/molecule reactions sequence one obtains transforms whose originals have to be separately evaluated. The general procedure is to decompose the transform

$$[27] \quad \frac{F_1(L)}{F_2(L)} = \frac{a_0L^m + a_1L^{m-1} + \ldots + a_m}{b_0L^n + b_1L^{n-1} + \ldots + b_n}$$

where the multinomials $F_1(L)$ and $F_2(L)$ have no common roots, into a sum of partial fractions:

$$[28]\quad \frac{F_1(L)}{F_2(L)} = \sum_{j=1}^{n} \frac{A_j}{L - L_j}$$

where L_j are the roots of the equation $F_2(L) = 0$. The decomposition coefficients A_j, given by

$$[29]\quad A_j = \frac{F_1(L_j)}{F_2'(L_j)}$$

are substituted into [28]:

$$[30]\quad \frac{F_1(L)}{F_2(L)} = \sum_{j=1}^{n} \frac{F_1(L_j)}{F_2'(L_j)}\left(\frac{1}{L - L_j}\right)$$

in which the original of $F_1(L)/F_2(L)$ can be readily determined, since each term of the sum of the right-hand portion of the equation is a constant multiplied by the factor $\{1/(L - L_j)\}$, the original of which is known. The final expression of the ratio is:

$$[31]\quad \frac{F_1(L)}{F_2(L)} = \sum_{j=1}^{n} \frac{F_1(L_j)}{F_2'(L_j)} \frac{1}{L_j} [\exp(L_j t) - 1]$$

Suitable computer programs were developed in order to solve eq. [31] for each ion species.

The application of this method to the simultaneous differential equations as a function of the residence time yields the following solution for the primary ions:

$$[32]\quad [C_3H_4{}^+] = \frac{\exp\{-(k_1 + k_2)\mathrm{Pt}\} - 1}{-(k_1 + k_2)P}$$

and four equations of the form:

$$[33]\quad [S^+] = \sum_{j}^{1-5} {}_sA_j[\exp(L_j t) - 1]/L_j$$

for $C_6H_7{}^+$ and its clustered species, where $[S^+]$ stands for the concentration of $C_6H_7{}^+\cdot(C_3H_4)_n$ ion species with $n = 0$, 1, 2, 3, respectively. The superscripts of the sum symbol [33] are related to the kinetic rate equations characterized by the rate coefficients, $k_{\pm j}$ (Fig. 1). The real roots, L_j, of the multinomial of the denominator in expression [33] are the same, and only the coefficients ${}_sA_j$ obtained from the decomposition of the ratio of multinomials into simple fractions are different for each species, S^+. Obviously, at the initial time, $t_0 = 0$, the fractional intensity of the primary ions $[C_3H_4{}^+]_0 = 1$.

In the case of the $C_7H_7{}^+$ formation channel we get the following solutions:

$$[34]\quad [C_7H_7{}^+] = \sum_{j}^{2,6} \frac{{}_\alpha B_j}{L_j} [\exp(L_j t) - 1] + \sum_{j}^{1,3-5,7,8} \frac{{}_\beta B_j}{L_j} [\exp(L_j t) - 1]$$

$$[35]\quad [C_{10}H_{11}{}^+] = \sum_{j}^{2,6,9,10} \frac{{}_\alpha C_j + {}_\beta C_j}{L_j} [\exp(L_j t) - 1] + \sum_{j}^{1-5,7} \frac{{}_{\beta'} C_j}{L_j} [\exp(L_j t) - 1]$$

where ${}_\alpha B_j$, ${}_\beta B_j$, ${}_\alpha C_j$, ${}_\beta C_j$, and ${}_{\beta'} C_j$ are the coefficients of the simple fractions and L_j are the real roots of the multinomials of the denominator in [28].

Enantioselective synthesis of isoquinoline alkaloids[1]

On démontre l'utilité de la condensation de Pictet–Spengler du (*R*)-(+)-glycéraldéhyde avec le chlorhydrate de la dopamine dans la synthèse énantiosélective des alcaloïdes de l'isoquinoléine en préparant la (*S*)-(−)-carnégine, la (*R*)-(−)-calycotomine et la (*S*)-(+)-laudanosine.

[Traduit par la revue]

Introduction

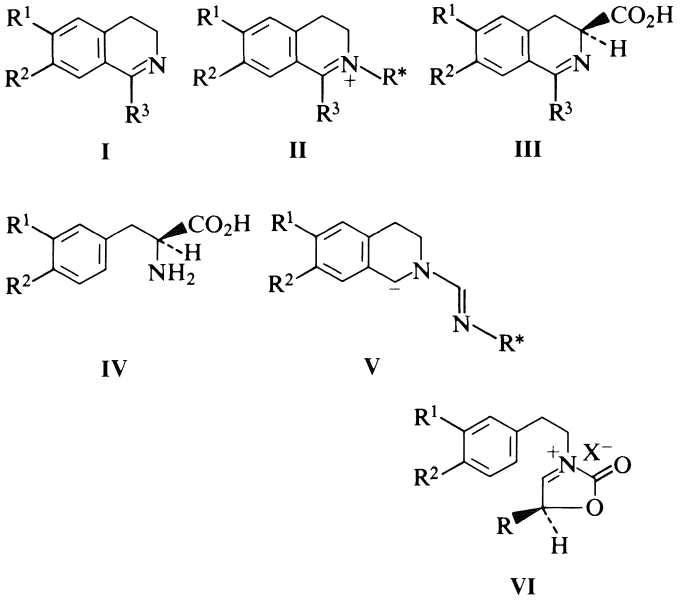
The asymmetric synthesis of isoquinoline alkaloids has been investigated widely in recent years because of the importance of these alkaloids in medicine and pharmacology (1). A variety of approaches have been explored to achieve the synthesis of the alkaloids in high optical purity.

Reduction of imines **I** using a chiral sodium prolinate – borane complex afforded products in enantiomeric excess (ee) up to 60% (2). A chiral rhodium complex as a homogeneous hydrogenation catalyst also has been used (3) to give products in optical yields in the range of 15–99%. Moderate optical yields were observed in reduction of chiral 3,4-dihydroisoquinolinium salts **II** (4). Several methods, other than reductive, have been used successfully. A compound of type **III**, formed by Bischler–Napieralski cyclization of an optically active amino acid of type **IV**, has been elaborated to the protoberberine alkaloid, xylopinine, in a photochemical enamide cyclization (5). The alkylation of carbanions **V** derived from chiral amidines has yielded products in high optical yields (90–99% ee) (6), and enantiomerically pure amino acids such as **IV** have been used to advantage in Pictet–Spengler condensations (7). A recent report has described the application of optically active *N*-oxyacyliminium salts **VI** for the enantioselective synthesis of 1-(α-hydroxyalkyl)-1,2,3,4-tetrahydroisoquinolines (8). In this article we describe the application of the Pictet–Spengler condensation in the enantioselective synthesis of isoquinoline alkaloids.

The ready availability of carbohydrates in pure enantiomeric form prompted us to investigate their use as chiral starting materials in alkaloid synthesis. Although the Pictet–Spengler condensation has been widely used in the synthesis of isoquinoline alkaloids, only a few examples of this reaction involving carbohydrates and other polyhydroxy compounds have been reported (9–11). In the present study the reaction of dopamine hydrochloride (**1**) and (*R*)-(+)-glyceraldehyde (**2**) has been studied.

Results and discussion

The Pictet–Spengler condensation of **1** and **2** in boiling methanol gave a mixture of diastereomers, **3***a* and **3***b*, in 93% yield. Treatment of the mixture with an excess of ethyl chloroformate converted the NH group into a carbamate and the OH groups into carbonates. The major component, designated **4***a*, was isolated by chromatography in 56% yield; however, the minor component (**4***b*) could not be obtained in a homogeneous state. Nevertheless, it was possible to estimate the relative proportions of **4***a* and **4***b* (~9:1) by comparing the specific rotation and ^{1}Hmr spectrum of **4***a* with those of the mixture. The stereoselectivity of the reaction may be ascribed to the influence of the chiral centre present in the intermediate iminium ion on the direction of nucleophilic attack by the aromatic ring. The observed stereochemical result (see below) can be rationalized on the basis of an analogy to Cram's rule (see ref. 12) (see Fig. 1). All of the carbonic ester functions were removed from **4***a* by treatment with methanolic ammonia, and the product **5** was then methylated at the phenolic hydroxyls with methyl



R^1 and R^2: H or alkoxy groups
R^3: alkyl, aryl, or aralkyl group
R*: a suitable, enantiomerically pure chiral group

[1]A preliminary account of part of this work has appeared in J. Chem. Soc. Chem. Commun. 1318 (1985).

iodide in the presence of potassium carbonate to give **6** in 44% yield from **1** (see Scheme 1).

In our initial attempts to synthesize simple 1-alkylisoquinoline alkaloids we investigated the cleavage of the glycol system of amine **7**, which had been obtained by reduction of **6** using lithium aluminum hydride. Treatment of **7** with sodium periodate followed by reduction of the reaction mixture with sodium borohydride gave compound **8**. A possible mechanism for the formation of compound **8** is shown in Scheme 2.[3] In contrast, cleavage of the glycol system in the carbamate **6**, followed by reduction of the intermediate with sodium borohydride, afforded the *N*-ethoxycarbonyl derivative **10** in 86% yield (see Scheme 3). In this experiment the intermediate aldehyde[4] was used without purification; however, its chromatographic and mass spectral properties were identical with those of the racemate, which had been prepared separately. If the periodate oxidation of **6** were performed under slightly basic conditions, then part of the starting material was converted into the tricyclic derivative **11**, (1*S*,11b*R*)-1,6,7,11b-tetrahydro-1-hydroxy-9,10-dimethoxy-2*H*,4*H*-[1,3]oxazino[4,3-*a*]isoquinolin-4-one.

Treatment of the *N*-ethoxycarbonyl derivative **10** with lithium aluminum hydride afforded our first target material, namely (*R*)-(−)-*N*-methylcalycotomine (**12**) (see ref. 14) in 82% yield. (*R*)-(−)-Calycotomine (**14**) itself was prepared by treatment of **10** with 10% potassium hydroxide in methanol to give the oxazolo[4,3-*a*]isoquinoline **13**, in 98% yield, which, when subjected to the conditions of Kano *et al.* (8, 15), afforded **14** of known absolute configuration (see ref. 1) in 95% yield and 80.1% ee (based on published data (13)). The *N*-ethoxycarbonyl derivative **10** was transformed also into (*S*)-(−)-carnegine (**16**); (±)-carnegine is the major alkaloid of the giant cactus, *Carnegiea gigantea* (16*a*). Compound **16** was obtained by reduction of the intermediate *O*-tosyl derivative **15** using lithium aluminum hydride; the chemical yield was 87% and the ee was 92.8% (based on published data (16*b*)).

In the present work a convenient route to the synthesis of 1-benzylisoquinolines has also been developed. Attempts to utilize the *O*-tosyl derivative **15** in reactions with a variety of organometallic reagents were unsuccessful. However, aldehyde **9** proved to be a suitable starting material for elaboration to the 1-benzylisoquinoline system. Thus, treatment of **9** with 3,4-dimethoxyphenyllithium afforded a product from which the *threo* isomer (+)-**17** was isolated in 64% yield (see Scheme 4); the presence of the *erythro* isomer was not detected by thin-layer chromatographic examination. The formation of the *threo* isomer can be rationalized on the basis of Cram's rule as shown in Fig. 2. The assignment of the relative stereochemistry of **17** was confirmed by the transformation of (±)-**9** into (±)-**17** by a procedure identical with that used in the preparation of (+)-**17**; subsequent reduction of (±)-**17** with lithium aluminum hydride afforded the previously described (17) (±)-*threo*-hydroxylaudanosine (**18**). Compound (+)-**17** was converted into (*S*)-(+)-laudanosine (**19**) by treatment with equimolar amounts of thionyl chloride and pyridine in tetrahydrofuran at −10°C followed by the direct addition of lithium aluminum hydride; (*S*)-(+)-**19** was obtained in 88% chemical yield and in 78.9% ee (based on published data (18)). The process employed for the removal of the hydroxyl group is noteworthy, since a variety of other attempted procedures failed to effect the desired transformation. The generality of the process is currently being investigated.

The work described in this article clearly demonstrates the usefulness of the aldehyde **9** as an intermediate in the enantioselective synthesis of 1-substituted 1,2,3,4-tetrahydroisoquinolines. The 1-benzylisoquinolines in particular are known to be precursors of many more-complicated ring systems amongst the isoquinoline family of alkaloids in both chemical and biochemical pathways. Other synthetic applications are currently under investigation to explore the versatility of **9** and its enantiomer.

[3]We acknowledge the suggestion made by a referee that the reaction may proceed by way of the cyclic intermediate shown in Scheme 2.

[4]The *N*-acetyl analog of **9** was an unisolated intermediate in the conversion of dehydromethopholine into *N*-acetylcalycotomine (13).

Experimental

The ^{1}Hmr spectra were recorded on a Varian EM390 spectrometer at 90 MHz, unless otherwise stated. Tetramethylsilane (TMS) was used as the internal standard for samples examined in organic solvents, and 1,4-dioxane for samples examined in aqueous solutions; chemical shifts are reported in ppm (δ) downfield from the signal of TMS. The symbols, s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br (broadened), are used to report the multiplicity and shape of signals. EI mass spectra were recorded on a VG Micromass 7070F mass spectrometer at an ionizing voltage of 70 eV, and CI spectra were recorded on the same instrument using NH_3 at ~1 Torr (1 Torr = 133.3 Pa) as reagent gas; data are given as m/z (% relative intensity). Infrared (ir) spectra were recorded on a Perkin–Elmer 283 spectrophotometer.

Melting points were determined using a Gallenkamp apparatus and are uncorrected. Optical rotations were measured using a Perkin–Elmer 247MC polarimeter in a 1-mL microcell that is 1 dm in length. The values for ee were calculated as described by Andersen *et al.* (19), and differ from those given in the preliminary account; in the latter, the values were actually enantiomeric percentages. Flash chromatography was performed on Kieselgel 60 (230–400 mesh). (+)-Glyceraldehyde and (±)-glyceraldehyde were purchased from the Aldrich Chemical Co.

The homogeneity of the products was established on the basis of chromatographic and spectroscopic (^{1}Hmr and mass spectral) examination. It is known that 1-substituted 1,2,3,4-tetrahydroisoquinolines of the type studied in this investigation fragment readily when examined by EI mass spectrometry and seldom show a molecular ion; consequently, most of the compounds studied were examined by CI mass spectrometry using ammonia as the reagent gas. In all cases except that of **4***a* satisfactory $(M + 1)^{+\cdot}$ ions were observed, which served as a measure of the molecular weights of the compounds. Fragmentation often accompanied the formation of the adduct ion and the patterns were sometimes useful in corroborating the assigned structures.

*Condensation of (*R*)-(+)-glyceraldehyde (**2**) with dopamine hydrochloride (**1**)*

A mixture of (*R*)-(+)-glyceraldehyde (2.00 g) and dopamine hydrochloride (1.36 g) in methanol (100 mL) was stirred overnight and heated at reflux temperature for 2 days. The solvent was evaporated and the residue was fractionated by column chromatography on silica gel, using 10% methanol in chloroform to remove unreacted dopamine and nonpolar impurities, and then 20% methanol in chloroform to obtain the condensation product; the fractions were monitored by ^{1}Hmr spectroscopy. The mixture of diastereomers **3***a* and **3***b* was obtained as a brown foam (1.50 g, 93% based on dopamine hydrochloride); ^{1}Hmr (D_2O) δ: 6.70 and 6.68 (two 1H s's, H-5 and H-8), 4.52 (1H, d, J = 6.0 Hz, H-1), 4.25–3.96 (1H, d of t, J = 4.5 Hz and 6.0 Hz, H-1′), 3.80 (2H, d, J = 4.5 Hz, 2H-2′), 3.68–3.46 (2H, m, 2H-3), 2.95 (2H, apparent t, J = 6 Hz, 2H-4); ms (CI): 226 $(M + 1)^+$ (100), 208 (28), 192 (36).

*Preparation of carbonate **4**a*

To a solution of **3***a* and **3***b* (316 mg) in 1% aqueous sodium hydroxide (50 mL) was added 1,2-dichloromethane (50 mL), and the mixture was stirred vigorously while ethyl chloroformate (3 mL) was added gradually over a period of 1 h. Stirring was continued for a further 0.5 h while the mixture was kept alkaline by the addition of 10% aqueous sodium hydroxide. The organic layer was then separated and washed twice with an aqueous solution of sodium chloride. The solution was dried over magnesium sulfate, and evaporation of the solvent afforded the mixture of diastereomers **4***a* and **4***b* (780 mg, 95%), $[\alpha]_D^{20}$ +28.5° (*c* 1.23, chloroform). The major component (**4***a*) was isolated as a colorless oil (56% based on the starting material) by flash chromatography on silica gel using 2% methanol in chloroform as the eluant; $[\alpha]_D^{23}$ +76.4° (*c* 1.61, chloroform); ^{1}Hmr ($CDCl_3$) δ: 7.30 and 7.17 (two 1H s's, H-5 and H-8), 5.27 (1H, br s, H-1), 4.50–4.07 (13H, m, 5CH_2CH$_3$, C*H*OR, CH_2OR), 3.77–3.45 (2H, m, 2H-3), 2.86 (2H, br t, 2H-4), 1.50–1.23 (15H, m, 5CH$_2$CH_3).

*Preparation of carbamate **5***

A sample of compound **4***a* (818 mg) was stirred overnight in 2% ammonia in methanol. The solvent was evaporated and the residue was chromatographed on silica gel using 7% methanol in chloroform as the eluant to afford **5** as a slightly brown oil (388 mg, 93%); ^{1}Hmr (CD_3OD) δ: 6.79 and 6.72 (two 1H s's, H-5 and H-8), 5.05 (1H, d, J = 6.0 Hz, H-1), 4.25 (2H, q, J = 7.5 Hz, CH_2CH$_3$), 4.17–3.55 (5H, m, 2H-3, H-1′, 2H-2′), 2.73 (2H, br t, J = 6.7 Hz, 2H-4), 1.28 (3H, t, J = 7.5 Hz, CH$_2$CH_3); ms (CI): 298 $(M + 1)^+$ (60), 280 (20), 236 (100).

*Preparation of **6***

A solution of compound **5** (388 mg) in dry acetone (50 mL) was treated overnight at reflux temperature with potassium carbonate (3.0 g) and methyl iodide (4 mL). The reaction mixture was cooled, the inorganic salts were removed by filtration, and the filtrate was evaporated under reduced pressure. The residue was dissolved in chloroform, and the solution was washed with an aqueous solution of sodium chloride, dried over magnesium sulfate, and evaporated to afford **6** as a colorless oil (369 mg, 86%), $[\alpha]_D^{23}$ +72.8° (*c* 0.61, chloroform); ^{1}Hmr ($CDCl_3$) δ: 6.76 and 6.62 (two 1H s's, H-5 and H-8), 5.18 (1H, d, J = 5.0 Hz, H-1), 4.37–3.97 (7H, m, D_2O exchange caused the disappearance of signals corresponding to 2H, CH_2CH$_3$, 2H-3, H-1′, 2OH), 3.83 (6H, s, 2OCH$_3$), 3.60 (2H, d, J = 7.5 Hz, 2H-2′), 2.80 (2H, m, 2H-4), 1.27 (3H, t, J = 8.0 Hz, CH$_2$CH_3); ms (CI): 326 $(M + 1)^+$ (100), 264 (75). High-resolution measurements were performed on the ion resulting from C-1—C-1′ fission in the EI mass spectrum. *Mol. Wt.* calcd. for $C_{14}H_{18}NO_4$: 264.1235; found (m/z): 264.1233.

*Preparation of amine **7***

A solution of compound **6** (150 mg) in tetrahydrofuran was heated at reflux temperature for 1 h in the presence of lithium aluminum hydride (100 mg), and to the reaction mixture were then added successively water (0.1 mL), 15% aqueous sodium hydroxide solution (0.1 mL), and water (0.3 mL). The reaction mixture was filtered, the residue was washed three times with dry ethanol, and the combined filtrate and washings were evaporated. Chromatography of the residue on silica gel using 10% methanol in chloroform as the eluant afforded **7** as a colorless oil (97 mg, 79%); ^{1}Hmr ($CDCl_3$) δ: 6.83 and 6.66 (two

1H s's, H-5 and H-8), 4.25 (2H, br s, 2OH), 3.84 (6H, s, $2OCH_3$), 3.93–3.50 (4H, m, H-1, H-1′, 2H-2′), 3.25–2.55 (4H, m, 2H-3, 2H-4), 2.46 (3H, s, NCH_3).

*Formation of 6,7-dimethoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline (**8**) by way of periodate oxidation of amine **7***

A solution of compound **7** (90 mg) in methanol (10 mL) was treated with a solution of sodium periodate (150 mg) in methanol (10 mL) at 5°C for 1 h; sodium borohydride (150 mg) was then added in small portions over a period of 0.5 h and the reaction mixture was left for 0.5 h. The reaction mixture was filtered, the residue was washed with cold methanol, and the combined filtrate and washings were evaporated. Chromatography of the residue on silica gel using 10% methanol in chloroform as the eluant afforded **8** as a colorless oil (74%) that solidified on standing; ^{1}Hmr (250 MHz, $CDCl_3$) δ: 6.58 and 6.49 (two 1H s's, H-5 and H-8), 3.82 and 3.81 (6H, $2OCH_3$), 3.48 (2H, s, 2H-1), 2.82 (2H, t, J = 5.8 Hz, 2H-3), 2.64 (2H, t, J = 5.8 Hz, 2H-4), 2.43 (3H, s, NCH_3); ^{13}Cmr data are identical with those reported by Hughes *et al.* (20); ms (EI): 207 (40), 206 (60), 164 (100). The product formed a picrate, mp 160–162°C (lit. (21) mp 161–162°C).

Preparation of N*-ethoxycarbonyl derivative **10***

A solution of compound **6** (122 mg) in methanol (20 mL) was treated with a solution of sodium periodate (160 mg) in water (2 mL) at 5°C for 1 h; sodium borohydride (80 mg) was then added in small portions over a period of 0.5 h and the reaction mixture was left for 0.5 h. The reaction mixture was filtered, the residue was washed with cold methanol, and the combined filtrate and washings were evaporated. Chromatography of the residue on silica gel using 1.5% methanol in chloroform as the eluant afforded **10** as a colorless oil (96 mg, 86%), $[\alpha]_D^{23}$ +88.8° (*c* 2.08, chloroform); ^{1}Hmr ($CDCl_3$) δ: 7.03 and 6.98 (two 1H s's, H-5 and H-8), 5.16 (1H, t, J = 6.0 Hz, H-1), 4.20 (2H, q, J = 7.0 Hz, CH_2CH_3), 3.78 (6H, s, $2OCH_3$), 3.60–3.15 (4H, m, 2H-3, 2H-1′), 2.90–2.52 (2H, m, 2H-4), 1.26 (3H, t, J = 7.0 Hz, CH_2CH_3); ms (CI): 296 $(M + 1)^+$ (100), 264 (38), 192 (7).

*Preparation of tricyclic derivative **11***

Compound **6** was treated as described in the preceding experiment, except that the reactions were performed in the presence of sodium hydroxide (200 mg) in the reaction mixture, to afford the *N*-ethoxycarbonyl derivative **10** (65%), and also the tricyclic derivative **11** as a colorless oil (25%), $[\alpha]_D^{23}$ −152° (*c* 1.13, chloroform); ^{1}Hmr ($CDCl_3$) δ: 6.63 (2H, s, H-9, H-10), 4.87 (1H, d, J = 5 Hz, H-11b), 4.53–4.38 (1H, m, H-6_{eq}), 4.25–3.95 (3H, m, H-1, 2H-2), 3.86 (6H, s, $2OCH_3$), 3.35–2.53 (3H, m, H-6, 2H-7), 2.38 (1H, br s, exchanged with D_2O, OH); ms (CI): 280 $(M + 1)^+$ (100), 279 (32).

*Preparation of (*R*)-(−)-*N*-methylcalycotomine (**12**)*

A solution of compound **10** (80 mg) in tetrahydrofuran (30 mL) was treated with lithium aluminum hydride (50 mg) for 1 h at reflux temperature. The reduction product, *N*-methylcalycotomine (**12**), was obtained, after chromatography on silica gel using 11% methanol in chloroform as the eluant, as a colorless oil (82%), $[\alpha]_D^{23}$ −48.3° (*c* 2.8, chloroform) (lit. (14) for the enantiomer, $[\alpha]_D$ +55° (*c* 0.4, chloroform)); ^{1}Hmr ($CDCl_3$) δ: 6.56 (2H, s, H-5, H-8), 3.83 (6H, s, $2OCH_3$), 3.80–3.53 (3H, m, H-1, 2H-1′), 3.25–2.63 (4H, m, 2H-3, 2H-4), 2.56 (3H, s, NCH_3); ms (CI): 238 $(M + 1)^+$ (100), 206 (80). The ^{1}Hmr data are in agreement with those reported for the enantiomer by Kerekes *et al.* (14). The product formed a picrate, mp 216°C (dec.).

*Formation of (*R*)-1,5,6,10b-tetrahydro-8,9-dimethoxy-3*H*-oxazolo[4,3-a]isoquinolin-3-one (**13**)*

Compound **10** (55.8 mg) was treated with 10% potassium hydroxide in methanol for 6 h at reflux temperature. The solvent was evaporated; water (5 mL) was added to the residue and the mixture was extracted with chloroform. The product **13** (15) was obtained, after chromatography on silica gel using 4% methanol in chloroform as the eluant, as a colorless oil (43 mg, 98%), $[\alpha]_D^{23}$ −154.3° (*c* 0.9, chloroform); ν_{max} (neat): 1750 cm^{-1} (lactone); ^{1}Hmr ($CDCl_3$) δ: 6.70 and 6.53 (two 1H s's, H-7 and H-10), 5.08–4.73 (2H, m), 4.30–4.08 (2H, m), 3.91 (6H, s, $2OCH_3$), 3.30–2.65 (3H, m, H-5_{ax}, 2H-6); ms (EI): 249 $(M)^+$ (100), 248 $(M - 1)^+$ (60), 218 (18), 191 (63).

*(*R*)-(−)-Calycotomine (**14**)*

Compound **13** was treated with 10% sodium hydroxide in ethanol for 6 h at reflux temperature, conditions described by Kano *et al.* (8, 15). The reaction mixture was processed as described in the preceding experiment, and chromatography on silica gel using 20% methanol in chloroform as the eluant afforded crystalline **14** (95%), mp 145–148°C, $[\alpha]_D^{22}$ −28.9° (*c* 1.05, water) (lit. (13) mp 149–150°C, $[\alpha]_D^{23}$ −36° (water)); ^{1}Hmr ($CDCl_3$) δ: 6.36 (2H, s, H-5, H-8), 3.88 (6H, s, $2OCH_3$), 3.80–3.66 (3H, m, H-1, 2H-1′), 3.10 (2H, apparent t, $J \simeq$ 6 Hz, 2H-4), 2.70 (2H, apparent t, $J \simeq$ 6 Hz, 2H-3), 2.36 (2H, br s, exchanged with D_2O, OH, NH); ms (CI): 224 $(M + 1)^+$ (100), 206 (25), 192 (65). The ^{1}Hmr data are in agreement with those reported by Rozwadowska and Brózda (22).

Conversion of N*-ethoxycarbonyl derivative **10** into (*S*)-(−)-carnegine (**16**)*

Compound **10** (38 mg) was treated with a solution of *p*-toluenesulfonyl chloride (49 mg) in pyridine (5 mL) for 12 h at 5°C. The solvent was evaporated under reduced pressure at ambient temperature to yield an oil, which was dissolved in chloroform; the solution was washed with a 2% aqueous solution of sodium carbonate and then with an aqueous solution of sodium chloride, dried ($MgSO_4$), and evaporated. A solution of the residue in tetrahydrofuran was treated with lithium aluminum hydride (100 mg) for 1.5 h at reflux temperature. The reduction product, (*S*)-(−)-carnegine (**16**), was obtained, after chromatography on silica gel using 7% methanol in chloroform as the eluant, as an oil (87% based on **10**), $[M]_D^{23}$ −106.7° (*c* 1.05, benzene) (lit. (16*b*) $[M]_D^{22}$ −115° (*c* ~4.5, benzene)); ^{1}Hmr ($CDCl_3$) δ: 6.60 (2H, s, H-5, H-8), 3.86 (6H, s, $2OCH_3$), 3.68 (1H, q, J = 6.5 Hz, H-1), 3.23–2.56 (4H, m, 2H-3, 2H-4), 2.50 (3H, s, NCH_3), 1.38 (3H, d, J = 6.5 Hz, $CHCH_3$); ms (CI): 222 $(M + 1)^+$ (100), 206 (20). The ^{1}Hmr data are in agreement with those reported by Rozwadowska and Brózda (22). The product formed a picrate, mp 228–230°C (lit. (16*b*) mp 233–234°C).

*Preparation of aldehyde **9** by periodate oxidation of **6***

To a solution of compound **6** (210 mg) in methanol (10 mL) was added sodium periodate (138 mg) in water (1 mL), and the mixture was stirred at 0°C for 1.5 h. The reaction mixture was filtered, the residue was washed with cold methanol, and the combined filtrate and washings were evaporated at ambient temperature. The residue was dissolved in dichloromethane, and the solution was dried ($MgSO_4$) and evaporated; this residue was dissolved in dry benzene, and the solution was evaporated to remove traces of water. The syrupy product (176 mg, 93%) was chromatographically homogeneous (thin-layer chromatography, 2% methanol in chloroform) and was used in the following step without further purification; ms (CI): 294 $(M + 1)^+$ (100), 264 (43), 248 (18), 192 (17). A sample of (±)-**9** was obtained from (±)-**6**, and its mass spectrum showed the same fragment ions as did that of **9**; ^{1}Hmr ($CDCl_3$) δ: 9.40 (1H, s, HC=O), 6.85 and 6.68 (two 1H s's, H-5 and H-8), 5.33 (1H, br s, H-1), 4.20 (2H, q, J = 7.5 Hz, CH_2CH_3), 3.85 (6H, s, $2OCH_3$), 3.75–3.61 (2H, m, 2H-3), 2.75 (2H, apparent t, J = 6 Hz, 2H-4), 1.27 (3H, t, J = 7.5 Hz, CH_2CH_3).

*Reaction of **9** with 3,4-dimethoxyphenyllithium*

A solution of bromoveratrole (725 mg) in tetrahydrofuran (20 mL) was treated with a 2.4 *M* solution of *n*-butyllithium in *n*-hexane (1.5 mL) at −78°C (Dry Ice – methanol) for 15 min. A solution of compound **9** (255 mg) in tetrahydrofuran (5 mL) was then added slowly, and the mixture was kept at −78°C for 30 min. Water (0.5 mL) was added, and the mixture was warmed to room temperature and evaporated. The residue was dissolved in chloroform, and the solution was washed with a 20% aqueous solution of ammonium chloride and then with an aqueous solution of sodium chloride; the solution was dried ($MgSO_4$) and evaporated. Chromatography of the residue on silica gel using 1% methanol in chloroform as the eluant afforded compound **17** as a viscous, colorless oil (240 mg, 64% based on **9**), $[\alpha]_D^{22}$ +29.9° (*c* 2.57, chloroform); ^{1}Hmr ($CDCl_3$) δ: 6.72–6.47 (4H, m, H-5, H-2′, H-5′, H-6′), 5.88 (1H, br s, H-8), 5.05 (1H, d, J = 7.0 Hz, H-1), 4.66

(2H, m, d after addition of D_2O, J = 7.0 Hz, H-7′, OH), 4.33–3.87 (4H, m, 2H-3, CH_2CH_3), 3.75 (6H, s, $2OCH_3$), 3.65 (3H, s, OCH_3), 3.38 (3H, s, OCH_3 at C-7),[5] 2.63–2.40 (2H, m, 2H-4), 1.11 (3H, t, J = 7.5 Hz, CH_2CH_3); irradiation at δ 5.05 caused collapse of the doublet at δ 4.66 to a singlet; ms (EI): 413 (20), 385 (25), 264 (100).

*(S)-(+)-Laudanosine (**19**)*

To a solution of compound **17** (120 mg) in tetrahydrofuran (25 mL) were added, under dry nitrogen and at −10°C, dry pyridine (0.024 mL) and then thionyl chloride (0.020 mL), and the reaction mixture was stirred for 45 min. Solid lithium aluminum hydride (200 mg) was then added in small portions, and the mixture was stirred at room temperature for 15 min and then heated at reflux temperature for 30 min. The reaction mixture was cooled and decomposed in the usual manner; the mixture was filtered, the residue was washed three times with hot chloroform, and the combined filtrate and washings were evaporated. Chromatography of the residue on silica gel using 5% methanol in chloroform as the eluant afforded **19** as a colorless oil (88%), $[\alpha]_D^{22}$ +78.9° (*c* 1.55, ethanol) (lit. (18) $[\alpha]_D$ +100° (ethanol)); ^{1}Hmr ($CDCl_3$) δ: 6.80–6.56 (4H, m, aromatic H's), 6.12 (1H, s, H-8), 3.86 (6H, s, $2OCH_3$), 3.80 (3H, s, OCH_3), 3.60 (3H, s, OCH_3 at C-7), 3.50–2.63 (7H, m, 2H-7′, H-1, 2H-3, 2H-4), 2.55 (3H, s, NCH_3); ms (CI): 358 $(M + 1)^+$ (100), 206 (21). The ^{1}Hmr data are in agreement with those reported by Konda *et al.* (23). The product formed a methiodide, mp 213–215°C (lit. (18) mp 215–217°C).

*Formation of (±)-*threo*-hydroxylaudanosine (**18**)*

A sample of (±)-**17** (241 mg, 0.56 mmol), obtained from (±)-glyceraldehyde by the same sequence of reactions as had been employed for the preparation of (+)-**17**, was treated with lithium aluminum hydride (1.8 g) in tetrahydrofuran (75 mL) for 1 h at reflux temperature. The reduction product, (±)-**18**, was obtained, after chromatography on silica gel using 5% methanol in chloroform as the eluant, in crystalline form (88%) and recrystallized from methanol–ether, mp 137–138°C (lit. (24) mp 138°C); ^{1}Hmr ($CDCl_3$) δ: 6.95–6.59 (4H, m, aromatic H's), 5.43 (1H, s, H-8), 4.38 (1H, d, J = 9 Hz, C*H*OH), 4.06 (1H, br s, OH), 3.85 (9H, s, $3OCH_3$), 3.33 (1H, d, J = 9 Hz, H-1), 3.30 (3H, s, OCH_3 at C-7), 3.16–2.73 (4H, m, 2H-3, 2H-4), 2.57 (3H, s, NCH_3); ms (CI): 374 $(M + 1)^+$ (100), 206 (17), 167 (4).

Received April 8, 1986

KUNIO KANO, DAVID SCARPETTI, JOHN C. WARNER, JEAN-PIERRE ANSELME, JAMES P. SPRINGER, and BYRON H. ARISON. Can. J. Chem. **64**, 2211 (1986).

The synthesis and unequivocal characterization of all six isomers of benzoyl phenyl 1-methylpyrazole (**2**) are described. The isomer of **2** isolated as one of the products of the reaction of 1,1-dimethyl-1-phenacylhydrazinium bromide (**1**) with base was shown to be the only previously reported isomer, 5-benzoyl-3-phenyl-1-methylpyrazole (**2***b*).

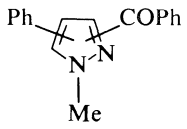
KUNIO KANO, DAVID SCARPETTI, JOHN C. WARNER, JEAN-PIERRE ANSELME, JAMES P. SPRINGER et BYRON H. ARISON. Can. J. Chem. **64**, 2211 (1986).

On décrit la synthèse et la caractérisation non-équivoque des six isomères du benzoyl phényl méthyl-1 pyrazole (**2**). On a isolé un isomère de **2** lors de la réaction du bromure de diméthyl-1,1 phénacyl-1 hydrazinium (**1**) avec de la soude; on a identifié ce produit comme étant le benzoyl-5 phényl-3 méthyl-1 pyrazole (**2***b*), le seul isomère rapporté jusqu'à maintenant.

[Traduit par la revue]

Introduction

In the context of another investigation (1), the synthesis of all six isomers of benzoyl phenyl 1-methylpyrazole (**2**) was



2

a 3-Ph, 4-PhCO; *b* 3-Ph, 5-PhCO
c 4-Ph, 3-PhCO; *d* 4-Ph, 5-PhCO
e 5-Ph, 3-PhCO; *f* 5-Ph, 4-PhCO

undertaken. At the outset of this study, only one isomer of **2** had been reported (2). We now describe the preparation and characterization of all the isomers of **2**.

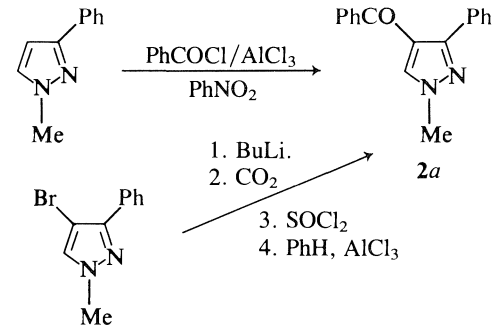
Results and discussion

3-Phenyl isomers

The few reported investigations of the Friedel–Crafts acylation of pyrazoles (3) indicate that reaction occurs at the 4-position (4, 5). This was confirmed in the present work by the benzoylation of 3-phenyl- and 4-phenyl-1-methylpyrazoles (6). While the open 4-position of the 3-phenyl isomer indeed underwent benzoylation to yield **2***a*, albeit in only 6% yield (eq. [1]), several attempts to introduce the benzoyl group into the pyrazole ring of 4-phenyl-1-methylpyrazole by various modifications of the Friedel–Crafts procedure resulted in benzoylation at the *p*-position of the phenyl substituent rather than the open 3- or 5-positions, as shown by nmr analysis and by the authentic synthesis of **2***c* and **2***d* (*vide infra*). An improved synthesis of **2***a*, starting from 4-bromo-3-phenyl-1-methylpyrazole, was achieved by the sequence shown in eq. [1].

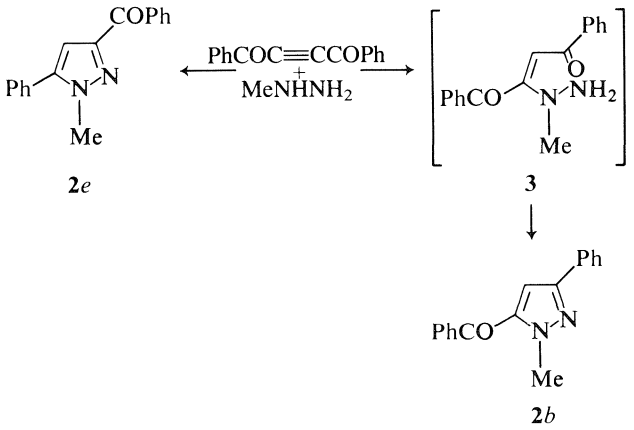
The benzoyl phenyl 1-methylpyrazole isolated from the

[1]



action of base on 1,1-dimethyl-1-phenacylhydrazinium bromide (**1**) (eq. [3]) (1) turned out to be identical to the compound obtained by Heine *et al.* from the reaction of methylhydrazine on dibenzoylacetylene (eq. [2]) (2). The assignment of structure

[2]



as **2***b* appeared secure since Heine also obtained **2***b* from alternate routes, and our rationale to explain the formation of **2***b* from **1** and base (1) (eq. [3]) postulates the same intermediate **3**. A careful reexamination of the reaction product of Heine *et al.* (2) did reveal the presence of a small amount of the isomeric pyrazole **2***e* whose authentic synthesis is described later in this paper (eq. [9]).

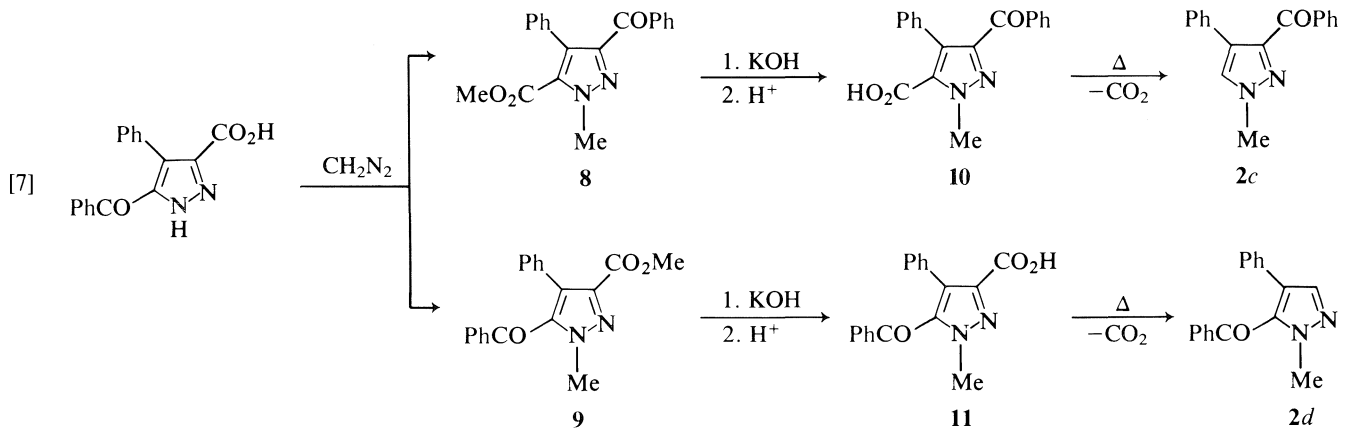
[3] 
4-Phenyl isomers

Our initial approach to the 4-phenyl isomers (**2***c* and **2***d*) was predicated on the reported cyclization of monohydrazones of α-diketones. In 1958, Domnin *et al.* (7) had described the presumed cyclization of benzil monodimethylhydrazone to a compound purported to be 1-methyl-3,4-diphenylpyrazole; subsequent and apparently independent reports of related cyclizations were disclosed by two other groups (8).

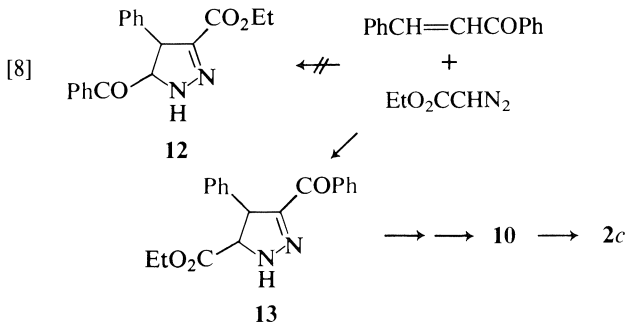
The preparation of the required *N*-methyl-*N*-phenacylhydrazone of phenylglyoxal was initially attempted by alkylation of the methylhydrazone of phenylglyoxal (obtained by controlled condensation of phenylglyoxal with methylhydrazine; compound **6** may also be a product of this reaction) was unsuccessful. This failure led to the synthesis of 5-benzoyl-4-phenyl-1-methylpyrazole (**2***d*) illustrated in eq. [4]. Treatment of **5** with sulfuric acid led to 3-benzoyl-4-phenyl-1-methylpyrazole (**2***c*) rather than **2***d*, which would have been the expected product on the basis of the literature precedents cited above. Indeed, three alternate routes, one involving the dehydrogenation of 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline (**7**) (eq. [5]), a second proceeding via the cycloaddition of 3-methylsydnone to benzoylphenylacetylene (eq. [6]), and a third using the decarboxylation of 3-benzoyl-4-phenyl-1-methylpyrazole-5-carboxylic acid (**10**) (eq. [7]) (9), each afforded the same product, which was identical to that obtained from the reaction described in eq. [4]. The confirmation of the structure of this compound as 3-benzoyl-4-phenyl-1-methylpyrazole (**2***c*),

[4] 
obtained by an X-ray crystallographic structure determination (10), raised doubt (11) regarding the validity or at least the generality of the purported cyclization described by Domnin *et al.* Authentic 5-benzoyl-4-phenyl-1-methylpyrazole (**2***d*) was obtained by the decarboxylation of 5-benzoyl-4-phenyl-1-methylpyrazole-3-carboxylic acid (**11**) (9), which in turn was obtained along with, and isolated from the isomeric acid **10** by the sequence shown in eq. [7]. The unequivocal assignment of the structure of **2***c* by X-ray crystallography thus establishes the structure of the product obtained by the decarboxylation of **11** as **2***d*; by the same token the original assignment of the structure of the precursor acids **10** and **11**, which was based solely on difference in their rates of esterification (9), was confirmed beyond doubt. These results also agreed with the structure of the 2-pyrazoline (see eq. [5]) originally assigned by Smith and Pings (12).

[5] 
[6] 
Kohler and Steele (13) had described the formation of ethyl 4-phenyl-5-benzoyl-2-pyrazoline-3-carboxylate (**12**) from the addition of ethyl diazoacetate to benzalacetophenone. Though it was somewhat surprising to us that the carbon–nitrogen bond should have entered into conjugation with the ester function to give **12** rather than with the ketone group (to give **13**), the ease of preparation of **12** suggested that, if the original assignment was correct, **12** would constitute an ideal starting material for

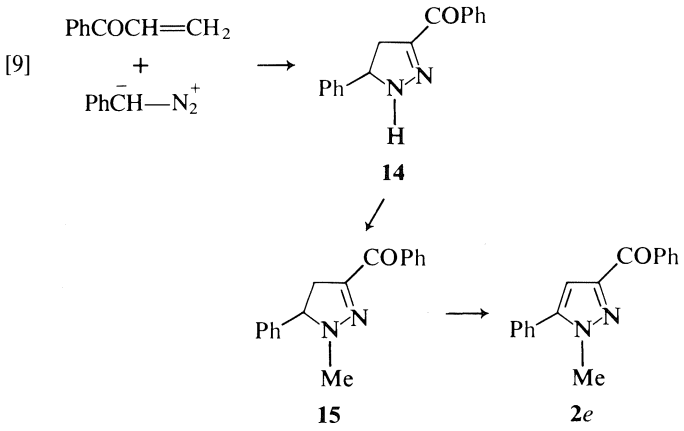


the preparation of **2***d*. However, methylation of putative **12** followed by oxidation and hydrolysis gave acid **10**, thus demonstrating that the product of the cycloaddition was **13** and not **12** as previously reported (eq. [8]) (14).



5-Phenyl isomers

The 5-phenyl isomers (**2***e* and **2***f*) were obtained as shown in eqs. [9] and [10]. 1,3-Cycloaddition of phenyldiazomethane to



acrylophenone provided the expected 3-benzoyl-5-phenyl-2-pyrazoline (**14**) whose extremely low carbonyl absorption (1605 cm^{-1}) prompted us to confirm its structure by an X-ray crystal structure. Methylation of the anion of **14** followed by oxidation with sulfur led to 3-benzoyl-5-phenyl-1-methylpyrazole (**2***e*). The last isomer **2***f* was obtained by the Friedel–Crafts acylation of benzene with the acid chloride of 4-carboxy-5-phenyl-1-methylpyrazole (eq. [10]). The required acid **16** was obtained by the cycloaddition of 3-methyl-4-phenylsydnone to dimethyl acetylenedicarboxylate followed by hydrolysis of the diester and selective decarboxylation (14) of the 3-carboxy group of the resulting diacid to acid **16**, which was identified by conversion to its methyl ester (15). Although the complete decarboxylation of 5-phenyl-1-methylpyrazole-3,4-dicarboxylic acid provides an easy access to pure 5-phenyl-1-methylpyrazole, which is otherwise tedious to obtain (16), the experimental difficulties encountered in the clean selective decarboxylation of the diacid to **16** led us to develop another synthesis, involving bromination of 5-phenyl-1-methylpyrazole (3–5) followed by

lithiation, carbonation, and finally Friedel–Crafts acylation of benzene (eq. [11]).

Spectra and X-ray data

X-ray crystal structure analysis of 3-benzoyl-4-phenyl-1-methylpyrazole (2c)

Suitable crystals for X-ray diffraction studies formed with space group symmetry of $P2_1/c$ and cell constants of a = 12.088(2) Å, b = 11.219(1) Å, c = 10.949(2) Å, and β = 106.27(1)° for Z = 4 and a calculated density of 1.222 g/cm^3. Of the 1900 reflections measured with an automatic four-circle diffractometer equipped with Cu radiation, 1623 were observed ($I > 3\sigma I$). The structure was solved with a multi-solution tangent formula approach and difference Fourier analysis and

refined using full-matrix least-squares techniques (17). Hydrogens were assigned isotropic temperature factors corresponding to their attached atoms. The function $\Sigma w(|F| - |F|)^2$ with $w = 1/(\sigma F_o)^2$ was minimized to give an unweighted residual of 0.042. No abnormally short intermolecular contacts were noted. Tables I, II, and III containing the final fractional coordinates, temperature parameters, bond distances, and bond angles are available upon request from the authors.

^{1}H and ^{13}C nuclear magnetic resonance analysis

Chemical shifts of the six isomeric benzoyl phenyl 1-methylpyrazoles are listed in Table 1. Since all aromatic signals are multiplets, the usual multiplicity designations are omitted. Although the pattern shifts are by and large unexceptional, a few comments on trends are in order. The absence of an aromatic substituent at the pyrazole C-4 position can always be inferred from the distinctive high-field shift of the pyrazole C4-H. A comparison of the two 3,4- and the two 4,5-disubstituted analogues indicates that the nuclear pyrazole proton resonates about 0.25 ppm downfield in the isomer having an adjacent benzoyl group.

The *N*-methyl signal can be perturbed by a substituent at C-5 although the effect can be modified significantly if the second aromatic group is located at C-4. This can be seen by comparing **2***b*, in which the *N*-methyl peak is displaced 0.25 ppm downfield by the C-5 benzoyl, with **2***d*, in which the deshielding influence of the benzoyl group is completely nullified by the neighboring C-4 phenyl. This compensating property can be attributed to the steric hindrance that forces the aromatic substituents out of planarity with the pyrazole ring. The fact that the chemical shifts of the benzoyl protons in **2***d* are approximately 0.2 ppm upfield from their typical values is consistent with the hindrance hypothesis. These findings thus indicate that, apart from identifying a C-4 pyrazole proton, the assignment of the individual isomers by proton nmr would be risky.

In contrast to the proton data, all six isomers could be assigned unambiguously from the proton decoupled and gated decoupled ^{13}C spectra by taking advantage of both chemical shifts and long-range proton ^{13}C couplings (Table 2). The C-4 pyrazole carbon, whether substituted or unsubstituted, could always be identified because of its high-field chemical shift (18). The distinctively large pyrazole one-bond coupling constants (J_{CH}: C-4, ca. 178 Hz; C-3 and C-5, ~188 Hz) distinguish the pyrazole proton-bearing carbon from the aro-

matic resonances, which all have a J_{CH} value close to 160 Hz (19, 20). Differences in the multiplicities of the substituted pyrazole carbons arising from two- and three-bond coupling with protons (J_{C-C-H} and $J_{C-C-C-H}$) could be used to locate the position of the aromatic substituents on the pyrazole ring. This approach appeared feasible for the present series since long-range couplings exhibited by the pyrazole carbons would result from interaction with the *ortho* protons of the phenyl ring, the lone nuclear proton, and the *N*-methyl, the latter affecting only the pyrazole C-5. The *ortho* benzoyl protons were not expected to contribute to the multiplicities since four-bond couplings ($J_{C-C-C-C-H}$) are normally very small. Based on this analysis, a doublet for a substituted pyrazole carbon would be diagnostic for either C-3 or C-4 bearing a benzoyl substituent, as seen in Table 2 for **2***a* (C-4), **2***c* (C-3), **2***e* (C-3), and **2***f* (C-4). Further, the substituted pyrazole C-5 can always be distinguished from C-3 because of its higher multiplicity, since it is coupled with the *N*-methyl as well as the nuclear proton and with the *ortho* phenyl protons when this group is located at C-5.

Experimental

Elemental analyses were carried out by the Microanalysis Laboratories of the University of Massachusetts at Amherst. The infrared spectra were recorded on a Perkin–Elmer model 137B spectrophotometer (Infracord) and the nmr spectra were obtained in $CDCl_3$ (except as may be noted otherwise) on a Hitachi–Perkin–Elmer R-24 (60 MHz) and Varian XL-400 MHz spectrometer using tetramethylsilane as an internal standard.

4-Bromo-3-phenyl-1-methylpyrazole

A solution of bromine (2.88 g, 20.5 mmol) in 2.5 mL of chloroform was added dropwise over a period of 10 min to a stirred solution of 3-phenyl-1-methylpyrazole (3.0 g, 20.5 mmol) in 5.0 mL of chloroform cooled in an ice bath, and the mixture was allowed to stir overnight. It was then washed with saturated sodium bicarbonate solution (4 × 25 mL) and the chloroform was evaporated *in vacuo* to yield 3.6 g (78%) of a brown liquid; ^{1}H nmr δ: 3.55 (s, 3H, CH_3), 7.10 (s, 1H, PyH), 7.50 (m, 5H, ArH).

3-Phenyl-1-methylpyrazole-4-carboxylic acid

To a solution of crude 4-bromo-3-phenyl-1-methylpyrazole (2.0 g, 7.0 mmol) in 20 mL of anhydrous ether cooled to −30°C in a Dry Ice – acetone bath, was added dropwise a 1.7 *M* solution of *n*-butyllithium in hexane (9.0 mL, 15.3 mmol) through a syringe and the solution was allowed to stir at that temperature for a period of 1 h. The solution was then cooled to −60°C in a Dry Ice – acetone bath and gaseous carbon dioxide was bubbled through for a period of 1 h. The solution was then stirred overnight and the temperature allowed to become ambient. The precipitated solid was collected; it was then suspended in 15 mL of water, acidified, filtered, and air-dried to give 1.6 g (95%) of the acid, mp 93–99°C.

*4-Benzoyl-3-phenyl-1-methylpyrazole (***2**a)

A solution of 3-phenyl-1-methylpyrazole-4-carboxylic acid (0.2 g, 1.0 mmol) in 5.0 mL of thionyl chloride was heated to reflux for 1.5 h. The excess thionyl chloride was evaporated *in vacuo*, to the residue was added benzene (3.0 mL), and the solution was evaporated again to remove any remaining thionyl chloride; this process was repeated. To the crude acid chloride obtained as a brown oil was added 10 mL of benzene and aluminum chloride (0.4 g, 3.0 mmol) and the solution was heated at reflux overnight. The benzene was evaporated *in vacuo* to yield a residue that was dissolved in ether and washed with saturated aqueous sodium bicarbonate (4 × 25 mL) and dried. The ethereal solution was evaporated to give 0.25 g (81%) of **2***a* as an oil. This sample was identical by tlc, ir, and nmr to **2***a* obtained below.

*4-Benzoyl-3-phenyl-1-methylpyrazole (***2**a)

A solution of 1.58 g (10 mmol) of 3-phenyl-1-methylpyrazole, 1.68 g (12 mmol) of benzoyl chloride, and 0.13 g (1 mmol) of aluminum chloride in 20 mL of nitrobenzene was heated to reflux for 2 days. The nitrobenzene was distilled *in vacuo* and the residue was dissolved in 30 mL of ether. The ethereal layer was washed with saturated sodium bicarbonate and water, dried over $MgSO_4$, and the ether was evaporated to give a viscous oil. It was purified by column chromatography (silica gel, benzene) to give 0.15 g (6%) of **2***a* as a very viscous oil, which was triturated with ether – petroleum ether to give a white solid; recrystallization from ethanol yielded white crystals, mp 85.5–86.5°C. *Anal.* calcd. for $C_{14}H_{14}N_2O$: C 77.84, H 5.38, N 10.68; found: C 77.62, H 5.31, N 10.71.

*4-(*p*-Benzoylphenyl)-1-methylpyrazole*

A solution of 4-phenyl-1-methylpyrazole (316 mg, 2 mmol), benzoyl chloride (350 mg, 2.5 mmol), and anhydrous aluminum chloride (27 mg, 0.2 mmol) in 5 mL of nitrobenzene was heated to reflux for 2 days. The solvent was distilled *in vacuo* and the residue was dissolved in 30 mL of ether. The ethereal solution was washed with 10% NaOH and water, dried over $MgSO_4$, and evaporated *in vacuo*. The residue was chromatographed on 15 g of silica gel (60–200 mesh) using a 1:1 mixture of benzene–hexanes as eluent. The solid obtained from the second fraction was recrystallized from ether – petroleum ether to give 0.05 g (10%) of white crystals, mp 161–163°C; ir (KBr): 1655 (C=O) cm^{-1}; ^{1}H nmr δ: 3.94 (s, 3H, CH_3), 7.65 (m, 11H, ArH, PyH). *Anal.* calcd. for $C_{17}H_{14}N_2O$: C 77.84, H 5.38, N 10.68; found: C 77.59, H 5.32, N 10.68.

*5-Benzoyl-3-phenyl-1-methylpyrazole (***2**b)

A solution of 5 g (20 mmol) of dibenzoylacetylene, 1 drop of concentrated sulfuric acid, and 1 g (20 mmol) of methylhydrazine in 150 mL of ethanol was stirred at room temperature for 2 h and heated to reflux overnight. Ethanol was removed and ether was added to the residue. The ethereal solution was washed with water, dried, and the solvent was evaporated. The residue was recrystallized from ether – petroleum ether to give 1.5 g (30%) of **2***b*, mp 64–66°C, lit. (2) mp 52–57°C.

In a separate run, the filtrate of the crystallized residue was concentrated and chromatographed on silica gel (70–230 mesh; elution with chloroform). One of the less mobile fractions, obtained as an oil, was identified as 3-benzoyl-5-phenyl-1-methylpyrazole (**2***e*) by ir, nmr (spiking with an authentic sample), and tlc; the yield of this isomer was not determined but was very small.

Phenylglyoxal N*-methylhydrazone*

To methylhydrazine (1.84 g, 40 mmol) and two drops of acetic acid in 20 mL of ethanol was added a solution of phenylglyoxal monohydrate (3.04 g, 20 mmol) in 30 mL of ethanol; the mixture was stirred at room temperature for 24 h. Ethanol was evaporated and 30 mL of ether was added to the residue. The ethereal layer was washed with water, dried, and the ether was evaporated to give a pale yellow oil, which was chromatographed on silica gel to give 2.7 g (83%) of product; ^{1}H nmr δ: 7.57 (m, 7H, ArH, CH=N, NH), 2.83, 3.05, 3.20 (d, d, d, 3H, CH_3).

*Addition product of phenylglyoxal methylhydrazone with phenylglyoxal (***6**)

A solution of phenylglyoxal monohydrate (0.45 g, 3 mmol), methylhydrazine (0.14 g, 3 mmol), and a drop of acetic acid in 20 mL of ethanol was stirred overnight at room temperature. Ethanol was evaporated *in vacuo* and the residue was dissolved in ether. The ethereal solution was washed with water, dried over anhydrous $MgSO_4$, and the ether was evaporated. The residue was recrystallized from methylene chloride – petroleum ether to yield 0.43 g (99%) of product, mp 112–113.5°C; ir (KBr): 3490, 1699, 1640 cm^{-1}; ^{1}H nmr δ: 2.98 (s, 3H, CH_3), 4.83 (d, 1H, OH exchangeable with D_2O), 6.1 (d, 1H, O—CH), 7.05 (s, 1H, CH), 7.60 (m, 10H, ArH). *Anal.* calcd. for $C_{17}H_{16}N_2O_3$: C 68.90, H 5.44, N 9.46; found: C 68.93, H 5.38, N 9.49.

1-Methyl-1-phenacylhydrazine ethylene glycol ketal

A solution of 17 g (70 mmol) of phenacyl bromide ethylene glycol

ketal (19) in 50 mL of methylhydrazine was heated to reflux for 4 days. The excess methylhydrazine was distilled and ether was added to the residue. The ethereal solution was washed with water, dried over $MgSO_4$, and the ether was evaporated. The white solid obtained, mp 46–65°C (dec.), may be recrystallized from ether – petroleum ether (11.5 g, 76%), but was used for the next step without purification; ^{1}H nmr δ: 7.37 (m, ArH, 5H), 3.94 (m, CH_2CH_2, 4H), 3.30 (s, NH_2, 2H), 2.89 (s, CH_2, 2H), 2.47 (s, CH_3, 3H).

Hydrazone **5**

A mixture of 11.5 g (53 mmol) of the ketal hydrazine obtained above, 8.1 g (53 mmol) of phenylglyoxal monohydrate, and 0.05 mL of acetic acid in 120 mL of ethanol was stirred at room temperature. After 20 min, a solid had precipitated and the solution was stirred for an additional period of 3 h; it was then stored in the refrigerator overnight. The solid was collected and the filtrate was concentrated to give additional product. The two crops were combined and recrystallized from ethanol to give 11.4 g (65%) of the hydrazone as white crystals, mp 108–109°C; ^{1}H nmr δ: 7.53 (m, 10H, ArH), 6.95 (s, 1H, CH=N), 3.94 (m, 4H, CH_2CH_2), 3.89 (s, 2H, CH_2), 3.11 (s, 3H, CH_3). *Anal.* calcd. for $C_{19}H_{20}N_2O_3$: C 70.35, H 6.22, N 8.64; found: C 70.44, H 6.31, N 8.69.

*3-Benzoyl-4-phenyl-1-methylpyrazole (***2***c)*

A solution of 3.24 g (10 mmol) of phenylglyoxal hydrazone **5** in 75 mL of 75% H_2SO_4 was stirred for 2 weeks at room temperature. It was then diluted with 100 mL of water, neutralized with solid $NaHCO_3$, and extracted with ether. The ethereal layer was dried over anhydrous $MgSO_4$ and ether was evaporated. The resulting yellow solid was recrystallized from ethanol to give 1.48 g (56%) of **2***c* as white crystals, mp 92.5–93.5°C. *Anal.* calcd. for $C_{17}H_{14}N_2O$: C 77.84, H 5.38, N 10.68; found: C 77.70, H 5.40, N 10.67.

3-Benzoyl-1-methyl-4-phenyl-2-pyrazoline

To 0.27 g (11 mmol) of *dry* sodium hydride was added dropwise 8 mL of dry DMSO at 18–20°C and the mixture was stirred at ambient temperature for 20 min. The mixture was then cooled to 18°C and a solution of 3-benzoyl-4-phenyl-2-pyrazoline (12) (1.6 g, 6.4 mmol) in 14 mL dry DMSO was added dropwise at 18–20°C; the color changed from yellow to green. The green reaction mixture was stirred at ambient temperature for 20 min and cooled to 18°C. Then a solution of 1.6 g (11 mmol) of methyl iodide in 2 mL of dry DMSO was added dropwise to the reaction mixture at 18–20°C; the color changed from green to yellow and the mixture was stirred at ambient temperature for 1 h, after which it was poured into 100 mL of ice water and extracted with 30 mL of ether. The ethereal layer was washed with water, dried over $MgSO_4$, and the solvent was evaporated *in vacuo* to yield 1.34 g (79%) crude product, mp 131–137°C; ir (KBr): 1615 (C=O) cm^{-1}; ^{1}H nmr δ: 3.05 (s, 3H, CH_3), 3.50 (t, 2H, CH_2), 4.55 (q, 1H, CH), 7.50 (m, 10H, ArH).

*3-Benzoyl-4-phenyl-1-methylpyrazole (***2***c) by sulfur dehydrogenation of 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline*

A mixture of 1.1 g (4.2 mmol) of 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline and 0.14 g (4.4 mmol) of sulfur was gently heated with a flame; the two solids melted and heating was continued until gas evolution subsided. Ether was added and the ethereal solution was washed with water, 10% NaOH, water, and dilute HCl. After a final wash with water, the solution was dried over $MgSO_4$ and concentrated to yield 0.45 g (41%) of a yellow solid, mp 92–93°C, identical in all respects with authentic **2***c* (*vide supra*), mp 92.5–93.5°C.

Other oxidations of 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline. General procedure

A stirred solution of the 2-pyrazoline (0.2 g, 1.0 mmol) and an equimolar amount of the oxidizing agent in the appropriate solvent (25 mL) were heated to reflux. Upon cooling, the precipitate (if any) was removed by filtration. Evaporation of the filtrate left a residue (which solidified in some cases) whose ir and nmr spectra indicated 3-benzoyl-4-phenyl-1-methylpyrazole (**2***c*) to be the product of the oxidation. The product was induced to crystallize by trituration with ether – petroleum ether at low temperature, or by chromatography on silica gel (70–230 mesh) by elution with a benzene–chloroform (5:2) mixture. Recrystallization may be effected from anhydrous ethanol, mp 90–92.5°C.

Oxidant	Solvent	Heating time (h)	Crude yield (%)
$Pb(OAc)_4$[a]	Acetic acid[b]	2	60
DDQ	Benzene	15	>95
NBS	CCl_4	3.5	95
NCS	CH_2Cl_2	7	20
10% Pd/C	*m*-Xylene	24	—[c]

[a]Reference 27.
[b]Volume of glacial acetic acid was 3.8 mL.
[c]Although the yield was not recorded, it is not negligible.

Photolysis of 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline

A solution of the 2-pyrazoline (1.0 g, 3.8 mmol), AIBN (0.31 g, 1.9 mmol),[4] and cumene (280 mL), under a nitrogen atmosphere, was irradiated overnight by a Hanovia high pressure mercury immersion lamp (Pyrex filter). The cumene was removed by distillation under reduced pressure. The nmr spectrum of the residue showed the presence of the starting pyrazoline as well as of **2***c* (spiking with an authentic sample).

syn-N-*Nitrososarcosine*

To a stirred solution of sarcosine (35.6 g, 0.40 mol), 67 mL of concentrated hydrochloric acid, and 100 mL of water at 0°C was added dropwise a solution of sodium nitrite (55.2 g, 0.80 mol) in water (200 mL) over a period of 40 min. The solution warmed gradually to ambient temperature. The aqueous solution was then extracted continuously with ether (ca. 300 mL) for 48 h and the ethereal extract was dried ($MgSO_4$). Evaporation of the ether *in vacuo* below 35°C afforded 44 g (93%) of yellow viscous liquid (^{1}H nmr δ: 3.20, 3.90 (3H, s, NCH_3), 4.40, 5.10 (2H, s, NCH_2), 5.70 (1H, s, OH)). To this viscous liquid was added ether (ca. 10 mL) and the solution was stored in a freezer overnight, whereupon the *syn* isomer crystallized. The colorless solid was collected by filtration and washed several times with small portions of ether – petroleum ether (1:1). The *syn-N*-nitrososarcosine should be stored in a freezer until use. The filtrate was concentrated carefully (because of the instability of nitroso acid) and the procedure above repeated twice, converting nearly all of the mixture to *syn-N*-nitrososarcosine; ir (neat): 1725 (C=O) cm^{-1}; ^{1}H nmr δ: 3.85 (3H, s, NCH_3), 4.30 (2H, s, NCH_2), 10.1 (1H, s, OH).

3-Methylsydnone

A solution of acetic anhydride (70 mL) and *syn-N*-nitrososarcosine (20.0 g, 0.169 mol) was heated to reflux for 5 min; color changes from colorless to green and eventually yellow were observed during this period. The reaction mixture was cooled and acetic acid and the excess acetic anhydride were removed by distillation (aspirator). The remaining orange liquid was distilled twice under reduced pressure (lit. (20) bp 125–128°C) to afford 9.28 g (56%) of pure 3-methylsydnone as a deliquescent solid, which was stored in a refrigerator; ir (neat): 1735 (sh 1775) (C=O) cm^{-1}; ^{1}H nmr δ: 4.15 (3H, s, NCH_3), 6.60 (1H, s, CH).

Reaction of 3-methylsydnone with benzoylphenylacetylene

A stirred solution of 3-methylsydnone (1.10 g, 11.0 mmol) and benzoylphenylacetylene (21) (2.06 g, 10.0 mmol) in *o*-dichlorobenzene (50 mL) was heated to reflux for 6 days under an atmosphere of nitrogen. The solvent was removed by distillation under reduced pressure. The dark viscous residue was chromatographed on silica gel (70–230 mesh) and eluted with benzene–chloroform (5:2); evaporation of the solvents afforded a mixture whose nmr spectrum (by spiking with authentic samples of **2***a* and **2***c*) showed that 3-benzoyl-4-phenyl-

[4]α,α′-Azobisisobutryonitrile.

1-methylpyrazole (**2***c*) and 4-benzoyl-3-phenyl-1-methylpyrazole (**2***a*) were formed (ratio of 1:2.2) in a nearly quantitative yield (2.6 g, 99%).

Cycloaddition of 3-benzylsydnone with benzoylphenylacetylene

A solution of 3-benzylsydnone (0.88 g, 5.3 mmol) (22) and benzoylphenylacetylene (1.03 g, 5.00 mmol) in *o*-dichlorobenzene (20 mL) was heated to reflux under nitrogen for 72 h. The solvent was removed by distillation *in vacuo* leaving a brown residue, which was chromatographed on silica gel (70–230 mesh) and eluted with benzene. Based on recovered benzoylphenylacetylene (0.14 g), the yield of the dark residue was nearly quantitative (1.46 g). The residue was shown to be a mixture of 3-benzoyl-4-phenyl-1-benzylpyrazole and 4-benzoyl-3-phenyl-1-benzylpyrazole in a ratio of 5:1 as determined by nmr integration. Further chromatography of this mixture as described above allowed the separation of these isomers as solids after evaporation of the solvent. The more mobile fraction was a yellow solid, mp 100–104°C; ir (KBr): 1650 (C=O) cm^{-1}; ^1H nmr δ: 5.23 (2H, s, NCH_2), 7.20 (14H, m, ArH, CH), 7.65 (2H, m, ArH). The other isomer crystallized as off-white crystals, mp 93–94.5°C; ir (KBr): 1650 (C=O) cm^{-1}; ^1H nmr δ: 5.25 (2H, s, NCH_2), 7.30 (14H, m, ArH, CH), 8.05 (2H, m, ArH).

Esterification and methylation of 5-benzoyl-4-phenylpyrazole-3-carboxylic acid

To a suspension of 5-benzoyl-4-phenylpyrazole-3-carboxylic acid (6.6 g, 22.6 mmol) in an ice bath was added dropwise an ethereal solution of diazomethane (50 mmol, 170 mL); the mixture was stirred at ambient temperature overnight. The ethereal solution was washed with water, aqueous sodium bicarbonate, and water, followed by the usual work-up to give 7.5 g of a crude solid, shown by nmr to be a mixture of the two esters. The solid was recrystallized from ethanol twice to give a white solid mixture of the two esters; the filtrate was concentrated to give a white solid, shown by nmr to be one isomer of the esters (nmr δ: 4.10 (s, 3H, N-CH_3), 3.83 (s, 3H, O-CH_3)), mp 118–119°C. The original solid (mixture) obtained was recrystallized from ethanol twice to give 2.86 g (40%) of isomeric ester (nmr ($CDCl_3$) δ: 4.21 (s, 3H, N-CH_3), 3.62 (s, 3H, O-CH_3)) as colorless needles, mp 121–122°C, and concentration of the filtrate gave the ester of mp 118–119°C; further concentration of the filtrates and crystallization (from ethanol) afforded additional amounts of the lower melting ester and the total yield was 1.45 g (20%). The residue, consisting of a mixture of the two esters, amounted to 1.8 g (25%). The melting point of a mixture of the two pure esters was depressed (95–100°C).

*3-Benzoyl-4-phenyl-1-methylpyrazole-5-carboxylic acid (**10**)*

A mixture of pyrazole ester (1.28 g, 4 mmol), mp 121–122°C, and aqueous potassium hydroxide (1 g in 5 mL of water) was heated to reflux for 4 h and some of the water and methanol produced were removed by distillation; 5 mL of water was added to the residue and it was heated to reflux overnight. The cooled mixture was washed with ether and then acidified with concentrated HCl to give a white solid, which was collected and washed with water. Recrystallization from aqueous ethanol afforded 1.06 g (87%) of colorless needles, mp 178–179°C, decomposition at 210°C (lit. (9) mp 181–182°C). The filtrate was extracted with ether followed by the usual work-up to give a white solid, which was then combined with the residue from the filtrate of the recrystallization and recrystallized from aqueous ethanol to yield 0.08 g (7%) of off-white crystals, mp 172–176°C; the total yield was 94%.

*5-Benzoyl-4-phenyl-1-methylpyrazole-3-carboxylic acid (**11**)*

A mixture of pyrazole ester (0.64 g, 2 mmol), mp 118–119°C, and aqueous potassium hydroxide (0.5 g in 3 mL of water) was heated to reflux overnight and 1 mL of a mixture of the water and the methanol formed as by-product was removed by distillation. Upon acidification of the residue with 10% hydrochloric acid, a white solid precipitated immediately; it was collected, washed with water until neutral, and air-dried. Recrystallization from aqueous ethanol yielded 0.48 g (78%) of white needles, mp 213–213.5°C (lit. (9) mp 213°C). Although the sample melted at 212–213°C (with some gas evolution at 218°C), the cooled sample melted at 212–213°C. This observation suggests that complete decomposition requires much higher temperatures.

*5-Benzoyl-4-phenyl-1-methylpyrazole (**2** d) by decarboxylation of pyrazole acid **11***

Pyrazole acid **11** (0.30 g, 1 mmol), mp 212–213°C, was heated at 280°C for 3 min and at 310°C for 15 min to yield 0.26 g of crude product; its tlc (SiO_2/$CHCl_3$) showed one major product and one small spot on the original starting point. Purification by column chromatography (SiO_2, $CHCl_3$) gave 0.24 g (94%) of 5-benzoyl-4-phenyl-1-methylpyrazole (**2***d*) as a thick oil.

*3-Benzoyl-4-phenyl-1-methylpyrazole by decarboxylation of acid **10***

Similar decarboxylation of pyrazole acid **10** gave a nearly quantitative yield of **2***c*, mp 91–93°C.

Ethyl 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline-5-carboxylate

To 0.43 g (18 mmol) of sodium hydride (dry) was added dry DMSO (12 mL) dropwise under N_2. The suspension was stirred for 20 min at 20–22°C. To this suspension was added dropwise ethyl 3-benzoyl-4-phenyl-2-pyrazoline-5-carboxylate (5.0 g, 15 mmol) (13) in dry DMSO (40 mL), while the temperature was kept at 20–22°C. The solution turned blood-red in color and stirring was continued for an additional 20 min. Then, a solution of iodomethane (2.5 g, 18 mmol) in dry DMSO (10 mL) was added dropwise and a gradual color change from red to yellow was observed. The yellow solution was stirred at ambient temperature overnight and was then poured into vigorously stirred ice water (200 mL). The product was extracted into ether (2 × 100 mL). The combined ethereal extracts were washed twice with water, dried over $MgSO_4$, and the ether evaporated, leaving 5.03 g (99%) of a residue whose ir and nmr spectra indicated it to be the desired methylated pyrazoline. It was used without further purification; ir (neat): 1740, 1720 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.30 (t, 3H, C-CH_3), 3.30 (s, 3H, N-CH_3), 4.20 (q, 2H, C-CH_2), 7.60 (m, 11H, ArH, PyH).

Ethyl 3-benzoyl-4-phenyl-1-methyl-5-pyrazolecarboxylate

To a stirred solution of ethyl 3-benzoyl-4-phenyl-1-methyl-2-pyrazoline-5-carboxylate (1.0 g, 3.0 mmol) in CCl_4 (10 mL) chilled in an ice bath was added dropwise a solution of bromine (0.64 g, 3.6 mmol) in CCl_4 (6 mL). After the addition, the solution was allowed to warm to ambient temperature and subsequently heated to reflux for 2 days. The solvent was removed by distillation and the residue was dissolved in ether (25 mL). The ethereal solution was washed successively with saturated aqueous sodium bicarbonate, water, saturated aqueous sodium thiosulfite, and water, then dried over $MgSO_4$ and evaporated *in vacuo* to give a quantitative yield of the pyrazole as a brown residue; ir (neat): 1720 (C=O) cm^{-1}; ^1H nmr δ: 0.97 (t, 3H, C-CH_3), 4.10 (q, 2H, C-CH_2), 4.22 (s, 3H, N-CH_3), 7.53 (m, 10H, ArH, PyH).

3-Benzoyl-4-phenyl-1-methyl-5-pyrazolecarboxylic acid

A solution of potassium hydroxide (0.67 g, 12 mmol) in water (6 mL) was added to ethyl 3-benzoyl-4-phenyl-1-methyl-5-pyrazolecarboxylate (1.00 g, 3.00 mmol) and the mixture was heated to reflux with stirring overnight. Excess water and ethanol (2 mL) were removed by distillation *in vacuo*. An additional portion of water was then added to the solution, which was subsequently washed twice with small portions of ether. The basic solution was then acidified with concentrated hydrochloric acid and extracted with ether (2×). The ethereal solution was washed with water until neutral, dried over $MgSO_4$, and concentrated to give 0.50 g (54%) of a tan colored solid, mp 165–167°C, which was identical in all respects (tlc, ir, and nmr) to the acid (**10**) obtained above.

Acrylophenone

β-Dimethylaminopropiophenone hydrochloride (88.0 g, 0.41 mol) was placed into a 1-L 3-necked round-bottomed flask and steam distilled. The distillate was extracted with ether, washed with water, and filtered. The ethereal extract was dried over magnesium sulfate and the solvent was evaporated *in vacuo* to yield 24.1 g (45%) of a pale

golden oil (23), used without further purification. The infrared and nmr spectra confirmed its structure.

*3-Benzoyl-5-phenyl-2-pyrazoline (**14**)*

To 13.2 g (0.10 mol) of acrylophenone in 100 mL of anhydrous ether in a 500-mL 3-necked round-bottomed flask fitted with a magnetic stirring bar, a reflux condenser, drying tube, and an addition funnel, and cooled to 0°C, was added dropwise a solution of phenyldiazomethane (24). When the addition was complete the mixture was stored in the freezer overnight. The precipitated yellow crystals were collected and recrystallized from anhydrous ether to yield 14.8 g (60%) of pale yellow crystals, mp 81–83°C; its *N*-acetyl derivative, mp 113–114.5°C (from ethanol) was prepared and analyzed. *Anal.* calcd. for $C_{18}H_{16}N_2O_2$: C 73.95, H 5.52, N 9.58; found: C 73.84, H 5.47, N 9.79.

*3-Benzoyl-5-phenyl-1-methyl-2-pyrazoline (**15**)*

To 0.27 g (11 mmol) of *dry* sodium hydride was added dropwise 8 mL of dry DMSO at 18–20°C and the mixture was stirred at ambient temperature for 20 min. The mixture was then cooled to 18°C and a solution of 3-benzoyl-5-phenyl-2-pyrazoline (1.6 g, 6.4 mmol) in 14 mL of dry DMSO was added dropwise at 18–20°C; the color changed from yellow to green. The green reaction mixture was stirred at ambient temperature for 20 min and cooled to 18°C. Then, a solution of 1.6 g (11 mmol) of methyl iodide in 2 mL of dry DMSO was added dropwise to the reaction mixture at 18–20°C; the color changed from green to yellow and the mixture was stirred at ambient temperature for 1 h. It was then poured into 100 mL of ice water and extracted with 30 mL of ether. The ethereal layer was washed with water, dried over $MgSO_4$, and the solvent was evaporated *in vacuo* to yield 1.77 g of a yellow oil; the oil solidified upon standing at room temperature. The solid was recrystallized from ether – petroleum ether to give an analytical sample, mp 79.5–81°C. The solid from the evaporation of the filtrate was recrystallized; the combined yield of recrystallized product was 1.02 g (60%). *Anal.* calcd. for $C_{17}H_{16}N_2O$: C 77.25, H 6.10, N 10.60; found: C 76.98, H 6.09, N 10.60.

Evaporation of the filtrate from the recrystallization of the second crop afforded a residual oil whose nmr spectrum showed, in addition to **15**, the presence of 3-benzoyl-5-phenyl- and 5-benzoyl-3-phenyl-1-methylpyrazoles.

*3-Benzoyl-5-phenyl-1-methylpyrazole (**2**e)*

A mixture of 1.0 g (3.8 mmol) of 3-benzoyl-5-phenyl-1-methyl-2-pyrazoline and 0.13 g (94 mmol) of sulfur was gently heated with flame. Two solids melted and two layers were observed. Heating was continued until the mixture became homogeneous. After cooling, ether was added and the ethereal solution was washed with water, 10% aqueous NaOH, water, dilute HCl (2 drops in 30 mL of water), and water. The dried ethereal solution was concentrated to dryness *in vacuo* to give 0.91 g of an oil. Column chromatography (silica gel, benzene) of the mixture gave 0.86 g (96%) of an oil (single spot by tlc), which was triturated with ether – petroleum ether and crystallized to give white crystals, mp 57–57.5°C. *Anal.* calcd. for $C_{17}H_{14}N_2O$: C 77.84, H 5.38, N 10.68; found: C 77.69, H 5.15, N 10.82.

3-Methyl-4-phenylsydnone

A mixture of *N*-nitroso-*N*-methyl-*C*-phenylglycine (4.0 g, 20.6 mmol) and acetic anhydride (15 mL) was stirred on a steam bath overnight (25). The mixture was cooled to room temperature and poured slowly into a mixture of ice and water with vigorous stirring to give 3.6 g (99%) of a tan precipitate, mp 126–130°C. Recrystallization from an ether–benzene mixture afforded colorless crystals, mp 130.5–131.5°C. *Anal.* calcd. for $C_9H_8N_2O_2$: C 61.35, H 4.58, N 15.92; found: C 61.33, H 4.55, N 15.94.

Dimethyl 1-methyl-5-phenylpyrazole-3,4-dicarboxylate

A mixture of 3-methyl-4-phenylsydnone (5.0 g, 28.0 mmol) and dimethyl acetylenedicarboxylate (8.0 g, 56.0 mmol) in 100 mL *p*-xylene was heated at reflux overnight. The *p*-xylene was distilled under vacuum (aspirator). Ether – petroleum ether was added to the residue to precipitate 5.9 g (77%) colorless crystals, mp 82–83°C.

1-Methyl-5-phenylpyrazole-3,4-dicarboxylic acid

A mixture of dimethyl 1-methyl-5-phenylpyrazole-3,4-dicarboxylate (12.0 g, 44 mmol) and 10% NaOH (480 mL) was heated at reflux for 14 h. The cooled solution was acidified with concentrated HCl and the precipitate was collected and washed with water to give 10.0 g (93%) of colorless crystals, mp 266°C (dec.); NE (neutralization equivalent): 125.75.

*1-Methyl-5-phenylpyrazole-4-carboxylic acid (**16**)*

A 1.0 g (4 mmol) sample of the diacid was heated in an oil bath at ~280°C. The acid melted, with gas evolution. After cooling, the residue was shaken with 2.5 *N* NaOH and 0.37 g (45%) of white crystals, mp 215–216°C. It was converted to the known methyl ester as described below.

Methyl 1-methyl-5-phenyl-4-pyrazolecarboxylate

A solution of 1-methyl-5-phenylpyrazole-4-carboxylic acid (0.2 g, 1 mmol), methanol (1 mL), and H_2SO_4 (0.5 mL) was heated at reflux for 1 h. After cooling to room temperature, the reaction mixture was extracted with CH_2Cl_2, washed with water, and then with aqueous $NaHCO_3$. After drying over $MgSO_4$, the mixture was evaporated to yield 0.14 g (65%) of the methyl ester as yellow crystals, mp 105.5–107°C. The melting point and spectra were identical to literature values (15).

5-Phenyl-1-methylpyrazole was obtained by heating a solution of 1-methyl-5-phenylpyrazole-3,4-dicarboxylic acid (4.0 g) in 12 g of diphenyl ether at reflux overnight. The brown oil was acidified with concentrated HCl, extracted with water, neutralized with 2.5 *N* NaOH, extracted with ether, and dried over $MgSO_4$. The ether was evaporated to yield 2.6 g (96%) of a yellow oil, identical in all respects (tlc, ir, and nmr) to an authentic sample (17).

Preparation of 5-phenyl-1-methylpyrazole

An approximately 1:1 mixture (32 g) of 3-phenyl-1-methyl-2-pyrazoline and 5-phenyl-1-methyl-2-pyrazoline (26) (bp 137–138°C/30 Torr; 1 Torr = 133.3 Pa) and sulfur (7 g) was heated to 230°C overnight. To the cooled reaction mixture was added 100 mL of 10% NaOH and it was stirred overnight. It was extracted with ether and the ethereal solution was washed with water, dried over $MgSO_4$, and the ether was evaporated. The mixture of pyrazoles was carefully distilled at 0.75 Torr three times to yield 16 g (51%) of a mixture, bp 105°C/0.75 Torr, which contained 80% of 5-phenyl-1-methylpyrazole (by nmr). To a solution of this mixture (16 g) in ethanol (20 mL) was added a saturated solution of picric acid in ethanol to precipitate the picrate, which was collected. The filtrate was treated in the same fashion and the process repeated until no more picrate formed. The precipitates were combined and recrystallized from ethanol to give 25 g of the picrate of 5-phenyl-1-methylpyrazole, mp 143–144°C, as yellow crystals (lit. (16) mp 142–143°C). A solution of the picrate (16.5 g, 0.043 mmol) in benzene (100 mL) was shaken with 10% NaOH and then with water. The benzene solution was dried over $MgSO_4$ and benzene was evaporated *in vacuo* to give an oil. It was distilled under vacuum to yield 5.3 g (82%) of 5-phenyl-1-methylpyrazole, bp 105°C/1.0 Torr (lit. (16) bp 118–119°C/12 Torr).

4-Bromo-5-phenyl-1-methylpyrazole

A solution of bromine (7.21 g, 45.1 mmol) in chloroform (10 mL) was added dropwise to a stirred solution of 5-phenyl-1-methylpyrazole (6.49 g, 41.10 mmol) in chloroform (7 mL) cooled in an ice bath. The mixture was then allowed to warm to room temperature and stirring continued overnight. The red reaction mixture was washed successively with a saturated aqueous solution of sodium bicarbonate, water, saturated aqueous sodium thiosulfite, and finally water. The organic phase was dried over $MgSO_4$ and concentrated, to afford a yellow liquid that solidified on standing to give 9.27 g (95%) of a yellow solid. Recrystallization from petroleum ether afforded pale yellow crystals of 4-bromo-5-phenyl-1-methylpyrazole, mp 51.5–52.5°C; ^{1}H nmr δ: 3.72 (s, 3H, CH_3), 7.35 (s, 5H, ArH), 7.45 (s, 1H, PyH).

*5-Phenyl-1-methyl-4-pyrazolecarboxylic acid (**16**)*

To a stirred solution of 4-bromo-5-phenyl-1-methylpyrazole (5.95 g, 25.1 mmol) in anhydrous ether (10 mL) under N_2 at −30°C was

added dropwise a solution of *n*-butyllithium in hexanes (31.4 mL, 50.2 mmol); the temperature was maintained between −30 and −35°C throughout the addition; during the addition, dry THF (20 mL) was added to prevent the mixture from freezing. After the addition, the mixture was allowed to warm to 0°C for a short while, and eventually to room temperature. Stirring at room temperature continued for 1.5 h. The resulting yellow suspension was then cooled back to −30 to −35°C and dry carbon dioxide was bubbled through the solution while the temperature was allowed to increase to 25°C. This process took a total of 2 h; stirring was continued overnight. The yellow solid that had formed was collected and it was immediately dissolved in 50 mL of water and acidified with concentrated hydrochloric acid, causing a precipitation of a cream colored solid, which was collected and washed with small portions of cold water. The carboxylic acid (3.6 g, 71%) was allowed to air-dry, mp 214–215°C, identical in all respects to the previous sample (*vide supra*); ir (KBr) 1700 cm^{-1}; ^1H nmr (DMSO-d_6) δ: (3H, s, NCH_3), 7.30 (6H, br s, ArH, CH), 7.80 (1H, br s, OH).

*4-Benzoyl-5-phenyl-1-methylpyrazole (**2**f)*

A solution of 5-phenyl-1-methyl-4-pyrazolecarboxylic acid (2.00 g, 10.0 mmol) in thionyl chloride (18 mL) was heated to reflux for 24 h. After removal of excess thionyl chloride by distillation (aspirator), benzene was added and the solution was evaporated; this procedure was repeated to insure the complete removal of any residual thionyl chloride. The resulting dark residue was dissolved in dry benzene (20 mL), treated with aluminum chloride (2.70 g, 20 mmol), and heated gently for 36 h. The reaction mixture was washed successively with a saturated aqueous solution of sodium bicarbonate (3 × 25 mL) and water (2 × 25 mL). The organic phase was dried (Na_2SO_4) and concentrated to afford a brown oil, 2.59 g (99%). The oil was chromatographed on silica gel (70–230 mesh) eluted with benzene (and gradually changed to chloroform) to yield an orange oil (2.25 g). All attempts to induce crystallization of the oil, including Kugelrohr distillation (bp 175–180°C), failed and only a viscous yellow oil was obtained. *Anal.* calcd. for $C_{17}H_{14}N_2O$: C 77.84, H 5.38, N 10.68; found: C 77.93, H 5.54, N 10.58.

A proton spin-lattice relaxation pathway analysis of conformational preferences of aryl and enol ethers in some cinchona and morphine alkaloids

WALTER J. CHAZIN AND LAWRENCE D. COLEBROOK[1]

Department of Chemistry, Concordia University, 1455 de Maisonneuve Blvd., West, Montreal (Que.), Canada H3G 1M8

Received April 29, 1986

WALTER J. CHAZIN and LAWRENCE D. COLEBROOK. Can. J. Chem. **64**, 2220 (1986).

The spin-lattice relaxation rates of protons adjacent to hydroxyl and methoxy groups in aryl and enol ethers are dependent on the orientation of the alkyl group. This property has been employed to identify preferred conformations of these groups in some cinchona and morphine group alkaloids.

WALTER J. CHAZIN et LAWRENCE D. COLEBROOK. Can. J. Chem. **64**, 2220 (1986).

On a observé que les taux de relaxation spin-réseau des protons adjacents des groupements hydroxyles et méthoxyles des éthers aryliques et énoliques dépendent de l'orientation des groupements alkyles. On a utilisé cette propriété pour identifier les conformations privilégiées de ces groupements dans quelques alcaloïdes des familles de la cinchona ainsi que de la morphine.

[Traduit par la revue]

Introduction

Conformational preferences of enol ethers, in particular, aromatic methoxy groups, have been a subject of interest to organic chemists for many years. These preferences have been observed by a number of experimental techniques, and investigated by a range of computational methods (1, 2). In general, it has been found that in alkyl enol ethers there is a decided preference for the *s–cis* conformation, where the alkyl group is coplanar and *syn* to the bond of higher order (1, 3). Recently, corresponding preferences in aromatic ethers have also been discussed (1, 2, 4, 5).

Nuclear magnetic resonance (nmr) has proven to be a very powerful technique for determination of the conformational bias of enols (6) and enol ethers (3–5, 7). Using a method that is closely related to techniques utilizing $^1H\{^1H\}$ nuclear Overhauser effects (nOe) (8), as reported by Sanders and co-workers (9) and Kruse *et al.* (5), the spin-lattice relaxation of vinylic, allylic, and ring protons of enol and aromatic ethers in some cinchona and morphine alkaloids[2] has been examined to gain insight into specific conformational preferences of the ether function.

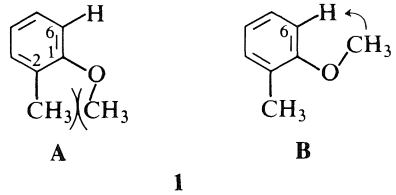
For organic molecules of molecular weight less than about 1000, proton spin-lattice relaxation in a dilute solution of a nonviscous solvent is usually dominated by intramolecular dipolar interactions between protons. The rate equation for dipolar relaxation of a proton, j, is given by:

$$[1] \quad R_{1_j} = 1/T_{1_j} = K\sum_i (1/r_{ij})^6 \tau_{c_{ij}} \qquad (i \neq j)$$

where K is a product of constants, r_{ij} is the distance between proton j and proton i, and $\tau_{c_{ij}}$ is the rotational correlation time for the r_{ij} interproton vector. Each term in eq. [1] represents the relative magnitude of the dipolar interaction between j and i, and is referred to as a specific relaxation pathway. Direct nuclear Overhauser effects are proportional to the relative weight of each relaxation pathway to the overall sum.

The strong inverse sixth power dependence on interproton distance implies that R_1 values and nOe enhancements can be useful for the determination of details of local structure. The method used in these studies involves detailed analysis of ^1H spin-lattice relaxation pathways based on calculation, followed by fitting to experimentally observed nonselective relaxation rates (10, 11). The interproton distances required for calculations are obtained from a structural model (e.g., crystal structure coordinates from diffraction data, molecular mechanics calculations, or Dreiding molecular models).

This approach can be understood by considering a simple example, 2-methylanisole, **1**. The conformational bias of the methoxy group in this, and related derivatives, is well characterized (1–5, 7); due to steric hindrance in 6-*trans* conformations, **A**, 6-*cis* conformations, **B**, are greatly favored. An examination of spin-lattice relaxation of the adjacent proton at C-6 was made, relative to the other ring protons. First, calculations of R_1 values were carried out for the molecule with various methoxy group conformations. If only 6-*trans* conformations were populated, the ^1H R_1 value of H-6 would be expected to be about 50% lower than the R_1 value for all other ring protons, because H-3, H-4, and H-5 all have two nearby neighbours giving significant relaxation contributions, whereas H-6 has only one. On the other hand, if only 6-*cis* conformations were populated, H-6 would have a significantly larger R_1 value than other ring protons due to the efficient relaxation pathway from the methoxyl protons, about 2.5 Å away in a standard (2) conformation.



A **B**

1

The experimentally observed ^1H R_1 value of H-6 is ~50% higher than those of the other ring protons, reflecting the strong preference for conformation **B**.

Results and discussion

The conformational bias of ether functions in the cinchona alkaloids quinine, **2**, and quinidine, **3**, and in the morphine alkaloids morphine, **6**, codeine, **7**, diacetylmorphine (heroin), **8**, and thebaine, **9**, have been determined using this ^1H R_1 method. The pertinent experimental ^1H R_1 values for quinine, **2**, and quinidine, **3**, are given in Table 1, and for the morphine alkaloids morphine, **6**, codeine, **7**, thebaine, **9**, and diacetylmorphine (heroin), **8**, in Table 2. Since the calculations of R_1 values play a key role in the method demonstrated here, a brief

[1]Author to whom correspondence may be addressed.

[2]A comprehensive discussion of the ^1H R_1 values of these and other alkaloids has been presented elsewhere (10).

TABLE 1. Normalized experimental R_1 values for cinchona alkaloids[a]

H	R_1 (s^{-1})			
	2	**3**	**4**	**5**
5′	0.52 (2.56)	0.52 (2.77)	0.48 (2.39)	0.49 (2.62)
7′	0.09 (0.60)	0.09 (0.62)	0.17 (0.96)	0.16 (0.96)
8′	0.10 (0.64)	0.08 (0.59)	0.09 (0.61)	0.09 (0.60)

[a]All measurements obtained from 0.1 *M* solutions of HCl salts in DMSO-d_6 at 20°C. The observed R_1 values (s^{-1}), given in parentheses, were corrected for the contribution from dissolved oxygen, and normalized to H-5ex. Estimated precision and accuracy are ±5% and ±10%, respectively.

TABLE 2. Normalized experimental R_1 values of morphine alkaloids[a]

H	R_1 (s^{-1})			
	Morphine, **6**	Codeine, **7**	Heroin, **8**	Thebaine, **9**
1	1.00 (1.05)	1.00 (0.83)	1.00 (0.91)	1.00 (0.96)
2	0.96 (1.02)	1.00 (0.83)	0.57 (0.59)	1.10 (1.03)
5	1.90 (1.82)	2.00 (1.51)	1.80 (1.47)	0.97 (0.94)
7	0.96 (1.02)	0.99 (0.82)	0.97 (0.89)	1.50 (1.36)

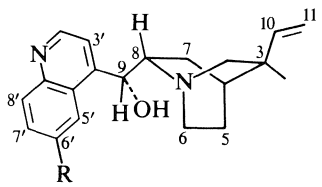
[a]All values obtained from 0.1 *M* DMSO-d_6 solutions of HCl salts, except for codeine as the phosphate salt, at 20°C. The observed R_1 values (s^{-1}), given in parentheses, were corrected for the contribution from dissolved oxygen, and normalized to H-1. Estimated precision and accuracy are ±5% and ±10%, respectively.

description of the analysis of cinchona alkaloids **2** and **3** is given below.

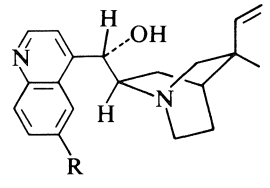
The methoxy group in the cinchona alkaloids is located at C-6′, thus we shall examine in detail the ^{1}H R_1 values of H-5′ and H-7′, to demonstrate that they indicate conformational preferences. Initially, interproton distances were obtained by generating proton coordinates using standard geometries from published X-ray crystal structures of cinchonine (12) and quinidine (13). These calculations served as a guide to understanding the relative importance of various relaxation pathways, but contained a number of unrealistic interproton distances, due to the inaccuracies inherent in *generating* H atom coordinates. Past experiences suggested that a more reliable set of interproton distances for protons within rigid substructures (in this case, the quinoline and quinuclidine rings) could be obtained from molecular models, so a second set of calculations was carried out using standard distances measured on Dreiding models.

A third set of calculations used a slightly different comparative approach, wherein it was assumed that **4** and **5** are good models for analyzing relaxation in **2** and **3**. Relaxation pathways involving protons within the quinoline ring were calculated using interproton distances from Dreiding models for all appropriate model substructures, while pathways from outside the ring were determined from comparisons of calculated and experimental data for **2** and **3** with **4** and **5**, respectively. The "internal" and "external" calculated results for **2** and **3** were then normalized, combined, and compared to the experimental data, to determine the presence or absence of conformational bias.

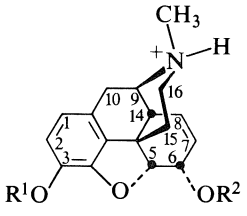
We now examine the spin-lattice relaxation of specific protons in detail. H-7′, rather isolated from the rest of the molecule, is relaxed primarily by protons at the 6′ and 8′



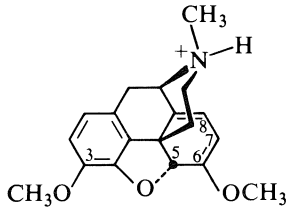
2 R = OCH_3
4 R = H



3 R = OCH_3
5 R = H



6 R^1 = R^2 = H
7 R^1 = CH_3, R^2 = H
8 R^1 = R^2 = $COCH_3$



9

positions (98%, calculated) in **4** and **5**, with a much smaller contribution from the proton at 5′ (2%, calculated). R_1 values for H-7′ in **2** and **3** are expected to be substantially different from those in **4** and **5** if the methoxy group at 6′ in **2** and **3** has a large preference for either the 5′-*cis* or 7′-*cis* conformation. In the 7′-*cis* orientation, the relaxation pathway from the methoxy group to H-7′ will be very efficient, so, if only these conformations are populated, the H-7′ R_1 values should be higher (up to a maximum of 55%, calculated) than the corresponding values in **4** and **5**. Alternatively, if the 5′-*cis* orientation is greatly preferred, the H-7′ R_1 values should be lower (by as much as 45%, calculated) than those in **4** and **5**. The lower H-7′ R_1 values for **2** and **3** (Table 1) indicate a bias of the methoxy group towards H-5′.

This conclusion can also be drawn from a comparison of the H-7′ R_1 values with those of H-8′. Calculations show that H-8′ is relaxed almost exclusively (>90%) by interaction with H-7′ in all four compounds, hence its R_1 value is relatively insensitive to modifications at C-6′. In **4** and **5**, H-8′ has a substantially lower R_1 value than H-7′ because H-7′ has two near neighbours (6′ and 8′), but H-8′ has only one (H-7′), yet in **2** and **3**, the R_1 values of H-7′ and H-8′ are nearly equivalent. This indicates that the major relaxation pathway to H-7′ from the 6′ proton(s) has been lost, and, in turn, implies that the 5′-*cis* methoxy conformation is preferred.

Whereas analysis of the relaxation of H-7′ and H-8′ is relatively straightforward because these protons are relaxed via dipolar interactions with protons within the rigid quinoline ring, analysis of H-5′ relaxation is complicated by the presence of several efficient relaxation pathways to protons outside the ring that may have additional degrees of motional freedom (e.g. H-8, H-9). These "external" relaxation pathways are evident upon inspection of model structures, and are the reason for the substantially greater magnitude of the R_1 values for H-5′ (relative to the other quinoline ring protons) in all four compounds.

In **4** and **5**, the C-6′ proton contribution to H-5′ relaxation is ~20% (calculated using crystal structure coordinates). Almost all of the other contributions are from protons outside the quinoline ring. If the methoxy group at C-6′ in **2** and **3** populates only those conformations with 5′-*cis* orientation, a greater contribution from C-6′ protons is expected. Using a model with a standardized methoxyl group conformation (2) (see

Experimental for further details), an increase in the H-5′ R_1, by as much as 21%, was calculated for **2** and **3**, relative to **4** and **5**. If the methoxy group populates only 5′-*trans* orientations, then the calculations predict a *decrease* of as much as 17% in the H-5′ R_1. The larger R_1 values observed for H-5′ in **2** and **3**, relative to the 6′-H analogues (**4** and **5**, respectively), are consistent with the H-7′ data in indicating a preference for the 5′-*cis* conformation.

As a check on the results obtained by our method, the combined R_1 and nOe method (5, 9) was used to determine the presence or absence of a specific methoxy conformational preference. This involves the determination of the OCH_3 conformational bias by comparing the nOe observed at adjacent protons (in this case, H-5′ and H-7′) upon presaturation of the CH_3 protons. We emphasize that a thorough relaxation pathway analysis is a prerequisite for proper interpretation of the nOe data. The ratio of the H-5′ to the H-7′ nOe enhancements upon presaturation of the 6′-OCH_3 was calculated to be <0.03 for 7′-*cis* only, 3.5 for 5′-*cis* only, and approximately 0.44 for a 1:1 equilibrium of 5′-*cis*:7′-*cis*. The observed ratios of 3 for both **2** and **3** confirmed that a significant preference for the 5′-*cis* orientation is present in these molecules. It is of interest to note that this particular conformation is observed in the X-ray crystal structure (13).

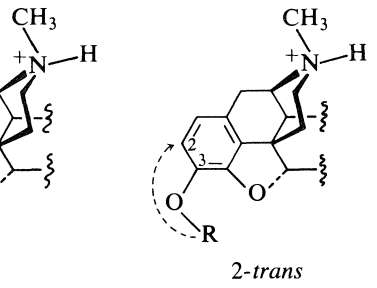
Working in a similar manner, the conformational bias of the 3-OH in morphine, **6**, the 3-OCH_3 in codeine, **7**, and thebaine, **9**, and the 3-acetoxyl group in diacetylmorphine (heroin), **8**, have been determined. We make note here of the observation of two species in solution for several morphine alkaloids, as has been reported by others (14). Data are reported only for the major isomer, that which is observed in X-ray crystallographic studies (15–17). Since a detailed analysis has already been given for **2** and **3**, only a summary of results for **6**–**9** will be presented.

To determine 3-OH and 3-OCH_3 conformational bias in these morphine alkaloids, the relaxation pathways for H-2 were analyzed in detail, by comparing experimental and calculated R_1 values. These comparisons were made relative to the values of H-1, for which previous calculations (X-ray crystal coordinates) had shown that the ^{1}H R_1 value would be insensitive to the C-3 substituent. In morphine, calculations indicated that if only the conformation with planar 2-*cis* OH orientation were populated, then the ^{1}H R_1 value of H-2 would be 20% higher than that for H-1. If only the conformation with the planar 2-*trans* OH orientation were populated, then the ^{1}H R_1 value of H-2 would be 50% lower than that for H-1. The close similarity in the experimentally observed ^{1}H R_1 values for H-1 and H-2 indicated a small preference for the 2-*cis* orientation.

In **7** and **9**, a methoxyl group is substituted at the C-3 position. Calculations indicated that for populations of conformations with standard (2) 2-*cis* orientations, the H-2 R_1 values should be higher (to a maximum of 26%) than those for H-1, whereas for 2-*trans* orientations, the H-2 R_1 values should be lower (by as much as 52%). The observed R_1 values of H-2 (Table 2) for **7** and **9** both indicate a preference for the 2-*cis* conformation.

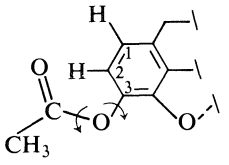
The same basic approach was used for detection of conformational bias of the 3-acetoxy group in heroin, **8**. The substantially slower relaxation of H-2 relative to H-1 (H-2:H-1 ratio of 0.57) indicated that the C-3 substituent relaxation pathway is greatly reduced, relative to **6**. This was also readily apparent from the normalized R_1 value of H-2 in **8**, $>\frac{1}{3}$ lower than the other morphine alkaloids.

Since an appreciable amount of motional freedom about the single bonds of the acetoxy group can be expected in solution, a detailed conformational analysis was not possible. The relaxation data do indicate that there is little or no population of conformations where the methyl group comes into close dipolar contact with the H-2 proton. In the solid state (17), the 3-(O-acetyl) group of **8** adopts a 2-*cis* orientation, but with the carbonyl oxygen in plane and facing H-2, and the methyl group turned away. Such a conformation is compatible with the ^{1}H R_1 data.



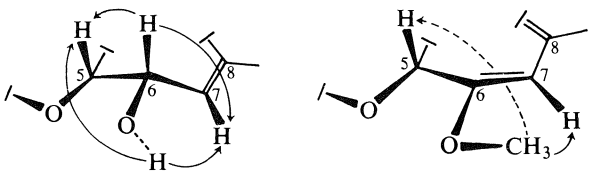
2-*cis* 2-*trans*

R = H, CH_3, acetyl



8

The conformational preference of the 6-OCH_3 group in thebaine, **9**, has also been determined. In morphine, **6**, calculations of H-5 relaxation, using X-ray coordinates, predict that the total contribution from H-6 and 6-OH is approximately 50%. A similar percentage contribution is predicted for relaxation of H-7. In **9**, the C-6 proton contributions to H-5 and H-7 relaxation are replaced by relaxation pathways to 6-OCH_3. On comparing the normalized experimental R_1 values of H-5 and H-7 in **9** to those in **6** (Table 2), a very substantial decrease in H-5 (~50%) and a significant increase in H-7 (~50%) are observed. These data can be interpreted in the following manner: in **9**, H-5 has lost nearly all contributions from the C-6 proton of the substituent, whereas H-7 has acquired a more efficient relaxation pathway from the C-6 protons. A 7-*cis* conformational bias for the 6-OCH_3 group is, therefore, clearly indicated.



6 **9**

A preference for the *s*–*cis* conformation has been observed in several enol ethers; the conformational preference observed in **9** is consistent with the previous observations that alkyl enol ethers prefer a conformation where the alkyl group is coplanar and *syn* to the double bond (3).

Conclusions

A method for determining conformational bias of aryl and enol ethers, in a qualitative manner, has been demonstrated. It has the advantages of being simple and efficient, because all ^{1}H

R_1 values can be obtained from a single set of nonselective inversion–recovery experiments, measured under standard ^{1}H nmr conditions. A second important aspect, which adds to the appeal of this ^{1}H R_1 method, is the *a priori* focus on the analysis of the complete set of relaxation pathways. This global approach is required for unambiguous qualitative or quantitative interpretation of all relaxation data. The method described here is generally applicable for studies of conformational preferences of enol ethers, and is complementary to previously reported methods.

Experimental

All spectra were measured at 400 MHz at ambient temperature (about 20°C) using a Bruker WH-400 spectrometer at the Montreal Regional High Field NMR Laboratory. Spectra (eight transients) were acquired into 32K (standard spectra and R_1 measurements) or 16K (nOed spectra) data blocks over a spectral range of 3900 Hz. Solutions were 0.1 *M* in deuterated solvent, and were not degassed, since highly accurate experimental R_1 values were not required. All relaxation data were, however, corrected for contributions from dissolved oxygen.

The basis for the method of oxygen correction is that the contribution from dissolved oxygen to proton relaxation is nonspecific, i.e. the contribution is equivalent for all of the protons in a molecule. This has been demonstrated for molecules similar in size and type to the alkaloids used in this study (18), and for other classes of compounds (19, 20).

The correction relies on a previous determination of the "degassed" R_1 value of TMS in the specific solvent, over the temperature range of interest. R_1 (degassed) of TMS in 99.8% $CDCl_3$ over the range 291–295 K was found to be 0.075 ± 0.005 s^{-1} (0.075 ± 0.002 s^{-1} at 293 K). The correction for the oxygen contribution was determined by subtracting the known R_1 for a degassed solution from the R_1 value measured for TMS in the solution that was not degassed. A direct comparison of results obtained by this method and from degassed solutions is given in refs. 19 and 20. In general, it was found that this method was adequate for *qualitative* analysis of relaxation parameters, of the type carried out in these studies. We note that this method is very useful for R_1 measurements of small molecules where relaxation times are long and, therefore, the total time for acquisition of a degassed R_1 data set is rather considerable (6–8 h) (20).

The ^{1}H R_1 values were measured by the standard inversion–recovery technique (21). The 180° pulse length was checked at the beginning of each experiment. R_1 data were obtained using the null point method (18). The absolute accuracy of R_1 measurements is typically ±10% but, within a single experiment, the relative R_1 values can be determined to a precision of better than ±5%. The nOe enhancements were measured by the difference technique (22), as described elsewhere (11).

Interproton distances for calculations of relaxation pathways were obtained from crystal structure coordinates of cinchonine (12), quinidine (13), morphine (15), codeine (16), and heroin (17), and from Dreiding molecular models. For calculating the relaxation contributions from methoxyl groups to adjacent ring protons, it was necessary to examine results from a number of models for methoxy conformation and dynamics. The best fit to the experimental data was obtained with a model in which the dihedral angle (C—O—C) is set to ~30°C and the rotation of the methyl group is described by a three-site jump model (23) between the three equivalent conformations, with the methyl protons staggered with respect to the adjacent ring proton.

Samples used in this study were obtained from the following suppliers: Baker, quinine; BDH, codeine; F. E. Cornell, heroin, morphine; Fisher, cinchonine; Sigma, cinchonidine, quinidine; T. and H. Smith, thebaine, and were dried before use.

Acknowledgments

This work was supported by an operating grant from the Natural Sciences and Engineering Research Council of Canada (NSERC), which also supplied funding towards the purchase of the 400-MHz spectrometer. We thank the Ministry of Education, Province of Quebec, and NSERC for post-graduate fellowships (to W.J.C.). The authors are indebted to Dr. Z. Amit and Mr. F. Rogan, Centre for Studies in Behavioral Neurobiology, Concordia University, for their collaboration.

An INDO investigation of the bonding modes occurring in five-membered heterocyclic thiones

GEORGE KAPSOMENOS AND PERICLES AKRIVOS

Department of Chemistry, Aristotelian University of Thessaloniki, P.O.B. 125, GR-540 06, Thessaloniki, Greece

Received January 28, 1986

GEORGE KAPSOMENOS and PERICLES AKRIVOS. Can. J. Chem. **64**, 2225 (1986).

A group of five-membered heterocyclic thioketo-compounds is studied by using results derived from the semi-empirical INDO method. The interest of these compounds from a theoretical point of view is the simultaneous presence of both sulfur and nitrogen in active positions so that a diversity of bonding schemes with metal ions could be encountered. The prediction of these coordination aspects are here explained quite satisfactorily by means of the computed HOMO eigenvalues of the ligands and by application of the energy-based HSAB criterion. This criterion is applied in cases where the coordination is not strongly pH dependent and the appropriate ligand form is considered. The straightforward derivation of the conclusions allows predictions of the bonding subtleties to be made in cases where experimental data are lacking or insufficient for clear conclusions.

GEORGE KAPSOMENOS et PERICLES AKRIVOS. Can. J. Chem. **64**, 2225 (1986).

On étudie toute une série de composés heterocycliques pentatomiques contenant un groupe latéral thionique par la méthode semi-empirique de calcul INDO. L'intérêt de ces composés du point de vue théorique consiste à la présence simultanée d'atomes de soufre et d'azote en positions actives, ce qui entraîne la possibilité de différents modes de coordination. Cet effet est expliqué ici d'une façon satisfaisante au moyen de valeurs propres HOMO des ligands et par l'application du critère énergétique HSAB. Ce critère peut être appliqué dans le cas ou la coordination n'est pas fortement dépendante du pH et quand le ligand approprié est considéré. La dérivation directe des conclusions donne le moyen par lequel on peut faire des prédictions pour la préférence de positions d'attaque dans le cas où les données expérimentales sont absentes ou insuffisantes pour soutenir des conclusions solides.

Introduction

Heterocyclic keto and thioketo compounds have attracted much interest in the past and have been the subject of numerous investigations covering practically every area of applied spectroscopy. Such compounds possess active sites closely resembling those of uracil, lumazine, and the flavins, this similarity challenging experimentalists to investigate their spectroscopic and redox properties in detail (1). These studies have been mainly based on the perspective of studying reactions of biological interest on small model compounds. Five-membered heterocyclic thiones form a subseries of the above-mentioned series of compounds. The combination of a thioketo group and an heteroatom, mainly N, O, or S, in the α-position results in considerable coordination ability. Thus, pentatomic heterocyclic thione coordination chemistry has been extensively studied and the main investigations of this field have appeared recently in an interesting review article (2).

In the present study we investigate the degree of electron delocalization from the thioketo group toward the α-heteroatoms in pentatomic thiones in which one α-atom is nitrogen and the other is nitrogen, oxygen, or sulfur. The effect of the hetero-atom occupying the 1-position and the influence of the C—C bond in the ring have been investigated. Both saturated and unsaturated systems have been considered, the series of compounds studied being completed by the benzo-analogues. The three classes under study are presented in Fig. 1.

Computational details

In the solid state the thione form of the compounds studied is the dominant one as has been experimentally verified. However, the tendency of π- and total electron population to diffuse toward the α-heteroatoms should be evident even if we base our considerations on the uncoordinated ligand geometry. Thus we use as sources of geometry data the references presenting X-ray results for a number of the studied compounds (3–6). The phenyl rings in the benzo-derivatives, while slightly distorted, were assumed to be strictly planar, while the C—C

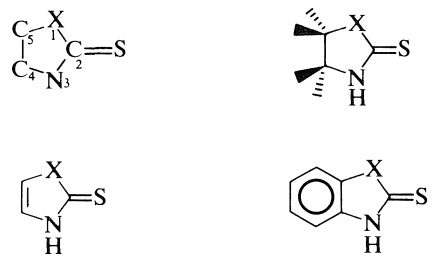

FIG. 1. The five-membered ring numbering and the three types of thione ligands considered within each class, possessing a single (*a*), double (*b*), or aromatic (*c*) C_4—C_5 bond. X stands for NH (class 1), S (class 2), or O (class 3).

bond distances in the pentatomic ring were modified when necessary in order to account for a single, double, or aromatic bond according to the molecule considered. We did not attempt to alter simultaneously the C=S bond length. In the case of saturated carbon atoms, a strict tetrahedral environment was assumed around them, the C—H bond distance set equal to 1.05 Å. In each case the pentatomic ring is placed in the *xy* plane while the C=S bond is along the *x* axis. The calculations were carried out by the semi-empirical INDO approximation (7), using the GEOMO program (8) with the appropriate corrections already proposed (9). A similar series of calculations have also been performed using the CNDO/2 option of the program. These results did not deviate significantly from the INDO ones as far as the MO's symmetry, ordering and atomic participation is considered, though changes up to 10% resulted in the corresponding energy eigenvalues. Thus the results presented and discussed herein emerged from INDO type calculations.

Discussion

Experimentation of varying degree has been carried out on the ligands considered, the most general conclusion drawn being the proposed bonding scheme toward metal centres and its verification by spectroscopic and in a few cases by X-ray

diffraction results. We therefore focus our interest on the determination of the site bonding effects that are important in the formation of the coordination compounds. The energy and constitution of a set of frontier molecular orbitals and a few reactivity indices derived from the Fock–Dirac density matrix are used to describe the donor–acceptor properties of the ligands considered. A common computational feature of the three classes of heterocyclic thiones examined must be noted here, since in all our calculations $3d$ functions for sulfur atoms are present in the basis set. This allows the importance of electron promotion from sulfur $3s$ and $3p$ orbitals toward $3d$ orbitals to be probed. The phenomenon is most clearly shown in the case of heterocyclic sulfur containing ligands (class 2), on the sulfur heteroatom. In this case the d-functions "are forced" to take part in the linear combination of atomic functions that produce the best-fit hybrid orbitals which overlap with the neighbouring atomic centres hybrids.

Since no geometry optimization has been carried out in those cases where structural data were not available, one does not hope to detect any significant change on going from the saturated through the unsaturated to the aromatic analogue in each class of thiones. Minor changes on level ordering and detectable energy differences do of course occur, and these are discussed presently for each group of compounds. One point of attention is that the conclusions drawn can not, without consideration, be valid in the case where the ligands form coordination compounds in strongly acidic or alkaline media or in the presence of strong reducing or oxidizing agents. It is obvious that since the protonated or deprotonated forms of the α-imidothiones have not been dealt with we are only discussing those cases where the complexes have been formed in neutral pH or non-polar solvents.

Within the above-mentioned limitations, both S- and N- or even simultaneous S- and N-donation have been detected toward metal ion coordination spheres. Our purpose is to deal with these bonding schemes by means of an HSAB (Hard and Soft Acids and Bases) treatment (10), considering the relative "softness" of the thione molecules as expressed by their frontier molecular orbital energies. Though it is not easy to draw a borderline between hard and soft metal ions, especially when other ligands occupying different sites in the coordination sphere perturb the initial "hard" or "soft" metal ion character, it is apparent that the lower the HOMO energy of the thione ligand, the more easily hard metals will react toward the α-nitrogen atom. In a similar way, as the ligand HOMO energy increases more metals will prefer to predominantly attack the sulfur site. According to the existing literature (2), no N-coordination has yet been reported for the soft metals of the third transition series, while S-donation has been established by X-ray data for the hard cations belonging to the first row. Intermediate bonding involving both S- and N-sites simultaneously is expected for the second transition series, the former playing the dominant role.

Class 1. Nitrogen-containing thiones

These belong to the most widely studied class of those discussed. Complexes with the most usual coordination numbers (4 and 6) have been reported (2) with practically every transition metal.

The HOMO eigenvalues of the three members of the series range from −0.3161 au for imidazoline-2-thione to −0.3477 au for imidazolidine-2-thione (au = Hartree). These values are high enough so as to classify the three ligands as soft donors. So far only sporadic cases are reported where N-donation

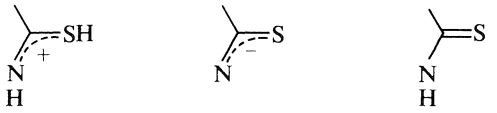

FIG. 2. The protonated (*a*), deprotonated (*b*), and neutral (*c*) forms of the thiones, occurring in acidic, alkaline, and neutral solutions respectively.

accompanies the well-established sulfur coordination and this only for **1***a*, which possesses the lowest HOMO eigenvalue. Crystal structure determinations and X-ray PES data confirm the above statement (11, 12). For the other two members there exists practically no evidence for N-participation in the metal coordination sphere. Besides the HOMO constitution presented in Table 1, which implies that S-donation is favoured, the virtual orbitals available for π-back bonding practically rule out every other possible coordination scheme as they are local to the C═S bond. The LUMO is not the appropriate MO for back donation as it is mainly localized on the carbon double bond or the aromatic ring when present, while for imidazolidine-2-thione it is distributed all over the five-membered ring. We have therefore to look further up (see Table 1) toward the next LUMOs for the appropriate MOs to take part in the π-back donation from the metal.

Class 2. Nitrogen- and sulfur-containing thiones

The degree of the exocyclic sulfur atom participation in the HOMOs of this group is significant though not as important as that occurring in class 1 members. Considerable contribution from the heterocyclic sulfur atom is present in both frontier MOs but this is partly due to the incorporation of d-orbitals in the basis set, that has been already discussed.

The computed HOMO eigenvalues range from −0.3373 au to −0.3634 au, the lower one corresponding to the saturated member (**2***a*) in analogy to the observation in class 1. The relative low HOMO eigenvalues imply that these compounds approach or even cross the borderline between soft and hard thiones and they are therefore expected to express a slight preference for N-participation in the coordination scheme they adopt. Naturally for thiazolidine-2-thione numerous cases are mentioned where coordination occurs mainly through nitrogen, though initial sulfur "attack" has been proposed in many cases. Sulfur donation has been confirmed in the crystal structure of $PdCl_2$(1,3-thiazolidine-2-thione)$_2$ (13), in accordance with the HSAB rule and our proposition is that, though certainly "harder" than the other members of this class, the saturated one must not be classified as "definitely" hard.

A few examples of coordination through nitrogen for **2***b* and **2***c* that are softer than the above-mentioned saturated ligand, should not be regarded as exceptions to the HSAB rule but have to be understood as the result of hydrogen migration from the nitrogen atom to the thione sulfur. Such a transfer has been assumed to take place either prior to or even after the initial coordination (14). Computational work has already been performed on analogous systems, namely the cyclic form of the CHS_2N_3 acid where the thiol-structure has been found to be more stable than its thione tautomer (15), but only by 2.4 kcal/mol, implying that both forms co-exist in solution.

Thiazoline-2-thione closely resembles its class 1 analogue since it is found to act as a sulfur-donating ligand in most of the few complexes reported. On the basis of our results we must express some scepticism about the proposition (16) that nitrogen coordination occurs in a complex with the formula $CdCl_2$(1,3-thiazoline-2-thione)$_2$. We tend to believe that in this case a four-membered ring is more likely to be formed involving

simultaneous sulfur and nitrogen coordination, but the available experimental data are not sufficient for a further discussion.

As for benzothiazoline-2-thione, the corresponding anion has received much more attention than the neutral ligand. The pK_a value of the compound and the less pronounced contribution of thione sulfur to the frontier MOs with respect to the other members of the class, leads us to suggest that hydrogen migration to the thione sulfur is facilitated, giving rise to the thiol-form. The experimentally confirmed observation that even in neutral media nitrogen coordination occurs (17) must therefore be understood on the basis of the above arguments.

Class 3. Nitrogen- and oxygen-containing thiones

The degree of thione sulfur participation in the HOMOs of this class is intermediate between the previous two groups (Table 2). The saturated compound is again predicted to be the

hardest of the class, while every specific member is harder than its class 1 and 2 analogues.

As for **3***c*, with a pK_a value of 6.58 it is easily converted to the corresponding anion and acts therefore as a nitrogen donor even in neutral media. Thus no firm conclusion can be drawn on its bonding ability as a neutral ligand. However, on the basis of its HOMO eigenvalue one could assume that N-coordination will predominantly occur when the ligand is present in complexes in its neutral form.

Oxazolidine-2-thione is predicted to be the hardest of all the studied ligands, and is for this reason, expected to coordinate via the imido-nitrogen. Unfortunately the conclusions drawn from the few studies of its coordination compounds are not so firm as to establish either sulfur or nitrogen or intermediate mode of bonding (18).

Lack of experimental data on oxazoline-2-thione allows us to make predictions only and hope to see them tested by experimentalists. On the grounds of the INDO calculations performed and on the arguments presented at the beginning of the discussion, we may assume that this ligand will act in a way quite similar to its benzo-analogue. It is thus expected to be readily converted to its anionic form in solution, giving rise to a through-nitrogen bonding scheme. Even as a neutral ligand, hydrogen migration must be favourable enough to lead to the tautomer form which would provide both nitrogen and sulfur sites for metal chelation. Our prediction therefore is that regarding first row transition elements, both sulfur- and nitrogen-donating must be expected, while sulfur coordination must be the dominant bonding scheme with soft metals such as Pd, Pt, Au, Hg etc.

Reactivity indices

Several sets of indices derived from the density matrix have been proposed in the literature (19–21) to act as reactivity representatives when using semi-empirical methods of calculation, such as

$$B_{AA}^{tot} = \Sigma P_{\mu\nu}^2 \qquad |\ \mu, \nu \text{ on A}$$

$$L_A = \sum\sum P_{\mu\nu}^2 - \sum_{l=0}\left(\sum_{\mu=l^2+1}^{\nu=(l+1)^2} P_{\mu\mu}\right)^2 \frac{1}{2l+1} \qquad |\ \mu, \nu \text{ on A}$$

$$S_E(A) = 2\sum_{j=1}^{occ}\sum_{m=1}^{N_A}\frac{(C_{mj}^A)^2}{\epsilon_j} \qquad |\ N_A \text{ number of AOs on A}$$

Here the symbols have their usual meaning, μ,ν running over all AOs and i,j over all occupied (for S_E) or virtual MOs (for S_N). Though such static indices are not universally accepted, we tried during this study to use their values for predictive purposes in comparison with directly derived quantities (HOMO eigenvalues and atomic participation). One of them, the superdelocalizability index is probably the most interesting one proposed so far since it succeeds in relating site occupancy with energy. From this, cancelling the summation over all occupied MOs, a certain MO superdelocalizability can be defined. Our goal is to obtain in this way a quantity related to the electron donor–acceptor properties of similar sites in different molecules. The HOMO resident fraction of the original S_E (21) which we indicate as $S_{HOMO}(A)$, is computed for both imido-nitrogen and exocyclic sulfur atoms and presented in Table 2. The difference of the two values also listed in the table is quite interesting as it succeeds in relating the sulfur-preferred bonding ability of the three groups of thiones to the electron-withdrawing ability of the heteroatom (N, O, S) at the 1-position of the ring. The more electron withdrawing the heteroatom is, the more nitrogen coordination is gaining importance relative to the existing sulfur donation.

Of the other indices known, B_{AA}^{tot} has been found to vary as the total charge on each atom and is therefore not listed in our table.

The local anisotropy L_A, which represents the deviation from an ideal spherical distribution of the electrons around each centre, is also computed and presented in the table. The values of this index indicate that the heterocyclic sulfur atom in the members of class 2 competes strongly with the thione sulfur in coordinating the metal. We believe therefore, that, in such a case, this index is misleading so that it has to be eventually replaced by a more appropriate one, like the free valence (22) or the net electron population of each atom.

Light-promoted catalysis of nickel hydride complexes in the isomerization and hydrogenation of *cis,cis*-1,5-cyclooctadiene: mechanistic studies

YUAN L. CHOW[1] AND HUALI LI[2]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received May 30, 1986

YUAN L. CHOW and HUALI LI. Can. J. Chem. **64**, 2229 (1986).

Xanthone-sensitized photoreduction of $Ni(acac)_2$ in benzene under hydrogen, in the presence of *cis,cis*-1,5-cyclooctadiene (1,5-COD), causes isomerization and hydrogenation of the diene according to the consecutive transformation 1,5-COD → 1,4-COD → 1,3-COD → cyclooctene → cyclooctane. Evidence was provided that (*i*) a nickel hydride complex was generated, (*ii*) the sensitized excitation of this complex caused addition to the double bond, (*iii*) subsequent elimination caused isomerization, and (*iv*) triplet excited xanthone sensitized the transformations.

YUAN L. CHOW et HUALI LI. Can. J. Chem. **64**, 2229 (1986).

La photoréduction du $Ni(acac)_2$, sensibilisée par la xanthone du $Ni(acac)_2$ et effectuée dans le benzène, sous un atmosphère d'hydrogène et en présence de cyclooctadiène-1-*cis*,5-*cis* (COD-1,5), conduit à une isomérisation et une hydrogénation du diène impliquant la série de transformations suivantes : COD-1,5 → COD-1,4 → COD-1,3 → cyclooctène → cyclooctane. On a obtenu des indications à l'effet que (*i*) il y a génération d'un complexe d'hydrure de nickel; (*ii*) l'excitation sensibilisée de ce complexe est la cause de l'addition à la double liaison; (*iii*) l'élimination subséquente est la cause de l'isomérisation et (*iv*) la xanthone excitée au niveau triplet sensibilise les transformations.

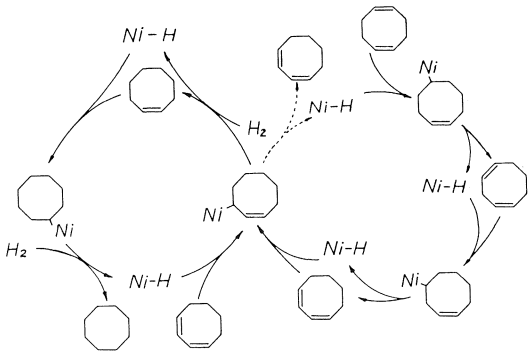
[Traduit par la revue]

Nickel hydride complexes are good homogeneous catalysts (1–5) for isomerization (6–8), oligomerization (9–11), and hydrogenation (12, 13) of olefins under moderate pressures and temperatures. The mechanism of isomerization and hydrogenation by these and other (14–17) transition metal complexes has been generally interpreted in terms of reversible addition of a metal hydride to coordinated olefins. Examples of light-promoted hydrogenation of olefins catalysed by other metal complexes are known (2, 4, 5). We wish to report (*i*) the generation of the transient Ni(I) complex by aromatic ketone sensitized photoreduction of bis(acetylacetonato)nickel(II), $Ni(acac)_2$, using hydrogen as a H-atom donor, (*ii*) the interaction of hydrogen with the transient complex to form a nickel hydride complex in the dark, and (*iii*) *in situ* utilization of the Ni—H complex in light-promoted catalytic isomerization and hydrogenation of *cis,cis*-1,5-cyclooctadiene (1,5-COD). The whole reaction is carried out at room temperature and atmospheric pressure in one operation. While this system is not necessarily the most efficient reaction it is an ideal one for mechanistic studies. The details of the pathway are summarized in Scheme 1, where Ni—H represents a hydride complex of an unknown structure. The pertinent evidence in support of the mechanistic proposal is discussed below.

Xanthone-sensitized photoreduction of $Ni(acac)_2$ has been demonstrated to generate coordinatively unsaturated Ni(acac) and acetylacetonyl radicals (18). The latter is trapped by H-atom donors (e.g., methanol used as solvent) to give acetylacetone.[3]

$$Ni(acac)_2 + H_2 \xrightarrow[C_6H_6]{h\nu,\ \text{xanthone}} Ni(acac)L_x + acacH$$

$$\xrightarrow{H_2} \text{H—Ni complexes} \quad L = 1,5\text{-COD, THF}$$



SCHEME 1

It is now shown that the same photoreduction occurs in benzene (or THF) under hydrogen which acts as a H-atom donor (Scheme 1). In THF, in the presence of 1,5-COD under nitrogen, the esr signal (6, 18) of $Ni(acac)L_x$ (*g*-value 2.183, ΔH_{pp} 25 G) was generated in a brief irradiation and decayed in the dark with double exponential decays of a fast second order reaction, $k_2 = (1.07 \pm 0.15) \times 10^{-2}$ unit^{-1} s^{-1}, followed by a slow first order reaction, $k_1 = (1.32 \pm 0.09) \times 10^{-2}$ s^{-1}. Similar esr signals generated *under hydrogen* also decayed with double exponential decays, but the slow pseudo-first order rate constant (k_1) decreased as hydrogen concentrations were reduced (Fig. 1): the fast second order rate constants, $k_2 = (1.10 \pm 0.13) \times 10^{-2}$ unit^{-1} s^{-1}, were very similar to those obtained under nitrogen. The kinetic pattern in Fig. 1 shows that the Ni(I) complex, assumed to be $Ni(acac)(THF)_x$, does react with hydrogen. The yellow photolysate under these conditions exhibited a singlet in the ^{1}H nmr spectrum at −15.7 ppm,

[3]Appropriate solution placed in a Quartz tube was saturated with hydrogen or nitrogen and sealed. The tube was irradiated in the cavity of a Varian E-4 spectrometer with >314 nm light. The conditions of esr spectroscopy and irradiation are described (19). At intervals the light passage was blocked and the decay was followed at the peak of the Ni(I) signal (18). As the net irradiation time accumulated, hydrogen was consumed to give lower concentration.

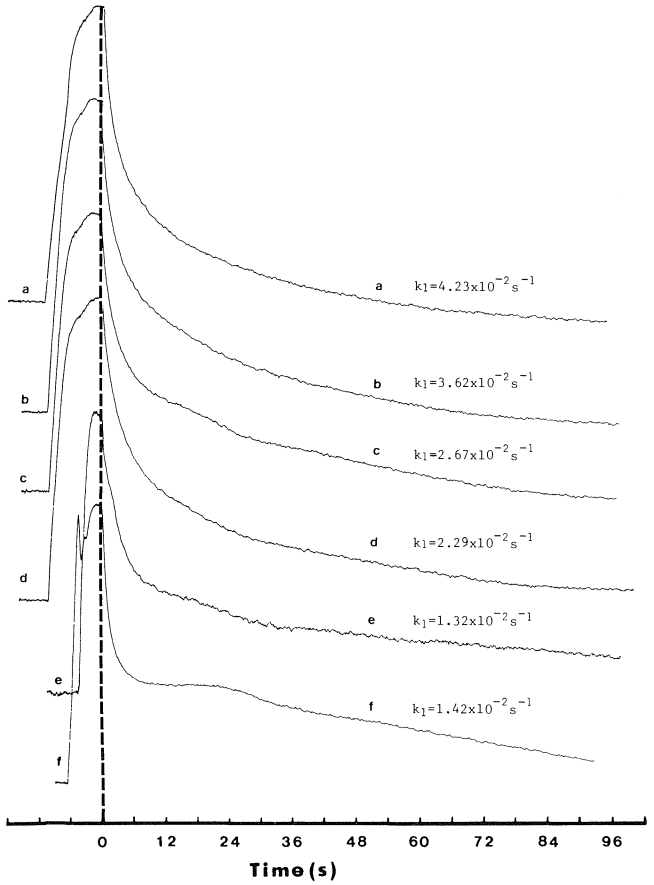

FIG. 1. Decay profiles of the Ni(I) complex, under hydrogen (*a–e*) and nitrogen (*f*), generated by photolysis of a sealed tube containing $Ni(acac)_2$ (1×10^{-2} *M*), xanthone (1.3×10^{-2} *M*), and 1,5-COD (6×10^{-2} *M*) in THF. Curves *a–e* were decays in the presence of hydrogen recorded after the net irradiation time of 10, 10, 10, 20, and 300 s; curve *f* was an example of decays under nitrogen (see ref. 19 for experimental conditions).

which was assigned to Ni—H (11) of the unknown complex[4] tentatively represented as a Ni—H complex which is sensitive to the air and has not been isolated.

Xanthone-sensitized photoreduction of $Ni(acac)_2$ under H_2 purging in benzene and in the presence of 1,5-COD caused isomerization of the diene to 1,4-COD and 1,3-COD, and hydrogenation to cyclooctene (COE) and cyclooctane (COA). These transformations are presumably catalyzed by nickel hydride complex. Since the composition of the products ceases to change in the dark (Fig. 2),[5] light energy is required for photoexcitation of xanthone which, in turn, induces the transformations (*vide infra*). Addition of xanthone to the olefins also occurs slowly to give the corresponding oxetanes as an

[4]The structures of η^1,η^2-cyclooctenyl(β-diketonato)nickel(II) complexes are well established and, together with H—Ni(acac), have been suggested as the intermediates in olefin oligomerization (9–11). We are not able to establish these species as intermediates in the present experiments.

[5]In a typical experiment, a benzene solution (50 mL) containing $Ni(ACAC)_2$ (5×10^{-3} *M*), xanthone (1×10^{-2}), and 1,5-COD (1×10^{-7} *M*) was irradiated through a Pyrex filter under a slow stream of hydrogen (1 bubble per second) with a Hanovia Medium Pressure mercury lamp (200 W). At intervals a sample of the photolysate was worked up and the organic products were analyzed by gc. When a Pyrex filter was replced by a GWV filter (cut off <380 nm) the variation of product yields also ceased.

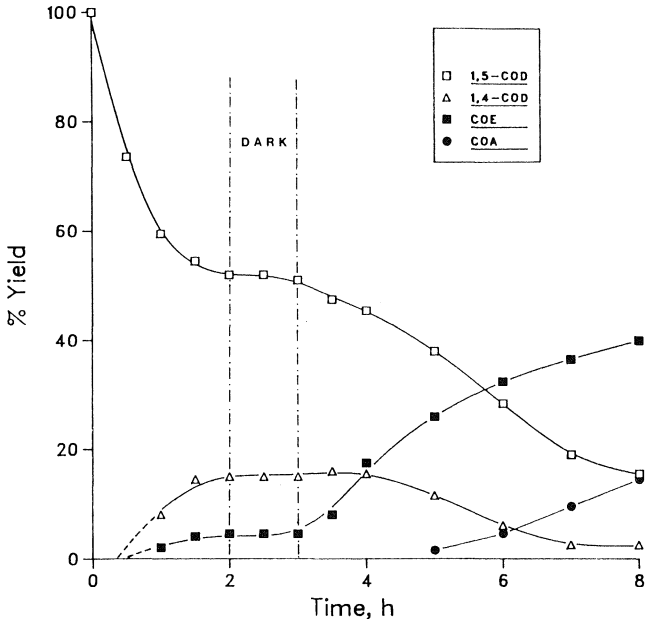

FIG. 2. The variation of C-8 hydrocarbon yields in irradiation at room temperature of a benzene solution containing $Ni(acac)_2$ (5.6×10^{-3} *M*), xanthone (8.3×10^{-3} *M*), and 1,5-COD (4.4×10^{-2} *M*) through a Pyrex filter under hydrogen purging; irradiation was interrupted in the 1.5–3 h period.

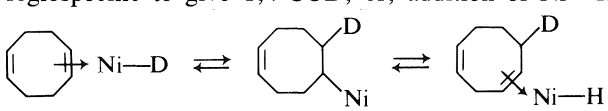
undesirable side reaction. The details of the photoprocesses remain to be investigated further.

The profiles of the product variations (Fig. 2) obviously indicate the sequential formation of 1,5-COD → 1,4-COD → COE → COA, on the basis of the consecutive appearance of the products as photolysis proceeds. That 1,3-COD was a part of the reaction sequence was demonstrated by subjecting 1,4-COD to similar reactions conditions to generate 1,3-COD in 3.1% in 15 min and <1% yields thereafter. The rapid hydrogenation of 1,3-COD → COE was also demonstrated by the addition of *a small amount* of 1,3-COD (2 m*M*) to a pre-photolyzed mixture of 1,5-COD, whereby, on continued irradiation, 1,3-COD quickly diminished to insignificant percentages and COE increased equally rapidly. Both observations indicate that the interaction of 1,3-COD with the Ni—H complex and the subsequent hydrogenation were much faster than other comparable processes. However, 1,3-COD added in a large concentration (≈10 m*M*) efficiently quenched triplet excited xanthone by energy transfer and was isomerized to *cis,trans*-1,3-COD (22); the changes in the yields of other products also stopped concurrently. This observation shows that triplet excited xanthone sensitizes the nickel–hydride complex causing addition to the double bonds of the olefins (*vide supra*).

Light-promoted transformations of 1,5-COD under D_2 gave partially deuterated products as determined by gc–ms: 1,5-COD-d_0, 100%; 1,4-COD-d_0, 43.5%; $-d_1$, 56.5%; COE-d_0, <2%; $-d_1$, 10%; $-d_2$, 45%; $-d_3$, 28%; $-d_4$, 14%; d_5, <1%; COA-d_2, <2%; $-d_3$, 23%; $-d_4$, 45%; $-d_5$, 30%; $-d_6$, 0%. The high deuterium incorporation in the products further along in the reaction sequence suggests that the isomerization pathway is addition–elimination. The recovery of undeuterated 1,5-COD indicates that either the elimination step is regiospecific to give 1,4-COD, or, addition of Ni—H to



1,5-COD and the subsequent reverse elimination to give 1,5-COD are both stereospecific. In the reaction, acetylacetone-d_1 (100% purity) was also identified, thereby unambiguously showing that hydrogen is the H-atom donor to the acetylacetonyl radical.

A highly convergent and enantiospecific synthesis of acyclic subunits of ionomycin from a single chiral progenitor

STEPHEN HANESSIAN AND P. J. MURRAY

Department of Chemistry, Université de Montréal, Montréal, P.Q., Canada H3C 3J7

Received June 12, 1986

STEPHEN HANESSIAN and P. J. MURRAY. Can. J. Chem. **64**, 2231 (1986).

The C_2–C_{10} and C_{11}–C_{22} subunits of ionomycin were synthesized from a chiron derived from L-glutamic acid or D-ribonolactone. A strategy is presented in which *C*-methyl and hydroxyl groups are introduced on appropriate carbon frameworks in a completely predictable fashion based on the replicating lactone method, thus chemically matching any substitution pattern arising from the propionate biosynthetic pathway.

STEPHEN HANESSIAN et P. J. MURRAY. Can. J. Chem. **64**, 2231 (1986).

Les sous-unités C_2–C_{10} et C_{11}–C_{22} de l'ionomycine ont été synthetisées à partir d'un chiron qui provient de l'acide L-glutamique ou de la D-ribonolactone. Une stratégie est présentée dans laquelle des groupements *C*-méthyle et hydroxyle sont introduits sur des chaînes carbonées avec un élément de prévision totale, donnant ainsi un contrôle stéréochimique sur la voie propionate.

The calcium selective ionophore antibiotic ionomycin (1) represents a rather novel structural type among this class of ion-binding natural products (for recent reviews see ref. 2). The acyclic C_1–C_{22} polyfunctional carbon chain, consisting of several alternating arrangements of *C*-methyl groups, presents a formidable challenge in design and stereocontrolled methods of assembly. Several innovative approaches that generate 1,3-relationships of *C*-methyl groups have been recently reported in connection with synthetic efforts directed at ionomycin (3). The asymmetric synthesis of the C_1–C_{10} and C_{11}–C_{16} subunits of ionomycin based on chiral enolate technology was recently reported by Evans and Dow (4), while the synthesis of the bis-furanoid segment had been disclosed earlier (5).

Although a symmetrical *C*-methyl substitution pattern is evident in the C_1–C_{22} acyclic segment of ionomycin, careful scrutiny reveals antithetic relationships in which the seemingly different left C_{17}–C_{22}, middle C_{11}–C_{16}, and right-hand C_1–C_{10} segments can be related to the inherent asymmetry of hidden chirons (6*a*).[1]

We demonstrate such an analysis in Scheme 1, and we further highlight how practically the entire acyclic subunit can be derived from a single chiral progenitor. In this paper, we report on the total synthesis of optically pure C_2–C_{10} and C_{11}–C_{22} subunits of ionomycin from a chiral butenolide that is readily available from D-ribonolactone (7, 8) or L-glutamic acid (9, 10).

The C_{11}–C_{16} subunit

Conjugate addition of lithio tris(trimethylthio) methane to the butenolide **1** (7–9)[2] gave a single crystalline adduct, mp 140–

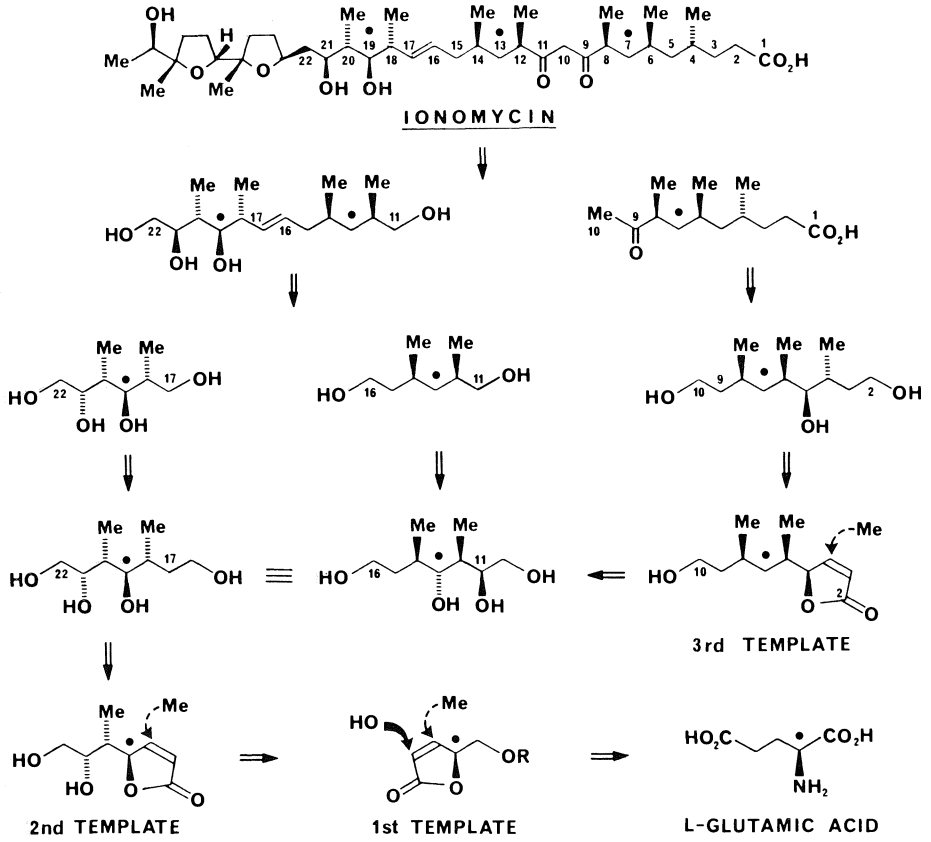

SCHEME 1

142°C, $[\alpha]_D$ 20.5° (*c* 1.1).[3] Hydroxylation of the corresponding enolate with the Vedejs reagent (10, 11) afforded only the hydroxy lactone **2**, $[\alpha]_D$ 8.1° (*c* 1.3), by virtue of the bulk of the vicinal substituent. Desulfurization led to the *C*-methyl derivative **3**, $[\alpha]_D$ 12.5 (*c* 2.2), which was reduced and protected as the acetonide derivative, **4**, $[\alpha]_D$, −0.3° (*c* 3.3). This polyol was then subjected to a two-carbon homologation and lactone replication process (10, 12) to give **6**. Oxidative elimination led to the crystalline butenolide **7**, mp 78–79°C, $[\alpha]_D$ 91.3° (*c* 6.3). Conjugate addition of lithium dimethylcuprate proceeded with anticipated stereocontrol to give the lactone **8**, $[\alpha]_D$ −32° (*c* 2.1). The template effect of the original and replicated butanolide had thus been fully exploited, and the required complement of functional groups was introduced with complete regio- and stereocontrol.

Reduction of **8**, followed by selective silylation, gave **9**, $[\alpha]_D$ 5.5° (*c* 1.9), which was deoxygenated to **10**, $[\alpha]_D$ 21.6° (*c* 2.1). Further manipulation and cleavage of the vicinal diol unit gave **11**, $[\alpha]_D$ 1.9° (*c* 1.8), which was finally transformed into the sulfone derivative **12**, $[\alpha]_D$ 6.7° (*c* 3.7). Compound **10** serves as a precursor not only to the C_{11}–C_{16} subunit, but it is utilized as a starting material for the C_2–C_{10} subunit as well, since C_5–C_{10} is functionally and configurationally identical to C_{11}–C_{16}.

The C_2–C_{10} subunit

The seven-carbon chiron **10** was homologated via the epoxide **13**, to give the replicated butenolide **14** (Scheme 3). With the side chain properly oriented vis-à-vis the enone system, it was possible to effect conjugate addition of lithium dimethyl cuprate with complete stereocontrol giving lactone **15**, $[\alpha]_D$ −8.4° (*c* 0.5). Reduction and deoxygenation at the secondary hydroxyl position gave the selectively protected trisubstituted diol **17**, which corresponds to the C_2–C_{10} subunit of the intended target after adjustment of the oxidation state at C_9.

The C_{11}–C_{22} subunit

The common intermediate **8** (Scheme 1), in which all the required substituents for the C_{17}–C_{22} segment are in place, was hydroxylated to give **9** as an epimeric mixture of lactones (Scheme 4). A one-carbon excision was now possible, via cleavage of the diol **19**. Selective protection and oxidation then provides the aldehyde **20**.

With the required optically pure chirons **12** and **20** in hand, we next addressed their coupling. Thus, reaction of the anion resulting from the sulfone **12** with aldehyde **20**, followed by acetylation and reductive elimination (13), gave **21** as a 9:1 mixture of *E*/*Z* olefins. There now remained the problem of adjusting the configuration at the carbon atom that corresponds to C_{21} in the target. This was accomplished by an inversion via epoxide formation to give the advanced C_{11}–C_{22} intermediate **22**, $[\alpha]_D$ −9.4° (*c* 0.51).

The five-carbon framework of the original L-glutamic acid or D-ribonolactone can be found hidden in the C_4–C_8, C_{10}–C_{14}, and C_{18}–C_{22} segments of ionomycin. Furthermore, the single asymmetric center present in L-glutamic acid (Scheme 1, black dot) dictates the stereochemical events that led to the elaboration of all other asymmetric centers in the acyclic subunits of ionomycin.[4]

[3]Optical rotations were measured in chloroform at room temperature.

[4]Efficient and expeditious access to advanced intermediates needed for the synthesis of the three fragments is now possible, based on our lactone enolate and replication methodology (ref. 10).[5] The overall yields are high, and the number of steps can be effectively halved compared to the conjugate addition–replication technology.

SCHEME 4

Our strategy for the regio- and stereocontrolled sequential functionalization of butenolide-type templates (9, 12, 14), coupled with the possibility of reiterating the process through replication (10, 12), offers a powerful and predictable tool for the total synthesis of a variety of other natural products. In effect, any stereochemical combination generated by nature via its obiquitous propionate biosynthetic pathway can now be directly addressed and chemically reproduced using the methodology described herein and variants thereof.[5]

A high temperature, pressure study of the comparative rates of enolization and oxidation of acetone in aqueous solution

JOHN W. THOMAS[1] AND JAY E. TAYLOR[2]
Department of Chemistry, Kent State University, Kent, OH 44242, U.S.A.

Received June 11, 1986

JOHN W. THOMAS and JAY E. TAYLOR. Can. J. Chem. **64**, 2235 (1986).

The rate of enolization and acetone has been determined as 6.6×10^{-4} s^{-1} at 193.5°C under nitrogen at 136 atm total pressure via isotopic exchange. The rate of oxidation was determined to be 8.8×10^{-6} s^{-1} at 193.5°C in 123 atm partial pressure of oxygen (136 atm total pressure). In a previous study it was shown that the rates of oxidation of several ketones correlated with the extents of enolization at room temperature. This prompted the suggestion that the enol is an intermediate in the oxidation. Since the rate of enolization exceeded the rate of oxidation by a factor of 75, this suggestion is further supported. A dependence of the rate of oxidation of acetone on oxygen concentration was also demonstrated.

JOHN W. THOMAS et JAY E. TAYLOR. Can. J. Chem. **64**, 2235 (1986).

Opérant à 193,5°C et sous une pression totale de 136 atm d'azote et se basant sur l'échange isotopique, on a déterminé que la vitesse d'énolisation de l'acétone est égale à $6{,}6 \times 10^{-4}$ s^{-1}. A 193,5°C et sous une pression partielle d'oxygène de 123 atm (pression totale de 136 atm), on a déterminé que la vitesse d'oxydation est égale à $8{,}8 \times 10^{-6}$ s^{-1}. Dans une étude antérieure, il a été démontré qu'il existe une corrélation entre les vitesse d'oxydation et les taux d'énolisation de plusieurs cétones. Cette observation suggère que l'énol est un intermédiare dans l'oxydation. Puisque la vitesse d'oxydation de l'acétone est 75 fois plus grande que la vitesse d'oxydation, on peut en déduire que cette hypothèse est supportée. On a aussi démontré qu'il existe une corrélation entre la vitesse d'oxydation de l'acétone et la concentration d'oxygène.

[Traduit par la revue]

Introduction

In an introductory study of the aqueous reactions of oxygen with a variety of organic compounds pressurized at high temperatures, it was suggested that the enol may be an intermediate in the oxidation of simple ketones (1). This conclusion was based on the observed correlation between the rates of oxidation of several ketones and their projected extents of enolization.

The purpose of this paper is to determine the validity of this hypothesis for acetone by determining the relative rates of oxidation and enolization at an elevated temperature. Thus, if the rate of oxidation exceeds the rate of enolization, the above proposal is obviously invalid but, if the reverse is true, then it remains acceptable.

Experimental

This investigation was done in an apparatus similar in principle to that previously described (1), but with a number of alterations to improve accuracy and reliability of the data. In particular there were changes in the stirring and temperature control systems and related equipment.

A vapor pressure bath greatly increased the accuracy of temperature control over the previously used air bath (1) (see Fig. 1). Bath G contained a refluxing liquid whose temperature was controlled by a mercury manostat with an adjustable mercury contact. This in turn activated a relay and air inlet valve (not shown). Thus, a selected temperature could be maintained at ±0.05°C. Refluxing liquids which were found to be stable and convenient to use were ethanediol, 193–197°C; 1-heptanol, 171–175°C; 2-heptanone, 142–147°C; and 1-butanol 115–118°C.

To initiate a reaction the ketone was sealed under vacuum at ~ −80°C in a 10 mm glass sphere, designed to implode at 136 atm or lower, and placed in reactor E along with a stirring bar and solvent water. E was pressurized to 17 atm, and then sealed inside bath G which was then warmed to the desired temperature with the internal pressure at 17 atm (250 psi). About one hour was required. The pressure was then increased to 136 atm (2000 psi) using O_2 or N_2, effecting rupture of the bulb and instantaneous initiation of isotope exchange or oxidation. Stirring was immediately started via the magnet I. Samples were removed at appropriate times by opening valve P, permitting the liquid to enter PQ. P was then closed and Q opened, releasing the sample for analysis. The major disadvantage of this technique was the low success rate (25–30%) in fabricating bulbs which would reliably perform as indicated. Also the fine particles of glass sometimes clogged the outlet tube.

The change in molarity of the oxidizing substrate was followed using a gas chromatograph. The relative standard deviation was ±2% with an external standard. Oxygen pressure was determined by subtracting the vapor pressure of water from the total pressure.

The determination of the rate of isotope exchange was done under a nitrogen atmosphere (136 atm) at 193.5°C and was followed by gas chromatograph – mass spectrometric analyses of the samples collected. The rates of enolization were evaluated by determining the rate of isotopic substitution of ^1_1H for ^2_1D in aqueous solutions of acetone-D_6. The data were corrected for the natural abundances of interfering C and O isotopes and for those fragmentation patterns observed in the spectral analysis of neat acetone $(M - D \text{ or } H)^+$ and $(M - 3D \text{ or } 3H)^+$ which would contribute ions in the mass range of 58–64. Thus the substitution of a proton for a deuteron was directly followed. The reverse reaction was neglected because of the excess of water. Since the plots of $\ln (M_{64}/M_{58-64})$ versus time were linear, the reactions were first order, and the slopes were equal to the rate constants.

Data and discussion

The enolization of acetone-D_6, as determined by the isotope exchange procedure, was shown to be first order. The data from three exchange runs are plotted in Fig. 2. The calculated values of the rate constants are 2.24×10^{-4}, 2.06×10^{-4}, 2.30×10^{-4} with a mean value of $2.2 \pm 0.1 \times 10^{-4}$ at 193.5°C and 136 atm pressure.

In order to relate the enolization of acetone-D_6 to that of acetone-H_6, it was necessary to estimate the kinetic isotope effect, KIE (i.e., k_H/k_D) since this has not been determined at

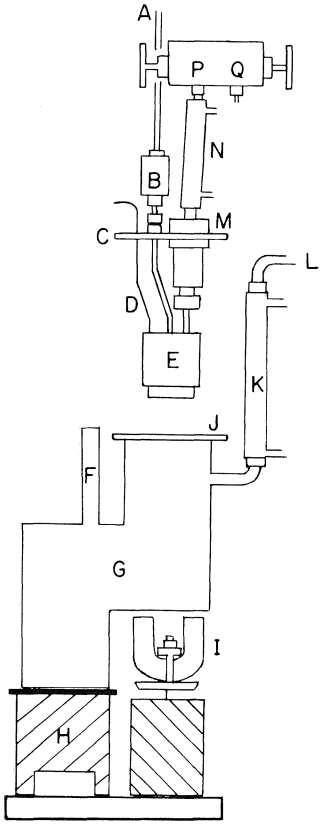

FIG. 1. Revised high pressure oxidation apparatus. A, oxygen inlet which leads to a shut-off valve, high pressure filter, pressure gauge, and oxygen tank with pressure regulator, not all shown; B, rupture disk; C—M copper plate to form a gas-tight seal on J; D, thermocouple lead; E, heavy steel reactor containing a Teflon liner and lid, magnetic stirring bar, glass bulb containing the ketone, sampling tube and thermocouple inside the reactor wall (the lower section of E was fabricated of nonmagnetic stainless steel); F, thermoregulator well; G, copper vapor pressure bath; H, heater; I, large rotating magnet; J, flange to accommodate the plate C—M; K, condenser; L, tube leading to the pressure control system, not shown; M, bulkhead union for sampling tube; N, cooling tube for samples taken from E; P, double valve for sampling; Q, sample outlet.

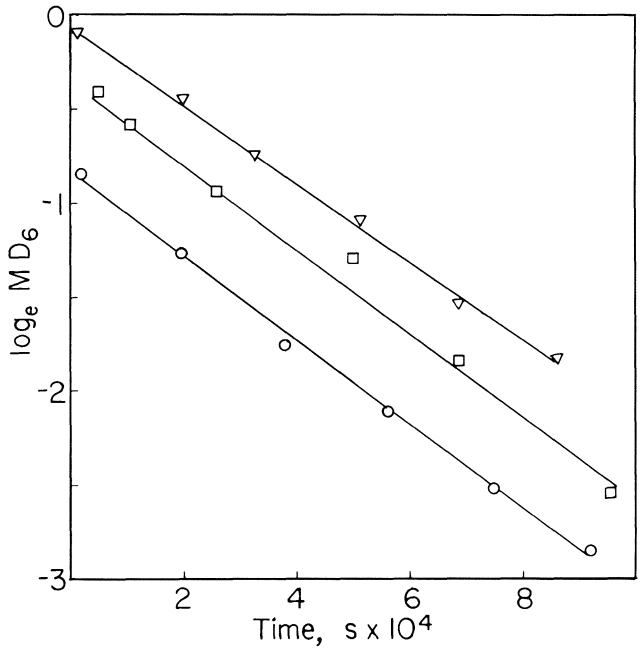

FIG. 2. Graphs of the first order of deuterium exchange of acetone-D_6 with water. M_{D_6} represents the effective molarity of acetone-D_6 remaining at the specified time. M_{D_6} was calculated from the initial molarity of acetone-D_6 multiplied by the relative ion abundance (M_{64}/M_{58-64} corrected as indicated).

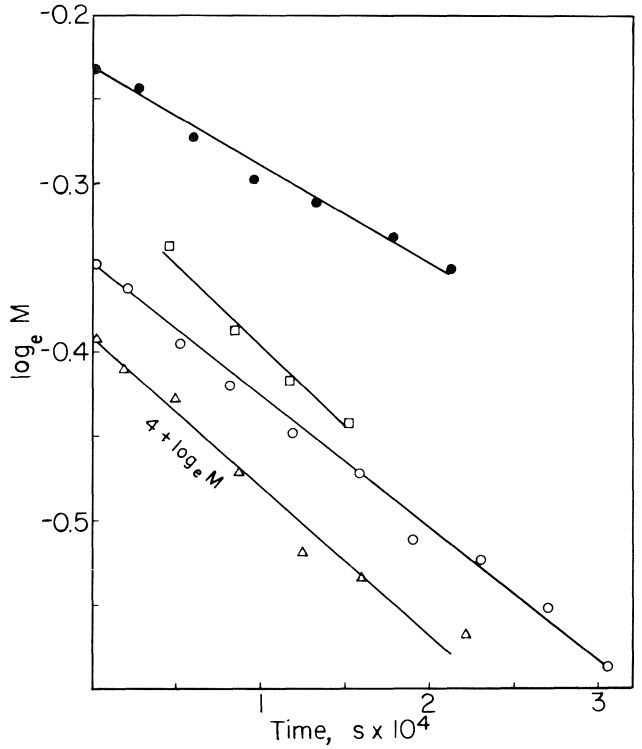

FIG. 3. The oxidation of acetone at 193.5°C and 123 and 56.4 atm partial pressure of oxygen. A plot of ln (acetone concentration) versus time. ●, ■, and ○ 123 atm oxygen partial pressure; △ 56.4 atm oxygen partial pressure.

elevated temperatures. Hine, Kaufman, and Cholod (2) have reported a KIE of 6.5 at 25°C, and this is deemed to follow the equation:

[1] $\text{KIE} = \exp(\Delta E_0/RT)$

Using E_0 = 1100 cal, the value of KIE (193°C) should be roughly 3.0. Thus the enolization rate for acetone-H_6 was estimated as $6.6 \times 10^{-4}\,s^{-1}$.

Three determinations of the rate of oxidation of acetone were performed at 193.5°C/123 atm O_2 and one at 193.5°C/56.4 atm O_2 (136 and 68 atm total pressure). These data are graphed in Fig. 3, and the calculated values for the rate constants at 123 atm (partial pressure O_2) are $8.0 \pm 0.25 \times 10^{-6}$, $9.5 \pm 0.4 \times 10^{-6}$, and $8.8 \pm 0.4 \times 10^{-6}\,s^{-1}$ giving a mean value of $8.8 \pm 0.5 \times 10^{-6}\,s^{-1}$. The value at 56.4 atm O_2 is calculated as $5.7 \pm 0.4 \times 10^{-6}\,s^{-1}$.

In keeping with the conclusion of the earlier paper (1), there appears to be a dependence of the rate of oxidation of acetone on oxygen concentration. Although the previous estimate was unity for both the ketone and oxygen kinetic dependencies (with some deviation), the present data indicate the oxidation to be first order in acetone and roughly one-half order in oxygen.

Comparison of the rates of enolization and oxidation demonstrates that enolization is much faster than oxidation by the factor $6.6 \times 10^{-4}/8.8 \times 10^{-6} = 75$. Thus it appears that the enolization of acetone is sufficiently rapid at this temperature to maintain an equilibrium enol concentration despite con-

sumption of the enol in the oxidation process. Hence the keto–enol reaction can justifiably be treated as a precursor to the final oxidation, and the previous suggestion to this effect is supported.

The equilibrium constant for the enolization of acetone was previously estimated (1) at 200, 220, and 240°C using the method of Benson (3). These calculations have been extended to 193.5°C giving a value of $K = 0.0022$. Based on this, the forward and reverse rates of enolization are $k_1 = 6.6 \times 10^{-4}\,s^{-1}$ and $k_{-1} = 0.3\,s^{-1}$ at 193.5°C.

In summary, the oxidation of acetone may be represented at this time by two equations:

[2] $CH_3COCH_3 \rightleftharpoons CH_2{=}COHCH_3$

[3] $CH_2{=}COHCH_3 + 2O_2 \rightarrow CH_3CO_2H + CO_2 + H_2O$

In keeping with reaction [3], oxygen must then interact with the enol by a series of reactions as yet undefined. Studies on the oxygenation of acetone and other ketones in the liquid phase are few in number and most have been done with neat ketones plus additives (see Denison (4) or Rouchad and Lutete (5)). Further, Zaikov *et al.* (6), have reported that 2-butanone is appreciably slower in aqueous solutions than in the pure state, and they explain this on the basis of hydration of the intermediate radicals. Rif *et al.* (7) reported that 6-undecanone was oxidized in a nonspecific manner with only partial regard for the positioning of the keto group. Since the keto group was in the center of a long chain, it is our conjecture that it may be relatively unavailable for reaction, and the reported oxidation was largely equivalent to that of a hydrocarbon.

Cation–anion combination reactions. 26.[1] A review

CALVIN D. RITCHIE
Department of Chemistry, State University of New York at Buffalo, Buffalo, NY, 14214, U.S.A.

Received July 11, 1986

CALVIN D. RITCHIE. Can. J. Chem. **64**, 2239 (1986).

Rate and equilibrium constants for reactions of carbocations, and a few other electrophiles, with anionic and neutral nucleophiles in several solvents are summarized. Equilibrium constants for such reactions are a measure of the carbon basicities of the nucleophiles, and are discussed in the context of differences in proton and carbon basicities. The factors affecting the kinetic reactivities of nucleophiles are not well understood, even though the reactivity patterns are frequently the same toward widely different electrophiles.

CALVIN D. RITCHIE. Can. J. Chem. **64**, 2239 (1986).

On présente un résumé des constantes de vitesses et d'équilibre des réactions de carbocations ainsi que de quelques autres électrophiles avec des nucléophiles anioniques et neutres, dans plusieurs solvants. Les constantes d'équilibre pour de telles réactions servent de mesure pour la basicité des nucléophiles vis-à-vis les carbones et on en discute dans le contexte de différences dans les basicités des protons et des carbones. Les facteurs affectant les réactivités cinétiques des nucléophiles ne sont pas très bien comprises, même si les réactivités, par rapport à des électrophiles forts différents, sont fréquemment très semblables.

[Traduit par la revue]

Introduction

The formation of a covalent bond between a Lewis acid and a Lewis base, and the reverse reaction, heterolytic dissociation of a covalent bond, are among the most fundamental of chemical reactions. Fundamental, unfortunately, does not imply simple. Nearly all of the "effects", steric, polar, resonance, solvent, etc., of chemistry are encountered in these reactions.

The well known fact that the order of acidities of Lewis acids depends on the reference base, and vice versa, immediately implies that at least two properties of each acid and of each base are operative in determining reactivities in the Lewis acid–base reactions. The Edwards equation (26), the Drago equation (27), and Pearson's concept of hardness and softness of acids and bases (28) are familiar attempts to correlate reactivities, quantitatively or qualitatively, in terms of the minimal four parameters.

The two parameters for each acid and two for each base do not allow for variable steric, resonance, polar, or solvent effects. Neither do they accommodate the special effect, pointed out by Edwards and Pearson (29), which appears to be associated with the existence of a lone pair of electrons on an atom adjacent to the reacting atom; the "α-effect". In addition, if one wishes to consider kinetic reactivity, the possible operation of reactivity–selectivity relationships must be taken into account (30).

