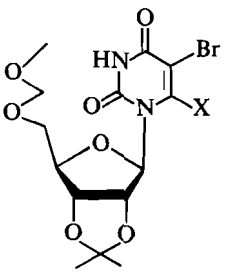
product (**16**) could not be obtained in pure form even after column chromatography on magnesium silicate, the mixture containing **16** was treated with tetrabutylammonium fluoride (TBAF) in THF for 1 h. This and successive column chromatography of the reaction mixture gave 6-ethynyl-2′-deoxyuridine (**17**, mp 202–204°C) in 32% yield from **15**.



9 X = H
10 X = I

Biological evaluation of the compounds involved in this study is presently under investigation.

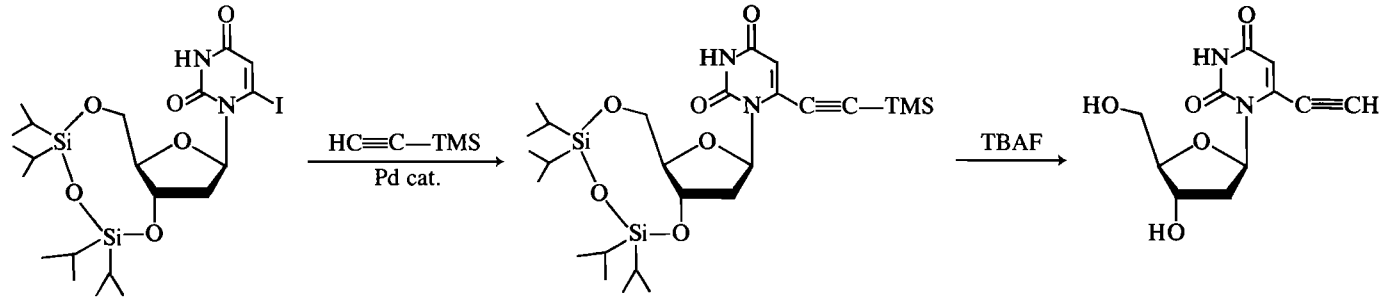
Experimental

Melting points were determined with a Yanagimoto micro melting point apparatus and are uncorrected. The ^{1}Hmr spectra were measured with an appropriate internal standard of tetramethylsilane (TMS) or sodium-2,2-dimethyl-2-silapentane 5-sulfonate (DSS), with a JEOL JNM-FX 100 spectrometer. The abbreviations used are as follows: s, singlet; d, doublet; dd, double doublet; t, triplet; q, quartet; m, multiplet; br, broad. Mass spectra were taken on a JEOL JMS-D 300 spectrometer. The uv and ir spectra were recorded on Shimadzu UV-240 and JASCO A-102 spectrophotometers, respectively. Unless otherwise noted, column chromatography was carried out on silica gel (Wakogel CC-200). Thin-layer chromatography (tlc) was performed on silica gel (precoated silica gel plate 60 F_{254}, Merck). Compounds **4**, **5**, **7**, and **8**, being noncrystalline, were not analyzed; however their crystalline deprotected products **11**, **12**, and **14** were analyzed.

TABLE 2. Yields and ^{1}Hmr data of **11–14**

Product	R	Yield (%)	Proton magnetic resonance chemical shifts (δ: ppm) in DMSO-d_6						
			H-1′	H-2′	H-3′	H-4′	CH_2-5′	H-5	Others
11	Ph	84	5.99	4.52 – 4.59		4.07	3.55	6.08	7.49–7.63 phenyl
12	$(CH_2)_3Me$	74	5.91	4.54	4.05	3.66	3.53	5.82	0.91, 1.50, and 2.50 hexynyl
13*	CH_2OH	83	6.14	4.82	4.38	3.97	3.83	6.13	4.53 C≡C—CH_2
14	H	62	5.87	4.58	3.69	3.56	3.27	6.00	5.28 C≡CH

*The ^{1}Hmr spectrum was measured in D_2O.



SCHEME 2

6-Iodo-2′,3′-O-isopropylidene-5′-O-methoxymethyluridine (2)

For the preparation and physical data of this compound see ref. 22.

6-Iodouridine (3)

A solution of **2** (500 mg) in 50% TFA (7 mL) was stirred for 6 h at room temperature. The mixture was evaporated to dryness and the whole residue was chromatographed on a silica gel column. Elution with 6% EtOH in $CHCl_3$ gave **3** (407 mg, 100%). Crystallization from EtOH furnished an analytically pure sample (327 mg, 80%, mp 130–132°C); $\lambda_{max}(H_2O)$: 269 nm (ε 9300), $\lambda_{min}(H_2O)$: 237 nm (ε 4200); ^{1}Hmr (DMSO-d_6, after adding D_2O), δ: 3.32 (2H, m, CH_2-5′), 3.78 (1H, m, H-4′), 4.08 (1H, t, H-3′), 4.54 (1H, dd, H-2′), 5.74 (1H, d, J = 3.4 Hz, H-1′), 6.35 (1H, s, H-5); ms m/z: 238 (B + 1). *Anal.* calcd. for $C_9H_{11}O_6N_2I$: C 29.37, H 3.12, N 7.85; found: C 29.20, H 3.00, N 7.57.

2′,3′-O-Isopropylidene-5′-O-methoxymethyl-6-[2-(phenyl)ethynyl]uridine (4)

Phenylacetylene (0.3 mL, 3.16 mmol) was added to a mixture of **2** (604 mg, 1.33 mmol), $Pd(Ph_3P)_2Cl_2$ (93 mg, 0.13 mmol), and CuI (25 mg, 0.13 mmol) in Et_3N (10 mL). The mixture was stirred at 60°C for 2 h under positive pressure of dry argon. The solvent was evaporated and the resulting residue was chromatographed on a silica gel column. Elution with 0.5% EtOH in $CHCl_3$ gave **4** (403 mg, 71%) as foam; ir (KBr) ν: 2180 cm^{-1}; λ_{max}(MeOH): 305 nm, λ_{min}(MeOH): 239 nm; ms m/z: 428 (M^+), 413 (M − Me), 212 (B + 1).

6-Hexynyl-2′,3′-O-isopropylidene-5′-O-methoxymethyluridine (5)

This compound was prepared from **2** (574 mg) and hexyne (207 mg) by the procedure for the preparation of **4**. Silica gel column chromatography (0.5% EtOH in $CHCl_3$) gave 395 mg (74%) of **5** as syrup; ir (KBr) ν: 2230 cm^{-1}; λ_{max}(MeOH): 284 nm, λ_{min}(MeOH): 246 nm; ms m/z: 408 (M^+), 393 (M − Me).

6-(3-Hydroxypropynyl)-2′,3′-O-isopropylidene-5′-O-methoxymethyluridine (6)

This compound was prepared from **2** (299 mg) and propargyl alcohol (74 mg) by the procedure for the preparation of **4**. Silica gel column chromatography (2% EtOH in $CHCl_3$) gave 182 mg (73%) of **6** as amorphous powder. Crystallization from EtOH furnished an analytically pure sample (71 mg, 28%, mp 146–148°C); ir (KBr) ν: 2220 cm^{-1}; λ_{max}(MeOH): 287 nm (ε 10 800), λ_{min}(MeOH): 251 nm (ε 3000); ms m/z: 382 (M^+), 367 (M − Me). *Anal.* calcd. for $C_{17}H_{22}N_2O_8$: C 53.88, H 7.05, N 5.98; found: C 53.50, H 7.32, N 5.80.

2′,3′-O-Isopropylidene-5′-O-methoxymethyl-6-[2-(trimethylsilyl)ethynyl]uridine (7)

This compound was prepared from **2** (1.24 g) and trimethylsilylacetylene (538 mg) by the procedure for the preparation of **4**. Silica gel column chromatography (1% EtOH in $CHCl_3$) gave 843 mg of **7** as a syrup; ir ($CHCl_3$) ν: 2100 cm^{-1}; λ_{max}(MeOH): 284 nm, λ_{min}(MeOH): 240 nm; ms m/z: 424 (M^+), 209 (B + 1).

6-Ethynyl-2′,3′-O-isopropylidene-5′-O-methoxymethyluridine (8)

A solution of **7** (166 mg) in NH_3/MeOH (10 mL) was kept standing at room temperature for 2 h. The mixture was evaporated to dryness and the resulting residue was chromatographed on a column of magnesium silicate (Florisil®). Elution with 10% EtOAc in benzene gave 104 mg (70%) of **8** as a foam; ir ($CHCl_3$) ν: 2100 cm^{-1}; λ_{max}(MeOH): 284 nm, λ_{min}(MeOH): 244 nm; ms m/z: 352 (M^+), 337 (M − Me).

5-Bromo-2′,3′-O-isopropylidene-5′-O-methoxymethyluridine (9)

5-Bromo-2′,3′-*O*-isopropylideneuridine (4.1 g) was added to a mixture of dry acetone (50 mL), dry dimethoxymethane (100 mL), and methanesulfonic acid (1.5 mL). The resulting solution was stirred at room temperature for 5 h. The reaction was quenched by adding aqueous $NaHCO_3$ and the organic solvents were removed by evaporation. Extraction with $CHCl_3$ followed by chromatographic purification on silica gel (1% EtOH in $CHCl_3$) gave 4.38 g (95%) of **9** as syrup. Crystallization from ether furnished an analytically pure sample (4.15 g, 90%, mp 134–135°C); λ_{max}(MeOH): 276 nm (ε 9400), λ_{min}(MeOH): 240 nm (ε 1700); ^{1}Hmr ($CDCl_3$) δ: 1.37 (3H, s, isopr. Me), 1.60 (3H, s, isopr. Me), 3.41 (3H, s, CH_2OCH_3), 3.80 (2H, m, CH_2-5′), 4.45 (1H, m, H-4′), 4.72 (2H, s, CH_2OCH_3), 4.77–4.89 (2H, m, H-2′ and H-3′), 5.99 (1H, d, J = 2.0 Hz, H-1′), 8.06 (1H, s, H-6), 8.64 (1H, br, NH); ms m/z: 407 and 405 (M^+), 392 and 390 (M − Me). *Anal.* calcd. for $C_{14}H_{19}N_2O_7Br$: C 41.34, H 4.75, N 7.16; found: C 41.29, H 4.70, N 6.88.

5-Bromo-6-iodo-2′,3′-O-isopropylidene-5′-O-methoxymethyluridine (10)

LDA (2.5 mmol) in THF (20 mL) was placed in a three-necked flask equipped with a nitrogen-inlet adapter, thermometer, and rubber

septum. To this, a solution of **9** (407 mg, 1.0 mmol) in THF (10 mL) was added, under positive pressure of dry argon, at a rate such that the temperature did not exceed −70°C. After the mixture was stirred for 1 h, iodine (569 mg, 2.2 mmol as I_2) in THF (15 mL) was added while maintaining the temperature below −70°C. The mixture was stirred for 1.5 h below −70°C, quenched with AcOH (0.14 mL), and allowed to warm to room temperature. The whole was evaporated to dryness and the residue was chromatographed on a silica gel column (0.5% EtOH in $CHCl_3$). This afforded 462 mg (87%) of **10**. Crystallization from acetone–hexane gave an analytically pure sample (329 mg, 62%, mp 198–199°C); λ_{max}(MeOH): 278 nm (ε 8200), λ_{min}(MeOH): 242 nm (ε 3400); ^{1}Hmr ($CDCl_3$) δ: 1.36 (3H, s, isopr. Me), 1.58 (3H, s, isopr. Me), 3.37 (3H, s, CH_2OCH_3), 3.74 (2H, m, CH_2-5′), 4.30 (1H, m, H-4′), 4.66 (2H, s, CH_2OCH_3), 4.85 (1H, dd, H-3′), 5.18 (1H, dd, H-2′), 6.35 (1H, d, J = 1.5 Hz, H-1′), 9.02 (1H, br, NH); ms m/z: 519 and 517 (M − Me), 318 and 316 (B + 1). *Anal.* calcd. for $C_{14}H_{18}N_2O_7BrI$: C 31.54, H 3.40, N 5.25; found: C 31.83, H 3.49, N 5.23.

*6-(2-Phenyl)ethynyluridine (**11**)*

A solution of **4** (143 mg) in 50% THA (2 mL) was stirred at room temperature overnight. The mixture was evaporated to dryness and the whole residue was chromatographed on a silica gel column. Elution with 4% EtOH in $CHCl_3$ gave **11** (100 mg, 84%) as amorphous powder; ir (KBr) ν: 2180 cm^{-1}; λ_{max}(MeOH): 308 nm (ε 19 100), λ_{min}(MeOH): 242 nm (ε 9400); ms m/z: 212 (B + 1). *Anal.* calcd. for $C_{17}H_{16}N_2O_6$: C 59.30, H 4.68, N 8.13; found: C 59.17, H 4.68, N 8.00.

*6-Hexynyluridine (**12**)*

This compound was prepared from **5** (363 mg) by the procedure for the preparation of **11**. Silica gel column chromatography (5% EtOH in $CHCl_3$) gave 212 mg (74%) of **12** as foam; ir ($CHCl_3$) ν: 2220 cm^{-1}; λ_{max}(H_2O): 287 nm (ε 12 000), λ_{min}(H_2O): 251 nm (ε 2000); ms m/z: 206 (B + 1). *Anal.* calcd. for $C_{15}H_{20}N_2O_6$: C 55.55, H 6.22, N 8.64; found: C 55.27, H 6.46, N 8.39.

*6-(3-Hydroxypropynyl)uridine (**13**)*

This compound was prepared from **6** (117 mg) by the procedure for the preparation of **11**. Silica gel column chromatography (5–10% EtOH in $CHCl_3$) gave 64 mg (83%) of **13**. Crystallization from EtOAc furnished an analytically pure sample (21 mg, 27%, mp 174–176°C); ir ($CHCl_3$) ν: 2220 cm^{-1}; λ_{max}(H_2O): 287 nm (ε 11 000), λ_{min}(H_2O): 250 nm (ε 2100); ms m/z: 166 (B + 1). *Anal.* calcd. for $C_{12}H_{14}N_2O_7$: C 48.32, H 4.73, N 9.39; found: C 48.14, H 4.73, N 9.28.

*6-Ethynyluridine (**14**)*

This compound was prepared from **8** (241 mg) by the procedure for the preparation of **11**. Column chromatography of Florisil gave 114 mg (62%) of **14**. Crystallization from MeOH furnished an analytically pure sample (59 mg, 32%, mp 217–219°C); ir (KBr) ν: 2100 cm^{-1}; λ_{max}(H_2O): 285 nm (ε 9900), λ_{min}(H_2O): 245 nm (ε 1100); ms m/z: 137 (B + 2). *Anal.* calcd. for $C_{11}H_{12}N_2O_6$: C 49.25, H 4.51, N 10.45; found: C 49.35, H 4.50, N 10.25.

*6-Ethynyl-2′-deoxyuridine (**17**)*

Ethynylation of **15** (500 mg) was carried out by the procedure for the preparation of **4** using trimethylsilylacetylene (165 mg) as a terminal alkyne. After column chromatography on Florisil, the mixture containing **16** was treated with TBAF·$3H_2O$ (1.25 g) in THF (10 mL) at room temperature for 1 h. Evaporation of the solvent followed by chromatographic purification on Florisil (5% EtOH in $CHCl_3$) gave **17** (68 mg, 32%) as crystalline powder, which was analytically pure (mp 202–204°C); ir (KBr) ν: 2280 cm^{-1}; λ_{max}(H_2O): 285.5 nm (ε 10 600), λ_{min}(H_2O): 243.5 nm (ε 1400); ^{1}Hmr (DMSO-d_6) δ: 1.92–2.13 (1H, m, H-2′), 2.64–2.92 (1H, m, H-2′), 3.41–3.70 (3H, m, H-4′ and CH_2-5′), 4.22 (1H, m, H-3′), 5.26 (1H, s, C≡CH), 5.97 (1H, d, H-5), 6.35 (1H, dd, H-1′), 11.52 (1H, br, NH); ms m/z: 136 (B + 1). *Anal.* calcd. for $C_{11}H_{12}N_2O_5$: C 52.38, H 4.80, N 11.11; found: C 52.46, H 4.92, N 10.83.

H–D exchange of 1-methylcycloalkenes in dilute acid at elevated temperatures

NICK HENRY WERSTIUK AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received January 13, 1986

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **64**, 1564 (1986).

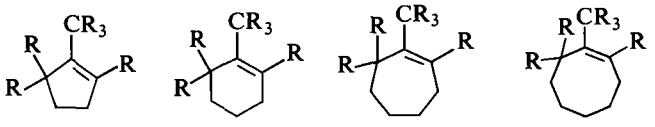
Specifically deuteriated cycloalkenes 1-trideuteriomethylcyclopentene-2,5,5-d_6 (**1***b*), 1-trideuteriomethylcyclohexene-2,6,6-d_6 (**2***b*), 1-trideuteriomethylcycloheptene-2,7,7-d_6 (**3***b*), and 1-trideuteriomethylcyclooctene-2,8,8-d_6 (**4***b*) have been prepared from the corresponding protiated substrates **1***a*, **2***a*, **3***a*, and **4***a* using a modified HTDA exchange method. The perlabelled analogues of **1***a* and **2***a*, **5** and **6**, have been synthesized by the same method.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **64**, 1564 (1986).

Faisant appel à une méthode d'échange au HTDA modifiée et utilisant les substrats protonés **1***a*, **2***a*, **3***a* et **4***a* comme produits de départ, on a préparé les cycloalcènes deutérés spécifiquement suivants: trideutérométhyl-1 cyclopentène-d_6-2,5,5 (**1***b*), trideutérométhyl-1 cyclohexène-d_6-2,6,6 (**2***b*), trideutéréméthyl-1 cycloheptène-d_6-2,7,7 (**3***b*) et trideutérométhylcyclooctène-d_6-2,8,8 (**4***b*). On a aussi synthétisé les analogues perdeutérés de **1***a* et **2***a*, **5** et **6**, en faisant appel à la même méthode.
[Traduit par la revue]

Introduction

Initial studies of the application of high temperature – dilute acid (HTDA) exchange have established that a wide range of aromatic compounds can be specifically labelled or perlabelled (1–6, 8). In continuing these studies, we examined a series of straight-chained alkenes and cycloalkenes in an attempt to prepare a group of labelled substrates that could be elaborated into labelled aliphatic compounds by standard transformations (7). To establish whether or not a methyl group can act as an anchor for the double bond and thereby promote specific H–D exchange of alkenes, we have studied the H–D exchange of 1-methylcyclopentene (**1***a*), 1-methylcyclohexene (**2***a*), 1-methylcycloheptene (**3***a*), and 1-methylcyclooctene (**4***a*). A modified HTDA method was used as described previously (7) to reduce the extent of substitution and to reduce the temperature and the reaction time. In the modified method, a cosolvent such as decalin is used and the reaction solutions are agitated by a rocking motion of the pressure vessel used to contain the reaction tubes. In this paper we report that specifically deuteriated cycloalkenes **1***b*, **2***b*, **3***b*, and **4***b* can easily be prepared using this method as well as the perdeuteriated analogues of **1***a* and **2***a*, **5** and **6**.



1 *a*, R = H; *b*, R = D

2 *a*, R = H; *b*, R = D

3 *a*, R = H; *b*, R = D

4 *a*, R = H; *b*, R = D

Results and discussion

*H–D exchange of 1-methylcyclopentene (1*a*)*

When **1***a* was treated under HTDA conditions using non-deuteriated medium (entry 1, Table 1), the major product was identified as **1***a* by its ^{1}Hmr spectrum. The ^{1}Hmr spectrum of the minor component indicated that it was a mixture of 3-methyl- and 4-methylcyclopentene (7). Under similar conditions in deuteriated medium (entry 2), **1***a* incorporates 6.03 D atoms per molecule (0.4% d_0, 0.5% d_1, 0.7% d_2, 1.2% d_3, 3.5% d_4, 15.2% d_5, 57.0% d_6, 11.5% d_7, 6.9% d_8, 2.7% d_9, and 0.5% d_{10} species). The ^{2}Hmr spectrum (Fig. 1a) showed three signals at δ 1.68 (CD_3), δ 2.17 (D-5), and δ 5.28 (D-2) and shoulders at δ 1.81 and δ 2.24 that correspond to small amounts of deuterium at C-4 and C-3, respectively. Confirmation of the deuterium distribution was obtained from the ^{1}Hmr spectrum that exhibited signals at δ 1.81 (bt, H-4), δ 2.24 (bt, H-3) and weak signals (<5%) due to residual protons at the other locations. This pattern of deuterium incorporation indicates that initial electrophilic attack by D_3O^+ occurs at C-2 to yield a tertiary cation and elimination of a proton from the methyl, C-2, or C-6 results in preferential H–D exchange at these three positions. The methyl group acts as an "anchor" for the double bond and thereby for the exchange. When a larger scale reaction was carried out (see Experimental), **1***b* was obtained in 79.6% yield by distillation from the decalin layer. It should be a simple matter to scale up the reaction even further. At 210°C (entry 3) full equilibration of the hydrogens with the deuterium pool was achieved and 9.43 D atoms per molecule (0.4% d_6, 2.2% d_7, 9.1% d_8, 30.4% d_9, 57.9% d_{10} species) are incorporated, but only 64.6% of perdeuteriated 1-methylcyclopentene (**5**) remained.

*H–D exchange of 1-methylcyclohexene 2*a

1-Methylcyclohexene, under the same conditions as **1***a*, reacts in a similar fashion (entry 4) and **2***a* is the major product as identified by its ^{1}Hmr spectrum. Although the minor products were not identified it is likely that they are identical to the products obtained from the exchange and rearrangement of cycloheptene (7) where the 1-methylcyclohexyl cation is an intermediate. When **2***a* was heated in deuteriated medium (entry 5), 5.82 D atoms (0.4% d_2, 0.6% d_3, 3.0% d_4, 17.5% d_5, 72.5% d_6, 3.3% d_7, 2.1% d_8, 0.5% d_9 species) were incorporated. The pattern of incorporation observed for **1***a* is seen in the ^{2}Hmr (δ 1.62, CD_3; δ 1.89, D-6; δ 5.40, D-2) (Fig. 1b) and ^{1}Hmr (δ 1.58, 4H, m, H-4 and H-5; δ 1.96, 2H, t, H-3) spectra. When a larger scale reaction was run (see Experimental), **2***b* (85%) was isolated as a mixture with lower-boiling isomers (15%) in 72% yield by distillation from the decalin layer. To obtain pure **2***b*, a preparative gc separation or a spinning band distillation would be required. At 210°C (entry

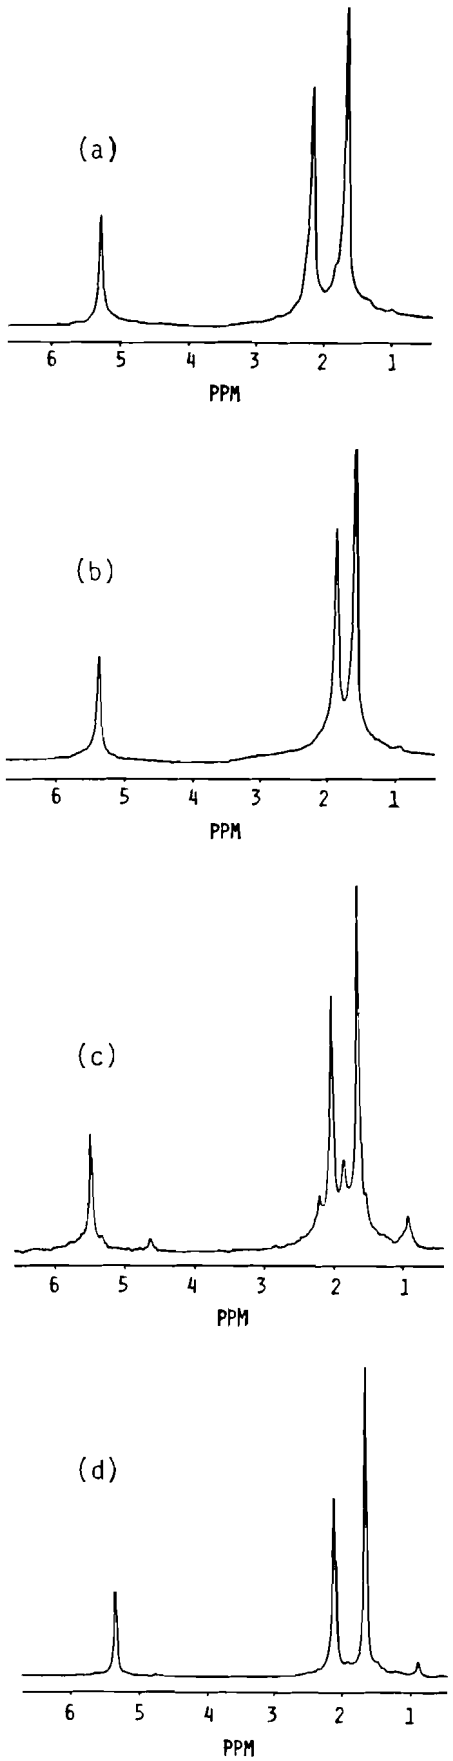

FIG. 1. The ^{2}Hmr (38.4 MHz, CCl_4) spectra of 1-methylcyclopentene-$d_{6.03}$ (a), 1-methylcyclohexene-$d_{5.82}$ (b), 1-methylcycloheptene-$d_{6.13}$ (c), and 1-methylcyclooctene-$d_{6.23}$ (d).

6), **2***a* is essentially equilibrated with the deuterium pool and 11.2 D atoms are incorporated per molecule (0.3% d_6, 0.9% d_7, 1.4% d_8, 4.1% d_9, 13.3% d_{10}, 34.1% d_{11}, and 45.9% d_{12} species) and by gc analysis it was established that **2***b* made up 62.4% of the product.

H–D exchange of 1-methylcycloheptane (3a)

Exchange of **3***a* at 162°C resulted in some rearrangement (entry 7), but the specifically deuteriated substrate was the major product. In this case, commercially supplied **3***a* used in the experiments was found to contain a major impurity (14%) of slightly longer retention time than **3***a* on the analytical gc. Because the boiling points were so similar, attempts to purify **3***a*, even by preparative gc, failed and the mixture was used in these exchange studies. Mass spectral analysis of the major product isolated from the reaction described in entry 7 established that 6.13 D atoms were incorporated per molecule. That the d_6 species (3.3% d_4, 14.6% d_5, 59.6% d_6, 5.1% d_7, 10.1% d_8, 2.0% d_9, 4.3% d_{10}) is the major component indicates that exchange of **3***a* is highly selective. The ^{2}Hmr spectrum (Fig. 1c) shows peaks at δ 5.52 (~1D, D-2), δ 2.05 (~2D, D-7), and δ 1.66 (~3D, CD_3) expected on the basis of the ^{1}Hmr if exchange occurs selectively at C-2, C-7, and the methyl group. The other peaks that make up 15–20% of the ^{2}Hmr signals are assumed to be due to the impurity in the starting material. Loss of the signals in the ^{1}Hmr of **3***b* at the shift positions listed confirms the presence of deuterium at these locations and corroborates our assignment.

H–D exchange of 1-methylcyclooctene (4a)

At 162°C (entry 8) **4***a* underwent some rearrangement, but the selectively deuteriated cycloalkene **4***b* was the major product. Mass spectral analysis of **4***b* (1.5% d_4, 11.6% d_5, 68.4% d_6, 7.7% d_7, 6.1% d_8, 2.0% d_9, 1.8% d_{10}, 0.8% d_{11}), isolated by preparative gc, showed that 6.23 D atoms were incorporated into **4***a*. The ^{1}Hmr showed the loss of signals at δ 5.28 (H-2), δ 2.07 (H-7), and δ 1.63 (CH_3). The ^{2}Hmr spectrum (Fig. 1d) confirms the location of the deuterium with the signals located at δ 5.47, δ 2.01, and δ 1.66.

Conclusions

This establishes that the modified HTDA method provides an easy route to specifically deuteriated 1-trideuteriomethylcycloalkenes **1***b*, **2***b*, **3***b*, and **4***b*, as well as the perdeuteriated analogues **5** and **6**. Since the methyl group is an effective "anchor" for the double bond in these systems, we expect that other groups (ethyl, phenyl, etc.) will exhibit this effect as well.

Experimental

Analyses were carried out on a Tracor model 560 chromatograph equipped with a Varian Areograph model 485 electronic integrator using 6 ft × 4 mm id 3% OV-1 on 100–120 mesh Supelcoport and 30 ft × 1/8 in. 23% SP-1700 on 80–100 mesh Chromosorb PAW columns. Preparative collections were performed on a Varian A-700 gas chromatograph equipped with a 5 ft × 1/4 in. 15% SE-30 on 80–100 mesh Chromosorb W column. Products were characterized by ^{1}Hmr spectroscopy. Deuterium analyses were carried out on a VG Micromass 7070F mass spectrometer at low ionizing voltage (12–15 eV).

H–D exchange of cycloalkenes

In a typical reaction, **1***a* (0.20 g), 0.26 *M* HCl/H_2O or 0.26 *M* DCl/D_2O (5 mL), and decalin (1 mL) were sealed under vacuum in a medium-walled Pyrex tube after the solution was degassed via three freeze–pump–thaw cycles. The tube was heated in a 600-mL Parr pressure vessel containing water to equalize the pressure. Mixing was

accomplished by a rocking motion of the vessel. The tube was cooled, opened, the decalin layer was withdrawn, analyzed by analytical gc, and the products isolated by preparative gc. The results of studies on **1***a*, **2***a*, **3***a*, and **4***a* are given in Table 1.

Preparation of deuteriated 1-methylcyclopentene

Two tubes prepared in the usual manner, each containing **1***a* (0.32 g), decalin (1.6 mL), and 0.26 *M* DCl/D_2O (8 mL), were heated at 142°C for 18.5 h in the Parr vessel. The tubes were cooled, opened, and the deuteriated cyclopentenes (0.55 g, 79.6%) were isolated from the decalin using a short-path distillation apparatus. Analytical gc analysis showed that the product consisted of 92% **1***b*, and 8% of the 3-methyl and 4-methyl isomers. Mass spectral analysis established that the cycloalkenes consisted of 0.1% d_4, 17.0% d_5, 76.5% d_6, 4.6% d_7, 1.3% d_8, and 0.5% d_9 species over natural abundance corresponding to an incorporation of 5.91 D atoms per molecule; ^{2}Hmr δ 5.28, δ 2.18, δ 1.68.

Preparation of specifically deuteriated 1-methylcyclohexene

Three tubes each, containing **2***a* (0.32 g), decalin (1.6 mL), and 0.26 *M* DCl/D_2O (8 mL), were heated at 160°C for 19 h in the Parr vessel. The tubes were opened and the deuteriated cyclohexenes (0.73 g, 72%) were isolated from the combined decalin layers by distillation through a 10-cm Vigreux column at atmospheric pressure into a Dry Ice cooled receiver. Analytical gc analysis showed that the product consisted of 75.9% **2***b* and another component (24.1%) of shorter retention time; ms: 0.2% d_3, 1.0% d_4, 11.4% d_5, 55.8% d_6, 9.1% d_7, 7.7% d_8, 6.0% d_9, 5.0% d_{10}, 2.9% d_{11}, 0.9% d_{12} species (6.60 D atoms per molecule); ^{2}Hmr δ 5.37, δ 1.86, δ 1.59.

Reaction of a series of diazonium salts with either hexamine or an aqueous mixture of ammonia–formaldehyde affords 3,7-bis(arylazo)-1,3,5,7-tetraazabicyclo[3,3,1]nonanes; several new examples of this novel class of bicycloheterocycle have been prepared and characterized. Analysis of the low-temperature nmr spectra of one compound in this series shows that the bicyclic system prefers the chair–chair conformation. The bis(arylazo)tetraazabicyclononanes, which are surprisingly stable in aqueous buffer compared to analogous triazenes of open-chain structure, do undergo slow decomposition at slightly acidic pH in an acetone–buffer mixture. The apparent product of this decomposition is the arylamine, which is observed as the Mannich condensation product, $ArNH.CH_2CH_2COCH_3$.

ROBERT D. SINGER, KEITH VAUGHAN et DONALD L. HOOPER. Can. J. Chem. **64**, 1567 (1986).

La réaction d'une série de sels de diazonium, soit avec de l'hexamine ou avec une solution aqueuse d'ammoniac et de formaldéhyde, conduit aux bis (arylazo)-3,7 tétraaza-1,3,5,7 bicyclo[3.3.1]nonanes; on a ainsi préparé et caractérisé plusieurs nouveaux composés de cette nouvelle classe d'hétérocycles bicycliques. L'analyse du spectre rmn, déterminé à basse température, de l'un des composés de cette série permet de démontrer que le système bicyclique existe d'une façon préférentielle dans la conformation chaise–chaise. Par comparaison avec les triazènes analogues en chaînes ouvertes, la stabilité des bis(arylazo) tétraazabicyclononanes dans des solutions aqueuses de tampons est surprenante; dans des solutions légèrement acides, dans un tampon dans de l'acétone, ils subissent toutefois une décomposition lente. Le produit apparent de cette décomposition est l'arylamine qui est observée sous la forme de produit de condensation de Mannich, $ArNH.CH_2CH_2COCH_3$.
[Traduit par la revue]

Introduction

The reaction of diazonium salt solutions with ammonia–formaldehyde mixtures is of interest to us for several reasons. Firstly, the expected 1:1:1 coupling product would be the novel monomethyloltriazene, **1***a*, which would be a new type of triazene and is the analogue of the previously reported (1) *N*-methyl-*N*-hydroxymethyltriazenes **1***b*. Stable hydroxymethyltriazenes of type **1***b* have been reported as the products of diazonium coupling of methylamine–formaldehyde mixtures (2, 3), and have been shown to have significant anti-tumour activity against mouse tumour models in vivo (4). Consequently, the extension of these diazonium coupling reactions to ammonia–formaldehyde mixtures might be expected to afford triazenes of type **1***a*, which should themselves have interesting biological properties. A particular biological significance attached to structure **1***a* is the possibility that a triazene of this type might be a metabolite of the cytotoxic 1-aryl-3-methyltriazene, $ArN{=}N{-}NHCH_3$; it has been shown that such a triazene undergoes metabolism under in vitro microsomal incubation (5), but free formaldehyde could not be detected (6).

Furthermore, it has been reported (7, 8) that diazonium coupling with hexamethylenetetramine (the condensation product of ammonia and formaldehyde) affords the bisarylazotetraazabicyclononanes (**2**). These bicyclic heterocycles are close structural analogues of the bis(triazenylmethyl)methylamines (**3**) (3, 9), which can also be obtained from diazonium coupling with methylamine–formaldehyde mixtures under appropriate conditions. We were interested to prepare the

bicyclic heterocycles **2**, to compare their solution chemistry with that of the bis-triazenes **3** and also to determine if the diazonium coupling with ammonia–formaldehyde could be persuaded to follow a pathway to triazenes of type **1***a* rather than of type **2**.

Results and discussion

Reaction of *p*-cyanobenzenediazonium chloride with hexamethylenetetramine (HMT) afforded a high yield of the

bis(arylazo)tetraazabicyclononane **2***c*, which was also obtained, in lesser yield, by reaction of the diazonium salt with varying composition mixtures of ammonia and formaldehyde. The optimum ratio of ArN_2^+:NH_3:CH_2O for maximum yield of **2***c* was observed to be 1:2:10 and these proportions were used to prepare the other bis(arylazo)tetraazabicyclononanes (**2***a*, *b*, *d*–*g*). Percentage yields are shown in Table 1*a*. These bicyclic heterocycles were characterized by ir, nmr, mass spectra, and elemental analysis.

The mass spectrum of the *p*-cyano derivative **2***c* shows a molecular ion at m/z 386, consistent with the bis(arylazo)tetraazabicyclononane structure. Principal fragments occur at m/z 130 (p-$NC.C_6H_4N_2^+$) and 256, arising from cleavage of the triazene moiety at the N2—N3 bond, and at m/z 358, due to loss of N_2 from the molecular ion. The ethyl ester analogue **2***e* was also characterized by mass spectroscopy, giving the expected molecular ion at m/z 480.

The formation of the bis(arylazo)heterocycles **2** from the ammonia–formaldehyde diazonium coupling suggests that the predominant species in the NH_3–CH_2O solution is HMT. A reasonable mechanism for the conversion HMT → **2** is shown in Scheme 1. Attachment of the electrophilic diazonium ion at one of the four equivalent nitrogen atoms of HMT affords the triazenium ion **4** and initiates ring cleavage, typical of an aminal (10), to give the iminium ion **5**. Hydrolysis of **5** and loss of formaldehyde leads to the mono(arylazo)tetraazabicyclononane **6**; further diazonium coupling to the secondary amino position of **6** gives the observed product (**2**). The apparent reluctance of **2** to undergo further diazo coupling at the bridgehead nitrogen atoms may simply be a consequence of the insolubility of **2** in the aqueous medium.

Formation of a triazene of type **1***a* requires diazonium coupling to the carbinolamine, NH_2CH_2OH, the 1:1 condensation product of ammonia and formaldehyde, which is recognized to be an intermediate in the formation of HMT from ammonia and formaldehyde (11). Accordingly, we investigated the reaction of *p*-cyanobenzenediazonium cation with NH_3:CH_2O mixtures ranging in composition from 2:1 to 1:10. The higher ratio of NH_3:CH_2O did result in lower yield of the HMT-derived product **2***c*, but we could find no spectroscopic evidence for formation of the monohydroxymethyltriazene **1***a* in any of the reaction mixtures. Furthermore, none of these reaction mixtures contained even trace amounts of the aniline (p-$NC.C_6H_4.NH_2$), which would be the most likely degradation product to arise from decomposition of **1***a*. If **1***a* is formed under these conditions, we must assume that it does not survive the reaction conditions or work-up, and undergoes further condensation with NH_3–CH_2O to give a product of type **2**.

Examination of the nmr spectra of the bis(arylazo)tetraazabicyclononanes **2** reveals the nature of the conformational structure of these fused saturated bicyclic heterocycles. The possible conformations for a tetraazabicyclo[3,3,1]nonane system are chair–chair, chair–boat, and boat–boat. Not surprisingly, the preferred conformation in a majority of cases is the chair–chair, but the introduction of bulky substituents at positions 3 and 7 results in preference for the chair–boat conformation (12).

The ^1H nmr spectra of the bis(arylazo)tetraazabicyclononanes **2** (Table 2) show considerable broadening of several signals. For example, in the spectrum of **2***c*, the higher-field portion of the aromatic AA'BB' system is slightly broadened, and all but one of the ring N-methylene signals are severely broadened. Similar broadening of N—CH_2 signals is observed in the ^1H nmr spectrum of the ethyl ester analogue **2***e*, although two of the broad signals overlap at δ 5.15 (compare **2***c*, which has broad signals resolved at δ 5.10 and 5.18). The equilibrium process responsible for this broadening also causes broadening of some signals in the ^{13}C nmr spectrum of **2***e* (Table 3); consistent with the ^1H nmr spectrum of **2***e*, one of the N—CH_2—N signals is sharp (δ 69.9), whereas those at δ 63.7 and 72.1 are broad.

The structure of **2***e* and the nature of the equilibrium process

TABLE 3. The ^{13}C nmr signals in the spectrum of 3,7-bis(*p*-ethoxycarbonylphenylazo)-1,3,5,7-tetraazabicyclo[3,3,1]nonane (**2***e*) in $CDCl_3$

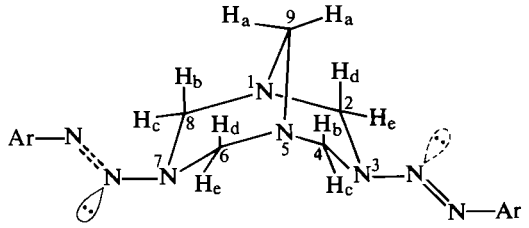
166.2	*C*=O

responsible for nmr line-broadening is revealed by an analysis of the ^1H and ^{13}C nmr spectra at low temperatures (−58°C). The broad signals in the ^{13}C spectrum at δ 63.7 and 72.1 split into two sets of two singlets at δ 62.86/72.27 and 63.59/71.68, of unequal intensity. The aromatic signals at δ 127.7, 130.1, and 153.0 are also split, each into two signals of unequal intensity, in the low temperature spectrum. The unequal intensity of these sets suggests that the low temperature system is a mixture of two nonequivalent thermodynamically distinguishable isomers. The only consistent interpretation of these observations is that the components of the mixture are the *syn* and *anti* forms of the chair–chair conformation, **7***a* and **7***b* respectively, which are essentially the rotamers arising from restricted rotation around the N2′—N3′ bond of the triazene moiety (13).[4] The major rotamer, presumably **7***b*, is responsible for the more intense set of signals at δ 62.86 and 72.27; on the basis of the proximity of the ring carbons to the electron lone pairs on the central nitrogens of the triazene unit, we can assign the low-field signal at δ 62.86 to the more deshielded equivalent carbons 2 and 6, and the high-field signal at δ 72.27 to carbons 4 and 8 in structure **7***b*. Similarly the signal at δ 63.59 is assigned to the equivalent carbons 2 and 8 and at δ 71.68 to carbons 4 and 6 in the minor rotamer **7***a*. The signal at δ 69.9, assigned to the bridging methylene group (C-9), is not distinguishable in the two rotamers, presumably because it is sufficiently far removed from the site of rotamerism.

The low temperature ^1H nmr spectrum of **2***e* confirms this interpretation. The aromatic signals resolve into two closely spaced sets of AA′BB′ systems, and the $O—CH_2$ group resolves into two closely spaced quartets, but the resolution of the signals in the N-methylene region provides unequivocal evidence for the proposed structures **7***a* and **7***b*. The bridging methylene (C-9) protons resolve into two singlets, at δ 4.5 for the major rotamer (**7***b*) and at δ 4.48 in **7***a*. This observation is clearly inconsistent with a chair–boat conformation, in which the protons at C-9 would be nonequivalent and give rise to one or more AB patterns. The remaining methylene protons of **7***b* separate into two quite different AB patterns, one with a large chemical shift difference (δ 6.10, 6.06, 4.54, and 4.50), the

[4]A much less likely interpretation would be similar rotamers of the boat–boat molecular conformation. It has recently been shown for the analogous 3,7-diazabicyclo[3,3,1]nonane that substituents such as nitroso or ethoxycarbonyl attached to the 3- and 7-nitrogens confer sp^2 hybridization character on these nitrogens. The geometry at these nitrogens is planar and the preferred conformation adopted is the "twin-chair" (15).



anti **7***b*

syn **7***a*

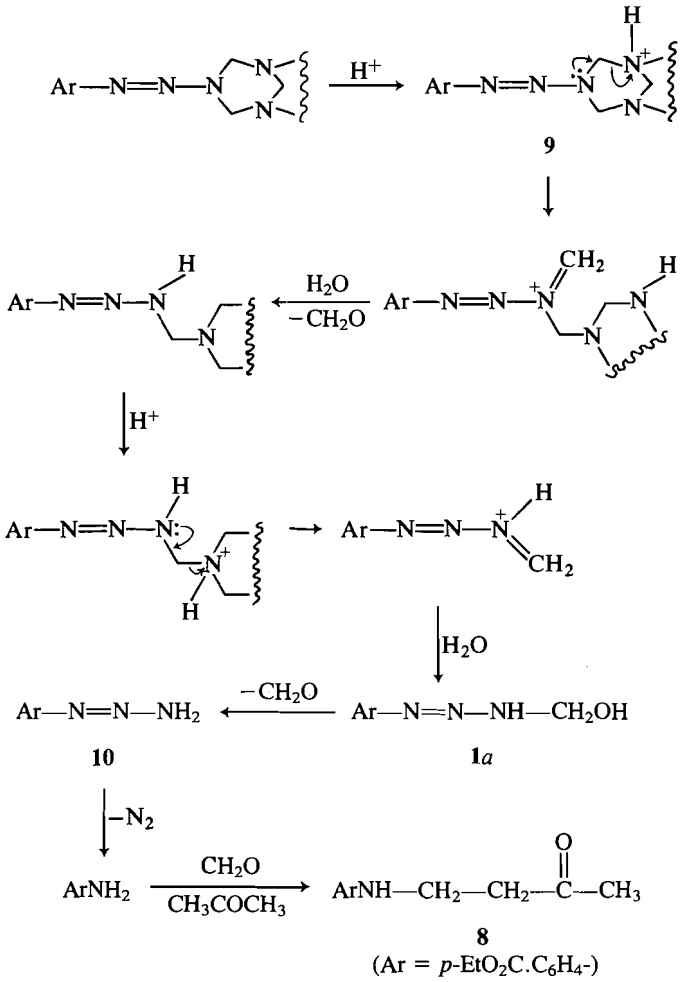
other with a small chemical shift difference (δ 5.19, 5.15, 5.13, and 5.09). The minor rotamer **7***a* also gives two distinguishable AB patterns from the N-methylene protons at carbons 2, 4, 6, and 8: δ 6.04, 6.00, 4.47, and 4.43, and δ 5.30, 5.26, 5.22, and 5.18. These observations are consistent with the equivalence of positions 4 with 8 and 2 with 6 in structure **7***b*, and of positions 2 with 8 and 4 with 6 in structure **7***a*, and thus confirms the conformational assignments.

These conclusions are consistent with the observations of Stefaniak *et al.* (8) with the analogous 3,7-bis(nitroso)- and 3,7-bis(acetyl)-1,3,5,7-tetraazabicyclo[3,3,1]nonanes, which exist as similar *syn* and *anti* isomers. However, the broadening of the signals from the ring methylene protons in 3,7-bis(arylazo) analogues was incorrectly presumed by them to arise from quadrapolar relaxation induced by the nitrogen nuclei in the 3,7 substituents (8).

In view of the close structural similarity of the tetraazabicyclononanes **2** to the previously reported (9) bis-triazenes **3**, it was of interest to us to compare the aqueous solution chemistry of these molecules. We have shown that bis-triazenes undergo facile hydrolysis in phosphate buffer (with 1.7% DMSO) at pH 7.5 to give the corresponding arylamine, via the intermediate 1-aryl-3-methyltriazene, ArN=N.NHMe; for example, the *p*-bromophenyl-bistriazene (**3***a*) decays with a half-life of 12.0 min at a pH 7.5 (13). This ease of decomposition has been attributed to the aminal character of the bis-triazene (14). The *p*-bromo- and *p*-ethoxycarbonylphenyl-tetraazabicyclononanes (**2***b* and **2***e*) were hydrolysed in pH 7.5 phosphate buffer under identical conditions to those used in the hydrolysis of **3***a*; surprisingly **2***b* and **2***e* were found to be stable under these conditions. No change in the uv spectrum of either substrate was seen over a 24-h period.

The ethyl ester **2***e* was also found to be stable in (*a*) a 4:1 (v/v) acetone–water mixture at 37°C, (*b*) acetone – pH 7.5 phosphate buffer at 37°C, and (*c*) refluxing ethanol. Slow decomposition of **2***e* was evident when dissolved in a mixture of acetone – phosphate buffer and the pH adjusted to 4.5. However, even after 20 h under these conditions some starting material remained. The reaction in acetone – pH 4.5 buffer was accelerated by refluxing for 5 h and afforded an identifiable product, the β-anilino-butanone (**8**).

Characterization of **8** is based on ir, nmr, and mass spectral



SCHEME 2

data, and on comparison with an authentic sample.[5] The formation of the ketone **8** from **2***e* must derive from hydrolysis of **2***e* to the aniline (ethyl *p*-aminobenzoate), which could then condense by a Mannich reaction with formaldehyde, released during hydrolysis, and acetone from the medium, eq. [1]:

$$[1]\quad ArNH_2 + CH_2O + CH_3{-}\overset{O}{\overset{\|}{C}}{-}CH_3 \xrightarrow{H^+} ArNHCH_2CH_2\overset{O}{\overset{\|}{C}}CH_3$$

The remaining question is the pathway of hydrolysis of **2***e* to the arylamine. A possible mechanism is shown in Scheme 2, in which the reaction is initiated by protonation at either N1 or N5 of **2** to give the cation **9**. Aminal type dissociation of **9** initiates a cascade of reactions resulting in formation of two moles of the elusive monohydroxymethyltriazene **1***a*. Loss of formaldehyde from **1***a* affords the unstable triazene **10**, which spontaneously loses nitrogen to afford the aniline.

The lower reactivity of **2** towards hydrolysis, compared to **1***a*, suggests weaker basic character of the N1 or N5 nitrogens in **2** compared to the analogous aminal nitrogen in the bis-triazene. The less basic character of these nitrogens could arise from the less exposed nature of the nitrogen lone pairs resulting from the constraints of the bicyclic system. The bonds around the analogous nitrogen in the bis-triazene **3** are much more mobile, giving more accessibility for protonation of the nitrogen lone pair.

Although we must conclude from this study that the 1-aryl-3-hydroxymethyltriazene **1***a* cannot be isolated from a 1:1:1 coupling reaction of the diazonium cation, ammonia, and formaldehyde, the possible intermediacy of **1***a* in the hydrolysis of **2** offers some encouragement that compounds of type **2** may be useful as "pro-drugs" for this hydroxymethyltriazene (**1***a*). Thus it is reasonable to assume that the bis(arylazo)tetraazabicyclononanes **2** may have useful biological properties; this is presently under investigation.

Experimental

Melting points were recorded with a Kofler hot-stage melting point apparatus and are uncorrected. Infrared spectra were recorded in Nujol mulls with Perkin Elmer 299 and 1300 spectrophotometers. The uv spectra were recorded with a Unicam SP8-400 uv–visible spectrophotometer, and nmr spectra were recorded with a Varian EM360 (60 MHz) or a Nicolet 360NB (360 MHz) spectrometer. Microanalyses were carried out by the Canadian Microanalytical Service, Vancouver, B.C.

3,7-Bis(arylazo)-1,3,5,7-tetraazabicyclo[3,3,1]nonanes (2)

General procedure

Method A. The arylamine (0.02 mol) was dissolved in 2 *M* hydrochloric acid (30 mL, 0.06 mol) and diazotized at 0°C with a solution of sodium nitrite (1.52 g, 0.022 mol) in water over a period of 1 h. The diazonium salt solution was filtered, if necessary, to remove turbidity and a mixture of concentrated ammonia (2.43 g, 0.04 mol) and 37% aqueous formaldehyde (16.17 g, 0.20 mol) was added slowly to the clear diazonium salt solution. After stirring for 0.25 h, the mixture was neutralized with saturated sodium bicarbonate, whereupon the product precipitated immediately. The precipitated triazene (**2**) was filtered, dried and recrystallized from an appropriate solvent. Yields and physical properties are given in Tables 1*a* and 1*b*.

Method B. In this slightly modified procedure, the diazonium salt (0.02 mol) was treated with a solution of hexamethylenetetramine (0.7 g) in water, the mixture neutralized with $NaHCO_3$ and worked up as described above.

4-(p-Ethoxycarbonylphenylamino)butan-2-one (8)

3,7-Bis(*p*-ethoxycarbonylphenylazo)-1,3,5,7-tetraazabicyclo[3,3,1]nonane (**2***e*) (70 mg) was dissolved in a mixture of acetone (25 mL) and phosphate buffer (5 mL, pH 7.5). The pH was adjusted to 4.5 by addition of 2 *M* hydrochloric acid (approximately 5 drops). The solution was refluxed for 5 h; the excess acetone was evaporated under vacuum, whereupon the product precipitated from the aqueous residue. Filtration, then washing with water and a little ethanol afforded the anilino-ketone **8** (30 mg, 87.5%), mp 95°C (from CH_2Cl_2); ir: 3370, 1710, and 1680 cm^{-1}; δ($CDCl_3$): 1.35(3H, t, *J* 7 Hz, CH_3), 2.16(3H, s, CH_3—CO), 2.75 (2H, t, *J* 6 Hz, CH_2—CO), 3.46(2H, t, *J* 6 Hz, N—CH_2), 4.30(3H, q + br s, O—CH_2 and NH), 6.48/6.59/7.80/7.91 (4H, m, AA′BB′, aromatic); M^+ 235, *m/z*: 192 ($EtO_2C.C_6H_4NHCH_2CH_2^+$), 190 ($M^+$ − OEt), 179 ($EtO_2C.C_6H_4NH{-}CH_3^+$), 178 ($EtO_2C.C_6H_4.NHCH_2^+$), 150 ($EtO_2C.C_6H_5^+$), 120 ($OC.C_6H_4.NH_2^+$).

Acknowledgements

The award of an NSERC Undergraduate Research Award (to R.D.S.) is gratefully acknowledged. Other financial assistance was provided by the Saint Mary's University Senate Research Committee. The authors are also grateful to the Atlantic Regional Magnetic Resonance centre, Dalhousie University, for the high-field nmr spectra. We also thank the Chemistry Department at Dalhousie University for the mass spectra.

[5]An authentic sample of **8** was prepared by a modified Mannich procedure. Ethyl *p*-aminobenzoate was refluxed with formaldehyde in acetone – pH 4.5 phosphate buffer for 24 h. Evaporation of the acetone and extraction with chloroform afforded, from the dry chloroform extract, a product identical with that obtained from reaction of **2***e* as described. The conventional Mannich procedure (Organic Syntheses, Coll. Vol. IV, p. 281) was too vigorous and afforded only a dark oil.

Effect of geometry on the thermodynamic properties of micellar systems: trialkylamine oxides in water

GASTON CARON, NADIA GÉLINAS, AND JACQUES E. DESNOYERS[1]

Department of Chemistry, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received January 3, 1986

GASTON CARON, NADIA GÉLINAS, and JACQUES E. DESNOYERS. Can. J. Chem. **64**, 1573 (1986).

The apparent molar volumes, heat capacities, relative enthalpies, and isentropic compressibilities of symmetrical trialkylamine oxides and cyclohexyldimethylamine oxide were measured in water at 25°C. The data were in most cases analyzed with a mass-action model which was previously developed (J. Phys. Chem. **87**, 1397 (1983)) for micellar systems. Trimethylamine oxide shows no sign of micellization while the three next members of this homologous series and cyclohexyldimethylamine oxide form aggregates with relatively low aggregation numbers. The thermodynamic data were compared with those of assymmetrical amine oxides to investigate the effect of geometry on the micellar properties. The thermodynamic properties of the solutes in the pre-micellar region show a very good group additivity which is independent of geometry. On the other hand, with symmetrical isomers, the CMCs are much larger, the aggregation numbers smaller and the thermodynamic functions of micellization larger. These geometrical factors can be taken advantage of for thermal energy storage.

GASTON CARON, NADIA GÉLINAS et JACQUES E. DESNOYERS. Can. J. Chem. **64**, 1573 (1986).

Les volumes, capacités calorifiques, enthalpies relatives et compressibilités isentropiques molaires apparents des oxydes de trialkylamines symétriques et du cyclohexyldiméthylamine ont été mesurés dans l'eau à 25°C. Les données ont été analysées, dans la plupart des cas, au moyen d'un modèle d'action de masse développé précédemment (J. Phys. Chem. **87**, 1397 (1983)) pour les systèmes micellaires. Il n'y a aucune évidence de micellisation dans le cas de l'oxyde de triméthylamine, alors que les trois prochains homologues ainsi que l'oxyde du cyclohexyldiméthylamine forment des aggrégats avec des nombres d'aggrégation relativement faibles. Les données thermodynamiques ont été comparées avec celles des oxydes d'amines symétriques pour étudier l'effet de la géométrie sur les propriétés micellaires. Les propriétés des solutés dans la région pré-micellaire démontrent en général une très bonne additivité de groupe, indépendante de la géométrie. Par contre, avec les isomères symétriques, les CMCs sont plus grandes, les nombres d'aggrégation plus petits et les fonctions thermodynamiques de micellisation plus grandes. Il est possible de prendre avantage de ces facteurs géométriques pour le stokage thermique de l'énergie.

Introduction

The solvation of hydrophobic solutes in water enhances the structure of water in the vicinity of the solute, and this is characterized by high apparent molar heat capacities (1). Even though the specific heat capacity of the pure additives is generally lower than that of pure water, these solute–solvent interactions may lead to an overall larger specific heat capacity of the solution relative to pure water. This phenomenon can in principle be exploited for thermal energy storage. Unfortunately, hydrophobic solutes often tend to micellize or undergo some microphase transitions in water, and these aggregation processes are accompanied by a large reduction in heat capacity. It would therefore be useful to investigate the conditions under which hydrophobic solutes can remain soluble in water up to relatively high concentrations and not undergo micellization.

It is well known that the geometry of hydrophobic solutes affects significantly their physical properties in water. For example, important differences are observed between *n*-butanol and *tert*-butanol (2). The differences are even more evident with tetraalkylammonium halides. Nonyltrimethylammonium bromide is a typical ionic surfactant with a critical micellar concentration (CMC) of 0.14 mol kg^{-1} (3). On the other hand, tetrapropylammonium bromide, which has the same formula weight, does not show any sign of association in water before 1.3 mol kg^{-1} (4).

For a better understanding of the geometrical factors, it is preferable to study nonionic systems where complications due to the charges are avoided. Alcohols are hydrophobic solute but their limited solubility in water prevents the study of the longer-chain homologs at high concentration where hydrophobic interactions and association are more pronounced. Amine oxides, on the other hand, are much more soluble in water, and recently the thermodynamic properties of alkyldimethylamine oxides were reported for alkyl chains up to decyl (5, 6). It was also shown that this homologous series was ideal for the testing of a mass-action model for micellization. The thermodynamic properties of the symmetrical trialkylamine oxides have not been investigated. This series could therefore be an appropriate one to investigate the influence of geometry of the solute on the thermodynamics of micellization. Cyclohexyldimethylamine oxide will also be investigated with some properties for the same purpose.

While our prime interest is in heat capacities, precise volume data are also required to convert the heat capacities per unit volume, obtained with a flow calorimeter, into specific heat capacities. Enthalpies are also useful to predict the equilibrium displacement contribution to heat capacities, and it is this contribution which causes the high heat capacities in the micellar region (6). Finally, it was felt that compressibilities could be informative on the influence of pressure on the system.

Experimental

The techniques used for the measurement of densities (7), heat capacities (8), enthalpies of dilution (9), and isentropic compressibilities (3) have all been described previously and are the same as the ones used for the long-chain amine oxides (5, 6) and alkylammonium bromides (3).

The symmetrical trialkylamine oxides (CX) and cyclohexyldimethylamine oxide (HC1) were prepared by the oxidation of the corresponding amine with hydrogen peroxide, as described previously for assymetrical amine oxides (6). The main difficulty encountered with the present amine oxides came from the difficulty, and often impossibility, of purification by recrystallization in view of the high hygroscopic nature of these substances.

Cyclohexylamine was purchased from Eastman Kodak and cyclohexyldimethylamine was then synthesized by methylation of the primary amine as described by Clarke *et al.* (10).

Trimethylamine oxide (C1) was purchased as such from Princeton Laboratories and used after filtration on millipore. For the other three homologs (C2, C3, and C4) and HC1, the purified amines, from Aldrich, were heated to 65°C, and cold hydrogen peroxide (30% solution from Fisher) was then added at the rate of one drop per second in the proportion of 1.2 mol of peroxide to 1 mol of amine. After the addition had been completed, the mixture was warmed to 70°C until the upper phase, the amine, had disappeared. The reaction time was about 5 h for C2 and 72 h for C4. After completion of the reaction, manganese dioxide was added in catalytic quantity to eliminate all excess of H_2O_2. The complete elimination of the peroxide was checked with iodide

starch paper. The excess amine was removed by three extractions with petroleum ether. The C2 and C3 products were used as such, while C4 and HC1 were recrystallized in diethyl ether.

Stock solutions were prepared and their molality determined by conductimetric titration with hydrochloric acid. Solutions were then prepared by dilution, by mass, using distilled deionized water.

Results

The changes in density ($d - d_0$) and in relative changes in heat capacity per unit volume $(\sigma - \sigma_0)/\sigma_0$ from which apparent molar volumes, $V_{2,\phi}$ and heat capacities $C_{P,2,\phi}$ can be derived (7, 8) are given in Table 1. The density and heat capacity per unit volume of pure water at 25°C were taken as 0.997047 g cm^{-3} and 4.1793 J K^{-1} cm^{-3}. The isentropic compressibilities β_s were calculated from sound velocities (10) and are given in Table 2 along with the derived apparent molar isentropic compressibilities $K_{S,2,\phi}$. The value of $\beta_{S,0}$ at 25°C was taken as 44.77×10^{-6} bar^{-1}. The integral enthalpies of dilution, ΔH_{ID} for a dilution ratio f are reported in Table 3. These enthalpies of dilution were converted to relative apparent molar enthalpies by least-squares fitting of the data with an equation of the type

$$[1] \quad L_{2,\phi} = Am + Bm^2 + \ldots$$

from which

$$[2] \quad \Delta H_{ID} = \Delta L_{2,\phi} = A(fm - m) + B(f^2m^2 - m^2)$$

The parameters A and B are given in Table 4.

The concentration dependence of the apparent molar quantities of the symmetrical amine oxides are shown in Figs. 1 to 4, while $V_{2,\phi}$ and $C_{P,2,\phi}$ of HC1 are shown in Fig. 5. The corresponding partial molar compressibilities are also shown in Fig. 4. These trends are typical of the behaviour of surfactants in water, except that the CMC is observed at much higher concentrations than with single chain surfactants. The enthalpies of dilution could not be measured in the post-micellar region since incomplete mixing was observed at these high

concentrations, and the magnitude of the enthalpies was becoming too large for the microcalorimeter.

Thermodynamic data of micellar systems can be fitted by least-squares using a recently developed mass-action model (6). The parameters that are extracted from the data, or those need to be fixed, are the following: Y_2^0 = partial molar quantity of solute 2 at infinite dilution; A_Y = second virial coefficient for the interactions between monomers; Y_2^M = partial molar quantity of the surfactant in the micellar form; A_Y^M = interaction

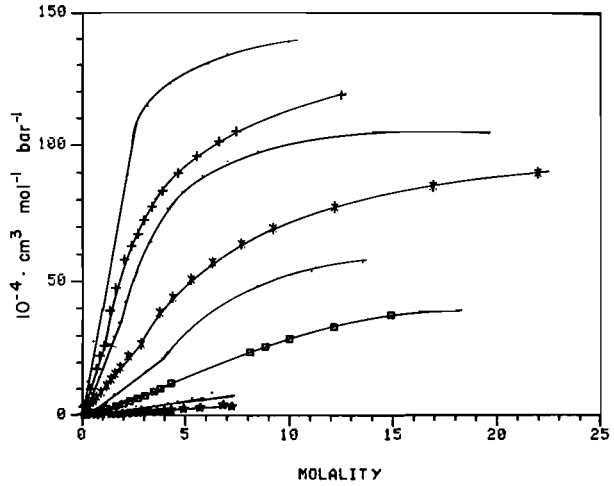

FIG. 4. Apparent and partial (full line) molar isentropic compressibilities of trialkylamine oxides in water at 25°C. The bottom curve is for C1 and the top curve for C4.