Against this background of complexity, the simplicity of behavior which we initially observed for several anionic nucleophiles (Lewis bases) reacting with several triarylmethyl cations, aryldiazonium ions, and aryltropylium cations, in several solvents, was truly astounding (1–8). The rate constants for these reactions were correlated by a two parameter equation:

$$[1] \quad \log k = \log k_0 + N_+$$

in which $\log k_0$ is a parameter depending only on the identity of the cation, and N_+ is a parameter depending on the identity of the nucleophile and the solvent (9). Equation [1], the N_+ equation, has now been tested for a wide variety of Lewis acid–base reactions (10–25). Although it is far from being general, and fails badly in some specific cases without apparent cause, it is probably as good as most of the more complex equations when applied to electrophile–nucleophile combination reactions. Within this class of reactions, it is not often that one encounters reactivities that are qualitatively different from expectations based on N_+ values.

There is no general theory of nucleophilic reactivity which anticipates the existence of the N_+ relationship, and most theories cannot even accommodate it (31). One of the major purposes of the present review is to present the body of experimental data now available on "simple" electrophile–nucleophile combination reactions in a summarized fashion to challenge theorists to think about this important area of chemistry.

Reactions of cations with water

The reactions of an electrophile (Lewis acid) with water and hydroxide ion must be fully characterized before the study of reactions with other nucleophiles can be attempted. The equilibrium constants for reactions of cations with water:

$$[2] \quad R^+ + H_2O \rightleftarrows ROH + H^+$$

$$[3] \quad K_R = \{ROH\}\{H^+\}/\{R^+\}$$

are frequently used measures of the "stabilities" of cations. In eq. [3], the quantities in brackets are activities of the indicated species, and the activity of water is defined as unity in dilute solution. For cations with pK_R's in the range from ca. 0–14, K_R is usually determined by measurement of pH and of the concentrations of alcohol and cation in dilute solution (7).

For cations having pK_R lower than zero, the H_R acidity function (32) is generally employed for determination of K_R. In special cases, such as *p*-dimethylamino triphenylmethyl cation, where water can add to the cation to form the alcohol protonated on the dimethylamino group, combinations of acidity functions are useful (12).

[1]For Parts 1 to 25, see refs. 1 to 25.

[j]Data from ref. 40.

Aryldiazonium ions react in basic aqueous solutions to form, in the first observable reactions, the *syn*-diazotates (2). Special techniques must be used (33) to obtain K_R values in these cases. Neutral electrophiles, such as carbonyl compounds, react with water in a reaction analogous to eq. [2]. For carbonyl compounds, the product of reaction is the conjugate base of a *gem*-diol. If the equilibrium constant for hydration of the carbonyl compound, and the acidity constant of the *gem*-diol, are known, the K_R value can be calculated.

The equilibrium constant, K_{OH}, for reaction of an electrophile with hydroxide ion:

[4] $R^+ + OH^- \rightleftarrows ROH$

is directly related to K_R:

[5] $K_{OH} = K_R/K_w$

where K_w is the ion-product of water ($K_w = 1.0 \times 10^{-14}\,M^2$ at 25°C).

Kinetically, the formation of alcohol from cation occurs simultaneously by reactions [2] and [4], with the pseudo-first-order forward rate constant in buffered solution, k_f, given by:

[6] $k_f = k_w + k_{OH}(OH^-)$

Note particularly that k_w, the forward rate constant for reaction [2], is given as a pseudo-first-order rate constant throughout the current series of papers. Many other authors, however, report a "second-order" rate constant obtained by dividing k_w by 55.5 *M*.

Reaction [2] is further complicated by being subject to general-acid–base catalysis (10, 12), so that eq. [6] strictly applies only with very dilute buffer solutions.

Rate and equilibrium constants for the reactions of several types of carbocations, and a few miscellaneous electrophiles, with water and hydroxide ion are shown in Table 1. The range of pK_R values included spans 21 units; rivalling, if not exceeding,

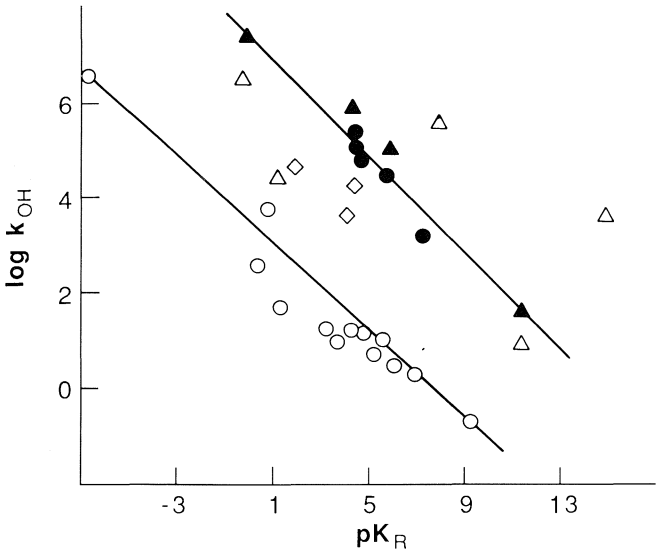

FIG. 1. log k_{OH} vs. pK_R. Open circles, Ar_3C^+; closed circles, $ArTr^+$; closed triangles, xanthylium cations; open triangles, miscellaneous; diamonds, 9-substituted xanthylium cations.

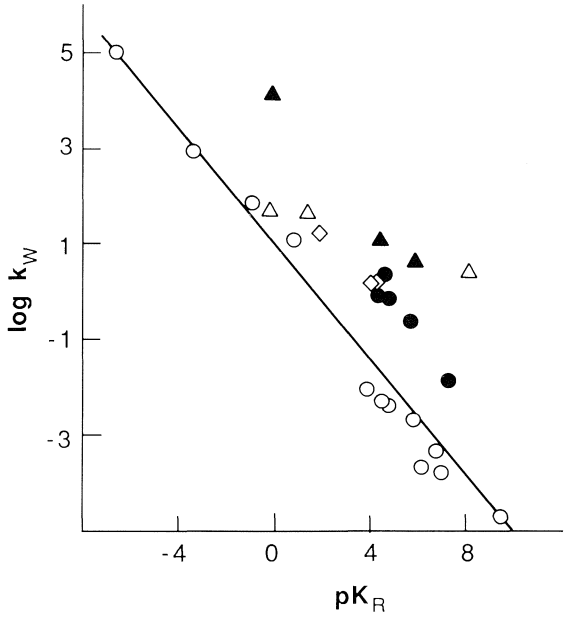

FIG. 2. log k_w vs. pK_R. Symbols are as in Fig. 1.

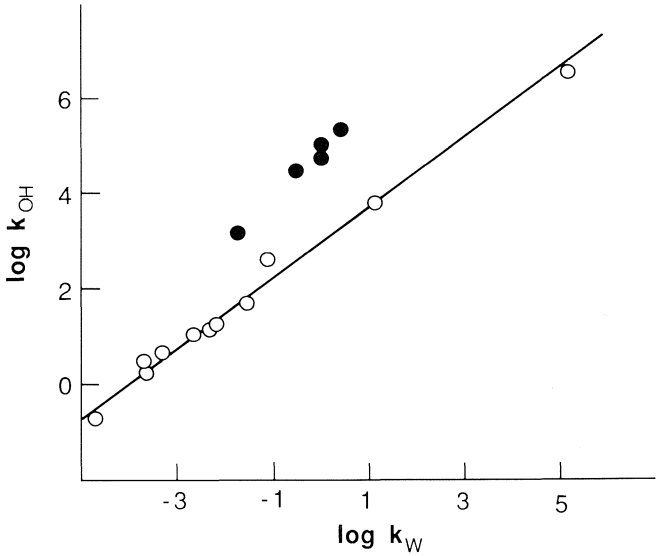

FIG. 3. log k_w vs. log k_{OH} for triarylmethyl and aryltropylium cations.

the range included in any other study of both rate and equilibrium constants for a single reaction type.

Figure 1 shows a plot of log k_{OH} vs. pK_R for all of the electrophiles in Table 1. The lower line in Fig. 1 is arbitrarily drawn through the extreme points for triarylmethyl cations and has a slope of 0.47. The upper line is arbitrarily drawn through the extreme points for xanthylium cations, has a slope of 0.51, and, interestingly, passes very close to the points for aryltropylium cations. Whether or not one attaches any significance to these lines, it is clear that, for a given pK_R, the order of reactivity of cation types is aryldiazonium > xanthylium $\simeq$ aryltropylium > triarylmethyl cations. This is what one might expect from either simple steric, or least-motion (41), considerations.

Figure 2 shows a plot of log k_w vs. pK_R. The line shown is arbitrarily drawn through the extreme points for triarylmethyl cations, and makes the point, contrary to Taft's early conclusion (34), that there is a rough correlation between log k_w and pK_R for the entire range of triarylmethyl cations. One could, however, draw "better" lines through selected groups of points as suggested by Taft (34).

There are differences and similarities in Figs. 1 and 2 which may be seen more clearly in Fig. 3 where log k_w is plotted against log k_{OH} for the triarylmethyl and aryltropylium cations. The line through the points for the triarylmethyl cations has a slope of 1.33 ($\Delta\log k_w/\Delta\log k_{OH}$). Although this non-unit slope has been interpreted (42) as an example of the operation of the reactivity–selectivity relationship, I think it is more likely to be due to a complete difference in the mechanisms of the water and hydroxide ion reactions.

It was noted above that the reactions of water with cations are subject to general-base catalysis. The existence of such catalysis has been confirmed for the least reactive (Crystal Violet) and the most reactive (triphenylmethyl cation) (36) of the triarylmethyl cations, and several of the other types of cations (13, 14, 37, 39) shown in Table 1. The reactions are believed to involve simultaneous carbon–oxygen bond formation and proton transfer to the base catalyst (12). Richard and Jencks (43) have discussed factors influencing the disappearance of the general-base catalysis for extremely reactive cations reacting with water and alcohols.

Although possible, it appears unlikely that the reactions of hydroxide ion with cations actually involve catalysis of the water reactions by hydroxide ion. Alkoxide ions, such as trifluoroethoxide ion, react with cations in aqueous solution to form ethers (23, 39). Hydroxide ion reacts more slowly than alkoxides of similar basicity. These facts indicate that hydroxide ion reacts in a direct cation–anion combination.

A difference in mechanism of the water and hydroxide ion reactions is also indicated by the results of a study of the α-deuterium isotope effect on the reactions of di-ferrocenylmethyl cation (38). The k_w shows $k_H/k_D = 0.91$, k_{OH} shows $k_H/k_D = 0.99$, and K_R shows $K_H/K_D = 0.85$. According to this measure, the water reaction has a transition state in which the cationic carbon has progressed well toward the carbinol carbon, while the hydroxide ion reaction has a transition state in which the cationic carbon has hardly changed from reactant state. This is consistent with the slope of greater than unity found in Fig. 3 for the triarylmethyl cations.

The mechanism of the reaction of water with carbonyl compounds has been discussed by Guthrie (44). Unfortunately, the conclusions were based on an unjustified (22) use of Marcus theory. There appear, however, several similarities between the carbonyl reactions and the cation reactions discussed here. It is particularly interesting that a plot of log k_w vs. log k_{OH} for the carbonyl reactions (not shown by Guthrie) has a slope of ca. 1.4, and that the water reactions are subject to general-base catalysis (45).

Gandler (46) has studied the general-base catalysis by substituted quinuclidines of the reactions of a series of triarylmethyl cations with water. Brønsted slopes of 0.33 to 0.52 are found, with, perhaps, a slight tendency for the slope to decrease with decreasing pK_R of the cations. It should be noted, however, that the log k_{Dab}/k_w, where k_{Dab} is the second-order rate constant for catalysis of the water reaction by Dabco (1,4-diazabicyclo[2.2.2]octane) and k_w is the first-order rate constant for the un-catalyzed (or water-catalyzed) water reaction, is 0.78 for Crystal Violet (46), 0.60 for tri-*p*-anisylmethyl cation (47), and 0.71 for triphenylmethyl cation (36). There is no appreciable change in this value as the pK_R of the cation changes from 9.39 to −6.63.

The relative reactivities of hydroxide ion and water, as given by k_{OH}/k_w, vary considerably for the cations shown in Table 1, ranging from a low of 8 for tris-(2,4-dimethoxyphenyl)methyl cation to ca. 10^5 for the aryltropylium cations. Values slightly greater than 10^7 have been reported for reactions of some quinolinium cations (48). The variations follow no obvious pattern, and the extremely low value for the tris-(2,4-dimethoxyphenyl)methyl cation is not found for the similarly substituted xanthylium cation.

In the initial paper on the N_+ relationship (9), log k_0 was defined as the logarithm of the rate constant for reaction of the given cation with water. The later finding of the difference in mechanism between water reactions and others (10–14) led to the suggestion (13) that water reactions not be included in the N_+ correlations, and that log k_0 be based on reactions of other nucleophiles. From a purely empirical standpoint, k_{OH}/k_w seldom varies outside the range of 10^3 to 10^5 and is only slightly more poorly behaved than some other relative reactivities which we have encountered in later work (17).

Equilibrium reactivities of nucleophiles

Parker suggested (49) and Hine developed (50) the concept of "carbon basicity", realizing that the common practice of comparing basicities of nucleophiles toward the proton with kinetic reactivities toward carbon compounds was not a proper rate-equilibrium comparison. The equilibrium constants, K^{RX}_{HX}, for the exchange reactions:

[7] $\quad R—OH + H—X \rightleftarrows R—X + H—OH$

were suggested by Hine (50) to be particularly appropriate for measuring the differences between proton and carbon basicities of various X^- bases. In an attempt to place water on the same basis as dilute solutes, HX, in aqueous solution, it is common to define the activity of water to be 55.5 *M* in dilute aqueous solutions. This definition will be used in the following discussion of reaction [7].

Equilibrium constants for reaction [7] can be calculated from those of simpler reactions in several ways. The most convenient method for the present purposes considers reaction [4] for OH^-, the corresponding reaction for X^-:

[8] $\quad R^+ + X^- \overset{K_X}{\rightleftharpoons} R—X$

TABLE 2. Values of log K^{RX}_{HX}

Nucleophile[a]	pK_a	log K^{RX}_{HX} Pyr[b]	Ar_3C^+	CH_3^+(gas)
$CF_3CH_2O^-$	12.4	−0.3		
CO_3^{2-}	10.3	0.2		
HOO^-	11.6	4.1		(6.6)[c]
n-PrS^-	10.8	7.6		9.6[d]
$HOCH_2CH_2S^-$	9.5	7.2	4.6	
$CH_3O_2CCH_2S^-$	8.0	7.6	4.9	
$C_6H_5S^-$	6.5	7.7		9.3
CN^-	9.1	(17.0)[e]		18.0
SO_3^{2-}	7.2	12.7	7.8	
N_3^-	4.0		3.4	
n-$BuNH_2$	10.5	3.0	0.2	18.6[f]

CH_3ONH_2	4.6	4.0	3.0	
$H_2NCONHNH_2$	3.9	3.2	2.6	
Piperidine	11.4	3.2		
Morpholine	8.5	2.8		

[a]In water at 20–25°C.
[b]For Pyronin-Y or aryltropylium cations.
[c]This value is for R^+ = *t*-Bu^+ from ref. 50.
[d]This value is actually for CH_3S^-.
[e]This is an estimated value; see ref. 52.
[f]This value is actually for CH_3NH_2. The value for CH_3NH^- is 6.5; the remaining 12.1 units comes from the differences in basicities of CH_3NH_2 and $(CH_3)_2NH$ in the gas phase. Thus, the value for CH_3NH_2 in water is ca. 6.5.

and the acid ionizations of the acids HX and HOH. The equilibrium constants for reaction [7] are then calculated as:

[9] $\quad \log K^{RX}_{HX} = \log K_X - \log K_{OH} - pK_{a(HX)} + pK_{a(HOH)}$

where the acid ionization constant for water is defined as the ion product of water, K_w, divided by 55.5 *M* (i.e.: at 25°C, $pK_{a(HOH)}$ = 15.74). For neutral nucleophiles such as primary and secondary amines, the reaction analogous to reaction [8] is

[10] $\quad R^+ + BH \rightleftarrows R—BH^+$

and the pK_a in eq. [9] is that for BH_2^+.

Values of log K^{RX}_{HX} for several types of R and for a range of nucleophiles are shown in Table 2. Since relative equilibrium reactivities of nucleophiles are the same toward Pyronin-Y and aryltropylium cations (22), the values of K^{RX}_{HX} are the same for the two types of cations and are shown in a single column of Table 2. Similarly, relative equilibrium reactivities are the same for all of the triarylmethyl cations, excepting the *ortho*-substituted ones, and a single column is needed in Table 2. For a few nucleophiles, data are given for R = CH_3 in the gas phase. These data are calculated from bond dissociation energies (51) as described by Hine (50).

It may be useful to note that the data in Tables 1 and 2 used in eq. [9] allow the solution for log K_X for specific cations and nucleophiles. Values thus obtained are expected to be very good estimates.

The value of log K^{RX}_{HX} for trifluoroethoxide ion reacting with Pyronin-Y or aryltropylium cations is precisely the value expected from symmetry if our standard state definition of water has accomplished its aim, and if the relative basicities of trifluoroethoxide and hydroxide ions are the same toward the proton and carbon, except for the symmetry of HOH. Similarly,

the basicity of carbonate ion, relative to hydroxide ion, is only marginally greater toward carbon than toward the proton.

None of the values of log K^{RX}_{HX} shown in Table 2 are significantly negative, indicating that none of the nucleophiles considered here, relative to hydroxide ion, are significantly more basic toward the proton than toward carbon. Hine and Weimer (50) have pointed out that this is consistent with expectations based on electronegativity if carbon is more electronegative than hydrogen. Hydrogen would then preferentially bond to the more electronegative X. The value of log K^{RX}_{HX} for X = F and R = isopropyl, in the gas phase, is −2.3. The absence of negative values in Table 2, according to this argument, is due to the fact that none of the X included there are more electronegative than OH.

It is interesting to note that in every case where comparisons are possible the value of log K^{RX}_{HX} is smaller for triarylmethyl cations than for Pyronin-Y cation, and, in the few cases available, is smaller for Pyronin-Y than for methyl cation. This is what would be expected from a simple steric argument based on OH being sterically smaller than any of the other X considered. A steric effect is also likely involved in the reactions of azide ion with *ortho*-substituted triarylmethyl cations (18). The value of log K^{RX}_{HX} for azide ion with tri-*p*-anisylmethyl cation is 3.4. Smaller values of 1.3 and 2.3 are found for *ortho*-SO_2CH_3 and *ortho*-SO_3^- compounds, respectively.

Dixon and Bruice (53) first pointed out that "α-effect" nucleophiles show large equilibrium constants for reactions with triarylmethyl cations. Peroxide ion, hydrazine, methoxylamine, and semicarbazide all show larger values of log K^{RX}_{HX} than do alkoxides or primary amines. This is not likely to be a steric effect since the values for secondary amines are also larger than those for primary amines, and, in the case of peroxide ion, it would be difficult to argue that peroxide is smaller than hydroxide ion.

There appears to be a trend for values of log K^{RX}_{HX} to decrease with decreasing pK_a of the conjugate acids of primary amines. This is consistent with the above arguments that the R's are more electronegative than hydrogen. It is also consistent with the fact that the pK_a's of the RBH^+ products of reaction [10] are lower than the pK_a's of the corresponding BH_2^+ ions (11, 22).

The largest values of log K^{RX}_{HX} are for thiolate and sulfite ions. It is even possible that the values for sulfite ion are higher than those reported in Table 2. The products of reaction of sulfite ion with cations almost certainly involve bond formation between carbon and sulfur. If the stable form of bisulfite ion in water is the isomer with a hydrogen–sulfur bond, then the values given in Table 2 are proper ones. If, however, the stable isomer is the one with a hydrogen–oxygen bond, then the measured pK_a is greater than the pK_a for the unstable isomer, which is the one which should be used in the calculation from eq. [9]. Guthrie (54) has argued that the stable isomer in aqueous solution is the H—S bonded form. If that is correct, then the values in Table 2 are the proper ones.

Arnett *et al.* have recently reported (56) studies of the reactions of carbocations with carbanions. Heats of reactions for trimethyl- and triphenylcyclopropenium cations with a series of substituted arylmalononitrile anions in acetonitrile solution, and for triphenylmethyl cation with a series of 9-substituted fluorenide ions in benzonitrile solution were measured. The pK_R's of the cations are known in aqueous acid, and the pK_a's of the conjugate acids of the carbanions are known in dimethyl sulfoxide solution. A plot of the molar heats of reactions vs. (pK_a − pK_R), amazingly, gave a reasonably good single straight line for all of the reactions in both solvents:

$$[11] \quad -\Delta H_{rxn} = 11.98 + 1.18(pK_a - pK_R)$$

Arnett *et al.* call this the "Master Equation" for the carbocation–carbanion reactions. They point out that relative pK_a's and pK_R's for delocalized ions such as those involved in the study are not sensitive to solvent, so that the use of values measured in solvents different from those used in the heat measurements is justified. In earlier work (57), it was found that the free energies are linearly related to the enthalpies for some of these reactions, with a slope of 1.16. If this relationship holds for all of the reactions obeying eq. [11], then the slope of a plot of the standard free energies vs. (pK_a − pK_R) will be 1.16 × 1.18 = 1.37, which is precisely (embarrasingly so) equal to 2.3RT at 25°C. This implies a constant value of log K^{RX}_{HX} for all of the carbocations and carbanions studied. It is very difficult to understand this constancy, particularly for the reactions of triphenylmethyl cation with fluorenides where steric effects would be expected to be huge.

In addition to the data shown in Table 2, values of log K^{RX}_{HX} are available for a good range of X for R = CH_3CO, mostly from Jencks' laboratory (55), and for α-hydroxy groups, R = R′CHOH, from studies of carbonyl addition reactions (52).

Although values of log K^{RX}_{HX} are not expected to be very solvent sensitive, the equilibrium constants for reaction [8] should vary tremendously with change of solvent from water to non-hydroxylic polar solvents. Some of these changes for solvents water, methanol, and dimethyl sulfoxide are shown in Table 3. If the free energies of transfer of the cations, nucleophiles, and products of reactions were determined by additive contributions of groups, it is easy to show (21) that:

$$[12] \quad \Delta\log K_X - \Delta pK_{a(HX)} = \text{constant} \equiv \Pi$$

where $\Delta\log K_X$ is the change in log K_X, and $\Delta pK_{a(HX)}$ is the change in the pK_a of HX, on changing solvent, and Π is defined by the equation and is expected to be independent of R^+ and X^-. For the change from water to methanol or to dimethyl sulfoxide, the values of Π are shown in Table 3 (23).

For the change from water to methanol solvent, values of Π range from −1.7 to +0.9, and for the change from water to dimethyl sulfoxide, values range from 2.5 to 4.3. Although the ranges are disappointingly large, indicating the breakdown of additivity, the average values of −0.4 for methanol and 3.3 for dimethyl sulfoxide allow reasonable estimates of equilibrium constants in these solvents if values are known in water. It is also interesting to note that the average value of Π for dimethyl sulfoxide solutions is equal to the negative of the logarithm of the activity coefficient of the proton in dimethyl sulfoxide relative to a standard state in water (52). This implies that the free energies of transfer from water to dimethyl sulfoxide of the cations considered here are all close to zero. This follows from the fact that:

$$[13] \quad \Delta\log K_X - \Delta pK_{a(HX)} = \log \gamma_R\gamma_{HX}/\gamma_H\gamma_{RX}$$

where the γ's are activity coefficients of the subscripted species (charges omitted) in dimethyl sulfoxide relative to a standard state in water, since the activity coefficients of HX and RX are expected to be close to unity (52).

Kinetic reactivities of nucleophiles

Relative reactivities of nucleophiles toward several different types of cations and a neutral electrophile are shown in Table 4. In the triarylmethyl cation series, relative reactivities of nucleophiles, with the exception of water, are independent of

TABLE 3. Solvent effects on equilibria (24)[a]

[a]ArF is 2,4-dinitrofluorobenzene. Data are from refs. 1–25 unless otherwise indicated.
[b]Data from ref. 58.
[c]Data from ref. 35.
[d]Data are for *n*-propanethiolate where available. Since thiolates all show essentially the same rate toward a given electrophile (see ref. 17), some of the data are for other thiolates.

the pK_R of the cation from 0.81 for tri-*p*-anisylmethyl cation to 9.39 for Crystal Violet (16, 42). Similar behavior is found for tropylium and aryltropylium cations (11, 14), although the pK_R range is only 4.7–7.3.

Comparisons of one cation type with another show substantial variations in relative reactivities of the nucleophiles, and, therefore, breakdowns of the N_+ relationship. The variations in relative kinetic reactivities, usually, are smaller than the variations in relative equilibrium reactivities discussed above. For example, sulfite ion gave log K^{RX}_{HX} of 12.7 for Pyronin-Y and of 7.8 for triarylmethyl cations, while log $k_{sulfite}/k_{OH}$ is 3.26 for triarylmethyl cations, 2.75 for aryltropylium cations, and 3.16 for Pyronin-Y cation. Similarly, for thiolate ions, log K^{RX}_{HX} varies by nearly 3 units while log k_{RS}/k_{OH} varies by ca. 1 unit for the change from triarylmethyl to Pyronin-Y cations.

In the comparison of Pyronin-Y with aryltropylium cations, however, substantial differences in relative kinetic reactivities are shown, while, as already remarked, the relative equilibrium reactivities are the same for the two types (22). Amines, particularly the secondary amines morpholine and piperidine, are more reactive, relative to other nucleophiles, toward Pyronin-Y than toward the aryltropylium cations. There are no obvious reasonable rationalizations of this behavior.

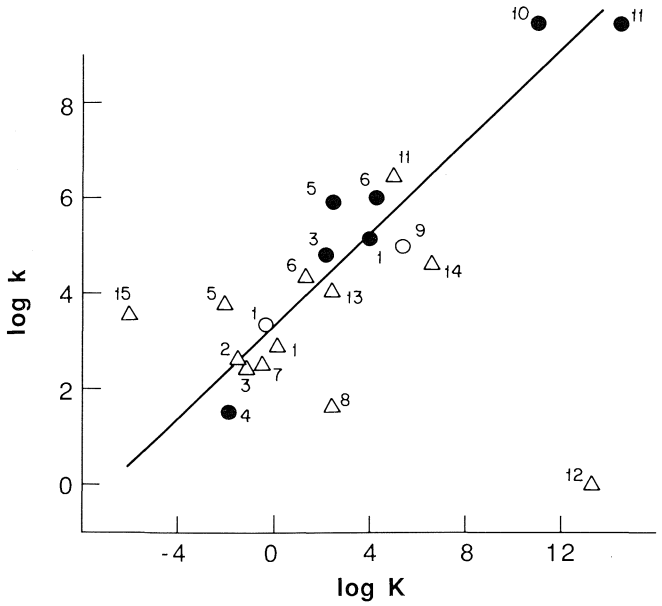

FIG. 4. Rate–equilibrium plot for pyronin-Y cation reactions. Triangles, aqueous solution; open circles, methanol solution; closed circles, dimethyl sulfoxide solution. Nucleophiles are identified as follows: 1-*n*-$BuNH_2$; 2-glycinate; 3-2-methoxyethylamine; 4-2,2,2-trifluoroethylamine; 5-morpholine; 6-piperidine; 7-hydrazine; 8-hydroxide ion; 9-methoxide ion; 10-methyl thioglycollate ion; 11-*n*-PrS^-; 12-CN^-; 13-HOO^-; 14-SO_3^{2-}; 15-N_3^-. Data for azide and cyanide ions estimated as described in ref. 52.

It is clear that there is no general correlation of the rates and equilibria of the reactions (22). A plot of log k vs. log K for reactions of nucleophiles with Pyronin-Y cation is shown in Fig. 4. The line shown is an arbitrary one having a slope of 0.5 and passing close to the points for reactions of primary amines. Azide ion and thiolate ions have much greater rate constants than do other nucleophiles with similar equilibrium constants, while sulfite ion, hydroxide ion, and cyanide ion have much smaller rate constants than other nucleophiles with similar equilibrium constants.

Relative kinetic reactivities are surprisingly similar toward aryltropylium cations and the neutral 2,4-dinitrohalobenzenes (15). Data are given in Table 4 for 2,4-dinitrofluorobenzene. Only thiolate ions and azide ion show significantly different relative reactivities toward the aryl halides than toward aryltropylium cations. The thiolate ion relative reactivities, log k_{RS}/k_{OH}, also vary with the halogen of the aryl halide, being 3.2 for F, 4.5 for Cl, 4.7 for Br, and 5.1 for I (15). The increasing value for increasing size of the halide is what one might expect from polarizability arguments (59), but it is the values for the Cl, Br, and I that are most "normal" when compared with those for cations. In a comparison of Pyronin-Y cation and its thio-analog, log k_{RS}/k_{OH} values were 4.9 and 5.9, respectively (22). The increase by one unit on substitution of S for O at the remote site is very nearly as large as the 1.3 unit change on substitution of Cl for F at the reaction site for the aryl halides.

For "families" of nucleophiles, values of log K_x are linearly related to pK_a's of the conjugate acids of the nucleophiles with slopes not far from unity, as we discussed in the earlier section of this paper. For such families, Brønsted slopes are nearly equal to slopes of log K vs. log k plots, and are frequently interpreted in terms of the extents of bond formation at transition states. For the reactions of a series of primary amines with any of the cations which we have studied, Brønsted slopes of ca. 0.4 are found (11, 13). The Brønsted slopes for reactions of thiolates with cations are all very close to zero (17), and the slopes for alkoxide ions (58) are ca. 0.2 to 0.3. These differences in slopes for the different families would be expected to be reflected in differences in relative rates of reactions of the cations if the interpretation in terms of bond formation is correct. The clearest comparisons are for Crystal Violet (pK_R = 9.39) and tri-*p*-anisylmethyl cation (pK_R = 0.81). The rate constant ratios, log k_{TAM}/k_{CV}, are 4.66 for ammonia, 4.61 for hydroxide ion, and 4.50 for 2-hydroxyethanethiolate ion. Since the difference in pK_R values is 8.6 units, the values of log k_{TAM}/k_{CV} indicate approximately 0.5 (i.e.: 8.6/4.5) "extent of reaction" for all of the nucleophiles, counter to the conclusion from differing Brønsted slopes.

Another measure of "extent of reaction" is furnished by the secondary α-isotope effects reported by Bunton *et al.* (38) for reactions of di-ferrocenylmethyl cation. Values of k_H/k_D of 1.00 ± 0.01 for reactions of all anionic nucleophiles, and of 0.96 for reactions of amines, compared with the equilibrium isotope effect K_H/k_D for reaction of hydroxide ion of 0.85, indicate no "progress" at the transition states for reactions of anions, and very little progress for reactions of amines.

It is obvious that interpretation of any of these measures in terms of a simple "extent of reaction" parameter (22) is not possible. These types of "imbalances" in various measures of extent of reaction have been discussed for several other reaction types (17, 55*a*, 60).

The constancy of the values of log k_{TAM}/k_{CV} remarked above for several nucleophiles is quite pertinent to the question of the operation of a reactivity-selectivity relationship in these reactions (42). The value of log k_{RS}/k_{OH} is 4.05 for Crystal Violet and 3.94 for tri-*p*-anisylmethyl cation. Thus, a difference of 10^4 in nucleophilic reactivity does not influence appreciably the difference of 10^4 in electrophilic reactivity, and vice versa. Other examples abound in our studies (9, 13), and were the basis of the N_+ relationship, which contains no cross terms, and, therefore, no allowance for change in selectivity.

The actual value of the rate constant for reaction of 2-hydroxyethanethiolate ion with tri-*p*-anisylmethyl cation is $7.1 \times 10^7\ M^{-1}\ s^{-1}$ in water at 25°C (17). This value is within two orders of magnitude of that expected for a diffusion-controlled reaction (Richard and Jencks (61) take $k_{DC} = 5 \times 10^9\ M^{-1}\ s^{-1}$), yet k_{RS}/k_{OH} is essentially the same as for Crystal Violet, for which $k_{RS} = 2.2 \times 10^3\ M^{-1}\ s^{-1}$. An even closer approach of rates to diffusion control occurs for the reactions of sulfite ion with aryldiazonium ions in water. For *p*-nitro- and *p*-cyanobenzenediazonium ions, $k_{SO_3} = 4. \times 10^8\ M^{-1}\ s^{-1}$, and log k_{SO_3}/k_{OH} = 3.0. For Crystal Violet, $k_{SO_3} = 5. \times 10^2\ M^{-1}\ s^{-1}$, and log k_{SO_3}/k_{OH} = 3.4. The selectivity for Crystal Violet is insignificantly greater than that of the aryldiazonium ions where the rate for sulfite is within an order of magnitude of diffusion control. In non-aqueous solutions, greater rate constants are frequently observed. In methanol solution, the *p*-nitro- and *p*-cyanobenzenediazonium ions react with thiophenoxide ion with rate constants slightly greater than $5 \times 10^9\ M^{-1}\ s^{-1}$; the unsubstituted benzenediazonium ion has $k_{PhS} = 1.4 \times 10^9\ M^{-1}\ s^{-1}$. Yet the value of log k_{PhS}/k_{OH} for benzenediazonium ion (5.5) is scarcely different from that for Malachite Green (5.7) which reacts more than 10^3 more slowly with either nucleophile (9).

This type of behavior led Jencks and co-workers (61, 62) to

use the reactions of the very reactive sulfite ion and azide ion in water with very reactive cations as "clocks" for the rates of reactions of the cations with solvent. The cations were generated as reactive intermediates in the presence of the reactive nucleophile. The product ratio resulting from trapping by solvent and by the reaction nucleophile then gives the rate ratio. In cases where this ratio is much less than those found for our "stable" cations, Jencks assumes that the rate constant for reaction of the reactive nucleophile is diffusion-controlled, with a value of $5 \times 10^9\ M^{-1}\ s^{-1}$, allowing the calculation of the rate constant for reaction of solvent.

The technique was first used in the acid-catalyzed breakdown of substituted acetophenone dimethyl ketals to give rate constants ranging from 7×10^6 to $4 \times 10^8\ s^{-1}$ for reactions of water with the intermediate oxocarbonium ions (62). More recently, rate constants up to $4 \times 10^9\ s^{-1}$ for reaction of water with aryl-substituted 1-phenylethyl cations generated as intermediates in solvolysis reactions have been calculated (61). Ta-Shma and Rappoport (63) have re-examined the trapping studies which have been carried out for solvolysis reactions by many workers and conclude that the results can most reasonably be interpreted in terms of diffusion-controlled trapping of intermediate cations and changes in mechanism from S_N1 to S_N2.

There is some question concerning the exact magnitudes of diffusion-controlled reaction rates in water for electrophile–nucleophile combination reactions (64). In the series of increasingly reactive 1-arylethyl cations (65), the rate ratios for two different anionic nucleophiles do not always level out at close to unity. For azide and acetate, for example, the rate constant ratio seems to level at $k_{az}/k_{ac} = 10$. Jencks suggests that basic oxyanions, such as acetate and alkoxide ions, have a barrier to desolvation which causes rate constants for their reactions to level at ca. $5 \times 10^8\ M^{-1}\ s^{-1}$. It is not obvious, however, why oxyanions differ in this respect from azide or thiolate ions. The change in pK_a on changing from water to dimethyl sulfoxide is ca. 7 units for acetic acid and ca. 6 units for 2-hydroxyethanethiol (21). If this change results largely from hydrogen bonding in water, as usually believed (66), then acetate and thiolate ions must have comparable hydrogen bonding stabilization in water.

In the studies of "stable" cations, the fastest rates measured in water give values of log k as follows: tri-*p*-anisylmethyl cation + 2-hydroxyethanethiolate (17), 7.85; tri-*p*-anisylmethyl cation + thiophenoxide ion (67), 8.26; *p*-dimethylaminophenyltropylium cation + thiophenoxide ion (23), 8.80; Pyronin-Y cation + *n*-propanethiolate ion (22), 6.60. There is no indication in any of these reactions that the rates have levelled off, causing a decrease in selectivity.

McClelland's very recent results for reactions of triphenylmethyl cation are particularly interesting (36). Although this study was actually carried out in 1:2 acetonitrile:water solvent, it does not seem likely that the results would be appreciably different in pure water (see, for example, the study by Bunton *et al.* (38) in a very comparable solvent). The rate constant for reaction of azide ion with the trityl cation, $k_{az} = 4 \times 10^9\ M^{-1}\ s^{-1}$, is very close to the value estimated by Richard and Jencks (61) for a diffusion-controlled reaction. For thioglycollate and sulfite dianions, both of which are more reactive than azide ion toward tri-*p*-anisylmethyl cation, the rate constants for reactions with trityl cation are $2. \times 10^8$ and $2.4 \times 10^8\ M^{-1}\ s^{-1}$, respectively. The rate constant for reaction of thioglycollate dianion with tri-*p*-anisylmethyl cation is expected (17) to be the same as that for reaction of 2-hydroxyethanethiolate, $k = 7. \times 10^7\ M^{-1}\ s^{-1}$, which is only a factor of three smaller than that for trityl cation, whose pK_R is 7 units below tri-*p*-anisylmethyl cation. This seems to indicate that, at least for the thioglycollate ion, the rate constant has levelled off below the diffusion-controlled limit for trityl cation reaction.

From the data given in Table 4, it is evident that reactions of trityl cation do not obey the N_+ relationship. This could conceivably be due to a levelling of rates at below diffusion control, as discussed above, or to the incursion of the reactivity–selectivity relationship in its originally conceived form (30). As McClelland *et al.* point out (36), the reactions of amines, with rate constants on the order of $10^7\ M^{-1}\ s^{-1}$ and an appreciable, although small, Brønsted slope, appear more consistent with the reactivity–selectivity relationship. The thioglycollate and sulfite reactions, however, seem more consistent with the levelling out postulate, possibly having to do with desolvation requirements (55*a*, 61, 68).

In this latter connection, it should be noted that thiolates of widely differing equilibrium reactivities have essentially identical kinetic reactivities toward cations both in water (17) and in dimethyl sulfoxide (21) solutions. The essentially zero Brønsted slopes for the thiolate reactions are not, therefore, due to hydrogen bonding of water as has been postulated for oxyanions (55*a*, 68).

Solvent effects on kinetics

One of the primary reasons for beginning the study of cation–anion combination reactions was the possibility that these reactions might be particularly susceptible of the types of solvent effects suggested by Caldin (69). The essential idea is that the solvation of transition states need not be analogous to that of stable species having the same structure (70). For cation–anion combination reactions, the transition states are expected to have structures which are in all senses intermediate between reactants and products. If the transition states were solvated as stable species, the solvation would also be expected to be intermediate between that of reactants and products. Quite specifically, the effect of changing solvent on the rate constant for such a reaction would be expected to be smaller than the effect of the equilibrium constant (1).

There are some indications that the transition states for cation–anion combinations are solvated in an unusual manner. For the reaction of Malachite Green cation with hydroxide ion in aqueous solution (12), $\Delta S^0 = -2.0$ eu, and $\Delta S^\dagger = -14.0$ eu. The entropy of the transition state is more negative than that of the reactants or the products. LeNoble *et al.* (71) find a similar situation for the volume of activation of the same reaction. The ΔV^0 is estimated to be $+15.0\ cm^3/mol$, and $\Delta V^\dagger$ is $+30.0\ cm^3/mol$.

In spite of some excitement based on limits (1) and estimates (21), however, no spectacular solvent effects on rates and equilibria have been found. In all cases where both rates and equilibria have been determined in more than one solvent, the solvent effects on rates are either smaller than the effects on equilibria, or are very small (23).

For the change of solvent from water to dimethyl sulfoxide, very large effects on both rates and equilibria are observed (1, 9, 21, 23). For cations reacting with cyanide ion (9), rate constants are ca. 10^5, and equilibrium constants ca. 10^7, greater in dimethyl sulfoxide than in water. Even for cations reacting with neutral amines, increases of ca. 10^2 in rate constants and of ca. 10^4 in equilibrium constants occur on going from water to dimethyl sulfoxide (23). In all cases actually measured,

however, the effect of solvent on log k is 0.3 to 0.8 times the effect on log K, as expected for "normal" solvation of transition states.

For the solvent change from water to methanol, there are a few reactions, all involving carbocations reacting with primary amines, for which the rate constants are affected more than, or even in the opposite direction from, the equilibrium constants (23). Only four of the nine reactions of carbocations with primary amines studied in both solvents show this unusual effect, and, in all of the reactions, the effect of changing from water to methanol solvent is small, producing a maximum of a factor of ten change in rate constant.

Even though there is, then, some evidence for an "unusual" solvent effect on some of the reactions, the "non-classical" solvation of transition states seems to have a minor effect, at most, on the rate constants. Kurz *et al.* (72) have discussed similar types of solvent effects in solvolyses of methyl compounds, and van der Zwan and Hyne (73) have developed a general theory of such effects.

General patterns of nucleophilic reactivity

The N_+ relationship, eq. [1], was first formulated (9) to describe the behaviors of reactions of carbocations and aryldiazonium ions with a few anionic nucleophiles in several solvents (31). The relationship was then found to apply reasonably well to the reactions of the carbocations with neutral amine nucleophiles (11). The next obvious step was to see if the relationship applies to reactions of neutral electrophiles.

Jencks and co-workers (74, 75) had reported rate constants for reactions of a good variety of nucleophiles with aryl acetates and with some very reactive acetyl- and acetoxypyridinium ions. The absence of selectivity–reactivity relationships in the reactions had been particularly noted (75). The data for the reactions were found to fit reasonably well to the N_+ relationship when allowance was made for changes in rate-determining step in some of the reactions (13). Some severe failures of the N_+ relationship were found for specific cases, however. In particular, azide ion, fluoride ion, and aryloxide ions could not be accommodated. Later work by Hupe and Jencks (55*a*) on reactions of oxyanions and thiolates with esters and our work (17) on reactions of thiolates with carbocations showed a particularly serious failure of the N_+ relationship for reactions of thiolates with esters. More recently, Palling and Jencks (76) have reported a study of reactions of nucleophiles with acetyl chloride and conclude that the N_+ relationship does not apply to these reactions.

As already mentioned in earlier sections, the reactions of nucleophiles with 2,3-dinitrohalobenzenes in water correlate very well with the reactions of the nucleophiles with aryltropylium cations (15). Some of the features of those reactions are also found in the reactions of nucleophiles with *trans*-3-methoxyacrylophenone and its thiomethyl analog (20). In comparing these reactions of neutral electrophiles with those of *p*-dimethylaminophenyltropylium cation, separate lines are generated by reactions in water and those in methanol solutions. That this is caused by a difference in free energy of transfer of the cationic and neutral electrophiles is indicated by a comparison of the reactions of *trans*-3-methoxyacrylophenone with those of 2,4-dinitrophenyl acetate in the two solvents; a single correlation line is found (20).

In connection with the interpretations of studies of trapping of solvolysis intermediates (6, 63), it seemed important to establish the patterns of reactivity of nucleophiles toward ion-pairs. This was accomplished by synthesizing and studying reactions of an intramolecular ion-pair, an *ortho*-sulfonate substituted triarylmethyl cation (18). The relative reactivities of positive, neutral, anionic, and di-anionic nucleophiles were not affected by the presence of the *ortho*-sulfonate group. This study and that of the neutral electrophiles demonstrate an absence of any significant electrostatic effects on the rates of electrophile–nucleophile combination reactions.

Bunton *et al.* (38, 67) have extended the N_+ relationship to reactions of ferrocenyl-substituted methyl cations, and to a few nucleophiles, such as borohydride ion, which are not simple Lewis bases. His studies of the α-isotope effects on the reactions have been discussed in earlier sections of this paper. Alavosus and Sweigart (77) have gone considerably farther into the organometallic area by showing that the N_+ relationship works remarkably well for the reactions of nitrogen and phosphorus nucleophiles with metal-complexed Π-hydrocarbons.

McClelland and co-workers' recent studies of very reactive cations (36, 40), and Richard and Jencks' studies of the 1-arylethyl cations (43, 61, 65) clearly indicate the need for more studies of cations less stable than the tri-*p*-anisylmethyl cation ($pK_R = 0.81$). As discussed above, the point to be established is whether or not limiting rates below diffusion control are common, and whether or not reactivity–selectivity relationships become operable for very reactive species.

The N_+ relationship is certainly not the final word on nucleophilic reactivity. It fails badly in some instances for no apparent reasons, and it may not apply to extremely reactive carbocations. It is, however, about as good as one can do at the present time in attempts to predict or correlate rates of electrophile–nucleophile combination reactions. Several sets of N_+ values are given in Table 5.

Theories of nucleophilic reactivity

Swain and Scott (78) were certainly among the very first to attempt an understanding of nucleophilic reactivity, at least in the empirical sense of correlating such reactions. The focus of their attention, however, was on S_N2 substitution and S_N1 and S_N2 solvolysis reactions. Edwards (26) gave attention to more general types of nucleophilic reactivity. Following an earlier suggestion by Foss (79), Edwards examined the possible relationship between oxidation potentials and nucleophilicity. The oxidation potentials considered were those for the oxidative dimerizations:

$$[14] \quad X^- \rightleftarrows \tfrac{1}{2}X_2 + e^-$$

The four parameter equation:

$$[15] \quad \log k/k_0 = AE + BH$$

was proposed, in which k and k_0 are rate constants for reactions of the given electrophile with the given nucleophile and with water, respectively, E is the oxidation potential (reaction [14]) of the nucleophile, relative to water, H is the pK_a of the conjugate acid of the nucleophile, relative to hydronium ion, and A and B are parameters giving the sensitivity of the electrophile to oxidation potential and basicity of the nucleophile.

Edwards was bothered by eq. [15] in that some reactions required negative values of the parameter A (80). Other authors (81) had expressed doubt about the appropriateness of reaction [14] as a "model process" for nucleophilic reactivity, since the potentials contain a large contribution from the X—X bond energies. The parameter E was then redefined by Edwards (80) as the polarizability of the nucleophile. Edwards and Pearson

TABLE 5. N_+ values[a]

Nucleophile	Solvent	N_+ Ar_3C^+[b]	N_+ Pyr-Y[c]	N_+ $ArTr^+$[d]
H_2O	Water	0.73		−0.26

[e]The rates measured were at the diffusion-controlled limit.

(29) discussed the applications of the modified eq. [15] to a wide range of reactions, considerd how the parameters A and B vary with the nature of the electrophile, and pointed out the existence of the "α-effect", which is not included in the equation.

One of the difficulties of the Edwards equations is that neither oxidation potentials nor polarizabilities, particularly anisotropic ones, are known for very many nucleophiles. In actual practice, the parameter E was "evaluated" by fitting eq. [15] to experimental data. Pearson *et al.* (82) attempted to solve this problem by using "model" reactions in which factors other than basicity are dominant in determining reactivity. He reached the conclusion that equations such as eq. [15] have very limited ranges of applicability and that the qualitative concept of "hardness and softness", which he had earlier introduced (28), was about all that one could hope for.

The concepts of hardness and softness are loosely (no pun intended) related to proton basicity and polarizability, but are defined in terms of empirical reactivities (28). Klopman (83) has attempted to relate these properties to quantum mechanical concepts.

Albery and Kreevoy (85) showed that the Marcus theory (84), which began as a theory for electron transfer reactions (84), could be applied reasonably to S_N2 reactions of nucleophiles. Lewis *et al.* (86) have provided an impressive body of supporting data for application of the Marcus equation to the specific case of methyl transfers in sulfolane solution. Albery (87) has applied the Marcus equations to cation–nucleophile combination reactions, but there appears to be no justification for the application (22), and the results cannot be taken seriously.

One of the interesting features of cation–anion combination reactions is that the reverse reactions, heterolytic dissociation of covalent bonds, take place frequently in solution, but not in the gas phase. In the gas phase, the dissociation of a covalent bond is almost always homolytic. In solution, as a bond begins to stretch, it probably follows a homolytic pathway for some distance before solvent can lower the energy of the heterolytic pathway sufficiently for it to be followed. In the combination reactions, two ions must come together to some critical distance, then an electron-transfer must occur as the distance shortens to that of the bond. For some extreme cases, the combination reaction can obviously become a two-step process in which an electron transfer precedes bond formation (88).

For the reactions discussed here, there is no evidence for a separate electron-transfer step. For some reactions of carbocations with carbanions, however, Arnett and co-workers have observed (57) major, or exclusive, side reactions resulting from electron transfer. For the reactions considered in the present paper, it is almost certain that the electron transfer and bond formation are simultaneous (24). Pross (89) has discussed such "electron shift" processes, and Hoz and Speizman (90) have pointed out the role of the LUMO of the electrophile in these reactions.

These considerations led to an examination of the possible relationship between nucleophilic reactivity and one-electron oxidation potentials for the half-cells:

[16] $X^- \rightleftarrows X\cdot + e^-$

Note that the half-cell in reaction [16] is quite different from that in reaction [14] used by Edwards. Although very few of the potentials for reaction [16] have been measured in solution, it was possible to devise a thermodynamic cycle (24, 90) from which the potentials can be estimated from bond-dissociation energies in the gas phase and acidities in solution of the HX molecules. Some pertinent data for potentials and related solvation energies are shown in Table 6.

Although a surprisingly good correlation of potentials for reaction [16] with reactivities of nucleophiles was originally

TABLE 6. Oxidation potentials and solvation energies of nucleophiles in water[a]

Nucleophile	B.D.E.[b]	E^0, eq. 16[c]	ΔG^{0d}_{sol}
HOO^-	88.6	20.5	−95.0

found (24), later data for more systems, and particularly for non-aqueous solutions, do not confirm the correlation (52). It was pointed out in the original paper (24) that the correlation is not expected on the basis of any of the quantum mechanical theories (90–94) of the reactions. These theories must deal with vertical transitions between states, while the potentials for reaction [16] are for non-vertical, adiabatic, processes.

The fact that solvation energies of ions are frequently on the order of bond energies (see Table 6), and that molecular orbital theories are poorly suited to the problem of such solvation has probably been responsible for the slow development of reasonable quantum mechanical theories of cation–anion reactions. Warshel and Weiss (91) cast the problem in valence bond formalism and presented an approximate treatment for handling the solvation energies. Shaik (92) generalized the valence bond curve crossing model, Pross and Shaik (93) have discussed qualitative features of the model, and Shaik (94) has presented quantitative details of the application of the model to S_N2 reactions. The latter paper by Shaik (94) also details how one may obtain the contributions of solvation in an approximate form. Thus, a quantum mechanical theory of the reactions discussed in this review exists. We may confidently look forward to seeing the details of its application.[2]

Acknowledgements

The work presented here has, continuously since its inception, been supported by grants from the Natural Science Foundation, most recently by Grant CHE 8205767. Less continuous, but significant, support has been provided by NIH-GMS and by PRF-ACS. Initial support was provided by AROD. I am grateful to these agencies.

Professors R. McClelland and S. Shaik have provided me with copies of manuscripts and outlines of ideas before publication. I am grateful for these and for several informative discussions.

C. SANDORFY and D. VOCELLE. Can. J. Chem. **64**, 2251 (1986).

The photochemical step in the functioning of visual and bacterial rhodopsins entails *cis–trans* or *trans–cis* isomerization and changes in the state of protonation of the retinylidene Schiff base chromophore. In this review our present knowledge on these two events is discussed as well as the role of interactions between the chromophore and the surrounding protein, opsin. The relation between protonation and hydrogen bonding at the Schiff base nitrogen, the problems of stabilization of the proton bridge and charge separation are also discussed. A new proposal is made which implies Schiff base to counter-ion proton translocation with concomitant isomerization and reprotonation of the chromophore.

C. SANDORFY et D. VOCELLE. Can. J. Chem. **64**, 2251 (1986).

L'étape photochimique dans le cycle des rhodopsines visuelles et bactériennes comprend de l'isomérisation *cis–trans* ou *trans–cis* et des changements dans l'état de protonation du chromophore, une base de Schiff du rétinal. Nous passons en revue nos connaissances actuelles relatives à ces deux processus et les interactions entre le chromophore et la protéine opsine. La protonation et la formation d'une liaison hydrogène sur l'azote de la base de Schiff et les problèmes de la stabilisation des ions ainsi formés et de la séparation des charges sont également discutés. On propose un nouveau mécanisme qui impliquerait un transfert de proton de la base de Schiff à son contre-ion qui irait de paire avec l'isomérisation et la reprotonation du chromophore.

Introduction

Only humans and animals can see; plants cannot. What a distressing thought that roses, tulips, anthuria, and all those beautiful flowers cannot see each other or themselves! But we can see them. Light is a decisive factor for life: photosynthesis, germination, and growth regulation of plants, vision and many other functions are initiated or conditioned by light. The light receptors are usually pigments; the chromophore is surrounded by a protein whose field and conformation have a decisive influence on its properties and in which lipids, sugar, water, metals also have roles to play. The principal visual chromophore which is a conjugated olefin containing six double bonds is covalently bound to the apoprotein opsin by a Schiff base linkage, forming rhodopsin.

The eye is a bio-optical device in which light of the appropriate wavelength range is focussed onto the site where the Schiff base of 11-*cis* retinal is located. Photons must be absorbed, initiating a photochemical process which must eventually give a signal to the nervous system; then our brain must somehow form an image which has to be read and interpreted. The field of vision research has been opened by the pioneering work of Wald and Hubbard, and their co-workers (1–16), the spectroscopic part of it by Yoshizawa, Wald, and their co-workers (17–21). The light absorbing molecule in the visual process is the Schiff base of 11-*cis*-retinal, a kin of vitamin-A, formed with lysine, an aminoacid of the protein opsin (Fig. 1). This review is only concerned with the photochemical event on which a great deal of information has been accumulated in recent years. The subsequent events in the mechanism of vision are also the object of intensive research. Exciting new developments can be expected in the coming decades.

Why did creation choose the Schiff base of 11-*cis*-retinal?

Conjugated olefins are known for their tendency to undergo *cis–trans* or *trans–cis* isomerization photochemically. It would be astonishing if nature did not use this property of them.

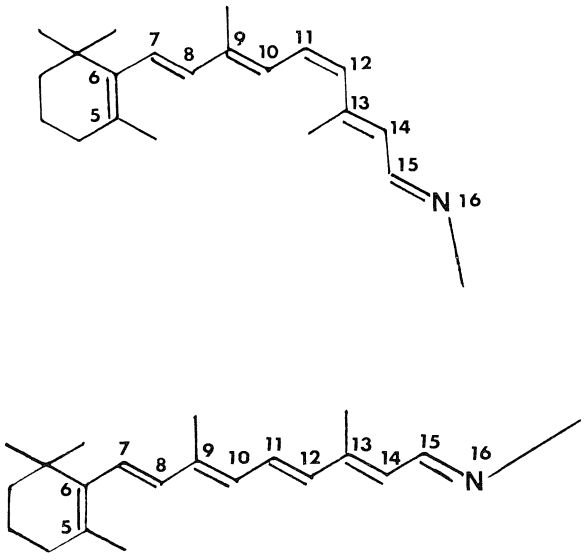

FIG. 1. 11-*cis*-Retinal and all-*trans*-retinal.

The eye is supposed to see light, not heat. Therefore the photochemical event of vision must occur in an excited state which cannot be reached by possible increases in temperature. Retinal derivatives are well suited for this. That *cis–trans* isomerization is the primary step was suggested at an early stage by Yoshizawa and Wald (22).

If this was the only requirement, most conjugated olefins, their aldehydes, alcohols, and other derivatives would be suitable. Why an imine, a Schiff base? The linkup with the protein might be an obvious reason. Another reason might be that nitrogen is needed because it can easily form hydrogen bonds or become protonated. Indeed, Rentzepis and co-workers found evidence for rapid proton transfer in rhodopsin following light absorption (23–25). So both isomerization and proton

transfer can be expected to play an important role in the photochemical event of vision.

A very surprising discovery was made in 1971 by Oesterhelt and Stoeckenius (26, 27). The purple membrane of halobacterium halobium, a bacterium dwelling in salt water, contains a chromophore which turned out to be an isomer of rhodopsin (Rh). Bacteria cannot see; bacteriorhodopsin (bR) functions as a proton pump. It pushes protons across a membrane against a chemical potential gradient using the energy of the absorbed photons. Because of a number of experimental advantages and the possibility of rapid progress much of the present research on rhodopsins is concentrated on bR. During the last few years still other rhodopsins have been discovered and more can be expected. Rhodopsins are devices whose use by nature is more widespread than was originally thought (27–30, 43, and references therein).

Some facts about Rh are intriguing to spectroscopists and photochemists. First, in a test tube in a relatively inert solvent, the Schiff base of retinal has its intense (π,π^*) band of lowest frequency at 370 nm. In human or bovine Rh, however, it is at about 500 nm. Moreover, this wavelength varies from species to species. Some fishes and frogs, for example, can see in the near ultraviolet (up to 350 nm in some cases) (31–35). This amounts to a range of about 350 to 600 nm. In addition to rods which make it possible to see in black and white, the eyes also contain cones which provide for color vision. They contain three or four pigments of different colors in the various animal species.

The remarkable fact is that all these pigments contain Rh as the chromophore. The differences are due to their different conformations and molecular environments, mainly the protein surrounding the chromophore. Only some species contain one more double bond in the β-ionone ring (porphyropsin) conjugated with the six double bonds present in all Rh (30, 36, 37).

Several excellent reviews have been published on rhodopsins (Yoshizawa (20); Honig (38, 39); Ottolenghi (40); Birge (41); Uhl and Abrahamson (42); Stoeckenius and co-workers (43*a*, *b*); Shichi (44); Balogh-Nair and Nakanishi (45); Kliger (46); see also the volume edited by Packer (47)).

The present review does not aim at complete coverage. It is rather intended as a provocative review introducing some unorthodox ideas into the discussion. The problems of isomerization and protonation in rhodopsins are intimately connected. For this reason some repetitions will be inevitable in the following discussions.

The cycles of Rh and bR are known to contain a photochemical primary step leading from Rh to B (bathorhodopsin) and from bR to K, respectively. This is followed by the successive formation of a number of intermediates which differ from one other by isomerism, protonation–deprotonation, and their protein environment. At the end of the cycle, in the visual pigments of vertebrates, the final (all-*trans*) isomer is hydrolyzed down from the apoprotein and is later chemically regenerated. In invertebrates and in bacterial rhodopsins at the end of the cycle the original Rh or bR is regained. The intermediates are usually characterized by the wavelength (in nm) of their visible absorption maxima, and their risetime and lifetime. We reproduce here the schemes relating to Rh and bR based on literature data. The temperatures at which the spectra were taken are also given (Figs. 2, 3).

The initial configuration of the chromophore of Rh is 11-*cis*. In bR it is all-*trans* (light adapted) or about 1:1 all-*trans* and 13-*cis* (dark adapted).

The excited state

The electronic spectra of conjugated polyenes were the object of thorough studies. 1,3-Butadiene can be taken as a school example. In the *trans* conformation which is present in the gas phase, butadiene has a co-planar ground state and C_{2h} symmetry, with a center of inversion. The four π electrons give rise to four π type molecular orbitals. In a first approximation the ground and valence-shell excited states of butadiene are obtained as transitions between these MOs. The ground state is totally symmetrical, ^1A_g while the first excited state is ^1B_u. The $^1A_g \rightarrow {}^1B_u$ transition is allowed and polarized in the molecular plane along the central C—C bond. While the more complicated polyenes present in Rh do not have C_{2h} symmetry this butadiene nomenclature is often used in an approximate sense. The corresponding band has its maximum near 210 nm (about

48000 cm^{-1}) and it is very intense. This preponderance of the first (π,π^*) band is characteristic of the *trans* or approximately *trans* conformation. There is a second $^1A_g \rightarrow {}^1B_u$ band at much higher frequencies. (About 130 nm or 77000 cm^{-1}) (48). The two other (π,π^*) bands correspond to $^1A_g \rightarrow {}^1A_g$ transitions and are forbidden by the Laporte rule for the *trans* polyenes. All this description of the spectrum of *trans*-butadiene is based on the Hückel approximation or SCF MO calculations aimed at the ground state. In 1967, Koutecky (49) drew attention to the fact that when configuration interaction is applied, the two ^1A_g states (obtained in a first approximation) will mix, so that one of them ($^1A_g^-$) moves to lower and the other ($^1A_g^+$) to higher energies. If the mixing is sufficiently large the A_g^- state might become lower in energy than the B_u^+ state and become the first excited singlet state. (The + and − signs refer to the sign in the linear combination resulting from configurational mixing (see refs. 40, 41). Koutecky put forward the idea that this could be so in the case of visual pigments. The photochemical consequences of this can be expected to be very important.

In *cis*-butadiene the situation is different: all four (π,π^*) bands are symmetry allowed, and the one of lowest frequency is no longer the most intense of them.

The importance of the A_g^- problem in the case of butadiene is largely academic. A_g^- does not appear to be the lowest excited state. However, if butadiene has such a low-lying band the higher conjugated polyenes which include retinal derivatives and carotenoids must also have A_g^- type bands. After Hudson and Kohler (50) and Schulten and Karplus (51) a series of investigations were devoted to this problem. It became accessible to experimental research thanks to the rapid development of two photon spectroscopy (see refs. 52–55). Transitions of the g ↔ g type are allowed in two photon absorption spectroscopy. The $^1A_g^-$ state has been shown to be the lowest excited singlet state in long chain linear polyenes (41, 55–65). While actual visual chromophores do not have a center of inversion, they "remember" C_{2h} symmetry sufficiently for transitions from the ground state to $^1A_g^-$-like states to remain weak and transitions to $^1B_u^+$-like states intense in one-photon spectra. On the other hand, the transition from the ground to the $^1A_g^-$ state is the major contributor to the two-photon transition. In EPA (5:5:2 mixture of diethyl ether, isopentane, and ethanol) at 77 K all-*trans*-retinol (61), all-*trans*-retinal (62), and its Schiff base have the $^1A_g^-$-like state at energies lower than the ^1B_u-like state (41, 61–63). The difference is of the order of 2000 cm^{-1}. This seems to apply to both the Franck–Condon maxima and 0–0 bands. Birge and co-workers extended their research to the protonated all-*trans*-retinal Schiff base at room temperature. Then a reversal occurred, the $^1B_u^+$-like state being at slightly lower frequencies. These results, interesting as they are, cannot be directly extended to Rh. Indeed, the order of these bands has been found to be highly sensitive to solvent and environmental conditions. However, Birge, Nakanishi, and their co-workers succeeded in taking the two-photon spectra (in D_2O, at room temperature) of locked-11-*cis*-rhodopsin (64) (Fig. 4). In this molecule the ring introduced at the central double bond makes isomerization impossible, so that this rhodopsin does not bleach. However, the chromophore occupies the same site as in a natural visual pigment with the same counterion environment. The $^1B_u^+$-like band was found to be at significantly lower frequencies than the $^1A_g^-$-like level. This is the opposite trend of what was found for the non-protonated Schiff base or the aldehyde or the alcohol.

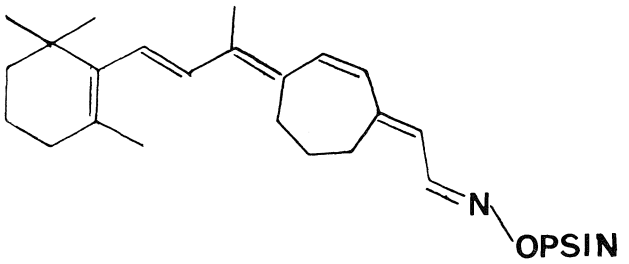

FIG. 4. Locked-11-*cis*-rhodopsin.

Birge *et al.* (64) consider this as a strong indication for the presence of a protonated Schiff base in Rh. It follows that the photochemical cycle of Rh starts in the $^1B_u^+$-like state. Moreover, since the true chromophore does not have C_{2h} symmetry (in a rigorous sense it has no symmetry at all), the excited A_g^- and B_u^+ states might actually mix.

The $^1B_u^+$-like state is a polar state in the valence-bond sense, meaning that resonance structures with large charge separations are predominant in the VB wave function. To the contrary, the $^1A_g^-$-like state is a covalent state (64*a*, 65). This means that the field of the surrounding molecules can affect these two states very differently and that the photochemical reactions occurring in them could also be very different. The $^1A_g^-$ state to which one-photon transitions are rare is a state of long lifetime whereas $^1B_u^+$ is a state corresponding to an intense band with a short lifetime.

As reported above, Birge *et al.* (41, 64*a*) were able to demonstrate that protonation of the Schiff base reverses the order of the lowest excited singlet states, so that $^1B_u^+$ is the lowest. However, according to Murray and Birge (64*b*) hydrogen bonding has the opposite effect; in the presence of methanol, for example, which forms hydrogen bonds with the Schiff base nitrogen the $^1A_g^-$ state is the lowest, actually more so than in retinol or retinal

—CH=N:...H—O—CH_3

(However, Das *et al.* (66) have shown that this H-bond effect is much greater in the excited state than in the ground state.) Since the formation of a hydrogen bond is a situation intermediate between that of the free base and the protonated base, the effect of hydrogen bond formation would also be expected to be intermediate. The reasons why this would not be so in the present case are discussed by Murray and Birge (64*b*) and by Das *et al.* (66).

Birge and Hubbard (67) suggested that the mixing between the $^1B_u^+$ and $^1A_g^-$ states is responsible for producing a barrierless excited state potential energy surface for *cis–trans* isomerization and that the extremely rapid formation of bathorhodopsin may be a consequence of the photochemical lability of the $^1A_g^-$-like state. They used the INDO-CISD method, a semi-empirical molecular orbital technique including a respectable amount of configuration interaction with both singly and doubly excited configurations combined with molecular dynamics calculations to investigate the *cis–trans* isomerization of Rh. They demonstrated that *cis–trans* isomerization around the 11–12 double bond can occur with high quantum efficiency (about 0.6) in approximately 2 ps. The mixing with the A_g^--like state into the largely ionic B_u^+-like state increases the covalent character of the latter. As a consequence, after photon absorp-

tion, a steep potential well with an energy minimum at a dihedral angle $\theta(11,12) = 90°$ is produced during the subsequent isomerization process. This amounts to the formation of an activated complex which preferentially decays to a distorted all-*trans* isomer. The barrier to isomerization is negative in the excited state. Moreover, Birge and Hubbard's calculations have shown that in the photochemical step leading from Rh to B, the lysine residue undergoes a conformational distortion which may distort the chromophore in B, preventing it from reaching a planar all-*trans* conformation. The calculations have also demonstrated the role of the counter-ion (near the C=N bond) in increasing the barrier to thermal ionization in the ground state. Furthermore, the location of the counter-ion is critical and the increase or decrease of the photochemical isomerization time is dependent on it (67).

A different approach was taken by Becker and Freedman (68) who studied photoisomerization quantum yields of 11-*cis*-retinylidene-*n*-butylamine and its protonated counterpart as a function of the nature of the solvent. For the Schiff base the quantum yield (ϕ) varied from 0.01 in hexane to 0.34 in acetonitrile. A hydrogen bonded complex with hexafluoroisopropanol had the high value of 0.31. It is interesting to note that this proton donor has the same effect as acetonitrile, a polar molecule with no hydrogen capable of H-bonding. For the protonated Schiff base they found a quantum yield equal to about 0.24, practically independent of solvent. This shows that protonation is not a prerequisite for *cis–trans* photoisomerization in a polar environment. Only in non-polar solvents does protonation increase the quantum yield. Becker and Freedman (68) interpret these variations in quantum yield by increased $B_u^+ - A_g^-$ mixing as a function of increased polarity of the environment. According to their results A_g^- does not especially promote isomerization; it would seem rather that B_u^+ facilitates it more. Both Birge and Becker agree, however, that the mixing of the two states is essential for promoting *cis–trans* photoisomerization. According to Becker the pK_a of the Schiff base and the negative charge on the nitrogen increase upon excitation with no twist; the charge density decreases upon twisting to 90° (68). Contrary to previous observations they found that the quantum yield (ϕ) for the protonated 11-*cis* Schiff base is independent from the excitation wavelength from 355 to 532 nm. This is the same behavior as that of Rh itself (70–72).

Becker *et al.* (68, 69) made the proposal that "... the primary photostep in vision involves the proton coming off in the excited state during the twisting to ~90° onto one site of the protein and returns from another site of the protein after relaxation to and twisting in the ground state from ~90° to whatever angle is appropriate to B". They also found a non-excited state transient in the photoisomerization reaction of the 11-*cis* Schiff base but not for the protonated Schiff base.

It appears then that the role of protonation (or hydrogen bonding, or a polar environment) is mixing together the $^1A_g^-$-like and $^1B_u^+$-like excited states thereby opening the way to photoisomerization with a high quantum yield.

In a subsequent paper, Freedman and Becker (68*b*) examined the 9-*cis*, 11-*cis*, 13-*cis*, and all-*trans* isomers, both unprotonated and protonated. Their results show that for the protonated species only the 11-*cis* isomer efficiently isomerizes, more than five times than the 9-*cis* or 13-*cis* isomers. This helps in understanding nature's choice of the 11-*cis* isomer. Their results on the unprotonated species show that a polar or hydrogen bonding environment must be provided for efficient isomerization.

An idea which appears to be complementary to the above was put forward by Leclercq and Sandorfy (73). The photochemically active excited state should have an appreciable amount of charge transfer character.

The electron donor is presumed to be a carboxylate group which could be either the primary counter-ion or a secondary counter-ion placed in the vicinity of the chromophore. The HOMO of the carboxylate ion containing the additional electron is a nearly non-bonding orbital while the LUMO is a low-lying empty π^* orbital of the Schiff base. Leclercq's calculations (73) by both the semiempirical CNDO/S and *ab initio* 6-31G methods have shown that upon protonation the lowest unoccupied molecular orbital undergoes a spectacular lowering in energy. (A hydrogen bond at the Schiff base nitrogen would also do this but to a lesser extent.) In consequence a new charge transfer state may exist, the transition to which from the ground state giving rise to absorption at low energies. Much depends on mutual chromophore – counter-ion separation and other geometrical and environmental conditions. It is also possible that without having a separate charge transfer state, the existing excited states acquire a significant CT character. Since no CT band has been identified so far this latter possibility is more likely. The problem should be further explored.

Triplet excited states do not seem to play any role in the photochemistry of vision. The reason that can be given for this is the low yield of singlet–triplet internal conversion. (For a discussion of this problem see Ottolenghi's review (40) and references therein.) The same seems to apply to the (n,π^*) and Rydberg excited states which are expected to be at frequencies higher than those of the $^1B_u^+$ and $^1A_g^-$ bands (74).

Isomerization

Since Rh uses 11-*cis*-retinal as a chromophore and since all-*trans*-retinal is ultimately obtained in the process of vision, at least one isomerization did occur during the bleaching of the visual pigment. In 1958, Hubbard and Kropf put forward the idea (15) that the isomerization of the 11-*cis* bond of the retinal Schiff base to *trans* occurred in the primary step, at the photochemical stage. The main reason supporting this proposition came from the fact that immediately after the light has struck rhodopsin the following equilibrium is produced (17):

$$\text{Isorhodopsin (9-}cis\text{)} \rightleftharpoons \text{bathorhodopsin} \rightleftharpoons \text{rhodopsin (11-}cis\text{)}$$

More recently it was found that 7-*cis* Rh could be included in the same equilibrium (75).

It was reasoned that since B is an intermediate of both 9-*cis*- and 11-*cis*-retinal derivatives, its structure must be all-*trans*. This became one of the key paradigms regarding the primary event in vision. The conclusion then was that the photoconversion of Rh to B meant the isomerization of the 11-*cis* double bond to a *trans* configuration.

This idea has been supported by data presented by Rosenfeld *et al.* (70), Green *et al.* (77), and Monger *et al.* (78). However, the validity of the argument has been weakened when Spalink *et al.* obtained evidence to the effect that the B formed from 9-*cis*-Rh is not the same as the B of 11-*cis*-Rh (25, 79). For this they used a 25 ps, 532 nm pulse at 85 ps after excitation of the 9- or 11-*cis* Rh sample. This is much more than the time needed for the Rh → B transformation and much more than the time needed for the transformation of B into the next intermediate, lumirhodopsin. The obtained visible absorption spectra are not very different, however, so that the assignment of a distorted all-*trans* configuration to B is still reasonable.

Simultaneously, several research groups used resonance Raman techniques to investigate the structures of Rh, isorhodopsin, and B. Among these, Oseroff and Callender published a work very often cited (76). Using low temperature (80 K) laser irradiation within the visible absorption band, they obtained well-defined photostationary states of Rh, isorhodopsin, and B. In order to distinguish between these three compounds, they used a double wavelength pump–probe technique (one laser creates a resonance Raman effect, the second changes the composition of the photostationary state). By this method, they were able to show that Rh, isorhodopsin, and B were all protonated (the C=N band at 1655 cm^{-1} shifts to 1630 cm^{-1} upon deuteration) and that B had three relatively intense bands at 856, 877, and 920 cm^{-1}. Since the fingerprint region of B differed markedly from that of both all-*trans*-retinylidene and 11-*cis*-retinylidene Schiff bases, they suggested that the retinylidene chromophore assumed some intermediate conformation between a *cis*- and a *trans* configuration (10). In similar works but using deuterated retinal isomers, Eyring *et al.* (80–82) were able to assign these three bands to CH out-of-plane wagging vibrations. They concluded that B had a perturbed all-*trans* configuration and that it is protonated.

The saga of the resonance Raman assault on Rh and bR started with the assignments made for "vitamin-A type molecules", among them *trans*-retinal, by Rimai, Gill, and Parsons in 1971 (83). A rather complete resonance Raman and infrared study was presented in 1978 by Cookingham *et al.* (84) on a number of retinals and their Schiff bases. The knowledge of the spectra of retinals, their Schiff bases and protonated Schiff bases is a prerequisite for the interpretation of the spectra of Rh and bR themselves and those of their intermediates. A representative list of references is found in a recent paper by Smith *et al.* (85), many of them due to the groups of Mathies, Lugtenburg, and Stockburger. We can only quote some of the most recent ones which are of direct importance from the point of view of this review: Eyring *et al.* (80) on the hydrogen out-of-plane vibrations in Rh and bR; Mathies on the conformation of retinal in Rh and in isorhodopsin (86); Eyring *et al.* on B (81); Braiman and Mathies on all-*trans* to 13-*cis* isomerization in bR (87, 88); Curry *et al.* on all-*trans*-retinal (89); and on 13-*cis*-retinal (90); Lugtenburg (91), and Pardoen *et al.* (92, 93) who synthesized series of highly useful labelled molecules; Smith *et al.* on the determination of the retinal Schiff base configuration in bR (85, 94); and Stockburger *et al.* (95) on bR and intermediates in its photochemical cycle, Massig *et al.* on all-*trans*, 13-*cis*, and 3-dehydroretinal (96) and Hildebrandt and Stockburger (97) on the role of water in bR's chromophore.

This list is by no means exhaustive. These investigations have shown that, as stated above, the chromophore of Rh, the protonated Schiff base of 11-*cis*-retinal is photochemically transformed into a distorted all-*trans* isomer in becoming B while the all-*trans* chromophore of light-adapted bR_{568} becomes 13-*cis* in the intermediate K. With the help of detailed normal coordinate analyses very secure assignments were made.

Originally, B was thought to be more unstable than Rh by some 5 to 13 kcal/mol (70). Cooper, in 1979 (98), was able to demonstrate by photocalorimetry that there existed a difference of 35 kcal/mol between B and Rh. Boucher and Leblanc (98*b*) have recently confirmed this value using photoacoustic spectroscopy. Since a simple *cis–trans* isomerization process could not explain such a large energy difference, new mechanisms were proposed (67, 99–101). Important contributions came from Nakanishi and Honig's groups (102–110). After hydrogenating sequentially every double bond of retinal and preparing the related synthetic visual pigments, they were able to show that the 11-*cis*-retinylidene Schiff base was protonated (existence of a salt bridge) and that a second external charge was located near C11–C13. The structure of B consists in a strained all-*trans*-chromophore where the salt bridge was broken and a charge separation had occurred (99). This charge separation is mainly responsible for the high energy of B (see below).

Charge separation without solvent stabilization being unlikely in a polar solvent, a non-polar environment was proposed. This mechanism has been widely acclaimed but criticism came fast also. Warshel in a series of papers (100, 111, 112) argued that the environment surrounding the ion-pair in Rh could not have a low dielectric constant since in such a milieu, a salt bridge should revert to a molecular form.

Since in a medium having a low dielectric constant a salt bridge could not exist between a weak base and a weak acid and since in a polar environment a charge separation is unlikely to occur, Warshel proposed an alternative. In Rh, a salt bridge is present in a polar environment; under the action of light, there is a *cis–trans* isomerization which moves the positive nitrogen of the Schiff base out of the salt bridge and into a non-polar environment so that an effective charge separation has occurred. Based on the works of Blatz's group (113), the increase in the distance between the iminium and its counter-ion should induce a red shift which is in concordance with what is observed.

The *cis–trans* isomerization process in the visual pigments was also proven in a more indirect way. Nakanishi's group synthesized 11-*cis*-locked chromophores such as the aldehyde shown in Fig. 4. This aldehyde (and many others, also locked) could form with opsin a synthetic pigment. This pigment was non-bleachable; that is, it could not be transformed into analogs of B, lumirhodopsin or meta I and meta II, rhodopsins. The conclusion was then given that the 11-*cis* bond is crucial to the visual cycle: it must be able to isomerize to a *trans* entity in order to have a bleachable pigment.

The C=N bond in the chromophore can also exist in a *syn* or *anti* configuration (Fig. 5). This possibility has not been fully exploited and only a few works or ideas have been submitted on the role that this isomerization could play in the mechanism of vision. Oesterhelt in 1973 (114) and Warshel (115) in 1976 have discussed this possibility and so has our group (116). It is important to recognize the role that *syn–anti* isomerization of the imine function could play in the mechanism of vision. As stated earlier, Warshel proposed that there is a charge separation occurring at the photochemical stage because isomerization of the 11-*cis* bond to a transoid configuration transfers the chromophore into a new environment, namely from a polar to a non-polar milieu. If, in addition, the likely *anti* configuration of the Schiff base could isomerize to a *syn* configuration, the environment surrounding the imine bond could well be completely different. Such an isomerization was detected recently by Harbison *et al.* (117). Using ^{13}C solid state nmr and MASS technique, they were able to show that lyophilized dark-adapted bR is composed of a mixture of all-*trans*, 15-*anti* (*E*), and 13-*cis*, 15-*syn* (*Z*) isomers. From this work it appears that the configuration around the C=N bond is of the utmost importance.

Finally the same group has shown (118) that in bR, the chromophore takes a 6-s-*trans* conformation, and that there are possibly three charges which are interacting with the polyenic chain. First, there is the counter-ion of the Schiff base; then

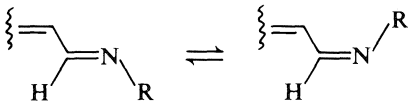

FIG. 5. *Syn–anti* isomerization of Schiff bases.

there is a negative charge near the ionone ring in conformity with the proposal of Nakanishi *et al.* (104). The third charge could be the counter-ion of the negative charge. The positive charge would be located near the C_7—C_8 double bond.

Interactions between opsin and the chromophore

As already stated in the Introduction the frequency of the $^1B_u^+$ band varies a great deal from one animal species to another and between rod and the different cone pigments and it is, in almost all cases, very different from the frequency of the isolated chromophore. This poses the problem of frequency regulation in visual pigments as well as in bacterial Rh. In view of the great importance of the $^1A_g^-$ state for the photochemical reaction of Rh it would be very desirable to know if the species to species changes of the frequency of this state parallel or not those of the $^1B_u^+$ state. However, most of the two-photon work known to us was done on bovine Rh. The knowledge of the $^1A_g^- - ^1B_u^+$ separation could be helpful in assessing the differences in the mechanism of vision from species to species. In the meantime, comparisons between unprotonated and protonated Schiff bases may serve as a guide.

Wavelength regulation can only be achieved by the protein opsin which surrounds the chromophore. (However, the possibility of interaction of the chromophore with the lipid membrane should not be dismissed lightly.) The protein contains a number of ionic and polar groups whose field affects the chromophore. One of them which we call the primary counter-ion, is expected to be hydrogen bonded to the protonated nitrogen of the Schiff base. Protonation alone would explain only a part of the bathochromic shift (see ref. 119 and references therein). So an additional effect is needed. In human or bovine Rh the maximum of the band is near 500 nm.

A fundamental proposal was made at an early stage (1958) by Kropf and Hubbard (15, 16). They suggested that the polar groups of the protein, like COO^-, O^-, S^- could act with their fields upon the Schiff base pushing down the $^1B_u^-$-like state. This idea is at the origin of the external point charge model. In 1968 Wiesenfeld and Abrahamson (120) carried out quantum chemical calculations using a simple model of point charges and the Pariser–Parr–Pople method. They were able to substantiate Kropf and Hubbard's suggestion. Their calculations indicated that the most appropriate place for the polar group is in the vicinity of carbons 5 to 9. We shall call it the secondary counter-ion although it might be actually a properly oriented dipole. Other theoretical results giving strength to Kropf and Hubbard's suggestion came from Abrahamson and Wiesenfeld (121) and Mantione and Pullman (121), Honig *et al.* (123), and Favrot *et al.* (124, 125).

Nakanishi, Honig, and their co-workers (102–110) have greatly developed the external point charge theory. Nakanishi's group prepared a number of synthetic retinals and dihydroretinals in order to secure clues for the location of the point charge. These dihydroretinals can be assumed to bind to the apoprotein in conformations that closely mimic that of the native chromophore (see previous section). Bovine Rh was used in the experiments. The wavelength of their $^1B_u^+$-like absorption maxima was compared to their respective solution values, the difference being the opsin-shift. Methanol was chosen as a solvent (104, 110), since λ_{max} in this solvent is independent from the counter-ion ("levelling effect", Blatz and Mohler (126)). This is not an ideal choice, since methanol as a polar, hydrogen bonding solvent promotes protonation that is, helps to push the proton onto the nitrogen in a salt bridge. However, provided the Schiff bases are 100% protonated anyway this does not make much difference. The opsin shift turned out to be 2700 cm^{-1} for the protonated Schiff base of 11-*cis*-retinal itself, about 1700–2100 cm^{-1} for the 5,6 or 7,8 or 9,10 dihydro compounds and 5300 cm^{-1} for the 11,12 dihydro compound (105, 127). In the latter molecule the insulation effect of the saturated-CH_2—CH_2-group reduces the chromophore to a diene. Thus a point charge placed in proximity of the 11,12 double bond is seen to cause the largest opsin shift. (Interestingly, Honig's calculations show that this can be obtained by a negative charge near C14 or a positive charge near C15). Both the relatively large shift of the 11,12 dihydro derivative and the smaller shift of the native chromophore can be explained by placing a negative charge in the C12—C14 area, 3 Å from C12 and 3.4 Å from C14 (127). This applies to (bovine) visual pigments. Similar data for bR lead to the conclusion that the external negative charge is located in the vicinity of the β-ionone ring. The carboxylate ions which are likely to be the point-charges cannot be considered as exact point charges. They actually contain two negative oxygens and one positive carbon. It is even possible that the primary counter-ion and the external point charge are two oxygen atoms of the same carboxylate ion (127, 128).

Much of our present thinking on the effect of counterions and wavelength regulation goes back to Blatz's pioneering work which will now be reviewed in some detail.

Following initial studies by Morton *et al.* (130–133) Blatz used model compounds (usually all-*trans* retinylidene *n*-butylamine, NRBA), different acids (mostly mineral acids like HCl), and various solvents in order to mimic Rh. For these systems he tried to correlate the variation of the λ_{max} of NRBA with the different acids and to assess solvent effects. In this last respect, using perchlorate salts of NRBA, Blatz *et al.* (113) showed that ion-pairs existed in a non-polar solvent (like chloroform) while in a polar one (like methanol), the cation (the protonated imine) and the anion (ClO_4^-) were fully solvated. With polar solvents, no ion-pairs were present and the λ_{max} of protonated NRBA remains the same irrespective of the polar solvent used (which cause a "levelling effect"). By varying the acid and choosing proper solvents (like 1,2-dichloroethane) Blatz *et al.* were able to obtain uv–visible absorption spectra quite similar to those obtained from a digitonin extract of bovine Rh.

After noting the very important red shift associated with linear conjugated odd-numbered alternant hydrocarbons compared to those which are even numbered (134–137), Blatz and co-workers tried to correlate the λ_{max} of protonated NRBA with some physico-chemical properties of the counterions (113, 138, 139). Using ionic radii, they were able to calculate the ionic electrostatic interaction that existed between the protonated imine function and the counter-ion (viz. —CH=$\overset{+}{N}$—H----X^-). They noted that λ_{max} of NRBA correlates fairly well with the strength of the acids and most importantly that it was the distance from the anion that regulated the λ_{max} of the cation. From this work, Blatz inferred that the protein part of the visual pigments could possibly regulate the absorption wavelength of the chromophore by moving the site of the negative charge density away from or nearer to the cation by conformational change.

Blatz has used systems where the Schiff base is protonated by

very strong acids (like HCl) and only in a few cases did he use a carboxylic acid. The protonating agents in the protein could come from different sources but the terminal carboxylic acids of aspartic and glutamic acids are likely candidates. These are weak acids (pK_a of 3.86 for Asp and 4.25 for Glu) and, in a non-polar environment, protonation of the chromophore could well be different. Furthermore, Rafferty and Shichi (140) and Hildebrandt and Stockburger (97) have shown that water molecules are in the proximity of the azomethine function. It must be said again that in a polar environment, charge separation without solvent stabilization is unlikely. Warshel and Barboy (100) have proposed an interesting alternative. They see the chromophore in a polar milieu but isomerization causes a movement that carries it into a non-polar environment. This would explain the red shift observed when Rh is transformed into B or bR into K. The behavior of weak carboxylic acids toward conjugated Schiff bases has been explored by us since no systematic studies existed on the subject. In works similar to those of Blatz, we tried to evaluate the interaction of several carboxylic acids of pK_as ranging from 0.2 to 4.8. We chose substituted acetic acids (XCH_2CO_2H) as protonating agents, chloroform and methanol as solvents and two different Schiff bases: *trans,trans*-2,4 heptadienylidene *tert*-butylamine (HtBA) and all-*trans* retinylidene *tert*-butylamine (RtBA). In a series of articles (141–143) we have shown that, in a non-polar solvent, weak carboxylic acids are not able to fully protonate a conjugated Schiff base. Actually, with acids in the 4.5 pK_a range, hardly any protonation can be observed. Weak acids can protonate the imine when the solvent is polar but then solvation causes a levelling effect. With moderately strong acids (pK_a = 2–3), only partial protonation is found while with strong acids such as trichloroacetic acid (TCA; pK_a = 0.6), complete protonation is observed. In the last case, in a non-polar solvent, ^1H nmr indicates rapid proton exchange between the Schiff base and the counter-ion. At −40°C, the exchange has stopped and only the protonated imine is obtained. ^{13}C and ^{15}N nmr data (144) indicate that protonation is related directly to the strength of the acids used. Infrared data obtained on the same systems lead to similar results (see below).

In conclusion, no definite answers have been given as to how the protein opsin can shift the λ_{max} of the 11-*cis*-retinylidene chromophore to longer wavelengths and how it can regulate it. But Blatz's observation concerning the salt bridge is pertinent even though the exact nature of the interactions remains to be elucidated. More must be known of the environment surrounding the chromophore for the exact mechanism to be unraveled.

The main problem could be stated in a few words: are point-charges the most important factor for wavelength regulation in Rh or is it the Blatz-effect (regulation by the distance Schiff base – counter-ion) which can govern the distribution of the positive charge in the conjugated system?

Protonation

As mentioned previously, protonation of the Schiff base in Rh has been invoked primarily to give an explanation for the surprising long wavelength absorption of most Rh. But could this shift not be explained otherwise?

Leclercq (see Favrot *et al.* (125)) carried out CNDO/S model calculations on the retinal Schiff base by placing a proton donor at the nitrogen and a carboxylate ion close to the β-ionone ring at C5. The result was that the observed absorption wavelength can be matched by placing the two counter-ions in such a way that the $N_{16}\ldots H^+$ distance is 2.0 Å and the C5—C (carboxylate) distance is about 3.10 Å or shorter. With an $N_{16}\ldots H^+$ distance of 2.0 Å the Schiff base is not protonated but "only" hydrogen bonded. This indicated that outright protonation is not an absolute prerequisite for interpreting the absorption spectra of Rh. The visible absorption spectrum is not, in itself, a proof for protonation.

Moreover, there is at present ample evidence that both protonated and non-protonated Schiff bases can "bleach", that is, undergo photoinduced isomerization yielding a colorless product (see below).

A wealth of infrared spectroscopic data and other physicochemical evidence show that whenever a nitrogen base is protonated the proton remains hydrogen-bonded to the "original" proton donor, or in other words, there must be a counter-ion, X^-:

$$C{=}N^+{-}H{\cdots}X^-$$

or, if the original proton donor was itself protonated:

$$C{=}N^+{-}H{\cdots}X$$

As a consequence of this a tautomeric equilibrium is likely to exist at the Schiff base nitrogen:

$$C{=}N{\cdots}H{-}X \rightleftharpoons C{=}N^+{-}H{\cdots}X^-$$

In the $^1B_u{}^+$ excited state the Schiff base can be expected to be more basic than in its ground state. This expectation is based on Förster's experiments (145), Becker's observation of a large pK_a change in the excited state (69), and on dipole moment measurements in the ground and excited states by Mathies and Stryer (146) and by Corsetti and Kohler (65).

Since this is so, chemical intuition would predict proton transfer in the excited state with only a H-bond on the Schiff base in the ground state. This interpretation could not apply, however, if the Schiff base was initially protonated.

The fact that there must be a counter-ion at the Schiff base nitrogen has been recognized by Schaffer *et al.* (69), Honig *et al.* (147), Peters *et al.* (24), and Favrot *et al.* (124, 125). If the equilibrium is 100% in favor of the $C{=}N^+{-}H$ form one can say that the Schiff base is entirely protonated. Even then the remaining "back-H-bond" (with X being probably a carboxylate ion) is important for shaping the structure and the spectrum of the chromophore. Moreover, even a, say, 10% departure from 100% protonation could have serious consequences for the functioning of the pigment. Protonated amines or imines without a counter-ion, in general, do not exist in nature, except as very short-lived transients. There is little doubt about the existence of what we called a primary counter-ion at the Schiff base nitrogen. The identity of the proton donor is not definitely known, however. It is very likely that it is either aspartic or glutamic acid, since according to our present knowledge on the structure of the protein in bR (148–157) such residues are found close to the chromophore.

That the Schiff base is protonated is, at present, a widely accepted view.

Raman arguments played an important role in the investigations relating to the structure of the chromophore in Rh. The Raman $\nu(C{=}N)$ band is at 1655 cm^{-1} in bovine Rh while the related band of the Schiff base itself is at about 1625 cm^{-1} (76, 158). This increase in frequency is expected if the Schiff base is protonated, not because of the charge displacements connected with protonation but on the ground of mechanical interactions, in particular the mixing of $\nu(C{=}N^+)$ with the NH^+ in-plane bending motion (99, 159). If the NH group is deuterated this mixing is largely reduced and the $\nu(C{=}N^+)$ band shifts downwards to about 1630 cm^{-1} (76). This is usually

taken for a strong indication of protonation. Less direct evidence to this effect comes from the detailed study of the CH and NH out-of-plane bending vibrations (80, 81, 85). The argument would be even more convincing if the bathochromic shifts in the electronic spectrum and the shift towards higher frequencies in the Raman spectrum would show parallelism. Unfortunately, this does not seem to be the case. For example, with visible bands at 568 and 610 nm respectively, bR and K must be assumed to be protonated. However, their ν(C=N) bands are at frequencies as low as 1641 and 1610 cm^{-1}, the latter being lower than that of an unprotonated Schiff base.

Support for protonation came also from infrared investigations. Indeed, since the most characteristic vibrations of the chromophore are due to polar bonds or groups, at first sight infrared spectroscopy should be a better means of gathering information concerning its structure than Raman where intensities are conditioned by the rate of change in polarizability, not that of the dipole moment. However, resonance Raman can, so to say, lift out the chromophore from the protein, an advantage that infrared does not have. In recent years, however, differential infrared techniques have been worked out in the laboratories of Rothschild (160, 161), Siebert (162–164), and Eisenstein (165–167) by which they were able to obtain infrared spectra of the chromophore despite the overwhelming absorption of the surrounding protein. In all cases which were investigated the infrared spectra confirmed the results obtained by resonance Raman spectroscopy.

The question of protonation in Rh and bR has been studied also by ^{13}C and ^{15}N nmr. This form of spectroscopy seems ideally suited for probing the extent of protonation in visual and bacterial pigments since it is a non-destructive method using low excitation energy that permits examination of molecules in their ground state. ^{13}C shifts, it must be remembered, are sensitive to pH variations, to fields induced by charged groups and by steric interactions (168). ^{15}N nmr is even more suited for answering the question at hand since there is a very large upfield shift of some 150 ppm between unprotonated retinal Schiff bases and protonated ones (169, 170).

Mateescu and co-workers using enriched ^{13}C Rh and bR as well as ^{15}N enriched Rh and bR arrived at the conclusion, that with a single exception (the case of ^{13}C-enriched retinal at C14), solubilized Rh and bR had signals close to those of model protonated N-retinylidene alkylamines (ref. 171 and references therein).

Harbison *et al.* also used the same technique of ^{13}C and ^{15}N enriched Rh and bR and by solid-state ^{13}C magic-angle sample spinning (MASS) nmr arrived at the same conclusion (117, 172–175) concerning the protonation of the Schiff base. These studies show that the Schiff base is protonated and that it is hydrogen bonded to the counter-ion, the strength of the hydrogen bond being similar to what a protonated Schiff base would form with an iodide ion (118). One may comment that while this hydrogen bond is weaker than those formed with Cl^- or Br^-, it is much stronger than those which would be formed with carboxylic acids without an additional mechanism of stabilization.

So let us agree that the Schiff base is protonated prior to light absorption. Even then some important questions remain to be answered: (*1*) Is the Schiff base entirely protonated, that is, is the tautomeric equilibrium at the nitrogen 100% in favor of the protonated species? (*2*) How is the ion-pair stabilized in the salt bridge? (*3*) How does the proton translocation observed by Rentzepis occur?

Protonation and hydrogen bonding

The first question entails what, in our opinion, is the fundamental problem: what is the shape of the potential surface governing the motions of the proton on the Schiff base nitrogen? The shape of the potential in hydrogen bonds, in particular those within ion pairs, received a great deal of attention. (For reviews see refs. 176–185). The potential may have one or two minima. It can be asymmetrical single well (as), asymmetrical double well (ad), symmetrical double well (sd), or symmetrical, broad single well (ss). An (as) or (ad) type potential with the proton in the deeper well at covalent distance from the Schiff base nitrogen means protonation. With the proton closer to the original donor (X), the Schiff base would be merely hydrogen bonded. A proton close to the midpoint ($N\cdots H^+\cdots X^-$) with an (sd) or (ss) type potential would mean a nearly symmetrical, usually strong and short hydrogen bond. There are examples for this even in cases where the two end atoms are different (176). It is much more likely, however, that the hydrogen bond is only nearly symmetrical with a double well potential, both wells having significant population. Then this would be the case of a "hesitating" proton with a possibility of rapid exchange between the two wells either thermally or by tunneling. Is such a situation probable in the case of Rh?

Zundel and co-workers (179, 186–191) investigated extensively, by infrared spectroscopy, systems in which the proton is close to the midpoint. They have shown that these "easily polarizable hydrogen bonds" are highly sensitive to environmental effects and since, in a random medium, these are variable, broad areas of continuous absorption are found in their spectra, especially in the O—H or N—H stretching region. This part of the spectrum, together with the NH bending bands, should be of diagnostic value for elucidating the problem of protonation. It is unfortunate that neither the Raman nor the differential infrared spectra make it possible to obtain them. For this reason model studies are of value for gaining knowledge on the protonation of Schiff bases. Certain aspects are seldom discussed in the context of Rh research, so we will go into some detail.

Favrot *et al.* (125, 192) took isobutylidene–isopropylamine, $(CH_3)_2CHCH{=}NCH(CH_3)_2$, a simple non-conjugated Schiff base as their model. This aldimine is stable due to the branched substituents on both the carbon and the nitrogen of the double bond (Thiollais (193)). The free ν(C=N) band is at 1664 in chloroform solution. With a weak acid like CF_3CH_2OH the spectrum was in line with C=N:---HO— association. With an *excess* of $(CF_3)_3COH$, a much stronger acid, the high value of ν(C=N), 1704 cm^{-1} and the low value of the broad ν(OH) stretching band, centered at 2530 cm^{-1}, gives evidence of much stronger association, $C{=}N^+{-}H\ldots{:}O^-$ or $C{=}N\cdots H^+{-}O^-$. However, when the imine was in excess the ν(C=N) band at 1664 cm^{-1} became more intense than the 1704 cm^{-1} band, showing that the equilibrium can be easily tilted in favor of C=N:---H—O—.

Many other examples were given in ref. 125. It is readily demonstrated that if the counter-ion was an aliphatic amine it would take the proton from the Schiff base; if it contains another C=N, like pyridine or the imidazole ring of histidine, for example, it would probably share the proton with the Schiff base; if it was a carboxylic acid, then all will depend on the strength of the acid.

According to our present knowledge, in Rh the proton donor (the primary counter-ion) is probably aspartic or glutamic acid which are somewhat more acid than perfluorotert–butanol in the

above example. Thus Lussier *et al.* (194) have undertaken a systematic study of protonation – hydrogen bonding conditions with a series of carboxylic acids and hydrochloric, hydrobromic, and hydroiodic acids.

The carboxylic acids used were trichloro-, dichloro-, monochloro-, monobromo-acetic acids and 3-chloropropionic- and propionic acid whose pK_a values (in water) are 0.66, 1.26, 2.85, 2.90, 3.99, and 4.87, respectively. (The corresponding pK_a values for aspartic and glutamic acids are 3.86 and 4.25.) All the spectra exhibit Zundel continua in the 2700–2000 cm^{-1} region, except that for the weakest acid (propionic) and the strongest acid (trichloro) they are weak. For non-conjugated Schiff bases the $\nu(C{=}N^+)$ bands are between 1708 and 1712 cm^{-1} and the (non-protonation) $\nu(C{=}N)$ bands are at 1667 cm^{-1}. The relative intensities of these two bands vary with the pK_a of the acid. The estimated percentages of protonation based on the band areas were found to be 90–95% for trichloroacetic acid, 80–90% for dichloroacetic acid, 75–55% for monochloro-, and monobromo acetic acids, and 10–20% for propionic acid. (For 1:1, 0.1 *M* solutions in chloroform.)

Non-conjugated Schiff bases are rather remote models for Rh, however. Thus, subsequently Lussier *et al.* (195) carried out similar infrared investigations on *trans*-retinal in chloroform. The percentages of protonation increased with respect to the non-conjugated imines. The approximate percentages of protonation obtained were 100% for trichloroacetic acid, about 80–90% for monochloroacetic acid, 60–70% for 3-chloropropionic acid, and 10–20% for propionic acid. Thus a significant fraction is still unprotonated. The continua in the 2700–2000 cm^{-1} region indicate that for the medium strong acids the proton is close to the midpoint of the proton bridge.

Previously Zundel and Merz (191) and Rastogi and Zundel (196) considered hydrogen bonds between retinylidene butylamine and various carboxylic acids and in a number of other model systems to see whether such hydrogen bonds show large proton polarizability and to determine the equilibria. If the proton is close to the midpoint, it can be easily shifted by electric fields due to the large proton polarizability of such hydrogen bonds. Zundel suggests (197, 198) that this is the case, among others, of protonated Schiff base/aspartate or phenolate systems. Hydrogen bonded chains with large proton polarizability could be important for the conduction of the positive charge in bR and in the proton pumping mechanism.

Should we definitely admit the 100% initial protonation of the retinal Schiff base chromophore in Rh and in bR?

The agreement of the resonance Raman and differential infrared values for $\nu(C{=}N)$ for all Rh and the results provided by nmr measurements appear to be convincing. In addition, it is noteworthy that the frequencies for Rh, B, and isorhodopsin are essentially the same. These are the three isomers which are in equilibrium when a photostationary state is produced upon illumination of Rh at low temperatures. At first sight this would mean that the state of protonation is the same for the three, that they are all protonated and that the strength of the back-hydrogen bond in the proton bridge is also the same. Caution should be exercised, however. The $\nu(C{=}N^+)$ frequency is obtained by compensation between two main effects. First, upon protonation a new chemical bond is created on the Schiff base nitrogen rendering $\nu(C{=}N)$ a less good "group frequency". This would be expected to *lower* its frequency. Second, the normal coordinate which entails C=N stretching motion as its dominant component will receive N^+—H in-plane bending (and other) admixtures. Since the mainly N^+—H in-plane bending vibration is almost certainly at about 1350 cm^{-1} (85, 96) this would push $\nu(C{=}N)$ to higher frequencies (85, 199). (It is noteworthy that the C_{15}—H rocking band is at almost the same frequency.) Now, since this is so, the uniform $\nu(C{=}N^+)$ might not correspond to the same potential, average proton position and charge distribution in the proton bridge. This is clearly illustrated by the recent differential infrared experiments of Bagley *et al.* (167). These researchers performed experiments on hydrated and deuterated films of native rod outer segment (ROS) and ROS regenerated with retinals with isotopic substitution at C-15. In differential infrared experiments two samples, for example, Rh and B are recorded against each other, so that what the two contain in common cancels out. So did the $\nu(C{=}N^+)$ band between Rh, B, and isorhodopsin. Most significantly, however, the three N-deuterated samples gave three different $\nu(C{=}N^+)$ frequencies (167). They are 1624 for B, 1631 for isorhodopsin, and 1624 cm^{-1} for Rh (164, 200) in agreement with previous results of Siebert *et al.* (164, 200). Since $\nu(C{=}N^+)$ also receives some admixture from C—C and C—H motions involving C-15, Bagley *et al.* (167) also applied ^{13}C labelling at C-15 and deuteration at C-15. The results were, in the above order, 1610, 1603, and 1602 cm^{-1} for $H^{13}C{=}N^2H$ and 1610, 1614, and 1602 cm^{-1} for $^2HC{=}N^2H$. Since the NH and CH bending vibrations shift to about 1000 cm^{-1} or lower upon deuteration, coupling with the C=N motion becomes negligible, so that the results obtained on the sample deuterated on both C-15 and the nitrogen can be considered representative of the purely electronic effect of protonation without mechanical coupling. Thus, while in the hydrated samples all three molecules have the same $\nu(C{=}N^+)$ frequency, in the deuterated samples they do not.

These differences are significant. They mean that the potential governing the motions in the proton bridge, and the average position of the proton are not the same for the three cases. This must be connected with environmental differences around the chromophore. Then the most intriguing question is the following: is the proton closer to the nitrogen in Rh than in B or is the opposite the case? As to bR whose ir $\nu(C{=}N^+)$ frequency is at 1639 cm^{-1} at low temperatures, Bagley *et al.* (201) found 1627 cm^{-1} for $HC{=}N^2H$, 1629 for $H^{13}C{=}NH$, 1610 for $H^{13}C{=}N^2H$, 1632 for $^2HC{=}NH$, and 1614 cm^{-1} for $^2HC{=}N^2H$. The $\nu(C{=}N^+)$ of K is at 1610 cm^{-1}. The low frequencies of (natural) bR and K would themselves require an explanation. Just like Eisenstein's (167, 201) deuteration experiments this can only mean that the role of mechanical coupling in determining the $\nu(C{=}N^+)$ frequency makes the latter an uncertain indicator of protonation. Favrot *et al.* (124) found cases with model Schiff bases where the $\nu(C{=}N)$ only differed from $\nu(C{=}N^+)$ by 7–9 cm^{-1}.

In the differential infrared spectra (167) several bands are found in the 1800–1600 cm^{-1} region which do not belong to the chromophore but to the adjacent protein and some of them, perhaps, to the lipid. This shows that changes occur around the amide carbonyl bands due to the Rh → B transformation. The residue mainly affected is probably lysine-296 which provides for the Schiff base linkage.

The N-deuteration shifts, 30–35 cm^{-1} for Rh and B would seem to be better indicators of protonation than the frequencies themselves. If there is no protonation, why should $\nu(C{=}N^+)$ be affected by changing H to D? However, bR only exhibits a shift of 12 cm^{-1}. Does this mean that the proton is, on the average, closer to the nitrogen for Rh than for bR? The

coupling-free values for $\nu(C{=}N^+)$ for Rh (1602) and for bR (1614 cm^{-1}) point to the same order. The visible band positions would seem to indicate the opposite, however: 500 nm for Rh and 568 nm for all-*trans* bR. In the same way, if we compare Rh to B we find that the ^1B_u-like bands are at 500 and at 543 nm, respectively, indicating closer protonation for B, while the coupling-free C=N frequencies (1602 and 1610 cm^{-1}) seem to indicate closer protonation for Rh.

All what one may conclude from the above reasoning is that neither the visible nor the C=N frequencies are absolute indicators of the degree of protonation. While the balance of evidence is in favor of protonation for Rh, B, I, bR, and K, significant differences might exist in the average position of the proton and the shape of the potential surface governing its motions in the proton bridge.

Now, as has been proposed earlier by Leclercq and Sandorfy (202, 203), this potential is likely to have two minima. This would be in conformity with the pK_a values of the acids available for protonation which are at about the limit of what can be expected to protonate a conjugated Schiff base, with the existence of Zundel continua in the infrared spectra and Lussier *et al.*'s finding (194, 195) that acids even stronger than aspartic or glutamic acids cannot protonate the Schiff base 100%.

The examination of the Raman effect leads, in certain cases to surprising predictions when a vibration is governed by a double well potential (202, 203). Let us suppose that we have two slightly unequal wells, so that both wells have a non-negligible population. Then the Raman lines might correspond to vibrations in one or the other branch of the potential surface. The relative intensities of the two will depend, in a resonance Raman experiment, on the respective Franck–Condon factors with the potential surface of the resonating excited state. This condition may become predominant and it may render the relative populations unimportant. As a consequence it may happen in certain cases that the less populated well becomes the only one to give rise to a band observable in the spectrum. The infrared spectra are not subject to these conditions but the $\nu(C{=}N^+)$ bands are expected to have much greater intensity than $\nu(C{=}N)$. While according to our present knowledge the population of the protonation well (the one closer to the nitrogen) is probably much higher than the population of the non-protonation well, the possibility that a significant fraction of the chromophore molecules are in the non-protonation well cannot be excluded. In ultraviolet pigments which are unlikely to be protonated (λ_{max} about 350 nm) the primary photochemical event might then be proton transfer onto the nitrogen followed by isomerization (see below).

Stabilization of the ion-pair

If we admit that the Schiff base is protonated in both Rh and bR we have to answer the following question: how can the Schiff base be protonated by the relatively weak acids available in the pigments?

In view of the tendency of protonated Schiff bases to hydrolyse in aqueous media it might seem logical to postulate that the chromophore is in a hydrophobic (low dielectric) environment (99). However, as Warshel (100, 111) pointed out, the $C{=}NH^+{---}COO^-$ ion-pair cannot be stable in low dielectric environments. They would be converted into C=N...COOH just as zwitterionic amino acids in non-polar solvents or amine salts in the gas phase. Also, the extensive infrared work by Zundel *et al.* (186–191) demonstrated that under neutral conditions the acids present in the pigment cannot protonate the Schiff base. The ion-pair needs stabilization by polar groups. This stabilization could be obtained in various ways. A simple way would be by a proton relay network often invoked by biochemists. In such a relay the primary counter-ion which is the proton donor with respect to the Schiff base accepts a proton from another donor. As a consequence the primary counter-ion becomes more acid. A suggestion to this effect was made by Khristoforov *et al.* in 1974 (204). The second donor could be another carboxylic acid and more than two may be involved. (See also Denisov and Golubev (205), Zundel and Merz (191), Kristof and Zundel (197, 198), and Rosenbusch (129) for a recent look at the problem.)

The ions could exist in a polar environment created by permanent dipoles of the surrounding protein. Models of this type were given in the literature (Warshel (112); Honig *et al.* (99); Birge *et al.* (64)).

Rafferty and Shichi (140) observed that in a dry nitrogen atmosphere the 500 nm band of bovine Rh underwent a large blue shift to 390 nm. This seems to indicate that the Schiff base lost its proton. The *in vacuo* Raman measurements of Hildebrandt and Stockburger (97) have given strong confirmation for this. Then it is logical to assume that the ion-pair in the proton bridge of the Schiff base is stabilized by water molecules. This goes in the sense of Warshel's suggestion that the local environment of the Schiff base must have a high dielectric constant (ref. 100 and references therein). A few tightly bound water molecules would not hydrolyse the protonated Schiff base.

Dupuis *et al.* (116) suggested that one (or more) water molecules might be intercalated between the carboxylate ion and the iminium ion, so that proton transfer between the two ions would occur via an oxonium ion. In all likelihood other water molecules would form a cluster around the system to lend it more stability. Either of these mechanisms, or a combination of them would make the assumption of a protonated Schiff base credible. The elucidation of this mechanism of stabilization should be, in our opinion, a prime target for future research. Connected to charge separation in the proton bridge is the problem of energy storage after photon absorption, in both Rh and bR.

The energy of a photon with λ = 500 nm (20 000 cm^{-1}) is about 2.5 eV or about 57.5 kcal/mol. Photon absorption leads to the creation of B followed by vibrational relaxation. B is very unstable at room temperature. According to Cooper's photocalorimetric measurements (98) the energy difference between the ground states of Rh and B is still about 35 kcal/mol. This amount of energy is "stored" in B for about 100 ns and is subsequently used to bring about the chemical changes that occur along the remainder of the cycle. Why is B so unstable? According to Honig *et al.* (99) the Schiff base is protonated, hydrogen bonded in a salt bridge to its counter-ion; the isomerization following light absorption breaks the hydrogen bond and twists the Schiff base of Rh into a distorted *trans* configuration. A protonated Schiff base without a counter-ion can only be a short-lived transient at room temperature. (B is stable, however, at liquid nitrogen temperature.) Thus the storage of energy is achieved by charge separation. Since B absorbs at longer waves (543 nm) than Rh (500 nm) this is in agreement with Blatz's original suggestion that pulling away the counter-ion from the chromophore allows a wider distribution of the positive charge in the conjugated double bond system and causes a red shift in the visible spectrum. Subsequently Warshel and Barboy (100) pointed out that it is very difficult to store a

significant amount of energy by charge separation in a *polar environment* which must be assumed in order to have Rh stable. They then suggested that "This dilemma can be resolved if the isomerization takes the protonated Schiff base from a polar environment to a non-polar environment" (100). They then went on to estimate the amount of electrostatic energy that can be stored in this way by microscopic dielectric approaches. It turned out that it can be approximated by the energy change produced by moving the protonated Schiff base from a polar to a non-polar environment and it amounts to about 30 kcal/mol. The Schiff base is contained in a cavity of the protein which has to adjust to the new situation. According to Warshel and Barboy "the relaxation of the protein dipoles can be sufficiently slow to allow for a significant energy storage during times of the order of microseconds at room temperature. At lower temperature, the protein relaxation can be frozen for a much longer period of time. It also follows from these model calculations that B can store a significant part of its excess energy as strain energy. These are then used for the subsequent transformations along the visual cycle." Warshel argues that the proton transfer observed by Rentzepis might occur in the ground state between two groups of the protein as a consequence of pK_a changes caused by the charge separation produced during the primary photochemical event. It "may provide a simple channel for electrostatic energy relaxation". Anyway, the role of the protein in the energy storage process is evident. The basic idea in both Honig's and Warshel's approaches is photo-induced charge separation in the salt bridge due to *cis–trans* isomerization in visual pigments and *trans–cis* isomerization in bR with energy storage in B or K and its transduction into chemical free energy for bringing about the subsequent chemical transformations. The present reviewers believe that this is sound. However, proton translocation is also a part of the photochemical event. Rentzepis and co-workers (23–25) studied the formation of B at temperatures ranging from 300 K to 4 K. The risetime of B was less than 6 ps at 30 K and even at 4 K it was still 36 ps. In view of the very fast risetime of B early doubts as to the possibility for a complete 11-*cis* to all-*trans* isomerization to occur within 6 ps were not without justification. However, detailed comparative studies of the resonance Raman spectra of Rh and B (and of bR and K) together with the attenuation of the all-*trans* requirement to distorted all-*trans* made this credible. On the other hand the more recent results of Rentzepis' group (79) further substantiated the involvement of proton translocation in the photochemical step. They performed measurements on the formation kinetics of B, deuterated on the nitrogen using 6 ps pulses at 530 nm. They observed a pronounced deuterium isotope effect at low temperatures, $k_H/k_D = 7$ for the rate of formation of B. At very low temperatures B exhibited a non-Arrhenius behavior, the rate being independent of temperature. This indicates proton translocation through tunneling, at least at low temperatures. The data made it possible to calculate the distance of the proton translocation, about 0.5 Å. This, together with the fact that with the method used the only exchangeable proton of the chromophore was the one in the proton bridge "provided is the basis for the suggestion that translocation of the Schiff base proton is at least a prominent component of the first event in vision" (25). (But see the next section for another point of view.)

As to bR, Applebury *et al.* (206) found a much more moderate deuterium isotope effect: k_H/k_D 1.6 for the formation of K at 298 K and 2.4 at 4 K. They observed the formation of a transient species (which they called S) between bR and K red shifted with respect to both bR and K. The formation of K from the transient had a (very low) thermal barrier but the rate of formation became practically independent of temperature at very low temperatures. Thus Applebury *et al.* (206) suggested that proton translocation at room temperature occurs mainly thermally but at low temperatures tunneling takes over. (The transient was renamed J by later authors (207).) Recently similar results were published on 11-*cis* and all-*trans*-retinal SB by Huppert and Rentzepis (208).

Some new ideas and developments

After photon absorption the excited molecule may have a great amount of vibrational energy and may start twisting (68, 69) making it possible for the proton to move away from the nitrogen despite its increased basicity. This would remove some of the extra stabilization provided by the proton bridge and give the green light to the Schiff base to isomerize. After twisting, the Schiff base, still in the excited state, would be rapidly reprotonated by a waiting acid. The acid could be Asp_{83}, or Glu_{122}, or Glu_{134} which according to Dratz and Hargrave (154) are in the vicinity of the chromophore. This would explain the rapid proton translocation and kinetic deuteration effect observed by Rentzepis and co-workers. It is believed that this is a more natural explanation than postulating proton transfer from one counter-ion to another. Rentzepis also observed that the quantum yield of the Rh → B transformation is higher at low temperature than at room temperature. This could be linked to the preponderance of transfer by tunneling at low temperature and by passing over the potential barrier at room temperature (Cf. Birge, ref. 67).

An interesting sequel to this hypothesis concerns the intermediates observed by a number investigators (209–215) *between* Rh and B and bR and K. Some of these intermediates like hypsorhodopsins absorb at wavelengths shorter than a protonated Schiff base and nearer to the free base. Now, the above hypothesis would seem to give a natural interpretation for hypsorhodopsins. They would correspond to Schiff bases nearly free from protonation observed between the removal of the "original" proton from the nitrogen and its reprotonation following isomerization.

This could be compatible with the existence of a double well potential governing the motions of the proton in the salt bridge, with both wells having a significant population. Then proton translocation would be possible either onto or away from the nitrogen.

The existence of ultraviolet pigments supplies us an argument in this respect (32–35). Harosi and Hashimoto (34) and Harosi (35) found cone pigments in the eyes of the japanese dace whose absorption maxima are at 350–370 and 405–415 nm. Since all these pigments can bleach, one is led to the idea that in such cases proton transfer onto the Schiff base would precede isomerization. In the above scheme this would correspond to a situation in which the non-protonation well of the double well potential (the one more distant from the nitrogen) is more populated than the protonation well, perhaps much more.

Further indications for this can be found in the experiments of Rafferty and Shichi (140) and Hildebrandt and Stockburger (97). The former observed that under anhydrous conditions the visible absorption maximum shifts hypsochromically from 500 nm to about 390 nm. This very likely is a consequence of deprotonation. Then if they shine light into the 390 band, the absorption maximum goes back to about 480 nm and bleaching occurs. This seems to entail a proton transfer *onto* the Schiff

base, again preceding isomerization. Thus, our original suggestion (116, 125) would correspond to reality in at least certain cases. It is significant that both protonated and non-protonated Schiff bases have a tendency to bleach.

Stoeckenius and co-workers have shown that both acidification and deionization cause color changes in bR (26, 216). Between pH 3 and 1 the color of the membrane changes from purple to blue while the absorption maximum shifts from 568 to 605 nm. The same happens when the membrane is deionized on a cation exchange column or when it is washed first with a sodium chloride solution and then with deionized water. However, the original color of bR can be restored by further lowering the pH to below one or by adding certain metal cations in appropriate concentrations. This phenomenon has been the object of thorough physico-chemical investigations by Kimura *et al.* (217) and, by resonance Raman spectroscopy, Massig *et al.* (218) and Smith and Mathies (219). According to Moore *et al.* (220), Mowery *et al.* (216), Fischer and Oesterhelt (221), and Muccio and Cassim (222) the first color change is due to protonation of a negative charge in the environment of the chromophore and the second one (which is unaffected by deionization) to protonation of another group in the chromophore environment. Kimura *et al.* (217) put forward the idea that the two groups are the two counter-ions near the Schiff base nitrogen and the β-ionone ring. While more detailed investigations are certainly needed at this point, the idea is attractive. At any rate, it is most important to note that the color regulation mechanism in bR (and possibly Rh) is even more refined than was hitherto believed and that metal cations play a role in it. This also makes it very likely for water molecules to be present in the vicinity of the Schiff base nitrogen (Dupuis *et al.* (116), Massig *et al.* (218)); they could be there in hydrated cations and regulate the extent of protonation of the chromophore and the surrounding protein and the conditions for proton translocation.

Recently Sharkov *et al.* (ref. 223 and references therein), Nuss *et al.* (224), and Polland *et al.* (ref. 225 and references therein) reinvestigated the photochemical event in bR. Nuss *et al.* and Polland *et al.* used light pulses as low as 160 fs, a time resolution of 5×10^{-13} s and low intensities. The main results of these investigations were as follows. Photon absorption excites bR to a short-lived excited state S_1. Then a rapid transition occurs into the *J* intermediate (ground state). The rise time of *J* was found to be 430 ± 50 fs (700 according to Sharkov *et al.* (223)). *J* then goes over to *K* which appears with a time constant of 5 ps (3 according to Sharkov). In accordance with the above mentioned work of Applebury *et al.* (206) *J* is red shifted by about 30 nm with respect to bR and *K* by 20 nm. Nuss *et al.* (224) and Polland *et al.* (225) also studied bR deuterated on the nitrogen but found no deuterium isotope effect for either the S_1 to *J*, or the *J* to *K* transformation. Their experiments were carried out at room temperature. An important comment of Polland *et al.* recalls that bR forms a two-dimensional hexagonal lattice (the purple membrane), where "three bR molecules are close enough to form excitonically coupled trimers." So after light absorption excitation is first delocalized for a very short time and then trapped into the S_1 excited state in one of the bR molecules with subsequent transformations into *J* and *K*. These new results would *seem to* exclude the possibility of proton translocation between bR and either *J* or *K*. Moreover, they indicate a large degree of isomerization in less than 1 ps. Before concluding we should like to wait until a consensus is reached in the world of ultrafast spectroscopists. Let us comment, however, that conditions may be different for visual pigments for which a much larger deuterium isotope effect has been found (25).

Concluding remarks

Present trends are directed partly towards the discovery of other bacterial rhodopsins and the study of their properties. They cannot anymore be considered as curiosities but rather as convenient photochemical devices often used by nature. On the other hand, a great deal of effort is deployed on the structure of the intermediates beyond *B* or *K*, the kinetics of their formation, and the concomitant changes in the surrounding protein. Among these we mention the results of Engelhard *et al.* (226), El-Sayed and co-workers (227–230), and Hess *et al.* (231) and a theoretical treatment by Tavan *et al.* (232). Other researchers are looking beyond the photochemical cycles and into the way in which the signal is given to the nervous system in vertebrates. Typical of these is the light scattering work by Abrahamson *et al.* (42, 233) and the electrochemical work by Keszthelyi *et al.* (234–237). The interesting reader might like to consult the volume edited by Packer (47).

A characteristic of publications on rhodopsins is the great number of co-authors on almost all the articles. This is a measure of the hard and diversified work that rhodopsin research entails. Biologists, biochemists, biophysicists, physicochemists, electronic, infrared, Raman, nmr spectroscopists, crystallographers, quantum chemists, are all needed to penetrate into the fascinating secrets of nature which are involved. Pigments are most important instruments in the interactions of light with living matter.

Squaraine chemistry. Synthesis of bis(4-dimethylaminophenyl)squaraine from dialkyl squarates. Mechanism and scope of the synthesis

KOCK-YEE LAW[1] AND F. COURT BAILEY
Xerox Corporation, 800 Phillips Road, 0114-39D, Webster, NY 14580, U.S.A.

Received February 18, 1986

KOCK-YEE LAW and F. COURT BAILEY. Can. J. Chem. **64**, 2267 (1986).

The mechanism and the scope of the synthesis of bis(4-dialkylaminoaryl)squaraines from di-*n*-butyl squarate and *N*,*N*-dialkylanilines have been studied. Results show that water and acid are key factors of the synthesis, and these two factors have been optimized. Yields of squaraine are also found to be sensitive to the steric effect provided by the alkyl chain in dialkyl squarates as well as to the concentration of the aniline reagent used in the synthesis. Mechanistic results suggest that alkyl squarate is the precursor of the synthesis, and that squaraine is formed by diarylation of alkyl squarate with an *N*,*N*-dialkylaniline derivative. Under optimized conditions, a number of squaraines have been synthesized. Yields, which are comparable to those synthesized from squaric acid, are obtained. Product analysis with good material balance has been achieved, and results show that arylation and diarylation of the starting di-*n*-butyl squarate are major side reactions in the squaraine synthesis.

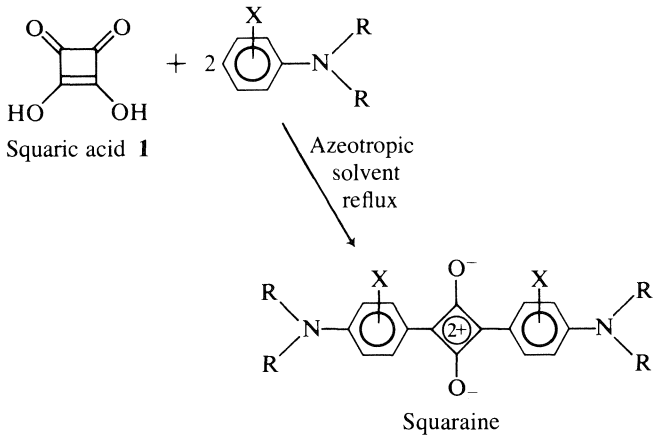
KOCK-YEE LAW et F. COURT BAILEY. Can. J. Chem. **64**, 2267 (1986).

On a étudié le mécanisme et la généralité de la synthèse des bis(dialkylamino-4 aryl) squaraïnes à partir du squarate de di-*n*-butyle et des *N*,*N*-dialkylanilines. Les résultats indiquent que l'eau et l'acide sont des facteurs déterminants dans la synthèse et on a optimisé ces deux facteurs. On a aussi trouvé que les rendements en squaraïne sont sensibles aux effets stériques des chaînes alkyles des squarates dialkylés ainsi qu'à la concentration de l'aniline utilisée dans la synthèse. Les résultats mécanistiques suggèrent que le squarate d'alkyle est un précurseur dans la synthèse et que la squaraïne se forme par une diarylation du squarate d'alkyle par un dérivé *N*,*N*-dialkylaniline. Utilisant des conditions optimisées, on a synthétisé un certain nombre de squaraïnes. On a obtenu des rendements qui sont comparables à ceux obtenus lors de la synthèse à partir de l'acide squarique. En se basant sur les produits détectés, on a obtenu une bonne balance des réactifs, et les résultats démontrent que l'arylation et la diarylation du squarate de di-*n*-butyle de départ sont des réactions secondaires importantes dans la synthèse de la squaraïne.

[Traduit par la revue]

Introduction

Bis(4-dialkylaminoaryl)squaraines[2] (for nomenclature, see ref. 1; for reviews on synthesis, see ref. 2) are known to possess photoconductive and semiconductive properties. Although this class of compounds exhibit sharp visible absorption in solution (λ_{max} ~620–670 nm, ε_{max} ~3 × 10^5 cm^{-1} M^{-1}), their absorption in the solid state is panchromatic (400–1000 nm) and is usually very intense (3). These features have made them very attractive for various technological applications in industry, e.g., xerographic photoreceptors (4), organic solar cells (3, 5), and optical recording media (6). Traditionally, these compounds are synthesized by condensing one equivalent of squaric acid (**1**) and two equivalents of *N*,*N*-dialkylaniline



Squaric acid **1**

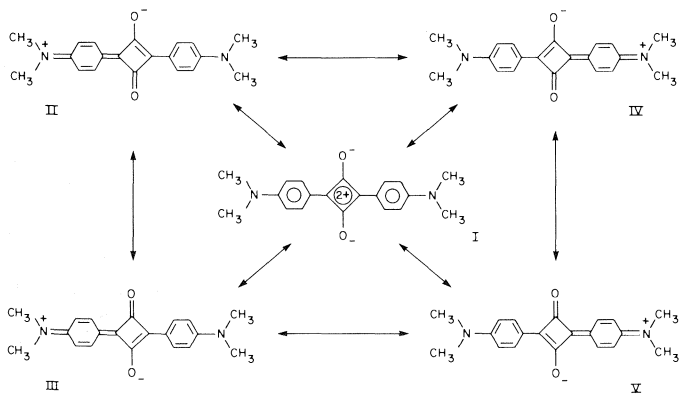
Squaraine

in an azeotropic solvent (7). Water is the by-product of the synthesis and is removed azeotropically during the squaraine synthesis.

Since the synthesis of squaraine starts with squaric acid, we shall refer to it as the acid route. This synthesis is simple and versatile and a large number of squaraines have been synthesized by this procedure (8). Squaraine pigments synthesized by this procedure are, however, often found to exhibit high dark-conductivity and low charge-acceptance values in

[1]Author to whom correspondence may be addressed.

[2]Squaraines are 1,3-disubstituted compounds derived from the squaric acid structure (1). Bis(4-dialkylaminoaryl)squaraines are a group of squaraine compounds synthesized from squaric acid and *N*,*N*-dialkylanilines (2). Recent single crystal X-ray data[3] and theoretical calculations[4] on the molecular orbitals of model squaraine compounds suggest that the π electrons in squaraine are fully delocalized. The π-orbitals in squaraine can be represented by resonance forms I–V.



For the purpose of conciseness, resonance form I is used in this paper.

[4]Reference 17.

photoreceptor devices (9).[5] Additional purification and processing steps to improve the xerographic properties have yet to be developed.

Earlier, we reported that bis(4-dialkylaminoaryl)squaraines can also be synthesized from dialkyl squarates.[6] Since the squaraine synthesis in this procedure starts with the esters of squaric acid, we refer to the synthesis as the ester route. Xerographic measurements show that squaraines synthesized from dialkyl squarates give consistently better electrical behavior (lower dark conductivity, higher charge acceptance, and higher sensitivity) than those synthesized from squaric acid.[6] Since the improvement in electricals is paralleled by the morphological changes, the enhanced electrical response is attributed to morphological effects. In this paper, we report our investigation on the synthetic aspects of the ester route. The mechanism of squaraine formation and the scope of the synthesis will be presented and discussed.

Experimental

Materials

Squaric acid, *N*,*N*-dimethylaniline, *NN*-diethylaniline, and *N*,*N*-dimethyl-*m*-toluidine were purchased from Aldrich. *N*,*N*-dimethyl-*m*-hydroxyaniline and *N*,*N*-diethyl-*m*-hydroxyaniline were bought from Fisher and were purified by sublimation and recrystallization (from *n*-heptane) before use. Other *N*,*N*-dimethylaniline derivatives were prepared by methylation of an aniline derivative (Aldrich) with trimethyl phosphate as described in the literature (10). Satisfactory elemental analyses and spectroscopic data were obtained for all the anilines synthesized. All solvents were spectro-analyzed grade from Baker and were used without further purification.

General techniques

Melting points were taken on a capillary melting point apparatus (Thomas Hoover) and are uncorrected. Elemental analyses were performed by Galbraith Laboratories. The ir spectra were recorded on a Perkin–Elmer 283 instrument.

Synthesis of dialkyl squarates

Dimethyl squarate was prepared according to the procedure described by Cohen and Cohen (11). Other dialkyl squarates were prepared as follows.

Squaric acid (11.4 g, 0.1 mol) was heated to reflux in a mixture of a 1-alkanol (150 mL) and an azeotropic solvent (150 mL) (benzene for 1-propanol, toluene for 1-butanol, and 1-heptanol). Water was distilled off azeotropically and removed by a Dean–Stark trap. After two equivalents of water were collected, the product mixture was cooled to room temperature. Solvents were removed on a rotatory evaporator. Dialkyl squarate product was then isolated by vacuum distillation.

Di-n-*propyl squarate*, yield 85%, bp ~152°C at 2.1 Torr (1 Torr = 133.3 Pa); ir (CCl_4): 1810 and 1735 (C=O) cm^{-1}; nmr (CD_2Cl_2) δ: 1.03 (t, J = 7 Hz, 6H), 1.6–2.1 (m, 4H), and 4.63 (t, J = 7 Hz, 4H); ms (m/z): 198 (M^+). *Anal.* calcd. for $C_{10}H_{14}O_4$: C 60.59, H 7.12; found: C 60.47, H 7.12.

Di-n-*butyl squarate*, yield 95%, bp ~152°C at 0.13 Torr (lit. (12) bp 139°C at 0.5 Torr); ir (CCl_4): 1808 and 1730 (C=O) cm^{-1}; nmr (CD_2Cl_2) δ: 0.96 (t, J = 7 Hz, 6H), 1.2–2.0 (m, 8H), and 4.66 (t, J = 7 Hz, 4H); ms (m/z): 226 (M^+).

Di-n-*heptyl squarate*, yield 91%, bp ~205°C at 0.19 Torr; ir (CCl_4): 1808 and 1730 (C=O) cm^{-1}; nmr (CD_2Cl_2) δ: 0.7–2.1 (m, 26H) and 4.66 (t, J = 7 Hz, 4H); ms (m/z): 310 (M^+). *Anal.* calcd. for $C_{18}H_{30}O_4$: C 69.64, H 9.74; found: C 69.40, H 9.80.

[5]There are four key steps in xerography, namely charging, photodischarge, image transfer, and development and cleaning. In order to achieve high imaging quality, a photoreceptor device should have high charge-acceptance and low dark-conductivity values. For a discussion on xerography, see ref. 18.

[6]K. Y. Law and F. C. Bailey, manuscript in preparation.

Synthesis of squaraines from di-n-*butyl squarate (general procedure)*

Di-*n*-butyl squarate (1.13 g, 5 mmol), concentrated sulfuric acid (0.1 mL), and water-saturated 1-butanol (5 mL) were discharged in a 100-mL three-neck flask, which was equipped with a magnetic stirring bar and a nitrogen inlet. This mixture was stirred and brought to reflux under a nitrogen atmosphere at an oil-bath temperature of 125–130°C. *N*,*N*-Dialkylaniline derivative (10.2 mmol) was added slowly and evenly in a 6–8 h period (e.g., 2 drops every 30 min) through a pressure equalizing funnel. The addition funnel was washed with 1 mL of 1-butanol when the addition was complete. The product mixture turned from colorless to light green (or yellow green) at the end of the aniline addition. Squaraine product was formed after overnight refluxing and the reaction was allowed to go to completion by further refluxing for 8–24 h. After cooling down the mixture to room temperature, 30 mL methanol was added, and the precipitated product was isolated by filtration. The yields of the squaraines synthesized by this procedure are summarized in Table 4.

Results and discussion

Synthesis

Reaction of di-*n*-butyl squarate, **2**, and *N*,*N*-dimethylaniline in freshly dried 1-butanol at reflux yields no squaraine product. Squaraine formation is found to be effected by the catalytic effects of sulfuric acid[7] and water. Results (Table 1) show that yield of HSq increases monotonically as the water concentration in the reaction medium increases. These results, in conjunction with the acid catalyst required in the synthesis, suggest that the (acid-catalyzed) hydrolyzed product(s) of di-*n*-butyl squarate is the precursor of the squaraine synthesis.

The effect of the concentration of sulfuric acid on the yield of HSq is more interesting (Table 2). At $[H_2SO_4] \leq 0.41 \times 10^{-3}$ M, yield increases as $[H_2SO_4]$ increases, suggesting that more di-*n*-butyl squarate is hydrolyzed and then reacts to form product when the amount of acid catalyst is increased. Yield of HSq, however, decreases at higher sulfuric acid concentrations. The decrease in chemical yield may be attributable to the significant decrease in reactivity of *N*,*N*-dimethylaniline due to its protonation by sulfuric acid at high acid concentrations.

In an independent mechanistic investigation of the reaction of squaric acid (**1**) with *N*,*N*-dimethylaniline, we found that no squaraine is formed when the synthesis is carried out in non-hydroxylic solvents, secondary alcohols, or tertiary alcohols.[8] These findings suggest that **1** is not the precursor of the squaraine. The only candidate for precursor is *n*-butyl squarate, **3**.[8,9] Arylation of **3** by *N*,*N*-dimethylaniline will generate intermediate **4**, which undergoes further arylation to form HSq.

The synthesis reported in this work, which involves partial acid-catalyzed hydrolysis of **2** → **3**, arylation of **3** → **4**, and

[7]In addition to sulfuric acid, trichloroacetic acid, oxalic acid, and toluenesulfonic acid are also found to be effective for the ester route synthesis.

[8]In secondary alcohol such as 2-amyl alcohol, no squaraine is formed when squaric acid is reacted with *N*,*N*-dimethylaniline. On the other hand, HSq can be isolated in 20–30% yield when methyl squarate or di-*n*-butyl squarate (in the presence of H_2SO_4 and water) are allowed to react with *N*,*N*-dimethylaniline in 2-amyl alcohol. These observations strongly suggest that *n*-alkyl squarate is the precursor of the squaraine and the lower yields of HSq in the latter two reactions are due to the transesterification of methyl squarate or *n*-butyl squarate to the unreactive 2-amyl squarate in 2-amyl alcohol (K. Y. Law, unpublished results).

[9]Squaraines can be synthesized from *n*-alkyl squarates (e.g. methyl squarate) in 1-butanol. The yields of squaraine are comparable to those of the acid route and the ester route reported in this work. See K. Y. Law, U.S. Patent 4,524,219.

SCHEME 1

TABLE 1. Effect of water concentration in 1-butanol on the yield of HSq[a]

Water conc. in 1-butanol (% of vol.)	Yield of HSq (%)
~0[b]	0–3
~0.1[c]	30±3
1[c]	39
16[d]	45±3

[a]Reactant: di-*n*-butyl squarate (1.13 g, 5 mmol), *N*,*N*-dimethylaniline (1.23 g, 10.2 mmol, added in 6–8 h); solvent: 5 mL 1-butanol of specified water concentration; catalyst: H_2SO_4 (0.1 mL).
[b]Freshly distilled over Mg.
[c]Specified amount of water was added to freshly dried 1-butanol.
[d]Water-saturated 1-butanol.

TABLE 2. Effect of sulfuric acid concentration on the yield of HSq[a]

H_2SO_4 ($\times 10^3$ *M*)	Yield of HSq (%)
0.13	30
0.26	38
0.41	45±3
0.51	35

[a]Reactants: di-*n*-butyl squarate (1.13 g, 5 mmol), *N*,*N*-dimethylaniline (1.23 g, 10.2 mmol, added over 6–8 h); solvent: 5 mL water-saturated 1-butanol; catalyst: sulfuric acid of specified concentration.

arylation of **4** → HSq, can be described in three steps, a → c → d, and we refer to the synthesis as the ester route.

Steric effect

As shown in Scheme 2, the ester route synthesis involves steps a → c → d. The acid-catalyzed hydrolysis of **2** → **3** and the arylation of **3** → **4** are expected to be sensitive to the steric factors provided by the alkyl groups in various dialkyl squarates. Table 3 summarizes the results of the effect of chain length of the alkyl group in dialkyl squarates on the yield of HSq. Our results show that yield decreases as the chain length of the alkyl group increases.

The relative rate of hydrolysis of various dialkyl squarates to alkyl squarates is not known. Several attempts have been made to determine this relative rate under the conditions of the squaraine synthesis. Such a study has been difficult due to the very similar retention times of the hydrolyzed products (squaric acid and alkyl squarates) in hplc analyses. On the other hand, assuming that the steric effects of dialkyl squarate to alkyl squarate and alkyl squarate to squaric acid are very similar, the relative rate of dialkyl squarate to alkyl squarate can be estimated by determining the amount of squaric acid formed in the hydrolysis of dialkyl squarate to squaric acid. The relative rate obtained in this fashion is given in Table 3, and results show the hydrolysis rate decreases, as expected, as the chain length of the alkyl group increases. Since this decrease is paralleled by a decrease in yield of HSq, we conclude that the decrease in yield of HSq is primarily a steric effect inherent in the hydrolysis of dialkyl squarate to alkyl squarate.

Thermodynamic estimation shows that hydrolysis of dialkyl squarate to alkyl squarate is endothermic by ~12 kcal/mol and arylation of alkyl squarate to form **4** is exothermic by ~8 kcal/mol. In accordance with Hammond's postulate (13), the hydrolysis reaction should have a later transition state where the impact of steric hindrance will be greater. The dependence of the yield of HSq on the hydrolysis of the starting dialkyl squarate is thus rationalized.

Effect of aniline concentration

Scheme 2 shows that the major side reaction of **3** is to re-esterify to **2**. The conversion of **3** to **4** will drive the reaction in the product-forming direction and will improve the yield of HSq. It is thus almost certain that the squaraine synthesis would be sensitive to the concentration of *N*,*N*-dimethylaniline used in the synthesis. The effect of the concentration of *N*,*N*-dimethylaniline on the yield of HSq was studied and results (Fig. 1) show that optimized yield is obtained when two equivalents of *N*,*N*-dimethylaniline are used. When less than 2 equivalents of *N*,*N*-dimethylaniline is used, yield increases with increasing concentration of *N*,*N*-dimethylaniline, and this can readily be attributed to the increased formation of **4** with increasing concentration of *N*,*N*-dimethylaniline. When more than 2 equivalents of *N*,*N*-dimethylaniline is used, yield decreases rapidly and reaches zero percent at 4 equivalents of *N*,*N*-dimethylaniline. Since optimal amounts of sulfuric acid are used in each experiment, the acidity of the reaction medium is then decreasing as the concentration of *N*,*N*-dimethylaniline increases. While yield of HSq also decreases as the concentration of sulfuric acid decreases when the acid concentration is less than optimal (Table 2), the decrease in yield of HSq observed at high *N*,*N*-dimethylaniline concentrations may be an acidity effect. However, the acidity of the reaction medium should only be decreased by a factor of two when four

[a]Reactant: specified dialkyl squarate (5 mmol), *N*,*N*-dimethylaniline (1.23 g, 10.2 mmol, added over 6–8 h); solvent: 5 mL water-saturated 1-butanol; catalyst: sulfuric acid, 0.1 mL.
[b]See text for method of estimation.

equivalents of *N*,*N*-dimethylaniline are used. In accordance with Table 2, the yield of HSq should be in the neighborhood of 30–40%; thus, acidity effect alone does not appear to account for the drastic drop in chemical yield. It has been reported in the literature that squaraines can form 1:1 adducts with amines; the significant decrease in yield of HSq is likely due to secondary reactions between HSq and *N*,*N*-dimethylaniline at high *N*,*N*-dimethylaniline concentrations.[10]

The role of water in the synthesis

The necessity of having water in the reacting solvent in the ester route, in contrast to the acid route where water is removed continuously by an azeotropic solvent during the course of the reaction, prompted us to examine the role of water in the synthesis. The water content of the reaction mixture throughout the reaction was monitored by measuring the boiling point of the reacting solvent. The temperature profile in Fig. 2 shows that the boiling point of the reacting solvent increases from the boiling point of the azeotrope of 1-butanol–water at ~96°C to the boiling point of pure 1-butanol at ~118°C as the reaction

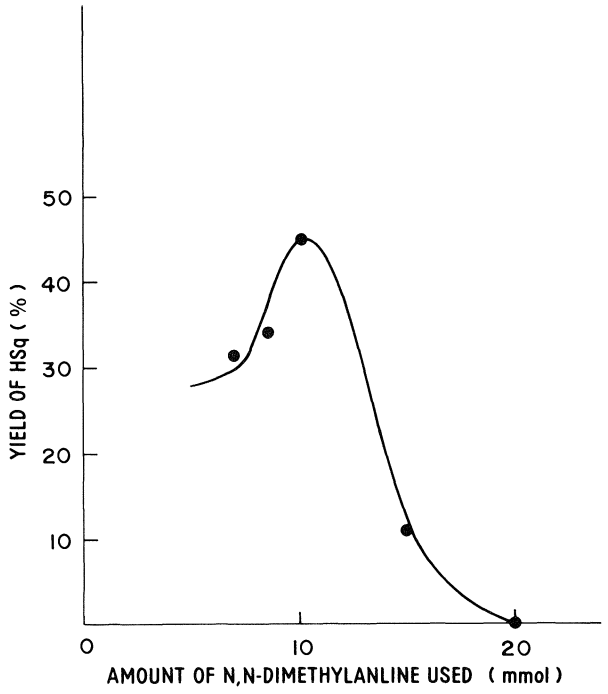

FIG. 1. Plot of yield of HSq as a function of the amount of *N*,*N*-dimethylaniline used (5 mmol scale).

[10]Squaraines are known to react with amines to form adducts. In the case of tertiary aromatic amines, 1:1 squaraine–amine adducts have been isolated and characterized (14). In this work, we have found in controlled experiments that squaraines react with *N*,*N*-dialkylanilines to form colorless products. Although these colorless substances have not yet been characterized, we believe that the decrease in chemical yield of squaraine is the result of the consumption of squaraine in secondary reactions.

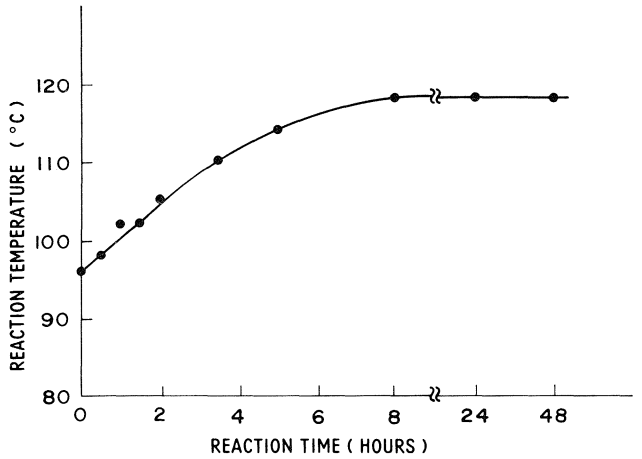

FIG. 2. Plot of reaction temperature as a function of reaction time.

proceeds. The low boiling points observed indicate the presence of water in the reacting solvent; its presence, which is a prerequisite for the occurrence of the synthesis, implies that the starting di-*n*-butyl squarate is hydrolyzing to *n*-butyl squarate, the precursor of the squaraine synthesis, in the initial stage of the reaction.

After ~8 h, the boiling point of pure 1-butanol is reached. This suggests that water is removed during the reaction, presumably by the slow stream of nitrogen under the refluxing condition. At the same time, the color of the reaction mixture turns from light yellow to yellow green (or green). Squaraine starts to precipitate out of the solution several hours later.[11] The necessity of water removal in the later stage of the reaction is consistent with the mechanism proposed in Scheme 2; since water is the by-product of the squaraine formation step (step d), the elimination of water drives the reaction in the product-forming direction.

In the experimental section, *N*,*N*-dimethylaniline derivative is shown to be added slowly in a 6–8 h period. The slow and even addition will permit the selective arylation of *n*-butyl squarate (less steric hindrance), so that side reactions, such as arylation of di-*n*-butyl squarate, can be suppressed. For highly reactive aniline derivatives, e.g., *N*,*N*-dimethyl-3-hydroxyaniline and *N*,*N*-diethyl-3-hydroxyaniline, slow addition is found to be very critical. Due to the slow rate of hydrolysis of di-*n*-butyl squarate relative to arylation reactions in these two cases, yields of squaraine decrease to the 30–50% range when the aniline derivatives are added in a single batch at the beginning of the reaction. The procedure presented in the experimental section is thus a general optimized procedure for squaraine synthesis from di-*n*-butyl squarate.

Scope of the ester route synthesis

A number of squaraines were prepared from di-*n*-butyl squarate using these optimized conditions, and the yields are tabulated in Table 4.[12] The yields of the same set of squaraines synthesized by the traditional acid route are also given for comparison (15). Comparison indicates that very similar chemical yields are obtained from both procedures. The similar synthetic efficiency for both procedures is not unexpected because of the similarity in the squaraine formation step in both procedures (Scheme 2).

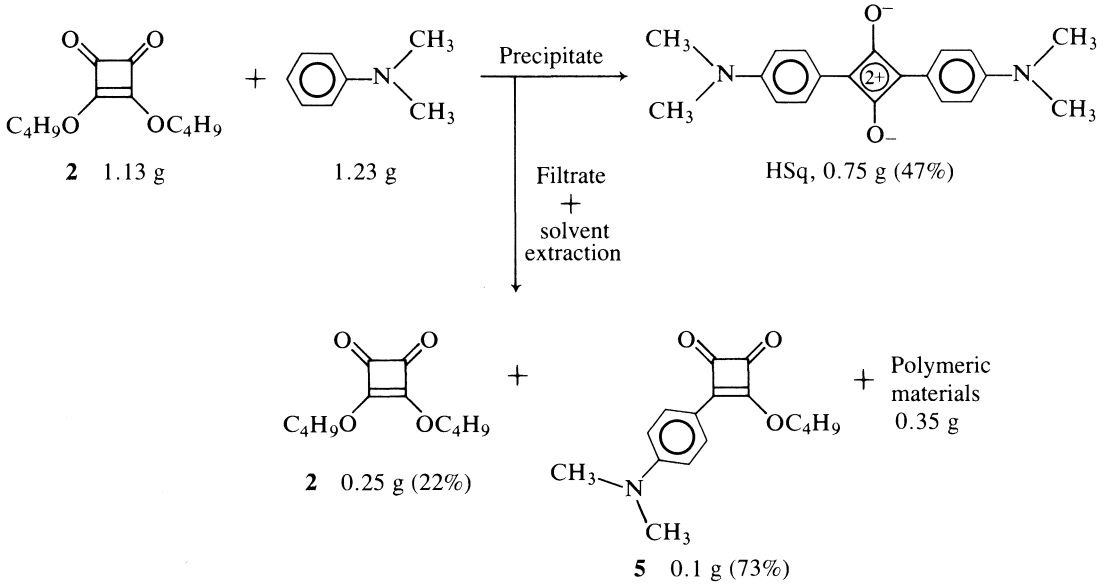
Product analysis and outlook for further yield improvement

Results in Table 4 show that most of the squaraine syntheses are not quantitative. We felt that mechanistic insight, which usually provides guidance for further yield improvement, may be obtained by analyzing the side products. Using di-*n*-butyl squarate and *N*,*N*-dimethylaniline as reactants, water-saturated 1-butanol as solvent, and sulfuric acid as catalyst, HSq was isolated by filtration in 47% yield in a typical 5-mmol run (see experimental section). The neutral side products in the acidic filtrate solution were isolated by solvent extraction (chloroform–water) techniques. Vacuum bulb-to-bulb distillation yielded two volatile fractions, a light yellow liquid (0.22 g) and an orange solid (0.1 g). The light yellow liquid was found to be di-*n*-butyl squarate by comparing its spectroscopic properties

[11]For more reactive anilines, e.g., *N*,*N*-dimethyl-3-hydroxyaniline, squaraine products precipitate out of the solution even before the completion of the aniline addition.

[12]Satisfactory elemental analyses and spectroscopic data are obtained for all the squaraines isolated in this work.



2 1.13 g 1.23 g HSq, 0.75 g (47%)

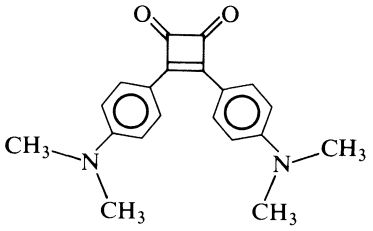
SCHEME 3

(ir, nmr, ms) with the starting material. The orange solid was identified as compound **5** (see Scheme 3) by spectroscopic techniques.[13] The residue was a brown solid (0.35 g). The spectroscopic data of this brown solid are ir ($CHCl_3$): 1600 cm^{-1}, no carbonyl bands; nmr (CD_2Cl_2) δ: ~2.8–3.1 (broad multiplets, ~6H, N-CH_3), 6.5–7.3 (very broad doublet, ~4H, aromatic protons). These spectroscopic data suggest that the residue is a polymeric material and has no high frequency C=O functions. The ^1H nmr data strongly suggest that this residue is made up of *N*,*N*-dimethylanilino moieties.

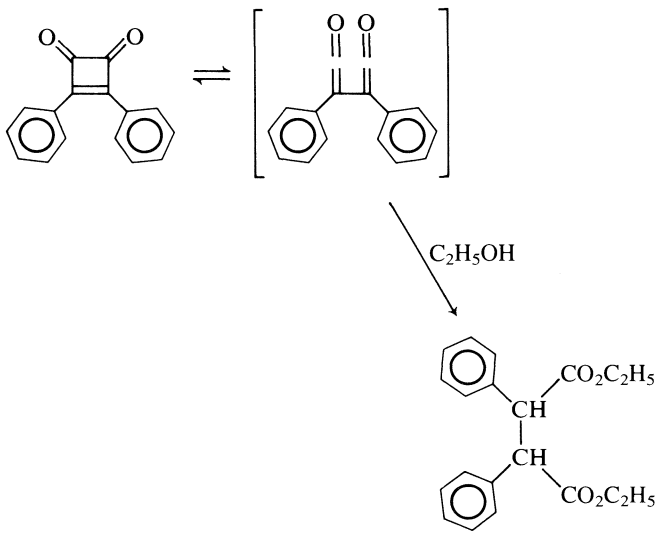
In a parallel experiment, another orange precipitate (~0.16 g) was isolated by adding an appropriate amount of diethyl ether to the acidic filtrate. This orange solid was identified as compound **6** by comparing its spectroscopic properties with those of an authentic sample.[14]



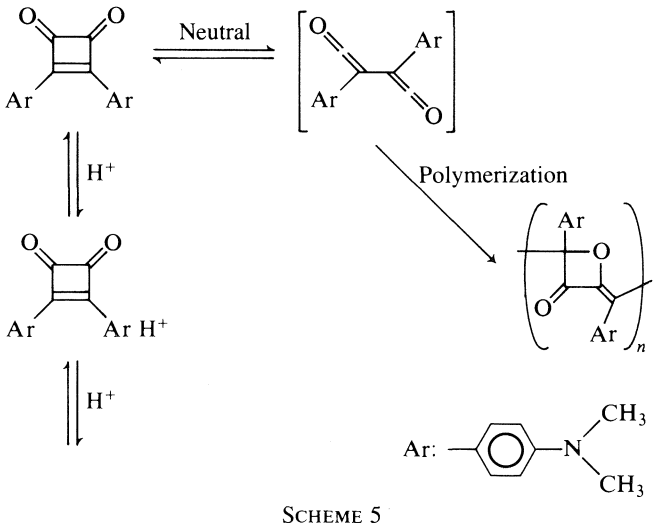
6

In 1961, Blomquist and LaLancette reported that the parent compound of **6**, 1,2-diphenylcyclobutene-3,4-dione (**7**), undergoes a ring-opening reaction at room temperature in ethanol to give diethyl α,α′-diphenylsuccinate (16).

In the present work, it appears that **6** is stable in acidic



SCHEME 4



SCHEME 5

[13]The spectroscopic data of **5** are ir ($CHCl_3$): 1782 and 1730 (C=O) cm^{-1}; nmr (CD_2Cl_2) δ: 1.01 (t, J = 6 Hz, 3H), 1.2–2.2 (m, 4H), 3.12 (s, 6H), 4.88 (t, J = 6 Hz, 2H), 6.78 (d, J = 9.2 Hz, 2H), and 7.95 (d, J = 9.2 Hz, 2H); ms (m/z): 273 (M^+) and 217 ($M^+ - 2CO$).

[14]1,2-Bis(*p*-dimethylaminophenyl)cyclobutene-3,4-dione, **6**, was synthesized from squaric acid dichloride and *N*,*N*-dimethylaniline in carbon disulfide, yield ~10%, mp 273–274.5°C; ir (KBr): 1755 and 1735 (C=O) cm^{-1}; nmr (CD_3Cl_2) δ: 3.12 (s, 6H), 6.79 (d, J = 9.5 Hz, 2H), and 8.09 (d, J = 9.5 Hz, 2H); ms (m/z): 320 (M^+) and 264 ($M^+ - 2CO$).

solution, presumably due to the protonation of the nitrogen atoms by sulfuric acid. In neutral chloroform solution, **6** undergoes a ring-opening reaction analogous to its parent compound to give a diketene intermediate that polymerizes to form a polymeric product. The proposed structure of the polymeric product is given in Scheme 5 and its yield was ~22%.

Our product analysis accounts for 98% of the materials. The major side reactions of the squaraine synthesis are arylation and diarylation of **2** to give **5** and **6** respectively. Further yield-improvement experiments should be focussed on the identification of reaction conditions where the competition between hydrolysis and arylation is minimal.

The yield optimization experiments performed in this work are concentrated on the yield of squaraine product isolated in each experiment, and the reaction conditions are not necessarily ideal for individual steps (e.g., steps a, c, and d in Scheme 2). It is anticipated that further yield improvement may be obtained by segmenting the squaraine synthesis into three steps (partial hydrolysis of **2**, arylation of **3**, and arylation of **4**) and optimizing them individually.

Nucleophilic attack on the carbon–carbon double bond. I. Reaction of primary and secondary amines with 2,2-di(4-nitrophenyl)-1,1-difluoroethene

KENNETH T. LEFFEK AND URSZULA MACIEJEWSKA[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6

Received April 30, 1986

KENNETH T. LEFFEK and URSZULA MACIEJEWSKA. Can. J. Chem. **64**, 2274 (1986).

The reaction of primary and secondary amines with 2,2-di(4-nitrophenyl)-1,1-difluoroethene (**1**) in acetonitrile solvent gives first 2,2-di(4-nitrophenyl)-1-fluoro-1-aminoethene (**2**) and then 2,2-di(4-nitrophenyl)-1,1-difluoro-1-aminoethane (**3**). With excess amine, pseudo-first-order rate constants for the production of **2** were measured, which showed a second-order reaction, together with a catalysed third-order reaction. In addition to the reagent amines, the reaction is also catalysed by tertiary amines and bases such as oxalate and acetate, but not by chloride and perchlorate, nor by ammonium ions. The enthalpy of activation for the reaction of piperidine with **1** in acetonitrile is 3.7 kcal mol^{-1}, but for the catalysed reaction an apparent value of -2.2 kcal mol^{-1} was obtained. It is concluded that the reaction proceeds via a pre-equilibrium to a zwitterion, followed by another equilibrium giving a carbanion that yields the product (**2**) by a rate-determining cleavage of the carbon–fluorine bond.

KENNETH T. LEFFEK et URSZULA MACIEJEWSKA. Can. J. Chem. **64**, 2274 (1986).

Lorsqu'on opère dans l'acétonitrile comme solvant, la réaction des amines primaires ainsi que secondaires avec le di (nitro-4 phényl)-2,2 difluoro-1,1 éthène (**1**) conduit initialement à la formation du di (nitro-4 phényl)-2,2 fluoro-1 amino-1 éthène (**2**) et finalement au di (nitro-4 phényl)-2,2 difluoro-1,1 amino-1 éthane (**3**). Opérant en présence d'un excès d'amine, on a mesuré les constantes de vitesse du premier ordre pour la formation du composé **2**; on a aussi noté la présence d'une réaction du deuxième ordre ainsi qu'une réaction catalysée du troisième ordre. En plus des réactifs aminés, les amines tertiaires et les bases comme l'oxalate et l'acétate catalysent aussi cette réaction; toutefois les ions chlorure, perchlorate ainsi qu'ammonium n'agissent pas comme catalyseurs. Dans l'acétonitrile, l'enthalpie d'activation pour la réaction du composé **1** avec la pipéridine est égale à 3,7 kcal mol^{-1}; toutefois, pour la réaction catalysée, on observe une valeur apparente de $-2,2$ kcal mol^{-1}. On en conclut que la réaction se produit par le biais d'un pré-équilibre conduisant à un zwitterion qui, par un autre équilibre, conduit à un carbanion qui conduit au produit **2** par un clivage de la liaison carbone–fluor qui détermine la vitesse de la réaction.

[Traduit par la revue]

Introduction

In the study of the β-elimination of 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane promoted by alkoxide bases, it was noted (1) that the first olefin product, 2,2-di(4-nitrophenyl)-1,1-difluoroethene reacted rapidly with the excess base to give further substituted olefins. Nucleophilic attack of fluoroolefins has been known since 1946 (2) and numerous synthetic applications have been reported (3). Koch *et al.* (4) have studied the reactions of *gem*-difluoroethenes with alkoxide bases. With the base in at least 10-fold excess, the major products were alkoxy-substituted ethenes, consistent with a mechanism involving partitioning of a carbanion intermediate.

A number of kinetic studies have also been carried out for nucleophilic additions to olefins, and for substitution via additions to olefins, activated by electron-withdrawing groups other than fluorine (5–8), and different rate-determining steps for the reactions were found under various sets of conditions. The rate-determining step varied from the departure of the leaving group (5), to proton transfer (6, 8), to the nucleophilic attack on the olefin (7). Rappoport *et al.* (9, 10) have studied the attack of primary amines on 1,1-dicyano-2-fluoroolefins, in which the fluorine is replaced to yield a cyanoenamine. The reaction was shown to be base catalysed and a mechanism involving a competition between carbon–fluorine bond cleavage and nitrogen–hydrogen bond cleavage was proposed.

The present study was carried out to determine the products, and the mechanism of their formation, of the reaction of primary and secondary amines with 2,2-di(4-nitrophenyl)-1,1-difluoroethene (**1**), under conditions where the initial products of the reaction were stable.

[1]Postdoctoral Fellow 1984–1985.

Results and discussion

Product analysis

The product of the reaction between amines and the olefin (**1**) in acetonitrile solvent depends on the ratio of the concentration of amine to olefin and also on the type of amine. With the amine in at least a threefold excess over the olefin, the secondary amines morpholine, piperidine, and pyrrolidine gave only the fluoroenamine (**2**) as product (Scheme 1). A separate experiment showed that the fluoroenamine **2** does not react with piperidine. With the primary amines, methoxyethylamine, *n*-propylamine, isobutylamine, benzylamine, and cyclohexylamine, the fluoroenamine was (**2**) produced, together with the saturated compound (**3**).

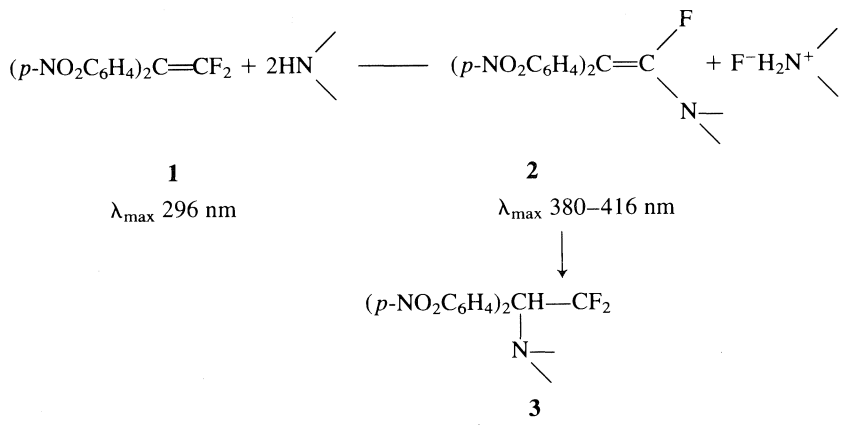
When the amine-to-olefin ratio was less than 3, all amines, both secondary and primary, gave both products **2** and **3**, with **2** the major product after short reaction times and **3** the major product after long reaction times. Therefore, **3** is interpreted as arising from **2** by the addition of the elements of HF as shown in Scheme 1.

In addition, small amounts of 2,2-di(4-nitrophenyl)-1,1,1-trifluoroethane were produced, which must derive from the addition of HF to the substrate olefin (**1**).

The stability of the fluoroenamine **2** with respect to nucleophilic addition by secondary amines, in contrast to the reactivity of the analogous 2,2-di(4-nitrophenyl)-1-fluoro-1-ethoxyethene towards ethoxide ion (1), makes the reaction of amines with the olefin **1** particularly suitable for a kinetic investigation.

Kinetics

All kinetic runs were carried out with a large excess of amine to give pseudo-first-order kinetics and to ensure that the substrate reacted only with the amine base, so that the initial



SCHEME 1

product was the enamine **2**. The reaction was followed spectrophotometrically by monitoring the decrease of absorption at 296 nm, the λ_{max} of the olefin substrate, and also the absorption in the visible region due to the enamine (400 nm for the piperidine reaction). The reactions were followed to 70–90% completion in acetonitrile solvent. Pseudo-first-order rate constants were calculated and divided by the amine concentration to obtain the second-order rate constants, $k_{2\,obs}$, which are shown in Table 1. The second-order rate constants increase linearly with the amine concentration and can be fitted to eq. [1].

$$[1] \quad k_{2\,obs} = k'_{2\,obs} + k_{3\,obs}[\text{amine}]$$

A linear least-squares fit of $k_{2\,obs}$ to eq. [1] gives the uncatalysed rate constant $k'_{2\,obs}$ as the intercept and the catalyzed rate constant $k_{3\,obs}$ as the slope. These values are given in Table 2 together with their standard deviations. The pK_a values quoted for the conjugate acids are those of Coetzee (11). It can be seen that, generally, the catalysed reaction accounts for more than half of the reaction at the amine concentrations used. Both $k'_{2\,obs}$ and $k_{3\,obs}$ show a rough correlation with the pK_a of the conjugate acid of the base for the four values of pK_a in acetonitrile shown in Table 2. The uncatalysed reaction gives a correlation coefficient of 0.93 between log $k'_{2\,obs}$ and pK_a with a slope of approximately unity. The catalysed reaction gives a correlation coefficient of 0.965 between log $k_{3\,obs}$ and pK_a with

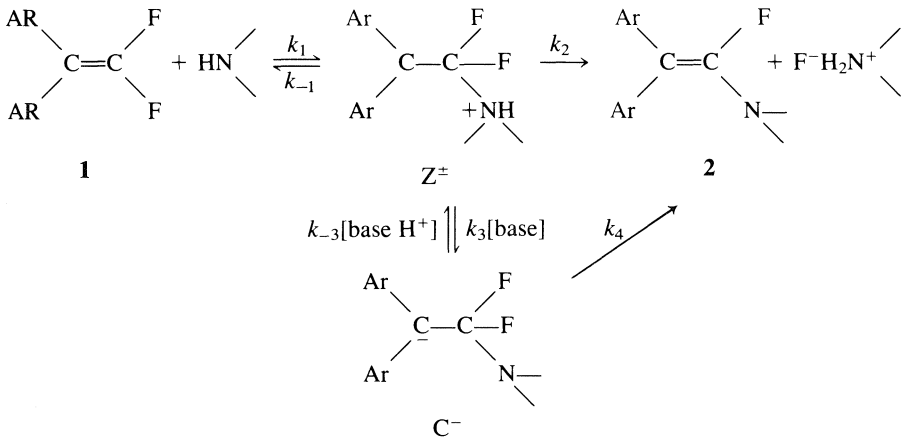

SCHEME 2

a slope of 1.1 ± 0.2. Both of these calculations were based on the four points for which the pK_a values in acetonitrile are quoted in Table 2.

Within the experimental error, both the catalysed and the uncatalysed rate constants show no significant difference between the determination based on the disappearance of the substrate and that based on the appearance of the enamine product **2**. Thus, the substrate is undergoing a reaction in which there is no accumulation of an intermediate between the substrate and the enamine **2**. Scheme 2 shows the probable reaction steps for the reaction.

Rappoport and co-workers (5, 9, 10) and Bernasconi *et al.* (12) proposed a similar mechanism for the reaction of primary and secondary amines to cyano and nitro olefins.

The observed kinetics can be fitted to Scheme 2 in either of two ways. The nucleophilic attack of the amine on the carbon atom of the olefin that bears the fluorine atoms could be the rate-controlling step, followed by a rapid loss of HF in one or two fast steps. On the other hand, there could be a fast pre-equilibrium to yield $Z^{\pm}$ and (or) C^- with a very small equilibrium constant, followed by a slow rate-controlling loss of fluoride. Since fluoride is generally a poor leaving group in nucleophilic substitution reactions, the latter alternative seems to be the more likely mechanism. Since the reaction does not take place with tertiary amines, it is clear that the proton on the nitrogen plays an important role in the departure of the fluoride.

The kinetics of the piperidine reaction were investigated at several temperatures in acetonitrile and tetrahydrofuran solvents. Using the same procedure as before, the uncatalysed and catalysed rate constants were determined and these are collated in Table 3, together with the activation parameters derived from these rate constants. The uncatalysed reaction shows normal activation parameters, but the catalysed reaction gives a negative $\Delta H^{\neq}$ in acetonitrile and a very low $\Delta H^{\neq}$ in tetrahydrofuran, indicating that at least the catalysed reaction involves a pre-equilibrium before the rate-determining step. Both the catalysed and uncatalysed rates are markedly slower in tetrahydrofuran, which may indicate that the solvent effect acts predominantly on the first equilibrium of Scheme 2. However, the experiments in tetrahydrofuran were done primarily to ensure that there was nothing unique about the results in acetonitrile solvent. Very small and negative $\Delta H^{\neq}$ values were also observed by Rappoport and Peled (5) for the catalysed reactions of piperidine and morpholine with fluoro and cyano-olefins in acetonitrile.

To elucidate the nature of the catalysed reaction, the catalytic effects on the piperidine reaction of added alkyl ammonium salts and tertiary amines were studied. The kinetic results were fitted to eq. [2], an extended form of eq. [1].

$$[2]\quad k_{2\,obs} = k'_{2\,obs} + k_{3\,obs}[\text{amine}] + k_{4\,obs}[\text{catalyst}]$$

A plot of $k_{2\,obs}$ vs. catalyst concentration gives ($k'_{2\,obs}$ +

†Inhibition rate constant.

$k_{3\,obs}$[amine]) as the intercept and $k_{4\,obs}$ as the slope. For each catalyst a series of runs was carried out at different catalyst concentrations. Values of $k_{2\,obs}$ were obtained by dividing $k_{1\,obs}$ by the piperidine concentration, and $k_{4\,obs}$ was calculated by a least-squares fit to eq. [2]. The results are summarized in Table 4. The reactions were monitored at 400 nm unless otherwise noted.

The results show that the reaction is catalysed by tertiary amines, oxalate and acetate ions, but not by alkyl ammonium ions, perchlorate or chloride ions. Rappoport and Ta-Shma (9) also found that the ammonium ion did not catalyse the reaction of *p*-toluidine with 1,1-dicyano-2-*p*-dimethylaminophenyl-2-fluoroethylene.

Thus, it is clear that the catalysed step is the deprotonation of the zwitterion rather than the departure of the fluoride ion, because fluoride ion departure would be expected to be catalysed by the ammonium ion. It would still be possible to have a rate-determining uncatalysed cleavage of fluoride if it can be assumed that F^- departs more rapidly from C^- than from $Z^{\pm}$. The catalysis would then take place by simply changing the position of the deprotonation equilibrium. This interpretation is supported by the fact that there is a reasonable correlation between log $k_{3\,obs}$ and pK_a for the catalysed reaction for the results shown in Table 2. This means that the sensitivity of the zwitterion $Z^{\pm}$ to deprotonation is essentially the same as that of the amine to protonation.

A steady-state approximation applied to Scheme 2 yields eq. [3], if it is assumed that $k_4 \gg k_{-3}$[base H^+] and $k_{-1} \gg k_2 + k_3$[amine], i.e., that the carbon–fluorine bond cleavage is not rate determining.

$$[3] \quad k_{2\,obs} = \frac{k_1}{k_{-1}} \cdot k_2 + \frac{k_1}{k_{-1}} \cdot k_3[\text{amine}]$$

This predicts that $\Delta H^{\neq}$ should not be dramatically different for the catalysed and uncatalysed reactions. Both would be expected to be positive values, but if one were negative, as a result of an unusual temperature dependence of k_1/k_{-1}, the other would also be negative or a very small positive value. Thus, the results in Table 3 do not fit this assumption.

The alternative assumption, that k_{-3}[base H^+] $\gg k_4$ and that $k_{-1} \gg k_2 + \dfrac{k_3 k_4[\text{amine}]}{k_{-3}[\text{base H}^+]}$, yields eq. [4].

$$[4] \quad k_{2\,obs} = \frac{k_1 k_2}{k_{-1}} + \frac{k_1}{k_{-1}} \frac{k_3 k_4[\text{amine}]}{k_{-3}[\text{amine H}^+]}$$

Equation [4] allows $\Delta H^{\neq}$ for the catalysed reaction to be distinctly different from that for the uncatalysed reaction, by the equilibrium constant k_3/k_{-3} having a different temperature dependence from that of k_1/k_{-1}.

The catalysis of the reaction results from an increase in the rate of the step k_3, in which the zwitterion $Z^{\pm}$ is converted to the carbanion C^-, by virtue of the additional base, relative to the reverse step k_{-3}. This additional base may be a secondary or

tertiary amine or an anion such as acetate or oxalate. Weak bases such as Cl^- and ClO_4^- show little or no catalytic effect. Adding ammonium ion without a moderately strong basic anion increases the rate of the back reaction of the carbanion C^- to the zwitterion and, therefore, retards the overall reaction, in general agreement with the results in Table 4.

Therefore, it is concluded that the reaction takes place by the mechanism in Scheme 2, in which the carbon–fluorine bond breaking is rate determining, but the overall rate is catalysed or retarded by changes in the rates of the steps that interconvert the zwitterion and the carbanion.

Experimental

Materials

2,2-Di(4-nitrophenyl)-1,1,1-trifluoroethane was prepared from α,α,α-trifluoroacetophenone as previously described (1). The substrate 2,2-di(4-nitrophenyl)-1,1-difluoroethene was prepared from this by reaction with excess sodium hydride in very carefully dried tetrahydrofuran. The reaction mixture was refluxed for 10 h protected from atmospheric moisture, during which time about 50% conversion to the ethene took place. After evaporation of the THF, ethyl ether was used to separate the organics from the inorganic residue. The mixture of product and starting material was separated by column chromatography with Kieselgel 60 and a 3:1 mixture of benzene and *n*-hexane as eluent. The ethene product gave mp 129–130°C; λ_{max}: 296 nm in CH_3CN; nmr δ (CD_3CN): 8.22 (d, 4H) and 7.5 (d, 4H).

The reagent amines were dried over KOH and fractionally distilled twice before use of the middle fraction. The concentration of the amine solutions was determined by tiration with standard perchloric acid in acetic acid solvent (13).

The ammonium salts were prepared by reacting the purified piperidine and quinuclidine with the appropriate acid in THF and precipitating the salt with a mixture of ethyl ether and benzene. The salts were washed and dried before use.

The acetonitrile solvent was purified by the method of O'Donnell *et al.* (14) and fractionally distilled first from P_2O_5 and then from CaH_2.

Product analyses

The reaction mixture was separated by column chromatography using Kieselgel 60 and an eluent made up of chloroform, benzene, and *n*-hexane in a ratio 12:3:1. The fractions were analysed by tlc, nmr, and uv spectroscopy.

Kinetics

A fresh 5×10^{-5} *M* solution of the olefin was prepared for each set of runs. Each set consisted of five runs, each with a different amine concentration. The five runs were carried out simultaneously in 1-cm uv cells in a Cary 219 spectrophotometer fitted with a temperature-controlled cell block. Pseudo-first-order rate constants were calculated by a least-squares fit to eq. [5]

$$[5] \quad k_{obs} = 1/t \ln \frac{D_0 - D_\infty}{D_t - D_\infty}$$

where D_0, D_t, and D_∞ represent the optical density of the reaction mixture at time zero, time t, and at infinity, respectively.

Electrosorption of vinyltriphenyl and propargyltriphenylphosphonium cations from methanolic solutions at the dropping and hanging mercury drop electrodes

ANASTASIA CHRISTODOULOU, ANASTOS ANASTOPOULOS, AND DEMETRIOS JANNAKOUDAKIS
University of Thessaloniki, Thessaloniki 54006, Greece

Received February 19, 1986

ANASTASIA CHRISTODOULOU, ANASTOS ANASTOPOULOS, and DEMETRIOS JANNAKOUDAKIS. Can. J. Chem. **64**, 2279 (1986).

The interfacial behaviour of vinyltriphenyl and propargyltriphenylphosphonium cations at the mercury electrode – methanolic solution interface is studied by phase selective ac polarography using dropping Hg electrodes of short (≤5 s) and long (≃20 s) drop times and the hanging Hg drop electrode.

The various adsorption parameters are determined on the basis of non-ionic adsorption isotherms involving capacitance data independent as well dependent on time.

ANASTASIA CHRISTODOULOU, ANASTOS ANASTOPOULOS et DEMETRIOS JANNAKOUDAKIS. Can. J. Chem. **64**, 2279 (1986).

Faisant appel à la polarographie à ca et à phase sélective et utilisant soit des électrodes à goutte tombante de mercure avec des temps de chute court (≤5 s) et longs (≃20 s) soit une électrode à goutte pendante de mercure, on a étudié le comportement interfacial des cations vinyltriphényl- et propargyltriphenyl-phosphonium.

On a déterminé les divers paramètres d'adsorption en se basant sur des isothermers d'adsorptions non-ioniques impliquant des données de capacitance tant indépendantes que dépendantes du temps.

[Traduit par la revue]

Introduction

Since the pioneering work of Gerovich *et al.* (1), a small but increasing amount of data concerning the adsorption of tetraphenyl and a series of alkyltriphenylphosphonium cations have now appeared in the literature (2–7).

Contrary to many works on the adsorption of quaternary ammonium cations, the interfacial behaviour of phosphonium cations is rarely treated (6) in terms of nonionic isotherms, thus limiting the information available to the characteristics of the development of the adsorption film. Although remarkable efforts have been made by Damaskin and co-workers (8–12) on the development of adsorption isotherms for organic cations, information resulting from non-ionic isotherms, though it will be criticized, may help our understanding on the adsorption behaviour of these substances.

In this work the electrosorption of quaternary phosphonium cations with alkyl groups having multiple bonds are analyzed by means of the Frumkin and Flory–Huggins isotherms to determine the standard free energy of adsorption, the interparticle forces, the maximum surface concentration, and the area per adsorbed particle of vinyltriphenyl- and propargyltriphenyl-phosphonium cations. The adsorption equilibrium of these substances is controlled by their diffusion from the bulk to the inferface and so the use of time-dependent capacitance data, when combined with theoretical adsorption isotherms, allows for a quantitative description of the adsorbed film characteristics.

Experimental

The variation of the differential capacity against the time and the dc polarization potential was recorded by fundamental harmonic phase selective ac polarography, similar to a previous publication (6). The electrochemical system used was the following:

Hg electrode	Phosphonium salt 0.1 *M* CsCl MeOH Working cell	0.1 *M* CsCl MeOH Electrolytic contact	0.1 *M* CsCl H_2O Reference cell	sce with NaCl

The characteristics of the DME with short drop times were 2.235 mg/s (flow rate) and a drop time of 4 s controlled to 2 s by a drop timer system. The DME with large drop times (≃20 s) had a flow rate of 0.35 mg/s and the HMDE was controlled under constant temperature to obtain a radius of 4.27×10^{-2} cm during all measurements.

Methanol (Merck, pro analysi), CsCl (Merck, pro analysi), and propargyltriphenylphosphonium bromide (Fluka, purum 99%) were used without further purification. Vinyltriphenylphosphonium bromide (Fluka, pract. > 95%) was twice recrystallized from water–ethanol solutions, subsequently dried at 140°C under reduced pressure and its melting point was found to be 182–183°C after the recrystallization process.

The solutions were deaerated by a stream of purified nitrogen, previously saturated with vapours of the base solution. All measurements were carried out at 25 ± 0.05°C. The standard deviation of the differential capacity values is less than 2% at the overall potential range studied.

Results and discussion

To study the electrosorption of vinyltriphenyl-, $(VPh_3P)^+$, and propargyltriphenyl-, $(PgPh_3P)^+$, phosphonium cations from methanolic solutions of 0.1 *M* CsCl, capacitance versus potential curves were recorded for various concentrations of the bromide salts of the above cations and they are provided in Figs. 1 and 2.

Capacitance current versus time measurements were also recorded at the DME, at the potentials −0.6, −0.8, −1.05, −1.2, −1.4 V/sce and some of them are shown in Fig. 3.

From the *C–E* curves in Figs. 1 and 2 it is seen that the adsorption of $(VPh_3P)^+$ and $(PgPh_3P)^+$ does not lead to the appearance of capacitance maxima. At the anodic region the lack of maxima must be attributed to the metal–adsorbate interactions between the phenyl groups and the Hg conduction band. At extreme negative polarizations the discharge of the adsorbed cations — occurring at the vicinity of −1.60 V/sce — prior to their complete desorption from the electrode surface, possibly justifies (2) the lack of cathodic adsorption–desorption peaks.

Two potential regions of limiting minimum capacitance were not observed, indicating the absence of condensation effects in the adsorption layer, this was in agreement with the behaviour of the phosphonium cations in non aqueous systems (5, 6).

The absence of discontinuities in the formation of the adsorption layer is also confirmed by the form of the i_c–t curves

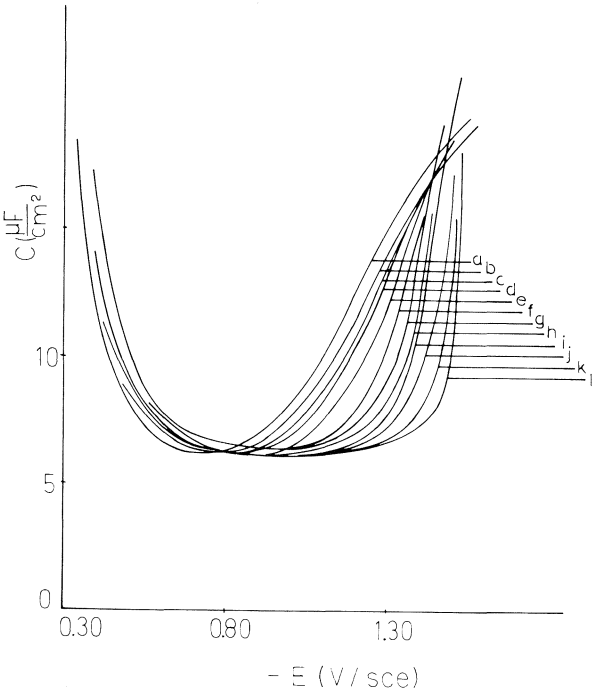

FIG. 1. Differential capacitance of 0.1 *M* CsCl methanolic solutions containing the following VPh_3PBr concentrations: *a*, 0.00; *b*, 2.5×10^{-5} *M*; *c*, 3.75×10^{-5} *M*; *d*, 5×10^{-5} *M*; *e*, 10^{-4} *M*; *f*, 2.5×10^{-4} *M*; *g*, 3.75×10^{-4} *M*; *h*, 5×10^{-4} *M*; *i*, 7.5×10^{-4} *M*; *j*, 10^{-3} *M*; *k*, 1.5×10^{-3} *M*; *l*, 2×10^{-3} *M* at the dme.

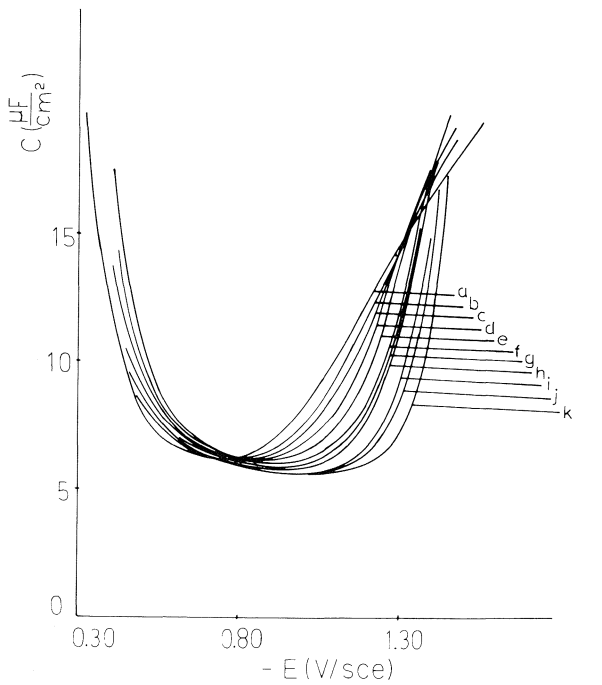

FIG. 2. Differential capacitance curves of 0.1 *M* CsCl methanolic solutions containing the following $PgPh_3PBr$ concentrations: *a*, 0.00; *b*, 2.5×10^{-5} *M*; *c*, 5×10^{-5} *M*; *d*, 10^{-4} *M*; *e*, 1.5×10^{-4} *M*; *f*, 2.5×10^{-4} *M*; *g*, 3.75×10^{-4} *M*; *h*, 5×10^{-4} *M*; *i*, 7.5×10^{-4} *M*; *j*, 10^{-3} *M*; *k*, 2×10^{-3} *M* at the dme.

of Figs. 3. Here a regular development of the adsorbed film is reflected without humps or abrupt changes, thus leading to the conclusion that the presence of methanol prevents the occurrence of surface condensation or other interfacial rearrangement effects.

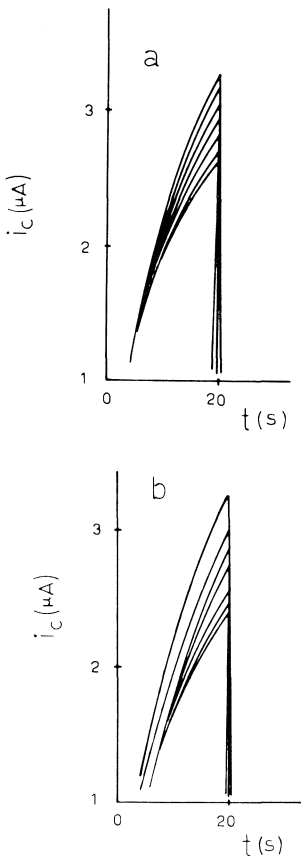

FIG. 3. Capacitance current vs. time curves, at −1.05 V/sce, of 0.1 *M* CsCl methanolic solutions in the presence of the following additions (from top to bottom) of (*a*) VPh_3PBr: 0.0 *M*, 5×10^{-6} *M*, 7.5×10^{-6} *M*, 1.25×10^{-5} *M*, 2.5×10^{-5} *M*, 3.75×10^{-5} *M*, 5×10^{-5} *M*. (*b*) $PgPh_3PBr$: 0.0 *M*, 1.25×10^{-5} *M*, 1.75×10^{-5} *M*, 2.5×10^{-5} *M*, 3.75×10^{-5} *M*, 5×10^{-5} *M*, 7.5×10^{-5} *M*.

The *C*–*E* curves of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations, in spite of their similar shape, reveal a difference in the adsorbate concentration at which the limiting minimum capacitance, C_{lim}, is attained.

In the presence of $(PgPh_3P)^+$ the increase in concentration causes a gradual depression of the minimum down to a limiting value, 5.30 $\mu F/cm^2$, attained at the concentration 7.5×10^{-4} *M*.

For $(VPh_3P)^+$ cations a limiting value, 5.97 $\mu F/cm^2$, is attained at concentrations $c \geq 10^{-5}$ *M*. This difference can be interpreted in terms of a corresponding difference in their adsorbabilities, which determines the influence of concentration on the formation of a saturation monolayer, as long as all the other characteristics and adsorption parameters do not differ appreciably.

Isotherm analysis

The capacitance potential data in Figs. 1 and 2 were analyzed by means of two well known nonionic isotherms, viz. Frumkin isotherm:

$$[1] \quad \ln \frac{\theta}{(1-\theta)c} = \ln \mathscr{C} + 2a\theta$$

and a type of Flory–Huggins isotherm:

$$[2] \quad \ln \frac{\theta}{(1-\theta)^r c} = \ln \mathscr{C} + 2ar\theta$$

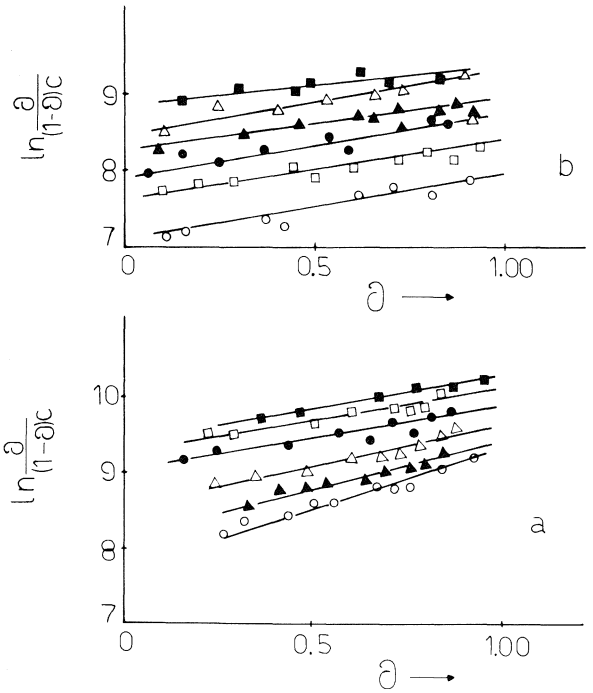

FIG. 4. Test of Frumkin isotherm for VPh_3PBr (*a*) and $PgPh_3PBr$ (*b*) at the following potentials in V/sce: ■ −1.05, △ −1.10, ▲ −1.15, ● −1.20, □ −1.25, ○ −1.30.

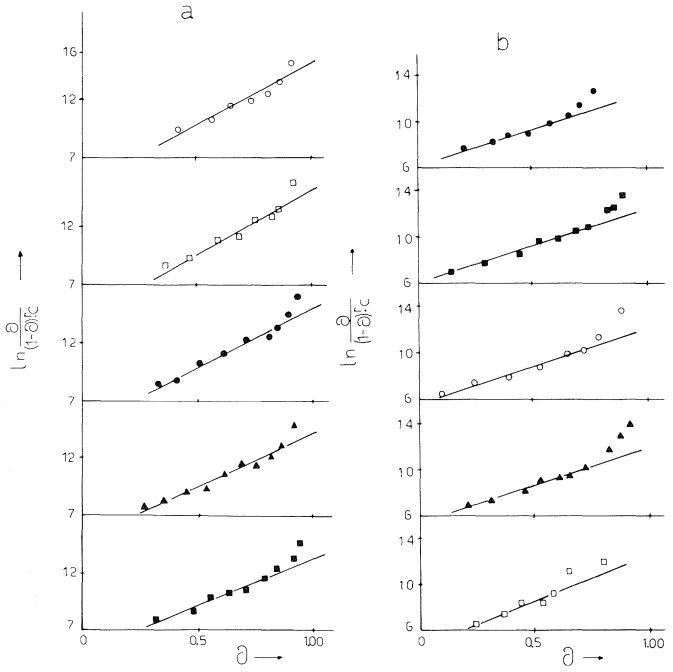

FIG. 5. Test of Flory–Huggins isotherm for VPh_3PBr (*a*) and $PgPh_3PBr$ (*b*) at the following potentials in V/sce: ● −1.00, ■ −1.05, ○ −1.10, ▲ −1.15, □ −1.20.

where θ is the surface coverage calculated by the relation $\theta = (C_0 - C)/(C_0 - C_{lim})$ at the potential region where the condition $d\theta/dE = 0$ is satisfied, C_0 is the capacitance of the base electrolyte, and C_{lim} is the minimum limiting capacitance at maximum coverage, determined by extrapolation of the minimum capacitance vs. concentration plot to high surfactant concentration. In eqs. [1] and [2], c is the bulk concentration, $\mathscr{C}$ is the adsorption equilibrium constant, and a is an interaction parameter. In eq. [2], r is the size ratio which is set equal

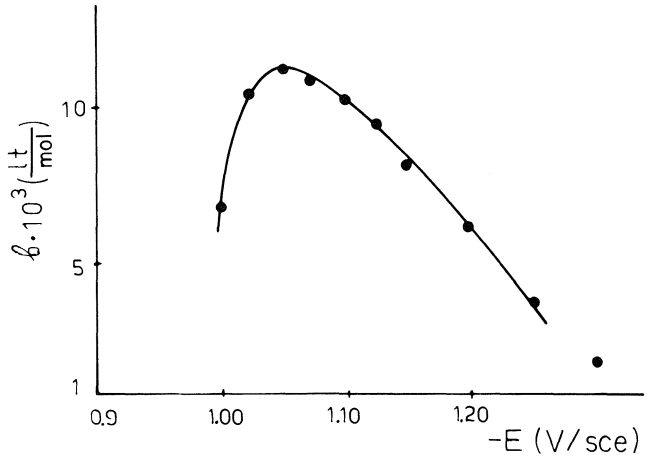

FIG. 6. Variation of the adsorption equilibrium constant of VPh_3PBr with potential.

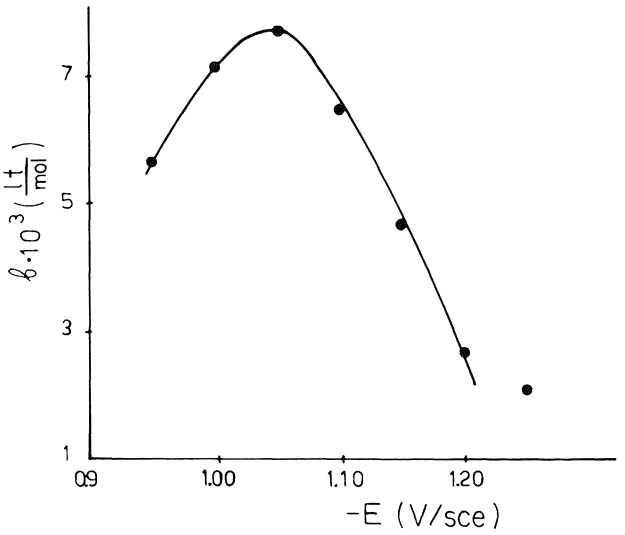

FIG. 7. Variation of the adsorption equilibrium constant of $PgPh_3PBr$ with potential.

to 4, estimated from the area per adsorbed phosphonium cation (approximately 0.75 nm^2) and methanol molecule (0.186 nm^2 according to ref. 13). The results on the test of isotherms [1] and [2] are provided in Figs. 4 and 5, revealing a fair agreement of these isotherms with our experimental data.

The lines in Figs. 4 and 5 have constant positive slopes corresponding to a prevalence of attractive interactions at the interface. However, due to the complex nature of the interaction parameter and the simplicity of the Frumkin and Flory–Huggins models, it is impossible to strictly correlate this parameter to the interactions occurring at the interface. In terms of the solvent–solvent, solvent–adsorbate, and adsorbate–adsorbate interactions, the positive slopes of the plots of Figs. 4 and 5 may be related to positive deviations from Raoult's law (14).

A small variation in slope with potential is only observed in Fig. 6*a* for $(VPh_3P)^+$ cations, where the slope is seen to increase with increasing cathodic potentials. Equations [1], [2], and the plots in Figs. 6, 7 enable the determination of the adsorption equilibrium constant and the potential of maximum adsorption.

The variation in the adsorption equilibrium constant of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations with potential is shown in Figs. 6 and 7, where it is seen that there is an approximately

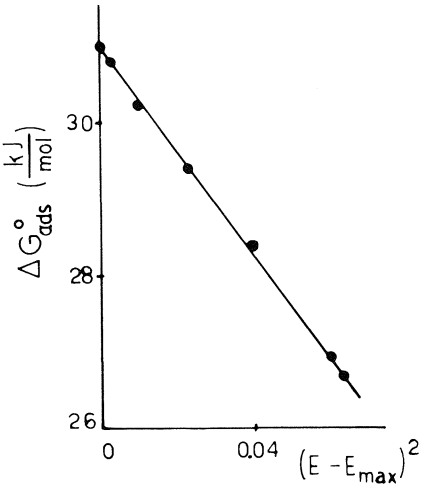

FIG. 8. Variation of the standard free energy of adsorption of VPh_3PBr against the quantity $(E - E_{max})^2$.

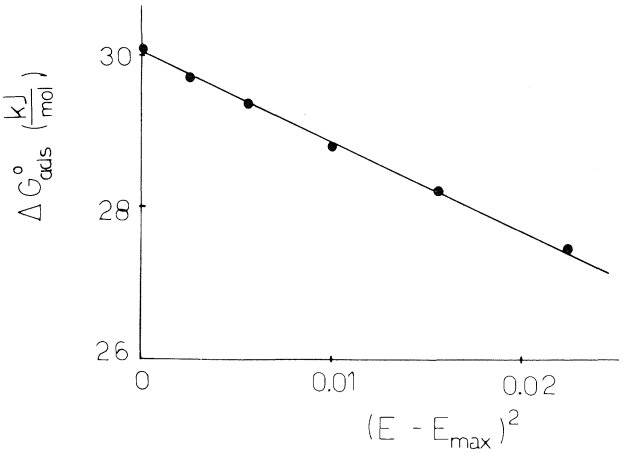

FIG. 9. Variation of the standard free energy of adsorption of $PgPh_3PBr$ against the quantity $(E - E_{max})^2$.

quadratic dependence of $\mathscr{C}$ on E, which reaches a maximum value of 11.2×10^3 and 7.7×10^3 L/mol, respectively.

As long as the value of the adsorption equilibrium constant at a certain potential is a measure of the adsorbability of the substance under examination, we can conclude that in methanol $(VPh_3P)^+$ cations present a moderate adsorbability while the adsorbability of $(PgPh_3P)^+$ is somewhat lower. The potential at which maximum adsorbability is detected can be identified with the potential of maximum adsorption, provided that the interaction parameter does not change significantly with potential.

For both substances examined E_{max} was found at -1.05 V/sce.

From the $\mathscr{C}$–E curves and the equation

$$[3] \quad \mathscr{C} = \frac{1}{24.56} \exp\left(-\frac{\Delta G^0_{ads}}{RT}\right)$$

we calculated the values of the standard free energy of adsorption against the quantity $(E - E_{max})^2$. The resulting plots for $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations are shown in Figs. 8 and 9.

It is seen that there is a linear dependence of ΔG^0_{ads} on $(E - E_{max})^2$, though for a narrow potential range. This feature is not typical of interfacial behaviour of ionic species. The values of ΔG^0_{max} corresponding to E_{max} were found to be -31.00 and -30.10 kJ/mol for $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations, respectively.

Maximum surface concentration of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations

The kinetics of adsorption of a species at the electrode–solution interface can be used as a means for the determination of its surface concentration. This can be achieved either by examining the dependence of differential capacitance values on the frequency of the ac signal or on the time of exposure of the electrode surface in the electrolyte solution. The latter is suitable for systems without adsorption–desorption maxima, as the C–E curves in Figs. 1 and 2. For this purpose capacitance–time measurements were carried out for $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations both at the DME with long drop times and at the HMDE. In Figs. 10 and 11 we provide the C—$t^{1/2}$ and C–$t^{-1/2}$ curves of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations, recorded at the potential of maximum adsorption and at the DME and HMDE, respectively.

According to Koryta (15) and Levich (16) the linearity of the experimental plots in Figs. 10 and 11 is evidence for diffusion

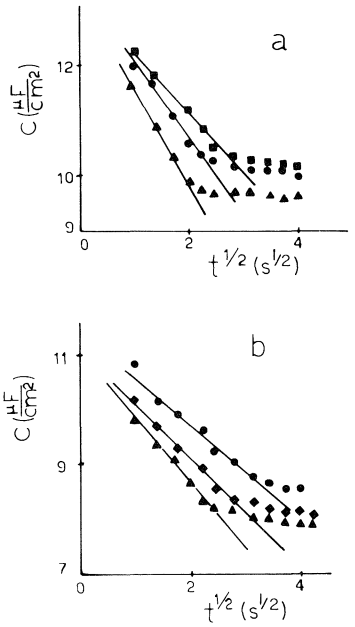

FIG. 10. Variation of the differential capacitance with $t^{1/2}$ at the dme. (*a*) For the following VPh_3PBr concentrations: ● 1.25×10^{-5} *M*, ■ 2.5×10^{-5} *M*, ▲ 3.75×10^{-5} *M*. (*b*) For the following $PgPh_3PBr$ concentrations: ● 2.5×10^{-5} *M*, ■ 3.75×10^{-5} *M*, ▲ 5×10^{-5} *M*.

control of the establishment of the adsorption equilibrium. The C–$t^{1/2}$ curves in Fig. 10 enable the calculation of the maximum surface concentration, Γ_{max}, with the aid (17) of equation

$$[4] \quad C_t = C_0 - 7.36 \times 10^{-4} D^{1/2}(C_0 - C_{lim})c\Gamma^{-1}_{max}t^{1/2}$$

where the symbols C_0 and C_{lim} are previously defined, C_t is the capacity at intermediate surfactant concentrations at time t, c is the phosphonium cation concentration, D is the diffusion coefficient, and Γ_{max} is the maximum surface concentration. The value of the diffusion coefficient was determined by polarographic measurements and was found equal to $(5 \pm 0.2) \times 10^{-6}$ cm^2/s. From eq. [4] the values of 2.05×10^{-10} and 2.11×10^{-10} mol/cm^2 were obtained for the maximum surface concentrations of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations, respectively.

At the potential of maximum adsorption according to ref. 18,

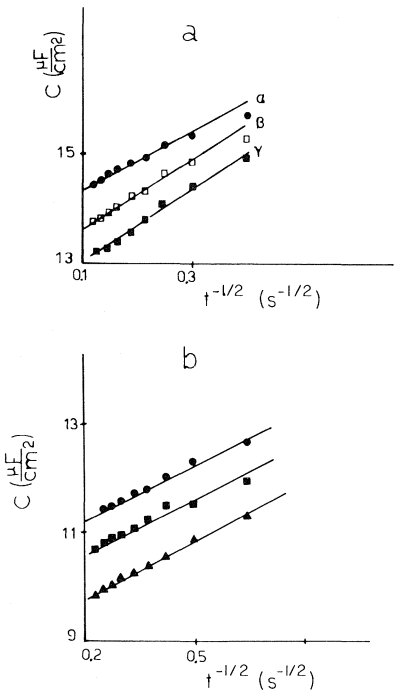

FIG. 11. Variation of the differential capacitance with $t^{1/2}$ at the HMDE. (*a*) For the following VPh_3PBr concentrations: ● 7.5×10^{-6} *M*, ■ 1.25×10^{-5} *M*, ▲ 2.5×10^{-5} *M*. (*b*) For the following $PgPh_3PBr$ concentrations: ● 2.5×10^{-5} *M*, ■ 3.75×10^{-5} *M*, ▲ 5×10^{-5} *M*.

for a system obeying the Frumkin isotherm, the following equation is valid:

$$[5] \quad \left[\frac{dC_t}{dt^{1/2}}\right]_{E=E_{max}} = \frac{(C_0 - C_{lim})\Gamma_{max}\theta_e^2(1-\theta_e)}{2c[1-2a\theta_e(1-\theta_e)]}\left(\frac{\pi}{D}\right)^{1/2}$$

where C_0, C_{lim}, Γ_{max}, c, and D have their usual meaning and $\theta = (C_0 - C_e)/(C_0 - C_{lim})$ is the equilibrium surface coverage, determined at times when the equilibrium value C_e is attained.

The application of eq. [5] to the experimental diagrams of Fig. 11 yields 2.25×10^{-10} and 2.20×10^{-10} mol/cm^2 for the maximum surface concentration of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations, respectively. When calculating with eqs. [4] and [5], $C_0 = 12.2$ μF/cm^2, $C_{lim}(VPh_3P)^+ = 5.97$ mF/cm^2, $C_{lim}(PgPh_3P)^+ = 5.3$ μF/cm^2, $a(VPh_3P)^+ = 0.45$, $a(PgPh_3P)^+ = 0.6$, $D = 5 \times 10^{-6}$ cm^2/s, $\theta_e \leq 0.5$, were used for low ($c \leq 2.5 \times 10^{-5}$ *M*) surfactant concentrations.

The selection of the most suitable values of Γ_{max} can be facilitated by comparison with theoretical predictions for the possible orientations and the area per adsorbed phosphonium cation. Therefore, taking into account the tetrahedral structure of $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations, two possible orientations can be predicted, viz., two phenyls and the alkyl group or the three phenyl groups oriented towards the Hg surface, the former leading to an approximate area of 0.64 and 0.70 nm^2, respectively, and the latter to an area of 0.77 nm^2 for both substances. Therefore, the experimental values of Γ_{max} determined by means of the HMDE and eq. [5] seem to offer a better approximation to the theoretically predicted value of 0.77 nm^2. The values of area per adsorbed $(VPh_3P)^+$ and $(PgPh_3P)^+$ cations thus obtained are equal to 0.74 and 0.76 nm^2, suggesting that these cations are adsorbed with their three phenyl groups oriented towards the metal surface.

The strong interactions of the π-electrons of the phenyl groups with the conduction band of Hg at positive and small negative polarizations offer support to such an orientation. Nevertheless, since there is no evidence of rearrangement of the adsorption film taking place at higher negative potentials in methanol in the *C–E* and i_c–*t* experimental curves, we can assume that the same orientation is maintained up to the discharge potentials of these cations.

Iodine chemistry in the +1 oxidation state. II. A Raman and uv–visible spectroscopic study of the disproportionation of hypoiodite in basic solutions[1]

J. C. WREN, J. PAQUETTE, S. SUNDER, AND B. L. FORD

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received March 14, 1986

J. C. WREN, J. PAQUETTE, S. SUNDER, and B. L. FORD. Can. J. Chem. **64**, 2284 (1986).

The kinetics of disproportionation of elemental iodine to iodide and iodate ions has been studied in basic aqueous media using Raman and uv–visible spectroscopy. The IO stretching vibrations for IO^- and I_2OH^- were observed at 430 ± 2 and 560 ± 2 cm^{-1}, respectively. The totally symmetric stretching vibration for IO_2^- was observed at 685 ± 2 cm^{-1}. The Raman results indicate that I_2OH^- is a linear molecule with a stronger I—O bond than IO^-. The rate expression at 25°C in 1 mol dm^{-3} NaOH was found to be

$$-\frac{d\Sigma[I]}{dt} = (0.05 + 2.60[I^-])(\Sigma[I])^2$$

where

$$\Sigma[I] = ([I_2] + [I_3^-] + [IO^-] + [I_2OH^-])$$

The reaction is primarily a reaction of the iodine +1 oxidation-state species IO^- and I_2OH^-. It proceeds through the +3 oxidation-state species IO_2^-. The following equilibrium and rate constants were determined:

$IO^- + I^- + H_2O \rightleftharpoons I_2OH^- + OH^-$	$K = 0.15 \pm 0.01$
$IO^- + IO^- \rightarrow IO_2^- + I^-$	$k \leq 7.2 \times 10^{-2}$ dm^3 mol^{-1} s^{-1}
$IO^- + HOI \rightarrow IO_2^- + I^- + H^+$	$k = 40 \pm 7$ dm^3 mol^{-1} s^{-1}
$IO^- + I_2OH^- \rightarrow IO_2^- + 2I^- + H^+$	$k = 6.0 \pm 0.2$ dm^3 mol^{-1} s^{-1}
$IO^- + IO_2^- \rightarrow IO_3^- + I^-$	$k = 0.5 \pm 0.1$ dm^3 mol^{-1} s^{-1}
$I_2OH^- + IO_2^- \rightarrow IO_3^- + 2I^- + H^+$	$k = 26 \pm 2$ dm^3 mol^{-1} s^{-1}

J. C. WREN, J. PAQUETTE, S. SUNDER et B. L. FORD. Can. J. Chem. **64**, 2284 (1986).

La cinétique de dismutation de l'iode en ions iodure et iodate a été étudiée en milieu aqueux basique, en utilisant la spectroscopie Raman et UV-visible. La vibration d'élongation pour IO^- et I_2OH^- a été observée à 430 ± 2 et 560 ± 2 cm^{-1}, respectivement. La vibration d'élongation totalement symétrique pour IO_2^- a été observée à 685 ± 2 cm^{-1}. Les résultats de la spectroscopie Raman indiquent que I_2OH^- est une molécule linéaire avec un lien I—O plus fort que dans IO^-. La loi cinétique à 25°C, en milieu NaOH 1 mol dm^{-3}, est

$$-\frac{d\Sigma[I]}{dt} = (0.05 + 2.60[I^-])(\Sigma[I])^2$$

où

$$\Sigma[I] = ([I_2] + [I_3^-] + [IO^-] + [I_2OH^-])$$

La réaction est principalement une réaction de l'iode dans l'état d'oxydation +1 et implique les espèces IO^- et I_2OH^-. L'iode dans l'état d'oxydation +3, sous forme de IO_2^-, est un intermédiaire réactif. Les constantes d'équilibre et de vitesse suivantes ont été mesurées :

$IO^- + I^- + H_2O \rightleftharpoons I_2OH^- + OH^-$	$K = 0{,}15 \pm 0{,}01$
$IO^- + IO^- \rightarrow IO_2^- + I^-$	$k \leq 7{,}2 \times 10^{-2}$ dm^3 mol^{-1} s^{-1}
$IO^- + HOI \rightarrow IO_2^- + I^- + H^+$	$k = 40 \pm 7$ dm^3 mol^{-1} s^{-1}
$IO^- + I_2OH^- \rightarrow IO_2^- + 2I^- + H^+$	$k = 6{,}0 \pm 0{,}2$ dm^3 mol^{-1} s^{-1}
$IO^- + IO_2^- \rightarrow IO_3^- + I^-$	$k = 0{,}5 \pm 0{,}1$ dm^3 mol^{-1} s^{-1}
$I_2OH^- + IO_2^- \rightarrow IO_3^- + 2I^- + H^+$	$k = 26 \pm 2$ dm^3 mol^{-1} s^{-1}

I. Introduction

The disproportionation of elemental iodine into iodide and iodate ions is a key reaction controlling the behaviour of iodine in aqueous media:

[1] $3I_2 + 3H_2O \rightleftharpoons 5I^- + IO_3^- + 6H^+$

The thermodynamic parameters for equilibrium [1] are known accurately for temperatures up to 150°C (1). The kinetics of the reverse reaction (Dushman reaction) have also been examined in detail (2–4), but the forward reaction has not been studied so extensively. Thomas *et al.* (5) have investigated its kinetics in neutral to weakly basic media, while other studies (6–11) have been performed in strongly basic media. These authors agree

[1]AECL No. 9037.

that the rate-determining step involves the reactions of the +1 oxidation-state species HOI/IO^-, the hydrolysis and disproportionation of elemental iodine into HOI/IO^- and I^- being a rapid process. However, there is disagreement in the suggested rate laws for further disproportionation to iodide and iodate. Skrabal (9, 10) and Forster (11), as well as Li and White (8), have reported a two-term rate law, with the second term having a first-order dependence on iodide concentration, an effect not observed in the more recent studies of Thomas *et al.* (5) and Haimovich and Treinin (6).

Although some of these studies were done using uv–visible absorption spectroscopy (5, 6), the transient iodine species have never been positively identified. There is no report in the literature on the Raman spectra of any of the intermediates formed during the disproportionation of iodine. For these reasons, we have used the following three reactions to study the kinetics of disproportionation of iodine in basic media, using both Raman and uv–visible spectroscopy:

[2] $I_2 + OH^- \rightleftharpoons IO^- + I^- + H^+$

[3] $HOCl + I^- \rightleftharpoons IO^- + Cl^- + H^+$

[4] $ICl + OH^- \rightleftharpoons IO^- + Cl^- + H^+$

Using Raman spectroscopy, we not only observed the transient iodine species, but also obtained reliable kinetic data for the reaction of these species. We also reinvestigated the kinetics using uv–visible spectrophotometry and iodide-specific electrode measurements to obtain accurate values of the rate constants.

Our interest in aqueous iodine chemistry arises from the importance of iodine compounds in nuclear reactor safety studies. Radioactive isotopes of iodine are among the more radiologically toxic products resulting from the fission of uranium. A knowledge of the aqueous chemistry of iodine is needed to design effective measures to prevent the release of volatile radioactive iodine species into the environment following a serious nuclear reactor accident.

II. Experimental

Reagents

The sodium iodide was of ACS grade and was used without further purification. The hypochlorite was either obtained as a stock solution from the Fisher Scientific Company or generated by slowly bubbling chlorine gas, from Canadian Liquid Air, into a cold 1 mol dm^{-3} NaOH solution. The iodine was resublimed ACS grade and was used as such. The iodine monochloride was obtained from the J. T. Baker Chemical Company and was used as received. Other stock solutions were prepared from ACS-grade chemicals and distilled deionized water.

The experiments at low initial iodide concentration were performed using an ICl_2^- stock solution, prepared by dissolving ICl(s) in 1 mol dm^{-3} HCl. The concentration of the stock ICl_2^- solution was determined from its light absorption at 345 nm (ϵ_{max} = 243 $dm^3\ mol^{-1}\ cm^{-1}$) (12).

The effect of iodide concentration was studied using I_2/I^- solutions prepared by dissolving I_2 in solutions containing various NaI concentrations. For the Raman studies, the I_2 concentration was fixed at 0.1 mol dm^{-3}, and the I^- concentration varied between 0.2 and 2 mol dm^{-3}. Some experiments were performed with added NaCl, to study the effect of the ionic strength. For the uv–visible spectrophotometric experiments, the I_2 concentration was fixed at 0.01 mol dm^{-3} and the I^- concentration varied between 0.1 and 1 mol dm^{-3}; the NaCl concentration was adjusted to provide a constant ionic strength of 1.5 mol dm^{-3}.

For the Raman studies at lower pH (12.0 and 10.5), 0.1 mol dm^{-3} OCl^- and 0.1 mol dm^{-3} I^- solutions were used, in borax buffer for a pH value of 12, and in phosphate buffer for a pH value of 10.5. The hypochlorite stock solutions were analyzed by titration with NaI in 0.01 mol dm^{-3} H_2SO_4, using an Orion iodide-specific electrode (Model 94-53) and an Orion double-junction reference electrode (Model 90-02) as an end-point indicator. The OCl^- absorption band at 290 nm (ϵ = 350 $dm^3\ mol^{-1}\ cm^{-1}$) was also used to analyze for hypochlorite.

Raman spectroscopy

The Raman spectra were obtained using a SPEX 1403 double monochromator equipped with two 1800 grooves/mm gratings, a SPEX 1459 uv–visible illuminator, a RCA C-31034 photomultiplier tube, and photon counting electronics. The spectrometer operates under the control of a SPEX-DATAMATE microcomputer system. The frequency scale was calibrated using the emission lines of a mercury lamp and the ν_1 band of liquid carbon tetrachloride. Most of the Raman spectra were excited using the 514.5-nm radiation from a Spectra-Physics Model 165-09 argon-ion laser. Some of the spectra were also excited with the 488.0-nm radiation, but no difference in the results could be noticed. The laser power at the sample was about 900 mW and the spectra were recorded at a spectral band pass of about 6 cm^{-1}.

The kinetic runs for Raman studies were initiated either by reacting I_2/I^- solutions with an equal volume of a 2 mol dm^{-3} NaOH solution (reaction [2]) or, at pH values of 12 and 10.5, by reacting a 0.1 mol dm^{-3} OCl^- solution with an equal volume of a 0.1 mol dm^{-3} I^- solution (reaction [3]). A flow system was used to observe the Raman spectra of the transient iodine species so obtained. The two reactant solutions were driven by a double-syringe pump into a small Plexiglass mixing chamber. The reacting mixture then travelled down a length of Tygon tubing attached to a fine glass capillary, producing a stable stream of solution in the open air in the sample compartment of the Raman spectrometer. The laser beam was focussed on a point in the stream, about 3 mm from the tip of the glass capillary. Flow rates of the order of 0.1 $cm^3\ s^{-1}$ were used. The spectra of the transient iodine species could be observed at various reaction times by changing the length of the Tygon tubing. The above procedure was necessary since bands due to glass, quartz, or sapphire were found to interfere with the spectra of the transient iodine species. This technique not only removed the extraneous bands, but also enhanced the observed Raman intensities by a factor of about ten compared with those obtained using a glass capillary. The experiments were performed at room temperature (22 ± 1°C).

Each spectrum was obtained by averaging at least five scans from the 300- to 900-cm^{-1} region and subtracting the average background spectra. The background spectra were obtained with a solution containing the same concentration of I^- and NaOH, but without I_2. For the studies done at pH values of 12 and 10.5, the background spectra were obtained with 0.05 mol dm^{-3} I^- in the appropriate buffer solution. Spectra from 50 to 300 cm^{-1} (ν_1 of I_3^- and I_2) and from 2800 to 3800 cm^{-1} (ν_{OH} of H_2O) were also recorded for each run. To compensate for any variation in the optical alignment or laser power, the intensities of the various Raman bands were normalized using the water band (OH stretching vibration) as an internal standard.

Ultraviolet–visible spectrophotometry

The uv–visible spectra were recorded in digital form using a double-beam diode-array spectrophotometer (Hewlett-Packard 8450A) interfaced to a Hewlett-Packard HP-85 microcomputer via a HP-82939A serial interface. Some experiments were also performed using a Cary-17D spectrophotometer interfaced to the HP-85 microcomputer via a HP-82941A BCD interface. The temperature was maintained at 25.0 ± 0.1°C using a recirculating water bath.

Kinetic runs at low iodide concentration were initiated by injecting, with a glass syringe, 1 mL of a NaOH solution into a 1-cm pathlength spectrophotometric cell containing an equal volume of an ICl^-_2/HCl solution (reaction [4]). A NaOH/NaCl solution was used as the reference. The spectrum between 240 and 500 nm was recorded as

a function of time for at least two half-lives. Due to the heat of neutralization, the temperature rose by about 5°C at mixing time; however, the temperature returned to 25.0 ± 0.2°C within 45 s. Since the half-reaction times are of the order of 3000 s, the results were unaffected by the initial temperature transient.

Kinetic runs to study the effect of iodide concentration were initiated by injecting, with a glass syringe, a NaOH solution into an equal volume of an I_2/I^-/NaCl solution contained in a 1-cm pathlength spectrophotometric cell (reaction [2]). A NaOH/I^-/NaCl solution was used as the reference. The absorbance at 363 nm was recorded as a function of time for at least two half-lives.

Iodide-specific electrode

The iodide concentrations were measured with an iodide-specific electrode (Orion 95-53) and a double-junction reference electrode (Orion 90-02) coupled to an Orion Model 701A ionalyzer. The electrode system was calibrated with standard NaI solutions in 1 mol dm^{-3} NaOH, using a 1 mol dm^{-3} NaOH solution in the outer chamber of the double-junction reference electrode. The iodide concentration was calculated from the potential of the electrode system using the relation

$$[5] \quad E = E^0 + B \log_{10} [I^-]$$

where E^0 is a constant that depends on the electrode system, B is the Nernst constant, and E is the measured potential. The experimental value of B, obtained in the I^- concentration range 10^{-2} to 10^{-4} mol dm^{-3}, agreed well with the theoretical value of 59.2 mV at 25°C.

III. Results

Raman spectroscopy

Reaction of I_2/I^-

Figure 1 shows the Raman spectra obtained by reacting an I_2(0.1 mol dm^{-3})/I^-(0.6 mol dm^{-3}) solution with an equal volume of a 2 mol dm^{-3} NaOH solution (reaction [2]). The spectrum of the unreacted I_2/I^- solution showed Raman bands due to I_2 and I_3^-, as expected, including the ν_1 fundamental of I_2 at ~212 cm^{-1} and the ν_1 fundamental of I_3^- at 115 ± 2 cm^{-1}, as well as the overtones of I_3^- ($2\nu_1$ at 235 ± 4, $3\nu_1$ at 352 ± 2, and $4\nu_1$ at 465 ± 2 cm^{-1}) (13). These bands disappeared on mixing, as two new bands, not present in the spectra of the reactants, appeared at 430 and 560 cm^{-1} immediately after mixing. After a short time, bands at 685 and 800 cm^{-1} could also be seen. At long reaction times, the spectra showed only one band at 800 cm^{-1}. The intensity of the 430- and 560-cm^{-1} bands decreased steadily with time, although the I_{560}/I_{430} ratio, where I_ν is the Raman intensity at frequency ν, remained constant throughout the reaction. The intensity of 685-cm^{-1} band increased from zero at short reaction time, went through a maximum, and then decayed to zero at long reaction times. The intensity of the 800-cm^{-1} band, which was initially zero, increased with time but levelled off at long reaction times.

Changing the initial I^- concentration at constant I_2 and OH^- concentrations affected the relative intensity of the 430- and 560-cm^{-1} bands, as well as the time behaviour of all four bands. Although the I_{560}/I_{430} ratio was constant as a function of time for a fixed concentration of I^-, its value increased linearly with the iodide ion concentration, as can be seen from Fig. 2(*a*). Figure 2(*b*) shows that the intensity of the 430-cm^{-1} band at mixing time decreased slightly with an increase in I^- concentration, whereas the intensity of the 560-cm^{-1} band at mixing time increased markedly with an increase in I^- concentration.

Plots of the inverse of the Raman intensities at 560 and 430 cm^{-1} as a function of reaction time for various initial iodide concentrations showed linear relationships (see Fig. 3), indicating that the species responsible for the Raman scattering at 560 and 430 cm^{-1} were decaying by a second-order process. For a second-order process, the slope is k'_ν/α_ν and the intercept is $(\alpha_\nu C^0_\nu)^{-1}$. Here k'_ν, α_ν, and C^0_ν are the apparent second-order rate constant, the Raman scattering probability, and the initial concentration of the species responsible for the Raman band at frequency ν, respectively. The k'_{560}/α_{560} and k'_{430}/α_{430} values are plotted as a function of iodide concentration in Fig. 4. The k'_{560}/α_{560} ratio decreases slightly with an increase in iodide concentration, whereas k'_{430}/α_{430} increases with the iodide concentration. Thus, the rate of decay of the species responsible for the Raman scattering at 560 cm^{-1} is second order in that species and close to zero order in iodide, whereas the rate of decay of the species responsible for the Raman scattering at 430 cm^{-1} is second order in that species and close to first order in iodide. The Raman intensity data are not accurate enough to determine if an iodide-independent term is present in the latter case; however, if such a term exists, it is small.

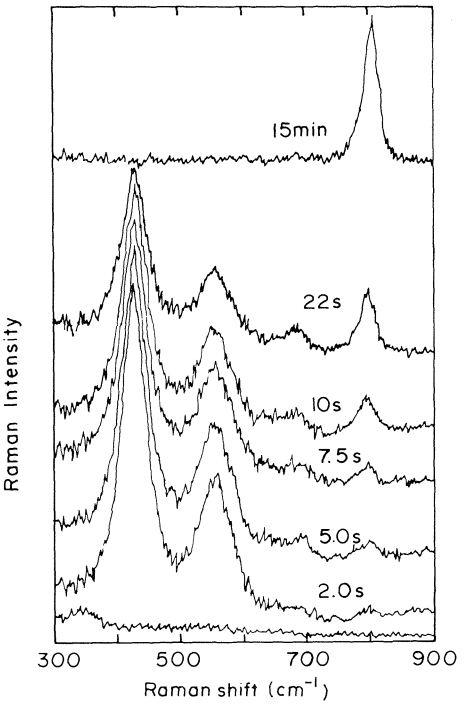

FIG. 1. Raman spectra as a function of time after reacting an I_2 (0.1 mol dm^{-3})/I^- (0.6 mol dm^{-3}) solution with an equal volume of a 2.0 mol dm^{-3} NaOH solution. The bottom spectrum is for the unreacted I_2/I^- solution.

The effect of ionic strength was studied by adding 1.4 and 0.2 mol dm^{-3} NaCl to the I_2/I^- solutions. No significant change was observed in the I_{560}/I_{430} ratio or in the time behaviour of any of the four Raman bands.

Reaction of HOCl/OCl^- with I^- at pH values of 12 and 10.5

The kinetics of iodine disproportionation were also studied at lower pH values using reaction [3]. The reactions at pH values of 12 and 10.5 were initiated by mixing 0.10 mol dm^{-3} HOCl with an equal volume of 0.10 mol dm^{-3} NaI. At a pH of 12, the results were similar to those observed from the reaction of I_2/I^- in 1 mol dm^{-3} NaOH (reaction [2]). Two bands, at 430 ± 2 and 575 ± 5 cm^{-1}, were seen immediately after mixing, and were then the only detectable spectral features. Two additional bands appeared at 685 ± 2 and 800 ± 2 cm^{-1} after a few seconds of reaction time. The intensities of the four bands as a function of time followed a pattern similar to that observed in 1.0 mol dm^{-3}

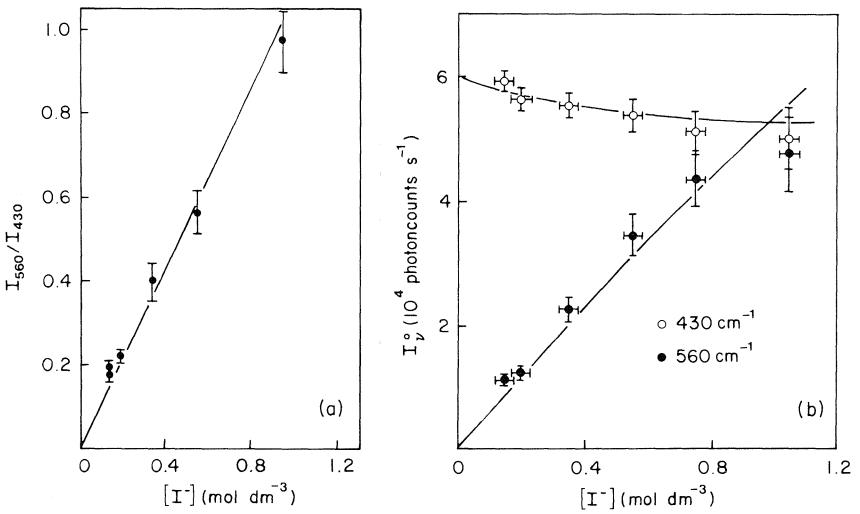

FIG. 2. (*a*) Ratio of the Raman intensity at 560 cm^{-1} to the Raman intensity at 430 cm^{-1}, and (*b*) Raman intensities at mixing time at 560 and 430 cm^{-1}, as a function of the iodide ion concentration, after reacting an I_2 (0.1 mol dm^{-3})/I^- solution with an equal volume of a 2.0 mol dm^{-3} NaOH solution. The solid lines in (*b*) are calculated results from equilibrium [7] and the determined K_7, α_{430}, and α_{560} values.

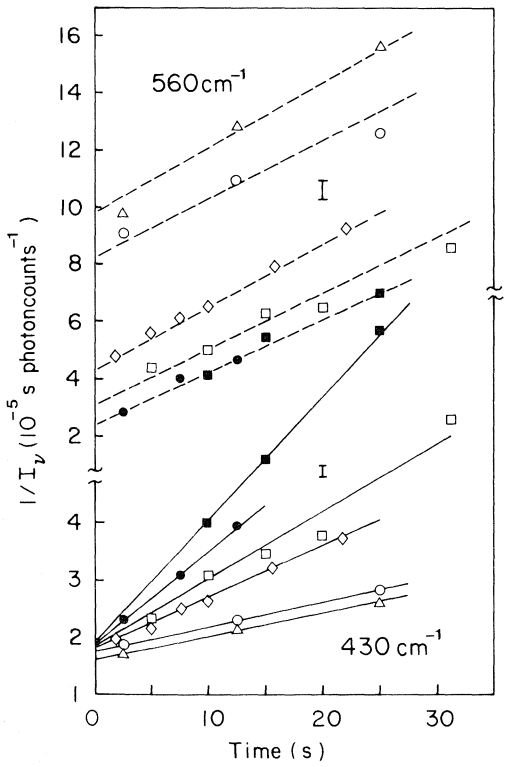

FIG. 3. Second-order plots for the decay of the Raman intensities at 560 and 430 cm^{-1} for various iodide ion concentrations. The reaction was initiated by reacting I_2 (0.1 mol dm^{-3})/I^- solutions with an equal volume of a 2.0 mol dm^{-3} NaOH solution. The I^- concentrations were △ 0.20, ○ 0.40, ◇ 0.60, □ 1.0, ● 1.4, and ■ 2.0 mol dm^{-3}.

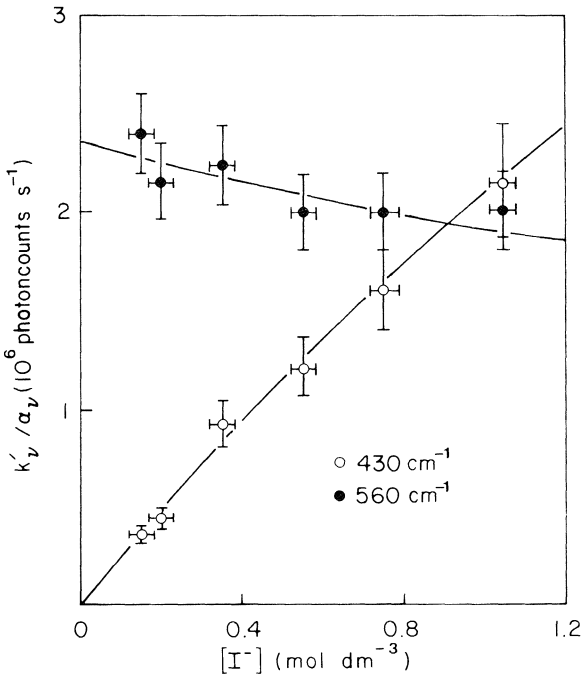

FIG. 4. Apparent second-order rate constants, divided by the Raman scattering probability, for the 430- and 560-cm^{-1} Raman bands, as a function of the iodide ion concentration.

NaOH using reaction [2]. No I_2 or I_3^- peak was observed during the course of the reaction. The differences observed at a pH of 12, compared with reaction [2] in 1 mol dm^{-3} NaOH, were (*1*) the band previously observed at 560 cm^{-1} shifted to 575 cm^{-1}, (*2*) the ratio (I_{575}/I_{430}) was smaller than that observed for all I^- concentrations studied (0.15 to 1.05 mol dm^{-3}) in 1 mol dm^{-3} NaOH, and (*3*) the reaction was faster than the reaction observed in 1 mol dm^{-3} NaOH for comparable I^- concentrations.

At a pH of 10.5, the Raman spectrum became simpler. The band at 430 ± 2 cm^{-1} was still present immediately after mixing, but no band was observed around 560 cm^{-1} or around 685 cm^{-1} during the course of the reaction. The intensity of the 430-cm^{-1} band decreased with time to zero. A band at 800 cm^{-1} appeared within a very short reaction time, increased steadily in intensity with time, and was the only band present at long reaction time. The reaction was much faster than at higher pH values. In addition to the transient iodine bands, an I_3^- band at 110 ± 2 cm^{-1} was also observed. The intensity of the I_3^- band increased from zero at mixing time, went through a maximum, then decayed back to zero at long reaction time. The maximum I_3^- concentration observed was 6.0 ± 5.0 × 10^{-3} mol dm^{-3}. It

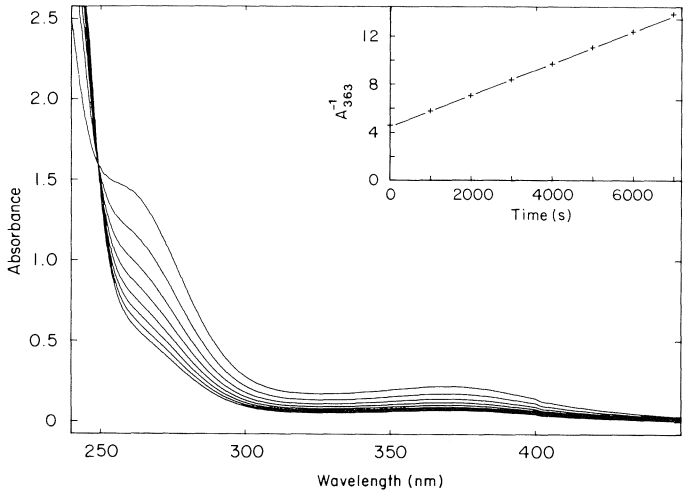

FIG. 5. Ultraviolet–visible spectra obtained as a function of time after reacting an ICl_2^- solution with a NaOH solution. The ICl_2^- and NaOH concentrations were, after mixing, 5×10^{-3} and 1 mol dm^{-3}, respectively. Arrows indicate the direction the absorbance moved with time. The insert is a second-order plot of the absorbance at 363 nm.

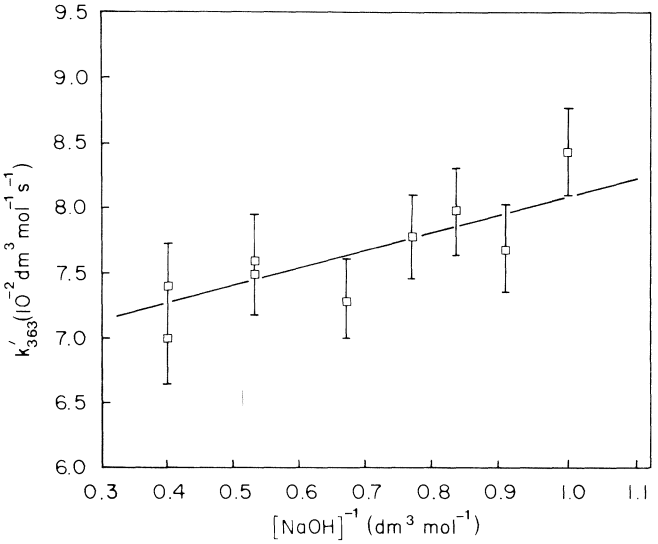

FIG. 6. Apparent second-order rate constant for the decay of IO^- at 363 nm as a function of the reciprocal NaOH concentration. Conditions were the same as those of Fig. 5, except that the NaOH concentration was varied.

was not possible to study the reaction at lower pH values using Raman spectroscopy due to the rapid increase in the rate on lowering the pH.

Ultraviolet–visible spectrophotometry

Reaction of ICl with NaOH

Figure 5 shows a series of uv–visible spectra obtained as a function of time using reaction [4]. The spectrum obtained at times close to mixing is due to the hypoiodite ion, IO^- (14). The spectra as a function of time display an isobestic point at 248 ± 1 nm with the absorbance decreasing with time at wavelengths greater than 248 nm and increasing with time at wavelengths less than 248 nm.

Plots of the inverse of the absorbance at 363 nm, A^{-1}_{363}, as a function of reaction time for various NaOH concentrations showed linear relationships, indicating that the species responsible for the light absorption at 363 nm, IO^-, is decaying by a second-order process. In that case, the slopes are k'_{363}/ϵ_{363} and the intercepts are $(\epsilon_{363}C_0)^{-1}$, where k'_{363} is the apparent second-order rate constant, ϵ_{363} is the molar absorptivity at 363 nm, and C_0 is the initial concentration of the reacting species, IO^-. From the intercepts and the known initial concentrations of IO^-, the molar absorptivity at 363 nm, ϵ_{363}, was found to be 60 ± 3 dm^3 mol^{-1} cm^{-1}, in agreement with the value reported previously (14). A plot of k'_{363} against the inverse of the NaOH concentration (see Fig. 6) or against the inverse of the square of the NaOH concentration is linear, whereas a plot of k'_{363} against the NaOH concentration displays a curvature. Thus, it appears that the rate of decay of the hypoiodite ion is second order in IO^-, and either inverse first order or inverse second order in OH^-. Iodate was found to retard the reaction both at high and at low NaOH concentration, with the reaction remaining second order. This effect has also been noted by Haimovich and Treinin (6).

Reaction of I_2/I^- with NaOH

Ultraviolet–visible spectra obtained using reaction [2] were very similar to the ones in Fig. 5 at wavelengths close to 360 nm. A plot of A^{-1}_{363} against time was also linear, giving an apparent second-order rate constant of (8.5 ± 0.8) × 10^{-2} dm^3 mol^{-1} s^{-1}, in good agreement with the value obtained above (Fig. 6) for the same NaOH concentration.

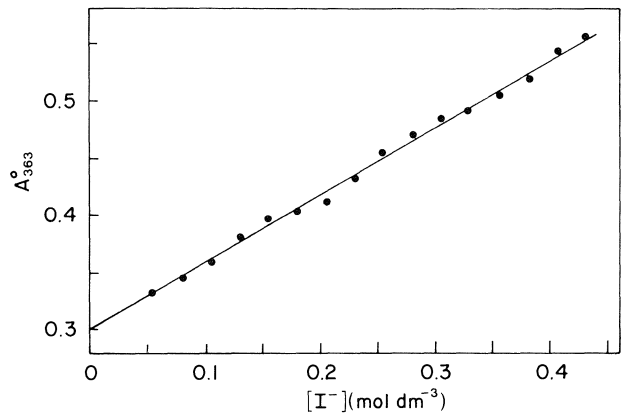

FIG. 7. Absorbance at mixing time at 363 nm as a function of the iodide ion concentration, after reacting an I_2 (5×10^{-3} mol dm^{-3})/I^- solution with an equal volume of a 2.0 mol dm^{-3} NaOH solution.

Varying the initial iodide concentration between 0.1 and 0.8 mol dm^{-3} for a fixed concentration of I_2 of 1×10^{-2} mol dm^{-3} and a fixed NaOH concentration of 1 mol dm^{-3} affected the uv–visible spectra and their time behaviour. The absorbance at 363 nm at the time of mixing, A^0_{363}, increased linearly with the iodide concentration (see Fig. 7). After an initial transient, plots of A^{-1}_{363} against time were linear (see Fig. 8), indicating that the light-absorbing species decay by a second-order process after an initial transient.

Iodide-specific electrode measurements

Reaction of ICl with NaOH

The iodide concentration, monitored using an iodide-specific electrode for reaction [4], is shown in Fig. 9(*a*). The iodide concentration increased steadily with time from zero to 3.2 ± 0.1 × 10^{-3} mol dm^{-3} at long reaction time. A comparison of the concentration of IO^- as a function of time from Fig. 5 and of the concentration of I^- as a function of time from Fig. 9(*a*) shows that the ratio $\Delta[IO^-]/\Delta[I^-]$ is −1.5 ± 0.1 for any given time interval. This confirms that the reaction is a

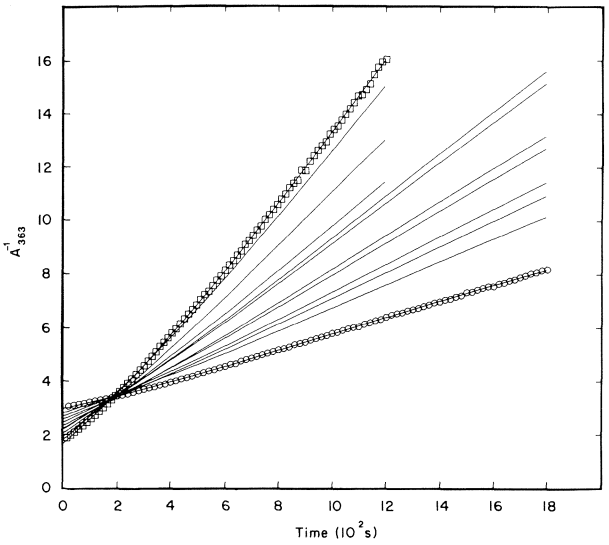

FIG. 8. Second-order plots for the decay of the absorbance at 363 nm for various iodide ion concentrations. The reaction was initiated by reacting an I_2 (5×10^{-3} mol dm^{-3})/I^- solution with an equal volume of a 2.0 mol dm^{-3} NaOH solution. For clarity, only alternate data points are indicated for the highest (□ 0.48 mol dm^{-3}) and the lowest (○ 0.05 mol dm^{-3}) I^- concentration.

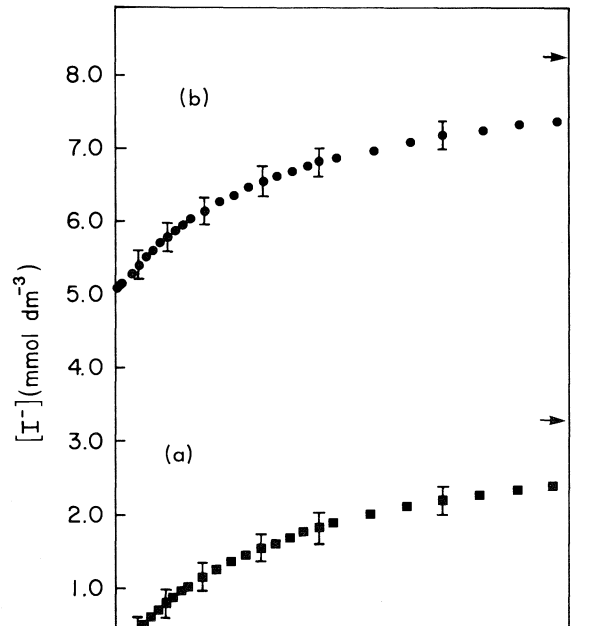

FIG. 9. Iodide ion concentration as a function of time after reacting (*a*), ■: an ICl_2^- solution with a NaOH solution. The concentrations of ICl_2^- and NaOH, after mixing, were 5×10^{-3} and 1 mol dm^{-3}, respectively, and (*b*), ●: a 10^{-2} mol dm^{-3} I_2 solution with an equal volume of a 2 mol dm^{-3} NaOH solution. Arrows indicate final concentrations after 48 h.

disproportionation and has the overall stoichiometry

[6] $3IO^- \rightarrow 2I^- + IO_3^-$

From the constancy of the above ratio and the presence of an isobestic point in the uv–visible spectra (see Fig. 5), any intermediate species besides IO^-, I^-, and IO_3^- must comprise less than 5% of the total iodine in solution at any given time.

Reaction of I_2 with NaOH

Reaction [2] was also monitored using the iodide-specific electrode (see Fig. 9(*b*)). The concentration of I^- very rapidly reached a value equal to the initial I_2 concentration and then increased slowly with time to a limiting value equal to 1.67 times the initial I_2 concentration. This is consistent the known stoichiometry of the overall reaction [1], and with the first step of the reaction being a rapid disproportionation of elemental iodine to the +1 and −1 oxidation states.

IV. Discussion

Raman spectroscopy

Kinetic analysis

The kinetic analysis of the reactions of I_2/I^- in 1 mol dm^{-3} NaOH (reaction [2]) will be considered first. The behaviour of the 685- and 800-cm^{-1} bands as a function of time, and the behaviour of the 430- and 560-cm^{-1} bands as a function of time and as a function of the iodide ion concentration, indicate that these four Raman bands belong to four different species. The band at 800 cm^{-1} can be unambiguously assigned to IO_3^- (15). The final IO_3^- concentration was determined by comparing the Raman intensities with that of standard $NaIO_3$ solutions. For the reactions of solutions 0.05 mol dm^{-3} in I_2 and from 0.1 to 1 mol dm^{-3} in I^- with 1 mol dm^{-3} NaOH, the final concentration of IO_3^- was 0.017 ± 0.002 mol dm^{-3} in all cases. This is consistent with the known stoichiometry of the overall reaction [1], the equilibrium being completely to the right at this low H^+ concentration. The assignment of the bands observed at 430, 560, and 685 cm^{-1} will be discussed later, after analysis of their time and iodide-concentration dependence.

The behaviour of the 560- and 430-cm^{-1} bands as a function of $[I^-]$, (see Fig. 2(*a*)) and as a function of time (see Fig. 3), suggests that these bands are due to two molecules participating in a rapidly established equilibrium involving I^-:

[7] $P_{430} + iI^- \overset{K_7}{\rightleftharpoons} qQ_{560}$

where P_{430} and Q_{560} represent species responsible for the 430- and 560-cm^{-1} bands. Equilibrium [7] implies that the ratio $(I_{560}\alpha_{560})^q/(I_{430}\alpha_{430}[I^-]^i)$ is a constant. Various combinations of q and i were explored. However, only a plot of I_{560}/I_{430} against the iodide concentration gives a straight line (see Fig. 2(*a*)), indicating that the coefficients q and i are unity.

The equilibrium quotient, K_7, can be calculated from the Raman data as follows. Immediately after mixing, only P_{430} and Q_{560} are present. Extrapolation of the Raman intensities at mixing time to zero $[I^-]$ (Fig. 2(*b*)) gives values of 0 and 5.9 ± 0.1 × 10^4 photon counts for I^0_{560} and I^0_{430}, respectively. Since the initial I_2 concentration is 0.05 mol dm^{-3}, α_{430} is found to be 1.2 ± 0.1 × 10^6 photon counts dm^3 mol^{-1} under the experimental conditions used here. The value of α_{560} can then be easily obtained at each $[I^-]$ from mass balance considerations. An average value of 5.5 ± 0.5 × 10^6 photon counts dm^3 mol^{-1} was found for α_{560}. From the slope of the I_{560}/I_{430} vs. $[I^-]$ plot (Fig. 2(*a*)), a value of 0.24 ± 0.07 dm^3 mol^{-1} is obtained for K_7.

The rapidly established equilibrium between P_{430} and Q_{560} has to be considered in the calculation of the rate constants. Since the mixture is ultimately converted to iodate via a second-order process, the rate law can be written as

[8] $$-\frac{d([P_{430}] + [Q_{560}])}{dt} = k_{obs}([P_{430}] + [Q_{560}])^2$$

[9] $$k_{obs} = \sum_i k_i f_i^2$$

TABLE 1. Observed rate constants, k_{obs}, determined from the values of k'_ν obtained using Raman spectroscopy

$[I^-]$/mol dm^{-3}	k_{obs} from k'_{430}	k_{obs} from k'_{560}
0.15	0.41	0.46
0.20	0.52	0.54
0.35	1.02	0.96
0.55	1.27	1.28
0.75	1.63	1.68
1.05	2.06	2.21

where k_i is the actual rate constant for the reaction of the species i and f_i is the fraction of the total iodine concentration for each of the reactive species. In that case, k_{obs} should be related to the apparent rate constants, k'_ν, presented in Fig. 4, by

$$[10] \quad k_{obs} = k'_{560}\left(\frac{K_7[I^-]}{1 + K_7[I^-]}\right)$$

$$[11] \quad k_{obs} = k'_{430}\left(\frac{1}{1 + K_7[I^-]}\right)$$

The k_{obs} values determined from both k'_{560} and k'_{430} values are given in Table 1 as a function of $[I^-]$, and are in good agreement. The k_{obs} increases with an increase in $[I^-]$. These observed rate constants can be used to determine the actual rate constants, k_i, from eq. [9]. If P_{430} was the only reactive species, k_{obs} would be proportional to

$$\left(\frac{1}{1 + K_7[I^-]}\right)^2$$

since $f_{P_{430}}$ is given by

$$\left(\frac{1}{1 + K_7[I^-]}\right)$$

If Q_{560} was the only reactive species, then k_{obs} would be proportional to

$$\left(\frac{K_7[I^-]}{1 + K_7[I^-]}\right)^2$$

since $f_{P_{430}}$ is given by

$$\left(\frac{K_7[I^-]}{1 + K_7[I^-]}\right)$$

These were not found to be the case. However, as can be seen from Fig. 10, a linear relationship is obtained for

$$[12] \quad k_{obs} = \frac{k_{PQ}K_7[I^-]}{(1 + K_7[I^-])^2}$$

indicating that P_{430} and Q_{560} are reacting together according to the rate equation

$$[13] \quad \frac{d}{dt}([P_{430}] + [Q_{560}]) = -k_{PQ}[P_{430}][Q_{560}]$$

with k_{PQ} having a value of 13 ± 1 dm^3 mol^{-1} s^{-1}, which was obtained from the slope in Fig. 10.

The Raman band at 685 cm^{-1} displays a kinetic behaviour typical of a species being formed in an earlier reaction step and destroyed in a subsequent step. This species, R_{685}, is likely the product of the reaction between P_{430} and Q_{560} discussed above, and can itself react to produce iodate. If R_{685} reacts with itself

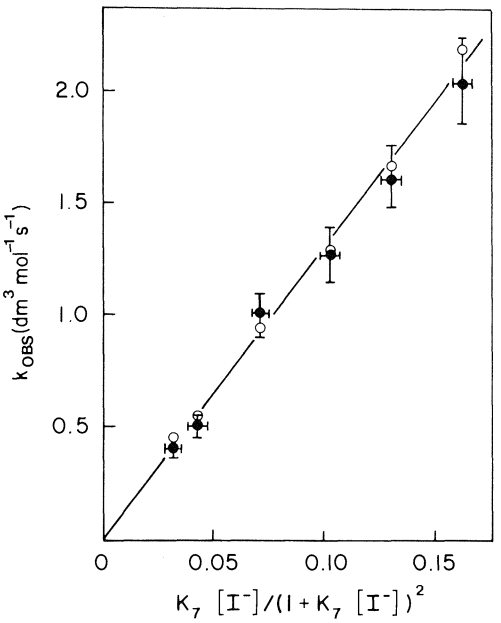

FIG. 10. Correlation of the observed rate constants with the iodide ion concentration for the Raman results in 1 mol dm^{-3} NaOH solutions.

in either a first-order or a second-order reaction, then the final IO_3^- concentration should be $(1/2)([P_{430}]^0 + [Q_{560}]^0)$ or $(1/4)([P_{430}]^0 + [Q_{560}]^0)$, respectively, where $([P_{430}]^0 + [Q_{560}]^0) = 0.05$ mol dm^{-3}. However, the final IO_3^- concentration was 1.7 ± 0.2 × 10^{-2} mol dm^{-3} in all cases, which is $(1/3)([P_{430}]^0 + [Q_{560}]^0)$. If R_{685} reacts with P_{430} and/or Q_{560} to form iodate, then the final concentration of iodate would be 1.67 × 10^{-2} mol dm^{-3}, which is in agreement with the experimental results. The mass balance at any given time after reacting the I_2/I^- solutions with the OH^- solution would then be

$$[14] \quad [P_{430}]_t + [Q_{560}]_t + 2[R_{685}]_t + 3[IO_3^-]_t = [I_2]_{t=0} = 0.05 \text{ mol dm}^{-3}$$

The observed Raman intensities of the four species at any given reaction time can be used to calculate α_{685} from the above mass balance equation and the known values of α_{430} and α_{560}. If the proposed mechanism is correct, then α_{685} obtained at any given reaction time and for any given $[I^-]$ should be constant. The value of α_{685} was found to be in the range (6.6 to 6.9) × 10^5 photon counts dm^3 mol^{-1}, which supports the proposed mechanism. The possibility of forming more than one molecule of R_{685} by reacting P_{430} and Q_{560} can also be rejected on the basis of mass balance.

The Raman results obtained at lower pH values using reaction [3] cannot be directly compared with the results obtained from reaction [2] in 1.0 mol dm^{-3} NaOH. In reaction [3], the I^- concentration is negligible at the time of mixing, but increases as the reaction proceeds, whereas the iodide concentration in the reaction of I_2/I^- in 1 mol dm^{-3} NaOH is nearly constant during the course of the reaction, for a given I_2/I^- solution.

Second-order plots for I_{430} at pH values of 12 and 10.5 are compared with the data obtained for the reaction of 0.05 mol dm^{-3} I_2/0.1 mol dm^{-3} I^- with 1 mol dm^{-3} NaOH in Fig. 11. The figure shows curvatures for pH values of 12 and 10.5, indicating that the iodide concentration is not constant during the reaction. Extrapolating the data to time zero at both

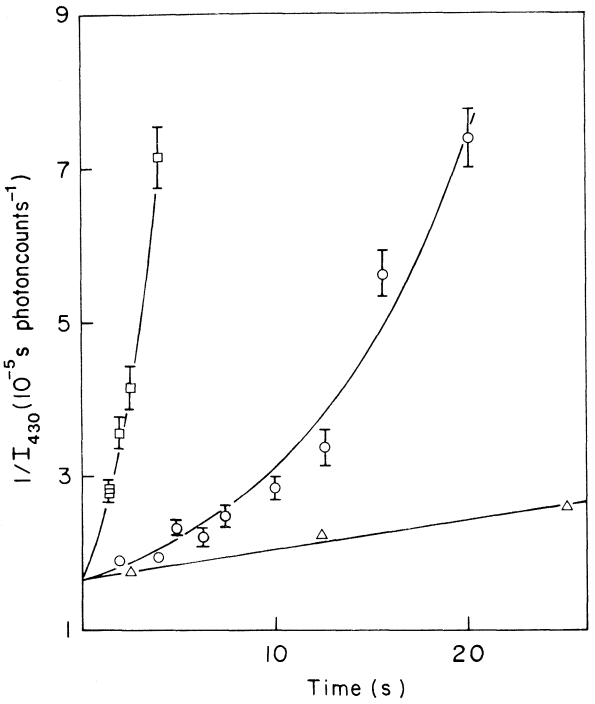

FIG. 11. Second-order plots for the decay of the Raman intensity at 430 cm^{-1} at pH values of 10.5 (□) and 12.0 (○), reaction [3]; and by reacting an I_2 (0.1 mol dm^{-3})/I^- (0.2 mol dm^{-3}) solution with an equal volume of a 2 mol dm^{-3} NaOH solution (△), reaction [2].

pH values gives an I^0_{430} value of $6.1 \pm 0.2 \times 10^4$ photon counts. This corresponds to $[P_{430}]^0 = 0.051 \pm 0.002$ mol dm^{-3} using the α_{430} determined from the data observed using reaction [2]. This indicates that the band observed at 430 cm^{-1} at pH values of 12 and 10.5 belongs to the same species responsible for the 430-cm^{-1} band observed using reaction [2] in 1 mol dm^{-3} NaOH, and that the iodide concentration at the time of mixing is negligible, as expected from reaction [3].

Assignment of Raman bands

The assignment of the band observed at 800 cm^{-1} to the symmetric stretching vibration of IO_3^- (symmetry A_1) is quite obvious, as stated earlier. We assign the band observed at 685 cm^{-1} to the symmetric stretching vibration of IO_2^-. We were unable to find any report in the literature on the Raman spectrum of IO_2^-. However, the Raman spectra of the corresponding chlorine and bromine compounds have been reported. The totally symmetric stretching vibration in ClO_2^- has been observed at 786 cm^{-1} by Tasaka and Toja (16). For BrO_2^-, this vibration has been assigned to the Raman band seen at 710 cm^{-1} by Sombret and Wallart (17) and Evans and Lo (18).

The assignment of the remaining two bands at 560 and 430 cm^{-1} is not so straightforward. These bands are most likely due to IO^- and I_2O^{2-} (or I_2OH^-). In 1 mol dm^{-3} NaOH solution, the equilibrium, $HOI \rightleftharpoons H^+ + IO^-$, is completely to the right. Thus, we will only consider the IO^- contribution in the following analysis. We first attempted to assign the 560-cm^{-1} band to IO^-, based on the literature assignment for the I—O stretch in HOI (the parent acid for the IO^- ion) at 572 cm^{-1} (19–22). Here it should be mentioned that the vibrational (infrared) spectrum for HOI has been reported only for molecules isolated and produced in solid N_2 or Ar matrices. The change in the I—O vibration frequency from 572 to 560 cm^{-1}, in going from the matrix isolated acid state (HOI) to the solution state (IO^-) also seemed typical of that observed for similar halogen systems: ν_{XO} in HOCl and ClO^- is 729 (23) and 713 cm^{-1} (16), and in HOBr and BrO^-, it is 626 (23) and 620 cm^{-1} (17), respectively. Although the assignment of the 560-cm^{-1} band to IO^- stretch would be consistent with the literature assignment for HOI, it makes it very difficult to explain the $[I^-]$ concentration dependence of relative Raman intensities at 560 and 430 cm^{-1} described above, as well as the uv–visible data and ion-specific electrode data. We were unable to arrive at a plausible mechanism that would assign the 560-cm^{-1} band to IO^- and the 430-cm^{-1} band to I_2O^{2-} (or I_2OH^-) and still explain the fact that the I_{560}/I_{430} ratio increases with an increase in iodide ion concentration. Thus, we have assigned the 430-cm^{-1} band to the IO^- stretching vibration and the 560-cm^{-1} band to the I—O stretching vibration in I_2O^{2-} (or I_2OH^-), to explain the intensity dependence on $[I^-]$. The assignment of the Raman band observed at 430 cm^{-1} to IO^- is also supported by the Raman spectra observed using reaction [3]. The reaction of HOCl with I^- is known to produce IO^- (14) and, as there is no excess I^- ions at short reaction times, the observed band at 430 cm^{-1} should be assigned to IO^- rather than I_2O^{2-} (or I_2OH^-).

The assignment suggested above implies that the I—O bond is much weaker for IO^- in aqueous alkaline solution than for HOI in inert matrices. One plausible explanation for this may be found in the description of similar systems by Pimentel (24). He suggested that species isoelectronic with X^- (i.e., OH^-) can combine with groups of electronic character similar to X_2 (i.e., IO^-), where X represents a halogen. According to the above, IO^- in alkaline solution may exist as

$$[15] \quad HO^- + IO^- \rightleftharpoons [HO\text{---}IO]^{2-}$$

The assignment of the I—O stretching vibration to a higher frequency for I_2O^{2-} than that for IO^- may seem unusual at first glance, yet it is not without precedent. The Cl—O stretching vibration has been assigned to a higher frequency for ClClO (962 cm^{-1}) and FClO (1038 cm^{-1}) than for ClO (850 cm^{-1}) by Chi and Andrews (25). These authors attributed the increase in the "Cl—O bond strength" in going from ClO to ClClO or FClO to the removal of the antibonding electron density from ClO, leaving a stronger Cl—O bond. A similar effect can also explain the increase in the I—O stretching vibration frequency in going from IO^- to $[IIO]^{2-}$. In solutions containing iodide ions, I^- may combine with IO^- ions to form I_2OH^-:

$$[16] \quad I^- + IO^- \rightarrow [I\text{---}IO]^{2-} \xrightarrow{H^+} [I_2OH]^-$$

The I_2OH^- would be a linear molecule, in agreement with the simple molecular orbital treatment of the bonding in the trihalide ions by Pimentel (24), which led him to predict that the hydroxide ion should be able to combine with I_2 to form I_2OH^-. Anbar and Taube (26) also proposed that Cl_2OH^- is a possible intermediate in the exchange reaction between Cl^- and HOCl, and suggested that its structure is analogous to that of Br_3^-.

The 560-cm^{-1} band shifted to 575 cm^{-1} at lower pH. We believe that the 560-cm^{-1} band is due to unprotonated I_2O^{2-}, and that the 575-cm^{-1} band is due to partially protonated I_2OH^-. This increase in frequency is consistent with a slight increase in I—O bond strength due to an overall decrease in electron density upon protonation.

Reaction mechanism

With the assignment of IO^-, I_2O^{2-} (or I_2OH^-), and IO_2^-

given to P_{430}, Q_{560}, and R_{685}, respectively, a mechanism can be proposed for the overall disproportionation of iodine in basic solutions. The rate-determining step clearly is the disproportionation of the +1 oxidation-state species (IO^-, I_2OH^-) to iodate and iodide, since the Raman bands due to I_2 and I_3^- disappear instantaneously upon mixing with NaOH. The following mechanism is compatible with all of the Raman results and the overall stoichiometry of reaction [1].

$$[2] \quad I_2 + OH^- \overset{K_2}{\rightleftharpoons} IO^- + I^- + H^+ \qquad K_2 = 1.37 \times 10^{-9}\ dm^3\ mol^{-1}\ (28)$$

$$[17] \quad I_2 + I^- \overset{K_{17}}{\rightleftharpoons} I_3^- \qquad K_{17} = 746\ dm^3\ mol^{-1}\ (29)$$

$$[18] \quad IO^- + I^- + H_2O \overset{K_{18}}{\rightleftharpoons} I_2OH^- + OH^-$$

$$[19] \quad IO^-/HOI + IO^- \xrightarrow{k_{19}} IO_2^- + I^- / + H^+$$

$$[20] \quad IO^- + I_2OH^- \xrightarrow{k_{20}} IO_2^- + 2I^- + H^+$$

$$[21] \quad IO_2^- + IO^- \xrightarrow{k_{21}} IO_3^- + I^-$$

$$[22] \quad IO_2^- + I_2OH^- \xrightarrow{k_{22}} IO_3^- + 2I^- + H^+$$

where equilibria [2], [17], and [18] are established rapidly. The equilibrium [18] is equivalent to equilibrium [7], and thus has a value of 0.24 ± 0.07 $dm^3\ mol^{-1}$. Equilibrium [2] is almost completely to the right at this high pH; thus, the concentrations of I_2 and I_3^- are negligible after mixing with NaOH. Reaction [19] is being considered here for completeness, since it was too slow to be observed in the Raman study (i.e., $k_{19} < k_{20}$). The rate constants, k_{21} and/or k_{22}, are larger than k_{19} and k_{20}. If both k_{21} and k_{22} were smaller than k_{19} and/or k_{20}, then the second-order plots shown in Fig. 4 would display curvature, and a substantial amount of IO_2^- (R_{685}) would accumulate in solution. On the other hand, if k_{21} and/or k_{22} were much larger than k_{19} and k_{20}, virtually no R_{685} would accumulate and k_{obs} would be given by $3k_{19}$ or $3k_{20}$. Since some R_{685} accumulates, the truth is somewhere between these two extremes.

Although we did not obtain enough data at pH 12 and 10.5 to attempt a detailed analysis, some qualitative comments can be made. The reaction was faster at lower pH, which can be explained if the reaction of HOI with HOI or IO^- is faster than the reaction of IO^- with IO^-. Also, the I_2OH^- responsible for the Raman band at 560 cm^{-1} was not observed at a pH of 10.5. At this low pH, equilibrium [2] is not completely to the right and a small amount of I_2 is present, which will react with I^- to form I_3^- according to equilibrium [17]. The values of K_{17} and K_{18} are such that only a small amount of I_2OH^- is expected at this low pH.

Ultraviolet–visible spectrophotometry and iodide-specific electrode measurements

Reaction of ICl with NaOH

The uv–visible and iodide-specific electrode results obtained at low initial iodide concentration for reaction [4] indicate that IO^-, formed by the rapid hydrolysis of ICl_2^-, disproportionates to iodide and iodate at a rate that is second-order in [IO^-] and either inverse first-order or inverse second-order in [OH^-]. These results suggest that both HOI and IO^- participate in the reaction. Since IO^- and HOI are in rapid acid–base equilibrium

$$[23] \quad HOI \overset{K_{23}}{\rightleftharpoons} IO^- + H^+$$

the general rate law for the disproportionation would be

$$[24] \quad -\frac{d[IO^- + HOI]}{dt} = k_{24a}[HOI]^2 + k_{24b}[HOI][IO^-] + k_{24c}[IO^-]^2$$

This can be rewritten in terms of IO^- only as

$$[25] \quad -\frac{d[IO^-]}{dt} = \left[\frac{k_{24a}\frac{[H^+]^2}{K_{23}} + k_{24b}\frac{[H^+]}{K_{23}} + k_{24c}}{1 + \frac{[H^+]}{K_{23}}}\right][IO^-]^2 = k_{obs}[IO^-]^2$$

The rate constant k_{24a} is known to be approximately 200 $dm^3\ mol^{-1}\ s^{-1}$ (5). The contribution from the term in $[HOI]^2$ would thus be quite small at the [OH^-] concentrations used (1 to 2.5 mol dm^{-3}) and can be neglected. The value of k_{24b} can be obtained from the slope of the plot of k_{obs} against $[NaOH]^{-1}$ (Fig. 6) and is 40 ± 7 $dm^3\ mol^{-1}\ s^{-1}$. Not much can be said about the value of k_{24c} except that, from Fig. 6, it is estimated to be less than $7.2 \times 10^{-2}\ dm^3\ mol^{-1}\ s^{-1}$.

Reaction of I_2/I^- with NaOH

The iodide-specific electrode and uv–visible spectroscopy results for reaction [2] are consistent with a rapid hydrolysis and disproportionation of elemental iodine to the +1 and −1 oxidation states, followed by a slower further disproportionation to iodide and iodate with the overall stoichiometry as shown in eq. [6].

For mixtures obtained by reacting I_2/I^- solutions with a NaOH solution, the absorbance at 363 nm at mixing time, A^0_{363}, increases with the initial concentration of iodide, in agreement with the observations of Sigalla (27) and Chia (28). This is likely due to the formation of other iodine compounds besides IO^-, probably I_3^- formed through equilibria [2] and [17]. However, the equilibrium amounts of I_3^- cannot account entirely for the increase in absorbance at mixing time with the iodide ion concentration. An additional light-absorbing species is required.

Both Sigalla (27) and Chia (28) have proposed the involvement of equilibrium [18] in solutions containing hypoiodite and iodide. Since I_2 and I^- have no appreciable light absorption at 363 nm, from equilibria [2], [17], and [18], the absorbance at 363 nm at mixing time would be given by

$$[26] \quad A^0_{363} = \frac{C_0(\epsilon^{IO^-}_{363} + \epsilon^{I_2OH^-}_{363} K_{18}[I^-]/[OH^-] + \epsilon^{I_3^-}_{363}[I^-]^2 K_{17}/K_2[OH^-]^2)}{(1 + K_{18}[I^-]/[OH^-] + [I^-]^2 K_{17}/K_2[OH^-]^2 + [I^-]/K_2[OH^-]^2)}$$

where C_0 is the initial iodine concentration. Here, $\epsilon^{OI^-}_{363}$ is the specific absorptivity for IO^- at 363 nm and has been determined above as being equal to 60 $mol^{-1}\ dm^3\ cm^{-1}$. The specific absorptivity for I_3^- at 363 nm is 19 000 $mol^{-1}\ dm^3\ cm^{-1}$ (29).

A non-linear least-squares fit to eq. [26] was used to determine $\epsilon^{I_2OH^-}_{363}$ and K_{18} from 17 measurements of A^0_{363} as a function of I^- concentration, covering the range from 0.05 mol dm^{-3} to 0.5 mol dm^{-3}. Values of 750 ± 50 $mol^{-1}\ dm^3\ cm^{-1}$ and

$0.15 \pm 0.01\ dm^3\ mol^{-1}$ were obtained, respectively, and could represent the data with an average deviation of 0.6% and a maximum deviation of 1%. Inclusion of additional species having the general formula $H_zO_xI_y$ did not significantly improve the fit, and was deemed unnecessary. The equilibrium constant value agrees well with the K_{18} value calculated from the Raman results.

Although hypoiodite was the predominant form of iodine in these solutions, the equilibria with I_2, I_3^-, and I_2OH^- have to be considered in the calculation of the rate constants. The rate for each experiment was found to obey the following relation after an initial transient:

$$[27] \quad -\frac{d(\Sigma[I])}{dt} = k_{obs}(\Sigma[I])^2$$

where $\Sigma[I]$ is $([I_2] + [I_3^-] + [IO^-] + [I_2OH^-])$, and can be calculated from the absorbance at 363 nm as a function of time using the relation

$$[28] \quad \Sigma[I] = A^t_{363}C_0/A^0_{363}$$

The values of k_{obs} were obtained from plots of the inverse of $\Sigma[I]$ vs. time, and are shown in Fig. 12(*a*). It becomes evident that at 25°C, in 1 mol dm^{-3} NaOH solution, k_{obs} can be written as

$$[29] \quad k_{obs} = k'_{29} + k''_{29}[I^-]$$

with $k'_{29} = 0.05\ dm^3\ mol^{-1}\ s^{-1}$ and $k''_{29} = 2.60\ dm^3\ mol^{-1}\ s^{-1}$.

Since at zero iodide ion concentration only IO^-, and very small amounts of I_3^- and I_2, are present, the first term, k'_{29}, should be equivalent to $k_{24c} + k_{24b}[H^+]/K_{23}$, as can be seen from eq. [25]. The second term would be expected to be composed of a combination of the four equilibrium iodine species, as given in eq. [9] in generalized form. If IO^- was the only reactive species, then the observed rate constant would decrease with an increase in $[I^-]$. If I_2OH^- was the only reactive species, then k_{obs} would be given by

$$[30] \quad k_{obs} = k'_{29} + k_{(I_2OH^-)^2}f^2_{I_2OH^-} = k'_{29} + k_{(I_2OH^-)^2}\left[\frac{1}{1 + [OH^-]/K_{18}[I^-] + K_{17}[I^-][H^+]/K_{18}K_2 + [H^+]/K_{18}K_2}\right]^2$$

where $f_{I_2OH^-}$ can be determined from equilibria [2], [17], and [18]. The terms $K_{17}[I^-][H^+]/K_{18}K_2$ and $[H^+]/K_{18}K_2$ are small. Therefore, $(k_{obs} - k'_{29})$ would be proportional to

$$\left(\frac{1}{1 + 1/K_{18}[I^-]}\right)^2$$

This was not found to be the case. Since neither of these attempts to correlate the data with a single reactive species was successful, various combinations of I_3^-, I_2, IO^-, and I_2OH^- were considered.

Assuming that IO^- and I_2OH^- are reacting together, a linear correlation was obtained for

$$[31] \quad k_{obs} = \frac{k_{IO^-,I_2OH^-}K_{18}[I^-]}{(1 + K_{18}[I^-])^2} + k'$$

as shown in Fig. 12(*b*). From the slope of the line in this figure and the K_{18} values determined above, k_{IO^-,I_2OH^-} is equal to $19.5 \pm 0.05\ dm^3\ mol^{-1}\ s^{-1}$. The rate law can be rewritten as

$$[32] \quad -\frac{d}{dt}([I_2] + [I_3^-] + [IO^-] + [I_2OH^-]) = 0.05[IO^-]^2 + 19.5[IO^-][I_2OH^-]$$

and is valid for 25°C and in 1 mol dm^{-3} NaOH.

Both the rate expression and the value of k_{IO^-,I_2OH^-} are entirely compatible with the mechanism proposed to explain the Raman results (eqs. [2], [17]–[22]). The iodide-independent term is quite small and was not detectable in the Raman experiments, since relatively high concentrations of I^- were required to dissolve a sufficient amount of I_2. According to the uv–visible results, k_{21} and/or k_{22} is larger than k_{19} and k_{20} in eqs. [19]–[22], but not immensely so. If k_{21} or k_{22} was much larger than k_{20}, then the plots of $(\Sigma[I])^{-1}$ against time would be linear with slopes of $3k_{19}[I^-]K_{18}$. Since a curvature is observed at short reaction times, k_{21} and/or k_{22} are somewhat larger than k_{19}.

The differential equations resulting from this mechanism were integrated numerically, using a modified Gear algorithm (30). The values of k_{20}, k_{21}, and k_{22} were obtained by using a non-linear least-squares routine incorporating Marquat's algorithm (31). The objective function was the absorbance of the solutions at 363 nm as a function of time and iodide concentration:

$$[33] \quad A^t_{363} = \epsilon^{IO^-}_{363}[IO^-]_t + \epsilon^{I_2OH^-}_{363}[I_2OH^-]_t + \epsilon^{I_3^-}_{363}[I_3^-]_t$$

where the various concentrations as a function of time were from the numerical integration, assuming that equilibrium between I_3^-, I_2, IO^-, and I_2OH^- is achieved rapidly. Values of 6.0 ± 0.2, 0.5 ± 0.1, and $26 \pm 2\ dm^3\ mol^{-1}\ s^{-1}$ were obtained for k_{20}, k_{21}, and k_{22}, respectively.

Thus, the Raman and the uv–visible spectrophotometric results can be interpreted in terms of a common mechanism. The Raman results provide an unambiguous identification of the species involved, whereas the uv–visible results provide accurate values of the rate constants. It appears that, if the concentration of iodide ions is above 5×10^{-2} mol dm^{-3}, in 1 mol dm^{-3} NaOH, the disproportionation of hypoiodite occurs preferentially through I_2OH^-.

Comparison with the literature

The formation of a weak complex between IO^- and I^- has been proposed in the past by Sigalla (27) and also by Chia (28) to explain the dependence of the uv–visible absorbance of IO^- solutions on the concentration of iodide ions. Chia reported a value of 0.13 for K_{18} at 25°C, whereas Sigalla reported a value of 3×10^{-2} for K_{18} at 25°C, after correction for ionic strength effects. The origin of the discrepancy is unclear. In Chia's experiments, IO^- and I_2OH^- were the dominant species in solution. Due to the large specific absorptivity of I_3^-, these three species contributed to the absorbance in similar proportions. Thus, Chia observed a larger than expected increase in absorbance with an increase in iodide ion concentration. In Sigalla's experiments, I_3^-, IO^-, and I_2OH^- were present in similar proportions. Due to the large specific absorptivity of I_3^-, this species was the only one contributing significantly to the absorbance, and Sigalla observed a lower than expected

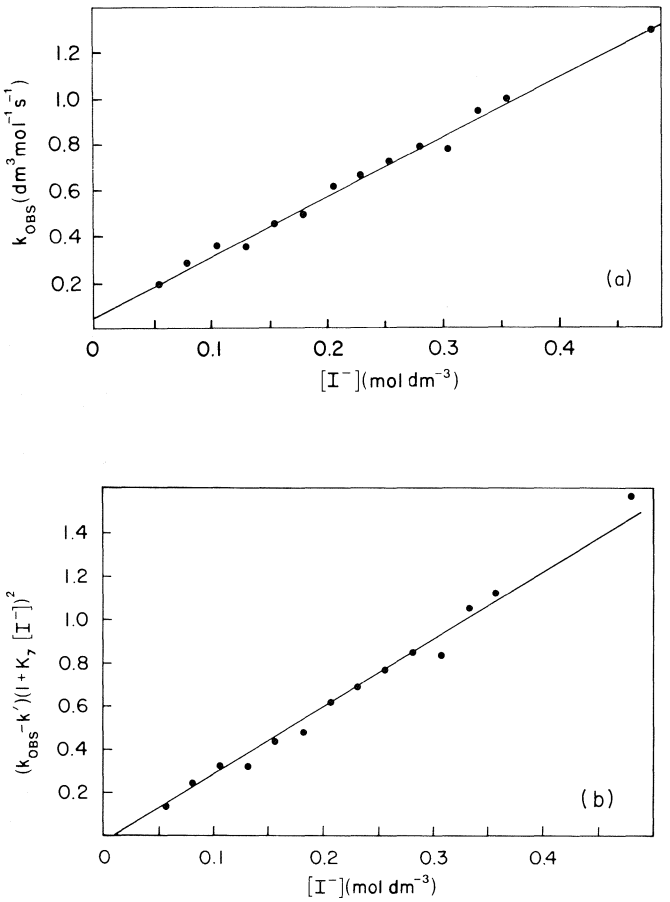

FIG. 12. For the reaction of Fig. 8, (*a*) observed rate constants for the decay of A_{363} as a function of [I^-], and (*b*) correlation of the rate constants with [I^-].

increase in absorbance as the iodide ion concentration was increased. Our experimental conditions were similar to Chia's and our value for K_{18} is in reasonable agreement with hers.

Li and White (8) have obtained, using a titration technique, the following rate law for the decomposition of hypoiodite in basic solutions:

$$[34] \quad -\frac{d[IO^-]}{dt} = k_r[IO^-]^2 + k_s\frac{[IO^-]^2[I^-]}{[OH^-]}$$

with k_r having a value of 5×10^{-2} dm^3 mol^{-1} s^{-1} and k_s having a value of 2.18 dm^3 mol^{-1} s^{-1}. Forster (11) and Skrabal (10) also concluded, using a titration technique, that the rate of reaction at high concentrations of OH^- and I^- ions is proportional to the concentration of IO^- and I^- ions, although they failed to detect the small I^--independent term. Forster (11) found a value of 1.2 for the rate constant k_s, whereas Skrabal (10) reported a value of 1.45. The second term of our rate law and our k''_{29} value of 2.60 dm^3 mol^{-1} s^{-1} agree with the results of these earlier studies.

In later experiments, in the presence of silver oxide and silver iodide, Skrabal and Hohlbaum (9) obtained evidence that the first term of the rate law at 25°C is

$$[35] \quad -\frac{d[IO^-]}{dt} = 0.03\frac{[IO^-]^2}{[OH^-]}$$

although Li and White (8) argued against a reciprocal [OH^-] dependence. Our results at low [I^-], obtained using reaction

TABLE 2. Rate constants for the disproportionation of the hypohalites at 25°C, in dm^3 mol^{-1} s^{-1}

X	k		X^- effect
	$XO^- + XO^-$	$XO^- + XO_2^-$	
Cl[a]	1.1×10^{-8}	1.8×10^{-6}	None
Br[b]	1.0×10^{-6}	1.5×10^{-5}	Slight positive
I[c]	$<7 \times 10^{-2}$	0.5	Marked positive

[a]Value from ref. 32.
[b]Value from ref. 33.
[c]Value from this work.

[2], indicate that the iodide-independent part of the rate law consists of two terms:

$$[36] \quad -\frac{d[IO^-]}{dt} = a[IO^-]^2 + b\frac{[IO^-]^2}{[OH^-]}$$

where a is less than 7×10^{-2} dm^3 mol^{-1} s^{-1} and b is 2×10^{-2} dm^3 mol^{-1} s^{-1}. This seems to reconcile the Li and White (8) and Skrabal and Hohlbaum (9) data.

Haimovich and Treinin (6) have also studied the decomposition of hypoiodite in alkaline solutions at low iodide ion concentrations. They reported a value of $(4.0 \pm 0.4) \times 10^{-2}$ dm^3 mol^{-1} s^{-1} for the rate constant in 4 mol dm^{-3} NaOH, and a value of $(2.7 \pm 0.2) \times 10^{-2}$ dm^3 mol^{-1} s^{-1} in 6 mol dm^{-3} NaOH, which leads to a value of 2×10^{-2} dm^3 mol^{-1} s^{-1} for the $[OH^-]^{-1}$-dependent term, in good agreement with our b value. They also noted that, for I^- concentrations less than 8×10^{-2} mol dm^{-3}, no effect on the rate could be detected and that, on further raising [I^-], the rate increased. This is in qualitative agreement with our observations.

The mechanism for the conversion of hypochlorite or hypobromite to chlorate or bromate ions is well known (32, 33). The reactions consist of two steps:

$$[37] \quad XO^- + XO^- \xrightarrow{\text{slow}} XO_2^- + X^-$$

$$[38] \quad XO^- + XO_2^- \xrightarrow{\text{fast}} XO_3^- + X^-$$

with the formation of the halite ion being the rate-determining step and the subsequent formation of halate ion being rapid. The geometry of the activated complex for the first step is likely

$$[39] \quad \left[\begin{matrix} X\ldots O\text{—}X \\ | \\ O \end{matrix}\right]^{2-} \rightarrow \left[\begin{matrix} X\text{—}O \\ | \\ O \end{matrix}\right]^{-} + X^-$$

The first step is, thus, a nucleophilic displacement of one base (X^-) by another (XO^-).

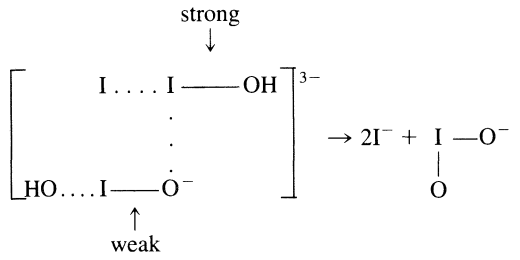
Using radioactive chlorine, Anbar and Taube (26) have demonstrated that, at least in the chlorine case, the second step involves the formation of a non-symmetrical intermediate in which the chlorine atoms remain distinct, such as

$$[40] \quad \left[\begin{matrix} Cl\text{—}O\ldots Cl\text{—}O \\ \quad\quad\quad\ | \\ \quad\quad\quad O \end{matrix}\right]^{2-} \rightarrow Cl^- + ClO_3^-$$

Presumably, this is also valid for the bromine system.

Our results for the iodine system indicate that the first step of iodine(I) disproportionation at high hydroxide and iodide ion concentrations consists of two parallel reactions: a slow reaction between IO^- (or HOI) and IO^-, and a faster reaction between IO^- (or HOI) and I_2OH^-. The slower path presumably is similar to the chlorine and bromine cases described above (reaction

[39]). The reason that the other path is more rapid can be readily explained. We suggest that IO^- in aqueous solution may exist as a loosely bound complex $[HO....IO]^{2-}$ with a weakened I—O bond, while the I—O bond is strengthened in I_2OH^-. Therefore, if the activated complex and the nucleophilic displacement occur as follows,



[41]

the activated complex would be more stable than that formed by HOI and $[HO....IO]^{2-}$. The second step in the disproportionation of iodine(I) also consists of two parallel reactions: a slow reaction between IO^- (or HOI) and IO_2^-, and a faster reaction between I_2OH^- and IO_2^-. The slow path likely proceeds by a mechanism similar to the chlorine system (reaction [40]). The other path is more rapid, presumably for the same reasons as in the first step.

A comparison of the rates for the slower paths with the analogous bromine and chlorine reactions can be found in Table 2. The rates increase on going from hypochlorite to hypoiodite. This trend is to be expected since the electronegativity of the halogen is in the order Cl > Br > I. This would cause the partial positive charge on the halogen to increase on going from ClO^- to IO^-, favouring electrostatic interactions. However, the increase on going from the Br to I system is too large to be explained by electrostatic interaction alone. We believe that the weakened O—I bond in $[HO....IO]^{2-}$ favours a more stable activated complex for the reaction of IO^- with IO^- and IO^- and IO_2^-, thus increasing the rate even further.

Chloride has no effect on the rate of disproportionation of hypochlorite. Bromide slightly increases the rate of disproportionation of hypobromite, whereas iodide has a marked accelerating effect on the disproportionation of hypoiodite. Our study indicates that the pronounced effect in the case of hypoiodite comes from the formation of the reactive species I_2OH^-, which is expected to have a structure similar to I_3^-. Since the order of stability for the trihalides is $I_3^- > Br_3^- > Cl_3^-$ (34), the relative effect of the halides on the hypohalites disproportionation can be explained if the X_2OH^- species follow the same order of stability as the trihalides.

It is tempting to try to relate our work to the complex topic of the mechanism of the Dushman reaction (reverse reaction [1]). Our experiments were performed in alkaline solutions whereas most of the studies of the Dushman reactions have been done in acidic media. This precludes quantitative calculations. However, some qualitative comments can be made.

Liebhafsky and Roe (2) have summarized the numerous studies of the Dushman reaction. They concluded that the kinetics of the reaction are best described by a rate law of the form:

$$[42] \quad R = (k_1 + k_2[I^-])([H^+]^2[IO_3^-][I^-])$$

The reaction is first order in iodide at iodide concentrations below 10^{-6} mol dm^{-3} and second order in iodide at higher concentrations. The two-term rate law is accounted for by a mechanism involving the polynuclear iodine species I_2O_2 (or $H_2I_2O_3$). Liebhafsky and Roe (2) state that the existence of such a species is also needed to explain the results of Skrabal (9, 10) on the disproportionation of I_2 into IO_3^- and I^- in alkaline solution. Our study shows that the results of Skrabal can be explained by the presence of the I_2OH^- species, which we have unambiguously identified using Raman spectroscopy. Although I_2OH^- is present in significant concentration at high pH, its concentration would be quite low at low pH. In fact we could not detect any Raman signal due to this species at pH 10 and below. However, Palmer and Van Eldik (35) have recently demonstrated that I_2OH^- plays an important role in the hydrolysis of I_2 to I^- and HOI at low pH, even if it is present in very low concentration. It would be interesting to see if I_2OH^- can be substituted for I_2O_2 in the mechanism of the Dushman reaction.

Far ultraviolet induced decomposition of thymine in deaerated and aerated aqueous solutions

BUNSHO OHTANI, HIROSHI NAGASAKI, SEI-ICHI NISHIMOTO, KOICHI SAKANO, AND TSUTOMU KAGIYA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606, Japan

Received January 2, 1986

BUNSHO OHTANI, HIROSHI NAGASAKI, SEI-ICHI NISHIMOTO, KOICHI SAKANO, and TSUTOMU KAGIYA. Can. J. Chem. **64**, 2297 (1986).

Thymine in aqueous solution was decomposed with quantum yields of 0.3 and 0.4 under N_2-saturated and aerated conditions by far-ultraviolet light (>180 nm, far-uv), and quantum yields of 2×10^{-4} and 3×10^{-4} by near-ultraviolet light (>220 nm, near-uv), respectively. The main photolytic products by far-uv were 5,6-dihydrothymine (DHT) (selectivity: S(DHT) = 0.2) and 5-hydroxymethyluracil (HMU) (S(HMU) = 0.1) under N_2-saturated conditions. *cis*- and *trans*-5,6-Dihydroxy-5,6-dihydrothymine (TG), 6(5)-hydroperoxy-5(6)-hydroxy-5,6-dihydrothymine (HTP) (S(TG) + S(HTP) = 0.2), and N^1-formyl-N^2-pyruvylurea (FPU) (S(FPU) = 0.4) were obtained under aerated conditions. These products were attributed to the reactions of thymine with the ·H and ·OH produced by photolysis of water.

BUNSHO OHTANI, HIROSHI NAGASAKI, SEI-ICHI NISHIMOTO, KOICHI SAKANO et TSUTOMU KAGIYA. Can. J. Chem. **64**, 2297 (1986).

Sous l'influence de la lumière ultraviolette lointaine (>180 nm, uv-lointain), on a mesuré que les solutions aqueuses de thymine se décomposent avec des rendements quantiques de 0,3 et 0,4 suivant que l'on opère sous des conditions saturées en N_2 ou aérées; par ailleurs, dans l'ultraviolet proche (>220 nm, proche-uv), les valeurs sont respectivement 2×10^{-4} et 3×10^{-4}. Dans l'ultraviolet lointain et sous des conditions saturées en N_2, les produits principaux de la photolyse sont la dihydro-5,6 thymine (DHT) (sélectivité; S(DHT) = 0,2) et l'hydroxyméthyl-5 uracile (HMU) (S(HMU) = 0,1). Dans des conditions aérées, les produits principaux sont les dihydroxy-5,6 dihydro-5,6 thymine-*cis* et -*trans* (TG), les hydroperoxy-6(5) hydroxy-5(6) dihydro-5,6 thymines (HTP) (S(TG) + S(HTP) = 0,2) et la N^1-formyl N^2-pyruvylurée (FPU) (S(FPU) = 0,4). On attribue la formation de ces composés aux réactions de la thymine avec les radicaux ·H et ·OH qui sont produits par photolyse de l'eau.

Introduction

Photoinactivation of living cells, which is applicable to the sterilization by near-ultraviolet light (near-uv, 240–290 nm) irradiation, is of great interest and has been extensively studied in recent years (1). Among the chemical reactions induced by near-uv, the photoinduced dimerization of pyrimidine bases of DNA likely accounts for such cell inactivation (for a review, see ref. 1).

In contrast, few reports have appeared concerning the far-ultraviolet light (far-uv, >180 nm) induced inactivation and/or chemical reaction of DNA-related compounds. Daniels and Grimison have reported the detailed investigation on far-uv photolysis of thymine under aerated conditions and demonstrated the intermediacy of radical species (2). On the other hand, the fate of such a DNA-related compound under deaerated conditions is of biological and biochemical interests in connection with phototherapy of hypoxic tumor cells. The present paper describes the far-uv induced photolysis of thymine under both deaerated (N_2-saturated) and aerated conditions. Particular emphasis is placed on the comparison of these two photoreaction systems with γ-radiolysis systems. The reaction mechanism is also discussed.

Experimental

Thymine (T), 5-hydroxymethyluracil (HMU), and 5,6-dihydrothymine (DHT) were obtained from Sigma and used as received. *cis*-5,6-Dihydroxy-5,6-dihydrothymine (TG) (3), 6-hydroperoxy-5-hydroxy-5,6-dihydrothymine (HTP) (4), 5-methylbarbituric acid (MBA) (5), 6-hydroxy-5,6-dihydrothymine (HOT) (6), and N^1-formyl-N^2-pyruvylurea (FPU) (7) were prepared by the reported procedures. The chemical structures of these compounds are shown in Fig. 1.

An aqueous solution of thymine (0.5 mmol dm^{-3}) was prepared with twice distilled water and adjusted to pH 7.0 ± 0.1 with phosphate buffer (2 mmol dm^{-3}). The solution (10 cm^3) in a quartz test tube

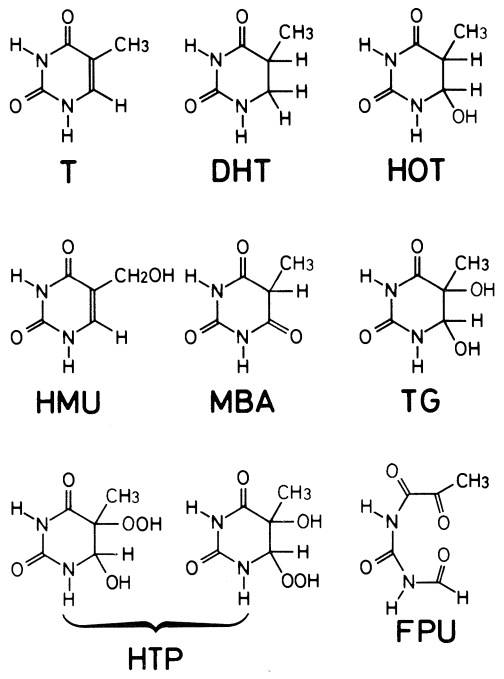

FIG. 1. Chemical structures of thymine and photolytic products.

(17 mm in diameter) was purged with N_2 or air for >15 min, sealed off, and irradiated with a coil-formed low-pressure mercury arc at room temperature. A vycor filter was used to cut off far-uv (<220 nm). The light flux incident upon the reaction vessel was measured to be 4.87×10^{-7} einstein min^{-1} at 185 nm by Farkas actinometry (8) or 1.40×10^{-5} einstein min^{-1} at 254 nm by ferric oxalate actinometry (9).

Typical procedure of γ-radiolysis was as follows. A solution of thymine (0.5 mmol dm^{-3}) was prepared with triply distilled water, buffered at pH 7.0 ± 0.1 with sodium phosphate, and purged with N_2

TABLE 1. Rates ($-\Delta T$) and quantum yields of thymine decomposition ($\phi(-\Delta T)$), and rates[a] and selectivities of products (S)[b] in the uv- and γ-irradiation of aqueous thymine solution in N_2 and air

or air. Irradiation was performed in a Pyrex tube (16 mm in diameter) with a ^{60}Co γ-ray source (380 Gy h^{-1}) at room temperature.

A portion (30 mm^3) of the photo- and γ-irradiated solutions was analyzed by high performance liquid chromatography (hplc), using a Shimadzu LC-3A equipped with a Cosmosil $5C_{18}$ reversed phase column (4.6 × 150 mm). Phosphate buffer containing 5% methanol (pH 2.5) was delivered as the mobile phase at a flow rate of 0.6 cm^3 min^{-1}. The column eluents were monitored with the ultraviolet absorptions at 210 and 260 nm. Products were confirmed by comparison with the authentic samples at both detector wavelengths. Calibration curve for each of the products was obtained at 210 nm.

The amount of peroxides produced in the irradiated solutions was analyzed by iodometry, using the molybdate-catalyzed oxidation of iodide to triiodide anion which was measured spectrophotometrically at 350 nm (10) (the molar extinction coefficient was 5.9×10^3 mol dm^{-3} cm^{-1}). This iodometry responds to both hydrogen peroxide (H_2O_2) and organic peroxides. The amount of H_2O_2 was separately measured by acidic titanium oxysulfate ($TiO(SO_4)$) method (11). These measurements showed the formation of H_2O_2 and organic peroxides only by the far-uv photolysis under aerated conditions. High performance liquid chromatographic separation of *trans*-TG and *trans*-HTP, or *cis*-TG and *cis*-HTP, was not successful. Determination of HTP content in each TG/HTP fraction of hplc was failed because of the unstability of HTP isomers at room temperature. Nevertheless, it seemed most likely that the fractions predominantly consist of HTP, since the amount of organic peroxide was almost equal (110%) to the sum of TG and HOT.

Total amount of some unidentified products listed in Table 1 was obtained as the difference in amount between the converted thymine and the sum of identified products. The products obtained by near-uv photolysis under both deaerated and aerated conditions were not identified. However, comparison of the hplc elution patterns with those obtained by the near-uv photolysis of thymine in ice under the reported conditions (ref. 1 and references therein) suggested that the products consisted mainly of the thymine dimers.

Results and discussion

Ultraviolet-induced decomposition of thymine in aqueous solution in the absence and presence of O_2

Irradiation at >180 nm led to decomposition of thymine (Fig. 2). The amount of the decomposed thymine under aerated conditions was 1.4 times as much as that under N_2-saturated conditions. Linear plots of ln ($[T]_0/[T]$), where $[T]_0$ and [T]

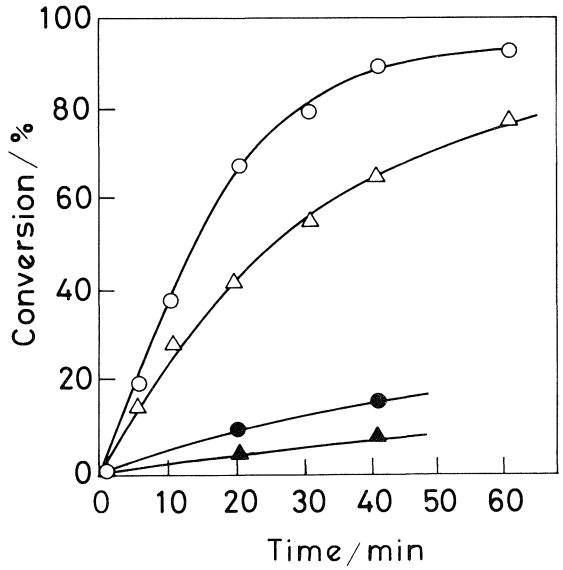

FIG. 2. Time-course of uv-induced decomposition of thymine in aqueous solution. ○ and △: irradiations at >180 nm under aerated and N_2-saturated conditions, respectively. ● and ▲: irradiations at >220 nm under aerated and N_2-saturated conditions, respectively.

refer to concentrations of thymine before and after photoirradiation, respectively, against photoirradiation time demonstrated pseudo-first order kinetics. The apparent rate constants (k), which depend on several terms, e.g., light intensity and quantum efficiency, were evaluated to be 9.4×10^{-4} and 4.4×10^{-4} s^{-1} for aerated and N_2-saturated conditions, respectively.

In both cases cutting off of the shorter wavelength region (<220 nm) by using a vycor filter reduced the apparent reaction rate to ca. 1/10. The low-pressure mercury arc emits photons mainly at 254 nm and 185 nm (Table 1). It follows that the mercury line at 185 nm, rather than 254 nm, is responsible for the decomposition of thymine. The order of quantum efficiency at 254 nm was evaluated as 10^{-4} from the ratio of thymine decomposition rate to the light flux incident upon the reaction

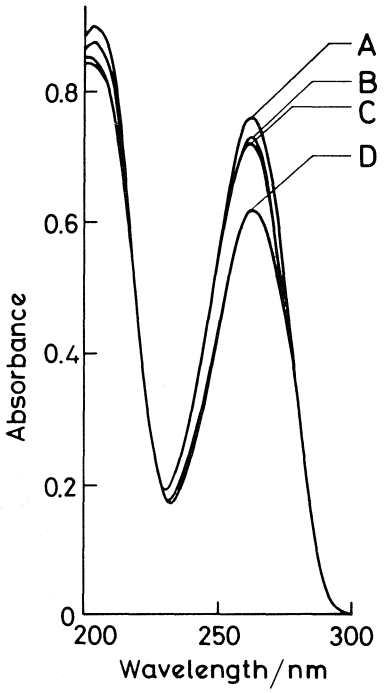

FIG. 3. Electronic absorption spectra of aqueous thymine solutions before (*A*) and after irradiation. *B* and *C*: irradiations of near-uv under N_2-saturated and aerated conditions, respectively, for 1 h. *D*: irradiations of far-uv under N_2-saturated and aerated conditions for 10 and 7 min, respectively.

vessel through a vycor filter (Table 1). This negligibly small efficiency shows that the light at 185 nm induces the reaction of thymine almost exclusively even in the irradiation without a cut-off filter. Thus, the efficiency at 185 nm was estimated to be 0.30 and 0.42 under N_2-saturated and aerated conditions, respectively, which was 200–300 times larger than those at 254 nm.

From the uv-absorption spectra of thymine and water, most of the incident photons at 254 nm were absorbed by thymine in the solution, while photons at 185 nm by not only thymine but also water (2). The fractions of photons of 185 nm absorbed by 0.5 mmol dm^{-3} of thymine and water were evaluated from the reported extinction coefficients (5.75×10^3 mol^{-1} dm^3 cm^{-1} and 1.52 cm^{-1}) (2) to be 66 and 34%, respectively, under the present conditions. Thus, it is suggested that the significantly larger quantum efficiency by 185 nm irradiation is attributed to the water photolysis via homolytic cleavage into hydroxyl radical (·OH) and hydrogen atom (·H) (12) (see Fig. 5).

Photolytic and γ-radiolytic products from thymine

Figure 3 shows the electronic absorption spectra before and after far-uv irradiation of aqueous thymine solution under N_2-saturated and aerated conditions. Characteristic absorption band due to π–π^* transition of *cis* olefinic bond of thymine was observed at 260 nm. The absorbance at this band decreased by photoirradiation, elucidating disappearance of the double bond by the photoirradiation. In accord with these facts the photoproducts under both N_2-saturated and aerated conditions exhibited intense hplc-detector response at 210 nm but negligible at 260 nm (except for the case of HMU) as shown in Fig. 4. Each yield of main photolytic products increased linearly with photoirradiation time within first 5 min. However, prolonged irradiation decreased the product yields to some extent, due to the secondary photolyses. The initial rate (<5 min) and quantum efficiency evaluated for each product were evaluated

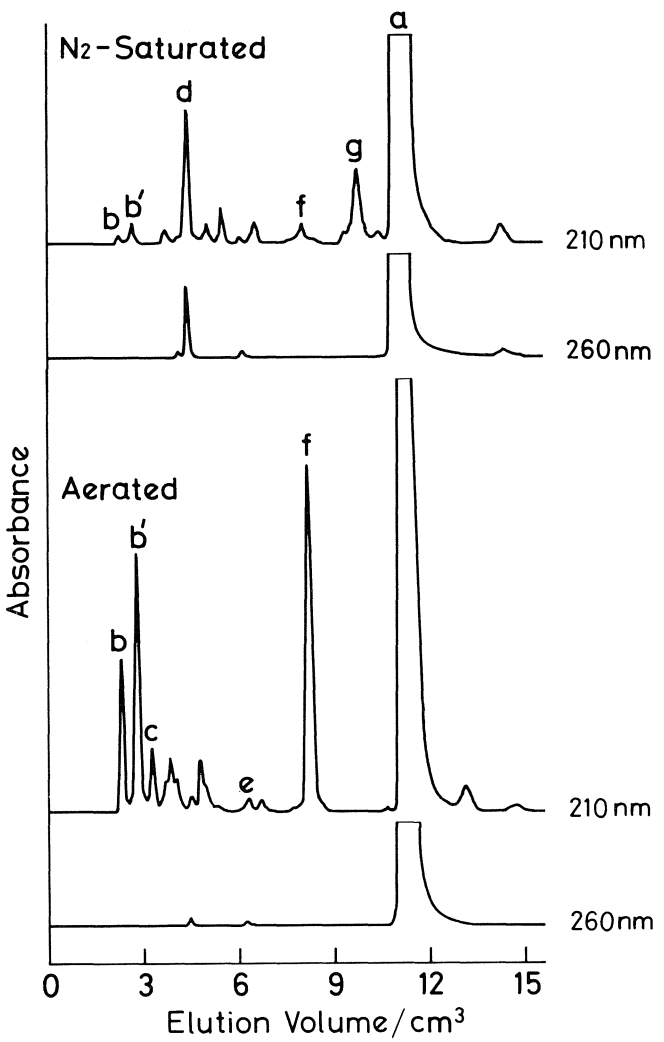

FIG. 4. Typical hplc patterns of far-uv irradiated aqueous thymine solutions.

from the linear portion of the yield–time plot, as listed in Table 1.

It is seen from Table 1 that main photolytic products under N_2-saturated conditions at 185 nm were DHT and HMU, neither of which was produced by the 254 nm irradiation. The selectivities of these products (0.20 and 0.10) were similar to those obtained by γ-radiolysis (0.21 and 0.06, respectively (Table 1)). In the γ-radiolysis, main active species produced in N_2-saturated aqueous solution are ·H (*G*-value (number of molecules per 100 eV-energy absorption at pH 7.0) is 0.55), hydrated electron (e^-_{aq}, $G = 2.7$), and ·OH ($G = 2.7$) (13). Reduction of thymine by e^-_{aq} to thymine anion radical (T·⁻) followed by the addition of H^+ gives hydrothyminyl radicals (·T—H). The addition of ·OH across the C_5—C_6 double bond of thymine produces hydroxythyminyl radicals (·T—OH). Either reduction by e^-_{aq} or recombination with ·OH of ·T—H leads to DHT or HOT.[1]

In the far-uv photolysis, ·H produced via photocleavage of water (see Fig. 5) presumably gives the same intermediate,

[1]The disproportionations among radical intermediates, ·T—H and ·T—OH, are responsible for the formation of DHT, HOT, and TG. Since the formal chemical change can be represented by T + 2·H → DHT and T + ·H + ·OH → HOT, the above processes involving disproportionation are illustrated as T + ·H → ·T—H, ·T—H + ·H → DHT, ·T—H + ·OH → HOT for convenience in Fig. 5.

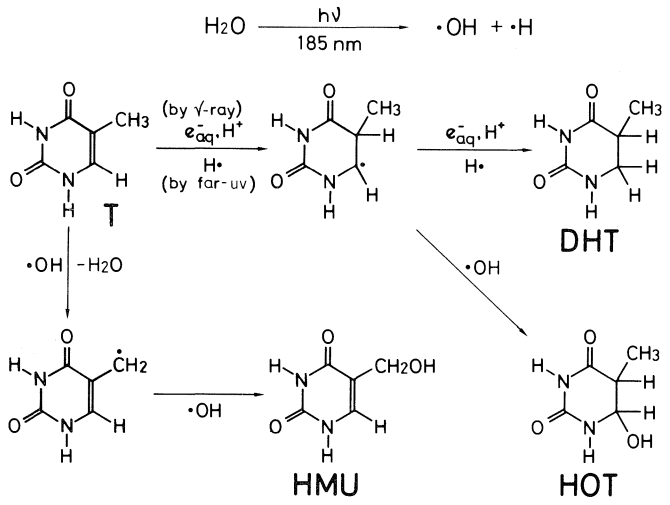

FIG. 5. Scheme of far-uv photolysis of thymine in aqueous solution under N_2-saturated conditions.

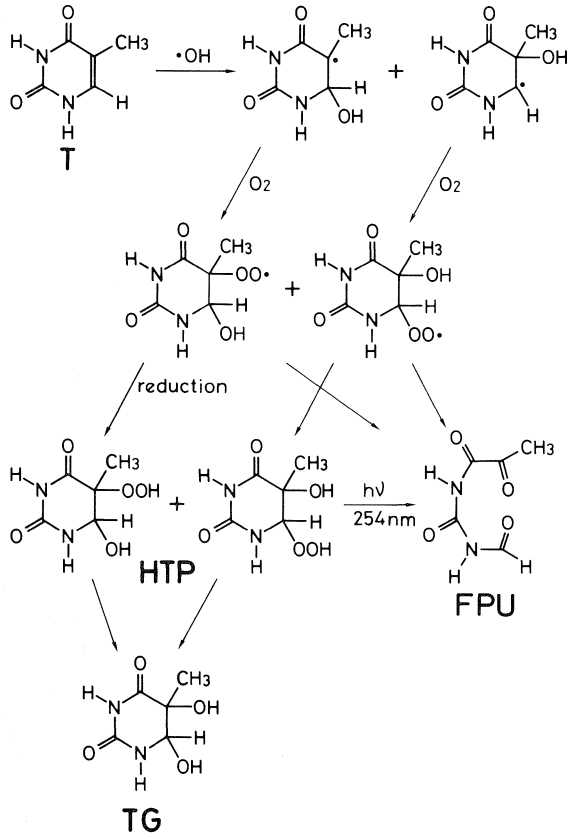

FIG. 6. Scheme of far-uv photolysis of thymine in aqueous solution under aerated conditions.

hydrothyminyl radical. The radical species, ·OH, also abstract hydrogen atom from the methyl group of thymine. The HMU formation is attributable to this hydrogen abstraction followed by the addition of ·OH in both γ-radiolysis and far-uv photolyisis.

In the presence of O_2, the main products were HTP and FPU in the far-uv photolysis (and γ-radiolysis, see Table 1). The peroxide formation is distinct from the N_2-saturated system.

The reduction of thymine to DHT became negligible in the O_2-saturated system, since the reducing species, ·H in both photolysis and γ-radiolysis, and e^-_{aq} in γ-radiolysis, are expected to react with O_2 to produce less active $HO_2\cdot$ and $O_2^{\cdot-}$, respectively. $HO_2\cdot$ is deprotonated to yield $O_2^{\cdot-}$ under neutral conditions. Such trapping of the reducing species with O_2 may also account for the decreased ratio of unidentified products, which would be produced by the reaction at labile N—H bond in thymine. Consequently, the reaction of thymine with ·OH occurs predominantly in both systems under O_2. O_2 addition to the intermediate ·T—OH thus produced leads to HTP and FPU (see Fig. 6).

In the far-uv photolysis the yield ratio of FPU to TG (HTP) was evaluated as 1.5, which is larger than that in the γ-radiolysis (0.5). This enhancement of FPU formation was accounted for by the direct photoreaction of HTP by irradiation at >220 nm, in accord with the observation that authentic sample of HTP in aqueous solution (0.5 mmol dm^{-3}) was photolysed into FPU (and unidentified products) under deaerated conditions.

In conclusion, thymine was decomposed efficiently in aqueous solution by far-uv irradiation. The decomposition was attributed to the active species, ·H and ·OH, produced by the far-uv photolysis of water under both deaerated and aerated conditions.

GUILLERMO LÓPEZ-CUETO and CARLOS UBIDE. Can. J. Chem. **64**, 2301 (1986).

When potassium hexacyanomanganate(III) dissolves in acidic solution it rapidly disproportionates into hexacyanomanganate(IV) and Mn(II). Hexacyanomanganate(IV) then slowly decomposes to yield Mn(II) and $(CN)_2$. Kinetics of the latter reaction has been studied. The reaction is found to be first order with respect to $Mn(CN)_6^{2-}$, H^+, and Mn(II) concentrations and the experimental rate law has the form $v = k_{obs}[Mn(IV)] = (k_a + k_b[H^+] + k_c[Mn(II)])[Mn(IV)]$. At 40°C and ionic strength 2.0, k_a, k_b, and k_c values are $(1.78 \pm 0.01) \times 10^{-4}$ s^{-1}, $(5.97 \pm 0.05) \times 10^{-5}$ s^{-1} M^{-1}, and $(3.40 \pm 0.18) \times 10^{-3}$ s^{-1} M^{-1}, respectively. A mechanism with three parallel pathways is proposed, the deduced rate law being similar to the experimental one. Activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the rate constants k_a, k_b, and k_c are also reported.

GUILLERMO LÓPEZ-CUETO et CARLOS UBIDE. Can. J. Chem. **64**, 2301 (1986).

Lorsqu'on place l'hexacyanomanganate(III) de potassium en solution acide, il se produit rapidement une réaction de disproportionation conduisant à l'hexacyanomanganate(IV) et au Mn(II); après, l'hexacyanomanganate(IV) se décompose lentement pour donner du Mn(II) et du $(CN)_2$. On a étudié la cinétique de cette dernière réaction. On a trouvé que la réaction est du premier ordre par rapport aux concentrations de $Mn(CN)_6^{2-}$, de H^+ et de Mn(II) et que la loi expérimentale de vitesse se présente sous la forme $v = k_{obs}[Mn(IV)] = (k_a + k_b[H^+] + k_c[Mn(II)])[Mn(IV)]$. A 40°C et à une force ionique égale à 2,0, les valeurs de k_a, k_b et k_c sont respectivement égales à $(1{,}78 \pm 0{,}01) \times 10^{-4}$ s^{-1}, $(5{,}97 \pm 0{,}05) \times 10^{-5}$ s^{-1} M^{-1} et $(3{,}40 \pm 0{,}18) \times 10^{-3}$ s^{-1} M^{-1}. On suggère que la réaction se produit par un mécanisme impliquant trois voies parallèles; la loi de vitesse qui est alors déduite est semblable à celle qui est observée expérimentalement. On rapporte aussi les paramètres d'activation, $\Delta H^{\neq}$ et $\Delta S^{\neq}$, pour les constantes de vitesse k_a, k_b et k_c.

[Traduit par la revue]

Introduction

Two different cyanomanganate(III) complexes have been reported in the literature, hexacyanomanganate(III) and μ-oxo-bis[pentacyanomanganate(III)], and they have mono-and binuclear structures, respectively (1, 2). The uv spectra of $Mn(CN)_6^{3-}$ in acidic and cyanide-containing solutions differ markedly (3); whereas the cyanide-containing solutions are stable, the acidic ones are not, and the absorption bands of their uv spectra slowly fade away because of slow decomposition. On the other hand, clear evidence has been reported that acidic solutions of hexacyanomanganate(III) actually contain hexacyanomanganate(IV), as their uv spectrum is quite similar to that of the $K_2Mn(CN)_6$ solution in DMF (4). Therefore it has been suggested that a disproportionation reaction takes place (5). This paper shows how the uv spectrum of the acidic solutions of $Mn(CN)_6^{3-}$ changes with time during both the disproportionation and the decomposition reactions. The kinetics and mechanism of the decomposition reaction are also studied.

Experimental

Apparatus

A Varian 634-S spectrophotometer with 1.0-cm glass cells and coupled with a Radiometer REC 80 Servograph recorder was used for the kinetic measurements. A water bath circulator Selecta Tectron Digiterm was used for the cells' temperature control.

When pH measurements were required, a Radiometer PHM 82 pH-meter was used.

Reagents

All chemicals were of analytical reagent-grade and doubly distilled water was used throughout.

Potassium hexacyanomanganate(III)

Firstly the potassium salt of the binuclear complex $K_7[(CN)_5MnOMn(CN)_5]CN$ was prepared following a reported procedure (6). $K_3Mn(CN)_6$ was then obtained from the remaining solution as previously described (7). The Mn(III) mononuclear complex in acidic and cyanide-containing media was characterized by uv spectrophotometry and by ir spectroscopy; our results agree with those of the literature (1, 3). Elemental analysis showed a content close to 100%.

Kinetics measurements

Solutions were prepared in a dark 250-mL standard flask by adding the required amounts of $MnSO_4.H_2O$ and $NaNO_3$ to adjust the ionic strength, and sulfuric acid solution of the required concentration to 220–230 mL. The resulting solution was kept in a thermostatic bath for 30 min; $K_3Mn(CN)_6$ was then added (zero time) with stirring and the volume was quickly adjusted to 250 mL by adding some more sulfuric acid solution. The solution was stirred again ($K_3Mn(CN)_6$ dissolves very quickly) and transferred to a spectrophotometric cell. The kinetic curve at 387 nm was recorded for 60 min using water as reference (diluted sulfuric acid of the same concentration was used for measurements in the ultraviolet region).

The temperature in the cell was kept constant within ±0.2°C during each experiment.

The rate constants were calculated by plotting ln A vs. time and linear regression analysis was applied. The temperature was varied between 20 and 50°C, the ionic strength between 0.27 and 2.0, the acidity between 0.08 and 0.75 M, the initial Mn(II) concentration between 0 and 2×10^{-2} M, and the initial $K_3Mn(CN)_6$ concentration between 1 and 6×10^{-4} M.

Results and discussion

Evolution of the uv spectrum in acidic solution

When $K_3Mn(CN)_6$ is dissolved in acidic solution the uv-spectrum that can be scanned at a temperature close to 0°C is similar to the one obtained in a cyanide-containing solution,

[1]To whom correspondence should be addressed.

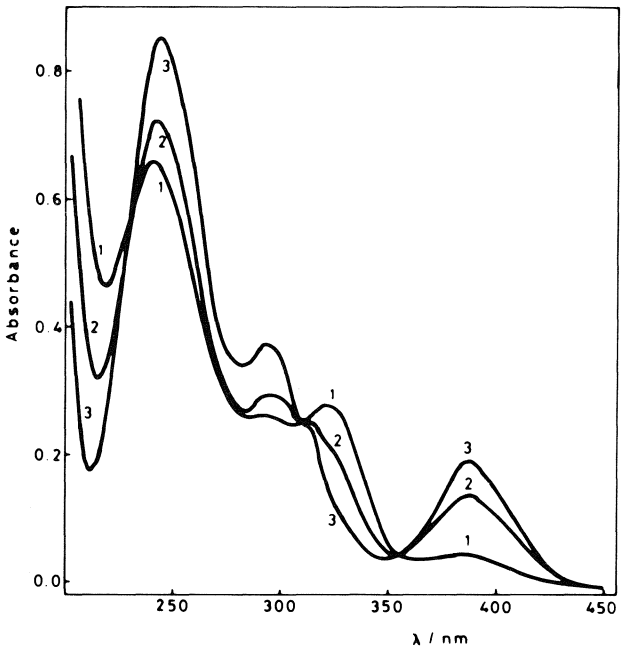

FIG. 1. Evolution of the uv spectrum of hexacyanomanganate(III) in acidic medium with time. Reaction of disproportionation: Mn(III), 10^{-4} *M*; H_2SO_4, 0.25 *M*; *I*, 0.27; *T*, ≅3°C. Scan starting time: (*1*), 0.5 min; (*2*), 3.4 min; (*3*), 12.25 min.

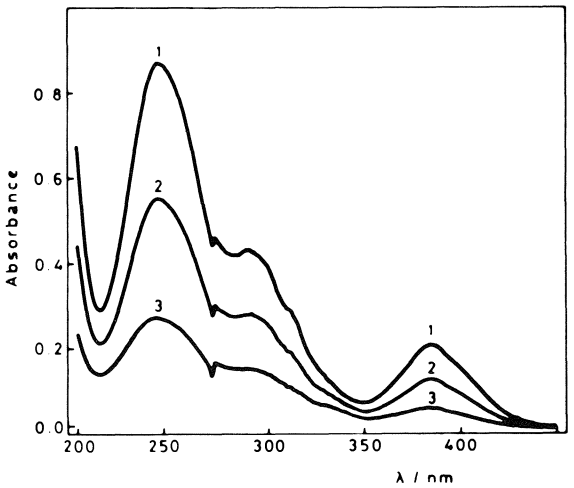

FIG. 2. Evolution of the uv spectrum of hexacyanomanganate(IV) in acidic medium with time. Reaction of decomposition: Mn(IV), 5×10^{-5} *M*; H_2SO_4, 0.25 *M*; *I*, 0.27; *T*, ≅40°C. Scan starting time: (*1*), 10 min; (*2*), 50 min; (*3*), 170 min.

with maxima at 324 and 268 nm. In this acidic medium two consecutive reactions take place. Firstly, the uv spectrum quickly changes to that of $Mn(CN)_6^{2-}$, with absorption maxima at 387, 292, and 244 nm (Fig. 1). This is the disproportionation reaction reported by Trageser and Eysel (5):

$$[1] \quad 2Mn(CN)_6^{3-} + 6H_3O^+ \rightarrow Mn(CN)_6^{2-} + Mn(H_2O)_6^{2+} + 6HCN$$

It is difficult to follow the reaction at room temperature as its rate is rather high (working at 15°C the reaction proceeds to completion in 2–3 min). At 3°C it has been possible to measure the reaction rate spectrophotometrically and its kinetics appears to be close to a pseudo first-order dependence. The reaction product, $Mn(CN)_6^{2-}$, is stable for at least several hours at a

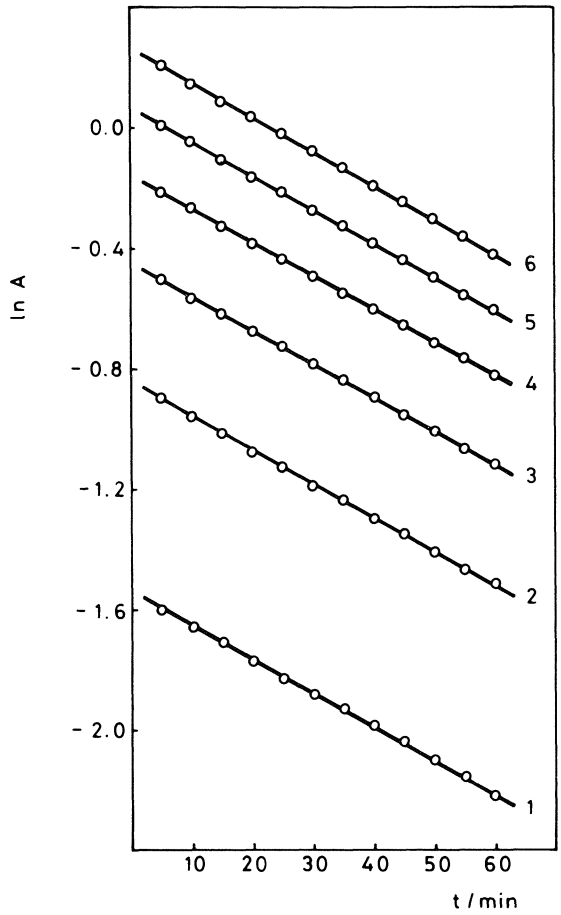

FIG. 3. Plots of ln *A* vs. time for the decomposition of hexacyanomanganate(IV) in acidic solution: H^+, 0.16 *M*; *I*, 2; *T*, 40°C; Mn(IV), $M \times 10^4$: (*1*), 0.5; (*2*), 1.0; (*3*), 1.5; (*4*), 2.0; (*5*), 2.5; (*6*), 3.0.

temperature close to 0°C, but at higher temperatures a slow and uniform fading of the uv-spectrum bands takes place (Fig. 2). This must be the decomposition reaction of the $Mn(CN)_6^{2-}$ species. It has been found in our laboratory that ultraviolet light increases the rate of the latter reaction; nevertheless, we have verified that the reaction proceeded to the same extent both in the spectrophotometric cell and in the flask kept in the dark.

Decomposition of $Mn(CN)_6^{2-}$ in acidic solution

Stoichiometry

If the reaction rate is followed both volumetrically (by adding at fixed times aliquots of the reaction mixture to an excess of Fe^{2+} and estimating the remaining Fe^{2+} with MnO_4^- solution) and spectrophotometrically, it can be proved that the oxidizing capacity of the solution and its absorbance decrease at the same rate. One must therefore conclude that a reduction of Mn(IV) to Mn(II) takes place, the probable stoichiometry being:

$$[2] \quad Mn(CN)_6^{2-} + 4H_3O^+ + 2H_2O \rightarrow Mn(H_2O)_6^{2+} + (CN)_2 + 4HCN$$

Effect of hexacyanomanganate(III) concentration

Reaction order: When Mn(II) is not added initially, plots of ln *A* against time (Fig. 3) are quite linear for at least three half lives, the slope being independent of the initial concentration of $Mn(CN)_6^{2-}$ (which according to [1] will be half the concentration of $Mn(CN)_6^{3-}$ added). This shows a first-order dependence on the hexacyanomanganate(IV) concentration, and hence, the rate law below must be followed:

TABLE 1. Activation parameters for the decomposition reaction of hexacyanomanganate(IV) in sulfuric acid medium at ionic strength 2.0

Parameter	Value at 40°C	$\Delta H^{\ddagger}$/kJ mol^{-1}	$\Delta S^{\ddagger}$/J mol^{-1} K^{-1}
k_a/s^{-1}	$(1.78 \pm 0.01) \times 10^{-4}$	69.5 ± 1.4	−95.3 ± 4.2
k_b/s^{-1} M^{-1}	$(5.97 \pm 0.05) \times 10^{-5}$	119.6 ± 3.2	57.4 ± 2.3
k_c/s^{-1} M^{-1}	$(3.40 \pm 0.18) \times 10^{-3}$	44.8 ± 2.3	−150.1 ± 23.3

$$[3] \quad \text{Rate} = -\frac{d[\text{Mn(IV)}]}{dt} = k_{obs}[\text{Mn(IV)}]$$

The pseudo first-order constant can be evaluated from the slope values. For $T = 40$°C, ionic strength = 2.0, and $[H^+] = 0.16\ M$,

$$k_{obs} = (1.87 \pm 0.01) \times 10^{-4}\ s^{-1}$$

When the concentration of Mn(II) is higher than 8×10^{-3} M, the slope of the logarithmic plot decreases slightly after the reaction has proceeded to a certain extent. In these cases, the values of the pseudo first-order constant were measured before the disturbing effect took place.

Effect of the ionic strength

A very slight positive primary salt effect was found for the reaction but no conclusions can be drawn on the ionic charge of reactants as the minimum amount of acid needed to avoid hydrolysis is too high for the Brønsted–Bjerrum law to apply.

Effect of acidity and Mn(II) concentration

Plots of the pseudo first-order constant, k_{obs}, vs. H^+ concentration give satisfactory straight lines with positive slope and intercept, indicating two parallel pathways for the reaction, one of them being first-order and the other one zero-order with respect to the H^+ concentration. Different initial concentrations of Mn(II) give straight lines with similar slopes but the intercepts get higher as the initial Mn(II) concentration increases, suggesting a third parallel reaction, first-order with respect to Mn(II) concentration but zero-order with respect to H^+ concentration. The obtained results can be described by the following equation:

$$[4] \quad k_{obs} = k_a + k_b[H^+] + k_c[\text{Mn(II)}]$$

From the slopes and intercepts of k_{obs} vs. H^+ concentration plots for different initial Mn(II) concentrations, k_a, k_b, and k_c values can be evaluated (Table 1).

For Mn(II) concentrations ranging from 0.5×10^{-4} to $3.0 \times 10^{-4}\ M$, H^+ concentrations ranging from 0.08 to 0.75 M and initial Mn(II) concentrations ranging from 0 to $2 \times 10^{-2}\ M$, the pseudo first-order constant values calculated from eq. [4] usually agree with the experimental ones, k_{obs}, within ±2%.

Reaction mechanism

The following mechanism, through three parallel pathways, is consistent with the experimental results

$$[5] \quad Mn(CN)_6^{2-} + H_3O^+ \overset{K}{\rightleftharpoons} Mn(CN)_5(CNH)^- + H_2O$$

$$[6] \quad Mn(CN)_6^{2-} \xrightarrow{k_a} Mn(CN)_4^{2-} + (CN)_2$$

$$[7] \quad Mn(CN)_4^{2-} + 4H_3O^+ + 2H_2O \xrightarrow{\text{fast}} Mn(H_2O)_6^{2+} + 4HCN$$

$$[8] \quad Mn(CN)_5(CNH)^- \xrightarrow{k_b'} Mn(CN)_3(CNH)^- + (CN)_2$$

$$[9] \quad Mn(CN)_3(CNH)^- + 3H_3O^+ + 3H_2O \xrightarrow{\text{fast}} Mn(H_2O)_6^{2+} + 4HCN$$

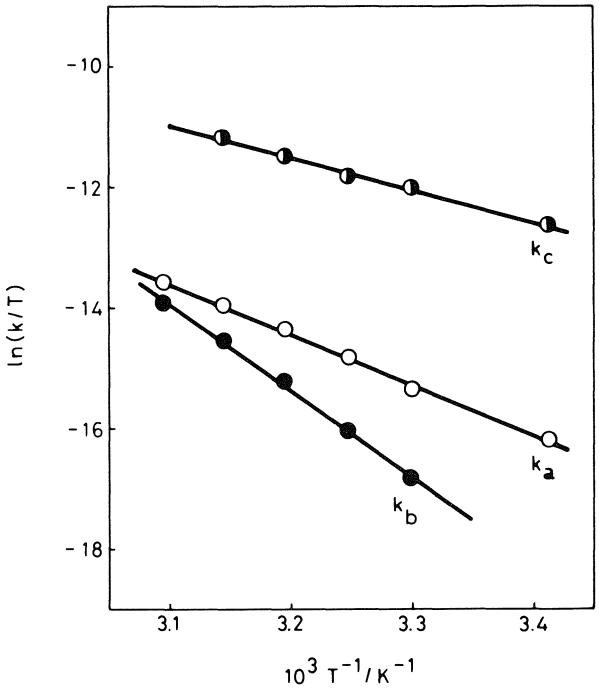

FIG. 4. Plots of ln (k/T) vs. T^{-1} for the decomposition of hexacyanomanganate(IV) in acidic solution. Mn(IV), $2.5 \times 10^{-4}\ M$; H^+, 0.16 M; I, 2.

$$[10] \quad Mn(CN)_6^{2-} + Mn(H_2O)_6^{2+} \xrightarrow{k_c} Mn(CN)_6^{2-}.Mn(H_2O)_6^{2+}$$

$$[11] \quad Mn(CN)_6^{2-}.Mn(H_2O)_6^{2+} + 4H_3O^+ + 2H_2O \xrightarrow{\text{fast}} 2Mn(H_2O)_6^{2+} + (CN)_2 + 4HCN$$

$Mn(CN)_5(CNH)^-$ (reactions [5] and [8]) and $Mn(CN)_3(CNH)^-$ (reactions [8] and [9]) are species partially protonated on the nitrogen of one of the coordinated cyano groups, as reported for some other cyano complexes (8). Reactions [6], [8], and [10] follow the equilibrium step [5] and they are the limiting steps of the three afore-mentioned parallel pathways: (*a*) monomolecular decomposition of the $Mn(CN)_6^{2-}$ ion, (*b*) monomolecular decomposition of the species $Mn(CN)_5(CNH)^-$, and (*c*) bimolecular interaction with Mn(II) ions (adduct formation). Reactions [7], [9], and [11] must proceed through consecutive steps and they are fast, so that none of them exert influence on the rate law.

Participation of Mn(II) ion in path (*c*) must be considered catalytic in nature, as this species remains unaltered at the end of each reaction cycle (reaction sequence [10], [11]). Moreover, since Mn(II) is also a product of the Mn(IV) reduction, the process is actually autocatalytic. Mn(II) appears to be present in the solution as the hexaaquocomplex, $Mn(H_2O)_6^{2+}$, rather than as any other complex with some anionic species; the kind of acid used as reaction medium (H_2SO_4, $HClO_4$, HCl, or HNO_3) shows no effect on the reaction rate.

From the proposed mechanism the following rate law is deduced:

$$[12]\quad \text{Rate} = -\frac{d[Mn(IV)]}{dt} = \left\{\frac{k_a}{1+K[H_3O^+]} + \frac{k'_b}{1+\dfrac{1}{K[H_3O^+]}} + \frac{k_c}{1+K[H_3O^+]}[Mn(H_2O)_6^{2+}]\right\} \times [Mn(IV)]$$

and if $K[H_3O^+] \ll 1$, eq. [12] becomes:

$$[13]\quad \text{Rate} = \{k_a + k_b[H_3O^+] + k_c[Mn(H_2O)_6^{2+}]\}[Mn(IV)]$$

where $k_b = k'_bK$. Equation [13] agrees with the experimental results derived from eq. [4].

Activation parameters

If the k_a, k_b, and k_c values are calculated, as previously stated at different temperatures, activation parameters can be estimated. Figure 4 shows plots of ln (k/T) vs. $1/T$ for the rate constants k_a, k_b, and k_c. The $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values can be obtained for each constant from the slopes and intercepts (see Table 1).

An infrared study of the interaction between ethyl *N*-(diphenylmethylene)glycinate with proton donors: comparison with *N*-benzylidenemethylamine

MARLEEN RUYSEN AND THÉRÈSE ZEEGERS-HUYSKENS
Department of Chemistry, University of Leuven, Celestijnenlaan 200F, 3030 Heverlee, Belgium

Received April 25, 1986

MARLEEN RUYSEN and THÉRÈSE ZEEGERS-HUYSKENS. Can. J. Chem. **64**, 2305 (1986).

The interaction between ethyl *N*-(diphenylmethylene)gylcinate (DPG) and hydroxy proton donors or pyrrole has been investigated by ir spectrometry. The equilibrium constants, enthalpies, and entropies of complex formation have been determined in carbon tetrachloride solution and compared with the data obtained for the complexes involving *N*-benzylidenemethylamine and the same proton donors. The ir spectra studied mainly in the ν_{OH}, $\nu_{C=N}$, $\nu_{C=O}$, and ν_{C-O} regions suggest that hydrogen bond formation occurs at the N atom of the imino group and at the O atom of the carbonyl group. The results are discussed in terms of the basicity at the two acceptor sites and of the accessibility of the lone pair of electrons. The ir spectra of the solid adduct of DPG with HCl show that protonation takes place on the N atom. The protonated structure is possibly stabilized by an intramolecular hydrogen bond.

MARLEEN RUYSEN et THÉRÈSE ZEEGERS-HUYSKENS. Can. J. Chem. **64**, 2305 (1986).

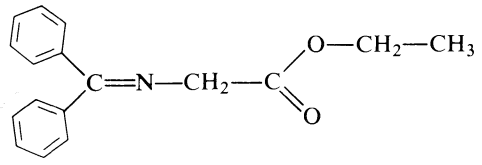
Utilisant la spectroscopie infrarouge, on a étudié l'interaction entre le *N*-(diphénylméthlène) glycinate d'éthyle (DPG) et des donneurs de protons hydroxylés ou le pyrrole. Opérant dans le tétrachlorure de carbone, on a déterminé les constantes d'équilibre, les enthalpies et les entropies de formation des complexes et on les a comparées avec les données obtenues pour des complexes impliquant la *N*-benzylidèneméthylamine et les mêmes donneurs de protons. Les spectres ir, qui ont été étudiés principalement dans les régions ν_{OH}, $\nu_{C=N}$, $\nu_{C=O}$ et ν_{C-O}, suggèrent que la liaison hydrogène se forme au niveau de l'atome d'azote de la fonction imino et au niveau de l'atome d'oxygène du groupement carbonyle. On discute des résultats en fonction de la basicité des deux sites accepteurs ainsi que de l'accessibilité de la paire d'électrons libres. Les spectres ir de l'adduit solide de DPG avec du HCl démontrent que la protonation se produit au niveau de l'atome d'azote. Il est possible que la structure protonée soit stabilisée par une liaison hydrogène intramoléculaire.

[Traduit par la revue]

Introduction

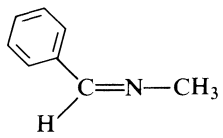
In recent years, there has been much interest on the proton acceptor ability of Schiff bases and on the spectroscopic characteristics of these complexes which undergo important changes when the hydrogen bonding in the solvent changes from non-polar to polar. These studies have been done using conventional infrared or Raman spectroscopies (1–5), resonance Raman spectroscopy (6–10), flash induced differential, kinetic infrared spectroscopy (11, 12), ^{13}C (13, 14) and ^{15}N nmr spectroscopy (15), or both nmr and uv spectroscopy (16–18). Recently, the possibility of a double well potential in the proton bridge of visual pigments interacting with proton donors has been discussed (19, 20). In most of these studies, proton donors such as halogenated alcohols, carboxylic acids, or hydrochloric acid have been studied and it was found that the strength of the interaction and the shape of the proton potential depended on their intrinsic acidity.

Despite the biological interest in the Schiff bases and the importance of their interactions with proton donors in biological media, the thermodynamic parameters for hydrogen bond formation have not been reported in the literature. In this work, we report the formation constants, the enthalpies, and entropies of complex formation for the interaction between ethyl *N*-(diphenylmethylene)glycinate (DPG)



DPG

with 2,2,2-trichloroethanol, phenol derivatives, and pyrrole that are very often taken as reference acids in hydrogen bond studies (21). Owing to the lack of quantitative data for the interaction between proton donors and bases containing an imino nitrogen atom, the results will be compared with those obtained in this work for *N*-benzylidenemethylamine (BMA)



BMA

DPG possesses two interaction sites available for hydrogen bonding formation and the study of the infrared spectrum in the 3500–1000 cm^{-1} region allows one to elucidate the nature of the interaction.

Finally, the infrared spectrum of the solid adduct with HCl will be discussed.

Experimental

The spectra have been recorded on the PE 325 and 580B spectrophotometers.

The equilibrium constants (K) have been calculated from the absorbance of the ν_{OH} band (hydroxylic derivatives) or of the ν_{NH} band (pyrrole). To avoid self-association, the formal concentrations of proton donors (F_A) was kept low and varied between 3 and 10 $\times$ 10^{-3} M. The initial concentrations of base (F_B) ranged between 1 and 3 $\times$ 10^{-2} M. The concentration of free donor C_A has been computed by the expression

$$C_A = A/\epsilon d$$

A, ϵ, and d being the absorbances of the free ν_{OH} (or ν_{NH}) band, ϵ the molar extinction coefficient, and d the cell length. The equilibrium constant was further computed by the expression

$$K = \frac{C_{AB}}{C_A C_B} = \frac{F_A - C_A}{C_A(F_B - C_{AB})}$$

where C_{AB} and C_B are the molar concentrations of the complex and free base, respectively.

TABLE 1. Formation constants (K) at 298 and 323 K, enthalpies, and entropies of formation for complexes between DPG and proton donors*

Proton donor	K^{298K*} (L mol^{-1})	K^{323K*} (L mol^{-1})	$-\Delta H^0$ (kJ mol^{-1})	$-\Delta S^0$ (J mol^{-1} K^{-1})
2,2,2-triCl ethanol	8.5	5.4	14.4	30.6
Phenol	18.5	10.7	17.5	34.5
3,5-DiCl phenol	144	63.8	26.2	46.6
3-CF_3, 4-NO_2 phenol	844	330	30	44.6
Pyrrole	3.8	2.9	8.1	16.1

*Standard deviation lower than 5%. Solvent = carbon tetrachloride.

TABLE 2. Formation constants at 298 and 323 K, enthalpies, and entropies of formation for complexes between BMA and proton donors

Proton donor	K^{298K*} (L mol^{-1})	K^{323K*} (L mol^{-1})	$-\Delta H^0$ (kJ mol^{-1})	$-\Delta S^0$ (J mol^{-1} K^{-1})
2,2,2-triCl ethanol	5.4	2.9	19.4	51.1
Phenol	12.6	5.9	24.4	60.8
3,5-diCl phenol	83	32.7	29.8	63.3
3-CF_3, 4-NO_2 phenol	208	82	30.2	57.1
Pyrrole	1.3	1	8.3	25.7

*Solvent = carbon tetrachloride.

The enthalpies and entropies of complex formation have been calculated from the equilibrium constants determined at 298 and 323 K.

The infrared spectra in the ν_{OH} (ν_{NH}), $\nu_{C=N}$, $\nu_{C=O}$, and ν_{C-O} regions have been recorded at higher concentrations of proton donors (0.01 to 1 M) and proton acceptors (0.03 to 0.20 M) in order to obtain higher complex concentrations in solution. The solvents were CCl_4 (3800–3000 cm^{-1}), CH_2Cl_2 (1800–1600 cm^{-1}), and CS_2 (1250–1100 cm^{-1}).

The solvents were dried by standard methods. DPG was prepared from the corresponding benzophenone imine and the amino ester salt according to published procedure (22); BMA was provided by Professor G. L'abbé. The solid adduct of DPG with HCl was prepared by passing gaseous HCl through a chloroform solution of DPG; the spectrum of the resulting precipitate was taken in a KBr pellet.

Results and discussion

Interaction with hydroxy derivatives and with pyrrole

Table 1 lists the equilibrium constants, the enthalpies and entropies of formation for the complexes between DPG and 2,2,2-trichloroethanol, three phenol derivatives, and pyrrole. The hydroxylic proton donors have been chosen to cover a wide range of pK_a (12 to 6). It is also noteworthy that these phenol derivatives and pyrrole are often taken as reference acids in hydrogen bond studies and as a result their proton donor ability towards a given base can be compared with previously studied systems.