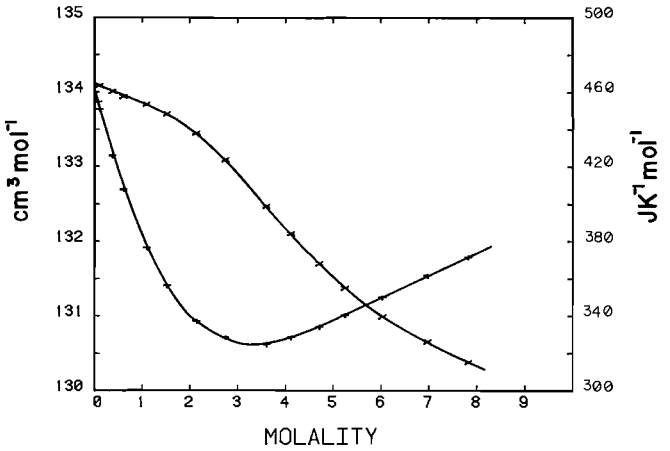

FIG. 5. Apparent molar volumes and heat capacities of cyclohexyldimethylamine oxide in water at 25°C.

parameter in the post-micellar region; m_I = critical micellar concentration on the molality scale and defined as the inflection point in the fraction of monomers; N = aggregation number; EQUIL = equilibrium displacement contribution to heat capacities, $(\Delta H_M/T)^2/R$, and to compressibilities, $(\Delta V_M)^2/RT$, where ΔH_M and ΔV_M are the enthalpies and volumes of micellization; and s is standard deviation.

With medium chain length surfactants, it is possible to extract all the above parameters from the least-squares fit. With alkyldimethylamine oxides, the model was quantitative, even without the parameter $A_Y{}^M$ (6). The aggregation numbers that were extracted were quite reasonable, independent of the property and to a first approximation independent of temperature. The model is not as successful with the symmetrical amine oxides, primarily due to the lack of data points at high concentration and in the inflection region. As a result, the convergence was difficult and some of the parameters extracted were not always realistic, especially $Y_2{}^M$ and EQUIL. Still, the aggregation numbers extracted were of the order of 3 for C2, 4 for C3, and 6 for C4. These aggregation numbers are of the correct magnitude for such surfactants. When convergence was not achieved or slow, some of the parameters were fixed at reasonable values. The parameters obtained from the least-

TABLE 5. Thermodynamic parameters of trimethylamine oxide in water at 25°C

Property	Y_2^0	A_Y
$V_\phi/(cm^3\ mol^{-1})$	73.15	−0.452
$C_\phi/(J\ K^{-1}\ mol^{-1})$	180.0	−4.8
$10^4\ K_{s,2,\phi}/(cm^3\ bar^{-1}\ mol^{-1})$	−9.9	0.68

squares are given in Tables 5 and 6. In the case of C1, no evidence of micellization is observed with most properties. Therefore, only Y_2^0 and A_Y are given.

The aggregation numbers, the CMC, and the thermodynamic changes during micellization of HC1 are comparable to those of the symmetrical amine oxides. Cyclisation of the chain therefore has no major effect on the micellization properties.

Discussion

The standard thermodynamic quantities Y_2^0 are functions of the intrinsic contribution and of the solute–solvent interactions. The parameters V_2^0 and $C_{P,2}^0$ of the symmetrical and assymmetrical (6) amine oxides are compared with the tetraalkylammonium bromides (3, 11) in Fig. 6. Symmetrical and assymmetircal amine oxides fall on the same lines and these slopes are, in a first approximation, identical to those of the ammonium salts. In the case of HC1 (not shown), both the volumes and heat capacities fall below the line of the other amine oxides as expected since there is one less H atom in this solute. The CH_2 contribution to these two functions is independent of the presence of a charge or of the symmetry. The CH_2 contribution of the amine oxides is 15.7 $cm^3\ mol^{-1}$ for V_2^0 and

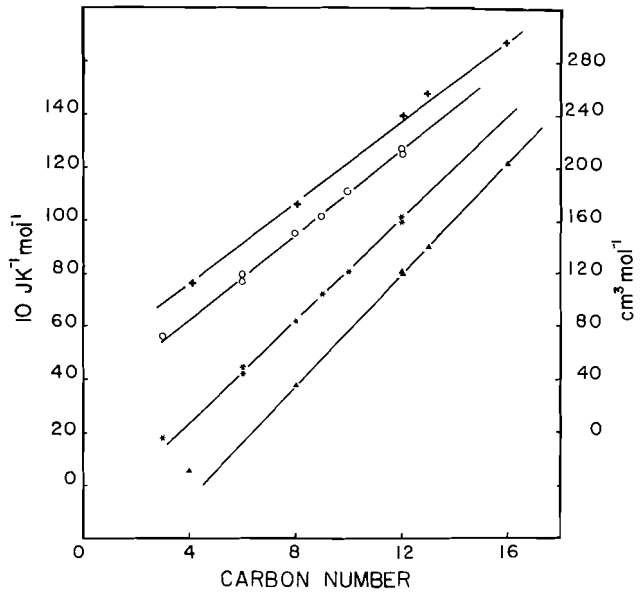

FIG. 6. Dependence of the standard thermodynamic functions on the total number of carbon atoms in the chains: + and ○, V_2^0 of R_4NBr and amine oxides, respectively; * and ▲, $C_{P,2}^0$ of amine oxides and R_4NBr, respectively.

95 $J\ K^{-1}\ mol^{-1}$ for $C_{P,2}^0$. These results are in good agreement with the values obtained by other authors (2, 12–14).

The situation is not as simple with compressibilities. The dependence of $K_{S,2}^0$ on the number of carbon atoms appears to be the same for all the systems (see Fig. 7) implying a constant CH_2 contribution of -1.5×10^{-4} $cm^3\ bar^{-1}\ mol^{-1}$, again in good agreement with other authors (15, 16). On the other hand,

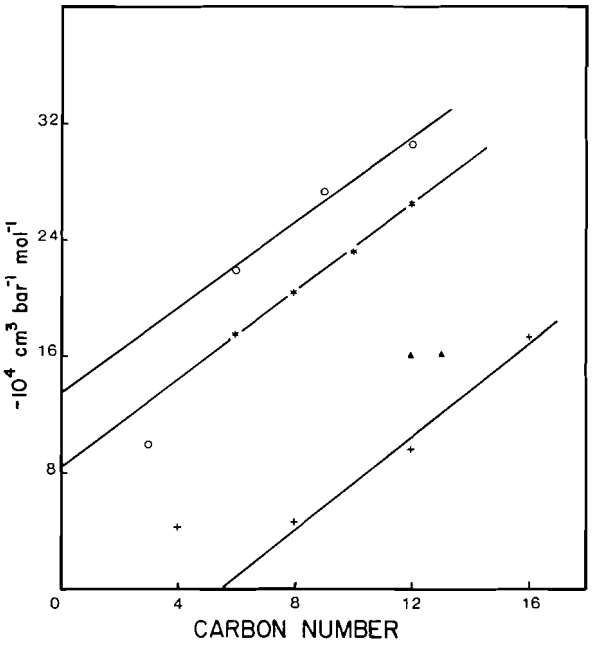

FIG. 7. Dependence of standard partial molar isentropic compressibilities on the total number of carbon atoms in the chains: ○, symmetrical amine oxides; *, assymmetrical amine oxides; +, symmetrical R_4NBr; ▲, assymmetrical R_4NBr.

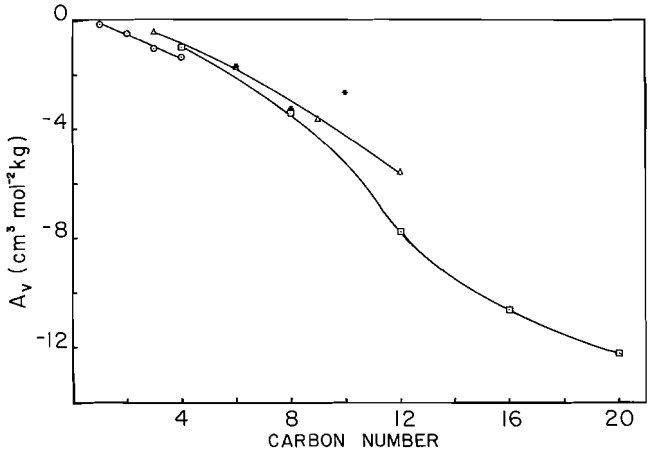

FIG. 8. Dependence of parameter A_V on the number of carbon atoms.

the symmetry of the solute affects the magnitude of $K_{S,2}^0$; the symmetrical amine oxides are more negative while the symmetrical ammonium salts (15) are more positive than the corresponding linear isomers (3). It is not easy to explain why the symmetry affects compressibilities but not heat capacities and volumes. It would be necessary to examine corresponding correlations in non-aqueous solvents and in the pure liquid state before venturing an explanation.

The second virial coefficients, as seen from Tables 5 and 6 change in a fairly regular way with chain length. The parameter A_V is plotted against the number of carbon atoms in the chains and compared with the assymmetrical amine oxides, tetraalkylammonium bromides and alcohols (17) in Fig. 8. All the solutes fall approximately on the same straight line. This is also approximately true for A_H. This linearity suggests that these virial coefficient are approximately additive as it was observed for free energies (18).

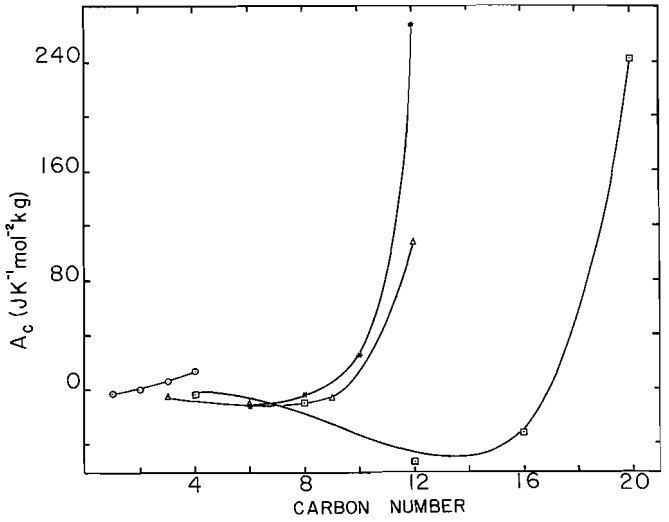

FIG. 9. Dependence of parameter A_C on the number of carbon atoms.

A similar plot is shown for A_C in Fig. 9. No simple correlation can be made in this case. The values of A_C of the amine oxides are approximately equal to zero up to 9 carbons and then increase sharply. The corresponding values for tetraalkylammonium bromides decrease up to 12 carbons and again increase. For the alcohols, A_C increases steadily. The interpretation of this parameter is not simple since it contains two main contributions. The interaction between two monomers as they approach each other lead to a partial dehydration of the hydrophobic chains and this causes a negative contribution to A_C. By analogy with equilibrium constants there is also a relaxational or equilibrium displacement contribution as the temperature is increased. This will cause a positive contribution to A_C since it is proportional to $(A_H)^2$. These two contributions cancel each other for the lower homologs, but the relaxational contribution rapidly takes over with the more hydrophobic solutes where A_H is large.

The equilibrium displacement contribution to heat capacities is again of similar magnitude for symmetrical and assymmetrical (6) amine oxides. This contribution is sufficiently large to produce a hump in $C_{P,2\phi}$ in the micellar region for octyldimethylamine oxide and C4. This, of course, implies that both these surfactants have comparable large enthalpies of micellization.

The main differences between the symmetrical and assymmetrical isomers are in the micellar parameters. With the symmetrical isomers, the CMCs are much larger, the aggregation numbers small and the change ΔY_2^M larger.

Conclusion

The present study indicates that the thermodynamic properties of monomeric hydrophobic solutes of different geometries can to a large extent be predicted by group additivity. On the other hand, the association or aggregation of such solutes in water depend significantly on the shape of the molecules; micellization is favored with long-chain amphiphilic solutes, while bulky solutes show much less tendency to aggregate. The thermodynamic functions of micellization are also strongly dependent on geometry.

The present study also shows that the heat capacity per unit volume of a solution of tributylamine oxide can be increased

by about 4% relative to pure water in the concentration region where the apparent molar heat capacity goes through a maximum. While this solute is not of much interest for energy storage in view of its thermal instability, these results suggest that bulky hydrophobic solutes might meet the requirements for improving the energy storage of aqueous solutions. The ideal solute would have to be hydrophobic, stable, highly soluble in water, with a large enthalpy of transition and a small heat capacity of transition. Such conditions can usually be met at low temperatures. Work is under way to investigate such possibilities.

Sulphur-33 nuclear magnetic resonance spectroscopy of sulphones[1]

JEFFREY HOYLE, J. STUART GROSSERT,[2] DONALD L. HOOPER, AND SUBRAMANIAN SOTHEESWARAN[3]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 5, 1985

JEFFREY HOYLE, J. STUART GROSSERT, DONALD L. HOOPER, and SUBRAMANIAN SOTHEESWARAN. Can. J. Chem. **64**, 1581 (1986).

The sulphur-33 nmr spectra of 28 sulphones were measured in deuterochloroform solutions at 27.716172 MHz. The spectra were referenced with respect to an external aqueous ammonium sulphate solution and the chemical shifts lay in the range 0 ± 20 ppm, with many lines having a half-height width of less than 200 Hz. Instrumental parameters that affect the spectra were studied. Some of the sulphur-33 resonances can be correlated well with carbon-13 or oxygen-17 resonances in appropriate analogous compounds, and with the Taft σ* parameter.

JEFFREY HOYLE, J. STUART GROSSERT, DONALD L. HOOPER et SUBRAMANIAN SOTHEESWARAN. Can. J. Chem. **64**, 1581 (1986).

Opérant à 27,716172 MHz et dans des solutions de deutérochloroforme, on a mesuré les spectres rmn du ^{33}S de 28 sulfones. Les déplacements chimiques, qui se situent dans l'intervalle de 0 ± 20 ppm, sont exprimés par rapport à une solution aqueuse de sulfate d'ammonium untilisée comme référence externe; les largueurs à mi-hauteur de plusieurs raies ne dépassent pas 200 Hz. On a étudié les paramètres reliés aux instruments qui peuvent affecter les spectres. On a pu établir une bonne corrélation entre les résonances en rmn du ^{33}S et soit le paramètre σ* de Taft ou les résonances en rmn du ^{13}C du ^{17}O de composés analogues appropriés.

[Traduit par la revue]

Introduction

Sulphur-33 was one of the first nuclei for which the nmr phenomenon was observed (1), yet for many years the nucleus received no further attention (2), undoubtedly due in a large measure to its low receptivity and to the quadrupole moment of the nucleus, which gives rise to significant line broadening in the spectra of many molecules. This line broadening is greatly decreased when the sulphur nucleus experiences a significant and reasonably symmetrical electric field gradient, such that the sulphur-33 resonance in SF_6 is actually a clearly defined septet (2, 3). Sulphones also give usefully narrow lines, although this fact was not reported until 1981 (4). This pioneering study suffers from rather large uncertainties in the values of the chemical shifts reported, presumably due to the use of a relatively low-field spectrometer. The increasingly wide availability of high-field, multinuclear nmr spectrometers has facilitated studies on the sulphur-33 nucleus, and a number of papers reporting useful nmr results on organosulphur compounds have recently appeared (5–9). These studies show that the sulphur-33 nucleus in sulphones resonates over a relatively narrow chemical shift range. The resonance frequencies are structure dependent and are generally quite different from the much broader lines found for other less oxidized sulphur-containing functional groups (6, 8). A range of sulphones has been studied, but as yet no systematic correlation of structures and chemical shifts has been reported. Furthermore, there is an unfortunate lack of standardization in the choice of reference compound, this ranging from carbon disulphide (5–7), which has a relatively broad resonance, to sulpholane (8), and ammonium sulphate (9, 10), which has a narrow resonance.

Results and discussion

As a result of other ongoing work (11, 12), we had in hand a series of sulphones with a wide range of substituents representing a systematic variation in the environment of the sulphone group. The results from measuring the sulphur-33 nmr resonances for these compounds are reported in Table 1.

The chemical shifts in this study are reported as δ values with respect to an external 5 *M* aqueous solution of ammonium sulphate. The sulphate ion gives a narrow line and its use as a reference line has been thoroughly investigated by Lutz *et al.* (10), who compared its suitability to that of carbon disulphide. Carbon disulphide has been used as a reference by a number of other workers (5, 7), but it exhibits a broad line ($W_{1/2}$ > 250 Hz), which means that accurate measurement of its resonance frequency is more difficult than a similar measurement for a narrow resonance.

A comparison of some chemical shifts reported in the literature and some from the present work is presented in Table 2. The results at times show sizeable differences between reported chemical shifts and line widths, such that some standardization of recording techniques is desirable.

The narrow chemical shift range required that a number of spectral variables were assessed. This was done using a sample of ethyl phenyl sulphone (Table 1, entry #13), which exhibits a resonance line of intermediate width (>100 Hz). The number of data points used to acquire a spectrum is important; for a spectral window of 1000 Hz, at least 8K data points were required to give reproducible values of line width and frequency. For any nucleus of low receptivity, detection requires the smallest possible delay time between switching off the transmitter and switching on the receiver. However, this exacts a penalty in the rolling baseline resulting from acoustic ringing, which was minimized by deleting ("left shifting") some points of the expanded FID (free induction decay) display. The number of points deleted is a function of the sample as well as the number of scans; for this particular sample at least 4 points had to be deleted to assure consistent measurements of line frequency and line width. In addition, it was found that very careful phasing of the resultant absorption signal was essential for accurate measurement of line frequencies. Variations of up to 1 ppm were observed for apparently trivial errors in phasing. Finally, it was also found necessary to use an FID exponential multiplicand more positive than −10 in order to obtain consistent line width values (136–140 Hz for this sample).

*For comparison purposes chemical shifts are all referenced to sulphate anions assuming that the carbon disulphide resonance is 332 ppm upfield from that of sulphate ions (3).

We have found that sulphone mixtures such as $MeSO_2CH_2Cl$ and $MeSO_2CHCl_2$ or $PhSO_2CH_2COMe$ and $MeSO_2CH_2COPh$ showed the same chemical shifts as were found for the individual compounds, viz. Table 1, entries 4, 5 and 15, 21, respectively. Entries 17–20 showed only a single sulphur-33 resonance and this arose from the more highly oxidized sulphur atom.

The correlation of chemical shifts with structure has long been studied and various empirical correlations such as that due to Lindeman and Adams (13) for carbon-13 chemical shifts in alkanes are widely used. Another correlation of possible relevance to sulphur-33 spectra is the report of a linear correlation of oxygen-17 chemical shifts in ethers with the carbon-13 chemical shift in the analogous alkanes. In the case of simple compounds, with only alkyl substituents to the oxygen, there is a linear correlation between these chemical shifts (δ-*O* vs. δ-*C*), with a resulting slope of 3.2, that has been suggested (19) can be related to the difference in size and electron density of the 2*p* orbitals of oxygen and carbon, although the actual agreement between the measured slope and the calculated difference is somewhat tenuous (3.2 vs. 2.3).

When we plotted the sulphur-33 chemical shifts of the simple dialkyl sulphones (entries 1–3, and literature values (5) for di-*n*-propyl sulphone, and di-*n*-butyl sulphone) versus the carbon-13 shifts of the analogous alkanes (13), a linear regression analysis gave a correlation of the form δ-*S* = 0.92 δ-*C*

σ is the Taft polar substituent parameter, cf. ref. 23.
†Taken from Table 1.
‡These values taken from ref. 5.
§This value is estimated from σ_1, cf. ref. 21.

− 26.5; however, the correlation coefficient was only 0.992. This correlation might well be improved by higher field measurements and the use of a narrow reference line for the spectra of the compounds that were not available to us. The slope of the line is only about 30% of the corresponding line from δ-*O* vs. δ-*C*, and, while the slope of this line has been suggested to be related to a function of the oxygen bonding orbitals (19), it is much less certain which orbitals would be involved in the bonding of a sulphone (a complex functionality) as compared to an ether (a simple functionality). However, it does appear that the sulphone sulphur atom in dialkyl sulphones is affected by changes of carbon atoms in the alkyl chains in a similar manner as is a carbon atom in an alkane, and thus substituent parameters based on the Lindeman–Adams approach (13) could be used to estimate approximate sulphur-33 chemical shifts in dialkyl sulphones. More examples are required to confirm this and will be the subject of further work.

In contrast to the simple dialkyl sulphones, the introduction of polar substituents in the side chain led to resonances at different values. Entries 4–12 in Table 1 contain haloalkyl or arylalkyl side chains. Regression analysis of the data for a plot of δ-*S* vs. δ-*C* yielded a line of slope 0.762 and a correlation coefficient of 0.909. No similar correlations were obviously possible for the remaining entries in the table, but it should be noted that some of the δ-*C* values were calculated and there will be uncertainties in these in the case of more complex structures.

Since we have shown that a plot of δ-*S* vs. δ-*C* for sulphones and analogous carbon compounds produces a straight line for simple dialkyl compounds, and other workers have shown a similar correlation for ethers (19), it seemed reasonable to investigate a correlation of δ-*S* vs. δ-*O* for simple dialkyl sulphones and ethers. Using the data for the same five dialkyl sulphones detailed above together with the corresponding data for ethers (19), a linear correlation was obtained with slope of 0.29 and a correlation coefficient of 0.991.

In addition to the above correlations between chemical shifts, we have also compared the sulphur-33 chemical shifts with a standard parameter that correlates electronic effects of substituents. Such Hammett-type correlations have been reported on for carbon-13 nuclei, in general concentrating on the study of substituted aromatic compounds (20, 21). Relatively few studies on aliphatic compounds appear to have been made (22); these have focused on the Taft polar substituent constant, σ* (23). We have examined similar correlations for both the sulphur-33 and carbon-13 resonances with σ* for the compounds from the first eight entries in Table 1, together with some values taken from the literature; these are presented in Table 3. Linear regression analysis of entries 1–5 produced an equation of the form $\delta\text{-}S = -155\,\sigma^* - 13.3$ with a correlation coefficient (r) of 0.967. Similar treatment of entries 6–10 gave $\delta\text{-}S = 8.78\,\sigma^* - 18.0$ ($r = 0.991$). Analogous treatments of the carbon chemical shifts and σ* gave $\delta\text{-}C = -160\,\sigma^* + 14.7$ ($r = 0.930$) and $\delta\text{-}C = 10.2\,\sigma^* + 18.6$ ($r = 0.951$), respectively.

The correlations between δ-*S* and δ-*C* or δ-*O* are superior to the correlations between δ-*S* or δ-*C* and σ*, but this is perhaps to be expected since in the former case correlations are being made between similar parameters whereas in the latter the correlation is between a chemical shift and a parameter derived from acid equilibrium constants. As has been mentioned previously (21), it may be unwise to attempt correlations between chemical shifts and reactivity of molecules. However, there does seem to be a better correlation between δ-*S* and σ* compared to δ-*C* vs. σ*, which may be indicative of the more polar nature of the sulphonyl group. Further work is required to substantiate this, but the results presented in the present work do offer three alternative approaches of some practical value for the prediction of the chemical shift of the sulphur-33 nucleus in a substantial range of sulphones.

Experimental

Spectroscopy

The sulphur-33 nuclear magnetic resonance spectra reported were obtained using a Nicolet 360 NB nmr spectrometer, coupled to an Oxford Instruments superconducting magnet and a Nicolet 1280 data acquisition system. The spectrometer was operated at a frequency of 27.716172 MHz with quadrature detection, a total sweep width of 5000 Hz, and a pulse width of 35 μs (90° pulse) with a pulse delay of 1 s between pulses. A delay of approximately 200 μs was used between the pulse and acquisition to minimize the effects of acoustic ringing, and hence a rolling base line; the spectrum was collected over 819.2 ms (acquisition time) and stored using 16K data points. The probe temperature was 20 ± 1°C and typically 500–10 000 transients were collected; a Butterworth filter was used for all measurements. The deuterium resonance of the solvent was used both for locking and shimming the spectrometer.

An external standard of 5 *M* ammonium sulphate in water was used to measure chemical shift values, the absolute frequency of which was measured before and after each series of runs, and was found to be invariant. Samples were run in regular 10-mm diameter tubes, in

$CDCl_3$ solutions, and had a concentration of 100–500 mg of sample per 2 mL of solvent. Chemical shift values are reported with an uncertainty of ±1%. Proton spin decoupling was not used.

Preparation of the sulphones

The sulphones in Table 1, entries 1–3, 8, 10, 13, and 27, were either commercially available or were prepared by oxidation of the corresponding sulphide using H_2O_2 in methanol containing ammonium molybdate (24). Those from entries 4–7, 15, 21, 23, 24, and 28 were available from previous work (11, 12, 25). All other compounds were prepared by literature procedures and their purities were checked using both nmr spectroscopy and comparison of melting points with the reported values (26–29).

Acknowledgements

All sulphur-33 nmr spectra were obtained at the Atlantic Regional Magnetic Resonance Centre in Halifax, N.S. and we are grateful to Mr. Bruce MacDonald for collecting these. We are also grateful to NSERC (Canada) and to Dalhousie University for financial support, and one of us (J.H.) is most appreciative of the award of an I. W. Killam Memorial Scholarship.

The metabolites produced in liquid culture by the Ascomycetous fungus *Gremmeniella abietina* (Lagerb.) Morelet, the causative agent of Scleroderris canker in pines, have been investigated. The major metabolite, which we have named sclerodin, is (−)-4,7-dihydroxy-2,3,3,9-tetramethyl-2,3-dihydronaphtho[1,2-*b*]furan-5,6-dicarboxylic anhydride (**1**), the enantiomer of the so-called "naphthalic anhydride from atrovenetin". Several highly colored compounds, including the enantiomer of atrovenetinone (**3**), the blue compound **6**, the red acenaphthenequinone derivative **8** (sclerodione), and the yellow 8-hydroxysclerodin (**12**) were also obtained. The blue compound **6**, named Scleroderris blue, has been prepared from **3**, and sclerodione (**8**) has been transformed into sclerodin (**1**).

WILLIAM A. AYER, YUMIKO HOYANO, M. SOLEDADE PEDRAS et IAN VAN ALTENA. Can. J. Chem. **64**, 1585 (1986).

On a étudié les métabolites qui sont produits dans un milieu du culture liquide par les champignons Ascomycetous *Gremmeniella abietina* (Lagerb.) Morelet, les agents qui causent la nécrose de Scleroderris dans les pins. Le métabolite principal, que l'on a appelé sclérodine, est l'anhydride de l'acide (−)-dihydroxy-4,7 tétraméthyl-2,3,3,9 dihydro-2,3 naphto[1,2-*b*]furanne dicarboxylique-5,6 (**1**), l'énantiomère du produit appelé «anhydride naphtalique de l'atrovénétine». On a aussi obtenu plusieurs composés fortement colorés, comme l'énantiomère de l'atrovénétinone (**3**), le composé bleu (**6**), le dérivé rouge de l'acénaphtènequinone (**8**, sclérodione) et l'hydroxy-8 sclérodine (**12**) qui est jaune. On a préparé le composé bleu (**6**), que l'on a dénommé bleu de Scléroderris, à partir du composé **3**; par ailleurs, on a transformé la sclérodione (**8**) en sclérodine (**1**).

[Traduit par la revue]

Introduction

The Ascomycetous fungus *Gremmeniella abietina* (Lagerb.) Morelet (= *Scleroderris lagerbergii*) is a virulent pathogen of pine trees in many parts of the world, causing defoliation, cankers, and mortality.[2] In North America the disease caused by this fungus, commonly known as *Scleroderris* canker, is regarded as one of the most serious tree nursery and reforestation diseases. The disease is also prevalent in Europe, where it is known as Brunchorstia dieback, and in Japan. We felt that an investigation of the metabolites produced when the fungus is grown in liquid culture might lead to identification of the compounds responsible for symptom expression and we now report the structures of the major metabolites.

Gremmeniella abietina was grown at 16–17°C on a medium of 10% V-8 juice containing 1% added glucose (3), either in still culture or in a stirred and aerated fermentation apparatus. Best yields of metabolites were obtained from the still cultures. Extraction (CH_2Cl_2) of the filtered culture broth yielded ca. 0.05 g/L of crude metabolites, while Soxhlet extraction (CH_2Cl_2) of the mycelium provided substantially more material (ca. 0.45 g from the mycelium of a 1-L growth).

The thin-layer chromatogram of the crude metabolites displayed a colorful array of compounds. These compounds were separated by silica gel chromatography to give, in order of elution, a blue compound, a colorless strongly fluorescent compound, a red compound, a dark burgundy compound, a yellow compound, and a mixture of brownish materials from which two compounds have been identified.

The colorless, strongly fluorescent compound, mp 256–257°C, $C_{18}H_{16}O_6$, shows carbonyl absorption in the ir at 1705 and 1665 cm^{-1} and readily forms a diacetyl derivative absorbing at 1778, 1760, and 1724 cm^{-1}. The ^1H nmr spectrum (Table 1) shows clearly defined signals for all sixteen protons: 2 methyl singlets, a secondary methyl doublet coupled to a methine hydrogen *geminal* to oxygen, an aromatic methyl, an aromatic hydrogen, and two H-bonded phenolic hydrogens.

The ^{13}C nmr spectrum shows five carbon singlets in the region δ 150–170 (three aromatic carbons bearing oxygen and two high-field carbonyls), six aromatic carbon singlets (δ 93–150), an aromatic carbon doublet (δ 117), and six aliphatic carbons (four methyl carbons, a secondary carbon bonded to oxygen (δ 92), and a quaternary carbon). A search of the literature revealed that this compound, for which we propose the name sclerodin, is the anhydride **1**, its diacetyl derivative being compound **1***a*. The enantiomer of sclerodin (**1**) was first obtained by oxidation of atrovenetin **2** (4) and later was isolated from cultures of *Penicillium herquei* (5) and subsequently from other fungi (6–8). Comparison of sclerodin (**1***a*) with an authentic sample of the enantiomer verified the identity in all respects other than optical rotation.[3]

Atrovenetin (**2**) has been shown to have the *R* configuration at C-2′ (9) and it provides the dextrorotatory form of **1** on oxidation (4). The absolution configuration of the (+) form of the anhydride has also been determined directly by X-ray crystallography (8). This is the first time the levorotatory form of the anhydride **1** has been isolated from natural sources. The (+) form has been obtained from *Penicillium herquei* (5), *Roesleria pallida* (6), *Roesleria hypogea*,[4] and *Aspergillus silvaticus* (8). The rotation of the anhydride isolated from *Fusicoccum putrefaciens* (7) was not reported.

The dark burgundy compound, which causes a green discoloration on contact with the skin and a blue-green discoloration of paper, was shown by high resolution electron impact mass spectrometry (eims) and chemical ionization mass spec-

[1]Preliminary accounts of parts of this work have already appeared (1, 2).

[2]For a good summary of all aspects of this disease see the book cited in ref. 2. This publication gives the proceedings of an international symposium on Scleroderris canker on conifers held in Syracuse, U.S.A., in 1983.

[3]We thank Professor L. C. Vining for kindly providing authentic samples of the enantiomer of **1** and of the ethanolate of atrovenetinone.

[4]H. Musso, personal communication.

TABLE 1. ^{1}H nuclear magnetic resonance data for metabolites and derivatives of *G. abietina*[a]

Compound	Signal (δ) (multiplicity, *J*(Hz))							
	H-4′(5′)	H-1′	H-5′(4′)	$ArCH_3$	H-2′	H-8	OH	Other

[c]In DMSO-d_6.

trometry (cims) to possess the molecular formula $C_{19}H_{16}O_6$. The ^{1}H nmr spectrum (Table 1) was very similar to that of the anhydride **1**. The ^{13}C nmr spectrum, determined in DMSO-d_6, shows carbonyl peaks at δ 198 and 196 (those of the anhydride **1** appear at ~δ 166) and a signal at δ 88, which is not present in the spectrum of the anhydride. When the spectrum is determined in CD_2Cl_2, additional carbonyl signals appear near δ 176 and the intensity of the signal at δ 88 is diminished. These data suggested that the compound is the triketone **3**, present mainly in DMSO as the hydrate **4***a*. The enantiomer of this compound, atrovenetinone, has previously been prepared (5) by oxidation of atrovenetin (**2**) with benzoquinone. Atrovenetinone was characterized as its crystalline ethanolate. Crystallization of the dark burgundy compound from ethanol provided pale yellow needles of **4***b*, which showed the same spectral characteristics (^{1}H nmr, ir) and tlc behavior as an authentic sample of the enantiomer.[2] Aerial oxidation of **4***a* gave the levorotatory anhydride, **1**, confirming the absolute stereochemistry at C-2′. It was found that when a solution of compound **3** was painted on freshly peeled pine, the characteristic blue-green color of *Scleroderris* infected wood developed.

When the solvent system used for the chromatographic separation of **3** contained acetone, the acetone adduct **5***a* (as a mixture of epimers) was obtained instead of compound **3**. Compound **5***a*, which readily forms a diacetyl derivative **5***b*, is an artifact formed during separation since it is not present in the original extract. Treatment of **3** with acetone in the presence of a catalytic amount of acetic acid readily gives **5***a*.

The blue compound proved rather unstable and difficult to purify, but after repeated silica gel chromatography and crystallization from ethanol, a deep blue crystalline material was obtained. Efforts to determine the molecular formula of this compound, which we believe to be responsible, at least in part, for the bluish-green coloration of the wood of *Scleroderris* infected pine, were initially unsuccessful. The highest mass peak in the eims appeared at *m/z* 337 and corresponded to the ion $C_{19}H_{15}NO_5$. Another prominent peak occurred at *m/z* 326 ($C_{19}H_{18}O_5$). The cims did not afford a recognizable parent ion. However, field desorption mass spectrometry[5] suggested a molecular weight of 663 amu. Addition of the two high mass eims fragments then suggested that the molecular formula is $C_{38}H_{33}NO_{10}$ (mw 663). The ^{1}H nmr spectrum is similar to that of the anhydride **1** and the triketone hydrate **4***a* with most signals doubled. When a solution of the blue compound in $CHCl_3$ is allowed to stand in the presence of air, sclerodin (**1**) is obtained. The ultraviolet–visible spectrum ($CHCl_3$) of the blue compound shows λ_{max} 268, 368, 405 (sh), and 608 nm. Narasimhachari and Vining (5) have previously suggested that the characteristic green pigment of *Penicillium herquei* might be formed by a ninhydrin-like reaction between atrovenetinone (**3**) and amino acids, but they were unable to completely characterize the pigment. In our hands, treatment of a buffered solution of glycine with atrovenetinone (**3**) in aqueous dioxane (10) and purification of the product by flash chromatography gave blue crystalline material identical in all respects with the compound isolated from *G. abietina*. The pigment, for which we suggest the trivial name Scleroderris blue, thus possesses structure **6**. Scleroderris blue (**6**) changes color with changing pH: in basic solution it appears green whereas in acidic solution it is deep blue. Since the uv spectrum of **6** is almost identical with that reported (5) for the green pigment of *P. herquei*, we believe that this pigment also has structure **6**.

The red compound, mp 210–212°C, $C_{19}H_{16}O_5$, has one

oxygen less than the anhydride **1**. The ^1H nmr spectrum (Table 1) is very similar to that of **1** but the ^{13}C nmr spectrum shows ketonic carbonyls at δ 189.8 and 186.3. The ir spectrum shows carbonyl absorption at 1714 and 1690 cm^{-1}. This compound readily forms a diacetyl derivative, the ir spectrum of which shows carbonyl absorption at 1780 and 1740 cm^{-1}. Acenaphthenequinone (**1**) absorbs at 1785 and 1724 cm^{-1} (11). This evidence suggested that the red compound, for which we propose the name sclerodione, has structure **8** (the diacetate is **8***a*). The structure was confirmed by alkaline peroxide oxidation of **8** to give, after acidification, the anhydride **1** (migration "a" in **10**), along with the lactone **9**, the product of Dakin oxidation (migration "b" in **10**) followed by peroxide cleavage of the resulting α-ketoacid. The orientation of the lactone ring in **9** was proven by methylation (CH_2N_2) to give **9***a*. The ether **9***a* shows two distinct methoxyl signals in the ^1H nmr, one at δ 4.17 and one at δ 4.50. The latter signal must be deshielded by the lactone carbonyl group. Irradiation of the methoxyl protons at δ 4.17 causes an 8.8% nOe (nuclear Overhauser effect) enhancement of the aromatic proton, whereas irradiation of the δ 4.50 methoxyl signal causes no detectable nOe enhancement. To the best of our knowledge, sclerodione (**8**) represents the first acenaphthenquinone isolated from natural sources. Biosynthetic studies (12) have shown that the naturally occurring phenalenones of the atrovenetrin (**2**) type are prenylated heptaketides formed from a heptaketide chain folded as in **11**. In a subsequent paper in this series[6] we will show that the *G. abietina* metabolites are formed by this pathway and that it is C-2 of **11** which is lost in the formation of both **1** and sclerodione (**8**).

The more polar components of the *G. abietina* extract (brownish streak on tlc) proved difficult to purify. However, after the crude material was treated with ethereal diazomethane, a bright yellow crystalline compound $C_{19}H_{18}O_7$ was isolated by ptlc. The compound is assigned structure **12***a* on the basis of the following observations. Its ^1H nmr spectrum (Table 1) is similar to that of the anhydride **1** except that it lacks the C-8 aromatic proton signal and it shows an aromatic methoxyl at δ 4.10. The ^{13}C nmr spectrum is similar to that of **1** except that the signal for C-8 in **1** (d, δ 117.4) is replaced by a singlet in the δ 150 ppm region and the aromatic methyl signal is shifted upfield to δ 15.1 (δ 23.6 in **1**) as is expected for a methyl *ortho* to a phenolic OH

[6]W. A. Ayer, M. S. Pedras, and D. E. Ward, manuscript in preparation.

(13). When the ^1H nmr spectrum is determined in pyridine-d_5, the aromatic methyl is shifted downfield by 0.26 ppm, indicating the hydroxyl at C-8 is not methylated (14). Since the methoxyl CH_3 did not experience a pyridine-induced shift, it is believed to be located at C-4 rather than C-9, although this is not rigorously established. Treatment of **12***a* with ethereal diazomethane furnished the trimethyl ether **12***b*. Trimethyl ether **12***b* was also isolated from the ptlc of the diazomethane treated polar compounds. It is presumed that compound **12** (8-hydroxysclerodin) is produced by the fungus and that **12***a* is formed during the diazomethane treatment. It is worthwhile noting that the anhydride carbonyls in the monomethyl ether **12***a* absorb at 1750 and 1685 cm^{-1}, while in the trimethyl ether they absorb at 1760 and 1725 cm^{-1}. In the anhydride **1**, where both carbonyls are H-bonded, the carbonyl absorption appears at 1705 and 1665 cm^{-1}.

Preliminary tests indicate that the crude metabolites of *G. abietina* cause symptoms (browning of needles) similar to those caused by the fungus in pine seedlings.[7] Biological testing of the individual compounds is being initiated. We feel that the greenish discoloration of the wood of pines suffering from Scleroderris canker may be due to the presence of the colored compounds described herein, particularly **6**, although we have not as yet attempted to isolate the compounds from diseased wood.

Experimental

All solvents except diethyl ether were distilled prior to use. ACS quality anhydrous diethyl ether was used without purification. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C. Pyridine was distilled from CaH_2 and stored over molecular sieves, acetic anhydride was dried over P_2O_5 and distilled from sodium acetate.

Analytical thin-layer chromatography (tlc) was carried out on glass microscope slides (75 × 25 or 75 × 50 mm) coated (ca 0.3 mm) with silica gel G (E. Merck, Darmstadt, or Terochem, Edmonton) containing 1% electronic phosphor (General Electric, Cleveland). Preparative thin-layer chromatography (ptlc) was carried out on glass plates (20 × 20 cm) coated (0.6 mm) with the same adsorbent. Materials were detected by visualization under an ultraviolet (uv) lamp (254 or 350 nm) or by spraying with a solution of vanillin (1%) in concentrated sulphuric acid. Flash chromatography (15) was performed using Merck Silica Gel 60 (40–63 μm). Small scale column chromatography was performed with Silica Gel 60 (<0.08 mm, Macherey Nagel, Dueren) whereas larger scale chromatography was carried out with Silica Gel 60 (0.05–0.2 mm, Macherey Nagel, Dueren).

High resolution mass spectra (hrms) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Chemical ionization mass spectra (cims) were recorded on an A.E.I. MS-9 spectrometer. Data are reported as *m/z* (relative intensity). Unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Infrared (ir) spectra were recorded on a Nicolet 7199 interferometer. Ultraviolet (uv) spectra were recorded on a Unicam SP 1700 ultraviolet spectrophotometer. ^1H nuclear magnetic resonance (^1H nmr) spectra were measured with a Varian HA-100 spectrometer, a Varian HA-100 spectrometer interfaced to a Digilab FTS/NMR-3 data system, a Brüker WH-200 spectrometer, or a Brüker WH-400 spectrometer. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Brüker HFX-90 spectrometer interfaced to a Nicolet 1085 computer, a Varian HA-100 spectrometer interfaced to a Digilab FTS/NMR-3 data system, or a Brüker WH-200 spectrometer. All nuclear magnetic resonance measurements employed tetramethylsilane (TMS) as an internal standard and are reported in ppm downfield from TMS (δ). Optical rotations were measured on a Perkin Elmer Model 141 polarimeter. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected.

Growth of Gremmeniella abietina *and isolation of metabolites*

Slant cultures of *Gremmeniella abietina* (strain C-699 or strain C-708, Canadian Forestry Service) were maintained on potato dextrose agar at 4°C. Two 250-mL shake cultures (10% filtered V-8 juice and 1% glucose medium) in 500-mL Erlenmeyer flasks were inoculated with one slant tube culture and the inoculum was gently shaken for 4 weeks at 15–17°C. Ten 2.8-L Fernbach flasks each containing 1 L of the same liquid medium were inoculated with ca. 50 mL each of an aqueous suspension of mycelium and the flasks were kept at 15–17°C for 4 weeks. The mycelium was separated by filtration through cheesecloth and the wet mycelium was extracted in a Soxhlet extractor with CH_2Cl_2 for 2 days. The broth was filtered again through a pad of Celite and the filtrate was extracted three times with CH_2Cl_2. The mycelium extract gave ~0.5 g/L of the crude metabolites while the broth extract gave ~0.05 g/L. Separation of the crude metabolites (mycelium) by flash chromatography (15) gave, in order of elution (solvent system $CHCl_3$:Skellysolve B:acetic acid (10:10:1)), fractions rich in a blue compound, a colorless, strongly fluorescent compound, a red compound, a dark burgundy compound, a yellow compound, and a mixture of brownish materials. The fractions were further purified as indicated for the individual components.

*Sclerodin (**1**)*

Sclerodin (**1**) was obtained after silica gel column chromatography (R_f 0.9 ($CHCl_3$:CH_3OH:acetic acid, 97:5:1)) and crystallization from 95% ethanol or CH_2Cl_2 – Skellysolve B, mp 256–257°C; $[\alpha]_D^{24}$ −72.6°C (*c* 1.34, $CHCl_3$); ir ($CHCl_3$ cast): 3100 (br), 1705, 1665, 1610, 1460, 1335, 1043, 870, 820 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr ($CDCl_3$) δ: 14.5, 20.7, 23.6, 25.6, 43.5, 92.1, 93.5, 97.3, 108.5, 117.2, 119.1, 135.4, 149.8, 164.9, 165.4, 166.0, 166.1; hrms, *m/z* calcd. for $C_{18}H_{16}O_6$ (M^+): 328.0948; found: 328.0944 (31), 313 (100). The ir and ^1H nmr spectra of sclerodin were identical with those of an authentic sample of the enantiomer.

*Diacetylsclerodin (**1**a)*

Sclerodin (**1**) was stirred in an excess of acetic anhydride and pyridine overnight at room temperature. The reaction mixture was evaporated to dryness. The pale yellow compound was recrystallized from chloroform – Skellysolve B, mp 178–180°C; $[\alpha]_D$ −32.5° (*c* 0.48, $CHCl_3$); ir ($CHCl_3$ cast): 1778, 1760, 1724, 1605, 1600 cm^{-1}; hrms, *m/z* calcd. for $C_{22}H_{20}O_8$: 412.1158; found: 412.1161 (10.5), 370 (26), 328 (64), 314 (26), 313 (100).

*Sclerodin dimethyl ether (**1**b)*

Sclerodin (**1**) (60 mg) in CH_2Cl_2 was treated with excess ethereal diazomethane for 12 h. After evaporation of the solvent, the residue was purified by chromatography (eluant benzene:acetone, 9:1) and crystallization (CH_2Cl_2 – Skellysolve B) to give the dimethyl ether **1***b*, mp 193–194°C; $[\alpha]_D$ −84.0° (*c* 0.42, $CHCl_3$); ir ($CHCl_3$): 1740, 1714, 1600, 1590, 1560 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr ($CDCl_3$): δ 14.0, 21.5, 24.0, 25.8, 43.9, 56.3, 62.6, 90.9, 100.6, 101.2, 110.7, 113.1, 125.1, 137.4, 147.3, 157.6, 157.8, 163.9, 164.3, 165.6; hrms, *m/z* calcd. for $C_{20}H_{20}O_6$: 356.1260; found: 356.1262 (55), 341 (100), 297 (19).

*Triketone (**3**) and triketone ethanolate (**4**b)*

The crude dark burgundy fraction was further purified by flash chromatography using ether:CH_2Cl_2 (4:1) as the eluant. Crystallization from acetone–benzene provided dark purple crystals of **3**, mp 220–222°C; ir (CH_2Cl_2 cast): 3390, 1720, 1634, 1605 cm^{-1}; ^1H nmr, see Table 1; hrms, *m/z* calcd. for $C_{19}H_{16}O_6$: 340.0947; found: 340.0942 (28), 327 (18), 312 (25), 297 (100), 269 (42). Crystallization of **3** from 95% ethanol gave pale yellow crystals of the ethanolate **4***b*, mp 223–226°C, identical (ir, ^1H nmr) with an authentic sample of atrovenetinone ethanolate. Because of the strong absorption of **3** in the visible, and because of the low solubility of **4***b* in ethanol, it was not possible to obtain meaningful $[\alpha]_D$ values for these substances.

*Acetone adduct of **3** (**5**a)*

Compound **5***a*, shown to be an artifact produced during isolation

[7] Y. Hiratsuka, Northern Forest Research Centre, Edmonton, personal communication.

when acetone was employed as an eluant, was prepared by stirring compound **3** (20 mg) in acetone (2 mL) containing acetic acid (10 drops) at room temperature for 2 h. The reaction was monitored by tlc until no compound **3** remained and then the product was isolated and purified by ptlc ($CHCl_3$:CH_3OH:acetic acid, 189:10:1) to give **5***a* (13 mg) as an amorphous solid; ir ($CHCl_3$ cast): 3400, 1730, 1710, 1635, 1605; uv (CH_3OH): λ_{max} (ε): 221 (33 000), 230 (27 000 shoulder), 252 (30 000 shoulder), 260 (41 000), 341 (15 000), 364 (11 000 shoulder) nm; ^1H nmr ($CDCl_3$), δ: 13.32, 12.80 (phenolic OH's), 6.76 (q, J = 1 Hz, H-8), 4.64 (q, J = 6.5 Hz, H-2′), 3.70 (bs, OH), 3.30 (s, $COCH_2$), 2.78 (d, 1 Hz, $ArCH_3$), 2.23 (s, $COCH_3$), 1.52 (s, H-5′ (4′)), 1.46 (d, J = 6.5 Hz, H-1′), 1.30 (s, H-4′ (4′)); hrms, m/z calcd. for $C_{22}H_{22}O_7$: 398.1368; found: 398.1364 (45); 383 (4), 355 (28), 313 (100), 297 (28), 157 (14).

Scleroderris blue (6)

Scleroderris blue (**6**), the least polar of the colored compounds, was isolated from the early dark blue colored fractions of the flash chromatography by ptlc over silica gel (double elution, eluant Skellysolve B:acetone:acetic acid (15:4:1)). Crystallization from ethanol gave tiny deep blue crystals, mp >300°C; ir ($CHCl_3$ cast): 2930, 2858, 1730, 1608, 1550, 1485, 1440, 1384, 1335, 1308; uv ($CHCl_3$) λ_{max} (ε): 268 (30 000), 368 (23 000), 405 (sh), 608 (18 000); ^1H nmr ($CDCl_3$),[8] δ: 1.12 (6H, bd), 1.18 (6H, bs), 1.35 (6H, bs), 2.73 (6H, bs), 4.58 (2H, m), 6.80 (2H, bs), 13.5 (2H, bs), 14.5 (2H, bs); ^1H nmr (pyridine-d_5),[8] δ: 1.20 (6H, bs), 1.36 (6H, bd), 1.41 (6H, bs), 2.74 (6H, bs), 4.55 (2H, m), 6.92 (2H, bs); molecular weight: 663 amu (determined by field desorption mass spectrometry).

Preparation of Scleroderris blue (6) from triketone 3

Triketone **3** (8.7 mg) was dissolved in dioxane (2 mL). Glycine (15 mg) in phosphate buffer (pH 7, 1 mL) was added and the reaction mixture was heated at 60°C overnight. The reaction mixture was concentrated and then extracted with CH_2Cl_2. The residue was purified by ptlc ($CHCl_3$: acetic acid, 99:1) to give compound **6** (2 mg) identical in all respects (tlc, uv, ir, ms) with naturally occurring Scleroderris blue.

Aerial oxidation of Scleroderris blue

A small amount of compound **6** was dissolved in dioxane and a drop of 6 *N* HCl was added. After a few minutes of shaking, the blue color disappeared. The solution was diluted with water and extracted with methylene chloride. The organic layer was dried and evaporated to give a white solid, which proved to be identical with sclerodin **1** (ir, tlc). The anhydride **1** was also obtained when a chloroform solution of **6** was left at room temperature for several days.

Sclerodione (8)

Sclerodione has an R_f on tlc only slightly less than the triketone **3** and is often difficult to observe. It may be visualized on tlc by spraying with vanillin – sulfuric acid to give a distinct purple spot. It may be separated by ptlc (double elution) using $CHCl_3$:Skellysolve B:acetic acid (14:5:1) as the eluant. Crystallization from CH_2Cl_2 – Skellysolve B gives bright red crystals, mp 210–212°C; $[\alpha]_D$ −115.3° (*c* 0.17, $CHCl_3$); ir ($CHCl_3$ cast): 3480, 1714, 1690, 1625, 1610 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr ($CDCl_3$), δ: 14.5, 21.0, 22.0, 25.8, 43.3, 92.0, 106.2, 107.2, 109.2, 117.4, 119.6, 146.4, 150.9, 154.3, 154.9, 164.3, 186.3, 189.8; hrms, m/z calcd. for $C_{18}H_{16}O_5$: 312.0998; found: 312.0997 (50), 297 (100), 284 (6), 269 (55).

Diacetylsclerodione (8a)

Sclerodione (5 mg) was treated with acetic anhydride and pyridine at room temperature overnight. Evaporation and chromatography of the residue on silica gel (eluant $CHCl_3$) gave diacetylsclerodione (**8***a*) as an oil; ir (film): 1780, 1740, 1710, 1610, 1590 cm^{-1}; ^1H nmr, see Table 1; hrms, m/z calcd. for $C_{22}H_{20}O_7$: 296.1202; found: 396.1214 (16), 354 (25), 312 (100), 297 (92), 269 (22).

Oxidation of sclerodione (8)

Sclerodione (**8**, 10 mg) was dissolved in dioxane (3 mL). Potassium hydroxide (50 mg) in methanol (2 mL) was added followed by 30% hydrogen peroxide (0.1 mL). The reaction mixture was heated at 50°C for 10 min, cooled and acidified with dilute H_2SO_4, then extracted with CH_2Cl_2. The residue (6 mg) was chromatographed on silica gel (5 g), eluting with Skellysolve B:$CHCl_3$ (1:1) containing 0.1% acetic acid. Sclerodin (**1**) (2 mg) was eluted first, then the lactone **9** (1.4 mg); ir ($CHCl_3$ cast): 1726, 1660, 1640, 1620 cm^{-1}; ^1H nmr, see Table 1; hrms, m/z calcd. for $C_{17}H_{16}O_5$: 300.0998; found: 300.0997 (60), 285 (100), 267 (10), 257 (9). The dimethyl ether **9***a* was prepared by treating compound **9** with ethereal diazomethane.

8-Hydroxysclerodin methyl ether (12a) and 8-hydroxysclerodin trimethyl ether (12b)

A portion (100 mg) of the brownish, polar fraction obtained from the extract by flash chromatography was dissolved in ether and treated with excess ethereal diazomethane for 1 h. The residue left after removal of the solvent was purified by ptlc (eluant, ether: Skellysolve B : acetic acid (75:25:1)) to give 8-hydroxysclerodin methyl ether (**12***a*, 10 mg) as yellow crystals (from ether – Skellysolve B), mp 213–214°C; $[\alpha]_D$ −16° (*c*, 0.11, $CHCl_3$); ir ($CHCl_3$ cast): 3400, 1750, 1685, 1600 cm^{-1}; uv (MeOH) λ_{max} (ε): 211 (28 400), 234 (17 300), 257 (26 900), 309 (3280), 356 (8360), 396 (10 700 sh), 409 (11 000) nm; ^1H nmr: see Table 1; hrms, m/z calcd. for $C_{19}H_{18}O_7$: 358.1052; found: 358.1064 (76), 343 (100).

The less polar trimethyl ether **12***b* (2 mg) was also isolated from the ptlc. It could be prepared from **12***a* by treatment with diazomethane. Compound **12***b* was obtained as a glassy solid: ir ($CHCl_3$ cast): 1760, 1725, 1575 cm^{-1}; ^1H nmr, see Table 1; hrms, m/z calcd. for $C_{21}H_{22}O_7$: 386.1366; found: 386.1366 (97), 371 (100), 353 (11), 343 (9), 327 (17).

[8]Most of the peaks are poorly resolved overlapping signals.

Alternaria molds produce numerous mycotoxins including many α-dibenzopyrones such as alternariol (AOH) and related polyketides. AOH, presumed to be the initial α-dibenzopyrone produced, has for 20 years been considered to be biosynthesized from a single polyketide chain in a single step reaction. The present study presents evidence that the reaction may proceed through an intermediate, norlichexanthone (NLX). Bond cleavage and rearrangement of NLX to form AOH may be similar to aflatoxin B_1 formation from sterigmatocystin. The 2-D INADEQUATE experiment was used to assign the ^{13}C spectrum of AOH and to distinguish between possible mechanisms by which AOH may be synthesized from 1-^{13}C and 2-^{13}C acetates via NLX.

E. E. STINSON, W. B. WISE, R. A. MOREAU, A. J. JUREWICZ et P. E. PFEFFER. Can. J. Chem. **64**, 1590 (1986).

Les moisissures *Alternaria* produisent diverses mycotoxines, y compris plusieurs α-dibenzopyrones, comme l'alternariol (AOH) et des polycétides apparentés. Il est supposé que le AOH est l'α-dibanzopyrone qui est produite initialement et, depuis plus de 20 ans, on a considéré que ce composé est produit par une biosynthèse impliquant une seule chaîne polycétide réagissant au cours d'une seule réaction. Dans le présent travail, on présente des données suggérant que le réaction procède peut-être par le biais d'un intermédiaire, la norlichexanthone (NLX). Il est possible que le bris de la liaison et la transposition de la NLX pour former le AOH se produisent d'une façon semblable à ce qui se produit lors de la formation de l'aflotoxine B_1 à partir de la stérigmatocystine. On a fait appel à des expériences de 2-D INADEQUATE pour attribuer le spectre rmn du ^{13}C du AOH et pour distinguer entre les mécanismes possibles pour la synthèse du AOH à partir d'acétates marqués au ^{13}C dans les positions 1 et 2 et par le biais de la NLX.

[Traduit par la revue]

The *Alternaria*, a group of molds frequently involved in food spoilage, produce a wide variety of metabolites including the mycotoxins alternariol (AOH) (**1**) and alternariol monomethyl ether (AME) (**2**). These have been identified in food products contaminated by *Alternaria* (1). We became interested in the biosynthesis of these substances during the course of an investigation into the structure of fungal polyketide synthetases. The soluble enzyme responsible for the production of AOH seemed a good candidate for this study because of what then appeared to be the direct nature of the reaction. The synthesis of AOH had been reported to involve assembling a heptaketide chain, aromatizing, and release of the AOH in a single step. The pattern given for assembly of AOH and AME from 1-^{14}C acetate is shown in **3** (2, 4). A procedure was given for partial purification of the enzyme. The resulting solution also possessed O-methyltransferase activity capable of forming AME from AOH by a transmethylation reaction involving S-adenosyl methionine (SAM) (2, 3).

We report results of the present study, which indicate that NLX is a precursor of AOH.

Results and discussion

During our investigation, repeated attempts to duplicate the purification procedure for AOH synthetase were unsuccessful (5, 6). Using a cell-free extract prepared from a high AOH-producing strain, NRRL 6434, of *A. tenuis*, the species employed in the earlier biosynthetic studies, no production of AOH could be confirmed upon addition of ^{14}C labeled Ac-CoA and Mal-CoA to the cell-free extract.

However, we observed incorporation of ^{14}C Ac-CoA and Mal-CoA into materials on numerous zones of the tlc (thin-layer chromatography) plate, with heavy ^{14}C incorporation into a zone immediately above AOH. The same cell-free extract also catalyzed the formation of large amounts of ^{14}C AME in the presence of AOH and ^{14}C SAM (as Gatenbeck had observed for his preparation), although whole cells of this strain of the fungus produce mainly AOH, not AME. Our inability to confirm the formation of AOH led us to consider the possibility that the previous group may actually have reported the formation of some other component that could not be separated from AOH by the methods then available.

Our detection method for AOH used the high resolution power of tlc and the automated linear analyzer for ^{14}C detection instead of the less selective paper chromatography used by the previous group (2).

Also, the previous group relied upon repeated recrystallization of product, which had been diluted with a large excess of exogenous AOH, to constant specific activity as confirmation that the counts were in the AOH rather than in some impurity. They used H_2O–EtOH mixtures as solvent, although it is known that recrystallization from solvent pairs often leads to impure material. In fact, it had been reported previously that recrys-

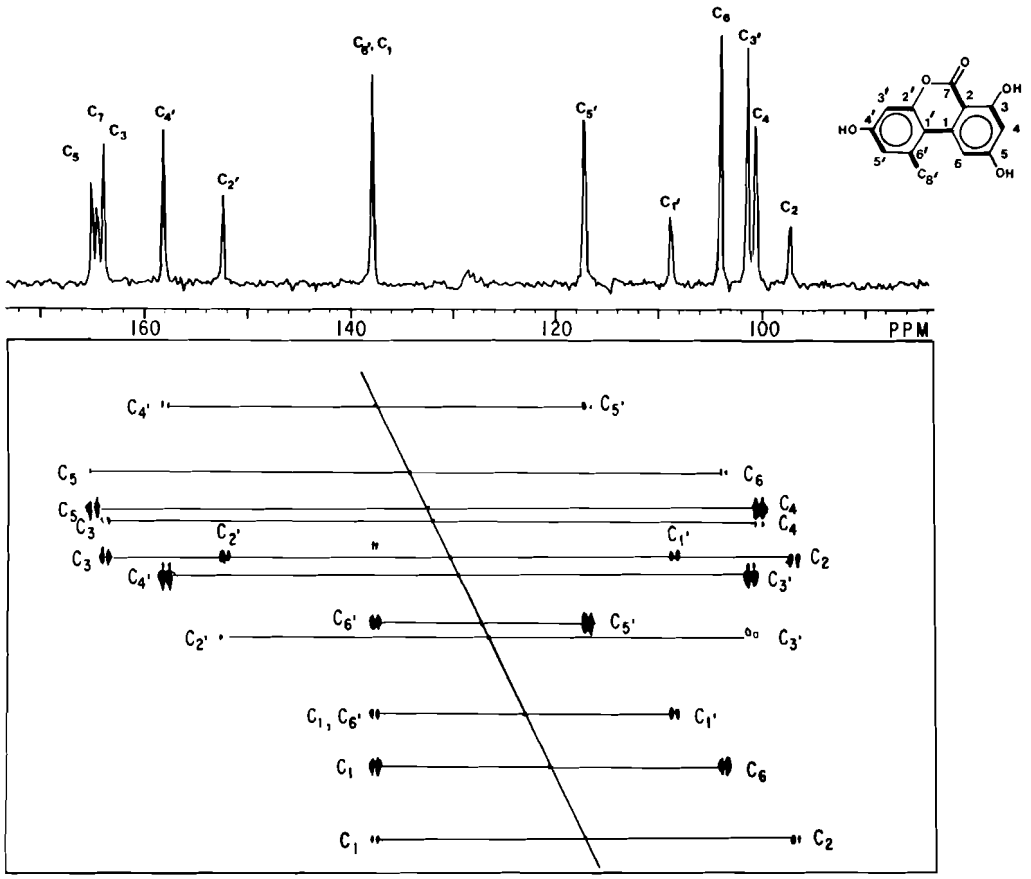

FIG. 1. 100-MHz ^{13}C 2-D INADEQUATE contour plot for a 0.95 *M* solution of alternariol (biosynthetically prepared from equal amounts of [1-^{13}C] and [2-^{13}C] acetates). Total acquisition time, 84 h. 1-D nmr shown above.

tallization from this solvent mixture (H_2O–EtOH) failed to remove a colored impurity from AOH (7). This was also our experience, as tlc examination disclosed that careful precipitation of AOH by the described method actually resulted in retention of a number of congeners.

An alternative mechanism for AOH biosynthesis has been suggested (1), which would proceed through the rearrangement of xanthone, in analogy to a well-documented step in aflatoxin biosynthesis (8). This notion is strongly supported by the recent isolation from *Penicillium notatum* of lichenxanthone (**4**) as a congener of AME (9). The same general mechanism, oxidative cleavage of an aromatic ring followed by rotation of the fragmented aryl structure, has also been reported in the formation of the α-pyrone structure of chartreusin in the *Streptomycetae* (10). These and other considerations led us to consider norlichexanthone, NLX (**5**), as a possible precursor.

Incorporation of norlichexanthone (NLX)

Particular care was taken with the purification procedure used to establish incorporation of norlichexanthone into AOH since it appears that the radioactivity measured in the earlier work (2, 3) may not have been associated with alternariol.

^{14}C-labeled norlichexanthone was added to a stationary culture of *Alternaria tenuis* shortly after vigorous growth had ceased (Day 10). Previous experiments in our laboratory had shown that this was the period for optimal incorporation of ^{14}C-labeled acetate into AOH. The mycelia were harvested after a suitable incubation period (Days 10–12), and extracted with ethyl acetate. AOH was isolated from this mycelial extract. Two different solvent systems were used in succession for flash chromatography, and a normal and a reverse phase system were used for final purification by preparative tlc. Purification of the metabolite to constant specific radioactivity by these procedures indicated 3.8% incorporation of NLX into AOH in vivo.