Table 2 gives the values of the same parameters for the BMA complexes.

Comparison of these data shows that the formation constants of the DPG complexes are higher than those reported for complexes involving the same proton donors and aliphatic esters; for the complex between 3,5-diCl phenol and methylacetate the K value is about 40 L mol^{-1} (23) and for the complex between the same ester and pyrrole a K value of 1.3 has been reported in the literature (24). At this stage of the discussion, it is difficult to compare the enthalpies and entropies of complex formation.

As mentioned in the Introduction, DPG has two basic sites

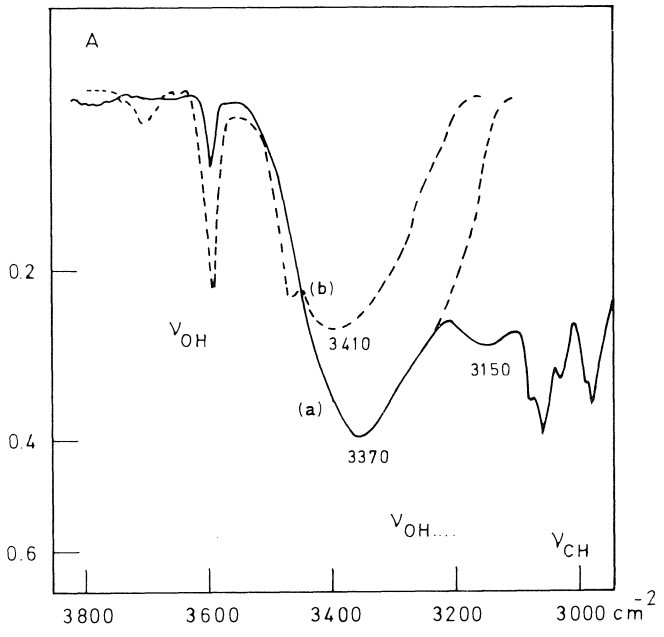


FIG. 1. Infrared spectra (3800–3000 cm^{-1}): (a) DPG (0.14 M) + 3,5-diCl phenol (0.014 M), d = 0.3 cm; (b) methylacetate (0.057 M) + 3,5-diCl phenol (0.06 M). Solvent = CCl_4.

available for hydrogen bonding, the oxygen atom of the carbonyl group and the nitrogen atom of the imino group. As shown in Fig. 1, two complex bands are observed in the ν_{OH} region. For comparison, the spectrum of the complex of methylacetate and the same hydroxylic derivative is also reproduced. For this last complex only one nearly symmetrical band is observed at about the same wavenumber. These two absorptions were observed for the hydroxylic proton donors and the observed wavenumbers depend on their acidity (Table 3). By analogy with the ester complexes having $\nu_{OH...O=C}$ bands

TABLE 3. $\tilde{\nu}/cm^{-1}$ of the bands observed in the $\nu_{OH(NH)}$ region

Proton donor	$\tilde{\nu}^{*}_{OH(NH)}$	$\Delta\tilde{\nu}$†	$\tilde{\nu}_{OH(NH)}$	$\Delta\tilde{\nu}$
2,2,2-triCl ethanol	3450	145	3290	305
Phenol	3440	170	3200	410
3,5-diCl phenol	3370	225	3150	445
3-CF_3, 4-NO_2 phenol	3350	240	3120	470
Pyrrole	3410	82	—	—

*Error on the absorption maxima = $\pm 10\ cm^{-1}$.

†Defined as the wavenumber of the free and complexed $\nu_{OH(NH)}$ band; the free bands ν_{OH} are observed between 3610 and 3595 cm^{-1}; the free ν_{NH} band of pyrrole is observed at 3492 cm^{-1}.

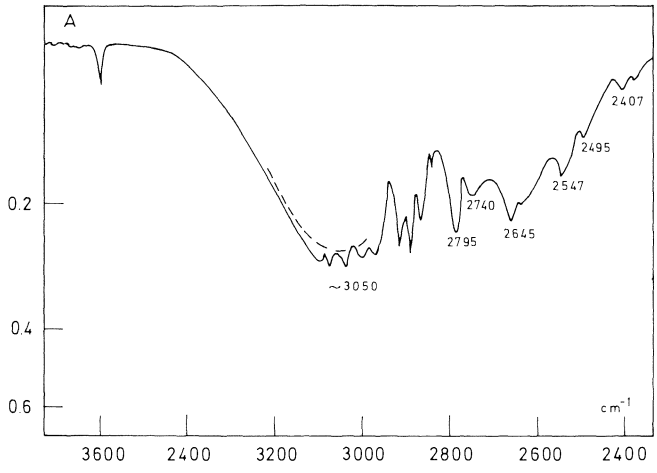

FIG. 2. Infrared spectra in the ν_{OH} range of BMA (0.17 *M*) + 3,5-diCl phenol (0.015 *M*), d = 0.2 cm, solvent = CCl_4.

between 3450 and 3350 cm^{-1} (21), the first band is attributed to hydrogen bonds formed on the ester group in DPG. This assignment is strengthened by the shift of the $\nu_{C=O}$ band to lower wavenumbers ($\Delta\nu_{C=O}$ = −18–20 cm^{-1} for all the complexes) and by the shift of the ν_{C-O} band to higher frequencies ($\Delta\nu_{C-O}$ = +13–15 cm^{-1}); such behaviour is typical for hydrogen bonds formed on an ester group (23). The second band is assigned to complexes formed on the imino nitrogen atom. Frequency shifts of 400–500 cm^{-1} are frequently observed for OH...N(sp^2) hydrogen bonds (21). The spectrum of the BMA complex is shown in Fig. 2 for comparison and a broad band (maximum near 3050 cm^{-1}) with several submaxima is observed; the same spectroscopic behaviour has been noticed for the pyridine–phenol complex and the submaxima have been attributed to a Fermi resonance with the internal modes of the proton donor moiety (25). The $\nu_{C=N}$ band of DPG at 1625 cm^{-1} becomes broader but does not show any shift (Fig. 3). This was also observed by Sandorfy *et al.* (2) who noticed the insensitivity of the $\nu_{C=N}$ band of *N*-benzylideneaniline to hydrogen bonding.

The concentration of OH...O=C complexes was estimated by computing the integrated absorption intensity of the complexes involving the same proton donor and methylacetate. The concentration of OH...O=C complexes was calculated by supposing that this intensity is the same in the DPG complexes. The concentration of OH...N complexes was then computed from the difference between the total concentration of complexes (calculated from *K*) and the concentration of OH...O=C species. It was found that in all the cases, about 60% of OH...O=C complexes are formed.

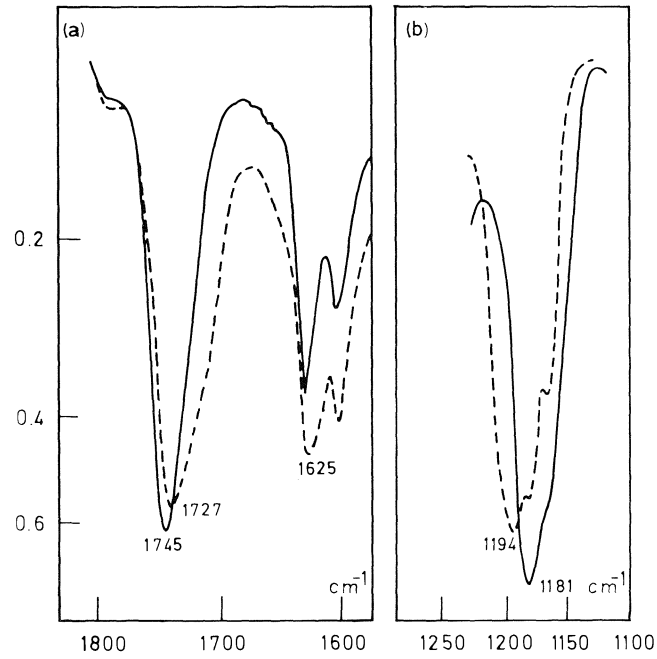

FIG. 3. Infrared spectra in the $\nu_{C=O}$ and $\nu_{C=N}$ region (*a*) and in the ν_{C-O} region (*b*). (*a*) — DPG (0.03 *M*), --- DPG + 2,2,2-triCl ethanol (1 *M*), d = 0.075 cm, solvent = CH_2Cl_2; (*b*) — DPG (0.05 *M*), --- DPG + 3,5-diCl phenol (0.08 *M*), solvent = CS_2.

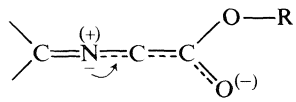
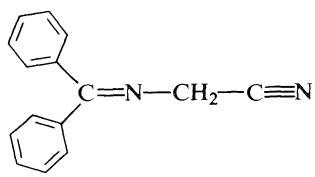
The $-\Delta H^0$ and $-\Delta S^0$ values reported in Table 1 are in fact the sum of two contributions and the classical correlations $-\Delta H$ vs. $\Delta\nu_{OH}$ could not be discussed in this work. However, we can compare the position of the two complex bands in the 3,5-diCl-phenol. DPG complex (3370 and 3150 cm^{-1}) with that of the complex between the same proton donor complexed with methylacetate (3410 cm^{-1}) and with BMA (3050 cm^{-1}). Although these two last bases do not have exactly the same degree of substitution as DPG, the comparison suggests that in DPG, the carbonyl complex is a little bit stronger than in methylacetate and that the imino complex is somewhat weaker than in BMA. This can be explained by a small delocalization of the electrons from the nitrogen to the carbonyl oxygen atom



that makes the nitrogen atom less basic and the oxygen atom more basic than in the individual imino- or ester bases; this has been discussed previously for enamino ketones (26).

However, another important factor governing the occupation of the different basic sites of a polyfunctional base (27) is the *accessibility* of the lone pair. It has indeed been found recently that in (diphenylmethylene)amino acetonitrile (28)



only C≡N...H—O— hydrogen bonds are formed. This violates the general rule that the energy of the hydrogen bond increases with decreasing amount of *s* character in the lone pair (29, 30). This rule predicts a higher hydrogen bond energy for

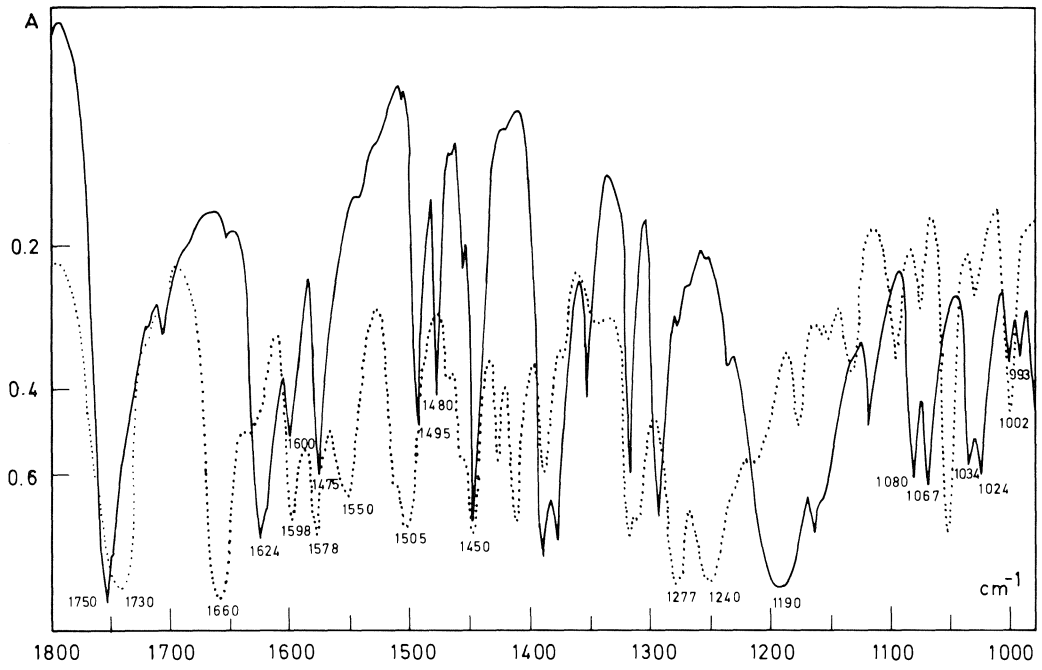


FIG. 4. Infrared spectrum (1800–1000 cm^{-1}), — DPG, --- DPG.HCl adduct (KBr pellet).

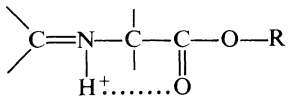
the imino nitrogen atom having close to sp^2 hybridization than for the nitrile nitrogen atom having a *sp* geometry. It can thus be concluded that the hydrogen bond interaction site cannot be predicted by energetic considerations alone, but is also governed by the accessibility of the free electron pair(s).

Interaction with HCl

The infrared spectra (1800–1000 cm^{-1}) of DPG and its solid adduct with HCl are reproduced in Fig. 4. Although a complete assignment of the vibrational modes of DPG is difficult, the 1800–1000 cm^{-1} region contains mainly the $\nu_{C=N}$ vibration at 1624 cm^{-1}, the $\nu_{C=O}$ and ν_{C-O} vibrations at 1750 and 1190 cm^{-1}, the ring vibrations R_{8a} and R_{8b} at 1598 and 1578 cm^{-1}, the R_{19b} and R_{19a} vibrations at 1495 and 1480 cm^{-1}, and the in-plane deformations of the CH_2 and CH_3 groups between 1450 and 1350 cm^{-1}. The ring vibrations R_{18b}, R_{12}, and R_1 show in-phase out-of-phase splittings at 1080 and 1067, 1034 and 1024, 1002 and 993 cm^{-1}, respectively.

In the DPG—HCl adduct, the $\nu_{C=N}$ at 1624 cm^{-1} disappears, the R_{8a} and R_{8b} vibrations do not shift appreciably, and two new bands at 1660 and 1550 cm^{-1} are observed. This behaviour is characteristic of nitrogen protonated Schiff bases (2, 3). The $\nu_{C=N}$ band is shifted to higher wavenumbers and in order to explain this apparent anomaly, Aton *et al.* (3) have proposed that upon protonation the C=N—H^+ stretching and the —N—H^+ deformation are coupled. Consequently the ν(C=N—H^+) band occurs at frequencies higher than would otherwise be expected. The spectra thus strongly suggest that protonation occurs at the nitrogen atom of DPG and clearly, nitrogen protonation is favoured over carbonyl protonation, even when in solution, hydrogen bonds are formed on the two sites.

Now, as shown in Fig. 4, the ester vibrations undergo also protonation shifts, the $\nu_{C=O}$ band decreasing by about 25 cm^{-1} and the ν_{C-O} band increasing by more than 50 cm^{-1}. In the absence of secondary effects, protonation should leave the ester vibrations almost unchanged. These important frequency shifts can be explained by an intramolecular NH^+ hydrogen bond that should increase the delocalization in the ester function



One can also note that the typical $NH^+...Cl^-$ band generally observed between 2600 and 2300 cm^{-1} is absent in the spectrum. A broad band near 3000 cm^{-1} is observed; this absorption could be assigned to water bound to Cl^- anions. This interpretation is supported by the absorption near 1630 cm^{-1} that can be assigned to the in-plane deformation mode of the water moieties. Therefore, it seems possible that the surrounding water molecules stabilize the preceding structure. A somewhat similar structure has been discussed in the Schiff base formation from ω-dimethylamino alkylamines (31).

Basicity of the thionamide group of α-aminothionamides. Attenuation of electrostatic effects by solvation

MARTINO PAVENTI, FENTON HEIRTZLER, AND JOHN T. EDWARD
Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, Que., Canada H3A 2K6

Received March 13, 1986

MARTINO PAVENTI, FENTON HEIRTZLER, and JOHN T. EDWARD. Can. J. Chem. **64**, 2310 (1986).

The first dissociation constants pK_1 of four diprotonated α-aminothionamides, determined spectrophotometrically, are between −8.1 to −8.8; the second dissociation constants pK_2, of three of these compounds, determined titrimetrically, are between 7.3 and 7.7. Both pK_1 and pK_2 values are close to those calculated from current electrostatic theory for equilibria in solutions of zero ionic strength, in spite of the fact that data for pK_1 values were obtained in solutions of high ionic strength. Results indicate a much larger effect of the charged ammonium group on the basicity of the thionamide group than on the basicity of the amide group. A possible explanation based on the greater hydration of the protonated amide group is advanced.

MARTINO PAVENTI, FENTON HEIRTZLER et JOHN T. EDWARD. Can. J. Chem. **64**, 2310 (1986).

Utilisant des méthodes spectrophotométriques on a déterminé les premières constantes de dissociation (pK_1) de quatre α-aminothioamides diprotonés; comme étant entre −8,1 et −8,8; faisant appel à des méthodes titrimétriques, on a aussi déterminé les deuxièmes constantes de dissociation (pK_2) de trois de ces composés comme étant entre 7,3 et 7,7. Les valeurs tant des pK_1 que des pK_2 sont proches des valeurs calculées à partir de la théorie électrostatique actuelle sur les équilibres dans des solutions de force ionique égale à zéro, même si les données relatives aux valeurs de pK_1 sont obtenues dans des solutions de forces ioniques élevées. Les résultats indiquent que le groupement ammonium chargé provoque un effet beaucoup plus important sur la basicité du groupement thionamide que sur la basicité du groupement amide. On propose une explication plausible qui est basée sur une plus grande hydratation du groupement amide protoné.

[Traduit par la revue]

Starting more than 60 years ago with Bjerrum (1), a long succession of investigations has elaborated an electrostatic theory of substitutent effects which is gradually winning general acceptance (2–9). However, the electrostatic effect can be profoundly altered by the presence of a solvent, and although "emphasis has shifted from continuum electrostatics to interactions between specific functionalities in the ions and appropriate sites in a few solvent molecules" (10), a discontinuous solvation model (11) of quantitative (as opposed to qualitative) predictive power has been slow to emerge.

The older continuum solvent model was applied to electrostatic effects by Kirkwood and Westheimer (4) in 1938. As an example, we may consider the fact that the dissociation constant K_2 of monoprotonated glycine **2** would be expected to be higher than K_{AH} of the parent acid, acetic acid, because the substituted acetate ion **3** is stabilized by electrostatic interaction between NH_3^+ and the negatively charged carboxylate group.[1] On the other hand, further dissociation of **3** should be made more difficult than the dissociation of the parent methylammonium ion (K_{BH^+}) by the same electrostatic stabilization, the substituent now being CO_2^-. Classical electrostatic theory shows that both the elevation of K_2 and the depression of K_3 (with respect to K_{AH} and K_{BH^+}) should be given by

$$[1] \quad \Delta pK = \log (K_2/K_{AH}) = -\log (K_3/K_{BH^+}) = e^2/2.3\ kTRD_{eff}$$

where e is the electronic charge, k Boltzmann's constant, T the absolute temperature, R the distance between the charges, and D_{eff} the "effective" dielectric constant. D_{eff} generally lies somewhere between D_e, the dielectric constant of the external solvent, and D_i, the dielectric constant (assumed to be 2.0) of the hydrocarbon framework of the molecule. Kirkwood and Westheimer (4), Ehrenson (5), and others have furnished equations whereby for molecules of spheroidal or ellipsoidal shape D_{eff} can be calculated from D_e and from the shape of the molecule and the location of the charged centres within it.

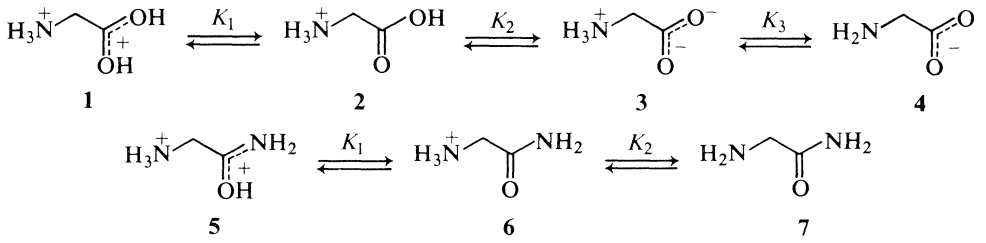
Values of ΔpK thus calculated are usually in fair agreement with experiment when NH_3^+ and CO_2^- are separated by more than three methylene groups (12), but can be seriously in error for smaller values of R. Thus the experimental ΔpK_2 for **2** is only about half the calculated value, and the experimental ΔpK_3 for **3** has the wrong sign, **3** being a stronger acid than the parent methylammonium ion (12). The reasons for these failures of [1] at smaller distances R are not altogether clear, but may be due to the intrusion of effects other than monopole–monopole interactions: to inductive (13), solvation (12), or monopole–dipole effects (14). The last are given by

$$[2] \quad \Delta pK = e\mu \cos \theta/2.3\ kTR^2D_{eff}$$

where μ is the dipole moment of the substituent and θ is the angle made by the dipole vector and the line joining the mid-point of the dipole to the centre of the charged group (2). They can be ignored for large but not for small values of R.

Equations [1] and [2] apply to reactions or equilibria in solutions of zero ionic strength (13). Sometimes it is possible to extrapolate experimental results to zero ionic strength by use of a modified Debye–Hückel equation, as in the studies of Westheimer *et al.* (15) on the effect of charged substituents on the rates of hydrolysis of esters in very dilute sodium hydroxide solution. However, most chemical reactions require more concentrated solutions of electrolytes for which such an extrapolation is impossible, and so it becomes of interest to discover empirically for such reactions whether the electrostatic effect is still evident. The limited data available at present (e.g. refs. 16, 17) indicate that [1] and [2] may apply moderately well even in unideal situations (contrary to what might be expected (13)). Thus ΔpK_1 for diprotonated glycinamide **5** (parent compound: protonated acetamide) is −2.7 (16), close to ΔpK_2 of −2.31 for protonated glycine **2** (12), in spite of the fact that protonation of the amide group requires moderately concentrated sulfuric acid, so that the H_A acidity function must be used

[1]This exposition differs slightly from that usually given (2, 4), but has been justified previously (6, 10).

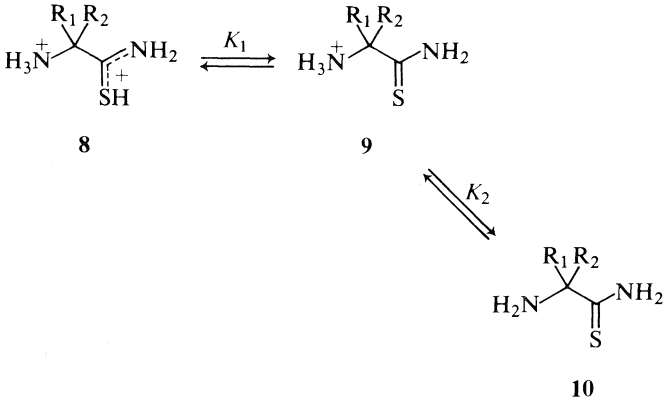


1 2 3 4

5 6 7

in measuring basicities (16). In these solutions the dielectric constant D_e will be reduced (18), and to a lesser extent D_{eff}; this might account for the larger ΔpK (−2.7). On the other hand, 100% sulfuric acid at 25°C has a dielectric constant of 100 (19), 28% higher than the dielectric constant of water, and so electrostatic effects in this solvent should be slightly reduced. The cryoscopic results of O'Brien and Niemann (20) show that the basicity of the carboxyl group in 100% sulfuric acid is decreased (relative to that of acetic acid) by the presence of the $—NH_3^+$ group in the series of protonated amino acids $H_3N^+(CH_2)_nCO_2H^+$, the effect diminishing progressively with increase of n from 1 to 4. A rough-and-ready calculation of ΔpK_1 values for **1** and its homologues from ionization ratios I (20) in 100% sulfuric acid is given in Table 1. Too many assumptions[2] are involved for the absolute values to be taken too seriously but the trend is unmistakable.

Most tests of [1] and [2] have involved compounds having charged or dipolar substituents in the vicinity of ionizable carboxyl or, more rarely, of ammonium groups. It would be useful to test [1] and [2] by observing the effects of charged substituents on the protonation of other groups. According to the continuum solvent model, ΔpK should be about the same for two molecules having different ionizable groups but similar geometry and charge separation R, the solvent attenuation depending only on D_{eff}. According to the newer discontinuous solvent models (10, 11), ΔpK might be different for two such molecules if solvation of the substituents or ionizing groups is grossly different. Accordingly, we have determined ΔpK_1 and ΔpK_2 values for four diprotonated α-aminothionamides of general structure **8**:



8 9 10

The thionamide grouping has an advantage over the amide grouping in giving more clear-cut changes in ultraviolet absorption spectrum upon protonation (26), which has been shown to follow the H_T acidity function (27). Thionamides, as shown in **8**, are *S*- and not *N*-protonated in strong mineral acid (28–30).

TABLE 1. Dissociation constants of $H_3N^+(CH_2)_nCO_2H_2^+(BH_2^{2+})$ in 100% sulfuric acid and of $H_3N^+(CH_2)_nCO_2H(AH)$ in water (relative to parent compounds)

	BH_2^{2+}			AH
n	I^a	pK^b	ΔpK^c	ΔpK^d
1	0.25	−6.1	−2.3	−2.1
2	2.3	−5.1	−1.3	−1.21
3	9.0	−4.5	−0.7	−0.73

Experimental

Materials

2-Aminothionacetamide (**10**; $R_1 = R_2 = H$), 2-amino-2-methylthionpropionamide (**10**; $R_1 = R_2 = Me$), 1-aminocyclohexane-1-thioncarbonamide (**10**; $R_1R_2 = (CH_2)_5$), and 2-amino-3-phenylthionpropionamide (**10**; $R_1 = PhCH_2$, $R_2 = H$) were prepared by modifications (to be published later) of methods in the literature (31, 32). They were stored as the stable hydrochlorides.

Determination of dissociation constants

(a) By spectrophotometry of strongly acid solutions

The 2-aminothionamide hydrochlorides **9** in water or in aqueous sulfuric acid up to 60% w/w concentration all had ultraviolet absorption peaks at about 260 nm, like thionacetamide in water (31). In 96% sulfuric acid these peaks were shifted to about 245 nm, with a drop in intensity, like thionacetamide in 11.9 *M* hydrochloric acid (31), indicating the structure **8** for the diprotonated compounds. Ionization ratios [**8**]/[**9**] in intermediate concentrations (60–96%) of sulfuric acid were determined at 24°C spectrophotometrically, following procedures already described (27), and are available as supplementary material.[3] Plots of log [**8**]/[**9**] against H_T (27)[4] gave straight lines with slopes of 1.00–1.01 (correlation coefficients 0.996 or better), from which the pK_1 values given in Table 2 were obtained in the usual manner.

[2]It was assumed that protonation of the carboxyl group (21) was governed by the H_A function, and that for 100% H_2SO_4 $H_A = -5.5$ (22, 23), so that in this concentration of acid $pK = \log I - 5.5$. I ($\equiv [H_3N^+(CH_2)_nCO_2H_2^+]/[NH_3^+(CH_2)_nCO_2H]$) was obtained from ref. 20. Acetic acid is half-ionized in ca. 75% H_2SO_4 (24, 25), and so has $pK = -3.8$ (22).

[3]A complete set of tabulated data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]A referee has suggested that pK_1 values of **8** should be obtained from plots of [**8**]/[**9**] against H_{T^+}, which should not coincide with H_T. This is not certain. Vetesnik *et al.* (33) established a H_+ scale by the Hammett–Deyrup overlap procedure, based on dilute aqueous solution as the standard state, for sulfuric acid concentrations up to 5.5 *M*; H_+ values do not differ appreciably from H_0 values over this concentration range. Gold (quoted by Brand *et al.* (34)) calculates that in 100% sulfuric acid $H_+ = H_0 - 0.28$. In any case, the evidence to date is that H_+ should differ only slightly from H_0, and presumably H_{T^+} only slightly from H_T.

TABLE 2. Dissociation constants K_1 and K_2 of protonated α-aminothionamides at 24°C

[e] pK_{BH^+} of 9.83 for parent β-phenylethylammonium ion from ref. 36.

(b) By titrimetry in dilute aqueous solution

The α-aminothionamide hydrochloride **8** (100–300 mg) in 10 mL of distilled water was titrated with 2 *N* sodium hydroxide solution at 24°, using a Radiometer (Copenhagen) TTT 80 titrator, ABU 80 auto burette, PHM 63 digital pH meter, and REC 80 servograph. The pK_2 values were obtained from the mid-points of the titration curves. The values recorded in Table 2 are the average of at least six titrations; effects of ionic strength have been taken into account using the Debye–Hückel equation.

(c) By rate measurements

Kinetic data were obtained at 60°C in solutions ranging from 24% to 85% aqueous sulfuric acid, using a Unicam SP-800 spectrophotometer to follow absorbance changes at 243–262 nm. The absorbance at infinite time was assumed to be given by that of a solution heated to 90°C for 2.5 h and then cooled to 60°C. Pseudo-first-order rate constants k_ψ are shown in Fig. 1.

Results and discussion

pK_1 values of diprotonated α-aminothionamides

The pK_1 values of the protonated thionamide groups of the four compounds in Table 2, determined by conventional spectrophotometric means, were much lower than anticipated. Consequently, it was considered worthwhile to confirm one of them by a kinetic method. This method depends on the fact that the pseudo-first-order rate constant k_ψ for the hydrolysis of thionamides (38, 39) (and also amides (40), thio-acids (41), thion-esters (42), and many other compounds) increases with acid concentration up to a maximum and then decreases (illustrated for thionacetamide in excess perchloric at 35°C (38) in Fig. 1). Such a rate – acid concentration profile is indicative of an A-2 mechanism, which for a thionamide is given by [3] and [4]:

[3] $$R{-}C(=S){-}NH_2 + H^+ \underset{}{\overset{K_{BH^+}}{\rightleftharpoons}} R{-}C(SH)=NH_2^+$$

[4] $$R{-}C(SH)=NH_2^+ + rH_2O \xrightarrow{k_2} R{-}C(SH)(NH_2)(O^+H_2) \rightarrow \text{products}$$

with the position of the maximum dependent, *inter alia*, on pK_{BH^+} (40). In fact, for ethyl thionbenzoate and seven substituted derivatives the maximum occurs in acid concentrations at which $H_T \cong pK_{BH^+}$ (43), and for thionacetamide the maximum

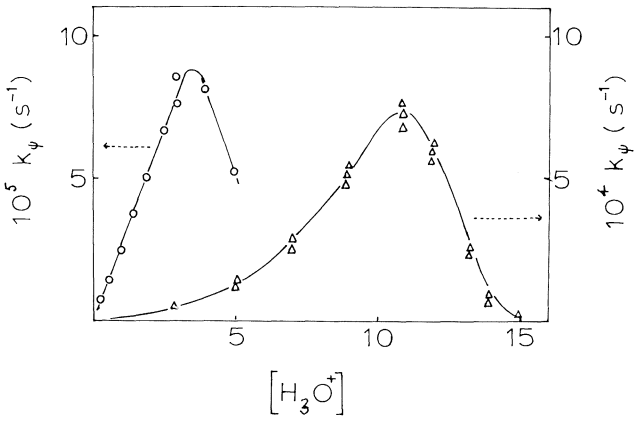

FIG. 1. Variation of pseudo-first-order rate constant k_ψ with molar concentration of acid for thionacetamide in perchloric acid at 35°C (○, ref. 32) and for α-aminothionacetamide in sulfuric acid at 60°C (△).

occurs at $H_T \approx -2.5$,[5] close to −2.56 for pK_{BH^+} (35). Consequently, the rate maximum for α-aminothionacetamide at $H_T = -8.5$ (Fig. 1) supports the pK_{BH^+} of −8.39 determined spectrophotometrically.[6]

Waring (45) has recently shown how pK_{BH^+} values may be obtained from kinetic data by various manipulations of the empirical rate expressions of Bunnett and Olsen (46) and of Yates and McClelland (47), which for moderately basic substrates contain pK_{BH^+} among other terms in the expression. However, the Yates–McClelland equation proved inapplicable to k_ψ for the acid-catalysed hydrolysis of thionacetamide and α-aminothionacetamide, giving curved and not straight-line plots (c.f. ref. 44). On the other hand, the Bunnett–Olsen equation, in the forms

$$[5] \quad \log k_\psi - \log\left(\frac{h_T}{h_T + K_1}\right) = \phi(H_0 + \log [H^+]) + \log k^0$$

$$[5a] \quad \log k_\psi + H_T = \phi(H_0 + \log [H^+]) - \log (h_T + K_1) + \log k^0$$

[5] Thionacetamide was hydrolysed in aqueous perchloric acid (38), for which no H_T scale has yet been determined. However, other acidity function scales almost coincide in perchloric and sulfuric acids of equal weight percent concentration (41), and we have assumed this to be true for H_T also.

[6] The rate curves in Fig. 1 were obtained at temperatures above 25°C, the temperature used for spectrophotometric determination of pK_{BH^+}. However, available evidence indicates that a change in temperature increases rates of hydrolysis but does not affect the rate profile or the position of the maximum (44).

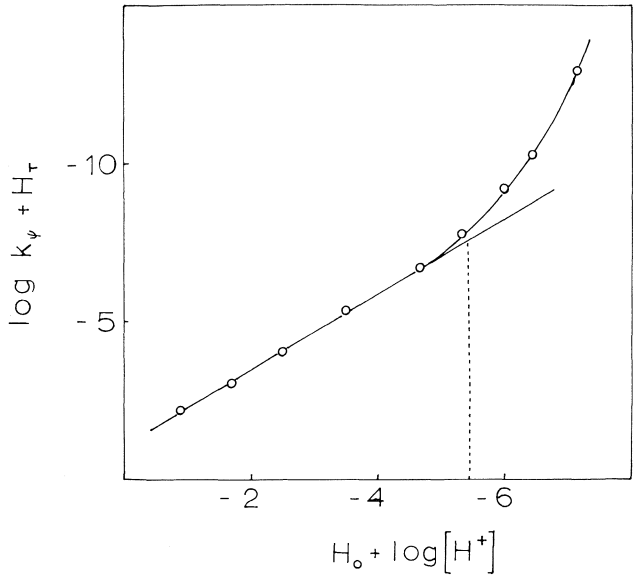

FIG. 2. Bunnett–Olsen plot for hydrolysis of α-aminothionacetamide in sulfuric acid at 60°C.

(see ref. 46 for definition of symbols) proved more useful. At low acidities $h_T \ll K_1$, and [5*a*] simplifies to

[6] $$\log k_\psi + H_T = \phi(H_0 + \log [H^+]) + pK_1 + \log k^0$$

which accounts for the straight-line portion of the experimental curve on the left-hand side of Fig. 2. At high acidities $h_T \gg K_1$, and [5*a*] simplifies to

[7] $$\log k_\psi + H_T = \phi(H_0 + \log [H^+]) + H_T + \log k^0$$

which accounts for the increasing divergence of the experimental curve from a straight line on the right-hand side of Fig. 2. At an acidity where $h_T = K_1$, [5*a*] becomes

[8] $$\log k_\psi + H_T = \phi(H_0 + \log [H^+] + pK_1 + \log k^0 + 0.3$$

and at this acidity the calculated curve should be 0.3 unit above the straight-line curve of [6]. As seen in Fig. 2, this divergence of 0.3 (shown by vertical line) is observed experimentally when $(H_0 + \log [H^+]) = -5.45$ and $H_T = -8.77$, in very rough agreement with the pK_1 value of −8.39 determined spectrophotometrically.

Different effect of the ammonium group on the basicity of the amide and thionamide groups: possible role of hydration in attenuating this effect

A ΔpK_2 of −5.42 may be calculated for protonated glycine **2** in water at 25°C from [1] (12), using D_{eff} according to Kirkwood and Westheimer (4). Since the molecular volume, shape, and intercharge distances of **3**, **5**, and **8** (R = H) are about the same, about the same ΔpK would be expected for all three compounds in a solvent of the same dielectric constant D_e if effects of ionic strength can be ignored. Lower values of D_e (and hence of D_{eff}) should lead to greater values of ΔpK, and so the ΔpK_1 values of Table 2 would appear to be in rough agreement with those calculated from [1]. (An exact comparison is impossible, because D_e values for aqueous sulfuric acid solutions are lacking (18).)

This would seem to indicate that the electrostatic effect of the $—NH_3^+$ group of **8** is not nullified by counter-ions, even in fairly concentrated sulfuric acid, but has about the value expected from [1]. Why, then, is the effect of $—NH_3^+$ group on the ionization of **5** and **2** ($\Delta pK \sim -2$) so much smaller? A partial answer may come from the fact that the protonated thionamide, according to much evidence (27), is less hydrated than the protonated amide group (and presumably than CO_2^-). It has been shown that to the extent that groups are hydrated, their electrostatic interaction with charged or dipolar substituents can be expected to be reduced (11). A difference in hydration would also explain the different Hammett ρ values for the ionization of protonated thionbenzamides (−1.29: ref. 35) and benzamides (−0.92: ref. 16) and the dissociation of benzoic acids (+1.00).

*Effect of the amide and thionamide groups on the acidity of the ammonium groups of **6** and **9** ($R_1 = R_2 = H$)*

We now consider the validity of [2] for explaining the ΔpK_2 values of Table 1. Since the substituent amide and thionamide groups of **6** and **9** ($R_1 = R_2 = H$) do not differ greatly in size or shape, we may expect R, $\cos\theta$, and D_{eff} to be approximately the same in these two compounds, so that the greater acidity of **9** ($R_1 = R_2 = H$) arises from the greater dipole moment of the thionamide group ($\mu = 4.53$ D for thionacetamide (48)) as compared with the amide group ($\mu = 3.8$ D for acetamide (48)):

[9] $$\frac{\Delta pK_1 (\mathbf{9}; R_1 = R_2 = H)}{\Delta pK_1 (\mathbf{6})} = \frac{4.53}{3.8} = 1.19$$

This result is in good agreement with the experimental ratio of 1.22 (49).

Conclusion

The present work indicates that in concentrated aqueous acid solutions the effect of the charged substituent $—NH_3^+$ on the protonation of the thionamide group is not cancelled by the high ionic strength, as might be expected (13), but rather has about the value calculated by [1] for infinitely dilute aqueous solution. In fact, the ionization behaviour of α-aminothionamides conforms better to [1] than does that of the α-aminocarboxylic acids. This suggests that a study of the ionization behaviour of other substituted thionamides in order to test [1] and [2] might be profitable.

P. M. AKER, J. J. A. O'BRIEN, J. M. PARSONS, and J. J. SLOAN. Can. J. Chem. **64**, 2315 (1986).

The vibrational distribution in the OH created by the reaction of $O(^1D_2)$ atoms with NH_3 has been recorded directly using low pressure infrared emission spectroscopy. The relative kinetic energy of the reagents is Boltzmann at 300 K. The OH product vibrational levels are populated statistically, indicating that the reaction probably involves a long-lived ONH_3 intermediate. There is some evidence that this may not be the case at higher reagent translational energies.

P. M. AKER, J. J. A. O'BRIEN, J. M. PARSONS et J. J. SLOAN. Can. J. Chem. **64**, 2315 (1986).

Faisant appel à la spectroscopie d'émission infrarouge à basse pression, on a enregistré directement la distribution vibrationnelle du OH qui est créé par la réaction des atomes de $O(^1D_2)$ avec le NH_3. A 300 K, l'énergie cinétique relative des réactifs est celle de Boltzmann. Il y a une distribution statistique des niveaux vibrationnels du produit OH et ceci indique que la réaction implique probablement un intermédiare ONH_3 possédant une longue vie. Quelques données suggèrent que tel ne serait pas le cas à des énergies de translation des réactifs qui seraient plus élevées.

[Traduit par la revue]

Introduction

Reaction of $O(^1D_2)$ with ammonia to produce the OH radical can proceed through two energetically-allowed channels;

[1] $O(^1D_2) + NH_3 \rightarrow OH(X^2\Pi, v) + NH_2(X^2B_1)$
$\Delta H_0^0 = -187.0$ kJ/mol

[2] $O(^1D_2) + NH_3 \rightarrow OH(X^2\Pi, v) + NH_2(A^2A_1)$
$\Delta H_0^0 = -64.4$ kJ/mol

The energy partitioning in reactions [1] and [2] has been measured previously (1–3) by combining laser photolysis of ozone at 266 nm (to generate $O(^1D_2)$) with laser-induced fluorescence detection of the OH product on the $A^3\Sigma \leftarrow X^2\Pi$ transition. The rotational excitation produced in the $v' = 0$ and $v' = 1$ vibrational states of the OH was reported in refs. 1 and 3 and the ratio of the populations in these two vibrational levels was also reported to be 1.0:0.66. In ref. 2, the $P(v' = 1)/P(v' = 0)$ ratio was given as 1.5 and an estimate of the $P(v' = 2)/P(v' = 0)$ ratio was given as 2.1. The exoergicity of the reaction $O(^1D_2) + NH_3 \rightarrow OH(X^2\Pi) + NH_2$ is such that levels up to $v' = 4$ in the OH product can be populated. The complete vibrational distribution for this reaction has not been published, however, as populations in levels greater than $v' = 1$ cannot be measured accurately using the LIF technique, due to predissociation of the $OH(A^2\Sigma)$ state in levels higher than $v' = 1$.

In recent experimental and theoretical work, the hydrogen abstraction reactions of $O(^1D_2)$ (4–7) have been classified into two categories — those which take place via the direct abstraction of a hydrogen atom by the $O(^1D_2)$ atom, and those which proceed by the formation of a highly energetic complex which results from the insertion of the $O(^1D_2)$ into the bond containing the hydrogen. The dynamics and hence the energy partitioned to the product OH would be different for the two mechanisms. For the case of the reactions of $O(^1D_2)$, it has been postulated (6) that abstraction might lead to the formation of a vibrationally hot but rotationally cold product distribution, whereas insertion might lead to a rotationally hot but vibrationally cold product distribution.

In the previous work on reactions [1] and [2], a small shoulder at low J' was observed in the rotational distribution of the $OH(v' = 0)$ level (1, 3). This was attributed to reaction [2]. The remainder of the distribution in the $v' = 0$ level and that in the $v' = 1$ level was assigned to reaction [1]. In a later study of the energy partitioning for the reaction of $O(^1D_2)$ with ND_3, the same authors (3) observed a rotational distribution similar to that found for the NH_3 reaction.

The shape of the rotational distribution which the authors of ref. 3 attributed to reaction [1] was found to agree with that expected from a purely statistical mechanism, in which the reaction proceeds via the formation of a long-lived complex, and the energy of reaction is partitioned among all the degrees of freedom prior to the formation of the product. The statistical energy distribution expected in the case of such a mechanism can be calculated simply by assuming that all product degrees of freedom are formed with equal probability. The statistical vibrational distributions can thus be obtained from a knowledge of the vibrational and rotational state densities of the products. These authors assumed this to be the case and subtracted a calculated statistical rotational distribution from the observed rotation in $v' = 0$, thus obtaining a distribution for the low-J' component. They then compared the population represented by this distribution with the total population, and obtained a branching ratio into the low-J' component of approximately 4% of the reaction. Excited $NH_2(^2A_1)$ was seen in approximately the concentration expected if the low-J' component of the rotational distribution arose from reaction [2]. The authors, however, did not rule out the possibility that this low-J' component could be attributed to an abstraction process with the overall form of reaction [1]. The OH vibrational distribution reported in ref. 3 is $P(v' = 0{:}1) = 1.0{:}0.66$ — a result which is more excited than the statistical case. This seems to be in conflict with the results obtained from the rotational distributions, which indicated statistical energy partitioning. It has been postulated that the modes of the NH_2OH complex which lead to OH vibrational excitation are not randomized, whereas those leading to OH rotation are (9), but the physics leading to such a result is difficult to visualize. The situation with respect to the vibrational distributions is further complicated by the fact that ref. 2 reported the OH vibrational distribution to be $P(v' = 0{:}1{:}2) = 1.0{:}1.5{:}2.1$. The rotational distribution obtained in that case, however, was in broad agreement with that reported in refs. 1 and 3.

In the following, we report a measurement of the complete

[1]NRCC No. 25871.

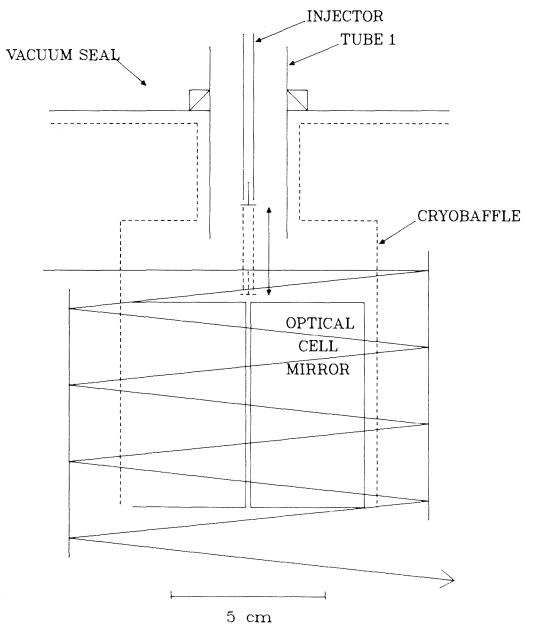

FIG. 1. The configuration of the reagent inlets, the excimer laser multipass mirrors and the Welsh optical cell.

vibrational distribution for reaction [1], obtained by low-pressure infrared emission spectroscopy. We find that the vibrational energy partitioning is statistical, suggesting complete randomization of the reaction exoergicity through the formation of a long-lived NH_2OH complex.

Experimental

The experiments were carried out in a modified version of the apparatus described in ref. 8. The reaction vessel is a stainless steel cylindrical vacuum chamber (25 cm diameter, 25 cm long) which is evacuated by a Varian VHS 400 diffusion pump through a 31 cm gate valve and a 38 cm cryobaffle. The cryobaffle was maintained at a temperature of −80°C throughout the experiments to eliminate backstreaming from the pump.

The reagents are introduced into the reaction chamber by the injector system shown in Fig. 1. The inlet assembly consists of two cylindrical quartz tubes labelled "injector" and "tube 1", located on the central axis of the reaction vessel. The injector, through which the NH_3 enters, can be adjusted vertically over a distance of 3 cm in order to allow variation of the mixing point location. Efficient mixing was ensured by the addition of a small Teflon deflector plate located at the tip of the injector tube (the "T" in Fig. 1). For the present experiments, the injector tip was located about 1 cm below the end of tube 1, in order to reduce the effect of a slow reaction which is known to occur between O_3 and NH_3 (10). This precaution and the short residence time of the reagents in the observation zone (less than 3 ms *vide infra*) reduced this potential interference.

The ozone for these experiments was produced in an ozone generator of conventional ac discharge design. Prepurified oxygen was passed through a type 5A molecular sieve at −80°C; then passed through a 20 kV, 4 amp ac discharge at atmospheric pressure. The ozone was trapped on silica gel which had been cooled to −80°C. After saturation of the silica gel, the ozone was stored under about 500 to 600 Torr of oxygen. Before each experiment, the ozone trap was pumped to a pressure of less than 5 Torr to remove the excess oxygen. The ammonia used for the experiments was obtained from Canadian Liquid Air Co. at a specified purity of 99%; it was used without further purification.

The ozone was photolysed using a KrF laser, operated at a repetition frequency of 360 Hz. The laser energy at this frequency averaged about 10 mJ per pulse. The unfocussed laser beam entered from the left in Fig. 1 and was multipassed through the reagent mixture (indicated by the zig zag lines in the figure) by a pair of dielectric mirrors, coated for maximum reflectance at 248 nm and mounted perpendicular to the axis of the Welsh cell. The infrared emission collected by the Welsh cell was coupled out of the reaction vessel, into a Fourier transform spectrometer, by a 2 inch diameter f/1 CaF_2 lens.

Following each pulse of the excimer laser, a burst of infrared emission having a fast risetime (limited by the detector's electronic bandwidth to about 30 μs and a decay time of about 300–800 μs (depending upon the pressure) was observed from the vibrationally-excited OH. These bursts of emission, in the form of an interferogram generated by the Michelson interferometer, were recorded digitally by the Fourier transform spectrometer. About 500 interferograms were co-added and Fourier transformed to obtain each spectrum. There was no phase relationship between the occurrence of the infrared emission and its digitization by the Fourier transform spectrometer. Consequently, the spectrum represents a time-average of the distribution of spectral intensities over the duration of the emission pulse, weighted by the intensity, which was highest in the early part of the pulse (the first 100–200 μs).

The recorded spectra were corrected for the variation in sensitivity of the detector with wavelength and populations were calculated using the rotationless Einstein transition probabilities of Rosmus (11) and the rotational dependences of Goldman (12). The spectral resolution used for these experiments was 0.48 cm^{-1}, adequate to resolve the rotational structure and spin doublets of OH but not the lambda doublets.

The total pressure in the reaction chamber was in the range of $4–6 \times 10^{-2}$ Torr. In some cases, only the reagents were used while in others, argon was added in order to translationally thermalize the $O(^1D_2)$ atoms, which are produced with some residual translational energy in the photolysis (13). The total pressure in the observation zone was controlled by adjusting the gate valve above the cryobaffle and diffusion pump in order to provide adequate spectral signal-to-noise. For the present experiments, the pumping speed was limited to about 500 L/s, hence the residene time in the effective volume of the Welsh cell (1 L) was about 2×10^{-3} s.

Results

The total energy available to the products of the $O(^1D_2)/NH_3$ reaction is about 188 kJ/mol — enough to populate the fourth vibrational level of the OH produced in reaction [1] but only the ground vibrational state of that created in reaction [2]. The spectra recorded in these experiments contained observable emission from $OH(v' = 1–3)$, which therefore must have come from reaction [1]. The reagent pressures and vibrational distributions for four representative experiments are listed in Table 1. The vibrational distributions for runs 1–3 are reproduced in Fig. 2, which also shows a statistical OH vibrational distribution (the dashed line) calculated for reaction [1]. The uncertainty in the experimental results is estimated to be +0.04 in each population. Although no emission from $v' = 4$ was found, the shape of the observed distributions indicates that this would have been very weak and likely not discernable above the noise.

In experiments 1–3, low partial pressures of reagents were used with a relatively large concentration of Ar. The latter was added to ensure thermalization of the $O(^1D_2)$ prior to reaction. (The probability for $O(^1D_2)$ quenching in collisions with Ar is very small (14).) Experiment 4 shows the result obtained when the Ar is omitted and the difference in pressure is made up by increasing the concentration of ozone. In this case, the product vibrational excitation is slightly higher than that observed for the experiments carried out in the presence of Ar and with a reduced concentration of ozone.

The partial pressure of the reagents in experiments 1–3 is 1.1×10^{-2} Torr while in experiment 4 it is 4.2×10^{-2} Torr. Although the relevant energy transfer rate constants are poorly-

known, both ozone and ammonia are thought to be fairly efficient vibrational deactivators of OH (15). The available measurements of these rate constants indicate that both O_3 and NH_3 remove OH($v = 9$) with a probability between 0.05 (15*a*, 15*c*) and 1.0 (15*f*) per gas kinetic collision. If we assume that the rate of removal by NH_3 scales with vibrational level in the same way as that by ozone, the deactivation probabilities for the lower levels OH($v = 1$–3) would be in the range 0.001 to 0.1 per gas kinetic collision. We assume that argon does not deactivate the OH significantly (14, 15*a*). The substantial increase in reagent concentration in experiment 4, therefore, might be expected to cause increased deactivation of the OH vibrational distribution.

In contrast to this expectation, the distribution observed in experiment 4 is slightly *more excited* than those from the experiments using lower reagent concentrations. There could be two possible explanations for this. First, it could be caused by the higher reagent translational energy (created in the photodissociation) which is present in the experiments having no Ar buffer gas. We believe this to be the most likely explanation and will explore it in more detail in the next section. The second (and also possible) explanation is that the increased concentration of $O(^1D_2)$ atoms (due to the increased ozone concentration) results in secondary reactions between these and the radical (NH_2) produced in reaction [1]. If the vibrational distribution created in these secondary reactions were more excited than that of the primary reaction, the result would be an overall increase in the product vibrational excitation, as observed. This effect has been observed, for example, in the reaction of F atoms with NH_3 (16, 17). In that case, for F atom concentrations in substantial excess over the NH_3, the HF vibrational distribution became more excited, as the concentration of F atoms was increased, due to the contribution of the F + NH_2 reaction. It is less likely to have caused the increased vibrational excitation in the present case, however, because it is not possible to sustain a large excess of $O(^1D_2)$ atoms until the necessary concentration of NH_2 radicals has been generated. The rate constants for the reaction of $O(^1D_2)$ with both NH_3 and O_3 are approximately gas kinetic (3×10^{-10} and 2×10^{-10} cm^3 molecule^{-1} s^{-1}, respectively) (2, 18) and thus virtually no $O(^1D_2)$ will remain after the first two or three gas kinetic collisions following the ozone photolysis. Its rapid disappearance while the NH_2 is being formed thus reduces the importance of the secondary reaction.

Using the energy transfer rates quoted above, the vibrational deactivation time for these experiments would be in the range of 10^{-4} to 10^{-3} s. This is of the same order as the estimated residence time of the emitters in the observation zone (2×10^{-3} s) and therefore there remains a possibility that the observed distributions have suffered some vibrational deactivation. The data in Table 1, however, show that the distributions for runs 1–3 and the statistical distribution are all the same within the stated uncertainty. These data cover the range of reagent partial pressures from 5 to 10 $\times 10^{-3}$ Torr for ozone and from 1 to 5 $\times 10^{-3}$ Torr for ammonia. Since changing the partial pressure of a reagent would change the extent of gas phase relaxation caused by that reagent, we conclude from the invariability of the distributions that gas phase deactivation by the unused reagents is not significant in these experiments. From this we conclude that the distribution represented by experiments 1–3 is the initial one created by reaction [1] and hence that the latter creates a statistical vibrational energy distribution.

Discussion

The OH vibrational populations recorded in these experiments decrease rapidly with increasing vibrational level. This result is usually associated with reactions forming a strongly-bound intermediate which lives long enough for the reaction exoergicity to be completely distributed among all product degrees of freedom. This conclusion was indicated by the previously-measured LIF rotational distributions (1–3) but not by the vibrational distributions extracted from those rotational data. It was pointed out in ref. 3 that vibrational distributions extracted from LIF rotational measurements are particularly sensitive to errors introduced by saturation effects and it was further suggested that the unusually high vibrational excitation reported in ref. 2 may have this origin. It is also possible, however, that some of this difference, as well as the smaller difference between the vibrational distribution reported in ref. 3 and that obtained here could be due to the different energetics of the experiments.

The photolysis of ozone at 248 nm (the laser wavelength used in our experiments) generates about 62 kJ/mol of relative translational energy in the $O(^1D_2)/O_2(^1\Delta)$ frame of ref. 13. If, as in the case of experiment 4, no attempt is made to thermalize the $O(^1D_2)$ the $O(^1D_2)/NH_3$ relative translational energy would be about 24.6 kJ/mol. The 300 K thermal translational

energy is only 3.7 kJ/mol. The excess energy might reduce the lifetime of the postulated intermediate ONH_3 species, thereby reducing the extent of energy randomization and increasing the vibrational excitation of the OH product. This is qualitatively consistent with the difference observed between experiment 4 and the other three experiments, where an increase in vibrational excitation was observed under conditions where the relative values of the gas phase energy transfer rate constants would indicate that a decrease should be expected. A similar effect has been suggested in the case of the $O(^1D_2)/H_2$ reaction (19, 20). (We note, however, that the results of the present experiments do not constitute proof of this translational energy effect, since the difference in the vibrational distributions observed here is within the experimental uncertainty.)

The excess translational energy from the photolysis would not have been thermalized before the observations were made in the LIF experiments. In this case, the reagent translational energy for the experiments in ref. 3 would have been approximately 12 kJ/mol, assuming that the proportions of the excess energy partitioned to translation are the same for both the 266 nm photolysis used in the LIF work and the 248 nm photolysis used here. This is substantially greater than the room-temperature energy, 3.7 kJ/mol, and could be expected to have an effect on the lifetime of the intermediate. The statistical $P(v' = 2)/P(v' = 1)$ ratio (0.15), which agrees with our observations, implies a $P(v' = 1)/P(v' = 0)$ ratio of 0.21. The $P(v' = 1)/P(v' = 0)$ ratio reported in ref. 3 is 0.66. It is possible that this difference could represent a translational energy effect on the energy partitioning, as described above. We hope that improvements currently being made to our apparatus will permit the existence of this effect to be confirmed and its quantitative influence measured.

Study of the CEE mechanism by voltammetry and chronoamperometry

ANDRZEJ LASIA
Department of Chemistry, University of Sherbrooke, Sherbrooke, Que., Canada J1K 2R1

Received June 4, 1986

ANDRZEJ LASIA. Can. J. Chem. **64**, 2319 (1986).

The electroreduction of bivalent metal cations may proceed by a CEE mechanism with a heterogenous chemical reaction on the electrode surface. The applications of the convolutive linear sweep voltammetry and chronoamperometry to study that mechanism are presented. The behaviour of the electrochemical reactions was simulated using an implicit finite difference technique for different values of kinetic parameters. The simulated curves were analysed and an agreement between the introduced and obtained data was found.

ANDRZEJ LASIA. Can. J. Chem. **64**, 2319 (1986).

L'électroréduction de cations bivalents peut procéder par le mécanisme CEE avec une réaction chimique hétérogène à la surface de l'électrode. Les applications de la voltampérométrie à balayage linéaire avec convolution et de la chronoamperométrie aux études de cette réaction sont présentées. Des courbes analytiques ont été simulées par la méthode des différences finies et un accord a été trouvé entre les paramètres introduits et calculés.

Introduction

The electroreduction of metal cations on mercury electrodes often involves a complex reaction mechanism. It was suggested that the electrodeposition proceeds through an adion intermediate which is partially desolvated and adsorbed on the electrode surface (1). The electrochemical reactions of bi- or polyvalent cations are usually more complicated than those of monovalent cations. Different mechanisms were proposed in the literature for the electrode reduction of metal cations, e.g., simple electron transfer process (2, 3), stepwise electron transfer (4), disproportionation (5) or dimerization (6) of the intermediates, adsorption (6), CE or CEE mechanism (7–13), and slow transport across the double layer (14), etc. Some possible mechanisms were discussed by Bongenaar *et al.* (12).

CE mechanisms have been suggested for the electroreduction of cations for which the solvent exchange is slow (7–11). It was also proposed for the electroreduction of alkali metals in HMPA (15, 16) where kinetically limited waves were obtained.

The recent works of Bongenaar *et al.* (12) and Strujis *et al.* (13) show that the electroreduction of Cd(II) in concentrated aqueous solutions of perchlorates and fluorides involves a CEE mechanism with a heterogenous chemical reaction, probably a partial desolvation of the depolarizer at the electrode surface. Alternating current admittance and demodulation technique were applied to study those reactions. Unfortunately the potential range available for the a.c. admittance technique is rather limited. Strujis *et al.* (12) have presented kinetic data in the range of about 130 mV. Larger (~200 mV) potential range is available for the demodulation technique (13) but this method is, up to now, of limited use. If the rate of electroreduction is slower it is possible to use other popular electrochemical techniques. We have attempted to show how linear sweep voltammetry and chronoamperometry are used to determine the kinetics of those reactions.

Theory

The equations presented below hold for the electroreduction of bivalent metal cations according to a CEE mechanism but they may be easily modified for a CE reaction mechanism.

The CEE mechanism for a bivalent metal cation A^{2+} on mercury with the subsequent formation of amalgam may be described as:

$$[1] \quad A^{2+} \overset{k_c}{\rightleftharpoons} B^{2+}$$

$$[2] \quad B^{2+} + e \overset{k_1}{\rightleftharpoons} B^{+}$$

$$[3] \quad B^{+} + e \overset{k_2}{\rightleftharpoons} B(Hg)$$

where B^{2+} is an electroactive form of A^{2+}, k_c is a heterogenous rate constant of the chemical reaction, and k_1 and k_2 are the forward rate constants of the first and second electron transfer.

Since B^{2+} is not detected in the bulk of the solution it is assumed that it is formed at the electrode surface only and that reaction [1] is a heterogenous chemical process. The equilibrium constant of that reaction is defined as:

$$[4] \quad K_c = [A^{2+}]_0/[B^{2+}]_0$$

where subscript "0" indicates surface concentrations.

The rates of reactions [1]–[3] are

$$[5] \quad v_c = k_c\{[A^{2+}]_0 - K_c[B^{2+}]_0\}$$

$$[6] \quad v_1 = k_1\{[B^{2+}]_0 - K_1[B^{+}]_0\}$$

$$[7] \quad v_2 = k_2\{[B^{+}]_0 - K_2[B(Hg)_0]\}$$

where K_1 and K_2 are equilibrium constants of reactions [2] and [3], respectively.

Since both B^{2+} and B^{+} do not exist in the bulk of the solution, one can assume that their surface concentrations are small and their fluxes negligible. Then the concentrations of the unstable intermediates may be eliminated assuming that $v_1 = v_2 = v_3$ and $i = FA(v_2 + v_3)$, where A is the electrode surface area and i is the current.

The solution leads to an equation (12)

$$[8] \quad i = 2FAk_f\{[A^{2+}]_0 - [B(Hg)]_0 \exp(2\phi)\}$$

where

$$[9] \quad \phi = F(E - E^{0\prime})/RT$$

and

$$[10] \quad 1/k_f = 1/k_c + K_cK_1/k_2$$

The last term in the eq. [10] may be written as $K_cK_1K_2/k_2K_2$ and after taking into account the Nernst equation $K_cK_1K_2 = [A^{2+}]/[B(Hg)] = \exp(2\phi)$ one can obtain

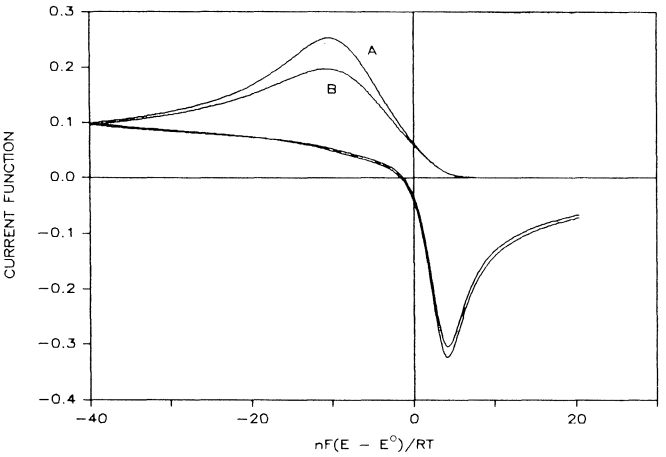

FIG. 1. Cyclic voltammetric curves simulated for EE (*A*) and CEE (*B*) mechanisms. The kinetic parameters are (*A*) $\Lambda_1 = 0.08$, $\Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$; (*B*) $\Lambda_c = 1.0$, $\Lambda_1 = 0.08$, $\Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$.

$$[11]\quad 1/k_f = 1/k_c + \exp(\alpha_1\phi)/(k_{s1}/K_c) + \exp[(1 + \alpha_2)\phi]/k_{s2}$$

where $k_1 = k_{s1}\exp(-\alpha_1\phi)$, $k_2 = k_{s2}\exp(-\alpha_2\phi)$, and k_{s1} and k_{s2} are standard rate constants of transfer of the first and second electron (reactions [2] and [3]).

Thus CEE mechanism is described by a simple Butler–Volmer type equation but k_f is a complex function of the electrode potential and kinetic parameters. Using that equation, the voltammetric and chronoamperometric curves were simulated employing the finite difference technique (17, 18).

Linear sweep voltammetry

The shape of the cyclic voltammetric curves depends strongly on the values of the kinetic parameters of the system, i.e., rate constants and transfer coefficients. For slow simple electron transfer processes with low transfer coefficients the cathodic part of the voltammetric curve is flattened and it is difficult to distinguish between simple charge transfer, EE or CEE mechanisms. This is illustrated in Fig. 1 where cyclic voltammetric curves simulated for EE (curve *A*) and CEE (curve *B*) mechanisms are shown. The following set of kinetic parameters was used in the digital simulations: *A*: $\Lambda_1 = 0.08$, $\Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$; *B*: $\Lambda_c = 1$, $\Lambda_1 = 0.08$, $\Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$. The dimensionless kinetic parameters Λ are defined as follows: $\Lambda_1 = k_{s1}/\sqrt{nFvD_0/RT}$ and $\Lambda_1 = (k_{s1}/K_c)\sqrt{nFvD_0/RT}$ for EE and CEE mechanism, respectively, $\Lambda_2 = k_{s2}/\sqrt{nFAvD_0/RT}$, $\Lambda_c = k_c/\sqrt{nFvD_0/RT}$, D_0 is the diffusion coefficient of A^{2+}, v is the sweep rate, and all other symbols have their usual meaning. A comparison of these two voltammetric curves shows smaller cathodic current for the CEE mechanism while the anodic currents are essentially the same.

It is relatively easy to identify the reaction mechanism by convolutive potential sweep voltammetry (19). The convolution integral (semiintegral) $I\Psi$ is defined as:

$$[12]\quad I\Psi = (1/\sqrt{\pi})\int_u^{\xi} \Psi(\xi)/\sqrt{\xi - v}\,dv$$

where $\Psi = i\Theta/nFAC_0^*D_0^{1/2}$ is the dimensionless current function, $\Theta = RT/nFv$, $\xi = nF(E - E^0)/RT$, $u = nF(E_i - E^0)/RT$, and E_i is the initial potential.

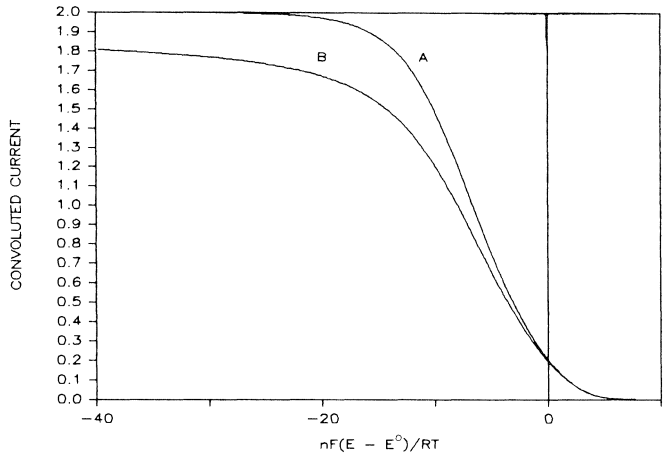

FIG. 2. Convoluted voltammetric curves for EE (*A*) and CEE (*B*) mechanisms. Values of the kinetic parameters are the same as in Fig. 1.

The convoluted current functions $I\Psi$ of the cathodic part of the voltamperometric curves are shown in Fig. 2. It is apparent that in the absence of the chemical step plateau $I\Psi_1 = 2$ is reached for an EE mechanism while for a CEE mechanism $I\Psi$ is always smaller than 2.

More systematic calculations of the influence of the rate constant of the chemical reaction [1] on the shape of the cyclic voltammetric curves were carried out. Figure 3 presents the simulated voltamperometric curves for a reversible electron transfer reaction with $\Lambda_1 = \Lambda_2 = 10^6$ and $\Lambda_c = 0.1, 0.3, 1.0$, and 10^6. When the chemical reaction rate decreases, the cathodic peak current also decreases and the latter is flattened. Semiintegration of the cathodic current (Fig. 4) gives the sigmoidal curves but the theoretical value of the limiting current is obtained only for $\Lambda_c = 10^6$ (which is equivalent to the EE mechanism). For the lower values of Λ_c, at negative potentials, the convoluted current increases with potential and its values are smaller than the theoretical values for the EE mechanism. These curves were further analysed to give the rate constants of the electrochemical process, Λ_f according to the relation (19)

$$[13]\quad \Lambda_f = \Psi/\{I\Psi_1 - I\Psi[1 + \exp(nF(E - E^0)/RT)]\}$$

where $\Lambda_f = k_f/\sqrt{nFvD_0/RT}$, k_f is the forward rate constant of the overall process and $I\Psi_1 = 2$ is limiting value of the convoluted current function in the absence of the chemical step [1].

Using that analysis to the curves presented in Fig. 4 the introduced values of Λ_c parameter were obtained at potentials more negative than the peak current.

The influence of the irreversibility of the electron transfer processes is illustrated in Fig. 5. The voltammetric curves were simulated using $\Lambda_1 = 0.08$, $\Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$, and different values of the kinetic parameter $\Lambda_c = 0.1, 0.3, 1.0$, and 10^6. The corresponding convoluted current functions are shown in Fig. 6. The theoretical value of the limiting convoluted current $I\Psi_1 = 2$ is obtained only for the fast chemical reaction ($\Lambda_c = 10^6$). The analysis using eq. [13] was also performed and the results are presented in Fig. 7. For the fast chemical reaction a linear dependence of $\ln \Lambda_f$ on potential was obtained. In the cases where the kinetics of the process was limited by the rate of the chemical step, constant (independent of the potential) value of Λ_f was obtained at negative potentials, equal to the values introduced in the simulations.

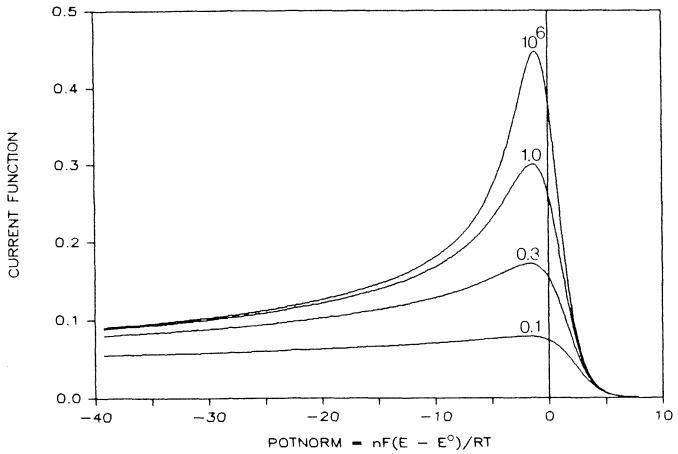

FIG. 3. Voltammetric curves simulated for CEE mechanism with fast electron exchange. The kinetic parameters are $\Lambda_1 = \Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$. The numbers represent the values of the dimensionless rate constant of the chemical reaction Λ_c.

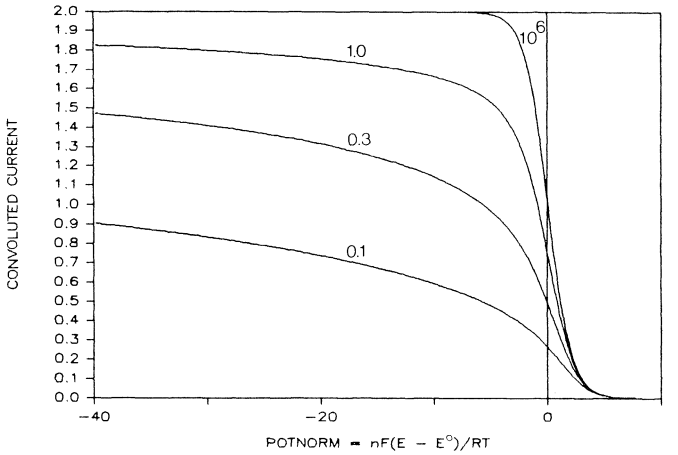

FIG. 4. Convoluted voltammograms of the curves in Fig. 3.

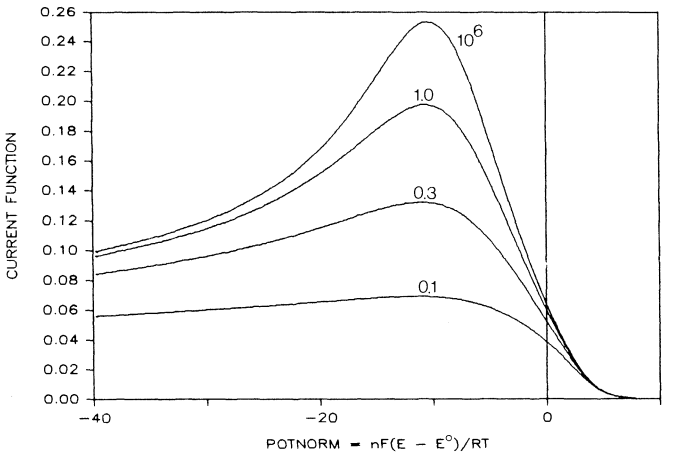

FIG. 5. Voltammetric curves simulated for CEE mechanism with slow electron exchange. The kinetic parameters are $\Lambda_1 = 0.08$, $\Lambda_2 = 10^6$, $\alpha_1 = \alpha_2 = 0.5$. The number on each curve is the value of Λ_c.

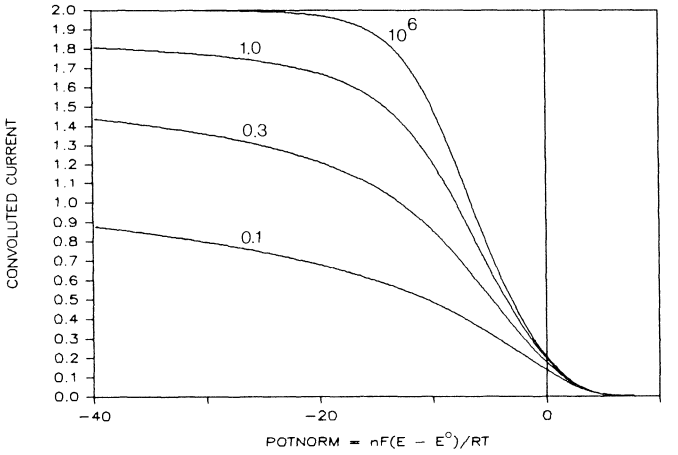

FIG. 6. Convoluted voltammograms of the curves shown in Fig. 5.

The nonlinear analysis of the dependence of the rate constant as a function of the potential according to eq. [11] gives all values for the introduced kinetic parameters Λ and α.

Chronoamperometry

Chronoamperometry has been already applied in the literature to the kinetics of the CE processes with a homogenous chemical reaction (9, 20). The results presented below are for EE and CEE mechanisms with a heterogenous chemical reaction to show the effect of the irreversibility of the electron transfer on the simulated curves. The kinetic parameter Λ was defined as $\Lambda_c = k_c\sqrt{\tau/D_0}$, $\Lambda_1 = (k_{s1}/K_c)\sqrt{\tau/D_0}$, and $\Lambda_2 = k_{s2}\sqrt{\tau/D_0}$, where τ is time at which the current is measured.

Figure 8 shows the simulated chronoamperometric current–potential curves for a reversible electron transfer processes with the dimensionless kinetic parameter Λ_c equal to 0.1, 0.3, 1.0, and 10^6. It is evident that the limiting value of current is quickly established and that it is constant, but its value depends on the rate of the preceding chemical reaction. For the slow electron transfer process (Fig. 9) the plateau is reached at more negative potentials. Its value does not depend on the reversibility of the electrode process.

At negative potentials where the kinetics of the overall process is limited by the rate of the chemical reaction the analytical solution of the problem is given by (20)

$$[14] \quad i/i_l = \pi^{1/2}\Lambda_c \exp(\Lambda_c^2)\,\mathrm{erfc}(\Lambda_c)$$

where i_l is the diffusion-limited current in the absence of the preceding chemical step. The values of the current obtained from simulations are in a very good agreement with the values obtained from eq. [14].

The analysis of the chronoamperometric curves at various potentials for quasi-reversible and irreversible processes was performed by solving the equation:

$$[15] \quad (i/i_l)\{1 + \exp[nF(E - E^0)/RT)]\} = \pi^{1/2}\lambda \exp(\lambda^2)\,\mathrm{erfc}(\lambda)$$

where λ is defined now as

$$[16] \quad \lambda = \Lambda_f[1 + \exp(nF(E - E^0)/RT)]$$

and $\Lambda_f = k_f\sqrt{\tau/D_0}$. The nonlinear approximation of the determined rate constants using eq. [11] gave the introduced kinetic parameters.

TABLE 1. Comparison of the EE and CEE mechanisms for cyclic voltammetry and chronoamperometry

Parameter	EE	CEE
$1/k_f =$	$\exp(\alpha_1\phi)/k_{s1} + \exp[(1+\alpha_2)\phi]/k_{s2}$	$1/k_c + \exp(\alpha_1\phi)/k_{s1}K_c^{-1} + \exp[(1+\alpha_2)\phi]/k_{s2}$
$E \rightarrow -\infty$	$k_f \rightarrow \infty$	$k_f \rightarrow k_c$
Cyclic voltammetry		
i–E curves	Difficult to distinguish	Cathodic part flattened, anodic almost the same
Convoluted curves	Plateau $I\Psi_1 = 2$ $I_l = 2FAD^{1/2}C^*$	Plateau not reached over large potential range $I\Psi_1 < 2$
Chronoamperometry		
Limiting current	$i_{l,EE} = 2FAD_0^{1/2}C^*/\sqrt{\pi t}$	Limiting current smaller than for EE mechanism $i_{l,CEE} = i_{l,EE}\pi^{1/2}\lambda \exp(\lambda^2)\,\mathrm{erfc}(\lambda)$

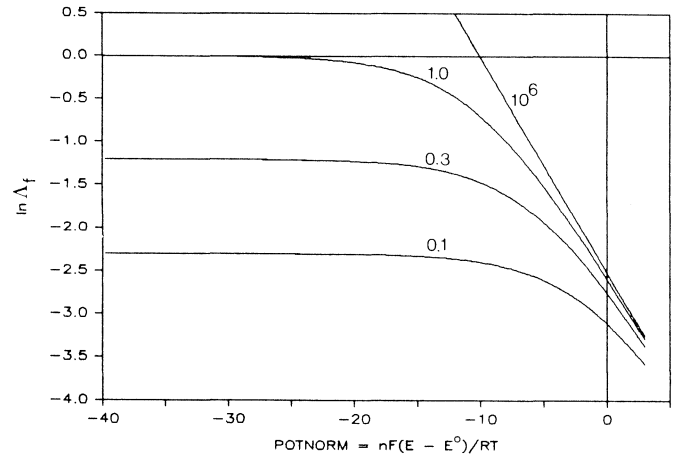

FIG. 7. The dependence of ln Λ_f vs. normalized potential obtained from the analysis of the convoluted curves shown in Fig. 6.

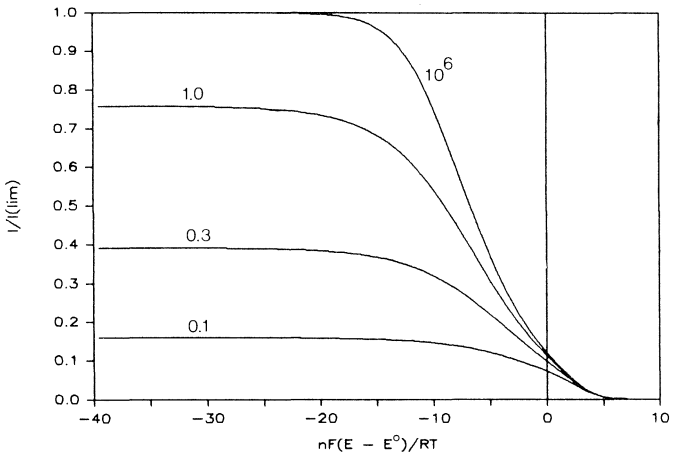

FIG. 9. Chronoamperometric curves i/i_l vs. normalized potential for CEE process with slow electron exchange. Kinetic parameters are the same as in Fig. 5. The number on each curve is the value of Λ_c.

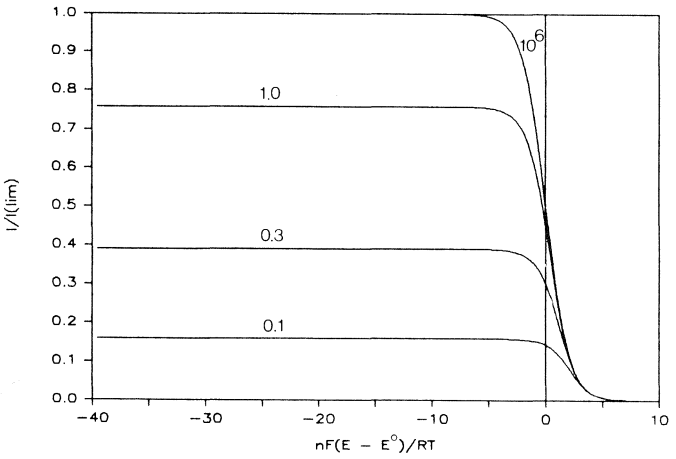

FIG. 8. Chronoamperometric curves i/i_l vs. normalized potential for CEE process with fast electron exchange. Kinetic parameters are the same as in Fig. 3. The number on each curve is the value of Λ_c.

Discussion

The analysis of the voltammetric and chronoamperometric curves for the CE/CEE mechanism gives the possibility of determining the kinetic parameters of that process.

The convolutive linear sweep voltammetry of the CEE process does not produce curves with a plateau. The convoluted current is continually increasing with the potential in a wide potential range even for the fast electron transfer process. However, detailed kinetic analysis gives the correct rate constants.

On the other hand, the chronoamperometric curves of CE/CEE mechanism show a well-established plateau of the limiting current whose value depends on the kinetics of the chemical reaction.

Both techniques may be used in the diagnostics of the electrode processes involved and for the determination of the kinetic parameters. The comparison of the results obtained for the EE and CEE mechanisms and the diagnostic criteria are presented in Table 1. The rate constant of the process may be studied over a wide potential range also at the negative

potentials where the electroreduction process is fast and the kinetics of overall process is limited only by the rate of the chemical reaction [1]. Voltammetric and chronoamperometric techniques have an advantage over a.c. techniques because the presence of a preceding chemical reaction may be confirmed on the basis of the comparison of the calculated and experimentally determined limiting convoluted or chronoamperometric currents, which is a direct evidence of the existence of that mechanism. On the other hand, using a.c. impedance technique one has to apply a nonlinear approximation of the determined k_f values as a function of the electrode potential. The use of convolution voltammetry or chronoamperometry is similar to the classical polarographic study of a slow desolvation of Ni^{2+} in aqueous solutions (see e.g. refs. 7 and 8).

Methods described above will be used for the further study of the kinetics of the electrode process of Cd(II) in DMSO (21).

Synthesis of the subterminally 6-*O*-phosphorylated trimannosides found on carbohydrate chains of lysosomal enzymes

OM. P. SRIVASTAVA AND OLE HINDSGAUL[1]

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 17, 1986

OM. P. SRIVASTAVA and OLE HINDSGAUL. Can. J. Chem. **64**, 2324 (1986).

The three possible subterminally 6-*O*-phosphorylated trimannosides (**2–4**) found on the asparagine-linked carbohydrate chains of lysosomal enzymes have been chemically synthesized as their 8-methoxycarbonyloctyl glycosides, R = $(CH_2)_8COOCH_3$. The key step in the syntheses involves glycosylation of suitably protected α-D-mannopyranosides **5–7** with the phosphorylated mannobiosyl donor 2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranosyl chloride (**14**), which produced mixtures of α- and β-linked trisaccharidic products. Compounds **2** (αDMan(1→2)αDMan 6-phosphate(1→2)αDManOR), **3** (αDMan(1→2)αDMan 6-phosphate(1→3)αDManOR), and **4** (αDMan(1→2)αDMan 6-phosphate(1→6)αDManOR) are being used in a study of the targeting of enzymes to the lysosomes by phosphomannosyl receptors.

OM. P. SRIVASTAVA et OLE HINDSGAUL. Can. J. Chem. **64**, 2324 (1986).

On a réalisé la synthèse chimique, sous la forme de glycosides méthoxycarbonyl-8 octyles (R = $(CH_2)_8COOCH_3$), des trois *O*-phosphoryl-6 trimannosides (**2–4**) possibles que l'on retrouve sur les chaînes de carbohydrates liées par l'asparagine dans les enzymes des lysosomes. L'étape clé dans la synthèse implique la glycosylation de α-D-mannopyranosides protégés d'une façon adéquate (**5–7**) avec le donneur mannobiosyle phosphorylé, le chlorure de *O*-(tétra-*O*-acétyl-2,3,4,6 α-D-mannopyrannosyl)-2 di-*O*-benzyl-3,4 *O*-diphénylphosphoryl-6 α-D-mannopyrannosyle (**14**), qui conduit à des mélanges des trisaccharides liés par les positions α et β. On utilise les composés **2** (αDMan(1→2)αDMan 6-phosphate(1→2)αDManOR), **3** (αDMan(1→2)αDMan 6-phosphate(1→3)αDManOR) et **4** (αDMan(1→2)αDMan 6-phosphate(1→6)αDManOR) dans une étude sur la relation des enzymes avec les lysosomes par le biais des récepteurs phosphomannosyles.

[Traduit par la revue]

Introduction

The asparagine-linked oligosaccharide chains of lysosomal enzymes carry a recognition marker required for the translocation of these enzymes from their sites of biosynthesis in the rough endoplasmic reticulum and golgi apparatus to the lysosomes (1–3). D-Mannose 6-phosphate residues are known to be the essential component of this recognition marker and correct intracellular targeting is mediated by specific phosphomannosyl receptors that bind with phosphorylated "high-mannose" oligosaccharides. The carbohydrate chains of lysosomal enzymes have been shown (4–6) to be highly heterogeneous in both size, degree, and type of phosphorylation. Structure **1** shows the mannose residues of the unprocessed high-mannose oligosaccharide chains where 6-*O*-phosphorylation has been found to occur. Smaller structures in which nonphosphorylated outer mannose residues have been enzymatically cleaved have also been identified (4–6).

To clarify the molecular features required for the specific recognition of these phosphorylated oligosaccharides by their receptors we are engaged in a synthetic effort to produce a panel of phosphorylated oligosaccharides, corresponding to partial structures of **1**, which are to be used in systematic binding studies with the purified (7) phosphomannosyl receptors. We have previously reported (8, 9) the syntheses of six phosphorylated di- and trimannosides corresponding to terminii of the composite structure **1**. Here we report the preparation of the 3 possible subterminally phosphorylated oligosaccharides **2**, **3**, and **4**. These structures were prepared as their 8-methoxycarbonyloctyl glycosides (10) to allow the preparation of synthetic glycoconjugates (11) for use in a study (12) of the intracellular transport of lysosomal enzymes.

Results and discussion

Our strategy for the syntheses of **2–4** centered on the availability, from previous work (9), of the protected 8-methoxycarbonyloctyl α-D-mannopyranosides **5–7** having hydroxyl groups at C-2, C-3, and C-6, respectively, that are free for glycosylation. The most direct route to the target structures **2–4** would then involve glycosylation of **5–7** with a suitable 2-*O*-(α-D-mannopyranosyl)-α-D-mannopyranosyl donor. Although such glycosyl donors have nonparticipating groups at O-2, stereoelectronic (anomeric) (13) effects should favor formation of the α-glycosidic linkage under appropriate conditions (14). Ogawa's group (15–17) has successfully used such mannobiosyl donors in the syntheses of both yeast cell-wall mannan structures and asparagine-linked oligosaccharides and, although α,β mixtures of products may be obtained, the α-linked glycosides were generally the major products. Our synthetic route to **2–4** then required the preparation of the phosphorylated mannobiosyl donor **14** and its coupling with the alcohols **5–7**.

Reaction of the glycosyl bromide **8** (8), readily prepared from 1,2,6-tri-*O*-acetyl-3,4-di-*O*-benzyl-α-D-mannopyranose (18), with allyl alcohol under standard Helferich conditions (14) provided the α-linked glycoside **9** (75%), which was de-*O*-acetylated to produce **10**. Selective phosphorylation of the primary hydroxyl group in **10**, using diphenylphosphoryl chloride (19, 20) gave an α-D-mannopyranose derivative **11** (78%) having the 2-OH group free for glycosylation by 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide. The α(1→2) linked disaccharide **12** was obtained in 71% yield.

Removal of the allyl protecting group in **12**, using tristriphenylphosphine rhodium(I) chloride followed by mercuric chloride in aqueous acetone (21), gave the reducing disaccharide derivative **13**, which was isolated as an anomeric mixture

R = —$(CH_2)_8COOCH_3$

(**13**α:**13**β = 4:1) in 83% yield. Reaction of **13**α,β with oxalyl chloride in the presence of *N*,*N*-dimethylformamide (22) then gave the D-mannobiosyl chlorides **14** (59%) and **15** (19%), which could be separated by chromatography on silica gel. The α-anomer (**14**) was stable for weeks on storage, as a solution in dichloromethane at −20°C, and was used in all subsequent glycosylation reactions.

Glycosylation of **5** with **14**, promoted by silver trifluoromethanesulfonate and *sym*-collidine in 1,2-dichloroethane, gave a mixture (82%) of the trisaccharides **16** (α) and **17** (β), in a ratio of 1.2:1, which were readily separable by silica gel chromatography. That all three glycosydic linkages in **16** had the α-configuration was supported by the observation, in its ^{13}C nmr spectrum, of three resolved signals for the anomeric carbons (Table 1) with $^1J_{C,H}$ of 173, 173, and 170 Hz, respectively, in accordance with the empirical rules formulated by Bock and Pedersen (23) for the dependence of one-bond C—H coupling constants on the anomeric configuration of glycopyranosides. The newly formed glycosidic linkage in **17** was assigned the β-configuration based also on its ^{13}C nmr spectrum, which showed a signal for an anomeric carbon having $^1J_{C,H}$ = 156 Hz. Other key spectroscopic data in support of the structural assignments of **16** and **17** are collected in Table 1.

Reaction of **14** with **6** again gave a reasonable yield (73%) of trisaccharidic product, this time in the ratio **18**(α):**19**(β) of 2.3:1. Anomers **18** and **19** comigrated in thin-layer chromatography and their separation required the use of high-pressure liquid chromatography. The assignment of the α-configuration to **18** was based on the characteristic (≈170 Hz) $^1J_{C,H}$ coupling constants for all three anomeric carbons (Table 1). The signal for C-1′ of the β-anomer **19** showed the characteristically smaller ($^1J_{C,H}$ = 155 Hz) one-bond coupling. Other nmr data in support of these structural assignments are also included in Table 1.

Condensation of **14** and **7** also provided a trisaccharidic product (79%), but this time with the β-linked derivative (**21**) as the major component (**20**:**21** = 1:3) as judged by the ^1H nmr spectrum of the chromatographically homogeneous mixture. The loss of α-stereospecificity in the glycosylation of more reactive alcohols has also been observed by Ogawa and Nukuda (17) in comparable reactions with primary alcohols and was therefore not unexpected. The low yield of **20**(α) was nevertheless disappointing, particularly since extensive attempts at separating **20** and **21** chromatographically failed. The mixture of **20** and **21** was therefore hydrogenated over palladium on carbon at atmospheric pressure, which cleaved the benzyl ether

groups with only modest (≤20%) loss of the phenyl protecting groups. Acetylation of the resulting material gave a mixture of **22**α (15% from **7**) and **23**β (45% from **7**), which was now readily separated by silica gel chromatography. The anomeric configurations of the glycosidic linkages in **22** and **23** were evident from the nmr data presented in Table 1. Although the overall yield of the required α-linked protected trisaccharide **22** obtained by this route was low, sufficient material was obtained to proceed to the final product (**4**), and other reaction conditions were consequently not explored.

The deprotection of **16**, **18**, and **22** proceeded without complications. Removal of the *tert*-butyldimethylsilyl group from **16** using aqueous acetic acid gave **24** in 85% yield. Hydrogenolysis of the benzyl ethers in **24** over palladium on charcoal followed by deprotection of the phosphate groups using hydrogenolysis over Adams' catalyst (PtO_2) and, finally, removal of the acetates by transesterification with methanol gave **2** (78% from **24**), which was isolated as its disodium salt after chromatography on Bio-Gel P-2 and ion exchange. Similar deprotection of **18** gave trisaccharide **3** in 81% yield. Deprotection of **22** involved only hydrogenation over Adams' catalyst followed by transesterification to produce **4** (81%). Key nmr data for compounds **2**–**4** are presented in Table 1.

Experimental

All solvents and reagents used were reagent grade and, in cases where further purification was required, standard procedures (24) were followed. All solid reactants for glycosylation were dried overnight over phosphorus pentoxide in a high vacuum prior to use. Solution transfers where anhydrous conditions were required were done under nitrogen using standard syringe techniques. Molecular sieves were purchased from BDH Chemicals.

Thin-layer chromatograms (tlc) were performed on precoated silica gel 60-F254 plates (E. Merck, Darmstadt) and visualized by quenching of fluorescence and (or) by charring after spraying with 5% sulfuric acid in ethanol. Unless otherwise stated, chromatography was performed on silica gel 60 (40–63 μm, E. Merck No. 9385). Iatrobeads refer to a beaded silica gel manufactured by Iatron Laboratories, Tokyo (product No. 6RS-8060). The Partisil column was from Waters Associates. Solvents were removed on a rotary evaporator under the vacuum of a water aspirator with bath temperatures of 40°C or lower. For gel filtration, Bio-Gel P-2 (200–400 mesh) (Bio-Rad Laboratories, Richmond, California) was used.

Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded at either 400 MHz (Bruker WH-400) or 360 MHz (Bruker WM-360) with either tetramethylsilane (δ = 0 in $CDCl_3$) or acetone (δ = 2.225 in D_2O) as internal standard at ambient temperature. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were recorded at either 100.62 MHz (Bruker WH-400) or 90.56 MHz (Bruker WM-360) with either internal tetramethylsilane (δ = 0 in $CDCl_3$) or external 1,4-dioxane (δ = 67.4 in D_2O) as reference standard. Phosphorus-31 nuclear magnetic resonance (^{31}P nmr) spectra were recorded at 145 MHz (Bruker WM-360) with external 85% H_3PO_4 as reference standard (δ = 0) in both $CDCl_3$ and D_2O. Only partial nmr data are reported. Other spectral features were in accord with the proposed structures. The ^{1}H coupling constants are reported as though they were first order. Assignments of ^{13}C resonances are tentative. Additional nmr data for compounds **2**–**4**, **16**–**19**, **22**, and **23** appear in Table 1. Optical rotations were determined on a Perkin–Elmer 241 polarimeter in a 1-dm cell at ambient temperature (23 ± 1°C).

*Allyl 2,6-di-*O*-acetyl-3,4-di-*O*-benzyl-α-*D*-mannopyranoside (**9**)*

To a solution of allyl alcohol (1.22 g, 18 mmol) in dry acetonitrile (5 mL) containing 4Å molecular sieves were added, sequentially, mercuric bromide (7.78 g, 21.6 mmol) and mercuric cyanide (5.45 g, 21.6 mmol), followed by a solution of 2,6-di-*O*-acetyl-3,4-di-*O*-benzyl-α-D-mannopyranosyl bromide (**8**, 21.6 mmol) in acetonitrile

[a]Spectra of **16**–**23** recorded in $CDCl_3$; spectra for **2**–**4** recorded in D_2O. Other experimental conditions and reference standards are described in the experimental section.
[b]Assignments are tentative, but ^{1}H connectivities are confirmed by homonuclear decoupling.
[c]Could not be accurately determined.

(5 mL). The reaction mixture was stirred for 15 h at room temperature, diluted with dichloromethane (25 mL), filtered, and evaporated to dryness. The residue was extracted 3 times with dichloromethane and the extracts were combined and washed with saturated KCl (×3), saturated $NaHCO_3$ (×3), and twice with water, and the solvent was removed by evaporation. Chromatography using hexane – ethyl acetate, (3:1) as eluent provided the title compound as a syrup (6.5 g, 75%); $[\alpha]_D$ +30.9° (*c* 0.69, chloroform); R_f 0.22 (hexane – ethyl acetate, 3:1); ^{1}H nmr ($CDCl_3$) δ: 5.700 (m, 1H, C*H*=CH_2), 2.110 and 1.995 (each s, 3H, $COCH_3$); ^{13}C nmr δ: 170.67 and 170.22 (*C*OCH_3), 138.03 and 137.79 (quat. arom.), 133.25 (*C*H=CH_2), 117.95 (CH=*C*H_2), 96.89 (C-1, $^1J_{C,H}$ = 171 Hz), 63.40 (C-6), 21.00 and 20.80 ($COCH_3$). *Anal.* calcd. for $C_{27}H_{32}O_8$: C 66.93, H 6.66; found: C 66.85, H 6.83.

*Allyl 3,4-di-*O*-benzyl-α-D-mannopyranoside (**10**)*

Compound **9** (6.2 g, 12.8 mmol) was dissolved in dry methanol (50 mL) containing sodium methoxide and left for 15 h at room temperature. After neutralization with IRC-50 (H) and filtration, the solvent was removed and the residue was purified by chromatography using hexane – ethyl acetate (1:1) as eluent, to provide the title compound as a syrup (4.5 g, 88%); $[\alpha]_D$ +56° (*c* 0.45, chloroform); R_f 0.17 (hexane – ethyl acetate, 1:1); ^{1}H nmr ($CDCl_3$) δ: 5.873 (m, 1H, C*H*=CH_2), 4.928 (d, 1H, $J_{1,2}$ = 1.5 Hz, H-1), 2.554 (d, 1H, $J_{OH,2}$ = 1.8 Hz, O*H*$_2$), 2.010 (dd, 1H, $J_{OH,6a}$ = 5.5, $J_{OH,6b}$ = 7.5 Hz, O*H*$_6$); ^{13}C nmr ($CDCl_3$) δ: 138.34 and 137.94 (quat. arom.), 133.57 (*C*H=CH_2), 117.35 (CH=*C*H_2), 98.45 (C-1), 61.59 (C-6). *Anal.* calcd. for $C_{23}H_{28}O_6$: C 68.98, H 7.05; found: C 68.68, H 6.98.

*Allyl 3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranoside (**11**)*

Diphenylphosphoryl chloride (2.40 mL, 11.5 mmol) was added to a solution of **10** (4.2 g, 10.5 mmol) in pyridine (20 mL) at 0°C and the reaction mixture allowed to warm to room temperature over 0.5 h. After 15 h, water (20 mL) was added and, after an additional 0.5 h, the reaction was taken to dryness. The residual syrup was dissolved in dichloromethane (150 mL) and washed sequentially with water, 5% HCl, water, saturated $NaHCO_3$, and, finally, water before concentration to a syrup that was purified by chromatography using hexane – ethyl acetate (2:1). Pure **11** was obtained as a syrup (5.2 g, 78.4%); $[\alpha]_D$ +41.8° (*c* 0.79, chloroform); R_f 0.20 (hexane – ethyl acetate, 2:1); ^{1}H nmr ($CDCl_3$) δ: 5.828 (m, 1H, C*H*=CH_2), 4.883 (d, 1H, $J_{1,2}$ = 1.5 Hz, H-1), 2.55 (br, O*H*$_2$); ^{13}C nmr ($CDCl_3$) δ: 137.98 and 137.80 (quat. arom.), 133.47 (*C*H=CH_2), 117.56 (CH=*C*H_2), 98.41 (C-1), 70.27 (C-5, $^3J_{C,P}$ = 7 Hz), 68.06 (C-6, $^2J_{C,P}$ = 6 Hz); ^{31}P nmr ($CDCl_3$) δ: −11.77. *Anal.* calcd. for $C_{35}H_{37}O_9P$: C 66.45, H 5.90; found: C 66.47, H 5.98.

*Allyl 2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranoside (**12**)*

A mixture of **11** (1.2 g, 1.90 mmol) and silver trifluoromethanesulfonate (2.9 g, 11.4 mmol) was dried *in vacuo* over phosphorous pentoxide for 5 h at 20°C and dissolved in 1,2-dichloroethane (5 mL) under argon. To this stirring mixture was added *N,N,N′,N′*-tetramethylurea (680 μL, 5.7 mmol) and 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide (25) (3.8 mmol) in 5 mL of 1,2-dichloroethane. After both 5 h and 20 h, further additions of *N,N,N′,N′*-tetramethylurea (680 μL, 5.7 mmol) and the same glycosyl bromide (3.8 mmol) were made. The reaction was then stirred for an additional 36 h and diluted with 1,2-dichloroethane (50 mL). *Sym*-collidine (1.5 mL, 11.4 mmol) followed by silver trifluoromethanesulfonate (975 mg, 3.8 mmol) were then added to destroy any unreacted glycosyl bromide and, after 0.5 h, excess silver was precipitated by addition of tetraethylammonium bromide (800 mg). Solids were removed by filtration and washed twice with saturated aqueous $NaHCO_3$ (150 mL) and twice with water (150 mL) before evaporation to a syrup. Purification by chromatography (hexane – ethyl acetate 1:1) provided the title compound (1.3 g, 71%) as a syrup; $[\alpha]_D$ +40.5° (*c* 0.60, chloroform); R_f 0.31 (hexane – ethyl acetate, 1:1); ^{1}H nmr ($CDCl_3$) δ: 5.808 (m, 1H, C*H*=CH_2), 4.978 (d, 1H, $J_{1',2'}$ = 1.5 Hz, H-1′), 4.878 (d, 1H, $J_{1,2}$ = 1.2 Hz, H-1), 2.097, 2.069, 1.992, and 1.983 (each s, 3H, $COCH_3$); ^{13}C nmr ($CDCl_3$) δ: 170.54, 169.79, 169.70, and 169.61 (*C*OCH_3), 138.01 and 137.88 (quat. arom.), 133.32 (*C*H=CH_2), 117.60 (CH=*C*H_2), 99.37 (C-1′, $^1J_{C,H}$ = 173 Hz), 97.61 (C-1, $^1J_{C,H}$ = 171 Hz), 71.00 (C-5, $^3J_{C,P}$ = 8 Hz), 68.06 (C-6, $^2J_{C,P}$ = 8 Hz), 62.50 (C-6′), 20.85, 20.71, and 20.65 (2 × C) (*C*O*C*H$_3$); ^{31}P nmr ($CDCl_3$) δ: −11.58. *Anal.* calcd. for $C_{49}H_{55}O_{18}P$: C 61.12, H 5.76; found: C 60.89, H 5.91.

*2-*O*-(2,3,4,6-Tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α,β-D-mannopyranose (**13**α and **13**β)*

A solution of **12** (1.25 g, 1.30 mmol), tristriphenylphosphinerhodium(I) chloride (84.1 mg, 0.09 mmol), and 1,8-diazabicyclo[2.2.2]octane (36.4 mg, 0.33 mmol) in ethanol–benzene–water (7:3:1; 50 mL) was heated at reflux for 36 h. The solvent was removed and the residue dissolved in acetone (50 mL) containing a trace amount of mercuric oxide. To this solution was added a solution of mercuric chloride (1.98 g) in acetone–water (9:1; 30 mL), and the mixture was stirred at room temperature for 2 h. Following evaporation of the solvent, the residue was taken up in dichloromethane (150 mL) and washed with 30% aqueous KBr followed by water. Drying (Na_2SO_4) and evaporation left an oily residue that was purified by chromatography using hexane – ethyl acetate (2:3) as eluent. The title compound was obtained as a syrup (998 mg; 83%); R_f 0.11 (hexane – ethyl acetate 1:1); ^{1}H nmr ($CDCl_3$) δ: 5.140 (br, 0.8 H, H-1α), 4.985 (d, 0.8 H, $J_{1',2'}$ = 1.5 Hz, H-1′β), 3.190 (br, 0.2 H, OHβ), 2.875 (d, 0.8H, OHα), 2.102, 2.077, 1.999, and 1.986 (COC*H*$_3$α), 2.126, 2.085, 2.018 (COC*H*$_3$β). *Anal.* calcd. for $C_{46}H_{51}O_{18}P$: C 59.87, H 5.57; found: C 59.66, H 5.66.

*2-*O*-(2,3,4,6-Tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranosyl chloride (**14**) and 2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-β-D-mannopyranosyl chloride (**15**)*

A solution of oxalyl chloride (910 μL, 10.4 mmol) in dichloromethane (2 mL) was added to a stirring solution of **13**α and **13**β (3.5 g, 3.79 mmol) and *N,N*-dimethylformamide (47 μL, 0.61 mmol) in dichloromethane (4 mL). The mixture was stirred for 1 h at room temperature and was poured into ice water. The organic layer was washed with cold water (3 × 25 mL), dried (Na_2SO_4), and concentrated to a syrup, which was purified by chromatography using hexane – ethyl acetate (3:2) as eluent. The title compounds **14** (2.10 g, 59%; R_f 0.13 in hexane – ethyl acetate, 3:2) and **15** (680 mg, 19%; R_f 0.27 in hexane – ethyl acetate, 3:2) were obtained as clear syrups.

Compound **14**: ^{1}H nmr ($CDCl_3$) δ: 6.170 (d, 1H, $J_{1,2}$ = 1.8 Hz, H-1), 5.457 (dd, 1H, $J_{1',2'}$ = 1.8 Hz, $J_{2',3'}$ = 3.2 Hz, H-2′), 5.360 (dd, 1H, $J_{3',4'}$ = 9.5 Hz, H-3′), 5.227 (dd, 1H, $J_{4',5'}$ = 10 Hz, H-4′), 4.843 (d, 1H, H-1′), 3.950 (dd, 1H, $J_{2,3}$ = 3.0 Hz, H-2), 2.137, 2.093, 1.997, and 1.967 (each s, 3H, COC*H*$_3$).

Compound **15**: ^{1}H nmr ($CDCl_3$) δ: 5.563 (dd, 1H, $J_{1',2'}$ = 1.8 Hz, $J_{2',3'}$ = 3.0 Hz, H-2′), 5.407 (dd, 1H, $J_{3',4'}$ = 10.0 Hz, H-3′), 5.323 (2H, dd, $J_{4',5'}$ = 10.0 Hz, H-4′ and s, H-1), 5.130 (d, 1H, H-1′), 4.128 (d, 1H, $J_{2,3}$ = 2.3 Hz, H-2), 3.822 (dd, 1H, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H-4), 3.610 (2H, H-5 and H-3), 2.087 (s, 6H, 2 × COC*H*$_3$), 2.027 and 1.983 (each s, 3H, COC*H*$_3$).

*8-Methoxycarbonyloctyl 2-*O*-[2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranosyl]-3,4-di-*O*-benzyl-6-*O*-tert-butyldimethylsilyl-α-D-mannopyranoside (**16**) and 8-methoxycarbonyloctyl 2-*O*-[2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-β-D-mannopyranosyl]-3,4-di-*O*-benzyl-6-*O*-tert-butyldimethylsilyl-α-D-mannopyranoside (**17**)*

A solution of **14** (298 mg, 0.32 mmol) was added dropwise, over 0.5 h, to a mixture of **5** (120 mg, 0.19 mmol), *sym*-collidine (36.9 μL, 0.28 mmol), silver trifluoromethanesulfonate (81.3 mg, 0.32 mmol), and pulverized 4Å molecular sieves (1.2 g) stirring in 1,2-dichloroethane (1 mL) at room temperature. After 15 h, 1,2-dichloroethane

(20 mL) was added and the sieves were removed by filtration and washed with more 1,2-dichloroethane (20 mL). *Sym*-collidine (37 μL) followed by silver trifluoromethanesulfonate (81 mg) were then added to the filtrate to destroy any unreacted **14** and, after 0.5 h, tetraethylammonium bromide (67 mg) was added to precipitate excess silver. Solids were removed by filtration and the resulting solution was washed twice with saturated $NaHCO_3$ and twice with water and taken to dryness. The residual syrup was purified by chromatography on Iatrobeads using hexane – ethyl acetate (3:2) as eluent. Evaporation of the later fractions provided the α-anomer **16** (131 mg, 45%) as a syrup (R_f 0.30 in hexane – ethyl acetate, 3:2); $[\alpha]_D$ +28° (*c* 0.25, chloroform); ^{1}H nmr ($CDCl_3$) δ: 5.388 (dd, 1H, $J_{3'',4''}$ = 9.5 Hz, H-3″), 5.279 (dd, 1H, $J_{4'',5''}$ = 10 Hz, H-4″), 3.650 (s, 3H, OCH_3), 3.257 (dt, 1H, OCHHCH$_2$), 2.275 (t, 2H, CH_2COO), 2.104, 2.016, 1.985, and 1.967 (each s, 3H, COCH_3), 0.884 (s, 9H, C(CH_3)$_3$), 0.064 and 0.053 (each s, 3H, SiCH_3); ^{13}C nmr ($CDCl_3$) δ: 174.25 (*C*OOCH$_3$), 170.50, 169.76, 169.69, and 169.63 (*C*OCH$_3$), 138.61, 138.37, 138.19, and 138.07 (benzyl. quat. arom.), 62.44 and 62.13 (C-6 and C-6″), 51.42 (OCH$_3$), 34.09 (*C*H$_2$COO), 26.01 (C(*C*H$_3$)$_3$), 20.49, 20.70 (2 × C) and 20.64 (COCH$_3$), 18.33 (*C*(CH$_3$)$_3$), −4.84 and −5.36 (SiCH$_3$). *Anal.* calcd. for $C_{82}H_{105}O_{25}PSi$: C 63.55, H 6.83; found: C 63.41, H 7.05.

The earlier fractions (R_f 0.41 in hexane – ethyl acetate, 3:2) contained the β-anomer **17** (107 mg, 37%); $[\alpha]_D$ +7.0° (*c* 0.18, chloroform); ^{1}H nmr ($CDCl_3$) δ: 5.446 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz, H-3″), 5.376 (dd, 1H, $J_{4'',5''}$ = 10.0 Hz, H-4″), 3.647 (s, OCH$_3$), 3.322 (dt, 1H, OCHHCH$_2$), 2.264 (t, 2H, CH_2COO), 2.107, 2.076, 1.971, and 1.643 (each s, 3H, COCH$_3$), 0.894 (s, 9H, C(CH_3)$_3$), 0.542 (s, 6H, SiCH_3); ^{13}C nmr ($CDCl_3$) δ: 174.24 (*C*OOCH$_3$), 170.70, 169.90, 169.66, and 169.58 (*C*OCH$_3$), 138.73, 138.66, 137.60, and 137.37 (benzyl quat. arom.), 62.93 and 62.36 (C-6 and C-6″), 51.40 (OCH$_3$), 34.06 (*C*H$_2$COO), 25.94 (C(*C*H$_3$)$_3$), 20.95, 20.76, 20.69, and 20.38 (COCH$_3$), 18.33 (*C*(CH$_3$)$_3$), −5.14 and −5.26 (SiCH$_3$). *Anal.* calcd. for $C_{82}H_{105}O_{25}PSi$: C 63.55, H 6.83; found: C 63.67, H 6.80.

*8-Methoxycarbonyloctyl 3-*O*-[2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranosyl]-2-*O*-benzyl-4,6-*O*-benzylidene-α-D-mannopyranoside (**18**) and 8-methoxycarbonyloctyl 3-*O*-[2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-β-D-mannopyranosyl]-2-*O*-benzyl-4,6-*O*-benzylidene-α-D-mannopyranoside (**19**)*

Reaction of **6** (112 mg, 0.21 mmol) with **14** (339 mg, 0.36 mmol) in the presence of silver trifluoromethanesulfonate and *sym*-collidine, exactly as described for the preparation of **16**, gave a chromatographically homogeneous (R_f 0.23 in hexane – ethyl acetate, 3:2) mixture of **18** and **19**, which could be resolved on a Partisil column using hexane – ethyl acetate 4:1 as eluent. The earlier fractions provided the α-anomer **18** (154 mg, 51%) as a syrup, $[\alpha]_D$ +34.4° (*c* 0.38, chloroform); ^{1}H nmr ($CDCl_3$) δ: 5.575 (s, 1H, C$_6$H$_5$CHOO), 5.356 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz), 5.228 (dd, 1H, $J_{4'',5''}$ = 10.0 Hz, H-4″), 3.650 (s, 3H, OCH_3), 3.325 (dt, 1H, OCHHCH$_2$), 2.272 (t, 1H, CH_2COO), 2.086, 2.025, 1.969, and 1.944 (each s, 3H, COCH_3); ^{13}C nmr ($CDCl_3$) δ: 174.23 (*C*OOCH$_3$), 170.45, 169.76, 169.69, and 169.57 (*C*OCH$_3$), 138.18, 138.01, 137.78, and 137.46 (3 benzyl and benzylidene quat. arom.), 101.63 (C$_6$H$_5$*C*HOO), 61.95 (C-6″), 51.41 (OCH$_3$), 34.07 (*C*H$_2$COO), 20.88, 20.77, 20.67, and 20.59 (COCH$_3$). *Anal.* calcd. for $C_{76}H_{89}O_{25}P$: C 63.68, H 6.26; found: C 63.63, H 6.39.

The later fractions provided the β-anomer **19** (66.3 mg, 22%) as a syrup, $[\alpha]_D$ 0° (*c* 0.89, chloroform); ^{1}H nmr ($CDCl_3$) δ: 5.560 (s, 1H, C$_6$H$_5$CHOO), 5.330 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz, H-3″), 5.291 (dd, 1H, $J_{4'',5''}$ = 10.0 Hz, H-3″), 3.650 (s, OCH_3), 3.308 (dd, $J_{3',4'}$ = 9.5 Hz, H-3′), 2.270 (t, 2H, CH_2COO), 2.083, 2.077, and 1.903 (each s, 3H, COCH_3); ^{13}C nmr ($CDCl_3$) δ: 174.23 (*C*OOCH$_3$), 169.76 (2 × C), 169.63 and 169.36 (*C*OCH$_3$), 137.73 (2 × C), 137.70 and 137.55 (3 benzyl and benzylidene quat. arom.), 100.88 (C$_6$H$_5$*C*HOO), 62.01 (C-6″), 51.41 (OCH$_3$), 34.07 (*C*H$_2$COO), 20.90, 20.82, 20.57, and 20.02 (COCH$_3$). *Anal.* calcd. for $C_{76}H_{89}O_{25}P$: C 63.68, H 6.26; found: C 63.38, H 6.29.

*8-Methoxycarbonyloctyl 6-*O*-[2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-α-D-mannopyranosyl]-2,3,4-tri-*O*-benzyl-α-D-mannopyranoside (**20**) and 8-methoxycarbonyloctyl 6-*O*-[2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-3,4-di-*O*-benzyl-6-*O*-diphenylphosphoryl-β-D-mannopyranosyl]-2,3,4-tri-*O*-benzyl-α-D-mannopyranoside (**21**)*

Reaction of **7** (215 mg, 0.35 mmol) with **14** (554 mg, 0.59 mmol) in the presence of silver trifluoromethanesulfonate and *sym*-collidine, exactly as described for the preparation of **16**, gave a chromatographically homogeneous (R_f = 0.23 in hexane – ethyl acetate, 2:1) mixture of **20** and **21** (418 mg, 79%) as a clear syrup, which could not be chromatographically resolved on either Iatrobeads or Partisil. The ^{1}H nmr spectrum of the mixture showed the ratio of **20**:**21** to be 1:3 based on the relative intensities of the following signals:

The minor isomer (**20**): ^{1}H nmr ($CDCl_3$) δ: 5.466 (dd, 1H, $J_{1'',2''}$ = 1.6 Hz, $J_{2'',3''}$ = 3.2 Hz, H-2″), 5.406 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz, H-3″), 5.304 (dd, 1H, $J_{1',2'}$ = 1.8 Hz, H-1′), 4.945 (d, 1H, H-1″), 4.797 (d, 1H, $J_{1,2}$ = 1.8 Hz, H-1), 3.649 (s, OCH_3), 2.095, 2.053, 1.976, and 1.951 (each s, 3H, COCH_3).

The major isomer (**21**): ^{1}H nmr ($CDCl_3$) δ: 5.531 (dd, 1H, $J_{1'',2''}$ = 1.7 Hz, $J_{2'',3''}$ = 3.2 Hz, H-2″), 5.389 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz, H-3″), 5.312 (dd, 1H, $J_{4'',5''}$ = 10.0 Hz, H-4″), 5.033 (d, 1H, $J_{1',2'}$ = 1.6 Hz, H-1′), 4.769 (d, 1H, H-1″), 3.653 (s, OCH_3), 3.424 (dd, 1H, $J_{2',3'}$ = 2.5 Hz, $J_{3',4'}$ = 9.0 Hz, H-3′), 3.351 (m, 1H, H-5′), 2.095, 2.010, 1.946, and 1.939 (each s, 3H, COCH_3).

*8-Methoxycarbonyloctyl 2,3,4-tri-*O*-acetyl-6-*O*-[3,4-di-*O*-acetyl-2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-6-*O*-diphenylphosphoryl-α-D-mannopyranosyl]-α-D-mannopyranoside (**22**) and 8-methoxycarbonyloctyl 2,3,4-tri-*O*-acetyl-6-*O*-[3,4-di-*O*-acetyl-2-*O*-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl)-6-*O*-diphenylphosphoryl-β-D-mannopyranosyl]-α-D-mannopyranoside (**23**)*

The mixture of **20** and **21** described above (240 mg, 0.16 mmol) was dissolved in 95% ethanol (4 mL) containing 5% palladium on carbon (120 mg) and stirred under a hydrogen atmosphere (1 atm; 1 atm = 101.3 kPa) for 2 days by which time tlc indicated the presence of a major product (~80%, R_f 0.24 in chloroform–methanol, 9:1) and a more polar product (~20%, R_f 0, presumably the monophenyl phosphate). The catalyst was removed by filtration, washed with 95% ethanol (20 mL), and taken to dryness. The residue (122 mg) was then treated with acetic anhydride – pyridine (1:1, 4 mL) for 18 h at room temperature. Excess acetic anhydride was destroyed by addition of cold water, the mixture was partitioned between dichloromethane (20 mL) and water, and the organic layer was washed sequentially with 1 *N* HCl, saturated $NaHCO_3$, and water, then taken to dryness. The residue was purified by chromatography on Iatrobeads using hexane – ethyl acetate (1:2). The early fractions (R_f 0.27 in hexane – ethyl acetate, 1:2) provided the α-anomer **22** (38.3 mg, 19%) as a syrup, $[\alpha]_D$ +44.2° (*c* 0.53, chloroform); ^{1}H nmr ($CDCl_3$) δ: 3.664 (s, OCH_3), 2.306 (t, 2H, CH_2COO), 2.146, 2.112, 2.074, 2.068, 2.025, 2.021, 2.007, 2.003, and 1.992 (each s, 3H, COCH$_3$); ^{13}C nmr ($CDCl_3$) δ: 174.25 (*C*OOCH$_3$), 66.56 (C-6), 62.39 (C-6″), 51.42 (OCH$_3$), 34.07 (*C*H$_2$COO). *Anal.* calcd. for $C_{58}H_{77}O_{30}P$: C 54.20, H 6.04; found: C 54.25, H 6.07.

The later fractions (R_f 0.21 in hexane – ethyl acetate, 1:2) yielded the β-anomer **23** (115 mg, 57%), $[\alpha]_D$ +16.4° (*c* 0.28, chloroform); ^{1}H nmr ($CDCl_3$) δ: 5.413 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz, H-3″), 5.370 (dd, 1H, $J_{4'',5''}$ = 10.0 Hz, H-4″), 5.331 (dd, 1H, $J_{3,4}$ = 9.5 Hz, H-3), 5.173 (dd, 1H, $J_{4,5}$ = 10 Hz, H-4′), 5.122 (dd, 1H, $J_{3',4'}$ = $J_{4',5'}$ = 10 Hz, H-4′), 5.025 (dd, 1H, H-3′), 3.661 (s, OCH_3), 3.408 (dt, 1H, OCHHCH$_2$), 2.300 (t, 2H, J = 7.5 Hz, CH_2COO), 2.148, 2.121, 2.094, 2.080, 2.022, 2.009, 2.004, 1.998, and 1.978 (each s, 3H, COCH$_3$); ^{13}C nmr ($CDCl_3$) δ: 174.25 (*C*OOCH$_3$), 68.83 (C-6), 67.89, 62.06 (C-6″), 51.40 (OCH$_3$), 34.09 (*C*H$_2$COO). *Anal.* calcd. for $C_{58}H_{77}O_{30}P$: C 54.20, H 6.04; found: C 54.34, H 6.06.

*8-Methoxycarbonyloctyl 2-O-[2-O-(2,3,4,6 tetra-O-acetyl-α-D-mannopyranosyl)-3,4-di-O-benzyl-6-O-diphenylphosphoryl-α-D-mannopyranosyl)-3,4-di-O-benzyl-α-D-mannopyranoside (**24**)*

Compound **16** (83 mg, 0.53 mmol) was dissolved in dichloromethane (1.5 mL) and 80% aqueous acetic acid (15 mL) was added. After 24 h, solvent was evaporated and chromatography of the residue using hexane – ethyl acetate (3:2) as eluent provided the title compound (R_f 0.38 in hexane – ethyl acetate, 1:1) as a syrup (65 mg, 85%); $[\alpha]_D$ 37° (*c* 0.18, chloroform); ^{1}H nmr ($CDCl_3$) δ: 5.448 (dd, 1H, $J_{1'',2''}$ = 1.5 Hz, $J_{2'',3''}$ = 3.0 Hz, H-2″), 5.403 (dd, 1H, $J_{3'',4''}$ = 10.0 Hz, H-3″), 5.295 (dd, 1H, $J_{4'',5''}$ = 10.0 Hz, H-4″), 5.185 (d, 1H, $J_{1',2'}$ = 1.6 Hz, H-1′), 4.893 (d, 1H, H-1″), 4.828 (H-1), 3.655 (s, OCH_3), 2.278 (t, 2H, *J* = 7.5 Hz, CH_2COO), 2.140 (4H, $COCH_3$ and br O*H*), 2.023, 2.005, and 1.980 (each s, 3H, $COCH_3$); ^{13}C nmr ($CDCl_3$) δ: 174.21 ($COOCH_3$), 170.47, 169.73 (2 × C), 169.66 ($COCH_3$), 100.17, 99.19, and 98.72 (C-1, C-1′, and C-1″), 71.51 (C-5′, $^3J_{C,P}$ = 8 Hz), 68.24 (C-6′, $^2J_{C,P}$ = 6 Hz), 62.22 and 62.12 (C-6 and C-6″), 51.39 (OCH_3), 34.06 (CH_2COO), 20.89, 20.68 (2 × C), and 20.62 ($COCH_3$); ^{31}P nmr ($CDCl_3$) δ: −11.42. *Anal.* calcd. for $C_{76}H_{91}O_{25}P$: C 63.59, H 6.39; found: C 63.82, H 6.45.

*8-Methoxycarbonyloctyl 2-O-[2-O-(α-D-mannopyranosyl)-α-D-mannopyranosyl 6-disodiumphosphate]-α-D-mannopyranoside (**2**)*

Compound **24** (38.5 mg, 0.27 mmol) was dissolved in 95% ethanol (3 mL) containing 5% palladium on carbon (40 mg) and stirred under one atmosphere of hydrogen for 36 h. The catalyst was removed by filtration and washed with 95% ethanol (20 mL) and the filtrate was evaporated and redissolved in 95% ethanol (3 mL). Hydrogenation (1 atm) over Adams' catalyst (PtO_2, 5 mg) for 3 h provided a product with R_f 0.25 in chloroform–methanol–water (60:35:6), which was devoid of ultraviolet absorption in tlc. Removal of the catalyst by filtration, followed by evaporation and drying for 15 h over phosphorus pentoxide, left a glass that was dissolved in dry methanol containing sodium methoxide and kept at 0°C until all the material was converted to a single new product with R_f 0.37 in isopropanol–water (4:1). After neutralization with IRC-50 (H^+), removal of the resin, and evaporation, the residue was passed through a column of Bio-gel P-2 (200–400 mesh) (50 × 2.5 cm) using 10% ethanol as eluent. The carbohydrate-containing fractions were pooled, concentrated, and passed through a column of Dowex 50-X8 (Na^+) (10 mL) and the eluate was lyophilized to provide a white powder (16.7 mg, 78%); $[\alpha]_D$ +41.5° (*c* 0.27, water); ^{1}H nmr (D_2O) δ: 3.685 (s, OCH_3), 3.553 (m, $OCHHCH_2$), 2.387 (t, 2H, CH_2COO); ^{13}C nmr (D_2O) δ: 178.42 (*C*O), 79.28, 78.80, 73.76, 73.33, 70.86, 70.75, 70.61, 70.19, 68.70 (OCH_2CH_2), 67.48, 67.38, 66.69, 61.57, and 61.35 (C-6 and C-6″), 52.57 (OCH_3), 34.22 (CH_2COO), 29.04, 28.75, 28.69, 28.63, 25.82, 24.79. *Anal.* calcd. for $C_{28}H_{49}O_{21}Na_2P\cdot 2H_2O$: C 40.29, H 6.40; found: C 39.89, H 6.18.

*8-Methoxycarbonyloctyl 3-O-[2-O-(α-D-mannopyranosyl)-α-D-mannopyranosyl 6-disodiumphosphate]-α-D-mannopyranoside (**3**)*

Compound **18** (50.4 mg, 0.35 mmol) was deprotected as described for the preparation of **2**, using 5% palladium on carbon (50 mg) for 2 days followed by Adams' catalyst (5 mg) for 3 h. After deacylation at 0°C, Bio-gel P-2 chromatography, and Dowex 50-X8 (Na^+) treatment and lyophilization, the product was obtained as a white powder (22.8 mg, 81.2%); $[\alpha]_D$ +60.6° (*c* 0.17, water); R_f 0.39 (isopropanol–water, 4:1); ^{1}H nmr (D_2O) δ: 3.687 (s, OCH_3); 3.530 (m, 1H, $OCHHCH_2$), 2.390 (t, 2H, CH_2COO); ^{13}C nmr (D_2O) δ: 177.44 (*C*O), 79.82, 78.44, 73.37, 72.84, 70.32, 70.15, 69.94, 69.57, 69.14 (OCH_2CH_2), 66.98, 66.58, 65.94, 63.40, 61.09, and 60.94 (C-6 and C-6″), 52.14 (OCH_3), 33.25 (CH_2COO), 28.04, 27.80, 27.73, 27.68, 24.83, 23.82. *Anal.* calcd. for $C_{28}H_{49}O_{21}Na_2P\cdot 2H_2O$: C 40.29, H 6.40; found: C 39.94, H 6.26.

*8-Methoxycarbonyloctyl 6-O-[2-O-(α-D-mannopyranosyl) 6-disodiumphosphate]-α-D-mannopyranoside (**4**)*

Compound **22** (35.4 mg, 0.028 mmol) was deprotected as described for the preparation of **2** but using only Adams' catalyst (8 mg) and sodium methoxide in methanol. The product was isolated as white powder (17.8 mg, 81%) after BioGel P-2 chromatography and ion exchange; R_f 0.41 in isopropanol–water (4:1); $[\alpha]_D$ +53.2° (*c* 0.19, water); ^{1}H nmr (D_2O) δ: 3.688 (s, OCH_3), 3.553 (m, $OCHHCH_2$), 2.393 (t, 2H, CH_2COO); ^{13}C nmr (D_2O) δ: 177.98 (*C*O), 78.65, 73.32, 71.15, 71.02, 70.33, 70.18 (2 × C), 70.10, 68.12 (OCH_2CH_2), 67.07, 66.54, 66.41, 66.06 (C-6), 61.19 (C-6″), 52.15 (OCH_3), 33.80 (CH_2COO), 28.50, 28.27, 28.25, 28.19, 25.35, 24.37. *Anal.* calcd. for $C_{28}H_{49}O_{21}Na_2P\cdot H_2O$: C 41.18, H 6.30; found: C 41.15, H 6.15.

Received March 4, 1986

TEODORO S. KAUFMAN, MIRTA P. MISCHNE, MANUEL GONZALEZ-SIERRA, and EDMUNDO A. RUVEDA. Can. J. Chem. **64**, 2331 (1986).

On the basis of the effects of the hydroxyl group on the ^{13}C nuclear magnetic resonance chemical shifts of the olefinic carbons, a new parameter was defined and a new rule was proposed for the assignment of the stereochemistry of secondary six-membered cyclic allylic alcohols.

TEODORO S. KAUFMAN, MIRTA P. MISCHNE, MANUEL GONZALEZ-SIERRA et EDMUNDO A. RUVEDA. Can. J. Chem. **64**, 2331 (1986).

En se basant sur les effets du groupement hydroxyle sur les déplacements chimiques des carbones oléfiniques, en rmn du ^{13}C, on a défini un nouveau paramètre et on propose une nouvelle règle pour attribuer la stéréochimie des alcools allyliques secondaires contenus dans des cycles à six chaînons.

[Traduit par la revue]

In 1979, Schroepfer and co-workers (1) reported that the effect of the introduction of an allylic hydroxyl substituent at C-7 or C-15 on the chemical shifts of the olefinic carbons of $\Delta^{8(14)}$ sterols, relative to the values observed in the parent sterol, is opposite to that observed for the olefinic carbon atoms of acyclic allylic alcohols. Later, Eggert and Djerassi (2), as a result of the analysis of some representative allylic hydroxyl substituted steroids, suggested that the variation of the shifts on the olefinic carbons is related to the conformational class (orientation) of the hydroxyl group as defined in ref. 3, rather than to the acyclic or cyclic structure of the allylic alcohol. They observed that when the hydroxyl group is at an antiperiplanar position, the shifts for the β carbons are larger than those for the γ carbon atoms; a similar effect is observed in acyclic allylic alcohols. However, when the hydroxyl groups are at synclinal or anticlinal positions, the effect is the opposite, that is, larger for the γ carbons than for the β, and, when the oxygenated substituent is at a synperiplanar position, both sp^2 carbons suffer the same downfield shifts.

The application of these simple rules allowed us to predict, by analyzing the ^{13}C nmr reported data (4), that the stereochemistry of the hydroxyl group at C-6 of two natural diterpenes related to grindelic acid (**1***a*) was erroneously assigned (5). In fact, we were able to confirm our predictions by analyzing the ^{13}C nmr spectra of model compounds and by the stereoselective synthesis of both epimers (**1***b* and **1***c*) (6).

To confirm and extend these observations, we analyzed several six-membered allylic alcohols of the diterpene family. We observed the expected shifts of the β and γ sp^2 carbons when the hydroxyl groups are at anticlinal (**2***b* and **3***b*) and antiperiplanar positions (**3***c*). However, we detected deshielding effects for the β carbons and upfield shifts for the γ carbon atoms in those allylic alcohols with hydroxyl groups at synperiplanar positions and carrying hydrogens at the γ carbon atoms (**2***c* and **4***b*) (Table 1).

As we have shown above, the Eggert and Djerassi rules are useful to determine the stereochemistry of allylic alcohols, especially for epimeric pairs. There are, however, a few restrictions on their general use. One of the epimers must always belong to a periplanar conformational class. There are some difficulties whenever there is a discrepancy between the value of the angle that defines the conformational class and that which

is actually responsible for the chemical shift variation of the sp^2 carbons. In every case, the ^{13}C nmr data of the parent hydrocarbon are needed.

As an extension of these rules, and to overcome some of the difficulties mentioned above, we propose a new parameter: Δδ(sp^2), defined for each allylic alcohol as the difference between the chemical shifts of the sp^2 carbons, that is: $\Delta\delta(sp^2) = \delta_{\gamma sp^2C} - \delta_{\beta sp^2C}$.

The correlation[1] of the pseudoaxial vs. pseudoequatorial allylic alcohol parameters allowed us to propose a new empirical rule stating, for any epimeric pair, that the larger Δδ(sp^2) value corresponds to the allylic alcohol with a pseudoaxial hydroxyl group.

In addition to the advantage of using just the ^{13}C nmr data of both epimeric alcohols, generally available by the reduction of the corresponding carbonyl compounds, our proposition establishes unambiguously the pseudoequatorial or pseudoaxial orientation of alcohols such as **5***b* and **5***c*, which, being both anticlinal, can not be solved by using the Eggert and Djerassi rules. The Δδ(sp^2) values are, however, 13.1 and 13.8 and, according to our extension, the hydroxyl group of **5***c* ought to be pseudoaxial (Table 2), as is actually the case.

The precise reason for the different Δδ(sp^2) values is not clear; however, it most probably results from the difference in the through-space effect of the oxygen atom on the resonances of the olefinic carbons, according to the position of the hydroxyl group (14).

[1]The Δδ(sp^2) values for the pseudoaxial allylic alcohols vs. the Δδ(sp^2) for the pseudoequatorial ones, by least-squares analysis, show a linear correlation with a slope of 0.882 and a constant term of 4.94 ($n = 13$; $r = 0.993$; $p < 0.001$).

Depending on molybdenum, phenol, and acid concentrations, and time and the method of solution preparation, molybdenum and phenol can react in several ways. In 96% sulphuric acid Mo(VI) can be reduced to Mo(V) by adding solid phenol to the solution. In other cases molybdenum and phenol form stable or unstable complexes which can be in equilibrium with each other. For excess phenol the recorded spectra show two bands at around 600 and 423 nm; the first one, decreasing with time, is ascribed to the formation of an unstable complex of phenol and Mo(VI). At approximately equal concentrations of molybdenum and phenol the band at 423 nm does not appear, but two time-dependent absorption maxima are formed at 600 and 470 nm with a well defined isosbestic point at 505 nm. The complex is unstable because of the sulphonation of phenol. In 80% sulphuric acid molybdenum and phenol form a stable 1:1 complex which absorbs at 480 nm; its pK_s value is 1.44 ± 0.03 at room temperature.

DRAGAN A. MARKOVIĆ, DRAGAN S. VESELINOVIĆ et MIRJANA V. OBRADOVIĆ. Can. J. Chem. **64**, 2334 (1986).

Le molybdène et le phénol réagissent de plusieurs façons différentes suivant soit les concentrations de molybdène, de phénol et d'acide, soit le temps de la réaction ou la méthode utilisée pour préparer la solution. Dans de l'acide sulfurique à 96%, le Mo(VI) peut être réduit en Mo(V) par l'addition de phénol solide à la solution. Dans d'autres cas, le molybdène et le phénol forment des complexes qui peuvent être stables ou instables et qui peuvent être en équilibre les uns avec les autres. Dans les cas où le phénol est en excès, le spectre du mélange présente deux bandes autour de 600 et de 423 nm; la première, dont l'intensité diminue avec le temps, est attribuée à la formation d'un complexe instable entre le phénol et le Mo(VI). A des concentrations approximativement égales de molybdène et de phénol, la bande à 423 nm n'apparaît pas; toutefois, il se forme deux bandes (à 600 et à 470 nm) dont l'absorption varie avec le temps ainsi qu'un point isosbestique bien défini à 505 nm. La raison de l'instabilité du complexe tient son origine dans la sulfonation du phénol. Dans de l'acide sulfurique à 80%, le molybdène et le phénol forment un complexe 1:1 qui est stable et qui absorbe à 480 nm; à la température ambiante, la valeur de son pK_s est égale à 1,44 ± 0,03.

Introduction

In concentrated aqueous solutions of strong mineral acids many metals, such as Mo, Ti, Nb, Ta, V, W, Sb, and U, form coloured complexes with hydroxybenzenes (1–13). The absorption of these complexes in the visible region generally decreases with decreasing acid concentration so that colour is rarely observed at an acidity corresponding to 60% sulphuric acid. Their stability constant values are relatively low with pK values for most of the complexes investigated vary between 1 and 5. The most commonly used ligand is 1,4-dihydroxybenzene, but 1,2-, 1,3-, 1,2,3-, and 1,3,5-, di- and trihydroxybenzenes have also been studied.

Spectrophotometric investigation of the reaction of titanium with phenol in 89% sulphuric acid has shown the formation of an unstable complex with an absorbance maximum at 430 nm (14). Instability of the complex has been ascribed to the sulphonation of phenol. A strong dependence of colour intensity on sulphuric acid concentration was observed with molybdenum complexes. For less than 80% sulphuric acid, the colour of the solution fades appreciably, and is completely gone at 60% H_2SO_4. In 90% sulphuric acid the composition of the complex changes with the ligand. Thus, molybdenum forms complexes in the ratio 2:3, 1:2, and 1:4 with 1,2,3-trihydroxybenzene, 1,4-dihydroxybenzene, and 1,2-dihydroxybenzene, respectively (6). The possibility of formation of hydroxybenzenes and metal complexes in other strong mineral acids has also been pointed out (6, 11).

Coloured complexes of metals in concentrated aqueous sulphuric acid solutions can be used for analytical purposes (1, 2, 5, 6). It should also be pointed out that the formation of such complexes is almost certain evidence for oxygen protonation of phenols (14). These complexes can therefore be used as "indicators" for recognizing the protonation of benzene derivatives with hydroxy- or alkoxy-groups in strongly acidic media. On the other hand, the state of metal ions and catalytic effect of metals in strong acidic media has not yet been well defined. The objective of this work is to obtain more information on reactions occurring in the investigated systems.

Experimental

Sulphuric acid solutions of required concentration were prepared by diluting 95–97% H_2SO_4 (d = 1.84) with distilled water. The concentration of these solutions was determined by pH-metric titration, using standard NaOH solution, or by density measurements with a pycnometer. Sodium molybdate solution in 96% sulphuric acid was standardized polarographically (15, 16) using the standard addition method (17). All chemicals used were pure analytical reagent grade.

Spectrophotometric measurements were performed with Specord UV-VIS Carl Zeiss, Unicam SP-600, and Cary 17 D spectrophotometers, at room temperature. Sulphuric acid of the appropriate concentration was used as a blank solution for spectrophotometric work. All measurements were performed using 1-cm quartz cells.

Results and discussion

Molybdenum(VI) reactions with phenol in aqueous sulphuric acid solutions

In the visible region the spectra of phenol and sodium molybdate solution in sulphuric acid depends on both acid

[1]Reaction of hydroxybenzenes in strongly acidic media. VIII. Part VII is ref. 11.

[2]Revision received July 16, 1986.

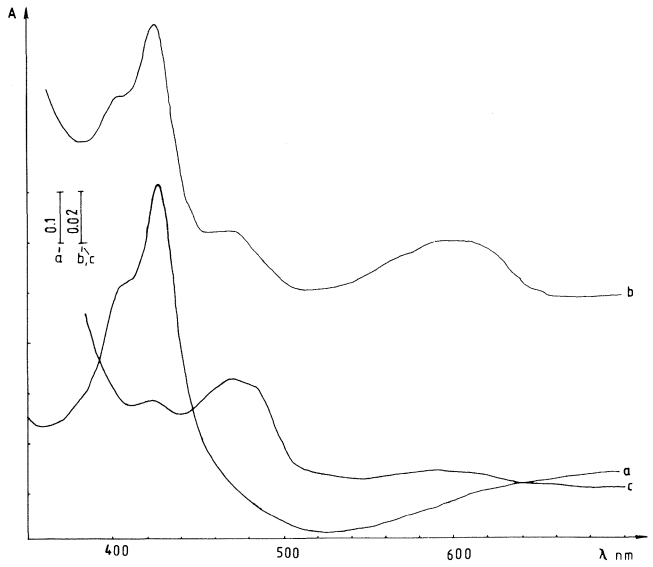

FIG. 1. Absorption spectra recorded in 96% H_2SO_4: *a*, 5.5×10^{-3} mol/dm^3 Na_2MoO_4 and 6×10^{-4} mol/dm^3 phenol 100 min after phenol addition; *b*, 1.20×10^{-2} mol/dm^3 Na_2MoO_4 and 3.50×10^{-2} mol/dm^3 phenol 80 min after preparation of solution; *c*, 2.70×10^{-2} mol/dm^3 Na_2MoO_4 and 2.20×10^{-2} mol/dm^3 phenol 60 min after preparation of solution. The absorbance unit is 0.1 for *a* and 0.02 for *b* and *c*.

concentration and the method of solution preparation. Figure 1 (*a*) shows the spectrum of Na_2MoO_4 solution (5.5×10^{-3} mol/dm^3) in 96% H_2SO_4 after adding sufficient solid phenol for a concentration of 6×10^{-4} mol/dm^3. The spectrum has an absorption band at about 425 nm. Except for a slight absorbance increase in the region 500–700 nm no change with time was observed. Immediately after adding phenol, the molybdate solution becomes dark blue.

In all other cases the form of the spectra depends on the time of contact between acid and phenol, i.e., on the time interval between the dissolution of phenol and its mixing with molybdate solution. Addition of phenol solution, after 15–20 min of standing, to a solution of molybdate in 96% sulphuric acid does not produce absorption in the visible region of the spectrum. A mixture of freshly prepared phenol and molybdate gives a green-blue solution whose spectral characteristics depend on time and reactant concentration. The spectra obtained for a 3:1 phenol to molybdate ratio have two maxima (Fig. 1 *b*). The first, at about 600 nm, decreases with time; the second, at 425 nm, is independent of time. The shorter wavelength maximum is similar in form and position to the maximum in the spectrum of a solution prepared by addition of solid phenol, but its absorbance is 7 to 8 times lower. About 10 min after mixing of the reactants a shoulder appears at the bottom of the shorter wavelength maximum, at 470 nm, which becomes more explicit with time. The spectra become stable within an hour and further changes are very slow.

The spectrum shown in Fig. 1 *c* is obtained at approximately equal molybdenum and phenol concentrations. The maximum at 425 nm, present in the previous cases, does not appear, but is replaced by a shoulder at the same wavelength. Two time-dependent absorption bands are formed, the first having a maximum at about 600 nm and the second a maximum at 480 nm, with a well-defined isosbestic point at 505 nm. The longer wavelength band disappears 2 h after mixing of the reactants, whereas the shorter one increases with time. Spectra

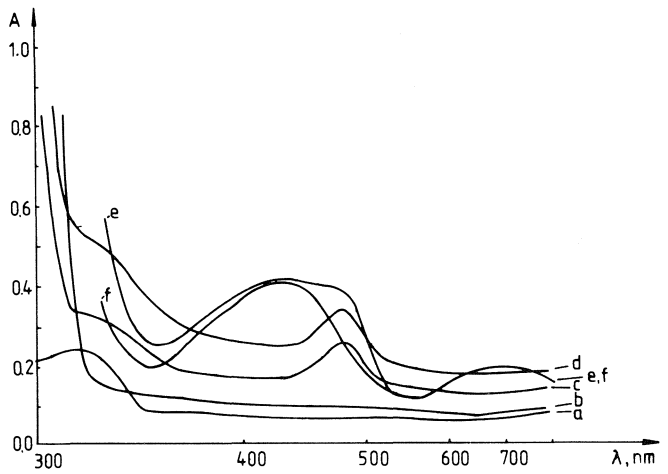

FIG. 2. Absorption spectra recorded in 80% H_2SO_4: *a*, 2.5×10^{-3} mol/dm^3 Na_2MoO_4; *b*, 3.500×10^{-1} mol/dm^3 phenol; *c*, 2.5×10^{-3} mol/dm^3 Na_2MoO_4 and 5.00×10^{-2} mol/dm^3 phenol; *d*, same as *c*, 24 h after preparation of solution; *e*, 2.5×10^{-3} mol/dm^3 Na_2MoO_4 and phenol in the presence of mercury (phenol added to solution 20 min after mercury); *f*, 2.5×10^{-3} mol/dm^3 Na_2MoO_4 24 h in contact with mercury (no change after phenol addition).

of mixtures of freshly prepared phenol and molybdenum solutions in 80% sulphuric acid have only one absorption band at around 480 nm (Fig. 2 *c* and *d*). One absorption band at this wavelength also appears in 96% acid (Fig. 1, *b* and *c*). The position of this band does not change with time, but total absorption in the spectral region from 350–700 nm increases and becomes constant after 4 h (Fig. 2 *d*). The band at 480 nm is assigned to a complex formed between phenol and molybdenum.

Spectra of the system in 71% and 80% acid are similar. In 60% sulphuric acid no colour was observed after mixing of the reactants. Similar results were observed with the other hydroxybenzenes (6).

It is known that the instability of phenol solutions in sulphuric acid is mainly due to sulphonation of phenol (14, 18, 19, 21). However, in spite of the prominent effect of sulphonation on the observed spectral changes in molybdenum–phenol solutions, the effect of a possible change of molybdenum oxidation state on the observed spectra could not be excluded.

In sulphuric acid solutions Mo(VI) can be reduced to Mo(V) by several reducing agents, such as ascorbic acid or 1,4-dihydroxybenzene (15), but we found that reduction can also occur in the presence of elemental mercury (16), whereby solutions take on the blue–green colour characteristic of Mo(V). The presence of Mo(V) has also been demonstrated in the reaction with potassium thiocyanate. In addition to the blue–green solution a gray–white precipitate appeared in molybdate solutions containing mercury and was identified as Hg_2SO_4. This demonstrates that mercury participated in the reaction.

Upon long standing of molybdenum solutions with elemental mercury (24 h or more), further addition of phenol solution did not produce any change in existing Mo(V) bands (Fig. 2*f*). One shoulder appears at 480 nm (Fig. 2*e*) when freshly prepared phenol solution was added to a Mo(VI) solution that only had a short contact time with mercury. This shoulder is produced by a complex between unreduced Mo(VI) and phenol. On this basis it can be concluded that Mo(V) does not form a complex with phenol in sulphuric acid solutions.

The spectra in Figs. 1 *a*, *b* and 2 *f* show absorption maxima at around 420 nm. Since Mo(VI) does not absorb in this region (Fig. 2*a*) and since the spectra in Fig. 1*a* do not contain absorption bands which could be ascribed to a molybdenum–phenol complex, it follows that addition of solid phenol to sodium molybdate solution in 96% sulphuric acid causes reduction of Mo(VI) to Mo(V), as manifested by an intense blue colour in the solution. Metal reduction is possible, since oxidation of phenol in sulphuric acid solutions, in the presence of metals, has been observed (16, 20).

The spectrum in Fig. 1*b* can be explained by postulating that with freshly dissolved phenol one part of the molybdenum is reduced to Mo(V) (spectral band at 425 nm). The spectra indicate that absorption at 425 nm is due to Mo(V). The other part of the metal forms an unstable complex with the as yet unsulphonated phenol which absorbs at around 600 nm.

At equal molybdenum and phenol concentrations in 96% acid the absorption band ascribed to Mo(V) does not appear at 420 nm (Fig. 1*c*). The shoulder at this wavelength is due to the presence of a small amount of reduced metal. The absorption band at 600 nm, which decreases with time, is assigned to an unstable complex of phenol and Mo(VI). This complex is slowly converted to a more stable form, which absorbs at about 480 nm, as is evident from the appearance of a shoulder at 480 nm and an isosbestic point at 505 nm. Molybdenum(VI) does not react with phenol which has been sulphonated by standing in 96% acid for some time. This can be explained by the formation of an intramolecular hydrogen bond between sulpho- and hydroxyl groups in ortho-substituted phenols which prevents the formation of complex (14). Cerfontain *et al.* have provided strong support for the presence of such bonds in phenol – sulphuric acid solutions (21).

Complexation between metals and hydroxybenzenes in aqueous solutions occurs by substitution of one or more hydrogen atoms of the hydroxyl groups by metal ions (6). According to some authors the bonding between metals and hydroxybenzenes in strongly acidic media is due to the presence of protonated OH groups (14). This is based on the fact that coloured complexes with metals are formed only by those benzene derivatives which have substituent groups with oxygen that are capable of being protonated in acid solution. For this reason it seems most probable that metal to ligand bonding can be ascribed to the proton binding oxygen from metal oxy-ions and protonated hydroxyl (alcoxy) groups. This is supported by the recent conclusion that phenol and anisol protonation takes place on oxygen, and at acidities of the medium that are optimal for complexation with metals (14, 21).

Sulphonation of phenol in the *ortho* positions can impede formation or affect the stability of the resulting complex by blocking hydrogen bonding to metal oxy-ions. This might also explain the absence of complexation upon addition of a sulphonated phenol to a molybdate solution, as well as the disappearance of the absorption band of the complex at 600 nm. In our opinion this band is due to the presence of an unsulphonated complex.

Spectral changes in sulphuric acid solutions of lower concentration, 70% and 80%, can also be ascribed to sulphonation. These changes are considerably slower at lower acidities because sulphonation is slower. Lower absorbance values at lower acid concentrations can be attributed to a smaller degree of phenol protonation. The complete absence of absorption between 350 and 700 nm in 60% acid supports the conclusion that complexation is possible only in the presence of protonated phenol. Judging by the pK_{BH^+} value for phenol of −6.4 (21), the concentration of protonated phenol in 60% sulphuric acid is negligible.

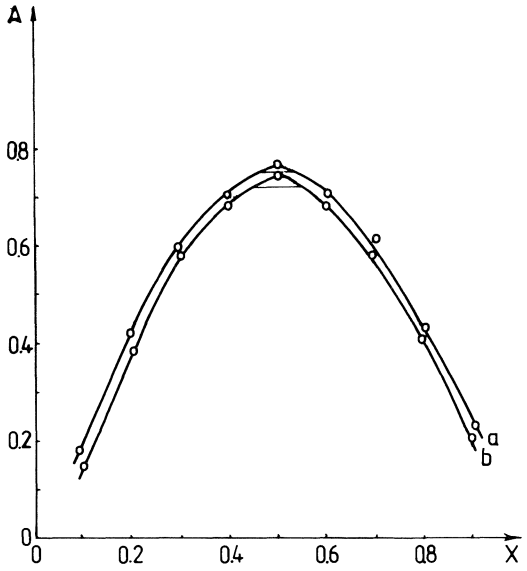

FIG. 3. Job's curves for Mo(VI)–phenol complex in 80% H_2SO_4: *a*, at 490 nm; *b*, at 530 nm; $c_{Mo} + c_{Ph} = 7.00 \times 10^{-2}$ mol/dm^3.

Determination of the composition and stability constant of the Mo(VI)–phenol complex

To investigate the composition and stability constant of a complex it is necessary for the complex to achieve stability with time, to prove the validity of Beer's law, and to determine a molar absorption coefficient. Due to the strong time dependence of complex formation in 96% acid, and due to the dependence on the method of preparation of the solution, it was not possible to satisfy all these conditions. However, an attempt to apply Job's method (22) gave an irregular curve with a maximum at a concentration ratio corresponding to a complex of 1:1 composition.

For the complex in 80% acid a molar absorption coefficient could be determined, and the validity of Beer's law tested, 24 h after mixing the reactants, i.e. after stabilisation of the system. Beer's law was tested at 490 and 530 nm at a constant phenol concentration ($c_{Ph} = 0.15$ mol/dm^3) and over a molybdenum concentration of 0.001 to 0.004 mol/dm^3. Under these conditions Beer's law was found to hold. Assuming that the concentration of complex is equal to that of the molybdenum present, the value obtained for the molar absorption coefficient was 52 cm^{-1} mol^{-1} dm^3 at 490 nm. The composition of the complex in 80% acid was investigated by Job's and Harvey–Manning's method (22); the results, shown in Figs. 3 and 4, indicate formation of a 1:1 complex. Figure 3 shows the Job's curve obtained by using freshly prepared phenol solutions at a total reactant concentration of 0.07 mol/dm^3. Absorbance measurements were performed at 490 nm 24 h after mixing the reactants.

Using Harvey–Manning's method two series of solutions were prepared. In the first the molybdenum concentration was held constant at 0.0025 mol/dm^3 and that of phenol varied from 0.0125 to 0.3000 mol/dm^3. In the second series the concentrations were reversed, i.e., the molybdenum concentration was varied from 0.0012 to 0.0300 mol/dm^3 at a constant phenol concentration of 0.0025 mol/dm^3. The straight lines in Fig. 4 were obtained by plotting the absorbance of the solutions

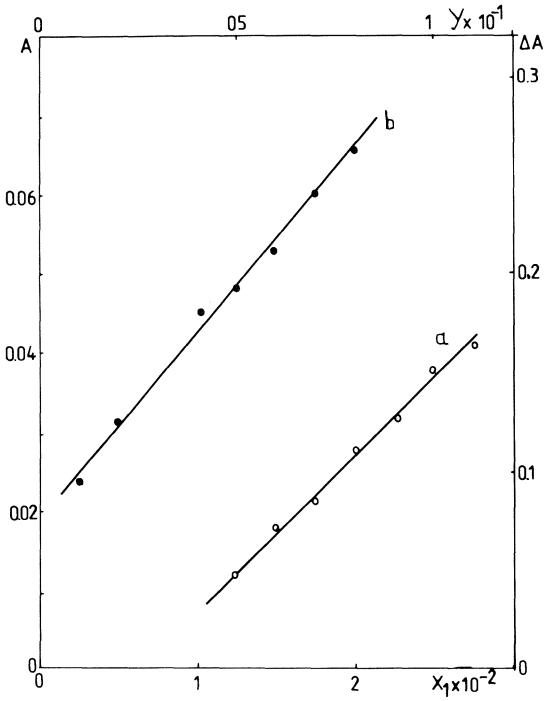

FIG. 4. Harvey–Manning's method for Mo(VI)–phenol complex in 80% H_2SO_4: *a*, 2.5×10^{-3} mol/dm^3 phenol; $c_{Mo} = X_1$; *b*, 2.5×10^{-3} mol/dm^3 Na_2MoO_4, $c_{Ph} = Y$, $\Delta A = A_{complex} - A_{phenol}$.

as a function of concentration. The metal-to-phenol ratio of the complex (1:1) was obtained from the slopes of these linear plots.

The stability constant of the complex formed in 80% sulphuric acid was determined by means of the equation $K_s = [ML]/[M][L]$, where [M] and [L] represent metal and ligand concentrations. The equilibrium concentration of the complex [ML] was calculated from corresponding absorbance values using Beer's law. Equilibrium concentrations of the metal and ligand were obtained by deducing complex concentration value from known initial reactant concentrations. The log stability constant value obtained this way was -1.44 ± 0.03 at room temperature.

The absorption band in the 480 nm region appears in all solutions with different acid concentrations, and is assigned to the 1:1 complex of unchanged composition. The total absorbance of the system, which depends on the time of contact between phenol and acid, actually increases after mixing phenol and molybdenum solutions in 80% and 71% acid. Increased nonselective absorption was also observed between molybdenum and 1,4-dihydroxybenzene complexes (15). A precipitate formed after a long standing of the solutions (several weeks or months). Different reactions (18, 19) may lead to precipitation and may increase nonselective absorption in the investigated system. These slow reactions and their products will be the subject of further studies.

The regioselective alkylation of 1,4,5-trihydroxy-9,10-anthraquinone via reaction of its leuco compound is significant for the synthesis of anthracyclinones. In the presence of pyrrolidine in toluene solution, the leuco compound **3** selectively forms the 4-pyrrolidino enamine **11**, which undergoes deamination to give 1,5-dihydroxy-9,10-anthraquinone. If an aldehyde is added, however, the enamine is alkylated, eventually yielding the 3-alkyl-1,4,5-trihydroxy-9,10-anthraquinone. Both of the above reactions of **3** give high yields with 100% regioselectivity. The enamine intermediate **11** has been trapped by oxidation to 4-pyrrolidino-1,5-dihydroxy-9,10-anthraquinone, which, after reduction, undergoes the same reactions as **3** giving either the alkylation or deamination product. The selective formation of **11** is explained in terms of an enhancement of carbonyl group electrophilicity by a relay of hydrogen bonds.

A. Douglas Broadbent, Wilfred Meschwitz et John M. Stewart. Can. J. Chem. **64**, 2338 (1986).

L'alkylation régiosélective de la trihydroxy-1,4,5 anthraquinone-9,10, par le biais de la réaction de son composé leuco, est une voie utile pour la synthèse des anthracyclinones. En présence de pyrrolidine, dans une solution dans le toluène, le composé leuco **3** conduit sélectivement à la pyrrolidino-4 ènamine **11** qui subit une déamination pour conduire à la dihydroxy-1,5 anthraquinone-9,10. Toutefois, si on ajoute un aldéhyde, l'aldéhyde est alkylé et il conduit éventuellement à l'alkyl-3 trihydroxy-1,4,5 anthraquinone-9,10. Les deux réactions du composé **3** mentionnées plus haut se produisent avec des rendements élevés et avec 100% de stéréosélectivité. On a piégé l'ènamine intermédiaire **11** grâce à une oxydation conduisant à la pyrrolidino-4 dihydroxy-1,5 anthraquinone-9,10 qui, après réduction, subit les mêmes réactions que le composé **3** en conduisant soit à une alkylation ou à un produit de déamination. On explique la formation sélective du composé **11** en fonction d'une augmentation du caractère électrophile du groupement carbonyle par un relais de liaisons hydrogènes.

[Traduit par la revue]

Introduction

1,4,5-Trihydroxy-9,10-anthraquinone **1** is an obvious starting material for the synthesis of anthracyclinones such as adriamycinone and daunomycinone **2** but necessitates the use of regioselective methods of alkylation because of the dissymmetry of such molecules.

Reduction of **1** with tin and HCl in acetic acid (1) gives the leuco compound **3** whose ^{1}Hmr and ir spectra show it to be a keto tautomer of the anthrahydroquinone (2). Recent publications (3–5) have described crossed aldol reactions of **3** with aldehydes, giving 2- or 3-alkyl derivatives of **1** with high regioselectivity. In hot aqueous basic solution, the reaction of **3** with aldehydes, based on the procedure devised by Marschalk *et al.* (6), gives the 2-alkyl derivative of **1** (e.g. **4**) in poor to moderate yields, but with 100% regioselectivity. In hot isopropanol with added piperidinium acetate, alkylation conditions developed by Lewis (7), the 3-alkyl isomer (e.g. **5**) is generated from the same reactants in moderate yield, but the product is contaminated with 10–20% of the 2-alkyl isomer.

We have confirmed the recent report (3) that quinizarins **6** and **1** can be dehydroxylated by reduction to their leuco compounds (**9** and **3** respectively) and by subsequent reaction with pyrrolidine in refluxing toluene to give the 1-hydroxy and 1,5-dihydroxy derivatives (**7** and **8** respectively).

This paper describes our results and conclusions on the origin of the regioselectivity of the above crossed aldol and deoxygenation reactions of **3** in the presence of cyclic secondary amines such as pyrrolidine. In both processes, product formation is controlled by the selective initial reaction of the cyclic amine at the 4-carbonyl group of **3**.

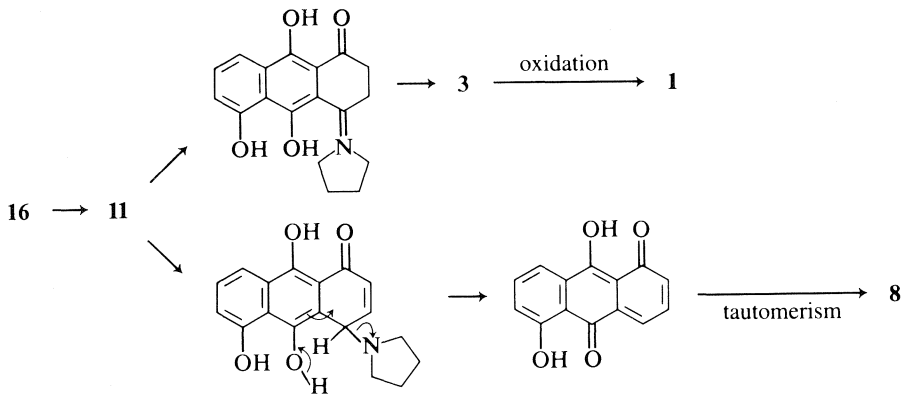


SCHEME 1

Results

Reaction of the leuco compounds **3** or **9** with pyrrolidine in refluxing toluene results in deoxygenation, giving **8** or **7**, respectively. Our study of this reaction established that the product is generated in excellent yield (>90% after chromatographic purification), that azeotropic removal of water is not necessary (3, 8), and that reaction of **3** is completely regioselective, giving only **8** and no 1,8-derivative **10**. Addition of sufficient acetic acid to just neutralize the pyrrolidine solution increased the reaction rate but decreased the selectivity, giving **8** containing a small proportion of **10** (<10%).

The mechanism suggested for this regioselective deoxygenation reaction (8), involving tautomerism of an enamine intermediate **11**, led us to consider that such an intermediate might be responsible for the regioselectivity of both the 3-alkylation of **3** with aldehydes, using piperidinium acetate, as well as its deoxygenation reaction with pyrrolidine, although the same authors have rejected this idea (3). The proposal was supported by our observation that reaction of **3**, in refluxing isopropanol with added piperidium acetate but no aldehyde, resulted in **8** with a little **10**, exactly as for the reaction in toluene with equimolar quantities of pyrrolidine and acetic acid.

Our hypothesis of a common reaction intermediate was confirmed by reactions of **3** with pyrrolidine in boiling toluene, with and without added propanal. In the absence of propanal, **3** reacted smoothly to give a 93% yield of only **8**. An identical reaction with excess propanal gave the 3-propyl derivative **5** in 82% yield. Both these reactions are quantitative, if based on starting material converted. They both proceeded more rapidly, but with lower selectivity, if the pyrrolidine was neutralized with an equimolar quantity of acetic acid.

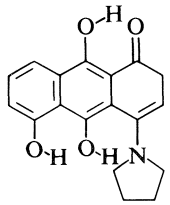
Although the isomeric 2- and 3-propyl derivatives could not be separated by tlc, the ^{1}Hmr spectra of **4** and **5** showed no cross-contamination with the other isomer, thus confirming the high regioselectivity of the reactions of propanal with **3**. These isomers are readily distinguished by their characteristic pattern of hydroxyl proton resonances. Published ^{1}Hmr spectra indicate that introduction of a 2-alkyl substituent into **1** causes a downfield shift of 0.45 ± 0.02 ppm of the 1-hydroxyl proton resonance, whereas a 3-alkyl substituent gives a downfield shift of 0.46 ± 0.03 ppm of the 4-hydroxyl proton resonance. The chemical shifts of the hydroxyl protons more distant from the alkyl substituent remain very close to the values of **1** (3, 5, 9, 10).

Since the previous distinction of **4** and **5** involved isolation and identification of extremely low yields of chemical degradation products (3), we examined the possibility of a distinction via their leuco compounds **12** and **13**. These were found to have almost identical ^{1}Hmr spectra, but the products of their reaction with pyrrolidine in boiling toluene were quite different. The leuco compound **12** underwent deoxygenation to give 1,5-dihydroxy-2-propyl-9,10-anthraquinone **14**, whereas **13** reacted very slowly to produce a low yield of 1,8-dihydroxy-2-propyl-9,10-anthraquinone **15**. Chromatographic analysis and ^{1}Hmr spectra indicated that both these deoxygenation reactions were highly regioselective. Unfortunately, the low yields of **14** and **15**, caused by the difficulties in separating these products from **4** and **5** respectively, and the very slow reaction of **13**, did not provide the simple, efficient distinction between **4** and **5** that had been anticipated.

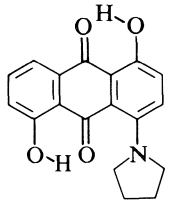
Reaction of **3** with pyrrolidine in toluene at room temperature, and subsequent air oxidation, gave about 50% conversion to 1,5-dihydroxy-4-pyrrolidino-9,10-anthraquinone **16**, with an overall 21% yield of the pure compound. The structure was assigned on the basis of the ir and ^{1}Hmr spectra and the fact that reduction by tin and concentrated HCl in acetic acid gave efficient conversion to about equal amounts of **1** from hydrolysis of **11**, and of **8** by deamination. These reactions are shown in Scheme 1. Treatment of **16** with activated Raney nickel in boiling toluene gave a 95% yield of **8**, whereas an identical reaction in the presence of propanal gave 36% conversion to **5**, thus supporting the proposal that the regioselectivity of the 3-alkylation and the deoxygenation reactions of **3** are the result of the regioselective formation of a 4-pyrrolidino substituion product of **3**, such as **11**, in the initial stage of both reactions. Attempts to improve the yield of **5** from the reaction of **16**, at various temperatures, were unsuccessful. Propanal had to be added as soon as deoxygenation of **11** became evident, which deactivated the Raney nickel and limited further formation of **11**.

In the absence of an aldehyde, the reaction may proceed by tautomerism of **11** followed by retro-Michael elimination of pyrrolidine to give **8** via the 1,9-dione tautomer (3, 8). An added aldehyde would react directly with the enamine **11** to give an iminium ion adduct, which, after hydrolysis in the moist toluene, would generate **5** by retro-Michael elimination of hydroxide ion from the 3-(1-hydroxypropyl) side chain. The isolation, identification, and subsequent reactions of **16** provide strong support in favour of the proposed enamine mechanism.

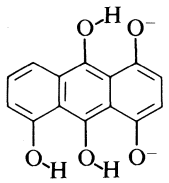
An explanation for the regioselective formation of a 4-pyrrolidino adduct of **3** was then considered, since the formation of this intermediate controls the overall regioselectivity of both the alkylation and deoxygenation reactions. Only the leuco compounds **3**, **12**, and **13** exhibit two closely spaced carbonyl



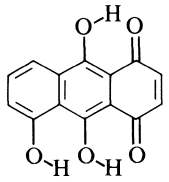
11



16



18



19

absorption bands in the ir spectra of their chloroform solutions. We believe that the selective formation of **11**, or a related derivative, is a consequence of the enhanced electrophilicity of the 4-carbonyl group in **3** brought about by the relay of two hydrogen bonds with that group, and that this is responsible for the regioselectivity of the reactions described and the splitting of the ir carbonyl absorption. Leuco compounds **9** and **17** show only a single carbonyl group absorption. This type of hydrogen bond relay may well be responsible for the regioselectivity of the 2-alkylation reaction of **3** and of the nitronate ion alkylation of **1** (3, 8, 11), the key steps being, respectively, reaction of the more nucleophilic enolate ion centre of **18** (position 2) with an aldehyde, and addition of the nitronate anion to the more electrophilic end of the 2,3-double bond of **19** (position 2) derived from tautomerization of **1**. In support of this idea, destruction of the hydrogen bond relay for a Marschalk reaction of **3** with propanal under more basic conditions (ethanol plus ethoxide) is essentially nonselective, giving about equal yields of **4** and **5**.

The deoxygenation of the leuco compound **13** was unusual in comparison to that of **12** and **3**. The reaction was very slow and gave a poor yield of a product that indicated the loss of the 1- rather than the 4-carbonyl group. This result is probably a consequence of steric hindrance, by the 3-propyl group, of the nucleophilic addition of the cyclic amine at the 4-carbonyl group of **13**, so that reaction occurs at the less hindered and less reactive 1-carbonyl group.

Conclusions

The studies described in this paper have clarified the role of pyrrolidine in the regioselective reactions of the leuco compound **3**. It seems likely that the regioselective alkylation of **3** with aldehydes in isopropanol in the presence of pyridinium acetate (3, 7) also involves the formation of an enamine such as **11**. The formation of 3-alkyl derivatives of **1** by reaction of **3** with aldehydes in toluene with pyrrolidine is, however, completely selective and gives higher yields. It is much more efficient than the method based on the alkylation of 1,5-dimethoxy-4-hydroxy-9,10-anthraquinone (9) and should prove valuable for the synthesis of precursors to anthracyclinones derived from **1**.