^{13}C spectral assignment of alternariol

As a prerequisite for investigation of the biosynthetic pathway to the production of AOH via NLX, it was necessary to establish an unambiguous assignment of the complete ^{13}C spectrum of this molecule. The ^{13}C shifts of alternariol have previously been only partly assigned (12), but we were able to make a full assignment by means of 2-D ^{13}C INADEQUATE nmr (13). To this end, we used alternariol produced by *Alternaria tenuis* grown on a medium supplemented with 1-^{13}C and 2-^{13}C acetate in equal amounts (Fig. 1). It was anticipated that ^{13}C–^{13}C coupling would be observed with greater probability (and thus the signal enhancement would be greater) between C1 and C2 of each pair of adjacent acetate residues, beginning at C6′–C5′. A similar phenomenon has been observed with 1-D ^{13}C nmr (14). The starting point in assigning the signals from the aromatic carbons was the signal of the ring carbon C6′ (138.3 ppm) directly bonded to the C8′ methyl group at 25.3 ppm. This signal was identified by the proton coupled ^{13}C spectra (not shown), which showed a quartet (5.8 Hz) at this location. In addition, long range 3-bond coupling was observed from the CH_3 group to the signal with split resonances (due to this geminal proton; 160 Hz) centered at 117.6 ppm, which was thus identified as C5′.

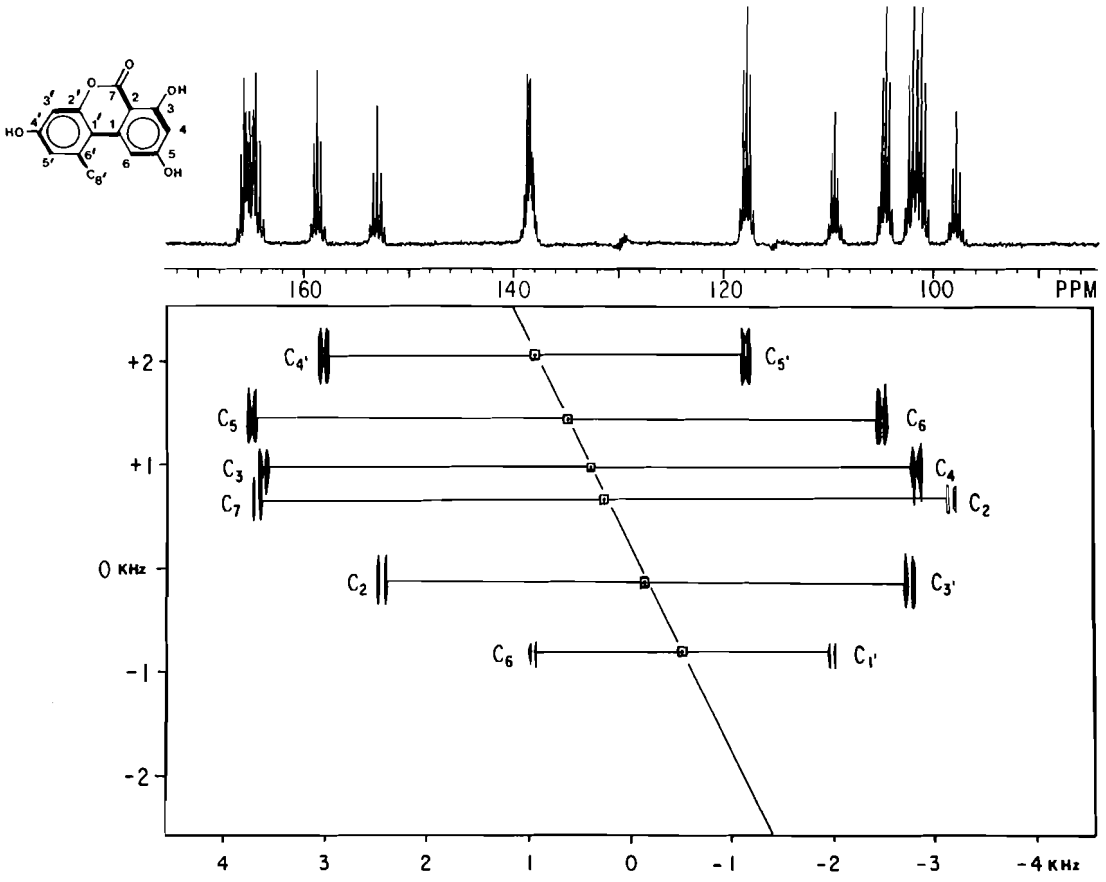

FIG. 2. 100-MHz ^{13}C 2-D INADEQUATE contour plot for a 0.47 *M* solution of alternariol (biosynthetically prepared from [1,2-^{13}C] acetate). Only the 5-kHz region in the vicinity of $F_1 = 0$ is shown. Total acquisition time from this spectrum was 38 h. 1-D nmr shown above.

The resulting 2-D contour plot (Fig. 1) of connectivities (one-dimensional spectrum displayed above) shows the expected lower intensity of response for connectivities between those carbon pairs originating from intact acetate units. The dynamic range difference between these and the enriched ^{13}C–^{13}C coupled carbons occurring at the junction between adjacent acetate units is not large enough to pose any observational difficulty and thus we were able to proceed with a full assignment of carbon signals from this single experiment. The longer spin-lattice relaxation times of the quaternary carbon pairs (C2′–C1′, C6′–C1′, C1–C2) contributed to the lower spectral responses for these resonances.

Possible mechanism for the biosynthesis of alternariol

Table 1 lists the full spectral assignment for alternariol.

Utilizing these assignments, an nmr experiment that examined AOH enriched using 2-^{13}C acetate established that the biosynthetic pathway for AOH starts at the C8′ and proceeds through the molecule with uniform enrichment of ^{13}C at alternate carbons located at 8′, 5′, 3′, 1′, 6, 4, and 2. This experiment agrees with the alternating pattern found with 1-^{14}C acetate (4) and presented in **3**.

To determine whether the biosynthesis of AOH involves cleavage of acetate units, we examined the nmr spectra of AOH synthesized by *Alternaria tenuis* when grown on medium containing 1,2-^{13}C acetates. The results of this experiment are clearly illustrated by the 2-D INADEQUATE contour plot shown in Fig. 2. As is evident, every carbon pair in this spectrum is coupled, which shows retention of intact acetate units throughout the molecule. This pattern of incorporation also agrees with **3**. This experiment gave no indication of a mixture of coupling patterns for AOH, indicating that no randomization had occurred.

No evidence that would indicate uncoupled carbon or a randomized pattern was observed in any of our ^{13}C nmr experiments. This would imply that the biosynthesis is under

TABLE 1. Nuclear magnetic resonance spectral assignment for AOH

Assignment	Shift σ[a]	Multiplicity[b]	σ[a] 2-D connectivities
C-8′	25.3	Quartet	—[c]
C-6′	138.3	Singlet	109.0, 117.6

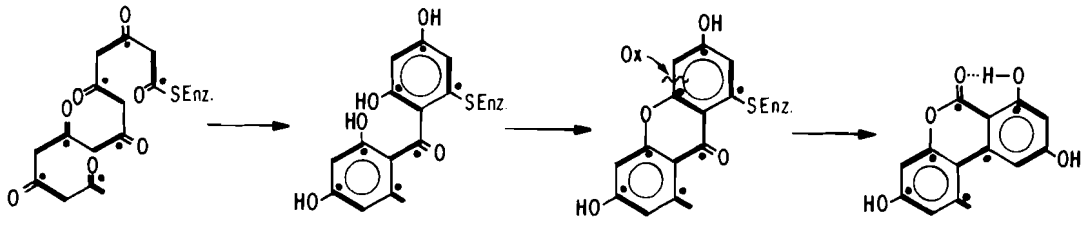

SCHEME 1

close steric control by the enzyme that prevents free rotation of aryl groups. The high rate of incorporation of NLX into AOH that is described in the Experimental probably indicates that NLX (or a very similar compound) is on the main biosynthetic route for AOH.

Scheme 1 presents a biosynthetic mechanism for biosynthesis of AOH that meets the above criteria. In this scheme, the point of attachment between the enzyme and the polyketide is shown as the active end of the polyketide chain, although the attachment could have migrated or could even involve several points of contact. The polyketide chain is assembled on the surface of the enzyme in a configuration that facilitated the formation of NLX. After rupture of the aromatic phloroglucinol ring, limited rotation of the aryl fragment and ring closure would produce the coupling pattern observed in AOH. This mechanism may require a second enzyme for oxidative cleavage of the aromatic ring. A reversible "retro-aldol" cleavage would result in destruction of an aromatic ring (which would be unlikely from free energy considerations), while oxidative fission of aromatic groups is widespread in the fungi (15, 16).

Other heptaketide assembly patterns and reactions can be suggested in addition to the mechanism shown in Scheme 1. For example, schemes can be devised in which (*1*) the phloroglucinol portion of the polyketide is assembled in a counterclockwise pattern, or (2) the polyketide chain could be assembled in the benzophenone configuration reported for griseofulvin biosynthesis (where NLX is also produced) (17). These mechanisms are more complex than that shown in Scheme 1 as they all require controlled rotation of aromatic groups to result in the observed AOH coupling pattern.

Experimental

Solvents were reagent "distilled in glass" quality. The yeast extract and potato dextrose agar were from Difco Laboratories (Detroit, Mich.). Analytical tlc was on scored, precoated plates fluorescent under 254 nm ("Uniplate", Silica Gel GF, 250 μm, Analtech, 75 Blue Hen Drive, Newark, DE 19711). Column chromatography was by the "flash chromatography" method (11) using the Ace Glass apparatus (Vineland, NJ) and 230–400 mesh silica gel (Merck, grade 60; Aldrich Chemical Co., Milwaukee, WI 53201). Sodium [1-^{13}C] and [1,2-^{13}C] acetate, 99% ^{13}C, and deuterated solvents were purchased from KOR (Cambridge, MA). Sodium [2-^{13}C] acetate, 99%, was purchased from Stohler Isotope Chemicals (Waltham, MA). Evaporations were done at room temperature or under a N_2 stream. Mass spectra were obtained using the direct injection probe (DIP) mode of the Hewlett–Packard 5885 mass spectrometer. The infrared spectra were obtained using a 237B Perkin–Elmer spectrophotometer and KBr discs. Authentic samples of norlichexanthone, both natural carbon and ^{14}C-labeled at the ketone carbon (30 000 cpm/mg), were kindly supplied by Dr. Constance M. Harris, Vanderbilt University, Nashville, TN.

Fungal cultures and production of labeled mycotoxin

The culture of *Alternaria tenuis* NRRL 6434, a strain with high production of AOH and a simple metabolic pattern that facilitated purification, was obtained from the Northern Regional Research Center, USDA/ARS, Poeria, IL. A single spore isolate from this strain was maintained on potato/dextrose agar. Fresh cultures of this isolate were started at frequent intervals, and portions of well sporulated 14–18 day old mycelia were used to innoculate 250-mL Erlenmeyer flasks each containing 60 mL of modified Czapex-Dox (MCD) medium. This medium contained 40 g glucose, 1.0 g yeast extract, 1.0 g $NaNO_3$, 1.0 g KH_2PO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.25 g NH_4Cl, 0.25 g KCl, 0.25 g NaCl, 0.01 g $FeSO_4 \cdot 7H_2O$, and 0.01 g $ZnSO_4 \cdot 7H_2O$, made up to 1 L with H_2O (18). These flasks were then incubated as stationary cultures in the dark at 25°C. Spiking with precursors was started on the 12th day and continued until the 16th day. The precursors were added by injecting the solutions into the MCD media beneath the mycelial cap. The flasks were then gently rotated without submerging any portion of the cap to mix the added precursor with the media. The acetates were added as 50 mg/0.2 mL aqueous solution per day and the NLX was added as 0.167 mg NLX/0.02 mL absolute EtOH per day. The mycelial cap was removed intact on the 17th day, and the cap was extracted three times by homogenizing with 30 mL MeOH for 1 min in a Waring Blendor and filtering. The extracts were combined and 50 mL H_2O was added. The solution was then extracted 3 times with 50 mL $CHCl_3$. The combined $CHCl_3$ solutions were concentrated by evaporation and the AOH was isolated and purified by flash chromatography. The column was developed first with 1 L of $CHCl_3$ to remove fast moving materials, and then developed with 1 L $CHCl_3$ solutions containing 2, 5, and 10% MeOH. The AOH emerged in the 2 and 5% MeOH eluates. The AOH was then repurified by flash chromatography using a hexane–EtOAc gradient. The AOH emerged at 25% EtOAc – hexane.

In a typical run, the yield of AOH obtained from 5 flasks was 307 mg. For unknown reasons, the yield of AOH and incorporation of precursors was highly variable. For most acetate runs under these conditions, incorporation into AOH was between 3 and 7% as determined by ms (mas spectra). The identity and purity of NLX and AOH were determined by ir, ms, and tlc with 5 solvent systems: toluene – glacial HOAc, 9:1; $CHCl_3$ – 1.6% EtOH; CH_2Cl_2–acetone, 95:5; toluene–EtOAc–HCO_2H, 6:3:1; and $(Et)_2O$–hexane–HOAc, 8:2:0.5. The yield of purified AOH from the flash column during the NLX incorporation experiment was 76.5 mg.

Thin-layer chromatography used 250-μm "Uniplates" (Analtech) using Silica Gel GF for normal phase and Silica Gel RPS for reversed phase tlc. The respective solvents were toluene – ethyl acetate – H_2O (6:3:1, v/v basis) and H_2O–methanol (65:35, v/v). ^{14}C activity on channeled tlc plates was detected by use of the tlc linear analyzer (Model LB 27 C, Berthold Analytical Instruments, 28 Charron Ave., Nashua, NH). Samples of the AOH obtained from the flash chromatographic columns were further purified by 3 preparative tlc purifications using each of these systems. Specific activity was determined by calculating ^{14}C activity (determined on a Beckman LS 8100 scintillation counter with "Aquasol" scintillation cocktail, New England Nuclear, Boston, MA) vs. peak height at 280 nm (Beckman Model 35 Spectrophotometer). The specific activity was constant after the first purification with each system.

Nuclear magnetic resonance parameters

Carbon-13 nmr spectra were measured in a 5-mm probe at 100.4 MHz using a JEOL GX-400 spectrometer system that included a 9.4 T Oxford narrow bore magnet and DEC LSI 11/23 data system. All data processing was with the JEOL Plexus software, version 2. Broadband ^{1}H decoupling was accomplished through the use of Waugh-type sequences (19, 20), and proton coupled ^{13}C spectra were measured

with grated decoupling in order to retain the nuclear Overhauser enhancements.

The two-dimensional studies were performed using the "INADEQUATE" pulse sequence proposed by Mareci and Freeman (21), where the final "read" pulse is allowed to have an arbitrary flip angle:

$$90°(X)-\tau-180°(Y)-\tau-90°(X)-t_1-\alpha(X)$$

τ was chosen to optimize conversion in double-quantum coherence in the usual manner, $\tau = (4J_{CC})^{-1}$, and the echo components emphasized by selecting $\alpha = 135°C$.

The 2-D INADEQUATE spectrum of alternariol (prepared utilizing [1-^{13}C] and [2-^{13}C] acetate) was obtained by processing an initial data matrix (t_1Xt_2) of 128 × 1024 points, representing spectra widths ($F_1 \times F_2$) of 5 kHz × 9 kHz. The $\pi/2$ pulse width was 11.4 μs, and τ was 4.386 ms corresponding to $J_{CC} = 57$ Hz. An overall recycle delay of 4.5 s was used to acquire 512 scans for each value of the incremented delay t_1. The 1-D spectrum reproduced above the 2-D contour plot was produced by transforming 1 K data acquired in a 9-kHz window using a 17.5 Hz broadening factor.

Finally, the 2-D data spectrum of alternariol (prepared utilizing [1,2-^{13}C] acetate) was obtained by processing an initial data matrix ($t_1 \times t_2$) of 512 × 1024 points representing spectral widths ($F_1 \times F_2$) of 100 kHz × 9 kHz. Other parameters were the same as in the previous experiment; however, only 64 scans were acquired at each t_1 value. The attached 1-D spectrum was prepared from a 32 K transform of data acquired in the same 9-kHz window, and a broadening factor of 2 Hz was used in data processing.

All 2-D data sets were double Fourier transformed utilizing trapezoidal window functions to approximate the sine-bell functions frequently used to improve the appearance of two-dimensional contour plots.

ROQUE RIGGIO, HECTOR E. MARTINEZ, and HORACIO N. SOLIMO. Can. J. Chem. **64**, 1595 (1986).

Three excess functions (molar volumes, viscosities, and molar enthalpies) for the methyl isobutyl ketone + *n*-pentanol and methyl isobutyl ketone + isoamyl alcohol systems at 298.15 K were calculated from measured densities, viscosities, and enthalpies, respectively. The UNIFAC group contribution method was used in order to estimate the activity coefficients which were then employed to calculate the excess molar Gibbs free energy. An attempt to explain the experimental results in terms of molecular interactions was made.

ROQUE RIGGIO, HECTOR E. MARTINEZ et HORACIO N. SOLIMO. Can. J. Chem. **64**, 1595 (1986).

En faisant appel aux valeurs mesurées à 298,15 K pour les densités, les viscosités et les enthalpies, on a calculé les valeurs respectives des fonctions d'excès (volumes, viscosités et enthalpies molaires) des systèmes méthyl isobutyl cétone/*n*-pentanol et méthyl isobutyl cétone/alcool isoamylique. Dans le but de déterminer les coefficients d'activité, qui ont été utilisés pour calculer l'énergie libre molaire en excès de Gibbs, on a utilisé la méthode UNIFAC des contributions des groupes. On a essayé d'expliquer les résultats expérimentaux en fonction d'interactions moléculaires.

[Traduit par la revue]

Introduction

The excess thermodynamic properties of binary liquid solutions are fundamental for the design of industrial equipment and for the interpretation of liquid state, particularly when polar–polar liquids are the components of the mixtures. Continuing our study on these type of systems (1) we report here the excess molar volumes (V^E), viscosities (η^E), enthalpies (H^E), and Gibbs free energies (G^E) for the following mixtures: (*i*) methyl isobutyl ketone (MIK) + *n*-pentanol (P_1) and (*ii*) methyl isobutyl ketone (MIK) + isoamyl alcohol (IA).

Experimental

Materials

Methyl isobutyl ketone, *n*-pentanol, and isoamyl alcohol (all Merck Darmstadt p.a.) were dried over anhydrous K_2CO_3 and fractionally distilled under nitrogen atmosphere. In each case the middle fraction was collected and maintained over 3 Å molecular sieve for *n*-pentanol and isoamyl alcohol and 4 Å molecular sieve for methyl isobutyl ketone to prevent water absorption. The mixtures were prepared by mixing accurately weighed quantities of the pure liquids. Caution was taken to prevent evaporation.

Density (ρ) and refractive index (n_D)

Densities were determined with an Anton Paar DMA46 calculating density meter with a built-in thermostat. We have estimated that the reported densities were accurate to within ± 0.1 kg m^{-3}. The refractive indexes of the pure components (sodium D line) were measured with a Jena dipping refractometer with an accuracy of ± 0.00002.

Viscosity (η)

The measurements were carried out with a Cannon-Fenske viscometer calibrated with doubly distilled water and benzene (accuracy $\pm 0.5\%$). For refractive index and viscosity, a thermostatically controlled bath, constant to ± 0.01°C, was used.

Calorimetric measurements

The heats of mixing of the binary systems were measured with an accuracy of $\pm 1\%$ in a modified adiabatic calorimeter as described by Loiseleur (2, 3).

Results

The experimental physical properties of the pure liquids are reported in Table 1, along with the literature values for comparison.

The excess thermodynamic functions were calculated with the following equations:

$$[1] \quad \eta^E = \eta - \eta^{id} = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

$$[2] \quad V^E = V - (x_1V_1 + x_2V_2) = [(x_1M_1 + x_2M_2)/\rho] - (x_1V_1 + x_2V_2)$$

$$[3] \quad H^E = H_m$$

$$[4] \quad G^E = RT(x_1 \ln \gamma_1 + x_2 \ln \gamma_2)$$

where V, V_1, and V_2 = molar volumes of the mixture and the pure components, respectively; H_m = molar enthalpy of the mixture; η, η_1, and η_2 = viscosities of the mixture and the pure components, respectively; η^{id} = viscosity of ideal mixture; γ_1 and γ_2 = activity coefficients of components 1 and 2 in the solution phase, based on the pure solvent standard state; ρ = density of solution; and x_1 and x_2 = molar fraction of the first and second component, respectively.

The experimental molar fractions, densities, viscosities, and excess molar enthalpies for the MIK + P_1 and MIK + IA systems at 298.15 K are listed in Table 2.

The excess thermodynamic functions were fitted to the equation:

$$[5] \quad Y^E = x(1 - x) \sum_{j=0}^{n} a_j(2x - 1)^j$$

where Y^E is the excess function (V^E, H^E, G^E, or η^E). The a_j's coefficients which gave the best fit to eq. [5] are summarized in

Table 3. The choice of the appropriate number of constants was based on the variation with n of the standard error of the estimated, as defined by:

$$[6] \quad \sigma_{Y^E} = [\Sigma(Y^E_{obs} - Y^E_{calcd})^2/(n_{obs} - n)]^{1/2}$$

where the sum is taken over the n_{obs} results.

The UNIFAC group contribution method (4) was used in order to estimate the activity coefficients γ_1 and γ_2, using the new parameters (5). They are listed in Table 4.

The following equation was used:

$$[7] \quad \ln \gamma_i = \ln \gamma_i^c + \ln \gamma_i^r$$

where γ_i^c = combinatorial term for the i component and γ_i^r = residual term for the i component.

The excess molar Gibbs free energy was calculated from eq. [4], using the γ_i's obtained by the UNIFAC method, and the excess molar entropy is defined by:

$$[8] \quad TS^E = H^E - G^E$$

Discussion

Figure 1 shows the dependence of the excess molar volume with the composition for the MIK + P_1 and MIK + IA systems, where the first one is negative and the second one positive over the entire range of concentration, but in both cases the values are close to zero.

When alcohols, which exist in a highly associated form in the pure state (6, 7), are mixed with polar solvents (ketones) the monomerization occurs and new specific interactions appear in the solution (8). The disruption of the hydrogen-bonded alcohol structure gives rise to a positive contribution to V^E, which depends: (*i*) on the dielectric constant of the ketone (9) and (*ii*) on the chain length (10) and degree of branching (11) in the alcohol which decrease the self-asociation in the pure state. On the other hand, the interactions between unlike molecules in both systems are surely weaker than the sum of the interactions between like molecules. This also produces a positive contribution to V^E. If the factors that affect V^E were only these, the excess molar volume for the MIK + P_1 and MIK + IA systems should be strongly positive. Since these systems show negative and positive (but close to zero) values, respectively, it is evident that other factors are involved. Among the main ones we can mention the interstitial accommodation of the ketone within the hydrogen-bonded alcohol structure (12, 13) and the possibility of formation of new chemical species in the solution both producing contraction effect that counterbalance the expansive effects mentioned above. From the experimental results we deduce that the interstitial accommodation of the ketone within the hydrogen-bonded alcohol structure is more important than the formation of new chemical species, since both systems are endothermic (see Figs. 2 and 3) and the excess viscosity is negative (see Fig. 1).

The possibility of the geometrical fit of the ketone decreases when the branching of the alcohol increases, yielding positive V^E values as a consequence of the steric hindering. In agreement with this, the system MIK plus the highly branched *t*-amyl alcohol (14) shows a $V^E \cong 0.27$ at the maximum (near $x_{MIK} = 0.6$).

The dependence of V^E on the chain length can be appreciated by comparison with the values obtained for the systems MIK + *n*-butanol and MIK + isobutyl alcohol (1) where greater negative values were obtained.

It was found that for *n*-alkanols + *n*-heptane mixtures the positive contribution produced by breaking of the hydrogen bond between the alcohol molecules diminished with the size of the alcohol (10, 15) which is opposite to the results observed between MIK + P_1 – MIK + *n*-butanol and MIK + IA – MIK + isobutyl alcohol. This dissimilarity is probably *due* to the greater size difference (13) within the MIK–butanols as compared to the MIK–pentanols systems. It is not possible to invoke that the more negative values of V^E observed for the systems employing butanols are due to the formation of stronger hydrogen bonds, since their η^E values are more negative than those for the systems with pentanols.

We conclude that the breakdown of the alcohol structure is the primary contributor to the mixture effect for the systems reported here. This leads to negative values for the excess viscosity (see Fig. 1) which is interpreted by Fort and Moore (26) in terms of dominant dispersion forces.

The endothermic behavior for the MIK + P_1 and MIK + IA systems (see Figs. 2 and 3) is due to the consumption of energy necessary to produce the breakdown of the alcohol structure which is not compensated by the energy developed by the formation of new chemical species in the solution. Conse-

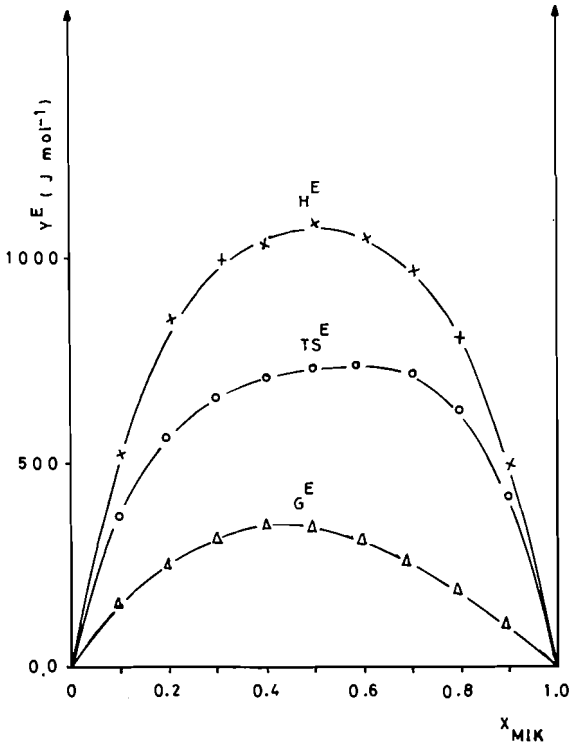

FIG. 3. Molar excess enthalpies, entropies and Gibbs free energies of methyl isobutyl ketone + isoamyl alcohol mixtures at 298.15 K. Curves are least-square representations by eq. [5].

quently, the global energy of the hydrogen bonds O—H···O in the *n*-pentanol and isoamyl alcohol must be greater than those of the same type of bonds in the intermolecular complexes (17). The greater positive values of H^E for the MIK + P_1 system with respect to the MIK + IA one could be interpreted in terms of the stronger self-association for the first system.

The positive values of S^E (see Figs. 2 and 3) are in agreement with the conclusions indicated above since this sign is indicative that the disruption of the alcohol structure is more important than the intermolecular association.

Received December 10, 1985

ROBERT CHÊNEVERT and SONIA THIBOUTOT. Can. J. Chem. **64**, 1599 (1986).

Bakers' yeast reduces 1-phenyl-1,3-butanedione with high chemo- and enantio-selectivity to give (*S*)-(+)-3-hydroxy-1-phenyl-1-butanone. The enantiomeric purity (>98%) was determined by nmr analysis using a chiral shift reagent and the absolute configuration was determined by correlation with ethyl (*S*)-(+)-3-hydroxybutyrate.

ROBERT CHÊNEVERT et SONIA THIBOUTOT. Can. J. Chem. **64**, 1599 (1986).

La levure de boulanger réduit la phényl-1 butanedione-1,3 d'une manière chimio et énantiosélective pour conduire à la (*S*)-(+)-hydroxy-3 phényl-1 butanone-1. La pureté énantiomérique (>98%) est mesurée par une analyse de rmn à l'aide d'un réactif de déblindage chiral. La configuration absolue est établie par corrélation avec le (*S*)-(+)-hydroxy-3 butyrate d'éthyle.

Introduction

Asymmetric synthesis has relied on the use, as starting materials, of optically active compounds that are members of the so-called "chiral carbon pool," i.e. easily available chiral substances produced by living organisms including amino acids, terpenes, carbohydrates, etc. (1–3). The composition of the chiral carbon pool is limited and there is an interest in its expansion. Biochemical transformation mediated by enzymes or microorganisms is an efficient tool for the preparation of chiral compounds. Reduction of unnatural ketone substrates by fermenting baker's yeast has received renewed attention for the preparation of chiral alcohols (4–8). We report here on the preparation of enantiomerically pure (*S*)-(+)-3-hydroxy-1-phenyl-1-butanone by bakers' yeast reduction of 1-phenyl-1,3-butanedione.

Results and discussion

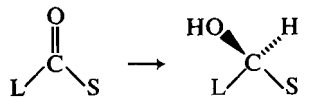
The reduction was carried out by treating 1-phenyl-1,3-butanedione with a fermenting yeast – sugar–water suspension according to the basic procedure currently used (9). This reduction gave a single product in 33% yield (40% yield based on the unrecovered starting material), which was identified as pure (*S*)-(+)-3-hydroxy-1-phenyl-1-butanone (eq. [1]). The

[1] 
reaction is characterized by extraordinary selectivity: First, only the carbonyl group in position 3 is reduced. This chemoselectivity is unexpected because yeast reduces substituted acetophenones (4). Second, the reaction is enantioselective and only the (*S*)-(+) enantiomer is produced.

Enantiomeric composition of the product was determined by nuclear magnetic resonance analysis using tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium(III) as a chiral shift reagent (10). Polarimetry cannot be used because, to the best of our knowledge, none of the pure enantiomers has been reported so far. The nmr analysis requires the use of racemic 3-hydroxy-1-phenyl-1-butanone, which was prepared by condensation between acetaldehyde and benzoylacetic acid according to a known procedure (11). We also prepared this racemate by double reduction of 1-phenyl-1,3-butanedione with sodium borohydride followed by selective oxidation of the benzylic alcohol with pyridinium dichromate (eq. [2]). Figure 1A shows

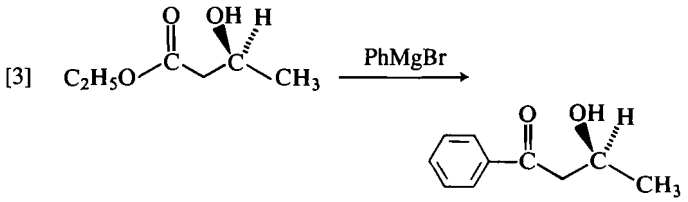
[2] 
the well-resolved ^{1}H nmr signals for the methyl group of racemic 3-hydroxy-1-phenyl-1-butanone in the presence of 0.1 equivalent of Eu(hfc)$_3$. The partial spectrum (Fig. 1B) of the yeast reduction product shows only one doublet and there is no trace of a second doublet. The optical purity obtained is above 98%.

Attention was next turned to the determination of the absolute configuration of the title compound. The absolute configuration of the product obtained by microbial reduction of a carbonyl group containing a large group L and a small group S to the alcohol may be determined by application of Prelog's rule (12). According to this rule, which was initially postulated for the reduction of decalones by *Curvularia lunata*, the hydrogen transfer proceeds on the Re-face of the prochiral ketone to give the *S* alcohol, thus the reduction reported here should give the *S* enantiomer. In view of the fact that yeast has now been shown to have at least three carbonyl-reducing enzymes at its disposal,



with different enantio-differentiating abilities (13), caution must be exercised, and the absolute configuration was confirmed by correlation with ethyl (*S*)-(+)-3-hydroxybutanoate obtained from yeast reduction of ethyl acetoacetate. The absolute configuration of this compound is firmly established (9). Reaction of phenylmagnesium bromide with ethyl (*S*)-(+)-3-hydroxybutanoate in the presence of triethylamine afforded (*S*)-(+)-3-hydroxy-1-phenyl-1-butanone (eq. [3]). In the presence of several equivalents of a tertiary aliphatic amine, the Grignard reaction with an ester gives a ketone as the major

[1]Author to whom correspondence may be addressed.



product (14). Therefore, the yeast reduction of 1-phenyl-1,3-butanedione gives the title compound with *S* configuration.

Experimental

The ^{1}H nmr spectra were recorded on a Varian XL-200 spectrometer. Eu(hfc)$_3$ and 1-phenyl-1,3-butanedione were purchased from Aldrich Chemical Co. bakers' yeast (*Saccharomyces cerevisiae*, type 1) was purchased from Sigma Chemical Co. Ethyl (*S*)-(+)-3-hydroxybutanoate was prepared according to known procedures (9, 15).

Bakers' yeast reduction of 1-phenyl-1,3-butanedione

A mixture of sucrose (30 g) and fresh bakers' yeast (20 g) in water (150 mL) gave, after 1 h at 30°C, a rapid evolution of carbon dioxide. 1-Phenyl-1,3-butanedione (1.62 g, 10 mmol) was added, and the fermenting suspension was stirred for another 24 h at room temperature. A warm (ca. 40°C) solution of 20 g sucrose in 50 mL of water was then added. Stirring was continued for 5 days at room temperature. The mixture was worked up by first adding 20 g of Celite and then filtering. The filtrate was saturated with sodium chloride and extracted with methylene chloride (continuous extraction). The organic phase was dried over magnesium sulfate, filtered, and concentrated with a rotary evaporator. The residue was purified by column chromatography (silica gel, methylene chloride – diethyl ether 96:4 as eluant) to give starting material (284 mg) and (*S*)-(+)-3-hydroxy-1-phenylbutanone (541 mg, 33% yield) as an oil; $[\alpha]^{25}$ +50.5° (*c* 0.12, $CHCl_3$); ir (neat): 3440, 3045, 2950, 1670, 1590, 1200, 1105, 1040 cm^{-1}; nmr ($CDCl_3$): 1.31 (3H, d, J = 6.5 Hz), 3.10 (2H, d, J = 6.0 Hz), 3.44 (1H, s), 4.40 (1H, m), 7.46 (3H, m), 7.93 (2H, dd, J_{ortho} = 8.0 Hz, J_{meta} = 2.0 Hz); ms *m/e* (relative intensity): 164 (M^+, 11), 146 (17), 105 (100), 77 (53).

3-Hydroxy-1-phenyl-1-butanone (racemic mixture)

1-Phenyl-1,3-butanedione (1.62 g, 10 mmol) reacts with sodium borohydride (0.38 g, 10 mmol) in ethanol (25 mL) to afford, after 90 min, 1-phenyl-1,3-butanediol (1.52 g) as a colorless liquid. Yield 92%; ir (neat): 3400, 3049, 2955, 1590, 1210, 1105 cm^{-1}; nmr ($CDCl_3$): 1.16 (3H, d, J = 6.5 Hz), 1.79 (2H, t, J = 7.0 Hz), 4.01 (1H, m), 4.92 (1H, m), 7.36 (5H, s); ms *m/e* (relative intensity): 166 (M^+, 10), 107 (85), 105 (70), 79 (100), 77 (87), 51 (26).

A solution of 1-phenyl-1,3-butanediol (5.6 mmol, 923 mg), and pyridinium dichromate (16) (2.1 g, 5.6 mmol) in methylene chloride (25 mL) was stirred at room temperature for 3 h. The reaction mixture was diluted with ether, filtered, and evaporated. The crude product was purified by column chromatography (silica gel, chloroform–ether, 50:50) to give racemic 3-hydroxy-1-phenyl-1-butanone. Yield 538 mg, 59%. Spectroscopic data are described above (see also ref. 11).

(S)-(+)-3-Hydroxy-1-phenyl-1-butanone from ethyl (S)-(+)-3-hydroxybutanoate

Ethyl (*S*)-(+)-3-hydroxybutanoate (528 mg, 4 mmol, ee (enantiomeric excess) = 85%) in anhydrous benzene (5 mL) was slowly added at 5–10°C to a freshly prepared solution of phenylmagnesium bromide (1.45 g, 8 mmol) and triethylamine (11) (2.42 g, 24 mmol) in anhydrous benzene – ether solution (6 mL – 4 mL). The reaction mixture was stirred at 5–10°C for 2 h and then treated with 4 *N* hydrochloric acid. The organic layer was washed first with water, then with 5% aqueous sodium hydrogen carbonate solution, and again with water, and evaporated. The crude product was purified by column chromatography (silica gel, chloroform–ether 60:40 as eluent) to give (*S*)-(+)-3-hydroxy-1-phenyl-1-butanone (360 mg, 55% yield); $[\alpha]^{25}$ +42.5° (*c* 0.70, $CHCl_3$); ir (neat): 3440, 3045, 2950, 1670, 1590, 1200, 1105, 1040 cm^{-1}; nmr ($CDCl_3$): 1.31 (3H, d, J = 6.5 Hz), 3.10 (2H, d, J = 6.0 Hz), 3.44 (1H, s), 4.40 (1H, m), 7.46 (3H, m), 7.93 (2H, dd, J_{ortho} = 8.0 Hz, J_{meta} = 2.0 Hz); ms *m/e* (relative intensity): 164 (M^+, 11), 146 (17), 105 (100), 77 (53).

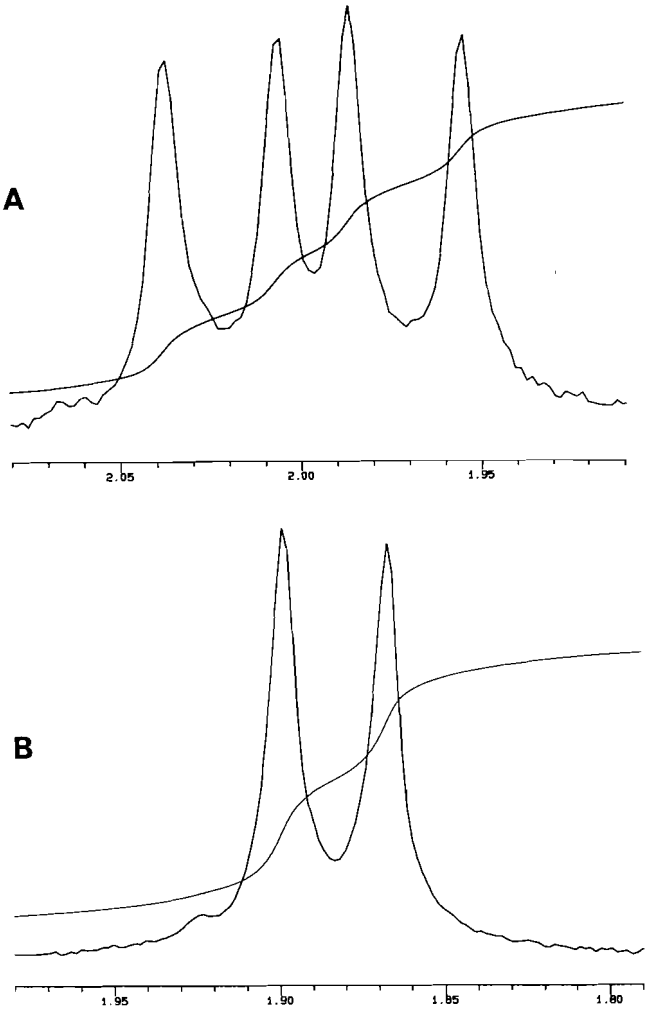


FIG. 1. 200-MHz ^{1}H nmr spectra of a solution prepared from (A) racemic 3-hydroxy-1-phenyl-1-butanone and (B) the product obtained by fermentation, in the presence of 0.1 equivalent of Eu(hfc)$_3$. The upper trace is slightly displaced to lower field due to the use of a slightly different concentration. The shoulder at δ 1.925 in (B), not being a doublet, cannot be due to the other enantiomer, and its signal area is less than 2% of the large doublet.

Received January 27, 1986

TED SCHAEFER, RUDY SEBASTIAN, GLENN H. PENNER, and S. R. SALMAN. Can. J. Chem. **64**, 1602 (1986).

The through-space or proximate nuclear spin–spin coupling constant, $^5J(F,CH_3) \equiv {}^5J$, between methyl protons and ring fluorine nuclei in alkylfluorobenzenes is postulated as $^5J/\text{Hz} = A\langle\cos^4\theta\rangle + B\langle\sin^2(\theta/2)\rangle$, θ being the torsional angle for the C_{sp^2}—C_{sp^3} bond. *A* and *B* are obtained from the known internal rotational behaviour in 2,6-difluoroethylbenzene and the corresponding cumene derivative. The parameterization is tested on the observed ^5J in derivatives of 2,4,6-tri-*tert*-butyl- and 2,4,6-tri-isopropyl-fluorobenzene, in 2-chloro-6-fluoroisopropylbenzene, 2,6-difluoro-α-methylstyrene, and *N*-methyl-8-fluoroquinolinium halides. A prediction is made for ^5J in 2,6-difluoro-*tert*-butylbenzene. It appears that the present parameterization allows the derivation of approximate torsional potentials from proximate couplings, for example in α,α-dimethyl-2,6-difluorobenzyl alcohol.

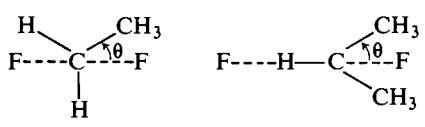
TED SCHAEFER, RUDY SEBASTIAN, GLENN H. PENNER et S. R. SALMAN. Can. J. Chem. **64**, 1602 (1986).

On considère que les constantes de couplage spin–spin à travers l'espace (ou par proximité nucléaire), $^5J(F,CH_3) \equiv {}^5J$, entre les protons méthyles et les noyaux de fluor d'alkylfluorobenzènes peuvent être représentées par l'équation $^5J/\text{Hz} = A\langle\cos^4\theta\rangle + B\langle\sin^2(\theta/2)\rangle$ dans laquelle θ est l'angle de torsion par la liaison C_{sp^2}—C_{sp^3}. On a obtenu les valeurs de *A* et de *B* à partir du comportement connu pour la rotation interne dans le difluoro-2,6 éthylbenzène et le dérivé cumène correspondant. On a évalué les paramètres sur la valeur de ^5J observée dans des dérivés des tri-*tert*-butyl-2,4,6 et tri-isopropyl-2,4,6 fluorobenzène, dans le chloro-2 fluoro-6 isopropylbenzène, le difluoro-2,6 α-méthylstyrène et dans les halogénures du *N*-méthyl fluoro-8 quinolinium. On fait une prédiction relative à la valeur de ^5J dans le difluoro-2,6 *tert*-benzène. Il semble que les paramètres actuels permettent de dériver les potentiels approximatifs de torsion à partir de couplage approximatifs, comme dans l'alcool α,α-diméthyl difluoro-2,6 benzylique.

[Traduit par la revue]

Introduction

Proximate spin–spin coupling constants are those for which nuclear spin state information is transmitted via interactions between electron orbitals in proximate bonds or even between orbitals centered on the coupled nuclei (1–4). It follows that the magnitude of the coupling constants is very sensitive to the distance between the coupled nuclei and is often difficult to calculate reliably (4–10) or to relate quantitatively to common conformational parameters such as torsion angles. An early study of some alkyl derivatives of fluorobenzene (3) demonstrated a steep dependence of $^5J(F,CH_3) \equiv {}^5J$, the coupling over five formal bonds to methyl protons in the sidechain, on the distance between the fluorine nucleus and the carbon nucleus of the methyl group. The distance was estimated from models. Although ^5J gives a good indication of the preferred conformation of the sidechain, it is not obvious how ^5J can be related quantitatively to the potential governing the internal rotation about the C_{sp^2}—C_{sp^3} bond. For example, it is very likely that this potential in 2,6-difluoroethylbenzene, **1**, is predominantly twofold (11–14) and that, as in ethylbenzene itself (12, 14), the most stable conformation has θ as 90°. Again, the cumene derivative, **2**, has θ as 60° in the conformation of lowest energy (11). It is therefore expected and observed that ^5J in **1** is less than



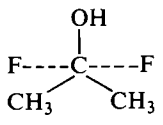
1 **2**

^5J in **2** (11). ^5J is relatively easily measured and can often be obtained by inspection of an nmr spectrum. Hence, if ^5J could be quantitatively related to θ, then it could be used to extract the hindering potential governing the motion of the sidechain.

Now, the proximate couplings $^5J(H,CH_3)$ in anisole and $^5J(F,CH_3)$ in 2-fluoroacetophenone apparently obey a $\cos^4\theta$ law (10, 15). For the former, INDO MO FPT computations (15) agree with such a θ dependence. However, such computations are unreliable for the proximate $^5J(F,CH_3)$ for reasons discussed previously (10). The assumption that $^5J \propto \cos^4\theta$ in 2-fluoroacetophenone, where θ is defined between 0 and 90° only, led to a reasonable interpretation of ^5J in this compound and its 6-fluoro derivative, and of its temperature dependence in the two compounds (10).

However, it is known[2] that the $2p_z$ orbital on the oxygen atom of the carbonyl group in acetophenone prevents efficient transmission of spin state information via the exocyclic bonds, so that the simple θ dependence for the proximate coupling mechanism may well have to be augmented by another contribution in alkylfluorobenzenes, particularly for $90° < \theta < 180°$.

In this paper, ^5J values in **1**, **2**, and **3** (α,α-dimethyl-2,6-



3

difluorobenzyl alcohol) are examined with a view to establishing ^5J as a quantitative measure of hindered rotation about the C_{sp^2}—C_{sp^3} bond. As applications, ^5J values in 2-chloro-6-fluoroisopropylbenzene, 3,5-dibromo-2-fluoroisopropylbenzene, and α-methyl-2,6-difluorostyrene are discussed, and a prediction is made for ^5J in 2,6-difluoro-*tert*-butylbenzene. Some literature values of ^5J are also examined.

The θ dependence of $^5J \equiv {}^5J(F, CH_3)$

The derivation of a relationship between ^5J and θ is facilitated by the following considerations. The values of $\cos^4\theta$ for rigid

[1]Permanent address: Department of Chemistry, University of Baghdad, Baghdad, Iraq.

[2]Unpublished work in this laboratory and private communication from Dr. R. Laatikainen.

conformers defined at 30, 60, and 90° are 0.5625, 0.0625, and zero, respectively. As the internal barrier decreases from infinity and approaches zero, $\langle\cos^4\theta\rangle$, the expectation value of $\cos^4\theta$, approaches 0.375 in each example. Hence, in **1** and **2** a vanishing barrier should yield identical values of ^5J. They are not identical, of course, and are ±0.301(3) and +0.956(3) Hz in **1** and **2**, respectively (11). In **1**, the most stable conformation has θ as 90°, whereas in **2** it is the one with θ = 60° (11). If ^5J were simply proportional to $\langle\cos^4\theta\rangle$ and if these two angles defined rigid conformations, then $^5J_0$, the value at θ = 0°, would follow as 31 Hz in **2** and infinity in **1**.[3] Neither value is reasonable, the latter for obvious reasons and the former because it also seems too large when compared, for example, to the $^5J_0$ of 8.15 Hz deduced for 2-fluoroacetophenone (10) or to the 8.8 Hz observed for the *N*-methyl-8-fluoroquinolinium iodide (8), in which θ approximates to zero. Because the C—C—C(H_3) bond angles in these latter two compounds are near 120° but are probably nearer 110° in **1** and **2**, a value of ^5J of about 10 Hz seems reasonable for the latter compounds.

Now, the barrier to rotation about the C_{sp^2}—C_{sp^3} bond in **1**, assumed twofold, is 25.5 ± 8.4 kJ/mol (11). At 300 K, such a barrier corresponds to a classical $\langle\cos^4\theta\rangle$ of 0.01 ± 0.01. Again, a dependence of ^5J only on $\cos^4\theta$ would imply a $^5J_0$ of 60 Hz or larger. It is apparent that another coupling mechanism contributes to ^5J.

Therefore, write eq. [1]

$$[1]\quad {}^5J/\mathrm{Hz} = ({}^5J_0/2)\langle\cos^4\theta\rangle + {}^5J_{180}\langle\sin^2(\theta/2)\rangle$$

in which the second term arises from a σ electron mechanism (16, 17) having its maximum in the all-*trans* arrangement of the intervening bonds. A σ–π electron contribution, varying as $\sin^2\theta$, is rejected because no coupling is observed between ^{19}F and methyl ^1H nuclei in 4-fluoroethylbenzene (18). For a twofold barrier, $\langle\sin^2(\theta/2)\rangle$ is 0.5 (16). Proceeding on this assumption and also taking ^5J in **1** as positive, one has $0.301(3) = ({}^5J_0/2)(0.01 \pm 0.01) + 0.5\,{}^5J_{180}$ for **1**. In **2** the enthalpy of activation for rotation about the C_{sp^2}—C_{sp^3} bond is 25.4(4) kJ/mol (11), yielding $+0.956(3) = ({}^5J_0/2)0.143(1) + 0.5\,{}^5J_{180}$. It follows that $^5J_0$ is 9.16 ± 0.65 Hz, an apparently reasonable magnitude in terms of the previous arguments, and that $^5J_{180}$ is 0.60 ± 0.10 Hz. In 2,6-difluoroalkylbenzenes, therefore, eq. [2] represents the θ dependence of ^5J. Note that

$$[2]\quad {}^5J(F_2CH_3)/\mathrm{Hz} = (9.16 \pm 0.65)/2(\langle\cos^4\theta\rangle) + (0.30 \pm 0.05)$$

twofold barriers are assumed and that $\langle\cos^4\theta\rangle$ is defined for $0 \le \theta \le 90°$ but that for $\langle\sin^2(\theta/2)\rangle$ this angle is defined between 0 and 180°. In a 2-fluoroalkylbenzene, for example, the coefficient of $\langle\cos^4\theta\rangle$ would become 9.16 ± 0.65 Hz and the second term would be $(0.60 \pm 0.10)\langle\sin^2(\theta/2)\rangle$ Hz.

Tests of the conformational eq. [2]

(i) 2,6-Difluoro-α,α-dimethylbenzyl alcohol, 3

In this molecule, ^5J is +2.031(1) Hz. Therefore $\langle\cos^4\theta\rangle$ is 0.38 ± 0.03 if the barrier is twofold. For a zero internal barrier $\langle\cos^4\theta\rangle$ is 0.375, so that an ambiguity is introduced by the error estimate. If **3** is the stable form, then V_2 ranges between 0 and 6 kJ/mol, because $0.3750 \le \langle\cos^4\theta\rangle \le 0.5625$. If the conformation analogous to **2** is the most stable, then $0.0625 \le \langle\cos^4\theta\rangle \le 0.375$ and an upper limit to V_2 becomes 1 kJ/mol. It is known[4] that the conformation analogous to **3** is favored by less than 25 kJ/mol in 2,6-difluorobenzyl alcohol. For the isopropyl derivative, **2**, the conformation with θ = 30°, analogous to **3**, lies 25 kJ/mol above **2**. Hence a simple additivity scheme for the interpretation of the barrier in **3** does not hold.

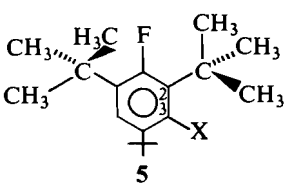
In order to ascertain the conformation of lowest energy for **3**, $^6J_p(^1H,^{13}C)$ was measured as (−)0.222(6) Hz in the derivative containing a $^{13}CH_3$ group (see Experimental). In 2,6-dichloroethylbenzene, this coupling is (−)0.618 ± 0.016 Hz (19) and is a close approximation to its value at θ = 90°. Furthermore, it seems clear that $^6J_p(^1H,^{13}C)$ varies as $\sin^2\theta$. Then, allowing for the electronegativity of the hydroxyl group in **3** and assuming that $^6J_{90}(^1H,^{13}C)$ is reduced in the same proportion (20*a*) as $^6J_{90}$(H,H), it follows that a *lower* limit to $\langle\sin^2\theta\rangle$ is 0.42. This value of $\langle\sin^2\theta\rangle$ corresponds to a V_2 of 3.3 kJ/mol *and* to a preferred conformation as shown in **3** (θ = 30°). For this choice of θ the proximate ^5J formulation suggests a V_2 of 3.0 ± 3.0 kJ/mol (from 0 to 6 kJ/mol). Equation [2] is successful to the extent of finding a very low barrier compared to those in **1** and **2**.

*(ii) Prediction for 2,6-difluoro-*tert*-butylbenzene, 4*

Because of the threefold symmetry of the *tert*-butyl group, $\langle\cos^4\theta\rangle$ will always average to 0.375, no matter what the most stable conformation or the barrier are. Consequently, eq. [2] predicts a ^5J of 2.0 ± 0.2 Hz because $\langle\sin^2(\theta/2)\rangle$ will be 0.5 under these conditions. **4** has not been made. However, ^5J is available for some 3-X-2,4,6-tri-*tert*-butylbenzenes (3) and is discussed next.

*(iii) $^5J(F,CH_3)$ in 3-X-2,4,6-tri-*tert*-butylbenzenes, 5*

As the size of X increases in **5**, the conformation in which one



5

methyl group eclipses the C—F bond increases in stability. Accordingly, ^5J increases from 0.9 Hz for X = H to 4.2 Hz for X = Br. For compounds of this symmetry, eq. [2] must be written as eq. [3].

$$[3]\quad {}^5J(F,CH_3)/\mathrm{Hz} = (9.16 \pm 0.65)\langle\cos^4\theta\rangle + (0.60 \pm 0.10)\langle\sin^2(\theta/2)\rangle$$

For free rotation (zero barrier) ^5J becomes 3.74 ± 0.39 Hz, while for a rigid **5**, where one methyl group eclipses the C—F bond, the average ^5J is 3.35 ± 0.27 Hz (remember that $\langle\cos^4\theta\rangle$ is defined for $0 \le \theta \le 90°$). Again, for a rigid **5** in which two methyl groups are staggered about the C—F bond, the average ^5J is reduced to 0.58 ± 0.06 Hz. Accordingly, when neither rigid conformers nor completely free internal rotations exist, ^5J should lie between 0.52 and 4.03 Hz in magnitude. The ^5J of 4.2 Hz when X = Br must be interpreted in this model as caused by distortion of the sidechain geometry by the relatively large bromine substituent, such that the methyl group eclipsing the C—F bond moves about 0.1 Å closer to the fluorine substituent. A distortion of this magnitude can cause an increase of about 0.6 Hz in ^5J (3). That a substituent at C-3 in **5** can distort the molecule is also indicated by the change in ^5J observed for the *tert*-butyl group at C-6. Of course, the barriers to internal rotation in **5** are not known, but are needed to compute ^5J from

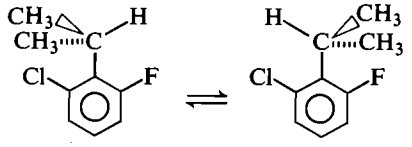
[3] Note that $^5J = ({}^5J_0/2)\langle\cos^4\theta\rangle$ because there are two *ortho* fluorine substituents and because, in line with the remarks in the introduction, $\langle\cos^4\theta\rangle$ is defined between 0° and 90° only.

[4] Unpublished work in this laboratory.

eq. [3]. That the barriers might well be substantial might be inferred from the following example.

(iv) 2-Chloro-6-fluoroisopropylbenzene, 6

Compound **6** obeys the equilibrium **6***a* ⇄ **6***b* with $K = 7.6$ at 300 K (20*b*).

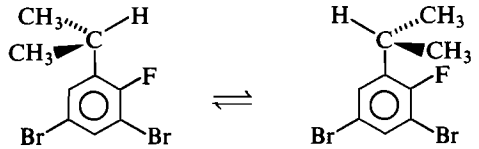


6*a* **6***b*

The enthalpy of activation for interconversion of **6***a* and **6***b* is 38.1(3) kJ/mol and $^5J(F,CH_3)$ is 1.61 Hz. Although the potential function for the rotation about the exocyclic C—C bond is not known from these data, the following approach allows an estimate of ^5J from eq. [3]. In **6***b* the potential hindering small amplitude torsions must be rather similar to V_2 in **2**, 25.5 kJ/mol. Therefore take $\langle\cos^4\theta\rangle$ to be 0.143(1) as discussed above for **2**, yielding ^5J as 1.46 ± 0.15 Hz in **6***b*. In **6***a*, only the term in $\langle\sin^2(\theta/2)\rangle$ contributes and will be 0.45 ± 0.08 Hz. Hence eq. [3] yields an estimate of 0.88 (1.46 ± 0.15) + 0.12 (0.45 ± 0.08) or 1.34 ± 0.14 Hz, where 0.88 is the fractional population of **6***b*. This estimate of ^5J lies 0.27 ± 0.14 Hz below the observed value of 1.61 Hz.

(v) 3,5-Dibromo-2-fluoroisopropylbenzene, 7

$^5J(F,CH_3)$ is 0.51(1) Hz in **7**. There is considerable freedom of motion about the C_{sp^2}—C_{sp^3} bond, as shown by the $^6J(H,CH)$ of −0.233(5) Hz. This coupling vanishes when the α C—H bond sits in the ring plane (11, 21–23). The simplest potential describing the motion of the isopropyl group contains onefold and twofold terms. An approximation to V_1 can be had from 2,6-diisopropylfluorobenzene, in which $^5J(F,CH_3)$ is 0.49(1) Hz in magnitude (same as in **7**) and $^5J_m(H,CH)$ is 0.420(7) Hz. The latter coupling is stereospecific (17, 24) and would be 0.63 Hz if this compound existed in a rigid conformation having the α C—H bond *cis* to the C—F bond.[5] Assuming a barrier sizeable compared to *kT* (see below), a free energy difference of 1.8 kJ/mol favoring the C—H *cis* over the C—H *trans* conformation can be deduced (24). The assumption that the entropy difference is negligible yields a value of 0.5 for the **7***a* ⇆ **7***b* equilibrium at 305 K.



7*a* **7***b*

For rigid conformers ^5J follows as 0.55 ± 0.03 Hz, compared to the observed value of 0.51 ± 0.01 Hz. Of course, the twofold barrier to rotation in the absence of the fluorine substituent is 7.6 ± 0.8 kJ/mol (25) and is 25.5 ± 0.4 kJ/mol in **2**. At 305 K some considerable torsional amplitudes about the C_{sp^2}—C_{sp^3} bond therefore occur, particularly in **7***a*. Therefore write $V = V_1\sin^2(\psi/2) + V_2\sin^2\psi$, where ψ is zero in **7***a*, as the most simple potential function governing the torsion. V_1 is taken as 1.8 kJ/mol. Computation of the classical averages of $\cos^4\theta$ and $\sin^2(\theta/2)$, with the proviso that contributions to $\langle\cos^4\theta\rangle$ occur only when the methyl group lies in the quadrant containing the C—F bond, proceeds for a range of V_2 values. A reasonable fit to the observed ^5J of 0.51 Hz occurs for a V_2 of 22 ± 2 kJ/mol.

(vi) 2,6-Difluoro-α-methylstyrene, 8

In this compound, ^5J is 0.95(2) Hz. If eq. [2] applies, then $\langle\cos^4\theta\rangle$ is 0.142 ± 0.012. Because $\langle\cos^4\theta\rangle < 0.375$, the most stable conformation must have the methyl group in a plane perpendicular to the benzene plane. The assumption of a twofold barrier yields V_2 as 5.8 ± 0.5 kJ/mol. Of course, the C(1)—C—CH_3 bond angle is no doubt larger than in an sp^3 bonding situation, which would cause a decrease in $^5J_0$ in eq. [2]. If $^5J_0$ were as small as 8.0 Hz, somewhat smaller than in 2-fluoroacetophenone, then $\langle\cos^4\theta\rangle$ would be 0.162, corresponding to a V_2 of 5.1 kJ/mol. The classical expectation value of θ is 63(1)° for this range of V_2 values, where θ is measured from the ring plane.

In α-methylstyrene, θ has been deduced as 30° from ultraviolet spectroscopy (26) and as 29 ± 6°C from photoelectron spectral data (27). In 4-fluoro-α-methylstyrene, $^6J(^{13}C,^{19}F)$ indicates a V_2 of 5.9 kJ/mol, the preferred conformation having θ as 0° and a $\langle\theta\rangle$ of 27 ± 1°. In other words, the presence of the two *ortho* fluorine substituents alters the stable conformers from one in which θ is 0° to the one in which θ is 90°. The change in the magnitude of the barrier is apparently about 11 kJ/mol.

However, in styrene V_4 amounts to 26% of V_2 (28) and is of opposite sign to V_2. Although the observed $^5J(F,CH_3)$ in **8** unequivocally establishes the perpendicular conformer as the one of lowest energy, the assumption that V_4 and V_2 are of comparable magnitude is also compatible with a $\langle\cos^4\theta\rangle$ of 0.142. Thus, measuring the zero of energy from θ = 90° gives V_2 and V_4 as 5.0 and −4.5 kJ/mol, respectively, or as 11.5 and 9.8 kJ/mol. Now, STO 3G MO computations with geometry optimization (29*a*) agree that V_2 and V_4 differ in sign in styrene, although they overestimate V_2 by 27%. Identical (29*a*) computations on **8** yield V_2 and V_4 as 11.5(8) and 9.1(8) kJ/mol, respectively. It seems that $^5J(F,CH_3)$ is therefore compatible with a twofold barrier of 5.8 kJ/mol or with a barrier consisting of larger twofold and fourfold components of very similar magnitudes (it may be noted that STO 3G MO computations on **1** yield a small V_4 component for the internal rotation barrier, consistent with the assumptions made in previous sections).

(vii) N-methyl-8-fluoroquinolinium iodide and chloride, 9a and 9b

$^5J(F,CH_3)$ is +8.8 Hz in these molecules (8). In terms of eq. [3], the coupling should be 9.1 ± 0.6 Hz, assuming a planar rigid structure. Of course, the intervening bond angles are distorted from ideal 120° bond angles (8), yet the molecule is effectively planar. Considering that the bond lengths in the fragments used to derive eq. [3] are probably somewhat larger than in **9**, the coupling magnitude in the latter is probably consistent with the discussion in the previous sections.[6]

[5]Full analysis of ^1H nmr and ^{19}F nmr spectra of 2,6-diisopropylfluorobenzene is problematic because of the nature of its spin system. However, $^6J_p(H,CH)$ is −0.22(3) Hz, the same as in **7**, implying very similar motional characteristics of the isopropyl groups in the two compounds.

[6]A referee asks how the present treatment applies to $^5J(F,CH_2)$ in 5-fluoro-3,3-dimethyl-1,2,3,4-tetrahydrophenanthrene (29*b*). This coupling is indeed an interesting one from the viewpoint of proximate coupling mechanisms. However, the present paper relates to reorienting methyl groups (hence $^5J(F,CH_3)$ refers to an average over three methyl protons), which, in general, are part of a larger reorienting part of the molecule (angle θ).

TABLE 1. The ^{1}H nmr spectral parameters for 2,6-difluoro-α-methyl-α-methyl-^{13}C-benzyl alcohol[a]

Parameter	Value	Parameter	Value
$\nu(CH_3)$[b]	705.333(0)[c]	^4J(H,F)	6.099(4)
$\nu(^{13}CH_3)$	704.871(0)	^5J(H,F)	−1.438(5)
$\nu_3 = \nu_5$	2251.098(2)	^4J(F,F)	6.769(7)
ν_4	2351.963(3)	^3J(H,H)	8.315(3)
^1J(H,C)	127.447(1)	^4J(H,H)	1.289(5)
^3J(H,C)	4.315(1)	$^4J(CH_3,CH_3)$	0.501(0)
^5J(H,C)	0.000(5)	Calcd. transitions	80[d] 544[e]
^6J(H,C)	(−)0.222(6)	Assigned transitions	63 355
$^5J(F,CH_3)$	2.030(1)	Largest difference	0.042 0.018
$^5J(F,^{13}CH_3)$	2.032(1)	RMS deviation	0.014 0.006
^3J(H,F)	12.040(4)

Experimental

The preparation and analyses of the ^{1}H and ^{19}F nmr spectra of **1** have been described (11), as have the synthesis and analysis of the ^{1}H nmr spectrum of **2** (11, 30).