Experimental

Leuco compounds

The leuco compounds were prepared by reduction of the corresponding anthraquinones with tin and HCl in boiling glacial acetic acid (1) and crystallized from the reaction solution after addition of water.

1,4-Dioxo-1,2,3,4-tetrahydro-5,9,10-trihydroxyanthracene (leuco 1,4,5-trihydroxy-9,10-anthraquinone), **3**: 80% yield, mp 209–210°C; ir ($CHCl_3$) ν_{max}: 1645, 1630 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 15.72 (s, 1H, OH), 13.53 (s, 1H, OH), 9.92 (s, 1H, OH), 7.95 (dd, J = 8 Hz, 1 Hz, 1H, H-8), 7.67 (t, J = 8 Hz, 1H, H-7), 7.18 (dd, J = 8 Hz, 1 Hz, 1H, H-6), 3.07 (s, 4H, CH_2—CH_2). *Anal.* calcd. for $C_{14}H_{10}O_5$: C 65.12, H 3.90; found: C 64.97, H 3.85.

1,4-Dioxo-2-propyl-1,2,3,4-tetrahydro-5,9,10-trihydroxyanthracene (leuco 2-propyl-1,4,5-trihydroxy-9,10-anthraquinone), **12**: 75% yield; ir ($CHCl_3$) ν_{max}: 1648, 1630 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 15.73 (s, 1H, OH), 13.38 (s, 1H, OH), 9.86 (s, 1H, OH), 7.93 (dd, J = 8 Hz, 1 Hz, 1H, H-8), 7.63 (t, J = 8 Hz, 1H, H-7), 7.14 (dd, J = 8 Hz, 1 Hz, 1H, H-6), 3.0 (m, 3H, ring CH_2—CH), 1.5 (m, 4H, propyl CH_2—CH_2), 0.9 (m, 3H, propyl CH_3). *Anal.* calcd. for $C_{17}H_{16}O_5$: C 67.99, H 5.37; found: C 67.92, H 5.32.

1,4-Dioxo-3-propyl-1,2,3,4-tetrahydro-5,9,10-trihydroxyanthracene (leuco 3-propyl-1,4,5-trihydroxy-9,10-anthraquinone), **13**: 80% yield; ir ($CHCl_3$) ν_{max}: 1648, 1630 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 15.73 (s, 1H, OH), 13.36 (s, 1H, OH), 9.86 (s, 1H, OH), 7.90 (dd, J = 8 Hz, 1 Hz, 1H, H-8), 7.61 (t, J = 8 Hz, 1H, H-7), 7.13 (dd, J = 8 Hz, 1 Hz, 1H, H-6), 3.0 (m, 3H, ring CH_2—CH), 1.5 (m, 4H, propyl CH_2—CH_2), 0.9 (m, 3H, propyl CH_3). *Anal.* calcd. for $C_{17}H_{16}O_5$: C 67.99, H 5.37; found: C 67.88, H 5.31.

Reactions of leuco 1,4,5-trihydroxy-9,10-anthraquinone

Leuco compound **3** (1 mmol) was reacted for 1.5 h with pyrrolidine (5 mmol) in boiling toluene under nitrogen. Evaporation of the reaction solution and column chromatography (SiO_2/toluene) gave **8** (0.93 mmol), identified by comparison of its tlc characteristics and ir spectrum (ν_{max} (C=O): 1630 cm^{-1}) with an authentic sample and literature data (12). It was readily distinguished from **10** (ir ν_{max} (C=O): 1670, 1620 cm^{-1}) by tlc (SiO_2/9:1 v/v petroleum ether – ethyl acetate) and ir spectroscopy (12).

With added excess propanal (10 mmol), an identical reaction procedure produced only **5**.

3-Propyl-1,4,5-trihydroxy-9,10-anthraquinone, **5**: 82% yield, mp 173–174°C (lit. (8) mp 193°C); ir (KBr) ν_{max}: 1605 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 13.06 (s, 1H, 1-OH), 12.72 (s, 1H, 4-OH), 12.18 (s, 1H, 5-OH), 7.87 (dd, J = 8 Hz, 1 Hz, 1H, H-8), 7.66 (t, J = 8 Hz, 1H, H-7), 7.28 (dd, J = 8 Hz, 1 Hz, 1H, H-6), 7.13 (s, 1H, H-2), 2.70 (t, J = 7 Hz, 2H, benzylic CH_2), 1.62 (hex, J = 7 Hz, 2H, propyl CH_2), 1.01 (t, J = 7 Hz, 3H, propyl CH_3).

An identical reaction conducted at room temperature for 1.5 h without added propanal gave about a 50% conversion to a major blue product from which **16** was isolated. The initial reaction mixture contained the deoxygenation product **8** and small quantities of two other blue amine substitution products of similar retention to **16**, which hindered the chromatographic purification of the main product.

4-Pyrrolidino-1,5-dihydroxy-9,10-anthraquinone, **16**: 21% yield; ir (KBr) ν_{max}: 1595 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 13.75 (s, 1H, OH), 13.45 (s, 1H, OH), 7.83 (dd, J = 8 Hz, 1 Hz, 1H, H-8), 7.59 (t, J = 8 Hz, 1H, H-7), 7.2 (m, 3H, H-6, H-3, H-2), 3.40 (m, 4H, CH_2—N—CH_2), 2.03 (m, 4H, CH_2—CH_2). *Anal.* calcd. for $C_{18}H_{15}O_4N$: C 69.89, H 4.89, N 4.53; found: C 69.81, H 4.79, N 4.58.

2-Propyl-1,4,5-trihydroxy-9,10-anthraquinone was synthesized by literature methods (3).

Deoxygenation reactions of leuco 2- and 3-propyl-1,4,5-trihydroxy-9,10-anthraquinone

The deoxygenation reactions of these compounds with pyrrolidine in toluene were conducted as described above for the reaction of **3**.

Deoxygenation of **12** gave 2-propyl-1,5-dihydroxy-9,10-anthraquinone, **14**: 10% yield. The initial yield was estimated to be 60–70%, but removal of **4** required three chromatographic separations; ir (KBr) ν_{max}: 1620 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 13.06 (s, OH), 12.72 (s, OH); remaining multiplets were obscured by noise, a consequence of the very low solubility. *Anal.* calcd. for $C_{17}H_{14}O_4$: C 72.33, H 5.00; found: C 72.06, H 4.82.

Deoxygenation of **13** gave 2-propyl-1,8-dihydroxy-9,10-anthraquinone, **15**: 3% yield. Purification to completely remove **5** required

four chromatographic columns. The initial yield was estimated to be only 10–20% because of the very slow reaction; ir (KBr) ν_{max}: 1670, 1622 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 12.42 (s, 1H, OH), 12.09 (s, 1H, OH), 7.8 (m, 2H, H-4, H-5), 7.61 (d, J = 8 Hz, 1H, H-3), 7.56 (t, J = 8 Hz, 1H, H-6), 7.27 (dd, J = 8 Hz, 1 Hz, 1H, H-7), 2.74 (t, J = 7 Hz, 2H, benzylic CH_2), 1.69 (hex, J = 7 Hz, 2H, propyl CH_2), 1.06 (t, J = 7 Hz, 3H, propyl CH_3). Insufficient material for analysis.

Reductions of 4-pyrrolidino-1,5-dihydroxy-9,10-anthraquinone

Reduction of **16** with tin and HCl in glacial acetic acid was carried out as described for the preparation of the leuco compounds above and gave quantitative conversion to about equal yields of **1** and **8**, which were separated by tlc.

The blue **16** was also reduced in boiling toluene using activated Raney nickel. In the absence of propanal, **8** was produced in 95% yield, whereas with added propanal, the reaction gave **5** (38% yield) and some **8**, along with several amine substitution products. Deactivation of the Raney nickel by the propanal prevented any improvement of the yield.

JESÚS M. AIZPURUA, BEGOÑA LECEA, and CLAUDIO PALOMO. Can. J. Chem. **64**, 2342 (1986).

The synthetic utility of hydrosilanes under the influence of trimethylsilyl-based reagents as new reducing systems is described. 1,1,3,3-Tetramethyldisiloxane (TMDS) reagent in combination with iodotrimethylsilane or bromotrimethylsilane produces alkyl halides from aldehydes in good to excellent yields. Polymethylhydrosiloxane (PMS) in the presence of iodotrimethylsilane also produces benzyl iodides in excellent yields. On the contrary, PMS reagent was found unsuitable for the synthesis of benzyl bromides. Similarly, TMDS reagent in combination with trimethylsilyl triflate produces symmetrical ethers from aldehydes without concomitant formation of competitive products. Under similar conditions, PMS reagent failed to provide the expected symmetrical ethers and Friedel–Crafts products were formed. Reduction of quinones to hydroquinones is also described.

JESÚS M. AIZPURUA, BEGOÑA LECEA et CLAUDIO PALOMO. Can. J. Chem. **64**, 2342 (1986).

On décrit les avantages que présentent en synthèse les hydrosilanes, sous l'influence de réactifs dérivés du groupement triméthylsilyle, comme systèmes de réduction. Sous l'action du réactif tétraméthyl-1,1,3,3 disiloxane (TMDS), utilisé de concert avec l'iodotriméthylsilane ou le bromotriméthylsilane, les aldéhydes sont transformés en halogénures d'alkyles, avec des rendements qui vont de bons à excellents. On a trouvé que le polyméthylhydrosiloxane (PMS), en présence d'iodotriméthylsilane, conduit aussi aux iodures de benzyles avec d'excellents rendements. Par ailleurs, on a trouvé que le réactif PMS n'est pas approprié pour la synthèse de bromures de benzyles. De la même manière, le réactif TMDS, utilisé de concert avec le triflate de triméthylsilyle, permet de transformer des aldéhydes en des éthers symétriques, sans formation concomitante de produits de compétition. Dans des conditions semblables, le réactif PMS de fournit pas les éthers symétriques attendus; toutefois, il se forme des produits de Friedel–Crafts. On décrit aussi la réduction de quinones en hydroquinones.

[Traduit par la revue]

Although reduction is one of the most widely used and extensively studied methods in organic chemistry, there remains considerable interest in the development of new reagents and synthetic methods for reduction. In recent years, several papers have revealed that silicon hydrides are useful reducing agents for a wide variety of transformations, most of them having been reviewed (1–6). Excluding photochemical reductions (7), four methods—trichlorosilane/tertiary amine reductions (8), Lewis acid catalyzed reductions (9), reductions in trifluoroacetic acid media (10), and potassium or cesium fluoride catalyzed reductions (11)—have received considerable interest for reduction of aldehydes and ketones. Triethylsilane **1** and polymethylhydrosiloxane **2** are the most popular and widely used hydrosilane reagents for these hydrogenation reactions. Recently, we reported the use of iodine together with hydrosilanes in related reactions and found that alkyl iodides were formed in excellent yields (12).

This paper describes a new reduction method for aldehydes and quinones promoted by 1,1,3,3-tetramethyldisiloxane **3** (TMDS) in the presence of the trimethylsilyl-based reagents chlorotrimethylsilane, iodotrimethylsilane, bromotrimethylsilane, and trimethylsilyl trifluoromethanesulfonate.

Results and discussion

Formation of alkyl halides

The 1,1,3,3-tetramethyldisiloxane reagent **3** has been reported (13) to be quite suitable for the direct reductive halogenation of aromatic aldehydes to benzyl halides in the presence of halosilanes. Thus, the halide groups were smoothly formed in high yields and short reaction times by treatment of benzaldehydes **4** with the reagent **3** and halosilanes, in anhydrous acetonitrile as solvent, in a molar ratio 1:1:1.5 respectively.

Aldehydes, in the absence of solvent, undergo similar reductive iodination with polymethylhydrosiloxane **2** (PMS) and sodium iodide/chlorotrimethylsilane. In contrast, reaction of aldehydes and lithium bromide/chlorotrimethylsilane with PMS reagent failed to provide the corresponding bromides. When benzaldehyde and 4-chlorobenzaldehyde were treated with reagent **2** and bromotrimethylsilane under reflux conditions for 4–6 h, partial halo-reduction took place as detected by tlc analysis; however, when TMDS reagent was added to this reaction mixture, a complete conversion into the corresponding benzyl bromides was accomplished within 30–60 min under reflux conditions. This fact shows that TMDS reagent is probably more active than the PMS reagent.

As shown by the data of Table 1, benzyl halides **5** can be conveniently prepared in good yields by TMDS or PMS reductions under the influence of halosilanes. With the exception of 3-nitrobenzaldehyde, aryl aldehydes form benzyl iodides in yields greater than 80% and benzyl bromides in yields in the range 70–90%. 4-Methoxybenzyl bromide was formed in 90% yield (84% isolated yield) when anisaldehyde was reduced at 80°C by TMDS in acetonitrile with lithium bromide/chlorotri-

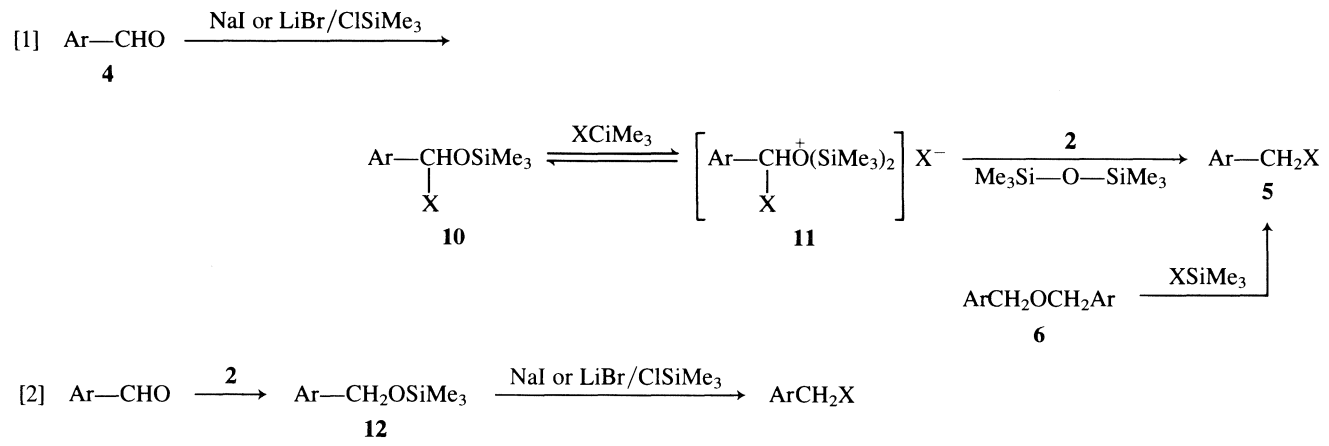
methylsilane; however, under the same conditions, 3-hydroxybenzaldehyde gave the expected 3-hydroxybenzyl bromide in 77% isolated yield and a second compound, which was characterized as the symmetrical ether **6**, in 23% yield.

On the other hand, when benzaldehyde was treated with the hydrosilane **3** under the influence of iodotrimethylsilane in catalytic amount, only traces of benzyl iodide and dibenzyl ether were detected by glc and nmr analysis of the crude reaction mixture, and the starting aldehyde remained intact in the solution after 3.5 h at 0°C. When the reaction mixture was refluxed for 60 min, the isolated products were found to be dibenzyl ether, benzyl iodide, and benzyl chloride in 85, 9, and 6% yield respectively. When the reaction was tested with *n*-pentanal and *n*-heptanal only the corresponding symmetrical ethers were formed. The same result was found when iodotrimethylsilane was used in equimolar amount, without formation of the expected aliphatic iodides.

Reaction between ketones such as 4-methylacetophenone and cyclohexanone, sodium iodide/chlorotrimethylsilane, and TMDS reagent was found troublesome and difficult to control, giving mixtures of products in which we have detected by glc and nmr analysis the corresponding starting materials, alkanes, symmetrical ethers, and traces of the respective iodides.

We next examined the use of chlorotrimethylsilane to obtain the corresponding benzyl chlorides **5** (X:Cl). In a preliminary experiment, we found that under conditions similar to those



SCHEME 2

used in the formation of benzyl iodides or bromides by TMDS reduction, chlorotrimethylsilane alone failed to provide the corresponding benzyl chlorides. Nevertheless, when the reaction was carried out in the presence of thionyl chloride and zinc iodide as catalyst, the corresponding chlorides were obtained in good yields, even if in some cases the corresponding symmetrical ethers were also formed. For example, whereas benzaldehyde gave only benzyl chloride, 2-chlorobenzaldehyde gave a mixture of 2-chlorobenzyl chloride (55%) and bis(2-chlorobenzyl) ether (45%), which was conveniently analyzed by nmr spectroscopy (Ar-CH_2Cl signal appeared at δ 4.5 ppm and Ar-CH_2O signal appeared at δ 4.56 ppm). On the basis of available data, the ratio of chloride/ether does not appear to be predictable as a function of aromatic ring substituents. In comparison, reaction of aldehydes with iodotrimethylsilane and bromotrimethylsilane gave the respective halides as the only reaction products, except for aromatic aldehydes having electron-withdrawing groups. On the other hand, in the absence of thionyl chloride, 4-chlorobenzaldehyde and 2-chlorobenzaldehyde give the symmetrical ethers **6** instead of the respective benzyl chloride **5**, and in the absence of Lewis acid catalyst, benzaldehyde gave a mixture of benzal chloride and benzyl chloride (molar ratio 57:43) after 3 h reflux. With aromatic aldehydes having electron-withdrawing substituents such as nitro or carbomethoxy groups, the reaction was first carried out at −70°C and then heated to reflux to exclude the formation of symmetrical ethers as major competitive products. For aromatic aldehydes having electron-donating substituents such as 4-methoxybenzaldehyde and 3-hydroxybenzaldehyde, the reaction was achieved in the same way, but using zinc chloride to prevent Friedel–Crafts products as a major competitive reaction.

The halide formation could occur in a number of ways: (*i*) by the reduction of an *O*-silylated halohydrin (18) intermediate **10** (eq. [1]), (*ii*) by the cleavage of an "*in situ*" generated symmetrical ether, or (*iii*) by reduction of the aldehyde into the corresponding alcohol derivative **12** followed by substitution of the hydroxyl function by the halide group (19) (eq. [2]).

Formation of symmetrical ethers

Doyle *et al.* (10) have reported that certain silanes, especially triethylsilane in trifluoroacetic acid, reduce carbonyl compounds to symmetrical ethers[3] with the concomitant formation of a carboxylate ester. An interesting observation of these authors is that increasing basicity of the carboxylic acid also increases the percentage of carboxylate ester to symmetrical ether. This consideration has led us to investigate the behavior of 1,1,3,3-tetramethyldisiloxane (TMDS) reagent **3** in the reduction of aldehydes under the influence of stronger acids than trifluoroacetic acid. As we have mentioned above, the use of iodotrimethylsilane (chlorotrimethylsilane/NaI) in catalytic amount produces the symmetrical ether **6** of the corresponding aldehyde along with the respective iodo and chloro compounds **5**. To avoid this latter reaction, we have examined the reduction of aldehydes under the influence of trimethylsilyl trifluoro-

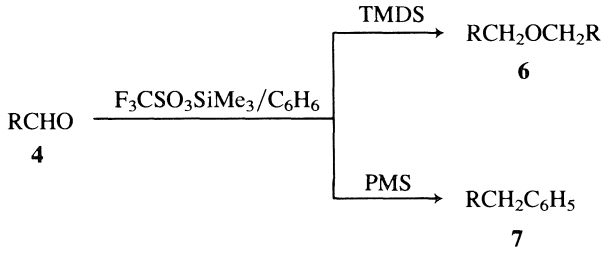

SCHEME 3

methanesulfonate (trimethylsilyl triflate) and have found that the use of this reagent enhances the formation of symmetrical ethers **6** without concomitant formation of competitive products. In the absence of trimethylsilyl triflate, no reaction takes place and the starting aldehyde is completely recovered. We have tested the method with a number of aromatic and aliphatic aldehydes and have found the results (Table 2) to be uniformly good. For aromatic and aliphatic aldehydes, the yields of the symmetrical ethers are in the range 90–97%. Whereas the reduction of 4-nitrobenzaldehyde by the triethylsilane method (10) gives a mixture of 4-nitrobenzyl ether in 33% yield and the corresponding trifluoroacetate in 67% yield, in the method described here only two products are formed depending on the reaction conditions used; thus, when the reaction is carried out at −78°C the major product is the *p*-nitrobenzyl alcohol with 91% yield and the by-product is the corresponding symmetrical ether. Under similar reaction conditions, benzophenone and benzhydrol were reduced at a much slower rate than aromatic and aliphatic aldehydes and only diphenylmethane was obtained from both of them in nearly quantitative yield.

On the other hand, it should be noted that reductions by means of TMDS reagent in trifluoroacetic acid (entries *d* and *j*) as solvent (instead of trimethylsilyl triflate catalysis) also produce symmetrical ethers, but the corresponding trifluoroacetate is formed in a competition process. In a similar manner, from 4-carboxybenzaldehyde, the percentage of the corresponding trifluoroacetate ester was found to be greater than the corresponding symmetrical ether, probably due to the stronger electron-withdrawing group in the *para* position.

Furthermore, we have found that under conditions similar to those used for the formation of symmetrical ethers **6** by TMDS reduction of aldehydes **4**, the reaction between aldehydes and aromatic compounds can take a different course in the presence of polymethylhydrosiloxane (PMS) to produce diphenylmethanes **7**. Thus, when a mixture of an aromatic aldehyde and a catalytic amount of TMS triflate was refluxed in benzene or toluene in the presence of PMS reagent, the corresponding arylmethane was produced in a few hours. As shown in Table 3, from unactivated aldehydes, symmetrical ethers are formed as competitive products. Since condensation of aromatic rings with aldehydes is severely limited by side reactions (14), our procedure constitutes an unusual Friedel–Crafts type alkylation. However, the method reaches a limit with aliphatic aldehydes, from which side products predominated.

Reduction of quinones

The reduction of the carbonyl function of quinones to hydroxyl group has enjoyed wide application in organic synthesis and in many naturally occurring substances (15). Various conventional reducing agents have been employed to convert quinones into hydroquinones (15); however, these procedures are generally accompanied by the formation of a large amount of inorganic salts. Other methods described involve the silylation technique to give, after hydrolysis, the corresponding hydroquinones. Chlorotrimethylsilane (16*a*, *b*), bis(trimethylsilyl)mercury (16*c*, *d*), 1,2-difluorotetramethyldisilane (16*e*), and hexamethyldisilane (16*f*) are silyl reagents used to convert *p*-quinones into bis(trimethylsilyloxy)benzenes. In some of these methods, the reaction takes place only in the presence of metals, involving forceful conditions, and gives yields in the range 40–60%. Some of these reagents are also expensive, and thus their application is limited.

Kursanov and co-workers have reported the reduction of benzoquinone to hydroquinone using triethylsilane in trifluoroacetic acid media (17). Because of the good yield reported for this silane reduction, we expected that TMDS reduction of benzoquinones under the influence of sodium iodide/chlorotrimethylsilane would represent a convenient and synthetically useful method for transforming quinones into hydroquinones.

Reductions were carried out in refluxing dichloromethane for 30–35 min, with TMDS and iodotrimethylsilane as catalyst. Some examples are listed in Table 4 and the results obtained are uniformly good. Triethoxysilane and polymethylhydrosiloxane were also found suitable for such reduction, but they require longer reaction times. Thus, reduction of quinones **8***a* and **8***c* by

[c]These compounds were identified by comparison with authentic samples (Fluka A.G.).

the first reagent under reflux conditions during 3 h gives 66 and 77% yields of the desired hydroquinones **9** and the last reagent reduces **8***a* in 56% yield after 10 h reflux. Indeed, as the results confirm, the method is rather similar to the iodine catalyzed hydrosilane reduction of hydroquinones (12).

Conclusions

In the presence of trimethylsilyl-based reagents, aldehydes are converted by TMDS reduction to alkyl halides and symmetrical ethers in high yields. The reaction product is dependent on the nature of the starting carbonyl compound. From aromatic aldehydes, only benzyl halides were obtained by means of 1,1,3,3-tetramethyldisiloxane TMDS reagent **3**, whereas PMS reagent **2** was found suitable for this transformation only for iodides, but not for bromides. From aliphatic aldehydes, the corresponding symmetrical ethers were formed instead of the respective alkyl halides by TMDS halo-reduction. Similarly, trimethylsilyl triflate catalyzed reductions of aldehydes, producing symmetrical ethers without competitive reactions.

The method described here presents a new reductive halogenation procedure for the direct conversion of benzaldehydes to benzyl halides and a mild catalytic procedure for the selective conversion of carbonyl compounds to symmetrical ethers, as well as hydroquinones from quinones, offering great versatility from the synthetic point of view as demonstrated here by a rather limited number of examples, which may be readily extended to further applications.

Experimental

Melting points were determined on a Büchi SMP-20 melting point apparatus and are uncorrected. Reported boiling points are those observed during distillation with a kugelrohr apparatus and are uncorrected. Proton nmr spectra were measured on a Varian EM-360 A spectrometer and are reported in parts per million downfield from internal tetramethylsilane. All the starting materials used in this work were either commercially available in 98% or higher purity and were used without further purification, or were prepared by standard literature procedures. Acetonitrile was purified (27) and stored over molecular sieves. 1,1,3,3-Tetramethyldisiloxane (TMDS) reagent was obtained from Wacker-Chemie GMBH (München, Germany). Iodotrimethylsilane was formed "*in situ*" from chlorotrimethylsilane and sodium iodide according to the method described by Olah *et al.* (19). Bromotrimethylsilane was also generated "*in situ*" from chlorotrimethylsilane and lithium bromide, similarly to the method reported by Schmidt and Russ (20). Trimethylsilyl triflate was prepared (21*b*) by a modification of the procedure described by Roeski and Giere (21*a*).

Formation of benzyl iodides

General procedure for TMDS reagent

A mixture of the corresponding benzaldehyde (10 mmol), chlorotrimethylsilane (1.92 mL, 15 mmol), and sodium iodide (2.25 mg, 15 mmol) in anhydrous acetonitrile (5 mL) is stirred at room temperature for 10 min and then cooled to 0°C. Immediately after, 1,1,3,3-tetramethyldisiloxane (1.79 mL, 10 mmol) is added dropwise giving an exothermic reaction. Stirring is maintained for 30 min, after which the siloxane products are destroyed with a 2.5 *N* solution of hydrofluoric acid in methanol (15 mL). The mixture is taken up in dichloromethane (30 mL) and washed with cool water (30 mL) and saturated $NaHCO_3$ solution (30 mL). Drying and evaporation of the solvent yields crude benzyl iodide, which is purified by reduced pressure distillation or recrystallization.

General procedure for PMS reagent

A mixture of sodium iodide (2.25 g, 15 mmol) and chlorotrimethylsilane (1.92 mL, 15 mmol) is stirred at room temperature for 10 min; then the corresponding benzaldehyde (10 mmol) is added and stirred for 3 min, after which PMS **2** is added giving an exothermic reaction. Stirring is maintained for 20–40 min. The mixture is taken up in dichloromethane (30 mL) and washed with water (2 × 20 mL) and saturated $NaHCO_3$ solution (2 × 20 mL). Drying and evaporation of solvent yield a crude mixture of the benzyl iodide and siloxane polymer compounds. The upper layer is separated and the lower one is purified by reduced pressure distillation to give the pure benzyl iodide.

Formation of benzyl bromides

4-Chlorobenzyl bromide **5**d*: typical procedure*

A suspension of 4-chlorobenzaldehyde (1.40 g, 10 mmol), lithium bromide (1.5 g, 1.72 mmol), chlorotrimethylsilane (1.92 mL, 15 mmol), and 1,1,3,3-tetramethyldisiloxane (1.79 mL, 10 mmol) in acetonitrile (10 mL) is refluxed with stirring for 20 min. The same work-up used for benzyl iodides is followed, affording crude 4-chlorobenzyl bromide, which is purified by recrystallization from MeOH (1.85 g, 90%); mp 48–50°C (lit. (22) mp 51°C).

Formation of benzyl chlorides

4-Methylbenzyl chloride **5**i*: typical procedure*

A mixture of 4-methylbenzaldehyde (1.18 g, 10 mmol), chlorotrimethylsilane (2.0 mL, 15.7 mmol), 1,1,3,3-tetramethyldisiloxane (1.79 mL, 10 mmol), and thionyl chloride (1.0 mL, 13.7 mmol) is cooled at 0°C. Then ZnI_2 (0.02 g) is added and a very exothermic reaction takes place; when the spontaneous heating has ended, the mixture is refluxed with stirring for 45 min, and a 2.5 *N* solution of hydrofluoric acid in methanol (10 mL) is added. After refluxing for 10 min the solution is cooled at 0°C, filtered, taken up in dichloromethane (30 mL)/water (40 mL), and the aqueous layer extracted with dichloromethane (2 × 10 mL). The combined organic phases are dried (Na_2SO_4) and the solvents evaporated to afford crude 4-methylbenzyl chloride, which is purified by reduced pressure distillation (1.22 g, 87%); bp 190–195°C (lit. (22) bp 192°C/760 Torr) (1 Torr = 133.3 Pa).

Formation of symmetrical ethers

Dibenzylether **6**a*: typical procedure*

Benzaldehyde (1.02 mL, 10 mmol) is added to a mixture of 1,1,3,3-tetramethyldisiloxane (1.79 mL, 10 mmol), trimethylsilyl trifluoromethanesulfonate (0.05 mL, catalyst), and benzene (20 mL). The resulting solution is refluxed for 20 min, until no aldehyde can be detected by tlc analysis (silica gel plates; eluent: EtOAc/hexane 1:3). Upon completion of the reaction, the solvent is evaporated and the residue purified by reduced pressure distillation, yielding dibenzyl ether (0.96 g, 97%); bp 92–94°C/0.3 Torr (lit. (22) 290–300°C/760 Torr).

*Bis(*n*-pentyl) ether* **6**k*: typical procedure*

A mixture of sodium iodide (0.15 g, 1 mmol), valeraldehyde

(1.06 mL, 10 mmol), and chlorotrimethylsilane (2.0 mL, 15.4 mmol) is stirred in acetonitrile (5.0 mL) at room temperature for 10 min, after which 1,1,3,3-tetramethyldisiloxane (1.79 mL, 10 mmol) is added. When the exothermic reaction has ended (30 min), a solution of 2.5 *N* hydrofluoric acid in methanol (30 mL) is added to the reaction mixture, and then refluxed for 5 min. Work-up is carried out by diluting the solution with dichloromethane (40 mL), washing with water (30 mL) and saturated $NaHCO_3$ solution (20 mL), drying, and evaporating the solvents. Crude bis(*n*-pentyl) ether is purified by reduced pressure distillation (0.65 g, 84%); bp 185–189°C/760 Torr (lit. (22) bp 187.5°C/760 Torr).

4-Nitrobenzyl alcohol

A solution of 1,1,3,3-tetramethyldisiloxane (1.79 mL, 10 mmol) and trimethylsilyl triflate (0.05 mL, catalyst) in dichloromethane (20 mL) is added dropwise (30 min) to a cooled solution of 4-nitrobenzaldehyde (0.76 g, 5 mmol) in the same solvent (30 mL) and the reaction mixture is stirred for 70 min. Then the solvent is evaporated and the resulting crude product is purified by column chromatography (silica gel; eluent: hexane/EtOAc 1:1). Yield of 4-nitrobenzyl alcohol: 0.71 g, 91%; mp 92–94°C (lit. (22) mp 93°C).

Diphenylmethane

Benzophenone **4***m* (1.81 g, 10 mmol) is added to a mixture of 1,1,3,3-tetramethyldisiloxane (3.57 mL, 20 mmol), trimethylsilyl triflate (0.05 mL, catalyst), and benzene (20 mL), and the solution is refluxed for 4 h. Then a 2.5 *N* solution of hydrofluoric acid in methanol (30 mL) is added and, after a 5-min reflux, the mixture is taken up over dichloromethane (50 mL) and washed successively with water (30 mL) and saturated $NaHCO_3$ solution (20 mL). Drying and evaporation of the solvent gives crude diphenylmethane, which is purified by reduced pressure distillation (1.59 g, 95%); bp 70–72°C/0.3 Torr (lit. (18) mp 26–27°C). From benzhydrol **4n** (1.8 g, 10 mmol), yield of diphenylmethane: 91%.

Arylmethanes 7 from aldehydes

General procedure

A mixture of the corresponding aromatic aldehyde (10 mmol), PMS reagent (1 mL), and TMS triflate (two drops) in benzene or toluene (20 mL) is refluxed for 2 h and then washed with water (2 × 20 mL). The organic layer is dried over Na_2SO_4. Evaporation of the solvent gives a waxy residue, which is treated with methanol (10 mL). The resulting precipitate of siloxane polymer is filtered off. Evaporation of the solvent gives an oil, which is analyzed by nmr spectroscopy to determine the isomer proportion. Then the crude product is distilled under reduced pressure to afford the corresponding arylmethanes (14*a*).

Reduction of p*-benzoquinones*

General procedure

A mixture of sodium iodide (0.15 g, 1.0 mmol) and chlorotrimethylsilane (0.13 mL, 1.0 mmol) is stirred in acetonitrile (2.0 mL) for 5 min, after which dichloromethane (30 mL), the corresponding *p*-benzoquinone **7** (10 mmol), and 1,1,3,3-tetramethyldisiloxane (2.69 mL, 15 mmol) are successively added. When the spontaneous exothermic reaction has ended, the solution is refluxed for 30 min and then extracted with 1 *N* NaOH (30 mL). The aqueous phase is acidified (HCl aqueous) and extracted with EtOAc (3 × 15 mL). The organic solution is dried (Na_2SO_4) and evaporated to give the respective hydroquinone **9**.

^1H and ^{13}C nuclear magnetic resonance and ultraviolet studies of the protonation of cytosine, uracil, thymine, and related compounds

ROBERT L. BENOIT AND MONIQUE FRECHETTE

Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received April 30, 1986

ROBERT L. BENOIT and MONIQUE FRECHETTE. Can. J. Chem. **64**, 2348 (1986).

The protonation of the three nucleic acid bases, cytosine, uracil, and thymine, and of related 4-amino-2,6-dimethylpyrimidine and 2-hydroxypyridine has been studied by ^1H and ^{13}C nuclear magnetic resonance and ultraviolet spectroscopies mostly in 0.18–18 *M* aqueous sulfuric acid. The experimental data have been interpreted on the basis of the excess acidity method. The pK_n values as well as the assigned protonation sites are discussed and contrasted with other data.

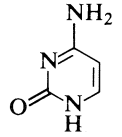
ROBERT L. BENOIT et MONIQUE FRECHETTE. Can. J. Chem. **64**, 2348 (1986).

La protonation des trois bases des acides nucléiques, cytosine, uracil, et thymine, et des composés voisins amino-4 diméthyl-2,6 pyrimidine et hydroxy-2 pyridine a été étudiée par les spectroscopies de rmn du ^1H et ^{13}C principalement dans l'acide sulfurique aqueux 0.18–18 *M*. On a interprété les résultats expérimentaux sur la base de la méthode dite «d'acité en excès». Les valeurs des pK_n ainsi que les attributions des sites de protonation sont examinées et comparées à d'autres données.

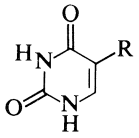
Introduction

We have recently reported the results of our research on the protonation of purines (1), important constituents of nucleic acids. Now we have extended our work to study the protonation of that other class of nucleic acid bases, the pyrimidines. We have considered here three biologically important hydroxypyrimidines: cytosine, uracil, and thymine. To assist the identification of the protonated sites of these polyfunctional bases, we have also examined two related compounds, 4-amino-2,6-dimethylpyrimidine (Dap) and 2-hydroxypyridine (Hypy). For this work we used ^1H and ^{13}C nmr spectroscopy as well as uv spectroscopy to confirm our results, since both methods involve widely different base concentrations.

Since the first protonation of cytosine takes place in dilute acid media and the pK_1 value, 4.58 (2), is well established, it was not studied here. Diprotonated cytosine has been identified in both HSO_3F and HSO_3F–SbF_5–SO_2 (3) but no pK_2 value was previously available. Uracil and thymine, which are dihydroxypyrimidines, are much less basic than cytosine and the reported somewhat conflicting pK_1 are −2.2 (4) and −3.0 (5) for uracil and −1.6 to −2.5 (4) for thymine respectively. Diprotonated uracil has been characterized in HSO_3F and HSO_3F–SbF_5–SO_2 (3), and Frederick and Poulter (6), using ^1H nmr, have obtained −7.3 and −6.8 for pK_2 for uracil and thymine respectively.



Cytosine (Cyt)



Uracil (Ura), R = H
Thymine (Thy), R = CH_3

We present here the results of our spectroscopic study of the protonation of the three hydroxypyrimidines and two related compounds, mostly in 0.18–18 *M* aqueous sulfuric acid. Our pK values and assigned protonation sites are contrasted with previously published data.

Experimental

Cytosine (Sigma), 1-methylcytosine (Vega Biochemicals, a gift from Prof. A. L. Beauchamp), uracil (Sigma), and thymine (Sigma) were used as received. Their uv spectra were in agreement with those published (7). 2-Hydroxypyridine (Hypy) (Aldrich) was used without purification. 4-Amino-2,6-dimethylpyrimidine (Dap) (Aldrich) was recrystallized in a 2:1 mixture of ethyl acetate and absolute ethanol and dried under vacuum at room temperature for 2 h. Acidimetric titration of the product in acetic acid showed a purity of 99.9 ± 0.3%. Sulfuric acid (BDH), sulfuric acid-d_2 (SIC), and 7% fuming H_2SO_4 (Fisher) were reagent grade. Triple distilled HSO_3F (Aldrich) was also used as received.

Proton nmr spectra were recorded at 28°C on a Bruker WH-90 spectrometer operating at 90 MHz. The ^1H chemical shifts for Ura and Thy were measured relative to internal Et_4NBF_4 and converted to the Me_4Si scale using the relationship $\delta_{Me_4Si} = \delta_{Et_4NBF_4} + 1.27$ ppm (8). The ^1H chemical shifts for Cyt were determined by using as reference external Me_4Si in Me_2SO-d_6. The ^1H nmr spectra in HSO_3F were recorded at −75°C on a Bruker WP-80 spectrometer operating at 80 MHz. The ^1H chemical shifts were measured relative to external acetone-d_6 (coaxial tube) and converted to the Me_4Si scale using $\delta_{Me_4Si} = \delta_{acetone\text{-}d_6} + 2.10$ ppm (8).

Carbon-13 nmr spectra were acquired at 28°C on a Bruker WP-80 spectrometer operating at 20.2 MHz. Proton decoupled spectra were recorded when needed to assist signal assignments. The ^{13}C chemical shifts were measured relative to external dioxane in D_2O (coaxial tube) and converted to the Me_4Si scale using $\delta_{Me_4Si} = \delta_{dioxane} + 67.40$ ppm (9). The nmr samples were prepared by dissolving weighed amounts of the solid bases in known volumes of titrated H_2SO_4 (^{13}C nmr) or D_2SO_4 (^1H nmr) solutions, 7% fuming H_2SO_4, and HSO_3F.

The ^1H nmr spectra were recorded for Cyt with 0.18–18 *M* H_2SO_4 solutions, and for Ura and Thy with 4.0–18 *M* D_2SO_4. The base concentrations were 0.16 *M* for Cyt and 0.12 *M* (0.04 *M* at low acid concentration) for Ura and Thy. The non-exchanging protons were assigned by using literature data (10) and by taking the C-6 (adjacent to N-1) proton to be less shielded than the C-5 proton. The Me protons of Thy appeared at high field and integrated 3 times the C-6 proton. The ^1H shifts of Cyt were corrected for bulk magnetic susceptibility (11) while those of Ura and Thy were not corrected since the internal reference used, Et_4NBF_4, is satisfactory in the range of acid concentrations used (11). The ^{13}C spectra were taken with H_2SO_4 solutions. For Hypy, H_2SO_4 was varied from 0 to 7.72 *M*. Dap was studied between 0 and 18 *M* H_2SO_4. For Cyt, the H_2SO_4 range was 0.18–18 *M* and for Ura and Thy, it was 6.3–18 *M*. For MeCyt two spectra were recorded, one in 1.8 *M* H_2SO_4 and the other in HSO_3F. The base concentrations were 0.30 *M* for Hypy, Ura, and Thy, 0.42 *M* for Dap, and 0.16 *M* for Cyt and MeCyt. The carbons of the bases were assigned by using off-resonance spectra and literature data on related compounds (9, 12).

The uv spectra were recorded on a 545 Perkin–Elmer spectrophotometer, and absorbances at a fixed wavelength were measured at 25°C on a PMQ II Zeiss spectrophotometer. Values were measured within 10 min of preparing the solutions because absorbances increased somewhat on standing. The uv samples were prepared by dissolving the

TABLE 1. Ultraviolet spectral data of uracil, thymine, and Dap

Base	$[H_2SO_4]$ (M)	λ_{max} (nm)	log ϵ_{max}
Ura	0	258, (258),[a] (259)[b]	3.92, (3.91),[a] (3.92)[b]
$UraH^+$	14.4, (10.3)[a]	276, (272)[a]	3.90, (3.82)[a]
Thy	0	263, (264)[b]	3.90 (3.89)[b]
$ThyH^+$	15.3	286.5	3.84

solid bases in titrated acid solutions and diluting aliquots with the same titrated acid to give (1–2) $\times 10^{-4}$ M base concentrations.

Results

Chemical shifts

To illustrate the variations of the ^1H and ^{13}C shifts of the bases with increasing acidity and to discuss qualitatively the protonation reactions, the ^1H and ^{13}C shifts of Cyt, Ura, Thy, and Dap were initially plotted against H_0 (1). While all protons move downfield with increasing acidity, the carbons move either upfield or downfield. The plots of the ^1H chemical shifts against H_0 are for the most part sigmoid curves, indicative of base protonation. For Ura and Thy, which are present as the neutral bases in the more dilute acid solutions, the ^1H plots then correspond to the first protonation step when H_0 passes from −2.5 to −9.0, with half protonation H_0 values of −4.0 for Ura and −5.0 for Thy respectively. The ^{13}C plots generally confirm these results, though the initial part of the curves is missing because Ura and Thy are too weakly soluble below 6.3 M H_2SO_4 to record their ^{13}C spectra. The ^{13}C data further indicate for both bases the beginning of a second protonation step for H_0 below −8. Additional ^{13}C spectra of Ura and Thy, taken in 7% fuming H_2SO_4 ($H_0 = -12.7$) and HSO_3F ($H_0 = -14.2$), show large shifts and confirm the presence of $UraH_2^{2+}$ and $ThyH_2^{2+}$. For Cyt, which is present as $CytH^+$ at the lowest acid concentration used, the ^1H and ^{13}C shifts show the onset of a second protonation step for H_0 lower than −6.0 but no plateau is reached in 18 M H_2SO_4 ($H_0 = -10$), while the spectra for the ^{13}C shifts in 7% fuming H_2SO_4 and HSO_3F are identical and thus are likely to correspond to full protonation. Finally, for Dap, which is monoprotonated in the most dilute H_2SO_4 solutions used, the ^{13}C plot indicates a second protonation step with an H_0 value at half protonation of −1.5. Additional ^1H spectra were taken at −75°C on HSO_3F solutions of Cyt, Ura, and Thy. The NH_2 protons of Cyt as well as the NH protons of all hydroxypyrimidines were now observed but no OH signals corresponding to C=O protonation could be detected. The values obtained for the chemical shifts in these HSO_3F solutions differ from those reported by Wagner and von Philipsborn (3) by 2.5 ppm, probably because of different references.

Ultraviolet spectra

The H_2SO_4 concentrations corresponding to the spectra of the various neutral and protonated species of Ura, Thy, and Dap are given in Table 1 together with λ_{max}, the wavelengths of maximum absorption, and ϵ_{max}, the corresponding molar absorptivities. For Ura and Thy, our spectra are similar to those reported by Gukovskaya *et al.* (4) who, however, give no ϵ_{max} values. The λ_{max} and ϵ_{max} for $UraH^+$ given in ref. 7 differ slightly from ours because, for the medium used, 10.3 M H_2SO_4, formation of $UraH^+$ is not complete. The absorbances of Ura, Thy, and Dap solutions were determined between 0 and 18 M H_2SO_4. The plots of the absorbances, measured at 8 selected wavelengths, against H_0 also gave sigmoid curves. The shorter plateaus at high acidities for Ura and Thy suggest the onset of the second protonation.

Calculation of pK_n

Initially, to compare our data with the published data (4, 5, 7), values of pK_n for the various protonated species BH^{n+} were calculated for the acidity functions H_0 and H_A using the standard equations (1). Values for pK_n of $UraH^+$ and $ThyH^+$ for the H_0 and H_A acidity functions are presented in Table 2 together with the corresponding slopes m_0 and m_A. Subsequently, the values of pK_n were obtained by the excess acidity method (13). The program developed by Cox was used, as we described previously (1), to calculate the pK_n values given in Table 3[1] with their standard deviations and the refined values of δ_{n+} and $\delta_{(n-1)^+}$ listed in Tables 4 (^1H nmr) and 5 (^{13}C nmr) respectively. The uv data (absorbances A or molar absorptivities ϵ) were similarly treated. To check the absence of medium effect, pK values were also calculated from values of ΔA or $\Delta\epsilon$ corresponding to pairs of wavelengths (14). Both sets of pKs, calculated from A (or ϵ) and ΔA (or $\Delta\epsilon$) were identical within experimental error, so that large medium effects can be ruled out. This point is further strengthened by the good agreement between pK values obtained from uv and nmr data (Table 3).

Discussion

Ionization constants

First, let us compare our protonation data for $UraH^+$ and

[1]Complete sets of nmr, uv, and program data have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

$ThyH^+$ with previous data (4, 5, 7). We note that the pK_1 values in Table 2 vary not only according to the acidity function selected but also according to the data used. For H_A, which on the basis of the slope m_A appears here to be the best acidity function, our pK_1 value of -2.9 for $UraH^+$ is in good agreement with -3.0, that of Poulter and Frederick (5), but in only passable agreement with -2.2 reported by Gukovskaya *et al.* (4). For $ThyH^+$, our pK_1 of -3.6 is at complete odds with -1.9, reported by the same group (4).

However, since our bases are different from the amides used to establish the H_A scale, we have selected the excess acidity method (13) to calculate the pK_n values that are listed in Table 3 together with the slopes m^*. We observed a good agreement between the values obtained by nmr and uv so that we can confidently reject the previously quoted pK_1 for $ThyH^+$ (4). Furthermore, the lower acidity found for $UraH^+$ ($pK_1 = -2.4$) compared with that of $ThyH^+$ ($pK_1 = -3.0$) is in agreement with what is expected from a methyl group (Thy is 5-methyluracil) in a conjugated system and in a position α to a protonated carbonyl on C-4, and, as we shall see, the proton in $ThyH^+$ is on O=C-4. For $CytH_2^{2+}$, our pK_2 of -6.4 is approximate and based on H_A because of the paucity of data at high acidities. It is worth noting that the differences between the pK_2 and pK_1 values in Table 3 indicate for $CytH^+$ a much stronger stabilization than for $UraH^+$, $ThyH^+$, and $DapH^+$, so that there must be additional factors to the conjugation of the amino group on C-4 with the ring, on protonation, to account for the increased stability of $CytH^+$. On the other hand, values of -NH deprotonation pK_0 (not reported here) for Cyt, Ura, and Thy show that this time neutral Ura and Thy are much more stabilized than Cyt with respect to deprotonation and monoprotonation. A comparison of first protonation data in solution with theoretical protonation energies and experimental gas phase proton affinities will be made later in a comparison of a larger series of nucleic acid bases.

Our ^{13}C nmr data have an interesting consequence. Previous researchers have used, for structural determinations, ^1H and ^{13}C nmr data obtained on trifluoroacetic (TFA) solutions of Ura (3) and Dap (15) with the assumption that $UraH^+$ and $DapH^+$ respectively were the species present in TFA. On the basis of our data, we calculate for TFA solutions $Ura/UraH^+ = 20:1$ and $DapH^+/DapH_2^{2+} = 3:1$. It is clear that when working with polyfunctional bases such as pyrimidines, dissolving the bases in one acid solvent and attributing to a single species the observed chemical shifts may be misleading.

Protonation sites

The values of pK_1 and pK_2 given for Cyt in Table 3 suggest that the first protonation of Cyt is likely to be on N-1 while its second protonation (and also both protonations of Ura and Thy) takes place on the exocyclic C=O. However, the ^{13}C data in Table 5 and particularly the direction and magnitude of the shifts on protonation give additional information on the protonation sites. First, for Dap, where there is only nitrogen protonation, we note that the first protonation expected on N-1 for this 4-aminopyrimidine (15) is indeed accompanied by an upfield

shift of C-2 and C-6, which are adjacent to the protonation site N-1; this is in accordance with the α effect observed by Pugmire and Grant (16) on five- and six-membered heterocycles. We also note, however, that for the second protonation of Dap on N-3, while the adjacent C-4 also moves upfield, the adjacent C-2 has this time a small downfield shift. This must be related to the presence of the first proton on N-1. Then for Cyt, we observed an upfield shift of C-2 (−8.9 ppm) and C-4 (−6.5 ppm) in line with a first protonation on N-3. This N-3 protonation of Cyt parallels that of cytidine, the nucleoside derived from Cyt, where the corresponding ^{13}C shifts are −8.6 ppm (C-2) and −6.1 ppm (17). Furthermore, we can state that the first protonation of Cyt occurs exclusively at N-3 since our C-2 and C-4 protonation shifts are very close to the average N-3 methylation shifts (−8.5 ppm (C-2) and −6.7 ppm (C-4)) found for cytidine and deoxycytidine (12*a*). Concerning the second protonation of Cyt, obviously occurring on the carbonyl O=C-2, we observe not only the expected downfield shift of C-2 (+5.2 ppm), which is admittedly much smaller than the +30-ppm shifts reported for aliphatic ketones (18), but, as well, a larger ≈9.6-ppm downfield shift of C-5 emphasizing the importance of conjugation effects in the pyrimidine ring. The ^{13}C shifts for $MeCytH^+$ (Table 5) and the protonation shift for $MeCytH_2^{2+}$ are very close to those found for the corresponding Cyt cations (except for C-6 adjacent to the methyl group) and thus confirm the exclusive second protonation of the carbonyl O=C-2, so that there is no need to postulate the presence of a tautomeric monocation $^+HO{=}C\text{-}2$ (3).

Let us now turn to the assignment of the protonation site in both $UraH^+$ and closely related $ThyH^+$. It is generally agreed that the most stable monocation $UraH^+$ is that which is protonated at O-4 (3, 5, 19, 20). Our ^{13}C data for $UraH^+$, $UraH_2^{2+}$, $ThyH^+$, and $ThyH_2^{2+}$ in Table 5 support this assignment. To begin with, the first protonation at O-4 and the second one at O-2 are in line with the expected downfield protonation shifts of the affected carbonyl carbons, first C-4 for $UraH^+$ (+3.0 ppm) and for $ThyH^+$ (+0.9 ppm because of the α methyl group), then C-2 for $UraH_2^{2+}$ (+4.0 ppm) and $ThyH_2^{2+}$ (+3.2 ppm), which may be compared with C-2 for $CytH_2^{2+}$ (+5.2 ppm). The reverse order for the carbonyl protonation (O-2 then O-4) would not lead to downfield shifts. The large downfield shift of C-5 (+5.2 ppm) in the *para* position, observed with the unambiguous C=O protonation of $CytH^+$ at C-2, is also observed for the protonation at O-2 in $UraH_2^{2+}$ (+8.3 ppm) and $ThyH_2^{2+}$ (+8.1 ppm). While a downfield protonation shift of C-5 (+8.9 ppm) is also found for the O-2 protonation of tautomerized Hypy, originally taken as our model compound, the carbonyl C-2 of Hypy undergoes an unexpected upfield shift upon protonation, thus emphasizing the difficulties inherent in the choice of a model compound, Hypy apparently not being a good model for hydroxypyrimidines, possibly because of different conjugation effects.

ENRIQUE SÁNCHEZ MARCOS, JOAQUÍN MARAVER, MANUEL F. RUÍZ-LÓPEZ, and JUAN BERTRÁN. Can. J. Chem. **64**, 2353 (1986).

An ellipsoidal cavity model has been used to study the energy changes in occupied molecular orbitals induced by solute–solvent electrostatic interactions. Some benzene derivatives have been selected as solutes. Calculations have been carried out at the CNDO and *ab initio* STO-4G levels. Important variations in the molecular orbital sequence, involving a change in the HOMO nature, have been observed. A perturbation analysis is employed to understand the orbital evolution from gas phase to solution.

ENRIQUE SÁNCHEZ MARCOS, JOAQUÍN MARAVER, MANUEL F. RUÍZ-LÓPEZ et JUAN BERTRÁN. Can. J. Chem. **64**, 2353 (1986).

On a utilisé un modèle à cavité ellipsoïdale pour étudier les changements énergétiques dans des orbitales moléculaires occupées, qui sont induits par des interactions électrostatiques soluté/solvant. On a choisi quelques dérivés benzéniques comme solutés. On a effectué des calculs aux niveaux CNDO et STO-4G *ab initio*. On a observé des variations importantes, impliquant un changement dans la nature de OM haute occupée, dans le cheminement des orbitales moléculaires. On a utilisé une analyse de perturbations pour comprendre l'évolution orbitale de la phase gazeuse à la solution.

[Traduit par la revue]

Introduction

The concept of frontier orbital (1) has been widely used in theoretical studies of chemical reactivity (2). The use of this static index can be theoretically justified by a perturbation treatment of intermolecular interactions (3, 4).

It has been rather general to apply Fukui's idea of frontier orbital from calculations where the molecules are isolated. However, chemical reactions of practical interest are usually performed in the liquid state.

The recent techniques of ICR (5), which permit the study of gas phase reactions, have shown the important variations that such processes can present when they are compared with the corresponding ones in the condensed phase. Therefore realistic values of the reactivity indexes are not easily derived in a scheme in which the solute–solvent interactions are neglected.

Two basic approaches are generally applied to these interactions. The first simulates the solvent by a limited number of solvent molecules which are placed around the solute, and is known as the supermolecule model (6). In the other approach, the solute is confined in a cavity surrounded by a dielectric continuum representing the solvent, which is characterized by a macroscopic quantity, i.e. the dielectric permittivity. Electrostatic interactions, which result from the polarization of the continuum in the presence of the solute charge distribution, can then be incorporated into the solute hamiltonian (7–11).

Several papers have been devoted to the study of the solvent effects on the frontier orbitals of a given molecule. Klopman (12) used the solvation model to predict the relative order or hard and soft Lewis acids and bases and nucleophilic or electrophilic reagents in a liquid. The influence of the solvent on electron affinities of cations has also been investigated (13). Other studies have considered systems including specific interactions (14–16) by using the supermolecule model. More recently, a cavity model, in which the electrostatic part of the solute–solvent interactions is computed by a multipole expansion of the electron distribution of the solute molecule, has been employed to analyze the role of these interactions in the frontier orbital energies of several small molecules, anions, and cations (17). This work was able to explain the changes in reactivity of various species when going from the gas phase into solution.

Apart from the crude representation of the solvent by a continuum, which has been discussed previously (18–20), the great limitation of the model employed by these authors is the use of a spherical cavity which makes it difficult to extend such calculations to molecules differing in spherical shape. This limitation can be overcome by the use of cavities fitting any molecular shape (7, 21). The application of such cavities is not very general owing to the fact that the electrostatic equations have to be integrated numerically. Constant coordinate cavities have been introduced because they allow analytic expressions for the electrostatic potential.

The use of a three-axes ellipsoidal cavity has recently been developed (22, 23). The equations derived allow us to write the perturbation hamiltonian in a form very similar to the expression obtained for the spherical cavity.

In this paper, the ellipsoidal cavity model has been employed in order to study the influence of the electrostatic solute–solvent interactions on a molecular orbital set of some molecules whose shape can not be fitted by a spherical cavity. The main aim of this work is to analyze the evolution of the HOMO on changing the medium. Given that strong solute–solvent interactions may be expected in some cases, a possible change in the nature of the HOMO should be envisaged. Therefore, we are interested in

analyzing the evolution of other occupied molecular orbitals. The molecules considered are some benzene derivatives. For such species the HOMO plays an important role in electrophilic substitution in which strong solvent effects have been emphasized.

Method of calculation

The method used to study the solvent effect is based on the spherical cavity model derived by Kirkwood, which has been adapted to quantum chemical calculations by Rivail and Rinaldi (8), and more recently extended to the use of three constant coordinate cavities (22, 23). This model has been widely used to evaluate solvation energies and solvent effects on molecular properties and has proved to be useful in the predictions of experimental values (24).

The Hartree–Fock equations for a solvated molecule are written

$$[1] \quad F_{\mu\nu} = F^0_{\mu\nu} + \sum_{l=0}^{\infty} \sum_{m=-l}^{+l} R_l^m \langle \mu | M_l^m | \nu \rangle$$

where M_l^m is a component of the spherical multipole moment of order l corresponding to the solute electron distribution and R_l^m is a component of the so-called reaction field. In the case of a spherical cavity these terms can be expressed in the simple form

$$[2] \quad R_l^m = f_l M_l^m$$

where f_l is the reaction field factor

$$[3] \quad f_l = \frac{(l+1)(\epsilon - 1)}{(l+1)\epsilon + l} \frac{1}{a^{2l+1}}$$

In the case of an ellipsoidal cavity the reaction field is written in a more involved form. Each component R_l^m is now expressed as a linear combination of spherical moments $M_{l'}^{m'}$ of the same parity and of the order $l' \leqslant l$, so that the reaction field factor adopts a tensorial form. Accordingly, one can write

$$[4] \quad R_l^m = \sum_{l'} \sum_{m'} F_{ll'}^{mm'} M_{l'}^{m'}$$

Detailed expressions for all these operators can be found in the original references (22, 23, 25).

The change in the solute molecular orbital levels where the solvent is considered is a consequence of two effects. First, the electrostatic interactions of the molecular orbital electron distribution with the reaction field, which modifies the initial eigenvalues, e_i^0, in the form

$$[5] \quad e_i = e_i^0 + \sum_{l,m} \langle R_l^m \rangle \sum_{\mu\nu} \langle \mu | M_l^m | \nu \rangle c_\mu^i c_\nu^j$$

Secondly, the polarization of the molecular wavefunction is a result of the non-homogeneous electric field. This effect can be taken into account by making a SCF calculation in which the total energy is minimized.

The results presented in this paper have been obtained by considering both electrostatic and polarization effects, i.e., SCF calculations where the total hamiltonian includes the solute – dielectric continuum interaction term. An attempt at interpretation of these results has been made by using the first-order perturbation theory which supplies a suitable picture to understand how the orbitals of isolated molecules are modified by the long-range solute–solvent electrostatic interactions.

The molecular geometries have been obtained by minimizing the total energy using the CNDO/2 method (26) and the wavefunctions have been evaluated by the CNDO/S technique (27). The calculations were performed by means of the GEOMO program (28), in which the electrostatic solute–solvent interaction, as described above, has been implemented. In the case of the benzoate anion, an additional *ab initio* calculation was made using a modified version (23) of the GAUSSIAN 76 program (29) including the method of cavity of Rivail and Rinaldi.

The volume of the cavities is taken as equal to the molecular volume of the pure liquid at room temperature. In the case of the anions the volume corresponding to their neutral molecule has been taken (17, 30).

Results

In a first step we will focus on the π MO's of the benzene derivatives (benzaldehyde, benzoic acid, nitrobenzene, benzoate anion, and phenolate anion). Table 1 shows the orbital energies in gas phase, $e(\epsilon = 1)$, for every occupied π orbital. In all cases the HOMO in the gas phase is the 1π orbital. From a second SCF calculation where the solute–solvent electrostatic interactions are taken into account (assuming $\epsilon = 78.0$), the MO's energies, $e(\epsilon = 78)$, have been obtained. The energy changes for the occupied π MO's, $\Delta e = e(\epsilon = 78) - e(\epsilon = 1)$ have also been included in Table 1. It is seen that these changes are very different for each orbital, even in the same molecule, and affect the Δe sign in some cases. Moreover, there are HOMO changes when the dielectric permittivity goes from 1 to 78.

We will begin analyzing the sign of Δe. A neutral solute must be chosen because in a charged solute the Born term is the main contribution leading to a global stabilization in all occupied MO's. Thus, Fig. 1 shows the scheme of the five occupied π MO's of nitrobenzene. This solute has been selected because its symmetry will simplify the discussion. 1π and 2π are the formerly degenerated orbitals of benzene, 3π is an oxygen lone pair orbital (non bonding, n), 4π is an orbital with nodal plane between the ring and the substituting group and 5π is the most stable bonding orbital. The dipolar interaction is the most important contribution to the stabilization energy of nitrobenzene given the strong dipole moment of this molecule. The molecular dipole moment, $\boldsymbol{\mu}_T$, and its associated reaction field term, $\boldsymbol{R}_1$, have the same direction as the C_2 molecular axis. The orbitals with high electron density in the oxygen atoms, 3π and 5π, give rise to orbital dipole moments parallel to $\boldsymbol{\mu}_T$, and so are stabilized when the dielectric permittivity goes from 1 to 78. On the contrary, the 1π, 2π, and 4π orbitals have the highest orbital coefficients associated with the ring atoms, giving rise to orbital dipole moments that go in the direction opposite to $\boldsymbol{\mu}_T$, thus their interactions with the reaction field are destabilizing.

Benzoic acid and benzaldehyde can be analyzed in the same way. Thus, we have predicted the sign of Δe for every studied π orbital of the neutral molecules considering only the dipolar interaction (Table 2). Comparing these results with those shown in Table 1, a good qualitative agreement is found except for the benzaldehyde 1π orbital. This case will be studied later.

A second fact deduced from Table 1 is the change in HOMO nature with the increase of the dielectric permittivity. Thus, at $\epsilon = 78$ the new HOMO is the 2π orbital for benzaldehyde and benzoic acid, and the 3π orbital for the benzoate anion. In the two former cases 2π was already the (HO-1)MO in gas phase, and therefore the crossing is only between π orbitals. However, in the crossing of the benzoate anion, σ orbitals are involved.

Figure 2 shows energy changes in the five higher occupied MO's of benzoate anion vs. dielectric permittivity. For charged solutes, the Born term, $l = 0$, is the main contribution to the

Nitrobenzene	+	+	−	+	−

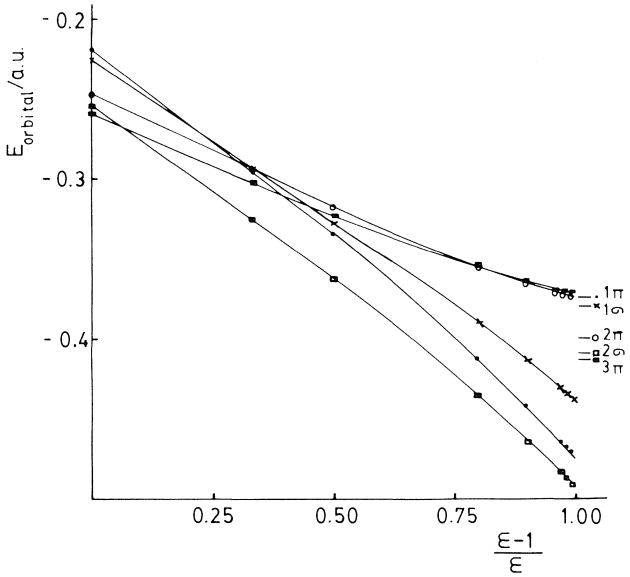

FIG. 2. Orbital energy evolution for the five higher occupied MO's of benzoate anion as a function of the dielectric permittivity. (The lines on the right hand represent the energy level that should have each MO if only the Born term was considered).

orbital energy change. This term affords a stabilizing and constant contribution for all occupied MO's, therefore the crossing between the MO's appearing in Fig. 2 have to be originated by the different kinds of interactions of each MO with the higher moments of the Reaction Field. Thus, 1π, 1σ, and 2σ are strongly stabilized (a larger extent than the Born contribution) while 2π and 3π are stabilized less than that corresponding to $l = 0$ term, i.e., the multipole terms give a destabilizing contribution to the MO energy. To explain these differential behaviors, in Fig. 3 the electron density of the benzoate anion MO's have been shown. Keeping in mind the constant contribution of the charge term, the relative energy changes can be explained by taking into account the dipole moments as done for neutral molecules, i.e., 2π and 3π have

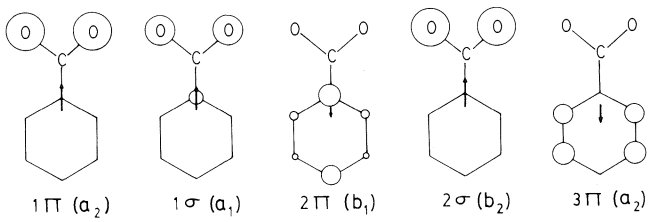

FIG. 3. Electron densities and orbital dipole moments of the five higher occupied MO's of benzoate anion.

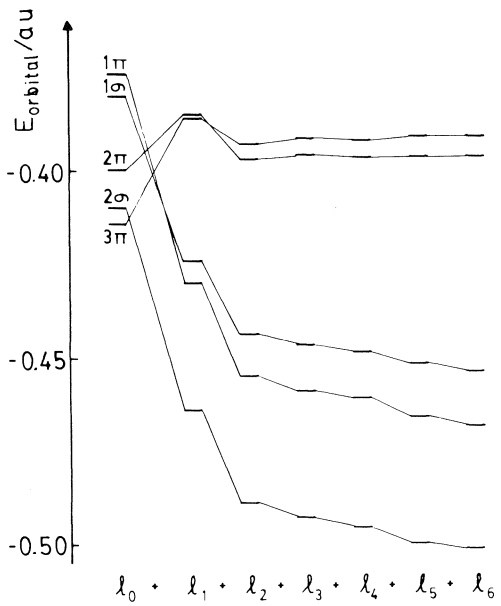

FIG. 4. Energy contribution, obtained by means of eq. [5], of each polar term to the five higher occupied MO's of benzoate anion.

TABLE 3.[a] Contributions of the first two polar moments to the 1π and 2π orbitals of benzaldehyde, obtained by means of the perturbational approach

	Contribution	
Polar moment	1π	2π
l_1	+0.0031	+0.0072
l_2	−0.0034	+0.0019

[a]Atomic units.

orbital dipole moments which point in the opposite direction from μ_T, while those of 1π, 1σ, and 2σ are parallel to μ_T.

A similar analysis may be applied to the phenolate anion. The 2π orbital, the one less stabilized due to the positive contribution to Δe of terms $l > 1$, corresponds to the benzoate anion 3π orbital, and the most stabilized one is 3π, an orbital with high electron density in the oxygen atom.

Nevertheless, the previous analysis does not allow the prediction of the orbital inversion but rather a qualitative idea of the energy gap between the different MO's. For this reason, to give a more quantitative estimate of the multipole moment effect, we have calculated the energy contribution of each multipolar term from eq. [5], in a perturbational way. A localized charge distribution in each atom has been taken. In Fig. 4 the energy vs. the l-polar term have been plotted for the MO's of the benzoate anion. A crossing appears for the dipolar term, l_1, but the order of orbitals does not match the sequence obtained by SCF calculations. To achieve this sequence the contribution of the quadrupolar term, l_2, must be taken into account. The terms higher than l_2 are small and do not alter the energy order.

A similar calculation has been carried out for benzaldehyde, and in Table 3 the contributions of the first two moments to the 1π and 2π orbitals are gathered. In this case the quadrupolar term cancels the dipolar one for the 1π orbital, changing our initial provisions. It must be pointed out that both contributions are nearly the total energy change shown in Table 1.

Finally, in order to test the charge distribution obtained by CNDO/S we have performed *ab initio* calculations of the benzoate anion using the STO-4G basis for $l = 1$ and $l = 78$. Table 4 shows the orbital energy variations obtained by means of CNDO/S and STO-4G, subtracting the constant contribution of the charge term.

Discussion

Solvation phenomenon is usually thought of as a unique effect, generally stabilizing, over the molecular system introduced in the condensed medium. In a cavity model the effect of solvation is envisaged as the interaction between the total charge distribution of the solute and the electrostatic potential generated by the reaction field of the polarized dielectric continuum within the cavity.

Given that the reaction field is generated by the charge distribution of the solute, it has the appropriate symmetry to lead to a global stabilizing interaction. Nevertheless, the charge distribution is not always the same in an orbital as in the whole molecule. Consequently, energy gaps of different sign may appear within the MO set. The estimate of Δe is not obvious in all cases. In a first approach the sign of the effect can be deduced taking into account the dipole moment, specially when this is the most important moment generated by the charge distribution, i.e. nitrobenzene. Thus, MO's with high contributions of electronegative atom orbitals, for instance the lone pair 3π orbital of nitrobenzene, show a strong stabilizing effect, since their dipole moment is parallel to the total dipole moment. On the other hand, MO's with high coefficients associated with the ring atom orbitals show a destabilizing effect because they have an orbital dipole moment whose direction is opposite to that of molecular dipole moment, i.e. the formerly degenerated π orbitals of benzene 1π, and 2π in nitrobenzene.

Nevertheless, this simple approach does not predict the solvation effect on the MO set when the solute does not have a strong dipole moment or when an orbital inversion takes place. In both cases a more thorough estimate of Δe using higher multipole moments must be carried out. As has been shown in the previous section, a perturbational analysis gives values of Δe near to the variational ones of Table 1. Calculations for the benzoate anion and benzaldehyde show that on considering the multipole expansion as far as the quadrupole moment, the results obtained agree quite well with those of SCF calculations. On introducing higher moments, small corrections to the final energy are obtained indicating the convergence of multipole expansion. Usually, good descriptions of solvation phenomena may be achieved with the main and the next two l-pole moments.

The small changes in the MO coefficient set observed when ϵ goes from 1 to 78 point out the minor role of polarization phenomena (31). It explains why our solvation energy estimates from perturbational calculations correlate quite well with the results obtained by SCF calculations. However, the behavior of the dipole expansion and its associated polarization phenomena are not general, due to the fact that a minimal basis set is used in all cases. This point will be dealt with below.

Changes in HOMO nature due to solvent effects may involve important alterations in chemical reactivity. For instance, Fig. 5 shows the shape of benzaldehyde HOMO in gas phase and condensed phase for $\epsilon = 78$. The orbital inversions found cause changes in the most suitable centers for electrophilic

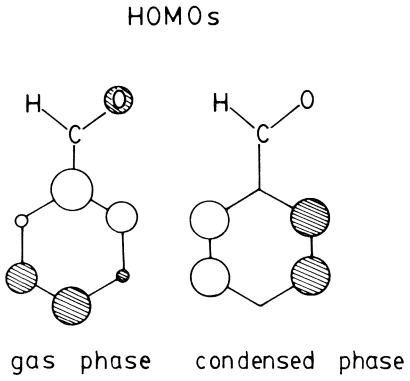

FIG. 5. HOMO's of benzaldehyde.

TABLE 4.[a] SCF results

MO	Orbital energy	
	CNDO/S	STO-4G
1π	−0.0968	−0.0638
1σ	−0.0541	−0.0510
2π	+0.0270	+0.0140
2σ	−0.0716	−0.0604
3π	+0.0403	+0.0326

[a]Atomic units. Orbital energy variations in benzoate anion are obtained by subtracting the Born term, $\Delta e' = \Delta e - I_0$.

substitution reactions if the conditions favor an orbital control. Nevertheless, a small energy gap between the HOMO donor level and the LUMO acceptor level is required for a frontier-controlled reaction. Therefore, in addition to the changes caused by the solvent in the MO set, the influence of solvation on the HOMO–LUMO gap must be kept in mind.

For the anions there is a loss of orbital control because the solvation strongly decreases all occupied orbital energies. However, reactions involving soft nucleophiles can allow a partial charge transfer which could make the HOMO play a more important role as the reaction progresses (1). This situation will be favored by the partial desolvation needed in reactant approximation, as Klopman has recently suggested (32).

For neutral molecules, there is a weaker influence of the solvent on the MO energies, since the strong stabilizing contribution of the Born term does not appear. Therefore, HOMO inversion may take place without a significant decrease in orbital control. On the other hand, the weak effect of the solvent prevents a great HOMO-(HO-1)MO energy gap. Nevertheless, following Fukui's principle of narrowing of inter-frontier level separation (1), the reaction progress will favor the increase of localized electron density over the interacting centers and it will increase the relative weight of HOMO within the MO set (33).

Analogous deductions were made from a solvation study of these molecules with the supermolecule model (34) using H_2O and HF as solvents. This similarity implies that specific and electrostatic solute–solvent interactions have common factors which must be linked to the properties of the solute more than to those of a particular solvent. Nevertheless, keeping in mind that hydrogen bonding itself is electrostatic to a large extent (31, 35), and that the solutes considered form strong hydrogen bonds in the supermolecule, one may deduce that the discrete study represents a limit of the specific interactions close to the interactions detailed by the continuum model.

For this explorative work we have chosen a semiempirical quantum chemical method because of its relatively low computational time. The CNDO method gave reasonable electron distribution (36) and afforded quite good answers to a number of problems in which the influence of the solvent on chemical and spectroscopy phenomena was under study (37). The *ab initio* calculations performed on the benzoate anion support this hypothesis, as shown in Table 4. The use of a minimal basis set probably underestimates the electronic effects derived from higher harmonics. However, in the cases studied these contributions do not imply large modifications in the effects, owing to the high values of the first terms of the multipole moment. Another problem is that the diffuse nature of the charge density of anions is rendered rather poorly by a minimal basis set. In any case, the picture given in this work may be a good starting point for more accurate calculations. The use of more complete basis sets is needed to supply a more correct representation of the electrostatic solute–solvent interactions. In order to get a deeper insight into the behavior of the multipole expansion and the role of the polarization phenomena, *ab initio* calculations using double-ζ and diffused basis sets are in progress.

A quantum approach to the mechanism of electrochemical reductions

JUAN J. NOVOA

Departamento de Quimica Fisica, Facultad de Quimica, Universidad de Barcelona, Av. Diagonal 647, 08028-Barcelona, Spain

Received July 19, 1986

JUAN J. NOVOA. Can. J. Chem. **64**, 2359 (1986).

Using the Hartree–Fock method and, in some cases, the second order Moller–Plesset perturbational method, with 4-31G, 4-31 + G, and 4-31 + G* basis sets, a first approach to the study of the mechanism of electrochemical reduction from formaldehyde to ethanol is presented. The total energy and optimized geometry of each of the molecules involved are also given. A proton–electron–proton–electron type mechanism is proposed.

JUAN J. NOVOA. Can. J. Chem. **64**, 2359 (1986).

Faisant appel à la méthode de Hartree–Fock et, dans quelques cas, à la méthode des perturbations du second ordre de Moller–Plesset, avec des ensembles de base 4-31G, 4-31 + G et 4-31 + G*, on présente une première approche à l'étude du mécanisme de la réduction électrochimique du formaldéhyde en éthanol. On rapporte aussi l'énergie totale ainsi que la géométrie optimisée de chacune des molécules impliquées. On a trouvé un mécanisme du type proton–électron–proton–électron.

[Traduit par la revue]

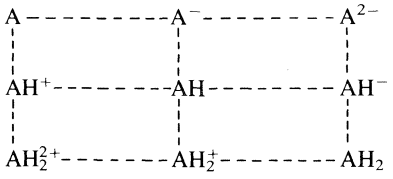
Introduction

The mechanism in an electrochemical reduction is one of the unresolved problems in electrochemistry. This is due to the difficulties encountered in experimental detection and the identification of the intermediates. This is therefore an area where quantum chemistry can be of some use since it enables one to study all the postulated intermediates, even if they are not available experimentally.

One of the problems in the theoretical study of the electrochemical reductions is the large variety of global processes present and the competition, between them, as shown by the types of final products present: monomers, dimers, and organometallic compounds. The product ratios depend on the compound studied and the medium characteristics (pH, temperature, solvent, ...). Let us start by focussing our attention on only one reaction, for example, the reduction of a compound A to its associated monomers AH_2, following the reaction

[1] $A + 2H^+ + 2e^- \rightarrow AH_2$

The mechanism is known once we can establish the order of the addition of the two protons and the two electrons. The following square diagram presents all possible paths going from A to AH_2 for reaction [1]:



where horizontal lines represent an electroaddition, and vertical lines the addition of a proton. Once the total energy for all the systems is known, and the transition states between them are located, one can establish the most stable pathway. This can be done by means of any of the currently available quantum chemical methods (1). In this work, we present a first approach to the problem by studying the gas phase mechanism. In further studies we will focus our attention on the solvent effect of the proposed mechanism using the appropriate methodology (2).

Methodology

In this study we have used the analytical form of the Hartree–Fock method (3) (RHF for the closed-shell systems, and UHF for the open-shell ones) and the 4-31G, 4-31 + G, and 4-31 + G* basis sets, while the electron correlation is computed by means of second order Moller–Plesset method (MP2). Previous studies have shown that with the 4-31G* basis set at the HF level one obtains a mean error lower than 10 kcal/mol in the computed proton affinities of neutral and charged compounds (4), while the error is considerably higher for the electron affinities (5, 6), the only two types of reactions present. When anions are present, it has been established (7) that it is necessary to include diffuse orbitals in the basis set to obtain a proper description of the electronic distribution. For this reason, we have used the 4-31 + G and 4-31 + G* basis sets, constructed by adding a set of *s* and *p* diffuse functions (7) to the 4-31G and 4-31G* bases. For the computation of electron affinities, one also needs to include the electron correlation to achieve a high enough accuracy when anions are involved (8). We bear in mind at all times that accurate results are essential in mechanistic studies.

In our case, the application of the Hartree–Fock method is straightforward. We compute the optimum geometry for each molecule in the square diagram, thereby we will know the total energy for all the molecules and therefore their relative stability. Using these relative stability indicators, we may derive a mechanism for the reaction. One can go somewhat further by computing the potential energy curve for the energetically allowed additions to find the possible transition states. Assuming the Franck–Condon approach is correct, then barriers only exist in exothermic proton additions, which simplify our computational effort. Using the relative stability data and those relative to the barriers it is possible to define a path for reaction [1].

All these computations are done with the same basis set to minimize the influence of the truncation error in energy differences. Therefore, even if there are better computations for some of the molecules using more extended basis sets, they would not be useful for our studies because the basis set truncation error changes from basis to basis and can be quite important. In this work we use three different standard bases widely employed in the literature to study the effect of the quality of these basis sets.

Results and discussion

The total energy computed for each molecule present in the square diagram corresponding to formaldehyde in its optimum geometry, together with the final symmetry group to which they

TABLE 1. Total electronic energy for the optimum geometry (see text) computed with each basis in the given electronic state; the final symmetry is also shown

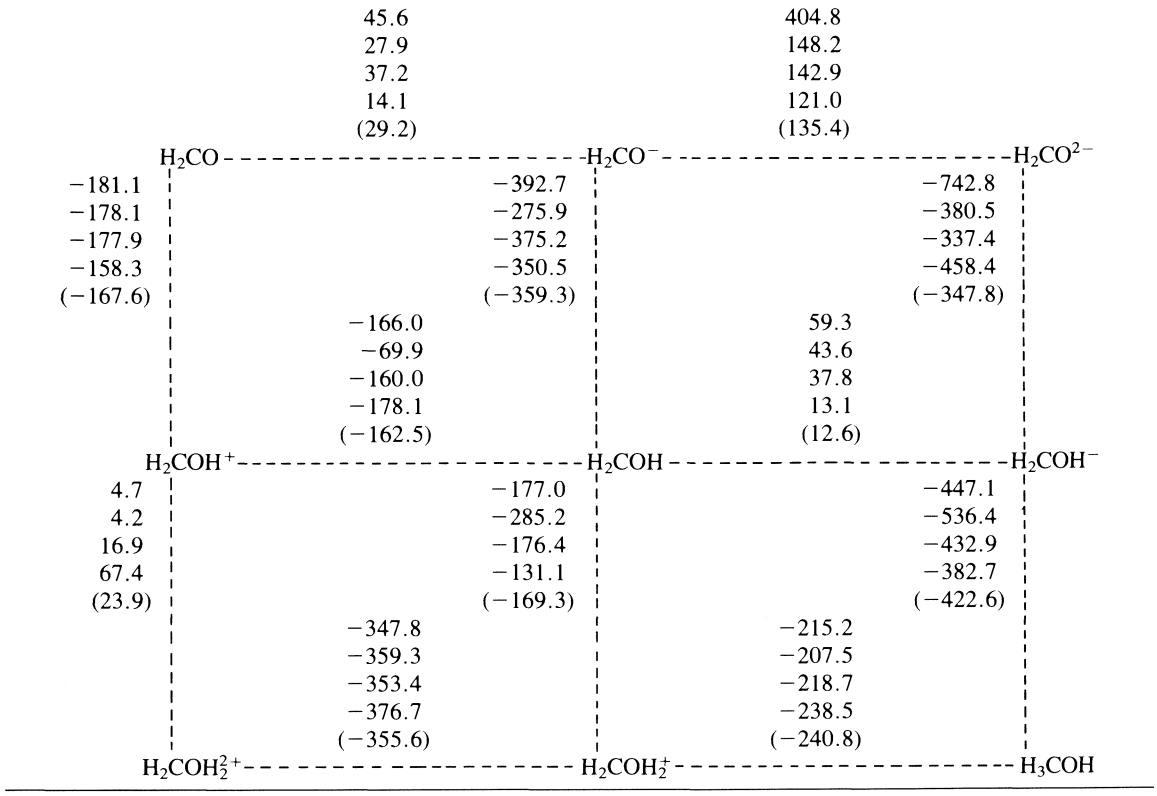
TABLE 2. Energetic differences (in kcal/mol) for the linked systems by the lines[a]



[a]The first value is the 4-31G result, the second one corresponds to the 4-31+G value, the third one is the 4-31+G* value, and the fourth is the MINDO/3 result. The values in parentheses are the MP2 values computed with the 4-31+G* basis set.

belong, and the associated electronic state, are given in Table 1 for all the basis sets employed. The values obtained in a previous computation (9) using the semiempirical MINDO/3 method (10) have also been included for comparison. From the results in Table 1 we have computed the energetic increment in each possible step of the reaction, following the normal procedure ($\Delta E = E_f - E_i$). Those results are included in Table 2 and, because the total energy of the isolated proton and electron are equal to zero, they also correspond to the relative stability of these systems.

With respect to the *ab initio* results, one must notice that the geometry optimization was only carried out with the 4-31G basis set. When the 4-31+G or 4-31+G* basis are used, we have used the 4-31G optimized geometry because previous experience has shown that there are only minor changes in the 4-31G geometry when reoptimized at the 4-31+G or 4-31+G* basis set level.

Even if geometry is not important in the reduction mechanism, it gives an idea of the route of transformations of the molecules. For this reason, we have included in Table 3 the values of the geometrical parameters together with a computer-generated tridimensional plot of the geometries, Fig. 1, which gives an overall idea of the transformations. All values are given in the usual units (Å for lengths, deg for angles). For comparison, the MINDO/3 values computed in ref. 9 are also given.

In all tables and in Fig. 1, we have used the following conventions for the names of the molecules: Each molecule is identified by its stoichiometry, but the hydrogen atoms are grouped near the atom to which they are bounded. This enables one to easily distinguish the various isomers of a molecule. Thus, H_2COH^+ is obtained by adding one proton to the oxygen atom in H_2CO while H_3CO^+ is the isomer with the proton on the carbon atom.

All computations have been done using the GAUSSIAN-80 set of programs (11).

Energy and geometry

The results included in Table 1 show, as expected, a decrease in total energy as with an increase in quality of the basis set. Computations with the 4-31G* basis set show that in all cases except for the dianion H_2CO^{2-}, the addition of a set of polarization functions seems to give better total energy than the inclusion of a set of *sp* diffuse functions. The same trend is observed when going from the 4-31+G to the 4-31+G* basis set. However, the inclusion of the diffuse set is very important to correctly describe the anions while it practically leaves the stability of the neutral systems unchanged in agreement with results from the literature (4, 6). All the total energies computed here are in good agreement with the values reported in the bibliography.

There are two remarkable facts about the results in Table 3. One is the good agreement of the experimental and *ab initio* results, in particular when the 4-31G basis is used. The other, is that MINDO/3 geometries are very similar to the *ab initio* ones and, therefore, the latter method describes remarkably well the type of geometrical changes the molecules undergo. This seems to be promising for this method to be used in the computation of the square diagrams of big molecules.

Results of Tables 1 and 3 show that the addition of an electron to a neutral molecule is always an endothermic process at the HF level with the basis set employed. However, the only reported

[a]All the distances in Å and angles in deg. The parameters are as follows: AB means the distance between atoms A and B; H1CH2 represent the angle formed by the bonds H1—C, and C—H2 (the hydrogens are numbered as in Fig. 1); H1CO—H4 is the dihedral angle between the atom H4 and the plane formed by the atoms H1, C, and O, looking from the atom bonded to H4 (see Fig. 1). Only the symmetry nonequivalent parameters are indicated. The MINDO/3 and experimental (ref. 10) values are also given for comparison.

[b]Only the geometry of the CO fragment is given. The two H^- fragments are at dissociation distance. The experimental CO distance is 1.128 Å.

[c]Corresponding to the staggered conformation (the most stable with a 4-31G base).

datum on these molecules is the electron affinity of the H_3CO molecule, whose experimental value is 36.7 kcal/mol. Previous studies in this field have shown that if one wants to reproduce the experimental electron affinity of the neutral compounds one needs, at least, to work with a 4-31+G basis set and the MP2 method (8). A computation at that level, using the optimized 4-31+G geometry, gives a total energy for the H_3CO molecule of −114.448669 au, while the same value for the H_3CO^- anion is −114.484130 au, that is, one obtains the correct stability between the systems and a value of 22.3 kcal/mol (experimental value of 41.3 kcal/mol), while at the 4-31+G* level, the same property takes the value of 29.13 kcal/mol. In any case, when compared to the Hartree–Fock results, we see that they are correct in sign, and the error is almost of chemical precision. Having these results in mind we have performed computations using the 4-31+G* basis for all the systems, at the MP2 level and with the 4-31G geometries. From these values, one can conclude that the addition of an electron to the neutral molecules H_2CO and H_2COH is endothermic, while the same process is exothermic for the cations, and endothermic for

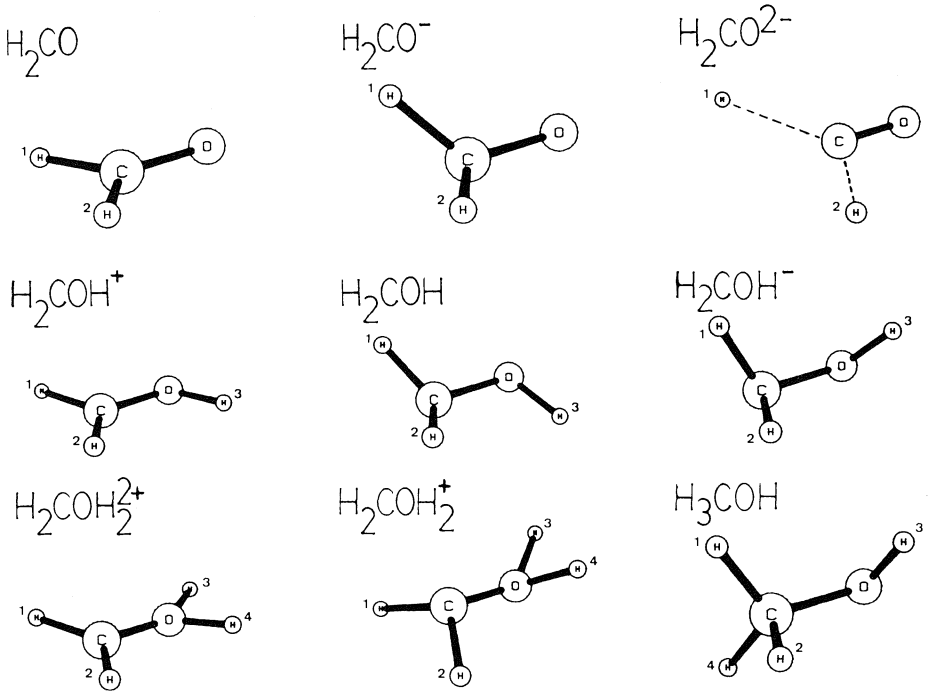

FIG. 1. Three dimensional plot of the optimized geometries of the molecules included in Table 2. The atoms are identified by their atomic symbol and the molecules to which they belong are indicated in the upper-left corner. Broken lines are used to represent non-bonds and solid ones for bonds.

H_2CO^-. At this point, one must notice that the MINDO/3 values reproduce remarkably well the MP2 values for the electronic affinity of all the systems, either neutral or not.

In relation to the proton addition process, the results computed here show that the protonation of formaldehyde is only possible on the oxygen atom and with a geometry which preserves the C=O double bond. After this step, a second protonation can happen on the formaldehyde molecule. Previous computations on both isomers (12), H_3COH^{2+} and $H_2COH_2^{2+}$, done under the constraint of C_{3v} symmetry on the methyl group of the first molecule, show that the most stable isomer is $H_2COH_2^{2+}$ because it preserves the double bond. A full optimization of both systems does not change the conclusion. The only new fact which appears is that H_3COH^{2+} is not stable and splits into $HCOH^+$ and H_2^+.

The addition of an electron to the planar and isoelectronic compounds H_2CO, H_2COH^+, and $H_2COH_2^{2+}$ breaks up their planarity. This is an endothermic process for the first compound, but an exothermic one in the last two cases. The exothermicity is proportional to the net charge of the system.

The addition of a second proton to the H_2COH molecule is possible on either the carbon or the oxygen. However, the $H_2COH_2^+$ isomer is 5 kcal/mol more stable than H_3COH^+ at the 4-31G* level, while in the other cases the stability is preserved. The addition of a new electron reverses the relative stability and the H_3COH isomer is about 100 kcal/mol more stable than H_2COH_2.

Energetics

From the results in Table 1, one can compute values in Table 2 as simple differences. Furthermore, we have also included for comparison the MINDO/3 results obtained from a previous study (9).

Let us take note that Table 2 do not include the H_3CO^+, H_3CO, and H_3CO^- molecules. H_3CO^+ does not exist as it transforms into H_2COH^+ without a barrier. Thus the H_3CO system can only be obtained through protonation of the H_2CO^- molecule. However, because the H_2CO^- molecule is energetically unstable, this path is not possible and H_3CO is never formed. Similarly, we can not obtain H_3CO^- as an intermediate in the reduction of H_2CO.

Before using results in Table 2 to establish a reduction mechanism, it is necessary to know the quality of these results, by comparing these with the experimental values for the two types of reaction described in this table: proton and electron additions. Electron additions have been dealt with above and we have concluded that MP2 computations done with a 4-31+G* basis describe the sign and value of the energy increment with almost chemical precision. The MP2 values obtained are included in parentheses, and can be used as reference for all the other results in the same table. For proton affinities, one can see that the experimental value for the proton affinity of formaldedyde in the gas phase (−177.2 kcal/mol) compares very well with the 4-31G* computed value of −180.7 kcal/mol, and with the 4-31+G and 4-31+G* values (−178.1 and 177.9 kcal/mol, respectively), while for the H_3CO^- system the theoretical value using a 4-31G* basis set gives a value of −411.1 kcal/mol while the experimental value is −384.6 kcal/mol. Both results lend confidence to the theoretical prediction of this property at the 4-31+G* level. We can conclude that the sign and the order of magnitude of the energetic variation involved in the reaction is correctly described by our best result. Therefore, we have the level of precision to establish the mechanism of reduction for our compound.

Electronic correlation exerts practically a uniform effect on the HF results of the cations and the neutral molecules (a lowering of about 0.2 au in the total energy) and a slightly higher results (a lowering of 0.3 au in the same property) for the anions. However, this correction does not affect the sign of the energy increments included in Table 2 and, therefore, for the reaction studied, the electron correlation does not affect the main facts of the reaction energetics.

Finally, we can compare the "best" results reported here with those computed with the other basis sets and with MINDO/3. In the first case, one can also see that the results from using 4-31G are very similar to those from using 4-31+G*, except when the dianion is also involved. In relation to the MINDO/3 results, the electron and proton affinities are very well matched for the compounds studied here. Thus, the MINDO/3 values computed for the proton affinity for H_2CO and H_3CO^- are −158.3, −322.7 kcal/mol, respectively (experimental values are −177.2, −384.6 kcal/mol) while the computed electron affinity of H_3CO is 45.2 kcal/mol (the experimental value is 36.7 kcal/mol). As to the relative stabilities shown in Table 2, one can see that the tendencies in the MINDO/3 results are exactly the same as those reported for 4-31+G* MP2.

Mechanism

Looking at Table 2, we can establish a mechanism for the reduction of formaldehyde to ethanol by successive addition of two protons and two electrons. This, as has already been indicated, can be done by, first, seeking the exothermic pathways and, then, studying their kinetic behaviours. Thus, the first step is the protonation of the initial compound on the oxygen atom (the only exothermic pathway). Since there is no activation barrier in this reaction, it is therefore kinetically allowed.

After the first protonation, the next step is an electroaddition, because the proton addition to the H_2COH^+ system to give $H_2COH_2^{2+}$ has a barrier and is endothermic (12). The third step can only be a new protonation for energetic reasons. Again, there is no barrier for this reaction. Finally, the fourth step is an electroaddition. This mechanism proton–electron–proton–electron is known experimentally as CECE because the proton addition is said to be the chemical step, while the electroaddition is the electrochemical one.

Conclusions and final comments

Previous results have shown that it is possible to elucidate the mechanism of electroreduction of a compound by using quantum chemical methods. Even if the experimental conditions are far from the isolated molecule, the chemical information behind the reported results are of interest. Thus, they show that the electroaddition of the formaldehyde is not energetically stable because the double bond is broken, an effect which is independent of the existence of a solvent, whose primary effect is to stabilize the charged systems. In any case, we are now starting a study to elucidate the effect of solvent in electrochemical reductions.

MAHMOOD HOJATTI and KENNETH T. LEFFEK. Can. J. Chem. **64**, 2365 (1986).

The equilibrium constants and second-order rate constants, both at 25°C, have been determined for the proton transfer reaction from 4-nitrophenylphenylcyanomethane to tetramethylguanidine in a number of different solvents. While the equilibrium constants show a good correlation with the dielectric constant function $D - 1/2D + 1$, the rate constants are randomly scattered with respect to this parameter and also the solvent parameter E_T. The rate constants do show a general trend in relation to the solvent parameters AN and DN. These results are interpreted as support for the hypothesis that the transition state of the proton transfer occurs early along the reaction path.

MAHMOOD HOJATTI et KENNETH T. LEFFEK. Can. J. Chem. **64**, 2365 (1986).

Opérant dans un certain nombre de solvants, à 25°C, on a déterminé les constantes d'équilibre ainsi que les constantes de vitesse du deuxième ordre pour la réaction de transfert de proton du nitro-4 phényl phénylcyanométhane à la tétraméthylguanidine. Alors que les constantes d'équilibre présentent une bonne corrélation avec la fonction de constante diélectrique $D - 1/2D + 1$, les constantes de vitesse sont réparties au hasard par rapport à cette fonction ainsi que par rapport au paramètre E_T du solvant. Les constantes de vitesse présentent une corrélation générale par rapport aux paramètres AN et DN du solvant. On croit que ces résultats supportent l'hypothèse selon laquelle l'état de transition du transfert de proton se produirait tôt au cours de la réaction.

[Traduit par la revue]

Introduction

Previous investigations of the proton transfer reaction of 4-nitrophenylphenylcyanomethane and substituted derivatives with tetramethylguanidine (TMG) studied the activation parameters, deuterium isotope effects, and the Hammett correlation (1, 2). These studies led to the conclusion that the transition state for the reaction occurred early along the reaction coordinate with the negative charge development still concentrated on the central carbon atom of the methane.

In this paper the variation of the equilibrium constant K_e and the second-order rate constant k_f with the solvent are studied to further test this hypothesis. A variety of pure solvents were selected in order to test whether K_e and k_f were governed by specific or non-specific solvation effects.

Results and discussion

In each solvent studied the reaction of 4-nitrophenylphenylcyanomethane with TMG base gave a product with a single broad absorption peak, λ_{max} varying between 565 nm and 590 nm, depending on the solvent. The product has been shown by previous work (1, 2) to be the ion-pair of reaction [1]. The equilibrium constants, K_e, were determined for the reaction

[1] $$NO_2C_6H_4\underset{\displaystyle C_6H_5}{\underset{|}{C}}HCN + HN{=}C(N(CH_3)_2)_2 \underset{k_b}{\overset{k_f}{\rightleftharpoons}} NO_2C_6H_4\underset{\displaystyle C_6H_5}{\underset{|}{C}}\bar{C}N\ldots H_2\overset{+}{N}{=}C(N(CH_3)_2)_2$$

using the Hildebrand–Benesi method (3). The method yields eq. [2] for reaction of the type shown in [1] in which

[2] $$a/A = \frac{1}{K_e b \epsilon} + \frac{1}{\epsilon}$$

the product is an ion-pair. The initial concentrations of the acid and base are represented by a and b, respectively, A is the absorbance at equilibrium and ϵ is the molar extinction coefficient of the ion-pair product.

In each solvent, for a given concentration of the methane within the range of 1×10^{-5} M to 5×10^{-5} M, the absorbance was measured at λ_{max} for a series of different base concentrations. The results were fitted to eq. [2] by a linear least squares calculation. The correlation coefficients for 7 to 9 base concentrations were generally 0.999 or better. Values of K_e and ϵ were calculated from the slope, $1/K_e\epsilon$, and the intercept, $1/\epsilon$, for each solvent. The results are summarized in Table 1.

Caldin and Mateo (4) carried out an investigation of the variation of the equilibrium constant with solvent for the proton transfer reaction from 4-nitrophenylnitromethane to tetramethylguanidine and found only a general trend for the variation of log K_e with the standard dielectric constant functions D^{-1} and $D - 1/2D + 1$ (5), indicating that in that reaction non-electrostatic interactions are important. In contrast to this, the results in Table 1 show quite a good correlation with both D^{-1} and $D - 1/2D + 1$. The plot of log K_e vs. $D - 1/2D + 1$ is shown in Fig. 1. With the exception of the value of log K_e in methanol, the remaining seven points give a correlation coefficient of 0.987. A similar plot of log k_e vs. D^{-1} gives a correlation with a slightly better coefficient of 0.991, again with the methanol point badly off the line correlating the other seven solvents. Attempted correlations with the solvent parameters E_T (6, 7), AN (8, 9), and DN (9, 10) give very low correlation coefficients.

It is concluded that the solvation factors controlling the value of the equilibrium constant, K_e, for the reaction in [1] in the solvents studied are general electrostatic effects and involve only a small amount of specific solvation, except for the reaction in methanol solvent. Either the methanol is acidic enough to result in specific solvation of the carbanion ion-pair or there is an acid–base equilibrium between methanol and TMG yielding a methoxide ion which then acts as the proton-abstracting base from the carbon acid. The latter reaction would lead to the same product as [1], but at least one methanol molecule would be specifically solvated to the carbanion. Also, the observed

equilibrium constant would be the product of K_e for reaction [1] and the equilibrium constant for the acid–base reaction between methanol and TMG.

The pseudo first-order rate constants, k_f, were determined for the proton transfer reaction using a large excess of base, as previously described (1). The results are shown in Table 2. The log k_f values show no correlation with the dielectric constant functions D^{-1} or $D - 1/2D + 1$ (correlation coefficient 0.04), nor with the solvent parameter E_T (6, 7) (correlation coefficient 0.4). There does exist a general trend, shown in Fig. 2, between log k_f and the electron acceptor parameter AN (8, 9) (correlation coefficient 0.60) and also between log k_f and the electron donor parameter DN (9, 10) (correlation coefficient 0.72) indicating that the transition state of the reaction may be stabilized by specific solvation of both the developing positive and negative charges.

The possibility of a contribution from proton tunnelling exists in the values of the rate constants, which is not the case for the equilibrium constants. Evidence for a significant contribution to k_f from proton tunnelling was found (1) for this reaction in acetonitrile and benzonitrile solvents, but it was not possible to make any quantitative estimate of its importance. However, it is unlikely that this effect would play a major role in determining the rate constant in comparison to specific solvation effects on the transition state.

The marked difference between the variation of the equilibrium constant with solvent and that of the second-order rate constant with solvent, clearly shows that the transition state of the reaction is not at all product-like. The fact that the

second-order rate constant does not correlate well with any solvent parameter probably means that the amount of charge development in the transition state varies from solvent to solvent, but is not extensive in any of the solvents studied. Thus, this study of solvent effects on the proton transfer from 4-nitrophenylphenylcyanomethane to TMG supports the hypothesis that the transition state occurs early on the reaction coordinate.

Experimental

The preparation and purification of the reactants have been described previously (2). The solvents were purified carefully by standard methods. Reagent grade ethyl acetate was purified by washing it with aqueous sodium carbonate (5%), then with a saturated solution of calcium chloride. After drying over anhydrous potassium carbonate, the solvent was fractionally distilled from P_2O_5.

Peroxide-free reagent grade tetrahydrofuran (THF) was dried over potassium hydroxide pellets and then refluxed over a mixture of sodium wire and benzophenone. The pure solvent was fractionally distilled from this mixture.

The alcohols were purified using the procedure of Lund and Bjerrum (11). Magnesium turnings (5 g) were added to the alcohol (60 mL) together with sublimed iodine (0.5 g) and the mixture was refluxed until the iodine colour had disappeared and all the magnesium was converted to the alkoxide. Additional alcohol (900 mL) was added, refluxed for 1 h, and then fractionally distilled. The purified alcohol was stored over 4A molecular sieves.

Reagent grade propylene carbonate was dried over 4A molecular sieves for 2 days. Potassium permanganate (10 g/kg) was added with constant stirring and the resultant MnO_2 was filtered off. The excess permanganate was destroyed by heating the solution to 120°C. The solvent was distilled at reduced pressure and passed through a column of alumina. It was then twice fractionally distilled at reduced pressure, each time taking the middle two-thirds fraction and storing it under an inert atmosphere.

Acetonitrile and benzonitrile were purified as previously described (1).

The equilibrium measurements were carried out using a Cary 219 spectrophotometer and the kinetic measurements were made with a Durrum-Gibson stopped-flow spectrophotometer as described previously (2).

Received June 17, 1985[3]

AFAF KAMAR, ALEXANDER BALDWIN YOUNG, and RAYMOND EVANS MARCH. Can. J. Chem. **64**, 2368 (1986).

Proton affinities have been determined for 4-methyl-3-penten-2-one, 2-propyl ethanoate, and 4-hydroxy-4-methyl-2-pentanone in the gas phase at 333 K. A quadrupole ion store (QUISTOR) was employed to study mass spectrometrically the equilibrium between a species of known proton affinity and one of the above compounds; equilibrium between protonated species was monitored over an ion storage duration of 100 ms. The values of the proton affinities were found to be 870.5 ± 0.8 kJ mol^{-1} for 4-methyl-3-penten-2-one (mesityl oxide); 842.7 ± 0.6 kJ mol^{-1} for 2-propyl ethanoate; and 831.6 ± 0.8 kJ mol^{-1} for 4-hydroxy-4-methyl-2-pentanone (diacetone alcohol).

AFAF KAMAR, ALEXANDER BALDWIN YOUNG et RAYMOND EVANS MARCH. Can. J. Chem. **64**, 2368 (1986).

Opérant en phase gazeuse, à 333 K, on a déterminé les affinités protoniques de la méthyl-4 pentène-3 one-2, de l'éthanoate de propyle-2 et de l'hydroxy-4 méthyl-4 pentanone-2. On a utilisé un emmaganisage quadrupolaire d'ions (QUISTOR) pour étudier par spectrométrie de masse l'équilibre entre une espèce d'affinité protonique connue et chacun des composés mentionnés ci-dessus; on a enregistré les équilibres entre les espèces protonées à des périodes d'emmagasinage ionique de 100 ms. On a trouvé que les affinités protoniques sont les suivantes : pour la méthyl-4 pentène-3 one-2 (oxyde de mésityle), 870,5 ± 0,8 kJ mol^{-1}; pour l'éthanoate de propyle-2, 842,7 ± 0,6 kJ mol^{-1}, et pour l'hydroxy-4 méthyl-4 pentanone-2 (diacétone alcool), 831,6 ± 0,8 kJ mol^{-1}.

[Traduit par la revue]

Introduction

In the course of a study of the ion chemistry of 2-propanone and the infrared multiphoton dissociation of protonated dimers of 2-propanone, it was found necessary to investigate the ion chemistry and photochemistry of both diacetone alcohol and mesityl oxide (1). In order to compare the reactivities of isomeric ions within the above systems, a knowledge of the proton affinities of diacetone alcohol and mesityl oxide was necessary. However, the proton affinities were not available in the literature (2). With the quadrupole ion store (QUISTOR) in which gaseous ions can be stored for up to 200 ms we believe that thermal equilibria can be measured (3), hence the relative proton affinities for diacetone alcohol and mesityl oxide, along with that for isopropyl acetate were determined.

A knowledge of the gas phase basicities or proton affinities (PA) of molecules is crucial in the calculation of enthalpies of formation of protonated species and further, the calculation of enthalpies of reaction for subsequent reactions and particularly for unimolecular dissociation. In addition, the hierarchy of gas phase basicities permits the investigation of structural and electronic substituent effects in the absence of the complicating and often considerable role of solvent.

Experimental

The basic apparatus used in this study consisted of a QUISTOR mounted in place of the ion source of a quadrupole mass filter (Vacuum Generators QXK 400). Known mixtures of gases were admitted to the QUISTOR and ionized with a pulsed electron beam. The temporal variation of ionic products of subsequent ion molecule reactions was monitored over a period of 100 ms. The ratio of protonated ion intensities was plotted as a function of time to ensure that equilibrium was established; as revealed by a constant ratio over the final 20–60 ms.

Although the apparatus has been described in detail previously (1, 4), a brief description of the technique used in this work is presented here. The QUISTOR was composed of three electrodes as required for the generation of a three dimensional quadrupole field, and consisted of a hyperboloid of one sheet combined with a hyperboloid of two sheets forming the ring and end-cap electrodes, respectively. These electrodes were fabricated from stainless steel and polished to a mirror finish. The radius of the ring electrode, from which the physical size of the QUISTOR may be established (4), was 1 cm. The end-cap electrodes were perforated to permit the passage of electrons or ions through the electrodes. The three electrodes were arranged symmetrically with the ring electrode located between the end-cap electrodes and were separated by ruby sphere spacers which provided both electrical insulation and accurate spacing of the electrodes. The reactant inlet system was contained in a heated oven and consisted of a 6 L glass bulb with a side arm and septum holder. The total pressure with the glass bulb was measured with a pressure gauge (Matheson, Model 63-5601, pressure range 0–760 Torr) while the pressures of each of the reactants was calculated from a knowledge of the temperature of the oven the volume of the reactant inlet system and the volume of sample injected. The temperature of the oven was such that all reactants existed in the vapour phase. The reactants were admitted to the vacuum tank surrounding the QUISTOR and quadrupole mass filter assembly through a heated stainless steel line in which the rate of flow was controlled by a micrometer needle valve (Whitey). The total pressure within the vacuum tank was measured using a Penning gauge.

Once the reactant mixture of known composition was admitted to the vacuum tank, gaseous positive ions were formed within the QUISTOR by a short pulse of electrons, of 100 μs duration and 70 eV energy, controlled by a pulse generator (Hewlett-Packard). Reactions between primary ions produced by electron impact and reactant molecules were initiated with the onset of the electron pulse and continued concurrently with reactions of secondary and tertiary ions with reactant molecules for up to 100 ms. A scan delay generator was used to vary continuously the storage time over this range of 100 ms at a predetermined rate. The scan delay generator triggered both an extraction pulse and a detection pulse. Equilibrium with respect to proton transfer between each pair of reactants was judged to have been attained when the ratio of protonated ion intensities remained constant during the final 20–60 ms of storage.

Results and discussion

A general proton transfer reaction may be written

[1] $AH^+ + B \rightleftharpoons A + BH^+$

[1]Registered in the Ph.D. programme in Chemistry at Queen's University, Kingston, Ont., Canada K7L 3N6.

[2]Adjunct Professor, Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6.

[3]Revision received July 31, 1986.

and the associated equilibrium constant, K_{eq} as

[2] $$K_{eq} = \frac{[A][BH^+]}{[B][AH^+]}$$

The ratio of the concentrations of A and B may be calculated from the known volumes of each injected into the bulb; the ratio of the concentrations of the protonated species AH^+ and BH^+ is determined mass spectrometrically from the respective ion intensities. The equilibrium constant may be expressed in terms of Gibbs' free energy, ΔG.

[3] $$\Delta G = -RT \ln K_{eq}$$

where R is the gas constant and T the absolute temperature.

[4] $$\Delta G = \Delta H - T\Delta S$$

The enthalpy change (ΔH) for reaction [1] is equal to the difference in proton affinity between molecule A and molecule B.

[5] $$\Delta H = PA(A) - PA(B) = \Delta PA$$

Thus in order to obtain ΔH or to obtain the proton affinity for either A or B when the proton affinity of either B or A is known, the $T\Delta S$ term or entropy contribution to ΔG must be evaluated. The ΔS term in eq. [4] may be subdivided into individual contributions due to translational, vibrational, and rotational entropies.

[6] $$\Delta S = \Delta S_{trans} + \Delta S_{vib} + \Delta S_{rot}$$

When the molecular masses of the species A and B in eq. [1] are approximately equal, the translational entropy contribution is insignificant; furthermore, vibrational changes due to the transfer of a proton from A to B may also be expected to be negligible when A and B are similar molecules. The contribution due to rotational symmetry changes may be calculated if structures are assumed for the gas phase protonated species. Save for the case of diisopropyl ether, ΔS_{rot} is assumed to be zero for the equilibria employed in these studies.

Diisopropyl ether has a rotational axis of symmetry about the oxygen atom which may be retained if a planar configuration with respect to the oxygen atom is adopted in the protonated ether. However, if the configuration adopted is pyramidal as is suggested in both protonated water and methanol (5), the axis of symmetry is lost in the protonated ether and a rotational entropy correction of $R \ln 2$ must be applied. Invocation of Occam's razor allows no rotational entropy contribution for the equilibrium between mesityl oxide and diisopropyl ether, i.e. $\Delta S^0_{rot\ sym} = 0$, hence for all the equilibria investigated

[7] $$\Delta G = PA(A) - PA(B) = \Delta PA$$

Since the proton affinity of one of the species in the equilibrium is known from the literature (2), the proton affinity of the other may be inferred from the calculated ΔPA.

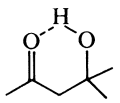
Diacetone alcohol

The relatively low volatility of diacetone alcohol and its facile dehydration to mesityl oxide at temperatures in excess of 350 K posed some experimental problems. Furthermore, attempts to establish equilibrium with respect to proton transfer with compounds of proton affinity lower than that of diacetone alcohol resulted in the rapid dehydration of protonated diacetone alcohol to form protonated mesityl oxide. Equilibrium for proton transfer was established at 330 K for mixtures of diacetone alcohol with 2-butanone (of higher proton affinity), typically 1:6, in the reaction

[8] 
at 333 K and a total pressure of 8×10^{-5} Torr. An equilibrium constant of 4.9 ± 0.4 was obtained, from which it was determined that the proton affinity of diacetone alcohol was 4.4 kJ mol^{-1} (1.05 kcal mol^{-1}) less than that of 2-butanone which is reported (2) as 836.0 kJ mol^{-1} (199.8 kcal mol^{-1}).

Thus as shown in Fig. 1, the proton affinity of diacetone alcohol is 831.6 kJ mol^{-1} (198.8 kcal mol^{-1}) with an experimental uncertainty of ± 0.8 kJ mol^{-1} (± 0.2 kcal mol^{-1}).

There is no information on the proton affinities of hydroxy ketones in the literature (2) from which an estimate of the proton affinity of diacetone alcohol may be made. However, an additivity route may be followed wherein the proton affinity of the unsubstituted ketone 4-methyl-2-pentanone is estimated and the effect of substitution of a hydroxyl group for hydrogen at position 4 is determined. On the basis of proton affinities for 2-butanone, 836.0 kJ mol^{-1} (2), 3-pentanone, 842.6 kJ mol^{-1} (2), 3-methyl-2-butanone, 841.4 kJ mol^{-1} (2), and 3,3-dimethyl-2-butanone, 846.6 kJ mol^{-1} (2), the proton affinity of 4-methyl-2-pentanone is estimated to be 848.5 kJ mol^{-1} (202.8 kcal mol^{-1}). Based on this estimate, the substitution of a hydroxyl group for a hydrogen at position 4 would appear to lower the proton affinity by some 16.9 kJ mol^{-1} (4.0 kcal mol^{-1}); this effect is attributed to electron withdrawal by the hydroxy group and the formation of an intramolecular H-bond in the neutral species as depicted by structure **1**.



1

When a bridged structure is assumed also for the protonated species it is anticipated, as one of the referees has pointed out, that stabilization due to cyclization will be probably greater in the protonated species than for the neutral species. Thus the above argument for the lowering of the proton affinity of diacetone alcohol from that calculated by additivity rules to that observed experimentally would be invalidated. Enhanced stability due to cyclization of the protonated species should be manifested as enhanced proton affinity, yet the experimental findings indicate a lowered proton affinity. Thus we conclude that the formation of a bridged structure for the protonated species which is indicated by the ready infrared multiphoton dissociation of this species (1) does not explain, in itself, the lower than anticipated proton affinity of diacetone alcohol.

Mesityl oxide

The proton affinity of mesityl oxide was found to be close to that estimated from the addition (6.3 kJ mol^{-1}) of a methyl group to 3-penten-2-one (PA 864.8 kJ mol^{-1} (2)). Equilibria with respect to proton transfer between mesityl oxide and 2-propoxy-2-propane were readily established for each of several optimum mixtures (1:7.5) of the two compounds at a total pressure of 8×10^{-5} Torr. The equilibrium constant for the reaction

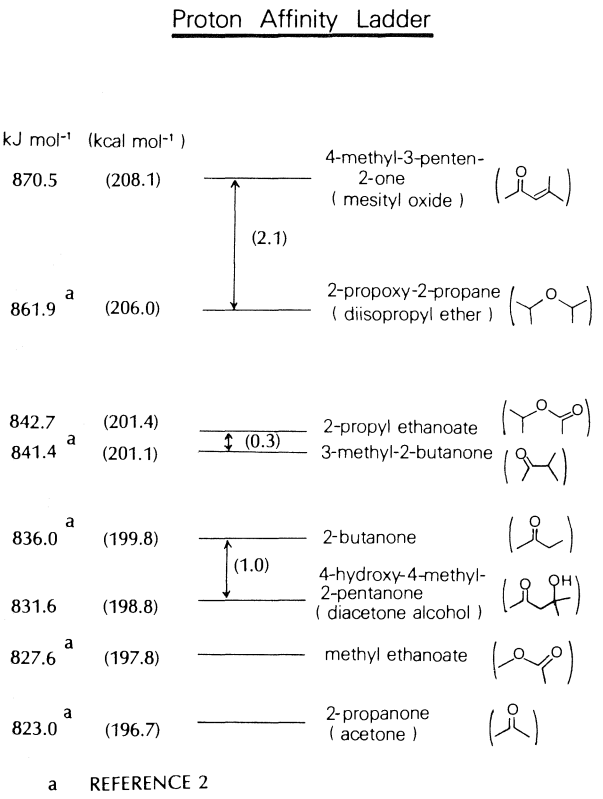


FIG. 1. Proton affinity ladder. Values for proton affinities are shown on the left hand side. Equilibria between pairs of compounds are shown by double-headed arrows with the value of ΔG for each equilibrium given in parentheses and in kcal mol^{-1}. Equilibria between each of 2-propanone and methyl ethanoate with diacetone alcohol could not be obtained as explained in the text.

[9] 
was determined to be 23 ± 2 at 333 K from which it was determined that the proton affinity of mesityl oxide exceeded that of 2-propoxy-2-propanone by 8.6 kJ mol^{-1}.

As the proton affinity of 2-propoxy-2-propanone is given (2) as 861.9 kJ mol^{-1} (206.0 kcal mol^{-1}), then the proton affinity of mesityl oxide is 870.5 kJ mol^{-1} (208.1 kcal mol^{-1}), as shown in Fig. 1 with an experimental uncertainty again of ±0.8 kJ mol^{-1}. The enhanced proton affinities of α,β unsaturated ketones with respect to aliphatic ketones we attribute to resonance stabilization of the protonated α,β unsaturated ketone.

[10] 
Isopropyl acetate

While the proton affinity of isopropyl acetate is not recorded in the literature, it was thought to be similar to that of the isomeric ester methyl 2-methyl propanoate which is given (2) as 843 kJ mol^{-1}. As the equilibrium is determined mass spectrometrically, a direct comparison between the two esters cannot be made without resorting to isotopic substitution.

Equilibrium between isopropyl acetate and 3-methyl-2-butanone, reaction [11], was readily established for several mixtures (1:1) at a total pressure of 8 × 10^{-5} Torr. Equilibrium was observed over a time period greater than that required to reach equilibrium.

[11] 
The equilibrium constant was found to be 1.6 ± 0.1 from which it was determined that the proton affinity of the former exceeded that of the latter by 1.3 kJ mol^{-1}. As the proton affinity of 3-methyl-2-butanone is given (2) as 841.4 kJ mol^{-1} (201.1 kcal mol^{-1}), then the proton affinity of isopropyl acetate is 842.7 kJ mol^{-1} (201.4 kcal mol^{-1}), as shown in Fig. 1, with an experimental uncertainty of ±0.6 kJ mol^{-1}.

Electrometric studies on molecular complexes. Part 1. Biamperometric study of some molecular complexes of iodine

RAM ADHAR SINGH
Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi-221 005, India

Received January 13, 1986[1]

RAM ADHAR SINGH. Can. J. Chem. **64**, 2371 (1986).

A simple method for separate determination of thermodynamic parameters of molecular complexes in solution is reported. It is based on a polyiodide dissociation equilibrium in conjunction with the biamperometry. The equilibrium constants and the enthalpies determined by this method are in good agreement with the recent literature data, lending support for the applicability of the method. The advantages of the present technique over the other have been outlined.

RAM ADHAR SINGH. Can. J. Chem. **64**, 2371 (1986).

On décrit une méthode simple pour déterminer séparément les paramètres thermodynamiques de complexes moléculaires en solution. Cette méthode est basée sur un équilibre de dissociation d'un poly-iodure, de concert avec la biampérométrie. Les constantes d'équilibre ainsi que les enthalpies qui ont été déterminées par cette méthode sont en bon accord avec le données récentes de la littérature; ceci laisse croire que la méthode peut être appliquée. On met en relief les avantages de cette méthode par rapport aux autres techniques.

[Traduit par la revue]

Introduction

A molecular complex between an electron donor and an electron acceptor is an association somewhat stronger than Van der Waal's association, having definite stoichiometry in which the identities of the molecules are retained to a large extent (1). The existence of the molecular complexes has been recognized for a long time (2, 3), but the recent interest in this field arose after the discovery of new absorption bands in the electronic spectra of iodine in organic solvents by Benesi and Hildebrand (4). Mulliken proposed the valence bond theory of the molecular complex formation on the basis of charge transfer from the electron donor to the electron acceptor molecules (5, 6). Since then, this field has been an active area of research as is evident from a number of monographs (7–9) and reviews (10). However, there are a number of reports in the literature in which the experimental results do not conform to theoretical predictions (1, 11–14). These raised doubts on the reliability of experimental data obtained by electronic spectroscopy, particularly for weak molecular complexes (11). This conventional spectral method yields the equilibrium constant (K_c) and molar extinction coefficient (ϵ_λ) of the complex from the composite spectral data $K_c\epsilon_\lambda$, obtained from the slope of BH plots and ϵ_λ from the intercept (4). Since for weak molecular complexes, K_c is of the order of 1 $dm^3\ mol^{-1}$ whereas ϵ_λ is of the order of 10^4–$10^5\ dm^2\ mol^{-1}$, a slight error in the intercept (ϵ_λ values) would lead to a sizable error in K_c values. It has been suggested that if the K_c values can be determined separately and reliably, a more accurate value of ϵ_λ can be obtained from the composite spectral data, $K_c\epsilon_\lambda$ (11, 15). Recently we have explored the possibility of separate determination of K_c by common physical techniques, e.g., refractometry (16–18), surface tension measurement (19), spectral–solubility method (20), and the radiotracer solubility technique (21–23) for a range of molecular complexes and have found them as feasible and convenient alternative to the conventional electronic spectroscopy. No doubt, these techniques have distinct advantages, but they do offer some difficulties. For example, in the spectral solubility method, a prior knowledge of isosbestic point is needed for the separate determination of K_c (11, 20). In the radiotracer solubility method a radioactive constant activity source [$(CH_3)_4NI_5$*] is to be synthesized using radioactive molecular iodine prior to the addition of donors (21–24). To overcome these difficulties we turned our attention to the electrometric techniques which are known to yield reliable and quantitative determinations of iodine concentrations. The polyiodide-solubility equilibria offer a unique advantage. Once the equilibria in the solvent and donor solutions are established and the solutions have been removed from the constant activity source, they can be analysed by any technique which bears a quantitative relationship with the iodine concentration, at any temperature, in any medium, and in any chemical form (11, 20–23).

Motivated by this fact, we have initiated a study on the use of electrometric techniques for the direct determination of equilibrium constants and enthalpies of molecular complex formation in liquid solutions. The techniques like potentiometry, biamperometry, conductometry, etc., are well known for quantitative analysis (25–29) but they have been used only rarely in the study of molecular complexes.

Only a few reports have appeared in the literature on the use of the electrometric techniques in the study of molecular complexes (30–37). The polarography has been used to determine the formation constants for some aromatic molecular complexes with strong electron acceptors (30, 31). The conductometric titrations have been used to determine stoichiometries and the trend in the stabilities of some charge transfer complexes in solution (32–37). However, to the best of our knowledge, the above and other electrometric techniques have not been used for the determination of all thermodynamic parameters in the molecular complex formation equilibria. In this report, we have used the biamperometric titration method in conjunction with the constant activity method to evaluate the equilibrium constants, enthalpies, free energy, and entropy changes associated with the formation of molecular complexes in liquid solution. The acceptor chosen is molecular iodine which forms molecular complexes with electron donors ranging from some of the weakest to some of the strongest complexes known (1, 9). Also, a convenient constant activity source, namely, tetramethylammonium pentaiodide, $(CH_3)_4NI_5$, is available for this acceptor. The donors chosen are such that the recent data are available for comparison so that accuracy of the technique can be tested. The electron donors used in this study to form typically weak and moderate molecular complexes with iodine

[1]Revision received August 6, 1986.

are aromatic hydrocarbons, namely, benzene, mesitylene, hexamethylbenzene, biphenyl, naphthalene, and anthracene and aromatic amines, namely, diphenylamine, aniline, and *o*-toluidine. The biamperometric titration method will be discussed in detail in the next section.

Materials and methods

Carbon tetrachloride and benzene (BDH both of spectral grade) were dried over molecular sieve (A_4 size). Naphthalene and anthracene (both of BDH microanalytical reagent grade), hexamethylbenzene (Ega Chemie), biphenyl and diphenylamine (both of BDH AnalaR grade) were purified by fractional crystallization in suitable solvents. Mesitylene (Koch-light), aniline, and *o*-toluidine (both of E. Merck) were purified by fractional distillation at reduced pressure, after drying over KOH pellets. Tetramethylammonium iodide, $(CH_3)_4NI$, and tetramethylammonium pentaiodide, $(CH_3)_4NI_5$, were synthesized as reported in the literature (38). Sodium thiosulphate (AnalaR grade) and KIO_3 (AnalaR grade) were used without further purification. Deionized water was used for making aqueous solutions.

Constant activity method

This method is based on the dissociation equilibrium of tetramethylammonium pentaiodide $(CH_3)_4NI_5$ (11, 20–23) and is as follows:

$$[1]\quad (CH_3)_4NI_5(\text{solid}) \underset{\text{solvent}}{\overset{K_d}{\rightleftharpoons}} (CH_3)_4NI_3(\text{solid}) + I_2(\text{solvent})$$

where K_d is the dissociation constant of $(CH_3)_4NI_5$. At a fixed temperature and in a non-polar solvent, e.g., CCl_4, $(CH_3)_4NI_5$ and $(CH_3)_4NI_3$ are insoluble and remain as solids whereas the molecular iodine goes into the solvent. After the above equilibrium is reached a constant iodine concentration is obtained in CCl_4. The addition of donor, D, to the system (reaction [1]) results in the formation of the donor–iodine molecular complex. Assuming the stoichiometry of the complex as 1:1, donor–iodine equilibrium in CCl_4 solution can be written as follows:

$$[2]\quad D + I_2 \overset{K_c}{\rightleftharpoons} D.I_2$$

where K_c is the equilibrium constant. The above complex formation results in the loss of iodine obtained through reaction [1]. To compensate for this loss, some more $(CH_3)_4NI_5$ dissociates to maintain the same iodine concentration as in reaction [1]. The system now becomes,

$$[3]\quad (CH_3)_4NI_5(\text{solid}) + D(\text{solution}) \rightleftharpoons (CH_3)_4NI_3(\text{solid}) + (D.I_2 + I_2)(\text{solution})$$

The increase in iodine concentration in reaction [3] over to that in reaction [1] is equal to the concentration of the complex whereas the free iodine concentration in reaction [3] is the same as that in reaction [1].

It has been established experimentally that no other equilibria exist between polyiodides and donor–polyiodides (since the donor is in solution and polyiodides are solids and have I_5^- and I_3^- centers thus no interaction with electron donor is expected). In the experimental concentrations range, I_3^- species have also not been detected. The equilibrium constant, K_c, for eq. [2] can be written as

$$K_c = \frac{[DI_2]}{[D][I_2]} = \frac{(C_2 - C_1)}{(C_0 - (C_2 - C_1))C_1}$$

or

$$[4]\quad K_c = \frac{(C_2 - C_1)}{(C_0 + C_1 - C_2)C_1}$$

where C_0 is the initial donor concentration, C_1 is the concentration of iodine in solution after equilibrium [1] is reached, at a particular temperature, and in a particular solvent, and C_2 is the concentration of iodine in solution after the equilibrium [3] is reached, i.e. after adding the donor to the solvent–polyiodides system.

Thus with the help of the constant activity method, determination of K_c requires only a reliable estimation of iodine concentration in reactions [1] and [3]. We have made use of the biamperometry to determine the iodine concentrations in solutions.

Biamperometry

The biamperometric determination of the concentrations is performed by observing the changes in current as a function of titrant volume. A small emf (100–150 mV) is applied between two indicator electrodes (Pt–Pt or Pt–graphite) which are immersed in a well stirred solution. A reversible redox couple (6) must exist before or after the end point (24–29). In this particular case, we have iodine–iodide reversible couple and the titrant is aqueous sodium thiosulphate solution. One indicator electrode is platinum and the other is graphite. This electrode system has been found to be more sensitive than the Pt—Pt combination (39) and is used in all experiments in this study. Bradbury (40–41) and Kolthoff (42) have shown mathematically that the current in the equivalence point region is proportional to the concentration of iodine remaining in solution. Before the titrant is added, a large amount of iodine is present and a high current is observed. However as the titration proceeds, iodine reacts with sodium thiosulphate and iodide is formed, resulting in a decrease in iodine concentration and thus a decrease in current. The current is calibrated in this study against the deflection in a ballistic galvanometer, the torsion in its wire being proportional to the current passing through it. The deflection is spotted on a linear scale with the help of a small mirror, illuminated by light. The biamperometric titration method for estimating iodine concentrations requires very simple instrumentation and offers great sensitivity (10^{-5}–10^{-6} *M*). It is the best electrometric technique for determining the tracer concentration (26). The equivalence point is the intersection of two straight line portions in the galvanometer deflection vs. titrant volume plots and can be determined reliably.

Experimental

About 150 mg of $(CH_3)_4NI_5$ was placed in different stoppered vessels containing 50 mL CCl_4 in one and 50 mL of donor solutions of different concentrations in CCl_4 in others. These vessels were shaken in a thermostat maintained at a particular temperature for 2–3 days after which the dissociation equilibria of $(CH_3)_4NI_5$ were established as evident from a constant iodine concentration as a function of time. No I_3^- species in measurable amounts in any solutions were present as no electronic absorption bands at 363 and 290 nm, characteristics of I_3^- species, were detected (9, 11, 20). The iodine solutions in CCl_4 were then separated from $(CH_3)_4NI_5$ and $(CH_3)_4NI_3$ and iodine concentrations were determined using biamperometric titration method. Since iodine in CCl_4 could not be analysed with aqueous sodium thiosulphate due to phase separations, 10–20 mL methanol and some solid KI was added to facilitate the extraction of iodine from CCl_4 to the aqueous phase. An emf of 50–150 mV was applied between the electrodes. A 2 mL semimicroburette with 0.01 mL division graduation connected to a self-filling reservoir was used for adding the titrant.

The current is measured with the help of a ballistic galvanometer, the torsion being proportional to the current passing through it. Thus the greater the current, the higher the torsion in the wire of the ballistic galvanometer which is calibrated on a linear scale on which the mirror reflection from the galvanometer is spotted. The equivalence point was obtained by plotting galvanometer deflection against the titrant volume. At least three titrations were performed for each solution and the results were reproducible within the experimental error. It was found that the presence of donors in CCl_4 solution does not interfere with the quantitative estimations of iodine concentrations as the iodine concentrations obtained by this method are comparable to the results obtained using other methods (20–23). The equilibrium constants at different tmeperatures (25, 30, 35, 40°C) were calculated using eq. [4] and $-\Delta H^0$, $-\Delta G^0$, and ΔS^0 values for the complexes evaluated using suitable thermodynamic relations. The data were analysed by least squares on a ICL 1905 S computer.

Results and discussion

A representative set of biamperometric titration plots between the galvanometer deflection and titrant volume for the estima-

tion of iodine solutions in CCl_4 and donor solutions as indicated have been shown in Fig. 1. For all other iodine solutions, i.e., obtained for different donor concentrations and at different temperatures, similar titration plots have been obtained. It is evident from the slanted portion of the figure that a linear relationship exists between the galvanometer deflection and the concentration of iodine before the equivalence point. At and after the equivalence point, no redox couple (I_3^-/I^-) is present as all the iodine present has been consumed by thiosulphate, no deflection in the galvanometer is observed. This is evident from the horizontal linear portion in Fig. 1. The equivalence point is the intersection of the two linear portions (40–42).

The iodine concentrations determined by this method are in excellent agreement with those obtained by the spectral and the radiotracer techniques. The heat of dissociation of $(CH_3)_4NI_5$ obtained from the concentration of iodine in pure solvent at different temperatures using this method (34.1 kJ mol^{-1}) also agrees well with the available data (33.9 kJ mol^{-1} by the spectral solubility method (20) and 34.3 kJ mol^{-1} by the radiotracer solubility method (21).

The total iodine concentrations in different donor solutions in CCl_4 at 25°C as determined by biamperometry when plotted against the equilibrium donor concentrations vary linearly as shown in Fig. 2. The concentration of the different molecular complexes formed, determined from the increase in iodine concentrations for different donors concentrations in CCl_4 over that in the pure CCl_4 at 25°C is also found to vary linearly with the equilibrium donor concentrations. This indicates that predominantly 1:1 molecular complexes are formed in the experimental range of donor concentrations. This supports the assumption (reaction [2]) of 1:1 stoichiometries for all the complexes studied. The equilibrium constants for different complexes in CCl_4 at 25°C calculated using eq. [4] by least squares method are reported in Table 1. In the same table, we have also given the standard enthalpies ($-\Delta H^0$), free energy ($-\Delta G^0$), and entropy changes (ΔS^0) for different complexes.

Literature data are included in parentheses for comparison. It is evident that the results obtained by using this technique are in very good agreement with those obtained by spectral solubility and radiotracer solubility methods based on polyiodide dissociation equilibria. As reported earlier (9, 11, 22, 23), the values obtained by these methods are slightly higher than those obtianed by conventional spectral methods using Benesi–Hildebrand and related equations (10). This can be explained on the basis of the solubility method which includes both the specific (charge-transfer) and non-specific (solvent effects) interactions whereas the conventional spectral method is based on specific charge-transfer interactions only. The non-specific solvent effects include solvent caging, dispersion, and polarization effects (11, 20, 21). There is also the possibility of different conformational isomers of the complexes in solution. Thus with solubility equilibria, we observe the total effect of all the above parameters in addition to the specific charge transfer interactions, and hence a higher K_c value. In the case of aromatic amines the existence of mixed complexes of $n - \sigma$ as well as $\pi - \sigma$ in the same solution may also be responsible for higher K_c values. It may be mentioned here that it is quite difficult to determine the different contributions proposed above but when the molar extinction coefficients of these complexes are reevaluated using the composite $K_c\epsilon_\lambda$ value obtained from the slope of BH plots and K_c values obtained by the present method, the new ϵ_λ values vary in accordance with the Mulliken's theory, i.e. higher molar extinction coefficients for stronger complexes in a particular series (1). K_c and $-\Delta H^0$ values using the present technique also vary in the same order as predicted theoretically on the basis of the electron donating ability of different donors, viz. benzene < naphthalene < biphenyl < mesitylene < hexamethylbenzene < anthracene < diphenylamine < aniline < *o*-toluidine. The plot of $-\Delta H^0$ vs. ΔS^0 values for different complexes is nearly linear indicating

TABLE 1. Equilibrium constants and other thermodynamic parameters for the molecular complexes of iodine with some donors in CCl_4 solution determined by biamperometry

Donor	K_c (dm^3 mol^{-1}) (25°C)	$-\Delta H^0$ (kJ mol^{-1})	$-\Delta G^0$ (kJ mol^{-1}) (25°C)	$-\Delta S^0$ (J K^{-1})
Benzene	0.38±0.01 (0.40,[a] 0.36[b])	6.1±0.3 (6.3[a])	−1.04	24.0
Naphthalene	0.58±0.01 (0.62,[a] 0.54[c])	7.7±0.4 (7.1,[a] 8.0[c])	−0.58	27.8

that sufficient charge-transfer contribution exists for the formation of these complexes.

Two systems, anthracene–iodine and diphenylamine–iodine, deserve special mention. These systems could not be studied by the spectral solubility method as their isosbestic points could not be located. Since the determination of isosbestic points is not needed in the present technique, these systems could be easily studied by the biamperometric technique and their K_c and $-\Delta H^0$ values have been determined. Thus this technique can be used successfully where other techniques have failed. Further study of alcohol–iodine, aliphatic amine–iodine, and some nitroamino–toluenes–iodine systems have indicated the general applicability of the present technique. These data are under publication elsewhere (44). The differential potentiometry has also successfully been used for separate determinations of equilibrium constants and enthalpies of the molecular complexes of iodine in liquid solution (45). This also supports the electrometric techniques as viable alternatives to conventional methods.

The results presented in this paper clearly show that the biamperometry solubility method is a convenient alternative to the conventional spectral method for the direct determination of equilibrium constants of molecular complexes in solution. It has some advantage over the spectral solubility method as the exact location of isosbestic points is not needed prior to establishing the solubility equilibria. In addition, the problem of overlapping spectral bands is avoided. The present method also has the advantage over the radiotracer solubility method as no labelled polyiodide source is needed. The biamperometry requires very simple instrumentation but offers great sensitivity. The method is relative and is best for electrometric determinations of low concentrations. The biamperometry–solubility is a useful combination which gives direct and reliable values of equilibrium constants and the other thermodynamic parameters for the molecular complexes in solutions.

GEORGE I. BIRNBAUM, JEAN-ROBERT BRISSON, SHI HSI CHU, ZHI HAO CHEN, and ELIZABETH C. ROWE. Can. J. Chem. **64**, 2376 (1986).

The title compound crystallizes in the triclinic space group $P\bar{1}$ and the cell dimensions are a = 16.890(3), b = 9.586(2), c = 6.316(1) Å, α = 91.09(1), β = 93.50(1), γ = 93.04(1)°. X-ray intensity data were measured on a diffractometer, and the crystal structure was determined by direct methods. Least-squares refinement, which included all hydrogen atoms, converged at R = 0.056 for 3454 observed reflections. Adjacent six-membered rings are approximately perpendicular to one another. The glycosidic torsion angle [C(6)—N(1)—C(1′)—O(4′)] is 96.2(2)°. In the acyclic moiety, both C—OH bonds are *gauche* with respect to C(4′)—O(4′). The *gauche* conformation is also dominant in solution, as determined by high-resolution ^{1}H nmr spectroscopy. Results of nuclear Overhauser experiments lead to conclusions about the flexibility of the molecule.

GEORGE I. BIRNBAUM, JEAN-ROBERT BRISSON, SHI HSI CHU, ZHI HAO CHEN et ELIZABETH C. ROWE. Can. J. Chem. **64**, 2376 (1986).

Le composé mentionné dans le titre cristallise dans le groupe d'espace $P\bar{1}$, avec a = 16,890(3), b = 9,586(2), c = 6,316(1) Å, α = 91,09(1), β = 93,50(1) et γ = 93,04(1)°. On a mesuré les données d'intensité des rayons-X à l'aide d'un diffractomètre et on a déterminé la structure cristalline par des méthodes directes. On a affiné la structure, incluant tous les atomes d'hydrogènes, par la méthode des moindres carrés jusqu'à une valeur de R = 0,056 pour 3454 réflexions observées. Les cycles à six chaînons qui sont adjacents sont pratiquement perpendiculaires l'un par rapport à l'autre. L'angle de torsion de la liaison glycosidique [C(6)—N(1)—C(1′)—O(4′)] est égal à 96,2(2)°. Dans la portion acyclique, les deux liaisons C—OH sont *gauche* par rapport à la liaison (C4′)—O(4′). D'après la rmn du ^{1}H à haute résolution, la conformation *gauche* prédomine aussi en solution. En se basant sur les résultats d'effets Overhauser nucléaires, on a tiré des conclusions relatives à la flexibilité de la molécule.
[Traduit par la revue]

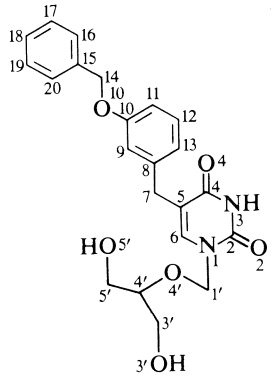
Introduction

The title compound, also called 4′-hydroxymethyl-5-benzyloxybenzylacyclouridine, HM–BBAU (1), is a derivative of 5-benzyloxybenzylacyclouridine (BBAU) (2–4) and is one of the most potent inhibitors known to date for the enzyme uridine phosphorylase (UrdPase). It is a uridine analog of the antiviral agent known variously as 9-(1,3-dihydroxy-2-propoxymethyl)guanine or DHPG (5), 2′-nor-2′-deoxyguanosine or 2′NDG (6), or BIOLF-62 (7), and was originally synthesized to improve the water solubility characteristics of BBAU.

Uridine phosphorylase is one of two important mammalian phosphorylases in the salvage pathway of nucleic acid metabolism. As inhibition of this enzyme would be expected to affect adversely the growth and replication of cells, it is a target enzyme in the design of drugs for cancer chemotherapy (8). Inhibitors of uridine phosphorylase are potentially useful not only as inhibitors of pyrimidine salvage but also as potentiators of the action of antineoplastic drugs such as 5-fluoro-2′-deoxyuridine (FUdR, FdUrd) which are subject to phosphorolytic cleavage *in vivo* to less active and more toxic bases (4).

The "acyclo" side chain (beta-hydroxyethoxymethyl-) of acyclovir and of BBAU is an open chain corresponding to the C(1′)—O(4′)—C(5′)—O(5′) portion of the furanose ring of natural nucleosides. HM derivatives carry the resemblance one carbon atom further, containing both C(5′)—OH and C(3′)—OH groups in the side chain.

The crystal structure and conformation of acyclovir have been determined (9), with especial attention to the conformation of the side chain (two orientations in the three independent molecules) and its possible relevance to antiviral activity. The inhibitory activity of the BBAUs against UrdPase (no antiviral activity) may be mediated by other parts of the molecule as well. For these reasons, we considered it worthwhile to determine the detailed conformation of HM–BBAU (**1**) in the solid state and in solution.



1

Experimental

HM–BBAU was prepared as previously described (1) and crystallized from ethanol. Precession photographs indicated the triclinic space group $P\bar{1}$. A prism measuring 0.15 × 0.25 × 0.50 mm was mounted on a CAD4 diffractometer; the crystal data are as follows:

$C_{22}H_{24}N_2O_6$ mw = 412.43
Triclinic, a = 16.890(3), b = 9.586(2), c = 6.316(1) Å, α = 91.09(1), β = 93.50(1), γ = 93.04(1)°, V = 1018.8 Å^3, ρ_c =

[1]NRCC No. 26398.

1.34 g cm^{-3}, $Z = 2$ (20°C, CuKα_1, $\lambda = 1.54056$ Å); $F(000) = 436$, μ(CuKα) = 7.7 cm^{-1}.

Unit cell dimensions were determined from a least-squares refinement of the angular settings of 25 high-order ($40 < \theta < 50°$) reflections. Intensities were measured with Ni-filtered CuKα radiation, using $\omega/2\theta$ scans with variable scan ranges and speeds. Three standard reflections were measured at regular intervals; their intensities decreased to 75% of the starting values during the data collection. Of the 4231 unique reflections with $\theta \leqq 76°$ there were 3458 (81.7%) with $I \geqq 3\sigma(I)$ which were considered observed. The intensities were corrected for crystal decay and for Lorentz and polarization factors; absorption corrections were unnecessary.

The structure was determined by direct methods with the aid of the computer program MULTAN 78 (10). Of the 64 starting sets subjected to tangent refinement, the solution with the highest combined figure of merit yielded an E map on which all 30 non-hydrogen atoms were located. The atomic parameters of these atoms were refined by block-diagonal least squares with anisotropic temperature parameters. All hydrogen atoms were found on difference Fourier maps and their parameters were refined with isotropic temperature factors. The scattering factors were taken from the "International tables for X-ray crystallography" (11). Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| \leqq 5$, $w_1 = 5/|F_o|$ for $|F_o| > 5$; and $w_2 = \sin^2\theta/0.5$ for $\sin^2\theta < 0.5$, $w_2 = 1$ for $\sin^2\theta \geqq 0.5$. This scheme made the average values of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. After the final cycle the average parameter shift equalled 0.06σ and the largest 0.50σ. Four strong, low-order reflections suffered from secondary extinction effects and were given zero weights. The final conventional residual index R is 0.056 and the weighted index R_w is 0.079. A final difference Fourier map showed no significant features. The coordinates of non-hydrogen atoms are listed in Table 1. Anisotropic temperature parameters, hydrogen atom parameters, and a list of observed and calculated structure factors are available from the Depository of Unpublished Data.[2]

The proton nuclear magnetic resonance spectrum of HM–BBAU at 300 K was obtained on a Bruker AM-500 spectrometer. The sample (10 mg) was dissolved in 0.5 mL DMSO-d_6 with a drop of tetramethylsilane as the internal reference. The ^{1}H nmr spectrum was assigned by spin decoupling and two-dimensional homonuclear shift-correlated experiments. The nuclear Overhauser experiments were performed by irradiation of each separate line in a multiplet (12) followed by subtraction of one off-resonance control.

Results and discussion

Solid-state structure

A stereoscopic view of the molecule is shown in Fig. 1. The pyrimidine ring is almost planar, C(2) deviating most from coplanarity (by 0.007(2) Å); the two benzene rings are completely planar. The dihedral angle between the pyrimidine ring and the benzene ring attached to C(7) is 82.0° while the angle between the two benzene rings is 96.1°. The former orientation is necessary in order to avoid steric interactions between two six-membered rings joined by a single carbon atom. However, the relative orientation of the two benzene rings, joined by —O—CH_2—, is not only unnecessary but is, in fact, highly unusual. We will discuss this feature in more detail below.

Most bond lengths in the pyrimidine moiety (Fig. 2) are in good agreement with average values which we recently calculated for thymine residues (13). The only exception is the lengthening of the C(4)—C(5) bond by 0.011 Å, probably attributable to the bulky substitution at C(7). The agreement in bond angles is also very good, except at C(2) where N(1)—C(2)—N(3) is 1.5° larger while N(1)—C(2)—O(2) is 1.7° smaller than normal; these deviations amount to 3σ.

The glycosidic torsion angle is 96.2(2)° (Fig. 3). This is exactly the mean value for ten molecules of acyclonucleosides in which C(1′) is a secondary carbon atom (14). In this conformation there is minimal steric interaction between the aglycon and its acyclic side chain. The conformations about the C(3′)—C(4′) and C(4′)—C(5′) bonds (Fig. 3) are those favored by the *gauche* effect (15). In the former case the orientation of adjacent C—O bonds is *gauche*$^-$ while in the latter it is *gauche*$^+$. The C(1′)—O(4′) bond is significantly shorter than C(4′)—O(4′). This phenomenon is commonly observed in nucleosides as well as in acyclonucleosides (9, 16, 17).

The following three intermolecular hydrogen bonds are observed in the crystal:

O(3′)—H···O(5′)—H···O(2) N(3)—H···O(4)

The distances and angles are listed in Table 2. The corrected H···A distances were calculated after extending the covalent O—H and N—H bond lengths to their nominal values of 0.97 and 1.04 Å, respectively. As expected on the basis of the cooperativity effect (18), the O(5′)—H···O(2) bond is the strongest one.

The packing of the molecules in the crystal is shown in Fig. 4. As in the individual molecules, benzene rings in adjacent molecules are almost perpendicular to one another. Thus, H(12)

and H(13) are pointed toward the π-electron cloud of the terminal benzene ring in a symmetry-related molecule, as indicated by fairly short H(12)···C(19) and H(13)···C(18) distances, 2.85 and 2.83 Å, respectively.

Solution conformation of the hydroxymethyl groups

The conformations about the C(4′)—C(3′) and C(4′)—C(5′) bonds are the same since the geminal protons of C(3′) and C(5′) have similar chemical shifts (Table 3) and coupling constants. In solution, the hydroxymethyl group is usually assumed to be in dynamic equilibrium between three staggered rotamers. The observed vicinal coupling constants are then an average of the coupling constants for each rotamer. Using the modified Karplus equation proposed by Haasnoot *et al.* (19), the coupling constants for each rotamer were obtained and from these the fractional populations of the three rotamers were estimated (Table 4). Since the assignment of the geminal protons can be reversed, there are two possible solutions. However, in the solid state both *gauche* rotamers are present, but not the *trans* rotamer (Fig. 3). Consequently, the first set of values in Table 4 is in better agreement with the X-ray results and with the *gauche* effect (15) and is therefore more likely (16).

Solution conformation about other bonds

The degree of flexibility of the molecule could be ascertained by observing that the protons of all the other CH_2 groups (i.e. at C(7), C(14), and C(1′)) appeared as single lines. If the molecule had been rigid or a CH_2 group slowly reorienting itself between different conformers, the individual protons in the CH_2 group would have different chemical shifts.

Nuclear Overhauser experiments presented in Table 5 also indicate that there is a high degree of internal motion in the molecule since both positive and negative nOe's were observed when irradiating different resonances. The sign of the nOe depends on the correlation times of the protons which experience an nOe, and as the degree of internal motion increases more positive nOe values should be observed (20). Thus, upon saturation of the H(1′) signal a negative enhancement was observed for H(6) while a positive enhancement was observed for H(4′), indicating that there is more internal motion between H(4′) and H(1′) than between H(6) and H(1′). Hence, there appears to be more rotation about the C(4′)—O(4′)—C(1′) linkage than about the N(1)—C(1′) bond. This interpretation of the nOe's is in agreement with the observed preference for a torsional angle of ~90° about the N(1)—C(1′) bond (see above). There is, nevertheless, sufficient flexibility about the glycosidic bond to allow a change from the *anti* to the *syn* conformation. This may be relevant to the interaction of HM–BBAU with UrdPase in view of the suggestion that the natural substrate, i.e. uridine, is in the *syn* conformation when bound to the enzyme (14). Upon saturation of the H(7) resonances a negative enhancement was observed for H(6) while positive values were detected for H(9) and H(13), again suggesting that the C(7)—C(8) bond is more flexible than C(5)—C(7). When the resonance of H(14) was irradiated, only positive enhancements were observed for H(9), H(11), H(16), and H(20), indicating a higher degree of internal motion about the C(10)—O(10)—C(14)—C(15) bonds.

Biological implications

In recent years it has been found (2, 21–23) that addition of the acyclo side chain to a series of uracils increases the inhibition of S-180 cytosol UrdPase by a factor of $10–10^2$ over that of the corresponding uracil. It was also found that a free terminal —OH group in the acyclo side chain was necessary for activity. Since substitution of the terminal —OH by a chloro or nitro group, or esterification, resulted in loss of the inhibitory capacity, and substitution by an amino group diminished but did not abolish it, it was concluded that hydrogen bonding in this region was important in binding the

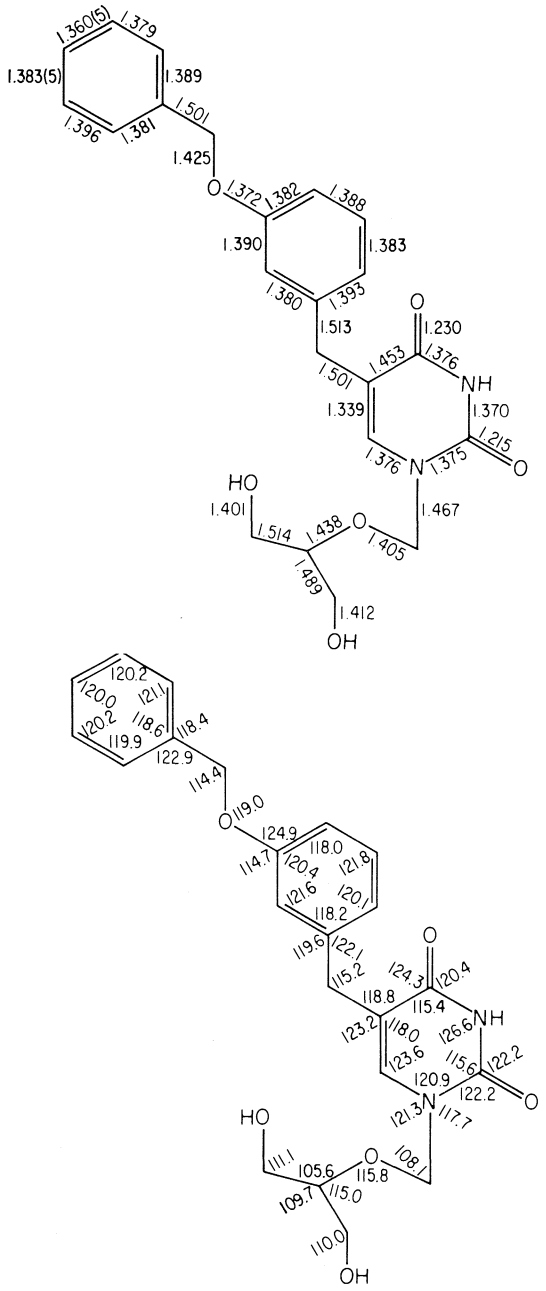

FIG. 2. (Top) Bond distances (in Å); unless otherwise indicated, their estimated standard deviations (esd's) are 0.003–0.004 Å. (Bottom) Bond angles (in deg); their esd's are 0.2–0.3°.

inhibitor to the enzyme (21). The participation of the —NH and 2-keto groups in hydrogen bonding also appears to be essential.

The early observation of increased binding of acyclothymidine over acyclouridine (21) and the comparative inhibitory activities of a series of uracil derivatives evaluated by Baker and Kelley (24) led to the speculation that a hydrophobic region exists adjacent to the active site of UrdPase and participates in the binding of effective inhibitors. In support of this conclusion, Niedzwicki *et al.* (2) have calculated from inhibition constants that the contributions of $\Delta G^{0\prime}$ brought about by substituting a benzyloxy group on the *meta* position of 5-benzyluracil and converting the uracil to an acyclouridine are very nearly additive. Both regions seem to be involved in the binding of the inhibitor to UrdPase.

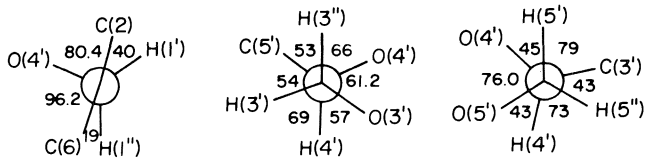

FIG. 3. Newman projections along N(1)—C(1′), C(3′)—C(4′), and C(4′)—C(5′). The esd's are 0.2–0.3° for torsion angles which do not involve hydrogen atoms and 2° for those which do.

6.1	4.6	20	43	37

As mentioned above, the orientation of the two benzene rings in HM–BBAU is unusual. A survey of the recent Cambridge crystallographic database (25) revealed twelve molecules with an Ar—O—CH_2—Ar fragment. In all of the them the C(Ar)—O—CH_2—C(Ar) torsion angle corresponds to a *trans* orientation about the O—CH_2 bond, the average absolute value of that angle being 174(3)°. In HM–BBAU the torsion angle C(10)—O(10)—C(14)—C(15) has the abnormal value of 82.1(3)°. The orientation about the C(14)—C(15) bond is also somewhat unusual, the O(10)—C(14)—C(15)—C(20) torsion angle being only 5.6(2)°. In only three of the twelve molecules surveyed was the corresponding angle less than 11°, the other nine ranged from 24 to 82°. The small angle in HM–BBAU brings about a non-bonded interaction between O(10) and H(20) which is relieved by increasing the bond angle O(10)—C(14)—C(15) to 114.4(2)°. The solid-state conformation of the benzyloxybenzyl moiety may be significant in view of the suggestion that this hydrophobic portion of HM–BBAU fits into a binding site adjacent to the active site of UrdPase.

The near-perpendicular orientation of the two benzene rings in the HM–BBAU molecule and the "herringbone" packing of these rings in the crystal lattice, where H atoms at the edge of one molecule point toward C atoms on the face of the adjacent molecule (Fig. 4), are reminiscent of recent findings by Burley and Petsko (26). Their analysis of four biphenyl peptides or peptide analogs and 34 proteins revealed similar aromatic–aromatic interactions which, it was suggested, may contribute to the stabilization of protein structures. Similarly, the binding of HM–BBAU to UrdPase must be stabilized by an interaction

Received January 9, 1986

GORDON W. BUSHNELL, ALFRED FISCHER, GEORGE N. HENDERSON, and SUMIT RAY MAHASAY. Can. J. Chem. **64**, 2382 (1986).

The adduct obtained on nitration of 4-bromotoluene in acetic anhydride is (*Z*)-3-bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate. Its stereoselective rearrangement product, obtained on thermolysis in the presence of *p*-cresol, is (*Z*)-5-bromo-2-methyl-6-nitrocyclohexa-2,4-dienyl acetate. Reaction with hydrogen chloride in ether is also stereospecific and gives (*Z*)-3-bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl chloride. The crystal structures of these compounds are reported.

GORDON W. BUSHNELL, ALFRED FISCHER, GEORGE N. HENDERSON et SUMIT RAY MAHASAY. Can. J. Chem. **64**, 2382 (1986).

L'adduit obtenu par nitration du bromo-4 toluène dans l'anhydride acétique est l'acétate de bromo-3 méthyl-6 nitro-6 cyclohexadiène-2,4 yle-(*Z*). Son produit de transposition stéréosélective, obtenu par thermolyse en présence de *p*-crésol, est l'acétate de bromo-5 méthyl-2 nitro-6 cyclohexadiène-2,4 yle-(*Z*). Sa réaction avec le chlorure d'hydrogène dans l'éther est aussi stéréospécifique et elle conduit au chlorure de bromo-3 méthyl-6 nitro-6 cyclohexadiène-2,4 yle. On a déterminé les structures cristallines de ces composés.

[Traduit par la revue]

Nitration in acetic anhydride of aromatic compounds in which a substituted position is of a comparable or greater degree of activation than an unsubstituted position often leads to the formation of nitronium acetate adducts (1, 2) in which the nitro group is attached to the activated substituted (*ipso*) position. Most commonly the 1,4 adduct is formed, normally as a pair of diastereomers. However, a 1,2 adduct is obtained when *p*-*tert*-butyltoluene (3), 2-methyl-2-(2′-methylphenoxy)propanoic acid (4), 4-methoxy- or a 4-halotoluene (5) is the substrate. Only one diastereomer of the 1,2 adduct is obtained. The 1,2 adducts undergo a 1,5 thermal rearrangement of the nitro group (6). Both stereospecific and stereorandom rearrangement processes have been observed (6). In the case of the diene from 4-bromotoluene, 3-bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**1***a*), the stereorandom rearrangement is made stereospecific when *p*-cresol is added. The *p*-cresol is believed to suppress a radical rearrangement process (6, 7). Two stereochemical questions arise from these observations. (*i*) What is the stereochemistry (*syn* or *anti*) of the nitration addition reaction? (*ii*) What is the stereochemistry of the stereospecific rearrangement process, i.e., is the nitro group rearrangement suprafacial or antarafacial? In the present work we report the results of single crystal X-ray diffraction structure determinations on **1***a* and its stereospecific rearrangement product, **2***a*, a diastereomer of 5-bromo-2-methyl-6-nitrocyclohexa-2,4-dienyl acetate, which provide the answers to these questions. We have also determined the structure of the single diastereomer of 3-bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl chloride, **3***a*, obtained on reaction of **1***a* with hydrogen chloride.

Results and discussion

Diene **1***a* was formed in 64% yield as a single diastereomer on the nitration of 4-bromotoluene in acetic anhydride containing trifluoroacetic anhydride and was isolated by crystallization of the crude reaction product. Diene **1***a* isomerized and partially aromatized when a solution in chloroform was allowed to stand at ambient temperature. The isomerization was carried out on a preparative scale by heating a solution of **1***a* in benzene at 74°C for 1 h when a mixture of **2***a* (35%), its diastereomer **2***b* (35%), unreacted **1***a* (26%), and its diastereomer **1***b* (4%), together with a trace of 5-bromo-2-methylphenyl acetate was obtained. The diastereomers **2***a* and **2***b* were isolated from the reaction mixture by fractional crystallization. Diene **1***b* was obtained from the mother liquor by treatment with aqueous ammonia to selectively aromatize the rearranged dienes **2***a* and **2***b*, followed by chromatography. The secondary nitro group makes the elimination of acetic acid from the rearranged dienes extremely facile, whereas the tertiary nitrodienes are unreactive under the same conditions. Isomerization of diene **1***a* in the presence of *p*-cresol gave only one product diene, **2***a*. The dienyl chloride **3***a* was obtained in 82% isolated yield when hydrogen chloride was bubbled through a solution of **1***a* in ether at −78°C and the mixture then worked up.

The structures of **1***a*, **2***a*, and **3***a* were determined by X-ray crystallography (Table 1). Dienes **1***b* and **2***b* decomposed too rapidly on irradiation for structure elucidation. Table 2 contains fractional atomic coordinates and isotropic temperature parameters for **1***a*, **2***a*, and **3***a*. Table 3 contains bond lengths, which agree well with the literature values for similar bonds as compiled in the Chemical Society's special publications (8). Table 4 contains bond angles and shows sp^3 and sp^2 hybridised atoms subtending angles close to 109.5° and 120°, respectively. Tables deposited[2] contain anisotropic temperature parameters for **1***a* and **3***a* (Tables S1, S2), intermolecular distances (Tables S3, S4, S5), mean planes, torsion angles, and Newman

projections (Tables S6, S7, S8), and structure factors (Tables S9, S10, S11). The intermolecular distances are all greater than 3.1 Å, demonstrating the molecular nature of the crystals. When the three structures are compared there are many similarities. The nitro groups plus the adjacent C atom are planar as are the acetate groups. The hexadienyl rings are non-planar, with the saturated atoms 0.24 Å (ave.) from the weighted least squares (w.l.s.) planes. Each saturated ring atom is on the opposite side of the plane relative to the nearest ethylene moiety, and the unsaturated ring carbon atoms are generally close to 0.10 Å from the w.l.s. plane. Birch, Hinde, and Radom attributed the non-planarity of the parent molecule, 1,3-cyclohexadiene, to angle strain at the saturated carbon atoms and steric interaction between eclipsed methylene hydrogen atoms outweighing the stabilizing effect of conjugation (9). Computed values for the C=C—C=C torsion angle in 1,3-cyclohexadiene range from 8 to 20°C (9–14) indicating a shallow minimum in the energy function (11). Experimentally obtained values are consistently close to 17.5° (15–18). Our experimental values for the substituted cyclohexadienes are lower, 9.9(13)°, 12(3)°, and 13.2(15)°, respectively.

The (*Z*) configuration of the *a* isomers is evident from the *cis* disposition of nitro and acetate in **1***a* and **2***a* and the *cis* arrangement of nitro and chlorine in **3***a* (Figs. 1–3). The structures of **1***b* and **2***b* follow from the fact that these are the diastereomers of the *a* isomers, as is indicated by the close similarity of the nmr spectra of **1***a* with those of **1***b* and of **2***a* with those of **2***b*. There are two possible conformations of each diastereomer and, in the cases of **1***a* and **3***a*, that in which the adjacent methyl and acetate or chlorine groups are (pseudo) *trans* diaxial and the nitro group and neighbouring hydrogen are therefore equatorial is preferred. This preference is reasonable in that the conformer with the smaller substituent (hydrogen) *gauche* to both methyl and nitro and the larger substituent (acetate or chlorine) *gauche* only to nitro, would exhibit less torsional strain than the other conformer in which the larger substituent is *gauche* to both neighbouring substituents. The preferred conformer of **2***a* is that which has axial nitro and equatorial acetate rather than vice versa. It is likely that this preference reflects a greater electronic repulsion between the neighbouring C—Br and C—NO_2 dipoles than that between the C—OAc and C—CH_3, the consequence being that the bromine and the nitro group are forced to be further apart (i.e. nitro axial) than the methyl and acetate or chlorine (acetate or chlorine equatorial). Interaction between the neighbouring dipoles at sp^2 and sp^3 carbons should be minimized when the substituent at the tetrahedral carbon is axial.

On nitration of 4-bromotoluene formation of the *cis* 1,2 adduct **1***a* is completely dominant, none of the *trans* diastereomer **1***b* being detected in the product mixture. Generally the formation of adducts is under kinetic control (19) as is evident in the present instance from the fact that in the thermal rearrangement, when equilibrium conditions are approached, both diastereomers **1***a* and **1***b* are present together. Thus we must look to the transition state to account for the stereoselectivity. Three possible explanations come to mind. Ridd has suggested that in acetic anhydride the nitronium ion is complexed with acetic acid and that it only becomes free in the encounter pair (20). If the reaction with the substrate occurs immediately after the nitronium ion is liberated, and the further reaction of the carbocation occurs before the solvation shell has had time to relax, then the acetic acid molecule which was

attached to the nitronium ion will be favourably placed to add to the 2-position in a *cis* manner. The second explanation proposes that the nitro group in the carbocation favours *cis* addition of the acetic acid molecule through hydrogen bonding of the latter to the nitro oxygen. This sets up the carbonyl group in a favourable position to add *cis* to the nitro group. The third explanation proposes that the carbocation is stabilized through carbon–carbon hyperconjugation involving the ring–methyl bond. This would result in the ring tending towards being planar with the carbon–nitrogen bond in the plane of the ring and the ring–methyl bond perpendicular to the ring. Approach of the acetic acid molecule would then be less hindered from the nitro face than from the methyl face.

Diene **2** is thermodynamically more stable than diene **1** (in the rearrangement reaction, **1** forms **2** to an extent of more than 50%) yet no diene **2** is obtained from the nitration reaction. Thus, even though some (8%) attack of nitronium ion occurs at the position *ortho* to the bromine, none of the resulting nitrocyclohexadienyl cation is trapped by acetate, all of it undergoing deprotonation to the 4-bromo-3-nitrotoluene. Likewise, none of the nitrocyclohexadienyl cation resulting from addition of nitronium ion *ortho* to methyl is trapped. Trapping of secondary nitrocyclohexadienyl cations is extremely rare (21, 22). The deprotonation reaction with its attendant gain in resonance energy is almost always greatly favoured over addition of a nucleophile. It is thus evident that the rearrangement cannot involve a cationic intermediate, rather stereorandom radical and stereospecific sigmatropic pathways are involved (4, 6, 7). This is of course also evident from the non-polar conditions under which the rearrangement is carried out. The addition of *p*-cresol suppresses the radical reaction and allows the observation of the sigmatropic process. Since (*Z*)-**1**

gives (*Z*)-**2** this process is suprafacial as would be required if the new C—NO_2 bond is formed synchronously with the fission of the original C—NO_2 bond.

Reaction of acetate **1***a* with hydrogen chloride gives the dienyl chloride with retention of configuration. This reaction would be expected to involve a carbocation intermediate or, at least, an incipient carbocation intermediate. A S_Ni type mechanism with a six-membered cyclic transition state can be envisaged in which hydrogen chloride, hydrogen bonded to carbonyl oxygen, is situated with the chlorine conveniently located to displace the acetate function. Alternatively, the chlorine could displace the acetate in an S_Ni' reaction by adding to the 5-position through a cyclic transition state. Both mechanisms would lead to the same diastereomer although, in principle, they can be distinguished since, if a single enantiomer of the reactant were used, different enantiomers of the product would be formed from the two pathways. If C—O bond breaking runs slightly ahead of C—Cl bond formation both the incipient carbocation intermediate and a cyclic transition state, accounting for retention of configuration, can be accommodated.

Experimental

Melting points are uncorrected and were determined on a Buchi SMP-20 melting point apparatus. Infrared spectra calibrated with polystyrene were recorded on a Perkin Elmer 283 spectrometer. Observations were made on potassium bromide discs for solids and on thin films between sodium chloride plates for liquids. Proton nuclear magnetic resonance spectra were recorded on Perkin Elmer R-32 (90 MHz) or Bruker WM 250 (250 MHz) spectrometers. The nmr spectra of the nitration reaction mixture was recorded with the acetic anhydride peak at 2.15 ppm as the lock signal. The substitution reaction with hydrogen chloride was followed using the ether peak at 1.85 ppm as the lock signal. For all other solutions, tetramethylsilane (90 MHz) or the solvent deuterium signal (250 MHz) was used as the lock signal. Carbon-13 nuclear magnetic resonance spectra were recorded on the Bruker WM 250 (62.9 MHz) spectrometer using solutions in $CDCl_3$ with TMS as the internal standard. Ultraviolet spectra were recorded on a Beckman DU-8 spectrophotometer. Elemental analyses were carried out by Canadian Microanalytical Service Ltd., Vancouver, B.C.