The analysis of the ^{1}H nmr spectrum of **3**, the compound being an intermediate in the synthesis of **2** (30), yielded $^5J(F,CH_3)$ as 2.032(1) Hz for a 3.1 mol% solution in CS_2 at 305 K. The ^{1}H nmr spectrum was calibrated on a HA100 spectrometer by procedures previously described in detail (31). $^5J(F,CH_3)$ was independent of concentration from 3 to 0.4 mol% in CS_2. Weak double irradiation experiments (32) showed that $^5J(F,CH_3)$ was of opposite sign to $^5J(F,OH)$ in **3**. The latter coupling is negative in 2-fluorobenzyl alcohol (33), implying $^5J(F,CH_3)$ as positive in **3**. The positive sign is expected, the coupling being positive in **2**, **7**, **8**, and **9**.

The synthesis of **3** containing a $^{13}CH_3$ group proceeded in a straightforward way by reaction of 2,6-difluoroacetophenone with the Grignard reagent prepared from ^{13}C-enriched methyl iodide. The ^{1}H nmr spectrum of a 3.0 mol% solution in CS_2, containing also 10 mol% C_6D_{12} and 0.5 mol% TMS, was obtained on an AM300 nmr spectrometer at a probe temperature of 300 K. This spectrum was analyzed with the computer program NUMARIT (34), as modified by R.S. The spectral parameters appear in Table 1. Figure 1 displays the ^{1}H nmr spectrum of the methyl group for this compound.

Compound **6** was prepared in the same manner as **2** (11, 30). Analysis of the ^{1}H nmr spectrum of **2** as a dilute solution in benzene-d_6 at 90 MHz yielded $^5J(F,CH_3)$ as 1.61(1) Hz.

Compound **7** was derived from 2-aminocumene via bromination and diazotization in the standard way. Its ^{1}H nmr and ^{19}F nmr spectra were accumulated on a WH90 nmr spectrometer from a dilute solution in acetone-d_6 by methods standard in this laboratory (31). Analyses of the spectra and double irradiation experiments yielded the germane result that $^5J(F,CH_3)$ was +0.51(1) Hz.

The 2,6-diisopropylfluorobenzene was synthesized via the diazonium salt of the corresponding aniline derivative. The ^{1}H nmr and ^{19}F nmr spectra of a 5 mol% solution in CCl_4, recorded on a WH90 spectrometer, arise from an ABB′XX′R spin system. The spectra were insensitive to $^4J_{46}$ and had other peculiarities that are of no interest here. However, an analysis gave $^5J(H,CH)$ as 0.420(7) Hz, $^5J(F,CH_3)$ as 0.492(5) Hz, and $^6J(H,CH)$ as −0.22(3) Hz, relevant to the discussion above. An analysis of the ^{19}F nmr spectrum, obtained while decoupling the methyl protons, utilized the self-assigning program DAVINS (35) in a manner described previously (11), and yielded $^4J(F,CH)$ as 0.40(1) Hz.

The styrene derivative, **8**, was also an intermediate in the synthesis of **2** (11, 30). For a dilute solution in CS_2, $^5J(F,CH_3)$ was 0.95(2) Hz.

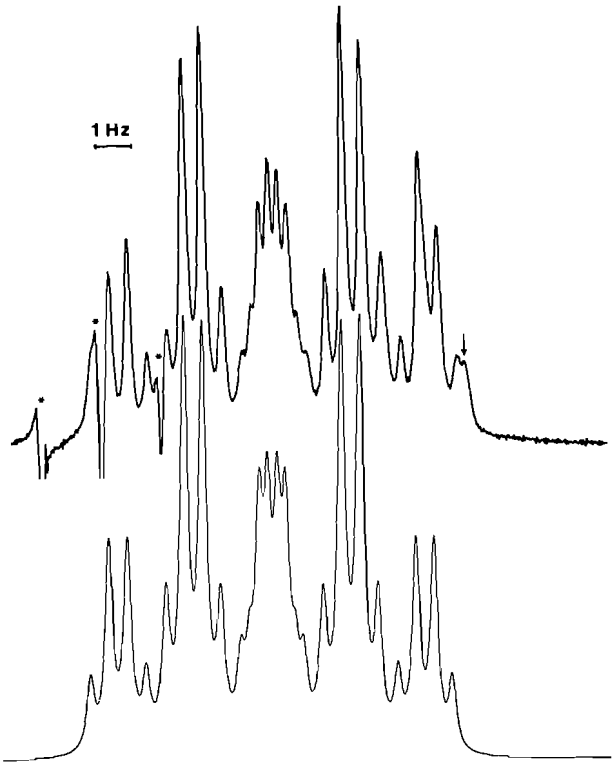

FIG. 1. The observed and calculated methyl ^{1}H nmr spectrum at 300 MHz and 300 K of a 3 mol% solution in CS_2 of 2,6-difluoro-α-methyl-α-methyl-^{13}C-benzyl alcohol. The line widths at half height are 0.2 Hz, probably arising from small unresolved long-range coupling to ring protons and the hydroxyl proton. The artifactual distortion of one side of the observed spectrum, indicated by asterisks, is not present in the ^{1}H nmr spectrum of the $^{13}CH_3$ group. An impurity peak, indicated by an arrow, is also present in the observed spectrum and impurities may also account for the anomalous intensity of a nearby peak.

Squaraine chemistry. On the anomalous mass spectra of bis(4-dimethylaminophenyl)squaraine and its derivatives

KOCK-YEE LAW,[1] F. COURT BAILEY, AND LYNN J. BLUETT
Xerox Corporation, 800 Phillips Road, 0114-39D, Webster, NY 14580, U.S.A.

Received May 13, 1985[2]

KOCK-YEE LAW, F. COURT BAILEY, and LYNN J. BLUETT. Can. J. Chem. **64**, 1607 (1986).

The electron impact (EI) mass specra of bis(4-dimethylaminophenyl)squaraine **1** and its derivatives **2–14** have been studied. Ions of mass number higher than the molecular ion, which are shown to be precursors of fragment ions of lower mass numbers, are observed. From the structure–property relationship, these ions are assigned to M + $CHR^{\dagger}$ and M + $H_2^{\dagger}$, where CH_2R is the alkyl group in the *N,N*-dialkylanilino moiety of squaraine. Evidence is provided that the formation of M + $CHR^{\dagger}$ and M + $H_2^{\dagger}$ is the result of alkyl transfer and H transfer reactions within a squaraine aggregate rather than intermolecular vapor phase reactions in the mass spectrometer. This molecular aggregate is later shown to be a trimer by analysis of metastable ion data and chemical ionization mass spectrometry. The fragmentation sequence of this trimeric species is elucidated with the assistance of metastable ions. Results show that the trimer may break down to monomeric and dimeric species upon electron impact; alternatively, the four-membered ring of the central squaraine in the trimer may cleave to generate two species of approximately equal mass number. These two species usually dominate the mass spectrum and further fragment into M + $CHR^{\dagger}$ and M + $H_2^{\dagger}$. Detailed fragmentation schemes for M + $CHR^{\dagger}$ and M + $H_2^{\dagger}$ are proposed and discussed.

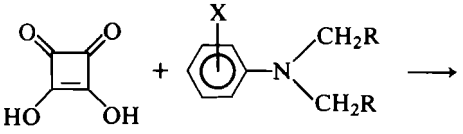
KOCK-YEE LAW, F. COURT BAILEY et LYNN J. BLUETT. Can. J. Chem. **64**, 1607 (1986).

On a étudié les spectres de masse sous impact électronique de la bis(diméthylamino-4 phényl)squaraine (**1**) et de ses dérivés **2–14**. On a observé la présence d'ions de masses plus élevées que celle de l'ion moléculaire et on démontre que ce sont les précurseurs d'ions fragmentés de masses plus basses. En se basant sur des relations entre la structure et les propriétés, on a attribué ces ions aux entités M + $CHR^{\dagger}$ et M + $H_2^{\dagger}$ dans lesquelles CH_2R représente un groupement alkyle de la portion *N,N*-dialkylamino de la squaraine. On présente des données confirmant que la formation des entités M + $CHR^{\dagger}$ et M + $H_2^{\dagger}$ provient de réactions de transfert d'hydrogène ou de groupements alkyles à l'intérieur d'un agrégat de squaraine plutôt que de réactions intermoléculaires en phase vapeur à l'intérieur du spectromètre. En se basant sur une analyse des données relatives aux ions métastables et sur la spectrométrie de masse par ionisation chimique, on démontre de plus que cet agrégat moléculaire est un trimère. On a élucidé l'ordre de fragmentation de cette espèce trimère en se basant sur les ions métastables. Les résultats démontrent que, sous impact électronique, le trimère se brise en des espèces monomère et dimère; il est aussi possible que le cycle à quatre chaînons de la squaraine centrale du trimère se brise pour générer deux espèces de masses approximativement égales. Ces deux espèces dominent habituellement les spectres de masse et les fragmentations subséquentes en M + $CHR^{\dagger}$ et M + $H_2^{\dagger}$. On propose et discute des schémas détaillés des fragmentations en M + $CHR^{\dagger}$ et M + $H_2^{\dagger}$.

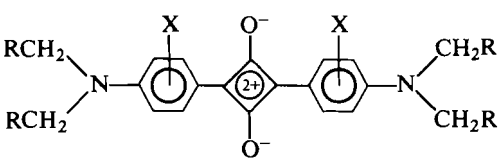
[Traduit par la revue]

Introduction

Squaraines are 1,3-disubstituted products obtained from squaric acid and *N,N*-dialkylanilines (1). The synthesis of squaraines is simple and has been reviewed several times in the literature (2). Owing to the strong exciton interactions, squaraines exhibit intense and panchromatic absorption from the visible to the near-infrared (400–1000 nm) in the solid state. These features have made them very attractive for various technological applications in industry, e.g., electrophotographic imaging (3), organic solar cells (4), ablative optical recording (5), etc.



Squaric acid *N,N*-dialkylaniline



Squaraine

While the technological use of these compounds has been extensive and a large number of squaraine structures have been synthesized (6), very little attention has been devoted to the fundamental properties of squaraines. Squaraines have been typically characterized by elemental analysis, visible absorption, and ir (infrared) (1). Mass spectrometry, one of the basic analytic tools for structure determination of organic compounds, has rarely been used.

During the course of our investigation on the photoconductive properties of squaraines, we have used electron impact (EI) mass spectrometry as a routine tool for structural characterization and have found that squaraines exhibit very unusual mass spectrometric properties.[3] Ions of mass numbers higher than the molecular ion (M^+) were frequently observed. Here we report our investigation on the anomalous mass spectra of squaraines **1–14** (structures in Fig. 1). The mechanism of formation of these high molecular weight ions and their subsequent fragmentation processes are studied. Our results show that molecular aggregates of squaraines are precursors of the lower mass number fragments observed in the mass spectra. These molecular aggregates fragment upon electron impact to either molecular ions or high molecular weight intermediate ions.

The latter species, which usually dominate the mass spectrum, further fragment into the characteristic mass spectrometric pattern of squaraine. The prospect of using mass spectrometry as an analytical tool for structure elucidation is discussed.

Experimental

Materials

Squaric acid, *N,N*-dimethylaniline, *N,N*-diethylaniline, *N,N*-dimethyl-*m*-toluidine, and *N,N*-di-*n*-butylaniline were purchased from Aldrich; *N,N*-diethyl-*m*-toluidine was obtained from Pfaltz & Bauer, *N*-ethyl-*N*-benzylaniline was a gift from Hardwicke Chemical Company. All these materials were used as received. *N,N*-Dimethyl-3-fluoroaniline, *N,N*-dimethyl-3-methoxyaniline, *N,N*-diethyl-3-methoxyaniline, *N,N*-dimethyl-3-ethylaniline, *N,N*-dipropylaniline, and *N,N*-dibutyl-3-methylaniline were prepared by alkylating an aniline derivative (Aldrich) with trialkyl phosphate (Aldrich) as described in the literature (7). All solvents were best commercial quality and were used without further purification.

General technique

Melting points were taken on a capillary melting point apparatus (Thomas Hoover) and are uncorrected. Elemental analyses were performed by Galbraith Laboratories. Spectra were recorded by means of the following instruments: infrared, Perkin–Elmer 283; ^{1}H nmr, Brüker WP-80; uv–vis, Cary 17.

Electron impact (EI) mass spectra were recorded on a Nuclide 12-90G magnetic sector mass spectrometer. Samples were introduced using the solid probe direct insertion inlet sytem and were usually heated slowly from ~25°C to a threshold temperature where strong ion current was obtained. The threshold temperature varied from 80°C to ~140°C and was at least 100°C below the melting point or the decomposition point of a specific compound. An ionization voltage of 70 eV regulated at 100 μA ionizing current was used.

Chemical ionization (CI) mass spectra of **1** were recorded on a triple quadrupole gc/ms spectrometer from Finnigan at Oneida Research Service. The vaporization temperature of **1** was ~150°C and the CI reagent gas (CH_4, NH_3, CH_2Cl_2, and N_2O) pressure was about 0.4 Torr (1 Torr = 133.3 Pa).

Squaraine synthesis

Squaraines were prepared by reacting one equivalent of squaric acid and two equivalents of *N,N*-dialkylanilines in a mixture of toluene (or benzene) and 1-butanol at reflux for ~8 h (8). Two work-up procedures were used and they are outlined as follows:

A. Pigment samples[4]

After cooling, the product was filtered, then washed with methanol and ether. All samples obtained are analytically pure.

B. Dye samples[4]

After cooling, solvent was removed under reduced pressure. Impurities were removed by extracting the mixture with ether. Squaraine product was then isolated from the residue by column chromatography on silica gel (Baker, 60–200 mesh) using chloroform as eluent. The physical properties and the spectroscopic data of these compounds are tabulated in Tables 1 and 2.

Results and discussion

Synthesis and characterization

Squaraines were prepared from squaric acid and *N,N*-dialkylanilines (8). Pigment samples were isolated from the product mixture by filtration and were usually analytically pure. As seen in Table 1, they all have high melting points (>200°C). As the length of the alkyl chain at the nitrogen increases, their solubility in organic solvents increases and this is accompanied by a decrease in melting point of the solid. The chemical yields of these soluble squaraines were low (<10%) and might be attributable to secondary reactions of squaraines with *N,N*-dialkylanilines in the product mixture.[5] Pure squaraines were isolated and purified by chromatographic techniques.

Squaraines exhibit intense absorption in the visible region in solution; their absorption maxima vary from 600 to 680 nm depending on the substituents at the nitrogen and in the phenyl ring. More detailed discussion on the electronic properties of squaraines will be addressed elsewhere.[6] In the ir spectra (Table 1) squaraines show no C=O stretching at ~1700 cm^{-1}. Instead, strong absorption bands at ~1600 cm^{-1} are observed and they are attributable to the C···C stretching in the four-membered ring and the phenyl ring. The absence of any C=O stretching is a strong indication of extensive bond delocalization in the four-membered ring of squaraine.

Owing to the high solubility of squaraine dyes prepared in this work, we were able to record ^{1}H nmr spectra on a routine nmr spectrometer. Results in Table 2 show that the chemical shifts of all the aliphatic protons are observed in the expected region. The chemical shifts of the aromatic protons are, however, quite characteristic and are worth further discussion.

Two sets of doublets at δ ~6.8 and ~ 8.3 ppm are observed for squaraines **2–4** and **12**, and they can be assigned to the β protons and the α protons in the phenyl ring, respectively. The

[4]Pigments denote colorants having very low solubility in various solvents and dyes generally refer to soluble colorants.

[5]Squaraines are known to react with amines to form adducts. In the case of tertiary aromatic amines, 1:1 squaraine–amine adducts have been isolated and characterized (9). In this work, we have found in controlled experiments that squaraines react with *N,N*-dialkylanilines to form colorless products. Although these colorless substances have not yet been characterized, we believe that the low chemical yield of squaraine dyes is at least in part the result of the consumption of squaraine in secondary reactions.

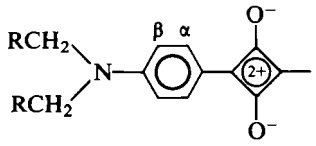
7	CD_2Cl_2	1.0 (t, 12H, J = 7.5 Hz), 1.1–1.9 (m, 16H), 2.88 (s, 6H), 3.43 (t, 8H, J = 8.3 Hz), 6.4–6.7 (m, 4H), and ~8.9 (d, 2H, J = 10 Hz)
9	$CDCl_3$	3.24 (s, 12H), 4.09 (s, 6H), 6.1–6.7 (m, 4H), and 8.55 (d, 2H, J = 9.2 Hz)
10	$CDCl_3$	1.27 (t, 12H, J = 7.5 Hz), 3.52 (q, 8H, J = 7.5 Hz), 4.0 (s, 6H), 6.0–6.5 (m, 4H), and 8.82 (d, 2H, J = 9.5 Hz)
11	CD_2Cl_2	1.23 (t, 6H, J = 7.5 Hz), 3.19 (s, 12H), 3.43 (q, 4H, J = 7.5 Hz), 6.5–6.7 (m, 4H), and 9.04 (d, 2H, J = 10 Hz)
12	CD_2Cl_2	1.3 (t, 6H, J = 7.5 Hz), 3.68 (q, 4H, J = 7.5 Hz), 4.72 (s, 4H), 6.87 (d, 4H, J = 9.6 Hz), 7.1–7.5 (m, 10H), and ~8.3 (d, 4H, J = 9.6 Hz).
13	$CDCl_3$	1.98 (p, 4H, J = 6.5 Hz), 3.83 (t, 4H, J = 6.5 Hz), 3.17 (s, 6H), 3.50 (t, 4H, J = 6.5 Hz), 6.69 (d, 2H, J = 9.2 Hz), and 8.15–8.45 (m, 4H).

coupling constant of the α and the β protons is ~9–10 Hz, a typical coupling constant for aromatic protons in the adjacent position. This assignment is supported by ^{1}H nmr data of squaraines **6**, **7**, **9**, **10**, and **11**. In these squaraines, because of the α substitution, the integration of low-field to high-field



aromatic protons is 2:4. On the other hand, when the β-position is substituted, such as in squaraine **13**, the integration becomes 4:2. A similar assignment was also reported earlier by Kazmaier *et al.* in their ^{1}H nmr study of squaraine pigment.[7]

The chemical shift of the α protons varies from δ 8.3 to 9 and is about 1–1.5 ppm lower field than the aromatic protons in the corresponding *N*,*N*-dialkylanilines (δ ~ 7–7.3 ppm). The mechanism of the deshielding of the α protons has recently been studied and will be reported elsewhere.[6]

Electron impact mass spectra of squaraines

The electron impact (EI) mass spectra of squaraines **1**–**4** are presented in Figs. 2–5. All four squaraines give apparently clean mass spectra. The unusual feature of the results lies in the consistent occurrence of ions of mass numbers higher than the expected molecular ion. Ions at *m*/*z* 334, 404, 474, and 544, which correspond to the addition of a CH_2, a C_2H_4, a C_3H_6, and a C_4H_8 unit to the molecular ions of **1**, **2**, **3**, and **4**, respectively, are observed. These results suggest that these high molecular weight ions have a general formula of (M + CHR). In addition to M + CHR$^{+\cdot}$, ions at (*M* + 2), which are assigned to the addition of two hydrogen atoms to M^+, are also observed. Molecular ions are usually detectable, but their relative intensities are weak. The observation of M + CHR$^{+\cdot}$ and M + $H_2$$^{+\cdot}$ suggests that some kind of intermolecular alkyl transfer and H transfer reactions are occurring in the mass spectrometer.

Lower mass number fragment ions also appear to be very general and unique. The structures of these fragment ions are assigned on the basis of the structure–property relationship established from the mass spectra of squaraines **1**–**11**.[8] The relative intensities of these fragment ions are tabulated in Table 3. The formation of fragment ions **15** and **18** is very unusual because the carbon α to the phenyl ring in squaraine is bonded to neither an oxygen atom nor a hydrogen atom; the formation of **15** and **18** indicates the occurrence of molecular rearrangement processes in the mass spectrometer. A more detailed discussion of these rearrangement processes will be presented in later sections.

The changes in fragmentation patterns as a function of ionization voltage have been studied for some of these squaraines. A gradual dominance of M + CHR$^{+\cdot}$ and M + $H_2$$^{+\cdot}$ in the mass spectrum is observed when the ionization voltage is lowered. These results, along with the metastable ion data and structure–property relationships presented in this paper, suggest that M + CHR$^{+\cdot}$ and M + $H_2$$^{+\cdot}$ are precursors of the lower mass number fragment ions (10).

Very similar mass spectrometric results are obtained for squaraines **5**–**7** (Table 3). In addition to M + $H_2$$^{+\cdot}$, M + CHR$^{+\cdot}$ at *m*/*z* 362, 432, and 572 are observed for **5**, **6**, and **7**, respectively. The fragmentation pattern is found to be very similar to those of **1**–**4** as well. Analogous mass spectra are also obtained for **8**–**11** and results are tabulated in Table 3.

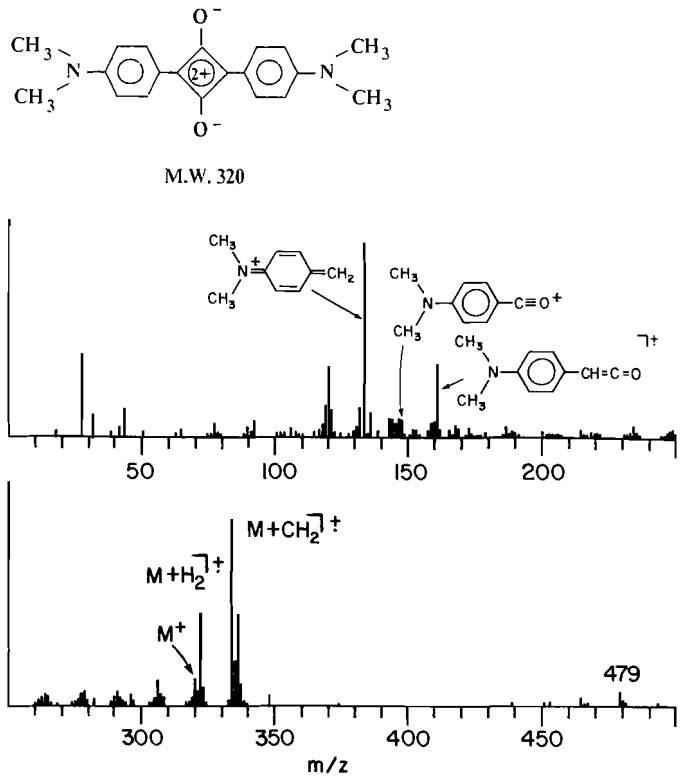


FIG. 2. EI mass spectrum of squaraine **1**.

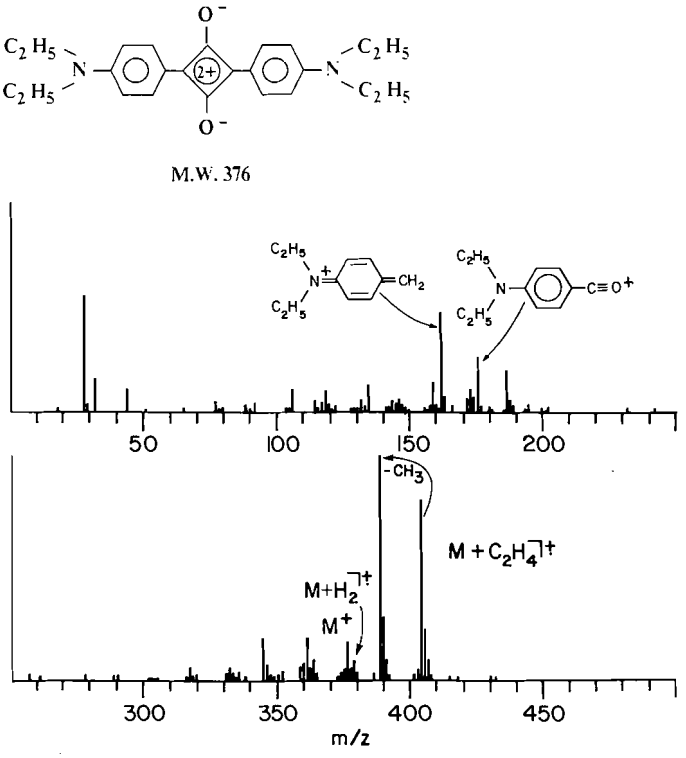

FIG. 3. EI mass spectrum of squaraine **2**.

[7]Reference 13.

[8]In the case of **1**, precise mass analyses were carried out for all fragment ions. Our results show that the observed values are in excellent agreement with the calculated values of all the proposed structures.

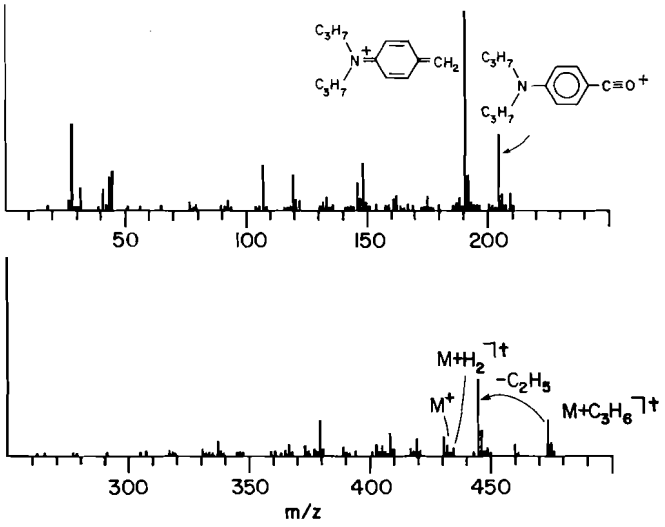

FIG. 4. EI mass spectrum of squaraine **3**.

The mass spectrum of **12** serves as another illustration of the interesting mass spectrometry of squaraine. There are two different alkyl groups at the nitrogen of **12** and two M + $CHR^{\dagger}$ are expected. Indeed, they are observed at m/z 528 and 590 and are assigned to M + $C_2H_4^{\dagger}$ and M + CH—$C_6H_5^{\dagger}$, respectively (Table 3). The mass spectrometric pattern of **12** is also found to be identical with those of **1–11** and the spectral data are included in Table 3.

Precursors of the fragment ions observed in the mass spectra of squaraines

The mass spectral data of **1–12** suggest that M + $CHR^{\dagger}$ and M + $H_2^{\dagger}$ are precursors of fragment ions of lower mass numbers. Their formation is presumably due to intermolecular alkyl transfer and H transfer reactions (see Scheme 1). Under the high vacuum conditions in the mass spectrometer, however, intermolecular reactions in the vapor phase are very unlikely. It is therefore very probable that these intermolecular reactions might just occur within a molecular aggregate of squaraine. In the following, we present methodology and results on the elucidation and identification of this aggregate.

(i) Cross-over experiment

Squaraines **3** and **7** were chosen for a cross-over experiment for the following reasons: (*1*) both **3** and **7** have a very similar vaporization temperature; (*2*) the mass spectra of **3** and **7** show no interference of the expected cross-over ions; (*3*) mixed aggregates of **3** and **7** can easily be prepared by solvent evaporation of a methylene chloride solution of **3** and **7**. The expected fragment ions in the cross-over experiments are summarized in Table 4.

The EI mass spectrum of the solid solution of **3** and **7** is shown in Fig. 6. In addition to the expected ions Pr_2SQ + $C_3H_6^{\dagger}$ at m/z 474 and Bu_2SQ + $C_4H_8^{\dagger}$ at m/z 572, two cross-over ions Pr_2SQ + $C_4H_8^{\dagger}$ at m/z 488 and Bu_2SQ + $C_3H_6^{\dagger}$ at m/z 558 are observed. While these spectral results clearly suggest that molecular aggregates of squaraines are precursors of the mass spectra of squaraines, a control experiment still must be performed so that the possibility of vapor phase reaction can be ruled out.

In the control experiment, **3** and **7** were placed in two fine capillary tubes. These two tubes were placed in the solid probe such that they were physically separated but were evaporated simultaneously. If vapor phase reactions were the cause of M + $CHR^{\dagger}$, cross-over M + $CHR^{\dagger}$ ions should be seen. The absence of cross-over M + $CHR^{\dagger}$ in Fig. 7 allows us to establish positively that molecular aggregates of squaraines are indeed precursors of the mass spectra.

The electronic properties of squaraines have been studied recently.[6] Squaraines are intramolecular charge-transfer complexes with the central four-membered ring being an electron acceptor (A) and the *N,N*-dialkylanilino moiety being an electron donor (D). In the solid state, intermolecular D–A interactions are shown to be very extensive and interplanar distances of squaraines are found to be ~3.5 Å[9] (*3b*, 11). It is thus not unreasonable to conclude that, due to the presence of strong D–A interactions in the solid state, squaraines vaporize as aggregates.

(ii) Metastable ion studies

Further questions that remain to be answered are the identity of the aggregate and the fragmentation processes of the aggregate. Numerous unsuccessful efforts have been made to search for the dimers and trimers of squaraines in the EI mass spectra. The absence of these species is presumably due to their low stability under the experimental conditions. The necessity of having an aggregate as a precursor for the mass spectrometry of squaraine has prompted us to study the metastable ions of

[9]K. Y. Law, unpublished X-ray data.

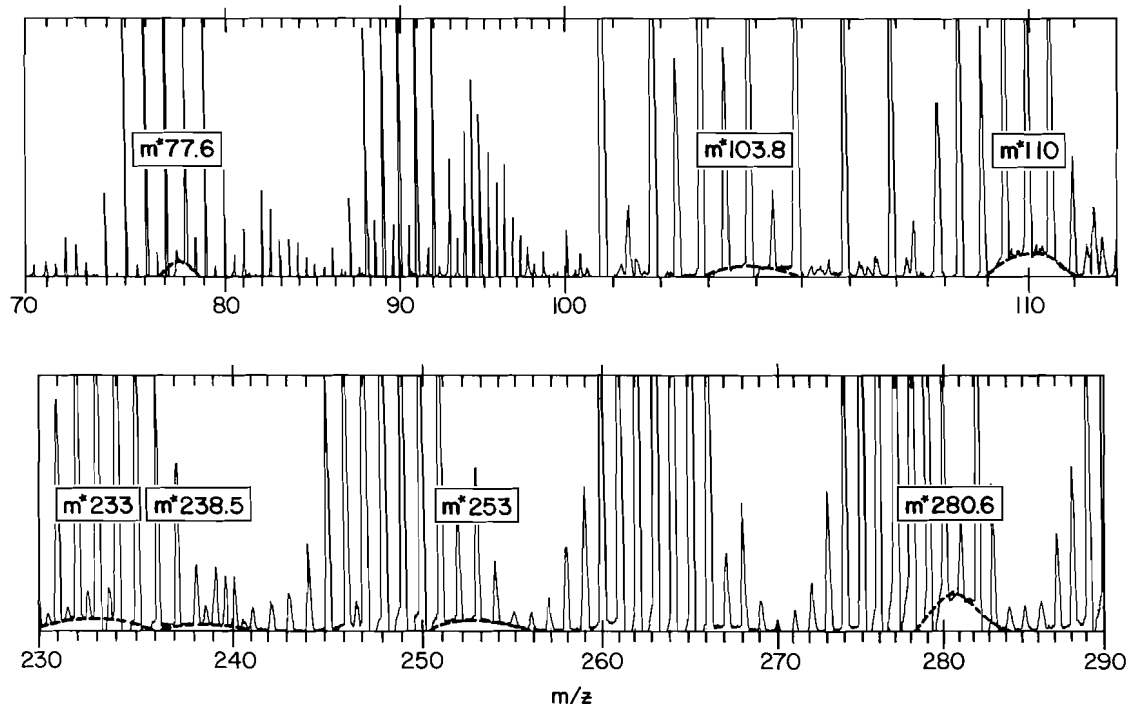

FIG. 8. Metastable ion peaks in the EI mass spectrum of **1**.

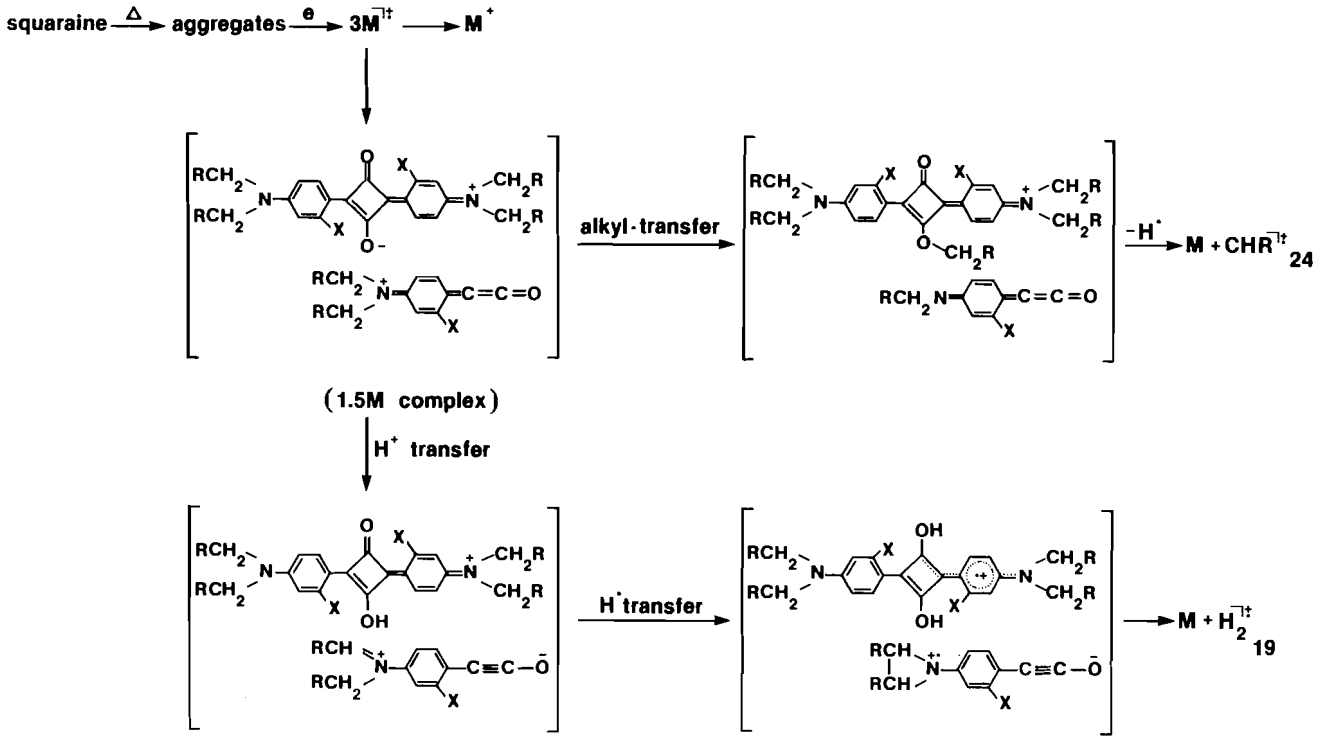
all our EI mass spectra. Our results show that metastable ions of squaraines bearing long alkyl chains are usually generated by dealkylation processes and they contribute very little to the understanding of the mass spectrometry of squaraine. On the other hand, metastable ions of squaraines having an *N,N*-dimethylamino moiety are very informative. Metastable ion peaks observed in the mass spectrum of **1** are presented in Fig. 8 and the data are tabulated in Table 5.

The impact of these metastable ions on the fragmentation processes will be discussed later. At present, we concentrate on the interpretation of evidence for the identity of the molecular aggregate. The metastable ion at *m/z* 238.5 is an exciting finding because it accounts for fragmentation of the trimer of **1** (*m/z* 960) to an ion at *m/z* 479. This 479 ion is actually observable in Fig. 2 and is assigned to $1.5M - H^{\cdot+}$ (see later for discussion). As seen in Table 5, one of the fragmentation processes of ion 479 is to fragment ion 334 ($M + CH_2{}^{\cdot+}$), which is the precursor of lower mass number ions; this result thus provides *the first evidence that the trimer is the precursor of the lower mass number fragment ions in the mass spectra of squaraines*.

Further evidence in support of the trimer comes from the metastable ions in squaraines **5** and **8**. Metastable ions at *m/z* 262.5 and 267.5 are observed in the EI mass spectra of **5** and **8**, respectively, and they may be explained in terms of fragmentation processes $3M^+ \rightarrow 1.5M - H^{\cdot+}$ and $3M^+ \rightarrow 1.5M^{\cdot+}$ for **5** and **8** respectively. These results not only suggest that the trimer precursor is very general, but also show that one of the fragmentation processes of the trimer is the cleavage of the four-membered ring of the central squaraine to form two species of approximately equal mass number.

(iii) Chemical ionization (CI) mass spectra of 1

The encouraging results in Table 5 prompted us to search for more direct evidence for the trimer. Using **1** as a model squaraine, we have performed a large number of CI experiments



SCHEME 1. Proposed fragmentation processes of squaraine aggregates.

in the hope that the trimer of **1** would become discernible under milder ionization conditions.

Several ionization gases, including methane, isobutane, ammonia, and methylene chloride, were used and CI mass spectra very similar to the one shown in Fig. 2 were obtained. On the other hand, a very different mass spectrum was recorded when N_2O was used as ionization gas. As seen in Fig. 9, a base peak at m/z 321, which is assigned to M + $H^{\cdot+}$, is observed.[10] Dimeric and trimeric species at m/z 641 and 961 are also observed at higher spectral sensitivities.[10] The identity of the 961 peak was further confirmed by a ms/ms experiment where two peaks at m/z 320 (base peak) and 642, which are assigned to M^+ and 2M + $H_2^{\cdot+}$ of **1** respectively, are seen (Fig. 10). On the basis of these findings, we conclude that the trimers of squaraines are precursors of the lower mass number fragments in the mass spectra.

Fragmentation processes

(i) Mechanism of the formation of M + $CHR^{\cdot+}$ and M + $H_2^{\cdot+}$

Two simple, logical fragmentation processes can be envisioned for these trimers and both have been observed experimentally. The first process involves the fragmentation of the trimer to monomeric and dimeric species. The occurrence of this process is supported by the CI ms/ms spectrum of **1** (Fig. 9).

The second process involves the cleavage of the four-membered ring of the central squaraine in trimer. The occurrence of this process is supported by results in Table 5 and the metastable ion data of squaraines **5** and **8**. This ring cleavage reaction is not unexpected, but the surprising result is the formation of a species with mass number ~1.5M. Squaraines are strong intramolecular D–A complexes and extensive intermolecular D–A interactions are known to occur in the solid state. As noted earlier, due to the preservation of this intermolecular D–A interaction squaraines vaporize as aggregates rather than monomeric species in the vapor phase. This in turn generates the unique mass spectrometry. The formation of this ~1.5M species can thus be visualized as an extension of the D–A interaction between a squaraine molecule and an *N,N*-dialkylanilino moiety after the ring cleavage.[11]

While there is sufficient evidence to support our conclusion that the trimer of squaraine is the precursor of the mass spectrum, and this trimer undergoes fragmentation to give immediate ions M^+, $1.5M^+$, or 1.5M − $H^{\cdot+}$ upon electron impact, the evidence from these intermediate ions to M + $CHR^{\cdot+}$ and M + $H_2^{\cdot+}$, which are shown to be precursors of the lower mass number fragment ions, is less strong. Major evidence for the formation of M + $CHR^{\cdot+}$ and M + $H_2^{\cdot+}$ from 1.5M − $H^{\cdot+}$ is obtained from the EI mass spectrum of **1** (Fig. 2). In addition to M + $CH_2^{\cdot+}$ and M + $H_2^{\cdot+}$, weak fragment ions corresponding to the addition of two CH_2 units (m/z 348) and to the addition of one hydrogen atom and one methyl group (m/z 336) are observed in the EI mass spectrum of **1**.[8] These results suggest that there are two active sites for radical reactions in a squaraine. In **1**, these two sites may combine with two hydrogen atoms to give M + $H_2^{\cdot+}$ at m/z 322, or they may combine with one hydrogen

[10]The peaks at m/z 321, 641, and 961 are assigned to M + $H^{\cdot+}$, 2M + $H^{\cdot+}$, and 3M + $H^{\cdot+}$, respectively. The addition of a hydrogen atom to these species is due to the presence of moisture in the ionization gas (Drs. R. Isensee and J. Slayback, private communication).

[11]The formation of a complex between squaraine and an electron donor was also observed in another occasion in the mass spectrometer. In the CI experiment of **1**, when CH_2Cl_2 was used as ionization gas, ion peaks at m/z 355 and 675 were recorded in the negative ion mass spectrum. These two ions are assigned to the complexes between chloride ion with the monomer and the dimer of **1** respectively.

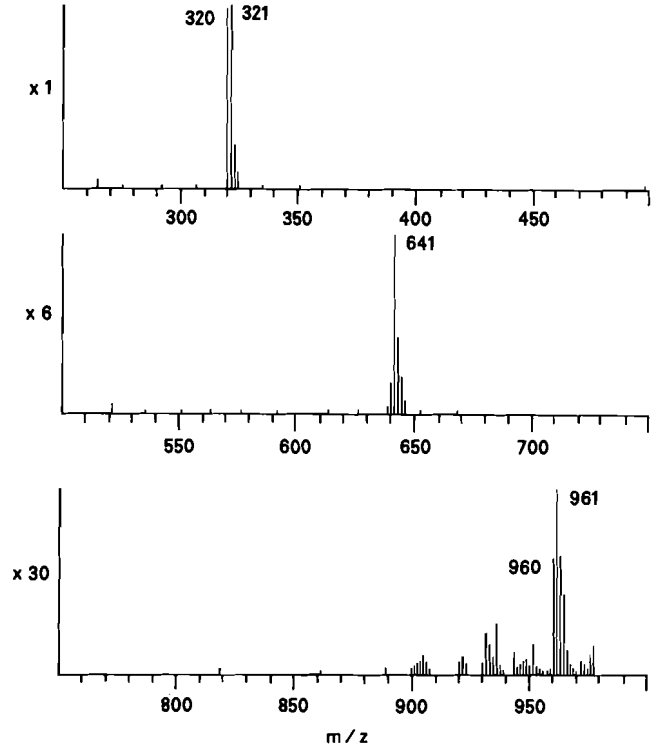


FIG. 9. CI (N_2O) mass spectrum of squaraine **1**.

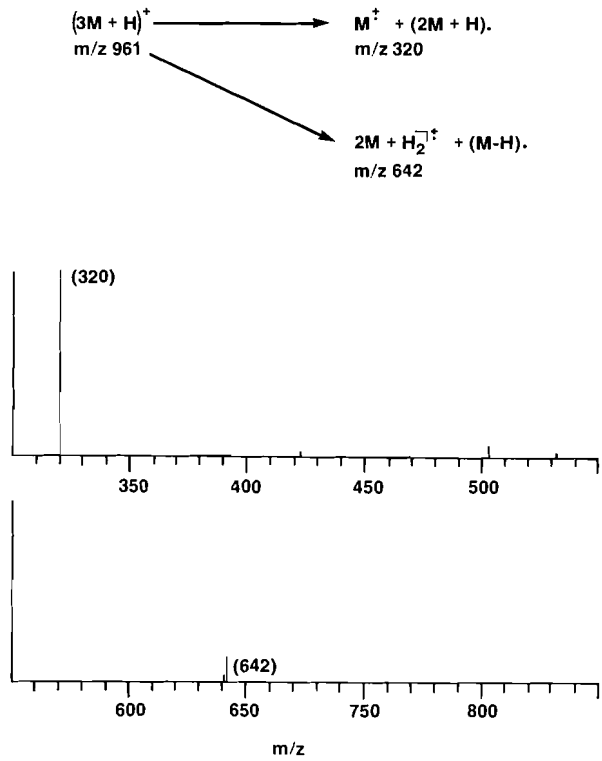

FIG. 10. CI ms/ms spectrum of ion 961.

atom and one methyl group to give M + H + $CH_3]^+$ at m/z 336. These two sites may combine with one or two methyl group(s) following radical disproportionation reactions to give M + $CH_2]^+$ at m/z 334 and M + CH_2 + $CH_2]^+$ at m/z 348. The only locations in **1** that are capable of accommodating these radical reactions are the C—O bonds. Using the metastable ion data in Table 5, we are able to show that at least two of these radical products, namely M + $CH_2]^+$ and M + CH_2 + $CH_2]^+$, are generated from 1.5M − $H]^+$. Because of the similar nature of the above radical reactions, we have assumed that M + $H_2]^+$ and M + H + $CH_3]^+$ are also generated in a similar way.

TABLE 6. Metastable ion data of **14**

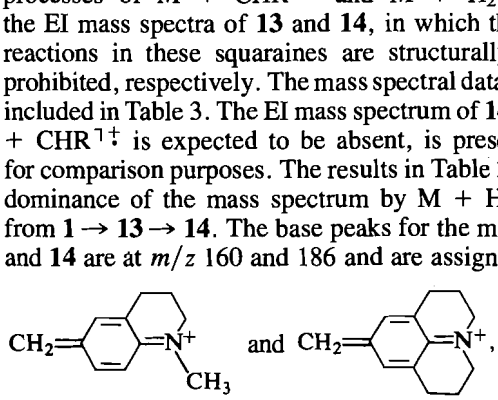
m/z metastable ion	Decay scheme	Fragmentation process
346.5	426 → 384	M + $H_2]^+$ − C_3H_6
161	214 → 186	0.5M + $H_2]^+$ − CO
134.5	186 → 158	186 − C_2H_4
120.9	172[a] → 144	172 − C_2H_4

[a]The structure of m/z 172 is assigned to 
The distribution of these radical reactions is expected to vary as the structure of squaraine changes. Usually, M + $H_2]^+$ and M + $CHR]^+$ are major fragmentation products of 1.5M + $H]^+$ (or $1.5M^+$). It may be a coincidence that all four possibilities of radical reactions are observed in the EI mass spectrum of **1**.

The mass spectrometry of *N,N*-dialkylaniline was also studied briefly and results show that dealkylation and dehydrogenation reactions are major fragmentation processes. It is, therefore, possible that, due to dealkylation and dehydrogenation reactions of the *N,N*-dialkylanilino moiety in the 1.5M species, hydrogen atoms or alkyl radicals are generated and captured by the neighboring squaraine molecule to form M + $CHR]^+$ and M + $H_2]^+$. As demonstrated earlier in the cross-over experiment, intermolecular vapor phase exchange reactions are not occurring in the mass spectrometer. If M + $CHR]^+$ and M + $H_2]^+$ are indeed formed by radical processes, they must be formed via some kind of intermediate complexes. A proposed scheme for the formation of M + $CHR]^+$ and M + $H_2]^+$ from $1.5M]^+$ is depicted in Scheme 1. More sophisticated experimentation is needed to elucidate the exact mechanism of these processes.

(ii) Fragmentation of M + $H_2]^+$

To facilitate our understanding of the detailed fragmentation processes of M + $CHR]^+$ and M + $H_2]^+$, we studied the EI mass spectra of **13** and **14**, in which the alkyl transfer reactions in these squaraines are structurally restricted and prohibited, respectively. The mass spectral data of **13** and **14** are included in Table 3. The EI mass spectrum of **14**, from which M + $CHR]^+$ is expected to be absent, is presented in Fig. 11 for comparison purposes. The results in Table 3 show a gradual dominance of the mass spectrum by M + $H_2]^+$ and ion **18** from **1** → **13** → **14**. The base peaks for the mass spectra of **13** and **14** are at m/z 160 and 186 and are assigned to



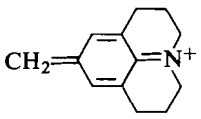
respectively. As expected, no M + $CHR]^+$ type species are detectable in the mass spectrum of **14** (Fig. 11).

Metastable ions of the mass spectrum of **14** have been studied. The data and the proposed fragmentation processes are shown in Table 6. Our results again reveal that dealkylation reactions are important fragmentation processes for the *N,N*-

TABLE 7. Additional metastable ion data for Schemes 2 and 3

Squaraine	*m/z* of metastable ion	Decay scheme	Fragmentation process	Remarks
2	374.6	404 → 389	$M + CHR^{\dagger\cdot} \xrightarrow{-R} M + CH^{\dagger\cdot}$	Scheme 3, path h
3	417.5	474 → 445	$M + CHR^{\dagger\cdot} \xrightarrow{-R} M + CH^{\dagger\cdot}$	Scheme 3, path h
	163.9	216 → 188	$0.5M^{\dagger\cdot} \xrightarrow{-CO}$ 	Scheme 2, path d
4	461.7	544 → 501	$M + CHR^{\dagger\cdot} \xrightarrow{-R} M + CH^{\dagger\cdot}$	Scheme 3, path h
6	402.6	432 → 417	$M + CHR^{\dagger\cdot} \xrightarrow{-R} M + CH^{\dagger\cdot}$	Scheme 3, path h
7	489.5	572 → 529	$M + CHR^{\dagger\cdot} \xrightarrow{-R} M + CH^{\dagger\cdot}$	Scheme 3, path h
8	127.0	179 → 151		Scheme 3, path i
11	137.5	189 → 161		Scheme 3, path i
	67.4	378 → 160		Scheme 2, paths b and d

dialkylanilino moiety. The most important metastable ion is at *m/z* 161 and is assigned to the decarbonylation reaction of 0.5M + $H_2^{\dagger\cdot}$ (*m/z* 214) to



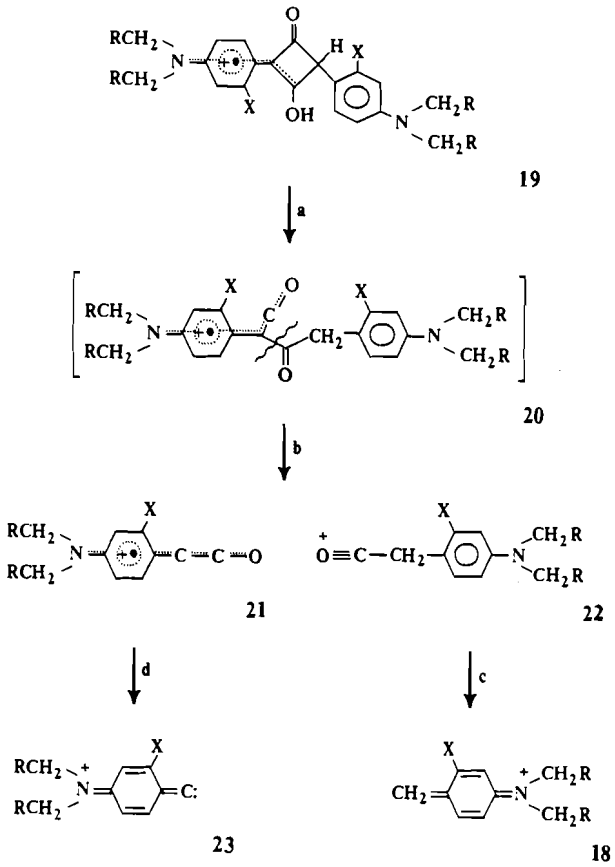
(*m/z* 186).

On the basis of the structure–property relationship for the mass spectra of **1**, **13**, and **14**, a general fragmentation scheme for M + $H_2^{\dagger\cdot}$ is shown in Scheme 2. The structure of M + $H_2^{\dagger\cdot}$, **19**, is drawn by analogy to the dihydrosquaraine species obtained from dimerization of ketene (12). Ring opening of the cyclobutenone structure in **19** will give **20**. After the cleavage of the weakest C—C bond in **20**, two species, **21** (*m/z* 0.5M) and **22** (*m/z* 0.5M + 2), are obtained. Decarbonylation of **21** and **22** (paths c and d) generates **23** and **18**, respectively. In **14**, the occurrence of path c is supported by metastable ion at *m/z* 161.

Additional evidence in support of Scheme 2[12] comes from metastable ions from the EI mass spectra of **3** and **11** (Table 7). Metstable ions at 163.9 and 67.4 are observed in the EI mass spectra of **3** and **11**, respectively, and they can be used to describe decarbonylation reactions as shown in path d of Scheme 2.

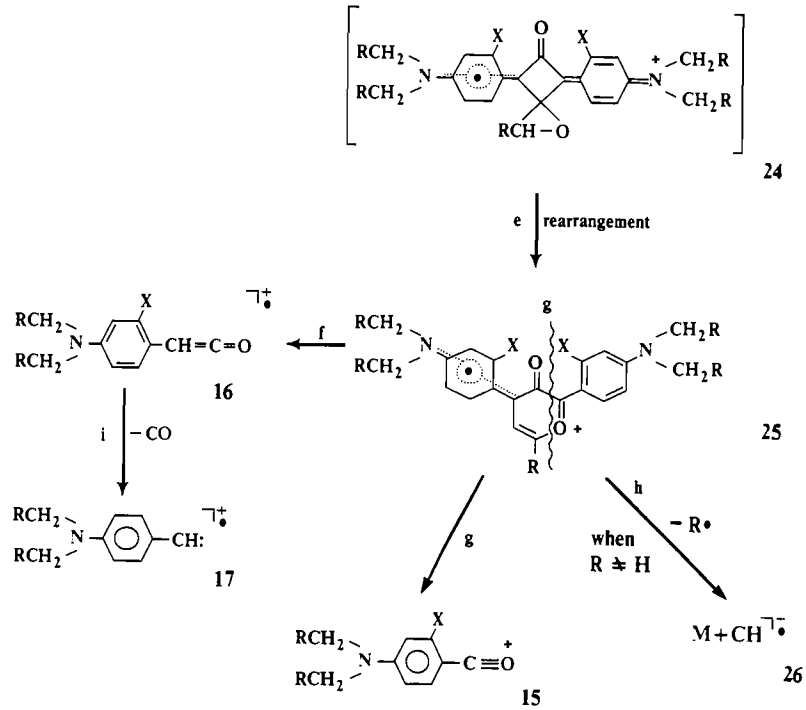
(iii) Fragmentation to M + CHR$^{\dagger\cdot}$

The mass spectral results of **1**, **13**, and **14** (Table 3) show that



SCHEME 2. Fragmentation of M + $H_2^{\dagger\cdot}$.

[12]The EI mass spectrum of the dihydrosquaraine reported in ref. 12 has recently been studied. Fragmentation processes identical to those described in Scheme 2 are observed.

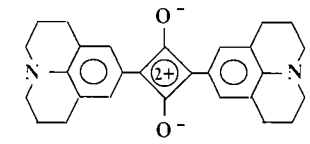


SCHEME 3. Fragmentation of M + CHR^{+}.

the intensity of fragment ion M + CHR^{+} decreases as the restriction of the alkyl transfer reaction increases. Assuming that there are two major fragmentation processes contributing to the EI mass spectrum of **1** (the fragmentation processes of M + CHR^{+} and M + H_2^{+}), the contribution of the fragmentation processes in Scheme 2 may be subtracted and results show that ions **15**, **16**, and **17** are associated with M + CHR^{+}. A general scheme for the formation of these three ions from M + CHR^{+} is presented in Scheme 3.

The proposed structure of M + CHR^{+} is **25**. Structure **25** fulfills all the requirements of M + CHR^{+} from the structure–property viewpoint. It has a very stable structure and is thus compatible with the observed high intensity of M + CHR^{+} in the mass spectra of squaraines. It can undergo sequential C—O and C—C bond cleavages (path g) to give a rearranged ion, **15**. Further evidence supporting structure **25** will be discussed later. In addition to the cleavage reaction in path g, **25** can also fragment into **16** (path f).[13] Ion **16** subsequently undergoes a decarbonylation reaction to give ion **17** (path i). The occurrence of paths f and i is supported by metastable ions of squaraine **1** (Table 5), and of squaraines **8** and **11** (Table 7). When R is not hydrogen, **25** will lose an R group to give ion **26** with general formula weight of (*M* + 13) (path h).[13] This dealkylation reaction is supported by a large number of metastable ion data (Table 7). The structure of **26**, however, cannot be deduced from the present data because there are five R groups in **25**.

As discussed earlier, M + CH_2^{+} of **1** is obtained from a radical addition–disproportion process, and the reaction site is the C—O group; thus the likely structure of M + CH_2^{+} would actually be an analog of **24**. The necessity of having a very stable M + CH_2^{+} that fragments into **15** leads us to propose that **24** is a primary product and that **24** undergoes a ring-expansion reaction (path e) to give a more stable ion **25**. In the case of squaraine **1**, the specific structure of M + CH_2^{+} is **27**.



M.W. 424

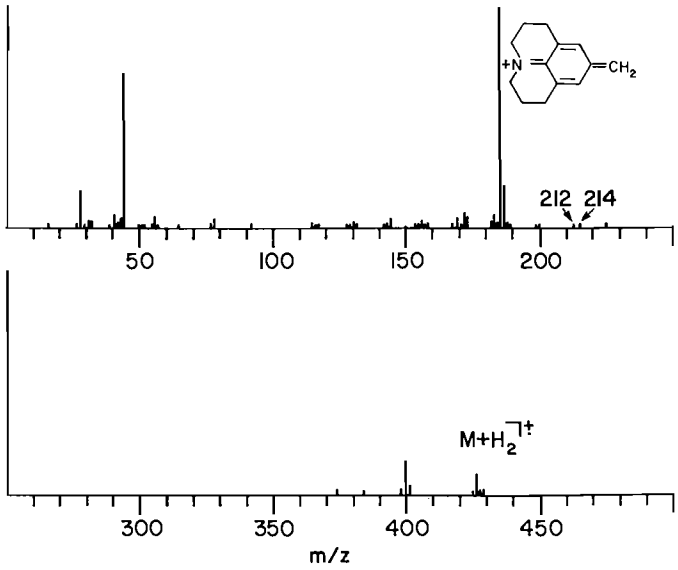


FIG. 11. EI mass spectrum of squaraine **14**.

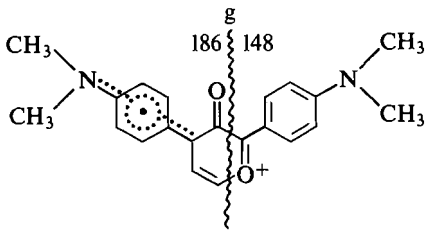
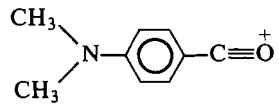
The structural assignment of **27** is substantiated by metastable ion data. Results in Table 5 show that three metastable ions are

[13]There is also a possibility that both ions **16** and M + CH^{+} are derived directly from **24** instead of from **25**. The present data do not allow us to distinguish these two possibilities.

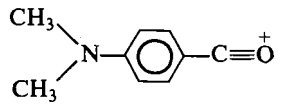


27 (*m/z* 334)

associated with **27**. The first metastable ion is at *m/z* 280.6 and is shown to derive from a decarbonylation reaction of **27**. The second metastable ion is at *m/z* 103.8 and is shown to derive from fragmentation process **27** (*m/z* 334) to an ion at *m/z* 186. The counter fragment of 186 is at *m/z* 148, which is assigned to



an analog of **15**. Therefore, metstable ion *m/z* 103.8 not only gives positive evidence of a parent–daughter relation between **27** and



(also **25** and **15**), but also provides structural information about the location of bond cleavage in path g. The third metastable ion is at *m/z* 77.6 and is due to fragmentation of **27** to *p-N,N*-dimethylaminophenyl ketene ion. The structural information obtained from the above three metastable ions suggests that **27** should have a carbonyl group and a *p-N,N*-dimethylaminophenyl ketene skeleton; it is also made up of two fragments, of *m/z* of 186 and 148. **27** appears to satisfy all these criteria comfortably and we are confident in the correctness of the structural assignment of **27** (also of **25**).

Summary and remarks

In summary, the EI mass spectra of squaraines **1–14** have been studied. Our results show that without exception, due to the strong intermolecular D–A interactions of squaraine molecules in the solid state, squaraines vaporize thermally as molecular aggregates in the mass spectrometer. The participation of non-exchanging molecular aggregates was revealed by a cross-over experiment. Metastable ion data and chemical ionization mass spectrometry subsequently showed that this aggregate is a trimer. Ionization of this aggregate by electron impact results predominantly in an intermediate fragment ion of formula weight about 1.5 times the molecular weight of the squaraine. This ion fragments primarily to M + $CHR^{\neg\ddagger}$ and M + $H_2^{\neg\ddagger}$. Further fragmentation of M + $CHR^{\neg\ddagger}$ and M + $H_2^{\neg\ddagger}$ generates the general and unique mass spectrometric pattern of squaraine. Since information about the substituents at the nitrogen can be revealed by M + $CHR^{\neg\ddagger}$ and the molecular weight of a squaraine can be obtained from M + $H_2^{\neg\ddagger}$ and M^+ or independent chemical ionization experimentation, it appears that, given the understanding of the fragmentation processes in this work, mass spectrometry may become a useful tool for structure determination of squaraines.

Synthesis of cyclopentane analogs of (2′- and 3′-deoxy-*erythro*-pentofuranosyl and ribofuranosyl)-2-thiouracil nucleosides

LUCJAN J. J. HRONOWSKI AND WALTER A. SZAREK
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 3, 1985[1]

LUCJAN J. J. HRONOWSKI and WALTER A. SZAREK. Can. J. Chem. **64**, 1620 (1986).

Three new carbocyclic analogs of nucleosides having the 2-thiouracil base have been synthesized. The cyclopentyl groups in these nucleosides are (±)-{(1β,3α,4β)-3-hydroxy-4-(hydroxymethyl)cyclopentyl} (see **31**), (±)-{(1β,2α,4β)-2-hydroxy-4-(hydroxymethyl)cyclopentyl} (see **32**), and (±)-{(1β,2α,3α,4β)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentyl} (see **33**). The nucleosides were prepared by coupling the appropriate hydroxy derivatives of *cis*-3-aminocyclopentanemethanol with 3-ethoxypropenoyl isothiocyanate (**21**) followed by cyclization in 15 *N* aqueous ammonia to give the 2-thiouracil nucleosides. In addition a modified and shortened synthetic route is described for the synthesis of (±)-(1β,2α,3α,4β)-4-amino-2,3-dihydroxycyclopentanemethanol (**19**). The ^{1}H nmr spectra at 200 MHz of all of the synthetic intermediates, the 2-thiouracil nucleosides, and of the corresponding carbocyclic analogs of uracil nucleosides are discussed. It is shown that each nucleoside has a characteristically unique ^{1}H nmr spectrum and that in general the protons in the sulfur-containing compounds resonate at lower fields than those in the corresponding oxygen-containing compounds. The magnitude of this downfield shift is inversely related to the number of bonds separating a particular proton from the sulfur atom.

LUCJAN J. J. HRONOWSKI et WALTER A. SZAREK. Can. J. Chem. **64**, 1620 (1986).

On a synthétisé trois nouveaux analogues carbocycliques de nucléosides qui possèdent une base thio-2 uracile. Les groupements cyclopentyles de ces nucléosides sont les suivants: le (±)-(hydroxy-3α (hydroxyméthyl)-4β cyclopentyle-1β) (voir le composé **31**), le (±)-(hydroxy-2α (hydroxyméthyl)-4β cyclopentyle-1β) (voir le composé **32**) et le (±)-(dihydroxy-2α,3α (hydroxyméthyl)-4β cyclopentyle-1β) (voir le composé **33**). On a préparé les nucléosides en procédant à un couplage des dérivés hydroxylés appropriés de l'amino-3 cyclopentaneméthanol-*cis* avec l'isocyanate d'éthoxy-3 propènoyle (**21**) qui est suivi par une cyclisation dans de l'ammoniaque 15 *N* pour donner les nucléosides le thio-2 uracile. De plus, on décrit une voie de synthèse modifiée et racourcié pour la synthèse du (±)-amino-4β dihydroxy-2α,3α cyclopentaneméthanol-1β (**19**). On discute des spectres rmn du ^{1}H à 200 MHz de tous les intermédiaires de synthèse, de tous les nucléosides du thio-2 uracile et des analogues carbocycliques correspondants des nucléosides d'uracile. On démontre que chaque nucléoside possède une spectre rmn du ^{1}H qui est caractéristique et que, en général, les résonances des protons des composés contenant du soufre apparaissent à des champs plus bas que ceux des résonances des produits contenant de l'oxygène. L'amplitude de ce déplacement vers des champs plus faibles est reliée d'une façon inverse avec le nombre de liaisons qui sépare un proton particulier de l'atome de soufre.

[Traduit par la revue]

Introduction

A variety of carbocyclic analogs of pyrimidine nucleosides have been shown to possess anticancer and (or) antiviral activity (1–5). In some of these analogs, for example, carbodine (2), which is the carbocyclic analog of cytidine, and the carbocyclic analog of thymidine (3), the only chemical modification from the naturally occurring compounds is the replacement of the furanose-ring oxygen by a methylene group; the antineoplastic and antiviral activities in these compounds are a consequence of this single modification. However, the carbocyclic analog of uridine was shown to be inactive against KB cells in culture or L1210 leukemia in vivo (6), and the carbocyclic analogs containing 5-fluorouracil showed only modest activity against P388 leukemia in vivo (4).

In a previous report (7) we described the regiospecific synthesis of cyclopentane analogs of (2′- and 3′-deoxy-*threo*-pentofuranosyl)-2-thiouracil nucleosides; in a preliminary study (8) the 2′-deoxy nucleoside was shown to inhibit the growth of K562 cells in culture. The observations by several workers (9, 10) that 2-thiouracil and various derivatives of 2-thiouracil are selectively incorporated into murine melanomas suggest that nucleosides containing the 2-thiouracil base should be synthesized and tested against the melanomas. The present report describes the synthesis of three carbocyclic analogs of 2-thiouracil nucleosides, **31**–**33**. These analogs were prepared by an approach similar to that used by Shealy and O'Dell (6) for the synthesis of the carbocyclic analogs of uracil nucleosides (**28**–**30**). The approach involves the prior preparation of appropriately substituted cyclopentylamines (11–13) followed by the elaboration of the base moiety at the amino substituent using the procedures of Shaw and Warrener (14, 15); in the present work, the cyclopentylamine **19** was prepared by a modified and shorter route.

[1]Revision received April 8, 1986.

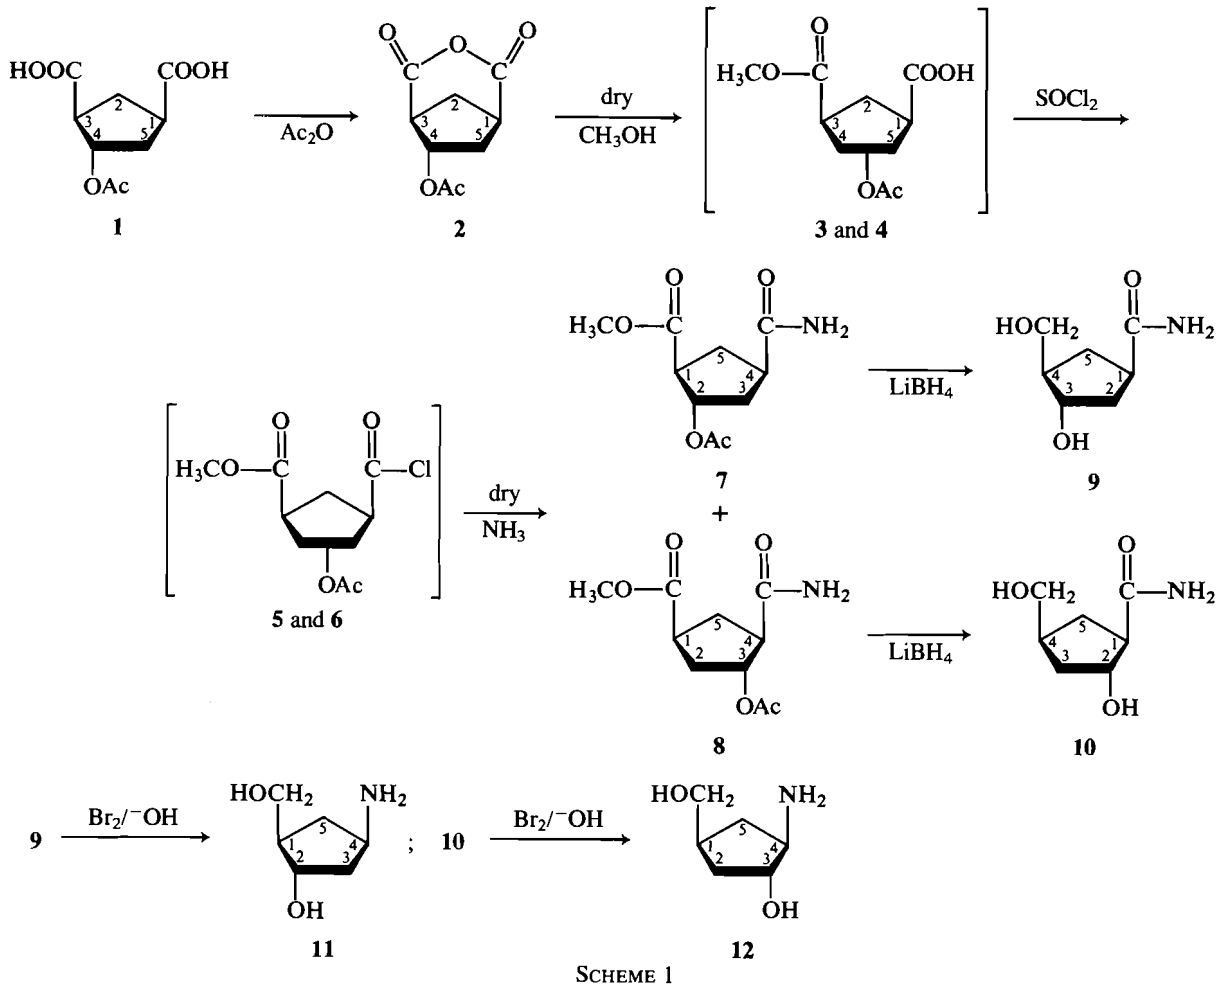
Results and discussion

The synthesis of all of the compounds shown in Scheme 1[2] has been described previously by Shealy and O'Dell (11, 12). Compound **1**, however, was prepared by oxidation of *exo*-5-norbornen-2-yl acetate with potassium permanganate using an adaptation of the method of Birch *et al.* (17) as described previously (7). Because of the important synthetic utility of the compounds, a detailed analysis of their high-resolution ^{1}Hmr spectra has been performed in the present work.

Characterization by 200-MHz ^{1}Hmr spectroscopy of the synthetic intermediates shown in Scheme 1

In Table 1 the ^{1}Hmr chemical shifts of **2** are compared to those of (±)-(1β,3β,4β)-4-acetoxy-1,3-cyclopentanedicarboxylic acid anhydride (**2***a*) (compound **3** in ref. 7), the isomer in which the acetoxy group is in the *cis* configuration. The spectra of these two compounds in $CDCl_3$ show some signifi-

[2]Structures **1**–**12**, **16**–**19**, and **22**–**33** depict only one enantiomer of racemic mixtures. The relative configurations of substituent groups on the cyclopentane ring are specified by the α,β system used for steroids (16). Substituents that are written below the plane of the cyclopentane ring are designated α and those above the plane of the ring as β.



SCHEME 1

TABLE 1. ^{1}H magnetic resonance chemical shift data[a] in $CDCl_3$ for **2** and **2***a*[b]

Proton	Compound 2	2a
1	3.34–3.40	3.26
2	2.17 (J = 12.9, 3.9 Hz)	1.94 (J = 13.1, 4.0 Hz)
2′	2.33	2.36
3	3.34–4.0	3.66
4	5.31 (^3J = 7.2, 2.6 Hz)	5.44 (^3J = 9.8, 6.4, 3.7 Hz)
5[c]	2.05–2.18	2.65 (J = 15.3, 9.8, 7.0 Hz)
5′[c]	2.63 (J = 15.6, 7.2, 1.6 Hz)	2.00
OAc	2.09	2.07

[a]More complete Hmr data for **2** are found in the experimental section, and for **2***a* in ref. 7.

[b]Compound **2***a* is (±)-(1β,3β,4β)-4-acetoxy-1,3-cyclopentanedicarboxylic acid anhydride (compound **3** in ref. 7).

[c]Assignments have been made on the basis of the coupling to H-4.

cant differences. The signal of H-4 resonates at δ 5.44 in the case of the *cis* compound (**2***a*) and at δ 5.31 in the case of **2**, and, as expected, much larger vicinal coupling constants are observed for this proton in the case of the *cis* compound than in **2** (see Table 1). The chemical shifts of H-1 and H-3 are also quite different in the two isomers. In the spectrum of the *cis* compound the signals of these protons are separated by 0.40 ppm, whereas in the spectrum of compound **2** they have similar chemical shifts with the multiplets overlapping in the δ 3.34–3.40 region. The vicinal coupling constants for H-2 and H-2′ are similar for both isomers although the chemical shifts of the H-2 protons are quite different (see Table 1). The chemical shifts of the acetoxy-methyl protons are very similar for both compounds.

Table 2 shows the chemical shifts in Me_2SO-d_6 of **7** and **8** and of the corresponding *cis* isomers (±)-methyl (1β,2β,4β)-2-acetoxy-4-carbamoylcyclopentanecarboxylate (**7***a*) and (±)-methyl (1β,3β,4β)-3-acetoxy-4-carbamoylcyclopentanecarboxylate (**8***a*) (compounds **5** and **9**, respectively, in ref. 7). The ^{1}Hmr spectra of each of the four isomers are quite different although they do show some trends. The signals for the amide protons ($CONH_2$) in the spectra of all four isomers appear as two well-separated, broadened singlets. The proton bonded to the carbon bearing the acetoxy group resonates at slightly different fields in the different isomers; however, the gross appearance of these multiplets in the spectra of compounds **7** and **8** is that of an overlapping doublet of triplets, whereas in the spectra of the *cis* isomers these multiplets appear as triplets of doublets, as would be expected for two *trans* vicinal couplings and one *cis* vicinal coupling in the former pair, and two *cis* vicinal and one *trans* vicinal coupling in the latter pair of isomers. In the spectra of compounds **7** and **8** the multiplets owing to the four methylene protons are very similar, having very similar coupling constants, although small differences in the chemical shifts do occur, as shown in Table 2. In the case of the corresponding *cis* isomers these multiplets are more complex and greater differ-

[a]More complete ^{1}Hmr data for **9** and **10** are found in the experimental section, and for **9***a* and **10***a* in ref. 7.

[b]Compound **9***a* is (±)-(1β,3β,4β)-3-hydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (compound **6** in ref. 7); compound **10***a* is (±)-(1β,2β,4β)-2-hydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (compound **10** in ref. 7).

ences in their appearance are observed at 200 MHz. The H-1 (and also the H-4) proton in each of the four isomers resonates at a characteristically different chemical shift, as shown in Table 2. Finally, the acetoxy-methyl protons in **7** and **8** resonate at δ 1.99 and 2.00, respectively, whereas in the *cis* isomers they resonate at δ 1.90.

The chemical shifts of the protons in compounds **9** and **10** and in their *cis* isomers are shown in Table 3. Each of the isomers has a characteristically different spectrum; however, in general, the signals for the *cis* isomers are found slightly further downfield relative to the corresponding ones for the *trans* compounds. In the spectrum of compound **9** the non-equivalence of the methylene protons of the hydroxymethyl substituent was clearly observed, as was also the case in the *cis* analog (±)-(1β,3β,4β)-3-hydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (**9***a*) (ref. 7); however, in **10**, as was seen also for the *cis* analog (±)-(1β,2β,4β)-2-hydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (**10***a*) (ref. 7), the chemical shifts of these protons were the same. Spin–spin decoupling experiments on compounds **9** and **10** allowed unambiguous and direct assignment of the multiplets and a confirmation of the structures assigned previously to these compounds by less direct methods using chemical and ^{1}Hmr evidence obtained on compounds that were derived from **9** and **10** (12).

TABLE 4. ^{1}H magnetic resonance chemical shift data[a] in Me_2SO-d_6 for **11**,**12**,**11***a*,[b] and **12***a*[b]

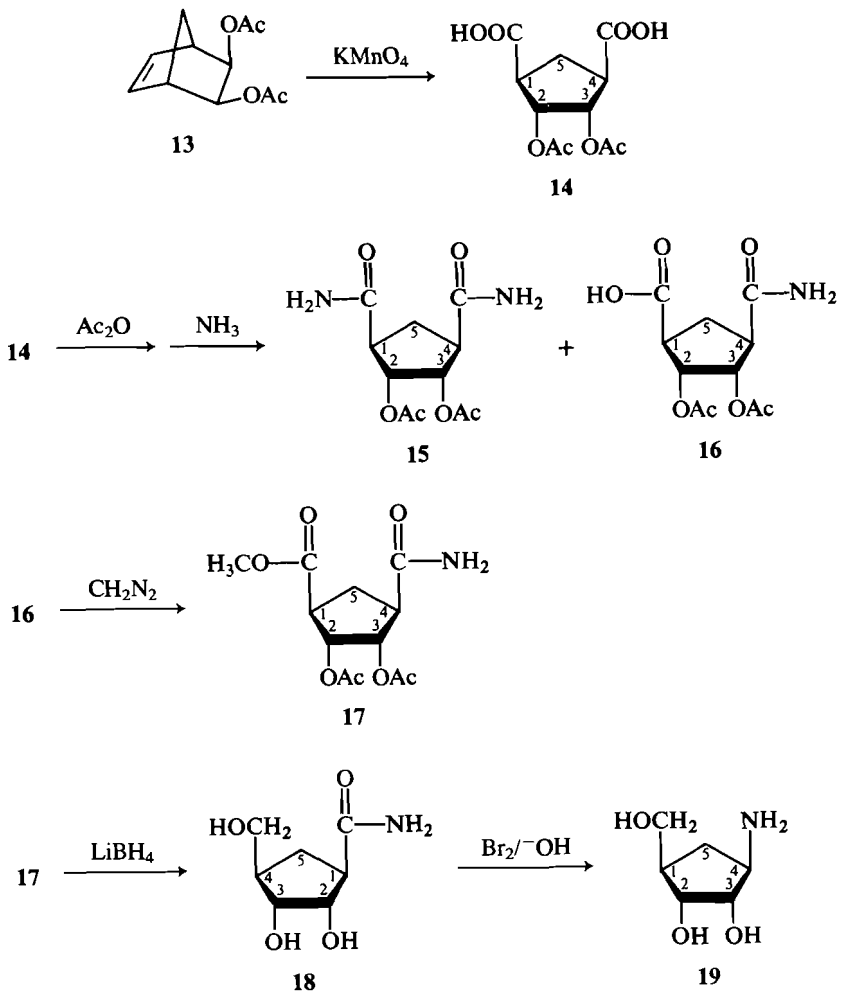
[a]More complete ^{1}Hmr data for **11** and **12** are found in the experimental section, and for **11***a* and **12***a* in ref. 7.

[b]Compound **11***a* is (±)-(1β,2β,4β)-4-amino-2-hydroxycyclopentanemethanol (compound **22** in ref. 7); compound **12***a* is (±)-(1β,3β,4β)-4-amino-3-hydroxycyclopentanemethanol (compound **17** in ref. 7).

The chemical shift data for **11** and **12** and for their *cis* analogs, given in Table 4, illustrate several interesting trends including shielding effects by vicinal hydroxyls. An identical chemical shift and coupling pattern were observed for the H-5 proton in the spectra of **11** and **12**. The chemical shifts of the protons at C-3 in **11** are essentially identical to those of the protons at C-2 in **12**; however, the coupling constants obtained from the two pairs of multiplets are quite different (see experimental section). The chemical shifts of the H-5′ proton in **11** and **12** are slightly different; however, the largest difference in chemical shifts for corresponding protons was observed for the protons at C-1 and C-4. In the spectrum of compound **11** these protons resonate at δ 1.78 and 3.3, respectively, whereas in the spectrum of **12** they resonate at δ 2.12 and 2.85, respectively. Thus, the effect of the *cis* vicinal hydroxyl group in these carbocyclic compounds is to shield adjacent protons, causing them to resonate further upfield; this type of shielding by a *cis* vicinal hydroxyl has been observed previously for a variety of carbohydrate derivatives including nucleosides and nucleotides (18–21). The ^{1}Hmr spectra of the *cis* analogs (**11***a* and **12***a*) also show a shielding effect by the *trans* vicinal hydroxyls, although of a slightly smaller magnitude, as illustrated by the chemical shifts for H-4 in the spectra of **11***a* and **12***a* (see Table 4). Similar shielding effects by vicinal hydroxyls were observed for compounds **9**, **10**, **9***a*, and **10***a* (see Table 3).

*Synthesis of (±)-(1β,2α,3α,4β)-4-amino-2,3-dihydroxycyclopentanemethanol (**19**)*

Since the time of the first stereoselective synthesis of compound **19** by Shealy and Clayton (13, 22) several different approaches have been developed for the synthesis of this amine



SCHEME 2

(23–25) and its protected derivatives (26, 27). The present approach (see Scheme 2) is a modification of the synthesis described by Shealy and Clayton (13, 22) and requires fewer synthetic steps. Compound **14** was prepared by oxidation of **13** with potassium permanganate, instead of sodium permanganate as was used by Shealy and Clayton (13, 22). Compound **16** was prepared as described previously (13); this procedure afforded also the diamide **15**. Esterification of **16** with diazomethane gave **17** in 79% yield; this compound was then reduced with lithium borohydride to give **18**, in high yield, from which compound **19** was prepared by a Hofmann reaction in aqueous medium.

^{1}H magnetic resonance spectra of compounds in Scheme 2

High-resolution ^{1}Hmr spectra at 200 MHz were obtained for the compounds shown in Scheme 2 (see Experimental). The assignment of the signals in the spectra of compounds **16** and **17** has been made with the aid of spin–spin decoupling experiments and by comparison of the chemical shifts of corresponding protons in the two compounds. All of the corresponding protons in compounds **16** and **17** have essentially identical chemical shifts and coupling constants except for the proton at C-1. In the case of compound **16** this proton resonates at δ 2.91, whereas in the case of the ester derivative **17** its signal is shifted downfield to δ 3.03. A similar downfield shift of the signal for the corresponding proton on esterification of the carboxyl group was observed previously in the spectra of the *cis* analogs (compounds **4** and **5** in ref. 7). Thus, once the identity of the H-1 signal had been established, it was possible to assign the remaining signals in the spectra of **16** and **17** by spin–spin decoupling. The assignment of the ^{1}Hmr signals in the spectra of compounds **18** and **19** also has been made with the aid of spin–spin decoupling experiments.

Synthesis of the nucleoside analogs

3-Ethoxypropenoyl isothiocyanate (**21**), which was synthesized as described by Shaw and Warrener (15), was coupled with the aminohydroxycyclopentanemethanols **11**, **12**, and **19** to give the corresponding thioureas **25**, **26**, and **27**, respectively (see Scheme 3). The thioureas were then cyclized using 15 *N* aqueous ammonia to give the 2-thiouracil nucleoside analogs **31**, **32**, and **33**, respectively. The analogous ureas, namely **22**, **23**, and **24**, and the uracil nucleoside analogs, namely **28**, **29**, and **30** (6), were also synthesized in the present study in order to determine their ^{1}Hmr spectra and to compare them to those of the thio analogs.

^{1}H magnetic resonance spectra of compounds in Scheme 3

The ^{1}Hmr spectra of the $C_2H_5OCH{=}CHCONHCONH{-}$ fragments in compounds **22–24** are very similar to each other with a variation in the chemical shifts of corresponding protons of less than 0.02 ppm. Similarly, the corresponding protons in the $C_2H_5OCH{=}CHCONHCSNH{-}$ fragments have essentially identical chemical shifts in the spectra of compounds **25–27**, with the largest variation, namely ±0.03 ppm, occurring for the CSNH protons. However, the chemical shifts of the

TABLE 5. ^{1}H magnetic resonance chemical shift data[a] in Me_2SO-d_6 for **22–27**

	Compound					
Proton	**22**	**23**	**24**	**25**	**26**	**27**
1′	4.16	3.69–3.85	3.87	4.65	4.28	4.38

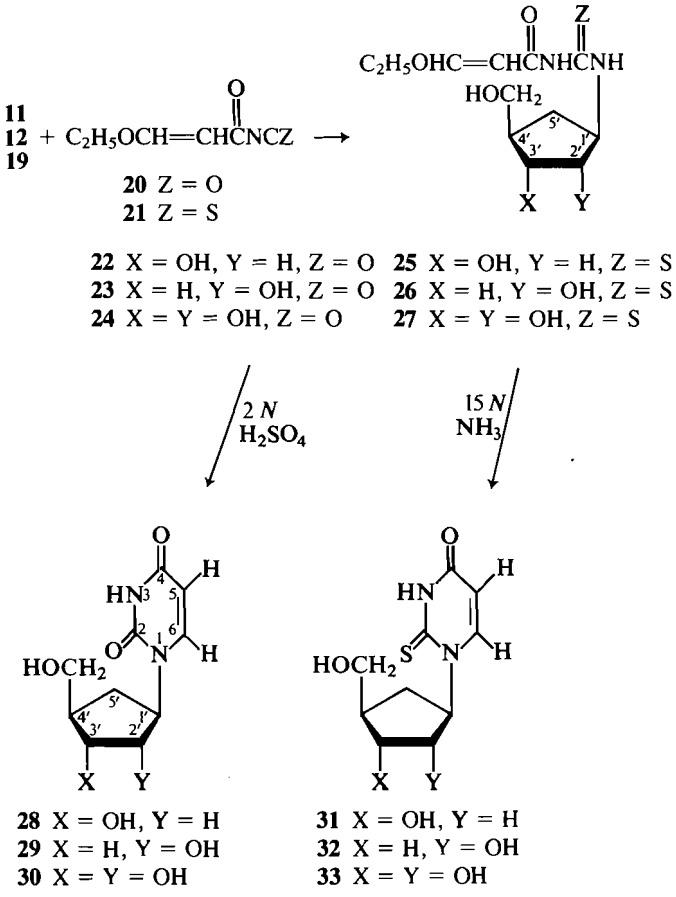
[a]More complete ^{1}Hmr data for each compound are found in the experimental section.

protons in the sulfur-containing fragments occur further downfield than those of the corresponding protons in compounds **22–24**. The magnitude of the downfield shift varies with the distance from the sulfur atom; for example, the CH_3 protons in compounds **25–27** resonate only 0.01 ppm further downfield, whereas the signals of the CSNH protons are shifted ~2.43 ppm downfield relative to the corresponding signals in the spectra of compounds **22–24**.

The chemical shift data for the cyclopentyl protons in compounds **22–27** are summarized in Table 5. In general, corresponding protons in compounds **25–27** resonate further downfield than those in compounds **22–24**. The magnitude of this downfield shift varies inversely with the number of bonds by which a particular proton is separated from the sulfur atom.



SCHEME 3

Thus, the signals for the protons at C-1′ in compounds **25–27** are shifted downfield by ~0.50 ppm relative to those of the corresponding protons in compounds **22–24**, whereas the signals for the protons at C-3′ or C-4′ are shifted downfield by only ~0.04 ppm. Table 5 also shows that, in the cases of compounds **22–27**, the *cis* vicinal hydroxyl has a shielding effect on H-1′ and H-4′ that is similar to that seen above for the cases of compounds **9–12** (see Tables 3 and 4).

Table 6 summarizes the chemical shift data of the nucleoside analogs **28–33**. The values for the corresponding protons on the uracil base are essentially identical in the cases of **28–30**, as are those for the corresponding protons on the 2-thiouracil base in the cases of **31–33**; however, the chemical shifts of the corresponding protons on the 2-thiouracil base are shifted downfield relative to those on the uracil base. In general, the chemical shifts of protons on the cyclopentane ring are shifted downfield in the spectra of the 2-thiouracil analogs relative to those of the uracil analogs. An exception to this pattern occurs for the H-5′ protons, which in the cases of the 2-thiouracil analogs resonate upfield relative to those in the cases of the uracil analogs (see Table 6). As shown by the chemical shift data for the H-1′ protons in Table 6, the *cis* vicinal hydroxyls have shielding effects in the nucleosides that are similar to those seen above for compounds **9–12** and **22–27**. The chemical shift data in Table 6 also show that each nucleoside has a unique and characteristic spectrum and one which is significantly different from the spectra of the nucleoside analogs that have the hydroxyls in the *cis* configuration (7).

Ultraviolet spectra of ***31–33***

The ultraviolet spectra of the 2-thiouracil nucleoside analogs **31–33** are very similar to each other and closely resemble those of 1-methyl-2-thiouracil (28) at the corresponding pH's.

Preliminary biological evaluation

Compounds **31–33** were tested for cell-growth inhibition using cultured L1210 cells as described previously (29). No cell-growth inhibition by these compounds was observed at concentrations as high as 10^{-3} *M*. Further biological studies are in progress.

Conclusions

Three new carbocyclic analogs of 2-thiouracil nucleosides have been synthesized. In addition, the carbocyclic analogs of uracil nucleosides first synthesized by Shealy and O'Dell (6) were synthesized and their ^{1}Hmr spectra were compared to those of the 2-thiouracil analogs. As shown previously for the carbocyclic analogs of uracil nucleosides, which contained the

hydroxyl in the *cis* configuration (7), the replacement of the oxygen by a sulfur atom at C-2 has a profound effect on the chemical shifts of not only the base protons but also of the protons on the cyclopentane ring. In general, the protons in the sulfur-containing compounds resonate at lower fields than the corresponding protons in the oxygen-containing compounds.

A modified route for the synthesis of (+)-(1β,2α,3α,4β)-4-amino-2,3-dihydroxycyclopentanemethanol (**19**) is described, which contains fewer steps than that described by Shealy and Clayton (13). The ^{1}Hmr spectra at 200 MHz of the synthetic intermediates leading to all of the nucleosides described in the present work have been determined also, and compared with the ^{1}Hmr spectra of the corresponding synthetic intermediates leading to the carbocyclic analogs of nucleosides having the hydroxyl group in the *cis* configuration (7).

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The ^{1}Hmr spectra were determined on a Brüker CXP-200 spectrometer at 200 MHz. Chemical shifts (δ) are given relative to Me_4Si (δ = 0). The coupling constants quoted are observed, uncorrected values; the instrument-resolution error is ±0.3 hertz. Assignments of chemical shifts and coupling constants were made with the aid of spin-decoupling experiments. The following abbreviations are used in describing ^{1}Hmr signals: singlet (s), doublet (d), triplet (t), quartet (q), quintuplet (qu), sextuplet (se), multiplet (m), and broadened (br). Ultraviolet spectra were recorded on a Perkin–Elmer 552 spectrophotometer. Thin-layer chromatography (tlc) was performed using silica gel 60 F-254 plates (BDH Chemicals). The developed plates were dried and sprayed with a solution of ceric sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150°C. Unless otherwise indicated, the same solvent was used for both tlc and column chromatography.

(±)-(1β,3β,4α)-4-Acetoxy-1,3-cyclopentanedicarboxylic acid anhydride (2)

(±)-*exo*-5-Norbornen-2-yl acetate (30) was oxidized with $KMnO_4$ to (±)-(1β,3β,4α)-4-acetoxy-1,3-cyclopentanedicarboxylic acid (7), which was then converted into compound **2** using acetic anhydride as described by O'Dell and Shealy (11); mp 118–120°C (lit. (11) mp 119–120°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.94 (1H, d of t, J_{gem} = 12.8, ^3J = 4.1 Hz, H-2), 2.03 (3H, s, OAc), 2.06 (1H, d of d of d of d, J_{gem} = 15.5, $^3J_{5,1}$ = 7.4, $^3J_{5,4}$ = 2.9, J = 1.5 Hz, H-5), 2.49 (1H, m, H-2′), 2.54 (1H, m, H-5′), 3.25–3.36 (2H, m, H-1 and H-3), 5.23 (1H, br d of d, $^3J_{4,5'}$ = 7.4, $^3J_{4,5}$ = 2.9 Hz, H-4). Spin–spin decoupling was performed at H-4; ^{1}Hmr (200 MHz, $CDCl_3$) δ: 2.05–2.18 (1H, m, H-5), 2.09 (3H, s, OAc), 2.17 (1H, d of t, J_{gem} = 12.9, ^3J = 3.9 Hz, H-2), 2.33 (1H, m, J_{gem} = 12.9 Hz, H-2′), 2.63 (1H, d of d of d, J_{gem} = 15.6, $^3J_{5',4}$ = 7.2, J = 1.6 Hz, H-5′), 3.34–3.40 (2H, m, H-1 and H-3), 5.31 (1H, m, $^3J_{4,5'}$ = 7.2, J = 2.6 Hz, H-4).

(±)-Methyl (1β,2α,4β)-2-acetoxy-4-carbamoylcyclopentanecarboxylate (7) and (±)-methyl (1β,3α,4β)-3-acetoxy-4-carbamoylcyclopentanecarboxylate (8)

Compound **2** was converted into compounds **7** and **8** as described by O'Dell and Shealy (11). Compound **2** was stirred in dry methanol at room temperature to give a mixture of compounds **3** and **4**. The solvent was removed and treatment of the mixture with $SOCl_2$ in benzene gave compounds **5** and **6**, which were then converted into compounds **7** and **8** using anhydrous NH_3 in benzene. Compounds **7** and **8** were isolated by silica gel column chromatography using toluene–acetone (3:2 (v/v)) as solvent. Compound **7** had R_f 0.23 (15:1 (v/v) methylene chloride – 2-propanol). mp 105–106°C (lit. (12) mp 108–109°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.81 (1H, d of t, J_{gem} = 12.7, ^3J = 10.0 Hz, H-5), 1.82 (1H, m, J_{gem} = 13.2, $^3J_{3,4}$ = 8.4, $^3J_{3,2}$ = 3.8 Hz, H-3), 1.99 (3H, s, OAc), 2.02 (1H, m, J_{gem} = 13.2, $^3J_{3',4}$ = 9.9, $^3J_{3',2}$ = 7.1 Hz, H-3′), 2.21 (1H, d of t, J_{gem} = 12.7, ^3J = 8.0 Hz, H-5′), 2.82 (1H, m, H-4), 2.87 (1H, t of d, $^3J_{1,2}$ = 4.2 Hz, H-1), 3.62 (3H, s, OMe), 5.20 (1H, m, $^3J_{2,3'}$ = 7.1 Hz, H-2), 6.87 (1H, br s, $CONH_2$), 7.38 (1H, br s, $CONH_2$). Spin–spin decoupling was performed at H-2. Compound **8** had R_f 0.38 (15:1 (v/v) methylene chloride – 2-propanol), mp 61–70°C (lit. (12) mp 73 and 80°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.80 (1H, d of t, J_{gem} = 12.7, ^3J = 10.1 Hz, H-5), 1.85 (1H, d of d of d, J_{gem} = 14, $^3J_{2,1}$ = 7.9, $^3J_{2,3}$ = 3.9 Hz, H-2), 2.00 (3H, s, OAc), 2.11 (1H, d of d of d, J_{gem} = 14, $^3J_{2',1}$ = 9.7, $^3J_{2',3}$ = 7.0 Hz, H-2′), 2.23 (1H, d of t, J_{gem} = 12.7, ^3J = 8.1 Hz, H-5′), 2.74 (1H, t of d, ^3J = 8.9, $^3J_{4,3}$ = 4.8 Hz, H-4), 2.98 (1H, m, H-1), 3.63 (3H, s, OMe), 5.11 (1H, d of t, $^3J_{3,2'}$ = 7.0, ^3J = 4.1 Hz, H-3), 6.94 (1H, br s, $CONH_2$), 7.39 (1H, br s, $CONH_2$). Spin–spin decoupling was performed at H-3.

(±)-(1β,3α,4β)-3-Hydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (9)

Compound **9** was prepared by reduction of **7** using lithium borohydride in tetrahydrofuran as described previously (11); mp 124–127°C (lit. (12) mp 127–128°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.29 (1H, d of d of d, J_{gem} = 11.9, $^3J_{5,1}$ = 9.2, $^3J_{5,4}$ = 7.3 Hz, H-5),

1.58 (1H, m, J_{gem} = 13.0, $^3J_{2,1}$ = 8.1, $^3J_{2,3}$ = 3.4 Hz, H-2), 1.76 (1H, d of d of d, J_{gem} = 13.0, $^3J_{2',1}$ = 9.2, $^3J_{2',3}$ = 6.2 Hz, H-2'), 1.75–2.0 (2H, m, H-4 and H-5'), 2.75 (1H, m, H-1), 3.25 (1H, m, J_{gem} = 10.5, $^3J_{to\,H\text{-}4}$ = 6.4 Hz, CH_2OH), 3.39 (1H, m, J_{gem} = 10.5, $^3J_{to\,H\text{-}4}$ = 6.1 Hz, CH_2OH), 3.85 (1H, m, $^3J_{3,2'}$ = 6.2, $^3J_{3,4}$ = 3.8, $^3J_{3,2}$ = 3.4 Hz, H-3), 4.45–4.51 (2H, m, OH), 6.68 (1H, br s, $CONH_2$), 7.24 (1H, br s, $CONH_2$). The amide and hydroxyl protons were exchanged with D_2O in the ^{1}Hmr determination. Spin–spin decoupling was performed at H-5, H-2, H-1, H-3, and CH_2OH.

*(±)-(1β,2α,4β)-2-Hydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (**10**)*

Compound **10** was prepared by reduction of **8** using lithium borohydride in tetrahydrofuran as described previously (11); mp 117–124°C (lit. (12) mp 123–124°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.28 (1H, d of t, J_{gem} = 12.7, ^3J = 9.5 Hz, H-5), 1.53 (2H, d of d, $^3J_{to\,H\text{-}4}$ = 7.9, $^3J_{to\,H\text{-}2}$ = 6.1 Hz, H-3 and H-3'), 1.87 (1H, d of t, J_{gem} = 12.7, ^3J = 7.7 Hz, H-5'), 2.14 (1H, m, H-4), 2.41 (1H, d of d of d, $^3J_{1,5}$ = 10.1, $^3J_{1,5'}$ = 8.0, $^3J_{1,2}$ = 5.9 Hz, H-1), 3.25 (2H, m, $^3J_{to\,H\text{-}4}$ = 6.4 Hz, CH_2OH), 4.08 (1H, m, H-2), 4.48 (1H, br t, ^3J = 4.7 Hz, CH_2OH), 4.72 (1H, br d, $^3J_{to\,H\text{-}2}$ = 4.3 Hz, OH at 2), 6.74 (1H, br s, $CONH_2$), 7.19 (1H, br s, $CONH_2$). Spin–spin decoupling was performed at H-5, H-5', H-4, H-3, H-2, H-1, and CH_2OH.

*(±)-(1β,2α,4β)-4-Amino-2-hydroxycyclopentanemethanol (**11**)*

A Hofmann hypobromite reaction in water was performed on **9** as described previously (11) to give compound **11**; R_f 0.41 (4:1 (v/v) ethanol – 15 *N* aqueous ammonia); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 0.94 (1H, d of t, J_{gem} = 12.6, ^3J = 7.4 Hz, H-5), 1.44 (1H, m, J_{gem} = 12.7, ^3J = 6.7 Hz, H-3), 1.62 (1H, m, J_{gem} = 12.7, $^3J_{3',4}$ = 6.8, $^3J_{3',2}$ = 4.6 Hz, H-3'), 1.78 (1H, m, H-1), 1.98 (1H, m, J_{gem} = 12.6, ^3J = 7.5 Hz, H-5'), 3.3 (1H, m, H-4), 3.3–3.4 (2H, m, CH_2OH), 3.88 (1H, d of t, $^3J_{2,3}$ = 6.7, $^3J_{2,3'}$ = $^3J_{2,1}$ = 4.6 Hz, H-2). Spin–spin decoupling was performed at H-2 and H-5.

*(±)-(1β,3α,4β)-4-Amino-2-hydroxycyclopentanemethanol (**12**)*

A Hofmann hypobromite reaction in water was performed on **10** as described previously (11) to give compound **12**; R_f 0.59 (4:1 (v/v) ethanol – 15 *N* aqueous ammonia); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 0.94 (1H, d of t, J_{gem} = 12.8, ^3J = 7.1 Hz, H-5), 1.45 (1H, m, J_{gem} = 13.3, $^3J_{2,1}$ = 9.2, $^3J_{2,3}$ = 5.2 Hz, H-2), 1.63 (1H, m, J_{gem} = 13.3, ^3J = 6.6 Hz, H-2'), 1.91 (1H, d of d of d, J_{gem} = 12.8, $^3J_{5',1}$ = 8.7, $^3J_{5',4}$ = 6.6 Hz, H-5'), 2.12 (1H, m, H-1), 2.85 (1H, t of d, ^3J = 6.8, $^3J_{4,3}$ = 5.1 Hz, H-4), 3.25 (2H, d, $^3J_{to\,H\text{-}1}$ = 6.0 Hz, CH_2OH), 3.53 (1H, m, H-3). Spin–spin decoupling was performed at δ 3.25 and 3.53.

*(1β,2α,3α,4β)-2,3-Diacetoxy-1,4-cyclopentanedicarboxylic acid (**14**)*

Compound **13** (13) (65.2 g, 0.31 mol) was dissolved in isooctane (0.7 L) and layered on top of water (3.5 L), and the mixture was cooled to 5°C. To the stirred mixture potassium permanganate (188 g, 1.19 mol) in water (3 L) was added over a period of 3 h. During the addition of the potassium permanganate a steady stream of CO_2 was passed through the reaction mixture and the temperature was maintained at 5–10°C using an external ice bath. Immediately after the potassium permanganate had been added, SO_2 was passed through the reaction mixture until it became clear, during which process the temperature was maintained below 15°C. The volume of the reaction solution was reduced to 1.2 L. It was then cooled in an ice bath, acidified with concentrated hydrochloric acid (85 mL), and extracted with diethyl ether (7 × 400 mL) to give a solid (72.6 g, 85%). This material was recrystallized from ethyl acetate to give **14** (65.2 g, 76.7%) as a white crystalline solid, mp 163–168°C (lit (13) mp 169–171°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.88 (1H, d of t, J_{gem} = 13.4, ^3J = 8.6 Hz, H-5), 2.01 (6H, s, OAc), 2.43 (1H, d of t, J_{gem} = 13.4, ^3J = 9.4 Hz, H-5'), 2.96 (2H, t of d, ^3J = 8.8, ^3J = 4.6 Hz, H-1 and H-4), 5.25 (2H, m, H-2 and H-3), 12.71 (2H, br s, CO_2H).

*(1β,2α,3α,4β)-2,3-Diacetoxy-1,4-cyclopentanedicarboxamide (**15**) and (±)-(1β,2α,3α,4β)-2,3-Diacetoxy-4-carbamoylcyclopentanecarboxylic acid (**16**)*

Compound **14** (32.0 g, 0.117 mol) was suspended in acetic anhydride (400 mL) and the mixture was heated on a steam bath for 1 h. Volatile components were evaporated to give a light brown oil (36 g). The oil was dissolved in dry tetrahydrofuran (500 mL) and the solution was cooled to 5°C. Anhydrous ammonia was blown over the stirred reaction solution (which was maintained at 5–10°C) for 25 min. The solvent was evaporated and the remaining white solid was dissolved in water (150 mL). Insoluble material was removed by filtration and washed with water (25 mL) that was combined with the filtrate. The filtrate was cooled to ice-bath temperature and an additional crop of a white solid was collected by filtration. The above two crops of solid (7.5 g) were shown to be (1β,2α,3α,4β)-2,3-diacetoxy-1,4-cyclopentanedicarboxamide (**15**), mp 230°C (dec.) (lit (13) mp 230°C (dec.)); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.67 (1H, d of t, J_{gem} = 12.9, ^3J = 9.9 Hz, H-5), 1.98 (6H, s, OAc), 2.20 (1H, d of t, J_{gem} = 12.9, ^3J = 8.9 Hz, H-5'), 2.84 (2H, t of d, ^3J = 9.2, ^3J = 4.8 Hz, H-1 and H-4), 5.15 (2H, m, H-2 and H-3), 7.00 (2H, br s, $CONH_2$), 7.46 (2H, br s, $CONH_2$). The cold filtrate was acidified (pH ~2) with concentrated hydrochloric acid and left at 4°C overnight. The solution was then extracted with diethyl ether (5 × 200 mL). On evaporation of the diethyl ether an oil (10 g) was obtained, which was shown by ^{1}Hmr spectroscopy to be a mixture consisting predominantly of compound **15**. The aqueous layer was then extracted with ethyl acetate (7 × 200 mL). On evaporation of the ethyl acetate a crystalline solid separated, which was collected by suction and washed with a small amount of ethyl acetate to give **16** (12.7 g 40%), mp 164°C (lit. (13) mp 166°C and 182–183°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.77 (1H, d of t, J_{gem} = 13.1, ^3J = 9.2 Hz, H-5), 1.99 (6H, s, OAc), 2.32 (1H, d of t, J_{gem} = 13.1, ^3J = 9.1 Hz, H-5'), 2.89 (1H, t of d, ^3J = 9.0, $^3J_{4,3}$ = 6.8 Hz, H-4), 2.91 (1H, t of d, ^3J = 9.6, $^3J_{1,2}$ = 5.4 Hz, H-1), 5.12 (1H, d of d, $^3J_{3,4}$ = 6.8, $^3J_{3,2}$ = 5.3 Hz, H-3), 5.28 (1H, m, H-2), 7.04 (1H, br s, $CONH_2$), 7.52 (1H, br s, $CONH_2$), 12.64 (1H, br s, CO_2H).

*(±)-Methyl (1β,2α,3α,4β)-2,3-diacetoxy-4-carbamoylcyclopentanecarboxylate (**17**)*

Compound **16** (12.7 g, 46 mmol) was dissolved in methanol (250 mL) and was methylated with diazomethane using procedures described previously (7, 31). The solution was left in the fume hood until the yellow color due to the slight excess of diazomethane faded. The solvent was evaporated and the residue was fractionated by column chromatography on silica gel to give a white solid (10.55 g, 79%), mp 85–90°C, R_f 0.35 (3:3:1 (v/v/v) toluene – ethyl acetate – 2-propanol); a second chromatographic separation on a silica gel column gave material having mp 89–91°C; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.79 (1H, d of t, J_{gem} = 13.2, J = 9.3 Hz, H-5), 2.00 (6H, s, OAc), 2.34 (1H, d of t, J_{gem} = 13.2, ^3J = 9.2 Hz, H-5'), 2.90 (1H, t of d, ^3J = 8.8, $^3J_{4,3}$ = 6.5 Hz, H-4), 3.03 (1H, t of d, ^3J = 9.3, $^3J_{1,2}$ = 6.2 Hz, H-1), 3.64 (3H, s, OMe), 5.13 (1H, d of d, $^3J_{3,4}$ = 6.5, $^3J_{3,2}$ = 5.3 Hz, H-3), 5.28 (1H, m, H-2), 7.09 (1H, br s, $CONH_2$), 7.55 (1H, br s, $CONH_2$). Spin–spin decoupling was performed at H-2. *Anal.* calcd. for $C_{12}H_{17}O_7N$: C 50.17, H 5.97, N 4.88; found: 50.00, H 5.86, N 4.85.

*(±)-(1β,2α,3α,4β)-2,3-Dihydroxy-4-(hydroxymethyl)cyclopentanecarboxamide (**18**)*

A solution containing lithium borohydride (6.5 g, 298 mmol) in tetrahydrofuran (400 mL) was refluxed in 1 h and cooled to ~40°C. To this solution was added a solution of compound **17** (13.73 g, 47.8 mmol) in tetrahydrofuran (100 mL), and the reaction solution was heated at reflux temperature for 2 h. The solution was cooled to ice-bath temperature and diluted dropwise with water (200 mL); there was then a slow addition of Amberlite IR-120 (H^+) cation-exchange resin (150 g). The mixture was stirred overnight. The resin was removed by filtration and washed with water (300 mL). The combined filtrate and washings were stirred with Amberlite IR-45 ($^-$OH) anion-exchange resin (260 g) to adjust the pH to neutrality. The resin was removed by filtration and washed with water (3 L). The combined filtrate and washings were evaporated to a semisolid, which was then evaporated with methanol (5 × 60 mL) to remove the boric acid as the methyl ester; an orange viscous oil (9.8 g) was obtained. The oil was stirred with tetrahydrofuran (60 mL) for 3 days and a light-brown solid was collected and dried over P_2O_5 at 60°C for 2 h to give a crude sample of **18** (7.83 g, 93%), which was shown by ^{1}Hmr spectroscopy to be

contaminated by small amounts of impurities. (The crude material was used for the preparation of **19**, as described below, without further purification.) A small sample (0.1 g) was purified by column chromatography on silica gel to give a single component having R_f 0.37 (5:1 (v/v) acetonitrile–water). This material was crystallized, from the minimal amount of ethanol necessary to dissolve the residue after evaporation of the chromatographic solvents and a drop of hexanes, to give a white solid that was collected by filtration and washed with diethyl ether, mp 135–137°C; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.25 (1H, m, H-5), 1.76–1.97 (2H, m, H-4 and H-5′), 2.48–2.61 (1H, m, H-1), 3.21–3.43 (2H, m, CH_2OH), 3.59 (1H, q, ^3J = 4.3 Hz, H-3), 3.80 (1H, m, $^3J_{2,1}$ = 7.1, $^3J_{2,3}$ = 5.2 Hz, H-2), 4.33 (1H, d, $^3J_{\text{to H-3}}$ = 4.7 Hz, OH at position 3), 4.47 (1H, d, $^3J_{\text{to H-2}}$ = 6.2 Hz, OH at position 2), 4.50 (1H, t, ^3J = 5.1 Hz, CH_2OH), 6.75 (1H, br s, $CONH_2$), 7.19 (1H, br s, $CONH_2$). Spin–spin decoupling was performed at H-2 and H-3. *Anal.* calcd. for $C_7H_{13}O_4N$: C 47.99, H 7.48, N 8.00; found: C 47.73, H 7.49, N 7.89.

*(±)-(1β,2α,3α,4β)-4-Amino-2,3-dihydroxycyclopentanemethanol (**19**)*

A freshly prepared solution of $Ba(OH)_2 \cdot 8H_2O$ (70.0 g, 222 mmol) in water (1.42 L) was filtered to remove any $BaCO_3$ present, and then cooled to 5°C. To this solution Br_2 (2.25 mL, 44 mmol) was added; immediately after the Br_2 had dissolved, compound **18** (7.73 g, 44 mmol) in water (100 mL) was added in one portion, and the reaction solution was left at room temperature for 1 h. It was then heated at 60–70°C for 1 h and left at 4°C overnight. The cold reaction mixture was acidified with 3 *M* H_2SO_4 (150 mL) and centrifuged to remove the $BaSO_4$. The reaction solution was passed through a column of Amberlite CG-120 (H^+) cation-exchange resin (200 g). The resin was washed with water (3.3 L), which was discarded. Elution of the resin with 2 *N* aqueous ammonia followed by evaporation of the solvent gave an orange-brown oil (3.12 g). The oil was dissolved in ethanol (30 mL), which caused a sticky brown material to precipitate. The ethanol solution was decanted and evaporated to give **19** (2.95 g, 46%) as an orange oil; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 0.88 (1H, m, J_{gem} = 11.8, ^3J = 7.3 Hz, H-5), 1.74–2.00 (2H, m, H-1 and H-5′), 2.96 (1H, m, H-4), 3.25–3.49 (3H, m, H-3 and CH_2OH), 3.66 (1H, t, ^3J = 4.7 Hz, H-2). Spin–spin decoupling was performed at H-2, H-4, and H-5.

*(±)-3-Ethoxy-*N*-{N′-[(1β,3α,4β)-3-hydroxy-4-(hydroxymethyl)cyclopentyl]carbamoyl}propenamide (**22**)*

Compound **22** was prepared by the coupling of 3-ethoxypropenoyl isocyanate (**20**) (6, 7, 14) with compound **11** as described by Shealy and O'Dell (6). After the volatile components had been evaporated, the crude oil was fractionated by column chromatography on silica gel to give **22** as a white solid, R_f 0.32 (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol), mp 148–151°C (lit. (6) mp 138–140°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.10 (1H, d of t, J_{gem} = 12.8, ^3J = 8.3 Hz, H-5′), 1.25 (3H, t, ^3J = 7.0 Hz, CH_3), 1.55 (1H, d of d of d, J_{gem} = 12.8, $^3J_{2',1'}$ = 7.9, $^3J_{2',3'}$ = 6.4 Hz, H-2′), 1.73–1.90 (2H, m, H-2″ and H-4′), 2.13 (1H, d of t, J_{gem} = 12.8, ^3J = 7.9 Hz, H-5″), 3.25–3.46 (2H, m, CH_2OH), 3.87 (1H, m, H-3′), 3.94 (2H, q, ^3J = 7.0 Hz, CH_3CH_2O), 4.16 (1H, se, ^3J = 7.7 Hz, H-1′), 4.55 (1H, t, $^3J_{\text{to }CH_2OH}$ = 5.2 Hz, CH_2OH), 4.59 (1H, d, $^3J_{\text{to H-3′}}$ = 4.5 Hz, OH at 3′), 5.50 (1H, d, ^3J = 12.2 Hz, H-2), 7.54 (1H, d, ^3J = 12.2 Hz, H-3), 8.49 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.7 Hz, CONHCON*H*), 10.00 (1H, br s, CON*H*CONH). Spin–spin decoupling was performed at H-1′, H-5″, and at H-3′.

*(±)-3-Ethoxy-*N*-{N′-[(1β,2α,4β)-2-hydroxy-4-(hydroxymethyl)cyclopentyl]carbamoyl}propenamide (**23**)*

Compound **23** was prepared by the coupling of 3-ethoxypropenoyl isocyanate (**20**) (6, 7, 14) with compound **12** as described by Shealy and O'Dell (6). After the reaction solvents had been evaporated, the residue was dissolved in a minimal amount of methanol and fractionated by column chromatography on silica gel to give **23** (49% yield) as a white solid, R_f 0.38 (2:2:1 (v/v/v) toluene–ethyl acetate–2-propanol), mp 128–130°C (lit. (6) 126–128°C); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.12 (1H, m, H-5′), 1.25 (3H, t, ^3J = 7.1 Hz, CH_3), 1.55 (2H, m, H-3′ and H-3″), 2.03–2.25 (2H, m, H-4′ and H-5″), 3.25–3.40 (2H, m, CH_2OH), 3.69–3.85 (2H, m, H-1′ and H-2′), 3.94 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.57 (1H, t, $^3J_{\text{to }CH_2OH}$ = 5.2 Hz, CH_2OH), 4.85 (1H, d, $^3J_{\text{to H-2′}}$ = 4.3 Hz, HO at position 2′), 5.50 (1H, d, ^3J = 12.5 Hz, H-2), 7.55 (1H, d, ^3J = 12.5 Hz, H-3), 8.52 (1H, br d, $^3J_{\text{to H-1′}}$ = 6.9 Hz, CONHCON*H*), 10.03 (1H, br s, CON*H*CONH). Spin–spin decoupling was performed at the H-5′ proton.

*(±)-3-Ethoxy-*N*-{N′-[(1β,2α,3α,4β)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentyl]carbamoyl}propenamide (**24**)*

Compound **24** was prepared by the coupling of 3-ethoxypropenoyl isocyanate (**20**) (6, 7, 14) with compound **19** as described by Shealy and O'Dell (6). After the reaction solvents had been evaporated, the crude oil was fractionated by column chromatography on silica gel to give **24** as a single component on tlc, R_f 0.43 (1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.04 (1H, d of t, J_{gem} = 13.0, ^3J = 7.8 Hz, H-5′), 1.24 (3H, t, ^3J = 7.1 Hz, CH_3), 1.88 (1H, m, H-4′), 2.11 (1H, d of t, J_{gem} = 13.0, ^3J = 8.7 Hz, H-5″), 3.25–3.44 (2H, m, CH_2OH), 3.50–3.66 (2H, m, H-2′ and H-3′), 3.87 (1H, qu, ^3J = 7.4 Hz, H-1′), 3.94 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.42 (1H, d, $^3J_{\text{to H-3′}}$ = 4.3 Hz, OH at position 3′), 4.59 (1H, t, $^3J_{\text{to }CH_2OH}$ = 5.1 Hz, CH_2OH), 4.66 (1H, d, $^3J_{\text{to H-2′}}$ = 5.5 Hz, OH at position 2′), 5.51 (1H, d, ^3J = 12.5 Hz, H-2), 7.55 (1H, d, ^3J = 12.5 Hz, H-3), 8.53 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.3 Hz, CONHCON*H*), 10.02 (1H, br s, CON*H*CONH). Spin–spin decoupling was performed at δ 1.88, 4.42, and 8.53.

*3-Ethoxypropenoyl isothiocyanate (**21**)*

Compound **21** was prepared from 3-ethoxypropenoyl chloride and potassium thiocyanate by a procedure similar to that of Shaw and Warrener (7, 15). A mixture of 3-ethoxypropenoyl chloride (7.27 g, 54 mmol) and potassium thiocyanate (5.25 g, 54 mmol) in acetonitrile (35 mL) was shaken at room temperature for 3.5 h and filtered to remove the potassium chloride. The salt was washed with a small amount of acetonitrile and the wash was combined with the filtrate. This acetonitrile solution of compound **21** was used immediately for the preparation of compounds **25**, **26**, and **27** without further processing.

*(±)-3-Ethoxy-*N*-{N′-[(1β,3α,4β)-3-hydroxy-4-(hydroxymethyl)cyclopentyl]thiocarbamoyl}propenamide (**25**)*

Compound **11** (3.32 g, 25 mmol) was dissolved in *N*,*N*-dimethylformamide (32 mL), and the solution was dried over 4 Å molecular sieves and cooled to ice-bath temperature; the acetonitrile solution (24 mL) of **21** (25 mmol, theoretical), prepared above, was added dropwise over a period of 10 min. The reaction solution was left at room temperature overnight and at 4°C for a day. The reaction solvents were evaporated and the resulting orange oil was evaporated with ethanol (2 × 10 mL). The oil was then fractionated by column chromatography on silica gel to give **25** (4.4 g, 61%) as a light-yellow solid, R_f 0.41 (3:3:1 (v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum showed only traces of impurities to be present in this material; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.18 (1H, m, J_{gem} = 12.8, ^3J = 8.0 Hz, H-5′), 1.26 (3H, t, ^3J = 7.1 Hz, CH_3), 1.65 (1H, m, J_{gem} = 13.2, ^3J = 7.3, ^3J = 6.3 Hz, H-2′), 1.85 (1H, m, H-4′), 1.94 (1H, m, J_{gem} = 13.2, ^3J = 7.7, ^3J = 4.6 Hz, H-2″), 2.28 (1H, d of t, J_{gem} = 12.8, ^3J = 8.0 Hz, H-5″), 3.2–3.5 (2H, m, CH_2OH), 3.90 (1H, m, H-3′), 3.98 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.58 (1H, t, $^3J_{\text{to }CH_2OH}$ = 5.1 Hz, CH_2OH), 4.65 (1H, m, H-1′), 4.66 (1H, d, $^3J_{\text{to H-3′}}$ = 4.1 Hz, OH at position 3′), 5.70 (1H, d, ^3J = 12.0 Hz, H-2), 7.59 (1H, d, ^3J = 12.0 Hz, H-3), 10.85 (1H, br s, CON*H*CSNH), 10.91 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.7 Hz, CONHCSN*H*). Spin–spin decoupling was performed at δ 2.28, 3.90, and 10.85.

*(±)-3-Ethoxy-*N*-{N′-[(1β,2α,4β)-2-hydroxy-4-(hydroxymethyl)cyclopentyl]thiocarbamoyl}propenamide (**26**)*

The procedure for the preparation of compound **26** was the same as that for **25**. To an ice-cold *N*,*N*-dimethylformamide solution (45 mL) of compound **12** (3.27 g, 25 mmol) was added 24 mL of the acetonitrile solution of **21** (25 mmol, theoretical) over a period of 10 min. This reaction solution was treated as described by the preparation of **25** and the resulting orange oil was fractionated by column chromatography on silica gel to give **26** (3.55 g, 49%) as a light-yellow gum, R_f 0.45 (3:3:1

(v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum showed only traces of impurities to be present in this preparation; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.17 (1H, m, H-5′), 1.26 (3H, t, ^3J = 7.1 Hz, CH_3), 1.59 (2H, m, H-3′ and H-3″), 2.13–2.36 (2H, m, H-4′ and H-5″), 3.29 (2H, m, CH_2OH), 3.90–4.04 (1H, m, H-2′), 3.98 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.28 (1H, m, H-1′), 4.59 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 5.0 Hz, CH_2OH), 4.96 (1H, d, $^3J_{\text{to H-2′}}$ = 4.3 Hz, OH at position 2′), 5.70 (1H, d, ^3J = 12.2 Hz, H-2), 7.60 (1H, d, ^3J = 12.2 Hz, H-3), 10.87 (1H, br s, CONHCSNH), 10.93 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.3 Hz, CONHCSNH). Spin–spin decoupling was performed at δ 3.29 and 4.28.

*(±)-3-Ethoxy-*N*-{N′-[(1β,2α,3α,4β)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentyl]thiocarbamoyl}propenamide (27)*

The procedure for the preparation of compound **27** was the same as that for **25**. To an ice-cold *N*,*N*-dimethylformamide solution (12 mL) of compound **19** (0.55 g, 3.7 mmol) was added 4 mL of the acetonitrile solution of **21** (4 mmol, theoretical) over a period of 5 min. The reaction solution was treated as described for the preparation of **25** and the resulting brown oil was fractionated by column chromatography on silica gel to give **27** (0.503 g, 45% crude) as a yellow oil, R_f 0.34 (3:3:1 (v/v/v) toluene – ethyl acetate – 2-propanol). This oil was used for the preparation of **33** without further purification, although its ^{1}Hmr spectrum showed minor peaks due to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.04 (1H, d of t, J_{gem} = 13.0, ^3J = 7.5 Hz, H-5′), 1.26 (3H, t, ^3J = 7.1 Hz, CH_3), 1.92 (1H, m, H-4′), 2.32 (1H, d of t, J_{gem} = 13.0, ^3J = 8.5 Hz, H-5″), 3.26–3.46 (2H, m, CH_2OH), 3.62–3.75 (2H, m, H-2′ and H-3′), 3.98 (2H, q, ^3J = 7.1 Hz, CH_3CH_2O), 4.38 (1H, qu, ^3J = 7.5 Hz, H-1′), 4.54 (1H, d, ^3J = 4.3 Hz, OH), 4.63 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 5.0 Hz, CH_2OH), 4.78 (1H, d, ^3J = 6.0 Hz, OH), 5.71 (1H, d, ^3J = 12.2 Hz, H-2), 7.60 (1H, d, ^3J = 12.2 Hz, H-3), 10.88 (1H, br s, CONHCSNH), 10.97 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.3 Hz, CONHCSNH). Spin–spin decoupling was performed at δ 3.69 and 4.38.

*(±)-1-{(1β,3α,4β)-3-Hydroxy-4-(hydroxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (28)*

A solution containing **22** (0.209 g, 0.77 mmol) in 2 *N* H_2SO_4 (15 mL) was heated at reflux temperature for 0.5 h, cooled in an ice bath, and neutralized with 2 *N* NaOH. The water was evaporated and the residue was extracted with warm ethanol (3 × 10 mL). After the ethanol had been evaporated, the residue was fractionated by column chromatography on silica gel to give **28** (0.166 g, 95%) as a white solid, mp 158–160°C (dec.) (lit. (6) mp 160–163°C (dec.)), R_f 0.43 (9:1 (v/v) acetonitrile–water); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.36 (1H, m, H-5′), 1.71–2.00 (3H, m, H-2′, H-2″, and H-4′), 2.08 (1H, d of t, J_{gem} = 12.5, ^3J = 7.7 Hz, H-5″), 3.34–3.56 (2H, m, CH_2OH), 3.97 (1H, m, H-3′), 4.63 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 5.1 Hz, CH_2OH), 4.75 (1H, d, $^3J_{\text{to H-3′}}$ = 4.2 Hz, OH at position 3′), 4.95 (1H, m, H-1′), 5.58 (1H, d, $^3J_{5,6}$ = 8.2 Hz, H-5), 7.69 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 11.21 (1H, br s, H-3). Spin–spin decoupling at δ 1.36 and 4.75.

*(±)-1-{(1β,2α,4β)-2-Hydroxy-4-(hydroxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (29)*

A solution of **23** (0.44 g, 1.61 mmol) in 2 *N* H_2SO_4 (20 mL) was treated as described above for the preparation of **28**. The residue from the ethanol extract was fractionated by column chromatography on silica gel to give **29** (0.275 g, 75%) as a white solid, mp 174–177°C (lit. (6) mp 174–176°C), R_f 0.46 (9:1 (v/v) acetonitrile–water); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.37 (1H, m, J_{gem} = 11.9, ^3J = 9.0 Hz, H-5′), 1.56 (1H, m, J_{gem} = 13.0, ^3J = 9.1, ^3J = 7.7 Hz, H-3′), 1.76 (1H, m, J_{gem} = 13.0, ^3J = 7.9, ^3J = 5.3 Hz, H-3″), 1.96 (1H, d of t, J_{gem} = 11.9, ^3J = 7.5 Hz, H-5″), 2.16 (1H, m, H-4′), 3.29–3.35 (2H, m, CH_2OH), 4.14 (1H, m, H-2′), 4.45 (1H, d of t, ^3J = 11.4, ^3J = 8.1 Hz, H-1′), 4.60 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 5.1 Hz, CH_2OH), 5.05 (1H, d, $^3J_{\text{to H-2′}}$ = 5.3 Hz, OH at position 2′), 5.59 (1H, d, $^3J_{5,6}$ = 8.2 Hz, H-5), 7.68 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 11.21 (1H, br s, H-3). Spin–spin decoupling was performed at δ 4.14.