4-Bromotoluene was from J. T. Baker, acetic anhydride was certified ACS from Fisher, trifluoroacetic anhydride was Aldrich gold label. Fuming nitric acid (Fisher, 300 cm^3) was purified by distilling from urea (10 g) and sulfuric acid (500 cm^3) at <35°C and was stored at −25°C.

Solvents for chromatography including pentane (reagent, Fisher), ether (Fisher), and petroleum ether (reagent, Fisher) were dried over sodium and distilled before use. Silica gel used for chromatography was 60–200 mesh, Davison Commercial grade H.

Nitration of 4-bromotoluene

A nitrating mixture was prepared by the careful addition of acetic anhydride (51.1 g, 0.5 mol) with stirring to freshly distilled nitric acid (12.6 g, 0.2 mol) at −78°C. After the completion of addition, the mixture was warmed to 0°C, stirred for 15 min at 0°C and cooled to −40°C. Trifluoroacetic anhydride (21.05 g, 0.1 mol) was then slowly added to the mixture at −40°C. A solution of 4-bromotoluene (17.1 g, 0.1 mol) in acetic anhydride (10.2 g, 0.1 mol) was added dropwise with stirring over 30 min to the nitrating mixture at −40°C. The reaction mixture was then stirred for an additional 90 min at −40°C and then cooled to −78°C and poured into ether (50 cm^3) at −78°C. Ammonium hydroxide (450 cm^3, 28%) was added in portions to the stirred mixture. After the addition was complete, stirring was continued for 1 h while the mixture warmed to room temperature. The ether layer was separated and the residue was washed with ether (300 cm^3). The combined ether solution was washed with cold water (4 × 300 cm^3) and then dried. Removal of ether on the rotovapor at 15°C yielded a reddish-brown oil (25.5 g). The ^1H nmr spectrum of the crude mixture gave the composition as (*Z*)-3-bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**1***a*) (64%), 4-bromo-3-nitrotoluene (8%) and 4-bromo-2-nitrotoluene (28%). Crystallization from ether–pentane mixture at −20°C afforded crude diene **1***a* (9 g) as pale yellow crystals which, after further recrystallization, had mp 48–49°C; ir (KBr): 1745 and 1230 ($OCOCH_3$), 1555 and 1365 (NO_2) cm^{-1}; uv (CH_2Cl_2): 266.4 nm (350 m^2 mol^{-1}); ^1H nmr (250 MHz, $CDCl_3$) δ: 1.77 (s, 3, CH_3), 1.98 (s, 3, $OCOCH_3$), 5.45 (dd, 1, H(1)), 6.13 (dd, 1, H(4)), 6.37 (ddd, 1, H(2)), 6.45 (ddd, 1, H(5)) ppm, J_{12} = 6.15, J_{15} = 1.76, J_{24} = 1.80, J_{25} = 0.55, J_{45} = 10.23 Hz; ^{13}C nmr ($CDCl_3$, 62.9 MHz) δ_c: 20.6 ($OCOCH_3$), 23.1 (CH_3), 70.4 (C(1)), 86.8 (C(6)), 122.0 (C(2)), 122.6 (C(3)), 127.8 (C(4)), 128.5 (C(5)), 169.0 ($OCOCH_3$) ppm. *Anal.* calcd. for $C_9H_{10}NO_4Br$: C 39.15, H 3.65, N 5.07; found: C 39.36, H 3.52, N 5.04.

*Isomerization of (Z)-3-bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**1**a)*

A solution of diene **1***a* (10 g, 36 mmol) in benzene (20 cm^3) was heated in a water bath at 74°C for 1 h. Removal of the benzene on the rotovapor at 25°C yielded a reddish-brown oil. The ^1H nmr spectrum of the oil indicated the presence of **1***a* (26%), its diastereomer **1***b* (4%), (*Z*)- and (*E*)-5-bromo-2-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2***a*) and (**2***b*) (70%), with traces of 4-bromo-3-nitrotoluene and 5-bromo-2-methylphenyl acetate. Fractional crystallization from 1:1 ether–pentane at −20°C gave diene **2***a* (2.56 g) in the first two crops. The third crop (0.96 g) contained a mixture of **2***a* and **2***b* (1:1). Further crystallization from 1:2 ether–pentane solution yielded a mixture of **2***b* and **2***a* (95:5) as the fourth crop (700 mg). Finally, from 1:3 ether – petroleum ether, diene **1***a* was obtained as the fifth crop (600 mg).

Recrystallization of the first crop (300 mg) from 1:1 ether – petroleum ether gave pure diene **2***a* as pale yellow crytals (240 mg), mp 93–95°C; ir (KBr): 1735 and 1230 ($OCOCH_3$), 1560 and 1370 (NO_2) cm^{-1}; uv (CH_2Cl_2): 279.75 nm (721 m^2 mol^{-1}); ^1H nmr (250 MHz, $CDCl_3$) δ: 1.82 (br dd, 3, CH_3), 2.17 (s, 3, $OCOCH_3$), 5.35 (d, 1, H(6)), 5.79 (ddq, 1, H(3)), 5.91 (ddq, 1, H(1)), 6.69 (d, 1, H(4)) ppm, J_{13} = 2.65, J_{16} = 8.70, $J_{1,2\text{-Me}}$ = 1.00, J_{34} = 6.25, $J_{3,2\text{-Me}}$ = 1.63 Hz; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_c: 18.0 (CH_3), 20.5 ($OCOCH_3$), 70.9 (C(1)), 87.5 (C(6)), 109.5 (C(5)), 119.5 (C(3)), 134.1 (C(4)), 135.1 (C(2)), 169.8 ($OCOCH_3$) ppm. *Anal.* calcd. for $C_9H_{10}NO_4Br$: C 39.15, H 3.65, N 5.07; found: C 39.08, H 3.67, N 5.07.

Recrystallization of the fourth crop (500 mg) from 1:1 ether – petroleum ether at −20°C gave pure diene **2***b* as pale yellow crystals (420 mg), mp 63–64°C; ir (KBr) 1745 and 1210 ($OCOCH_3$), 1558 and 1360 (NO_2) cm^{-1}; uv (CH_2Cl_2): 279.75 nm (820 m^2 mol^{-1}); ^1H nmr (250 MHz, $CDCl_3$) δ: 1.83 (d, 3, CH_3), 2.15 (s, 3, $OCOCH_3$), 5.24 (d, 1, H(6)), 5.86 (dq, 1, H(3)), 5.93 (d, 1, H(1)), 6.66 (d, 1, H(4)) ppm, J_{16} = 3.47, J_{34} = 6.32, $J_{3,2\text{-Me}}$ = 1.04 Hz; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_c: 19.9 (CH_3), 20.7 ($OCOCH_3$), 70.8 (C(1)), 90.1 (C(6)), 109.1 (C(5)), 122.4 (C(3)), 132.2 (C(4)), 132.5 (C(2)), 169.8 ($OCOCH_3$) ppm. *Anal.* calcd. for $C_9H_{10}NO_4Br$: C 39.15, H 3.65, N 5.07; found: C 39.3, H 3.54, N 5.18.

The ^1H nmr spectrum of the mother liquor at this stage showed the presence of dienes **2***a* and **2***b* (37%), **1***a* (37%), **1***b* (5%), 5-bromo-2-methylphenyl acetate and 4-bromo-3-nitrotoluene (21%). In order to isolate diene **1***b*, the dienes **2***a* and **2***b* were selectively aromatized. A solution of the reaction mixture (2 g) in ether (10 cm^3) was stirred in an ice bath with ammonium hydroxide (5 cm^3, 28%) for 15 min. The mixture was diluted with ether (80 cm^3), washed with cold brine (4 × 20 cm^3), and the solution dried over anhydrous magnesium sulfate. The ^1H nmr of the residual oil, obtained after removal of solvent at 15°C, revealed the presence of 4-bromo-3-nitrotoluene (37%), 5-bromo-2-methylphenyl acetate (21%), diene **1***a* (37%), and diene **1***b* (5%). The mixture (1.3 g) was separated by column chromatography on silica gel (180 g) using a mixture of ether –

petroleum ether as eluent at −40°C. Initial fractions eluted with 3% ether gave 4-bromo-3-nitrotoluene. Mixtures of phenyl acetate, bromonitrotoluene, and diene **1***a* were eluted next with 6% ether. Further elution with 10% ether gave mixtures containing diene **1***b* (95%) and 4-bromo-3-nitrotoluene (5%). Diene **1***b* did not crystallize from ether – petroleum ether and was characterized in solution. It had ^{1}H nmr (250 MHz, $CDCl_3$) δ: 1.74 (s, 3, CH_3), 2.13 (s, 3, $OCOCH_3$), 5.94 (m, 1, H(2)), 6.23 (m, 3, H(1), H(4) and H(5)) ppm; ^{13}C nmr (62.9 MHz, $CDCl_3$, −15°C) δ_c: 18.2 (CH_3), 19.6 ($OCOCH_3$), 70.8 (C(1)), 87.0 (C(6)), 117.1 (C(3)), 126.5 (C(2)), 127.2 (C(4)), 129.1 (C(5)), 169.5 ($OCOCH_3$).

In some small scale reactions, diene **1***a* was isomerized by heating a solution in $CDCl_3$ in an nmr tube in a thermostated water bath. *p*-Cresol was added to some reactions as an inhibitor. Reactions were followed by ^{1}H nmr at 90 MHz. Typical results were as follows: after 1 h at 60°C in the absence of inhibitor the composition was **1***a* (72%), **1***b* (trace), **2***a* (19%), **2***b* (9%); after 15 h in the presence of *p*-cresol (0.25 mol proportion) the composition was **1***a* (32%) and **2***a* (68%) and no **2***b* was detected at any prior stage.

*(Z)-3-Bromo-6-methyl-6-nitrocyclohexa-2,4-dienyl chloride (**3**a)*

Hydrogen chloride was bubbled through a solution of **1***a* (275 mg, 1 mmol) in ether (5 cm^3) at −78°C, for 15 min, and the mixture was then stirred for 45 min while the bath was allowed to warm to −40°C. The ^{1}H nmr spectrum of the mixture at this stage showed the presence of a new diene as the only product. The solution was diluted with ether (20 cm^3) at −78°C and neutralized by the addition of excess aqueous ammonia. The ether was separated and the aqueous layer extracted with ether. The combined ethereal extracts were dried ($MgSO_4$) and the ether removed on the rotavapor at 15°C to give chloride **3***a* (206 mg, 82% isolated yield). Crystallization from ether – petroleum ether at −20°C gave pale yellow crystals, mp 87°C; uv (CH_2Cl_2): 273 nm (351 m^2 mol^{-1}); ir: 1540 (NO_2), 740 (C—Cl) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 1.81 (s, 3, CH_3), 4.89 (dd, 1, H(1)), 6.20 (dd, 1, H(4)), 6.36 (dd, 1, H(2)), 6.54 (dd, 1, H(5)) ppm, J_{12} = 6.47, J_{15} = 1.72, J_{24} = 1.81, J_{45} = 10.30 Hz; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ_c: 24.2 (CH_3), 58.6 (C(1)), 89.1 (C(6)), 121.2 (C(3)), 124.2 (C(2)), 128.1 (C(4)), 129.1 (C(5)) ppm. *Anal.* calcd. for $C_7H_7NO_2ClBr$: C 33.29, H 2.79, N 5.55; found: C 33.39, H 2.67, N 5.51.

X-ray diffraction studies

Compounds **1***a*, **2***a*, and **3***a* were examined on Weissenberg and precession cameras to determine the symmetry and approximate cell dimensions, and subsequently transferred to a Picker 4-circle diffractometer automated with a PDP11/10 computer and using Zr filtered Mo radiation. The crystal data are given in Table 1. The symmetry positions for **2***a* were $x, y, z; -x, -y, -z; (\frac{1}{2}+x), (\frac{1}{2}-y), (\frac{1}{2}+z)$; and $(\frac{1}{2}-x), (\frac{1}{2}+y), (\frac{1}{2}-z)$. The cell dimensions were refined by least squares using pairs (19, 13, and 8, respectively) of 2θ measurements obtained by an automatic centering routine. The asymmetric unit was one molecule in each case. In measuring the intensities θ/2θ scans were used. Three standard reflections preceded each batch of 50 measurements and the sum of their intensities was used to correct for crystal decomposition. The class of compounds under study was soft and low melting. **1***a*, **2***a*, and **3***a* were selected as the best and most durable single crystals, but melting terminated the measurements on **2***a*. Lp corrections were done. Absorption corrections were applied by numerical integration for compounds **1***a* and **3***a* using Gaussian grids (4 × 10 × 12 for **1***a*, 12 × 8 × 8 for **3***a*). No reflections were omitted from the data sets.

Structure solution and refinement

SHELX (23), MULTAN (24), and ORTEP (25) and local programs were used. The structures were solved using direct methods and refined using electron-density maps and the method of least squares minimising $\Sigma w||F_o| - |F_c||^2$. The atomic scattering factors were those included in the SHELX program (23, 26). The weighting schemes employed were $w = 1/(\sigma^2(F) + 0.001F^2)$ for **1***a* and **3***a*, and unit weights for **2***a*. No special positions were occupied. For **3***a*, the *z* coordinate of the Br atom was fixed, since there was no reference point in the *z* direction provided by the symmetry elements. For compounds **1***a* and **3***a* anisotropic thermal parameters were used for all atoms, but for compound **2***a* isotropic temperature factors were employed. Hydrogen atoms were not found. Final difference maps were calculated as a further check and the maxima, given in Table 1, indicate no chemical mistakes.

Reaction of D-arabinose diethyl dithioacetal with one equivalent of benzaldehyde dimethyl acetal in the presence of *p*-toluenesulfonic acid at −40°C gave a mixture of the two epimers of 5-*O*-methoxyphenylmethyl-D-arabinose diethyl dithioacetal initially. After 14 h at −20°C, the major products were *R*- and *S*-4,5-*O*-benzylidene-D-arabinose diethyl dithioacetal. The structure of the *S* isomer was determined by X-ray crystallography. The crystal was orthorhombic, with space group $P2_12_12_1$, cell dimensions $a = 5.179(4)$, $b = 12.469(3)$, $c = 27.150(4)$ Å, and $Z = 4$. The crystal structure was solved using the SHELX (76) system and refined to $R = 0.060$ for 714 reflections. The sugar chain was in a zigzag conformation, the 4,5-*O*-benzylidene ring in a $^{0-5}T_c$ conformation, and the plane of the phenyl ring was nearly perpendicular to the plane of the five-membered ring (88° angle). There were two short OH—S hydrogen bonds, one intramolecular and one intermolecular. Reaction of the diethyl dithioacetals of D-glucose, D-galactose, D-mannose, and D-ribose at −20°C as above also gave mixtures of the terminal five-membered ring *O*-benzylidene diastereomers.

T. Bruce Grindley, Srihari Kusuma et T. Stanley Cameron. Can. J. Chem. **64**, 2388 (1986).

La réaction du diéthyl dithioacétal du D-arabinose avec un équivalent du diméthyl acétal du benzaldéhyde, en présence d'acide *p*-toluènesulfonique, à −40°C, conduit initialement à un mélange des deux épimères du diéthyl dithioacétal du *O*-méthoxyphénylméthyl-5 D-arabinose. Après 14 h, à −20°C, les produits principaux sont les diéthyl dithioacétals des *O*-benzylidène-4(*R*) et 4(*S*), 5 D-arabinoses. En faisant appel à cristallographie par rayons-X, on a déterminé la structure de l'isomère *S*. Les cristaux sont orthorhombiques et appartiennent au groupe d'espace $P2_12_12_1$, avec $a = 5,179(4)$, $b = 12,469(3)$ et $c = 27,150(4)$ Å et $Z = 4$. On a résolu la structure cristalline en faisant appel au système SHELX (76) et on l'a affinée jusqu'à une valeur de $R = 0,060$ pour 714 réflexions. La chaîne de sucre existe dans une conformation en zigzag, le cycle *O*-benzylidène-4,5 existe dans une conformation $^{0-5}T_c$ et le plan du noyau phényle est pratiquement perpendiculaire au plan du cycle à cinq chaînons (angle = 88°). Il existe deux liaisons hydrogènes OH—S qui sont courtes, l'une est intramoléculaire alors que l'autre est intermoléculaire. Les réactions des diéthyl dithioacétals du D-glucose, du D-galactose, du D-mannose et du D-ribose, à −20°C, dans les conditions décrites plus haut, conduisent à des mélanges des *O*-benzylidènes à cinq chaînons diastéréoisomères en positions terminales.

[Traduit par la revue]

Introduction

Monosaccharide diethyl dithioacetals can be easily prepared and are potentially attractive synthons for chiral synthetic targets. Their acyclic structure allows the employment of protecting group strategies different from those adopted from pyranose and furanose sugars. Study of techniques for selective blocking of the various hydroxyl groups of these compounds has not been extensive. Cyclic acetals are convenient protecting groups and a particularly useful one is the benzylidene acetal. In the past few years, this "protecting group" has been shown to also be a versatile functional group that can be selectively transformed in a large number of ways.[2]

The preparation of *O*-benzylidene derivatives of acyclic carbohydrates has been studied to some extent. In most known cases, products have been obtained under conditions of thermodynamic control (5, 6). Typical reaction conditions involve benzaldehyde as the solvent and give products of multiple acetalation. The structures of the major products can be predicted on the basis of the Hann–Hudson rules (7) and compounds containing 2-phenyl-1,3-dioxane rings are normally obtained. For instance, dithioacetals of D-ribose, D-xylose, and D-lyxose formed 2,4:3,5-di-*O*-benzylidene acetals (8).

Kinetic acetalation has a number of advantages over thermodynamic acetalation (9, 10). Most notable is the ease with which partially acetalated products can be obtained. In addition, the products often have different structures than the thermodynamic products. For instance, kinetic isopropylidenation of unsubstituted hexoses gave 4,6-*O*-isopropylidene derivatives (9), quite different products than those obtained under thermodynamic control. The reaction of methyl hexopyranosides with one equivalent of α,α-dimethoxytoluene (benzaldehyde dimethyl acetal) in *N*,*N*-dimethylformamide containing a trace of acid at 60°C under reduced pressure was shown by Evans (11) to give better yields of the normal 4,6-*O*-benzylidene derivatives than the typical 50% or lower yields obtained under thermodynamic conditions.[3] A number of other workers have used this reagent to make benzylidene derivatives of pyranose and furanose sugars (12). Brecknell and Carman (14) obtained a mixture of the diastereomeric 5,6-*O*-benzylidene derivatives of D-glucose phenylosotriazole in unspecified yield by reaction with benzaldehyde in dimethyl sulfoxide containing a trace of concentrated sulfuric acid at room temperature for 4 h. In this publication, we describe the kinetic benzylidenation of aldose diethyl dithioacetals using benzaldehyde dimethyl acetal.

Results and discussion

*Benzylidenation of D-arabinose diethyl dithioacetal (**3**a)*

The reaction of **3***a* with benzaldehyde dimethyl acetal in dimethylformamide at −40°C in the presence of a trace of *p*-toluenesulfonic acid was slow. Thin-layer chromatography suggested that one product formed initially, followed by two others. The initial product was shown to be a mixture of the

[1]Revision received July 22, 1986.

[2]For a summary, see ref. 1. More recent methods are reported in refs. 2 and 3. The related *p*-methoxybenzylidene acetal can also be selectively transformed (4).

[3]Another efficient way of performing benzylidenations has recently appeared (13).

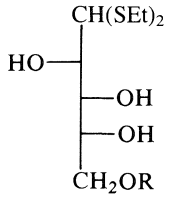
two epimers of 5-*O*-methoxyphenylmethyl-D-arabinose diethyl dithioacetal (**3***b*), chiefly on the basis of spectral data (discussed below), and also because it rearranged on standing to a mixture of the other two products. Compound **3***b* was shown to contain a methoxyphenylmethyl group by means of its mass spectrum and also from the observation of signals assignable to a methoxyl group both in the ^1H and ^{13}C nmr spectra. The mass spectrum contained an M^+ peak, minor peaks corresponding to loss of CH_3OH and ·CHOMePh, as well as a major peak at m/z 121, corresponding to $CHOMePh^{+}$. The location of this group was assigned from the observation of downfield shifts of 3.3 and 3.7 ppm for the signals of C-5 in the ^{13}C nmr spectrum of the two isomers present in **3***b* in comparison to the shift in the starting material, **3***a* (see Table 1). No other signals were shifted significantly. Downfield shifts of similar magnitude were always observed for hydroxyl-bearing carbon atoms when the hydroxyl group became attached to a benzylidene acetal carbon (see later).



3*a* R = H
3*b* R = CHOMePh

Reaction under similar conditions at −20°C produced **3***b* initially, but after 14 h **3***b* had disappeared and the other two components from the previous reaction, **3***c* and **3***d*, were the sole products. These two components were separated by column chromatography. The component (**3***c*) that moved faster on tlc gave crystals suitable for X-ray crystallography.

The crystal structure was solved using the SHELX (76) package with a final R-factor of 6.0%. Tables 2 and 3 show atomic parameters and torsional angles. Figure 1 shows the crystal structure and Fig. 2 shows the crystal packing. In Fig. 1, hydrogen atoms are numbered in relation to the numbers of the carbon atoms to which they or, if hydroxyl hydrogens, their oxygen atoms, are attached. To avoid clutter, the minimum number of hydrogen atoms associated with a single carbon is

labelled. In the following discussion, carbohydrate numbering (see structures) indicated by a dash (e.g. C-1) will be used except in the discussion of the crystal structure where crystallographic numbering will be used (see Fig. 1). This numbering method is indicated by labels without dashes (e.g. C1).

The crystal structure demonstrated that compound **3c** was *S*-4,5-*O*-benzylidene-D-arabinose diethyl dithioacetal. The sugar chain was in the zigzag conformation, as expected for an arabinose derivative (15, 16). There was considerable thermal motion in the ethyl groups of the diethyl dithioacetal. Similar observations have been made for these groups in other diethyl dithioacetal derivatives (17).

This crystal structure determination is the first for a compound containing a five-membered benzylidene ring. The five-membered ring was in the $^{0-5}T_c$ conformation with O2 0.324(16) Å above the plane defined by O1, C8, and C9 and the acetal carbon, C7, 0.264(20) Å below the plane. The phenyl group adopted a quasi-equatorial orientation and was approximately perpendicular to the five-membered ring; a plane defined by O1, C7, and O2 had an angle of 88(3)° with a plane defined by the benzene ring (atoms C3, C4, C5, and C7 were used to define the plane). This orientation of the phenyl group resulted in short nonbonded distances between the acetal hydrogen and the nearly eclipsed aromatic *ortho* carbon, 2.42(10) Å, and its hydrogen, 2.35(14) Å.

The torsional angle that the phenyl ring makes with the 1,3-dioxane ring in 2-phenyl-1,3-dioxanes has attracted considerable interest (18–25). Two extreme conformations, termed parallel and perpendicular, are defined by the angle that the plane of the phenyl ring makes with the α-C—H bond. Compounds containing 2-phenyl-1,3-dioxane rings have adopted a wide range of conformations in the solid state (18–23). Results from calorimetric investigations were consistent either with free rotation about the acetal C to phenyl C bond or with a low barrier (<1.0 kcal mol^{-1}) (23, 24). Nuclear magnetic resonance results suggested that the parallel conformation is slightly favoured (0.4 ± 0.2 kcal mol^{-1}) (25) and recent molecular mechanics calculations supported the conclusion that this conformation is more stable (by about 1 kcal mol^{-1}) (23).

Application of the nmr method, the *J* technique, to a 2-phenyl-1,3-dioxolane derivative indicated that the parallel conformation was favoured to a greater extent (1.0 kcal mol^{-1}) for this ring size (25). In agreement with this result, compound **3c** was found here to adopt the same conformation.

Molecular mechanics calculations have now been performed on 2-phenyl-1,3-dioxolane using an MM2 program (26) modified to include improvements for alkylbenzenes (27) and the anomeric effect (28). The results were not consistent with the above conclusion. Initial calculations determined that the most stable ring conformation of 2-phenyl-1,3-dioxolane was the envelope conformation with the acetal C out of the plane and the phenyl group equatorial. Other conformations were examined by driving the various torsional angles internal to the 1,3-dioxolane ring. The barrier to rotation about the bond from the acetal C to the phenyl carbon was calculated by driving the *ortho*-C—C—C—αH torsional angle in 10° steps. The maximum for this latter process occurred at 40°, 0.1 kcal mol^{-1} above the 90° value and 0.3 kcal mol^{-1} above the 0° value. Allinger and Chung had calculated a 0 kcal mol^{-1} barrier for 2-phenyl-1,3-dioxane using the earlier MM1 force field (29). They ascribed the negligible barrier to a balance between *ortho*-hydrogen/ring oxygen repulsion in the perpendicular conformation and *ortho*-hydrogen/αH repulsion in the parallel conformation (29). Introduction of the anomeric effect in the recent calculation (23) shortened the C—O bonds and hence destabilized the perpendicular conformation. The smaller O—C—O bond angle in a 1,3-dioxolane ring should decrease the *ortho*-hydrogen/ring oxygen repulsion in the perpendicular conformation, which should cause the energy difference between the two extreme conformations to become smaller. The results of the calculations were in agreement with this expectation. The contradiction between the limited experimental results and those from the molecular mechanics calculations do not allow a firm conclusion to be drawn at this time.

There was only one OH—O hydrogen bond, a weak intramolecular bond between H102 and O4; the O4—O3 and O4—H102 distances were 2.767(11) Å and 2.53(8) Å, respectively, and the O4—H102—O3 angle was 99(6)°. However, there were two short OH—S hydrogen bonds. An intramole-

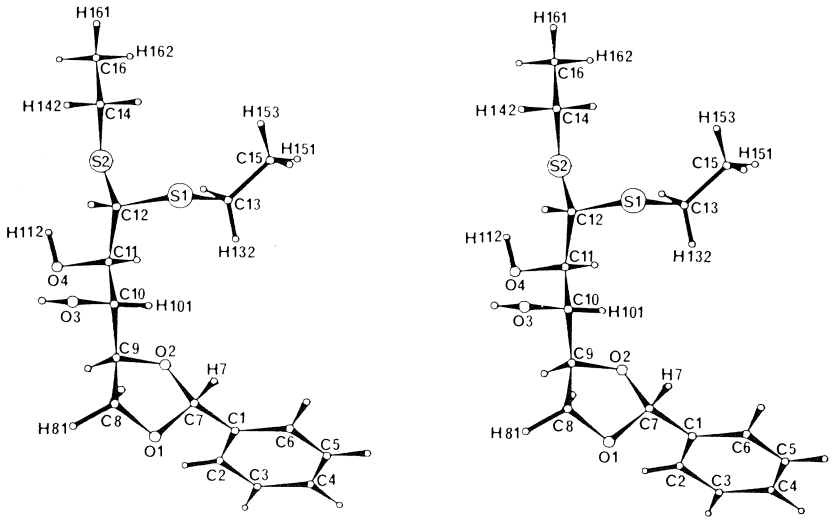

FIG. 1. Stereoview of **3***c* with the crystallographic atom numbering scheme.

cular bond was present between H112 and S2; the O4—S2 and H112—S2 distances were 2.934(9) and 2.26(10) Å, respectively, and the O4—H112—S2 angle was 130(8)°. The second hydrogen bond was intermolecular, between H102 on the adjacent molecule in the cell and the same sulfur atom S2; the O3—S2 and H102—S2 distances were 3.253(9) and 2.50(8) Å, respectively, and the S2—H102—O3 angle was 158(7)°. The O3—H102 bond distance was short, 0.80(8) Å. Because the O—H—S angle for this hydrogen bond was close to 180°, any increase in the O—H bond distance results in a decrease in the S—H distance of almost the same amount. Experimental evidence indicates OH—S hydrogen bonds have about the same strengths as OH—O hydrogen bonds (30) although theoretical studies suggest they are somewhat weaker (31). The S—H hydrogen bond distances observed here were considerably less than the sum of the van der Waals radii (3.05 Å) and are among the shortest known (30–32).

The structure of the slower moving component was unambiguously established as *R*-4,5-*O*-benzylidene-D-arabinose diethyl dithioacetal (**3***d*) from selective decoupling experiments in the ^{1}H nmr spectrum of its di-*O*-acetate derivative. The key experiment is shown in Fig. 3. It is known that signals of protons on secondary carbons bearing *O*-acetate groups are shifted downfield by ~1 ppm when compared to those of the hydroxy compounds (33). In the 361.08-MHz ^{1}H nmr spectrum of the diacetate, signals of two protons appear as doublets of doublets having chemical shifts greater than 5.0 ppm. Selective irradiation at the positions of either of these downfield signals reduces the other to a doublet, indicating that the signals arise from protons on adjacent carbons. Irradiation at 5.37 ppm, the position of one of these two quartets, reduces the doublet at 3.98 ppm to a singlet. Since only H-1 in these compounds can give rise to a doublet in its ^{1}H nmr spectrum, the two downfield signals are those of H-2 and H-3. Therefore the parent compound (**3***d*) has the 4,5-*O*-benzylidene structure. The assignment of the *R*-configuration in the 4,5-*O*-benzylidene ring of **3***d* followed from the previous assignment of the *S*-configuration to its epimer **3***c*.

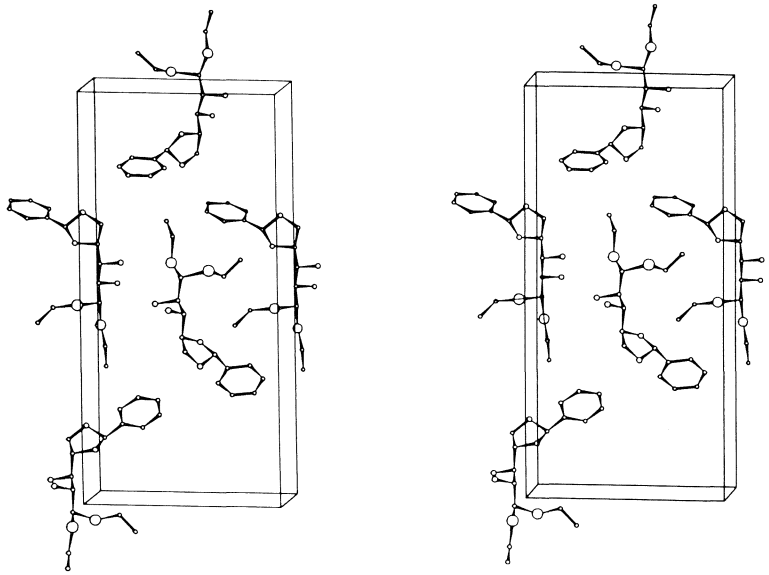

FIG. 2. Stereoview of the crystal packing of **3***c*.

Previous assignments of configuration in 2,4-disubstituted 1,3-dioxolanes have been based on unambiguous synthesis of *cis*-2,4-dimethyl-1,3-dioxolane (34, 35). Comparison of various physical properties including refractive index, thermodynamic stability, and chemical shift of the acetal proton for many *cis–trans* pairs indicated that the relationship of these properties for each pair was the same as in the unambiguously assigned dioxolanes, allowing further assignments to be made. The most useful technique is the last of the three above; the ^{1}H nmr signal from the acetal proton of the *trans* isomer is normally downfield of that of the *cis* isomer (36). For the D-aldose diethyl dithioacetal derivatives considered here, a 2-phenyl-1,3-dioxolane ring formed using the two terminal hydroxyl groups has the *S*-configuration at carbon-2 of the 1,3-dioxolane ring in the *trans* isomer. The definitive assignment of configuration made for compounds **3***c* and **3***d* allows an additional check of the reliability of the previous method of assignment. Compound **3***c*, the *trans* isomer, exhibited a more downfield shift of 5.93 ppm for the signal of the benzylidene acetal proton as compared to 5.78 ppm for this signal of **3***d*, in agreement with previous assignments (35, 36).

Other structural assignments

Assignment of structures of other compounds to be described later was made using the ^{1}H nmr chemical shift of the benzylidene acetal proton and also a number of ^{13}C nmr parameters. It has been shown that various ^{13}C nmr parameters may be used for ring-size determination of benzylidene acetals (37) and for configurational assignment in 2-phenyl-1,3-dioxolane rings fused to pyranose sugars (38). In chloroform-*d*, 2-phenyl-1,3-dioxolane derivatives have ^{1}H nmr chemical shifts for the proton on the benzylidene acetal carbon of 5.71–6.43 ppm, ^{13}C nmr chemical shifts for this carbon atom of 101.9–105.8 ppm, and $^1J_{C,H}$ values between these carbon and hydrogen atoms of 166.6–170.5 Hz (37). In contrast, the corresponding values for 2-phenyl-1,3-dioxane derivatives lie in the ranges 5.44–5.58 ppm, 100.6–101.4 ppm, and 159.7–161.8 Hz (37). The values of all of these parameters for the major products of the reaction of aldose diethyl dithioacetals fall in the ranges expected (37) for 2-phenyl-1,3-dioxolane derivatives (see Table 1 and Experimental).

In the ^{13}C nmr spectra of compounds **3***c* and **3***d*, signals of the primary carbon and of one secondary carbon were ~4 ppm downfield of those of the same carbons in the parent compound. Liptak *et al.* have noted that the signals of secondary carbons of pyranose sugars are shifted downfield by 4–8.6 ppm when the carbon becomes part of a 2-phenyl-1,3-dioxolane ring (39).

The ^{13}C nmr assignments of signals of carbons in aldose diethyl dithioacetals in dimethyl sulfoxide-d_6 had previously been made by Schnarr *et al.* (40). The ^{13}C chemical shifts obtained here for the same compounds in chloroform-d_6 containing a few drops of dimethyl sulfoxide-d_6 were ~0.5 ppm from the previous observations and all values recorded here were larger. Thus, the previous assignments were used (40). In all cases, the signal of the primary carbon in the ^{13}C nmr spectrum shifted downfield by 4 ± 1 ppm on formation of the *O*-benzylidene derivative. Thus, the major products of kinetic benzylidenations were terminal 2-phenyl-1,3-dioxolane derivatives.

It was also found that pairs of epimers were always produced. When these pairs could be separated, the compound with the larger R_f value always had the lower mp, the more downfield shift for the benzylidene acetal proton, the more upfield shift for the acetal carbon, and larger magnitude for the value of the coupling constant between the acetal carbon and proton, as also did **3***c* with respect to **3***d*. On this basis, the compound with the more downfield shift for the benzylidene acetal proton was assigned the *trans*- or *S*-configuration.

Reactions with the diethyl dithioacetal derivatives of D-*glucose,* D-*galactose,* D-*mannose, and* D-*ribose*

Reactions of the above compounds with 1.2 equivalents of benzaldehyde dimethyl acetal for 14 h at −20°C, under the same conditions as with D-arabinose diethyl dithioacetal, in all cases produced a mixture of the two epimeric *O*-benzylidene acetals having terminal 1,3-dioxolane rings as the major products in isolated yields ranging from 37 to 57%. The structures of these mono-*O*-benzylidene derivatives were assigned from the ^{1}H and ^{13}C nmr parameters as discussed above. In two cases (for D-glucose and D-mannose derivatives) the epimeric products could be separated by column chromatography. On one occasion, the reaction with D-glucose diethyl dithioacetal at −20°C for 15 h produced a mixture of the two epimeric 6-*O*-(methoxyphenylmethyl) derivatives in substantial amounts as well as

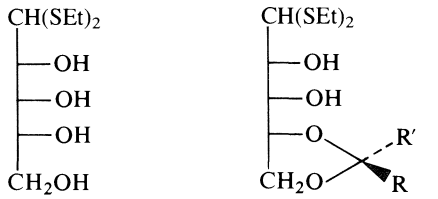
the normal products. For most of these reactions, the major products were accompanied by minor amounts (<4%) of materials that were not fully characterized but that were thought to be chiefly 2-phenyl-1,3-dioxane derivatives involving the terminal primary carbon, on the basis of their ^{1}H and ^{13}C nmr spectra.

The mass spectra of aldose diethyl dithioacetals have been investigated by DeJongh (41). The mass spectra of the present compounds showed most of the features observed (41), of which the most notable were prominent molecular ions, loss of thioethyl radical from the molecular ion (often supported by metastables), and base peaks at m/z 135 ($^+$CH(SEt)$_2$). The relative intensities of the peaks at m/z 149 and 179 were related, to some extent, to ring size. These ions probably arise from cleavage of the two or three terminal carbon atoms of the sugar chain along with the attached benzylidene acetal. In the compounds described in this paper, the peak at m/z 149 was normally more intense; the compounds in the following paper (42), which have a six-membered ring spanning the three terminal carbon atoms, gave rise to spectra with more intense peaks at m/z 179. However, there were enough exceptions (**4***c*, *d*) that these observations cannot be considered diagnostic of ring size.



4*a*
4*c* R = Ph, R′ = H
4*d* R = H, R′ = Ph

The present results provide some information about the mechanism of this reaction. Isolation of the acyclic *O*-methoxyphenylmethyl acetal (**3***b*) from the reaction at −40°C indicates that the reaction at −20°C proceeds through this intermediate. This acyclic acetal rearranged to the five-membered ring acetals on standing in a chloroform-*d* solution as well as in the reaction medium at −20°C. The preference for attack by the primary alcohol is caused by steric factors. The five-membered ring diastereomers do not rearrange into one another or other products at −20°C. Thus, they are the kinetic products at this temperature. Presumably, they are preferred over the thermodynamically more stable six-membered rings because of the more favorable entropy of activation for their formation (10).

The rate constants for formation of the acyclic intermediates, e.g. **3***b*, were observed to be of the same order of magnitude as that for ring closure from this intermediate. In contrast, the rate constants for epimerization or rearrangement (42) are smaller by at least two orders of magnitude. Epimerization or rearrangement must take place through carbocation intermediates. Formation of the acyclic intermediate and its ring closure could occur via carbocation intermediates or via an S_N2 process. Both types of reactions would have an initial equilibrium protonation step, followed by the rate-determining step. The oxygen atom being protonated is in a methoxyl group for the faster reactions and is attached to a primary or secondary carbon for the slower ones. The latter type of oxygen atom is probably more basic (2). Thus, the difference in the rates of reaction must occur in the rate-determining step. This step is therefore different in mechanism for the faster reactions and involves an S_N2 process. The greater steric interactions present in an S_N2 transition state are more consistent with the great

discrimination between primary and secondary hydroxyl groups observed here.

Experimental

Melting points were determined with a Fischer–Johns melting point apparatus and are uncorrected. The ^1H and ^{13}C nmr spectra were recorded at 79.6 and 20 MHz, respectively, on Varian CFT-20 or FT-80 spectrometers in chloroform-*d* with tetramethylsilane as the internal standard, unless otherwise specified. Selective homonuclear decoupling was performed with a Wavetek Model 171 frequency synthesizer. The ^1H nmr spectra at 60 MHz and ^1H nmr spectra at 361.08 MHz or ^{13}C nmr spectra at 90.8 MHz were measured on Varian T-60 and Nicolet NT-360 NB spectrometers, respectively. The ^1H nmr spectra were analysed on a first-order basis. Mass spectra were obtained with a CEC 21-104 mass spectrometer with an inlet temperature of 150°C operating at a 70-eV ionizing voltage unless otherwise specified. The ir spectra were recorded on a Pye Unicam SP 1000 spectrophotometer. Optical rotations were determined on Perkin–Elmer 141 or Bellingham and Stanley polarimeters. Bath temperatures between −20°C and room temperature were controlled with a Haake FK bath while those at −20°C and below were controlled in a Neslab bath by a Neslab CC-100 cooler and an Exatrol 30 control unit. Thin-layer chromatography (tlc) was performed on 0.25 mm thick precoated (BDH EM reagents) silica gel 60F-254 glass plates cut to be approximately 7 cm long. Plates were developed by spraying with a 2% ceric sulfate solution in 1 *M* sulfuric acid and heating for a few minutes at 150°C. The term pet. ether refers to petroleum ether 30–60°C unless otherwise specified. Compositions of eluent systems used were as follows: A, pet. ether:ethyl acetate, 2:1; B, pet. ether:ethyl acetate, 2:3; C, pet. ether:ethyl acetate, 7:3; D, pet. ether:ethyl acetate, 3:1; E, benzene:methanol, 9:1; F, pet. ether:ethyl acetate, 1:1. Column chromatography was performed using silica gel 60 (70–230 mesh) (Merck). Anhydrous *p*-toluenesulfonic acid was obtained from the commercial monohydrate by heating 5 h at 56°C under vacuum (0.5 Torr; 1 Torr = 133.3 Pa) in a drying pistol in the presence of phosphorus pentoxide. *N,N*-Dimethylformamide was purified by distillation from calcium hydride. Microanalyses were performed by the Canadian Microanalytical Service, Ltd., Vancouver, B.C.

General method for benzylidenation under kinetic control

A solution of dried aldose diethyl dithioacetal (10 mmol) and anhydrous *p*-toluenesulfonic acid (**1**) (50 mg, 0.58 mmol) in dry *N,N*-dimethylformamide (DMF) (20 mL) was cooled to −20°C. α,α-Dimethoxytoluene (**2**) (12 mmol) was added and the reaction flask attached to a water aspirator. After 14 h at −20°C, when tlc indicated complete conversion of starting material, the solution was poured into a 5% sodium bicarbonate solution (50 mL) and the mixture was extracted with ether (3 × 30 mL). The combined extracts were washed with water (2 × 30 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated on a rotary evaporator at 40°C. All recrystallizations of solid products were from dichloromethane/pet. ether 65–75°C, and all crystals were colorless.

*Benzylidenation of D-arabinose diethyl dithioacetal (**3**a) at −20°C*

Compound **3***a* (2.56 g, 10 mmol) in DMF (10 mL) was treated with compounds **1** (100 mg) and **2** (1.824 g, 12 mmol) as in the general method. The product, a pale yellow syrup, contained two components by tlc (solvent A), which were separated by column chromatography on silica gel (100 g) using solvent A as eluent.

The first fraction (0.936 g, 27%, R_f 0.44) crystallized and was recrystallized to give fine needles of *S*-4,5-*O*-benzylidene-D-arabinose diethyl dithioacetal (**3***c*), mp 71–72°C; $[\alpha]_D^{24}$ −31° (*c* 4.00, chloroform); ^1H nmr δ: 1.26, 1.28 (2t, 6H, 2 SCH_2CH_3, J = 7.3, 7.5 Hz), 2.50 (br s, exchanged with D_2O, OH-3), 2.67, 2.69 (2q, 4H, 2 SCH_2CH_3, J = 7.3, 7.5 Hz), 3.37 (d, 1H, exchanged with D_2O, OH-2, $J_{2,OH}$ = 2.6 Hz), 3.79 (dd after D_2O exchange, 1H, H-2, $J_{1,2}$ = 9.7 Hz, $J_{2,3}$ = 2.0 Hz), 4.05 (d, 1H, H-1, $J_{1,2}$ = 9.3 Hz), 4.12–4.36 (complex m, 5H), 5.93 (s, 1H, benzylidene H), 7.24–7.51 (m, 5H, Ph); *m/z*: 344 (19, M^+), 283 (2, M − ·SEt), 177 (19), 149 (5), 137 (14), 136 (11), 135 (100, $^+CH(SEt)_2$), 107 (16), 105 (23), 91 (13), 75 (13). *Anal.* calcd. for $C_{16}H_{24}O_4S_2$: C 55.78, H 7.02; found: C 55.62, H 7.16.

The second fraction (1.404 g, 41%, R_f 0.33) crystallized and was recrystallized to give very fine needles of *R*-4,5-*O*-benzylidene-D-arabinose diethyl dithioacetal (**3***d*), mp 87–88°C; $[\alpha]_D^{24}$ −60° (*c* 4.00, chloroform); ^1H nmr δ: 1.24 (t, 6H, 2 SCH_2CH_3, J = 7.4 Hz), 2.65, 2.68 (2q, 4H, 2 SCH_2CH_3, J = 7.6, 7.5 Hz), 2.90 (br s, 1H, exchanged with D_2O, OH-3), 3.34 (d, 1H, exchanged with D_2O, OH-2, $J_{2,OH}$ = 2.3 Hz), 3.78 (dd after D_2O exchange, 1H, H-2, $J_{1,2}$ = 9.3 Hz, $J_{2,3}$ = 1.8 Hz), 4.01 (d, 1H, H-1, $J_{1,2}$ = 9.3 Hz), 4.04–4.36 (complex m, 5H), 5.78 (s, 1H, benzylidene H), 7.25–7.53 (m, 5H, Ph); *m/z*: 344 (4, M^+), 283 (6, M − ·SEt), 177 (16), 149 (7), 135 (100, $^+CH(SEt)_2$), 107 (21), 105 (24), 91 (16), 77 (13), 75 (16); metastable: 232–235 (344–283). *Anal.* calcd. for $C_{16}H_{24}O_4S_2$: C 55.78, H 7.02; found: C 55.77, H 7.23.

*Benzylidenation of D-arabinose diethyl dithioacetal (**3**a) at −40°C*

Compounds **1** (50 mg), **2** (0.912 g, 6 mmol), and **3***a* (1.28 g, 5 mmol) were kept in DMF (10 mL) at −40°C for 100 h. The product, a pale yellow syrup, was separated by column chromatography, on silica gel (100 g) using solvent A as eluent, into 3 fractions, A (0.078 g, 5%, R_f 0.44), B (0.098 g, 6%, R_f 0.33), and C (0.306 g, 18%, R_f 0.20). Fractions A and B were shown to be identical to compounds **3***c* and **3***d*, respectively.

Fraction C, a solid, was recrystallized to give fine needles, a mixture of *R*- and *S*-5-*O*-(methoxyphenylmethyl)-D-arabinose diethyl dithioacetal (**3***b*), mp 71–73°C; $[\alpha]_D^{24}$ +4° (*c* 1.56, chloroform); ^1H nmr (60 MHz) δ: 1.28 (t, 6H, 2 SCH_2CH_3, J = 7.5 Hz), 2.70, 2.72 (2q, 4H, 2 SCH_2CH_3, J = 7.5 Hz), 2.95–3.22 (m, exchanged with D_2O, 3H, 3OH), 3.32 (s, 3H, OCH_3), 3.46 (br s, exchanged with D_2O, OH), 3.66–4.32 (complex m, 6H), 5.48 (s, 1H, benzylidene H), 7.28–7.60 (m, 5H, Ph); ^{13}C nmr δ: 50.0, 50.2 (2 OMe C); *m/z*: 376 (4.5%, M^+), 344 (11, M − CH_3OH), 283 (10, 344 − ·SEt), 256 (3), 255 (5, M − $CHPhOCH_3$), 209 (6, 344 − 135), 179 (10), 177 (29), 135 (100, $^+CH(SEt)_2$), 121 (50, $^+CHOMePh$), 107 (34), 105 (35), 91 (20), 77 (26), 75 (24).

A reaction, as above, but for 253 h, yielded **3***b* (6%), **3***c* (20%), and **3***d* (22%).

S-*2,3-Di*-O-*acetyl-4,5*-O-*benzylidene-D-arabinose diethyl dithioacetal*

Compound **3***c* (0.258 g, 0.75 mmol) in dry pyridine (1.184 g, 15 mmol) and acetic anhydride (3.06 g, 30 mmol) was stirred 14 h, then poured into ice-water (30 mL). The mixture was extracted with ether (3 × 30 mL), and the ether extracts were combined, washed with saturated cupric sulfate solutions (3 × 30 mL), saturated sodium bicarbonate solutions (3 × 30 mL), and water (3 × 30 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The resulting pale yellow syrup (0.295 g, 89%) was homogeneous on tlc (R_f 0.75 in solvent A); ir (neat): 1745 cm^{-1} (C=O), no OH stretching band; ^1H nmr δ: 1.22 (t, 6H, 2 SCH_2CH_3, J = 7.3 Hz), 2.10 (s, 6H, $2COCH_3$), 2.67 (q, 4H, 2 SCH_2CH_3, J = 7.3 Hz), 3.92–4.23 (complex m, 4H), 5.43 (dd, 1H, H-3), 5.77 (m, 1H, H-2), 5.95 (s, 1H, benzylidene H), 7.29–7.47 (m, 5H, Ph); ^1H nmr (benzene-d_6) δ: 1.05, 1.09 (2t, 6H, 2 SCH_2CH_3, J = 7.4 Hz), 1.79, 1.85 (2s, 3 $COCH_3$), 2.52, 2.61 (2q, 4H, 2 SCH_2CH_3, J = 7.2 Hz), 3.94–4.29 (complex m, 4H), 5.68 (dd, 1H, H-3, $J_{3,4}$ = 7.0 Hz, $J_{2,3}$ = 3.5 Hz), 5.95 (s, 1H, benzylidene H), 6.04 (dd, 1H, H-2, $J_{1,2}$ = 6.6 Hz, $J_{2,3}$ = 3.5 Hz), 7.12–7.21 (complex m, 3H, 3 phenyl H), 7.41–7.55 (m, 2H, 2 phenyl H).

R-*2,3-Di*-O-*acetyl-4,5*-O-*benzylidene-D-arabinose diethyl dithioacetal*

Compound **3***d* (0.258 g, 0.75 mmol) was acetylated as in the previous reaction. The product (R_f 0.66 in solvent A) crystallized and was recrystallized twice to give feathery crystals of the title compound (0.26 g, 31%); mp 87–88°C; $[\alpha]_D^{24}$ +30° (*c* 3.04, chloroform); ^1H nmr (361.08 MHz) δ: 1.18, 1.19 (2t, 6H, 2 SCH_2CH_3, J = 7.29, 7.34 Hz), 2.08, 2.15 (2s, 6H, $2COCH_3$), 2.59 (q, 4H, 2 SCH_2CH_3, J = 7.36 Hz), 3.98 (d, 1H, H-1, $J_{1,2}$ = 7.0 Hz), 4.02 (dd, 1H, H-5, $J_{4,5}$ = 7.2 Hz, $J_{5,5'}$ = 8.3 Hz), 4.13 (dd, 1H, H-5′, $J_{4,5'}$ = 4.6 Hz, $J_{5,5'}$ = 8.5 Hz), 4.28 (dt, 1H, H-4, $J_{3,4}$ = 6.8 Hz, $J_{4,5'}$ = 4.6 Hz, $J_{4,5}$ = 6.8 Hz), 5.37 (dd, 1H, H-2, $J_{1,2}$ = 7.1 Hz, $J_{2,3}$ = 3.2 Hz), 5.76

(dd, 1H, H-3, $J_{2,3}$ = 3.1 Hz, $J_{3,4}$ = 6.8 Hz), 5.78 (s, 1H, benzylidene H), 7.27–7.37 (complex m, 3H, 3 phenyl H), 7.46–7.49 (m, 2H, 2 phenyl H).

Attempted rearrangements of R- *and* S-*4,5-*O*-benzylidene-*D*-arabinose diethyl dithioacetal (**3**d *and* **3**c, *respectively) at* −21°C

Compound **1** (10 mg) was added to a solution of compound **3***d* (126 mg) in dry DMF (2 mL) at −21°C. The solution was kept at −21°C for 14 h, then worked up in the normal fashion. The product was shown to be identical with starting material (**3***d*) by tlc and ^{1}H nmr.

Attempted rearrangement of **3***c* under the same conditions for 14 h also produced starting material only.

Benzylidenation of D*-ribose diethyl dithioacetal (**4**a)*

Compound **4***a* (1.28 g, 5 mmol) in dry DMF (7 mL) was treated with compounds **1** (50 mg) and **2** (0.912 g, 6 mmol) as in the general method but for 49 h. The product, a pale yellow syrup, was fractionated by column chromatography, on silica gel (100 g) using solvent A as eluent, into a major compound (0.982 g, 57%, R_f 0.50) and two very minor components (R_fs 0.20 and 0.17), which were not examined further. The major component was a mixture of *R*- and *S*-4,5-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***c* and **4***d*), $[\alpha]_D^{24}$ +0.1 (*c* 4.52, chloroform); ^{1}H nmr δ: 1.24, 1.25 (2t, 6H, 2 SCH_2CH_3, *J* = 7.1, 7.5 Hz), 2.67, 2.70 (2q, 4H, 2 SCH_2CH_3, *J* = 7.4, 7.2 Hz), 3.00–4.26 (complex m, 8H), 5.79, 5.98 (2s, 1H, benzylidene H's from *R* and *S* isomers, intensity ratio δ 5.79:δ 5.98, 2:3), 7.26–7.46 (complex m, 5H, Ph); *m/z*: 344 (17, M^+), 283 (4, M − ·SEt), 256 (9), 221 (3), 209 (2), 179 (13), 177 (29), 159 (3), 149 (4), 135 (100, $^+CH(SEt)_2$), 133 (9), 117 (9), 107 (48), 105 (49), 104 (16), 103 (15), 77 (20), 75 (34), metastable: 232–235 (344–283).

Benzylidenation of D*-glucose diethyl dithioacetal (**5**a)*

Compound **5***a* (8.58 g, 30 mmol) in dry DMF (60 mL) was treated with compounds **1** (300 mg) and **2** (5.472 g, 36 mmol) as in the general method. The product, a pale yellow solid, was fractionated by column chromatography, on silica gel (300 g) using solvent B as eluent, into three fractions, A (1.80 g, 16%, R_f 0.66), B (3.89 g, 35%, R_f 0.60), and C (0.31 g, 3%, R_f 0.40 (not examined further)).

Fraction A crystallized and was recrystallized to give fine needles of *S*-5,6-*O*-benzylidene-D-glucose diethyl dithioacetal (**5***c*), mp 91–92°C; $[\alpha]_D^{24}$ +65° (*c* 4.00, chloroform); ^{1}H nmr δ: 1.25 (t, 6H, 2 SCH_2CH_3, *J* = 7.3 Hz), 2.66, 2.69 (2q, 2H, 2 SCH_2CH_3, *J* = 7.5 Hz), 3.20 (d, exchanged with D_2O, 1H, OH-2, $J_{2,OH}$ = 8.9 Hz), 3.61–4.36 (complex m, 9H), 5.92 (s, 1H, benzylidene H), 7.28–7.48 (complex m, 5H, Ph); *m/z*: 374 (38, M^+), 313 (2, M − ·SEt), 251 (1, 313 − HSEt), 239 (10), 209 (2), 207 (3), 177 (3), 149 (8), 135 (100, $^+CH(SEt)_2$), 107 (30), 105 (28), 103 (12), 91 (19), 77 (11), 75 (13), metastable: 260–264.

Fraction B crystallized and was recrystallized to give flakes of *R*-5,6-*O*-benzylidene-D-glucose diethyl dithioacetal (**5***d*), mp 108–109°C; $[\alpha]_D^{24}$ +28° (*c* 4.00, chloroform); ^{1}H nmr δ: 1.25 (t, 6H, 2 SCH_2CH_3, *J* = 7.3 Hz), 2.64, 2.69 (2q, 4H, 2 SCH_2CH_3, *J* = 7.5 Hz), 2.95 (d, exchanged with D_2O, 1H, OH, *J* = 8.8 Hz), 3.58–4.34 (complex m, 9H), 5.81 (s, 1H, benzylidene H), 7.32–7.47 (m, 5H, Ph); *m/z*: 374 (23, M^+), 313 (9, M − ·SEt), 251 (5, 313 − HSEt), 239 (44), 209 (8), 207 (11), 177 (7), 149 (25), 135 (100, $^+CH(SEt)_2$), 117 (13), 107 (83), 105 (75), 103 (44), 91 (57), 77 (36), 75 (41), metastable: 260–264. *Anal.* calcd. for $C_{17}H_{26}O_5S_2$: C 54.52, H 7.00; found: C 54.44, H 7.11.

In only one of several reactions performed as above on compound **5***a* (5.12 g, 20 mmol), poor yields of the normal products, **5***c* (0.98 g, 13%) and **5***d* (1.62 g, 25%), were obtained and another product, 6-*O*-(methoxyphenylmethyl)-D-glucose diethyl dithioacetal (**5***b*) (0.84 g, 11%, R_f 0.43 in solvent B), was also isolated. **5***b* was probably the same compound as fraction C above. Compound **5***b* was a syrup, $[\alpha]_D^{24}$ +25° (*c* 4.8, chloroform); ^{1}H nmr δ: 1.24 (t, 6H, 2 SCH_2CH_3, *J* = 7.5 Hz), 2.70, 2.72 (2q, 4H, 2 SCH_2CH_3, *J* = 7.5 Hz), 3.32 (s, 3H, OCH_3), 3.52–4.68 (complex m, 11H), 5.50 (s, 1H, benzylidene H), 7.34–7.62 (m, 5H, Ph); *m/z*: 406 (0.4, M^+), 374 (12, M − CH_3OH), 313 (3, 374 − ·SEt), 286 (4, M − $PhCOCH_3$), 239 (11, 374 − 135), 207 (5), 149 (8), 135 (100, $^+CH(SEt)_2$), 121 (49, $^+CHOMePh$).

Benzylidenation of D*-galactose diethyl dithioacetal (**6**a)*

Compounds **6***a* (8.58 g, 30 mmol), **1** (300 mg), and **2** (5.472 g, 36 mmol) were kept in DMF (80 mL) as in the general method. The pale yellow syrupy product was fractionated by column chromatography, on silica gel (300 g) using solvent D as eluent, into two components, A (4.15 g, 37% yield, R_f 0.66) and B (0.47 g, 4%, R_f 0.32).

Fraction A crystallized and was recrystallized to give colorless flakes, a mixture of *R*- and *S*-5,6-*O*-benzylidene-D-galactose diethyl dithioacetal (**6***c* and **6***d*), mp 106–107°C; $[\alpha]_D^{24}$ +66° (*c* 3.53, chloroform); ^{1}H nmr δ: 1.27 (t, 6H, 2 SCH_2CH_3, *J* = 7.4 Hz), 2.55–2.86 (m, 4H, 2 SCH_2CH_3), 3.41 (d, 1H, exchanged with D_2O, OH, *J* = 2.3 Hz), 3.92–4.37 (complex m, 9H), 5.82, 5.97 (2s, 1H, benzylidene H's, intensity ratio δ 5.82:δ 5.97, 2:3), 7.32–7.55 (m, 5H, Ph); *m/z*: 374 (4, M^+), 313 (3, M − ·SEt), 295 (2), 251 (8), 239 (10), 221 (7), 209 (3), 207 (8), 189 (5), 179 (4), 177 (13), 175 (3), 149 (11), 145 (6), 137 (14), 136 (13), 135 (100, $^+CH(SEt)_2$), 133 (7), 127 (4), 117 (5), 115 (3), 107 (32), 105 (17), 104 (7), 103 (11), 91 (17), 85 (6), 79 (7), 77 (11), 75 (13). *Anal.* calcd. for $C_{17}H_{26}O_5S_2$: C 54.52, H 7.00; found: C 54.49, H 6.91.

On tlc in solvent E, fraction A could be separated into two components (R_f's 0.37 and 0.40). Fraction B was a syrup, a mixture of two compounds from its ^{1}H nmr spectrum (60 MHz): δ 5.40 and 5.90 (2s in intensity ratio 4:1). It was not examined further.

Benzylidenation of D*-mannose diethyl dithioacetal (**7**a)*

Compounds **7***a* (2.002 g, 7 mmol), **1** (100 mg), and **2** (2.55 g, 16.8 mmol) were kept in DMF (15 mL) as in the general method. The pale yellow syrupy product was fractionated by column chromatography, on silica gel (115 g) using solvent F as eluent, into two components, A (1.02 g, 40%, R_f 0.50) and B (0.49 g, 19%, R_f 0.35).

Fraction A crystallized and was recrystallized to give needles of *S*-5,6-*O*-benzylidene-D-mannose diethyl dithioacetal (**7***c*); mp 76–77°C; $[\alpha]_D^{24}$ +13° (*c* 0.86, chloroform); ^{1}H nmr δ: 1.27 (t, 6H, 2 SCH_2CH_3, *J* = 7.3 Hz), 2.68, 2.72 (2q, 4H, 2 SCH_2CH_3, *J* = 7.4 Hz), 3.00–3.12 (br m, 2H, exchanged with D_2O, OH-3, and OH-4), 3.25 (d, 1H, exchanged with D_2O, OH-2, *J* = 3.3 Hz), 3.97–4.34 (m, 7H), 5.95 (s, 1H, benzylidene H), 7.25–7.41 (m, 4H, Ph); *m/z*: 374 (37, M^+), 313 (5, M − ·SEt), 295 (2), 251 (2, 313 − HSEt), 239 (13), 209 (3), 207 (9), 189 (5), 177 (7), 149 (10), 145 (6), 135 (100, $^+CH(SEt)_2$), 107 (35), 105 (37), 103 (17), 91 (20), 77 (14), 75 (18), metastable: 261–263. *Anal.* calcd. for $C_{17}H_{26}O_5S_2$: C 54.52, H 7.00; found: C 54.30, H 6.98.

Fraction B crystallized and was recrystallized to give fine needles of *R*-5,6-*O*-benzylidene-D-mannose diethyl dithioacetal (**7***d*); mp 85–86°C; $[\alpha]_D^{24}$ −3° (*c* 3.56, chloroform); ^{1}H nmr δ: 1.24, 1.26 (2t, 6H, 2 SCH_2CH_3, *J* = 7.4 Hz), 2.64, 2.69 (2q, 4H, 2 SCH_2CH_3, *J* = 7.5 Hz), 3.00–3.12 (br m, 2H, exchanged with D_2O, OH-3 and OH-4), 3.17 (d, 1H, exchanged with D_2O, *J* = 3.7 Hz), 3.94–4.33 (complex m, 7H), 5.78 (s, 1H, benzylidene H), 7.30–7.52 (m, 5H, Ph); *m/z*: 374 (6, M^+), 313 (3, M − ·SEt), 295 (2), 251 (2), 239 (12, *M* − 135), 207 (5), 189 (4), 179 (1), 177 (4), 149 (68), 137 (9), 136 (8), 135 (100, $^+CH(SEt)_2$), 133 (3), 127 (3), 117 (5), 115 (3), 107 (29), 105 (27), 104 (8), 103 (16), 91 (17), 79 (7), 77 (9), 75 (13), metastables: 263–261 (374–313), 277–280 (313–295).

X-ray crystallographic study of **3**c

Recrystallization of **3***c* twice more from dichloromethane/pet. ether 65–75° gave needles suitable for the crystallographic study.

Crystal data

$C_{16}H_{24}O_4S_2$ fw = 344.5

Crystal size (mm), 0.3 × 0.3 × 0.4, orthorhombic, space group $P2_12_12_1$ with *a* = 5.179(4) Å, *b* = 12.469(3) Å, *c* = 27.150(4) Å, *V* = 1753.3 Å^3, *Z* = 4, D_c = 1.305 g cm^{-3} (20 ± 2°C); MoKα radiation, λ = 0.70926 (graphite monochromator), μ(MoKα) = 2.70 cm^{-1}, *F*(000) = 736 e.

Structure determination

An Enraf–Nonius CAD-4 diffractometer was used to determine the unit-cell dimensions from 25 general reflections with 10 < θ < 14°C. 953 unique reflections were collected, of which 714 had $I > \sigma(I)$, 0 < 2θ < 46°. These were used in the structure solution and refinement.

The intensities were reduced by routine procedures described previously (43). Lorentz and polarization corrections were applied, but no absorption or extinction corrections. Scattering factors were taken from ref. 44 and were corrected for the real part of the anomalous dispersion effect. The structure was solved using the SHELX (76) system (45).

The non-hydrogen atoms were located from the E-map. Full-matrix least-squares refinement was performed using first isotropic, then anisotropic, temperature factors. The hydrogen atoms were located from a difference Fourier map, except for H161, H162, and H163, which were placed geometrically in chemically reasonable positions. Refinement was continued with anisotropic temperature factors on the non-hydrogen atoms and isotropic temperature factors on the hydrogens until $R = 0.60$, $R_w = 0.061$. The least-squares weights were calculated from $w^{-1} = \sigma^2|F_o| + 0.10414|F_o|^2$. In the final cycle, the maximum parameter shift (Δ/σ) was 0.01. The final atomic parameters for the non-hydrogens atoms are given in Table 2 and torsional angles in Table 3.[4]

Molecular mechanics calculations

Molecular mechanics calculations were performed using the MM2 program (1980 version), modified for use on a Perkin–Elmer computer (26). The program was modified locally to incorporate improvements in the force field for alkylbenzenes (27) and for the anomeric effect (28). Calculations were performed on a Perkin–Elmer 3230 computer.

Kinetic benzylidenation. Part II. Rearrangement of the kinetic products from benzylidenation of aldose diethyl dithioacetals

T. Bruce Grindley and Srihari Kusuma
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 30, 1985[1]

T. Bruce Grindley and Srihari Kusuma. Can. J. Chem. **64**, 2397 (1986).

Terminal five-membered *O*-benzylidene derivatives of aldose diethyl dithioacetals can be rearranged at room temperature in *N*,*N*-dimethylformamide, often in high yields. Derivatives with the *arabino* configuration for their three terminal secondary hydroxyl groups, i.e. D-glucose, D-mannose, and D-arabinose derivatives, rearranged to structures containing terminal six-membered *O*-benzylidene rings. 4,5-*O*-Benzylidene-D-ribose diethyl dithioacetal rearranged chiefly to the 2,4 isomer, which was obtained by crystallization. Chromatography yielded some of the 3,5 isomer. 5,6-*O*-Benzylidene-D-galactose diethyl dithioacetal rearranged to a mixture of the two 4,5-*O*-benzylidene diastereomers, contrary to predictions based on the Hann–Hudson rules. A revised set of rules for acetal stability in *N*,*N*-dimethylformamide has been formulated. D-arabinose and D-ribose diethyl dithioacetal were shown to react with α,α-dimethoxytoluene under rearrangement conditions to give the products noted above in good yields.

T. Bruce Grindley et Srihari Kusuma. Can. J. Chem. **64**, 2397 (1986).

Dans le *N*,*N*-diméthylformamide, à la température ambiante, on peut provoquer une transposition, généralement avec de bons rendements, des dérivés *O*-benzylidènes à cinq chaînons de diéthyl dithioacétals d'aldoses situés en position terminale. Les dérivés possédant une configuration *arabino* pour leurs trois groupements hydroxyles secondaires en position terminale, par exemple, les dérivés du D-glucose, du D-mannose et du D-arabinose, se transposent en structures contenant des cycles *O*-benzylidènes à six chaînons situés en position terminale. Le diéthyl dithioacétal du *O*-benzylidène-4,5 D-ribose se transpose principalement en son isomère-2,4 qui est obtenu par cristallisation. Par chromatographie, on a aussi obtenu un peu de l'isomère-3,5. Le diéthyl dithioacétal du *O*-benzylidène-5,6 D-galactose se transpose en un mélange des deux *O*-benzylidènes-4,5 diastéréoisomères; ce résultat est contraire à celui prévu sur la base des règles de Hann–Hudson. On propose une nouvelle formulation décrivant la stabilité des acétals dans le *N*,*N*-diméthylformamide. On démontre que le diéthyl dithioacétal du D-arabinose et du D-ribose réagissent tous les deux avec l'α,α-diméthoxytoluène, dans les conditions de la transposition, pour conduire aux produits mentionnés ci-dessus, avec de bons rendements.

[Traduit par la revue]

Introduction

The preceding paper outlines a convenient method for the preparation of terminal monosubstituted five-membered ring *O*-benzylidene derivatives of aldose diethyl dithioacetals under kinetic conditions (1). These monosubstituted derivatives would be considerably more useful if they could be rearranged to other monosubstituted derivatives in a predictable fashion. The results herein demonstrate that such rearrangements can be achieved.

The stabilities of di- and tri-*O*-benzylidene derivatives of alditols and related acyclic carbohydrates have been studied extensively (2–4). However, monosubstituted derivatives have been considerably more difficult to prepare and hence few reports of their rearrangements have appeared.

Results

Structural assignments

Literature methods for structural assignments to compounds containing 2-phenyl-1,3-dioxolane rings have been discussed in the preceding paper (1). In addition, chemical shift changes on formation of five-membered *O*-benzylidene rings were outlined (1). Similar considerations are useful for determining the location and confirming the ring size of six-membered *O*-benzylidene acetals. Table 1 outlines a comparison of the chemical shifts of the carbons of some model diols with those of the same carbons in the derived 2-phenyl-1,3-dioxane compounds. The chemical shift of carbon-2 of a 1,3-propanediol was shifted upfield markedly (6–10 ppm) on formation of an *O*-benzylidene acetal, as had previously been noted for formation of *O*-methylene (5), *O*-isopropylidene (5), *O*-cyclohexylidene (5), and *O*-ethylidene acetals (6). Since this effect occurs only on formation of six-membered rings, it, along with other indicators (7), can confirm the presence of this ring size. Conway *et al.* had observed a marked upfield shift for the signal of carbon-5 in pyranose sugars on formation of 4,6-*O*-benzylidene derivatives (8). The signals of carbons-1 and -3 of a 1,3-propanediol are shifted downfield by approximately 4–

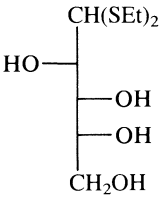
8 ppm on benzylidenation; the size of the effect decreases with increases in substitution.

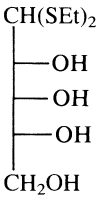
This latter observation was applied extensively in the current study. Most products were 2-phenyl-1,3-dioxane derivatives with alkyl substituents only at position-4. The signal of the primary carbon in these products was assigned readily by off-resonance decoupling. A significant downfield shift (>6 ppm) for this signal in comparison with that of the same carbon in its precursor allowed the structure of the product monobenzylidene derivative to be assigned unambiguously.

Reactions

R-4,5-*O*-Benzylidene-D-arabinose diethyl dithioacetal (**3***d*)[2] rearranged slowly at room temperature in *N*,*N*-dimethylformamide containing 6% *p*-toluenesulfonic acid to *R*-3,5-*O*-benzylidene-D-arabinose diethyl dithioacetal (**3***e*). The rearrangement was complete after 100 h and the product was isolated in high yield (93%). Yields were lower at higher temperatures. The product was shown to contain a six-membered ring by the chemical shifts of the acetal C (101.1 ppm) (7) and the acetal proton (5.52 ppm) (7), the $^{1}J_{C,H}$ value of the acetal carbon (160 Hz) (7), and the upfield shift of a secondary carbon (C-4, −9.8 ppm). The location of the ring was apparent from the downfield shift obtained for the ^{13}C nmr signal for C-5 when its position in the spectrum of **3***e* was compared with its position in D-arabinose diethyl dithioacetal acetal (**3***a*) (shift +7.2 ppm). The same product (**3***e*) was obtained under the same conditions from the *S*-epimer of **3***d* (**3***c*)[2] slightly more slowly (140 h) and in slightly lower yield. **3***e* was also obtained in 76% yield directly from D-arabinose diethyl dithioacetal (**3***a*) by reaction



3*a*



4*a*

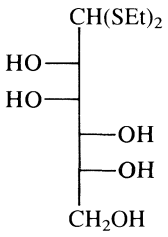
6*a*

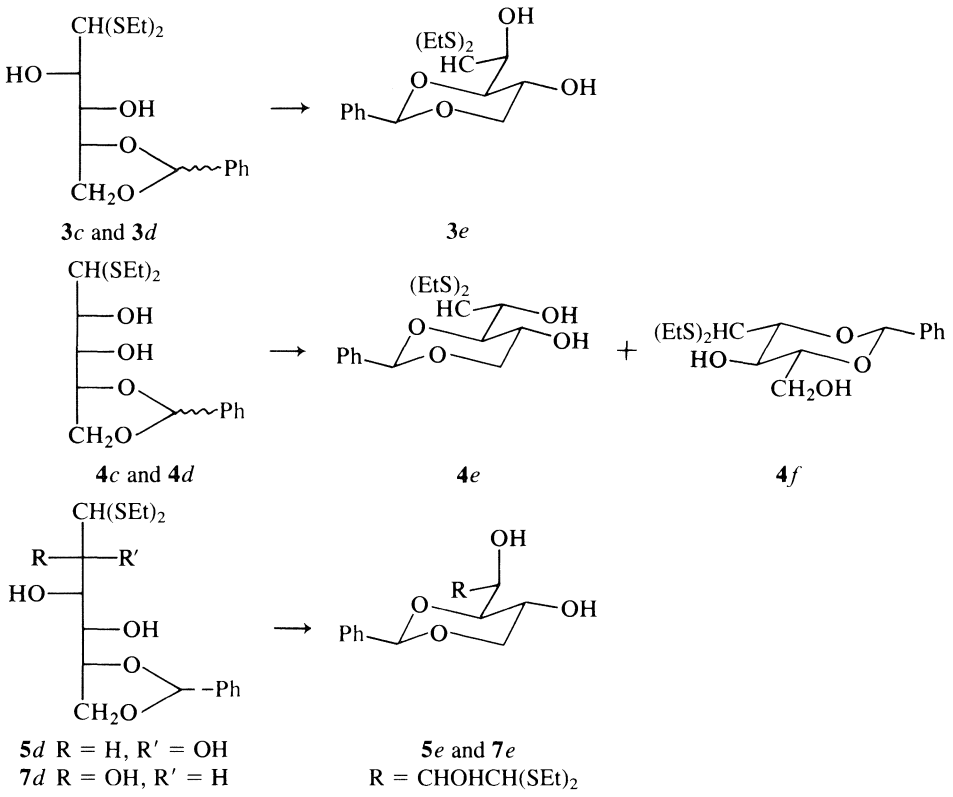


7*a*

with α,α-dimethoxytoluene under the conditions for the above rearrangements.

The rearrangement of a mixture of *R*- and *S*-4,5-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***c*) was more complex. After 63 h, two components were evident, one of which had the same R_f as the starting material. The compound which moved much slower on tlc was *R*-2,4-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***f*). This compound had previously been prepared indirectly by Zinner (9). An efficient method of preparation of the analogous derivative of the dipropyl dithioacetal has been developed (10). The faster moving component (obtained by preparative tlc) was a mixture of **4***c* and *R*-3,5-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***e*) from which the latter compound was crystallized. The structure of this compound was assigned as for **3***e* (see Table 2). The ratio of **4***f* to **4***e* in the

[2]Numbering of compounds in this paper is based on that in Part I (1). The *a* series of compounds are the unsubstituted aldose diethyl dithioacetals while the *b* series do not appear in this publication.

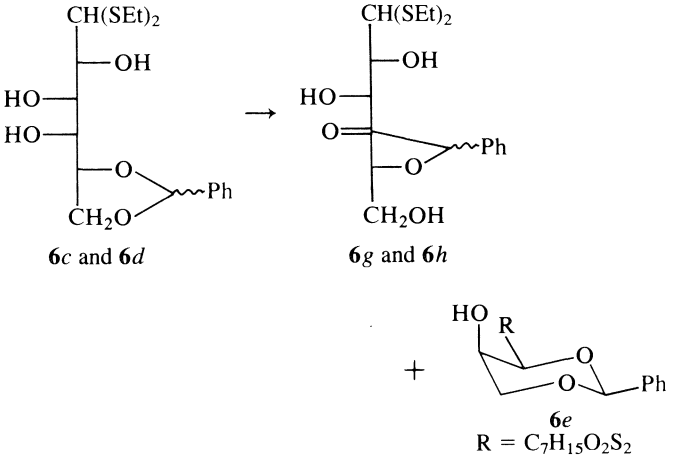


original product was 2:1. The product after 142 h of rearrangement contained only **4***f* and **4***e* in the ratio of 6:1 and **4***f* was isolated by recrystallization (61% yield). Reaction of D-ribose diethyl dithioacetal (**4***a*) with α,α-dimethoxytoluene under rearrangement conditions for 133 h gave a mixture of **4***f*, isolated by crystallization (64%), **4***e* (19%), and the known (9) 2,4:3,5-di-*O*-benzylidene-D-ribose diethyl dithioacetal (10%). Unidentified five-membered ring derivatives were present in trace amounts but were not isolated.

Rearrangements of the *R*-5,6-*O*-benzylidene derivatives of D-glucose (**5***d*) and D-mannose diethyl dithioacetal (**7***d*) for 100 and 40 h gave the *R*-4,6-*O*-benzylidene isomers **5***e* and **7***e* in 57 and 84% yields, respectively. The structures of both products could be assigned unambiguously as outlined above (see Table 2).

Rearrangement of a mixture of *R*- and *S*-5,6-*O*-benzylidene-D-galactose diethyl dithioacetal for 140 h gave two products, *R*- and *S*-4,5-*O*-benzylidene-D-galactose diethyl dithioacetal (**6***g* and **6***h*), which were separated by column chromatography. The location of the *O*-benzylidene ring was assigned by analysis of part of the ^{1}H nmr spectra of the triacetates of each of these compounds and confirmed by homonuclear decoupling experiments. The configurations at the acetal centers in the five-membered rings were not assigned. The crude product contained a lesser amount of a third compound (**6***e*), which was not isolated. **6***e* had an ^{1}H nmr signal for an acetal proton at 5.56 ppm, consistent only with a 2-phenyl-1,3-dioxane ring without axial substituents at positions-4 and -6 (7). Only one such *O*-benzylidene derivative can be obtained from D-galactose diethyl dithioacetal, *R*-4,6-*O*-benzylidene-D-galactose diethyl dithioacetal (**6***e*).

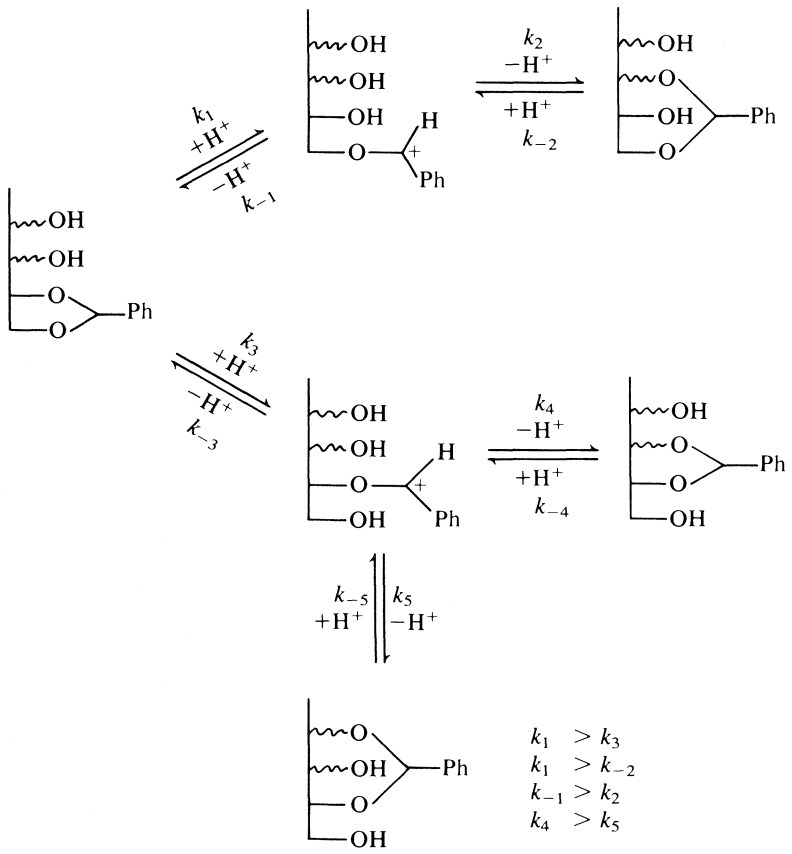
Rearrangement for a shorter period of time (70 h) yielded more of the first product (**6***g*) (47% vs. 17%). However, the second fraction was a mixture of two compounds, **6***h* and **6***e*, which were not separated.



Discussion

If the rearrangement occurred via an intramolecular mechanism, the product distribution would be determined solely by product stability. The stability of benzylidene acetals derived from acyclic polyols has been extensively investigated (2–4). Stability orders for all acetals under the conditions of preparation (generally in the aldehyde in the presence of an acid catalyst) have been codified as the Hann–Hudson rules (4, 11). For the *O*-benzylidene acetals, the order (4) of decreasing stability is: 4,6-*cis*-disubstituted-2-phenyl-1,3-dioxane rings > 4-substituted-2-phenyl-1,3-dioxane rings > 4,5-*trans*-disubstituted-2-phenyl-1,3-dioxolane rings = 4-substituted-2-phenyl-1,3-dioxolane rings > 4,6-*trans*-disubstituted-2-phenyl-1,3-dioxane rings = 4,7-*trans*-disubstituted-2-phenyl-1,3-dioxepane rings.

Of the compounds rearranged, only the D-glucose and D-ribose derivatives could form the most stable type of *O*-benzylidene acetal, a 2,4-*O*-benzylidene derivative in each case. This



SCHEME 1. Mechanism pathways available for rearrangements of terminal *O*-benzylidene derivatives of aldose diethyl dithioacetals.

derivative was the major product from the D-ribose reactions but was predominant only after very long rearrangement times. It was not isolated from any D-glucose reactions although a compound with an ^{1}H nmr signal at 5.58 ppm was a major component in the crude product (not separated) from a rearrangement reaction performed over a long time (163 h). The 4,5-*O*-benzylidene isomers obtained in the galactose reaction were *trans*-4,5-disubstituted-2-phenyl-1,3-dioxolanes. The 2,3-*O*-benzylidene-D-galactose diethyl dithioacetal diastereomers not observed would also have 4,5-*trans* disubstitution in a 1,3-dioxolane ring and should have about the same stabilities as their 4,5 isomers. Thus, the major and perhaps sole route for these rearrangements was intramolecular.

An intramolecular rearrangement would proceed in stepwise fashion up the carbohydrate chain. A probable mechanism is illustrated in Scheme 1. The reaction of 4,6-*O*-benzylidene-hexopyranosides with hydrogen chloride and sodium cyanoborohydride to give 6-*O*-benzyl derivatives (12) indicated that the acetal C—O bond to a secondary oxygen is cleaved more rapidly than the bond to primary oxygens in the presence of Bronsted acids. Ring closure of the carbocation to form the five-membered ring of the starting material is faster (1) but the terminal six-membered ring product obtained as the final product in the arabinose, glucose, and mannose cases is more stable.

The rapid appearance of 2,4-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***f*) (the major rearranged product after 13 h) suggests that it was obtained directly from starting material. Protonation of the primary oxygen, cleavage to give the carbocation, and ring closure is a possible route to **4***f*. Alternatively, 3,4-*O*-benzylidene-D-ribose diethyl dithioacetal, a relatively unstable *cis*-4,5-disubstituted-1,3-dioxolane derivative, could be an intermediate. Cleavage of 2-phenyl-1,3-dioxane rings would be expected to be slower on the principle of microscopic reversibility and has been observed to be slower in hydrogenolysis reactions (13). The very slow appearance of 2,4-*O*-benzylidene-D-glucose diethyl dithioacetal in the rearrangement of **5***d* supports this contention. The former compound could be obtained directly from the first rearranged product, the 4,6-*O*-benzylidene isomer.

The rearrangement of 5,6-*O*-benzylidene-D-galactose diethyl dithioacetal to *R*- and *S*-4,5-*O*-benzylidene-D-galactose diethyl dithioacetal in preference to the 4,6-*O*-benzylidene isomer (**6***e*) was a violation of the Hann–Hudson rules of acetal stability (4, 11), if the reaction was thermodynamically controlled. The slightly decreased amount of **6***e* present in the crude product after 140 h, as compared to the amount after 60 h, suggests that the three products were close to equilibrium. The Hann–Hudson rules were formulated on the basis of the products obtained from benzylidenation of alditols in benzaldehyde, sometimes containing water or ethanol. The stated preference for 4-substituted-2-phenyl-1,3-dioxanes over *trans*-4,5-disubstituted-2-phenyl-1,3-dioxolanes was originally based on the reactions of galactitol (14) and D-glycero-D-galactoheptitol (D-perseitol) (15). 1,3:4,6-Di-*O*-benzylidenegalactitol and 1,3:5,7-di-*O*-benzylidene-D-perseitol were obtained in 93 and 89% yields, respectively. However, in both cases, the product crystallized in the reaction mixture, which was allowed to stand overnight to continue crystallization. Thus, this particular part of the Hann–Hudson rules was based on the ability of the product to crystallize rather than on its stability in solution.

A number of publications that are related to this problem have

recently appeared. The most relevant was on the benzylidenation of 1-deoxy-D-galactitol in benzaldehyde (16). Separation of the product mixture by chromatography gave a 1:1 mixture of 2,3:4,5- and 2,3:4,6-di-*O*-benzylidene isomers (680 mg) plus a pure 2,3:4,5 isomer (160 mg). Thus, the ratio of products containing 4,5-*O*-benzylidene rings to their 4,6 isomers was about 3:2, contrary to the Hann–Hudson rules, and the individual 4,5 isomers were present to almost the same extent as the 4,6 isomers (assuming the two configurations in the 4,5 rings were equally populated).

The reaction of D-glucitol with benzaldehyde in aqueous *N,N*-dimethylformamide containing hydrochloric acid gave a mixture of the 2,3-*O*-benzylidene diastereomers, which rearranged slowly to the 2,4-*O*-benzylidene isomer. Although the reaction was followed by gas–liquid chromatography and ^{1}H nmr spectroscopy, no evidence for the presence of either the 1,3- or 4,6-*O*-benzylidene isomers was obtained at any reaction time (17). The results in the preceding paper (1) suggest that the initial products of this reaction are the 1,2- and 5,6-*O*-benzylidene derivatives, which rearrange to the 1,3- 4,6-, and 2,3-*O*-benzylidene isomers. However, benzylidenations with benzaldehyde are probably not as selective for primary hydroxyl groups as those with α,α-dimethoxytoluene.

A number of publications have reported alkylidenation of alditols (18–22). Although a consistent pattern of preference was not observed for all aldehydes and conditions, the results (18–22) suggest that 4-monosubstituted-2-alkyl-1,3-dioxane rings are favoured over *trans*-4,5-disubstituted-2-alkyl-1,3-dioxolane rings (19, 20) in contrast to the results for benzylidenation. The actual preferences must be small and hence are strongly dependent on reaction conditions. Where conditions can be characterized (present study, and refs. 16–20), it appears that solvents of greater polarity (present study) lead to more of the dioxolane ring containing products. This observation is not what would be expected on the basis of the polarity of the parent ring systems; the dipole moments of 1,3-dioxane (23), 2-phenyl-1,3-dioxane (24), 1,3-dioxolane (25), and 2-phenyl-1,3-dioxolane (24) are 2.13 (benzene), 2.05 (carbon tetrachloride), 1.47 (benzene), and 1.37 D (carbon tetrachloride), respectively. However, the stabilities of the acetalated products depend on the polarities of the whole molecules, which are difficult to predict.

Another factor that could be important is hydrogen bonding. The OH group on C-5 of 4,6-*O*-benzylidene-D-galactose diethyl dithioacetal has an axial orientation at the C-5 position of the 1,3-dioxane ring. The hydrogen bonding of an axial hydroxyl group at position-5 made *cis*-2-isopropyl-5-hydroxy-1,3-dioxane more stable than its *trans*-isomer (26), by amounts which decreased in more polar and hydrogen bond accepting solvents. The change in stability was 0.64 kcal mol^{-1} when the position of equilibrium in cyclohexane was compared with that in 1,2-dimethoxyethane. A similar change in stability for the two types of rings in benzaldehyde, as opposed to *N,N*-dimethylformamide, could explain the difference in the results obtained here as compared to those in ref. 16. The combination of these results indicates that in the absence of hydrogen bonding, 4,5-*trans*-disubstituted-2-phenyl-1,3-dioxolane rings are more stable than 4-substituted-2-phenyl-1,3-dioxane rings.

The above conclusion suggests that rearrangements of any mono-*O*-benzylidene-D-arabinose diethyl dithioacetal should lead eventually to a mixture in which the 2,3-*O*-benzylidene derivatives are prominent, and any mono-*O*-benzylidene-D-mannose diethyl dithioacetal should give 3,4-*O*-benzylidene derivatives. However, attempts to equilibrate 2,3- and 3,5-*O*-benzylidene-D-arabinose diethyl dithioacetal were unsuccessful. Loss of the *O*-benzylidene group occurred faster than equilibration, particularly for the latter compound.

In conclusion, the above results support a somewhat different order for benzylidene acetal stability in *N,N*-dimethylformamide than that presented in the Hann–Hudson rules (4). The order of decreasing stability is: 4,6-*cis*-disubstituted-2-phenyl-1,3-dioxane rings > 4,5-*trans*-disubstituted-2-phenyl-1,3-dioxane rings > 4-substituted-2-phenyl-1,3-dioxane rings > 4-substituted-2-phenyl-1,3-dioxolane rings > 4,5-*cis*-disubstituted-2-phenyl-1,3-dioxolane rings. No information was obtained about the relative stabilities of 1,3-dioxepane rings.

Experimental

For general methods, see Part I.

General method for the rearrangement of O-*benzylidene rings*

R-*3,5*-O-*Benzylidene*-D-*arabinose diethyl dithioacetal (***3***e) by the rearrangement of* R-*4,5*-O-*benzylidene*-D-*arabinose diethyl dithioacetal (***3***d)*

A solution of **3***d* (0.344 g, 1 mmol) and anhydrous *p*-toluenesulfonic acid (**2**) (10 mg, 0.058 mmol) in *N,N*-dimethylformamide (2 mL) was stirred for 100 h, when tlc (solvent A) indicated that all of the starting material had disappeared and a single product had been obtained (R_f 0.33). The solution was poured into an ice-cold sodium hydrogen carbonate solution (2%, 10 mL), which was extracted with ether (3 × 10 mL). The combined ether extracts were washed with water (2 × 10 mL), dried ($MgSO_4$), filtered, and concentrated under reduced pressure at 40°C. The crystalline product (0.320 g, 93%) was recrystallized from dichloromethane/pet. ether (65–75°C) to give colorless crystals of the title compound (**3***e*); $[\alpha]_D^{20}$ −66° (*c* 4.00, chloroform); mp 125–126°C; ^{1}H nmr δ: 1.26 (t, 6H, 2 SCH_2CH_3, *J* = 7.4 Hz), 2.70 (q, 4H, 2 SCH_2CH_3, *J* = 7.3 Hz), 3.14 (d, 1H, OH, *J* = 6.4 Hz), 3.57–4.55 (complex m, 7H), 5.52 (s, 1H, benzylidene H), 7.17–7.62 (m, 5H, Ph); *m/z*: 344 (19, M^+), 283 (6, M − ·SEt), 265 (1), 221 (4), 179 (16), 177 (12), 149 (5), 135 (100, $^+CH(SEt)_2$), 117 (5), 115 (3), 107 (30), 105 (21), 103 (7), 91 (11), 79 (11), 77 (13), 75 (9). *Anal.* calcd. for $C_{16}H_{24}O_4S_2$: C 55.78, H 7.02; found: C 55.85, H 6.88.

3e *by the rearrangement of* S-*4,5*-O-*benzylidene*-D-*arabinose diethyl dithioacetal (***3***c)*

Compound **3***c* (0.344 g, 1 mmol) was rearranged as in the general method, but for 140 h. The crystalline product (0.289 g, 81%) (R_f 0.33, solvent A) was recrystallized to give colorless crystals, mp 123–125°C, undepressed when mixed with the product from the rearrangement of **3***d*.

3e *from* D-*arabinose diethyl dithioacetal (***3***a)*

A solution of **3***a* (5.12 g, 20 mmol), α,α-dimethoxytoluene (3.648 g, 24 mmol), and anhydrous *p*-toluenesulfonic acid (**2**) (0.2 g, 1.16 mmol, 6%) in *N,N*-dimethylformamide (40 mL) was stirred 100 h, then worked up as in the general method for rearrangement reactions. The pale yellow crystalline product (5.213 g, 76%) (R_f 0.33, solvent A) was recrystallized to give colorless crystals, mp 123–125°C, undepressed when mixed with **3***e*.

R-*1,3*-O-*Benzylidene*-D-*ribose diethyl dithioacetal (***4***f)*

(a) By rearrangement

The mixture of *R*- and *S*-4,5-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***c*) (1) (0.344 g, 1 mmol) was rearranged for 63 h as in the general procedure. The pale yellow crystalline product (0.28 g, 82%) contained two components (R_f's of 0.50 and 0.21, solvent A). The ratio of integrals of signals in the ^{1}H nmr spectrum of 5.58 and 5.49 ppm was 2:1.

Recrystallization gave the slower moving component, the title compound (**4***f*), as colorless needles (0.155 g, 45%). A second recrystallization from methanol/water gave needles, mp 121–122°C (lit. (9) mp 119–120°C); $[\alpha]_D^{22}$ −26.3° (*c* 1.68, chloroform) (lit. (9) α_D −22.4°); ^{1}H nmr (60 MHz) δ: 1.27 (t, 6H, 2 SCH_2CH_3, *J* = 7 Hz), 2.75 (q, 4H, 2 SCH_2CH_3, *J* = 7 Hz), 3.20 (br s, 1H, OH), 3.62–4.32 (complex m, 7H), 5.57 (s, 1H, benzylidene H), 7.15–7.46 (m, 5H,

Ph); *m/z*: 344 (23, M^+), 283 (5, M − ·SEt), 265 (3), 221 (6), 209 (7), 179 (4), 177 (23), 149 (3), 137 (9), 138 (8), 135 (100, $^+CH(SEt)_2$), 117 (9), 108 (4), 107 (45), 105 (12), 104 (5), 103 (11), 91 (5), 89 (6), 87 (8), 79 (13), 77 (12), 75 (34). *Anal.* calcd. for $C_{16}H_{24}O_4S_2$: C 55.79, H 7.03, S 18.61; found: C 55.69, H 6.96, S 18.55.

Preparative tlc (solvent F) on the mother liquor from the first recrystallization of **4***f* gave a crystalline product recrystallized from dichloromethane/pet. ether, then from methanol/water. The colorless needles of *R*-3,5-*O*-benzylidene-D-ribose diethyl dithioacetal (**4***e*) had mp 68–69.5°C; $[\alpha]_D^{22}$ −47.0° (*c* 3.57, chloroform); ^{1}H nmr (60 MHz) δ: 1.22 (t, 6H, 2 SCH_2CH_3, *J* = 7 Hz), 2.60, 2.70 (2q, 4H, 2 SCH_2CH_3, *J* = 7 Hz), 3.30 (br d, 1H, OH, *J* = 3 Hz), 3.50–4.55 (complex m, 7H), 5.49 (s, 1H, benzylidene H), 7.31–7.55 (m, 5H, Ph); *m/z*: 344 (17, M^+), 283 (4, M − ·SEt), 265 (1), 221 (3), 179 (23), 177 (16), 149 (2), 137 (9), 136 (8), 135 (100, $^+CH(SEt)_2$), 117 (4), 115 (3), 107 (37), 105 (10), 91 (6), 79 (14), 77 (10), 75 (10), metastable: 232–235 (344 → 283).

Rearrangement exactly as above, but for 142 h, gave **4***f* in 61% yield after recrystallization. The ^{1}H nmr spectrum of the crude product had signals for the benzylidene H of **4***f* and **4***e* with a peak height ratio of 6:1.

(b) Directly from D-*ribose diethyl dithioacetal (***4**a*)*

Compound **4***a* (8.04 g, 31.4 mmol), α,α-dimethoxytoluene (5.73 g, 35 mmol), and anhydrous *p*-toluenesulfonic acid (0.47 g) were stirred in anhydrous *N,N*-dimethylformamide (70 mL) for 133 h. Normal work-up gave a solid product, which on recrystallization from dichloromethane/hexane gave colorless needles of **4***f* (6.1 g). The mother liquor (4.72 g) was separated by column chromatography on silica gel (200 g) (solvent D). Three crystalline fractions A (1.40 g, 10%), B (2.10 g, 19%), and C (0.84 g) were obtained.

Fraction A was recrystallized from dichloromethane/hexanes to give colorless needles of 2,4:3,5-di-*O*-benzylidene-D-ribose diethyl dithioacetal, mp 125–126°C (lit. (9) mp 122–123°C); $[\alpha]_D^{22}$ −71.0° (*c* 1.68, chloroform (lit. (9) $[\alpha]_D$ −64.2°); ^{1}H nmr δ: 1.23 (t, 6H, SCH_2CH_3, *J* = 7.5 Hz), 2.76 (q, 4H, 2 SCH_2CH_3, *J* = 7.5 Hz), 3.72–4.50 (complex m, 6H), 5.67, 5.72 (2 s, 2H, benzylidene H), 7.17–7.63 (m, 10 H, Ph); ^{1}C nmr δ: 14.5, 14.6 (Me), 25.3 (SCH_2), 51.0 (C-1), 72.5 (C-5), 75.3, 72.5 (C-3, C-4), 83.7 (C-2), 101.6, 101.8 (acetal C, $^1J_{C,H}$ = 162.7, 162.4 Hz), 126.1, 128.2, 129.1 (Ph), 137.0, 137.2 (quaternary Ph).

Fraction B was shown to be **4***e* while Fraction C was **4***f*. The total yield of **4***f* was 6.94 g, 64%.

R-*4,6-*O*-Benzylidene-*D*-glucose diethyl dithioacetal (***5**e*)*

R-5,6-*O*-Benzylidene-D-glucose diethyl dithioacetal (**5***d*) (2.47 g, 6.6 mmol) was rearranged for 100 h with the same proportions of reagents as in the general method. The crude pale yellow syrupy product (2.213 g) contained one major and one minor component, which were separated by column chromatography on silica gel (solvent B).

Fraction A (1.40 g, 57%), a solid, was recrystallized to give colorless crystals of the title compound (**5***e*); mp 114–115°C; $[\alpha]_D^{20}$ −9° (*c* 2.09, chloroform); ^{1}H nmr (60 MHz) δ: 1.21 (t, 6H, 2 SCH_2CH_3, *J* = 7.5 Hz), 2.40–2.85 (m, 4H, 2 SCH_2CH_3), 3.45–4.53 (complex m, 10H), 5.40 (s, benzylidene H), 7.00–7.60 (m, 5H, Ph); *m/z*: 374 (0.3, M^+), 288 (1), 287 (2), 286 (11), 225 (1), 207 (3), 193 (2), 177 (3), 163 (6), 145 (3), 137 (11), 136 (26), 135 (100), 117 (4), 107 (24), 106 (6), 105 (35), 104 (10), 103 (11), 102 (10), 75 (7), 73 (13), 71 (8).

An intermediate fraction (0.24 g, 10%), had ^{1}H nmr signals at 5.90 (major), 5.80, 5.64 (minor), 5.52 (minor), and 5.40 (minor) ppm.

Fraction B (0.17 g, 7%, R_f), a pale yellow syrup, had ^{1}H nmr signals at 5.52 and 6.05 ppm and was not investigated further.

Rearrangement of **5**d *for 163 h*

Rearrangement of **5***d* (1.496 g) as previously, but for 163 h, gave a pale yellow syrup (1.104 g), a complex mixture on tlc; ^{1}H nmr δ: 6.04, 5.94, 5.58, and 5.44 with peak heights in the ratio 2:8:4:5, respectively.

R-*and* S-*4,5-*O*-benzylidene-*D*-galactose diethyl dithioacetal (***6**g and **6**h)*

A mixture of *R*- and *S*-5,6-*O*-benzylidene-D-galactose diethyl dithioacetal (**6***c* and **6***d*) (1) (1.870 g, 5 mmol) was rearranged as in the general procedure for 140 h. The colorless crystalline product (1.7 g, 91%) (partial ^{1}H nmr, δ: 5.54, 5.88, and 5.95 (3s, benzylidene H, intensity ratio 13:19:22, respectively)) was separated by column chromatography on silica gel (100 g) using solvent F as eluent.

Fraction A (0.032 g, 2%, R_f 0.60), the starting material, was followed by an overlapping fraction (0.034 g, 2%).

Fraction B (0.314 g, 17%, R_f 0.49), a solid, was recrystallized to give colorless crystals of 4,5-*O*-benzylidene-D-galactose diethyl dithioacetal (**6***g*); mp 106–107°C; $[\alpha]_D^{20}$ +5° (*c* 3.72, methanol), ^{1}H nmr (60 MHz) δ: 1.24 (t, 6H, 2 SCH_2CH_3, *J* = 7 Hz), 2.67, 2.70 (2q, 4H, 2 SCH_2CH_3, *J* = 7 Hz), 3.40 (br s, 1H, OH), 3.53–4.33 (complex m, 9H), 5.88 (s, 1H, benzylidene H), 7.06–7.50 (m, 5H, Ph); *m/z*: 374 (34, M^+), 313 (8, M − ·SEt), 312 (8), 279 (7), 256 (5), 251 (7), 207 (7), 206 (11), 179 (9), 177 (9), 167 (6), 150 (6), 149 (43), 137 (11), 136 (12), 135 (100, $^+CH(SEt)_2$), 107 (32), 105 (36), 91 (23), 79 (9), 77 (12).

Fraction C (0.675 g, 36%, R_f 0.36), a solid, was recrystallized to give colorless crystals of 4,5-*O*-benzylidene-D-galactose diethyl dithioacetal (**6***h*), mp 85–86°C; $[\alpha]_D^{20}$ +13° (*c* 3.08, methanol); ^{1}H nmr (60 MHz) δ: 1.21 (t, 6H, 2 SCH_2CH_3, *J* = 7 Hz), 2.62 (q, 4H, 2 SCH_2CH_3, *J* = 7 Hz), 3.45 (br d, 1H, OH, *J* = 3 Hz), 3.55–4.42 (complex m, 9H), 5.95 (s, 1H, benzylidene H), 7.12–7.62 (m, 5H, Ph); *m/z*: 374 (14, M^+), 327 (2), 326 (2), 313 (7), 312 (5), 295 (3), 279 (7), 251 (9), 239 (3), 221 (3), 207 (7), 206 (6), 189 (3), 179 (8), 177 (9), 149 (23), 145 (5), 137 (12), 136 (13), 135 (100, $^+CH(SEt)_2$), 133 (7), 122 (11), 107 (32), 106 (6), 105 (30), 104 (13), 103 (13), 91 (12), 85 (6), 79 (9), 77 (12), 75 (11), 73 (10).

Rearrangement of **6***c* (0.374 g, 1 mmol) as above, but for 70 h, gave a syrupy product with ^{1}H nmr signals at 5.94, 5.88, and 5.54 ppm with peak heights in the ratio 10:21:14. The mixture was separated by column chromatography into two fractions, A and B. Fraction A (0.218 g, 47%) was compound **6***g*. Fraction B (0.105 g, 23%) was a mixture of compound **6***h* and compound **6***e*; partial ^{1}H nmr, δ: 5.58, 5.95 (2s, benzylidene H).

*2,3,6-Tri-*O*-acetyl-4,5-*O*-benzylidene-*D*-galactose diethyl dithioacetal (***6**i)*

Compound **6***g* (0.28 g, 0.75 mmol), acetic anhydride (3.06 g, 30 mmol), and dry pyridine (1.184 g, 15 mmol) were stirred 14 h, then poured into ice-water (30 mL). The mixture was extracted with ether (3 × 30 mL) and the combined extracts were washed with saturated cupric sulfate solutions (3 × 3 mL), saturated sodium hydrogen carbonate solutions (3 × 30 mL), and water (3 × 30 mL), then dried ($MgSO_4$), filtered, and concentrated to a pale yellow syrup (0.309 g, 83%), homogeneous on tlc (R_f 0.42, solvent C); $[\alpha]_D^{24}$ +48° (*c* 1.415, chloroform); ir (neat): 1746 cm^{-1} (acetate CO), no OH stretch; ^{1}H nmr δ: 1.13–1.42 (m, 6H, 2 SCH_2CH_3), 2.06, 2.13, 2.15 (3s, 9H, 3 $COCH_3$), 2.67 (q, 4H, 2 CH_2CH_3, *J* = 7.3 Hz), 3.90–4.45 (complex m, 4H, H-4, H-5, H-6, H-6′), 4.12 (d, 1H, H-1, $J_{1,2}$ = 6.4 Hz), 5.44 (dd, 1H, H-2, $J_{1,2}$ = 6.5 Hz, $J_{2,3}$ = 3.8 Hz), 5.83 (dd, 1H, H-3, $J_{2,3}$ = 3.8 Hz, $J_{3,4}$ = 8.6 Hz), 5.98 (s, 1H, benzylidene H), 7.35–7.42 (m, 5H, Ph).

*2,3,6-Tri-*O*-acetyl-4,5-*O*-benzylidene-*D*-galactose diethyl dithioacetal (***6**j)*

Compound **6***h* (0.374 g, 1 mmol), dry pyridine (1.58 g, 20 mmol), and acetic anhydride (4.08 g, 40 mmol) were stirred 14 h, then worked up as for **6***h*. The pale yellow syrup (0.44 g, 88%), homogeneous on tlc (R_f 0.30, solvent C); $[\alpha]_D^{24}$ +71° (*c* 1.09, chloroform); ir (neat): 1750 cm^{-1} (acetate, CO), no OH stretch; ^{1}H nmr δ: 1.08–1.42 (m, 6H, 2 SCH_2CH_3), 2.11, 2.11, 2.13 (2s, 9H, 3 $COCH_3$), 2.58 (q, 4H, 2 SCH_2CH_3, *J* = 7.3 Hz), 3.42–4.78 (complex m, 4H, H-4, H-5, H-6, H-6′), 3.98 (d, 1H, H-1, $J_{1,2}$ = 6.6 Hz), 5.38 (dd, 1H, H-2, $J_{1,2}$ = 6.5 Hz, $J_{2,3}$ = 3.3 Hz), 5.75 (dd, 1H, H-3, $J_{2,3}$ = 3.4 Hz, $J_{3,4}$ = 7.6 Hz), 5.95 (s, 1H, benzylidene H), 7.28–7.51 (m, 5H, Ph).

R-*4,6-*O*-Benzylidene-*D*-mannose diethyl dithioacetal (***7**e)*

R-5,6-*O*-Benzylidene-D-mannose diethyl dithioacetal (**7***d*) (1) (1.015 g, 2.71 mmol) was rearranged for 40 h as in the general procedure. The pale yellow crystalline product (0.835 g, 84%), homogeneous on tlc (R_f 0.50, solvent F), was recrystallized to give fine

colorless needles of the the title compound (**7***e*), mp 175–176°C, $[\alpha]_D^{24}$ −1° (*c* 3.39, chloroform); ^{1}H nmr δ: 1.27 (t, 6H, 2 SCH_2CH_3, J = 7.3 Hz), 2.69, 2.75 (2q, 4H, 2 SCH_2CH_3, J = 7.4 Hz), 2.83 (br s, 1H, OH), 3.41–4.33 (complex m, 8H), 4.76 (br s, 1H, OH), 5.53 (s, 1H, benzylidene H), 7.20–7.50 (m, 5H, Ph); *m/z*: 374 (1, M^+), 327 (1), 313 (9), 295 (2), 251 (3), 239 (5), 209 (3), 207 (5), 189 (4), 179 (5), 177 (9), 149 (4), 145 (8), 137 (9), 136 (9), 135 (100, $^+CH(SEt)_2$), 107 (42), 105 (26), 104 (9), 103 (18), 91 (9), 85 (8), 79 (12), 77 (12), 75 (14), 73 (9). *Anal.* calcd. for $C_{17}H_{26}O_5S_2$: C 54.52, H 7.00, S 17.12; found: C 54.23, H 6.94, S 16.83.

*Rearrangement of 2,3-O-benzylidene-D-arabinose diethyl dithioacetal (**3**g)*

Compounds **3***g* (27) (180 mg) and **2** (20 mg) in *N,N*-dimethylformamide (2 mL) were kept 192 h, then worked up normally. The ^{1}H nmr spectrum of the product had signals at 6.09 and 5.51 ppm with integrals in the ratio 3.4:1. Signals having intensities approximately 1/10 that of the signal at 5.51 ppm were apparent at 5.78, 5.91, and 6.23 ppm.

Rearrangement exactly as above, but for 336 h, gave a product with ^{1}H nmr signals at 6.09 and 5.52 ppm having a ratio of integrals of 4.1:1.

To the product from immediately above (100 mg) in *N,N*-dimethylformamide (2 mL) was added **2** (150 mg). Aliquots removed after 120 and 264 h and worked up normally both had intensity ratios for ^{1}H nmr signals at 6.09 and 5.52 ppm of 3:2.

*Rearrangement of 3,5-O-benzylidene-D-arabinose diethyl dithioacetal (**3**e)*

Compounds **3***e* (30 mg) and **2** (10 mg) in *N,N*-dimethylformamide (1 mL) were kept 288 h, then worked up normally to give a syrup; partial ^{1}H nmr, δ: 6.09 and 5.52 (2s, intensity ratio 1:5).

A second rearrangement reaction identical to the above was kept 288 h, then more **2** (100 mg) was added and the reaction kept a further 288 h, and worked up to give a syrup (3 mg); partial ^{1}H nmr, δ: 5.55 (s, only benzylidene H signal visible).

Freeze-drying Fourier transform infrared attenuated total reflection spectroscopy of surface adsorbed layers. Water-assisted proton transfer in cytidine-5′-phosphoric acid

SIMONA BADILESCU AND CAMILLE SANDORFY
Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3J7

Received May 8, 1986

SIMONA BADILESCU and CAMILLE SANDORFY. Can. J. Chem. **64**, 2404 (1986).

The zwitterionic structure of cytidine-5′-phosphoric acid (5′-CMP) in the acid form has been studied by means of freeze-drying ATR spectroscopy. Surface deuteration and protonation studies of the hydrated sample were accomplished and some band assignments are made. The dependence of the proton transfer process in the zwitterionic CMP(H) on relative humidity is evidenced. The ability of the water molecules adsorbed on the thallium bromide iodide crystal to act as proton donors and the enhancement of the degree of dissociation of the adsorbed water are demonstrated.

SIMONA BADILESCU et CAMILLE SANDORFY. Can. J. Chem. **64**, 2404 (1986).

Nous avons examiné la structure de l'acide-5′-cytidyl-phosphorique (5′-CMP) par spectroscopie infrarouge de réflexion totale atténuée, combinée avec la technique de la congélation suivie par sublimation ("freeze drying"). Des études de deutération et de protonation ont été accomplies sur le composé hydraté adsorbé sur une surface de KRS-5 (TlBrI). L'équilibre de protonation dans le CMP(H) zwitterionique dépend de l'humidité relative. On démontre que les molécules d'eau adsorbées sur la surface d'un cristal de bromure-iodure de thallium sont capables d'agir comme des donneurs de proton. L'augmentation du degré de dissociation de l'eau adsorbée est également mise en évidence.

Introduction

The site of protonation in some ^{15}N-labeled cytosine derivatives in water solution has been studied by high-resolution proton and nitrogen-15 nmr spectroscopy (1, 2). The results were compatible with protonation at the N(3) nitrogen of the cytosine. Strong delocalization of the unshared electron pair on the amino nitrogen to N(3) has been inferred.

X-ray investigations have shown (3–6) that the free acids of cytidine 5′- and 3′-monophosphates (CMP) occur as zwitterions in the solid state. The protonation results from the migration of one of the phosphate protons onto the N(1) of the cytosine. Significant differences in molecular dimensions (bond lengths and bond angles) between the protonated and unprotonated cytosine bases were observed. Protonation results in a distortion from coplanarity of the pyrimidine ring and in enlarged bond angles and bond distances at the site of protonation. A shortening of the exocyclic amino carbon–nitrogen bond has been also observed. The hydrogen atoms were located and the state of ionization of the phosphate has been established. The phosphate group in CMP is present as the monovalent anion $RHPO_4^-$ and the individual P—O bonds differ significantly from each other. Generally, the protonated P—O(H) distance is longer than the unprotonated P—O^- or the P=O distance. In the sodium salt of 5′-CMP the phosphate group is a double anion with two negative charges distributed between the three oxygen atoms. The P—O distances are all nearly equal (7).

X-ray studies have evidenced (5) a very specific association pattern of the molecules in the zwitterion form instead of the well-known base stacking association. The molecules are linked together through hydrogen bonds involving the amino hydrogen atoms, the hydrogen atoms of the protonated N(3) nitrogen and the phosphate groups forming an infinitely extended right handed spiral around the screw axis.

Important frequency shifts toward higher frequencies in comparison with the neutral form have been observed for the double bond stretching and "amino" scissoring bands (1800–1500 cm^{-1}) of the protonated cytosine and poly C (8–11). The observed shifts have been accounted for by increased π-electron "localization" in specific double bonds. Normal coordinate analysis of cytosine was performed (12) with a valence force field and the potential energy distribution among the internal coordinates was calculated. The complexity of this region and the high degree of coupling between different modes has been emphasized.

Infrared spectra of zwitterions involving phosphate groups have been particularly studied in model phospholipid head molecules (13). In these molecules, asymmetrical intramolecular hydrogen bonds with large proton polarizability have been evidenced. The absorbance of the infrared continuum which is characteristic of the easily polarisable hydrogen bonds with a double minimum potential well (14) has been investigated as a function of the degrees of deprotonation and protonation. The samples were deprotonated by addition of various amounts of sodium hydroxide to the solution of the zwitterion. At 100% deprotonation (Na^+ salt) all easily polarisable hydrogen bonds have disappeared.

The spectroscopic behaviour of some phospholipids with respect to hydration has been related to the polar head interaction of the terminal part of the molecule (15, 16). The perturbation of the intramolecular hydrogen bond between the PO_2^- and NH_3^+ groups by the insertion of water molecules between the two head groups has been assumed.

Freeze-drying FT-IR-ATR (FD-FT-ATR) spectroscopy has been proposed as a method for hydration studies of biologically important molecules in two previous papers (17, 18). We have studied the ATR spectrum of hydrated cytidine-5′-phosphoric acid as a function of relative humidity and have observed a strong dependence of the general spectral pattern on the degree of hydration. Surface deuteration experiments have evidenced the involvement of most parts of the molecule of 5′-CMP in surface hydration. We have observed a contribution of the water bending band to the intensity of some of the 5′-CMP bands in the solid state spectra (1800–1600 cm^{-1}). Our previous results have indicated that this effect is more important in the free acid spectra. The "hydration" behavior of the different vibrations in the CMP molecule seems to be different in the acid and in the

sodium salt forms. The zwitterion structure determines a very specific association pattern and the strong involvement of the phosphate groups in these associations has been evidenced.

A study of the zwitterion–water interaction by freeze-drying FT-IR-ATR spectroscopy will be presented in this paper.

Experimental

The spectra were recorded on a Nicolet 5DXB FT-IR spectrometer, with a resolution of 2 cm^{-1} equipped with a DTGS detector. Collection times for the spectra (100 co-added interferograms) were less than 2 min. The Model 300 ATR attachment (Barnes Analytical) with a parallelogram (25 × 10 × 3 mm) KRS-5 plate was used.

The ATR crystals have been hydrated (before the deposition of the sample) by keeping them for a day in an atmosphere of constant relative humidity (r.h.). Constant r.h. was maintained by a saturated solution of an appropriate salt contained in a flat dish. Humidities were chosen so that the controlling salts had a constant temperature coefficient between 20 and 27°C for their relative humidity (19).

The ATR spectrum of the adsorbed sample was recorded and the crystal was kept in the sealed container holding the appropriate saturated salt solution at a controlled temperature. The attainment of equilibrium between the water of the adsorbed layers and the r.h. of the ambient atmosphere was followed spectroscopically and was found to require several hours.

Cytidine-5′-phosphoric acid (5′-CMP, MW 323, from yeast) and cytidine-5′-monophosphate (disodium salt) were obtained from the Sigma Chemical Company, and used without further purification. A solution (250 μL) (0.1–0.2 mg mL^{-1} in deionized water) of the compound was deposited on the hydrated crystal surface and the freeze-drying procedure was accomplished. The stages of freeze-drying and the cleaning procedure of the crystal have been described elsewhere (17). The crystal with the adsorbed sample was kept again for several hours in a controlled r.h. atmosphere.

Surface deuteration experiments were performed. A layer of liquid deuterium oxide was deposited on the hydrated sample and freeze-dried. The frozen deuterium oxide was removed by sublimation. CMP molecules were deposited on the hydrated crystal surface by freeze-drying and then the crystal was kept for several hours in the corresponding r.h. atmosphere. After recording of the ATR spectrum, an aqueous solution of HCl (pH ≃ 2) was deposited and the freeze-drying procedure was performed again.

Hydration experiments were carried out at different mechanical states of the crystal surface. When the surface is pumped at 50°C for 4 h, water is removed from the microvoids of the surface. During the freeze-drying procedure, molecules are trapped into the microvoids and the control of the r.h. is no more possible.

Results and discussion

The structure and atom numbering of cytidine-5′-phosphoric acid, 5′-CMP(H), in the zwitterion form is given in Fig. 1. The ATR spectra of the 5′-CMP(H) show infrared continua extending over the entire range from 4000 to 1800 cm^{-1} and again below 1400 cm^{-1}. Such a continuum is characteristic of easily polarisable hydrogen bonds with a double minimum potential well (14, 20, 21). According to X-ray data (5) this type of hydrogen bond may be formed between the phosphate group and the protonated cytosine base nitrogen. For the cytidine-3′-phosphate molecule, Sundaralingam and Jensen (3) have found 2.783 Å between the purine(3) nitrogen and the phosphate oxygen atoms and the hydrogen–oxygen distance is 1.679 Å. This hydrogen bond is represented by the proton boundary structures P—OH^+...N and P—O^-...$^+$HN, the second being of greater weight. The ir continuum in this system may also be caused by the polarizable H-bonds formed by the excess and defect protons which occur due to protolytic splitting of the adsorbed molecules (14).

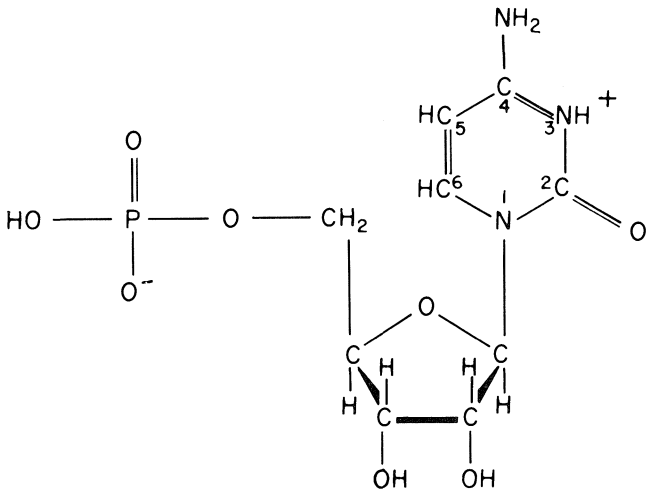

FIG. 1. Structure and numbering the 5′-CMP molecule.

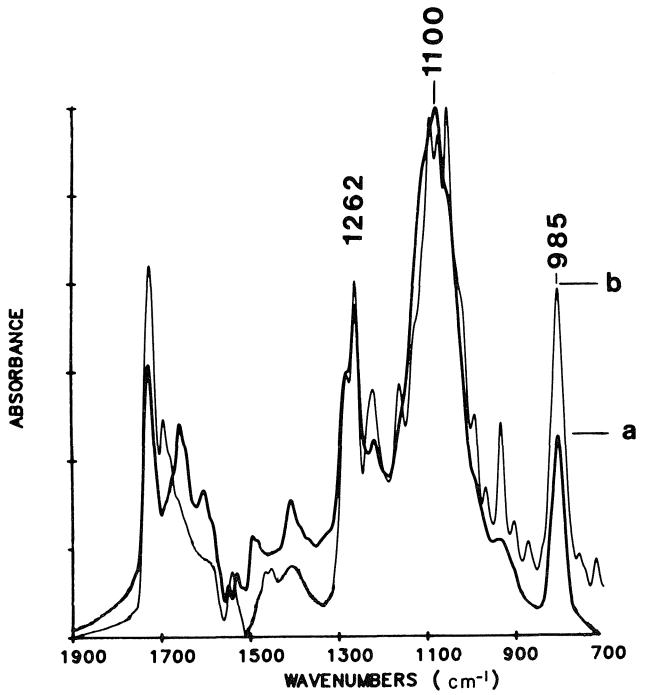

FIG. 2. ATR spectra of highly hydrated 5′-CMP(H) (1800–400 cm^{-1} region): (*a*) 66% r.h.; (*b*) 86% r.h.

In the spectrum corresponding to 66% r.h., the continuous absorption extends towards low wavenumbers and the absorbance of the continuum exceeds significantly the values corresponding to both 20% and 92% r.h. The strong absorption in the 4000–3600 cm^{-1} region has been assigned in a previous paper (17) to the stretching vibration of the water adsorbed on the thallium bromide iodide crystal surface. Figure 2 shows the 1900–700 cm^{-1} region in the 5′-CMP(H) spectra for two different r.h. values — 66% (*a*) and 86% (*b*). As r.h. is increased (Fig. 2*b*) the bands become sharper and better defined in the phosphate region. A strong dependence of the absorbance ratio A_{1280}/A_{1262} on the r.h. is observed. The absorption of the 1280 cm^{-1} band increases with increasing amounts of water in the 66–92% r.h. range. For the main 1100 cm^{-1} band, at lower r.h. values the bands are broad, many bands overlap, and the

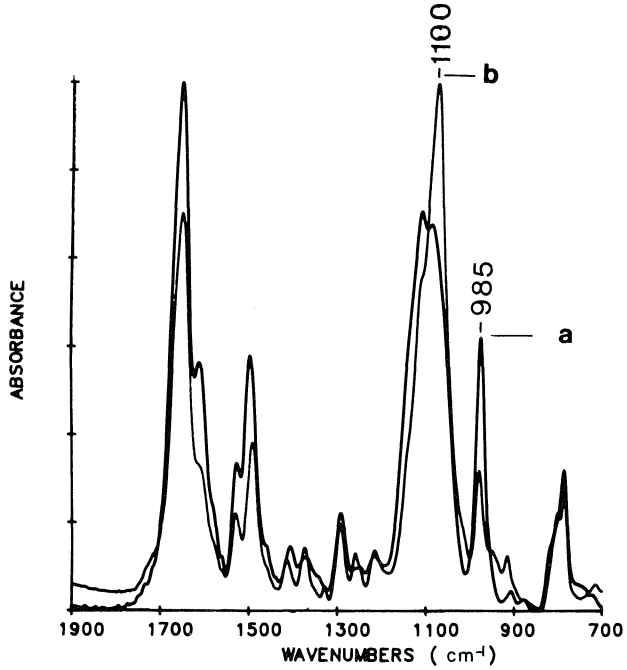

FIG. 4. ATR spectra of the hydrated 5′-CMP in sodium salt form at different r.h. values: (*a*) 20% r.h.; (*b*) 76% r.h.

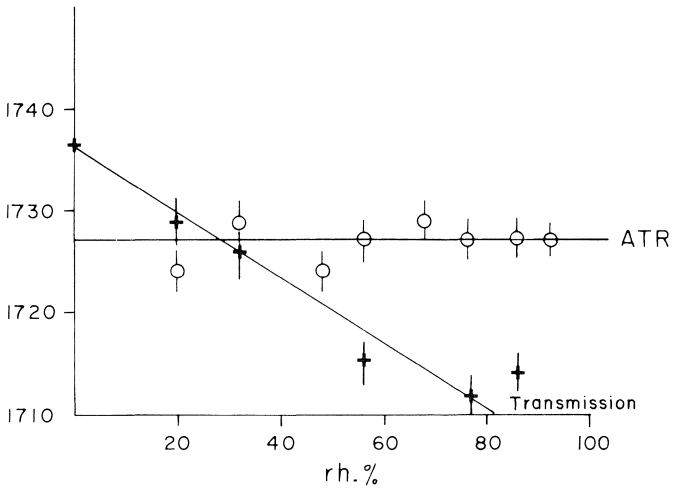

FIG. 5. Dependence of the frequency of the carbonyl band ($\nu_{C=O}$) on the r.h. values in transmission and ATR.

resolution of the spectral features is not possible. In a previous paper (19) the ATR spectra of 5′-CMP were given for six different r.h. values and some assignments of the bands were made. A thorough examination of the phosphate region in both zwitterion and ionic forms (Fig. 3) leads to a tentative assignment of the observed bands. In the sodium salt form (Fig. 4) the asymmetrical and symmetrical $\nu_{PO_3^{2-}}$ vibrations corresponding to the fully ionized phosphate group have been assigned to the bands near 1100 and 985 cm^{-1}, respectively. Figure 4 shows that the intensity of the asymmetrical phosphate band (1100 cm^{-1}) increases with increasing r.h. but no significant frequency displacements have been observed. As we have previously (17, 18) pointed out the phosphate group is the main hydration site in the mononucleotide molecule.

In the zwitterion structure in the solid state ionized and unionized phosphate groups occur simultaneously and both of them are influenced by the degree of hydration. Therefore, the complexity of the zwitterion spectrum (Fig. 3*a*) may be accounted for by a further lowering of the symmetry of the molecule with respect to the Na^+ salt form. In addition, adsorption effects due to the field of the ATR crystal lattice have been observed. At lower r.h. the broad absorption centered at 942 cm^{-1} can be assigned to hydrated ionic phosphate groups. The presence of water molecules affects the intramolecular hydrogen bond by insertion between the two groups. As Bertoluzza *et al.* (16) have recently pointed out in the case of some phospholipids an indirect perturbation of the intramolecular hydrogen bond by interaction of water molecules with the P—O^- group is also possible.

The shoulder at the lower frequency side of the broad band between 1050 and 1000 cm^{-1} can be assigned to unionized P—OH groups (22) hydrogen bonded to the adsorbed water (in the first layers of the surface). This absorption is markedly reduced in the Na^+ salt form (Fig. 3*b*) as well as in the highly hydrated acid form (Fig. 2). The band located at 1280 cm^{-1} may receive an important contribution from the external C—N vibration, but the strong coupling with C—C and ring C—N vibrations (10) does not allow a precise assignment. The other band in this region, the 1262 cm^{-1} band was assigned to the $\nu_{P=O}$ vibration (22, 23).

The important contribution of water to the absorption band of the CMP zwitterion structure has been demonstrated. The spectral pattern changes due to the surface deuteration of a highly hydrated sample. In the 1800–1600 cm^{-1} region, both the water bending (about 1650 cm^{-1}) and the 1680 cm^{-1} band (assigned previously (9, 10) to the scissoring vibration of the amino group) are removed by deuteration. The strong dependence of $\nu_{C=O}$ on the r.h.% values has been observed in the transmission measurements (Fig. 5). The decrease of the frequency with increasing r.h. can be accounted for by the presence of C=O..H—O—H hydrogen bonds in the hydrated molecule. The lack of this relationship in the surface hydration

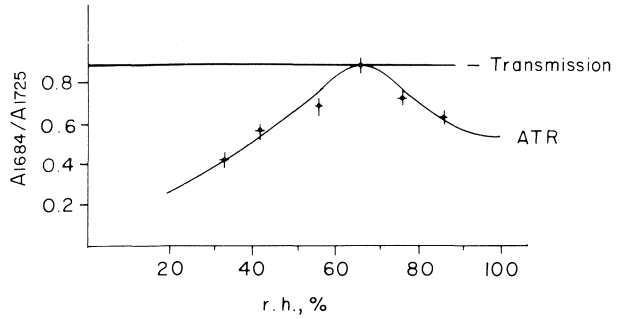

FIG. 6. Dependence of the protonation degree (A_{1684}/A_{1725}) on r.h. values.

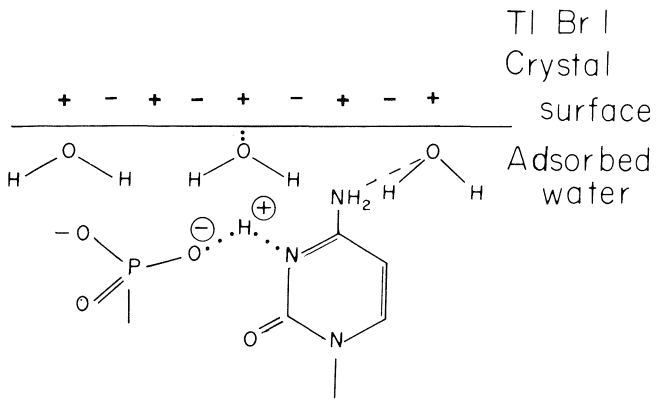

FIG. 7. Water-assisted proton transfer at the crystal surface.

(ATR measurements) seems to show that the carbonyl groups are less involved with hydrogen bonding with surface water.

Further protonation of CMP(H) results in an enhanced absorbance of the 1680 cm^{-1} band. This band belonging to the "amino" scissoring receives an important contribution from the protonated structure (–CO—NH^+). In addition, a weak absorption band near 2700 cm^{-1} has been observed. We have considered the A_{1680}/A_{1725} absorbance ratio as a measure of the degree of protonation. This ratio does not depend on the degree of hydration in the transmission measurements (Fig. 6). To the contrary, a strong dependence of this ratio on the r.h. has been found in the ATR spectra. The degree of protonation seems to be the highest when the r.h. value is approximately 66%. These results show the involvement of the surface adsorbed water molecules in the proton transfer processes (Fig. 7). The mechanism of this water-assisted proton transfer is not known. Zundel (14) pointed out that proton transfer equilibria are strongly shifted to the right when water molecules are added to the water-free solutions or to films of polymers. The ability of the adsorbed water to act by itself as a proton donor is evidenced by the following experiment. The crystal was pretreated under vacuum at 50°C and this has provoked a partial surface dehydration. In this way a network of very fine pores accessible to water was developed and the contact surface between the crystal and water strongly increased. Trapped CMP molecules in a crystal pretreated in this manner are strongly protonated by the adsorbed water molecules. In Fig. 8 the intensity of the 1684 cm^{-1} band is strongly increased. The general pattern of the spectrum corresponding to the trapped molecules is the same as that of molecules protonated by addition of HCl. These results show that the adsorbed water may act as a strong donor by releasing its proton.

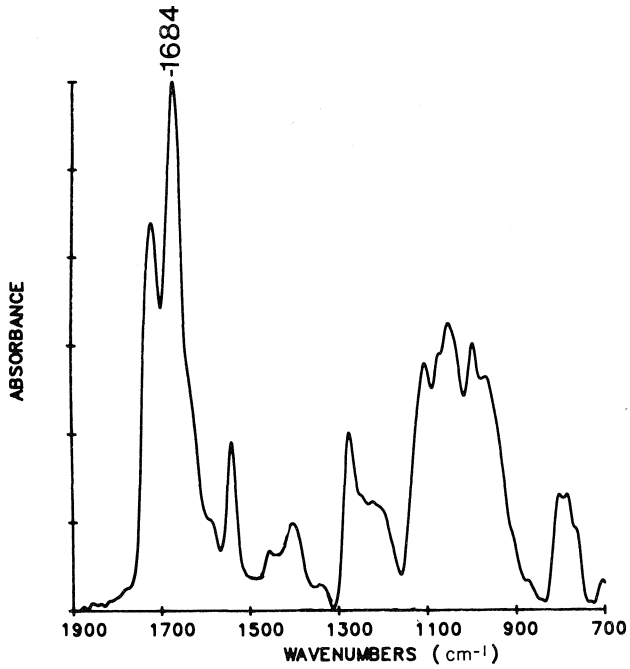

FIG. 8. Enhanced protonation in the "trapped" molecules.

The increased degree of dissociation of the adsorbed water was reported in many of the earlier works on the special properties of the water adsorbed on silica glass surfaces (24, 25). Because of the stronger ionic character of the thallium bromide iodide surface as compared to silica, one may also expect a high degree of dissociation for water adsorbed on this surface. In order to explain the increased surface electrical conductivity a strong enhancement of the water dissociation by surface electrical fields was assumed by Fripiat *et al.* (24). Recently Ibach (26) and Chabal *et al.* (27, 28) showed that water adsorption on Si (100) is dissociative. Hydride formation upon molecular chemisorption of water on annealed surfaces has been indicated. Moreover, the electronic structure of molecularly adsorbed water has been computed theoretically (29, 30) with a semiempirical approach and it was demonstrated that water is chemisorbed to silicon surfaces.

We have observed the occurrence of very narrow (microscopical) scratches on the surface when the crystal was submitted to a great number of freeze-drying procedures. Freezing of water in the voids involving volumetric expansion produces some mechanical destruction (frost action) (31–33). This mechanical inhomogeneity of the surface induces an energetic and structural inhomogeneity in the adsorbed water layers. Therefore, with low amounts of water (degassed crystal) the strongly adsorbed water can enhance proton transfer in the molecule. At higher r.h. values the depth of the adsorbed water layer becomes too thick and its properties are similar to those of bulk water. Our results show the importance of the mechanical state of the crystal in the FD-ATR measurements. Crystals having many microscopical channels adsorb water very strongly and the keeping of a constant r.h. level is quite difficult.

Conclusions

The freeze-drying ATR spectra of hydrated 5′-CMP in both acid and Na salt forms have been studied. Intramolecular hydrogen bonding with proton transfer resulting in an infrared

continuum has been found for zwitterionic 5′-CMP(H) on the hydrated crystal.

The dependence of the general spectral pattern of 5′-CMP(H) on the r.h. has been pointed out. Assignments for the bands in the phosphate region of the hydrated 5′-CMP(H) are proposed.

Surface deuteration of the semiprotonated 5′-CMP(H) showed the important contribution of the water bending vibration to the absorbance of the bands in the 1800–1600 cm^{-1} region. Deuteration and protonation studies on the hydrated samples were carried out in order to ascertain some assignments for the bands in this region. The 1684 cm^{-1} band has been assigned to a vibration having mainly NH^+ character.

The role of the adsorbed water in the proton transfer process has been underscored. The ability of the water molecules to act as proton donors has been accounted for by an increased degree of dissociation of the water adsorbed on the thallium bromide iodide crystal surface.

Comparison of oxygen and sulphur adsorption on the (0001) surface of zirconium

P. C. WONG AND K. A. R. MITCHELL

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received June 27, 1986

P. C. WONG and K. A. R. MITCHELL. Can. J. Chem. **64**, 2409 (1986).

Low energy electron diffraction (LEED) and Auger electron spectroscopy (AES) have been used to compare the adsorption and coadsorption of O_2 and H_2S on the (0001) surface of zirconium where exposures are in the one to five Langmuir regime. The new observations made are as follows: (*i*) that sulphur forms a stable (3 × 3) surface structure after heating to 600°C; (*ii*) that the Zr(0001) surface with high O coverage adsorbs H_2S, whereas the surface with high S coverage does not adsorb oxygen in detectable amounts; and (*iii*) that for surfaces with adsorbed H_2S a sudden increase in the 150 eV to 92 eV Auger peak ratio occurs on heating to 530°C.

P. C. WONG et K. A. R. MITCHELL. Can. J. Chem. **64**, 2409 (1986).

On a utilisé la diffraction électronique à basse énergie (DEBE) et la spectroscopie électronique du Auger (SEA) pour comparer l'adsorption et la coadsorption du O_2 et du H_2S sur la surface (0001) du zirconium, où les expositions se situent dans le régime un à cinq de Langmuir. Les nouvelles observations qui ont pu être faites sont les suivantes : (*i*) après avoir été chauffé à 600°C, le soufre forme une structure de surface (3 × 3) stable; (*ii*) la surface (0001) du Zr très couverte par le O adsorbe le H_2S alors que la surface très couverte par le S n'adsorbe pas de quantités détectables d'oxygène et (*iii*) dans le cas des surfaces qui ont adsorbé du H_2S et qui ont été chauffées à 530°C, il se produit une augmentation rapide du rapport des pics à 150 eV et 92 eV du spectre électronique de Auger.

[Traduit par la revue]

1. Introduction

There is considerable technological interest in the surface chemistry of zirconium (1–3), although information is still very limited on the structural aspects of chemisorption at coverages of the order of a monolayer (formed by exposures of just a few Langmuir, where 1 L = 10^{-6} Torr s). Some studies have recently investigated the chemisorption of small molecules like H_2, O_2, N_2, CO, and NO on polycrystalline zirconium (4–7), and concluded that dissociative chemisorption occurs followed by diffusion into the bulk on heating at above 500 K (except hydrogen which desorbs at above 700 K). In addition, preliminary surface structural analyses with low-energy electron diffraction (LEED) for surface structures involving oxygen chemisorption provide support for the model of subsurface incorporation at low coverages (8, 9). In this model, O atoms occupy octahedral hole sites in zirconium, and therefore the structure relates to that of bulk ZrO rather than to that of the final oxidation product ZrO_2, which forms at higher oxygen exposures or higher temperatures (3, 10).

This present paper uses LEED and Auger electron spectroscopy (AES) to compare the adsorption and coadsorption of O_2 and H_2S on the Zr(0001) surface. It is believed that such studies can provide further insight into the surface structures formed by low-exposure chemisorption on zirconium.

2. Experimental

The apparatus and cleaning procedures used were as described previously from this laboratory for a LEED crystallographic analysis for the clean Zr(0001) surface (11). Adsorption studies were made on surfaces which showed sharp (1 × 1) LEED patterns, with hexagonal symmetry at normal incidence, and for which no contaminants were apparent with AES measured by a cylindrical mirror analyser. The experiments used high-purity oxygen or H_2S which were directed to the Zr(0001) surface via a nozzle. For various exposures of the adsorbing gas, the relative amounts of adsorbed species were assessed with appropriate Auger peak height ratios; specifically for oxygen

$$R_O = A_{510}/A_{92}$$

(i.e. the ratio of the Auger peak height for O at 510 eV to that of Zr at 92 eV), and for sulphur

$$R_S = A_{150}/A_{92}$$

(where A_{150} is the peak height for overlapping Zr and S Auger signals at 150 eV). For Zr it appears advantageous to use the Auger peak which involves emission from the N shell; this limits the influence of attenuation and shift/broadening effects which have been noted in the valence shell spectra (4, 12). After each adsorption experiment, the sample surface was cleaned by Ar^+ bombardment and re-ordered by heating to 600°C followed by immediate cooling (heating and cooling rates are approximately 1°C s^{-1}). The cleaned zirconium surface is characterized with $R_O = 0.0$ and $R_S = 1.4$.

3. Results and discussion

3.1. O_2 adsorption

Exposure of a clean, ordered Zr(0001) surface to oxygen at room temperature yields (1 × 1) LEED patterns with high background, although (2 × 2) patterns can be observed after heating at below 220°C. This is less than the temperature at which diffusion into the bulk occurs, and therefore we interpret the heating as providing just an ordering effect. The sharpest (2 × 2) pattern was obtained for an initial oxygen exposure (1.2 L) which gives R_O equal to 0.16; the associated surface structure appears sufficiently stable at room temperature and 10^{-10} Torr for the sharp LEED pattern to be maintained for at least 3 days. With larger initial exposures to oxygen the (2 × 2) pattern gives way to a (1 × 1) pattern, which is best established with an exposure of about 3.6 L and a surface coverage corresponding to $R_O = 0.23$. The LEED intensity-versus-energy curves for this structure have clear differences from those of the clean Zr(0001) surface; examples for (1,1) beams are included in Fig. 1.

3.2. H_2S adsorption

When a cleaned and ordered Zr(0001) surface was exposed to about 4.2 L of H_2S at room temperature, sulphur adsorption occurred ($R_S = 2.8$), but no extra LEED beams were detectable even after heating to 500°C. However, on heating to 530°C, R_S was found to increase to 3.1, an observation, which in conjunction with a report by Lin and Gilbert (7), appears to be associated with hydrogen desorption. Further, with a short heating to 600°C, a very sharp (3 × 3) LEED pattern was observed on cooling to room temperature, for which R_S remained at 3.1. Higher S coverages, as measured by R_S, can be

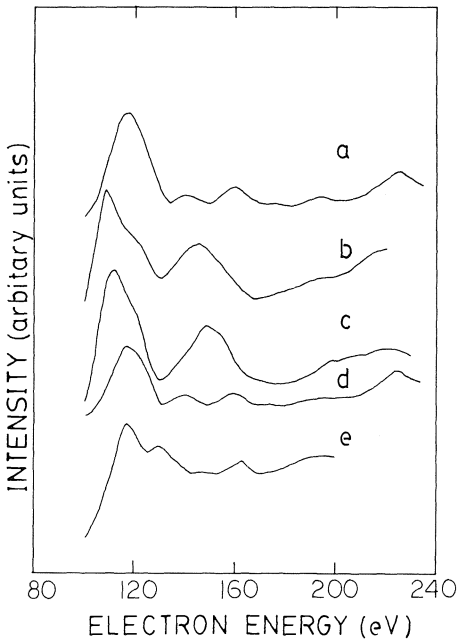

FIG. 1. Intensity versus energy curves measured for the (1,1) beam from (*a*) clean Zr(0001), (*b*) Zr(0001)—(2 × 2)—O with $R_O = 0.16$, (*c*) Zr(0001)—(1 × 1) with $R_O = 0.23$, (*d*) Zr(0001)—(3 × 3)—S with $R_S = 2.4$, (*e*) Zr(0001)—(3 × 3)—S with $R_S = 3.1$.

obtained by giving larger initial exposures to H_2S; however, following annealing at 600°C, the (3 × 3) LEED patterns show increasing disorder as R_S increases beyond 3.1. Intensity-versus-energy curves for the diffracted beams (e.g. Fig. 1) suggest that the moderate coverage (3 × 3) structures with R_S less than 3.1 correspond to mixed regions of clean surface and of (3 × 3) domains. The latter regions appear to be stable for long periods.

3.3. O_2 and H_2S coadsorption

A series of experiments for assessing structural aspects of the coadsorption of O_2 and H_2S on an initially clean Zr(0001) surface have been made, and the results are summarized in the following subsections.

3.3.1. O_2 on Zr(0001)—(3 × 3)—S with $R_S > 3.1$

No evidence could be found from AES or LEED for oxygen chemisorption occurring on (3 × 3) surfaces with R_S greater than 3.1 when exposed to oxygen at room temperature. The same statement holds for these surfaces when annealed following the procedures used above for the formation of the Zr(0001)—(2 × 2)—O and Zr(0001)—(1 × 1)—O surface structures.

3.3.2. O_2 on Zr(0001)—(3 × 3)—S with $R_S < 3.1$

When a partially S covered (3 × 3) structure was exposed to oxygen, and treated according to the conditions that give the (2 × 2)—O structure as in 3.1, the LEED pattern shows a superposition of the individual (2 × 2)—O and (3 × 3)—S patterns. This observation is consistent with the existence of separate (2 × 2)—O and (3 × 3)—S domains on the surface, with linear dimensions larger than the transfer width of the instrument used (~100 Å) (13). For an initial partially S covered surface with $R_S = 2.3$, values of R_S and R_O were found to be 2.1 and 0.13, respectively, after the preparation of the mixed surface. The decrease of R_S appears associated with the effect of oxygen on the Auger zirconium signal at 150 eV (12). On further heating to 600°C, the (3 × 3) part of the LEED pattern remains essentially unchanged and R_S returns to 2.3, while the (2 × 2) pattern disappears and R_O goes to zero as expected for oxygen diffusion into the bulk.

3.3.3. H_2S on Zr(0001)—(2 × 2)—O

When an oxygen surface which shows a (2 × 2) LEED pattern with $R_O = 0.16$ and $R_S = 1.3$ was exposed to about 3.5 L of H_2S at room temperature and annealed at 530°C, a diffuse (1 × 1) LEED pattern with high background was observed. However, with further heating at 600°C, a very sharp (3 × 3) LEED pattern was recovered on cooling to room temperature ($R_O = 0.0$, $R_S = 2.3$).

3.3.4. H_2S on Zr(0001)—(1 × 1)—O

The observation in 3.3.3 was found to extend even to a surface with the highest oxygen coverage considered here (viz. Zr(0001)—(1 × 1)—O with $R_O = 0.23$). After exposure to H_2S at room temperature, the LEED pattern becomes diffuse with high background ($R_S = 2.3$, $R_O = 0.26$), but after annealing at 600°C and cooling to room temperature a sharp Zr(0001)—(3 × 3)—S pattern results with $R_S = 2.9$ and $R_O = 0.0$.

3.3.5. Coadsorption without annealing

AES shows that the basic tendencies observed in 3.3.2 and 3.3.4 extend also to a Zr(0001) surface which is treated entirely at room temperature. Specifically it was found that oxygen does not significantly adsorb on a high S coverage Zr(0001) surface, whereas H_2S will adsorb on a high O coverage surface.

4. Concluding remarks

This work highlights the contrasting behaviours of oxygen and sulphur chemisorption on the Zr(0001) surface. Thus while the highest coverage oxygen surface is still able to adsorb H_2S, the highest coverage sulphur surface does not adsorb oxygen in detectable amounts. These observations are consistent with oxygen forming subsurface structures (8), whereas sulphur probably forms a coincidence-site (3 × 3) structure in which the overlayer involves either a sufficiently high density of S atoms to block O adsorption, or a protective combined layer of Zr and S, perhaps with a zirconium sulphide structure. Analyses of the surface geometries of these systems are in progress, but the general chemical observations reported here do appear to set some limits on the possible structural arrangements. Investigations are also underway to probe the origin of the increase in R_S at 530°C for surfaces which initially contain H_2S. Finally it is noted that this work provides no evidence for significant sulphur and oxygen combination processes, either when surfaces with coadsorbed S and O are heated, or when S-saturated surfaces are heated in oxygen.

A fuel-rich, conical, premixed, methane–oxygen flame at atmospheric pressure was doped separately with 0.2 mol% of H_2S, OCS, and SO_2 to probe the chemistry of sulphur at its source during combustion. These three additives represent a broad range of fuel-sulphur contaminants since they occur early, intermediate, and late in the sulphur oxidation sequence. A wide variety of sulphurous cations, formed by chemical ionization reactions, is observed for each additive by sampling the flame into a mass spectrometer. The total ionization profile measured along the flame axis is enhanced in the reaction zone when a sulphur additive is present; the mechanism involves the formation of sulphurous negative ions which reduces the rates of cation loss by electron–ion recombination and ambipolar diffusion. Mass spectra measured in the mass range 10–110 u at fixed points on the flame axis are very similar for all three additives, and are not helpful in the identification of the additive. However, the general presence of sulphur is evident from large signals measured near the reaction zone at five principal mass numbers; namely, 45 u (CHS^+), 47 u (CH_3S^+), 58 u ($C_2H_2S^+$), 59 u ($C_2H_3S^+$), and 69 u (C_3HS^+) related to CS, thioformaldehyde, thioketene, and C_3S.

Dans le but d'étudier la chimie du soufre à sa source au cours de sa combustion, on a dopé une flamme oxygène/méthane, prémélangée, conique, riche en carburant et opérant à la pression atmosphérique avec 0,2 mol% de l'un ou l'autre des composés suivants, soit le H_2S, le OCS ou le SO_2. Ces trois additifs correspondent à un évantail large de contaminants carburant/soufre, puisqu'ils se retrouvent tant au début, qu'à la fin ou au cours du stade intermédiaire de la suite des oxydations du soufre. Pour chacun des additifs et faisant appel à un échantillonage par spectrométrie de masse, on peut observer une grande variété de cations sulfureux, qui se forment par des réactions d'ionisations chimiques. Lorsqu'un additif de soufre est présent, le profil total d'ionisation, tel que mesuré en suivant le développement de l'axe de la flamme, subit une augmentation dans la zone de la réaction; le mécanisme implique une formation d'ions sulfureux négatifs qui réduit les taux de perte de cations par recombinaison électron/ion et par diffusion ambipolaire. Les spectres de masses, mesurés entre 10 et 100 u et à des points fixes de l'axe de la flamme, sont très semblables pour chacun des trois additifs et ne sont pas utiles pour l'identification de l'additif. Toutefois, la présence générale de soufre est évidente à partir de signaux très importants qui sont mesurés près de la zone réactionnelle, à cinq valeurs principales de masse, soit 45 u (CHS^+), 47 u (CH_3S^+), 58 u ($C_2H_2S^+$), 59 u ($C_2H_3S^+$) et 69 u (C_3HS^+) qui sont reliées respectivement au CS, au thioformaldéhyde, au thiocétène et au C_3S.

[Traduit par la revue]

Introduction

Combustion processes account for more than 90% of the energy consumed in the United States (1). Also, more than 90% of SO_x emissions result from combustion (1). A Canadian emissions inventory indicates that 80% of the total SO_2 emissions arise from a relatively few point sources concentrated in industrial sectors involving smelters, major utilities, and fossil fuel production plants (2). Our objective has been to learn as much as possible about the chemistry of sulphur in combustion by observations of sulphurous ions formed in a hydrocarbon flame doped with fuel-sulphur additives. By sampling the flame at atmospheric pressure into a mass spectrometer, it is possible to probe the sulphur chemistry at its source in and around the flame reaction zone.

Initially, studies of sulphurous anions were carried out in a premixed, fuel-rich, CH_4–O_2 flame doped with OCS (3), and with H_2S and SO_2 in addition for comparison purposes (4). The sulphur chemistry gives rise to a variety of species of high electron affinity leading to large sulphurous anion signals confined mainly to the flame reaction zone. The positive ion chemistry is more complex, but extends through the reaction zone into the burnt gas downstream. In a recent study of the same flame with OCS additive, more than 40 sulphurous cations were observed in the mass range below 110 u (5). The ion chemistry leading to the formation of these cations has been considered in detail involving reactions of primary sulphur ions with neutral hydrocarbon flame constituents (5).

The present study extends the observations of sulphurous cations in the same fuel-rich, CH_4–O_2 flame doped separately with 0.2 mol% of H_2S, OCS, and SO_2. These three additives were chosen to be early, intermediate, and late in the sulphur oxidation sequence. As such, they cover a broad range of possible fuel-sulphur contaminants. We hoped to establish mass-spectrometric fingerprints in different flame regions from which the nature of the sulphur contaminant could be identified. In fact, the three additives give very similar mass spectra, indicative of extensive pyrolysis of the fuel-sulphur early in the reaction zone. However, general fingerprints for sulphur compounds are evident at five principal mass numbers. Also, the sulphur additives enhance the observed total positive ion signals primarily in the flame reaction zone. The mechanism of the latter enhancement has been traced to the formation of sulphurous anions which affect the normal rates of cation loss by electron–ion recombination and ambipolar diffusion.

Experimental

All of the ion concentration measurements were performed on the same CH_4–O_2 flame of fuel-rich composition (equivalence ratio $\phi = 2.15$) whose ion chemistry we have studied extensively in the past (6, 7). It was of the laminar premixed type with a conical luminous reaction zone (height 5 mm, base diameter $\simeq$ 3 mm, thickness $\simeq$ 0.3 mm) to facilitate ionic sampling along the flame axis into the mass spectrometer. The flame has a burnt gas velocity of approximately 1 m s^{-1} and an adiabatic flame temperature of 2460 K, although the measured temperature of the equilibrium burnt gas was close to

2200 K. The flame was stabilized at atmospheric pressure on a simple, tubular, quartz burner (2.3 mm id) surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. Provision was made to add separately 0.2 mol% of H_2S, OCS, or SO_2 to the premixed gas in exactly the same way as was done previously for the study with OCS (5). The additive could be introduced or removed without altering the flame. All gases were used straight from the cylinders without further purification ($CH_4 > 99.0\%$, $O_2 > 99.6\%$, $Ar > 99.9\%$, $H_2S > 97.5\%$, $OCS > 97.5\%$, $SO_2 > 99.90\%$). The burner was mounted on a motor-driven carriage with accurate alignment of the flame axis with the sampling orifice of the mass spectrometer. The calibrated burner drive provided spatial resolution of ± 0.02 mm along the flame axis (designated z) for measurements of ion concentration profiles.

The flame-ion mass spectrometer has been described previously in detail (6). The flame burned against a 60°, conical, chromium, sampling nozzle of orifice diameter ca. 0.1 mm mounted in a water-cooled flange of the type described by Hayhurst and Telford (8). The sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday collector connected to a vibrating reed electrometer having a grid-leak resistance of 10^{10} ohms. The ion signal magnitudes in the figures are quoted in volts based on the detected ion current passing through 10^{10} ohms. The mass spectra shown below have been corrected for mass discrimination in the filter against ions of high m/e measured at high resolving power. The dynamic range of sensitivity of the apparatus is five orders of magnitude.

A method has been described (6) involving a relatively sharp minimum in the pressure profile of the sampled gas for locating a reproducible origin ($z = 0$) in the *flame* (not referred to the burner). It corresponds to the downstream edge of the luminous reaction zone on the flame axis. In this way, a family of ion profiles at different mass numbers m/e can be accurately overlaid on the distance scale z. It is also an important consideration when comparing mass spectra at fixed points on the flame axis (e.g. $z = -0.15$ mm upstream in the reaction zone, and $z = 0.2$ and 1.5 mm downstream) for the undoped flame with those measured in the presence of an additive. Small changes in position can alter the spectra considerably.

Results and discussion

Ion profiles

Figure 1 gives profiles of the total positive ion signal measured along the flame axis for the undoped flame and for the flame doped separately with 0.2 mol% of H_2S, OCS, and SO_2. These signals are obtained by removing the dc voltage from the rods of the quadrupole mass filter so that ions of every m/e are transmitted. Although the peak magnitude of all four profiles is constant within experimental error, the upstream ion signals in the reaction zone are enhanced. A shoulder is evident on the profiles, particularly that for SO_2 where the total ion signal is almost doubled. The effect is progressively smaller with OCS and H_2S although still clearly evident. One possible explanation is the occurrence of a new chemi-ionization reaction involving sulphur species such as

$$[1] \quad CH + S \rightarrow HCS^+ + e^- \qquad \Delta H^0 = +38$$

which is analogous to the usual fundamental chemi-ionization process normally associated with hydrocarbon flames (9)

$$[2] \quad CH + O \rightarrow HCO^+ + e^- \qquad \Delta H^0 = -5$$

(standard heats of reaction ΔH^0 are given in kcal mol^{-1} at 298 K). However, reaction [1] is unlikely because it is so endothermic. Also, it is difficult to explain the constant profile peak magnitude if a second chemi-ionization reaction is operative. In the previous OCS study (5), we stated that we did not have a satisfactory explanation of the enhanced total ion signal in the flame reaction zone. However, the correct explanation of the phenomenon is now forthcoming and has far-reaching consequences, particularly for the mass spectra observed with the SO_2 additive.

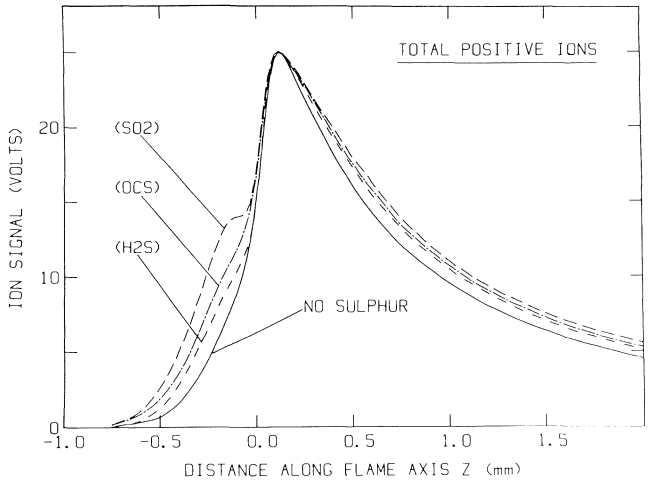

FIG. 1. Total positive ion profiles in the absence of sulphur (solid line) and with the flame doped with 0.2 mol% of H_2S, OCS, and SO_2. The reaction zone is located upstream of $z = 0$ (negative z).

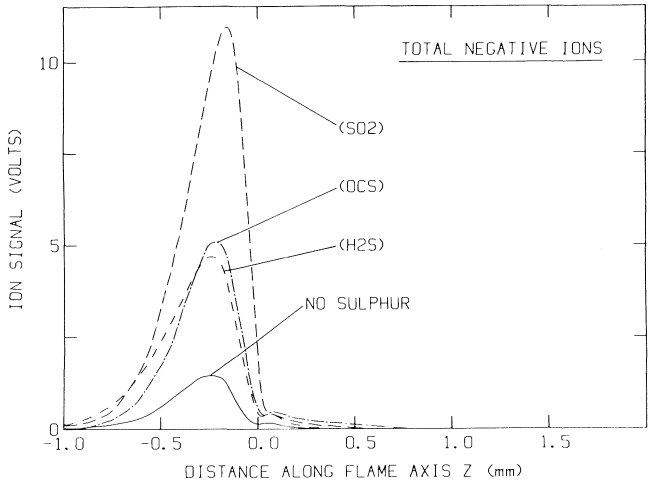

FIG. 2. Total negative ion profiles in the absence of sulphur (solid line) and with the flame doped with 0.2 mol% of H_2S, OCS, and SO_2. The reaction zone is located upstream of $z = 0$ (negative z).

At each point in the flame, the steady-state ion signal observed is governed mainly by the advection of ions (i.e. transport by the neutral flow) to and from that point. The *slope* on the total ion profile depends on the relative rates of ion production, essentially by reaction [2], and ion loss via recombination processes and ambipolar diffusion. Upstream in the reaction zone, the profiles with sulphur additives rise more steeply than the undoped flame profile. The steeper rise is indicative of either increased ion production or decreased loss. Decreased loss is the logical candidate for the following reason.

Figure 2 shows total negative ion profiles for the undoped flame and for the same three sulphur additives under the same flame conditions taken from an earlier study of sulphurous anions (4). The order of anion peak magnitudes is undoped $< H_2S < OCS < SO_2$. Since a flame is a quasi-neutral plasma, an increased negative ion concentration implies a decreased concentration of free electrons. Rate coefficients α for ion–ion recombination are, in general, about an order of magnitude

smaller than electron–ion recombination coefficients (10–12). Also, for a plasma at thermal equilibrium, it is easy to show that the ambipolar diffusion coefficient D_a for ion–ion diffusion can decrease by at most a factor of two compared with D_a for electron–ion diffusion (13). Thus, relatively fast electron–ion loss processes are replaced by slower ion–ion processes in the presence of sulphur additives, with a concomitant increase in the total positive ion signal. In the reaction zone, the rate of diffusion loss $-D_a d^2n/dz^2$ along the flame axis z involving the second derivative of the charge concentration n can be estimated from the upstream undoped profile given in Fig. 1. It amounts to 2×10^{13} ions cm^{-3} s^{-1} for $D_a = 2$ cm^2 s^{-1} at 1500 K and 1 atm (9, 14) and a peak ion concentration of 2×10^{10} cm^{-3} (15). Diffusion loss in a radial direction can be neglected because the radial concentration profile is flat near the flame axis in the reaction zone. The electron–ion recombination loss rate αn^2 has the same value for $\alpha = 2 \times 10^{-7}$ cm^3 s^{-1} (9, 14). When the negative ion concentration is increased by the addition of sulphur compounds, α decreases more than D_a and the change of the recombination rate is probably dominant. However, the approximate equivalence of diffusion loss and recombination loss in the reaction zone is a rather surprising result for a flame at atmospheric pressure. In contrast, near the peak of the positive ion profile "at pressures above about 30 mm Hg, ambipolar diffusion does not play an important role" (16). In any event, Fig. 1 shows that the upstream positive ion signal magnitudes follow the expected negative ion order given in Fig. 2: namely, undoped < H_2S < OCS < SO_2. It is not necessary to invoke a new chemi-ionization reaction for ion production involving sulphurous neutrals.

A bit further downstream in the reaction zone near $z = -0.2$ mm, the shoulders on the positive ion profiles in Fig. 1 are observed to occur near the negative ion profile peaks given in Fig. 2. At this point in the reaction zone, the flame temperature is rising rapidly and the negative ion signals decrease sharply due to thermal detachment processes which regenerate free electrons. The slower loss of cations by ion–ion processes is replaced by faster electron–ion processes; the slopes of the cation profiles decrease and bend over to form the shoulders observed in Fig. 1. The shoulders indicate an enhanced rate of ion loss by electron–ion processes, and the profiles for the doped flames "catch up" to the undoped flame profile. By the time the peak position of the total positive ion curves is reached all of the profile magnitudes are the same within experimental error. In general, the anion and the cation chemistry proceed independently in flames. This upstream phenomenon is a rare case where the anions and cations interact, albeit indirectly.

Downstream of the peak in Fig. 1, the profile magnitudes for the doped flames are slightly greater than the magnitude of the undoped flame profile. In this region, the negative ion concentration is too small to alter the cation signal significantly and a different explanation must be invoked. The outstanding difference between the undoped and the doped flames is that the latter all show a number of sulphurous cations whose profiles maximize just downstream of the total ion peak. The major sulphurous ion profiles are given in Fig. 3 for the flame doped with OCS, together with the H_3O^+ profiles for the doped and undoped flames. In decreasing order of signal magnitude these ions are assigned to 45 u (CHS^+), 47 u (CH_3S^+), 58 u ($C_2H_2S^+$), 69 u (C_3HS^+), and 59 u ($C_2H_3S^+$). That is, the large sulphurous cations at this point in the flame are protonated forms of CS, HCHS, CH_2CS, and C_3S except for ionized thioketene $C_2H_2S^+$. The latter is probably formed from protonated

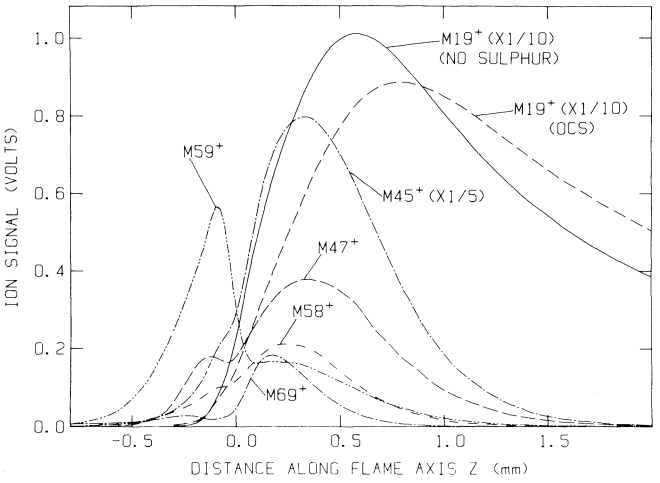

FIG. 3. Profiles of the five major sulphurous cations at 45 u (CHS^+), 47 u (CH_3S^+), 58 u ($C_2H_2S^+$), 59 u ($C_2H_3S^+$), and 69 u (C_3HS^+) for the flame doped with 0.2 mol% of OCS additive. The profile at 19 u (H_3O^+) is also shown with OCS present (dashed line) and absent (solid line). The reaction zone is located upstream of $z = 0$ (negative z).

thioketene $C_2H_3S^+$ by exothermic reactions such as (5)

[3] $C_2H_3S^+ + H\,(OH) \rightleftharpoons C_2H_2S^+ + H_2\,(H_2O)$

All of these sulphur species have high proton affinities (17). Their presence effectively *delays* the protonation of water to a region further downstream in the flame, as shown by the shift of the H_3O^+ profile in Fig. 3. The behaviour with H_2S and SO_2 additives is similar to that shown for OCS. The enhanced total ion signals downstream in Fig. 1 for the sulphur-doped flames indicate a lower rate of electron–ion recombination for the sulphurous cations. That is, a reduced ionic loss rate correlates with an enhanced total ion signal. The expected loss process for protonated cations is dissociative recombination of the type

[4] $XYH^+ + e^- \rightarrow XY + H$

involving the proton bond. It is tempting to hypothesize a correlation of a high proton affinity with a low electron–ion recombination coefficient, but available data are inadequate to substantiate such a claim.

Mass spectra

In our previous study with the OCS additive (5), it was shown that primary sulphur ions CH_xS^+ ($x = 1, 3, 5$) in the reaction zone undergo extensive ion–molecule reactions with CH_4/CH_3, C_2H_2, and OCS to form a considerable variety of secondary sulphurous cations. Just downstream of the reaction zone, the ion chemistry appears to be dominated by reactions of primary sulphur ions including H_xS^+ ($x = 0$–3) with C_2H_2 present as an intermediate. A few ions (H_xS^+, SO^+, S_2^+) persist throughout the burnt gas region in equilibrium with the natural flame ions HCO^+ and H_3O^+. As a general comment about the present study, much of the detailed ion chemistry observed with OCS appears to be operative with the H_2S and SO_2 additives as well. However, it was not the purpose of the present study to reiterate the sulphur ion chemistry in detail discussed previously for OCS (5). Rather, it was the intention to see if different additives provide distinctive sulphurous cation signals at various points in the flame which can be identified with a particular additive.