*(±)-1-{(1β,2α,3α,4β)-2,3-Dihydroxy-4-(hydroxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (30)*

A solution of **24** (0.113 g, 0.39 mmol) in 2 *N* H_2SO_4 (10 mL) was treated as described above for the preparation of **28**. The residue from the ethanol extract was fractionated by column chromatography on silica gel to give **30** (0.079 g, 84%), mp 165–173°C (lit. (6) mp 176–179°C), R_f 0.35 (9:1 (v/v) acetonitrile–water); ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.26 (1H, m, H-5′), 1.85–2.08 (2H, m, H-4′ and H-5″), 3.33–3.45 (2H, m, CH_2OH), 3.71 (1H, m, H-3′), 3.97 (1H, m, H-2′), 4.57–4.68 (1H, m, H-1′), 4.60 (1H, d, $^3J_{\text{to H-3′}}$ = 4.1 Hz, OH at position 3′), 4.70 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 5.0 Hz, CH_2OH), 4.89 (1H, d, $^3J_{\text{to H-2′}}$ = 6.4 Hz, OH at position 2′), 5.59 (1H, d, $^3J_{5,6}$ = 7.7 Hz, H-5), 7.69 (1H, d, $^3J_{6,5}$ = 7.7 Hz, H-6), 11.20 (1H, br s, H-3). Spin–spin decoupling was performed at δ 1.26, 3.71, 3.97, and 4.89.

*(±)-2,3-Dihydro-1-{(1β,3α,4β)-3-hydroxy-4-(hydroxymethyl)cyclopentyl}-2-thioxo-4-(1*H*)-pyrimidinone (31)*

A solution of **25** (4.2 g, 14.6 mmol) in 15 *N* aqueous ammonia (125 mL) was heated in a 90°C oil bath for 25 min. The solution was cooled to room temperature and the reaction solvents were evaporated. The residue was evaporated with ethanol (50 mL) and triturated with warm ethanol (50 mL). The mixture was cooled in an ice bath, and the precipitated material was collected by filtration and washed with ethanol to give a light-yellow solid (2.148 g), mp 169–172°C. The volume of the combined filtrate and wash was reduced and an additional amount (0.562 g) of a light-yellow solid was obtained, mp 167–173°C, for a total yield of 2.71 g (77%). An analytical sample was prepared by recrystallization from ethanol to give a faintly yellow solid, mp 174–175°C, R_f 0.46 (1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol); uv λ_{max} (C_2H_5OH): 219 (ε 17 200), 273 (13 700) nm; λ_{max} (0.01 *N* HCl in C_2H_5OH): 219 (ε 17 200), 273 (13 600) nm; λ_{max} (0.01 *N* NaOH in C_2H_5OH): 240 (ε 19 600), 273 (16 300) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.32 (1H, d of t, J_{gem} = 12.7, ^3J = 9.5 Hz, H-5′), 1.80–1.99 (3H, m, H-2′, H-2″, and H-4′), 2.20 (1H, d of t, J_{gem} = 12.7, ^3J = 7.8 Hz, H-5″), 3.34–3.56 (2H, m, CH_2OH), 4.01 (1H, m, H-3′), 4.65 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 4.7 Hz, CH_2OH), 4.79 (1H, d, $^3J_{\text{to H-3′}}$ = 3.9 Hz, OH at position 3′), 5.96 (1H, qu, ^3J = 8.8 Hz, H-1′), 5.99 (1H, d, $^3J_{5,6}$ = 8.2 Hz, H-5), 7.85 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 12.53 (1H, br s, H-3). Spin–spin decoupling was performed at δ 2.20, 4.01, and 4.65. *Anal.* calcd. for $C_{10}H_{14}O_3N_2S$: C 49.57, H 5.82, N 11.56; found: C 50.14, H 6.00, N 11.79.

*(±)-2,3-Dihydro-1-{(1β,2α,4β)-2-hydroxy-4-(hydroxymethyl)cyclopentyl}-2-thioxo-4-(1*H*)-pyrimidinone (32)*

A solution of **26** (3.515 g, 12.2 mmol) in 15 *N* aqueous ammonia (100 mL) was heated in an oil bath at 90°C for 20 min. It was then treated as described for the preparation of **31** to give (in two crops) **32** (2.081 g, 71%) as a white solid, mp 217–220°C, R_f 0.45 (1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol, mp 219–220°C; uv λ_{max} (C_2H_5OH): 220 (ε 17 000), 274 (13 400) nm; λ_{max} (0.01 *N* HCl in C_2H_5OH): 220 (ε 16 800), 274 (13 300) nm; λ_{max} (0.01 *N* NaOH in C_2H_5OH): 240 (ε 20 000), 274 (15 700) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.20 (1H, m, H-5′), 1.59 (1H, d of t, J_{gem} = 13.1, ^3J = 8.4 Hz, H-3′), 1.78 (1H, m, J_{gem} = 13.1, ^3J = 8.1, ^3J = 5.0 Hz, H-3″), 2.04–2.26 (2H, m, H-4′ and H-5″), 3.29–3.35 (2H, m, CH_2OH), 4.22 (1H, m, H-2′), 4.64 (1H, t, $^3J_{\text{to CH}_2\text{OH}}$ = 5.2 Hz, CH_2OH), 5.11 (1H, d, $^3J_{\text{to H-2′}}$ = 5.0 Hz, OH at position 2′), 5.55 (1H, d of t, ^3J = 10.9, ^3J = 7.9 Hz, H-1′), 6.00 (1H, d, $^3J_{5,6}$ = 8.0 Hz, H-5), 7.85 (1H, d, $^3J_{6,5}$ = 8.0 Hz, H-6), 12.58 (1H, br s, H-3). Spin–spin decoupling was performed at δ 1.20 and 4.22. *Anal.* calcd. for $C_{10}H_{14}O_3N_2S$: C 49.57, H 5.82, N 11.56, S 13.23; found: C 50.09, H 5.98, N 11.88, S 13.26.

*(±)-2,3-Dihydro-1-{(1β,2α,3α,4β)-2,3-dihydroxy-4-(hydroxymethyl)cyclopentyl}-2-thioxo-4-(1*H*)-pyrimidinone (33)*

A solution of **27** (0.487 g, 1.60 mmol) in 15 *N* aqueous ammonia (25 mL) was heated in an oil bath at 100°C for 20 min. The reaction solvents were evaporated and the residue was fractionated by column chromatography on silica gel to give a while solid (0.263 g, 64%), R_f 0.53 (9:1 (v/v) acetonitrile–water). An analytical sample was prepared by recrystallization from methanol–ethanol to give a crystalline solid, mp 196–198°C; uv λ_{max} (C_2H_5OH): 220 (ε 16 900), 274 (13 100) nm; λ_{max} (0.01 *N* HCl in C_2H_5OH): 220 (ε 17 100), 274 (13 000) nm; λ_{max} (0.01 *N* NaOH in C_2H_5OH): 240 (ε 19 900), 273 (15 500) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6) δ: 1.08 (1H, m, J_{gem} = 12.2, $^3J_{5',4'}$ = 7.7 Hz,

H-5′), 1.95 (1H, m, H-4′), 2.18 (1H, d of t, J_{gem} = 12.2, ^3J = 8.5 Hz, H-5″), 3.33–3.47 (2H, m, CH_2OH), 3.73 (1H, m, H-3′), 4.05 (1H, m, $^3J_{2',1'}$ = 9.6, $^3J_{\text{to OH at 2'}}$ = 6.5, $^3J_{2',3'}$ = 5.8 Hz, H-2′), 4.67 (1H, d, $^3J_{\text{to H-3'}}$ = 3.5 Hz, OH at position 3′), 4.73 (1H, t, $^3J_{\text{to C}H_2\text{OH}}$ = 5.0 Hz, CH_2OH), 4.94 (1H, d, $^3J_{\text{to H-2'}}$ = 6.5 Hz, OH at position 2′), 5.67 (1H, q, ^3J = 9.6 Hz, H-1′), 6.01 (1H, d, $^3J_{5,6}$ = 8.0 Hz, H-5), 7.87 (1H, d, $^3J_{6,5}$ = 8.0 Hz, H-6), 12.6 (1H, br s, H-3). Spin–spin decoupling was performed at δ 1.08, 3.4, 3.73, and 4.05. *Anal.* calcd. for $C_{10}H_{14}O_4N_2S$: C 46.50, H 5.46, N 10.85, S 12.41; found: C 46.62, H 5.54, N 10.84, S 12.18.

Alkyl dialkylphosphinates, thionates, thioates, and dithioates have been studied under alkaline hydrolysis conditions in 60% DME – H_2O and pure H_2O. Substitution of S for O in the phosphoryl group has only a small rate retarding effect, typically less than a factor of 10. The effect of the similar replacement in the leaving group, however, can lead to rate increases greater than a factor of 100. Activation parameters were determined and the ΔS^* values range from −19 to −49 eu for the bimolecular reactions. The more negative values are for the esters with higher sulfur content and/or sterically large substituents. The results are discussed in terms of a pathway involving a pentacoordinate intermediate.

ROBERT D. COOK, SELIM FARAH, LABIB GHAWI, ADNAN ITANI et JUBRAIL RAHIL. Can. J. Chem. **64**, 1630 (1986).

Opérant dans un mélange à 60% de DME/eau ainsi que dans de l'eau pure, on a étudié les dialkylphosphinates, les thionates, les thioates et les dithioates d'alkyles dans des conditions d'hydrolyse alcaline. La substitution du S par un O dans le groupement phosphoryle provoque un faible ralentissement de la vitesse de la réaction et le rapport des deux vitesses est plus petit que 10. Toutefois, si l'on effectue un remplacement semblable dans le groupement nucléofuge, la vitesse de la réaction est augmentée par un facteur de plus de 100. On a déterminé les paramètres d'activation et, pour les réactions bimoléculaires, les valeurs des ΔS^* varient de −19 à −49 ue. Les valeurs les plus négatives sont liées aux esters comportant le plus grand nombre d'atomes de soufre et/ou les substituants les plus encombrants d'un point de vue stérique. On discute des résultats en fonction d'une voie réactionnelle impliquant un intermédiaire pentacoordonné.

[Traduit par la revue]

Introduction

The alkaline hydrolysis reactions of phosphorus esters, especially those of phosphates (1), have been extensively investigated. The reactions of phosphonates (1) and phosphinates (1, 2) have also been the subject of several reports. There have been, however, only a few reports on the effect of the replacement of oxygen by sulfur on the reactivity of these esters. There is interest in the reactivity of phosphorothioates because of their use as phosphate analogues in stereochemical studies of phosphoryl transfer reactions (3).

Ketelaar, Gersmann, and Koopmans have reported that a series of *p*-nitrophenyl phosphorothioates (P=S) hydrolyze 30 to 160 times slower in base solution than the corresponding phosphates (4). Breslow and Katz have shown that in the aqueous hydrolysis of the mono *p*-nitrophenyl ester of the phosphate dianion, the P=O esters reacts 60 times slower than the P=S (5). However in the enzymatic hydrolysis catalyzed by alkaline phosphatase the opposite is true with a reactivity ratio (P=O/P=S) of approximately 100. The authors suggested that a P=O/P=S ratio greater than 1 is an indication of an associative mechanism, while values less than 1 suggest a dissociative pathway (5). Chlebowski and Coleman have also reported a large rate difference in favor of the P=O ester in the Zn(II) alkaline phosphatase catalyzed hydrolysis of a phosphate monoester (6). Benkovic and Schray have, however, suggested that the use of the P=O/P=S reactivity ratio as a basis for the choice of reaction pathway may be misleading (7).

Little has been published on the hydrolysis of phosphinothionates. In one report (8), the authors find that, for $(ClCH_2)_2P(X)OC_2H_5$, the P=O/P=S ratio is 4 while, for $(C_2H_5)_2P(X)OC_2H_5$, the ratio is 0.70 for the reaction in base.

In order to understand more the effect of sulfur on the reactivity of phosphorus esters a series of phosphinate esters **1**–**4** was synthesized and studied under alkaline hydrolysis conditions. In these esters not only is the effect of sulfur in the P=X group studied but also in the leaving group.

Phosphinates, in general, hydrolyze via an associative pathway (2) and there is strong evidence that the reaction precedes via a pentacoordinate intermediate (reaction [1]).

[1] $R_2P(O)OR' + {}^-OH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}}$  $\xrightarrow{k_2} R_2PO_2^- + R'OH$

Support for such an intermediate is plentiful in cyclic phosphorus esters (9) and there are also two reports supporting their existence in acyclic systems, one in a phosphonate (10) and one in a phosphinate (11). The results of this study will be analyzed in terms of a pathway involving an intermediate (reaction [1]).

phosphinothioates (**3**), and phosphinodithioates (**4**) are given in Tables 1–4, respectively.

The activation parameters for selected esters are given in Table 5.

Discussion

General trends

(a) Influence of substituents on phosphorus

The alkyl substituents on phosphorus have a large effect on the reaction rate, especially in the esters with alkoxy leaving groups. Table 6 gives the relative rate data for the four ester systems, and for the sake of comparison, the results in a carboxylic ester series (12). Attempts to correlate the results in series 1 and 5 of Table 6 with the Taft polar equation (13) (eq. [2]), the Taft steric equation (eq. [3]), and the combined equation (eq. [4]) were not successful. Although phosphinates

$$[2] \quad \log k_R/k_{CH_3} = \sigma^*\rho^*$$

$$[3] \quad \log k_R/k_{CH_3} = \delta E_s$$

$$[4] \quad \log k_R/k_{CH_3} = \sigma^*\rho^* + \delta E_s$$

usually undergo hydrolysis by attack of ^-OH at phosphorus with subsequent P—O bond (2*a*) cleavage, Haake and Rahil (2*b*) have recently reported that the sterically hindered phosphinate, methyl diisopropylphosphinate, hydrolyzes with approximately 25% C—O bond cleavage. It is not surprising then that, with this mixed cleavage pattern for some esters, there is no correlation with the Taft equation when applied to the effect of substituents on phosphorus.

Alkyl substituents have a greater effect on phosphinate hydrolysis than on carboxylic ester hydrolysis in keeping with a tetrahedral phosphorus ground state going to a pentacoordinate intermediate rather than trigonal carbon going to a tetrahedral intermediate.

(b) Influence of the leaving groups

This topic can be discussed in two parts: (*i*) the influence of the atom Y (O or S) on the reaction rate and (*ii*) the influence of the alkyl group R′ on the reaction rate. Table 7 gives sample data for several compounds and indicates the general trend in which the SR′ esters are more reactive than the OR′ esters. This reactivity order is found in other phosphorus ester systems and reflects the lower basicity of the $^-SR'$ groups (14). It is, however, clear from the data that the difference in rate is larger in the less reactive more sterically hindered esters.

The effect of R′ on the reaction rate is shown in the relative rate data in Table 8. The nature of R′ has a much greater influence on the less reactive OR′ esters than on the SR′ esters. Also the structure of the leaving group appears to be much more important in phosphorus (OR′) ester hydrolysis (15) than in carboxylic ester hydrolysis (16) (Table 8). For series 1 and 3 there is an excellent correlation with Taft's σ* values (eq. [2]). For series 1 $\rho^* = 14.1$ ($r = 0.998$) and for series 3 $\rho^* = 3.0$ ($r = 0.994$). Haake and co-workers (2*a*) have previously obtained a $\rho^* = 8$ and $\delta = 1.5$ for three esters of the series $(C_2H_5)_2P(O)OR'$ and $\rho^* = 11$ and $\delta = 0.6$ for seven esters in the series $(C_6H_5)_2P(O)OR'$ using the Taft combined equation

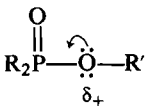
(eq. [4]). The use of the Taft equation for alkyl substituents only has been recently criticized (17), however these excellent correlations for quite large rate differences especially in the case of series 1 would appear to be significant. It has previously been suggested that the large values of ρ* are due to the changing polarization of the oxygen from slightly positive in starting ester (**5**) to an oxygen which is negative in the transition state of the



5

reaction (2*a*). A similar analysis of the results of Jones and Thomas (series 4 in Table 8) using the Taft equation (eq. [3]) gives a rather poor correlation with a ρ* value of 7.1 (r = 0.966). For carboxylic esters formation of the tetrahedral intermediate has been proposed as the rate-determining step in alkaline hydrolysis (18). The higher value of ρ* for alkyl diethylphosphinates supports a reaction in which there is a greater charge density on the oxygen of the leaving group in the rate-determining step than there is in the reaction of carboxylic esters.

The value of ρ* for the series with SR′ leaving groups is almost the same as that obtained by Kreevoy and co-workers (19) for the ionization of aliphatic thiols (ρ* = 3.5). The significance of this is discussed later.

(c) Influence of the atom doubly bonded to phosphorus

Table 9 gives a number of comparisons for the effect of the change in atom in P=X on the rate of hydrolysis of the phosphinates. Also given in Table 9 are selected literature values for other reactions of phosphorus and carboxylic esters. The general trend is that P=O compounds are more reactive than P=S compounds although there are some exceptions. This difference in reactivity has been attributed to differences in polarizability and solvation in the two systems (20).

In the case of the alkaline hydrolysis of a carboxylic ester and thionester, Campbell and Lapinskas (21) have suggested that a $k_{C=O}/k_{C=S} > 1$ supports rate-determining formation of a tetrahedral intermediate while a ratio less than 1, found for an aminolysis reaction, supports a rate-determining collapse of the intermediate. There are no similar trends in the hydrolysis reactions of phosphorus esters as reported in Table 9; it appears that the ratio is substituent, solvent, leaving group and nucleophile dependent. The only trend which is suggested by the results is that the effect of X in P=X appears to be greater when the nucleophile is neutral. The reactivity ratio P=O/P=S is also greater in the less reactive phosphate systems mentioned in the Introduction (4–6).

(d) Solvent effects

The hydrolysis reactions were carried out in two solvents only (60% DME – H_2O and H_2O). For P=O esters, regardless of the leaving group, the rates were slightly faster in the mixed solvent system (compound **1***i* is the only exception). If the transition state is considered as a large monoanion with its charge highly dispersed then the net change in solvation can be thought of as a highly solvated hydroxide going to a less solvated transition state, and it is, therefore, reasonable that the reaction rate would decrease in water. However, for the two P=S esters (**2***a* and **2***b*) studied in both solvents the opposite solvent effect is observed. Unfortunately the limited solubility of the P=S

esters in water prevented determining whether or not this is a general reversal of behavior. It is known that the P=S bond is considerably less solvated than the P=O bond (11, 14, 22) and this difference could account for the observed change but more esters should be studied as well as rates measured in a wider range of solvents.

(e) Activation parameters

The most obvious trends in the data of Table 5 are the lower ΔH^* for the P—S—R′ esters and the more negative ΔS^* for the esters with larger alkyl groups as well as for the esters with higher sulfur content. The lower ΔH^* can be attributed to the weak P—S bond (23) leading to an earlier transition state, while the change in ΔS^* can best be explained by the differences in solvation of the starting neutral S and O esters, which should be greater than the differences for the monocharged transition states. In the case of the esters with large alkyl groups, steric inhibition of solvation of the ester may be important. Such inhibition has been observed for these esters during the process of protonation (24).

Mechanistic considerations

There is clear evidence for pentacovalent intermediates in the alkaline hydrolysis of cyclic phosphorus esters (9, 25) as well as in the acid-catalyzed hydrolysis of an acyclic phosphinothionate (11). The strongest kinetic evidence for intermediate formation in the alkaline hydrolysis of acyclic phosphinates comes from linear free energy data on the hydrolysis of aryl phosphinates where, with one exception, the rate constants correlate with Hammett's σ values and not with the σ^- values of the substituents (26). These results suggest that there is no charge generation on the leaving group in the rate-determining step and therefore formation of the intermediate is suggested as the slow step. Formation of the intermediate should be rate-determining with any leaving group which is less basic than ^-OH (e.g., $^-SR'$ or ^-OAr) while breakdown of the intermediate will be rate-determining for $^-OR'$ leaving groups. The ρ* values obtained in this work for the OR′ and SR′ leaving groups are consistent with this hypothesis.

The closeness of the ρ* value for RSH ionization where some negative charge must exist on sulfur and the ρ* value of $R_2P(O)SR'$ esters appears to be an anomaly. It might be better to compare the latter value with that obtained for the hydrolysis of acetates (ρ* = 7.1) (16) where formation of the intermediate is also suggested as the rate-determining step (18). The ratio of the insulating effects of the S and O atoms has been calculated from ^{13}C—H coupling constants (Z_S/Z_O = 0.90) (27) and therefore the value of ρ* for the SR′ esters is even smaller than that which would be predicted from the hydrolysis of carboxylic esters.

The relative rate data of Table 6 also supports these conclusions in as much as the steric effects of the groups attached to phosphorus would be expected to be larger in the reaction where the intermediate is already fully formed before the transition state is reached (OR′ esters). These steric effect arguments can also account for the increasing $k_{POR'}/k_{PSR'}$ ratio with increasing size of the substituents on phosphorus (Table 7).

Conclusions

The general trend observed for phosphorus esters which hydrolyse via an associative pathway is that the P=O esters are more reactive than the P=S esters and, the more reactive the systems, the less the difference in reactivity. The greatest effect of this substitution should be observed in phosphate reactions with neutral nucleophiles and the least effect in phosphinate reactions with nucleophiles like ^-OH.

The results obtained for the effect of changing the leaving group are in line with most other observations on phosphorus esters where the basicity of the leaving group has a considerable influence on the reactivity of the ester.

Solvation appears to play an important role and more work in this area is certainly needed.

All of the results are consistent with a reaction pathway involving an intermediate.

Experimental

Synthesis of the esters (for general synthesis, see ref. 28)

The esters were synthesized by known methods or variations of known methods as mentioned below:

Method 1: (for **1***a–c* and **1***g–k*)

[5] $3RMgX + P(S)Cl_3 \rightarrow R_2P(S)P(S)R_2$ (29)

Thiophosphoryl chloride in ether was added dropwise over a period of 4–5 h to an ether solution of the appropriate Grignard reagent at 0°C. The final mixture was poured carefully into an ice-cold 10% sulfuric acid solution. The product was extracted with ether.

[6] $R_2P(S)P(S)R_2 + 3SO_2Cl_2 \rightarrow R_2P(O)Cl + SOCl_2$ (30)

The sulfuryl chloride in benzene was added dropwise to a benzene solution of the biphosphine disulfide at room temperature. The solvent and $SOCl_2$ were distilled at atmospheric pressure and the acid chloride was distilled under diminished pressure.

[7] $R_2P(O)Cl + R'ONa \rightarrow R_2P(O)OR'$ (31)

A benzene solution of the acid chloride was added to a solution of alkoxide in its corresponding alcohol. The reaction mixture was initially filtered (-NaCl), then distilled at atmospheric pressure to remove solvents and finally the ester was vacuum distilled.

Method 2: (for **2***a–c* and **2***g–k*)

[8] $R_2P(S)P(S)R_2 + SO_2Cl_2 \rightarrow R_2P(S)Cl$ (32)

The procedure used was identical to reaction [6] except in this case with equimolar amounts of the reagents.

[9] $R_2P(S)Cl + R'ONa \rightarrow R_2P(S)OR'$ (31)

The procedure was identical to that of reaction [7].

Method 3: (for **2***a–c*, **3***g*, **3***h*, and **3***j*)

[10] $R_2P(S)Cl + 2NaOH \rightarrow R_2P(O)SNa$ (33)

An aqueous solution of sodium hydroxide was added to the acid chloride. The resulting mixture was evaporated to dryness giving a salt which is a mixture of the product and NaCl.

[11] $R_2P(O)SNa + R'X \rightarrow R_2P(O)SR'$ (34)

The above salt was refluxed with excess alkyl halide in acetonitrile. The solvent was partially evaporated and then the mixture was filtered. The resulting solution was fractionally distilled.

Method 4: (for **4***a–c*, **4***g*, **4***h*, and **4***j*)

[12] $R_2P(S)Cl + 2NaSH \rightarrow R_2P(S)SNa$ (35)

The acid chloride was added to a methanol solution of NaSH. The solution was evaporated to dryness giving the product and NaCl.

[13] $R_2P(S)SNa + R'X \rightarrow R_2P(S)SR'$ (34)

The procedure was identical to that of reaction [11].

Method 5: (for **1***d–f*, **2***d–f*, **3***d–f*, and **4***d–f*)

[14] $PCl_3 + 2RMgX \rightarrow R_2PCl$ (36)

An ether solution of the Grignard was added dropwise with vigorous stirring to an ether solution of PCl_3 at −40°C and under an inert atmosphere. The product was filtered and transferred to a distilling flask; the solution was then vacuum distilled.

[15] $R_2PCl + O_2 \rightarrow R_2P(O)Cl$

Oxygen was bubbled into a benzene solution of the phosphine. The reaction isotherm was moderated by a 10 volume excess of benzene. The acid chloride was vacuum distilled.

[16] $R_2PCl + S \rightarrow R_2P(S)Cl$

[a]Separation of the individual upfield resonances was not usually possible. All spectra integrated exactly for the downfield protons (PSC*H*) versus all the others.
[b]Reference 46.

Equimolar amounts of sulfur and the phosphine were gently warmed in benzene. Catalytic amounts of $AlCl_3$ were also occasionally used. The acid chloride was vacuum distilled.

The esters are now synthesized by reaction [7] for **1***d–f*, reaction [9] for **2***d–f*, reactions [10] and [11] for esters **3***d–f* and reactions [12] and [13] for esters **4***d–f*.

Method 6: (for **4***k*)

[17] $(C_2H_5)_2P(S)P(S)(C_2H_5)_2 + LiAlH_4 \rightarrow (C_2H_5)_2PH$ (29)

An ether suspension of the hydride was added to an ether solution of the biphosphine disulfide. The reaction was carried out in an inert atmosphere and was warmed for 1 h on a steam bath. After cooling, water was added carefully and the ether layer was separated and dried. The product was distilled in an inert atmosphere.

[18] $(C_2H_5)_2PH + (s\text{-}C_4H_9)_2S_2 \rightarrow (C_2H_5)_2P(S)SC_4H_9\text{-}s$ (37)

Equimolar amounts of the reagents in benzene were refluxed overnight under an inert atmosphere. The product was vacuum distilled.

Purification and identification of the esters

All esters were first distilled through a Vigreux column and then further purified by distillation on a Perkin-Elmer Model 151 teflon annular spinning band column. The uncorrected boiling points, nmr chemical shifts, and the P=X stretching frequencies are given in Table 10 as well as the literature values for the boiling points of the previously reported esters.

The identity and purity of the esters were checked by nmr; all of the esters have downfield bands due to $R_2P(Y)XCH$ which could be easily integrated versus all the upfield CH bands.

Kinetics

All rates were run in 50 mL volumetric flasks thermostatted in a constant temperature bath ($T \pm 0.2$°C). Weighed amounts of ester and $NaClO_4$ (to keep ionic strength constant at 0.1 *M*) were added to the flask followed by enough NaOH solution to make the ester and base concentrations equivalent. In the cases where a mixed solvent system was used, the DME was added to the ester and salt followed by the base and then the flask was topped up by the addition of 60% DME – H_2O solution. The DME was purified by the method of Wiberg (38). During the course of the reaction 4 mL aliquots were withdrawn and quenched in standard perchloric acid. The solution was back-titrated with standard base using a Radiometric Model ABU 11 autoburette and Radiometer Model 28 pH meter. Glass and standard calomel electrodes were used. The rate constants were calculated from eq. [19] where the slope is determined from a plot $1/(mL_{calcd} - mL_{titr})$ versus time in seconds; mL_{calcd} is the number of millilitres of titrating base necessary to neutralize the quenching acid and mL_{titr} is the number of millilitres of base necessary to titrate the aliquot of quenched reaction solution.

$$[19] \quad k_2(M^{-1}\,s^{-1}) = \frac{(\text{slope})(\text{No. of mL of aliquot})}{(\text{normality of back-titrating base})}$$

The reported rate constants were determined from a least-squares analysis of the data. The rate constants are averages of at least two kinetic runs; the correlation coefficients of the plots and the reproducibility of the data are excellent. The range of the rate constants reported in Tables 1–4 is better than ±5%. The ΔS^* values reported in Table 5 are not better than ±3 eu.

Rate studies could not be carried out on all the esters reported in Table 10 especially those of general structure $R_2P(S)OR'$. These esters when they contain more than 5 carbons are not soluble in H_2O and we were unable to measure their rates in 60% DME – H_2O because of problems of solvent decomposition over the period of time necessary for their reaction (2*b*).

Nuclear magnetic resonance monitoring in a reaction and analysis of products for $(C_2H_5)_2P(S)OCH_3$ indicates neither desulfurization, as was observed during the acid-catalyzed hydrolysis of $(CH_3)_2P(S)OCH_3$ (22*b*), nor alkyl group migration from O to S.

Kinetic solvent effects on acid-catalyzed hydrolysis of sucrose in aqueous mixtures of some protic, aprotic, and dipolar aprotic solvents

URMILA MANDAL, KAUSHIK DAS, AND KIRON KUMAR KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta – 700 032, India

Received November 11, 1985[2]

URMILA MANDAL, KAUSHIK DAS, and KIRON KUMAR KUNDU. Can. J. Chem. **64**, 1638 (1986).

Rate constants of acid-catalyzed hydrolysis of sucrose (S) to D-glucose and L-fructose have been determined at 25°C by optical rotation measurements in aqueous mixtures of protophobic protic glycerol (GL), protophilic protic urea (UH), aprotic dioxane (D), and dipolar aprotic dimethyl sulphoxide (DMSO). Transfer free energies of the substrate sucrose, $\Delta G_t^0(S)$ have also been determined in the solvents from solubility measurements. These values as well as those of H^+, as obtained earlier by use of the widely used tetraphenylarsonium tetraphenylboron (TATB) reference electrolyte assumption, yielded transfer free energies of the transition state. The observed log (k_s/k_w) – composition profiles reveal that the rates increase monotonically in GL–water mixtures, that decrease more or less monotonically in UH– and DMSO–water mixtures, and decrease up to 10 mol% D in D–water mixtures, beyond which the values tend to increase. Examination of $\Delta G_t^0(i)$–composition profiles for the different species in each case indicates that the initial and transition state solvation get more or less compensated and the observed rates are dictated by the increased solvation of H^+ in aqueous UH, DMSO, and D co-solvent systems. But in GL–water mixtures the decreased solvation of the transition state compared with the initial state is overcome by the decreased solvation of H^+, thus resulting in the gradual enhancement of the rates of the reaction. The observed linearity of the correlative plots of $-\delta(\Delta G^{\neq})$ $[=RT \ln (k_s/k_w)]$ vs. $\Delta G_t^0(H^+)$ with distinctly different slopes in the two cases also substantiates the relative importance of H^+ solvation in dictating the rates of the reaction in these widely different aqueous co-solvents.

URMILA MANDAL, KAUSHIK DAS et KIRON KUMAR KUNDU. Can. J. Chem. **64**, 1638 (1986).

Opérant à 25°C, dans des mélanges aqueux de glycérol (GL) (protophobe et protique), d'urée (UH) (protophile et protique), de dioxanne (D) (aprotique) et diméthylsulfoxyde (DMSO) (depolaire et aprotique) et faisant appel à des mesures de rotation optique, on a mesuré les constantes de vitesse pour l'hydrolyse acido-catalysée du sucrose (S) en D-glucose et en L-fructose. En faisant appel à des mesures de solubilité, on a aussi déterminé les énergies libres de transfert $\Delta G_t^0(S)$ dans ces solvants. Ces valeurs ainsi que celles relatives au H^+ qui ont été obtenues antérieurement en utilisant l'hypothèse de l'électrolyte de référence tétraphénylborure de tétraphénylarsonium (TBTA) ont permis de déterminer les énergies libres de l'état de transition. Les courbes reliant la composition avec le log (k_s/k_w) révèlent que les vitesses augmentent d'une façon monotone dans le mélanges GL/eau, qu'elles diminuent d'une façon plus ou moins monotone dans les mélanges UH/eau et DMSO/eau alors que, dans des mélanges de D/eau, il se produit un ralentissement jusqu'à 10 mol% de D qui est suivi par une augmentation de la vitesse à des concentrations en D qui sont de plus en plus élevées. L'examen des courbes reliant la composition avec les $\Delta G_t^0(i)$ pour les différentes espèces, dans chaque cas, indique que la solvatation de l'état initial et de l'état de transition est plus ou moins compensée et que les vitesses observées sont dictées par une augmentation de la solvatation des ions H^+ dans les systèmes de co-solvants UH/eau, DMSO/eau et D/eau. Toutefois, dans les mélanges de GL/eau, la solvatation qui est plus faible dans l'état de transition que dans l'état initial est compensée par une solvatation réduite des ions H^+ et ceci conduit à une augmentation graduelle des vitesses de réaction. On a observé que les courbes établissant une corrélation entre le $-\delta(\Delta G^{\neq})$ $[= RT \ln (k_s/k_w)]$ et le $\Delta G_t^0(H^+)$ sont linéaires et qu'elles possèdent des pentes légèrement différentes; ces données confirment la relative importance de la solvatation des ions H^+ dans l'orientation de la réaction dans ces différentes co-solvants aqueux.

Introduction

Until recent years kinetic solvent effects of reactions in different media were usually correlated with various empirical parameters of "solvent polarity" which sum up all the specific and non-specific interactions of the media with initial and transition states and are derived with the aid of the principle of linear free energy (LFE) relationships (1). Lately, however, increasing efforts (2–8) have been made to rationalize the kinetic solvent effects from thermodynamic points of view. One of these essentially involves splitting up the activation parameters into contributions of initial and transition states and hence to correlate and understand their behaviour in the light of the relevant physico-chemical properties of the solvents.

In a previous paper (9) such an attempt has been made for the alkaline hydrolysis of a triphenylmethyl dye viz crystal violet (CV^+), in aqueous mixtures of a number of protic, aprotic, and dipolar aprotic co-solvents with varied physico-chemical properties. The results revealed that the kinetic solvent effect of that reaction is not guided solely by OH^- or lyate S^-, as is widely believed, but also by the differences in relative stabilization of the initial and transition states of the substrates, which were found to vary with the nature of the co-solvents. Besides, while the stabilization of hydrophobic CV^+ is chiefly guided by dispersion and hydrophilic interactions of the co-solvents, that of the transition state, believed possibly to be outer-sphere complex, $[CV^+]S^-$, is augmented by the increased hydrogen-bonding propensity of the hydroxylic co-solvents in particular. Thus it transpires that, for complete understanding of the kinetic solvent effects on nucleophilic reactions, dissection of the activation parameters such as free energy of activation ($\Delta G^{\neq}$) into the contributions of the inidividual species involved should be highly rewarding.

In this paper we have extended our studies on kinetic solvent effects on the well known H_3O^+-catalyzed hydrolysis of D-sucrose to D-glucose and L-fructose, otherwise known as the inversion of cane sugar, in aqueous mixtures of protophobic protic glycerol (GL), protophilic protic urea (UH), aprotic dioxane (D), and dipolar aprotic dimethyl sulphoxide (DMSO) at 25°C. In fact, recently evaluated (10–12) transfer free energies of (ΔG_t^0) of different ions, including H^+ and OH^- or the lyate ion, S^-, (based on the widely used tetraphenylarsonium

tetraphenylboron (TATB) reference electrolyte assumption (13), $\Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4AsPh_4B)$ in different aquo-organic solvents including the above-noted co-solvents, have prompted us to take up the present study. The choice of these co-solvents rests on the fact that while $\Delta G_t^0(H^+)$ values are found to be increasingly positive in the case of less basic GL, and negative in the case of more basic protic UH and dipolar aprotic DMSO, that in aqueous D though increasingly negative at initial compositions, is less so beyond 10 mol% D. And these results led us to expect that if the relative catalytic activity of H^+ is largely dictated by the relative solvation of H^+, the rate of inversion of cane sugar will be enhanced in aqueous GL and increasingly inhibited in aqueous UH and DMSO and up to 10 mol% D and reversed beyond that composition, provided the relative solvation of the initial and transition states is not untowardly different from each other in each of these aquo-organic solvent systems. It was therefore considered particularly interesting to examine if the expected correspondence is more or less true or not. As the contributions of initial state solvation of the substrate are not known in these solvents, these have been determined by measuring the solubilities of sucrose in the solvents.

Experimental

The organic solvents were purified by the methods described earlier (9). The mixed solvents were prepared by mass dilution with triple distilled water. AnalaR (BDH) grade sucrose was used without further treatment. The rates of hydrolysis of sucrose were studied in aqueous mixtures of 0, 23, 33, 50, and 70 wt.% GL, 10, 30, and 50 wt.% D and DMSO and 10, 20, 30, and 40 wt.% UH, using 10% sucrose solution and an optimum concentration of 0.25 M HCl as the catalyst in the respective solvents. The rates of the reaction were followed after Guggenheim and Wiseman (14) by measuring the optical rotation of aliquots of the reaction mixtures with the help of a Hilger Standard Polarimeter, after duly freezing the rates of the reaction in the aliquots by adding minute excess of alkali beyond the point of neutralization. The latter was to eliminate "mutarotation lag" (14). As Guggenheim and Wiseman indicated, the hydrolysis of sucrose into D-glucose and L-fructose is followed by mutarotation of the products at rates greater by a factor of about 10^2 than that of the hydrolysis. Thus the optical rotation at any moment will differ by a small but not constant amount from the value it would have if mutarotation were instantaneous. This is often called the "mutarotation lag". The mutarotation lag if not estimated, could introduce an error in the rate constant of less than 1% but greater than 0.1%. Therefore, as suggested by Guggenheim and Wiseman, aliquot samples (10 mL) of the reaction mixtures were neutralized with a slight excess of alkali and diluted to 25 mL before measuring the optical rotation. Neutralization of the acid completely stops the hydrolysis of sucrose and further addition of minute excess of alkali completes mutarotation practically instantaneously.

Solubilities of sucrose in the solvents were determined at 25°C by measuring the optical rotation of the saturated solutions in the respective solvent mixtures. The saturated solutions were prepared (15) by adding sufficient amounts of sucrose to 30–40 mL of the respective solvents taken in tightly stoppered Jena bottles and shaken in a mechanical shaker for about 2–3 h. The solutions were then thermally equilibrated in a thermostat kept at 25°C for a few days with occasional shaking. Aliquots of these solutions were taken at 2–3 days intervals using specially designed pipettes fitted with G_3-Gooch discs at the delivery ends and after diluting appropriately with water the solutions were analyzed by noting the optical rotation. The procedure was repeated until successive readings agreed within ±1%. The solubilities in mol dm^{-3} so obtained for each of the mixtures in different solvent systems are given in Table 1. The transfer free energies of sucrose from water to the mixed solvents, $\Delta G_t^0(S)$ were obtained on molar scale by the usual relation (15, 16) and presented in Table 1.

Results and discussion

As the kinetic behaviour of the reaction in all the aquo-organic solvents is found to be exactly similar to that in water, the reaction can be assumed to be a case of specific hydrogen ion catalysis as in water (17). Thus we can for all these water-rich solvent mixtures postulate the equilibrium

$$S + H_3O^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [S.H_3O]^+ \xrightarrow{k_2} \text{products}$$

where S is the substrate sucrose, H_3O^+ the solvated hydrogen ion and $k_2 \ll k_{-1}$. Now for a given concentration of HCl, $K(= k_1/k_{-1})$ will vary from solvent to solvent and the resulting changes in the concentration of the collision complex $[S.H_3O^+]$ will cause a change in the measured velocity constant k. Under these conditions

$$-\frac{dC_S}{dt} = k_2 C_{[S.H_3O]^+}$$

$$= k_2 K C_{H_3O^+} \frac{Y_{H_3O^+} Y_S}{Y_{[S.H_3O]^+}} C_S$$

We assume tentatively that the activity coefficient factor $(Y_{H_3O^+} Y_S / Y_{[S.H_3O]^+})$ being a ratio of the activity coefficients of the singly charged species multiplied by that of an uncharged species, is likely to be nearly unity at the low concentration of HCl used in each case. Thus, neglecting the effect of activity coefficient factor the rate can be expressed as follows

$$-\frac{dC_S}{dt} = k_2 K C_{H_3O^+} C_S = k C_S$$

where k, the observed pseudo-first-order rate constant, is $k_2 K C_{H_3O^+}$ at a particular concentration of H_3O^+ and $k_{H_3O^+}$, the second-order rate constant, is given by

$$k_{H_3O^+} = k/C_{H_3O^+} = k_2 K$$

So, at a particular concentration of HCl i.e. $C_{H_3O^+}$, the observed velocity constant k was obtained from the slope of the first order linear plot of $-\ln(\alpha_t - \alpha_\infty)$ vs. t where α_t and α_∞, were the optical reactions of the aliquots at time $t = t$ and $t = \infty$.[3]

In Table 1 are given the values of the velocity constant $k(\text{min}^{-1})$ (the number of moles of sucrose reacting per mole of sucrose per min) for the solvents at 25°C. Notably, the observed value of k in pure water compares fairly well with the value computed from Leininger and Kilpatrick's data (17) at different concentration of HCl.

The k values are referred to a particular catalyst concentration (viz. 0.25 *M* HCl) for all the co-solvent compositions and the effect of activity coefficient factor in the rate equation is likely to be negligibly small. Therefore these values, and in particular log (k_s/k_w) (where the subscript s refers to solvent and w to water), can be tentatively taken as a relative measure of the kinetic solvent effect on the reaction in the different solvents.

Thus from Fig. 1 where log (k_s/k_w) values are plotted against mol% co-solvents, it can be seen that the observed rate constant relative to that in water increases almost linearly with increasing composition of GL, while it decreases more or less monotonically with increasing composition of UH, DMSO, and up to 10 mol% D, beyond which the values take an upward trend. These results conform at least qualitatively with what is expected from the inverse behaviour of the transfer free energy of H^+, $\Delta G_t^0(H^+)$ with co-solvent compositions as indicated earlier. Thus, H^+ becomes a more active catalyst with increasing composition of GL as it becomes increasingly less stabilized due to the decreased basicity of the solvents (10). The reverse is true in the cases of more basic co-solvents like UH, DMSO, and to 10 mol% D beyond which it takes an opposite trend conforming to its decreased stabilization and hence increased catalytic activity. Thus it appears that the kinetics of the reaction

[3]A complete set of the experimental data obtianed at $C_{HCl} = 0.25$ *M*, may be purchased from the Depository of Unpublished Data CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

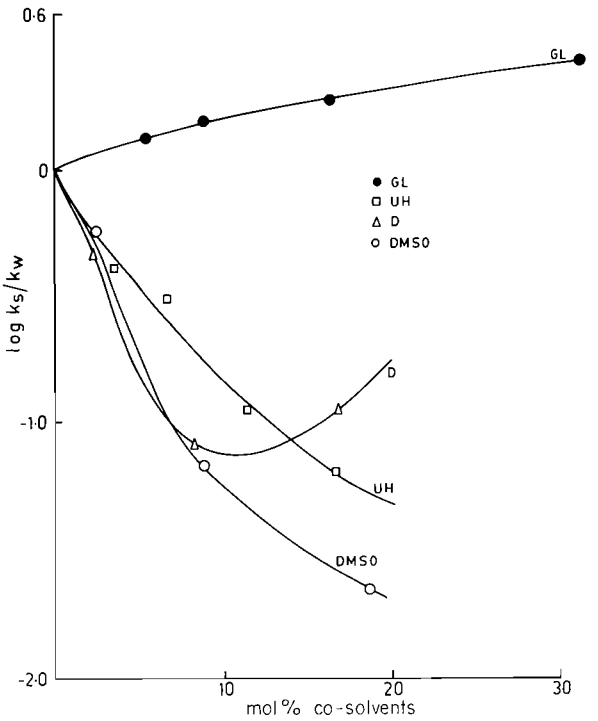

FIG. 1. Variation of log k_s/k_w with mol% co-solvent for the hydrolysis of sucrose (S) at 25°C in aqueous mixtures of glycerol (GL, ●); urea (UH, □); dioxane (D, △) and dimethyl sulphoxide (DMSO, ○).

are to a large extent dictated by the relative solvation of H^+; the more solvated the H^+, the less effective it is as a catalyst for the inversion of cane sugar.

To get a better indication of the relative contributions of different species guiding the rates of hydrolytic reactions a detailed analysis of the relative transfer free energies of activation $\delta(\Delta G^{\neq})$ would be useful. $\delta(\Delta G^{\neq})$ values were obtained after the Eyring equation

$$k = \frac{RT}{Nh} \exp^{-\Delta G^{\neq}/RT}$$

Moreover, as the concentration dependence of $\delta(\Delta G^{\neq})$ is expected to be fairly small (*vide* ref. 17), $\delta(\Delta G^{\neq})$ can be tentatively related to transfer free energies of the species involved in the reaction as follows (7)

$$\delta(\Delta G^{\neq}) = \Delta G_t^0(X^{\neq}) - \Delta G_t^0(S) - \Delta G_t^0(H^+)$$

The tentative values of the transfer free energies of the transition state, $\Delta G_t^0(X^{\neq})$ were then evaluated by use of the corresponding values of $\Delta G_t^0(S)$ and $\Delta G_t^0(H^+)$ (10–12) for the solvents. All these values are presented in the table.

Figure 2 illustrates $\Delta G_t^0(i)$–composition profiles of the different species involved, viz. H^+, S, and $X^{\neq}$ and also $\delta(\Delta G^{\neq})$ in the aqueous mixtures of the co-solvents GL and UH, and Fig. 3 those for DMSO and D. It is interesting to note that in GL–water mixtures ΔG_t^0 values of all the species are increasingly positive with the increase of GL and their relative order is $\Delta G_t^0(X^{\neq}) > \Delta G_t^0(H^+) \gg \Delta G_t^0(S)$. Evidently, while the observed increased destabilization of H^+ is the result of smaller basicity of glycerol (ROH) (10) compared to that of water, due to two electron-withdrawing —OH groups in the alkyl group R [$= CH_2(OH)CH(OH)CH_2$] that of sucrose is seemingly the result of steric effect imparted by GL molecules

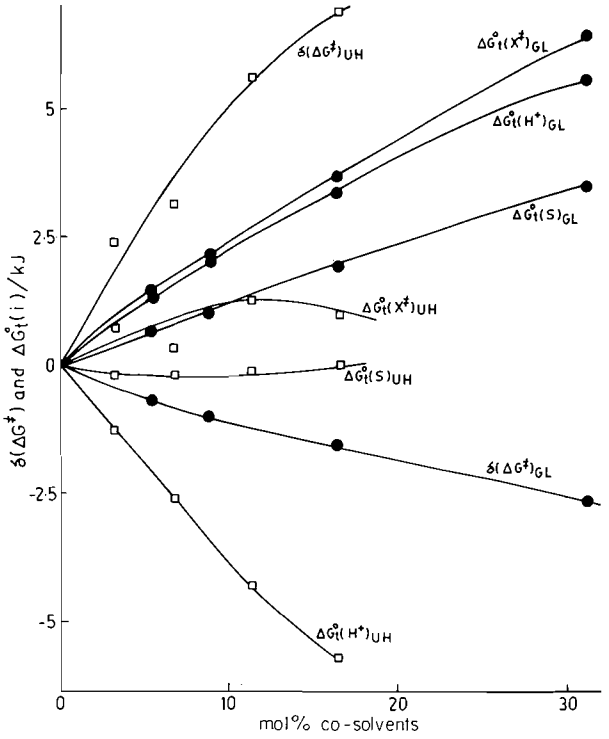

FIG. 2. Kinetic solvent effects $\delta(\Delta G^{\neq})$ for the hydrolysis of sucrose (S) and the involved transfer free energies (ΔG_t^0) of H^+, S and the transition state ($X^{\neq}$) on molar scale in aqueous mixtures of glycerol (GL, ●) and urea (UH, □) at 25°C.

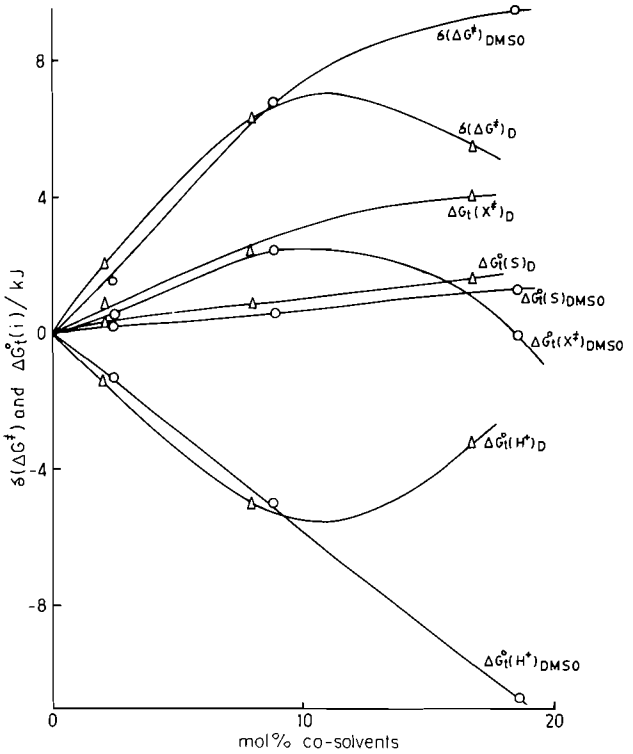

FIG. 3. Kinetic solvent effects $\delta(\Delta G^{\neq})$ for the hydrolysis of sucrose (S) and the involved transfer free energies (ΔG_t^0) of H^+, S and the transition state ($X^{\neq}$) on molar scale in aqueous mixtures of dioxane (D, △) and dimethyl sulphoxide (DMSO, ○) at 25°C.

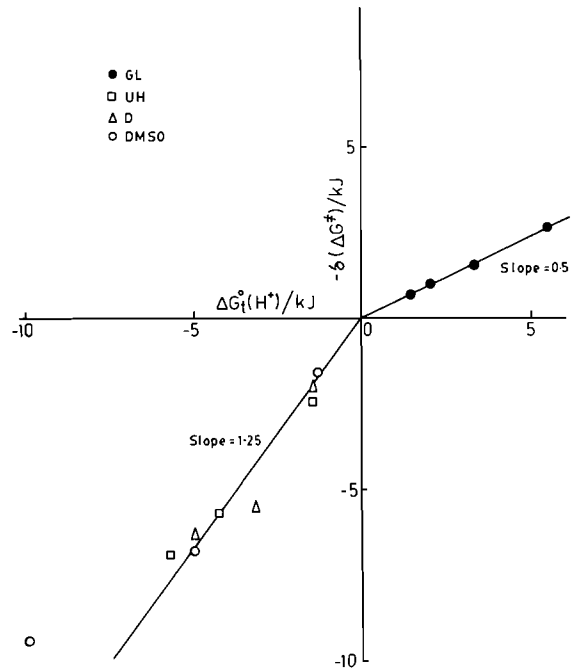

FIG. 4. Plots of $-\delta(\Delta G^{\neq})$ vs. $\Delta G_t^0(H^+)$ for the hydrolysis of sucrose in different aquo-organic solvents.

as compared to water. Evidently, the more pronounced destabilization observed of the transition state ($X^{\neq}$) which is effectively a protonated sucrose $[S.H_3O]^+$ (17), is attributable to the resultant effect of the steric hindrance of GL molecules and the decreased basicity of GL–water mixtures. Thus, it appears that although the transition state is increasingly destabilized relative to the initial state, the opposing resultant effects of increased destabilization of both H^+ and initial-state substrate (S) overcompensate the effect of the former and thus enhance the rate of the reaction with increased proportion of GL.

In the case of aqueous urea, however, the reverse is seemingly true. Thus, while $\Delta G_t^0(X^{\neq})$ values are slightly positive and have a tendency to pass through a maximum, $\Delta G_t^0(S)$ values remain almost invariant with UH composition, thus making $[\Delta G_t^0(X^{\neq}) - \Delta G_t^0(S)]$ values slightly positive. Evidently, increasingly large $-\Delta G_t^0(H^+)$ values result in the observed increasingly positive magnitudes of $\delta(\Delta G^{\neq})$ with increased proportion of use. Notably, while the increased pronounced stabilization of H^+ in UH–water mixtures is attributable to the resultant effects of increased basicity (11) and increased dielectric constant (18) of the solvents, the observed nearly invariant stabilization of sucrose with increased proportion of urea is possibly the effect of urea–water clusters (19) formed through 3 H-bond centres of zwitterionic forms of urea. The observed slight destabilization of the transition state $[S.H_3O]^+$ at initial composition of urea is also indicative of the larger interaction of water than that with possible urea–water clusters because of steric effect. And the observed trend of larger stabilization at higher composition is the result of the superimposed effects of increased basicity as well as the increased dielectric constant of the solvents. Thus the observed relatively small solvation of initial and transition states of sucrose is indicative of the small propensity of urea to form "specific complexes" with carbohydrates, as suggested by Moulik *et al.* (20) from the studies of alkaline degradation of D-fructose and D-glucose in the presence of urea.

In aqueous DMSO solutions while the composition profile of $\Delta G_t^0(S)$ (*vide* Fig. 3) remains almost invariant up to 20 mol% DMSO and that for X^+ takes a downward trend after exhibiting a small and broad maximum around 10 mol% DMSO, that for H^+ takes a sharp downward trend from the beginning. Seemingly, the stabilization of sucrose remains virtually unaltered because of opposing effects of hydrophobicity of 2 (—CH_3) groups and H-bonding propensity of the unhindered basic O-centre of the DMSO molecule. Also, the pronounced stabilization of the positively charged transition state $[S.H_3O]^+$ at higher compositions is the effect of increased basicity of DMSO–water mixtures resulting from the pronounced negative charge density on the O-centre of DMSO molecule due to the inductive effect of 2 (—CH_3) groups, and as reflected in the increased $-\Delta G_t^0$ values of H^+ and some alkali metal cations in these solvents (11). Evidently, at lower compositions enhanced solvation of H^+ dictates the decreased rate of reaction. But at higher concentrations enhanced solvation of the transition state over the initial state opposes the decreased catalytic activity of H^+ to some extent and thus results in the observed downward trend of $\delta(\Delta G^{\neq})$–composition profile (Fig. 3).

Exactly similar is the case in aqueous D at initial compositions but the reverse holds at higher compositions. In fact $\Delta G_t^0(H^+)$ has a downward trend at initial compositions because of the increased basicity of D + H_2O mixtures resulting from larger protophilicity of two basic O-centres of dioxane molecules (21). But, as explained earlier (12), because of the possible shifting of the equilibria between the aquo-complexes of "boat" and "chair" forms of dioxane molecules with increased proportion of D, the basicity decreases at higher compositions. Consequently, as $\Delta G_t^0(H^+)$ values have an upward trend at higher compositions, $\delta(\Delta G^{\neq})$ values take a downward trend, reflecting that the relative solvation of H^+ dictates the rate of the reaction. Moreover, as in DMSO–water mixtures, the observed invariance in solvation of sucrose with addition of D seemingly results partly from the opposing effects of hydrophobicity of 4 (—CH_2—) groups and the H-bonding propensity of the two basic O-centres of D molecules and partly from the possible aquo-dioxane complexes with little solvating capability because of steric factor. And the observed slight destabilization of the transition state $[S.H_3O]^+$ is possibly the resultant effects of steric hindrance of the solvating species like aquo–dioxane complexes, Born-type electrostatic interaction and the decreased basicity at higher compositions. Thus the effect of destabilization of transition state also partly contributes to the inhibition of the reaction, though to a small extent.

Thus if we sum up as in Fig. 4, where the correlative plots of $-\delta(\Delta G^{\neq})$ vs. $\Delta G_t^0(H^+)$ are depicted, it is found that while all the points in GL–water mixtures fall on a straight line in the first quadrant with a slope of about 0.5, those in aqueous D, DMSO, and UH fall on a single straight line in the third quadrant but with a slope of about 1.25. While the observed line in the first quadrant indicates that the rate of the reaction is largely enhanced due to the increased desolvation of H^+, that in the third quadrant indicates that the reaction is largely inhibited due to the increased solvation of H^+. The observed slope in the former case viz. 0.5 instead of 1.0, further suggests that initial and transition state solvation do not cancel each other but their resultant effect reduces the desolvation effect of H^+ by about 50%. In fact, as the ΔG_t^0–composition profiles of different reacting species viz. H^+, S, and X^+ in Fig. 2 suggest, the resultant effects of both H^+ and S overcome the opposing effect of the increased desolvation of the transition state and thus cause the observed enhancement of the reactions. On the other hand, in the cases of aqueous mixtures of UH, D, and DMSO, the observed slope of the linear plot in the third quadrant, viz. 1.25 instead of 1, suggests that the increased inhibition of the effect of H^+ due to increased solvation is further augmented by the resultant effects of initial and transition state solvation. As indicated earlier from the analysis of the relative $\Delta G_t^0(i)$–composition profiles of H^+, S, and X^+ in these solvent mixtures (Figs. 2 and 3), although the effect of initial state solvation is negligibly small, the increased desolvation of the transition state is responsible for further slowing down the reaction.

Thus it may be concluded that just as in the case of alkaline hydrolysis of crystal violet in different aquo-organic solvents, the present results also clearly demonstrate that the correlation of the relative solvation of the involved species of the reactions with relative physico-chemical properties of the solvents offer good insights into the kinetic solvent effects of reactions.

D. A. COOPER, S. J. RETTIG, A. STORR, and J. TROTTER. Can. J. Chem. **64**, 1643 (1986).

The synthesis and characterization of complexes containing the 2-mercapto-1-methylimidazolyl ligand are described. $Me_2Ga(SCNCHCHNMe)$ occurs as a dimer, crystals of which are monoclinic, $C2/c$, a = 14.140(2), b = 7.4098(4), c = 18.024(2) Å, β = 106.38(1)°, Z = 4 dimers; the structure was determined by conventional heavy atom methods and refined by full-matrix least-squares techniques to a final R value of 0.039 for 1767 reflections. The crystal contains centrosymmetric dimeric molecules, with a central 8-membered ring, formed by mercaptoimidazolyl ligand bridging between dimethylgallium groups; gallium has tetrahedral geometry, with no tendency to five-coordination, Ga—S = 2.3697(8), Ga—N = 2.019(2) Å. Reaction of $Me_2Ga(pz)(SCNCHCHNMe)^-$, L^-, with $[Re(CO)_4Cl]_2$ results in the formation of $LRe(CO)_3$, whose physical properties indicate a *fac* arrangement of the organogallate ligand. Attempts to synthesize corresponding $LMo(\eta^3\text{-}C_4H_7)(CO)_2$ and $LMo(\eta^3\text{-}C_3H_5)(CO)_2$ complexes yielded the dimeric species $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(SCNCHCHNMe)]_2$ and $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(SCNCHCHNMe)]_2$. Crystals of the $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(SCNCHCHNMe)]_2$ complex are monoclinic, $I2/a$, a = 15.057(2), b = 9.4853(9), c = 18.240(2) Å, β = 108.67(1)°, Z = 4 dimers, R = 0.028 for 2363 reflexions. The structure contains dimeric molecules with C_2 symmetry, and five fused rings, a central group of three 4-membered rings being formed by bonding of the S atoms of the ligands to both Mo atoms (in contrast to the gallium complex). The molecule has a U-shape, with Mo atoms having pseudo-octahedral environments, Mo—S = 2.6868(7), 2.5576(7), Mo—N = 2.253(2), Mo—CO = 1.950(2), Mo—C(allyl) = 2.259(3), 2.326(3) Å. Considerable strain in the chelate rings is indicated by angles as low as S—Mo—N = 63.9(1)°.

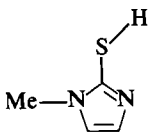
D. A. COOPER, S. J. RETTIG, A. STORR, and J. TROTTER. Can. J. Chem. **64**, 1643 (1986).

On décrit la synthèse et le caractérisation de complexes contenant le ligand mercapto-2 méthyl-1 imidazolyle. Le $Me_2Ga(SCNCHCHNMe)$ existe sous forme de dimère dont les cristaux sont monocliniques, groupe d'espace $C2/c$, avec a = 14,140(2), b = 7,4098(4), c = 18,024(2) Å, β = 106,38(1)° et Z = 4 dimères; on a déterminé la structure par les méthodes conventionnelles aux atomes lourds et on l'a affiné par la méthode des moindres carrés (matrice entière) jusqu'à une valeur finale de R de 0,039 pour 1767 réflexions. Les cristaux comportent des molécules dimères centrosymétriques, avec un noyau central à 8 chaînons, qui sont formés de ligands mercaptoimidazolyes servant de pont entre les groupements diméthylgallium; le gallium possède une géométrie tétraédrique, il n'a aucune tendance à donner une penta-coordination et Ga—S = 2,3697(8) alors que Ga—N = 2,019(2) Å. La réaction du composé $Me_2Ga(pz)(SCNCHCHNMe)^-$, L^-, avec le $[Re(CO)_4Cl]_2$ conduit à la formation du $LRe(CO)_3$ dont les propriétés physiques indiquent que le ligand arganogallate se trouve dans un arrangement *fac*. Des essais en vue de préparer les complexes correspondants $LMo(\eta^3\text{-}C_4H_7)(CO)_2$ et $LMo(\eta^3\text{-}C_3H_5)(CO)_2$ n'ont conduit qu'à la formation des espèces dimères $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(SCNCHCHNMe)]_2$ et $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(SCNCHCHNMe)]_2$. Les cristaux du complexe $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(SCNCHCHNMe)]_2$ sont monocliniques, groupe d'espace $I2/a$, avec a = 15,057(2), b = 9,4853(9), c = 18,240(2) Å, β = 108,67(1)°, Z = 4 dimères et R = 0,028 pour 2363 réflexions. Chacune des structures contient des molécules dimères avec une symétrie C_2 et des cycles à cinq chaînons condensés, avec un groupement central de cycles à 4 chaînons qui sont formés par la liaison des atomes de S des ligands avec les deux atomes de Mo (et ceci est en opposition avec ce qui est observé avec le complexe de gallium). La molécule existe sous une forme en U et les atomes de Mo possèdent des environnements pseudo-octaédriques, Mo—S = 2,6868(7), 2,5576(7), Mo—N = 2,253(2), Mo—CO = 1,950(2), Mo—C(allyle) = 2,259(3), 2,326(3) Å. Une tension importante dans les cycles chélatés se réflète par des angles S—Mo—N qui sont aussi bas que 63,9(1)°.

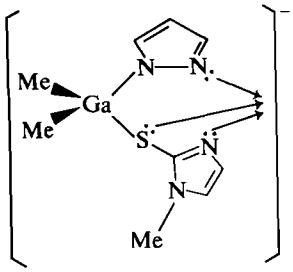
[Traduit par la revue]

Introduction

In our continuing investigations on the reactivity of organogallium species with "active" hydrogen compounds, and the synthesis of anionic pyrazolylgallate ligands (ref. 1 and references therein), our attention has recently focussed on 2-mercapto-1-methyl-imidazole, **1**, as a molecule of potential interest.



1



2

Thus, on the one hand, reaction of this molecule with Me_3Ga, with resulting elimination of methane, should afford a product for which numerous possible modes of oligomerization may be envisaged. On the other hand, reaction of the mercaptan with the $Me_3Ga(pz)^-$ anion should lead to the novel anionic ligand system, **2**. This has in fact been demonstrated by the synthesis of the octahedral $LRe(CO)_3$ complex in which the ligand **2** acts as a tridentate chelating ligand, thus extending the range of such complexes containing unsymmetrical pyrazolyl–gallate ligand systems (1). The present account also details X-ray analysis data on two novel structures, the dimers $[Me_2Ga(SCNCHCHNMe)]_2$ and $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(SCNCHCHNMe)]_2$.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran (THF), benzene, and CH_2Cl_2 were dried by refluxing over Na/benzophenone, potassium, and CaH_2, respectively, followed by distillation. $Mo(MeCN)_2(\eta^3\text{-}C_3H_5)(CO)_2Br$ and $Mo(MeCN)_2(\eta^3$-

$C_4H_7)(CO)_2Cl$ were prepared by literature methods (2). The allyl halides and acetonitrile were distilled before use, the latter being dried by refluxing over P_4O_{10}. $[Re(CO)_4Cl]_2$ was synthesized by a literature procedure (3) from rhenium carbonyl (Strem) and chlorine gas (Matheson). 2-Mercapto-1-methylimidazole (Aldrich) was used as supplied.

Preparation of $[Me_2Ga(SCNCHCHNMe)]_2$

$$2Me_3Ga + 2HSCNCHCHNMe \xrightarrow[\text{room temp./3 h}]{\text{THF}} [Me_2Ga(SCNCHCHNMe)]_2 + 2CH_4$$

2-Mercapto-1-methylimidazole (2.0 g; 18 mmol) and trimethylgallium (2.1 g; 18 mmol) were stirred in THF at room temperature for 3 h. After solvent removal *in vacuo* the residue was extracted with benzene. The filtrate, upon slow evaporation of the solvent, afforded colourless crystals of $[Me_2Ga(SCNCHCHNMe)]_2$ in approximately 90% yield. Analytical and spectroscopic data for the complex are given in Tables 1 and 2.

Preparation of $Na^+[Me_2Ga(pz)(SCNCHCHNMe)]^-$,

An equimolar amount of the mercaptoimidazole, **1**, in THF was added to a THF solution of $Na^+Me_3Ga(pz)^-$ (4) and the resultant mixture refluxed for ~40 h. An ir spectrum of the solution at this time indicated the complete absence of the ν_{SH} band (~2800 cm^{-1}) of the starting material. The cooled solution was then diluted to a known volume with THF and the standard solution stored under a nitrogen atmosphere.

Preparation of $[Me_2Ga(pz)(SCNCHCHNMe)]Re(CO)_3$

A two molar equivalent of the ligand was added to $[Re(CO)_4Cl]_2$ (0.292 g; 0.44 mmol) in THF. A 19-h reflux of the reactant solution effected the total disappearance of the carbonyl bands of the starting material in the ir spectrum of the reacting mixture. The solvent was then removed under vacuum and the residue extracted with benzene. The filtrate afforded small white crystals of the product, $[Me_2Ga(pz)(SCNCHCHNMe)]Re(CO)_3$, in approximately 50% yield. Analytical and spectroscopic data for the compound are presented in Tables 1 and 2.

Attempted preparation of $[Me_2Ga(pz)(SCNCHCHNMe)]Mo(\eta^3\text{-allyl})(CO)_2$, *and preparation of* $[Mo(\eta^3\text{-allyl})(CO)_2(SCNCHCHNMe)]_2$ *where* η^3-*allyl* = η^3-C_3H_5 *or* η^3-C_4H_7

$$2Mo(MeCN)_2(\eta^3\text{-}C_3H_5)(CO)_2Br + 2Na^-[Me_2Ga(pz)(SCNCHCHNMe)]^- \xrightarrow[\text{room temp./16 h}]{\text{THF}} [Mo(\eta^3\text{-}C_3H_5)(CO)_2(SCNCHCHNMe)]_2 + 2NaBr + 4MeCN + [Me_2Ga(pz)]_2$$

A similar equation holds for $Mo(MeCN)_2(\eta^3\text{-}C_4H_7)(CO)_2Cl$.

Addition of an equimolar amount of $Na^+[Me_2Ga(pz)(SCNCHCHNMe)]^-$ to a clear orange THF solution of $Mo(MeCN)_2(\eta^3\text{-allyl})(CO)_2X$ (~0.34 mmol) immediately resulted in precipitation of a fine white solid (presumably NaX), with concomitant shifts in the carbonyl stretching frequencies in the ir spectrum of the mixture. After stirring the reaction mixture at room temperature for 20 h, the solvent was removed *in vacuo* and the residues extracted with benzene. Subsequent evaporation of the solvent from the filtered solutions afforded orange crystals characterized as benzene solvate compounds. Heating at 70°C whilst under vacuum removed the residual benzene and gave analytically pure samples of $[Mo(\eta^3\text{-allyl})(CO)_2(SCNCHCHNMe)]_2$ in approximately 60% yields. Analytical and spectroscopic data for the two compounds are included in Tables 1 and 2. No $[Me_2Ga(pz)\cdot(SCNCHCHNMe)]Mo(\eta^3\text{-allyl})(CO)_2$ compounds were obtained.

X-ray crystallographic analyses

Bis(μ*-1-methylimidazole-2-thiolato-S,N2′)bis[dimethylgallium(III)]*

A crystal bounded by the six faces (followed by their distances in mm from a common origin: {0 0 1}, 0.24, {1 0 0}, 0.17, (1 2 0), 0.27, (0 −1 1), 0.28 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 40–52°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

*Here and elsewhere primed atoms are related to unprimed atoms by the centre of symmetry $(1-x, 1-y, 1-z)$ for the Ga complex and by the twofold axis $(1/2-x, y, 1-z)$ for the Mo complex.

864, μ(Mo-$K\alpha$) = 30.9 cm^{-1}. Absent reflections: hkl, $h+k$ odd, and $h0l$, l odd, space group $C2/c$ (C_{2h}^6, No. 15) and molecular symmetry 1, from structure analysis.

Intensities were measured with graphite-monochromatized Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 2.87–10.06° min^{-1} over a range of (0.90 + 0.35 tan θ) deg in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 60°$ for $\pm h, +k, +l$. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3.5%. After data reduction,[2] an absorption correction was applied using the analytical method (5, 6). Transmission factors ranged from 0.240 to 0.416. Of the 2621 independent reflections measured, 1767 (67.4%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S-B))^2$ with S = scan count and B = normalized background count.

The systematic absences allow space groups Cc or $C2/c$, the latter being suggested by the E-statistics and by the Patterson function, from which the coordinates of the Ga and S atoms were determined. The remaining atoms, including hydrogen, were positioned from subsequent difference maps. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. The scattering factors of ref. 7 were used for non-hydrogen atoms and those of ref. 8 for hydrogen atoms. Anomalous scattering factors from ref. 9 were used for the Ga and S atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 135 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.039$ and $R_w = 0.045$ for 1767 reflections with $I \geq 3\sigma(I)$. For all 2621 reflections $R = 0.064$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.35σ, respectively. The mean error in an observation of unit weight was 1.716. A final difference map showed maximum fluctuations of −1.46 to +0.82 e Å^{-3} near gallium and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 3 and 7,[3] respectively. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 4–6, respectively. Bond lengths and angles involving hydrogen and a complete list of torsion angles (Tables 8–10) have been deposited.[3] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

Bis(μ-1-methylimidazole-2-thiolato-S,N²,S′)bis[(η³-2-methylallyl)dicarbonylmolybdenum]

Experimental details are as above except where noted. The six bounding faces of the crystal were: ±(1 1 0), 0.07, ±(−1 1 0), 0.08, {0 0 1}, 0.14 mm (from a common origin). Reflections used in the refinement of the unit-cell constants had $2\theta = 30$–40°. Crystal data are:

$C_{20}H_{24}Mo_2N_4O_4S_2$ fw = 640.4

Monoclinic, a = 15.057(2), b = 9.4853(9), c = 18.240(2) Å, β = 108.67(1)°, V = 2467.9(5) Å^3, Z = 4, ρ_c = 1.724 Mg m^{-3}, $F(000)$ = 1280, μ(Mo-$K\alpha$) = 11.9 cm^{-1}. Absent reflections: hkl, $h+k+l$ odd, and $h0l$, h odd, space group $I2/a$ [non-standard setting of $C2/c$ with equivalent positions: (0, 0, 0), (1/2, 1/2, 1/2) ± (x, y, z; 1/2 − x, y, $-z$)] and molecular symmetry 2, from structure analysis.

An ω–2θ scan at 1.06–10.06° min^{-1} over a range of (0.57 + 0.35 tan θ)° in ω was employed. Of 3586 independent reflections measured (to $2\theta = 60°$), 2363 had intensities greater than or equal to $3\sigma(I)$ above background. The intensities of the three standard reflections remained constant to within 2.5%. The data were corrected for absorption using the Gaussian integration method (5, 10), transmission factors ranging from 0.811 to 0.873 for 72 sampling points.

The choice of the centrosymmetric space group and the solution and refinement of the structure parallel that described above for $[Me_2Ga(SCNCHCHNMe)]_2$. Convergence was reached at $R = 0.028$ and $R_w = 0.030$ and 2363 reflections with $I \geq 3\sigma(I)$. For all 3586 reflections, $R = 0.066$. The mean and maximum parameter shifts of the final cycle of refinement were 0.028 and 0.29σ, respectively, and the mean error in an observation of unit weight was 1.217. The maximum fluctuations on the final difference map were −0.82 and +0.42 e Å^{-3}, both near Mo.

Spectra

Infrared spectra were recorded on a Perkin-Elmer 598 spectrometer. ^{1}H nmr spectra were recorded on Bruker WP-80 and Varian XL-300 instruments.

Results and discussion

The elimination of methane from the reaction of trimethylgallium and 2-mercapto-1-methylimidazole follows the pattern established for similar reactions involving gallium alkyls and compounds containing active hydrogen (1). The solid state structure of the product is shown in Fig. 1. The compound exists as dimeric units that display a novel eight-membered ring with the two gallium atoms in tetrahedral environments. In the structure the imidazolyl rings remain planar, allowing delocalization of the 6π electrons with concomitant gain in stabilization energy. There appears to be no tendency for the gallium centres to become 5-coordinate via an involvement with the second S atom (Ga···S = 3.711(1) Å), an arrangement that would lead to the existence of three fused 4-membered rings similar to those

observed in the structure of the molybdenum complex described below. The reason for this reluctance of the gallium centres to become five-coordinate is not clear, since this coordination number is common in "Ga—O" dimer species (11–14). The Ga—N distance of 2.019(2) Å in the present complex is comparable to, but slightly longer than the Ga—N distances of ~1.97 Å in other tetrahedral gallium species (15–17). Little information is available on Ga—S bond lengths; the length of 2.370(1) Å in the present structure lies between that of 2.321(2) Å in an aminomethylene–benzo[6]furanthionate complex (18), and those of 2.408–2.466(2) Å in a dithiocarbamate (19).

The reaction of the ligand **2** with $[Re(CO)_4Cl]_2$ resulted in a moderate yield of the tricarbonyl product $[Me_2Ga(pz)(SCNCHCHNMe)]Re(CO)_3$. The expected *facial* arrangement of the organogallate ligand in the product was confirmed by the ir and ^1H nmr data obtained for the complex. Thus, three strong ν_{CO} bands are expected for a *fac* arrangement, whereas a *mer* arrangement would lead to two weak ν_{CO} bands and one strong ν_{CO} band in the ir spectrum (20). The ir spectrum observed, although showing only two strong ν_{CO} bands, displays a broad lower frequency vibration that we attribute to two unresolved ν_{CO} bands. The ^1H nmr spectrum of the complex in C_6D_6 solvent (Fig. 2) is consistent with a *fac* arrangement for the organogallate ligand. Thus the "$GaMe_2$" grouping displays two distinct singlets at ~10τ, whereas for a *mer* arrangement a plane of symmetry in the molecule would render the two Ga—Me groups equivalent and hence lead to one signal in this region of

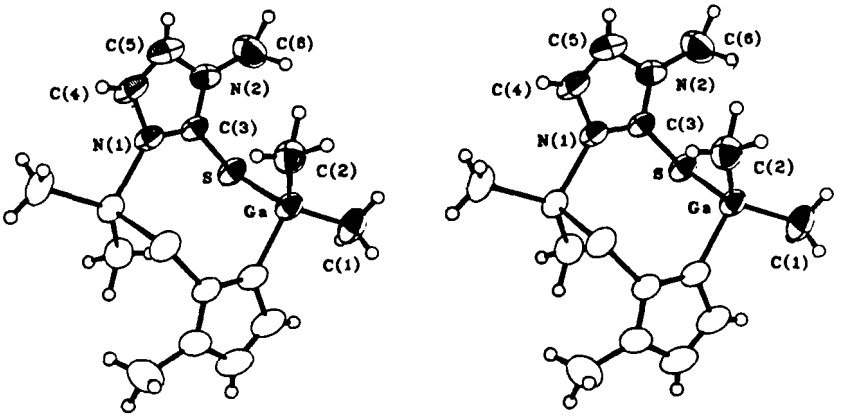

FIG. 1. Stereoscopic view of the $[Me_2GaS\overline{CNCHCHNMe}]_2$ molecule. 50% probability thermal ellipsoids are shown.

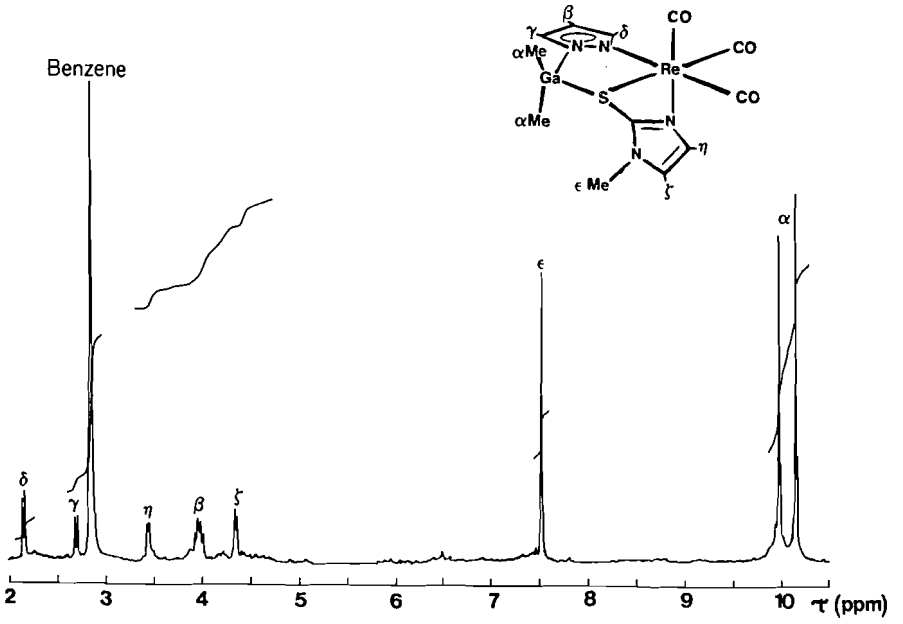

FIG. 2. 80 MHz ^1H nmr spectrum of $[Me_2Gapz(S\overline{CNCHCHNMe})]Re(CO)_3$ in C_6D_6.

the spectrum. It is worth noting that in the proposed structure the sulphur atom is three coordinate, unlike the sulphur atom in the $[Me_2Ga(S\overline{CNCHCHNMe})]_2$ dimer species, but analogous to the sulphur coordination in the $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(S\overline{CNCHCHNMe})]_2$ dimer species described below.

In contrast to the successful coordination of the ligand **2** to the "$Re(CO)_3$" unit, attempts to synthesize analogous octahedral complexes incorporating the "$Mo(CO)_2(\eta^3\text{-allyl})$" moiety failed. However, the products obtained from these attempts were themselves of great interest. Thus, instead of the anticipated reaction sequence it became apparent that degradation of the ligand **2** had occurred and resulted in the formation of the dimeric species $[Mo(\eta^3\text{-allyl})(CO)_2(S\overline{CNCHCHNMe})]_2$. A second product in the reaction was identified as the $[Me_2Ga(pz)]_2$ dimer compound, which has been characterized previously (21).

The molybdenum-containing dimers have been characterized by ir, ^1H nmr, and mass spectral studies and, in addition, the X-ray structure determination of the $\eta^3\text{-}C_4H_7$-containing compound has been performed. The ir spectra of the complexes show four strong ν_{CO} bands, a pattern which would be predicted for the C_2 point group of these dimeric species (22). The ^1H nmr spectra of the complexes are also consistent with the dimeric structure found in the solid state (see below). The spectrum of the $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(S\overline{CNCHCHNMe})]_2$ complex in d_6-acetone is shown in Fig. 3. Thus, the two *anti* protons of the allyl group are inequivalent, as are the two *syn* protons (these have very similar chemical shifts but are resolved at 300 MHz). The *N—Me* groups of the two imidazolyl ligands appear as a singlet in the spectrum, indicating equivalent environments in the molecule.

The mass spectra of the two complexes demonstrate their dimeric nature in the gas phase. For example, the mass spectrum of the $\eta^3\text{-}C_3H_5$ derivative displays a weak parent-ion signal at ~612, as well as other strong signals attributable to ions containing the dimeric unit $[Mo(S\overline{CNCHCHNMe})]_2$.

The results from the above-mentioned physical methods indicated the dimeric nature of the $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(S\overline{CNCHCHNMe})]_2$ and $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(S\overline{CNCHCHNMe})]_2$ complexes. Two possible structures that would account for our data are shown in Fig. 4*a* and *b*. In both of these proposals the molybdenum atoms attain an 18-electron configuration via a

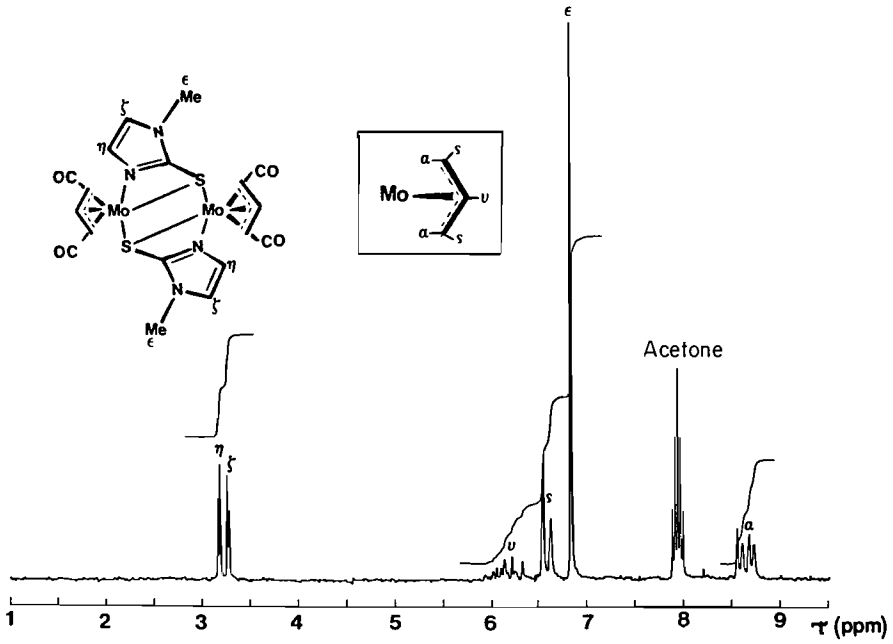

FIG. 3. 80 MHz ^{1}H nmr spectrum of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(\overline{SCNCHCHNMe})]_2$ in d_6-acetone.

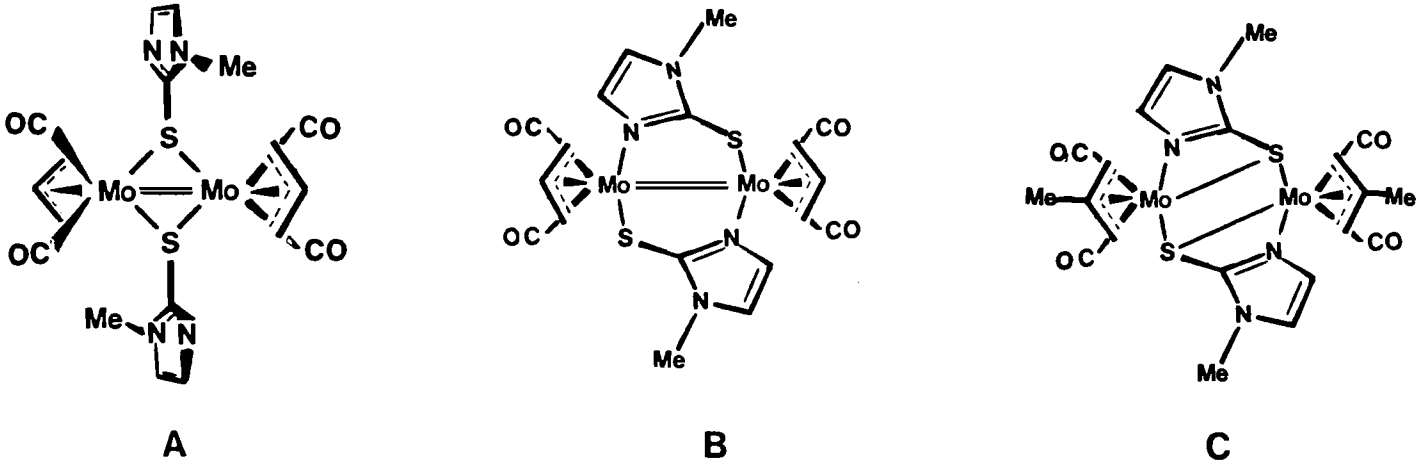

FIG. 4. Possible structures for the dimeric species, $[Mo(\eta^3\text{-allyl})(CO)_2(\overline{SCNCHCHNMe})]_2$.

Mo=Mo double bond. Although there are numerous examples of sulphur-bridged dimolybdenum species (23–26), the availability of the nitrogen lone pair on the unsubstituted nitrogen atom of the imidazolyl ligand prompted us to predict the arrangement shown in Fig. 4*b*. A single crystal X-ray structure determination of the $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(\overline{SCNCHCHNMe})]_2$ complex was undertaken to examine this prediction. The resulting structure is shown in Fig. 5. The complex is indeed dimeric in the solid state but does not, in fact, display any Mo—Mo bonding interaction. The 18-electron count on each molybdenum centre is achieved by bridging S atoms. These 3-coordinate sulphur atoms adopt an arrangement similar to that predicted for the sulphur atom in the $[MeGa(pz)(\overline{SCNCHCHNMe})]$-$Re(CO)_3$ compound, but are evidently very different from the 2-coordinate sulphur atoms observed in the structure of the $[Me_2Ga(\overline{SCNCHCHNMe})]_2$ dimer species. The structure observed (Figs. 4*c* and 5) has crystallographically-imposed C_2 molecular symmetry, and exhibits a system of five fused rings arranged in an unusual U-shape. The ring sizes involved are, in order, five-, four-, four-, four- and five-membered. The central Mo_2S_2 ring is puckered (bond torsion angles of 24°, Table 6, Mo—S = 2.6868(7) Å in the MoSCN four-membered chelate ring, and Mo—S′ = 2.5576(7) Å; these distances are within the rather wide range found for Mo—S distances, the difference between the two values resulting probably from strain caused by the small bite of the mercaptoimidazole ligand (S···N = 2.640(2) Å) and from the influence of the different (carbonyl and allyl) *trans* ligands. The angles in the Mo_2S_2 ring are S—Mo—S′ = 80.96(2), Mo—S—Mo′ = 93.83(2)°, and the Mo···Mo cross-ring distance of 3.8313(4) Å precludes the possibility of significant metal–metal interaction. The Mo atoms are in a pseudo-octahedral environment, with the η^3-C_4H_7 ligand occupying one octahedral position, *cis* to one S and *trans* to the second S atom. Important bond distances are Mo—N = 2.253(2), mean Mo—CO = 1.950(2), Mo—C(allyl) = 2.259(3) (central C), mean = 2.326(3) Å (terminal carbons). Bond angles at Mo differ markedly from 90 and 180°C, as a result of the fused ring structure; in particular, S—Mo—N =

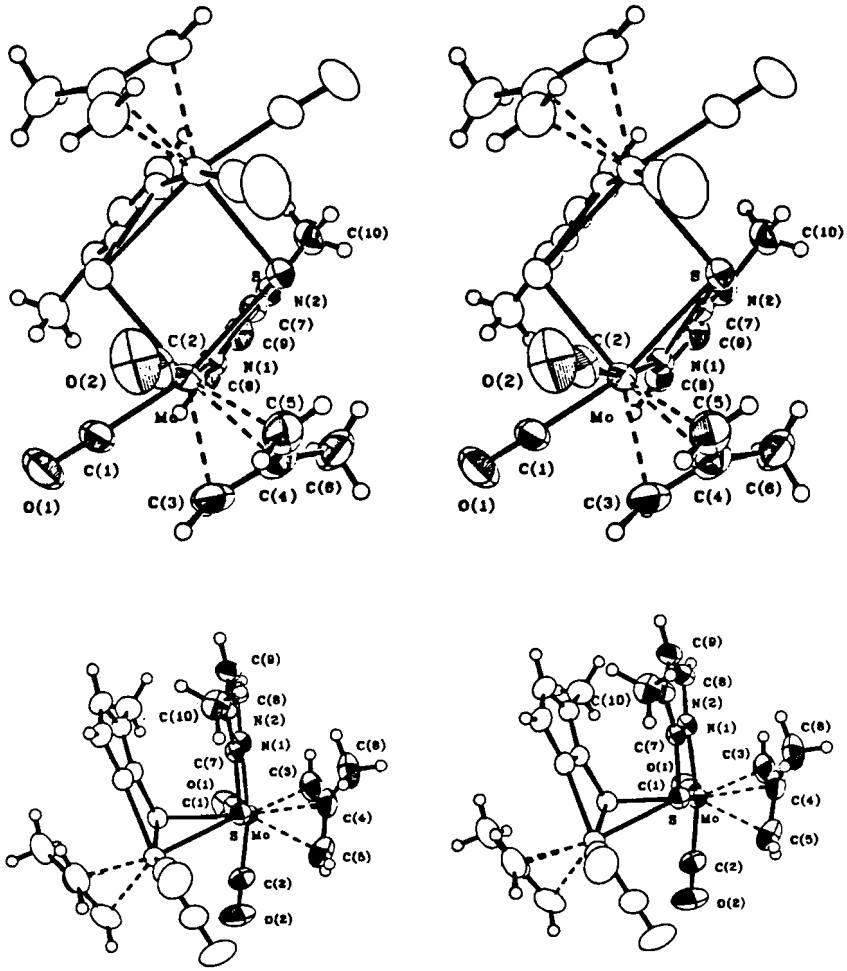

FIG. 5. Stereoscopic view of the $[Mo(\eta^3\text{-}C_4H_7)(CO)_2(S\overline{CNCHCHN}Me)]_2$ molecule. 50% probability thermal ellipsoids are shown.

63.9(1) and Mo—S—C = 75.7(1)° in the four-membered MoSCN ring. These latter angles suggest considerable strain in the MoSCN ring, although the ring is not far from planar (bond torsion angles 3–6(2)°, Table 6). The constraints introduced by the small bite of the mercaptoimidazole ligand probably also account for the non-occurrence of five-coordinate Ga in the dimethylgallium dimer (Fig. 1); here the S···N bite is 2.752(2) Å, and the formation of a Ga—S bond of about 2.40 Å would involve excessive strain in the four-membered chelate ring. The U-shape of the Mo complex (Fig. 5) results in the two imidazole rings being roughly parallel, with possible overlap of the two π-electron systems; the distances between the atoms of the rings are however too long (all >4 Å) to permit any significant interaction.

The proton-transfer chemical ionization mass spectra of the C_3 to C_5 monoalkyl amines as well as a number of di- and tri-alkyl amines have been determined using H_3^+ and (in some cases) HCO^+ as protonating agent. The RNH_3^+ ions fragment to form alkyl ions R^+ and eliminate alkenes to form NH_4^+. In addition, abundant immonium ions are observed in the CI mass spectra corresponding to elimination of alkane from RNH_3^+ or to direct alkide ion abstraction from RNH_2; these ions serve to characterize the alkyl groups attached to the α-carbon atom of the amine. Although alkane elimination from RNH_3^+ is the thermochemically favoured reaction, only R^+ and NH_4^+ are formed in decomposition of metastable RNH_3^+ ions. The potential energy profile for fragmentation of i-$C_3H_7NH_3^+$ has been calculated by *ab initio* molecular orbital methods. These calculations show that CH_4 elimination has a large energy barrier additional to the reaction endothermicity while formation of NH_4^+ has only a small additional barrier and formation of $C_3H_7^+$ has no barrier additional to the endothermicity. It is concluded that the immonium ions probably arise primarily by direct alkide ion abstraction reactions.

ERIC J. REINER, RAYMOND A. POIRIER, MICHAEL R. PETERSON, IMRE G. CSIZMADIA et ALEX G. HARRISON. Can. J. Chem. **64**, 1652 (1986).

Utilisant le H_3^+ et (dans quelques cas) le HCO^+ comme agents protonants, on a déterminé les spectres de masse par ionisation chimique par transfert de proton des amines primaires en C_3 à C_5 ainsi que d'un certain nombre d'amines secondaires et tertiaires. Les ions RNH_3^+ se fragmentent pour former des ions alkyles R^+ ou pour éliminer des alcènes avec formation de NH_4^+. De plus, on observe la formation abondante d'ions immonium dans les spectres de masse par ionisation chimique et ceux-ci correspondent à une élmination d'alcane de l'ion RNH_3^+ ou à un enlèvement direct d'ion alkide à partir du RNH_2; ces ions servent à caractériser les groupements alkyles attachés à l'atome de carbone en α de l'amine. Même si l'élimination d'alcane à partir de l'ion RNH_3^+ est la réaction qui est thermodynamiquement favorisée, il ne se forme que les ions R^+ et NH_4^+ lors de la décomposition des ions métastables RNH_3^+. Utilisant des méthodes d'orbitales moléculaires *ab initio*, on a calculé les profiles d'énergie potentielle pour la fragmentation de l'ion i-$C_3H_7NH_3^+$. Ces calculs démontrent que l'élimination de CH_4 est soumise à une forte barrière énergétique qui s'additionne à l'endothermicité de la réaction alors que la formation de l'ion NH_4^+ n'est soumise qu'à une faible barrière additionnelle et que la formation de l'ion $C_3H_7^+$ n'est soumise à aucune barrière additionnelle par rapport à l'endothermicité de la réaction. On en conclut que les ions immonium proviennent probablement de réactions primaires d'abstractions directes de l'ion alkide.

[Traduit par la revue]

Introduction

The proton transfer chemical ionization mass spectra of aliphatic amines have seen little systematic study (1). By analogy with the behaviour of protonated aliphatic alcohols, which have been studied extensively (2–4), the major fragmentation reactions of the protonated amines, RNH_3^+, might be expected to be elimination of NH_3 forming the corresponding alkyl ion. In agreement with this prediction two early limited studies (5, 6) reported significant yields of R^+ ions, although, because of the high proton affinity of ammonia, fragmentation was not particularly facile (7). In contrast to these few results Colosimo and Brancaleoni (8) have reported that, in the H_2 chemical ionization mass spectra of the C_1 to C_4 alkyl amines, very low or negligible intensities are observed for the alkyl ions formed by loss of NH_3 from RNH_3^+. Rather, the base peak reported corresponds either to formation of NH_4^+ or to formation of immonium ions resulting, nominally, from elimination of an alkane molecule.

We report here the results of a detailed study of the proton transfer chemical ionization mass spectra of the C_3 to C_5 monoalkyl amines as well as selected dialkyl and trialkyl amines. In contrast to the results of Colosimo and Brancaleoni (8), we observe, for the monoalkyl amines, RNH_2, significant yields of R^+ alkyl ions although, in agreement with them, we also observe significant yields of NH_4^+ and immonium ions arising, nominally, by alkane elimination from RNH_3^+. Thermochemically, alkane elimination is the most favourable fragmentation reaction for protonated alkyl amines. However, this reaction is not observed for low energy RNH_3^+ ions fragmenting in the metastable ion time frame; rather formation of R^+ and NH_4^+ are the only metastable ion fragmentation reactions observed for the RNH_3^+ ions studied. Clearly the critical reaction energies are not the same as the reaction enthalpies. Metastable ion fragmentation reactions occur near the threshold for fragmentation of the decomposing species and it is well known (9, 10) that, near the threshold, the relative rates are determined primarily by the critical reaction energies. Thus the unimolecular chemistry of such ions is best understood in terms of the potential energy profile (11) for the ion. For species such as protonated amines it is extremely difficult to establish such a potential energy profile by experimental methods. Therefore, to reach a better understanding of the unimolecular chemistry of protonated alkyl amines we have calculated by *ab initio* molecular orbital methods the potential energy surface for a representative case, protonated isopropyl amine. The results of these calculations, as well as the detailed chemical ionization and metastable ion studies, are presented in the following.

Experimental

Proton transfer chemical ionization mass spectra were obtained using either a DuPont 21-290 single-focusing magnetic deflection mass spectrometer equipped with a chemical ionization source or with an

[1]Present address: Department of Chemistry, Memorial University, St. John's, Nfld., Canada A1B 3X7.

[2]Author to whom correspondence may be addressed.

AEI MS-902 double-focusing (BE) mass spectrometer also equipped with a chemical ionization source. Comparable spectra were obtained from each machine. In both cases the source temperature was ~150°C with samples being introduced from a heated inlet system at ~150°C. Reagent gas pressures were ~0.3 Torr and the ionizing electron energy was 70 eV. Reagent gases used were H_2 and 10% CO/90% H_2. The former produces H_3^+ as the proton transfer reagent ion while the latter produces HCO^+. The proton affinity of H_2 is ~422 kJ mol^{-1} (1) while that of CO is ~590 kJ mol^{-1} (1). Since the proton affinities of the amines are of the order of 920 kJ mol^{-1} (1) protonation of the amines by H_3^+ is ~500 kJ mol^{-1} exothermic and protonation by HCO^+ is ~330 kJ mol^{-1} exothermic, an exothermicity similar to protonation by the common proton transfer reagent CH_5^+; the use of HCO^+ has the advantage that the background is less extensive.

The unimolecular fragmentation reactions of the protonated amines, which occur in the metastable ion time-frame ($k = 10^4$–10^6 s^{-1}), were investigated by the MIKES technique (12) using a VG Analytical ZAB-2FQ mass spectrometer. The feature of the ZAB-2FQ instrument essential for the present work is that it is a reverse geometry (magnetic sector preceding the electric sector) double-focusing mass spectrometer. This configuration permits selection of the ion corresponding to the protonated amine by the magnetic sector, unimolecular fragmentation of this mass-selected ion in the drift region between the two sectors with identification of the ionic fragmentation products from their kinetic energies by scanning the electric sector (12). In studying the unimolecular metastable ion fragmentation reactions the protonated amines were preprared using H_2, CH_4, and i-C_4H_{10} as chemical ionization reagent gases. The CH_4 reagent gas produces CH_5^+ and $C_2H_5^+$ ($PA(CH_4)$ = 546 kJ mol^{-1} (1), $PA(C_2H_4)$ = 684 kJ mol^{-1} (1)) as reagent ions while i-C_4H_{10} produces $C_4H_9^+$ ($PA(i\text{-}C_4H_8)$ = 824 kJ mol^{-1} (1)) as the reagent ion. The variation of reagent gas thus permits a study of the effect of protonation exothermicity on the metastable ion characteristics.

All compounds used were commercially available and showed no detectable impurities in their mass spectra.

Results and discussion

Chemical ionization mass spectra

Table 1 records the H_2 and CO/H_2 chemical ionization mass spectra of n-propyl and i-propyl amine. Despite the high proton affinity of NH_3, which is a measure of the R^+—NH_3 bond strength (7),[3] the MH^+ ion signals are very low because of the large exothermicity of the protonation reaction. Two fragmentation reactions of the MH^+ ion are clearly established, reaction [1] involving elimination of NH_3 and reaction [2] involving formation of the ammonium ion.

[1] $C_3H_7NH_3^+ \rightarrow C_3H_7^+ + NH_3$

[2] $\rightarrow NH_4^+ + C_3H_6$

The $C_3H_5^+$ ion presumably arises by further fragmentation of the $C_3H_7^+$ ion. Two additional primary product ions are the $(M - H)^+$ ion at m/z 58 and the immonium ion (m/z 30 and m/z 44, respectively). This latter ion may arise either by direct alkide ion abstraction from RNH_2 by the reagent ion or by elimination of an alkane molecule from the MH^+ ion (reaction [3]).

[3] $R_1\text{—}CH(R_2)\text{—}NH_3^+ \rightarrow R_2CH{=}NH_2^+ + R_1H$

$\rightarrow R_1CH{=}NH_2^+ + R_2H$

The origin of this product will be discussed in detail later; the important point is that it serves to identify the alkyl group(s) attached to the α-carbon of the amine.

[3]Implicit in this statement is the assumption that alkyl cation affinities will parallel proton affinities.

44	$MH^+ - CH_4$	32	12	89	85
43	$C_3H_7^+$	100	100	100	77
42	$C_3H_6^+$	4	1	6	1
41	$C_3H_5^+$	46	22	22	12
30	$MH^+ - C_2H_6$	96	37	5	1
18	NH_4^+	90	79	80	100

The present H_2CI mass spectra are in quantitative disagreement with the spectra reported by Colosimo and Brancaleoni (8). Thus, they report the intensity ratios m/z 43:m/z 30:m/z 18 = 12:100:26 for n-propyl amine compared to 100:96:90 in our work. For i-propyl amine they do not report any ion signals at m/z 44 or m/z 43 which is in sharp contrast to our results. Although chemical ionization mass spectra are less reproducible than electron impact spectra these differences are greater than one would expect to observe. By comparison with earlier studies of the CI of amines (5, 6) and the known behaviour of alcohols under proton transfer CI conditions (2–4) the present results would appear to be a better representation of the behaviour expected of gaseous protonated amines.

Tables 2 and 3 record, respectively, the H_2 and CO/H_2 CI mass spectra of the four butyl amines as well as the spectra of diethyl amine and dimethyl ethyl amine. The butyl amines show the same fragmentation reactions as the propyl amines with NH_4^+ and $C_4H_9^+$ ($RNH_3^+ - NH_3$) being prominent as well as the immonium ions arising by nominal alkane elimination from MH^+. Thus, in the latter category, the two primary amines show intense $(M - C_3H_7)^+$ ion signals, t-butyl amine shows an intense $(M - CH_3)^+$ ion signal and s-butyl amine shows both $(M - CH_3)^+$ and $(M - C_2H_5)^+$ ion signals, the latter being more intense. These ion signals provide direct information on the alkyl group(s) attached to the α-carbon of the amine. The $C_3H_5^+$ ion presumably arises by further fragmentation of $C_4H_9^+$; the $C_2H_5^+$ ion also would be expected to arise by further fragmentation of $C_4H_9^+$ (13); however, formation of this ion is obscured by ion signals in the reagent ion spectrum (HCO^+ in CO/H_2 and a background N_2H^+/HCO^+ ion signal in H_2). Again our H_2CI mass spectra are in disagreement with the results of Colasimo and Brancaleoni (8) who do not report any ion signals for $C_4H_9^+$ (m/z 57).

The spectra of diethyl amine and dimethylethyl amine, also recorded in Tables 2 and 3, show more abundant MH^+ and $(M - H)^+$ ion signals than do the monoalkyl amines. This is in agreement with the CH_4CI mass spectra of triethyl amine and a number of polytertiary amines (14) which also show abundant MH^+ and $(M - H)^+$ ion signals. The di- and tri-alkyl amines of Tables 2 and 3 also show abundant ion signals arising, nominally, by CH_4 elimination from MH^+. In addition, a new reaction channel opens, involving ethylene elimination from MH^+, forming protonated ethyl amine and protonated dimethyl amine, respectively, at m/z 46.

*This ion is not seen in H_2CI mass spectra and may arise by reaction of HCO^+ with amine, possibly

$$HCO^+ + RNH_2 \rightarrow HCONH_3^+ + (R - H)$$

spectra of eight isomeric pentyl amines. A major reaction channel involves elimination of NH_3 from MH^+ to form $C_5H_{11}^+$ (m/z 71), which shows extensive fragmentation to form $C_3H_7^+$ (m/z 43). For the purposes of identifying the amine the most important ions are those arising by nominal akane elimination from MH^+. Thus the primary amines of formula $C_4H_9CH_2NH_2$ show an abundant ion signal at m/z 30 corresponding to elimination of C_4H_{10}, amines with the structure $C_3H_7CH(NH_2)CH_3$ show an intense signal at m/z 44 corresponding to C_3H_8 elimination while $C_2H_5CH(NH_2)C_2H_5$ and $C_2H_5C(NH_2)(CH_3)_2$ both show an intense peak at m/z 58 corresponding to elimination of C_2H_6. The elimination of CH_4 is a much less structure-specific reaction and, thus, provides little structural information.

Figure 1 compares the H_2CI mass spectra of 2-amyl amine and t-amyl amine with the H_2CI of the corresponding alcohols. The H_3O^+ ion signal, analogous to the NH_4^+ ion signal, was not recorded for the alcohols because of interference from background water in the instrument. Two major differences are observed between the amines and the alcohols. First, the intensities of the alkane elimination products are much more intense for the amines, thereby providing much more definitive information concerning alkyl substitution on the α-carbon. Second, the $C_5H_{11}^+$ alkyl ions, formed by HX elimination from RXH^+, show much more extensive fragmentation for the amines. The origin of this latter difference has been discussed previously (15).

Table 5 records the H_2CI mass spectra of four C_5 di- and tri-alkyl amines. Abundant $(M - H)^+$ ion signals are observed as well as the immonium ions arising by nominal alkane elimination from MH^+; this latter reaction involves cleavage of the C—C bond α to the nitrogen function. In addition, as discussed previously for the C_4, di- and tri-alkyl amines, olefin elimination from MH^+ is quite prominent. Thus both the

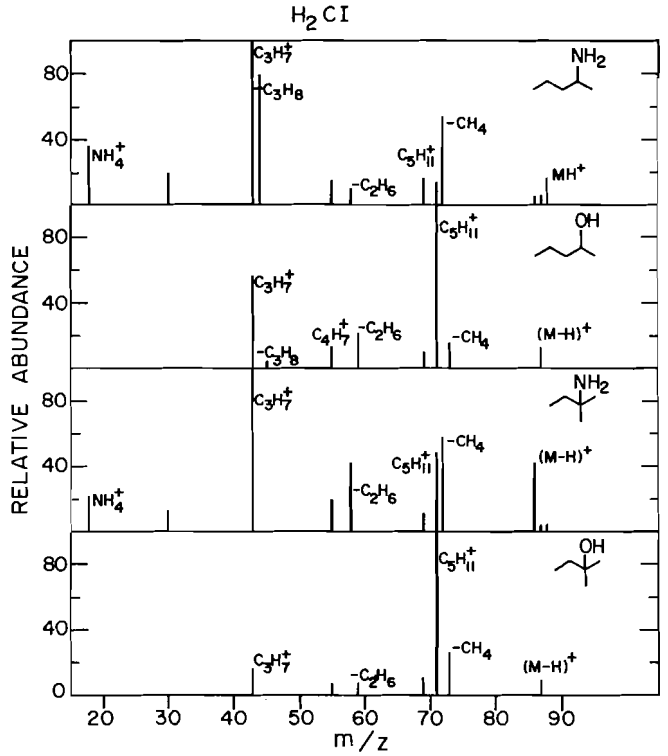

FIG. 1. Comparison of the H_2CI mass spectra of amyl amines and amyl alcohols.

protonated methyl butyl amines show elimination of C_4H_8 while *N*-ethyl propyl amine shows elimination of C_3H_6 and *N*-methyl diethyl amine shows elimination of C_2H_4. These olefin elimination reactions also help to characterize the amines.

Fragmentation of protonated amines as metastable ions

Two fragmentation channels are observed for RNH_3^+ ions in the metastable ion time frame, formation of NH_4^+ by elimination of alkene and formation of the alkyl ion, R^+, by loss of NH_3. Thus, *n*-$C_3H_7NH_3^+$ showed formation of $C_3H_7^+$ and NH_4^+ in the ratio 23:100 while *i*-$C_3H_7NH_3^+$ showed a ratio of 1:100 in metastable ion fragmentation reactions. The results obtained for the protonated butyl amines are presented in Table 6 for three different protonating reagents with different protonation exothermicity. The protonated primary amines, *n*-$C_4H_9NH_3^+$ and *i*-$C_4H_9NH_3^+$ show abundant formation of $C_4H_9^+$ on the metastable ion time scale, with the relative abundance of NH_4^+ increasing with increasing exothermicity of the initial protonation reaction. By contrast, the protonated secondary and tertiary amines show dominant formation of NH_4^+ in metastable ion fragmentation reactions with the relative product yields being insensitive to the exothermicity of the protonation reaction. The pentyl amines were studied only following protonation by *i*-C_4H_{10}. The results, presented in Table 7, are similar to the results for the protonated butyl amines in that the primary amines favour formation of the alkyl ion, $C_5H_{11}^+$, while the secondary and tertiary amines strongly favour formation of NH_4^+ in the metastable ion fragmentation reactions.

The metastable ion fragmentation reactions correspond to reactions with rate constants in the range 10^4 to 10^6 s^{-1} defined by the parameters of the instrument; normally the relative ion abundances depend strongly on the critical reaction energies. Changing the exothermicity of the protonation reaction does not change the range of rate constants but appears to change the

distribution of internal energies in the metastable ion energy window (16). By contrast, fragmentation reactions occurring in the ion source following protonation represent higher energy reactions ($k > 10^6$ s^{-1}) and the relative product yields may reflect both the effect of critical reaction energies and frequency factors on the rates of fragmentation. The relative metastable ion abundances observed for the butyl amines suggest that for the primary amines formation of $C_4H_9^+$ has a lower critical reaction energy than formation of NH_4^+ with the opposite prevailing for the secondary and tertiary amine. The absence of any metastable transition corresponding to elimination of alkane implies that this reaction has a considerably higher critical reaction energy.

It is of interest to compare this approximate ordering of critical reaction energies with calculated reaction endothermicities. This comparison is made in Table 8 for the propyl and butyl amines which shows the calculated ΔH_{react} and relative ion abundances for metastable ion fragmentation reactions and in the H_2 and CO/H_2 chemical ionization mass spectra. In the thermochemical calculations we have assumed that primary alkyl ions are not formed but that hydrogen shifts occur to form the appropriate secondary or tertiary alkyl ion. The thermochemical data used in the calculations are summarized in the Appendix.

Several interesting points arise from the comparison of the relative abundances with the reaction thermochemistry. First, for the secondary and tertiary protonated amines, alkane elimination has by far the lowest enthalpy of reaction yet this fragmentation reaction is not observed for metastable ion fragmentation reactions. This strongly suggests that the critical energy for alkane elimination is considerably greater than the reaction endothermicity. The high yields of the alkane elimination products in the CI mass spectra, which emphasize fragmentation reactions of ions with greater internal energies, are consistent either with a very favourable frequency factor for the reaction *or* with formation of these products by a direct alkide ion abstraction reaction. For the secondary and tertiary amines the favoured formation of NH_4^+ over R^+ in metastable ion fragmentation reactions is in agreement with the reaction thermochemistry; the increase in the relative yields of the alkyl ions in the CI mass spectra indicates that the reaction forming these products has a more favourable frequency factor. For the primary amines the relative metastable fragmentation yields of alkyl ions and NH_4^+ are not in agreement with the calculated enthalpies of reaction since large yields of alkyl ions are observed despite the fact that the reaction has a greater endothermicity. These results imply that, at least for the primary amines, formation of NH_4^+ has a critical reaction energy greater than the reaction endothermicity. The variation of relative metastable ion yields with protonation exothermicity (Table 6) also supports the conclusion that formation of $C_4H_9^+$ has the

†CH_4CI.

lower critical reaction energy for the primary amines. This result contrasts with the conclusions derived for the protonated secondary and tertiary amines.

These differences between the calculated reaction endothermicities and the apparent critical reaction energies prompted us to undertake the calculation of the potential energy surface for the fragmentation of a representative protonated amine by *ab initio* molecular orbital methods. We have chosen protonated *i*-propyl amine for study. The details of these calculations are presented in the following section. Further discussion of the fragmentation of protonated amines follows in light of these calculations.

Potential energy profile for fragmentation of i-$C_3H_7NH_3^+$

The potential energy profile for fragmentation of protonated isopropyl amine was determined by *ab initio* self-consistent field (SCF) molecular orbital calculations. Three fragmentation reaction were considered, viz.

[3] i-$C_3H_7NH_3^+ \rightarrow CH_3CHNH_2^+ + CH_4$

[4] $\rightarrow i$-$C_3H_7^+ + NH_3$

[5] $\rightarrow NH_4^+ + C_3H_6$

A 3-21G (17) split valence basis set was used to optimize the geometries of all the species by use of *ab initio* SCF calculations in the MONSTERGAUSS system (18).[4] Geometry optimization of all species, except the transition states, was achieved by simultaneous variation of bond lengths and bond angles using the analytic first derivatives of energy in conjunction with Davidon's optimally conditional (OC) algorithm (20). The norm of the gradient vector was less than 5×10^{-4} mdyn at convergence for all cases. Geometry optimization of the transition state structures (TS $-$ NH_4^+ and TS $-$ CH_4) was accomplished using the VA05AD (VA) sum of squares optimization technique (21). In this method the Hessian matrix was evaluated by gradient differences and diagonalized to determine the order of the critical point. Again the norm of the gradient vector was less than 5×10^{-4} mdyn for convergence. The structures of all stable species are listed in Table 9 while the structures of the two transition states and the one intermediate detected are shown in Fig. 2.

The single point energies of the 3-21G-optimized structures were calculated using a 6-31G* (22) basis set and are listed in Table 10. Because all the reactions are isodesmic reactions of closed shell species, the correlation and relativistic energies may be assumed to be relatively constant and neglect of these terms will introduce errors of no more than 4–17 kJ mol^{-1} in calculated energy differences (30). All calculations were performed on the Gould 32/9705 computer, Department of Chemistry, University of Toronto.

The calculated potential energy profile is shown in Fig. 3. Reaction [3], elimination of CH_4, entails a 1,3-hydrogen/proton shift from nitrogen to carbon in which the hydrogen/proton inserts itself between the central carbon (C_1) and the departing methyl group; the transition state structure is shown in Fig. 2. The calculated barrier for this reaction is 389 kJ mol^{-1}, much higher than the theoretically calculated endothermicity of 50 kJ mol^{-1}; this latter value is in good agreement with the endothermicity (52 kJ mol^{-1}) derived from the thermochemical data. Reaction [4], loss of NH_3, was found to proceed without a barrier additional to the endothermicity with the $C_3H_7^+$ and NH_3 products merely drifting apart with no maximum in the potential energy curve. The calculated reaction endothermicity is in good agreement with the experimental endothermicity.

Reaction [5], formation of NH_4^+, was found to proceed by a transition state with an energy 40 kJ mol^{-1} above the final products; the structure of this transition state is shown in Fig. 2. In essence, in this reaction the C—N bond lengthens and the NH_3 group moves towards one of the methyl groups with some lengthening of a C—H bond. Of particular interest is the observation of the minimum in the surface between the transition state and the final products. This minimum corres-

[4]MONSTERGAUSS includes GAUSSIAN 80 (19) and geometry optimization by analytic first derivative methods.

ponds to a proton bound dimer of propene and ammonia and has the structure shown in Fig. 2. The binding energy of the dimer was found to be 42 kJ mol^{-1}.

The calculated potential energy profile adequately rationalizes the experimental data obtained for the fragmentation of protonated isopropyl amine. The high critical reaction energy for elimination of CH_4 precludes observation of this reaction channel in metastable ion fragmentation reactions despite the favourable thermochemistry. Instead formation of NH_4^+ has the lowest critical reaction energy and, in agreement, this is the dominant metastable ion fragmentation product. The high abundance of the CH_4 elimination product, particularly in the CO/H_2 CI mass spectrum, remains to be resolved. Protonation of isopropyl amine by ground state HCO^+ is only ~324 kJ mol^{-1} exothermic while the barrier for elimination of CH_4 is ~389 kJ mol^{-1}; thus elimination of CH_4 should not be

TABLE 10. Calculated energies of participating species with 3-21G geometries

observed. However, to qualify this statement it should be noted that it is unlikely that all of the HCO^+ ions are in their ground state under our experimental conditions. In view of the high energy barrier for alkane elimination it might be argued that alkane elimination does not occur from protonated amines but rather that the relevant signals in the CI mass spectra arise by a different mechanism such as direct alkide ion abstraction by the reagent ion. We have observed (unpublished results) that alkane elimination occurs from protonated alkyl amines activated by a high energy (8 keV) collision but that it is of only minor importance for protonated amines activated by a low energy (100 eV) collision. The results to date suggest that the average energy transformed from translational energy into internal energy is approximately the same for both high energy and low energy collisions (23, 24) but that in the high energy collisions there is a low probability tail extending to high internal energies (24). It appears that it is these high energy ions which fragment by alkane elimination. Such high energies probably are not achieved to a significant extent in chemical ionization systems and it is likely that the reaction occurring is largely an alkide ion abstraction reaction rather than alkane elimination from the protonated amine.

There remains the question of why the protonated primary butyl amines show abundant formation of $C_4H_9^+$ in metastable ion fragmentation reactions while the secondary and tertiary amines do not. The reasons are not clear. The thermochemistry favours formation of NH_4^+ and the calculated barrier for this reaction is not sufficient to reverse the thermochemical arguments. We must assume that, for reasons unknown, for protonated *n*-butyl and *i*-butyl amines, the barrier is even higher than that calculated for the *i*-propyl amine. We have not attempted to calculate this barrier since for the butyl amines there is a possible ambiguity concerning the mechanism of the reaction, i.e., an uncertainty as to the hydrogen lost with the NH_4^+.

Appendix

The enthalpies of formation of the protonated amines were derived from the reported proton affinities through the relationship

[6] $$PA(RNH_2) = \Delta H_f^0(RNH_3^+) - \Delta H_f^0(RH^+) - \Delta H_f(RNH_2)$$

using $\Delta H_f^0(H^+) = 1531.4$ kJ mol^{-1} (27). The relevant data are summarized in Table 11. Other thermochemical data used were $\Delta H_f^0(i\text{-}C_3H_7^+) = 803$ kJ mol^{-1}, $\Delta H_f^0(s\text{-}C_4H_9^+) = 766$ kJ mol^{-1} and $\Delta H_f^0(t\text{-}C_4H_9^+) = 699$ kJ mol^{-1}, all taken from Lossing and Semeluk (28). $\Delta H_f^0(NH_3) = -46.0$ kJ mol^{-1}, $\Delta H_f^0(CH_4) = -75.3$ kJ mol^{-1}, $\Delta H_f^0(C_2H_6) = -83.7$ kJ mol^{-1} and $\Delta H_f^0(C_3H_6) = -20.9$ kJ mol^{-1} were from ref. 27 while the enthalpies of formation of the immonium ions are (29) $\Delta H_f^0(CH_2NH_2^+) = 745$ kJ mol^{-1}, $\Delta H_f^0(CH_3CHNH_2^+) = 657$ kJ mol^{-1}, $\Delta H_f^0(CH_3CH_2CHNH_2^+) = 636$ kJ mol^{-1}, and $\Delta H_f^0((CH_3)_2CNH_2^+) = 590$ kJ mol^{-1}.

Ternary charge-transfer complexes. III.[1] Complexes with Group V elements in the anion[2]

SYDNEY BROWNSTEIN,[3] ERIC GABE, FLORENCE LEE, AND ANDREJ PIOTROWSKI
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received October 8, 1985[4]

SYDNEY BROWNSTEIN, ERIC GABE, FLORENCE LEE, and ANDREJ PIOTROWSKI. Can. J. Chem. **64**, 1661 (1986).

$NOMX_6$·aromatic charge-transfer complexes are formed where M may be P, As, or Sb, X may be F or Cl, and aromatic may be benzene or a methyl-substituted benzene. Nuclear magnetic resonance and optical spectral parameters are given and three crystal structures reported. Appreciable conductivity is found for $NOSbCl_6$·polystyrene and $NOSbF_6$·hexamethylbenzene.

SYDNEY BROWNSTEIN, ERIC GABE, FLORENCE LEE et ANDREJ PIOTROWSKI. Can. J. Chem. **64**, 1661 (1986).

On a observé qu'il se forme des complexes de transfert de charge du type $NOMX_6$·aromatique, dans lesquels M = P, As ou Sb, X = F ou Cl et aromatique = du benzène ou un benzène substitué par un groupement méthyle. On rapporte les données relatives aux spectres rmn et optiques ainsi trois structures cristallines. On a trouvé que les composés $NOSbCl_6$·polystyrène et $NOSbF_6$·hexaméthylebenzène donnent lieu à une conductivité appréciable.

[Traduit par la revue]

Introduction

The preparation of stable charge transfer complexes of NOCl, MCl_n, and an aromatic hydrocarbon has been reported (1). The variation in properties and stabilities of such complexes as a function of the anion has been described when a Group III or IV element is the central atom in the anion (2). In this article the properties of such complexes will be presented where the central element of the counter ion is from Group V of the periodic table and the halogen is chlorine or fluorine.

Following is a brief history of the nitrosyl salts which were used in this study. $NOPF_6$ is well characterized (3). There is some evidence for a complex between NOCl and $AsCl_3$ but no complex has been isolated (4, 5). $NOAsF_6$ (3), $NOSbCl_6$ (6), and $NOSbF_6$ (3) have been well characterized.

Antimony pentachloride itself reacts with aromatic hydrocarbons to give charge-transfer complexes (7) and to substitute chlorine for hydrogen (8). Under some conditions $SbCl_5$ will react with hexamethylbenzene to give the stable radical cation 4-methylene-1,2,3,5,6-hexamethylcyclohexadiene-2,5 (9). Antimony pentachloride also reacts with $SOCl_2$ to give $SOCl_2 \cdot SbCl_5$ (10) and with $POCl_3$ to give $POCl_3 \cdot SbCl_5$ (11). Complex formation has been reported between antimony pentachloride and NO (12), NO_2Cl (13), ICl_3 (14), and SCl_4 (15).

Nitrosyl tetrachloroantimonate has been prepared by the decomposition of $SbCl_3 \cdot 2NOCl \cdot NOBCl_4$ (4). $POCl_3$ and $SbCl_3$ are also reported to form a complex (16). There has been some study of complexes between $SbCl_3$ and aromatic compounds and 1:1 complex formation is claimed (17).

Experimental

Chemicals

Nitrosyl chloride, nitrosyl fluoride, arsenic trichloride, arsenic pentafluoride, phosphorus trifluoride, phosphorus tri- and pentachloride, nitric oxide, anthracene, *p*-dichlorobenzene, hexamethylbenzene, anisole, 4-methyl-*N*,*N*-dimethylaniline, 9,10-dimethylanthracene, and antimony trifluoride were used as purchased. Phosphorus pentafluoride was stored over phosphorus pentoxide in order to inhibit formation of POF_3. Antimony pentachloride and pentafluoride were vacuum-distilled and antimony trichloride vacuum-sublimed before transfer under vacuum to storage containers. $POCl_3$, $SOCl_2$, and SCl_2 were also transferred to storage containers by vacuum distillation. Benzene, toluene, *p*-xylene, sulfur dioxide, methylene chloride, and neopentane were purified and stored as previously described (18). *N*,*N*-Dimethylaniline and *t*-butylbenzene were distilled under vacuum from sodium. Chlorobenzene was purified by low temperature crystallization and napthalene by vacuum sublimation. The salt $ICl_2^+SbCl_6^-$ was prepared from ICl, Cl_2, and $SbCl_5$ and purified by recrystallization.

$NOAsF_6 \cdot C_6(CH_3)_6$

AsF_5 (2.0 mmol) and NOF (2.0 mmol) were condensed into a reaction vessel closed with a "Teflon" stopcock along with 2 mL of sulfur dioxide. The mixture was thawed, shaken briefly to get a slurry of white solid, and all volatile materials removed under vacuum to give 1.82 mmol of $NOAsF_6$. An equivalent amount of hexamethylbenzene was added and the mixture dissolved in SO_2 to give a deep red solution. Methylene chloride was added and the solvent slowly removed to give a black crystalline solid which was stable in air.

$NOSbCl_6 \cdot (C_6H_5CH_3)_2$

To 0.3918 g of $NOSbCl_6$ dissolved in 3 mL of SO_2 was added 0.5 g of toluene by vacuum transfer. Some of the SO_2 was evaporated overnight and the remaining solution was held at −20°C for 20 h. The crystalline complex was separated by low temperature filtration: It is exceedingly sensitive to moisture. *Anal.* calcd. for $NOSbCl_6 \cdot C_{14}H_{16}$: H 2.94, C 30.64, N 2.55, Sb 26.66; found: H 3.06, C 30.16, N 2.69, Sb 23.39.

$NOSbCl_6 \cdot C_6(CH_3)_6$

Equivalent quantities of $NOSbCl_6$ and hexamethylbenzene were dissolved in SO_2 and the solvent slowly evaporated to give a nearly saturated solution at room temperature. Upon cooling crystals separated. The solution was decanted from the crystalline material, which is not sensitive to atmospheric moisture.

Magnetic resonance spectra were obtained on a Bruker AM 400 spectrometer at a magnetic field strength corresponding to 400 MHz for protons. Carbon and proton chemical shifts are reported with respect to tetramethylsilane, although neopentane was used as an internal reference since it is inert with respect to the compounds studied. A correction of 0.92 ppm was applied for protons and 31.4 ppm for ^{13}C. Fluorine resonance shifts are reported with respect to internal $CFCl_3$.

Visible spectra were obtained on a Carey 210 Spectrometer. Samples for conductivity measurements were prepared as pressed pellets in the same manner as, and using a die for, KBr infrared pellets. The resistance was measured between the parallel, adjustable plates of a General Radio type 1690 A dielectric sample holder with a General Radio type 1673 A automatic capacitance bridge operating at 1 kHz.