Mass spectra were scanned in the range 10–110 u in the undoped flame and in the flame doped separately with 0.2 mol% of H_2S, OCS, and SO_2. The spectra were measured at three

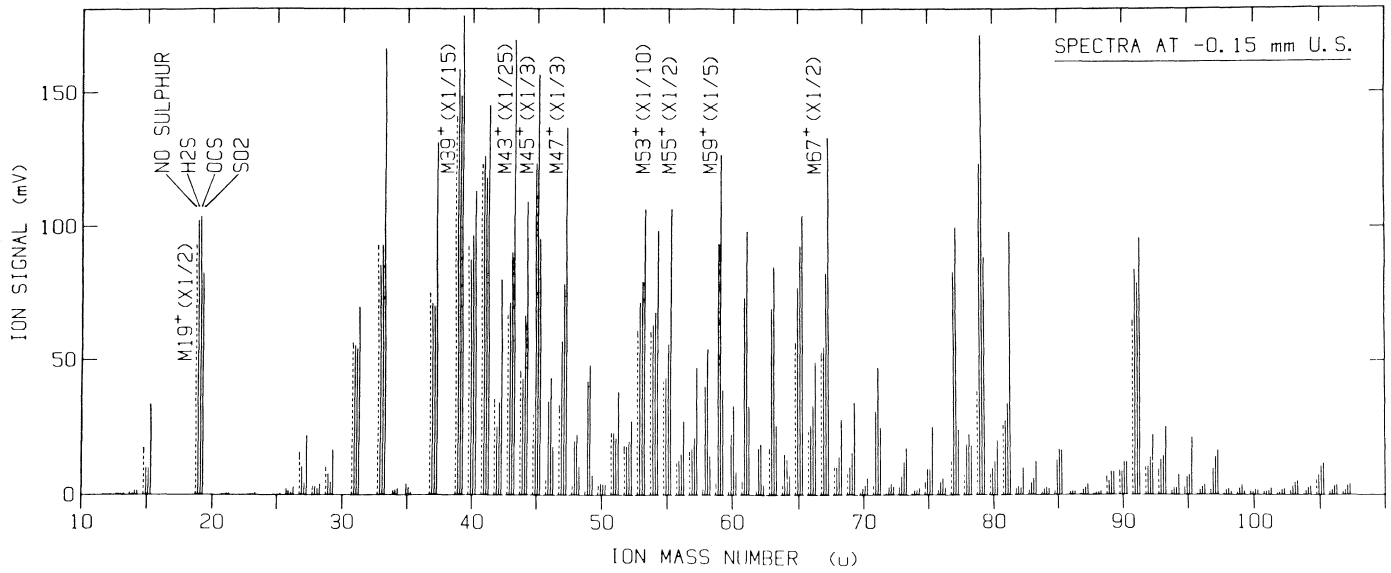

FIG. 4. Mass spectra measured at $z = -0.15$ mm upstream in the flame reaction zone. The spectra are presented in groups of four at each mass number corresponding (from left to right) to the undoped flame (dashed line) and the flame doped with 0.2 mol% of H_2S, OCS and SO_2 (solid lines).

fixed points on the flame axis: upstream in the reaction zone, near the peak of the total positive ion profile, and downstream in the burnt gas. Figure 4 refers to a point in the reaction zone at $z = -0.15$ mm upstream near the shoulder position on the total positive ion profiles. At each mass number, the spectra are presented in groups of four corresponding (from left to right) to the undoped flame (dashed) followed by the H_2S, OCS, and SO_2 additive signals. Essentially two types of behaviour are observed. Firstly, the presence of sulphurous cations is evident at those mass numbers where all three additives produce a substantial increase in signal magnitude compared with that of the undoped flame. Prominent examples occur at 45–49 u (CH_xS^+, x = 1–5), 58–61 u ($C_2H_xS^+$, x = 2–5), 71 u ($C_3H_3S^+$), 77–79 u ($CH_xS_2^+$, x = 1–3 and possibly also $(CH_3)_2SOH^+$ at 79 u), 85 u ($C_4H_5S^+$), and 97 u ($C_5H_5S^+$). Within many of these groups, the highest ion signal is observed with OCS, the next highest with H_2S, and the smallest with the SO_2 additive. As mentioned previously (5), OCS appears to be an effective donor of S atoms in ion–molecule reactions of the type

[5] $XY^+ + OCS \rightarrow XYS^+ + CO$

In general, most of the sulphurous cations involve the formation of a C—S bond. For a given ion, the relative signal magnitudes for the three additives correlate with the inverse order of their bond dissociation energies which is OC—S (71.6 kcal mol^{-1}) < HS—H (89.0) < OS—O (130.5). In the case of SO_2, both S—O bonds must ultimately be broken to form a $C_nH_xS^+$ ion but the initial formation of SO as a reactive intermediate is probably required for sulphurous cation formation.

The second type of behaviour is evident at mass numbers where the additives produce little change from the undoped flame signal (e.g. H_3O^+ at 19 u, $C_3H_3^+$ at 39 u, etc.). In a number of these cases, however, H_2S and OCS produce little change but SO_2 shows a substantial increase (e.g. protonated ions of formaldehyde CH_3O^+ at 31 u, methyl alcohol CH_5O^+ at 33 u, ketene $C_2H_3O^+$ at 43 u, and hydrated hydronium $H_5O_2^+$ at 37 u, etc.). The reason for the enhancement with SO_2 follows directly from the explanation already given for the upstream shoulders on the total ion profiles shown in Fig. 1. Negative ions are most readily formed with the electronegative SO_2 additive so that the loss rates of individual ions by electron–ion recombination and ambipolar diffusion are correspondingly decreased. In general, an increase in signal magnitude at a given mass number in the presence of a sulphur additive is not sufficient evidence for the production of a sulphurous cation, and caution must be exercised.

The prospects for the identification of a particular sulphur additive from the mass spectra are disappointing. This is exemplified in the present study involving the three additives H_2S, OCS, and SO_2 which occur early, intermediate, and late in the sulphur oxidation sequence. Distinguishable behaviour of different additives is most likely to be observable in the reaction zone before very much time for chemical reaction has elapsed. From these spectra it is evident that pyrolysis of the additive precedes the ion chemistry to a considerable degree such that all three additives show substantially the same sulphurous cation signals. Even the behaviour observed with SO_2 is not unique since any electronegative additive will show the same phenomenon. The high mobility of free electrons permits them to diffuse upstream against the flow to some degree where they attach to electronegative species to form negative ions; the process is aided by the lower upstream flame temperature.

The behaviour further downstream with the three additives is even more regular as equilibrium is approached. Figure 5 presents spectra at $z = 0.2$ mm, a point on the flame axis near the maximum of the total positive ion profiles. The same groups of four signals are given at each mass number for the updoped flame (dashed) and for the flame doped with H_2S, OCS, and SO_2. Series of sulphurous cations are evident at 34 and 35 u (H_2S^+ and H_3S^+, protonated HS and H_2S), 44–49 u (CH_xS^+, x = 0–5), 57–61 u ($C_2H_xS^+$, x = 1–5), 68–71 u ($C_3H_xS^+$, x = 0–3), 81–86 u ($C_4H_xS^+$, x = 1–6), and >92 u ($C_5H_xS^+$, $x > 0$) although the signal magnitudes are very small above 72 u.

Those ions which persist well downstream in the burnt gas are shown in Fig. 6 measured at $z = 1.5$ mm for the undoped and sulphur-doped flames. The usual signals are obtained for H_3O^+ (19 u) with its ^{18}O isotopic derivative (21 u) and first hydrate $H_5O_2^+$ (37 u). The presence of HCO^+ (29 u) is indicative of the

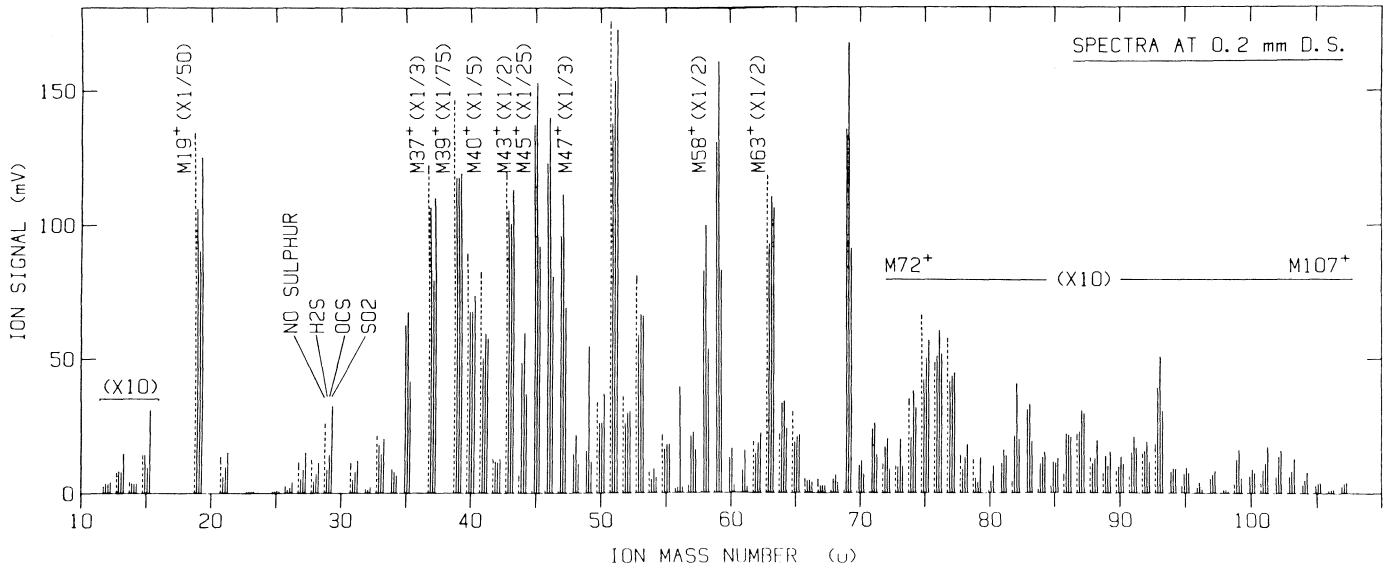

FIG. 5. Mass spectra measured at $z = 0.2$ mm, just downstream of the flame reaction zone. The spectra are presented in groups of four at each mass number corresponding (from left to right) to the undoped flame (dashed line) and the flame doped with 0.2 mol% of H_2S, OCS, and SO_2 (solid lines).

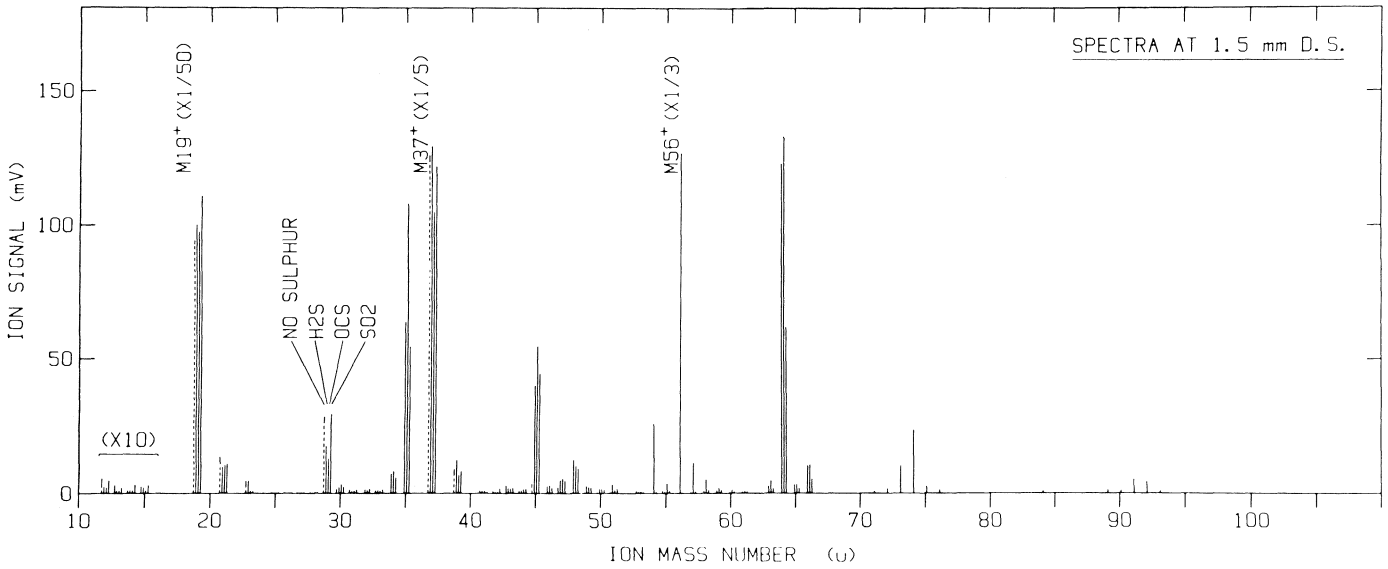

FIG. 6. Mass spectra measured at $z = 1.5$ mm downstream in the burnt gas. The spectra are presented in groups of four at each mass number corresponding (from left to right) to the undoped flame (dashed line) and the flame doped with 0.2 mol% of H_2S, OCS, and SO_2 (solid lines).

proton transfer equilibrium

[6] $HCO^+ + H_2O \rightleftharpoons H_3O^+ + CO$

where CO (mole fraction 0.30), not CO_2, is the major carbon-containing product in the burnt gas of this fuel-rich flame. The remnants of the very large $C_3H_3^+$ signal (39 u) are still observable, and a trace of Na^+ impurity (23 u) is observable too. The very curious groups of signals around 56, 74, and 91 u have been traced to $Fe(CO)_5$ present as an impurity in the lecture bottle of OCS. In addition to the major isotope ^{56}Fe (91.8% abundance), iron has the stable isotopes ^{54}Fe (5.8%), ^{57}Fe (2.1%), and ^{58}Fe (0.3%). The major isotope produces the ions Fe^+ (56 u), FeH^+ (57 u), $FeOH^+$ (possibly formed by protonation of FeO, 73 u), $Fe^+.H_2O$ (= protonated FeOH, 74 u), $FeOH^+.H_2O$ (= protonated $Fe(OH)_2$, 91 u), and $Fe^+.2H_2O$ (= the first hydrate of protonated FeOH, 92 u), with a hint of $FeCO^+$ (84 u). The same signals were reproduced by spraying an aqueous solution of $Fe(Cl)_3$ into the flame using an atomizer. A number of these iron ions, notably Fe^+ (56 u), are also evident in Fig. 5 for the OCS additive. The flame-ion chemistry of transition metals is the subject of ongoing research in our laboratory.

The persistent sulphurous cations in Fig. 6 include H_2S^+ (protonated HS, 34 u), H_3S^+ (protonated H_2S, 35 u) and the remnants of some of the CH_xS^+ ions ($x = 0$–5 at 44–49 u) whose profiles decrease to zero somewhat further downstream. Within this latter group, SO^+ (48 u) is evident for all three additives. Relatively large signals are obtained for S_2^+ (64 u) and its ^{34}S isotopic derivative (66 u, 4.2% natural abundance). The flame was doped separately with an equal concentration (0.2 mol%) of the three sulphur additives, although these sulphur compounds tend to "stick" in the tygon tubing connect-

ing the flow meter to the burner. Even allowing for some experimental variation in additive concentration, the sulphurous cation signals at a given mass number from the three additives are not constant. Evidently the sulphur species have not attained equilibrium 1.5 mm downstream of the reaction zone.

Conclusions

A fuel-rich, CH_4–O_2 flame was doped separately with 0.2 mol% of H_2S, OCS, and SO_2 chosen to be early, intermediate, and late in the oxidation sequence of fuel-sulphur. A number of conclusions can be drawn about the comparative behaviour of the three additives.

(*1*) A great variety of sulphurous cations is observed in the mass range 30–110 u, but the same cations are observed with all three additives.

(*2*) The total ionization profile is enhanced in the flame reaction zone when sulphur additives are present. The *magnitude* of the enhancement increases with increasing tendency of the additive to form negative ions.

(*3*) The *mechanism* of the enhancement involves a decreased rate of loss for positive ions when relatively fast cation–electron recombination and ambipolar diffusion are replaced by the corresponding cation–anion processes which have slower rates. The change of the recombination rate is probably the dominant effect.

(*4*) When a sulphur additive is present, the observation of an enhanced ion signal does not constitute *a priori* evidence for the formation of a sulphurous cation. The above mechanism is also applicable to non-sulphurous ions in the flame reaction zone, and caution must be exercised.

(*5*) This phenomenon is a rare case in flame-ion chemistry in which the positive ion chemistry and the negative ion chemistry interact, albeit indirectly.

(*6*) Just downstream of the reaction zone, the maximum total positive ion signal observed is the same whether or not a sulphur additive is present. This provides evidence that the sulphurous species are not involved in any new chemi-ionization reaction.

(*7*) Downstream throughout the burnt gas, the total ion signal is slightly enhanced when a sulphur additive is present. In general, sulphurous species have higher proton affinities than their oxygen analogues (17). The formation of a number of protonated sulphurous cations early in the burnt gas appears to delay the normal recombination of H_3O^+ ions to a region further downstream.

(*8*) Mass spectra of sulphurous cations scanned at fixed points in the flame are very similar for all three additives, even at an early stage in the flame reaction zone. Evidently appreciable pyrolysis of the sulphur additive precedes the ion chemistry.

(*9*) The mass spectra are not helpful in revealing the identity of the sulphur additive. The detailed sulphurous ion chemistry has already been discussed for the OCS additive (5). It is expected to be very similar for H_2S and SO_2, and also for other sulphur compounds present as fuel contaminants.

(*10*) For analytical or monitoring purposes, sulphurous cations are best observed just downstream of the flame reaction zone where the sulphur ion chemistry is fully developed. In order of increasing mass number or, coincidentally, decreasing signal size, the major ions occur at 45 u (CHS^+), 47 u (CH_3S^+), 58 u ($C_2H_2S^+$), 59 u ($C_2H_3S^+$), and 69 u (C_3HS^+). Most of the total sulphurous cation signal is encompassed by these five ionic species.

Dopamine, a physiologically important biogenic amine, is readily sulfoconjugated in vivo to give the 3- and 4-*O*-sulfates of pharmacologic importance. A major synthetic source of these esters has involved reaction of dopamine with sulfuric acid; however, the homogeneity of the products of this apparently straightforward reaction has been questioned. For this reason, in the present study this reaction was studied in considerable detail and our results establish that the concern about the authenticity and purity of dopamine-*O*-sulfates used for pharmacological studies is justified. In addition to the esters, difficultly separable dopamine-2, -5, and -6-sulfonic acids, plus several unidentified products, were obtained. A detailed account of the isolation and physicochemical characteristics of the identified products is presented. The dopamine-*O*-sulfates, whose structures have recently been established unequivocally by single crystal X-ray diffractometric analysis in this laboratory, were further characterized by means of mass (electron impact, field desorption, and fast atom bombardment) and ^{1}H and ^{13}C nuclear magnetic resonance spectroscopy. In addition, redox potentials for the isolated reaction products, as well as high performance liquid chromatography, thin-layer chromatography, and color reactions of the dopamine-*O*-sulfates, are reported. Thermolysis of the 3- and 4-*O*-sulfates yielded similar mixtures of products.

La dopamine, une amine physiologiquement importante, est facilement sulfoconjuguée in vivo, donnant les sulfates-3-*O* et -4-*O* de dopamine qui ont une importance pharmacologique. Une source synthétique principale de ces esters est la réaction de la dopamine avec l'acide sulfurique; cependant, l'homogénéité de ces produits a été mise en doute. Pour cette raison, cette réaction a été étudiée en détail. En plus des esters, les acides sulfoniques de la dopamine et de plusieurs autres produits non identifiés ont été obtenus. Un compte rendu detaillé du procédé de séparation et des caractéristiques physico-chimiques des produits identifiés est présenté. Les sulfates-*O* de la dopamine, dont les structures ont été établiés sans ambiguïté au moyen de l'analyse par diffraction d'un monocristal par les rayons X, ont été caracterisés de plus au moyen de la spectrométrie de masse et de la résonance magnétique nucléaire ^{1}H et ^{13}C. Les résultats obtenus indiquent que ces doutes concernant l'authenticité et la pureté des sulfates de dopamine utilisés dans les études pharmacologiques étaient justifiés. En plus, les potentiels oxydo-réducteurs des produits isolés, la chromatographie en phase liquide, la chromatographie en couche mince et les analyses des couleurs de réaction des sulfates-*O* de dopamine sont aussi décrits dans ce rapport. La thermolyse des sulfates-3 et -4-*O* ont donnés des mélanges semblables.

Dopamine (**1**) is an important neurotransmitter and biosynthetic intermediate in the conversion of tyrosine to the biogenic amines norepinephrine (**2**) and epinephrine (**3**) (1). Both dopamine and its metabolites undergo extensive sulfoconjugation in humans and animals (2). High performance liquid chromatographic (hplc) analysis of human urine (3) indicates that the major metabolic products are the *O*-sulfates **4** and **5**. The possible physiological role of these conjugates has received considerable attention in recent years; however, their precise function is uncertain. They may simply represent metabolic products that are readily eliminated (4). Alternatively, they may act as protected forms of the biogenic amine, which serve as a reservoir that can be transported in the mammalian system to release dopamine via sulfatase catalyzed hydrolysis (5). Jenner and Rose (6) in 1973 first demonstrated the in vitro conversion of dopamine to its 4-*O*- (**4**) and 3-*O*-sulfates (**5**) by phenolsulfotransferase-containing rat liver preparations. These researchers also reported the preparation of **4** and **5** by treating dopamine with concentrated sulfuric acid (6). For the past ten years, dopamine-*O*-sulfates used for pharmacological studies have derived primarily from this procedure. Unfortunately, until recently the chemical characterization and homogeneity of these products had not been established unequivocally (7).

For this reason, as described in this paper, we undertook a critical examination of the reaction between dopamine and concentrated sulfuric acid under identical conditions (6), giving particular emphasis to spectral and physicochemical characterization of the products. Fractionation of the reaction products by Dowex (H^+ and $\bar{O}Ac$) column chromatography was accomplished as described in the literature (6). The course of fractionation was monitored by thin-layer chromatography (tlc) using ultraviolet light (uv), ninhydrin, and Gibbs' and Pauly's reagents for visualization. More importantly, unlike the literature procedure, selected chromatographic fractions were examined by FT (Fourier transform) ^{1}H nmr spectroscopy. This eventually led to the isolation of hitherto unknown nuclear sulfonated products together with the dopamine-*O*-sulfates; of special interest was the isolation of dopamine-2-sulfonic acid.

The initial fractions of the column chromatography (see Experimental) yielded two crystalline products. On the basis

of FT ^{1}H nmr spectroscopy these substances were identified as dopamine-6- and -5-sulfonic acids (**7**, **8**), respectively.[4] Perhaps significantly, these products, which were not described in the original report (6), have tlc mobility profiles that are remarkably similar to those of dopamine-3-*O*-sulfate (**5**) and its 4-isomer (**4**). For this reason, ^{1}H nmr examination of the reaction product is a particularly important determinant of homogeneity.

Further elution of the Dowex (H^+) column with water yielded dopamine-4-*O*-sulfate, mp 265–267°C, whose ^{1}H nmr spectrum was consistent with the structure. Compared to dopamine, the aromatic proton on C-5 (δ 7.06, *ortho* coupled, J = 8.11 Hz) was deshielded by the 4-sulfate ester (Δδ 0.38 ppm). The mother liquors of the above crystalline crops were pooled and chromatographed over a Dowex ($\bar{O}Ac$) column. Elution of the column with 0.05 *M* HOAc yielded a further crystalline material. This was identified as dopamine-2-sulfonic acid (**9**) by ^{1}H and ^{13}C nmr spectroscopy.

Interestingly, **9** is slightly more mobile than dopamine and the tlc spot turns characteristically pink upon standing in air. Further elution of the column with 0.15 *M* HOAc yielded fractions that upon crystallization from water gave additional dopamine-4-*O*-sulfate, mp 257–258°C. The mother liquors of the crystalline crops were pooled and chromatographed over a Dowex ($\bar{O}Ac$) column to give dopamine-3-*O*-sulfate, mp 268–270°C (dec.).[5] Again compared to dopamine, the proton on C-2 (δ 7.07, *meta* coupled, J = 1.5 Hz) was deshielded by the 3-sulfate ester (Δδ 0.44 ppm).

Some of the physicochemical properties of **4** and **5**, whose structures have been unequivocally confirmed by single-crystal X-ray diffractometric analysis in this laboratory (12, 14), were also examined. The ^{13}C nmr spectra of dopamine sulfonic acids (Table 1) are diagnostic. Interestingly, the sulfonic acid group had a greater deshielding effect at C-6 (Δδ 21.74 ppm) than at C-2 (Δδ 12.74 ppm) and at C-5 (Δδ 11.79 ppm). Relatively, the sulfonic acid group in the form of the *O*-ester (Table 2) has very little effect on the carbon shift, e.g. Δδ 3.17 ppm for **4** and 5.56 ppm for **5**.

In aqueous solution dopamine-3-*O*-sulfate (**5**) failed to undergo appreciable hydrolysis upon standing at room temperature for eight hours. Conversely, under similar conditions or upon storage of an aqueous solution at 0–5°C for several days, **4** was partially hydrolyzed to dopamine in tlc detectable amounts. However, identical hydrolytic behavior of the two *O*-sulfates was observed during our cyclic voltametric measurements in phosphate buffer at pH 7.4, where a second peak at 0.24 and 0.28 volts appeared to originate from hydrolysis of dopamine-4-*O*- and -3-*O*-sulfates, respectively. The cyclic voltammograms of the sulfonic acids (Table 3) showed a characteristic oxidation at 0.40 V against a standard calomel electrode. This value is considerably lower than those observed for the *O*-methyl or *O*-sulfate derivatives. Thus this procedure offers a means to distinguish the sulfonic acid derivatives from the *O*-sulfates at relatively low concentrations. Thermolysis of dopamine-*O*-sulfates, like treatment of **1** with concentrated sulfuric acid, gave an array of products of which the dopamine sulfonic acids are the major identifiable products. Perhaps significantly, the overall ratios of identifiable products from both reactions are almost similar. This suggests that the dopamine sulfonic acids (**7**, **8**, and **9**) may be thermolytic products originating from dopamine-*O*-sulfates that may be the primary reaction products deriving from sulfation of **1**.

The mass spectra of dopamine-*O*-sulfates and sulfonic acids have been studied in some detail using electron impact, field desorption (FD), and fast atom bombardment (FAB) techniques. The FAB and FD mass spectra of dopamine-3-*O*-sulfate display relatively more intense peaks at m/e 153 than do those of dopamine-4-*O*-sulfate. This fragment, resulting from the expulsion of SO_3, seems a characteristic feature of dopamine-3-*O*-sulfate. The peak at m/e 169 represents the benzylic ion fragment containing a cyclic sulfate unit, i.e., **10**, which may also exist as the corresponding tropylium ion. The expulsion of SO_3 as well as of the $—CH_2NH_2$ unit of the ethylamine side chain to yield the benzylic ion fragment **11** seems a common feature among both dopamine sulfonic acids and dopamine-*O*-sulfates.

In summary, in our study possible contaminants in dopamine-*O*-sulfates prepared by the sulfation method have been identi-

[4]After our isolation of **7** and **8**, Osikowska *et al.* (8) employed preparative hplc to isolate a product, mp 272–275°C (dec.) from the sulfation of dopamine. This was identified as dopamine-6-sulfonic acid on the basis of ^{1}H nmr spectroscopy. The published ^{1}H nmr spectrum corresponds to that of our crystalline dopamine-6-sulfonic acid (**7**), mp 215–220°C; however, the reported mp corresponds more closely to that of our crystalline dopamine-5-sulfonic acid (**8**), mp 279–283°C. This inconsistency is unexplained.

[5]Melting points reported for both **4** and **5** vary considerably. Thus mp's of 257–259°C (9), 264–265°C (10), 278–280°C (11), 265–267°C (12), and 273–274°C (13) have been reported for **4** and mp's of 275–277°C (11), 254–256°C (10), and >250°C (9) are given for **5**. We have isolated various analytically pure crystalline crops with different degrees of hydration and melting point range. All these preparations displayed identical high-field nmr spectral features. Thus, for an unambiguous identification of dopamine-*O*-sulfate, one must rely on the proton nmr, not on the melting point, of the crystalline material.

fied and characterized. Thus, caution should be exercised in evaluating reported pharmacological data for dopamine-3- and -4-*O*-sulfates prepared by treatment of dopamine with concentrated sulfuric acid. This method is impracticable for the synthesis of dopamine-3-*O*-sulfate, unlike that of dopamine-4-*O*-sulfate, since it involves a tedious isolation procedure coupled with a low yield. The recently reported synthetic procedure (9) is clearly preferable for the preparation of the former.

Experimental

Melting points were obtained using a Thomas–Hoover Uni-Melt® capillary melting point apparatus and are uncorrected. Electron impact, field desorption (FD), and fast atom bombardment (FAB) mass spectra were recorded on Varian Mat CH-5 DF and VG ZAB 1-F mass spectrometers, respectively. FAB mass spectra were run in glycerol DMF matrix. The ^1H and ^{13}C nmr spectra were obtained in DMSO-d_6 with a Bruker IWP 200 spectrometer; for the sake of brevity and relevance only the aromatic region is reported. The data in Table 2 were generated using a Bruker WP 360 spectrometer. Unless otherwise specified, hplc was performed on a Waters HPLC using Partisil 5-ODS-3 RAC II columns (5.0 μm, 10 cm, id 4.60 mm) with mobile phase (0.025 *M* $ClCH_2COOH$ and 0.001 *M* EDTA adjusted to pH 2.8 by NaOH plus 0.004 *M* *n*-octylamine) at 0.7 mL/min with a Kratos SF 769 detector at 280 nm. The tlc plates (Analtech 20 × 20 cm, prescored) were developed in a *n*-BuOH–HOAc–H_2O (4:1:5, upper phase) system. The tlc spots were visualized by uv light, aerial oxidation, ninhydrin, and Gibbs' and Pauly's reagents. The tlc plates sprayed with Gibbs' reagent (1% ethanolic solution of 2,6-dichloroquinone-*p*-benzoquinone-4-chlorimine) were exposed to ammonia vapors. Freshly dissolved Pauly's reagent (diazotized sulfanilic acid, 1%, aqueous Na_2CO_3 solution, 10%) was used for spraying purposes.

Cyclic voltammetry experiments were performed using EG&G Princeton Applied Research equipment including a Model 175 universal programmer and Model 173/179 potentiostat/digital coulometer. A three-electrode system consisting of a glassy carbon working electrode, a platinum wire auxiliary electrode, and a saturated calomel electrode was used for all voltammetric studies. The cyclic voltammograms were recorded on a Houston Instrument Model 2000 X–Y recorder with a scan rate of 200 mV/s. All samples were prepared at a 5 m*M* concentration using 0.1 *M* phosphate buffer at pH 7.4 as the supporting electrolyte.

Reaction of dopamine and concentrated H_2SO_4

Dopamine hydrochloride (4.0 g; 21 mmol), after being dried at 100°C over P_2O_5 *in vacuo* for 6 days, was added with vigorous stirring in small portions to 11 mL of concentrated H_2SO_4 (206 mmol; d = 1.84) maintained at 0°C throughout the experiment. The addition took about 53 mins. Stirring was continued for an additional 7 min. The reaction mixture was then quickly poured with vigorous stirring into 100 mL of water – crushed ice mixture and the resulting solution was immediately applied to a column (30 × 5 cm) of Dowex 50W (X8, 200–400 mesh, H^+ form, 450 g).

Fractionation and isolation of products

The column was eluted with water and fractions were collected at the rate of 20 mL/10 min (total fractions = 150); each fraction was evaluated by tlc and color reactions of the spot, pooled according to the R_f values and color reactions. Fractions 1–20 contained highly polar and uv positive material and the solutions were highly acidic. These fractions were not pursued. The tail fractions (101–150) upon lyophilization gave a trace of white solid material, which was combined with the mother liquors for Dowex (ŌAc) column chromatography (*vide infra*).

*Dopamine-6-sulfonic acid (**7**)*

Fractions 21–35 upon standing at 0–5°C gave crystalline material as stout rectangular crystals of dopamine-6-sulfonic acid (500 mg; overall yield: 8.2%): mp 215–220°C (dec.); tlc: R_f 0.40, spot turns brown upon standing in air; hplc: retention time 2.76 min; ^{1}H nmr δ: 7.34, 6.62 (s, 1H each); ms (70 eV) *m/e* (% relative abundance (% RA)): molecular ion at 233 absent, 153 (10; $M^+ - SO_3$), 124 (71, **11** + H), 123 (26, **11**); FD *m/e* (% RA): 233 (60, M^+), 123 and 153 absent; FAB (+ mode) *m/e* (% RA): 234 (44, *M* + 1), 153, 123, 124; (− mode): 232 (33, *M* − 1), 152, 121. *Anal.* calcd. for $C_8H_{11}NO_5S \cdot 1\ H_2O$: C 38.24, H 5.18, N 5.58, S 12.75; found: C 38.05, H 5.06, N 5.52, S 12.26. An aqueous solution on standing at room temperature develops coloration.

*Dopamine-5-sulfonic acid (**8**)*

The pool containing fractions 36–60 was lyophilized and crystallized from water to give dopamine-5-sulfonic acid (200 mg; overall yield: 3.3%); mp 279–283°C (dec.); tlc: R_f 0.29, spot turns brown in air; hplc: retention time 3.87 min; ^{1}H nmr δ: 6.84 (d, 1H, *J* = 2 Hz), 6.63 (d, 1H, *J* = 2 Hz); ms (70 eV) *m/e* (% RA): no molecular ion at 233, 153 (29, $M^+ - SO_3$), 124 (100, **11** + H), 123 (59, **11**); FD *m/e* (% RA): 234 (>90, *M* + 1), 123 and 153 absent; FAB (+ mode) *m/e* (% RA): 234 (78, *M* + 1), 153, 123, dimeric fragments: 466, 467; (− mode) *m/e* (% RA): 232 (100, *M* − 1), 153, 123. *Anal.* calcd. for $C_8H_{11}NO_5S \cdot H_2O$: C 38.24, H 5.18, N 5.58, S 12.75; found: C 38.37, H 5.32, N 5.49, S 12.56. A clear aqueous solution upon standing at room temperature decomposes to give a colored solution.

*Dopamine-4-*O*-sulfate (**4**)*

Lyophilization of fractions 61–100 yielded a white powder that after three crystallizations from water gave dopamine-4-*O*-sulfate (300 mg; overall yield: 4.9%); mp 265–267°C; hplc: retention time 8.04 min; ^{1}H nmr δ: 7.06 (d, H-5, *J* = 8.1 Hz), 6.74 (d, H-2, *J* = 2.1 Hz), 6.63 (dd, H-6, *J* = 2.1 and 8.1 Hz); ^{13}C nmr: see Table 2; ms (70 eV) *m/e* (% RA): no molecular ion at 233, 169 (3, 10), 153 (2, $M^+ - SO_3$), 124 (19, **11** + H), 123 (8, **11**); FD *m/e* (% RA): 234 (27, *M* + 1), 154 (5), 153 (2, $M^+ - SO_3$), 124 (1), 123 (absent); FAB (+ mode) *m/e* (% RA): 234 (3, *M* + 1), 153 (1), 124 (0.3), 123 (0.7); (− mode): 232 (11, *M* − 1), 151 (6), 122, 121 (absent). *Anal.* calcd. for $C_8H_{11}NO_5S \cdot 0.5\ H_2O$: C 39.67, H 4.96, N 5.79, S 13.22; found: C 39.40, H 4.80, N 5.82, S 13.25.

*Dowex 1 (X8, ŌAc) column chromatography: dopamine-2-sulfonic acid (**9**)*

The mother liquors of the above crystalline crops containing some dopamine were combined and applied on a column of Dowex 1 (X8, 200–400 mesh, ŌAc form, 500 g) and eluted with water (2 L). Elution of the column with 0.05 *M* HOAc (200 mL) followed by lyophilization and crystallization from water yielded dopamine-2-sulfonic acid (**9**, 150 mg; overall yield: 3.1%); mp 260°C; tlc: R_f 0.58, spot turns pink in air; hplc: retention time 4.68 min: FT ^{1}H nmr δ: 6.57 (AB quartet, 2H, *J* = 8.0 Hz); ms (70 eV) *m/e* (% RA): molecular ion at 233 absent, 153 ($M^+ - SO_3$), 154 (M + 1 − SO_3), 123 (31, 11), 124 (87, **11** + H); FD *m/e* (% RA): 234 (*M* + 1), 233 (100, M^+), 154, 153; FAB *m/e* (% RA) (positive mode): 234 (85, *M* + 1), dimeric fragments: 466, 467. *Anal.* calcd. for $C_8H_{11}NO_5S \cdot 0.5\ H_2O$: C 39.67, H 4.96, N 5.79; found: C 39.82, H 4.84, N 5.34.

*Dopamine-3-*O*-sulfate (**5**)*

Elution of the above column with 0.15 *M* HOAc (500 mL) and 0.5 *M* HOAc (200 mL) gave 20-mL fractions, which were evaluated by tlc and Pauly's reagent. Fractions showing yellowish-pink color were pooled, lyophilized, and crystallized from water. The crystalline crops (mp 257–258°C) were identified as dopamine-4-*O*-sulfate by 360-MHz ^{1}H nmr spectroscopy. The mother liquors of the crystalline crop were chromatographed over Dowex 1 (X8, 200–400 mesh, ŌAc form, 100 mL) and eluted with 0.15 *M* HOAc (200 mL) and 0.5 *M* HOAc (75 mL). Fractions showing pink reactions with Pauly's reagent were pooled, lyophilized, and crystallized from water to give dopamine-3-*O*-sulfate (8 mg; overall yield: 0.13%); mp 268–270°C (dec.); hplc: retention time 7.53 min; 360-MHz ^{1}H nmr δ: 7.07 (d, 1H, *J* = 1.5 Hz), 6.86–6.76 (m, 2H); ^{13}C nmr: see Table 2; ms (70 eV) *m/e* (% RA): no molecular ion at 233, 169 (1, 10), 153 (50, $M^+ - SO_3$), 124 (100), 123 (74, **11**); FD *m/e* (% RA): 234 (12, *M* + 1), 154 (59), 153 (6), 124 (0.24), 123 (1); FAB (+ mode) *m/e* (% RA): 234 (34, *M* + 1), 154 (15), 153 (8), 124 (4), 123 (1.1); (− mode): 232 (100, *M* − 1), 153 (0.8), 152 (8), 123 (1), 122 (1). *Anal.* calcd. for $C_8H_{11}NO_5S$: C 41.20, H 4.75, N 6.01; found: C 40.98, H 4.76, N 5.96.

An aqueous solution of dopamine-3-*O*-sulfate standing at room temperature for 8 h did not show any decomposition to dopamine (by hplc and tlc), whereas dopamine-4-*O*-sulfate displayed some decomposition to dopamine (by tlc).

Redox potentials

Cyclic voltammetric measurements of dopamine, dopamine-*O*-methyl ethers, and dopamine sulfonation products were carried out in 0.1 *M* phosphate buffer at pH 7.4 using a glassy carbon paste electrode. The oxidation and reduction peaks are given in Table 3 with reference to a saturated calomel electrode.

*Thin-layer chromatography and color reactions of dopamine-*O*-sulfates*

Identical concentrations of the solutions of dopamine-*O*-sulfates were spotted on tlc plates (20 × 20 cm) and the plates were run in the same tank containing the upper phase of *n*-butanol – acetic acid and water (4:1:5). The plates were air dired and sprayed under identical conditions using dopamine (**1**) as a control. The results are given below:

	DA (**1**)	DA-4-*O*-sulfate (**4**)	DA-3-*O*-sulfate (**5**)
R_f	0.43	0.32	0.40
Aerial oxidation on plate	dark	light yellow	bright yellow
Ultraviolet light	++	+	++
Pauly's reagent	dark	yellow	pink
Ninhydrin	yellowish	brown	purplish brown
Gibbs' reagent	dark	blue	brown

Mixed spot analysis with authentic samples of dopamine-*O*-sulfates yielded identical results.

*Thermolysis of dopamine-*O*-sulfates*

A few crystals of dopamine-3-*O*-sulfate (mp 268–270°C) and dopamine-4-*O*-sulfate (mp 257–258°C) were allowed to melt in capillary tubes for less than a second. The capillary tubes containing the melt were immediately chilled and extracted with water. The tlc analysis of the extract revealed the presence of three sulfonic acids, proven by mixed spot analysis. The hplc analysis of the thermolysate of dopamine-3-*O*-sulfate revealed the presence of dopamine (20%), dopamine-6-sulfonic acid (21%), dopamine-5-sulfonic acid (38%), dopamine-2-sulfonic acid (7%), dopamine-3-*O*-sulfate (0.3%), dopamine-4-*O*-sulfate (7%), plus unidentified peaks with retention times 7.92 min (7%), 12.24 min (0.5%), and 18.93 min (2%). The hplc analysis of the thermolysate from dopamine-4-*O*-sulfate showed the presence of dopamine (19%), dopamine-6-sulfonic acid (19%), dopamine-5-sulfonic acid (20%), dopamine-2-sulfonic acid (3%), dopamine-3-*O*-sulfate (2%), and dopamine-4-*O*-sulfate (6%).

High performance liquid chromatographic analysis of dopamine-O-sulfates

The hplc analysis of **4** and **5** was demonstrated by using a sample of "dopamine-3-*O*-sulfate" prepared by the method of Jenner and Rose (6). Analysis of this sample using solvents A and B[6] in the ratio of 8:92 yielded a major peak with retention time of 5.79 min and a minor peak with retention time of 5.56 min, corresponding to dopamine-3-*O*- and -4-*O*-sulfates, respectively. The areas of two peaks were in the ratio of 6:1.

Acknowledgments

We are grateful to Drs. A. A. Manian and J. Stephen Kennedy of the NIMH for authentic synthetic samples of dopamine-*O*-sulfates and the samples prepared by the method of Jenner and Rose (6). The FD and 70-eV mass spectra reported herein were recorded by Walter Johnson.

Mobility of thermal cations in low density alkane gases[1]

NORMAN GEE, M. ANTONIO FLORIANO, AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 27, 1986

NORMAN GEE, M. ANTONIO FLORIANO, and GORDON R. FREEMAN. Can. J. Chem. **64**, 2423 (1986).

Mobilities μ of thermal cations were measured in gases of six linear *n*-alkanes, ethane to *n*-decane, and in *i*-butane and *neo*-pentane, as functions of density n and temperature T. The low density limit was reached where $n\mu$ and the temperature coefficient at constant n, $(dn\mu/dT)_n$, were constant. At all temperatures the average momentum transfer cross sections σ_{ave} equalled (1.2 ± 0.4) times the cross sections expected from simple polarization. At high temperature σ_{ave} might be approaching a hard sphere limit.

NORMAN GEE, M. ANTONIO FLORIANO et GORDON R. FREEMAN. Can. J. Chem. **64**, 2423 (1986).

On a mesuré les mobilités, μ, des cations thermiques dans des gaz de six *n*-alcanes linéaires, de l'éthane au *n*-décane, ainsi que dans l'isobutane et le néo-pentane; on a mesuré ces mobilités en fonction de la densité, n, ainsi que de la température, T. On atteint la limite minimale de la densité lorsque $n\mu$ ainsi que le coefficient de température à valeur constante de n, $(dn\mu/dT)_n$, sont constants. A toutes les températures, les sections droites moyennes des moments de transfert, σ_{ave}, sont égales à 1,2 ± 0,4 fois les valeurs auquelles on pourrait s'attendre pour les sections droites en se basant sur une polarisation simple. A des températures élevées, il est possible que les valeurs de σ_{ave} approchent une limite de sphère dure.

[Traduit par la revue]

Introduction

We have previously reported mobility values μ for radiolytically generated cations in simple molecular fluids (1) and hydrocarbons (1–3) over wide ranges of conditions, from the normal liquid where μ is determined by the fluid viscosity η to moderately dense gases where the number density n determines μ. The transition between viscosity and density control occurred at $0.6 \lesssim \eta/\eta_c \lesssim 3$ (subscript c denotes critical fluid), corresponding to $0.5 \lesssim n/n_c \lesssim 1.9$. This transition zone is the dense gas – low density liquid region. Clustering effects were important, especially in the saturated gas. In hydrocarbon gases, clustering persisted down to the lowest n used and appeared as a density dependence of $n\mu$ and of $(dn\mu/dT)_n$, the temperature coefficient at constant n. In ethene and cyclopropane gases density independence of $n\mu$ and of $(dn\mu/dT)_n$ was reached at $n < 3 \times 10^{25}$ molecules/m^3 (4). The present work extends measurements of μ in alkanes to $n < 3 \times 10^{25}$.

Experimental

The suppliers of the hydrocarbons, the purification techniques, a diagram of a conductance cell, a listing of the voltage supplies, a description of temperature control and sources of density values are given in ref. 5. A sample current against time signal trace, a description of the signal amplifier and data collection system, and the method of checking that results at high temperature are free from effects of thermal decomposition of the hydrocarbons or outgassing of the cell are given in ref. 4.

To obtain the mobility we ionized the sample in the conductance cell with a 100 ns pulse of X rays from a van de Graaff accelerator. The pulse delivers $\sim 6 \times 10^{10}$ eV/g to the sample. The ion drift distance l in the conductance cells was measured directly with an inside micrometer to within ±0.001 cm; values for the five cells used ranged from 0.465 to 1.058 cm. The drift time t_d was measured from a current–time trace (see Fig. 1 of ref. 4), and $\mu = l^2/Vt_d$.

Results and discussion

A. Field independence

The mobility was measured typically at field strengths $0.4 \leq (E/n)(\text{Td}) \leq 5$, where Td = 10^{-21} V m^2/molecule; occasionally fields as low as 0.13 Td and as high as 50 Td were used. No field dependence was found. At each (n,T) more than 10 measurements (half using positive and half with negative applied voltage) were averaged to give μ with average deviation of 1–3%.

The density normalized mobilities $n\mu$ in the saturated vapors are in Fig. 1. The nonsaturated gases are used to study the effect of temperature on $n\mu$. The effect is more clearly shown by normalizing the different density sets to an average $n\mu$ at a given T (4). The present results (Fig. 2) were normalized at 294 ± 1 K to (10^{21} molecules/m V s): C_2H_6, 2.82; C_3H_8, 1.86; *n*-C_4H_{10}, 1.32; *i*-C_4H_{10}, 1.35; *n*-C_5H_{12}, 1.07; *neo*-C_5H_{12}, 1.23. The exceptions were $n\mu$ for *n*-C_8H_{18} which were normalized to 6.14×10^{20} molecules/m V s at 382 K and *n*-$C_{10}H_{22}$ which were not normalized. The average change in $n\mu$ on normalization was ±3% and the maximum change 8%.

Ion mobilities are often referenced to $n = 2.69 \times 10^{25}$ molecules/m^3 and symbolized as K_0. The present results (Figs. 1 and 2) can be expressed as K_0 using K_0 (cm^2/V s) = $n\mu$ (molecules/m V s)/2.69×10^{21}.

The observed mobilities are independent of applied field strength because the threshold for ion heating was not reached. Ion heating is appreciable when the ion drift velocity $v_d = \mu E$ approaches the speed of random thermal motion of the molecules, $v_{mol} = (3k_BT/M_{mol})^{1/2}$ where k_B is Boltzmann's constant and M_{mol} is the molecular mass (6, 7). This indicates that the threshold field for ion heating is

$$E_{thr} \approx v_{mol}/\mu \text{ (low field)}$$

or

$$[1] \quad (E/n)_{thr} \approx v_{mol}/n\mu \text{ (low field)}$$

Equation [1] gives $(E/n)_{thr} \approx 160$ Td in ethane at 293 K (2*b*).

In many cases ion heating is observed when v_d approaches the speed of sound c_0 in the gas (8, 9). This result is similar to [1], because $c_0 = (\gamma k_BT/M_{mol})^{1/2}$, where the heat capacity ratio γ (10) ranges from 1.66 in ethane to 1.15 in *n*-decane (11). Hence $c_0 \approx 0.7v_{mol}$, which would give $(E/n)_{thr} \approx 110$ Td in ethane at 293 K. Similar calculations indicated that the values of $(E/n)_{thr}$ at 300 K in the other alkanes are larger than 110 Td.

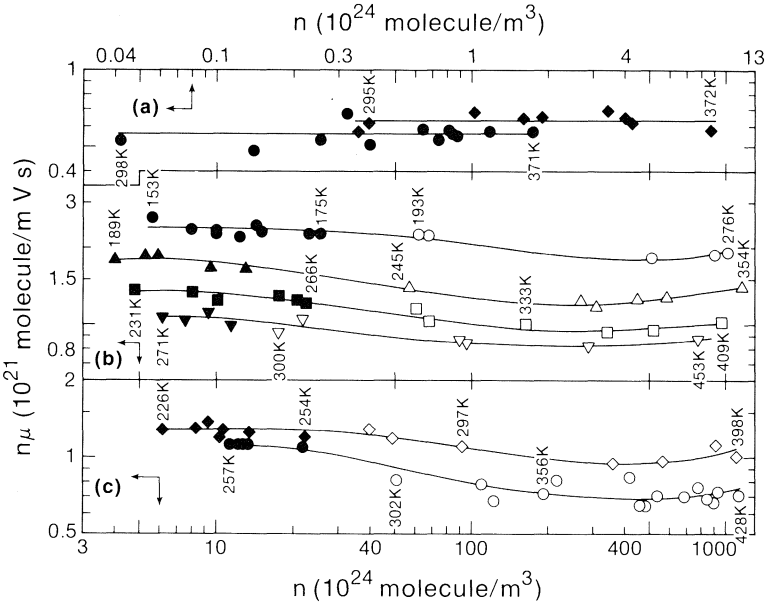

FIG. 1. Density dependence of $n\mu$ in saturated vapors: (*a*) *n*-octane, ◆; *n*-decane, ●; (*b*) ethane, ●, ○; propane, ▲, △; *n*-butane, ■, □; *n*-pentane, ▼, ▽. (*c*) *i*-butane, ◆, ◇; *neo*-pentane, ●, ○. Solid symbols are present work. Open symbols are refs. 2*b* and 3. The temperatures for some $n\mu$ accompany the symbol.

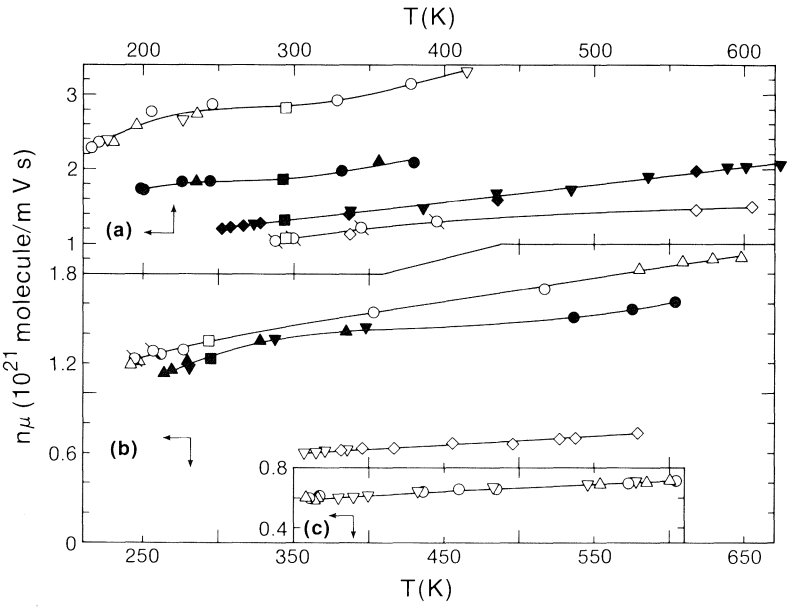

FIG. 2. Temperature dependence of present $n\mu$ values in nonsaturated gases at ($n/10^{25}$ molecules m^{-3}): (*a*) ethane, ○ (1.40); ▽ (1.50); △ (2.70); propane, ● (0.69), ▲ (1.38); *n*-butane, ◆ (1.10), ▼ (2.26); *n*-pentane, ◇ (0.59), ⬡ (1.13); (*b*) *i*-butane, △ (1.17), ⬡ (1.46), ○ (2.56); *neo*-pentane, ● (0.59), ▲ (1.37), ▼ (2.63); *n*-octane, ▽ (0.485), ◇ (0.99); (*c*) *n*-decane, △ (0.096), ○ (0.105), ▽ (0.228). □, ■: average of room temperature values, used to normalize the different density sets to remove random scatter produced by uncertainties in the gas densities and cell dimensions. The *n*-octane values had been normalized at 382 K by shifting one set up and the other down by 2.3%.

All of our measurements were taken at E/n less than $(E/n)_{thr}$, therefore the mobilities are those of thermal cations.

B. Low density limit

At constant T, low n and very low ion mole fraction the product $n\mu$ should be independent of n (6). Along the liquid–vapor coexistence curve n and T increase concomitantly; a 10-fold increase in n can occur for a 1.3-fold increase in T (Fig. 1). Since at constant n, the temperature coefficient $(dn\mu/dT)_n \geq 0$ (2*b*), then in saturated gases $dn\mu/dn \geq 0$ was expected. However, at $n > 2 \times 10^{25}$ molecules/m^3 we found that $n\mu$ in most hydrocarbon gases initially *decreased* before increasing at yet higher n (refs. 2*b*, 3 and Fig. 1).

At these densities $(dn\mu/dT)_n$ increased strongly with n. In terms of an Arrhenius model, the activation energy at constant n in C_2–C_4 alkanes increased from ~3 kJ/mol at $\sim 0.07 \times 10^{27}$ molecules/m^3 to ~13 kJ/mol at $\sim 1.4 \times 10^{27}$ and ~30 kJ/mol at $n_c = (3 \pm 1) \times 10^{27}$ molecules/m^3 (2*b*). Hence $dn\mu/dn < 0$ in the saturated gas was attributed to clustering of neutral molecules on the cations yielding lowered $n\mu$ values (1, 2*b*).

We chose therefore to consider the low density limit for cation behavior to be attained when $n\mu$ (T) and hence

[c]Equation [6].
[d]Bimolecular neutral–neutral cross section from Lennard–Jones diameter, ref. 20.

$(dn\mu/dT)_n$ becomes density independent. At such densities $n\mu$ in the saturated gas is also expected to be approximately constant over a fairly large range in n, as it would correspond to a small range in T (Fig. 1 and ref. 4). For cations in ethene and cyclopropane the low density limit was reached at $n < 3 \times 10^{25}$ molecules/m^3 (4). All the present measurements were near or at the low density limit (Figs. 1 and 2).

C. Average cross sections

The product $n\mu$ is related to the average ion–molecule momentum transfer cross section σ_{ave} by (12):

$$[2] \quad \sigma_{ave} = (3e/4M_r)/\langle v\rangle n\mu$$

where M_r is the ion–molecule reduced mass, e the protonic charge, v the relative velocity of the ions with respect to the molecules, and for a Maxwellian distribution,

$$[3] \quad \langle v\rangle = (8k_BT/\pi M_r)^{1/2}$$

The averaging in eq. [2] is equivalent to:

$$[4] \quad \sigma_{ave} = \langle v^3\sigma_m\rangle/\langle v^3\rangle$$

where σ_m is the momentum transfer cross section. Equation [2] is derivable from eq. [5-3-18] of ref. 6 in which $\overline{\Omega}^{(1,1)}$ is σ_{ave}. For N_4^+ in N_2, σ_m at low collision energy $\xi = M_r v^2/2$ was equal to that of the simple polarization potential σ_{pol}, and at high ξ it was close to the hard sphere value for N_2–N_2 collisions (13). This behavior is expected from the Langevin model (14, 15).

In the radiolysis of the present hydrocarbons, the initial monomer or dimer cations (16–18) might polymerize with product olefins, so M_r in eqs. [2] and [3] can vary from $0.5M_{mol}$ to M_{mol}. Using $n\mu$ from Fig. 2 and $M_r = M_{mol}$ gave lower limit values of σ_{ave} (Table 1). At a given temperature increasing the carbon skeleton length from ethane to n-octane increased σ_{ave}; on going from n-octane to n-decane σ_{ave} seemed to decrease ~9%. Comparison of n- and i-butane σ_{ave} at a given T revealed little isomeric structure effect, but σ_{ave} in neo-pentane was consistently less than in n-pentane at the same T. This is attributed to fragmentation of the neo-pentane ions to t-butyl ions. Our previous finding of a larger σ_{ave} in neo-pentane at 7.2×10^{25} molecules/m^3 than in n-pentane at 2.25×10^{25} (3) is due to the effect of density at $n > 3 \times 10^{25}$ (Fig. 1).

The σ_{ave} values can be compared with values of the average polarization $\sigma_{pol,ave}$. Substitution of σ_{pol} (15)

$$[5] \quad \sigma_{pol}/m^2 = 2.21\pi(\alpha e^2/32\pi^2\epsilon_0^2\xi)^{1/2}$$

where α (C m^2/V) is the polarizability of the molecule and ϵ_0 is the permittivity of vacuum, into eq. [4] gives

$$[6] \quad \sigma_{pol,ave}/m^2 = 0.0133(\alpha/4\pi\epsilon_0 T)^{1/2}$$

Values of $\alpha/4\pi\epsilon_0$, corresponding to polarizability in the non-SI units of volume, were taken from ref. 19 to calculate values of $\sigma_{pol,ave}$ listed in Table 1. At all temperatures the ratio of experimental to polarization average cross section expt/pol equalled 1.2 ± 0.4. This is much different from the case of electron scattering in these same gases where expt/pol ranged from 0.02 to 0.2 (5).

At high temperatures σ_{ave} might be expected to approach a hard sphere value σ_{hs} (14, 15). A lower limit to σ_{hs} is the neutral molecule – neutral molecule cross section $\sigma_{mol} = \pi d_{LJ}^2$, where d_{LJ} is the Lennard–Jones diameter (20); multimer formation would increase σ_{hs}, so $\sigma_{hs} > \sigma_{mol}$ would result. Values of σ_{mol} from ref. 20 are listed in Table 1. Above 600 K σ_{ave} approaches σ_{mol}. However, even in the butanes where $\sigma_{ave} < \sigma_{pol,ave}$ at $T > 620$ K, σ_{ave} is still about 20% larger than σ_{mol}. These results are consistent with either incomplete transition between polarization and hard sphere potential controlling the mobility, or with the cations being multimers.

Short synthesis of 1,3*Z*,6*Z*,9*Z*-tetraene hydrocarbons. Lepidopteran sex attractants[1]

JOCELYN G. MILLAR[2] AND EDWARD W. UNDERHILL

National Research Council, Plant Biotechnology Institute, 110 Gymnasium Road, Saskatoon, Sask., Canada S7N 0W9

Received May 13, 1986

JOCELYN G. MILLAR and EDWARD W. UNDERHILL. Can. J. Chem. **64**, 2427 (1986).

A short, convergent synthesis of 1,3*Z*,6*Z*,9*Z*-tetraene hydrocarbons was developed. A key step was the regioselective alkylation of 1,5-dibromo-2-pentyne. The method was used to synthesize tetraenes of chain lengths C_{18}–C_{20}, to be used in field trials as sex attractants and (or) inhibitors of the winter moth, *Operophtera brumata* L., and the Bruce spanworm *O. bruceata* H. (Lepidoptera: Geometridae).

JOCELYN G. MILLAR et EDWARD W. UNDERHILL. Can. J. Chem. **64**, 2427 (1986).

On a mis au point une courte synthèse convergente des hydrocarbures tétraéniques-1,3(*Z*),6(*Z*),9(*Z*). Une étape clé implique l'alcoylation régiosélective du dibromo-1,5 pentyne-2. On a utilisé la méthode pour synthétiser des tétraènes comportant de 18 à 20 atomes de carbone; on a utilisé ces hydrocarbures pour déterminer leurs propriétés comme attractant sexuel et (ou) inhibiteurs des espèces *Operophtera brumata* L. et *O. bruceata* H. (Lepidoptera; Geometridae).

[Traduit par la revue]

To date, two 1,3*Z*,6*Z*,9*Z*-tetraene hydrocarbons **1** (Scheme 1) have been reported as lepidopteran sex attractants. These are the nonadecatetraene **1***b*, which appears to be the sole component in the sex pheromone of the winter moth, *Operophtera brumata* L. (Lepidoptera: Geometridae) (1, 2), and the heneicosatetraene **1***d*, which is one of several components in the sex pheromone of *Utetheisa ornatrix* L. (Lepidoptera: Arctiidae) (3). As these homologous hydrocarbons were found in species from two different families, it is very likely that these compounds or their homologs are sex pheromone components for other lepidopteran species as well (4). As part of our work in screening potential sex attractants, we were interested in obtaining a series of these compounds for field testing. In particular, we wanted the tetraenes **1***a–c* to test as sex attractants and (or) inhibitors for two sympatric species, *O. brumata*, mentioned above, and the Bruce spanworm, *O. bruceata* H. Both species are morphologically very similar, and can only be differentiated by dissection. In addition, they both appear to use the nonadecatetraene **1***b* as a sex attractant (1). One species, *O. brumata*, is an economic pest of hardwoods and fruit trees (1), while the other is of lesser economic importance (5, 6). It would therefore be advantageous to develop sex attractant lures that were specific for each species.

To construct efficiently the series of homologous tetraenes, we required a common intermediate to which a chain of varying length could be appended. Of the five previously reported syntheses of tetraenes of this type, three routes (2, 7, 8) involved progressive extension of the carbon skeleton from the saturated end of the chain, which is not efficient for synthesis of a series of homologs. The other two routes (4, 9), one of which (9) appeared while our work was in progress, were amenable to synthesis of a homologous series. However, both routes made use of protecting groups, thus necessitating extra steps for the introduction and removal of these groups, and for the subsequent manipulation of the deprotected functionality. We felt that a considerably shorter synthesis that did not require protecting groups could be devised, by judicious choice of the sequence of steps and of regioselective reaction conditions.

This more direct approach has proven to be successful (Scheme 1). Thus, cuprous salt-catalyzed reaction of 3-butyn-1-ol **2** with aqueous formaldehyde gave diol **3** (55–62%) (10). The diol was converted to the dibromide **4** (89%) by treatment with carbon tetrabromide and triphenylphosphine (11). The diynes **6***a–c* required for the alkylation step were constructed by cuprous salt-catalyzed reaction of the Grignard reagent of the appropriate terminal alkyne **5** with propargyl bromide (12, 13). Cuprous iodide-catalyzed reaction of the Grignard reagents of the diynes **6** with dibromide **4** (12, 13) selectively gave the desired 1-bromo-3,6,9-alkatriynes **7**, contaminated with small amounts (6–12%) of isomeric impurities. The impurities were easily removed by recrystallization of the crude bromotriynes from pentane at 0°C (64–69%). The pure bromotriynes **7** were stereoselectively reduced with dicyclohexylborane to the bromotrienes **8** (59–65%) (14, 15). In our hands, this method of partial hydrogenation has proven to be completely stereospecific, with no trace of *trans* isomers detected by capillary gc/ms of the crude product. In contrast, we and others (16) have found that catalytic semihydrogenation of methylene-interrupted poly-ynes is frequently beset with problems such as catalyst poisoning with trace impurities, isomerization of the resulting *cis* double bonds, and over-reduction.

The syntheses were completed by base-induced elimination of HBr. Thus, heterogeneous mixtures of potassium *tert*-butoxide, bromotrienes **8**, and phase transfer catalyst (18-crown-6), stirred in hexane at −10 to 0°C (17), gave tetraenes **1** (58–65% isolated yields). Temperature control was critical in this reaction, as warming the mixture to room temperature gave reduced yields and some isomerization, while the reaction proceeded very slowly below −15°C.

This method thus represents a short and highly stereoselective route to 1,3*Z*,6*Z*,9*Z*-tetraene hydrocarbons.

Experimental

All reactions were carried out under N_2, in oven-dried glassware. THF was distilled from benzophenone ketyl under N_2 before use. Routine capillary gc runs were carried out with a Hewlett–Packard 5790 instrument, fitted with DB-5 column (30 m × 0.25 mm). Proton nmr spectra were recorded at 360 MHz on a Bruker AM-360-WB spectrometer. The ir spectra were recorded on a Perkin–Elmer 237B instrument. Electron impact (EI) mass spectra (70 eV unless otherwise stated) were recorded on a Finnigan 4000E gc–ms unit with an Incos 2300 data system, using an SP2100 capillary gc column. The ms data are reported in the form *m/z* (relative intensity). Accurate mass measurements were performed by the Mass Spectrometry Laboratory, Psychiatric Research Unit, University of Saskatchewan, with an

Preparation of 2-pentyn-1,5-diol (3)

The preparation of **3** was a minor modification of that previously reported (8). Cuprous chloride (4.0 g, 40 mmol) was dissolved in 12% aqueous HCl (60 mL), and the solution was cooled in an ice bath. 40% Aqueous KOH (60 mL) was added dropwise over 1 h, giving a brown suspension. The mixture was filtered with suction, and the solid residue was washed well with water. The moist solid residue was added to a mixture of 3-butyn-1-ol **2** (13.0 g, 186 mmol), 37% aqueous formaldehyde (21.67 g, 267 mmol), water (4 mL), and $CaCO_3$ (0.2 g). The mixture was refluxed under N_2 for 3 days, cooled to room temperature, diluted with ethyl acetate (250 mL), and dried with anhydrous Na_2SO_4 (10 g). The mixture was filtered with suction through a plug (2.5 cm × 5 cm) of anhydrous Na_2SO_4, and the solids were rinsed thoroughly with ethyl acetate. The filtrate was concentrated and distilled, giving diol **3** as a viscous oil (10.23 g, 55%), bp 90–91°C (0.1 Torr (1 Torr = 133.3 Pa)) (lit. (10) bp 90–95°C (0.03 Torr)); ir (neat) λ_{max}: 3700–3000 (s), 2235 (w), 1100–990 (s) cm^{-1}; nmr (D_2O) δ: 4.09 (t, 2H, J = 2.1 Hz, H-1), 3.56 (t, 2H, J = 6.7 Hz, H-5), 2.35 (tt, 2H, J = 6.7, 2.1 Hz, H-4); ms: 100 (M^+, 0.03), 99 (0.24), 82 (20.6), 70 (7.5), 69 (8.5), 53 (20.8), 52 (100), 51 (18.9), 50 (12.5), 44 (13.9).

Preparation of 1,5-dibromo-2-pentyne (4)

A solution of diol **3** (2.0 g, 20 mmol) and carbon tetrabromide (14.94 g, 45 mmol) in dry CH_2Cl_2 (100 mL) was cooled to 0°C, and triphenylphosphine (11.79 g, 45 mmol) was added in portions over 20 min. The mixture was warmed to 20°C over 1 h. The CH_2Cl_2 was removed on a rotary evaporator, with no heating, and hexane (100 mL) was added to the residue. The mixture was cooled to 0°C and filtered. The solid residue was washed with ice-cold hexane (2 × 25 mL), and the filtrate was concentrated and distilled under vacuum. After a large forerun of bromoform and excess carbon tetrabromide, dibromide **4** was obtained as a pale yellow oil (4.01 g, 89%), bp 40–43°C (0.04 Torr); ir (neat) λ_{max}: 2240 cm^{-1} (w); nmr ($CDCl_3$) δ: 3.80 (t, 2H, J = 2.4 Hz, H-1), 3.33 (t, 2H, J = 7.2 Hz, H-5), 2.71 (tt, 2H, J = 7.2, 2.4 Hz, H-4); ms: 228 (3.5), 226 (6.8), 224 (3.5), 147 (55.1), 145 (56.7), 95 (2.8), 93 (3.5), 66 (50.4), 65 (100), 63 (11.7). *Exact Mass* calcd. for $C_5H_6{}^{79}Br_2$: 223.8836; found 223.9118.

Preparation of 1,4-diynes (6)

Ethyl magnesium bromide (approximately 65 mmol) was prepared from ethyl bromide (7.63 g, 70 mmol) and Mg turnings (1.58 g, 65 mmol) in THF (75 mL). 1-Decyne **5***a* (8.28 g, 60 mmol) was added dropwise, and the solution was heated at 40–45°C for 2 h. The solution was then cooled to < −10°C in an ice–salt bath, CuI (190 mg, 1 mmol) was added, and the mixture was stirred 20 min. Propargyl bromide (7.3 g, 61 mmol) was then added dropwise, maintaining the temperature < −10°C. The mixture was warmed to 20°C over 3 h, stirred overnight, quenched with aqueous NH_4Cl (100 mL), and extracted with hexane (3 × 100 mL). The combined organic extracts were dried (Na_2SO_4), concentrated, and distilled under vacuum, giving diyne **6***a* (7.85 g, 74%) as a colourless oil, bp 53°C (0.2 Torr), which yellowed rapidly upon exposure to air; ir (neat) λ_{max}: 3330 (m), 2960 (m), 2935 (s), 2860 (m), 2130 (w) cm^{-1}; nmr ($CDCl_3$) δ: 3.12 (dt, 2H, J = 2.7, 2.4 Hz, H-3), 2.13 (tt, 2H, J = 7.1, 2.4 Hz, H-6), 2.03 (t, 1H, J = 2.7 Hz, H-1), 1.46 (br quintet, 2H, J = 7.0 Hz, H-7), 1.4–1.1 (m, 10H, H-8 to H-12), 0.86 (t, 3H, J = 7 Hz, H-13); ms (25 eV): 176 (M^+, 0.1), 119 (20.4), 105 (35.7), 95 (29.5), 91 (100), 81 (46.7), 79 (32.6), 78 (27.0), 67 (40.2), 55 (44.8).

The known 1,4-tetradecadiyne **6***b* was similarly prepared in 75% yield, bp 65°C (0.15 Torr) (lit. (7) bp 125°C (25 Torr)). 1,4-Penta-

decadiyne **6***c* was prepared in 76% yield, bp 82°C (0.1 Torr). The ir and nmr spectra were analogous to those of **6***a*. Mass spectra (25 eV) were characterized by a base peak at m/z 91, diagnostic fragments at $M - 39$ (2–4%) and $M - 81$ (3–9%), and a series of ions at $M - C_nH_{2n+1}$. The molecular ion was very small or absent.

Capillary gc/ms showed that the diynes **6** were contaminated with small amounts of isomeric materials (≃5%). These isomeric impurities were carried through to the next step, where they were removed during the purification procedure. The diynes appeared to be stable for several months if stored at −25°C under N_2.

Preparation of 1-bromo-3,6,9-triynes (7)

Diyne **6***a* (1.85 g, 10.5 mmol) was added to a freshly prepared solution of ≃11.5 mmol of ethyl magnesium bromide (prepared from 280 mg Mg (11.5 mmol) and ethyl bromide (1.36 g, 12.5 mmol)) in THF (15 mL) at 20°C. The resulting solution was warmed at 40–45°C for 2 h, then cooled to 0°C, and CuI (95 mg, 0.5 mmol) was added. The mixture was stirred for 20 min, then cooled to < −15°C in an ice–salt bath, and a solution of dilbromide **4** (2.26 g, 10 mmol) in THF (5 mL) was added dropwise over 20 min. The mixture was warmed to 0°C over 2 h, stirred at 0°C for 8 h, and warmed to 20°C overnight. The mixture was poured into 5% aqueous NH_4Cl (50 mL), extracted with hexane (3 × 25 mL), backwashed with brine (1 × 25 mL), dried (Na_2SO_4), and filtered with suction through a plug (3 cm × 3 cm) of Na_2SO_4. The filtrate was concentrated under reduced pressure, and the residue was recrystallized from hexane at −25°C, giving **7***a* (2.21 g, 69%) as white plates, mp 26–27.5°C, which slowly yellowed after exposure to air and (or) light; ir (neat) λ_{max}: 2960 (m), 2930 (s), 2860 (m), 2215 (w) cm^{-1}; nmr ($CDCl_3$) δ: 3.39 (t, 2H, J = 7.4 Hz, H-1), 3.13 (m, 4H, H-5, H-8), 2.71 (tt, 2H, J = 7.4, 2.2 Hz, H-2), 2.13 (tt, 2H, J = 7.2, 2.2 Hz, H-11), 1.46 (m, 2H, H-12), 1.5–1.1 (m, 10H, H-13 to H-17), 0.86 (t, 3H, J = 6.7 Hz, H-18); ms (25 eV): 279, 277 ($M - 43$, 1.2), 155 (33.0), 143 (34.7), 137 (48.4), 129 (46.7), 128 (48.1), 95 (54.4), 91 (35.0), 82 (45.4), 81 (100), 67 (61.4). *Exact Mass* calcd. for $C_{18}H_{25}{}^{81}Br - C_3H_7$: 279.0572; found: 279.0493.

1-Bromo-3,6,9-nonadecatriyne **7***b* was similarly prepared in 81% crude yield. In this case the crude material was used directly in the next step; an analytical sample recrystallized from hexane at −10°C gave mp 30–32°C. 1-Bromo-3,6,9-eicosatriyne **7***c* was obtained in 64% yield after recrystallization from hexane, mp 35–37°C. The ir and nmr spectra of **7***b* and **7***c* were analogous to those of **7***a*. Mass spectra (25 eV) were characterized by a base peak at m/z 81, doublets of ions at (279, 277), (265, 263), etc., and diagnostic fragments at $M - C_8H_8Br$ (30–50%), $M - C_5H_6Br$ (9%), and m/z 211 (2–4%). The molecular ion was very small or absent.

The pure crystalline compounds gave a single peak on capillary gc, and appear to be stable when stored at −25°C under N_2.

Preparation of 1-bromo-3Z,6Z,9Z-trienes (8)

A suspension of dicyclohexylborane (21 mmol) was prepared by dropwise addition of cyclohexene (3.45 g, 42 mmol) to a solution of borane–dimethylsulfide complex (10 *M*, 2.1 mL, 21 mmol) in THF (25 mL), maintaining the temperature at 0–5°C. The resulting mixture was warmed to 20°C, stirred 2 h, then cooled to 0°C again, and bromotriyne **7***a* (1.61 g, 5.0 mmol) in THF (5 mL) was added. The mixture was warmed to 20°C over 2 h, and stirred an additional 2 h. Glacial acetic acid (8 mL) was then added dropwise and the resulting solution was stirred overnight. The solution was then cooled and made basic by slow addition of aqueous NaOH (5 *M*, 30 mL), followed by dropwise addition of 30% aqueous H_2O_2 (8 mL). The resulting mixture was diluted with water (100 mL) and extracted with pentane (3 × 50 mL). The combined organic extracts were dried (Na_2SO_4) and concentrated, and low-boiling by-products were removed by warming at 45°C under vacuum (0.1 Torr). The residue was purified by flash chromatography on silica gel (3.5 cm id × 20 cm), eluting with hexane, giving **8***a* (1.07 g, 65%) as a colourless oil, isomerically pure by capillary gc; ir (neat) λ_{max}: 3020 (m), 2960 (m), 2930 (s), 2860 (m), 1210 (m) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.51 (dtt, 1H, J = 10.7, 6.3, 1.4 Hz, H-4), 5.42–5.32 (m, 4H, H-3, H-6, H-7, H-10), 5.31 (dtt, 1H, J = 10.6, 6.9, 1.3 Hz, H-9), 3.36 (t, 2H, J = 7.1 Hz, H-1), 2.80 (m, 4H, H-5, H-8), 2.64 (m, 2H, H-2), 2.04 (m, 2H, H-11), 1.5–1.1 (m, 12H, H-12 to H-17), 0.86 (t, 3H, J = 6.9 Hz, H-18); ms: 328, 326 (M^+, 0.6), 188 (29.3), 186 (30.6), 95 (19.3), 93 (33.8), 82 (20.0), 81 (27.9), 80 (55.7), 79 (100), 67 (41.5), 55 (15.6).

Exact Mass for **8***a* could not be measured due to interference from the internal standard. *Exact Mass* for a pure sample of **8***b*, calcd. for $C_{19}H_{33}{}^{81}Br$: 342.2745; found: 342.1914.

Known triene **8***b* (4, 9) was similarly prepared from crude triyne **7***b*, in 71% overall yield from **4**. The isolated material was contaminated with isomers (7%), and was used in the next step without further purification. Triene **8***c* was prepared in 59% yield from pure **7***c*. The ir and nmr spectra of **8***b* and **8***c* were analogous to those of **8***a*. Mass spectra were characterized by a base peak at m/z 79, a doublet at $M - C_4H_6$ (1%), a doublet at m/z 186 and 188 (15–20%), and doublets at (91, 93), (105, 107), etc. The molecular ions were small but discernable (1%).

Preparation of 1,3Z,6Z,9Z-tetraenes (1)

A solution of bromotriene **8***a* (0.50 g, 1.53 mmol) in hexane (15 mL) was cooled to −23°C (CCl_4/CO_2 slush) and potassium *tert*-butoxide (250 mg, 2.23 mmol) and 18-crown-6 (40 mg, 0.15 mmol) were added sequentially. The mixture was slowly warmed to 0°C, and stirred at 0°C for 3 h. The reaction was quenched by addition of powdered NH_4Cl (1 g) and stirring for 1 h at 0°C. The mixture was then poured into ice-water (25 mL), and the organic layer was separated, washed with brine, and passed through a short column of neutral alumina (2 cm id × 5 cm). The column was rinsed well with hexane, and the combined eluate was concentrated, giving tetraene **1***a* (215 mg, 58%), >98% pure by capillary gc (the only impurity detected was 1.4% unreacted starting material); ir (neat) λ_{max}: 3085 (w), 3020 (m), 2960 (m), 2930 (s), 2860 (m), 995 (m) cm^{-1}; nmr ($CDCl_3$) δ: 6.65 (dddd, 1H, J = 16.9, 10.8, 10.6, 1.1 Hz, H-2), 6.00 (br t, 1H, J = 10.8 Hz, H-3), 5.46–5.26 (m, 5H, H-4, H-6, H-7, H-9, H-10), 5.19 (br d, 1H, J = 16.9 Hz, H-1 *cis*), 5.10 (br d, 1H, J = 10.1 Hz, H-1 *trans*), 2.95 (t, 2H, J = 6.1 Hz, H-5), 2.80 (t, 2H, J = 6.1 Hz, H-8), 2.04 (br dt, 2H, J = 6.8, 6.7 Hz, H-11), 1.41–1.1 (m, 12H, H-12 to H-17), 0.86 (t, 3H, J = 6.6 Hz, H-18); ms (25 eV): 246 (M^+, 4.2), 192 (15.4), 119 (25.0), 106 (29.0), 105 (24.2), 93 (44.4), 92 (46.1), 91 (64.1), 80 (100), 79 (87.1), 78 (33.0), 67 (29.6). *Exact Mass* calcd. for $C_{18}H_{30}$: 246.2348; found: 246.2356.

Known tetraene **1***b* (2, 4, 7, 9) was prepared from the isomerically impure **8***b*. After purification by flash chromatography on $AgNO_3$-impregnated silica gel (10%), eluting with stepwise gradients of ether in pentane, chemically and isomerically pure tetraene **1***b* was obtained in 63% yield. All spectra were identical to literature data. Tetraene **1***c* was prepared in 65% yield as described for **1***a*. The ir and nmr spectra were completely in accord with those of **1***a* and **1***b*. Mass spectra of **1***b* and **1***c* were characterized by a base peak at m/z 80, diagnostic peaks at $M - 41$ (2–3%) and $M - 54$ (10–15%), and clusters of ions centered at m/z 80, 91, 106, 119, 133, 147, 161, and 175. The molecular ion was easily discernable (4–6%).

Cellules photoélectrochimiques de phtalocyanine d'hydroxyaluminium déposées par rotation

GÉRARD PERRIER ET LÊ H. DAO[1]

Institut National de la Recherche Scientifique (INRS–Énergie), C.P. 1020, Varennes (Qué.), Canada J0L 2P0

Reçu le 12 mai 1986

GÉRARD PERRIER et LÊ H. DAO. Can. J. Chem. **64**, 2431 (1986).

Des cellules photoélectrochimiques à base de phtalocyanine d'hydroxyaluminium (PcAlOH) ont été fabriquées par la méthode de déposition par rotation («spin-coating»). Le comportement spectral et électrique des cellules NESA/PcAlOH/BQ/HQ/Pt est étudié et comparé à celui de cellules où les films de PcAlOH sont produits par sublimation. À cause de la faible solubilité de PcAlOH dans les solvants organiques volatils, le DMSO utilisé pour la déposition par rotation semble rester piégé dans le film solide et diminue le rendement de la cellule photoélectrochimique. L'étude de l'influence de la contre-électrode sur l'efficacité des cellules a permis de montrer qu'une contre-électrode en vanadium conduisait à des valeurs plus élevées de J_{sc}, V_{oc} et η comparée à une contre-électrode en platine, mais présentait des phénomènes de corrosion.

GÉRARD PERRIER and LÊ H. DAO. Can. J. Chem. **64**, 2431 (1986).

The spin-coating technique was used to produce hydroxyaluminum phthalocyanine (PcAlOH) photoelectrochemical cells. The spectral and electrical behavior of NESA/PcAlOH/BQ/HQ/Pt cells is studied and comparisons are made with cells based upon sublimed PcAlOH films. Due to the weak solubility of PcAlOH in volatile organic solvents, the DMSO used in the spin-coating method seems to be trapped in the solid film, and leads to a decrease in the photoelectrochemical cell efficiency. Studies on the influence of the counter-electrode showed that a vanadium counter-electrode gave higher values of J_{sc}, V_{oc}, and η than a platinum one, but corrision phenomena were observed in that case.

1. Introduction

Une approche intéressante de la conversion de l'énergie lumineuse en énergie électrique consiste en l'utilisation de cellules solaires à base de semiconducteurs organiques. L'intérêt en est surtout économique, le coût du matériau semiconducteur étant peu élevé car les techniques de synthèse et de purification sont en général assez simples, de même que les méthodes de fabrication des films minces.

Les propriétés des semiconducteurs organiques ont été connues dès les années 1950 alors que leurs forces photo–électromotrices ont été mesurées sur des substrats inorganiques (1, 2). Des progrès remarquables ont été réalisés dans l'augmentation de l'efficacité de conversion des cellules photovoltaïques organiques, passant de 10^{-5}% au début des années 1970 à 1% actuellement (3). Les composés de type phtalocyanine ont reçu une attention particulière en tant que colorants pour la sensibilisation spectrale et la stabilisation de semiconducteurs inorganiques (4–9) et en tant que semiconducteurs formant des jonctions liquides avec des couples rédox (10–25).

On connait de nombreuses formes polymorphiques de phtalocyanines, en particulier les formes α, β et x (26). Ces formes correspondent à un empilement différent des molécules planaires; les formes α et x sont les plus conductrices (27–29). La présence de l'oxygène augmente grandement la conductivité des phtalocyanines (30) et intervient dans la formation d'états de surface accepteurs d'électrons (31).

La sublimation est la technique de déposition la plus fréquemment utilisée pour la fabrication de films de phtalocyanines (10–19), mais on retrouve aussi l'électrodéposition (20) et la déposition par monocouches (32, 33). Les phtalocyanines peuvent être aussi dispersées dans un polymère et le mélange obtenu peut être étalé en films minces à l'aide d'un couteau ou d'un rouleau (23, 24), ou déposé par rotation (27, 34) sur un support transparent.

Ce travail présente une nouvelle cellule photoélectrochimique à base de phtalocyanine d'hydroxyaluminium où le film mince de semiconducteur organique pur a été déposé par rotation («spin-coating»). Le comportement spectral et électrique de ces cellules est étudié et comparé à celui de cellules où le film mince de phtalocyanine d'hydroxyaluminium a été déposé par sublimation; la cellule est ensuite optimisée et un diagramme des niveaux d'énergie est élaboré.

2. Partie expérimentale

2.1 Matériaux

La phtalocyanine d'hydroxyaluminium (PcAlOH) a été préparée comme suit. La phtalocyanine de chloroaluminium a d'abord été synthétisée en chauffant de l'*o*-phtalonitrile et du chlorure d'aluminium dans de la quinoline; le produit purifié est ensuite chauffé à reflux dans une solution aqueuse d'ammoniaque (30%) en présence de pyridine (35) pour donner PcAlOH. Après des extractions répétées avec des solvants organiques, PcAlOH est dissoute dans l'acide sulfurique concentré et la solution obtenue est versée dans un mélange eau–glace. Le solide bleu foncé est filtré et lavé successivement avec l'eau, l'éthanol et l'acétone.

Les films organiques ont été déposés sur des supports conducteurs transparents de dimensions 25 mm × 50 mm constitués de lamelles de NESA (SnO_2 dopé, PPG Industries); ces lamelles ont été nettoyées par immersion successive dans une solution de détergent, dans l'eau du robinet et l'eau distillée, puis dans le méthanol. La méthode de déposition par rotation consiste en la déposition d'une goutte d'une suspension de PcAlOH dans du DMSO au centre du substrat en rotation; la force centrifuge permet ainsi l'étalement de la goutte sur le substrat. L'épaisseur des films (de 100 à 3000 Å) peut être variée en jouant sur la vitesse de rotation (de 1000 à 3500 r/min) ainsi que sa durée, et sur la concentration de PcAlOH dans le DMSO; le séchage est effectué à l'air libre pendant une dizaine de jours. La méthode de déposition par sublimation utilise le système décrit par Linkous *et al.* (13); la température de sublimation est de 520°C à des pressions typiques de 5×10^{-6} Torr (1 Torr = 133.3 Pa). L'épaisseur du film (de 100 à 5500 Å) peut être variée en jouant sur la durée de la sublimation (de 5 min à 1 h).

Les contacts électriques sont réalisés à l'aide d'un fil de cuivre collé sur la partie conductrice du substrat et recouvert d'une peinture à l'argent (G.C. Electronics). Une surface active variant de 1 à 4 cm^2 est définie en recouvrant l'électrode d'un vernis incolore limitant le contact avec la solution. L'épaisseur des films est déterminée à l'aide d'un

1. Auteur à qui adresser toute correspondance.

profilomètre de surface Sloan Dektak II, puis une courbe d'étalonnage absorbance maximale – épaisseur est tracée. Les spectres d'absorption visible ont été enregistrés avec un spectrophotomètre Hitachi 100-60.

2.2 Mesures photoélectrochimiques

La photoélectrode est plongée dans une solution aqueuse non-déoxygénée, agitée magnétiquement et contenant un sel (Na_2SO_4 0,1 *M*) et un couple rédox (benzoquinone/hydroquinone) dans une cellule électrochimique. La surface du semiconducteur organique est placée à 2 mm de la fenêtre transparente pour minimiser l'absorption de la lumière par la solution, et l'interface semiconducteur–électrolyte est éclairée directement. Une contre-électrode en platine (8 cm^2) sert d'électrode auxiliaire. Une source de lumière blanche (lampe au tungstène-halogène) de 650 W (Schoeffel) et un monochromateur Kratos (Schoeffel) fournissent la lumière monochromatique. L'intensité lumineuse est mesurée par un radiomètre United Detector Technologies 21A et le courant de court-circuit est mesuré par un électromètre Keithley 616. La variation des courants avec le potentiel appliqué fait intervenir un potentiostat PAR 362 et les courbes courant–tension (J–V) ainsi obtenues sont tracées à vitesse lente (2 mV/s). La cellule électrochimique comprend alors une troisième électrode, une électrode de référence au calomel saturé (ECS). Sauf indication contraire, l'intensité de lumière blanche sera $I = 10$ mW/cm^2 (fournie par la lampe ELH de 300 W d'un projecteur Kodak Ektagraphic AF2).

3. Résultats et discussion

3.1 Morphologie des films

Des photographies de la surface des films ont été prises au microscope électronique à balayage dans le cas d'un film d'épaisseur 700 Å déposé par rotation (figures 1*A* et 1*B*) et d'un film d'épaisseur 600 Å sublimé (fig. 1*C*). Les grossissements sont de 2 000 (*A*) et de 20 000 (*B* et *C*). Un film déposé par rotation présente de gros grains (de 1 à 4 μm) dépassant une structure plus fine mais néanmoins rugueuse (fig. 1*A*). La surface des films minces, obtenus à des vitesses de rotation plus élevées, présente des grains plus petits et moins nombreux que la surface des films plus épais où l'effet centrifuge a été moins grand. Dans le cas d'un agrandissement de 20 000 (fig. 1*B*), il n'apparait pas de fissure dans les films. Par contre, la surface des films sublimés présente une structure de «nouilles» qui ont une longueur dépassant 1 μm pour une section de 0,1 μm (fig. 1*C*). Cet aspect de la surface ne dépend pas de l'épaisseur des films et de grands espaces sont visibles entre les «nouilles». La morphologie des films sublimés est typique d'un taux de sublimation élevé (15–17), qui est ici d'environ 40 Å/min. De grands espaces sont visibles entre les solides, laissant supposer une certaine porosité du film aux couples rédox; ceci a d'ailleurs été confirmé par voltamétrie cyclique pour des films sublimés de PcAlOH sur du platine et avait été montré pour des morphologies semblables de films minces de InPc-Cl et GaPc-Cl (13, 17).

3.2 Paramètres de l'électrolyte

Comme les autres phtalocyanines et la plupart des semiconducteurs organiques, PcAlOH est un semiconducteur de type *p*, menant à l'observation de photocourants cathodiques en court-circuit. La variation du courant de court-circuit J_{sc} et de la tension en circuit ouvert V_{oc} pour une irradiation en lumière blanche avec le pH de la solution est montrée à la figure 2. Le couple rédox utilisé est le couple benzoquinone/hydroquinone (BQ/HQ) de concentration 10^{-2} *M* et la contre-électrode est en platine; l'épaisseur du film de PcAlOH est de 280 Å. Des valeurs maximales pour J_{sc} et V_{oc} sont atteintes pour un pH de 2,5.

Les phtalocyanines (H_2Pc, SnPc, MgPc) ne sont pas connues comme ayant leurs niveaux d'énergie reliés au pH (14); on pense qu'il en est de même pour PcAlOH et la variation de J_{sc} et V_{oc} avec le pH serait due à la variation du potentiel rédox du couple BQ/HQ. Cette variation change le recouvrement des niveaux d'énergie de la benzoquinone avec ceux du semiconducteur organique. Nous verrons plus loin que la variation du pH de la solution BQ/HQ induit un déplacement du potentiel de bande plate de la phtalocyanine. Le meilleur recouvrement est obtenu à pH 2,5 où le potentiel rédox du couple BQ/HQ est de 0,28 V/ECS dans les conditions optimales de concentration.

La figure 3 représente l'allure des variations de J_{sc} et V_{oc} avec la concentration du couple rédox (quinhydrone, fig. 3*A*). Le courant de court-circuit J_{sc} augmente quand la concentration augmente, puis tend à se stabiliser à partir de 4×10^{-3} *M*; ceci indique que les recombinaisons à l'intérieur du semiconducteur, plutôt que la réduction du couple rédox, sont un facteur limitatif du courant dans la phtalocyanine (23, 24). La tension en circuit ouvert V_{oc} diminue de façon monotone dans le domaine de concentration considéré.

En choisissant la concentration de l'oxydant (BQ) égale à 4×10^{-3} *M* et en faisant varier la concentration du réducteur (HQ), on obtient la figure 3*B* en reportant J_{sc} et V_{oc}. Le maximum de courant est atteint pour une concentration du réducteur égale à la moitié de celle de l'oxydant, suggérant que le transfert des électrons de l'hydroquinone sur le platine est plus rapide que celui de PcAlOH à la benzoquinone. La variation de V_{oc} avec la concentration d'hydroquinone est négligeable. Les paramètres de l'électrolyte ont ainsi été optimisés : $[BQ] = 2[HQ] = 4 \times 10^{-3}$ *M* à pH 2,5. Les valeurs de J_{sc} et V_{oc} décroissent lentement avec le temps à cause du brunissement de la solution jaune clair. Une solution fraîche restaure les valeurs initiales.

3.3 Spectres d'absorption et d'action

Les spectres d'absorption des films de PcAlOH déposés par rotation ne présentent qu'une seule bande à 640 nm (fig. 4*A*, épaisseur 250 Å). PcAlOH a été aussi électrodéposé à partir d'une suspension dans le butanol-1 et l'isooctane et ne présente aussi qu'une seule bande d'absorption. Par contre, les spectres d'absorption des films de PcAlOH produits par sublimation présentent, en plus de la bande principale située autour de $\lambda =$ 635 nm, un épaulement qui apparait lorsque l'épaisseur du film augmente et qui devient un pic d'absorption situé à $\lambda = 735$ nm pour les épaisseurs élevées (fig. 5*A*, où les spectres des films d'épaisseur 80 Å, 2800 Å et 4200 Å sont présentés sur une échelle arbitraire relative au spectre du film d'épaisseur 150 Å). Ces spectres ont une allure similaire à ceux des films sublimés de diverses phtalocyanines (H_2Pc, MgPc, FePc, CuPc, CoPc, ZnPc) décrits par Davidson (36), lesquels présentent en général deux bandes d'absorption dans le visible. Dans le cas de MgPc, les deux bandes ont une importance relative qui varie avec l'épaisseur, expliqué en termes de vibrations moléculaires variant avec l'environnement de la molécule. Ce phénomène se retrouve dans le cas de PcAlOH, comme le montrent les spectres d'absorption de la figure 5*A*, où l'intensité relative de l'absorbance à 735 nm passe de 13% (80 Å) à 80% (4200 Å).

Ceci peut être raisonnablement expliqué par le fait qu'il y ait deux formes d'aggrégation de PcAlOH. Ces deux formes pourraient bien être les formes α et β que l'on retrouve chez la plupart des phtalocyanines (26). La forme β est obtenue à partir de la forme α pour des températures du substrat plus élevées (environ 200°C) pour des films de H_2Pc (37). Dans notre cas, la forme α aurait sa contribution à 635 nm (38) et la forme β à

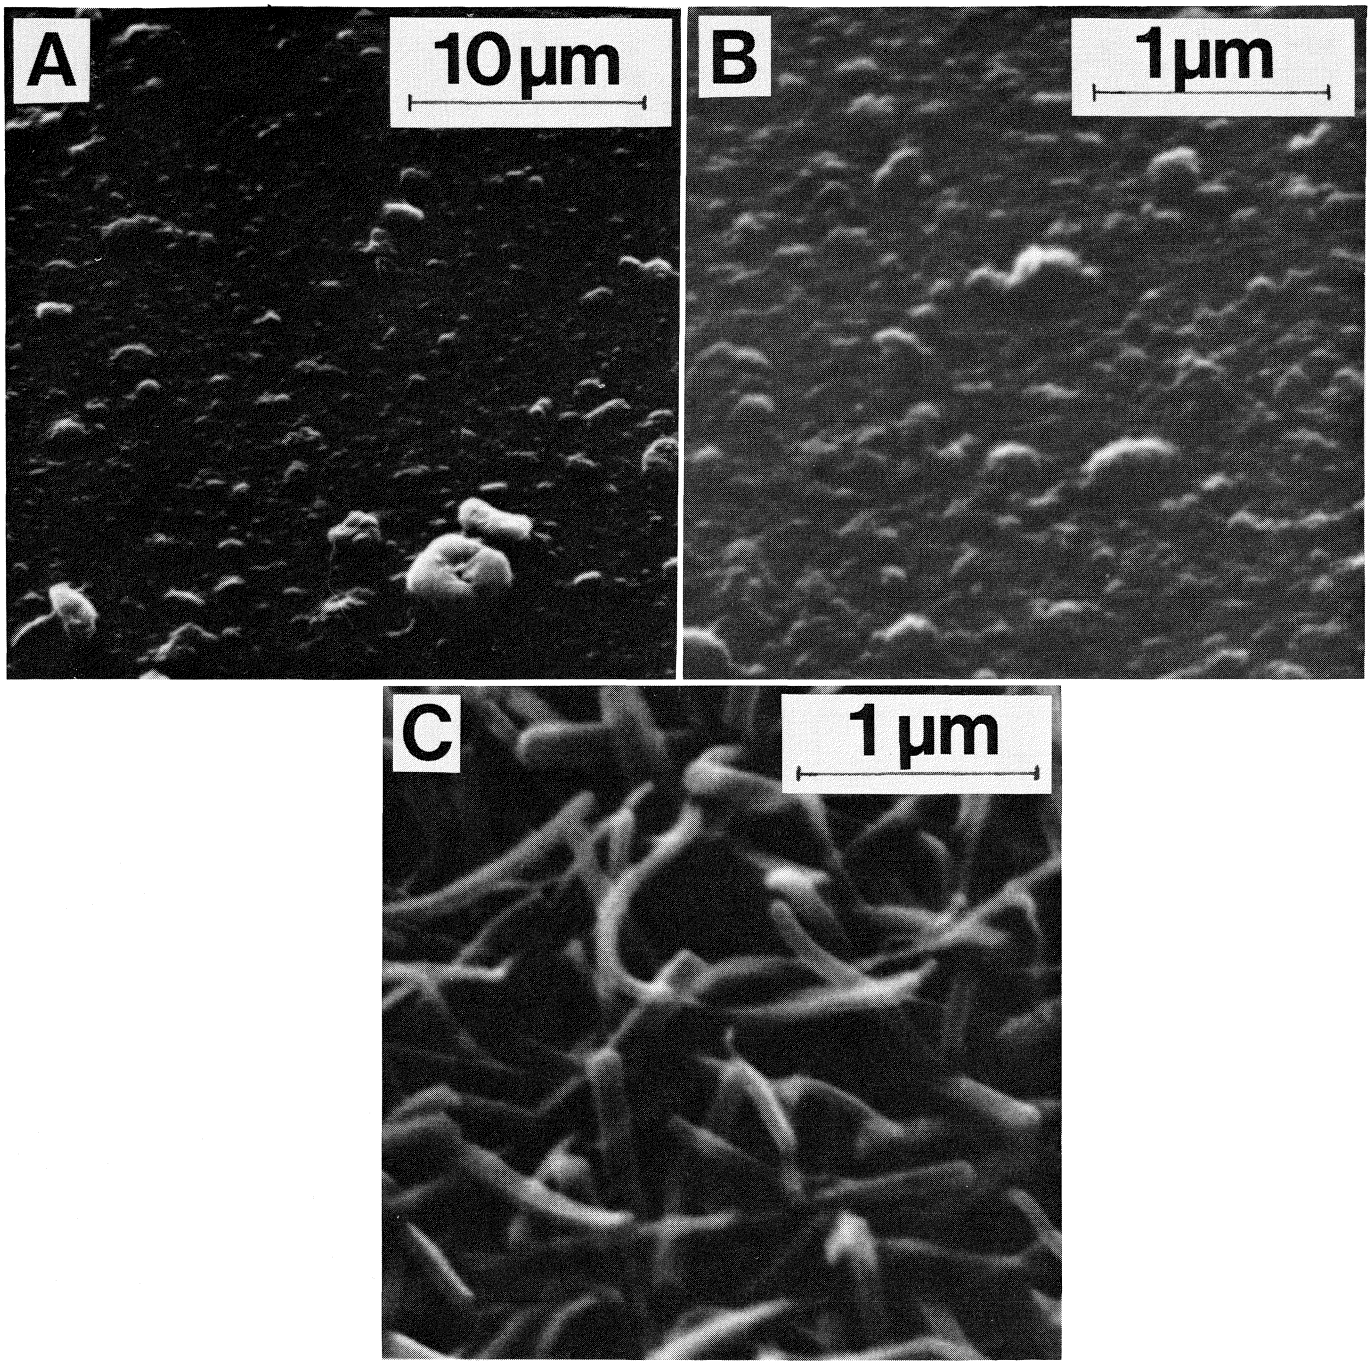

FIG. 1. Photographies obtenues au microscope électronique à balayage de la surface de films de PcAlOH : *A* : film d'épaisseur 700 Å déposé par rotation, grossissement 2 000; *B* : film d'épaisseur 700 Å deposé par rotation, grossissement 20 000; *C* : film d'épaisseur 600 Å sublimé, grossissement 20 000.

735 nm; celle-ci se trouve en plus grande quantité dans les films épais, obtenus pour des temps de sublimation plus longs, où le substrat a atteint des températures plus élevées.

Les spectres d'action des cellules à base de PcAlOH déposée par rotation et sublimée sont présentés aux figures 4*B* et 5*B* pour des épaisseurs de 250 Å et 150 Å, respectivement. Le courant mesuré doit être corrigé pour l'intensité de la lampe, ainsi que pour la réponse du détecteur et la variation du courant J_{sc} avec l'intensité lumineuse I (variée en modifiant la tension d'alimentation de la lampe). Cette variation prend la forme (29) :

$$[1] \quad J_{sc} = kI^{\gamma}$$

où k est une constante de proportionnalité et γ l'exposant de lumière de la cellule, dont la valeur se situe autour de 0,90 pour toutes les cellules. Les spectres d'action corrigés représentent alors le photocourant obtenu en court-circuit pour un flux constant de photons à chaque longueur d'onde; il est donné par la formule :

$$[2] \quad J_{\lambda_{corrig}} = J_{\lambda_{mesur}} \left(\frac{N_{max}}{N_{\lambda}}\right)^{\gamma}$$

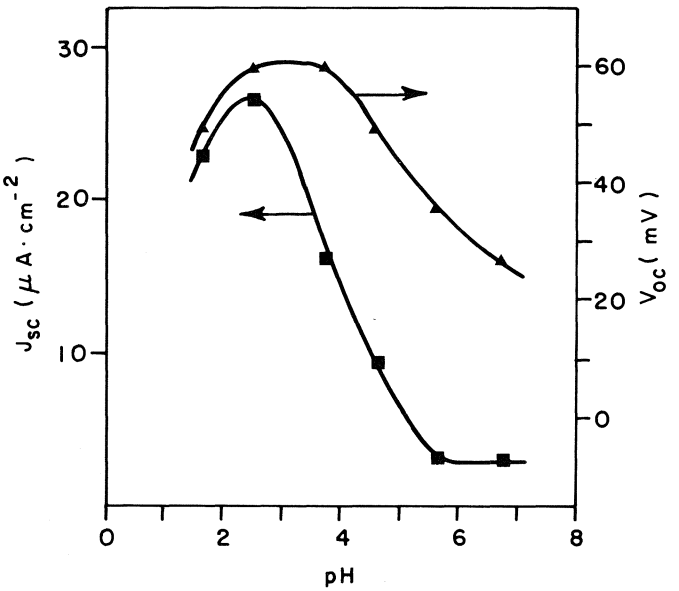

FIG. 2. Variation de J_{sc} et V_{oc} avec le pH de la solution ([BQ] = [HQ] = 10^{-2} M et I = 10 mW cm^{-2}).

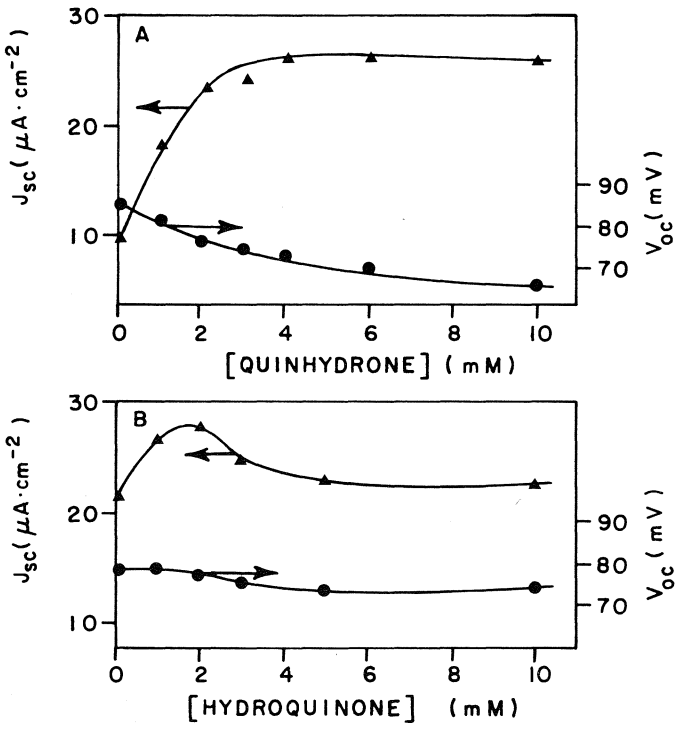

FIG. 3. *A* : Variation de J_{sc} et V_{oc} avec la concentration du couple rédox ([BQ] = [HQ]; pH 2,5; I = 10 mW cm^{-2}). *B* : Variation de J_{sc} et V_{oc} avec la concentration du réducteur ([BQ] = 4 × 10^{-3} M; pH 2,5; I = 10 mW cm^{-2}).

où N_{max} et N_λ sont le flux de photons incidents maximum et le flux de photons incidents pour la longueur d'onde considérée, respectivement. Le flux de photons maximum est ici de 8,3 × 10^{14} photons cm^{-2} s^{-1} pour une irradiation directe de l'interface. Les spectres d'action suivent l'allure des spectres d'absorption pour les deux types de films. Dans le cas d'un film sublimé, la forme α serait la plus photoactive; la contribution de la forme β au photocourant est assez faible et ne varie que très peu avec l'épaisseur du film de PcAlOH.

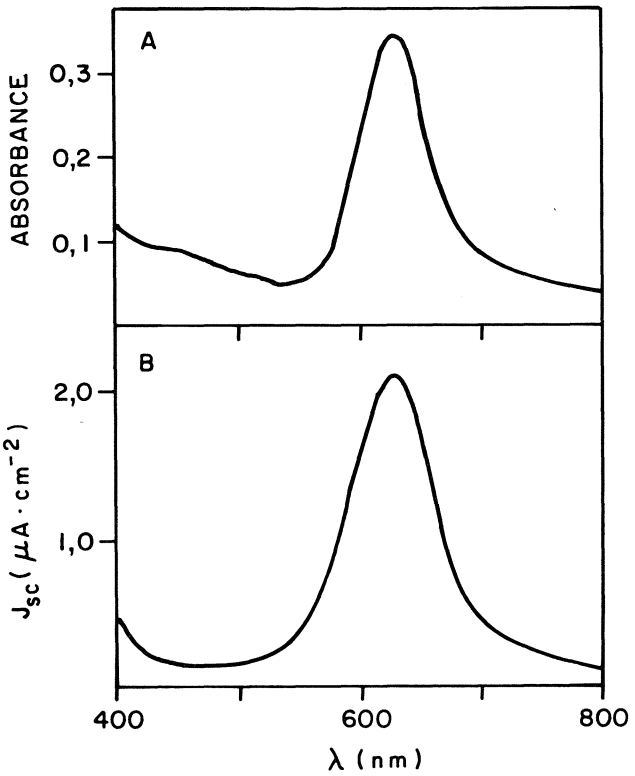

FIG. 4. *A* : Spectre d'absorption d'un film d'épaisseur 250 Å de PcAlOH déposé par rotation. *B* : Spectre d'action du même film.

On peut tirer le rendement quantique de la cellule à partir du spectre d'action à l'aide de l'éq. [3] (39) :

[3] $\phi(\%) = 100\, J_{sc} h\nu / qI$

qui peut aussi s'écrire :

[4] $\phi(\%) = 100\, J_{sc} / qN$

où $h\nu$ est l'énergie du photon, q la charge de l'électron et N le flux de photons incidents. Le rendement quantique est alors le rapport entre le nombre d'électrons collectés et le nombre de photons incidents et prend une valeur de 1,58% à 628 nm pour un film d'épaisseur 250 Å déposé par rotation et 0,93% à 618 nm pour un film sublimé d'épaisseur 150 Å. Cependant, la réponse spectrale d'un film sublimé couvre une part plus grande du spectre visible.

3.4 Courbes courant–tension

La figure 6*A* nous montre les caractéristiques *J–V* d'une cellule NESA/PcAlOH/BQ/HQ/Pt dans les conditions optimales d'électrolyte; la courbe 1 représente les caractéristiques du NESA dans le noir, les courbes 2 et 3 celles d'un film d'épaisseur 250 Å déposé par rotation, dans le noir (2) et sous illumination (3), et les courbes 4 et 5 celles d'un film sublimé d'épaisseur 150 Å dans le noir (4) et sous une même illumination (5). Les courbes *J–V* de PcAlOH dans le noir montrent des rectifications moyennes, les rapports de rectification étant, à 0,2 volts, de 5,8 pour le film déposé par rotation et de 2,2 pour le film sublimé. Lorsque les électrodes sont irradiées en lumière blanche, on note l'apparition de photocourants cathodiques dans la zone de polarisation inverse, indiquant que les électrons provenant du semiconducteur organique vont réduire la benzoquinone en solution.

Dans la région où la polarisation de l'électrode est directe, un

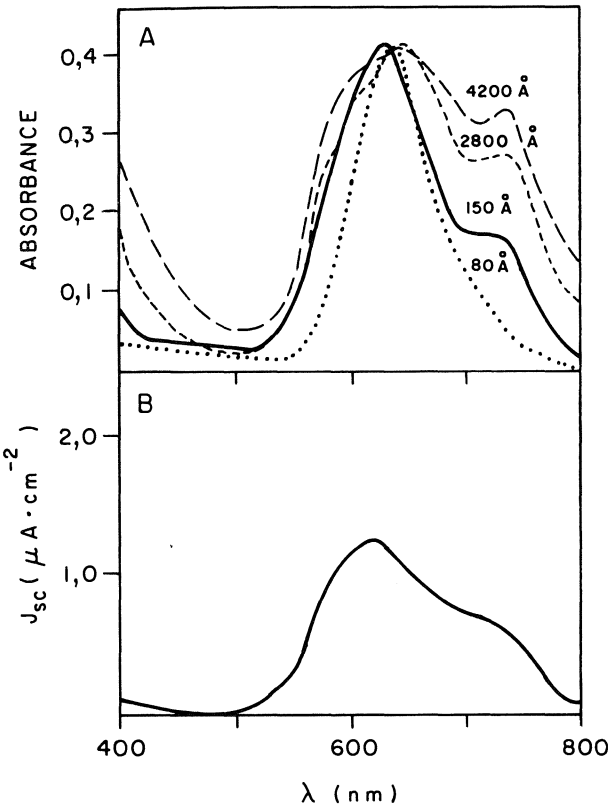

FIG. 5. *A* : Spectre d'absorption de films sublimés de PcAlOH pour différentes épaisseurs. *B* : Spectre d'action d'un film sublimé de PcAlOH d'épaisseur 150 Å.

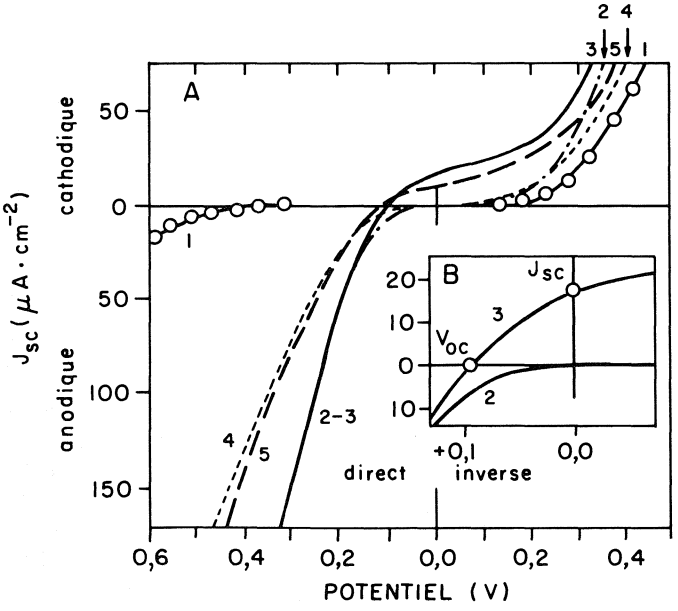

FIG. 6. *A* : Caractéristiques *J–V* (1) du NESA dans le noir; (2) d'un film d'épaisseur 250 Å de PcAlOH déposé par rotation, dans le noir et (3) sous illumination en lumière blanche de 10 mW cm^{-2}; (4) d'un film de PcAlOH sublimé d'épaisseur 150 Å, dans le noir et (5) sous même illumination. *B* : Détermination graphique de J_{sc} et V_{oc}.

photocourant anodique apparait pour le film sublimé, contrairement au film déposé par rotation, pour lequel il n'existe aucun photocourant. D'autre part, la pente des courbes *J–V* en polarisation directe dans le noir est assez différente; ces portions de courbes suivent l'équation suivante (20) :

TABLEAU 1. Courant d'échange à l'équilibre J_0, paramètre de la diode m et résistance en série R_s de la cellule NESA/PcAlOH/BQ/HQ/Pt selon la technique de déposition du film organique

Méthode de déposition	J_0 (μA/cm^2)	m	R_s (Ω)
Rotation	0,4	1,4	500
Sublimation	0,1	1,2	1220

$$[5] \quad J = J_0\left[\exp\left(\frac{q(V - JR_s)}{mkT}\right) - 1\right]$$

où J_0 est la densité de courant d'échange, m est un paramètre ajustable et R_s est la résistance en série de la cellule photoélectrochimique. Cette expression est similaire à celle qui décrit les caractéristiques *J–V* dans l'obscurité pour une barrière de Schottky à la jonction métal–semiconducteur (40).

Lorsque $V \geqslant 3kT/q$, le dernier terme entre parenthèses peut être négligé (20). Si $R_s = 0$, un graphique de ln *J* en fonction de *V* donne une droite avec J_0 comme ordonnée à l'origine; m est obtenu à partir de la valeur de la pente. Si $R_s \neq 0$, sa valeur peut être déterminée par la déviation de la courbe à la linéarité lorsque le potentiel appliqué est élevé. Les valeurs de J_0, m et R_s pour les deux types de films sont rapportées dans le tableau 1. On remarque principalement que le film déposé par rotation présente une résistance en série beaucoup plus faible que le film sublimé. Ce phénomène ainsi que l'absence de courant anodique dans le film déposé par rotation pourrait être dû à la présence de traces de solvant dans la masse du semiconducteur organique.

L'intersection de la courbe *J–V* sous illumination avec les axes des courants et tensions nous donne le courant en court-circuit J_{sc} et la tension en circuit ouvert V_{oc}, respectivement (fig. 6*B*). On peut ainsi calculer le facteur de remplissage *ff* défini comme suit :

$$[6] \quad ff = \frac{(J \cdot V)_{max}}{J_{sc} \cdot V_{oc}}$$

Cette valeur de *ff* varie peu d'une cellule à l'autre et se situe autour d'une valeur moyenne de 0,35. L'efficacité des cellules est alors donnée par :

$$[7] \quad \eta(\%) = 100\, J_{sc} V_{oc} ff / I$$

Les valeurs de J_{sc}, V_{oc}, *ff* et η sont présentées dans le tableau 2 pour les deux types de films. Des courants plus élevés et des tensions plus faibles sont produits lorsque le film de PcAlOH est déposé par rotation, conduisant à des valeurs très semblables de rendement de conversion qui se situent pour les deux types de films aux alentours de 5×10^{-3}%.

3.5 Photocourants et potentiels de bande plate

Les variations d'amplitude et de signe du photocourant en lumière blanche avec le potentiel appliqué sont tracées sur la figure 7 pour un film d'épaisseur 250 Å déposé par rotation à pH 2,5 (*a*) et pour un film sublimé d'épaisseur 230 Å à pH 2,5 (*b*), 4,5 (*c*) et 6,0 (*d*). Le couple rédox est BQ/HQ aux conditions optimales de concentration; les potentiels rédox dans les conditions de pH sont indiqués par de flèches.

Dans la gamme de potentiels utilisée, le photocourant atteint un maximum lorsque le potentiel est augmenté dans la direction cathodique. La décroissance du courant cathodique lorsque des tensions cathodiques élevées sont appliquées est due à la

	6,0	0,10	0,12	−0,02	—

compétition entre les électrons produits dans le noir et les électrons photogénérés pour les espèces oxydées disponibles à l'interface (20). Cette compétition est visible sur la figure 6*A* où les valeurs des courants dans le noir réjoignent celles des courants sous illumination.

On observe des photocourants cathodique et anodique lorsque le film est déposé par sublimation, tandis qu'aucun courant anodique n'apparait pour un film déposé par rotation, comme l'indique la figure 6*A*.

Dans le modèle de bande du semiconducteur organique, en considérant que le contact PcAlOH/NESA est ohmique (24), le point où le photocourant passe de cathodique à anodique correspond au potentiel de bandes plates (V_{fb}) du pigment (10). Si un potentiel est appliqué du côté cathodique de V_{fb}, une région de charges d'espace est créée dans PcAlOH; les trous et les électrons photogénérés sont séparés par le champ électrique présent dans la région de charges d'espace, et les électrons sont injectés dans la solution. Du côté anodique de V_{fb}, PcAlOH se comporte comme une résistance variable pour le transfert des trous dans la solution. Lorsque PcAlOH est illuminée, sa résistance diminue à cause de l'augmentation de la densité en porteurs de charges. Les photocourants anodiques ne sont pas dus à une sensibilisation de SnO_2 car ils sont présents aussi lorsque le substrat est le platine. PcAlOH déposée sur du NESA n'est pas une simple couche résistive, mais sa présence modifie la disponibilité du rédox à l'interface comme le montre la figure 6*A* si on compare les courbes directes pour le NESA nu et recouvert de PcAlOH. Le tableau 3 rapporte les valeurs de V_{fb} mesurées sur la figure 7. Quand aucun photocourant anodique existe, on utilise une extrapolation des courbes pour déterminer V_{fb}. La différence ΔV est définie comme suit :

$$[8] \quad \Delta V = V_{fb} - E_{red}$$

et correspond à la tension maximale que peut fournir la cellule. Le potentiel de bande plate varie beaucoup avec le pH de la solution dans le cas du couple rédox BQ/HQ, alors qu'il a été trouvé indépendant du pH dans le cas du couple rédox I_3^-/I^-. Un comportement identique a été observé (20) pour un film de SAlPc. Il peut être expliqué en formulant l'hypothèse de la formation d'un faible complexe de transfert de charge entre PcAlOH et la benzoquinone à la surface du film. Un complexe de transfert de charge à l'état fondamental a déjà été observé

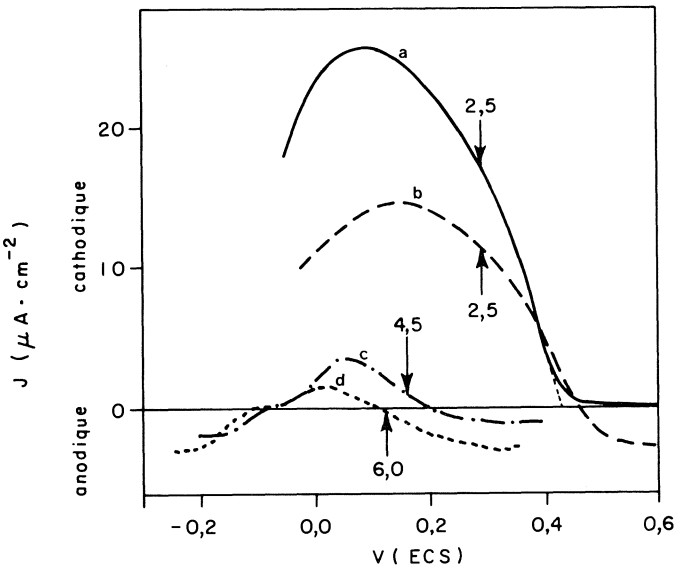

FIG. 7. Variation du photocourant avec le potentiel appliqué sur un film d'épaisseur 250 Å déposé par rotation à pH 2,5 (a) et pour un film sublimé d'épaisseur 230 Å à pH 2,5 (b), 4,5 (c) et 6,0 (d).

entre H_2Pc et le chloranil; il augmente la conductivité dans le noir et la photoconductivité du pigment (14, 41, 42). La benzoquinone est un accepteur plus faible que le chloranil, mais un complexe à l'état fondamental a été rapporté dans l'acétone entre BQ et des tétratolylporphines libres et de zinc (43), qui sont des molécules très proches de PcAlOH. La diminution de $E_{rédox}$ est de 0,059 V par unité de pH, et la présence de la benzoquinone sur l'électrode doit causer un déplacement du potentiel de bande plate si l'hydroquinone est aussi adsorbée sur la surface du semiconducteur. De pH 2,5 à pH 6,0, la diminution de $E_{rédox}$ doit être de 0,21 V (valeur mesurée : 0,17 V), et la variation de V_{fb} avec le pH est de 0,36 V dans le même sens. Cet effet est similaire au déplacement de V_{fb} avec le pH pour les oxydes semiconducteurs (44). Si BQ/HQ n'affectait pas le potentiel de bande plate de PcAlOH, on s'attendrait à une augmentation de la tension en circuit ouvert V_{oc} avec le pH, le potentiel rédox devenant de plus en plus cathodique. Ceci n'est pas observé expérimentalement.

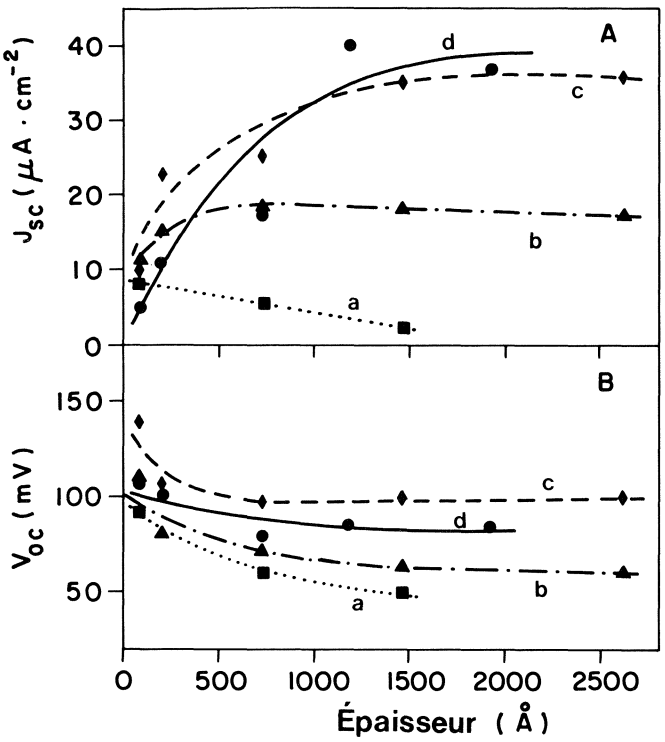

FIG. 8. Illumination en lumière blanche de I = 10 mW cm^{-2} : *A* : Variations de J_{sc} avec l'épaisseur du film de PcAlOH déposé par rotation. *B* : Variations de V_{oc} avec l'épaisseur du film de PcAlOH déposé par rotation. Courbes a : films fraîchement déposés; courbes b : laissés à l'air libre pendant 12 jours; courbes c : films laissés à l'air libre pendant 21 mois; courbes d : films plongés rapidement dans du DMSO.

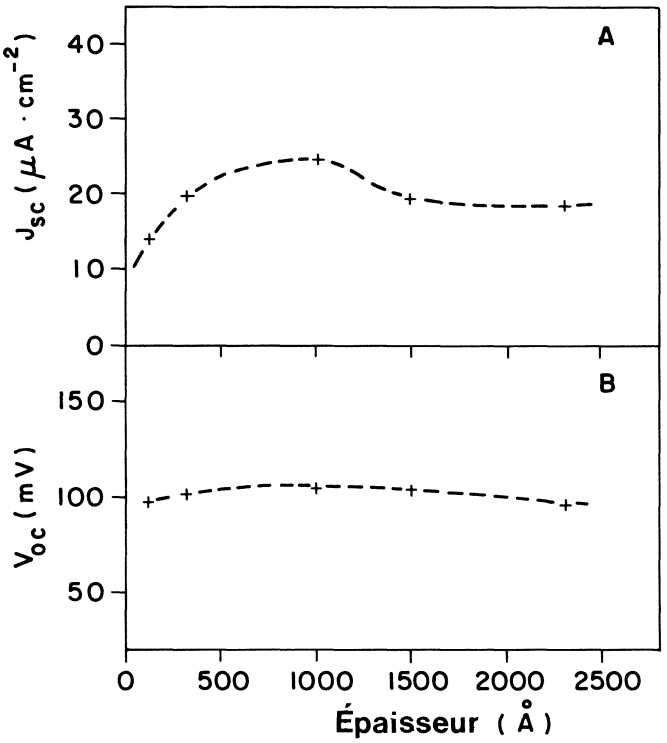

FIG. 9. Illumination en lumière blanche de I = 10 mW cm^{-2} : *A* : Variation de J_{sc} avec l'épaisseur du film sublimé de PcAlOH. *B* : Variation de V_{oc} avec l'épaisseur du film sublimé de PcAlOH.

La valeur de ΔV représente la tension maximale que peut fournir la cellule. Les valeurs de ΔV sont de 0,14 V pour un film déposé par rotation et 0,17 V pour un film sublimé, et des valeurs expérimentales respectives de 0,10 V et 0,12 V ont été atteintes.

3.6 Épaisseur des films

Les films de PcAlOH déposés par rotation ont été préparés en versant une goutte d'une suspension de PcAlOH dans du DMSO sur un support en rotation. Le DMSO est un solvant ayant un point d'ébullition relativement élevé (189°C) et il semble que sa présence ait un effet important sur la photoactivité du film semiconducteur. En effet, les films de différentes épaisseurs séchés à l'air libre pendant 12 jours donnent un courant de court-circuit plus important que les mêmes films fraîchement déposés (fig. 8*A*, courbes a et b). Cette évolution est continuelle et on observe une plus grande augmentation de J_{sc} (fig. 8*A*, courbe c) après avoir laissé les films à l'air libre pendant plusieurs mois. L'augmentation de J_{sc} est d'autant plus importante que le film est épais et contient plus de DMSO. L'allure de la courbe c (fig. 8*A*) est typique d'une absorption faible dans des films minces (jusqu'à 2600 Å) où la lumière pénètre tout le film de PcAlOH (14). Plonger rapidement ces films dans le DMSO fait chuter de nouveau le courant pour les films minces, mais ne semble pas affecter les films plus épais (fig. 8*A*, courbe d), probablement car le DMSO n'a pas eu le temps de diffuser suffisamment dans les films. Le même phénomène est observé pour la mesure de la tension en circuit ouvert V_{oc} et cette fois les variations sont indépendantes de l'épaisseur (fig. 8*B*, courbes a–d).

Les films préparés par sublimation présentent un maximum de courant de court-circuit pour une épaisseur de 1000 Å environ, tandis que la tension en circuit ouvert est pratiquement indépendante de l'épaisseur du film jusqu'à une épaisseur de 2500 Å (figures 9*A* et *B*).

Ainsi, le DMSO a une grande influence sur le comportement des cellules NESA/PcAlOH/BQ/HQ/Pt où le film de PcAlOH a été déposé par rotation. Sa présence dans les cellules fraîches limite le courant et la tension délivrés par la cellule, surtout pour les grandes épaisseurs. Cet effet disparait avec le temps et est réversible; plonger les lamelles dans le solvant diminue à nouveau le photocourant et la phototension. Il est probable que les molécules de DMSO agissent comme des sites de recombinaison pour les électrons et les trous formés par l'absorption de la lumière dans le corps du semiconducteur. Le point d'ébullition élevé du DMSO fait en sorte que son action dure longtemps, son taux d'évaporation dans l'air étant faible. Le fait de placer les lamelles fraîchement déposées dans une étuve à 160°C fait craqueler les films organiques. Le DMSO semble fortement piégé dans la structure du film car aucun changement n'est survenu après avoir placé une lamelle sous vide primaire (10^{-2} Torr) pendant une nuit.

Enfin, il est connu que l'oxygène s'adsorbe sur les phtalocyanines et a un effet important sur la photoconductivité de leurs films minces (30, 31, 45). Le DMSO pourrait altérer cet effet en occupant certains des sites préférentiels de l'oxygène.

3.7 Contre-électrode

Loutfy et McIntyre (23, 24) ont réalisé une étude systématique de différents métaux M utilisés dans des cellules NESA/x-H_2Pc/rédox/M. Il en résulte que les photocourants les plus élevés sont obtenus avec des contre-électrodes en aluminium et en indium, mais aucune remarque sur la stabilité de ces systèmes n'a été faite. Dans nos conditions d'électrolyte utilisées, certaines contre-électrodes donnent des courants très

TABLEAU 4. Variation du courant de court-circuit sous illumination (J_{sc}) et dans le noir (J_{noir}), du rapport $|J_{noir}|/J_{sc}$, de la tension en circuit ouvert sous illumination (V_{oc}) et dans le noir (V_{noir}), du rapport $|V_{noir}|/V_{oc}$ et de l'efficacité de conversion η en fonction de l'épaisseur du film de PcAlOH, de la puissance lumineuse incidente et de la nature de la contre-électrode (films déposés par rotation)

Épaisseur (Å)	Puissance lumineuse (mW cm^{-2})	Contre-électrode	J_{sc} (μA cm^{-2})	J_{noir} (μA cm^{-2})	$\lvert J_{noir}\rvert/J_{sc}$ (%)	V_{oc} (mV)	V_{noir} (mV)	$\lvert V_{noir}\rvert/V_{oc}$ (%)	η (%)
100	10	Au	7,8	−0,02	0,3	88,8	+0,4	0,5	0,002
100	10	Pt	13,8	−0,2	1,4	70,9	−19,0	26,8	0,003
250	10	Pt	21,8	−0,2	0,9	74,2	−11,2	15,1	0,006
250	10	Zr	41,8	+1,3	3,1	210,0	+103,0	49,0	0,030
600	85	Pt	32,0	−0,5	1,6	93,0	−14,7	15,8	0,001
600	85	Zr	117,2	+0,9	0,8	266,0	+136,0	51,1	0,012
600	85	V	175,2	+27,4	15,6	337,0	+216,0	64,1	0,024

faibles (Ta, Nb, Pb, Sn, Cu, Fe, Ti, Zn, Al) ou s'oxydent très rapidement (Sc). Les électrodes du tableau 4 (Pt, Au, Zr, V) ont une réponse stable (films de PcAlOH déposés par rotation). Le meilleure réponse est fournie par une contre-électrode en vanadium avec $J_{sc} = 175{,}2\ \mu A/cm^2$ et $V_{oc} = 337$ mV pour une puissance lumineuse de 85 mW/cm^2. Des valeurs élevées sont aussi obtenues avec le zirconium ($J_{sc} = 117{,}2\ \mu A/cm^2$ et $V_{oc} = 226$ mV). Il semble donc que le rendement de la cellule soit limité par le taux de réaction du réducteur à l'électrode métallique. Cependant, l'électrode de zirconium est soumise à une corrosion assez rapide (10 h) due à un mécanisme électrochimique catalysé par les photocourants, et on pense qu'il en est de même avec le vanadium; en effet, les courants et tensions dans le noir sont importants (15,6% et 64,1% des courants et tensions totaux), bien qu'aucune corrosion ne soit visible à la surface de l'électrode métallique. Les contre-électrodes en platine et en or sont par contre très inertes dans les conditions d'expérience et nous permettent d'éviter la corrosion, mais elles conduisent à des valeurs plus faibles.

3.8 Modèle de bandes

L'absorption de photons par l'électrode semiconductrice conduit, à travers un processus excitonique, à la création de paires électron–trous; ces derniers se séparent sous l'effet du champ électrique de la jonction. Les électrons (porteurs minoritaires) arrivent à l'interface semiconducteur–électrolyte et vont réduire une espèce oxydante en solution. Les trous se déplacent à travers le semiconducteur lui-même; ils recombinent ensuite au contact ohmique (NESA) avec les électrons venant du circuit extérieur qui sont fournis par la réaction d'oxydation du réducteur à la contre-électrode. Le transfert d'électrons du semiconducteur à l'espèce électroactive de l'électrolyte est possible théoriquement si la distribution d'énergie de l'espèce en solution recouvre la bande de conduction du semiconducteur de type *p*.

Ainsi, il est possible de tracer un diagramme montrant les niveaux d'énergie du semiconducteur et le potentiel rédox du couple en solution (fig. 10). Le niveau de Fermi, E_F, de la solution est représenté par le potentiel rédox du couple, mesuré dans les conditions expérimentales ($E_{red} = 0.29$ V/ECS pour BQ/HQ à pH 2,5) et les bandes d'énergie du semiconducteur sont celles trouvées par Lawrence *et al.* (46) pour SAlPc, soit $E_c = 3{,}90$ eV pour la bande de conduction et $E_g = 1{,}80$ eV pour le saut de bande interdite. Le potentiel de bandes plates, V_{fb}, correspondant au niveau de Fermi du semiconducteur sous illumination, est déterminé par l'intersection avec l'axe des

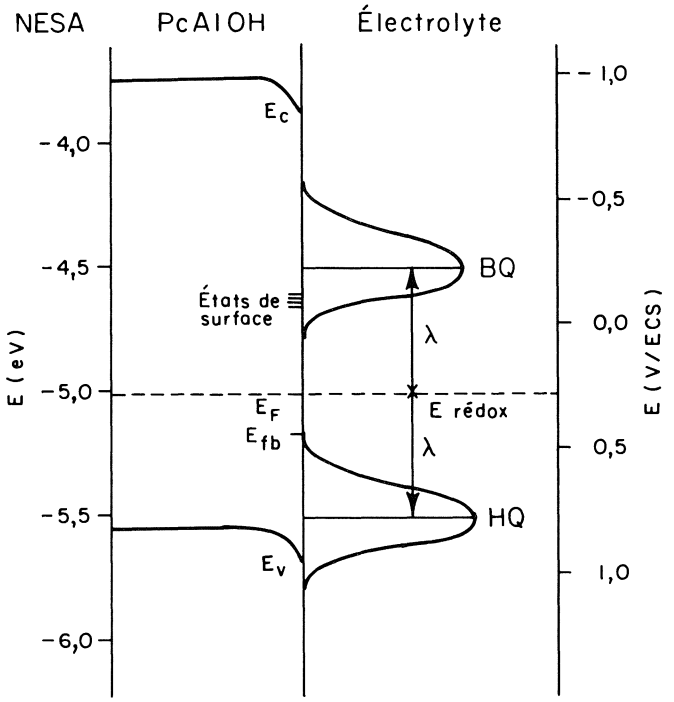

FIG. 10. Diagramme des bandes d'énergie de la cellule NESA/PcAlOH/BQ/HQ/Pt à pH 2,5.

tensions de la courbe photocourant–tension appliquée (photocourant = courant sous illumination − courant dans le noir). Quand aucun photocourant anodique n'est mesuré, on utilise une extrapolation de la courbe pour trouver V_{fb}. Dans le cas de la cellule formée d'un film de PcAlOH d'épaisseur 250 Å obtenu par rotation, la valeur de V_{fb} mesurée est de 0,43 V/ECS pour BQ/HQ. Après le contact avec l'électrolyte, les électrons passent de la solution au semiconducteur pour égaliser les niveaux de Fermi. Il en résulte une distribution de charges à l'intérieur du semiconducteur sur une profondeur *W*, ce qui crée un champ électrique conduisant à la séparation des paires électron–trou générées par la lumière. La vitesse de transfert des charges entre la phtalocyanine et l'oxydant en solution est la plus rapide quand l'énergie de l'état excité de la phtalocyanine (représenté par l'énergie de la bande de conduction) est proche de celle de l'accepteur d'électrons. D'après Gerisher (47), les fonctions de distribution des niveaux d'énergie du couple rédox BQ/HQ sont données par leur potentiel rédox et leur énergie de réorientation $\lambda = 0{,}5$ eV. Le recouvrement entre les niveaux

d'énergie de la benzoquinone et de la bande de conduction de la phtalocyanine n'est pas grand, mais de nombreuses données expérimentales (21, 23, 24) portent à croire qu'il existe chez les phtalocyanines des états de surface par l'intermédiaire desquels se fait l'échange de charges. Ces états de surfaces sont situés autour de $-0,1$ V/ECS et on observe alors un bon recouvrement d'énergie entre ces états de surface et la benzoquinone en solution, comme le représente la figure 10.

4. Conclusion

Des films minces de semiconducteurs organiques ont été préparés par déposition par rotation sur des substrats transparents. Les efficacités des cellules photoélectrochimiques ainsi obtenues sont du même ordre de grandeur que celles obtenues pour des films sublimés. Cependant, le solvant DMSO utilisé durant la déposition est difficile à éliminer et sa présence tend à diminuer l'efficacité des cellules photoélectrochimiques.

La formation d'un faible complexe de transfert de charge entre la benzoquinone et PcAlOH peut être à l'origine du déplacement du potentiel de bande plate avec le pH de la solution. L'emploi d'une contre-électrode en vanadium a permis d'atteindre des valeurs élevées pour le courant de court-circuit ($J_{sc} = 0,175$ mA/cm^2) et pour la tension en circuit ouvert ($V_{oc} = 0,337$ V) sous une irradiation de 85 mW/cm^2 en lumière blanche avec le couple rédox BQ/HQ. Le rendement de la cellule est alors de $2,4 \times 10^{-2}$%, mais des phénomènes de corrosion apparaissent à la contre-électrode. Une cellule stable NESA/PcAlOH/BQ/HQ/Pt possède une efficacité de conversion de 0,006% sous illumination de lumière blanche d'intensité 10 mW/cm^2. Ce rendement peut être amélioré en augmentant la photoconductivité et en élargissant le spectre d'absorption de la phtalocyanine d'hydroxyaluminium par un traitement chimique approprié (38, 48, 49).

Remerciements

Ce travail est supporté par des subventions du Conseil de recherches en sciences naturelles et en génie. Les auteurs tiennent à remercier Monsieur J. P. Ricbourg et l'INRS–Géoressources pour les expériences de microscopie électronique à balayage, ainsi que le professeur F. Rheault de l'INRS–Énergie pour son soutien constant.

DAVID C. THACKRAY, SARA ARIEL, TAK W. LEUNG, KUSUM MENON, BRIAN R. JAMES, and JAMES TROTTER. Can. J. Chem. **64**, 2440 (1986).

The rhodium(III) octaethylporphyrin complex Rh(OEP)(PPh_3)Cl (**1**) has been synthesized via Rh(III) or Rh(I) precursors, and fully characterized both by spectroscopy and single crystal data. The crystals, available as a bis(chloroform) solvate are triclinic, $P\bar{1}$, $a = 13.478(5)$, $b = 14.300(5)$, $c = 15.346(4)$ Å, $\alpha = 102.33(2)$, $\beta = 102.89(2)$, $\gamma = 90.56(3)°$, $Z = 2$, $D_x = 1.384$ g cm^{-3}. The structure was determined from Mo diffractometer data and refined by least-squares methods to $R = 0.095$, $R_w = 0.068$ for 5189 reflections. The octahedrally coordinated rhodium atom is displaced by 0.077 Å from the mean plane of the four N atoms, towards the triphenylphosphine group. The average Rh – ring nitrogen distance is 2.024 Å, Rh—P is 2.306(3) Å and Rh—Cl, 2.442(2) Å. Solution equilibria studies on **1** describe formation of Rh(OEP)L_2^+ (L = PPh_3, P^nBu_3) via thermal reactions (including thermodynamic data for the PPh_3 system), and formation of Rh(OEP)Cl(L′) species (L′ = CO, THF, MeCN) via photochemical processes.

DAVID C. THACKRAY, SARA ARIEL, TAK W. LEUNG, KUSUM MENON, BRIAN R. JAMES et JAMES TROTTER. Can. J. Chem. **64**, 2440 (1986).

On a synthétisé le complexe d'octaéthylporphyrine rhodium(III), Rh(OEP)(PPh_3)Cl (**1**) à partir de précurseurs de Rh(III) ou de Rh(I) et on l'a complètement caractérisé tant par spectroscopie que par diffraction des rayons-X sur un cristal unique. Les cristaux, obtenus sous une forme solvatée par deux molécules de chloroforme, sont tricliniques et ils appartiennent au groupe d'espace $P\bar{1}$ avec $a = 13,478(5)$, $b = 14,300(5)$ et $c = 15,346(4)$ Å et $\alpha = 102,33(2)$, $\beta = 102,89(2)$ et $\gamma = 90,56(3)°$, $Z = 2$ et $D_x = 1,384$ g cm^{-3}. On a déterminé la structure à partir de données de diffraction au Mo et on a affiné la structure par la méthode des moindres carrés jusqu'à des valeurs de $R = 0,095$ et de $R_w = 0,068$ pour 5189 réflexions. L'atome de rhodium, de coordination octaédrique, est déplacé vers le groupe triphénylphosphine et il s'éloigne ainsi de 0,077 Å du plan moyen des quatre atomes de N. La distance moyenne Rh-azote du cycle est égale à 2,024 Å, celle de Rh—P à 2,306(3) Å et celle de Rh—Cl à 2,442(2) Å. Des études d'équilibres en solution (qui incluent des données thermodynamiques pour le système PPh_3), effectuées sur le composé **1**, décrivent la formation de Rh(OEP)L_2^+ (L = PPh_3, P^nBu_3) par le biais de réactions thermiques ainsi que la formation d'espèces Rh(OEP)Cl(L′) (L′ = CO, THF, MeCN) par le biais de processus photochimiques.

[Traduit par la revue]

Introduction

Of particular interest to us is the investigation and development of metalloporphyrin chemistry as it relates to catalysis involving small molecules such as O_2, CO, and H_2. While most of the focus has been on ruthenium porphyrin chemistry (1–8), we have renewed interest in our earlier work on rhodium porphyrins (9).

In this paper, we report the details of the preparation and characterization of Rh(OEP)(PPh_3)Cl,[2] **1**, including an X-ray structure and some solution chemistry. Solution data on the formation of the bisphosphine cations Rh(OEP)$(L)_2^+$, where L is PPh_3 or P^nBu_3, are also presented. The latter complexes are of interest because isoelectronic ruthenium porphyrin complexes containing tertiary phosphines as axial ligands have a key role in catalytic decarbonylation of aldehydes (3), and oxidation of phosphines and thioethers by molecular oxygen (6). Coordination of tertiary phosphines to a Rh(III) porphyrin superoxide complex at low temperature has been suggested from esr data (10), but to our knowledge **1** is the first reported isolated rhodium porphyrin complex containing a phosphine.

Experimental

Materials and methods

Elemental analyses were performed by P. Borda (University of British Columbia). Electronic spectra were recorded on a Cary 17D or a Perkin-Elmer 552A uv/vis spectrophotometer fitted with a Perkin-Elmer Model C550–0555 Thermoelectric single cell holder and a Model C570–0701 Digital Controller. Solution infrared spectra were obtained using a Nicolet 5DX FT-IR instrument. Nuclear magnetic resonance spectra were obtained on a Bruker WP-80 or a Varian XL-300 instrument in FT mode. Conductivity measurements were made at 25°C under anaerobic conditions using a Thomas Serfass conductivity bridge and a cell from Yellow Springs Instrument Co.

Spectral grade benzene, toluene, and THF from Fisher Scientific were freshly distilled from benzophenone ketyl, and were freeze–pump–thaw degassed prior to use. *N,N′*-Dimethylacetamide was vacuum-distilled from CaH_2. Samples for uv/vis experiments were handled anaerobically under vacuum or an argon atmosphere using tonometers (1 mm pathlength) described elsewhere (11). Deuterated solvents were from MDS Isotopes and were used without further purification. All other solvents used were either spectral or reagent grade and used as purchased. The phosphines were reagent grade from Strem Chemicals Inc.

Rhodium was obtained as $RhCl_3 \cdot 3H_2O$ (42.61% Rh) from Johnson, Matthey Ltd. H_2OEP was a gift from Dr. D. Dolphin (University of British Columbia). The $[Rh(COE)_2Cl)]_2$ dimer (12) and Rh(OEP)Cl·$2H_2O$ (13) were prepared by the literature methods.

Chloro(octaethylporphyrinato)(triphenylphosphine)rhodium(III) monohydrate

Method A: 82 mg (0.12 mmol) Rh(OEP)Cl·$2H_2O$ and 33 mg (0.12 mmol) PPh_3 were placed in a small Schlenk tube under argon. The solids were dissolved in 20 mL freshly dried benzene. After ~15 min the solution was filtered and the filtrate volume reduced *in vacuo* to ~3 mL. The product was precipitated by addition of freshly dried hexanes and collected on a frit, and washed 3 times with 2 mL portions of hexanes before drying *in vacuo*. Yield was 52 mg (50%) of a red purple powder. *Anal.* calcd. for $C_{54}H_{61}N_4RhClPO$: C 68.20,

[h] Formed *in situ* by dissolving Rh(OEP)Cl·$2H_2O$ in THF-d_8.
[i] In CD_3CN at 121.421 MHz.
[j] In CD_2Cl_2 at 121.421 MHz.
[k] In toluene at 32.21 MHz.
[l] In DMA at 32.21 MHz.

H 6.31, N 5.89, P 3.26, Cl 3.78; found: C 68.3, H 6.7, N 5.6, P 3.3, Cl 3.8.

Method B: 400 mg (0.56 mmol)of $[Rh(COE)_2Cl]_2$[3] were suspended in 100 mL of mesitylene together with 0.6 g (1.1 mmol) of H_2OEP. A stream of CO gas was passed through the mixture while refluxing for 6 h. To the resulting red solution, 0.3 g (1.1 mmol) of PPh_3 were added and the CO flow replaced by a N_2 flow. Refluxing was continued for 1 h. After cooling the solution to room temperature, the solvent was removed *in vacuo*. The crude product was purified by recrystallization from CH_2Cl_2/hexane. Typical yields were ~65%.

Crystals for X-ray crystallographic analysis were obtained with two solvate $CHCl_3$ molecules by slow evaporation of a solution of $RhOEP(PPh_3)Cl\cdot H_2O$ in $CHCl_3$/hexane. The solvated complexes were soluble in MeOH, EtOH, acetone, $MeNO_2$, THF, $CHCl_3$, DMA, DMSO, MeCN, C_6H_6, and toluene, slightly soluble in diethyl ether, and insoluble in alkanes. Dilute solutions were found generally to be light-sensitive; the MeCN solutions were non-conducting.

^{1}H and ^{31}P data are given in Table 1: uv/vis. λ_{max}/nm (log ϵ) in C_6H_6, [Rh] = (0.9–6.0) × 10^{-3} M, 25°C *in vacuo*: 608 (3.41), 563 (4.47), 533 (4.41), 422 (5.20), 351 (4.59); in Nujol mull: 617, 564, 535, 418, 350.

Solution equilibrium measurements

Equilibrium constants for replacement of chloride by PPh_3 in CH_2Cl_2 solution, reaction [1], were measured by a spectrophotometric

$$[1]\quad \underset{\mathbf{1}}{Rh(OEP)(PPh_3)Cl} + PPh_3 \overset{K}{\rightleftharpoons} \underset{\mathbf{2}}{Rh(OEP)(PPh_3)_2^+} + Cl^-$$

titration technique. Ambient light was excluded during sample manipulations by using dimmed room lighting and by covering all exposed surfaces with black plastic tape. Aliquots (μL) of 10^{-1} M PPh_3 in CH_2Cl_2 (or alternatively solid PPh_3) were added to dilute solutions (~5 × 10^{-4} M) of **1** in CH_2Cl_2. Formation of **2** within seconds was evidenced by a red shift of the Soret from 419 to 429 nm, and the α and β bands from 560 to 568 and 529 to 537 nm, respectively, with a concomitant decrease in the intensity of the α band relative to the β band (Fig. 1). Measurements were also performed on solutions containing various amounts of $[Ph_4As]Cl$, $[^nBu_4N]Cl$ or $[^nBu_4N][ClO_4]$ to examine the effect of ionic strength and $[Cl^-]$. No change from the initial spectrum of the complex was noted on addition of the chloride salts to solutions of **1**.

The value of K was found by using visible data (at 560 nm) obtained using different combinations of initial concentrations of **1** (C_0), and added Cl^- (Cl_0) and PPh_3 (P_0). By defining A and A_0 as the absorbances measured at 560 nm with and without added PPh_3, and ϵ_0 and ϵ_∞ as the extinction coefficients of **1** and **2**, eq. [2] may be derived (l = path length):

$$[2]\quad K_{obs} = \frac{\left\{C_0 - \left[\frac{A_0 - A}{(\epsilon_0 - \epsilon_\infty)l}\right]\right\}\left\{Cl_0 + C_0 - \left[\frac{A_0 - A}{(\epsilon_0 - \epsilon_\infty)l}\right]\right\}}{\left\{\frac{A_0 - A}{(\epsilon_0 - \epsilon_\infty)l}\right\}\left\{P_0 - C_0 - \left[\frac{A_0 - A}{(\epsilon_0 - \epsilon_\infty)l}\right]\right\}}$$

The ϵ_0 (23 350) and ϵ_∞ (6 500 M^{-1} cm^{-1}) values were available experimentally because the limiting spectra of **1** and **2** for the equilibrium could be measured under readily attainable conditions (high $[Cl^-]$ with no added phosphine, and high $[PPh_3]$ with no added Cl^-, respectively). Since ionic products are involved, the thermodynamic equilibrium constant (K) will be a function of the mean ionic activity coefficient ($\gamma_\pm$) and the experimental equilibrium constant (K_{obs}).

$$[3]\quad K = \gamma_\pm^2 \times \frac{[\mathbf{2}][Cl^-]}{[\mathbf{1}][PPh_3]} = \gamma_\pm^2 K_{obs}$$

where $\gamma_\pm$ is defined by the familiar Debye–Hückel limiting law

$$[4]\quad \log_{10}\gamma_\pm = Az_+z_-\mu^{1/2}$$

The value of K was determined from the intercept of $\log_{10} K_{obs}$ plotted vs. $\mu^{1/2}$ at a particular temperature. Figure 2 shows such a plot for the data at 25°C (Table 2), and, for the data at $\mu < 7 \times 10^{-4}$ M, the line drawn gives an intercept corresponding to $\log_{10} K = -1.75$ (K = 0.0174). The slope of the least squares line drawn (of slope $-2Az_+z_-$

[3] Similar results were obtained using $[Rh(NBD)Cl]_2$ or $Rh(py)_3Cl_3$ as starting materials.

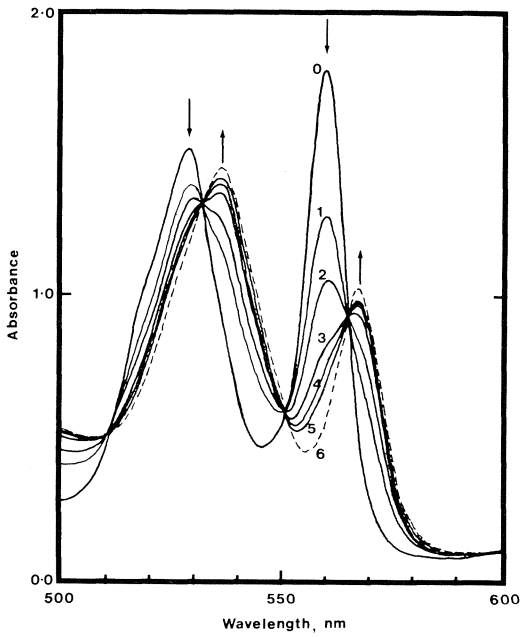

FIG. 1. Spectrophotometric titration of $Rh(OEP)(PPh_3)Cl$ with added PPh_3 in CH_2Cl_2 at 25°C, [Rh] = 8×10^{-4} *M*; curves *0–5* result added [PPh_3] of 0.0, 0.38, 1.09, 2.69, 5.01, and 7.18 $\times 10^{-2}$ *M*, respectively. *6* shows the spectrum of $Rh(OEP)(PPh_3)_2^+$ (formed at [PPh_3] ~ 5×10^{-2} *M* and $\mu \sim 0.02$ *M*).

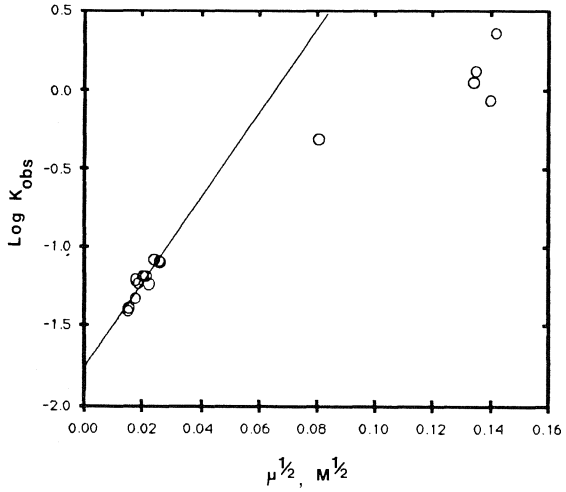

FIG. 2. Plot of $\log_{10} K_{obs}$ vs. (ionic strength)$^{1/2}$ for data of Table 2.

or +2*A* for this particular equilibrium) is 26.9. The calculated value for the slope using the standard expression for *A* (14)[4] is 26.7, showing remarkably good agreement.

Thermodynamic parameters for equilibrium [1] were obtained by repeating the equilibrium measurements (log K_{obs} vs. $\mu^{1/2}$) at four other temperatures over the range 10–30°C. Values of *K* (temp) are 0.0327 (10°C), 0.0262 (15°C), 0.0202 (20°C), and 0.0128 (30°C). The data give an excellent Van't Hoff plot from which values of ΔH^0 ($-7.8 \pm 0.5 \pm$ kcal mol^{-1}) and ΔS^0 (-34.8 ± 0.8 cal mol^{-1} K^{-1}) were estimated.

[4] $A = \dfrac{(2\pi N)^{1/2}}{2.303}\left(\dfrac{e^2}{10\epsilon kT}\right)^{3/2}$, where *N* = Avogadro's number, *e* = electronic charge, ϵ = dielectric constant (8.90 for CH_2Cl_2 at 25°C), *k* = the Boltzmann constant, *T* = absolute temperature.

TABLE 2. Variation of K_{obs} for reaction [1] in CH_2Cl_2 at 25°C[a]

$\mu \times 10^4$ *M*	$K_{obs} \times 10^2$	$\mu \times 10^4$ *M*	$K_{obs} \times 10^2$
2.16	3.91	5.94	8.53
2.26	4.06	6.49	8.28
2.97	4.77	6.74	8.13
3.11	6.29	64.8[b]	49.9
3.45	6.06	179[c]	114
4.05	6.65	182[d]	136
4.50	6.44	196[e]	86
4.88	5.83	203[f]	240

[a] Up to $\mu = 6.74 \times 10^{-4}$ *M*, the ionic strength results solely from the ions generated by reaction [1], i.e., no salt has been added. Initial [$Rh(OEP)(PPh_3)Cl$] between $(4.0–8.0) \times 10^{-4}$ *M*.
[b] Added 6.48×10^{-3} *M* $Ph_4AsCl \cdot H_2O$.
[c] Added 1.79×10^{-2} *M* $Ph_4AsCl \cdot H_2O$.
[d] Added 1.82×10^{-3} *M* $Ph_4AsCl \cdot H_2O$; addition of H_2O to 2×10^{-2} *M* had no measurable effect on the equilibrium reaction.
[e] Added 1.76×10^{-2} *M* $^nBu_4NClO_4$.
[f] Added 2.03×10^{-2} *M* $^nBu_4NCl$.

X-ray crystallographic analysis

A reddish-brown crystal of $Rh(OEP)(PPh_3)Cl \cdot 2CHCl_3$, with {100}, {010}, and {001} faces and of dimensions $0.35 \times 0.43 \times 0.20$ mm, was mounted on an Enraf-Nonius CAD4-F diffractometer in a general orientation. Unit cell parameters were refined by least squares treatment of sin θ values measured with Mo$K\alpha_1$ radiation for 25 reflections with $30 \leq 2\theta \leq 40°$. Crystal data (at 22°C) are:

$C_{56}H_{61}Cl_7N_4PRh$ fw 1172.18

Triclinic, $a = 13.478(5)$, $b = 14.300(5)$, $c = 15.346(4)$ Å, $\alpha = 102.33(2)$, $\beta = 102.89(2)$, $\gamma = 90.56(3)°$, $V = 2812(3)$ Å^3, $Z = 2$, $D_x = 1.384$ g cm^{-3}, Mo$K\alpha_1$ radiation, $\lambda = 0.70930$ Å, $\mu = 6.6$ cm^{-1}. Space group $P\bar{1}$, from structure analysis.

Intensities were measured for $\pm h$, $\pm k$, l reflections with $4 \leq 2\theta \leq 54°$, with graphite-monochromatized Mo$K\alpha$ radiation, ω–(5/3)θ scan at 0.7–10.1°min^{-1}, ω range $(1.00 + 0.35 \tan \theta)°$ (extended by 25% on both sides for background measurements), horizontal aperture $(2.0 + \tan \theta)$ mm, vertical aperture 4 mm, Lorentz polarization and absorption corrections (transmission factors from 0.787 to 0.887); three standard reflections (500, 530, 525) were monitored for orientation and intensity control (intensity decay during data collection of 35%, probably resulting from loss of chloroform, limited the accuracy of the data set). 9394 Independent reflections were measured, and 5189 with $F \geq 3\sigma(F)$ were used in the analysis; $\sigma^2(I) = S + 2B + [0.04(S - B)]^2$, *S* = scan count, *B* = background count.

The coordinates of the Rh and P atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference Fourier map; the asymmetric unit contains one porphyrin–rhodium complex and two chloroform molecules. The structure was refined by block-diagonal least-squares methods, with minimization of $\Sigma w(F_o - F_c)^2$, $w = 1/\sigma^2(F)$; SHELX computer programs (15) were used, with scattering factors of ref. 16 and anisotropic thermal parameters. Hydrogen atoms were included at calculated positions but were not refined positionally, apart from adjustment of methyls as rigid groups. Isotropic temperature factors of the H atoms were refined. Refinement converged at $R = 0.095$, $R_w = 0.068$ for 5189 reflections and 721 variables refined in three blocks of 209, 270, and 242 variables, respectively. The error in an observation of unit weight was 2.02e, the mean and maximum shifts in the final cycles were 0.2 and 0.9σ, respectively, and the maximum fluctuations in a final difference map were ± 1.6 e Å^{-3}. The chloroform molecules and the outer atoms of the ethyl and phenyl groups exhibit large thermal motion, with rms displacements of up to 0.5 Å.

Final positional parameters for the non-hydrogen atoms are given in Table 3, with equivalent isotropic thermal parameters ($U_{eq} = 1/3 \times$ trace *U*). Anisotropic thermal parameters, bond lengths and angles, hydrogen parameters, and measured and calculated structure factors

[a] U_{eq} is one third the trace of the diagonalized temperature factor matrix.

(Tables 4–8, respectively) have been placed in the Depository of Unpublished Data.[5]

Discussion

The synthesis of Rh(OEP)(PPh_3)Cl, **1**, via addition of phosphine to Rh(OEP)Cl·$2H_2O$ (method A) is straightforward but the route to the precursor Rh(III) complex via $[RhCl(CO)_2]_2$ involves separation from other rhodium porphyrin products (13). The second method (B) described, via the readily synthesized $[Rh(COE)_2Cl]_2$ precursor, is somewhat more convenient, but **1** is obtained from what is undoubtedly a complex mixture of rhodium porphyrin species. The labile cyclooctene is likely to be readily displaced by the CO to form $[RhCl(CO)_2]_2$ and the synthesis then becomes akin to that described in method A. However, *in situ* monitoring by infrared in the carbonyl region reveals a myriad of bands that indicate the presence of several carbonylporphyrin complexes (see ref. 13), including what is probably Rh(OEP)(CO)Cl, 2085 cm^{-1}, from which **1** can be formed by treatment with PPh_3 (see below).

Structure description

The molecule of the porphyrin complex (Fig. 3) contains a central Rh(III) ion coordinated to the four N atoms, with a PPh_3 and Cl ligand completing distorted octahedral geometry at Rh. Rh is displaced from the mean plane of the four N atoms towards the phosphine ligand by 0.077 Å. The whole porphyrin nucleus shows deviations from exact planarity, with a maximum deviation of 0.098 Å and a root-mean-square deviation of 0.06 Å from a mean plane. The eight outer C atoms of the peripheral ethyl groups are displaced from the porphyrin plane by about 1.3 Å, all on the same side of the plane as the phosphine group. There are no obvious non-bonding interactions that force the Rh atom to lie out of the plane towards the phosphine, and it is not clear why all the ethyl groups point towards the phosphine, although the analogous situation exists in the structure of Ru(OEP)(PPh_3)Br (5). The variable orientations found for the ethyl groups within OEP structures have been discussed previously but not rationalized (17).

The Rh–N distances are 1.982–2.061(8) Å, the average distance of 2.024 Å being reasonably close to values observed in the few other Rh—porphyrins which have been studied (18–21). The Rh—P and Rh—Cl distances of 2.306(3) and 2.442(2) Å are also with the ranges usually observed. The P—C bond lengths are 1.828–1.839(10) Å, mean 1.834 Å. The angles at P show some large variations from the tetrahedral value, with Rh—P—C = 110.9, 113.5, 123.0(4)° and C—P—C = 99.0, 100.5, 108.3(4)°. These variations presumably result from steric interaction between the phenyl

[5] The structure factor table, anisotropic thermal parameters, hydrogen parameters, bond distances and angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

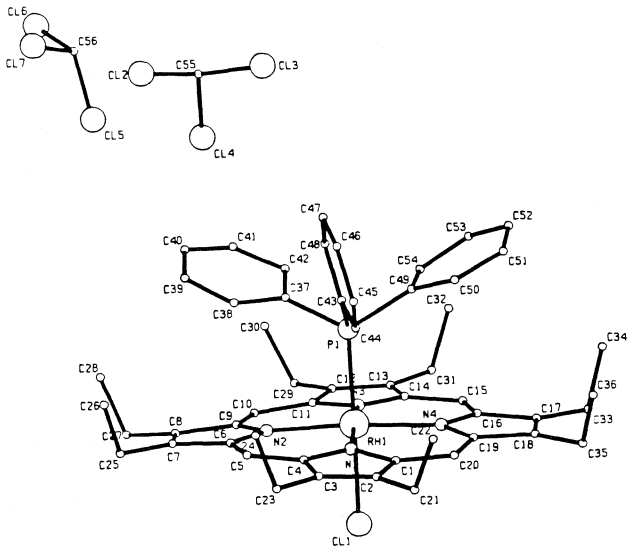

FIG. 3. Structure of the $Rh(OEP)(PPh_3)Cl \cdot 2CHCl_3$ complex.

rings and the porphyrin nucleus; the large Rh—P(1)—C(43) angle of 123.0(4)° involves the P—C bond which eclipses the Rh—N(1) bond. There are some variations in bond distances and angles within the porphyrin nucleus, but the lengths and angles are generally close to normal values (5).

Intermolecular distances correspond to normal van der Waals interactions. The two solvent chloroform molecules have normal dimensions, mean C—Cl = 1.73 Å.

Solution species

The non-ionic chlorotriphenylphosphine complex **1** remains 6-coordinate in solution. Beer's law was obeyed over the range $(0.9–8.0) \times 10^{-4}$ *M* in benzene solution, *in the dark*. The ^1H nmr spectrum of solutions at $10^{-3}–10^{-2}$ *M* (Table 1) is consistent with the presence of a diamagnetic metallo-octaethylporphyrin complex, that is substituted unsymmetrically with regard to the porphyrin plane, i.e., two different axial ligands are present (5–8). Within such complexes the methylene protons of the ethyl side-chains become anisochronous and appear as an ABX_3 multiplet (6, 22). In symmetrically substituted species, e.g. the bisphosphine complexes (see below), the $—CH_2—$ protons appear as a single quartet due to coupling with the adjacent $—CH_3$ group. There is no evidence for free phosphine in solutions of **1**, and the uv/vis spectrum is unaffected by addition of Cl^-. Coordination of a single PPh_3 is shown by integration of the *o*-, *m*-, and *p*-protons which are shifted upfield from their normal positions by the ring current of the porphyrin (7, 17). Further, the solid state uv/vis spectrum shows absorption maxima that correspond closely to those measured in solution.

Addition of PPh_3 or P^nBu_3 to the complex in polar solvents (MeCN, CH_2Cl_2, diethyl ether, DMA) resulted in formation of cationic bisphosphine complexes, reactions [1] and [5].

[5] $Rh(OEP)(PPh_3)Cl + 2P^nBu_3 \rightarrow Rh(OEP)(P^nBu_3)_2^+ + Cl^- + PPh_3$

The nmr spectroscopic evidence was cleanest for the reaction with P^nBu_3. Upon addition of two equivalents of phosphine to CD_3CN or CD_2Cl_2 solutions of **1**, the ^1H nmr spectrum of **1** was replaced by a new set of signals due to $Rh(OEP)(P^nBu_3)_2^+$ (Table 1). The methylene protons of the ethyl side chains appear as the expected quartet, while the upfield resonances due to coordinated P^nBu_3 were in a 2:1 equivalent ratio relative to the porphyrin. Reaction [5] was also monitored by $^{31}P\{^1H\}$ nmr, free PPh_3 being clearly observed. An excess of PPh_3 (to $\sim 10^{-1}$ *M*) was required for *in situ* formation of $Rh(OEP)(PPh_3)_2^+$, which was observable by ^1H and $^{31}P\{^1H\}$ nmr of CD_2Cl_2 solutions (Table 1). The conductance of a MeCN solution of **1** after addition of PPh_3 rose to a limiting value of 125 Ω^{-1} cm^2 mol^{-1}, consistent with formation of a 1:1 electrolyte (23, 24). Essentially identical nmr data in CD_2Cl_2 and CD_3CN argue against formation of the ion-pair $[Rh(OEP)(PPh_3)_2^+ \ldots Cl^-]$ in dichloromethane. Stronger binding of P^nBu_3 relative to triarylphosphines has been reported for the isoelectronic, d^6 Ru(II)OEP and Ru(II)TPP complexes (17) and was accounted for by the higher basicity of the trialkylphosphines (25).

Formation of mixed PPh_3/P^nBu_3 or $Rh(OEP)(P^nBu_3)Cl$ complexes was not evident by nmr. Also, the ionic bisphosphine complexes were not formed at all in toluene or benzene solution. The more polar CH_2Cl_2 ($\epsilon \approx 9$) or MeCN ($\epsilon \approx 36$) were required to promote equilibria [1] or [5].

Reactions [1] and [5] could also be monitored by uv/vis spectroscopy. Addition of phosphine resulted in a red shift of the Soret and visible bands (see Experimental section) with a marked diminution of the α band (Fig. 1). These findings are qualitatively consistent with coordination of an additional strong ligand (26). A corresponding reverse blue shift of the spectrum of $Ru(OEP)(P^nBu_3)(S)$ (S = DMSO or MeCN) compared with that of $Ru(OEP)(P^nBu_3)_2$ has been noted previously (17).

Equilibrium [1] was studied quantitatively using uv/vis spectroscopy, following qualitative observations on the inhibition of the forward reaction in the presence of added chloride. The same isosbestic points (Fig. 1) were observed during a spectrophotometric titration with PPh_3 at a given temperature, or during variation of temperature over the range 10–30°C at any chosen $[PPh_3]$. Indeed, the latter type of experiment allows for a rapid estimation of K_{obs} as a function of temperature using just a single solution; such values were in good agreement with those estimated from the more extensive data sets described in the Experimental.

The net rapid substitution reaction [1] almost certainly occurs via a dissociative process and a 5-coordinate intermediate, reactions [6], [7]. The overall *K* value ($= K_1K_2$) shows that a $[PPh_3]$ of ~ 0.2 *M* is required to convert 90% of **1** (initially at $\sim 5 \times 10^{-4}$ *M*) into **2** at 25°C.

[6] $\underset{\mathbf{1}}{Rh(OEP)(PPh_3)Cl} \overset{K_1}{\rightleftharpoons} \underset{\mathbf{3}}{Rh(OEP)(PPh_3)^+} + Cl^-$

[7] $\mathbf{3} + PPh_3 \overset{K_2}{\rightleftharpoons} \underset{\mathbf{2}}{Rh(OEP)(PPh_3)_2^+}$

The stoichiometric conversion with P^nBu_3 implies that the equilibrium constant for [5] is $>10^3$ at corresponding conditions. The large negative ΔS^0 value (-34.8 cal mol^{-1} K^{-1}) for reaction [1] is reasonable for transformation of neutral species into solvated charged ones. Chloride is expected to form a stronger bond than PPh_3 to Rh(III), and thus the overall exothermicity (-7.8 kcal mol^{-1}) of the forward reaction presumably results from contributions of the solvation enthalpies of the product ions.

Under dark (thermal) conditions (see below), CH_2Cl_2 solutions of **1** do not react with 1 atm CO ($\sim 5 \times 10^{-3}$ *M*), implying that CO at this concentration cannot compete for **3** with the back

reaction of equilibrium [6], even though the [Cl$^-$] must be very low since K_1 is immeasurably small. At an added [PPh$_3$] of about 5×10^{-3} *M*, reaction [1] with [**1**] ~ 5×10^{-4} *M* would generate ~35% of the bisphosphine cation. This implies that K_2 (reaction [7]) is much smaller for CO addition than for PPh$_3$ addition. Isoelectronic with **3**, the neutral, isolated Ru(OEP)(PPh$_3$) species reacts more readily with CO (3, 6, 17), presumably because the better π-acceptor properties of CO (vs. PPh$_3$) are more compatible with the lower oxidation state of Ru(II). The lack of reaction with CO also indicates negligible dissociation of PPh$_3$ under these conditions to form Rh(OEP)Cl, which is known to react with CO to form Rh(OEP)(CO)Cl (27, and see below), reactions [8] and [9]:

[8] Rh(OEP)(PPh$_3$)Cl ⇌ Rh(OEP)Cl + PPh$_3$

[9] Rh(OEP)Cl + CO ⇌ Rh(OEP)(CO)Cl

Complex **1** in benzene, THF, or MeCN, however, is photochromic in the presence of 1 atm CO, and reacts according to reactions [8] and [9]. Exposure to laboratory light or sunlight yields within minutes an *in situ* carbonyl (ν_{CO} = 2087 cm^{-1} in THF) with concomitant release of PPh$_3$, and the nmr data (Table 1) are consistent with the presence of Rh(OEP)(CO)Cl. Quantitative re-formation of **1** occurs in the dark over a few hours via intermediate Rh(OEP)(solvent)Cl species (as judged by comparison with the visible spectrum of Rh(OEP)Cl dissolved in the appropriate solvent). Solutions of **1** in THF or MeCN on exposure to light in the absence of CO also yield the Rh(OEP)(solvent)Cl species. Visible spectral data are given in Table 9.

The noted reversible carbonylation–decarbonylation reaction, in the daylight and dark, respectively (somewhat atypical in that the *decarbonylation* process is often photo-assisted), is of potential interest as a further model for solar energy storage in biological systems (28).

The ^{1}H and ^{31}P nmr data for all the species (Table 1) show shifts that are typical for diamagnetic, octahedral, metalloporphyrin complexes (2, 17, 29), and the magnitudes of the ^1J(RhP) coupling constants are appropriate for octahedral Rh(III) products (30).

The findings on reactivity can be summarized as shown in Scheme 1. Phosphine ligation of **1** is thermodynamically favoured relative to CO ligation. However, reactivity towards CO is enhanced in the presence of these ligands by "forcing" the system through unsaturated intermediates generated photochemically. These equilibria are of particular relevance to the reactions of M(porp)L$_2$ complexes (M = Fe, Ru; L = phosphine, MeCN, THF, etc.) with gas molecules such as CO and O$_2$, that also go via a dissociative mechanism (1, 3, 31–35).

[10] $$M(porp)(L)_2 \underset{+L}{\overset{-L}{\rightleftharpoons}} M(porp)L \underset{-gas}{\overset{+gas}{\rightleftharpoons}} M(porp)L(gas)(L)$$

Enhancement of the concentration of the 16-electron, 5-coordinate complexes is important in a catalytic context, such as decarbonylation of aldehydes which can proceed via the M(porp)(CO)L species (3, 33). In this regard, preliminary data indicate that phenylacetaldehyde can be used as a carbonyl source, instead of CO gas, to form Rh(OEP)(CO)Cl from Rh(OEP)(PPh$_3$)Cl, under conditions of laboratory lighting.

Concluding remarks

The synthesis, along with characterization by uv/vis, ^{1}H and ^{31}P{^{1}H} nmr spectroscopy and X-ray crystallography, of the complex Rh(OEP)(PPh$_3$)Cl, **1**, are presented. Additionally, spectroscopic evidence is presented for solution equilibria of **1**

involving formation of $Rh(OEP)L_2^+$ (L = PPh_3, P^nBu_3) via thermal reactions, and Rh(OEP)(Cl)(L′) (L′ = CO, THF, MeCN) via photochemical processes. Thermodynamic data have been estimated for formation of the bis(triphenylphosphine) species.

The reactions of trichloromethylium with oxygen- and sulfur-containing compounds

JOHN ALFRED STONE AND NANCY JOAN MOOTE
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received June 25, 1986

JOHN ALFRED STONE and NANCY JOAN MOOTE. Can. J. Chem. **64**, 2447 (1986).

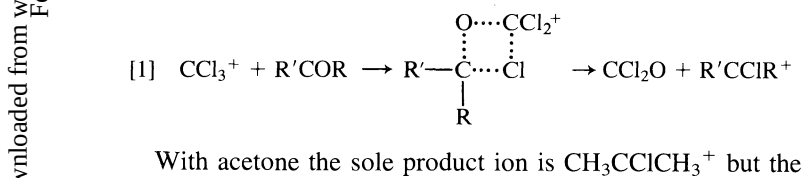
The gas phase reactions of CCl_3^+ with acetone, diethyl ketone, dimethyl ether, diethyl ether, several cyclic ethers, sulfides, and disulfides have been examined using high pressure mass spectrometry. In many of the reactions a stabilized ion–molecule complex is observed which may or may not react further. With disulfides a second reaction channel is electron transfer, the observation of which shows that the 0–0 ionization energies of these compounds are lower than the ionization energy of CCl_3 (8.28 eV) and hence lower than the values obtained by photoelectron spectroscopy. Rate constants for the disappearance of CCl_3^+ in general show an increase in value with increase in reaction exothermicity. The lack of a measurable effect of pressure on rate constants is discussed for some association reactions which have reaction efficiencies well below unity.

JOHN ALFRED STONE et NANCY JOAN MOOTE. Can. J. Chem. **64**, 2447 (1986).

Utilisant la spectrométrie de masse à haute pression, on a étudié les réactions en phase gazeuse du CCl_3^+ avec l'acétone, la pentanone-3, le méthoxyméthane, l'éthoxyéthane et plusieurs éthers, sulfures et disulfures cycliques. Dans plusieurs de ces réactions, on a observé la formation de complexes ion/molécule qui peuvent éventuellement donner d'autres réactions. Avec les disulfures, les transferts d'électrons offrent une deuxième voie de réaction; leur observation démontre que les énergies d'ionisation 0–0 de ces composés sont plus basses que l'énergie d'ionisation du CCl_3 (8,28 eV) et donc plus basses que les valeurs obtenues par spectroscopie photoélectronique. Les vitesses de disparition du CCl_3^+ augmentent généralement avec une augmentation de l'exothermicité de la réaction. On discute du fait que, pour quelques réactions d'association qui ont des efficacités réactionnelles bien au-dessous de un, il n'y a pas d'effet mesurable de la pression sur les constantes de vitesse.
[Traduit par la revue]

Introduction

The mechanisms of the reactions of CCl_3^+ with carbonyl-containing compounds were examined by Ausloos and co-workers (1) using ion cyclotron resonance (icr) at pressures in the range 10^{-6}–10^{-5} Torr (1 Torr = 133 Pa) and ambient temperature. For aldehydes and ketones it was suggested that the preferential addition of CCl_3^+ to oxygen is immediately followed by a four-centre reaction leading to the formation a mono halogenated carbonium ion:



[1] $CCl_3^+ + R'COR \rightarrow R'—C(\cdots O\cdots CCl_2^+)\cdots Cl \; (R) \rightarrow CCl_2O + R'CClR^+$

With acetone the sole product ion is $CH_3CClCH_3^+$ but the more exothermic reaction of CCl_3^+ with diethylketone results in the further decomposition of 95% of the initially produced $C_2H_5CClC_2H_5^+$ by loss of HCl to give $C_5H_9^+$.

The measured rate constants for the reactions of CCl_3^+ and other halomethyl ions with carbonyl-containing compounds appeared to correlate well with reaction exothermicity. For example, the second order rate constants for the reactions of CCl_3^+ with CH_3COCH_3 and $C_2H_5COC_2H_5$ were respectively $< 3 \times 10^{-11}$ and 9×10^{-10} cm^3 molecule^{-1} s^{-1}. It was concluded that not only does reaction efficiency (defined as $k_{reaction}/k_{collision}$ where k is a specific rate constant) vary directly with exothermicity but that the results also indicate that the lifetime of the ion–molecule complex is probably an even more important factor; the shorter the complex lifetime, the lower the reaction efficiency. Such lifetimes are, however, not readily determined.

In earlier experiments with CCl_3^+ using high pressure mass spectrometry (HPMS) with ion source pressures in the range 2–5 Torr, we found that stable aromatic·CCl_3^+ adducts were observable (2) whereas previous studies at much lower ion source pressures ($\sim 10^{-4}$ Torr) had failed to detect such species (3, 4). Thus while collisional stabilization is not of importance at low pressures, it can be of significance at the higher pressures of our HPMS studies. The mean times between collisions of ions with neutrals at 4 Torr and 10^{-5} Torr are roughly 10^{-9} and 10^{-3} s, respectively, at 300 K. There is thus the possibility, using HPMS, of investigating whether Ausloos' claim that the very low reaction efficiency of CCl_3^+ with acetone (1) is due to a very short ion–molecule complex lifetime. If this complex can be observed using HPMS then its lifetime is at least 10^{-9} s.

The reactions of CCl_3^+ with another major class of oxygen bases, namely, the ethers have not been reported. We have examined such reactions using both linear and cyclic ethers and make comparisons with the results for carbonyl compounds. These ether results have also been compared with those obtained for thioethers.

Thiosulfonium ions of the type $(CH_3SSCH_3)R^+$ (R = H, alkyl) have been generated by displacement reactions in icr studies (5) and although they have been known and studied for some time in the condensed phase (6), their gas phase reactions have received little attention. We have therefore investigated the possibility of generating thiosulfonium ions by the addition of CCl_3^+ to RSSR under HPMS conditions. If this is possible then other thiosulfonium ions might be generated in a similar manner.

Experimental

The pulsed electron beam, high pressure ion source mass spectrometer has been described previously (7). Premixed samples of accurately known composition are flowed into the field free ion source from a heated reservoir via a heated leak valve. The source is operable in the pressure range 1–4 Torr, the ion beam being most intense at the higher pressures. Kinetic data are obtained by pulsing the electron beam, the temporal profiles of the different ion currents emerging from the ion source exit slit after the electron beam pulse being monitored with ion counting equipment and a multichannel analyser.

Methane (Matheson Ultra-high Purity) had a stated purity exceeding 99.99%; carbon tetrachloride (Fisher Spectrograde) was used as received; all other compounds were of the highest purities available. In no cases were ions attributable to impurities observed in any mass spectrum.

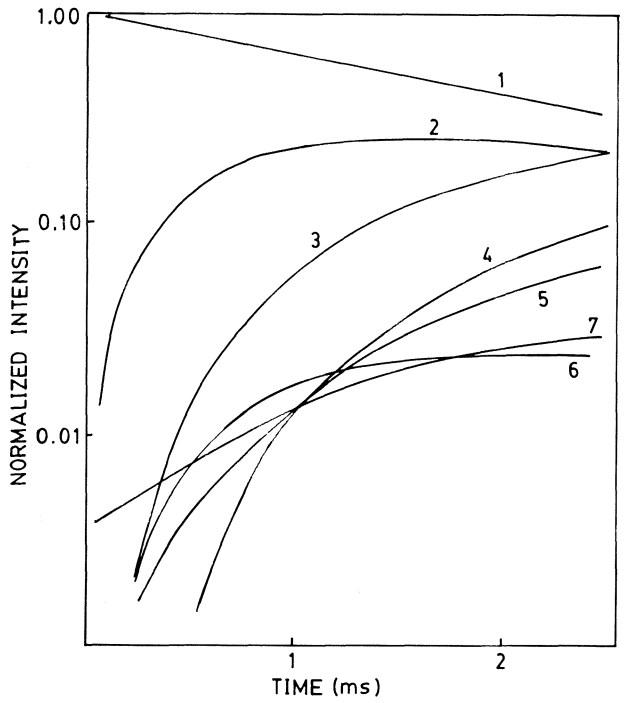


FIG. 1. Normalized ion intensities after a 85 μs pulse of ionizing electrons in a $CH_3COCH_3/CCl_4/CH_4$ (0.0011/0.46/99.5) mixture at 1.37 Torr and 300 K. To enhance clarity no experimental points are shown. The curves show the temporal profiles of *1*, CCl_3^+; *2*, $CH_3COCH_3 \cdot CCl_3^+$ (m/z 175); *3*, $C_4H_5OCl_2$ (m/z 139); *4*, $(CH_3COCH_3)_2H^+$ (m/z 117); *5*, $C_6H_{11}O^+$ (m/z 99); *6*, $C_7H_{11}O_2Cl_2^+$ (m/z 197); *7*, $CH_3COCH_3 \cdot H^+$ (m/z 59). The (m/z) value for the most abundant form of the ion is given but the graph shows the total normalized intensity for the ion.

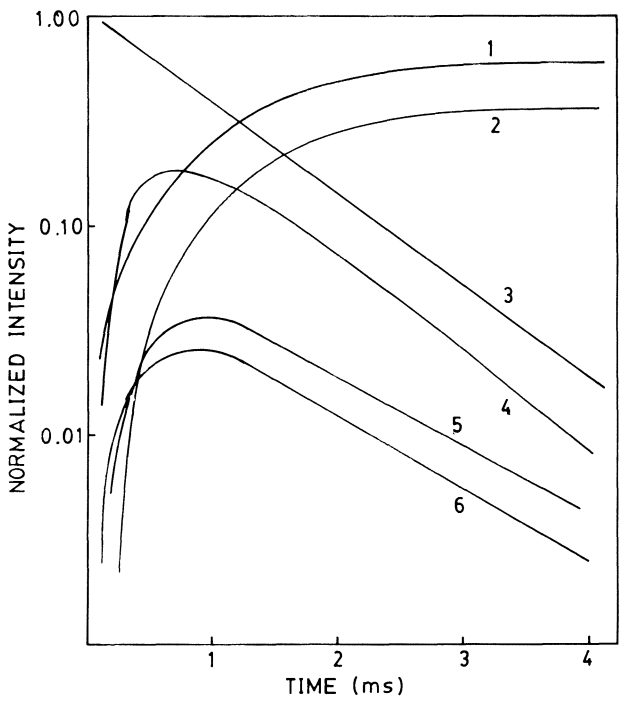

FIG. 2. Normalized ion intensities after a 50 μs pulse of ionizing electrons in a $C_2H_5COC_2H_5/CCl_4/CH_4$ (0.0059/0.32/99.7) mixture at 3.6 Torr and 455 K. The curves show the temporal profiles of *1*, $C_2H_5COC_2H_5 \cdot H^+$ (m/z 87); *2*, $(C_2H_5COC_2H_5)_2H^+$ (m/z 175); *3*, CCl_3^+; *4*, $C_2H_5COC_2H_5 \cdot CCl_3^+$ (m/z 203); *5*, $C_5H_9^+$ (m/z 69); *6*, $C_2H_5CClC_2H_5^+$ (m/z 105).

Results and discussion

CCl_3^+ is formed from CCl_4 by dissociative proton transfer from CH_5^+ and $C_2H_5^+$, the major reagent ions in methane (2).

[2] $CH_5^+(C_2H_5^+) + CCl_4 \rightarrow CH_4(C_2H_4) + HCl + CCl_3^+$

It is the only ion present at times greater than 100 μs after a pulse of ionizing electrons in a CH_4/CCl_4 (100/0.3) mixture at ion source pressures from 1–4 Torr and temperatures from 300–600 K. The CCl_3^+ ions formed then react with molecules of interest introduced into the gas mixture at very low concentrations (<0.01 mol%).

The plots of normalized ion currents as functions of time such as those in Figs. 1 to 4 can be interpreted to show the sequences of reactions following the interaction of CCl_3^+ with an added neutral. In addition, the linear decay with time of the logarithm of the normalized CCl_3^+ ion current allows the determination of the pseudo first order rate constant of the reaction of CCl_3^+ with the neutral. Knowing the concentration of the latter in the ion source the second order rate constant may be determined.

[3] $M + CCl_3^+ \rightarrow$ products

$$[4] \quad \frac{-d[CCl_3^+]}{dt} = k[M][CCl_3^+] = k'[CCl_3^+]$$

Taking the measured ion current i_t as being proportional to ion concentration in the ion source at time t and i_0 that at time zero, eq. [4] may be integrated to yield

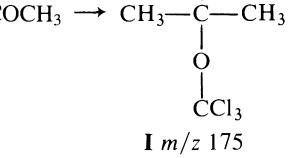
$$[5] \quad \ln \frac{i_t}{i_0} = -k't$$

Values of k for the various neutrals studied under a variety of temperatures and pressures are given in Table 1. Also given are the efficiencies of reaction per ion–neutral collision, k/k_{ADO}, where k_{ADO} is the rate constant for collision calculated using the average-dipole orientation theory of Su and Bowers (8).

CCl_3^+ + acetone

This system was examined at pressures around 3.8 Torr at several temperatures and also at a pressure of 1.37 Torr at 302 K. The results for the latter experiment are shown in Fig. 1. The results for the other conditions do show some marked changes from those in Fig. 1 but these changes involve secondary reactions occurring at long ion residence times. The only primary reaction observed in all cases is the formation of the acetone·CCl_3^+ adduct

[6] $CCl_3^+ + CH_3COCH_3 \rightarrow$



I m/z 175

The tertiary carbocation **I** reacts further with acetone via four different channels whose relative importances change markedly with change of temperature and to a much lesser extent with change of ion source pressure.

The structures shown for the products of reaction [7] are plausible but not proven. At 302 K channel [7b] is dominant (Fig. 1) but with increasing temperature the protonation reaction [7a] increases in importance. Above 462 K neither m/z 139 nor m/z 197 are observed, the only chlorine-containing ion being **I**, which is of course only present at short reaction times. m/z 59

[7a] $\mathbf{I} + CH_3COCH_3 \rightarrow (CH_3)_2COH^+ + C_4H_5OCl_3$

m/z 59

[7b] $\rightarrow CH_2{=}C(CH_3^+)O{-}CCl_2^+ + C_3H_7OCl$

m/z 139

[7c] $\rightarrow CH_3{-}C^+(CH_3){-}O{-}C(CH_3){=}CH_2 + HCl + COCl_2$

m/z 99

[7d] $\rightarrow CH_3{-}C(CH_2){-}O{-}C(CH_3)_2{-}O{-}CCl_2^+ + HCl$

m/z 197

reacts rapidly with neutral acetone to yield m/z 117 the proton-bound dimer $((CH_3)_2CO)_2H^+$.

It is noteworthy that the sole product ion observed using icr at pressures of $\sim 10^{-5}$ Torr, and ambient temperature $CH_3CClCH_3^+$ (1) formed in reaction [1], was not observed in this HPMS study. The reported reaction efficiency of 0.015 in the icr study is much less than the value of 0.5 for the association reaction observed in this study at 302 K (Table 1). There is the possibility that any $CH_3CClCH_3^+$ formed reacts immediately by chloride abstraction from the CCl_4, which is present in high concentration, to regenerate CCl_3^+ so that it itself is not observable. Such a reaction was not reported in the icr study.

CCl_3^+ + diethylketone

The adduct $(C_2H_5)_2COCCl_3^+$ is the only product at 298 K. It reacts rapidly by proton transfer yielding first $(C_2H_5)_2COH^+$ which is further solvated to $((C_2H_5)_2CO)_2H^+$. At 455 K two other initial products first appear, viz. $C_5H_9^+$ and $(C_2H_5)_2CCl^+$ in approximately equal but quite low yields (Fig. 2) whose relative values change little with pressure. In the icr study at $\sim$320 K the only two products were $C_5H_9^+$ (95%) and $(C_2H_5)_2CCl^+$. The present higher temperature, higher pressure results show that decomposition of the nascent diethyl ketone·CCl_3^+ complex is possible in a manner similar to that which occurs at low pressure but only if sufficient thermal energy is available. The total energy available in the CCl_3^+ adduct of diethyl ketone at any temperature before a stabilizing collision occurs is greater than that for the acetone·CCl_3^+ adduct under the same conditions because of the larger number of atoms present and because of the greater exothermicity of the adduct forming reaction. The latter is presumed to follow from the greater basicity of diethyl ketone. Although the four-centre intermediate illustrated by reaction [1] is possible for both

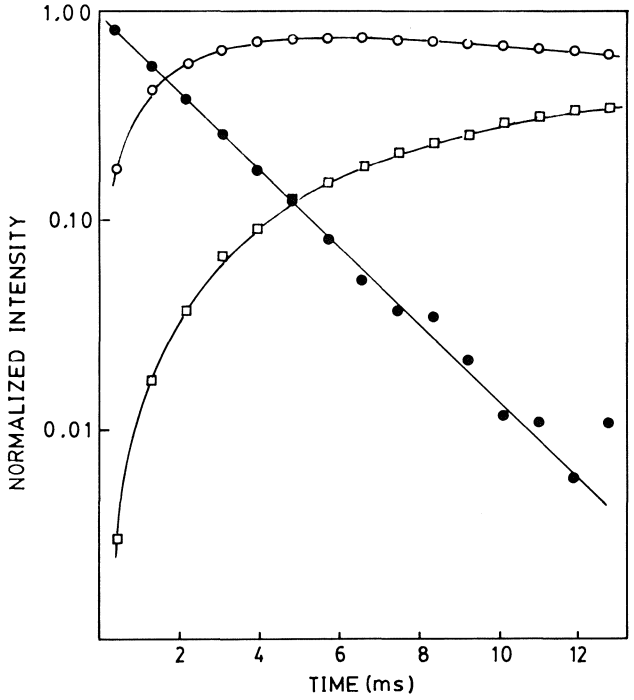


FIG. 3. Normalized ion intensities after a 100 μs pulse of ionizing electrons in a $(CH_3)_2O/CCl_4/CH_4$ (0.0031/0.44/99.6) mixture at 4.6 Torr and 360 K. ● CCl_3^+; ○ $(CH_3)_2OCCl_3^+$ (m/z 163); □ $(CH_3)_3O^+$ (m/z 61).

The curves show the temporal profiles of *1*, $C_2H_5OCCl_2^+$ (m/z 127); *2*, CCl_3^+; *3*, $(C_2H_5)_3O^+$ (m/z 103); *4*, $(C_2H_5)_2O{\cdot}H^+$ (m/z 75); *5*, $C_4H_9O^+$ (m/z 73).

dimethyl and diethyl ketone, only the CCl_3^+ complex of the latter decomposes in such a manner under HPMS conditions.

The only reactions observed for $(C_2H_5)COCCl_3^+$, $(C_2H_5)_2CCl^+$, and $C_5H_9^+$ are proton transfer to the neutral ketone, again followed by further solvation to give the proton bound dimer.

[b]Efficiency for formation of $(C_3H_7S)_2CCl_3^+$ or $(C_2H_5S)_2CCl_3^+$.

CCl_3^+ + dimethyl ether

The adduct $(CH_3)_2OCCl_3^+$ is the sole initial product. Its yield decreases with increasing temperature until at temperatures above 530 K no reaction is observed. There is no evidence for an equilibrium between complex and reactants and the complex, an oxonium ion, reacts further with the neutral ether to yield the more stable trimethyloxonium ion (Fig. 3).

[8] $$CCl_3^+ + (CH_3)_2O \rightarrow (CH_3)_2OCCl_3^+$$

[9] $$(CH_3)_2OCCl_3^+ + (CH_3)_2O \rightarrow (CH_3)_3O^+ + CH_3OCCl_3$$

Reaction [9] is slow, $k = 2.5 \pm 1 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} at both 298 K and 360 K. It may be regarded as a bimolecular nucleophilic displacement, i.e., attack by the neutral ether on one of the methyl groups of $(CH_3)_2OCCl_3^+$. There are at least two possible explanations for this low reaction rate constant. The reaction is thermoneutral or more probably slightly endothermic since the stabilizing effect of a CCl_3 on a positively charged centre is a little greater than that for CH_3 (9). The lack of a significant temperature coefficient for the rate constant shows that the endothermicity cannot be large, and indeed if it were the reaction would not be observed. Another explanation might be that displacement occurs with high efficiency but attack occurs mainly at CCl_3 leading to no net change. However, it has long been known that the substitution of hydrogen by halogen on a carbon atom engenders a lowering of reaction rate for liquid phase S_N2 reaction at that carbon (10, 11), suggesting that attack will be mainly at CH_3.

CCl_3^+ + diethyl ether

Unlike dimethyl ether, diethyl ether produced no observable CCl_3^+ adduct. The reaction was studied only at 464 K when the sole product was $C_2H_5OCCl_2^+$ formed by loss of C_2H_5Cl or C_2H_4 + HCl from the initial collision complex.

[10] $$(C_2H_5)_2O + CCl_3^+ \rightarrow C_2H_5OCCl_2^+ + C_2H_5Cl(C_2H_4 + HCl)$$

Figure 4 shows that the disappearance of CCl_3^+ has two components, an initial rapid decay followed by a much slower decay. At long times the decay curves for CCl_3^+ and $C_2H_5OCCl_2^+$ have identical slopes, a behaviour that was found to be independent of both diethyl ether and carbon tetrachloride concentrations. This may be rationalized by invoking a reaction which regenerates CCl_3^+.

[11] $$C_2H_5OCCl_2^+ + CCl_4 \rightarrow C_2H_5OCCl_3 + CCl_3^+$$

$C_2H_5OCCl_2^+$ also disappears by a slow reaction with diethyl ether yielding mainly the triethyloxonium ion and a much smaller amount of the protonated ether.

[12a] $$C_2H_5OCCl_2^+ + (C_2H_5)_2O \rightarrow (C_2H_5)_3O^+ + COCl_2$$

[12b] $$\rightarrow (C_2H_5)_2OH^+ + C_3H_4Cl_2O$$

Because of the occurrence of reaction [11] it is impossible to obtain a satisfactory rate constant for reaction [10] using eq. [5]. A minimum value of 3×10^{-10} cm^3 molecule^{-1} s^{-1} is obtained from the initial slope of the decay curve. A better value is obtained by noting that reactions [10] and [11] are much faster than any other reactions involving CCl_3^+ and $C_2H_5OCCl_2^+$ and that in a given experiment the concentrations of both diethyl ether and carbon tetrachloride, which are much greater than those of the ions, remain constant. Reactions [10] and [11] may

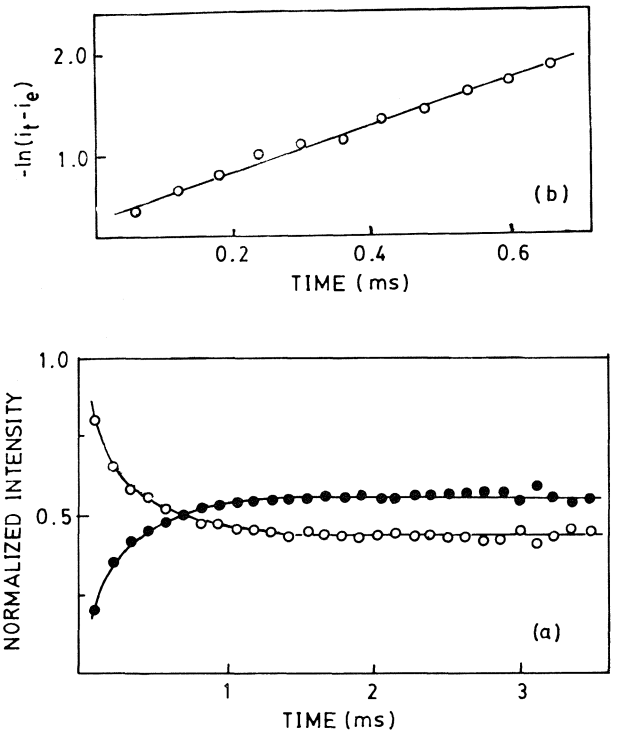

FIG. 5. (*a*) The temporal profiles of $C_2H_5OCCl_2^+$ (●) and CCl_3^+ (○). The data are from Fig. 4 and have been renormalized. (*b*) The kinetic plot for the data in (*a*) according to eq. [14].

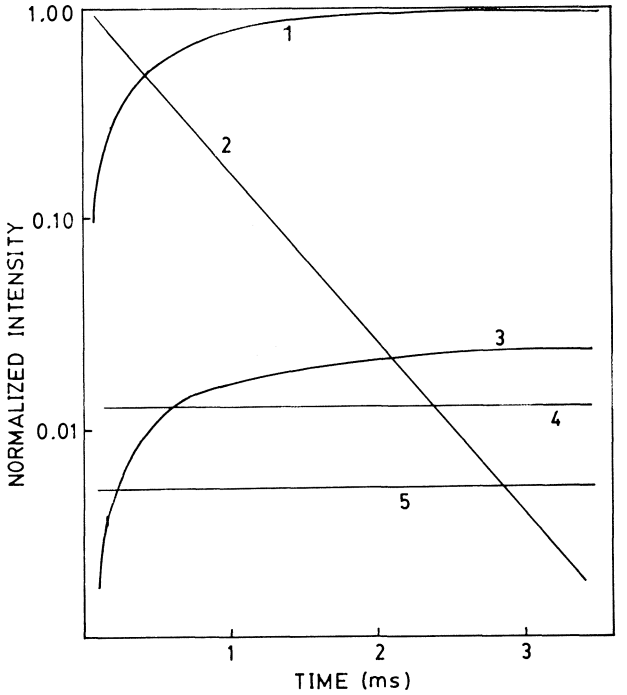

FIG. 6. Normalized ion intensities after a 60 μs pulse of ionizing electrons in a furan/CCl_4/CH_4 (0.0079/0.32/99.6) mixture at 3.5 Torr and 458 K. The curves show the temporal profiles of *1*, $C_4H_4O{\cdot}CCl_3^+$ (*m/z* 185); *2*, CCl_3^+; *3*, $C_4H_3OCCl_2^+$ (*m/z* 149); *4*, $C_4H_4OH^+$ (*m/z* 69); *5*, $C_4H_4OC_2H_5^+$ (*m/z* 97).

therefore be combined as a pair of opposing pseudo first order reactions

$$[13] \quad CCl_3^+ \underset{k_-}{\overset{k_+}{\rightleftharpoons}} C_2H_5OCCl_2^+$$

where $k_+ = k_{10}[(C_2H_5)_2O]$ and $k_- = k_{11}[CCl_4]$. The CCl_3^+ and $C_2H_5OCCl_2^+$ ion currents in Fig. 4 are renormalized in Fig. 5*a* in which the approach to equilibrium is given by (12)

$$[14] \quad \ln\frac{i_t - i_e}{i_0 - i_e} = -(k_+ + k_-)t$$

where i_0, i_t, and i_e are the renormalized ion currents for either ion at times zero, t, and after attainment of equilibrium. The approach to the equilibrium normalized ion current value is exponential for both ions in Fig. 5*a* as shown by the plot of $\ln(i_t - i_e)$ vs. t (Fig. 5*b*). The slope of this plot gives $(k_+ + k_-)$ and the ratio k_+/k_- is obtained from the ratio of renormalized equilibrium ion currents. The values of k_{10} and k_{11} are obtained from k_+ and k_- using appropriate diethyl ether and carbon tetrachloride concentrations. Four different experiments gave $k_{10} = (9 \pm 2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} and $k_{11} = (2 \pm 1) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, the error limits representing one standard deviation.

CCl_3^+ + cyclic ethers

The reactions of CCl_3^+ with a number of furans and 2,3-dihydropyran were briefly examined. The results of the rate constant measurements which are shown in Table 1 are generally for single measurements and are therefore to be taken only as indications of the magnitudes of the values, each result should, however, be within ±25% of the average value that would be obtained if multiple determinations had been performed.

Both furan and 2-methylfuran give the CCl_3^+ adduct as the major primary product. The only other product observed with both compounds is formed by loss of HCl from the adduct. As shown in Fig. 6 for furan, this ion has the same temporal profile as that of the adduct implying that it is formed competitively with the adduct and not by its further reaction. This lack of further reaction of the adducts shows that CCl_3^+ probably adds at oxygen and not at the double bond. Under HPMS conditions, addition to the double bond would lead to an ion which condenses with or transfers a proton to the neutral ether. No such reactions were observed, the very small constant yields of protonated furan and ethyl furan cation seen in Fig. 6 almost certainly arise from protonation by CH_5^+ and $C_2H_5^+$ and addition of $C_2H_5^+$ from the methane reagent gas. CCl_3^+ addition to furan is therefore different to protonation for which the preferred site is the α carbon (13) even though the most basic site is oxygen (14). Protonation probably occurs first at oxygen but subsequent transfer to an α carbon with concurrent geometry relaxation leads to a more stable structure. The oxonium ion is the preferred structure for the CCl_3^+ adduct because a CCl_3 group at the α carbon would have a destabilizing effect on the resulting carbocation.

When the heterocyclic ring is partially or fully hydrogenated the CCl_3^+ adduct is not observed at all (2,3-dihydrofuran, tetrahydropyran, 2,5-dimethyltetrahydrofuran) or its yield is very small (tetrahydrofuran). In all cases the spectra are very complex. Ions are observed which are formed by hydride transfer to CCl_3^+ and by loss of HCl, 2HCl, and $COCl_2$ from an initially formed adduct. For example, the reaction of CCl_3^+ with 2,3-dihydropyran (C_5H_8O) yields, in decreasing order of intensities, $C_5H_7Cl_2^+$, $C_5H_7O^+$, and $C_3H_3Cl_2^+$.

CCl_3^+ + sulfides and disulfides

The sulfur compounds are different to the oxygen compounds in their behaviour towards CCl_3^+ in that very stable adducts are invariably formed. For example, while tetrahydrofuran gives $C_4H_7^+$ and $C_3H_4OCl^+$ as major products, tetrahydrothiophene

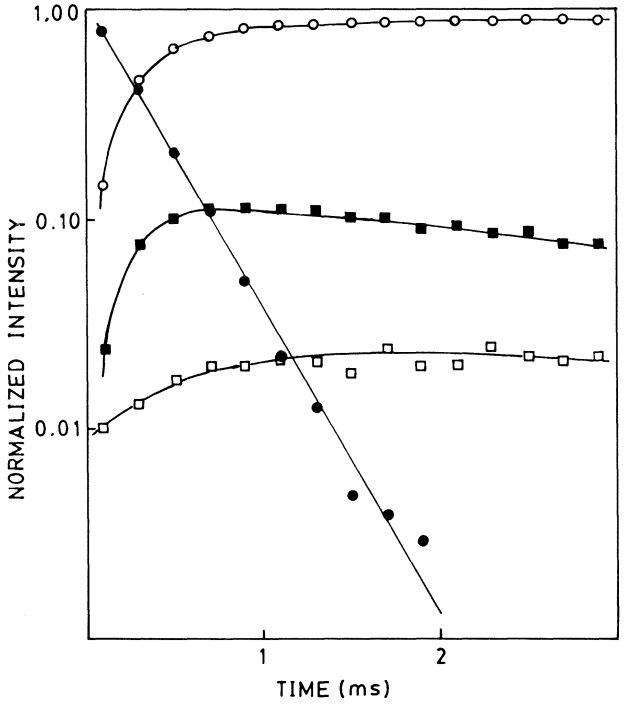

FIG. 7. Normalized ion intensities after a 60 μs ionizing pulse of electrons in a $(C_2H_5)_2S/CCl_4/CH_4$ (0.0050/0.46/99.5) mixture at 4.1 Torr and 460 K: ● CCl_3^+; ○ $(C_2H_5)_2SCCl_3^+$ (m/z 207); ■ $C_4H_9S^+$ (m/z 89); □ $(C_2H_5)_2SH^+$ (m/z 91).

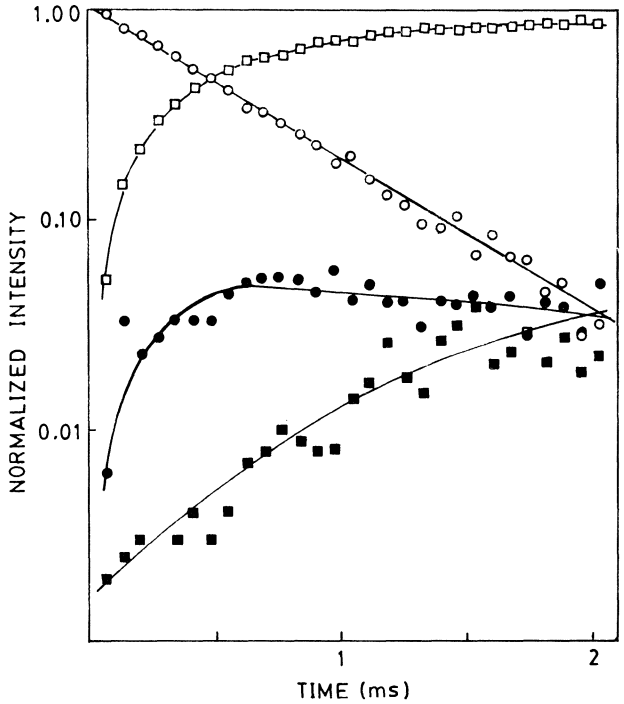

FIG. 8. Normalized ion intensities after a 60 μs ionizing pulse of electrons in a $(C_3H_7S)_2/CCl_4/CH_4$ (0.0025/0.51/99.5) mixture at 3.4 Torr and 570 K. ○ CCl_3^+; □ $(C_3H_7S)_2^+$ (m/z 150); ● $(C_3H_7S)_2CCl_3^+$ (m/z 267); ■ $(C_3H_7S)_3^+$ (m/z 225).

gives the adduct (90%) and $C_4H_7S^+$ formed by hydride transfer to CCl_3^+. Neither of these ions reacts further with neutral thiophene. Dimethyl sulfide (CH_3SCH_3) shows similar behaviour, the adduct comprises 92% of the products, the remainder being $CH_3SCH_2^+$ formed by hydride ion transfer. The latter ion reacts further by association with neutral sulfide to give $C_4H_{11}S_2^+$. There is no evidence for the formation of a trialkylsulfonium ion analogous to the trialkyloxonium ion observed with dimethyl ether (reaction [9]) even though such ions are much more stable than the analogous trialkyloxonium ions (15).

Both diethyl sulfide and di-*n*-propyl sulfide give the adduct as the major product, diethyl sulfide also yields 10% $C_2H_5SC_2H_4^+$ formed by hydride ion transfer. The analogous product for di-*n*-propyl sulfide is isobaric with $C^{35}Cl_3^+$ at m/z 117, but using the known isotopic pattern of chlorine to subtract the contribution from CCl_3^+ it is calculated that the yield of $C_3H_7SC_3H_6$ is much less than 10% of the total product ions. These results are to be contrasted with those for diethyl ether for which the sole product is $C_2H_5OCCl_2^+$. Also in contrast to the dimethyl ether adduct, these sulfide adducts, like that of dimethyl sulfide are unreactive and do not yield a trialkylsulfonium ion. Figure 7 shows that $C_2H_5SC_2H_4^+$ formed in the reaction of CCl_3^+ with diethyl sulfide reacts slowly, probably by proton transfer, to the neutral sulfide.

With the disulfides a new reaction channel opens up as electron transfer becomes competitive with adduct formation. For example, in the case of di-*n*-propyl disulfide the reactions are

[15a] $C_3H_7SSC_3H_7 + CCl_3^+ \rightarrow C_3H_7SSC_3H_7^+ + CCl_3$

[15b] $\rightarrow (C_3H_7S)_2CCl_3^+$

Temperature has a significant effect on the relative yields of the products, electron transfer being favoured at high temperature (Fig. 8) while adduct formation is favoured at low temperature (Fig. 9). At long ion residence times both products react further to give the dithiosulfonium ion $(C_3H_7S)_3^+$

[16] $(C_3H_7S)_2CCl_3^+ + (C_3H_7S)_2 \rightarrow (C_3H_7S)_3^+ + C_3H_7SCCl_3$

[17] $(C_3H_7S)_2^+ + (C_3H_7S)_2 \rightarrow (C_3H_7S)_3^+ + C_3H_7S$

The rate constants for reactions [16] and [17] were calculated from the linear slopes of the ion current curves at long reaction times for a temperature of 298 K (Fig. 8*b*); $k_{16} = 7 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} and $k_{17} = 2 \times 10^{-11}$ cm^{-3} molecule^{-1} s^{-1}. Values cannot be calculated at higher temperatures since the decay curves have a small slope and the precursor ion CCl_3^+ is still present in significant amounts.

One of the few studies of the ion chemistry of disulfide systems involved dimethylsulfide using ion cyclotron resonance (5). No rate constants were measured but the molecular ion, $(CH_3S)_2^+$ was found to react only very slowly with the disulfide, the reaction product being $(CH_3S)_3^+$. However, it was found that the thiosulfonium ion $(CH_3S)_2CH_3^+$, unlike $(C_3H_7S)_2CCl_3^+$ in this study, did not react further; a reaction analogous to 16 was calculated to be endothermic by about 3 kcal mol^{-1}. We have no estimate of the enthalpy change for reaction [15] but since it occurs with almost unit efficiency it must be exothermic by >4 kcal mol^{-1}.

Since most of the dithiosulfonium ion, $(CH_3H_7S)_3^+$, arises via reaction [16], as seen from the slopes of the decay curves in Fig. 8*b*, the branching ratio k_{15a}/k_{15b} may be obtained with small error from the ratio $\{[(C_3H_7S)_2CCl_3^+)] + [(C_3H_7S)_3^+]\}/[(C_3H_7S)]_2^+$. The ratio shows very little variation with pressure over the range 2–4 Torr but does tend to decrease by about 20% over the ion residence times. Table 2 shows that such variations are small compared with the dramatic effect of temperature.

Table 1 shows that the rate constant for the disappearance of

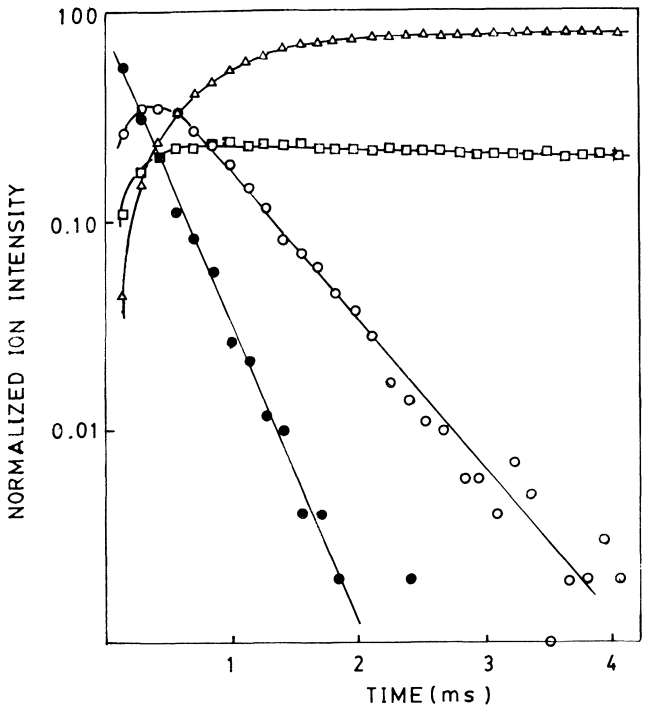

FIG. 9. Normalized ion intensities after a 60 μs pulse of ionizing electrons in a $(C_3H_7S)_2/CCl_4/CH_4$ (0.0025/0.51/99.5) mixture at 3.1 Torr and 298 K. ● CCl_3^+; □ $(C_3H_7S)_2^+$ (m/z 150); ○ $(C_3H_7S)_2CCl_3^+$ (m/z 267); △ $(C_3H_7S)_3^+$ (m/z 225).

CCl_3^+ in the presence of disulfide which is equal to (k_{15a} + k_{15b}) is essentially independent of temperature and is equal to the rate constant for collision. The factor of fifty change in the branching ratio which strongly favours electron transfer at high temperature probably reflects the decreased lifetime of the collision complex at high temperature. Since electron transfer is one of the accessible channels, the ionization energy of CCl_3 is greater than those of $(C_3H_7S)_2$ and $(C_2H_5S)_2$. Electron transfer can occur over a much greater distance than group or atom transfer and will occur upon first collision. Presumably with disulfides electron transfer to CCl_3^+ is always the first step in the ion–neutral encounter. This may or may not be followed by the formation of a stabilized complex. At high temperature the ion–molecule collision complex contains significant thermal energy as well as the ion–molecule interaction energy and consequently has a much shorter lifetime than at lower temperatures. The association reaction [15b] which may require third body stabilization is therefore discriminated against. At low temperature the association complex has a much reduced energy content, and hence a longer lifetime and a stabilized complex can be formed, i.e. [15b] is favoured over [15a].

The occurrence of the electron transfer reaction [15a] supports the contention that the reported ionization energies of alkyl disulfides do not correspond to a 0–0 transitions (16). For example, photoelectron spectroscopy yields ionization energies for diethyl- and di-*n*-propyl disulfides of 8.44 and 8.34 eV, respectively (17), well above the ionization energy of CCl_3^+ (8.28 eV (18)). Both CCl_3^+ and CCl_3 are planar, or almost planar, the lone electron in the radical being accommodated in a P_z orbital. There will be little geometry change on ionization of the radical and the reported ionization energy obtained using monochromatic electrons corresponds to the 0–0 transition. The neutral disulfides have a CSSC dihedral bond angle close to 90° (19) while calculations suggest an angle close to 180° for $CH_3SSCH_3^+$ (20). There are therefore very large geometry changes on ionization and photo electron spectroscopy ionization potential values will be larger than those for 0–0 transitions. Kinetic considerations suggest that the 0–0 ionization energy of CH_3SSCH_3 is 7.4 eV (16) which is consistent with the present results.

TABLE 2. The branching ratio (electron transfer/complex formation) for CCl_3^+ + RSSR

R	Temperature (K)	Branching ratio
C_3H_7	570	8.0

C_3H_7	300	0.32
C_2H_5	453	1.6

Rate constants for the reactions of CCl_3^+

Under icr conditions (10^{-6}–10^{-5} Torr, 320 K) no stable adducts are observed when CCl_3^+ reacts with acetone, the only product being $CH_3CClCH_3^+$ (1). Under HPMS conditions (3–3.5 Torr, 300–460 K) the adduct $CH_3COCH_3CCl_3^+$ is the only product. The measured second order reaction rate constants are also very different at 300 K, viz. icr 3×10^{-11} cm^3 molecule^{-1} s^{-1} and HPMS 1×10^{-9} cm^3 molecule^{-1} s^{-1}. In addition, in the present study, the efficiency of reaction at 300 K is 0.5, a value independent of pressure. The efficiency of the reaction of CCl_3^+ with acetone was not measured as a function of pressure at other temperatures but the association reaction of CCl_3^+ with dimethyl ether was studied. Although the rate constant decreases when the temperature is raised from 298 to 345 K, the reaction efficiency is essentially independent of pressure at both temperatures. The above facts have several implications.

At 10^{-5} Torr the mean time between ion–molecule collisions is 10^{-3} s while at 3 Torr it is 5×10^{-9} s. Since the reaction efficiency is 0.5 for CCl_3^+ + acetone at high pressure and 300 K, based on the measured pseudo second order rate constant, 50% of the initially formed reaction complexes must have lifetimes of at least 10^{-8}–10^{-9} s. The lack of a pressure dependence of the rate constant over the range 1–4 Torr implies that the lifetimes of these collision complexes which are finally detected as stabilized species are somewhat longer. Since only ~50% of the initial collisions between CCl_3^+ and acetone and 30% of those between CCl_3^+ and dimethyl ether at 300 K lead to a stabilized complex then respectively 50% and 70% of the collision complexes have lifetimes much shorter than 10^{-8} s. There are three possible explanations for this behaviour. (*a*) There are two populations of initial collision complexes, those with lifetimes sufficiently long for stabilization to occur under HPMS but not icr conditions and those with much shorter lifetimes which decompose to reactants. This is equivalent to invoking a geometrical or steric factor in the initial collision which selects reactive versus non-reactive collisions. Such a factor would not be strongly temperature dependent, contrary to what is observed. (*b*) Secondly, it is possible that the first collision with a neutral molecule by a long-lived collision complex may be either stabilizing or dissociative. The general scheme would be

$$[18] \quad A^+ + B \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} AB^{+}*$$

$$[19a] \quad AB^{+}* + M \xrightarrow{k_2} AB^+ + M$$

$$[19b] \quad AB^{+}* \xrightarrow{k_3} A^+ + B + M$$

The branching ratio k_2/k_3 would be temperature dependent and would decrease as the total energy of AB^+* increases with increasing temperature as collisions of AB^+* with M become less efficient at stabilizing the complex. This energy includes both the thermal energy and the energy of the interaction of the ion and neutral molecule. (*c*) The third possibility is a radiative stabilization of a fraction of the initially formed association complexes in competition with back dissociation. Smith and Adams (21) favour such an explanation for their observation that above their experimental minimum pressure of 0.2 Torr the association reaction between CH_3^+ and H_2O has a constant, less than unit efficiency. An explanation for the absence of a pressure dependence on the efficiency is not given.

The problem encountered when trying to decide between (*b*) and (*c*) is the lack of data covering a sufficiently large but continuous pressure range. A phase space model for the association reaction $CH_3^+ + HCN \rightarrow CH_3 \cdot HCN^+$ in which both radiative and third body stabilization are considered shows a linear dependence of reaction efficiency on pressure only at very low pressure (22). At pressure above 0.2 Torr the model predicts that the observed second order rate constant changes only slowly with pressure and has values which are considerably less than the collision rate constant if the efficiency of the third body stabilization reaction is well below unity. Such a slow change of measured second order rate constant with pressure may not then be experimentally observable over a small range of pressure such as used in the present work. If radiative stabilization is a significant factor in the association reaction of CCl_3^+ with acetone, then $CH_3COCH_3CCl_3^+$ should be observed in icr experiments at very low pressures where the mean lifetime between collisions is larger than in HPMS. The fact that no such complexes were observed does not necessarily negate the argument in favour of radiative stabilization. As Adams and Smith (23) have pointed out, the presence of residual excitation energy from their method of formation in ions taking part in association reactions under icr conditions leads to results which may be far removed from those obtained when the ions are thermalized. In the icr study (1), CCl_3^+ was formed by electron impact dissociative ionization of CCl_4 in mixtures containing 5–10% CH_3COCH_3 in CCl_4. The ten to twenty thermalizing collisions of CCl_3^+ with CCl_4 prior to an encounter with acetone may not have been sufficient to eliminate all the excess energy of formation, although if Cl^- transfer occurs at a significant rate in CCl_3^+/CCl_4 collisions it is generally accepted that thermalization can be very efficient.

Adams and Smith (23) have recently discussed the kinetics of ion–molecule association reactions with special emphasis on the association of small species. Their conclusions regarding such relatively simple systems are similar to those stated above, in particular the difficulty in determining the role of radiative association and indeed in determining whether the measured effective rate constants for some quite simple association reactions (eg. $CH_3^+ + HCN \rightleftharpoons CH_3^+ \cdot HCN$) do exhibit pressure dependences in the pressure range 0.2–4 Torr, i.e., has or has not "saturation" occurred? The mechanisms of reactions involving more complex species such as those reported here will probably be even more difficult to decipher.

The reaction efficiencies shown in Table 1 are computed in terms of the experimental second order rate constants. As stated previously none of these rate constants shows a significant pressure dependence and so even nominally third order reactions may be discussed in terms of the efficiencies per initial ion–molecule collision. In general, the efficiency for the oxygen bases increases with increasing complexity of the neutral. For example, CCl_3^+ reacts with diethyl ketone in 16% of the encounters at 455 K while only 1.2% of the encounters with acetone lead to product. In both cases the major initial product is formation of $R_2CO \cdot CCl_3^+$ (R = CH_3, C_2H_5). Similarly, dimethyl ether has a lower reaction efficiency than diethyl ether at the same temperature. The reactions in this case are of course different in that dimethyl ether forms a stabilized complex whereas no stabilized complex is observed with diethyl ether.

The cyclic ethers show a rather limited range of reaction efficiencies. Furan, which mainly forms the adduct has the lowest efficiency while the efficiency increases as the degree of hydrogenation and the complexity of the ring increases. Since many of these results are from single experiments this can only be a generalization. The relatively high efficiency of tetrahydrothiophene compared with furan or tetrahydrofuran is consistent with the greater efficiencies of reaction of CCl_3^+ with the thioethers compared with the ethers. Although the disulfides react with essentially unit efficiency at all temperatures and pressure, the efficiency for chemical reaction other than electron transfer is little different from that of the sulfides, in both cases this is mainly an association reaction.

Conclusion

The reactions of CCl_3^+ with many of the compounds studied are very efficient even at the temperature of ~460 K used in most of the studies. This is in spite of the fact that for many of the compounds the primary product is a stabilized ion–neutral complex. As suggested by Ausloos and co-workers (1), reaction efficiency does appear to increase with increasing exothermicity of reaction, e.g. diethyl ketone > acetone and diethyl ether > dimethyl ether. For the ketones this implies that a greater number of ion–molecule complexes have sufficiently long lifetimes for stabilization to occur when the size of the neutral molecule increases, which is also in agreement with a suggestion of Ausloos and co-workers. In their icr work no stabilized complexes were observed and bimolecular chemical changes were studied. The present results show that such changes, provided that they are initiated by excited ions, will be preceded by long-lived ($>10^{-8}$ s) ion–molecule complexes.

The lack of a significant pressure dependence of the experimental second order rate constants for association reactions is not a unique observation but the explanation for it is still unclear. An examination of such reactions might profitably be carried out using a selected ion flow tube at pressures in the range 0.05 to 1 Torr.

Received June 6, 1986

J. Peter Guthrie, John Cossar, and Brian A. Dawson. Can. J. Chem. **64**, 2456 (1986).

Dimeric steroids can be formed by reductive amination of terephthalaldehyde with 3-amino steroids using cyanoborohydride. An amino group in the 11β-position can be blocked using a formyl group, and this can be removed by acid hydrolysis after dimerization. Trifluoroacetyl is not a suitable blocking group; although it can be removed by acid hydrolysis from monomeric steroids, it was only removed from the dimer under forcing conditions which caused degradation. The dimeric steroid is a catalyst for the hydrolysis of arylpropionate esters with good leaving groups. Acylation is markedly accelerated by hydrophobic binding of the aryl group of the substrate to the steroids. Rate enhancements, relative to imidazole, of up to 5.5×10^2 were obtained, and analysis of the data shows that the potential rate enhancement is 1.1×10^5. The magnitude of the hydrophobic binding is consistent with what was seen with earlier catalysts. Aggregation, even at very low concentrations, was a problem with anionic substrates.

J. Peter Guthrie, John Cossar et Brian A. Dawson. Can. J. Chem. **64**, 2456 (1986).

On peut former des stéroïdes dimères par amination réductrice du téréphtalaldéhyde avec des amino-3 stéroïdes, sous l'influence du cyanoborohydrure. On peut bloquer un groupement amino-11β à l'aide d'un groupement formyle qui peut être enlevé par une hydrolyse acide, à la suite de la dimérisation. Le groupement trifluoroacétyle n'est pas approprié pour bloquer, même si on peut l'enlever des stéroïdes par hydrolyse acide; en effet, on ne peut l'enlever monomères qu'en utilisant des conditions fortes qui provoquent une dégradation. Le stéroïde dimère est un catalyseur pour l'hydrolyse des esters arylpropionates portant de bons groupement nucléofuges. L'acylation est fortement accélérée par une fixation hydrophobe du groupement aryle du substrat par les stéroïdes. On a observé des augmentations de vitesses, relatives à l'imidazole, allant jusqu'à $5{,}5 \times 10^2$ et une analyse des données démontre qu'il est possible d'obtenir des augmentations de vitesse de l'ordre de $1{,}1 \times 10^5$. L'amplitude de la fixation hydrophobe est en accord avec ce qui a été observé antérieurement avec d'autres catalyseurs. Même à de faibles concentrations, l'aggrégation est un problème avec les substrats anioniques.

[Traduit par la revue]

Introduction

We have reported studies of various catalytic molecules based on a steroid skeleton, which provided a hydrophobic binding surface (1–4). By linking two steroid moieties in a dimeric catalyst we were able to achieve larger rate enhancements (5), but encountered severe experimental difficulties as a result of the very low solubility of this catalyst. We now wish to report the preparation of a very soluble dimer, which should allow extensive studies of the hydrophobic interaction. We have confirmed the large rate enhancements previously reported for phenanthryl substrates. In the initial experiments we found that, despite the high solubility of the catalyst, there can be severe problems of aggregation when the substrate has the opposite charge.

Results

Preparation and proof of structure for model dimers

Our plan was to prepare steroid dimers by reductive amination of 3-β-aminosteroids using terephthalaldehyde and cyanoborohydride (6). We first examined two model systems to test the reaction conditions. We prepared the dimer derived from cyclohexylamine, as shown in Scheme 1. Initial experiments using methanol as solvent led to the desired compound but in impure form. Addition of molecular sieves improved the efficiency, but the presence of pulverized sieves at the end of the reaction was undesirable. Upon changing to methoxyethanol as solvent we found that the reductive amination gave quite pure material in 90% yield with no further attempts at optimization. We tried to titrate this material to obtain pK_a values for use with the dimeric steroid but were frustrated by the extreme insolubility of the neutral compound; even at 0.00065 *M* precipitation occurred at pH 9.85. The pH after addition of half an equivalent of OH^- can be taken as an approximation to the first pK_a; with a solution at 0.1 *M* ionic strength (KCl) this value was 9.0; with a somewhat more concentrated solution at 1.0 *M* ionic strength the value observed was about 10.0 (this required a short extrapolation past the point where precipitation occurred).

Then we prepared 3-β-amino-androstane-17-β-ol (7), **5**, and the dimer derived from it, as outlined in Scheme 1. The amine function was introduced stereospecifically by dissolving metal reduction of the oxime, **4** (7, 8). That the reduction occurred with the desired stereochemistry was shown by the broad signal in the spectrum of the dimer attributed to $\rangle CH\text{—}NH_2^+\text{—}$. The width at half height, $w_{1/2}$, was ca. 24 Hz; for $\rangle CH\text{—}OH$, which we assume is a reasonable model, an α-H has $w_{1/2}$ = 7 Hz, while a β-H has $w_{1/2}$ = 20 Hz (9). The monomeric amine was obtained as the hydrochloride, and was very insoluble, so that the signals from the methine protons were not readily visible; it was simpler to examine the dimer to establish the stereochemistry of the first reduction step. Dimerization proceeded smoothly; a yield of 54% was obtained with little effort at optimizing the conditions. The identity of the dimer, **5**, was established by its ^1H nmr spectrum and its exact mass.

Dimerization of 17-β-(4(5)-imidazolyl)-11-β-trifluoroacetamido-5α-androstan-3-β-amine

In order to prepare the desired dimer of 17-β-(4(5)-imidazolyl)-5α-androstane-3-β,11-β-diamine, **8**, was necessary to block the 11-β-amino group. Trial experiments at reductive amination of **6** using terephthalaldehyde had led to insoluble gelatinous precipitates.[2] This was interpreted as polymerization involving reaction at both the 3- and 11-amino groups. Since we had found that the trifluoroacetyl group resisted base hydrolysis

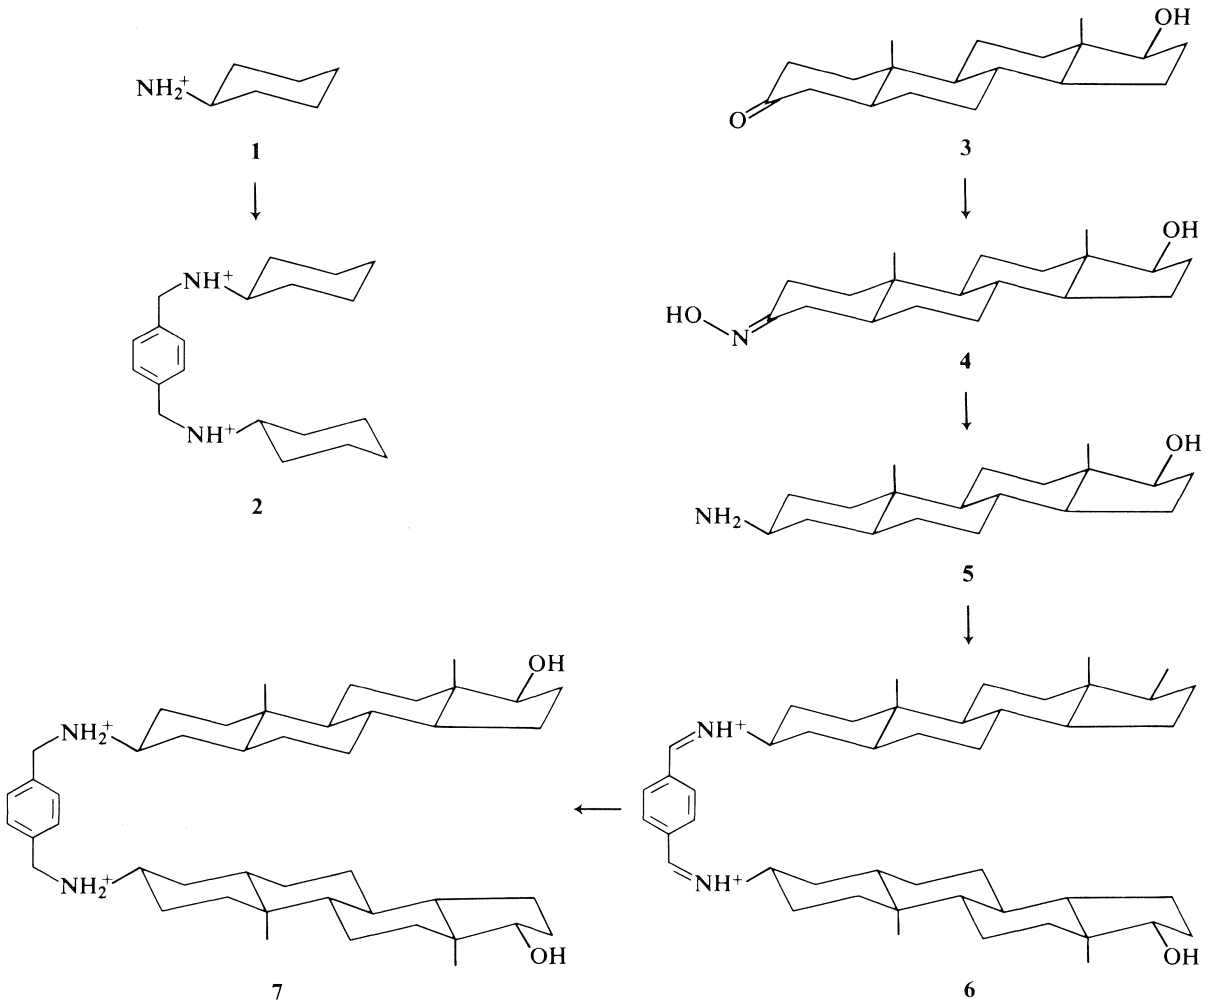


SCHEME 1

from an 11-β-amide, but could be hydrolyzed in acid (4), we initially tried this blocking group, as outlined in Scheme 2. Dimerization of 17-β-(4(5)-imidazolyl)-11-β-trifluoroacetamido-5α-androstan-3-β-amine, **10***a*, proceeded reasonably well, to give a material with an nmr spectrum consistent with structure **12***a*, but on attempting to hydrolyze the blocking groups we found that they did not come off under conditions which sufficed for the monomeric steroid (either refluxing 6 *N* HCl or refluxing 6 *N* CH_3SO_3H), and use of more vigorous conditions led to extensive degradation of the dimer.

Dimerization of 17-β-(4(5)-imidazolyl)-11-β-formamido-5α-androstan-3β-amine

We found that formyl was a suitable blocking group for the 11-β-amino function, since it could be put on readily, resisted alkaline hydrolysis (which hydrolyzed a 3-formamido group), and could be removed by acid hydrolysis. Conditions were found which gave the desired dimerization of **10***b*, and for **12***b* the blocking groups were removable by acid hydrolysis using 3 *N* HCl at 100°C for 6 h. The stereochemistry of **8** has been established (1), and this establishes the stereochemistry of **13**. The integration of the ^1H nmr proves that two steroids have been linked by one *p*-xylylene bridge. The ^{13}C nmr spectrum proves the symmetry of the molecule because we observe the correct number of peaks for two identical steroid residues linked by a *p*-xylylene bridge. Without further experiments a detailed assignment cannot be made with any confidence. The exact mass confirms the composition of **13**.

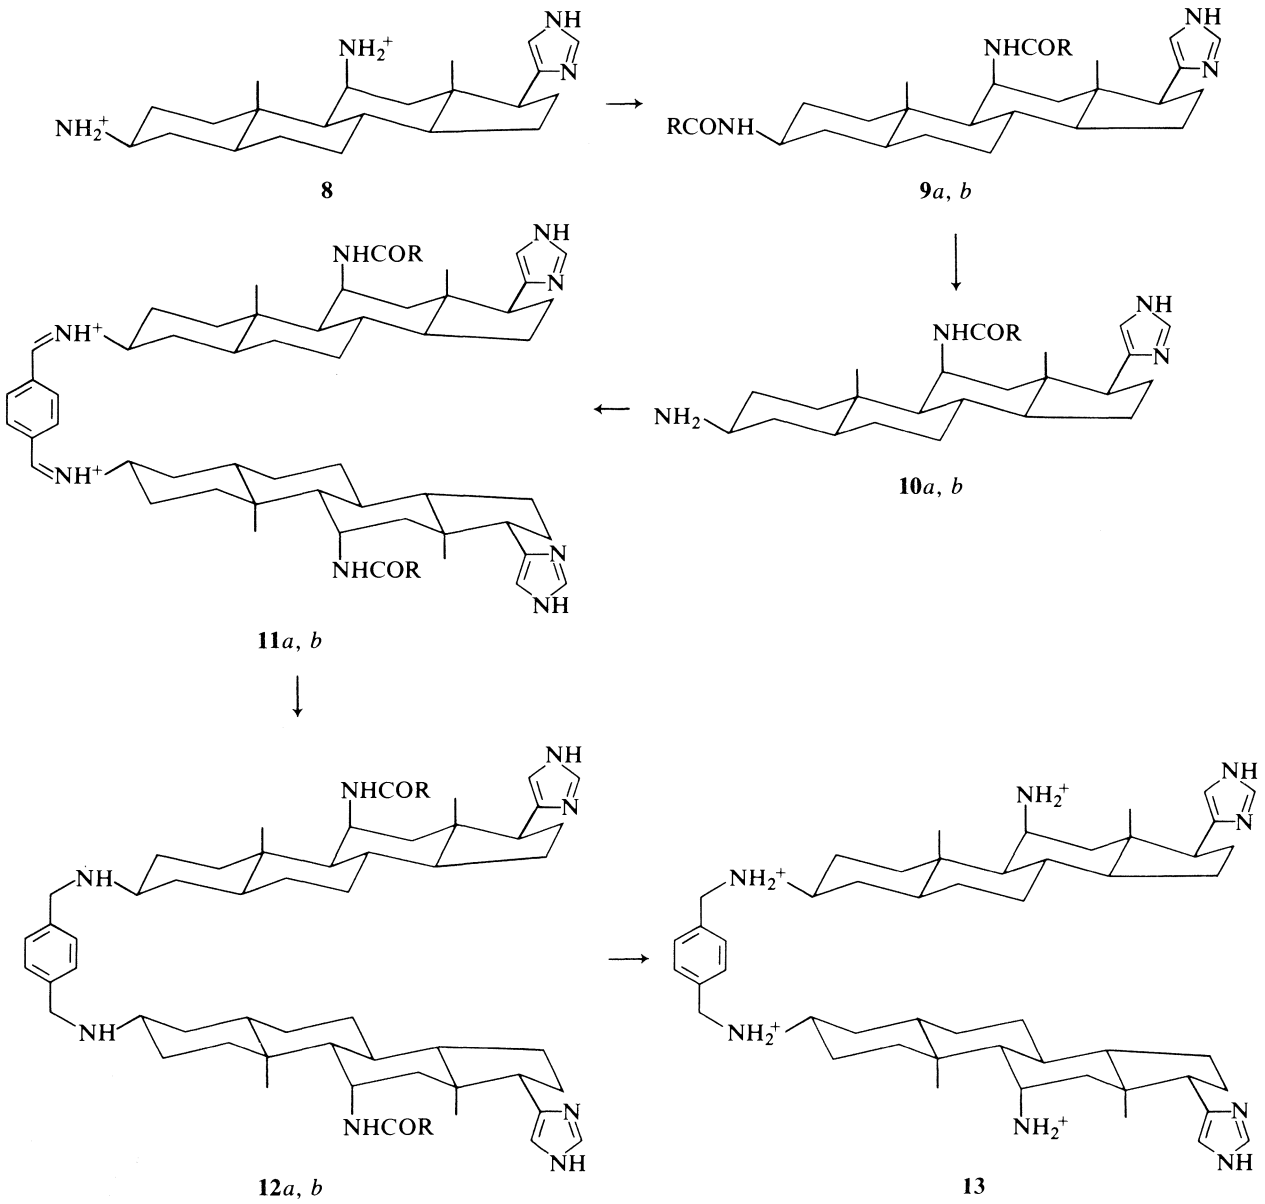
Kinetics of reactions with p*-nitrophenyl esters*

All of the kinetics data are found in Table 1. By working at low substrate concentrations it was possible to obtain rate constants for the reaction of **13** with **14***b*, **15***b*, and **16***b*. In the case of **16***b* it was necessary to use concentrations of less than 10^{-7} *M* to avoid precipitation and/or aggregation which led to spuriously low rates. We found that the use of tris buffers led to erratic and irreproducible behavior, which we have also observed in other reactions (10), but that borate buffer was well behaved. The second order rate constants obtained from plots of k_{obs} vs. [**13**] are found in Table 2.

Figures 1, 2, and 3 show the kinetics behavior of the phenyl-, naphthyl-, and phenanthrylpropionate substrates. In each case it should be noted that the inherent reactivity of the substrates, as shown by the rates of uncatalyzed hydrolysis, was trimethylammonionitrophenyl > carboxynitrophenyl > nitrophenyl, but the rate constants for **13** catalyzed reactions were in the order carboxynitrophenyl > trimethylammonionitrophenyl > nitrophenyl, except for the esters of 3-(3-phenanthryl)propionic acid. As we have observed in related studies (4), the electrostatic interactions of substrate and catalyst have a powerful influence on the observed reactivity patterns.

Kinetics of reactions with esters of 3-hydroxy-4-nitrobenzoic acid

These esters had been the best ester substrates for **8**, so we had expected that they would also be best for **13**. Although **14***a* and **15***a* were relatively straightforward to study, we had extra-



SCHEME 2

ordinary difficulty getting readily interpretable rate constants from the reaction of **13** and **16***a*. It was only possible to get simple behavior by using solutions where the reagent in excess was at a concentration less than 3×10^{-6} *M* with the other reagent at about a ten-fold lower concentration. Figure 3 illustrates the simple behavior shown at low concentrations, and the major and variable inhibitory effects seen at higher concentrations with either catalyst or substrate in excess. The second order rate constants are found in Table 2. In the case of **14***a* simple kinetic behavior was observed even at high concentrations of **13**; plots of k_{obs} vs. [**13**] showed distinct curvature, which could be analyzed in terms of preassociation. An Eadie–Hofstee (11, 12) plot was reasonably linear, see Fig. 4, and led to an apparent binding constant of $(6.3 \pm 1.4) \times 10^{-4}$ *M*. Although the behavior seen is qualitatively what would be expected for binding of substrate by catalyst, the linearity of the Eadie–Hofstee plot is imperfect, so that what was observed may be the result of some more complex aggregation process. In any case the binding constant determined from such an analysis need not refer to the productive mode of binding which leads directly to the catalytic transition state, but may refer to some form of non-productive binding which has the substrate improperly oriented relative to the catalytic groups. The phenomenon of non-productive binding is a well known complication in enzymology (13). For the other carboxynitrophenyl esters no signs of binding, or at least of simple binding behavior, were apparent.

Kinetics of reactions with 4-trimethylammonio-6-nitrophenyl esters

These substrates were, as anticipated, well behaved. The second order rate constants are found in Table 2. In the case of **16***c* we carried out experiments over a wide range of concentrations of **13** and observed apparent saturation kinetics. Figure 5 shows an Eadie–Hofstee plot for the data; although there is considerable scatter, it is clear that we have observed saturation kinetics, with an apparent binding constant of $(4.62 \pm 0.98) \times 10^{-5}$ *M*. At this point it would be rash to build much interpretation upon this number because of the possibilities for non-productive binding or aggregation. We have frequently

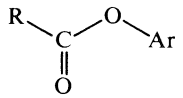
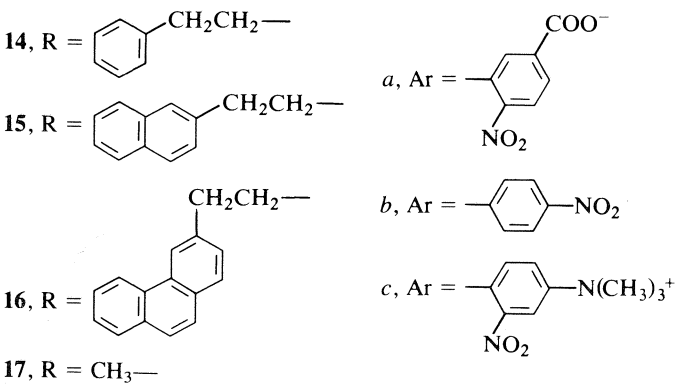
[a]All reactions in aqueous solution at 25°C, ionic strength 0.1 (KCl), pH 8.00 maintained by 0.0928 *M* borate buffer. Substrates were added as acetonitrile solutions; the final solutions were 0.01–3.6% acetonitrile (v/v). Data were fitted to $y = a_1 + a_2 \exp(-a_3 t)$; if there was a drift in absorbance at long times the data were fitted to $y = a_1 + a_2 \exp(-a_3 t) + a_4 t$.
[b]Followed at 425 nm using 10 cm cells unless otherwise noted.
[c]2 cm cell.
[d]Omitted from the fit of k_{obs} vs. [reagent in excess].
[e]1 cm cell.
[f]Fitted by least squares; $k = a + b$[reagent in excess]; in most reactions the catalyst is in excess.
[g]This run was carried to completion and showed the pattern of an initial burst of phenoxide release followed by a long pseudo zero order phase of phenoxide production.
[h]Followed at 450 nm.
[i]Data fitted to $y = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t)$; the absorbance time curve showed a small but definite decrease in absorbance at long times, constituting a second exponential phase. a_4 and a_5 are given in the second row for this experiment.
[j]5 cm cell.
[k]Followed at 402 nm.
[l]Followed at 400 nm using 10 cm cells unless otherwise noted.
[m]Followed at 350 nm.
[n]Fitted by least squares to $y = a_1/(1 + a_2/x)$.

encountered considerable scatter in kinetics when aggregation of the reagents influences the overall rate of reaction (10, 14).

The behavior for all of the substrates is shown in Fig. 6, which plots the observed second order rate constants for all nine substrates with **13**, as well as the two times the rate constants for the reactions of imidazole and **8** with the corresponding acetate esters as a function of π, the Hansch hydrophobicity parameter (15, 16) for the aryl group in the arylpropionic acids. The lines have no theoretical significance but simply join related points. For the overall rate constants the dependence upon the hydrophobicity of the aryl binding group is clearly non-linear, suggesting that the observed rate constants are not simple



14, **15**, **16**, **17***a–c*



SCHEME 3

quantities. It should be noted that the rates of reaction of the smaller substrates are strongly affected by electrostatic interactions between catalyst and substrate, but that for **16***a–c* the reactivity order is the same as for imidazole as catalyst, i.e. the inherent reactivity of the substrates has reasserted itself.

Discussion

Analysis of hydrophobic effects

To analyze the effect of hydrophobic stabilization of the transition state upon the rates of reaction of **13** with the various substrates we must correct for all other modes of reaction than the one of special interest, namely, reaction with both steroid residues interacting with the aryl group in the arylpropionate substrate molecule. The imidazolyl groups are able to react by themselves without any hydrophobic interaction, and reaction could occur with only one steroid residue in contact with the substrate. We can achieve the desired correction by subtracting twice the rate constant for the reaction of **8** with a substrate from the observed rate constant for the reaction of **13** with the substrate. This can be done with the negatively charged substrates which have been thoroughly studied with various catalysts. As a measure of hydrophobicity we use the π (15, 16) value of the aryl binding group. The results of this analysis are seen in Fig. 7. It is clear that there is a linear dependence of $\log k_{corr}$ upon the hydrophobicity of the aryl group; if we extrapolate to $\pi = 0$, i.e. to the hypothetical rate of reaction of a priopionate ester reacting by the same transition state as the aryl propionates, it is possible to calculate the stabilization of the transition state for the observed reactions relative to this hypothetical reference state. For the phenanthryl substrate this rate enhancement amounts to a factor of 1.1×10^5-fold, or 6.9 kcal/mol in stabilization. As we have observed before (4, 5) only part of this potential rate enhancement is actually observed;

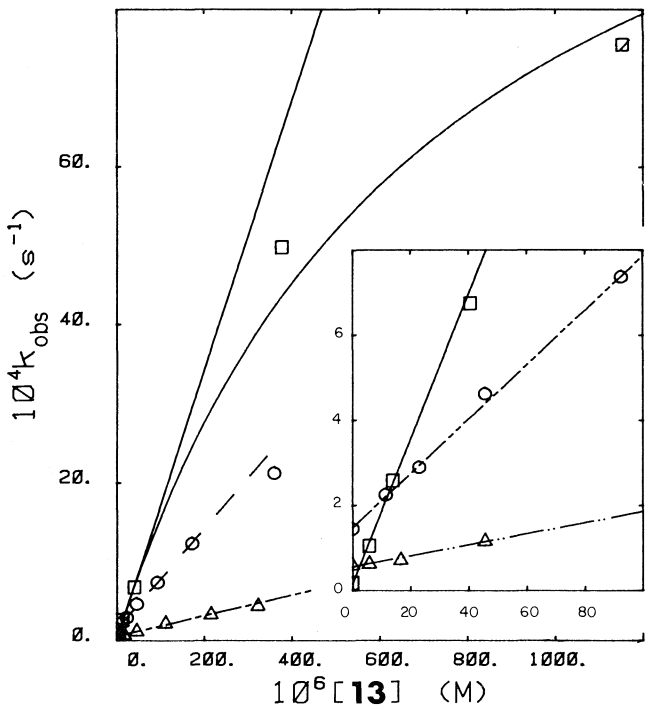

FIG. 1. Rates of reaction of esters of 3-phenylpropionic acid as a function of the concentration of **13**; (□) 5-carboxy-2-nitrophenyl esters; (○) 4-trimethylammonio-2-nitrophenyl esters; (△) 4-nitrophenyl esters. Inset: data for low concentrations of **13** only.

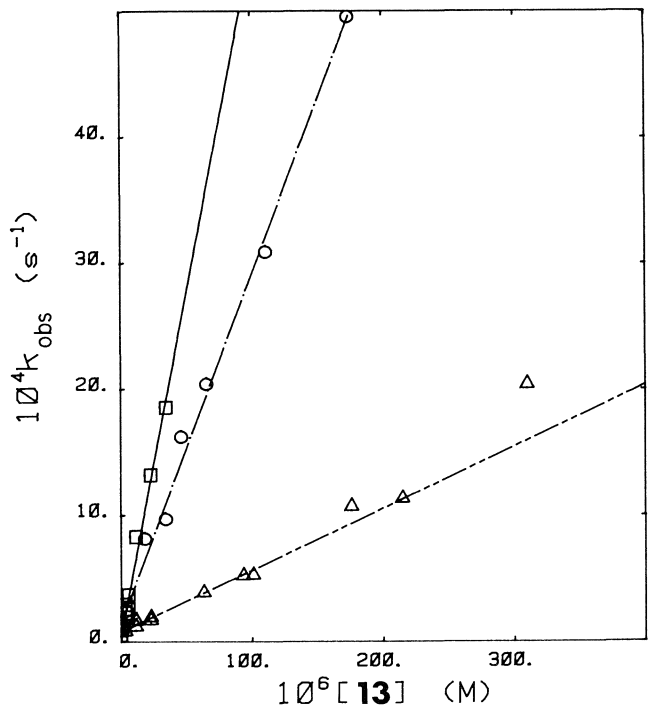

FIG. 2. Rates of reaction of esters of 3-(2-naphthyl)propionic acid as a function of the concentration of **13**: (□) 5-carboxy-2-nitrophenyl esters; (○) 4-trimethylammonio-2-nitrophenyl esters; (△) 4-nitrophenyl esters.

this is attributed to the crowding and torsional strain involved in achieving a transition state where the imidazole has attacked the ester carbonyl and simultaneously the aryl substituent is arranged parallel to the hydrophobic face of the steroid bearing the imidazole. Despite this unfavorable interaction we have now achieved an observable effect of 550-fold in rate. By using alternative substrates, less subject to steric interactions, we hope to obtain more of the potential rate enhancement. The next class of substrates to investigate will be ketones subject to general base catalyzed elimination reactions (3).

We wished to relate the observed stabilization energy to the surface area of the substrates removed from contact with solvent. A rough approximation to this surface area can be calculated by taking the area of the polygon whose vertices lie

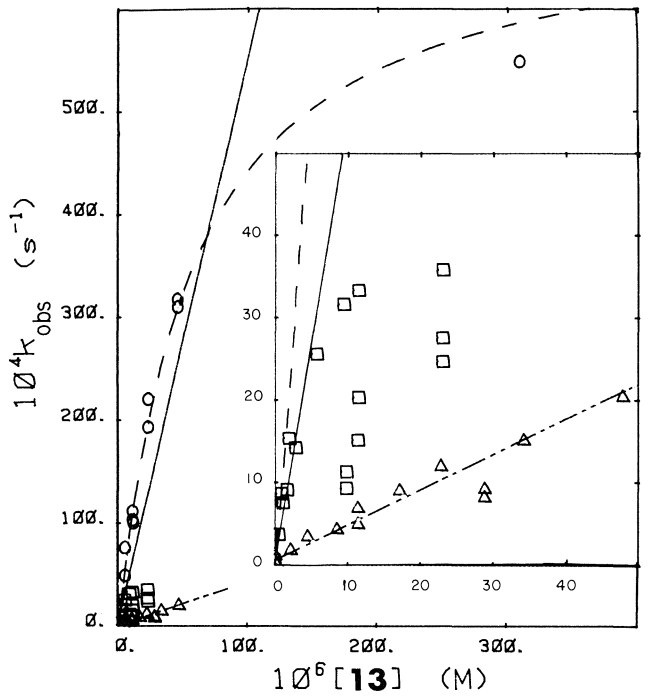

FIG. 3. Rates of reaction of esters of 3-(3-phenanthryl)propionic acid as a function of the concentration of **13**: (□) 5-carboxy-2-nitrophenyl esters; (○) 4-trimethylammonio-2-nitrophenyl esters; (△) 4-nitrophenyl esters.

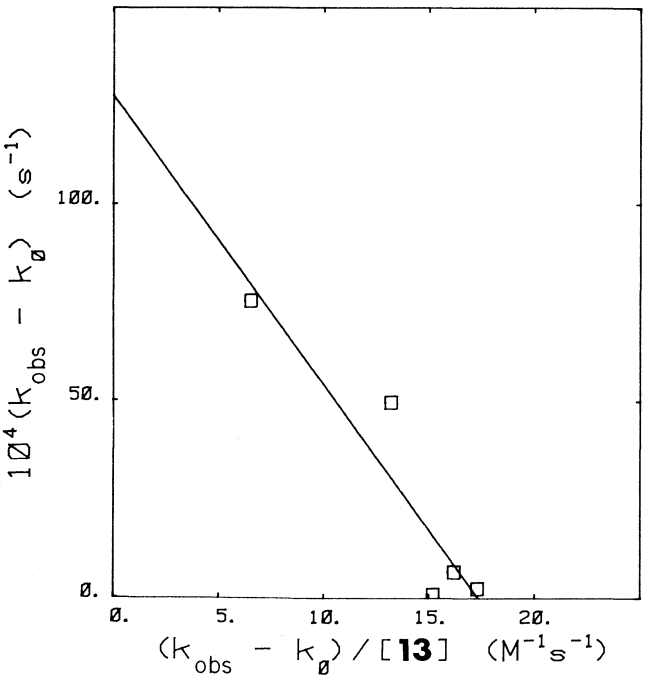

FIG. 4. Eadie–Hofstee plot of the data for the reaction of **14***a* with **13**. The line was fitted by least squares, and gives $k_{max} = (1.28 \pm 0.24) \times 10^{-2}\,s^{-1}$; $K_m = (7.36 \pm 1.67) \times 10^{-4}\,M$.

along the C—H bonds of the arene at the van der Waals radius of hydrogen. This gives a value of 144 Å^2 for the combined upper and lower surfaces of phenanthrene. When a phenanthryl group is bound by **13** both surfaces should be removed from contact with water, as well as some part of the edge surface which is near the bridging *p*-xylylene group. Since this interaction produces 5.4 kcal/mol of potential stabilization, we may calculate the strength of the hydrophobic interaction as 0.038 kcal/Å^2.

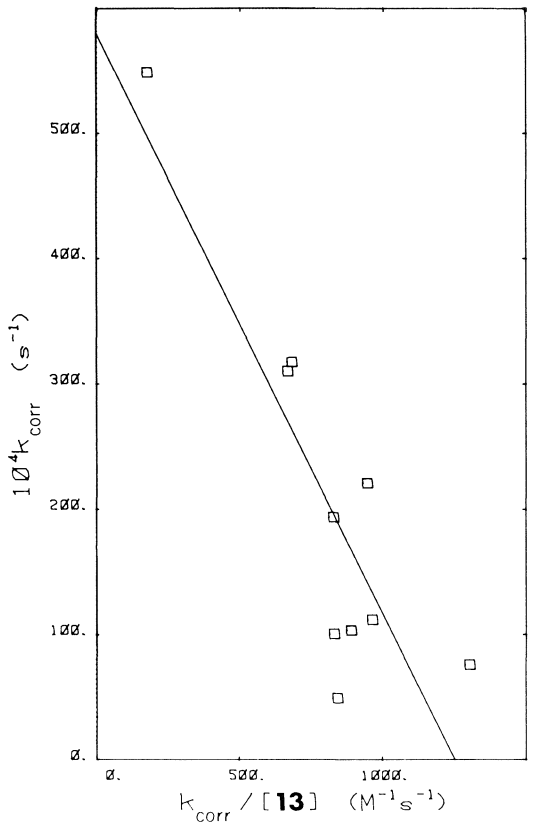

FIG. 5. Eadie–Hofstee plot of the data for the reaction of **16***a* with **13**. The line was fitted by least squares, and gives $k_{max} = (5.79 \pm 0.84) \times 10^{-2}\,s^{-1}$; $K_m = (4.62 \pm 0.98) \times 10^{-5}\,M$.

Figure 8 shows the absorbance vs. time curve for an experiment in which **16***a* was allowed to react with a catalytic amount of **13**, and the reaction was followed to completion. The pattern seen is of "burst" kinetics (17) with rapid acylation of the catalyst, followed by slower turnover kinetics, with hydrolysis of the acylimidazole intermediate regenerating catalyst which is promptly acylated again. The reaction, once the burst was over, was roughly zero order in substrate until the substrate was consumed. Observation of this behavior confirms that **13** is a catalyst, although the deacylation is in fact quite slow, since nothing in the design of **13** acts to facilitate it.

Our preliminary results with trimethylammonionitrophenyl esters suggest that the above calculation of the hydrophobic interaction energy may be too low. We were surprised to find that the rate constants for the reaction of the ester of 3-(3-phenanthryl)propionic acid with a cationic phenol were faster than for the corresponding ester of an anionic phenol. This contradicts our previous findings concerning the electrostatic effects on catalysis by **8** (4). However, the rate effect shows up consistently for all three cationic esters of arylpropionic acids. When we compare rates for each type of substrate relative to the rate constant for **8** plus the corresonding acetate, the relative rates for corresponding anionic and neutral esters are quite similar but those for the cationic esters are faster. The effect is less striking for the smaller aryl groups.

Two hypotheses spring to mind to expain these results: (*1*) That the anionic esters, although they have a stabilizing electrostatic interaction in the transition state for imidazole attack, obtain this stabilization at the price of less than optimal hydrophobic interactions. Thus an anionic ester with a large binding group is superior for **8**, where the total hydrophobic

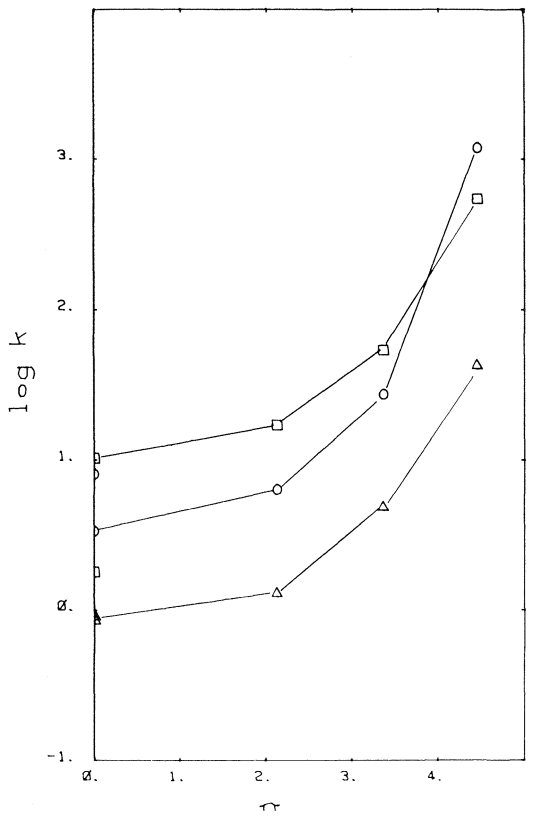

FIG. 6. log k_2 for various substrates as a function of the hydrophobicity parameter, π. The lines are arbitrary, serving only to join related points. The points at $\pi = 0$ are for imidazole (unfilled) and **8** (filled) as catalyst, and are twice the observed rate constant to allow for the two imidazolyl groups in **13**; (□) carboxynitrophenyl esters; (○) trimethylammonionitrophenyl esters; (△) nitrophenyl esters.

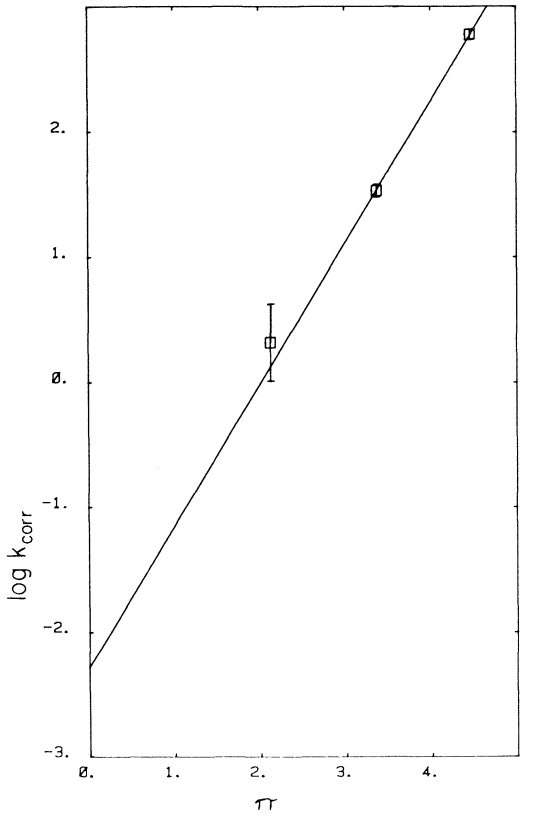

FIG. 7. log k_{corr} for **14***a*, **15***a*, and **16***a* as a function of the hydrophobicity parameter, π. The line was fitted by least squares: $\log k_{corr} = -2.28 \pm 0.14 + (1.13 \pm 0.04)\pi$.

stabilization available is modest, but not for **13** where much stronger hydrophobic stabilization is potentially available. (*2*) That the rates observed for **16***a* are subject to inhibition resulting from aggregation, even at the lowest concentration which we could use, and the true value is actually larger than for **16***c*.

To test these hypotheses will require further experiments and in particular an investigation of the effect of ionic strength on the behavior of these substrates. At 1 *M* ionic strength the importance of electrostatic stabilization should be much decreased, as should the severity of aggregation problems.

The first hypothesis is given some support by the imperfect parallelism between the rate constants for the reaction of carboxynitrophenyl esters with **13** and the 11-keto analog (5) as summarized in Table 2. Although the rate constants for **16***a* are the same within experimental error, the rate constant for **15***a* is greater for the 11-keto steroid, and that for **14***a* is greater for the 11-ammonio steroid. This could be the result of the sort of trade off between hydrophobic and electrostatic stabilization discussed above.

Aggregation

A distressing finding in these experiments was that even though the dimeric steroid with four positive charges was very soluble, there were still extreme difficulties with aggregation of substrates and/or catalyst plus substrate, leading to spuriously low reaction rates. For the *p*-nitrophenyl esters, which are of very low solubility in water, these results were not surprising, but the difficulties encountered with the hydroxynitrobenzoate esters, which had been relatively well behaved with **8**, constituted an unpleasant surprise. It is, however, not without precedent that hydrophobic anions and cations show precipitation at very low concentrations (18). We are forced to conclude that the use of anionic substrates with **13** is unlikely to be desirable. By contrast the cationic trimethylammonionitrophenyl esters were well behaved, despite the inherent rate inhibiting effect of repulsions between substrate and catalyst. These substrates are, however, very reactive and difficult to purify. Our finding of peculiar behavior, probably attributable to precipitation of anionic substrate by cationic catalyst at low concentrations suggests that in the design of enzyme models it would be more desirable to avoid the use of one charge type of solubilizing substituent, and use enzyme models with a small net charge.

Conclusions

The experiments reported above demonstrate that with a soluble, stereochemically defined catalyst, it is possible to achieve significant rate enhancements, of up to 5.5×10^2, resulting from hydrophobic stabilization of a transition state, and there is the potential for considerably larger effects, of 1.1×10^5. Two design principles for artificial enzymes emerge from our work: the hydrophobic binding energy for simple binding regions such as we have used amounts to 0.038 kcal/mol Å^2; hydrophobic artificial enzymes should not have high electrostatic charges.

Experimental

Methods

Compounds containing imidazole were visualized on tlc plates by spraying first with a freshly prepared 1:1 mixture of saturated

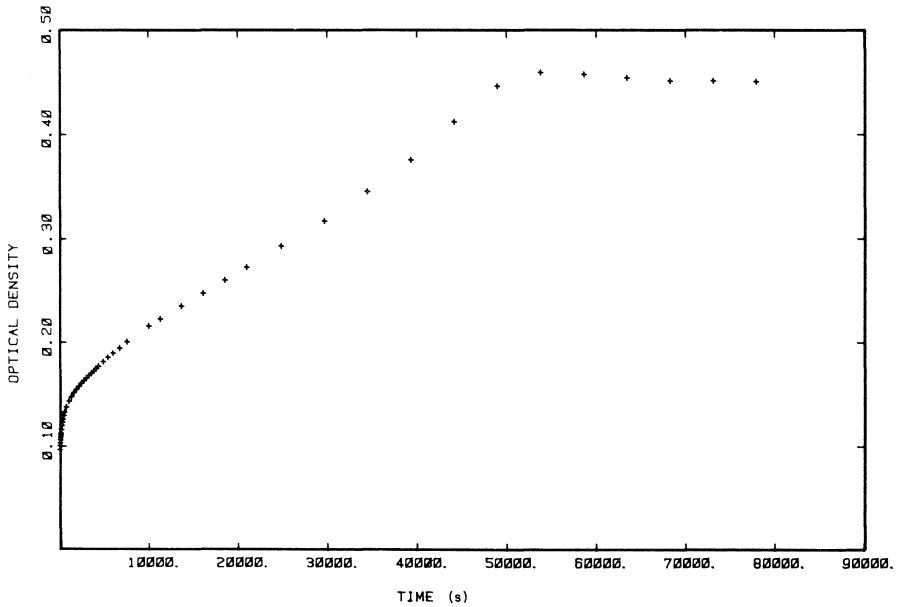

FIG. 8. Absorbance vs. time curve for the reaction of 9.52×10^{-6} *M* **16***a* with 1.16×10^{-6} *M* **13**. Acylation of the catalyst is followed by turnover, giving zero order kinetics.

methanolic sodium nitrite and 1% sulfanilic acid in 1 *M* HCl, and immediately afterwards spraying with 2 *M* methanolic KOH. Column chromatography was carried out using Glenco columns and mixing chambers, which allow the use of linear solvent gradients. Samples, dissolved in the minimum volume of solvent, were mixed with dry silica and evaporated. The dry residue was placed on top of the column and rinsed in with a little of the initial elution solvent. Elution was carried out under pressurization by nitrogen at 10–15 psi to give a flow rate of 2 mL/min. The water content of solvents was determined using a Photovolt Aquatest IV moisture analyzer. The presence of borohydride was tested for using aqueous triiodide–starch solution. A few drops of a solution containing active borohydride dispelled the color. Silica for column chromatography was Merck Silicagel 60 PF254. Thin layer chromatography was carried out using Analtech Uniplates with silica gel GF. Nuclear magnetic resonance spectra were recorded on Varian T60, EM360, XL200, or XL300 instruments. TMS, for organic solvents, and DSS (4,4-dimethyl-4-silapentanesulfonic acid), for D_2O were used as internal standards.

Materials

Sodium cyanoborohydride was purified as described by Borch *et al.* (6), and assayed by iodometric titration. A weighed amount of cyanoborohydride was washed (methanol) into a flask containing excess potassium iodide and a known volume of potassium iodate standard solution which had been acidified with excess acetic acid. Each hydride in cyanoborohydride reduced one molecule of iodine to two iodides. The remaining iodine was titrated using thiosulfate solution freshly standardized against potassium iodate. Terephthaldehyde was purified by sublimation in vacuum. Ethyl formate for use as a formylating agent was freshly distilled from sodium carbonate. 2-Methoxyethanol (Fisher Certified) was distilled; the fraction boiling at 123–124°C was used. A test for peroxides was negative; the water content was 500 μg/mL. The last 25% of the distillate had only 60 μg/mL of water. Dimethylformamide, DMF, was dried by storing it over CaH_2. Acetonitrile used as a solvent for stock solutions of substrates was purified by distillation.

α,α′-Biscyclohexylamino-p-*xylene*

Terephthaldehyde, 335 mg (2.5 mmol), was dissolved by heating in dry (60 μg/mL water) 2-methoxyethanol, 5.0 mL cyclohexylamine, 0.50 g (5.0 mmol), was added and the mixture refluxed gently for 30 min. On cooling to room temperature, the di-aldimine crystallized out. A few drops of the reaction mixture, reheated to dissolve the product, were used for a proton spectrum in $CDCl_3$: δ 7.75 (s) aromatic protons; 8.30 (s) aldimine CH; 0.5–1.7 cyclohexyl CH_2. The cyclohexyl CH—H was obscured by solvent absorptions from δ 3–5. A small portion of the di-imine was recrystallized from methanol, mp 128.5–129.5°C.

To the reaction mixture was added acetonitrile, 2 mL and more methoxyethanol, 4 mL, and it was warmed gently until the solids dissolved. $NaBH_3CN$, 200 mg (9.5 mequiv.), dissolved in methanol, 2 mL, was added after the mixture had cooled to ca. 50°C. Acetic acid, 1 drop, was added and bubbles slowly started to form. The mixture was cooled to room temperature. Acetic acid, 0.3 mL, in 3 mL acetonitrile, 3 mL, was added over a period of 5 min and the mixture stirred for another hour without heating. After evaporating about half the solvents, the mixture was left overnight. By morning it had partially solidified. Rewarming gently dissolved the solids; the ^{1}H-nmr ($CDCl_3$) showed that all of the aldimine signal at 8.3 had disappeared. There was no signal at ca. 10δ indicating the absence of aldehydes. The signal attributed to the aromatic protons had shifted to 7.5δ. After adding methanol, 20 mL, and water, 20 mL, the solution was homogeneous and the pH was 7.6. The solution was washed into a separatory funnel with 1 *M* HCl, 25 mL, and ether, 30 mL. The ether layer was discarded and the aqueous layer was basified with NaOH to pH 13, and extracted four times with ethyl acetate, 50 mL. The ethyl acetate extracts were dried (Na_2SO_4), evaporated, and dried at 70°C, 0.25 Torr. The residue, 664 mg of slightly yellow oily liquid (93% of expected weight), would not crystallize. ^{1}H-nmr ($CD_3OD/CDCl_3$) δ: 7.25 (s), 2H, aromatic protons; 4.7–4.8, 3H, overlapping Ar—CH_2 and N*H*; 2.2–2.8, 1H, cyclohexyl CH—N; 0.5–2.2, 10H, aliphatic CH_2. Exact mass: expected for $C_{20}H_{32}N_2$: 300.25654; found 300.25531.

The oily liquid diamine was treated with 2 *M* HCl in methanol, 3 mL, and the mixture allowed to cool in the freezer. Crystallization was complete after 2 h and the solid dihydrochloride was washed with cold ethanol, yielding 486 mg (55%) white non-hygroscopic fine crystals, mp 335 with partial decomposition and partial sublimation. ^{1}H-nmr (D_2O; DSS as internal reference) δ: 7.60 (s) 4H, aromatic C*H*; 4.30 (s), 4H, Ar—CH_2; 3.14 (br, $w_{1/2}$ = 26 Hz), 2H, cyclohexyl C*H*—N; 1.0–2.4, aliphatic CH_2.

5α-Androstan-17β-ol-3β-amine

5α-Androstan-17β-ol (stanolone, Sigma) was converted to the oxime by reaction with hydroxylamine hydrochloride in pyridine. The crude product had mp 203–209°C; lit. (7) mp 213–214°C. ^{1}H-nmr ($CDCl_3$) δ: 18-CH_3, 0.75 (s); 19-CH_3, 0.93 (s). The oxime was reduced to the amine by refluxing with sodium in propanol. The crude

product had mp 153–156°C; three recrystallizations from ether – petroleum ether gave material with mp 169–170°C; lit. (7) mp 170–171°C; (19) mp 167–169°C. ^{1}H-nmr ($CDCl_3$:CD_3OD) δ: 18-CH_3, 19-CH_3, 0.70 (s), 0.80 (s); (0.5 *M* DCl in D_2O:CD_3OD) δ: 18-CH_3, 0.87 (s); 19-CH_3, 1.01 (s). Exact mass: expected for $C_{19}H_{33}NO$ 291.25621; found 291.25573.

α,α′-Bis-(17β-hydroxy-5α-androstan-3β-amino)-p-*xylene*

5α-Androstan-17β-*ol*-3β-amine, 249 mg (0.854 mmol), and terephthalaldehyde, 54 mg (0.40 mmol), were each dissolved in 2-methoxyethanol, 1 mL, and washed together into a 100 mL flask with an extra 6 mL of the solvent. A precipitate formed almost immediately upon mixing. More solvent, 20 mL, was added and the mixture heated to a gentle reflux with stirring, but the precipitate did not completely dissolve. The mixture was cooled to 50°C and treated with $NaBH_3CN$, 200 mg, dissolved in methoxyethanol, 5 mL. After stirring 5 min, glacial acetic acid, 60 μL, was added and the mixture kept warm (60–70°C) for 2 h, during which time another seven portions of acetic acid, 60 μL, were added at intervals (ca. 0.5 mL acetic acid in all). Midway through the reaction, the mixture became homogeneous and the cloudiness disappeared, but a different kind of precipitate began to form almost immediately after the solution cleared. It dissolved when the temperature was raised to 100°C but came out of solution again on cooling to room temperature at the end of 2 h. The mixture was cooled in an ice-bath and the precipitate filtered, washed with cold methanol–water, and air-dried. The pH of the mother liquor was 4.6. The solid was most soluble in chloroform–methanol. Thin layer chromatography with 50:50 $CHCl_3$:1 *M* NH_3/MeOH gave one iodine-staining spot, rf = 0.9. The proton nmr spectrum showed two singlets at 0.87 and 0.73 ppm, assigned to the methyl groups, with the same separation as the signals from the methyl groups in 5α-androstan-17β-ol-3β-amine HCl. A singlet at 2.0 ppm suggests that the compound was the diacetate salt of the dimer desired, and the rest of the spectrum was consistent with that. A signal assigned to the benzylic methylene was apparent at 4.0 ppm. Aromatic protons appeared at 7.4 ppm. The yield of product as the diacetate (mw 805.2; mp 270–280) was 187 mg (0.232 mmol). Yield based on terephthalaldehyde 58%; based on steroid, 54%.

After dissolving in aqueous methanol, basifying, and extracting with ethyl acetate, 149 mg of the free base was recovered; mp 270–280 decomp.; yield, 54% based on aldehyde, 51% based on steroid. ^{1}H nmr ($CDCl_3$/CD_3OD): δ: CH_3 (s) 0.73, 0.83; CH—N (br.) 2.2–2.7; CH—O (br) 3–3.5; ArCH_2—N (s) 3.77; aromatic CH (s) 7.28. The compound was essentially pure by tlc (rf = 0.5 with 5% Et_2NH/20% EtOH/75% benzene, I_2 stain). Exact mass: expected for $C_{46}H_{72}N_2O_2$ 684.55936; found 684.55954.

α,α′-Bis-(17β-4(5)-imidazolyl-11β-trifluoracetamido-5α-androstan-3β-amino)-p-*xylene,* ***12****a*

17β-4(5)-Imidazolyl-3β,11β-diamino-5α-androstane trihydrochloride, **8**, 100 mg, was dissolved in trifluoroacetic acid, 2 mL, and cooled in an ice bath before addition of trifluoroacetic anhydride, 1 mL. Sodium carbonate, 400 mg, was then added and the mixture stirred, with cooling in ice, for 2 h. Then methanol, 2 mL, was added and the reaction mixture was basified using 30% aqueous ammonia, 10 mL, and extracted with ethyl acetate, 3 × 30 mL. The extracts were dried (Na_2SO_4) and evaporated. The crude 17β-4(5)-imidazolyl-3β,11β-bistrifluoracetamido-5α-androstane, **9***a*, was dissolved in 2 *N* methanolic KOH and left 3 h at room temperature. Aqueous HCl (2 *N*), 5 mL, and water, 10 mL, were then added and the solution extracted with ethyl acetate, 5 mL. The aqueous solution was then basified using 30% aqueous ammonia, 5 mL, and extracted with 1:9 methanol:chloroform, 4 × 40 mL. The organic layer was evaporated and then purified by preparative layer chromatography (silica) developing with 50:50 chloroform:1 *M* methanolic ammonia. The extract from the thick plate was freed of silica by extracting from aqueous ammonia using chloroform. The material so obtained was used for dimerization experiments. An amount of **10***a* corresponding by Pauly assay (25) to 167 mg (0.358 mmol) of **8**.3HCl was dissolved in 2-methoxyethanol, 5 mL, to form a nearly clear solution and combined with a solution of purified terephthalaldehyde, 19.9 mg (0.148 mmol), in the same solvent, 5 mL. The solution was heated gently and allowed to cool under a stream of nitrogen. No precipitate formed. Dry $NaBH_3CN$, 100 mg, was added and dissolved with stirring. Glacial acetic acid, 0.3 mL, was added in five portions, 60 μL, at 15 min intervals while the mixture was gently heated and stirred under a stream of nitrogen. The mixture was left at room temperature under a stream of nitrogen overnight and by morning, about 80% of the solvent had evaporated and a small amount of fine precipitate had settled. After adding water, 20 mL, a voluminous semi-solid separated; the pH was 4.35. The iodine test indicated that borohydride was still present.

The mixture was cautiously acidified with concentrated HCl, 8 mL, and made up to 75 mL with aqueous methanol. Most of the precipitate dissolved after stirring on a steam bath for 30 min. The solution was washed into a separatory funnel with water, 50 mL, methanol, 10 mL, and ether, 25 mL, and shaken. The ether layer yielded about 20 mg of white solid which was not Pauly positive; this was discarded. The aqueous layer was basified, 5 *M* NaOH, 40 mL, to give a pH of 12.5. A fluffy precipitate formed; the mixture was extracted with ethyl acetate, 3 × 75 mL. The first three extracts yielded 228.8 mg of slightly yellow glassy solid. Thin layer chromatography, 15% diisopropylamine:10% methanol:75% $CHCl_3$, visualized with Pauly spray, showed two red spots at rf = 0.7 and 0.55, an orange spot at rf = 0.4, and a red spot attributed to starting material at rf ca. 0.2. Column chromatography on 14 g of silica gel eluted with a gradient from $CHCl_3$ to 3% *i*-Pr_2NH, 15% MeOH, 82% $CHCl_3$ gave 53 mg of a fraction consisting mainly of what is believed to be 17β-4(5)-imidazolyl-3β-(4′-hydroxymethylphenylmethylamino)-11β-trifluoroacetamido-5α-androstane (^{1}H nmr ($CDCl_3$/CD_3OD) δ: 0.6 (s), 0.9 (s), CH_3; 4.6 (s) ArCH_2OH; 6.7 (s), 7.4 (s) imidazolyl CH; 7.3 (s) *p*-phenylene CH), and 58 mg of the desired dimeric compound (^{1}H-nmr ($CDCl_3$/CD_3OD) δ: 0.62 (s), 0.94 (s) CH_3; 2.60 (br, $w_{1/2}$ = 20 Hz) C3H—N; 3.83 (br, $w_{1/2}$ = 6 Hz) C11H—N; 4.57 (s) ArCH_2; 6.73 (s), 7.49 (s) imidazolyl CH; 7.32 *p*-phenylene CH), as well as 30 mg of starting material. There were small amounts of other unidentified byproducts.

Attempted hydrolysis by refluxing for 24 h in 6 *M* methanesulphonic acid, basifying with a large excess of 20% Na_2CO_3 and extracting with ethyl acetate gave mixtures showing that there had been extensive degradation.

17β-4(5)-Imidazolyl-11β-formamido-5α-androstane-3β-amine, ***10****b*

8.3HCl, 595 mg, dissolved in methanol, 10 mL, and triethylamine, 10 mL, was added to ethyl formate, 50 mL. A white precipitate formed. The mixture was refluxed under nitrogen for 7 days. The precipitate was nearly dissolved after day 3. The reaction solution was evaporated to near dryness then MeOH, 50 mL, was added and the mixture evaporated again. Then it was washed into a separatory funnel with MeOH, 20 mL, and water, 100 mL. K_2CO_3 (3 *M*), 20 mL, was added and the mixture extracted with EtOAc, 7 × 150 mL. Drying and evaporating to dryness yielded a caked glassy solid weighing 645 mg: 90.6% of expected. It had only one major Pauly positive spot (rf = 0.7 with 20% MeOH:3% Et_3N:77% $CHCl_3$). ^{1}H nmr ($CDCl_3$/CD_3OD) δ: 0.66 (s), 0.99 (s) CH_3; 2.62 (br, $w_{1/2}$ = 14 Hz) C17H—imidazolyl; 3.68 (br, $w_{1/2}$ = 22 Hz) C3H—N; 4.59 (br, $w_{1/2}$ = 8 Hz) C11H—N; 6.76 (v br), 7.52 (v br) imidazolyl CH; 7.93 (s), 7.97 (s) CHO—N. The crude formylation product, 645 mg, was dissolved in 0.6 *M* methanolic KOH, 50 mL, and left 7 days at room temperature under nitrogen. The base was neutralized with CO_2 gas, concentrated NH_3, 30 mL, added and the mixture washed into a 500 mL separatory funnel with water, 125 mL, and extracted with 7% MeOH:93% $CHCl_3$, 7 × 100 mL. Evaporation yielded 615 mg of residue, 102%. Column chromatography on silica, eluting with a gradient from $CHCl_3$ to 3% ET_3, 20% MeOH in $CHCl_3$. The major product recovered was 11β-formamido-17β-4(5)-imidazolyl-5α-androstan-3β-amine, 306 mg, 51%, (^{1}H-nmr (CD_3OD/$CDCl_3$) δ: 0.67 (s), 0.98 (s) CH_3; 7.83 (s) CHO—N; 7.5 (s) CHOO$^-$) with some byproducts running ahead and behind. The slower eluting material, 117 mg, was in part the corresponding diamine, which could be recycled.

Acid hydrolysis of 11β-formamido-17β-4(5)-imidazolyl-5α-androstan-3β-amine, ***10*** b

10*b*, 20 mg, was refluxed 18 h in 2 *M* methanolic HCl, 10 mL, washed into a separatory funnel with water, 10 mL, 20% Na_2CO_3, 30 mL, and 1 *M* KOH – saturated KCl, 10 mL. Extraction with ethyl acetate, 6 × 6 mL, yielded 16 mg, identified by ^{1}H nmr and tlc behaviour as 17β-4(5)-imidazolyl-5α-androstane-3β,11β-diamine. The imidazole protons could be seen at 6.6 and 7.4 but no formyl protons could be seen at 7.9. Thin layer chromatography gave one major spot at low rf which ran side-by-side with the 3,11-diamine and several minor spots with higher rf's.

*α,α′-Bis-(17β-4(5)-imidazolyl-11β-formamido-5α-androstan-3β-amino)-*p*-xylene,* ***12*** b

11β-Formamido-17β-4(5)-imidazolyl-5α-androstan-3β-amine, **8***b*, 242 mg (0.629 mmol), was dissolved in dry 2-methoxyethanol, 10 mL, and methanol, 4 mL. Terephthalaldehyde, 38.25 mg (0.285 mmol), was dissolved in 2-methoxyethanol, 5 mL. The two solutions were mixed to form a clear solution containing a calculated 10% excess of amine. Most of the methanol was evaporated by gentle heating under a stream of nitrogen. A white precipitate formed on cooling, $NaBH_3CN$, 340 mg, dissolved in MeOH, 3 mL, was added. (6.8 mequiv., a 6-fold excess). A solution of acetic acid, 0.5 mL, in MeOH, 10 mL, was added in 1 mL portions over a period of 2 h, at a temperature of ca. 30°C. Reaction continued overnight at room temperature under a slow stream of N_2. A positive iodine test confirmed that cyanoborohydride was still present. The solution was clear and colorless. Acetic acid, 5 mL, was added and produced no visible effect. The reaction mixture was washed into a beaker with methanol, 20 mL, and 2 *M* HCl, 5 mL, added. Hydrogen evolution stopped after about 1 h. The solution was extracted using ether. The ether extract was discarded. The pH of the aqueous phase was 1.6. Basifying with concentrated NH_3, 40 mL, brought the pH to 10.1 and caused precipitation of product. Extraction with 7% MeOH: 93% $CHCl_3$, 5 × 200 mL, drying with Na_2SO_4, and evaporating yielded 300 mg of white solid. Repeated column chromatography was necessary to separate the desired material from monomeric steroid. The second column was eluted with a gradient from 10% MeOH, 90% $CHCl_3$ to 20% MeOH:3% Et_3N:77% $CHCl_3$. This gave 118 mg of pure dimer and 75 mg mixed dimer and monomer. The third column was eluted using a gradient from 10% MeOH, 90% $CHCl_3$ to 30% MeOH:3% Et_3N:67% $CHCl_3$. This gave 57 mg of pure dimer, 7 mg of a mixture of dimer and monomer, and 9 mg of monomer. With 118 mg of pure dimer from the second column this gave 175 mg product (0.201 mmol, 71% based on terephthalaldehyde and 64% based on monomer. Exact mass: expected for $C_{54}H_{78}N_8O_2$, 870.62477; found 870.62066. The fragmentation pattern showed an ion with nearly equal intensity 15 amu lower, and no equal or greater intensity ions above 627 amu. The most prominent fragment above 400 amu is the one at 486 corresponding to a loss of one steroid skeleton without its attached benzyl carbon. There are almost as prominent fragments 14 amu lighter and 17 amu heavier than 486. The most prominent mass between 100 and 400 is 384 which is the mass of 11-formyl monomer.

Acid hydrolysis of ***12*** b

Chromatographically purified **12***b*, 100 mg, was dissolved in 1 *M* DCl in D_2O, 1 mL. After four cycles of addition of D_2O, 1 mL, and evaporation to dryness, the deliquescent crystalline solid was dissolved in D_2O, 0.4 mL. ^{1}H-nmr δ: 0.5 (s), 0.9 (s) CH_3; 4–4.5 (v br) ArCH_2 and C*H*—N; 7.3 (s), 1H, 7.9 (s), 1H, imidazolyl C*H*; 7.5 (s), 2H, aromatic C*H*; 8.5 (s), 1H, C*H*O—N. When 0.1 mL of 35% DCl/D_2O was added, the spectrum was hardly changed except that the exchange signal was increased and shifted from 5.0 to 5.5 ppm. It appears that the benzylic CH protons, expected to absorb at 4–5 ppm by comparison with the model compound dicyclohexylamino-*p*-xylene dihydrochloride do not give as sharp a signal as expected. The dimer was left in the ~2 *M* DCl solution to allow time for hydrolysis at room temperature, anticipating a slight change in spectrum. The growth of a new signal at 8.0 ppm at the expense of the *N*-formyl signal at 7.75 ppm permitted the reaction to be followed. It was slow at 25°C, but after 4 h at 85°C hydrolysis was 90% complete. ^{1}H-nmr δ: 0.9 (s), 1.1 (s) CH_3; 3.9 (br, $w_{1/2}$ = 8 Hz) C11*H*—N; 4.2 (br, $w_{1/2}$ = 6 Hz) ArCH_2; 7.2 (s), 8.4 (s) imidazolyl C*H*; 7.4 (s) *p*-phenylene C*H*. Heating for another half-hour at 95°C completed the reaction. ^{13}C-nmr spectrum: (D_2O with excess DCl) δ wrt TMS (formic acid used as internal standard): 133.63, 133.27, 132.60, 130.94, 116.24, 57.03, 56.66, 54.89, 48.66, 48.11, 46.97, 45.33, 42.16, 35.76, 35.16, 31.57, 31.24, 30.48, 27.19, 25.99, 24.32, 23.84, 15.07, 14.55.

*α,α′-Bis-(17β-4(5)-imidazolyl-11β-amino-5α-androstan-3β-amino)-*p*-xylene,* ***13***

12*b*, 459 mg (0.53 mmol) was dissolved in 3 *N* HCl and heated 6 h on a steam bath. Basification and extraction yielded 248 mg of material shown by tlc analysis to contain some Pauly positive impurities. This material was chromatographed on silica, 70 g, slurried in toluene, and packed in a 2.5 cm diameter column. Elution was carried out with a gradient from 20% methanol:1% aq. NH_3:79% toluene to 75% methanol:5% aq NH_3:20% toluene a pressure of 12 psi (N_2) to give a flow rate of 2 mL/min, yielding 126 mg of almost pure dimer (21% based on monomer). Exact mass: expected for $C_{52}H_{78}N_8$: 814.635; found 814.632. The fragmentation pattern showed a mass of 3/4 intensity 17 amu lower than 814.6 and no equal or greater intensity masses above 500 amu. The most prominent fragment heavier than 400 is the one at 458 corresponding to a loss of one steroid skeleton. There are fragments with half this intensity 17 amu heavier and 15, 16, and 17 lighter than 458. The most prominent mass between 200 and 400 amu is 356, which is the mass of the monomer.

13 which had been purified by column chromatography, 100 mg, was dissolved in methanol, 3 mL, and an excess of 1 *M* HCl was added, 0.8 mL. Ethyl ether, 20 mL was added to cause precipitation of the dimer hydrochloride. 200 MHz ^{1}H nmr (D_2O) δ: 0.72 (s), 3H, C18H_3; 1.00 (s), 3H, C19H_3; 2.90 (t, J = 9 Hz), 1H, C17*H*; 3.30 (br, $w_{1/2}$ = 20 Hz), 1H, C3*H*; 4.00 (br, $w_{1/2}$ = 12 Hz), 1H, C11*H*; 4.32 (s), 2H, Ar—CH_2—; 7.34 (d, J = 1.4 Hz), 1H, imidazole (C5′*H*; 7.57 (s), 2H, *p*-phenylene C*H*; 8.61 (d, J = 1.4 Hz), 1H, imidazole C2′*H*.

Substrates for kinetics

14*a*, **15***a*, **16***a*, **15***b*, **15***c*, and **17***b* were prepared and purified as previously described (4).

p-*Nitrophenyl hydrocinnamate,* ***14*** b

Hydrocinnamic acid, 900 mg (6 mmol) was dissolved in a mixture of CH_2Cl_2, 10 mL, $SOCl_2$, 3 mL, and DMF, 0.5 mL, and the mixture refluxed under N_2 for 6 h. It was evaporated to near dryness, redissolved in ethyl acetate, 10 mL, and added to a solution of sodium *p*-nitrophenoxide, 1 g, in pyridine, 30 mL, refluxed for 3 h, poured into a mixture of ice, 100 g, and 6 *M* HCl, 100 mL, extracted once with ethyl acetate, 75 mL, washed once with water, 25 mL, dried over Na_2SO_4, evaporated and purified by column chromatography on 60 g silica eluting with 10% ethyl acetate:90% hexanes as solvent. One recrystallization of the eluate from CCl_4 gave pure material, mp 97–97.5°C in 16% yield. 200 MHz ^{1}H-nmr ($CDCl_3$) δ: 2.94, 3.08 (distorted triplets of A_2B_2), 4H, —CH_2—CH_2—; 7.18 (d, J = 9.2 Hz), 7.2–7.4 (complex), 7H, nitrophenyl C2*H* and C6*H* overlapping *Ph*—CH_2—; 8.25 (d, J = 9.2 Hz), 2H, nitrophenyl C3*H* and C5*H*. Exact mass: expected for $C_{15}H_{13}NO_4$ 271.08444; found 271.08469.

p-*Nitrophenyl-3-(2-naphthyl)-propionate,* ***15*** b

This was prepared using the same procedure: mp 124.5–125°C (ether:petroleum ether) Lit. mp 126–128°C (95% ethanol) (4). 200 MHz ^{1}H-nmr ($CDCl_3$) δ: 3.00, 3.22 (distorted triplets of A_2B_2, J = 7.4), 4H, —CH_2—CH_2—; 7.13 (d, J = 9.2), 2H, nitrophenyl C2*H* and C6*H*; 7.3–7.8 (complex), 7H, naphthyl; 8.17 (d, J = 9.2 Hz), 2H, nitrophenyl C3*H* and C5*H*. Exact mass: expected for $C_{19}H_{15}NO_4$ 321.10009; found 321.10000.

p-*Nitrophenyl-3-(3-phenanthryl)-propionate,* ***16*** b

Phenanthrylpropionic acid, 176 mg, was heated to reflux with $SOCl_2$, 2 mL, DMF, 0.5 mL, CH_2Cl_2, 25 mL, for 2 h. The solvent and excess $SOCl_2$ were evaporated, CH_2Cl_2, 25 mL, added followed by a solution of sodium *p*-nitrophenoxide, 200 mg, in dry pyridine, 5 mL, with stirring at room temperature for 2 h. The mixture was

poured into a separatory funnel and partitioned between water and ethyl acetate. The organic layer was washed twice with 1 *M* HCl and once with saturated aqueous sodium chloride. After drying and evaporating, the last traces of pyridine were removed by heating to 100°C at 0.5 mm for 10 min. The red oil was chromatographed through a column of 85 g silica with 30% ethyl acetate:1% acetic acid:69% hexanes. A crystallization from 5 mL cold CCl_4 yielded 25 mg of light yellow solid, mp 108–110°C. 200 MHz ^{1}H-nmr ($CDCl_3$) δ: 2.94 (t, J = 7.4 Hz), 3.23 (t, J = 7.4 Hz), 4H, —C*H*$_2$—C*H*$_2$—; 6.99 (d, J = 9.2), 2H, nitrophenyl C2*H* and C6*H*; 7.4–8.6 (complex), 9H, phenanthryl; 8.02 (d, J = 9.2 Hz), 2H, nitrophenyl C3*H* and C5*H*. Exact mass: expected for $C_{23}H_{17}NO_4$, 371.11574; found 371.11535.

A condensation between 3-PPA and *p*-nitrophenyl using trifluoroacetic anhydride both as solvent and condensing agent all in one step gave a purer product, mp 111–112°C, after column chromatography and crystallization as above.

A stock solution of **16***b* was prepared using 5.23 mg in 5.0 mL, using 40% acetic acid:60% acetonitrile as the solvent. This solution was 0.00252 *M* in ester. This stock solution (300 μL) added to 75 mL 0.1 *M* aqueous KCl gave a cloudy mixture (1.0×10^{-5} *M* in ester) which, after stirring 2 days was clear and colorless with white solid floating on top. After filtering and adding solid NaOH to make it 1.0 *M* in hydroxide, the uv spectrum was measured. The absorbance at 400 nm was 0.0124 and that at 500 nm was 0.0036. The spectrum from 500 to 250 was an almost featureless rise with barely discernible lumps at 400 nm, 320 nm (A = 0.025), and 270 nm (A = 0.05). This puts an upper limit on the solubility of PNP–PPA, based on the known extinction coefficient of *p*-nitrophenoxide of 17500 ± 2500 (20), of 7×10^{-7} *M*.

4-Trimethylammonio-6-nitrophenyl-3-phenylpropionate iodide, ***14****c*

Prepared by the method used for **15***c* (2); mp 160–160.5°C. 200 MHz ^{1}H nmr (DMSO-d_6) δ: 3.02 (s), 4H, —C*H*$_2$—C*H*$_2$—; 3.83 (s), 9H, $N^+(CH_3)_3$; 7.30 (distorted s), 5H, C_6H_5—; 7.65 (d, J = 9.0 Hz), 1H, nitrophenyl C6—*H*; 8.58 (d of d, J = 9.0, 3.2), 1H, nitrophenyl C5—*H*; 8.81 (d, J = 3.2 Hz), 1H, nitrophenyl C3—*H*.

4-Trimethylammonio-6-nitrophenyl-3-(2-naphthyl)-propionate iodide, ***15****c* (2)

For this compound, mp 158–160°C. 200 MHz ^{1}H-nmr (DMSO-d_6) δ: 3.02 (distorted triplet — A_2B_2), 4H, —C*H*$_2$—C*H*$_2$—; 3.76 (s), ?H, $N^+(CH_3)_3$; 7.4–7.5 (complex), 3H and 7.8–7.9 (complex) 4H, naphthyl; 7.74 (d, J = 9.2 Hz), 1H, nitrophenyl C6—*H*; 8.54 (d of d, J = 9.4, 3.2), 1H, nitrophenyl C5—*H*; 8.80 (d, J = 3.0 Hz), 1H, nitrophenyl C3—*H*.

4-Trimethylammonio-6-nitrophenyl-3-(3-phenanthryl)propionate iodide, ***16****c*

3-(3-Phenanthryl)propionic acid, 515 mg (2.06 mmol), was dissolved in dry DMF, 3 mL, containing dry Et_3N, 0.30 mL (2.1 mmol). Ethyl chloroformate, 0.2 mL (2.1 mmol) was then added and the mixture stirred for 15 min. 4-Hydroxy-3-nitrophenyltrimethylammonium iodide (2, 21), 676.2 mg (2.087 mmol), dissolved in dry DMF, 4 mL, containing Et_3N, 0.3 mL (2.1 mmol), was added to the first solution and the mixture was stirred at room temperature for 1 h. The reaction mixture was then poured into ether, 100 mL, and the precipitate was filtered, washed with ether and petroleum ether, and then dried. The crude yield was 1.25 g. This material was dissolved in CH_2Cl_2, 150 mL, and methanol, 10 mL, and then poured into ether, 200 mL. The precipitate, 850 mg, had mp 130–133°C. The solid was dissolved in $CHCl_3$, 200 mL, and methanol, 3 mL, and poured into ether, 250 mL; after cooling in ice, 624 mg of solid, mp 133–134°C, was recovered. Recrystallization from methanol:acetic acid:benzene:ether 5:5:20:10 gave mp 135–136°C. Recrystallization from acetic acid:ethanol, with cooling to −10°C gave mp 137–138°C. 200 MHz ^{1}H-nmr spectrum (DMSO-d_6): δ: 3.27 (A_2B_2 pattern), 4H, Ar—C*H*2—C*H*2—CO; 3.76 (s), 9H, N—C*H*$_3$; 7.71 (d, J = 9.4 Hz), 1H, nitrophenyl C6—*H*; 7.5–8.8 (complex), 9H, phenanthryl H; 8.55 (d of d, J = 3.2, 9.2 Hz), 1H, nitrophenyl C5—*H*; 8.82 (d, J = 3.4 Hz), 1H, nitrophenyl C3—*H*. Peaks attributed to the trimethylammonionitrophenyl residue are assigned by comparison with a spectrum of the phenol. 200 MHz ^{1}H-nmr (DMSO-d_6) δ: 3.71 (s), 9H, $N^+(CH_3)_3$; 7.32 (d, J = 9.4 Hz), 1H, C6—*H*; 8.24 (d of d, J = 9.4, 3.2 Hz), 1H, C5—*H*; 8.49 (d, J = 3.4 Hz), 1H, C3—*H*.

Spectra in DMSO of all of these esters had signals corresponding to minor amounts of unesterified phenols, signals which grew in intensity after the DMSO solutions were kept at room temperature for a few hours, and which became major ones after heating. It was confirmed by taking a spectrum of the acetate that this compound, which had a reasonably sharp melting point, 155–158°C, lit: mp 152–155°C (21); mp 154–156.5°C (4), also appeared contaminated in DMSO. It seemed likely that solvolysis was occurring in DMSO.

Spectrophotometric analysis for trimethylammonionitrophenyl esters

Stock solutions of the phenol and the esters were made up in purified acetonitrile. The absorbance changes at 400 nm were determined for replicate injections, and the extinction coefficients determined. Compound, extinction coefficient (number of injections); 4-hydroxy-3-nitrophenyltrimethylammonium iodide, 4940 ± 20 (7); **14***c*, 4970 ± 20 (5); **15***c*, 4920 ± 40 (8); **16***c*, 4920 ± 50 (6). We conclude that these esters are pure within the limits of this assay, i.e. 1%.

Kinetics

Kinetics experiments were carried out as previously described (5). A stock solution of **13** was prepared from 6.00 mg **13**.6HCl in 2.0 mL water. Initial experiments were carried out using pH 8 tris buffer, as previously employed (5), but we encountered severe problems of non-reproducible rates, and spuriously fast reactions, which have been seen in other reactions (10). The kinetics reported in Table 1 were carried out using borate buffer, ionic strength 0.1, pH 8.00 (22); 0.0928 *M* $B(OH)_3$, 0.0072 *M* NaOH, and 0.0928 *M* KCl. Stock solutions of the esters were prepared in purified acetonitrile.

Data were fitted to theoretical equations by weighted least squares (5, 23, 24), using suitable computer programs. Kinetics data were fitted to $y = a_1 + a_2 \exp(-a_3 t)$, $y = a_1 + a_2 \exp(-a_3 t) + a_4 t$, or $y = a_1 + a_2 \exp(-a_3 t) + a_4 \exp(-a_5 t)$.

The pK_a values of simple aldehydes determined by kinetics of chlorination

J. Peter Guthrie[1] and John Cossar

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 20, 1986

J. Peter Guthrie and John Cossar. Can. J. Chem. **64**, 2470 (1986).

From the kinetics of chlorination of acetaldehyde and isobutyraldehyde we have been able to determine the pK_a values of the free aldehydes (corrected for covalent hydration) as 16.9 ± 0.5 and 15.7 ± 0.5, respectively. These values are in reasonable accord with other work and show that our kinetic method for ketone pK_a's can be extended to aldehydes. For isobutyraldehyde the transition from rate-determining halogenation to rate-determining enolization occurs at [OCl^-] values around 10^{-3} *M* for hydroxide concentrations of 0.1 to 1. For acetaldehyde the transition would only occur at much higher [OCl^-].

J. Peter Guthrie et John Cossar. Can. J. Chem. **64**, 2470 (1986).

En se basant sur la cinétique de la chloration de l'acétaldéhyde et de l'isobutyraldéhyde, on a pu déterminer que les valeurs des pK_a des aldéhydes libres (corrigées pour l'hydratation covalente) sont respectivement 16,9 ± 0,5 et 15,7 ± 0,5. Ces valeurs sont en bon accord avec d'autres travaux et ces concordances démontrent que notre méthode cinétique pour déterminer des pK_a de cétones peut être étendue aux aldéhydes. Dans le cas de l'isobutyraldéhyde, la transition entre une halogénation qui détermine la vitesse de la réaction et une énolisation qui détermine la vitesse de la réaction se produit à des valeurs de [OCl^-] qui se situent autour de 10^{-3} *M* pour des concentrations d'ions hydroxydes allant de 0,1 à 1 *M*. Dans le cas de l'acétaldéhyde, la transition ne se produirait qu'à des valeurs beaucoup plus élevées de [OCl^-].

[Traduit par la revue]

Introduction

We have reported (1–3) a method for determining the pK_a of a simple ketone by analysis of the kinetics of alkaline

halogenation. The kinetics are normally carried out with the halogenating agent in excess, under pseudo-first order conditions, so that

$$v = k_{obs}[\text{ketone}]$$

$$k_{obs} = k_2[\text{halogen}]_{total}$$

$$k_2 = k_2^0 + k_2^-[OH^-]$$

The basis of the method is the evaluation of the term in the rate law which is first order in carbonyl compound and first order in halogenating agent, but zero order in base; this is expressed as k_2^0. Such terms were first detected by Bartlett (4, 5). We have shown (1, 2) that these terms represent diffusion-controlled reaction of the enolate with the hypohalous acid, i.e. the conjugate base of one reagent and the conjugate acid of the other. The other term in the rate law, k_2^-, represents reaction of the enolate ion with the hypohalite ion. The pK_a of the carbonyl compound is then easily calculated from:

$$[1] \quad \log k_2^0 = \log k_{diff} + pK_a^{HOX} - pK_a^K$$

where k_{diff} is the rate constant for a diffusion-controlled reaction, pK_a^{HOX} is the acid dissociation constant for the hypohalous acid, and pK_a^K is the acid dissociation constant for the keto tautomer of the carbonyl compound. We have examined the question of the best value to use for the rate constant of a diffusion-controlled process involving an unsymmetrical reagent such as a carbon–carbon double bond and proposed that the best value is log $k_{diff} = 9.2 \pm 0.5$ (2). A value of this magnitude, $k_{diff} = (2.8 \pm 0.2) \times 10^9\ M^{-1}\ s^{-1}$, has been reported recently for the reaction of bromine with acetophenone enol (6).

[1]Author to whom correspondence should be addressed.

Recently Kresge has reported a pK_a of 15.49 ± 0.04 for isobutyraldehyde (7), based on measurements of the rates of ketonization of the enolate and of base-catalyzed enolization. Kresge has also determined a pK_a of 16.73 ± 0.06 for acetaldehyde (8, 9).[2]

In addition to our work on acetone (1–3) we have been investigating a number of other ketones in work now nearing completion, and have examined the question of whether our method can be applied to simple aldehydes. We wish now to report a determination of the pK_a of acetaldehyde, and a less detailed examination of the behavior of isobutyraldehyde showing that our method is consistent with the results of Kresge and co-workers (7, 10).

Results

When the observed pseudo-first order rate constants for the chlorination of acetaldehyde with hypochlorite in excess are plotted vs. [OCl^-], good linear relations are obvious; see Fig. 1. For some of the sets of data the best straight lines appeared to have non-zero intercepts. When straight lines are fitted to the data by least squares it is found that the intercepts are small and show little sign of any simple dependence upon the hydroxide concentration. For some of the data sets it was noticed that the point at highest [OCl^-] falls below the line determined by the other points. This suggests that the first signs of curvature are being detected; the data do not, however, define a curve. The best data treatment appears to be the use of straight lines constrained to pass through the origin. As shown in Fig. 1, such lines give a reasonable description of the data, and correspond to the expected pattern.

The slopes of these plots constitute the apparent second order rate constants for the chlorination reaction; when they are plotted against [OH^-], as shown in Fig. 2, the trend is monotonic, but non-linear. It is, however, necessary to correct for both addition of water and ionization of the hydrate, as shown in Scheme 1. Good values for K_h (11) and K_h^- (12, 13)[3] are available and permit calculation of corrected rate constants

[2]We thank Professor Kresge for communicating this result prior to its publication.

[3]$K_h^- = K_a/K_w$; pK_a = 13.57 (12, 13).

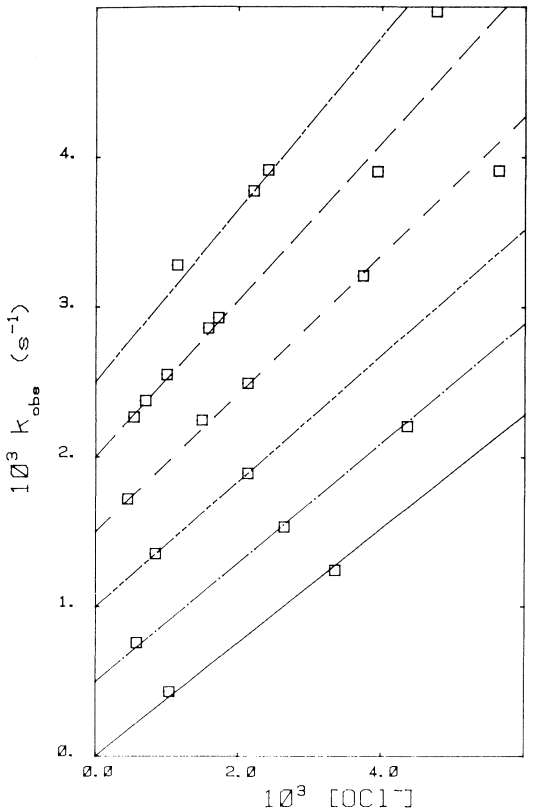

FIG. 1. Kinetics of chlorination of acetaldehyde at various hydroxide concentrations. Successive offsets of 0.5 in 10^3 k have been added to the rate constants so that the different data sets do not overlap: (—) $[OH^-] = 0.026$; (-·-·-) $[OH^-] = 0.054$; (-···-) $[OH^-] = 0.106$; (--) $[OH^-] = 0.243$; (––) $[OH^-] = 0.486$; (–––) $[OH^-] = 0.984$.

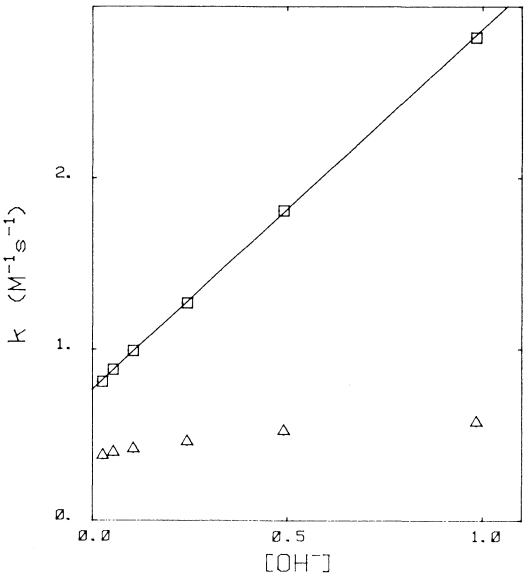

FIG. 2. Pseudo-second order rate constants for the chlorination of acetaldehyde: (△) k_{2app}, the slopes derived from Fig. 1; (□) k_{2corr}, the same values corrected for hydration and hydrate anion formation as described in the text.

corresponding to reaction of the free aldehyde. When these k_{corr} values are plotted against $[OH^-]$, as shown in Fig. 2, an excellent straight line results, with a slope of 2.10 ± 0.02 and an intercept of 0.769 ± 0.0022. This leads to a carbon pK_a for the aldehyde of 16.8 ± 0.5.

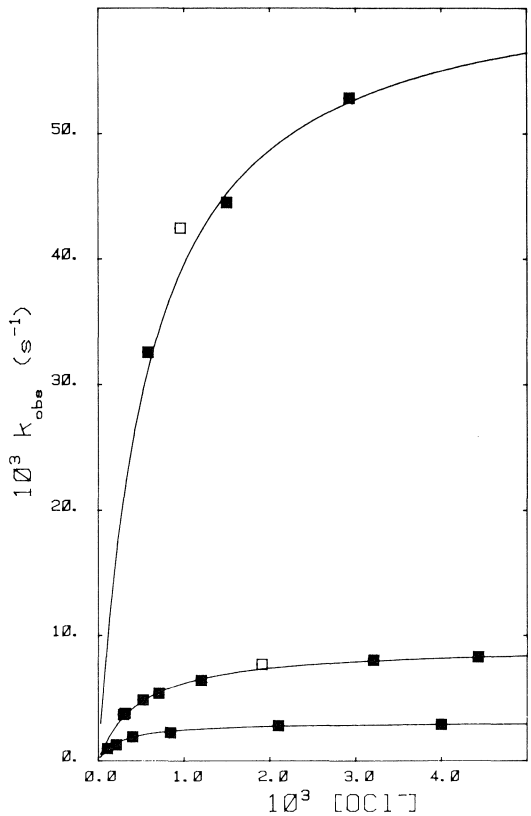

FIG. 3. Kinetics of chlorination of isobutyraldehyde at various hydroxide concentrations. The lines were determined by least squares fitting: (■) points included in the least squares fitting; (□) points omitted in the least squares fitting.

One process which might lead to non-zero intercepts for plots of k_{obs} vs. $[OCl^-]$ at fixed $[OH^-]$, corresponding to hypochlorite independent consumption of acetaldehyde, would be aldolization. However, the equilibrium constant for this process is only 400 M^{-1} (14) and it would not proceed to a significant extent at 10^{-4} M acetaldehyde.

When the observed pseudo-first order rate constants for the chlorination of isobutyraldehyde are plotted vs. $[OCl^-]$ at fixed $[OH^-]$ a non-linear dependence is obvious, see Fig. 3, with leveling off at high $[OCl^-]$. The data were fitted to eq. [2] by

$$[2] \quad k_{obs} = a_1/(1 + a_2/[OCl^-])$$

non-linear least squares. For each of two sets of data one point was clearly divergent from the line defined by the others; in the final calculations these two divergent points were omitted. The theoretical lines based on the least-squares parameters are shown in Fig. 3.

In analyzing the hydroxide and hypochlorite dependence of these kinetics we make use of the mechanism shown in Scheme 1. In terms of this mechanism, the observed rate constant is given by eq. [3]

$$[3] \quad k_{obs} = \{k_1[OH^-]/\{1 + K_h(1 + K_h^-[OH^-])\}\}/ \{1 + k_{-1}/\{k_2^0 K_w/K_a^{HOCl}[OH^-] + k_2^-\}[OCl^-]\}$$

K_h, the equilibrium constant for hydration of isobutyraldehyde, and K_h^-, the equilibrium constant for ionization of the hydrate, are available from the work of Hine *et al.* (15). The quantity $k_1[OH^-]$ can be extracted from the a_1 values using these equilibrium constants. At 0.034 M OH^- $k_1[OH^-]$ is 0.00500 ± 0.00008; at 0.106 M OH^- $k_1[OH^-]$ is 0.0153 ± 0.002; at

[a]All in aqueous solution at 25°C, ionic strength = 1.0 *M* (KCl). Data were fitted to $y = A_1 + A_2 \exp(-A_3 t)$ or $y = A_1 + A_2 \exp(-A_3 t) + A_4 t$. Quantities in parentheses are estimated standard deviations of the parameters calculated by the least-squares program. The calculated standard deviations for A_1 and A_2 were ≤ 0.001 in all cases except the last entry in the table (where $A_1 = 2.439$) for which both were ca. 0.002. All reactions in cells with 1 cm path unless noted.

[b]10 cm path length.

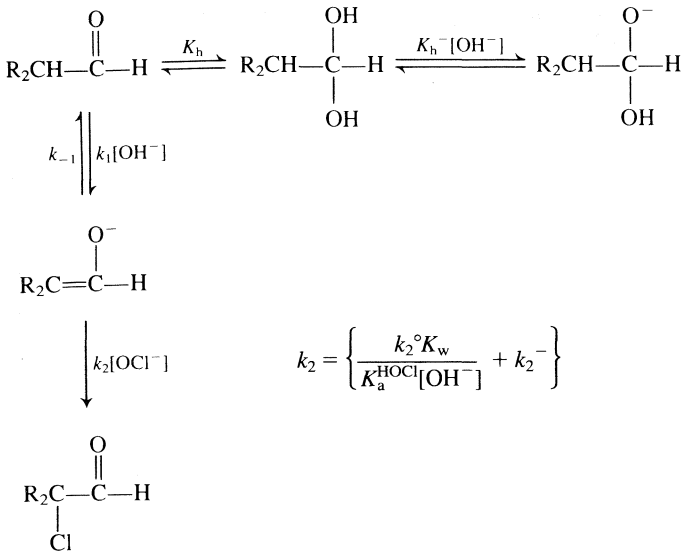
[c]5 cm path length.

[d]2 cm path length.

0.992 *M* OH^- it is 0.140 ± 0.006. From these values k_1 = 0.145 ± 0.001 was calculated, which is in excellent agreement with Kresge's value of 0.142 ± 0.011 (10). The apparent second order rate constant, which would be obtained directly at very low [OCl^-], can be calculated as a_1/a_2. The values so obtained are 12.13 ± 0.85 ([OH^-] = 0.034); 19.1 ± 0.7 ([OH^-] = 0.106); and 106 ± 13.8 ([OH^-] = 0.992); see Fig. 4. Uncertainties in the apparent second order rate constants were calculated including the covariance between a_1 and a_2 (16). After correcting for hydration and hydrate anion formation we obtain 19.6 ± 1.4, 31.8 ± 1.1, and 235 ± 31, respectively. Least-squares fitting gives k_2 = (12.17 ± 2.43) + (190.7 ± 27.0)[OH^-]. From the intercept we calculate (2) a pK_a value of 15.67 ± 0.51. Kresge *et al.* reported 15.49 ± 0.04 (7).

Discussion

It is a striking observation that the kinetics of alkaline chlorination of acetaldehyde show almost no signs of a tendency to undergo a change in rate-determining step with increasing [OCl^-] in the range covered by our experiments, while for isobutyraldehyde the change in rate-determining step is quite apparent, and indeed becomes nearly complete at low [OH^-]. A major reason for the difference lies in the carbon acidities of the two carbonyl compounds, and in the fact that the rates of



SCHEME 1

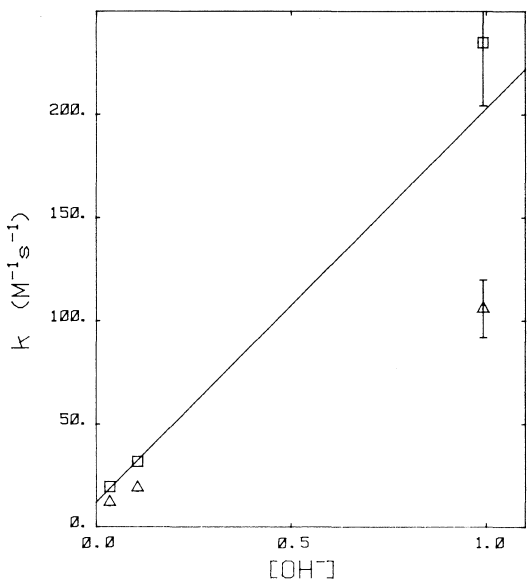


FIG. 4. Pseudo-second order rate constants for the chlorination of isobutyraldehyde: (△) k_{2app}, the values derived from the data in Fig. 1; (□) k_{2corr}, the same values corrected for hydration and hydrate anion formation as described in the text. The line is calculated by weighted least squares.

base-catalyzed proton abstraction are in the reverse order compared to acidity. The pK_a values are 16.8 and 15.7, and the rates of proton abstraction are 1.17 M^{-1} s^{-1} (9)[2] and 0.145 M^{-1} s^{-1} for acetaldehyde and isobutyraldehyde. As a consequence the rate of reprotonation of acetaldehyde enolate by water is about 100 times faster than for isobutyraldehyde enolate. Since partitioning between the two available paths determines which step is rate determining, a larger rate constant for reprotonation of the enolate will require a higher [OCl^-] to cause a change in rate-determining step, if the rates of halogenation of the enolates are the same. This is the case at low [OH^-], where diffusion-controlled reaction with HOCl dominates the kinetics of halogenation. At high [OH^-] the rate of halogenation is dominated by the contribution from reaction of OCl^- with the enolate. These rate constants are not expected to be the same, and are well below the diffusion-controlled limit. Surprisingly, however, it seems unavoidable to conclude that the relative rates of the reactions of the enolates with OCl^- are in the unexpected sense, with isobutyraldehyde being the more reactive. Thus the more hindered and the more stable enolate is the more reactive. The rate constants for the reactions of the enolates with OCl^- are 1.3×10^3 for acetaldehyde and 9.5×10^3 for isobutyraldehyde. A possible explanation for this unexpected order might be a transition state for the reaction of enolate with hypochlorite ion which resembles a charge transfer complex between the alkene and hypochlorite ion.

The change in absorbance for each reaction provides a measure of the stoichiometry. Although there is considerable scatter in the values for both aldehydes, it seems clear that for acetaldehyde the stoichiometry is greater than 2 but less than 3. There is no clear dependence of the observed stoichiometry upon the hypochlorite concentration. For isobutyraldehyde the observed values scatter about the expected value of 1. Observation of a stoichiometry less than 3 for acetaldehyde suggests that for this compound as for acetone (3) hydrolysis of the intermediate partially chlorinated aldehydes is a major side reaction.

Our method for the determination of pK_a values of simple carbonyl compounds has now been shown to work for aldehydes as well as ketones. The major disadvantage of the method is that it relies upon an imprecisely known value of the rate constant for a diffusion-controlled reaction. Although the uncertainties in this value will diminish as more absolute determinations become available, it will probably be found to vary for different compounds and/or reactions even though it is very insensitive to the chemical nature of the reaction occurring after diffusion. The major advantage of the method is that it uses standard, widely available, apparatus and inexpensive chemicals.

Experimental

Materials

Isobutyraldehyde, Aldrich 98%, was distilled at atmospheric pressure and the middle fraction boiling at 62–63°C was used for kinetics. A stock solution, 0.168 *M*, was prepared using glass-distilled water as solvent.

Acetaldehyde dimethyl acetal, Eastman, was distilled at atmospheric pressure and the middle fraction boiling at 63–64°C was used for kinetics. Weighed amounts of the acetal were hydrolyzed in 0.001 *M* HCl (4 h at room temperature), neutralized to pH 8 (pH meter) using 1 *M* NaOH, and then made to a known volume with water. Two stock solutions, 0.191 *M* and 0.0446 *M*, were used.

Solutions containing sodium hydroxide and sodium hypochlorite were made up and titrated as previously described (2, 3). The ionic strength was held at 1 *M* using KCl.

Methods

Kinetics procedures were as previously described (2, 3). Reactions were initiated by injecting small volumes of an aldehyde stock solution into alkaline hypochlorite solution; the volume change was always less than 1%.

Calculations. Data were fitted to theoretical equations by non-linear least squares (16, 17), using computer programs written for the purpose.

COMMUNICATION

Total syntheses of the sesquiterpenoids (±)-axamide-1, (±)-axisonitrile-1, and the corresponding C-10 epimers

EDWARD PIERS AND BIK WAH ANISSA YEUNG
Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received July 7, 1986

EDWARD PIERS and BIK WAH ANISSA YEUNG. Can. J. Chem. **64**, 2475 (1986).

Total syntheses of (±)-axamide-1 (**1**), (±)-axisonitrile-1 (**2**), and the corresponding C-10 epimers **16** and **17** are described. The key steps of the synthetic sequence involve methylenecyclohexane annulation of 2-methyl-2-cyclopenten-1-one and $TiCl_4$-catalyzed conjugate addition of 3-methyl-1,1-bis(trimethylsiloxy)-1-butene to the bicyclic enone **8**.

EDWARD PIERS et BIK WAH ANISSA YEUNG. Can. J. Chem. **64**, 2475 (1986).

On décrit les synthèses totales des (±)-axamide-1 (**1**), (±)-axisonitrile-1 (**2**) et de leurs épimères en C-10, **16** et **17**. Les étapes clés de la synthèse impliquent l'annelation de la méthyl-2 cyclopentène-2 one-1 avec le méthylènecyclohexane et l'addition conjuguée, catalysée par le $TiCl_4$, du méthyl-3 bis(triméthylsiloxy)-1,1 butène-1 sur l'énone bicyclique **8**.

[Traduit par la revue]

The structurally unusual natural products (+)-axamide-1, (+)-axisonitrile-1, and (+)-axisothiocyanate-1, isolated from the marine sponge *Axinella cannabina*, have been shown to possess the constitution (1) and absolute stereochemistry (2)[1] depicted in structural formulas **1**–**3**, respectively. These substances, which belong to the relatively small group of axane-type sesquiterpenoids (carbon skeleton **4**), appear to be biogenetically related to the eudesmane family of terpenoids (carbon skeleton **5**). We report herein a total synthesis of (±)-**1**, (±)-**2**, and the corresponding C-10 epimers (**16** and **17**, respectively) via a route (see Scheme 1) in which our recently developed methylenecyclohexane annulation method (3) played a key role.

Conjugate addition of 2-(5-chloro-1-pentenyl)magnesium bromide (3) to 2-methyl-2-cyclopenten-1-one (**6**) and subsequent intramolecular alkylation of the resultant product provided (85%) the *cis*-fused bicyclic ketone **7**.[2] Conversion (4) of **7** into the corresponding α-bromo ketone, followed by dehydrobromination (5) of the latter substance, gave the enone **8** (77% from **7**). Interestingly, at least under the conditions employed for the formation of **8**, the exocyclic double bond showed no inclination to migrate into conjugation with the enone function.

It is evident from an examination of molecular models that conjugate addition to the enone system of **8** would occur preferentially from the convex (β) face of the molecule. In the event, treatment of **8** with 3-methyl-1,1-bis(trimethylsiloxy)-1-butene[3] in the presence of $TiCl_4$ gave, in 88% yield, a mixture of two keto acids **9** and **10**, in a ratio of about 3:2, respectively.[4] Separation of this mixture by a combination of fractional crystallization and column chromatography (silica gel) provided the pure substances **9** (44%, mp 172–173°C) and **10** (32%, mp 120–121°C). Removal of the keto function from **9** by Wolff–Kishner reduction gave the acid **11**[5] (90%, mp 120–121°C), which was converted via the acid chloride **12** into the acyl azide **13**. Curtius rearrangement of the latter substance, followed by treatment of the resultant isocyanate with 2-trimethylsilylethanol (7), afforded the crystalline carbamate **14** (mp 79.5–80.5°C, 89% from **11**). Reaction of **14** with tetra-*n*-butylammonium fluoride (7) provided (72%) the primary amine **15**, which, when treated with acetic formic anhydride (8) gave (±)-axamide-1 (**1**), a viscous oil, in 90% yield.

The ^{1}H nmr spectrum of (±)-**1** indicated that it consisted of a 3:2 mixture of rotamers associated with the amide linkage.

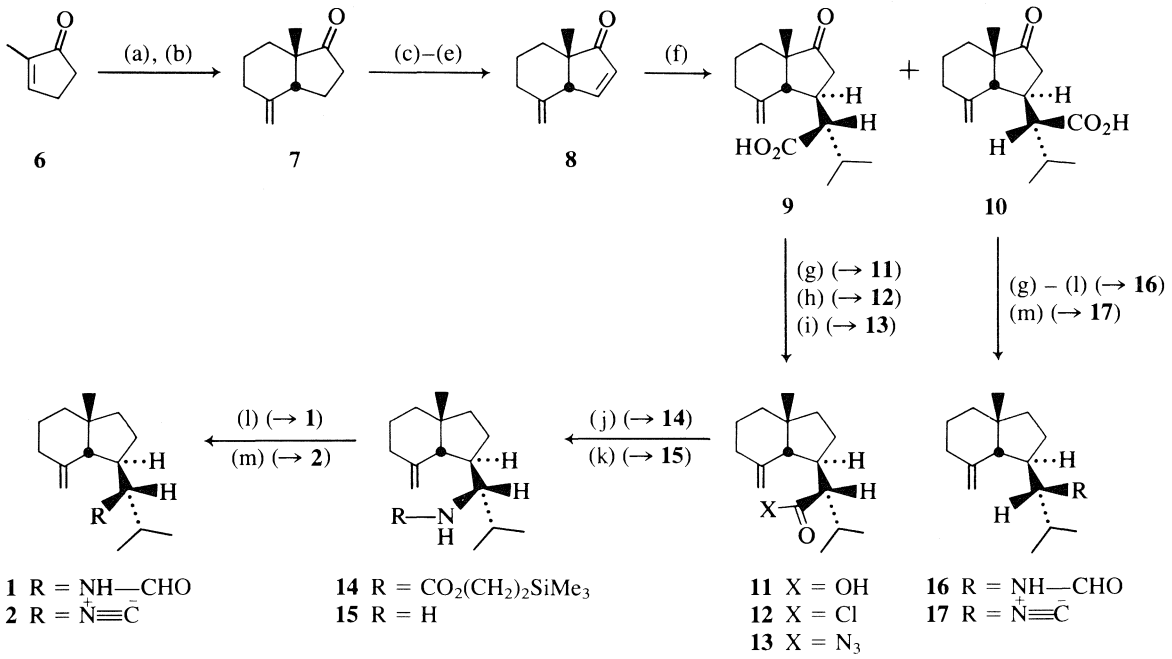
[1] In ref. 2*a*, the absolute configuration at C-10 of compounds **1**–**3** is depicted incorrectly.

[2] All compounds reported herein exhibited spectra in accord with structural assignments. New compounds gave satisfactory molecular mass determinations (high resolution mass spectrometry).

[3] This reagent was prepared (86%) by treatment of 3-methylbutanoic acid with $LiNPr^i_2$ (2.2 equiv.) in dry tetrahydrofuran (THF) – hexamethylphosphoramide, followed by trapping of the resultant dianion with Me_3SiCl (2.4 equiv.).

[4] Titanium tetrachloride-catalyzed addition of (*E*)-1-ethoxy-3-methyl-1-trimethylsiloxy-1-butene to the enone **8** (see ref. 6) provided (89%) a mixture of ethyl esters corresponding to **9** and **10** (ratio ≈ 45:55, respectively). Hydrolysis of this mixture with potassium hydroxide in refluxing ethanol was slow and caused (some) synthetically unproductive epimerization of the chiral center adjacent to the ester function. Acids **9** and **10** were produced in a ratio of about 1:2, respectively (82% yield).

[5] In the ^{1}H nmr spectrum of **11**, the angular (C-8) proton gives rise to a doublet (J = 10.5 Hz) at δ 1.86. In what appears to be the most stable conformation of **11**, the dihedral angle between the *trans*-related protons at C-8 and C-1 (axane numbering) is close to 180° and, thus, the observed coupling constant is consistent with the assigned stereochemistry. Similar observations were made for 10-*epi*-**11** (Wolff–Kishner reduction product of **10**).



(a) 2-(5-Chloro-1-pentenyl)magnesium bromide (1.3 equiv.), $CuBr \cdot Me_2S$ (0.32 equiv.), $BF_3 \cdot Et_2O$ (1.3 equiv.), THF, −78°C, 3 h; NH_4Cl, H_2O; (b) KH, THF, room temperature, 2 h; (c) $LiNPr^i_2$, THF, −78°C; Me_3SiCl, −78°C to room temperature, 1.5 h; (d) *N*-bromosuccinimide, THF, 0°C, 15 min; (e) LiBr, Li_2CO_3, *N,N*-dimethylformamide, reflux, 3 h; (f) 3-methyl-1,1-bis(trimethylsiloxy)-1-butene, $TiCl_4$, CH_2Cl_2, −78°C, 2 h; H_2O; (g) $H_2N–NH_2$, diethylene glycol, 110°C, 3 h; 190°C, 30 min; cool, add KOH, then heat at 190°C, 6 h; H^+; (h) $(COCl)_2$, $PhCH_3$, room temperature; (i) NaN_3, acetone–H_2O, 0°C; (j) $PhCH_3$, 80°C, 2 h; $Me_3SiCH_2CH_2OH$, $PhCH_3$, 80°C, 20 h; (k) *n*-Bu_4NF, THF, 50°C, 35 min; (l) CH_3CO_2CHO, Et_2O, room temperature, 10 h; (m) *p*-toluenesulfonyl chloride, pyridine, room temperature, 3 h.

SCHEME 1

Comparison of the (limited) spectral data reported (1*b*) for natural (+)-axamide-1 with those exhibited by our synthetic material did not lead to an unambiguous conclusion regarding compound identity. However, dehydration (9) of (±)-**1** afforded (86%) (±)-axisonitrile-1 (**2**), which exhibited mp 45–46°C (recrystallization from petroleum ether); ir (CCl_4): 3070, 2136, 1645, 1390, 1376, 899 cm^{-1}; ^1H nmr ($CDCl_3$, 400 MHz) δ: 0.88, 1.03 (d, d, 3H each, J = 6.5, 6.5 Hz), 0.99 (s, 3H), 1.20–1.26 (m, 1H), 1.41–1.57 (m, 5H), 1.60–1.71 (m, 1H), 1.96–2.12 (m, 3H), 2.15–2.22, 2.18 (superimposed m, d (J = 10 Hz), respectively, 2H), 2.42–2.52 (m, 1H), 3.20–3.26 (m, 1H, $w_{1/2}$ = 17 Hz), 4.79–4.85 (m, 2H, $w_{1/2}$ = 5.5 Hz). The chromatographic behavior (glc, tlc) and the 400-MHz ^1H nmr spectrum of our synthetic (±)-**1** were found to be identical with those of an authentic sample of (+)-axisonitrile-1.[6]

Subjection of the keto acid **10** to a sequence of reactions very similar to that described above provided (±)-10-*epi*-axamide-1 (**16**) (47% from **10**), which, upon dehydration (9), gave (±)-10-*epi*-axisonitrile-1 (**17**) (87%). The latter substance exhibited mp 53–54°C; ^1H nmr (400 MHz, $CDCl_3$) δ: 0.92, 1.04 (d, d, 3H each, J = 6.5, 6.5 Hz), 1.00 (s, 3H), 1.22–1.30 (m, 1H), 1.39–1.59 (m, 4H), 1.60–1.75 (m, 2H), 1.75–1.92 (m, 2H), 1.93–2.03 (m, 1H), 2.05 (d, 1H, J = 11 Hz), 2.14 (br d, 1H, J = 14 Hz), 2.22–2.34 (m, 1H), 3.18–3.25 (m, 1H, $w_{1/2}$ = 15 Hz), 4.72 (t, 1H, J = 2 Hz), 4.80 (t, 1H, J = 2 Hz). The chromatographic behavior (glc) and ^1H nmr spectrum of (±)-**17** were clearly different from those of natural (+)-axisonitrile-1.[6]

[6]We are grateful to Professor D. Sica for a sample of (+)-axisonitrile-1 and for a copy of its ^1H nmr spectrum.

K. R. Fountain, Pamela Heinze, Mark Sherwood, Dave Maddox, and Greg Gerhardt. Can. J. Chem. **58**, 1198 (1980). Acylation of aromatic substrates with ketenes. An example of vinyl oxocation reactivity.

Page 1201. In Table 6 (Substrate specificity for diphenylketene), the first entry under "Area ratio (mols/mol)" should read 189 instead of 18.9.

K. R. Fountain, Pamela Heinze, Dave Maddox, Greg Gerhardt and Paul John. Can. J. Chem. **58**, 1939 (1980). Acylation of aromatic substrates with ketene. II. Hammett–Brown studies on substituted aromatic compounds.

Page 1944. The last paragraph on the right hand column "The results for the 5:1 experiment were used to determine the toluene/benzene ratio as follows." should read "The results of the 5:1 experiment were used to calculate the partial rate factor for the methyl group as follows."

J. Peter Guthrie and John Cossar. Can. J. Chem. **64**, 1250 (1986). The chlorination of acetone: a complete kinetic analysis.

Page 1262. The expression for the stoichiometry of chlorination of acetone should be:

$$n_{\text{acetone}} = 1 + f_1(1 + f_2) + (1 - f_1) + [(1 - f_1) + f_1(1 - f_2)]f_3$$

Page 1264. Figure 7, which is calculated using this expression should be:

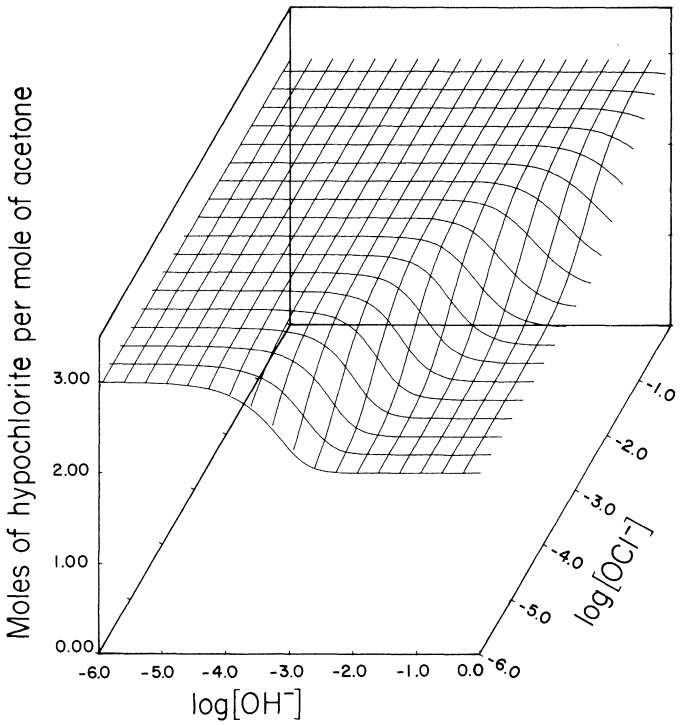

FIG. 7. Stoichiometry for chlorination of acetone in aqueous alkali. Number of moles of hypochlorite consumed per mole of acetone reacting, as a function of hydroxide and hypochlorite concentrations.