X-ray reflections were measured with Mo $K\alpha_1$ monochromatized radiation, (λ = 0.70932 Å) using a Picker diffractometer with the $\theta/2\theta$ scan technique and profile analysis (19). Reflections were considered significant with $I_{net} > 2.5\sigma(I_{net})$. The intensity data for $NOAsF_6$·hexamethylbenzene and $NOSbCl_6$·2toluene were collected at low temperature (115 K) in an attempt to minimize the effects of the

NO and AsF_6 disorder. This was only partially successful and the accuracy of all these structures suffers because of disorder. Lorentz and polarization factors were applied but absorption corrections were not applied. X-ray structural data for $NOAsF_6$·hexamethylbenzene, $NOSbCl_6$·hexamethylbenzene and $NOSbCl_6$·2toluene are listed in Table 1. The structures of $NOAsF_6$·hexamethylbenzene and $NOSbCl_6$·hexamethylbenzene were solved by MULTAN (20) and refined by full-matrix least squares. The structure of $NOSbCl_6$·2toluene was solved by Patterson and heavy-atom techniques. Attempts to locate H-atoms from difference maps were not successful and positions for H-atoms on the ring were calculated. All calculations were performed with the NRC VAX system of programs (21). Scattering factors were taken from the International tables for X-ray crystallography (22). The final atomic positional parameters and mean temperature factors are given in Table 2 and the anisotropic temperature factors and structure factors are deposited as supplementary material.[5] The structure of $NOSbCl_6$·hexamethylbenzene has previously been reported in preliminary form (1). Bond lengths and angles are reported in Table 3.

The structure of $NOAsFx$·hexamethylbenzene consists of four entities $\frac{1}{2}(AsF_6)$, $\frac{1}{2}(AsF_x; x \approx 6)$, NO, and $C_6(CH_3)_6$. For AsF_6, the As atom is coordinated to six F atoms (three of them are equivalent atoms generated with a crystallographic two-fold rotation axis) to form an octahedron. The maximum deviation from an ideal octahedral angle is 0.9° and the As—F distances are 1.709(6) to 1.724(7) Å. For the disordered AsF_x, the As atom is coordinated to twelve partially occupied F atoms (six of them are equivalent atoms generated by a crystallographic center of symmetry) to form two distorted octahedra (one is As2 with F4, F5, F6, and their equivalents, the other is As2, F7, F8, F9, and their equivalents). The occupancy factors of the six F atoms are 0.59, 0.82, 0.51, 0.23, 0.41, and 0.33, with a sum of 2.89 × 2 = 5.78. The thermal parameters in this, and in the toluene adduct, have an unusual distribution. In particular the B_{iso} value of F5 is very high (9.7 Å^2) but this is probably an artifact of the refinement which has also given the highest occupancy to F5 (0.82). In our experience it is a mistake to attempt to explain such deviations when there is a high degree of disorder. The maximum deviation from an ideal octahedral angle is 6°. The As—F distances are 1.62(2) to 1.76(2) Å. The N—O distance is 1.13(2) Å. The aromatic C—C distances are 1.41(2) to 1.45(2) Å and the aromatic C—C methyl distances are 1.48(2) to 1.53(3) Å. The C—C—C angles are 119(1) to 122(1)°. The distances from the plane of the ring to the N atom and the O atom are 2.07(2) and 2.81(2) Å, respectively.

[5]Complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The molecule $NOSbCl_6$·2toluene contains a mirror plane. The atoms Sb, N, O, Cl1, Cl2, Cl3, and Cl4 are situated on the plane with a toluene ring on either side of it. The shortest contact between the NO group and the aromatic ring is 2.41(3) Å.

For all three of these adducts, because of the structural disorder, it is not possible to unambiguously assign the nitrogen and oxygen atoms as shown. Reversing their relative positions causes an insignificant change in the agreement indices. The present assignment is preferred since it agrees with theoretical calculations (23).

Results and discussion

The typical deep red–brown colour associated with this family of charge transfer complexes is observed when $NOPF_6$ is brought into solution in sulfur dioxide by benzene and methyl-substituted benzenes. The fluorine resonance results of Table 4 show that complex formation has occurred. From the relative intensities of the signals from PF_6^- and the $CFCl_3$ reference it was found that complex formation was incomplete with $NOPF_6$ and benzene but essentially complete with the methyl-substituted benzenes. Proton and carbon resonance shifts and uv maxima are listed in Table 5. There is no reaction between PCl_5 and NOCl. PF_3 reacts with both NOF and NOCl to give POF_3.

The reddish-brown colour associated with this family of charge transfer complexes is observed in the ternary systems NOCl–$AsCl_3$ and mesitylene or hexamethylbenzene. Since the extent of association could not be readily established the systems were not studied further. $NOAsF_6$ and hexamethylbenzene form a stable charge-transfer complex. From the fluorine magnetic resonance results in SO_2 solution, listed in Table 4, there appears to be little effect of complexation upon AsF_6^-. Other spectral parameters for $NOAsF_6$ hexamethylbenzene are listed in Table 5. Pertinent structural features of the solid complex are listed in Tables 2 and 6. The unit cell contains two formula units of which one has the AsF_6^- in a disordered fashion. This is shown in Fig. 1, with the second NO and hexamethylbenzene units deleted for clarity. AsF_3 does not appear to complex with either NOCl nor NOF.

Spectral parameters for many complexes of $NOSbCl_6$ with aromatic compounds are listed in Table 5. The magnetic resonance and uv values are similar to those found for the corresponding compounds of the Group III and IV chlorides and fluorides (2). It was not possible to obtain the extinction

[a]The estimated standard deviations refer to the last digit printed.
[b]B_{iso} is the mean of the principal axes of the thermal ellipsoid.

coefficient for the charge transfer band of the benzene complex since it appears as a shoulder on a more intense, shorter wavelength signal. It was also not possible to isolate a stable solid benzene adduct.

The stoichiometry of the toluene complex in solution is not established. With 2 equiv. of toluene for each $NOSbCl_6$ the proton chemical shifts are approximately intermediate between those for a 1:1 solution and for toluene itself. The extinction coefficient has been calculated on the basis of 1:1 and 2:1 complexes. In the solid, however, both elemental analysis and the crystal structure, which will be discussed in conjunction with those of the hexamethylbenzene adducts, indicate a 2:1 complex.

A solid adduct of 1:1 stoichiometry was isolated with *t*-bu-benzene. From the change in uv absorption with change in concentration an equilibrium constant of 1.2×10^4 was calculated for adduct formation. From the proton magnetic resonance spectrum as a function of concentration the solution stoichiometry was determined to be 1:1 for the *p*-xylene complex. The equilibrium constant for formation of this complex was calculated as 1.0×10^4 from the concentration dependence of the uv absorption.

The hexamethylbenzene adducts of $NOAsF_6$ and $NOSbCl_6$, and the toluene adduct of $NOSbCl_6$, whose crystal structures have been determined, have the parameters listed in Tables 2 and 6. It is immediately apparent that the N—O bond length for $NOSbCl_6$·hexamethylbenzene is much longer than for the other two complexes. It is also much longer than those found for $NOAlCl_4$ at 0.997 Å (25), NO at 1.15 Å (26), and NOCl at 1.14 Å (27). For $NOSbCl_6$·hexamethylbenzene the nitrogen is placed nearly symmetrically at an average separation of only 2.04 Å from the six ring carbons of hexamethylbenzene. The NO moiety is disordered with the oxygen appearing at either of two positions. Three of the $SbCl_6^-$ chlorines are 3.9 Å from an edge of the aromatic ring. There is no obvious regular stacking of units involving the aromatic rings but the closest description of long range order would be planes of aromatic rings alternating with planes of N—O groups with the $SbCl_6^-$ units in the same plane as the aromatic rings, but offset from the NO groups. At 45° to these planes are bands of $SbCl_6^-$ units alternating with bands containing the NO groups and the hexamethylbenzene moieties. The structure is illustrated in Fig. 2.

Packing in the toluene complex is not the same as for hexamethylbenzene because of the different stoichiometry. There are planes of toluene units alternating with planes of $SbCl_6^-$ units and bands of toluene and NO^+ species. The structure is shown in Fig. 3. There is considerable disorder in the orientation of the NO moiety which could not be fitted by reasonable models to improve the refinement of the structure. Therefore the NO bond length and the C—C bond lengths and angles are less precise than determined by the least-squares analysis. There do not appear to be simple planes of the various constituent units in the $NOAsF_6$·hexamathylbenzene complex.

The hexamethylbenzene adducts of $NOAsF_6$, $NOSbCl_6$, and $NOSbF_6$ are exceptional in that their reactivity towards moisture is sufficently slight that they may be manipulated in air without decomposition. The infrared spectrum of $NOSbCl_6$·hexamethylbenzene in a KBr pellet has a strong absorption at 1849 cm^{-1} assigned to the NO stretching mode and no signals at higher frequencies until those assigned to C—H stretching modes at 2920 and 2990 cm^{-1}. This NO absorption is at considerably lower energy than that found for $NOSbCl_6$ at 2189 cm^{-1} and for $NOAlCl_4$ at 2242 cm^{-1} (3), but in the region

of co-ordinated nitrosyl groups. There was no strong ir signal from the NO group in $NOAsF_6$·hexamethylbenzene. The extreme moisture sensitivity of the toluene complex prevented measurement of its conductivity and infrared spectrum.

The conductivity of a crystalline sample of the $NOSbCl_6$·hexamethylbenzene adduct was found to be 4.2×10^{-4} ohm^{-1} cm^{-1} and it had a weak esr signal with $g = 2.008$ (1). A second, purer, sample had conductivity of 2.3×10^{-3} ohm^{-1} cm^{-1} and no esr signal. $NOSbCl_6$ and polystyrene also form a complex which is stable in air. Its conductivity as a pressed pellet was found to be 1.9×10^{-4} ohm^{-1} cm^{-1} and as a film cast from methylene chloride 1.6×10^{-2} ohm^{-1} cm^{-1}. Many other species reacted with $NOSbCl_6$ to initially yield colours similar to those of the already described charge transfer complexes followed rapidly by a further reaction, presumably chlorination. With anthracene as aromatic compound, 9,10-dichloroanthracene was isolated in 70% yield after hydrolysis of the reaction mixture. From *N,N*-dimethylaniline the *para* chloro product was identified by proton resonance spectroscopy.

The chemical shift of the ^{121}Sb resonance was not sensitive to complex formation but the line width decreased from extremely broad for $SbCl_5$ dissolved in SO_2 to 1 280 Hz for $NOSbCl_6$, to 610 Hz for the benzene complex and 370 Hz for the toluene complex.

Although $SOCl_2$ and $SbCl_5$ form a 1:1 complex (10) there is no evidence for a ternary charge-transfer complex with aromatic hydrocarbons. There is rapid chlorination of benzene by $SOCl_2 \cdot SbCl_5$ with gas evolution. A mass spectrum of the product is interpreted as mixture containing up to four chlorine atoms per molecule. The proton and carbon resonance spectra of a solution of $SOCl_2$, $SbCl_5$, and hexamethylbenzene in SO_2 are the same as those for $SbCl_5$ and hexamethylbenzene without $SOCl_2$. Presumably complex formation of $SbCl_5$ with hexamethylbezene is stronger than with $SOCl_2$. Chlorination was also observed with ICl_2SbCl_6.

The crystal structure of the 1:1 complex of $POCl_3$ and $SbCl_5$ has been determined (11). It was verified by ^{31}P resonance spectroscopy that complex formation also occurs in methylene chloride solution. Upon addition of 1 equiv. of hexamethylbenzene the ^{31}P signal of free $POCl_3$ appears as well as the proton and carbon resonance signals of the $SbCl_5$ hexamethylbenzene complex. It is therefore more likely that complex formation between $SbCl_5$ and hexamethylbenzene is higher than that between $SbCl_5$ and $POCl_3$ or a possible ternary complex, as was also observed with $SOCl_2$.

The reaction of NOCl and $SbCl_3$ yields $NOSbCl_6$. The only product isolated from the reaction of NO, $SbCl_3$, and hexamethylbenzene was $NOSbCl_6$—hexamethylbenzene. There was

no evidence from phosphorous resonance spectroscopy for complex formation between $POCl_3$ and $SbCl_3$ in CH_2Cl_2 solution, nor for formation of a ternary complex with hexamethylbenzene. Therefore among the systems studied with antimony chlorides, $NOSbCl_6$ is unique in the formation of charge-transfer complexes with aromatic compounds.

Fluorine resonance results for some antimony—fluorine species and for $NOSbF_6$·hexamethylbenzene are listed in Table 2. SbF_5 co-ordinates strongly with the SO_2 solvent to give axial and equatorial fluorine ligands (28). The chemical shifts and observable fluorine spin coupling in this system are strongly temperature- and concentration-dependant, the present results being for concentrated room temperature solutions. It was not previously possible to measure the antimony–fluorine spin coupling of SbF_6^- from the fluorine resonance spectrum of the ion due to rapid quadrupolar relaxation. An estimate of $J_{^{19}F-^{121}Sb}$ of 1 840 Hz for aqueous $KSbF_6$ was found from the ^{121}Sb spectrum (29). Figure 4 presents the fluorine resonance spectrum of $NOSbF_6$·hexamethylbenzene in SO_2 solution. Both the $^{19}F-^{121}Sb$ and $^{19}F-^{123}Sb$ spin couplings are clearly visible with a ratio of 1.86 which agrees with that of the gyromagnetic ratios (1.85). The spectral pattern is characteristic of coupling to a quadrupolar nucleus with the outer lines narrower and more intense (30). There is a broad impurity peak under the low field part of the pattern.

Ultraviolet and magnetic resonance parameters for the $NOSbF_6$·hexamethylbenzene complex are listed in Table 5, and the infrared and conductivity results are listed in Table 6. The high conductivity of this compound is noteworthy and might possibly lead to interesting applications (31). There appears to be a correlation of long N—O bond length, low N—O stretching frequency and high conductivity for the compounds listed in Table 6. It is possible that the conduction mechanism involves the unusually weakly bonded NO group and the π electrons of the nearby aromatic rings.

The characteristic colour of these charge transfer complexes is also found in the system SbF_5, NOCl, and hexamethylbenzene. The fluorine resonance spectrum shows the characteristic signal of the $NOSbF_6$·hexamethylbenzene species and other unassigned signals. Disproportionation amongst fluorine and chlorine containing antimony species probably occurs to give a mixture of products. The reaction of SbF_3, NOF, and hexamethylbenzene also gives $NOSbF_6$·hexamethylbenzene.

The fluorine-containing nitrosyl salts give stronger complexes than those containing chlorine as was also found for the Groups III and IV elements (2). Thus $NOPF_6$ gives complexes, but $NOPCl_6$ does not exist. $NOAsF_6$ gives a complex stable to dissociation while there is significant dissociation with the complex of $NOAsCl_4$. The conductivity of the $NOSbF_6$·hexamethylbenzene complex is much greater than that for the $NOSbCl_6$ complex suggesting stronger complex formation. The strength of complex formation appears to increase as one goes down the periodic table as with the Group IV elements (2). Thus there are no nitrosyl chloride complexes of phosphorus, partially dissociated ones with arsenic and strong ones with antimony.

The structure of methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester has been determined by X-ray crystallographic analysis. The N—C—C—S(thiol) and C—N—C—C(S) torsional angles are 141(1)° and −69(2)°, respectively. Consequently, the N and thiono (C=S) sulfur atoms are in close contact and the N···S(thiono) distance is 3.078(5) Å. The structure is a perturbed **A** conformer, which we designate **A′**, by analogy to a previously characterised **A** conformer (Huber *et al.*, Biochemistry, **21**, 3109 (1982)). The $\bar{\Phi}$, $\bar{\Psi}$ angles for the Phe residue are −87(2) and 151(2)°, respectively. A Raman spectroscopic study of a single crystal of the LL form and a resonance Raman (RR) spectroscopic study of powdered methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester establish the RR signature of the dithio moiety for the compound in the **A′** form. The RR spectrum of the dithioester in CCl_4 defines the RR signature for the $\mathbf{C_5}$ form in solution, while the RR spectrum from a solution in H_2O/CH_3CN provides information on the signatures of the **A** and **B** conformers. As for the case of *N*-benzoyl-DL-alanine dithioester, the **A** and $\mathbf{C_5}$ signatures of the title compound closely resemble those for glycine-based dithioesters but the key marker bands for the **B** conformer are shifted by ≈30 cm^{-1} to lower frequency compared to those for a glycine dithioester.

K. I. VARUGHESE, R. H. ANGUS, P. R. CAREY, H. LEE, and A. C. STORER. Can. J. Chem. **64**, 1668 (1986).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure du dithioester éthylique de la méthyloxycarbonyl L-phénylalanyl L-alanine. Les angles de torsion N—C—C—S(thiol) et C—N—C—C(S) sont respectivement 141(1) et −69(2)°. En conséquence, les atomes d'azote et de soufre du thione (C=S) sont très près les uns des autres et la distance N···S(thiono) est égale à 3,078(5) Å. La structure est un conformère **A** déformé que l'on a appelé **A′** par analogie avec un conformère **A** caractérisé antérieurement (Huber et collaborateurs, Biochemistry, **21**, 3109 (1982)). Les angles $\bar{\Phi}$ et $\bar{\Psi}$ du groupement Phe sont respectivement −87(2)° et 151(2)°. Une étude par spectroscopie Raman d'un cristal unique de la forme LL et une étude par spectroscopie de résonance Raman (RR) du dithioester éthylique de la méthyloxycarbonyl L-phénylalanyl DL-alanine a permis de déterminer la signature RR de la portion dithio du composé dans sa forme **A′**. Le spectre RR du dithioester en solution dans le CCl_4 définit la signature RR de la form $\mathbf{C_5}$ en solution alors que le spectre RR du même composé en solution dans H_2O/CH_3CN fournit de l'information sur les signatures des conformères **A** et **B**. Comme ce fut le cas avec le dithioester de la *N*-benzoyl DL-alanine, les signatures **A** et $\mathbf{C_5}$ du composé mentionné dans le titre ressemblent beaucoup à celles des dithioesters des dérivés de la glycine; toutefois, par comparaison avec les bandes d'un dithioester de la glycine, les bandes principales du conformère **B** sont déplacés par environ 30 cm^{-1} vers les fréquences plus basses.

[Traduit par la revue]

Introduction

The reaction of amino acid or multipeptide thionoesters, $RC(=O)NHCHR'C(=S)OCH_3$, with a cysteine proteinase such as papain generates a transient dithioacyl-enzyme intermediate $RC(=O)NHCHR'C(=S)S$—papain, where the substrate is linked to the enzyme by the thiol sulfur of cysteine 25 (1, 2). The dithioester moiety has an intense electronic absorption band near 315 nm which provides the opportunity to obtain the resonance Raman (RR) spectrum of the dithioester group and the adjacent bonds (1, 2). By this means it is possible to monitor the vibrational spectrum of the group undergoing transformation in the active site and arrive at a detailed description of conformational events during enzymolysis.

Interpretation of the RR spectra of the enzyme-substrate intermediates has been greatly facilitated by joint Raman and X-ray crystallographic studies on model compounds of the type $RC(=O)NHCHR'C(=S)SC_2H_5$, which have led to a set of precise spectra–structure correlations. It has also been necessary to undertake an analysis of the conformational properties of these dithioesters in solution by Raman, RR, and FTIR spectroscopy (3, 4). Taking the crystallographic and spectroscopic results together, the findings are that in non-hydrogen bonding solvents such as CCl_4, glycine-based dithioesters exist in a major populational state known as $\mathbf{C_5}$ (1) in which the N—H forms a hydrogen bond to the thiono sulfur and the resultant five-membered ring is essentially planar (Fig. 1). There is a minor population of a state known as conformer **B** (1) in CCl_4 and this is the predominant form in H-bonding solvents such as H_2O. The **B**-form is also shown in Fig. 1 and has the N atom *cis* to the thiol sulfur as a consequence of a N···S(thiol) interaction. This form is essentially unique to dithio- and thiol-esters (5) and is of importance for the dithioacyl-enzymes with glycine in the P_1 position (which is the substrate amino acid linked to cysteine 25) since it is the sole conformational state in native $RC(=O)NHCH_2C(=S)S$—papains (6) and other plant cysteine proteinases (7). Returning to the model compounds, there is another conformational state found in hydrogen bonding solvents. This is the **A** form shown in Fig. 1; it is converted to the $\mathbf{C_5}$ conformer by a 90° rotation about the NH—CH_2 bond and the N—H group participates in H-bonding to solvent rather than bonding intramolecularly to the thiono sulfur. Conformers **A**, **B**, and $\mathbf{C_5}$ have separate and characteristic RR spectra which we refer to as RR signatures.

Initial studies on dithioacyl enzymes and their corresponding dithioester model compounds focused on species having glycine next to the dithio group. Since glycine is a rather atypical amino acid and since papain shows marked variations in reactivity with different amino acids in the P_1 position we have begun to extend our analysis to other amino acids. Firstly, we are investigating the conformational and RR spectral properties of dithioesters based on alanine. A recent study (8) demonstrated that

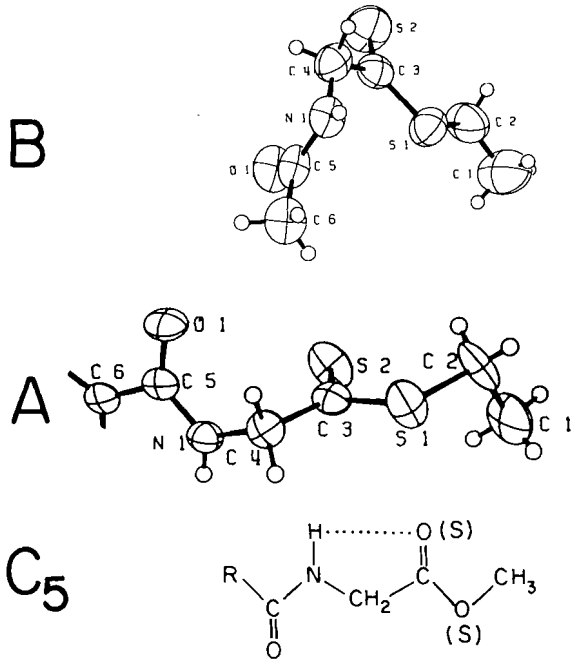

FIG. 1. Conformers **B**, **A**, and $\mathbf{C}_5$. The molecules shown are glycine derivatives; it is believed that alanine-based dithioesters have similar conformational preferences. Structures **A** and **B** are reproduced from ref. 16 with permission.

N-benzoylalanine ethyl dithioester crystallised as a **B**-like conformer and defined the RR signatures of the **B**, **A**, and $\mathbf{C}_5$ conformers for this molecule. The present work extends the analysis of alanine compounds to methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester whose thionoester analog (—C(=S)OCH_3) is a particularly good substrate for papain (unpublished work, this laboratory). The LL form of the dithioester crystallised in a novel, perturbed **A**-like conformational state. It is the first reported structure of a dithioester based on a dipeptide and provides a useful addition to the catalogue of structure – RR spectra correlations.

Experimental

Materials

N-Methyloxycarbonylphenylalanyl-DL-alanine ethyl dithioester was prepared from its nitrile using a procedure previously described (9). The nitrile was produced by first, preparing the α-aminopropionitrile (0.01 equiv.) *in situ* (8), treating the α-aminopropionitrile mixture with *N*-methylmorpholine (0.01 equiv.) and then slowly adding it dropwise through a constant addition funnel into a cooled (−15°C, ice–salt) reaction mixture of methyloxycarbonylphenylalanine (0.01 equiv.), dissolved in CH_2Cl_2, previously treated with *N*-methylmorpholine and isobutyl chloroformate to produce the mixed anhydride of the *N*-protected amino acid (9). The reaction mixture was stirred for 1.5 h at −15°C and then at RT overnight. The water/organic mixture was separated and the water layer extracted twice with CH_2Cl_2. The organic extracts were combined, washed with 5% $NaHCO_3$, H_2O, 1 *N* HCl, H_2O, saturated NaCl solution and then dried over Na_2SO_4. The CH_2Cl_2 was removed and the oily residue was triturated with ether producing a white precipitate which was filtered, washed with ether, and air dried. The yield was 70%.

The purity of the *N*-methyloxycarbonylphenylalanyl-DL-alanine ethyl dithioester was checked by nmr and elemental analysis.

Crystal data

$C_{16}H_{22}N_2O_3S_2$ fw = 354.49

Tetragonal, $I4_1$, a = 15.198(3), c = 16.503(4) Å, ρ_c = 1.2354 g cm^{-3}, λ(CuKα) = 1.54178 Å, μ(CuKα) = 25.7 cm^{-1}. Crystal dimensions 0.1 × 0.2 × 0.5 mm.

Yellow crystals of *N*-methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester were obtained by diffusing *n*-hexane into a solution of the DL compound in ether. The unit cell constants were measured using 23 reflections in the 2θ range 36 to 45°.

The intensity data were measured using Ni-filtered CuKα radiation (λ_1 = 1.5405 Å, λ_2 = 1.5443 Å) with a CAD4 diffractometer to a 2θ limit of 150°, by scanning ω/2θ; Δω = 0.70 + 0.35 tan θ (deg); aperture 4.0 + 0.4 tan θ (mm) and take off angle of 2.5°. The intensities of the reflections were monitored using three standard reflections and there were no systematic changes in the intensities. An empirical φ absorption correction (10) was applied. The intensity data reduction and the application of absorption correction were carried out by a program written by K. I. Varughese and G. Kartha (unpublished work). The ratio of the maximum to minimun transmissions was 1.28. Of the 2031 unique reflections measured 1746 had $F_o \geqq 2\sigma(F)$ and were used in the least-squares refinements. The structure was solved using the computer program MULTAN 80 (11) and refined by the block-diagonal least-squares program. Hydrogens were located with the help of difference electron density maps and stereochemical criteria. None of the hydrogens bonded to C(1) were located, but all the remaining 19 hydrogens were included in the structure factor calculations and refinement. In the refinement, thermal vibrations of hydrogens were treated isotropically while nonhydrogens were treated anisotropically. The *z*-coordinate of the S(1) was held fixed during the refinement. The refinement converged at an R ($\Sigma|\Delta F|/\Sigma|F_o|$) of 0.066. In the refinement weights were assigned from the counting statistics. The final weighted R was 0.075. The atomic scattering factors were taken from the International tables for X-ray crystallography (12). All crystallographic calculations otherwise noted were done with the NRC set of crystallographic programs (13). The final ΔF map was essentially featureless. The maximum peak and minimum trough in it were 0.5 and −0.4 e Å^{-3}, respectively.

Spectral data

The 647.1 nm excited Raman spectrum of methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester was obtained using a Jarrell-Ash 25-400 spectrometer-based system (14); approximately 50 mW of laser power and a spectral slit width of 8 cm^{-1} were used. The 324 nm excited RR spectra of methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester in a powdered form were obtained using a system equipped with a multichannel detector (15). The solid material was used to coat the inside of a spinning quartz nmr tube and examined in the backscattering geometry. RR spectra from the dithioester in solution were obtained from 1–2 mL of solution, stirred by a small magnetic "pip", and contained in a quartz cuvette. The solution samples were examined in the 90° excitation–observation geometry. For the RR spectra, approximately 70 mW of 324 nm Kr^+ laser power was used and the spectral slit width of the spectrograph was set at 12 cm^{-1}.

Results and discussion

The crystal structure of methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester

Crystals were grown from a solution containing both the LD and LL forms but the crystals selected for X-ray crystallographic analysis were solely in the LL form. The positional and thermal parameters of non-hydrogen atoms in methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester are given in Table 1. For the hydrogen atoms these parameters are available as supplementary material.[3] The structure is depicted in Fig. 2.

[3]Tables of observed and calculated structure factors, positional and thermal parameters of hydrogen atoms and anisotropic temperature factors of non-hydrogen atoms may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

C(16)	13358(4)	5248(4)	4992(4)	5.5

*B_{eq} is calculated as $(8\pi^2/3)(U_{11} + U_{22} + U_{33})$. The coordinates are multiplied by 10^5 for sulfur atoms and by 10^4 for the rest.

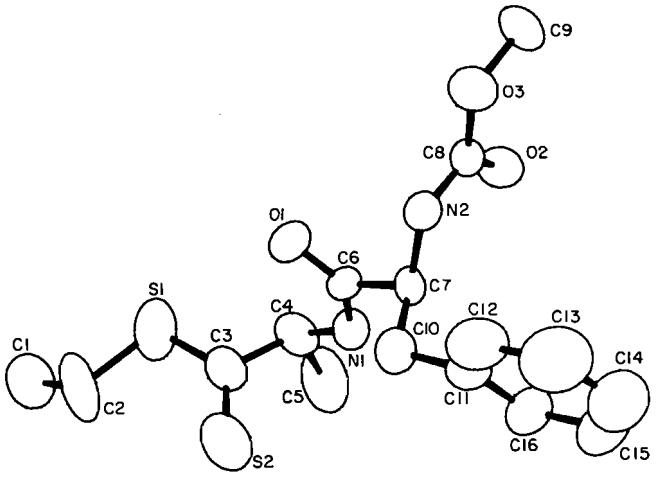

FIG. 2. The thermal elipsoid plot of methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester.

Some relevant torsional angles are given in Table 2 and bond distances and bond angles are given in Fig. 3.

Since the RR spectrum is a sensitive probe of conformation in the —C(=O)NHCH(CH_3)C(=S)SC_2H_5 fragment, emphasis is given to the conformational properties of this part of the molecule. For the nine glycine- and alanine-based dithioesters analysed thus far eight structures have been found to occur as the so-called conformer **B**, in which the C(=O)NHCHRC(=S)SC_2H_5 nitrogen and thiol sulfur atoms are essentially *cis*, i.e. the NHCHR—CS torsional angle is small, between +10 and −20° (Fig. 1). Only one structure, *N*-(*p*-nitrobenzoyl)glycine ethyl dithioester, has been found where the N and thiol S atoms are *trans*, with the $NHCH_2$—CS(thiol) torsional angle equal to −172° (16); this structure we call conformer **A** (Fig. 1). Therefore, the present structure (Fig. 2) makes a valuable addition to our knowledge of *non*-**B** conformers. The key N(1)C(4)—C(3)S(1) torsional angle (designated $\overline{\Psi}'$) is 141.1(14)° (standard deviations refer to the least significant digit) with the C(6)N(1)—C(4)C(3) angle (Φ') being −69.2(22)°. These compare with the corresponding values for the conformer **A** of *N*-(*p*-nitrobenzoyl)glycine of −171.7° ($\overline{\Psi}$) and −86.2° (Φ) and contrast to typical conformer **B** values of ±15° ($\overline{\Psi}'$) and −80° ($\overline{\Phi}'$). Obviously the $\overline{\Phi}'$, $\overline{\Psi}'$, values are more **A**-like than conformer **B**-like and we describe the present compound as an **A**′ conformer.

One interesting observation is that the N···S(thiono) distance is 3.078(5) Å for the present compound compared to 3.043 Å in the crystalline form of *N*-(*p*-nitrobenzoyl)glycine ethyl dithioester. As the absolute values of the $\overline{\Psi}'$ angles differ by 32° a larger difference in N···S distances might be expected. However, in the present PheAla dithioester compared to the *p*-nitrobenzoylglycine structure the N(1)—C(4)—C(3) and C(4)—C(3)—S(2) angles are contracted by 3.6 and 2.3°, respectively. The N···S(thiono) distances are shorter than the sum of the van der Waals radii for N and S (3.35 Å) in both compounds, suggesting that an attractive N···S interaction exists and the contraction of the N(1)—C(4)—C(3) and C(4)—C(3)—S(2) angles in the present PheAla analog gives some support to this idea. Since there is a paucity of data concerning sulfur to nitrogen interactions for C=S groups, compared to sulfur nitrogen interactions involving sulfur in a X—S—Y bonding scheme (17, 18), further structures with C=S···N contacts are needed to develop stereochemical criteria for the interaction and to confirm that it does indeed exist.

For the phenylalanine residue the Ramachandran ($\overline{\Phi}$, $\overline{\Psi}$) values are −87.0(20) and 150.9(16)°, respectively. The χ_1 (N(2)—C(7)—C(10)—C(11)) and χ_2 (C(7)—C(10)—C(11)—C(12)) torsional angles are −68.6(19) and 106.1(21)°, respectively. At the dithioester end of the molecule, the —SC_2H_5 group takes up a fairly extended configuration with C(1)—C(2)—S(1)—C(3) equal to −153.9(18)°, a wide range of values have been determined for this parameter (8) and the values are probably determined by crystal packing forces. The bonds meeting at C(3) and C(6) are planar and there is no evidence for pyramidalisation at either atom. There are two intermolecular hydrogen bonds in the crystal; the parameters for these are given in Table 3.

Resonance Raman signatures of the different conformations of methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester

The 647.1 nm excited Raman spectrum of a single crystal of methyloxycarbonyl-L-phenylalanyl-L-alanine ethyl dithioester is given in Fig. 4. It is not possible to obtain 324 nm excited resonance Raman spectra from a single crystal due to problems associated with photodecomposition. Therefore, RR spectra of the solid form were obtained from powdered material coating the inside of a quartz spinning nmr cell and examined in the back-scattering geometry. Powdered samples from various origins were examined, e.g. from crushed crystals of the LL stereoisomer, or precipitated from a LL, LD mixture in a number of solvents. The RR spectrum shown in Fig. 5 is from a powder containing a 50:50 mixture of the LD and LL forms and the major features are indistinguishable from the RR spectrum of a powder sample of crushed crystals of the LL stereoisomer. There were insufficient quantities of the LL crystals to obtain high quality RR data from the LL form alone. Most of the features in the RR

spectrum can be associated with peaks in the normal Raman spectrum of the single crystal. It appears that the normal Raman features at 1186 and 1162 cm^{-1} (Fig. 4) are both RR-active and that they are unresolved in the RR spectrum to form the broad band seen at 1174 cm^{-1} (Fig. 5). The intense RR peak at 1099 cm^{-1} probably corresponds to the shoulder seen at 1096 cm^{-1} in the normal Raman spectrum (Fig. 4). The weak to medium RR peaks at 1033, 1008, and 902 cm^{-1} can also be seen in the Raman spectrum at or near these frequencies the (1008 cm^{-1} band appears as a shoulder on the intense 1003 cm^{-1} feature). The broad RR feature centered at 667 cm^{-1} cannot be identified in the Raman spectrum due to interference, in the latter, from a laser plasma line. This line could not be removed completely under the experimental conditions employed. The RR peaks near 578 and 561 cm^{-1} probably correspond to the features seen at 577 and 555 cm^{-1} in the Raman spectrum of the single crystal. The intense RR peaks at 1174, 1099, and 667 cm^{-1} were observed in the same position in the poorer quality RR spectrum of the LL form (data not

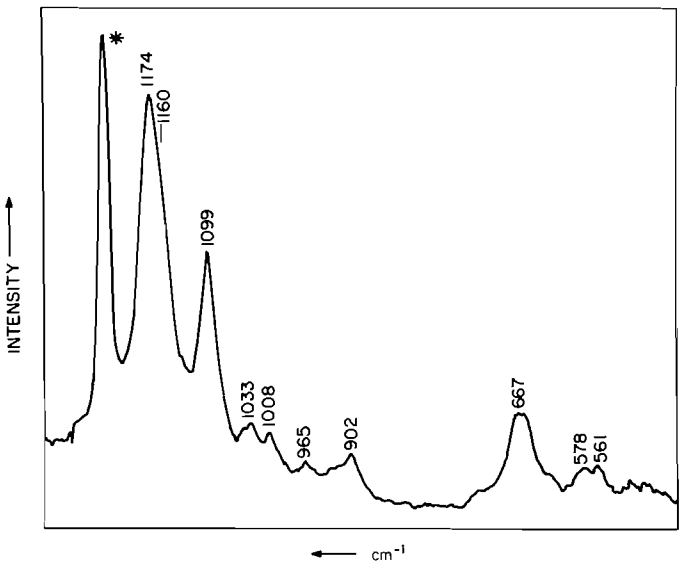

FIG. 5. The 324 nm excited resonance Raman spectrum of powdered methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester. The peak marked with an asterisk is due to a laser plasma line.

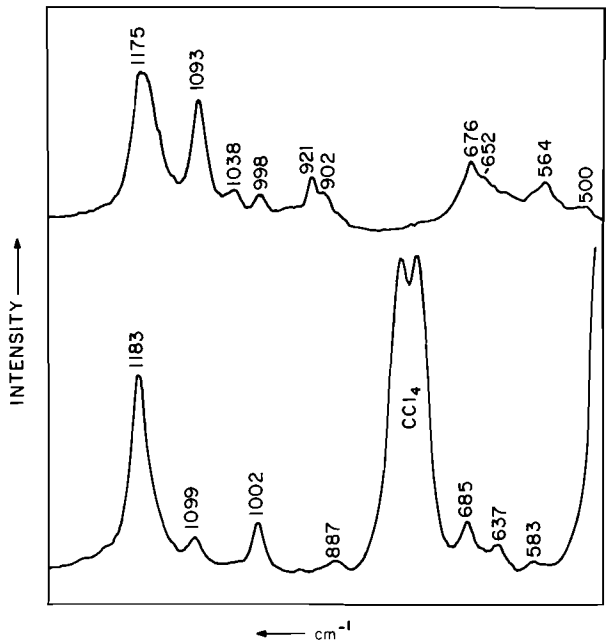

FIG. 6. Resonance Raman spectra (324 nm excitation) of methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester, $\sim 5 \times 10^{-4}$ *M* in H_2O/CH_3CN (19:1) (top) and $\sim 10^{-3}$ *M* in CCl_4 (bottom). In the top spectrum the peak at 921 cm^{-1} is due to CH_3CN; in the bottom spectrum the doublet near 750 cm^{-1} is due to CCl_4.

shown), thus these data establish a partial RR signature of an alanine-based dithioester in an **A′** type conformation which, in turn, constitutes a useful addition to our catalogue of spectra–structure correlations.

Our knowledge of the conformational properties of *N*-acyl glycine dithioesters (3, 4) and *N*-benzoylalanine ethyl dithioester (8) in solution allows us to delineate the structure – RR spectra correlations, for the major RR peaks, for methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester in solution. Figure 6 compares the RR spectra of the PheAla dithioester in H_2O/CH_3CN (19:1 v/v) and CCl_4. The spectra in Fig. 6 are very similar to the RR spectra of *N*-benzoylalanine ethyl dithioester in H_2O/CH_3CN and CCl_4 (Figs. 7 and 8 in ref. 8); thus, the conformational preferences in the $—C(=O)NHCH(CH_3)C(=S)SC_2H_5$ fragment of this molecule and the present PheAla dithioester must be very similar. In H_2O/CH_3CN both molecules assume a mixed population of **A** and **B** type conformers about the dithioester moiety. In the spectrum in H_2O/CH_3CN the **A** conformer makes the major contribution to intensity in the 1175 and 652–676 cm^{-1} regions and, on the basis that it increases in intensity in CCl_4 solution, probably to the peak near 1000 cm^{-1}. Further evidence that the 1000 cm^{-1} band is found for only **A** or $\mathbf{C_5}$ conformers is that it is absent in the RR spectrum of solid *N*-benzoylalanine ethyl dithioester, which is in a **B** conformer, but is present when this compound is dissolved in H_2O or CCl_4 where the **A** and $\mathbf{C_5}$ conformers, respectively, are expected. The RR spectrum of the solid (Fig. 5) also indicates that the **A** conformer contributes part of the intensity of the 1093 cm^{-1} feature seen in Fig. 6 (top). The position of the peaks near 1175 and 660 cm^{-1} are very similar to those found for the **A** conformers of *N*-acylglycine ethyl dithioesters. The main **B** conformer markers occur in the spectrum from H_2O/CH_3CN solution (Fig. 6) at 1093 and 564 cm^{-1}. Unlike the **A** conformer case, the alanine **B** conformer peaks at 1093 and 564 cm^{-1} are shifted to lower frequency by some 30 cm^{-1} compared to the corresponding **B** features in *N*-acyl glycine dithioester.

A further difference between *N*-acylglycine and *N*-acylalanine dithioesters concerns the overlap of **A** and **B** conformer markers in the 1090–1190 cm^{-1} region. For the **A**-like conformers, *N*-acylglycine dithioesters have just a single intense

feature near 1170 cm^{-1} (16), in addition to this feature *N*-acylalanine dithioesters have a medium intensity peak near 1100 cm^{-1} (Fig. 5). For the **B**-like conformers, *N*-acylglycine dithioesters have an intense band near 1135 cm^{-1} and a weak to medium intensity peak near 1165 cm^{-1} (17) whereas in the most thoroughly studied *N*-acylalanine dithioester case, *N*-benzoylalanine ethyl dithioester, the intense 1100 cm^{-1} **B**-marker is accompanied by two medium intensity bands near 1140 and 1169 cm^{-1} (8). Thus, it appears that in the 1090–1190 cm^{-1} region greater care has to be taken to disentangle **A** and **B** markers in the case of the alanine-based dithioesters than in the case of glycine-based dithioesters.

In CCl_4, the predominant conformation of the glycine- and alanine-based dithioesters examined thus far is $\mathbf{C}_5$. From the marked similarity between the RR spectra of these molecules (4, 8) and the present example it is very likely that the alanine—dithioester portion in the majority of molecules of methyloxycarbonyl-L-phenylalanyl-DL-alanine ethyl dithioester in CCl_4 takes up a $\mathbf{C}_5$ conformation. The 1183, 685, and 637 cm^{-1} are characteristic $\mathbf{C}_5$ markers. The peak seen in Fig. 6 at 1002 cm^{-1} is also observed at this position for *N*-benzoylalanine ethyl dithioester in CCl_4 (8), but not for any *N*-acylglycine derivatives (4). Therefore it is likely that this feature is alanine specific. It may be associated with the C_α—CH_3 moiety (8) and appears to increase in relative intensity in the $\mathbf{C}_5$ conformer (Fig. 6). A further point of note is the 1099 cm^{-1} feature in CCl_4, which may contain contributions from the $\mathbf{C}_5$ conformer and from the small amount of the **B**-form present, is much less intense than the corresponding band in the spectrum of the solid. Thus, the 1099 cm^{-1} peak is less intense in the $\mathbf{C}_5$ compared to the corresponding band in the **A** conformer.

ERWIN BUNCEL, T. KRISHNAN VENKATACHALAM, and ULF EDLUND. Can. J. Chem. **64**, 1674 (1986).

A variable temperature ^{7}Li nmr study of equimolar mixtures of two structurally related phenylsilyllithiums supports a bimolecular exchange mechanism between monomeric structures as being responsible for the collapse of the ^{7}Li signals of the two species. The different exchange rates indicated in MTHF and THF parallel the observations from a Si—Li coupling study. The experimental data provide support for a mainly ionic Si—Li bond, although some orbital interaction is indicated.

ERWIN BUNCEL, T. KRISHNAN VENKATACHALAM et ULF EDLUND. Can. J. Chem. **64**, 1674 (1986).

Les résultats d'une étude des spectres rmn du ^{7}Li, effectuée à des températures variables sur des mélanges équimoléculaires de deux phényl silyl lithium reliées par leur structure, sont en accord avec la suggestion qu'un mécanisme d'échange bimoléculaire entre les structures monomères est responsable de la coalescence des signaux ^{7}Li des deux espèces. Les diverses vitesses d'échange dans le MTHF et le THF sont parallèles à celles obtenues lors d'une étude du couplage Si—Li. Les données expérimentales fournissent un support à l'hypothèse d'une liaison Si—Li qui serait principalement ionique, même s'il semble exister quelques interactions entre orbitales.

[Traduit par la revue]

Introduction

The precise nature of bonding in organolithium compounds has been a topic of considerable controversy (1). On the basis of recent *ab initio* calculations it has been argued that the carbon–lithium bond is predominantly ionic, i.e. ca 80% ionic character, and in fact more ionic than the Li—F bond (2). ^{13}C nmr studies of organolithium compounds have been most informative of the carbon–lithium bonding character in solution where the existence of ^{13}C—^{6}Li coupling has been taken as strong evidence of covalent character of the carbon–lithium bond (3).

Less attention has been paid to the bonding situation in organosilyllithium compounds. However, based on the very similar ^{7}Li chemical shifts, it was claimed that the ionicity of the Si—Li bond should be similar to that of the C—Li bond (4). Additionally, in the nmr study of diisopropylphenylsilyllithium, the diastereotopic isopropyl groups remain nonequivalent up to 185°C, indicating a slow inversion on the ^{1}H nmr time-scale (4). The ionic character of the Si—Li bond has recently received support from *ab initio* study, which showed that the Si—Li bond is to some extent stronger than the C—Li bond, and also that the ionic bonding in the $SiH_3^-Li^+$ ion pair is more extensive than in $CH_3^-Li^+$, due to the greater electron affinity of SiH_3 compared to CH_3 (5).

We have found by means of a ^{13}C nmr study of phenylsilyllithium and other phenyl-substituted germyl, stannyl, and plumbyl anions, a strong similarity in the charge distribution of the phenyl rings, indicating that most of the negative charge resides on the metal atom, contrasting with the situation in the corresponding phenylmethyl carbanion systems (6). Moreover, a lithium-nmr study of the phenylsilyllithium species suggested that the Si—Li interaction was equal to or stronger than the association found for Ph_3CLi, in ethereal solvents (7).

Additional support for this suggestion was recently provided by a study (8) of these phenylsilyllithiums using ^{29}Si nmr. The existence of ^{29}Si—$^{6(7)}$Li couplings provided evidence of sufficient Si–Li orbital overlap to allow a mechanism for some charge transfer with spin-polarization necessary for scalar coupling. Moreover, a slight concentration dependence of the coupling in $PhMe_2Si^7Li$ in THF solvent at −80°C, suggested that a bimolecular exchange process could be responsible for the collapse of the coupling (8). However, an alternative explanation would be that ion-pair dissociative processes are responsible for the collapse of the coupling as a result of temperature and medium changes.

We have sought further evidence to distinguish between these possibilities using a methodology which has been established in various organometallic exchange processes (9). If the ^{7}Li resonances for two structurally related species rapidly equilibrating at ambient temperature are significantly different, then one should, by lowering the temperature, be able to see separate ^{7}Li signals. The following experiments have been performed using a Bruker AM-400 multinuclear nmr instrument with LiCl (1 *M*) in D_2O as external standard (Table 1).

(*1*) The two species Ph_3SiLi and $Ph_2MeSiLi$, obtained by lithium metal cleavage of Ph_3Si—$SiMePh_2$ in THF, gave a single resonance of ca. 1 Hz linewidth at room temperature. Successive lowering of the temperature to −90°C resulted in a line broadening up to 18 Hz but no distortion in the Lorentzian line shape could be detected. This observation parallels that in the ^{29}Si nmr study (8) of the two separate compounds in the

		−90	2.33, 2.10	54.0
Ph_3SiLi + $Ph_2MeSiLi$	MTHF	22	2.20	13.0
		−40	2.20	28.0
		−60	2.22	37.0
		−70	2.19	37.0
		−75	2.26, 2.17	41.0
		−80	2.28, 2.17	45.0
		−85	2.30, 2.17	48.0
		−90	2.30, 2.17	51.0

same solvent in which no coupling was revealed even at −100°C.

(*2*) Similar experiments using the pair of silyllithiums Ph_3SiLi and $PhMe_2SiLi$ showed a different kind of behaviour. At ca. −80°C a distorted signal was observed which on further lowering of the temperature to −90°C showed two overlapping peaks with a separation $\Delta\delta = 0.23$. This shift difference is approximately the same as the difference calculated from ^{7}Li nmr data of the separate species ($\Delta\delta = 0.13$) (7). This observation compares with the well resolved multiplet of the ^{29}Si signal observed in THF at −100°C of $PhMe_2SiLi$ found previously (8).

(*3*) The final experiment refers to the pair of species Ph_3SiLi and $Ph_2MeSiLi$ but changing the solvent to 2-methyltetrahydrofuran (MTHF). In this case the non-Lorentzian behaviour is already noted at −70°C and on lowering the temperature to −90°C, two partially resolved peaks of equal intensity are observed (Fig. 1). Again, the chemical shift difference of $\Delta\delta = 0.13$ could be measured, which within experimental accuracy is the same as the value derived for the separate species ($\Delta\delta = 0.10$). In the scalar coupling study (8), both these compounds gave rise to multiplets at −100°C in MTHF solvent.

It is noteworthy that the coupling constant ($^1J[^{29}Si, ^7Li] = 51$ Hz) (7) and the ^{7}Li peak separation (20 Hz) are of reasonably similar magnitude in these cases. This suggests that the coalescence point in the two experiments should be found in a comparable temperature range, provided that the collapse is caused by the same mechanism. This is in agreement with the observations.

One would have expected that a dissociative process would lead to some change in π-polarization of the ^{13}C signals of the phenyl carbons, the ^{29}Si chemical shifts and, most significantly, of the ^{7}Li nmr signals. Such changes were not observed in our earlier studies (6–8) or in the present study. Especially noteworthy is the approximate temperature independence found for the ^{7}Li chemical shifts of all these silyllithium species (Table 1). If a change in ion-pair equilibrium is occurring one would expect a significant upfield shift of several ppm on going to solvent separated species (7, 10). The fact that in the present study the splitting was observed in a narrow temperature

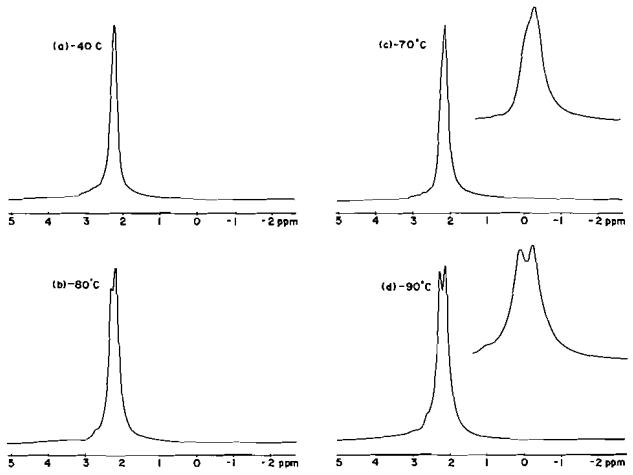

FIG. 1. Variable temperature ^{7}Li nmr spectra of an equimolar mixture of Ph_3SiLi and $Ph_3MeSiLi$ in 2-methyltetrahydrofuran (MTHF).

interval, added to the earlier observations that there is a slight concentration dependence of the ^{29}Si–^{7}Li coupling at a given temperature, provides strong support for a bimolecular exchange process between the monomeric species.

No attempt has been made to evaluate rate constants for exchange due to the possibility of trace amounts of radical anions which could be formed during the lithium metal reduction and which could cause efficient line broadening. This is suggested by the exchange experiments where the line-width reproducibility at ambient temperature is unsatisfactory for a line-shape analysis to be performed. Moreover, anion – radical anion exchange could be a dynamic process on the nmr time scale (11). A further consideration is that line-broadening of the ^{7}Li signal at low temperature could arise from a more efficient quadrupolar relaxation (3*a*, 12), as well as slow exchange. This complication could, however, be avoided if the less quadrupolar ^{6}Li isotope were used (3).

The data presented in this study are thus consistent with a significant, although minor, Si—Li bonding character (orbital interaction) in the organosilyllithium compounds under investigation. Further support for an ionic description is given by the very similar lithium chemical shifts of the phenylsilyllithiums. Thus the lithium chemical shifts do not respond to the significant ^{29}Si chemical shift changes observed along the series Ph_3SiLi ($\delta_{THF}^{^{29}Si} = -9.0$) → $Ph_2MeSiLi$ ($\delta_{THF}^{^{29}Si} = -20.6$) → $PhMe_2SiLi$ ($\delta_{THF}^{^{29}Si} = -27.8$) (13).

The observation of a well-resolved ^{29}Si–^{7}Li coupling at low temperature also supports a mainly ionic description. The ^{29}Si–^{7}Li coupling is expected to be quenched by quadrupolar-induced relaxation if the bond covalency is significantly large, in parallel with the behaviour of propyllithium (14). The silicon–lithium bonding character therefore seems to be closer to that found for lithium acetylides (15). In this context, it is noted that through-space mechanisms have been suggested, for instance to account for the observation of ^{19}F, ^{19}F coupling in certain sterically congested bicyclic structures (16).

To conclude, the present study of the structures of phenylsilyllithiums supports an orbital interaction between the silicon and lithium atoms, although the bonding is believed to be mainly ionic. Moreover, the results are consistent with the observation of Si–Li scalar coupling at low temperature and with conclusions from *ab initio* calculations (5).

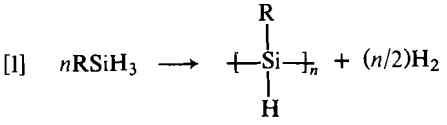
Dimethylzirconocene and dihydridozirconocene both catalyze the dehydrogenative coupling of primary and secondary organosilanes. Primary silanes give linear polysilanes and secondary silanes give tetraorganodisilanes. The reaction of dimethylzirconocene with a small excess of phenylsilane gives the unusual unsymmetrically substituted zirconocenesilylhydride dimer: $Cp_2Zr(SiMePhH)(\mu\text{-}H)_2(PhH_2Si)ZrCp_2$. The structure of this product is deduced from a combination of nmr and crystallographic results. Although the nmr data suggest that dihydridozirconocene reacts with phenylsilane to give the corresponding symmetrical dimer (Me replaced by H) in solution, attempts to isolate this compound have not been successful.

CLAIRE AITKEN, JOHN F. HARROD et EDMOND SAMUEL. Can. J. Chem. **64**, 1677 (1986).

Le diméthylzirconocène et le dihydridozirconocène catalysent tous les deux le couplage déshydrogénant des organosilanes primaires et secondaires. Les silanes primaires conduisent à des polysilanes linéaires; les silanes secondaires donnent des tétraorganodisilanes. La réaction du diméthylzirconocène avec un léger excès de phénylsilane conduit à un produit inhabituel, le dimère substitué d'une façon non symétrique de l'hydrure de zirconocènesilyle, $Cp_2Zr(SiMePhH)(\mu\text{-}H)_2(PhH_2Si)ZrCp_2$. On a déduit la structure de ce produit en se basant sur une combinaison de données rmn et cristallographiques. Même si les données de la rmn suggèrent que, en solution, le dihydrozirconocène réagit avec le phénylsilane pour conduire au dimère symétrique correspondant (le Me est remplacé par un H), on n'a pas réussi à isoler ce composé.

[Traduit par la revue]

We recently reported that dimethyltitanocene and its analogues are effective catalysts for the dehydrogenative coupling of primary organosilanes to organopolysilanes according to reaction [1] (1, 2)

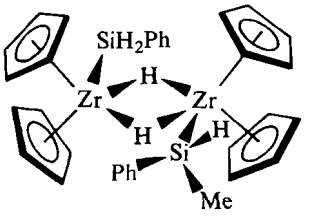


[1] $n\text{RSiH}_3 \longrightarrow \text{-[-Si(R)(H)-]}_n\text{-} + (n/2)\text{H}_2$

We now report that dimethylzirconocene, **1**, is also an effective catalyst for the same reaction. Unlike the analogous titanium compound, **1** also catalyses the coupling of secondary organosilanes to tetraorganodisilanes. The zirconium system has also provided a novel organometallic product which, whilst showing little catalytic activity, probably throws light on the mechanism of the polymerization reaction.

Shortly after the addition of a small amount of **1** (ca. 1 mol%) to phenylsilane, **2**, either neat or in solution in a hydrocarbon solvent, the initially colourless solution turns yellow and then deep orange. Accompanying these color changes there is a vigorous evolution of hydrogen and rapid formation of poly(phenylsilylene) (for details of polymer characterization, see refs. 1, 2). At room temperature a similar reaction with diphenylsilane was extremely sluggish, but at 65°C a smooth coupling to 1,1,2,2-tetraphenyldisilane occurred. Dimethyltitanocene does not effectively catalyze this dimerization reaction, but gives an oligomeric polysilane mixture in small yield.

Reaction of **1** in toluene with a severalfold excess of **2** gave a dark orange solution from which precipitated a yellow crystalline solid, **3**. (*Anal.* calcd. for $C_{33}H_{38}Si_2Zr_2$: C 58.87, H 5.69, Si 8.34; found, C 58.41, H 5.86, Si 8.73). After washing with ether to remove traces of polymer, this solid gave the ^{1}H-nmr spectrum shown in Fig. 1. The spectrum of the product arising from a reaction with an excess of $PhSiD_3$ is also shown in Fig. 1. From these spectra we can draw the following conclusions: the molecule contains (*1*) two slightly inequivalent bridging hydrides coupled to each other (AB quartet at δ −5.09 and −4.96, J_{H-H} = 11 Hz), (*2*) a methyl group of the kind $(CH_3)SiH$ (doublet at δ 0.58, J_{H-H} = 4 Hz, becomes a singlet in the deutero-compound), and a multiplet at δ 4.87 (coupled to the δ 0.58 resonance and absent in the deutero-compound), (*3*) a sharp singlet at δ 4.78, absent in deutero-compound, assigned to $PhSiH_2$, (*4*) four inequivalent η^5-cyclopentadienyl groups (δ 5.28, 5.37, 5.43, and 5.50), (*5*) two phenyl groups (peaks at δ 7.55–7.65 due to *ortho*-protons and complex multiplet at δ 7.20–7.35 due to *meta*- and *para*-protons). A natural abundance ^{29}Si spectrum, obtained using a DEPT (distortionless enhancement by polarization transfer) pulse sequence (3) is shown in Fig. 2. Two Si resonances are observed: a doublet of unresolved multiplets (δ 15.81, J_{Si-H} = 168 Hz) and a triplet of doublets (δ −7.86, J_{Si-H} = 147 and 15 Hz). These results lead to the conclusion that the compound **3** has the following structure:



3

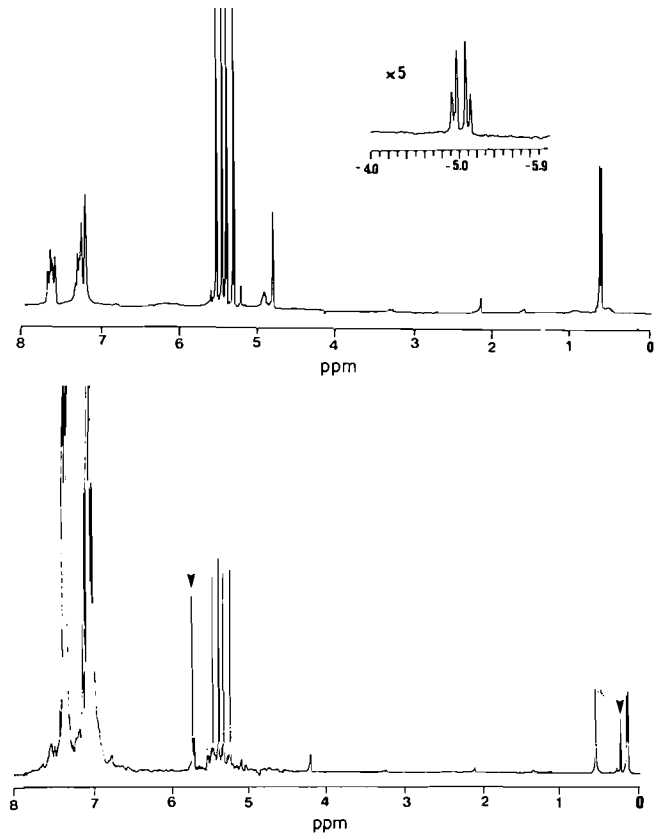


FIG. 1. Upper spectrum: ^{1}H-nmr spectrum of **3** in benzene-d_6. Lower spectrum: the product of an in situ reaction of Cp_2ZrMe_2 with an excess of $PhSiD_3$ in benzene-d_6. The resonance at ca. 0.1 ppm is due to CH_3D liberated in the reaction. Arrows indicate peaks due to an impurity.

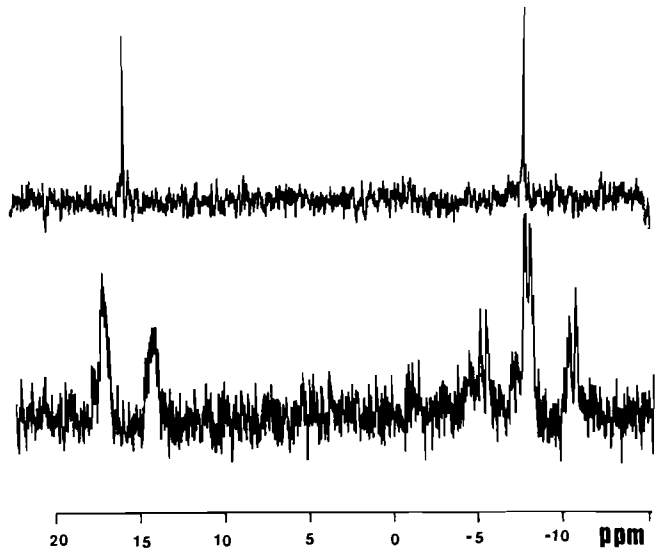

FIG. 2. Natural abundance ^{29}Si-nmr spectrum of **3**. Upper spectrum proton decoupled.

The observation of the high field hydride protons as an AB quartet and of the four inequivalent Cp resonances allows definitive exclusion of the possibility that **3** is a mixture of two different symmetrical silyl complexes. The chemical shifts of the hydride and Cp resonances are in the same region as has been observed for the structurally similar $[Cp_2ZrH_2]_2$ (4, 5), where Cp is either η^5-cyclopentadienyl or η^5-methylcyclopentadienyl. The ^{29}Si resonances are at unusually high field, compared to shifts reported for other transition metal silyls (6). The orange solution resulting from dissolution of $[Cp_2ZrH_2]_2$ in a toluene solution of **2** gives a sharp, single Cp resonance at δ 5.4 and a singlet due to hydride at δ −4.9. We have not been able to isolate this product as a crystalline solid, but it is almost certainly the symmetrical —SiH_2Ph compound.

Complicated disorder problems have so far hindered the refinement of the crystal structure of **3** to a statisfactory confidence level. However, the gross features of the molecule, as concluded from the nmr study, are supported by the X-ray results.[1]

The compound **3** is formally a dimer of (*a*) the product of oxidative addition of $PhSiH_3$ to zirconocene and (*b*) the product of the insertion of a phenylsilylene moiety into the Zr—C bond of a zirconocenemethylhydride species. The sequence of reactions which eventually lead to the formation of this species is clearly very complicated. Even though it is produced almost quantitatively in near-stoichiometric reactions and is the only zirconocene species observable by nmr in catalytic reactions, its low activity as a catalyst for the phenylsilane polymerization reaction indicates that it is possibly aborted from the catalytic cycle. One possible interpretation is that the trapping of a silylene by insertion into a Zr—CH_3 bond, rather than a Zr—Si bond somehow blocks the reaction. It is also possible that the actual catalytic species are not observable by nmr, either due to rapid dynamic rearrangements, or to paramagnetism. Although paramagnetic Zr compounds are relatively rare (7, 8), weak esr signals are observed in the reaction products of **1** with **2**. The strength of these signals is enormously increased by irradiation with uv light. The intense signals consist of a doublet (g = 1.990, $A(^1H)$ = 5.6 G), reminiscent of the paramagnetic hydrides produced by irradiation of zirconocenedihydride dimers (8), and a doublet of triplets (g = 2.0047, $A(^1H_1)$ = 11.2 G, $A(^1H_2)$ = 5.6 G) reminiscent of the mixed valence hydride of titanocene produced by reaction of dimethyltitanocene with silicon hydrides (9).

[1]The crystallographic study is being carried out by the Laboratoire de Diffraction des Rayons-X, Université de Montréal. The crystals studied were monoclinic, a = 8.86, b = 16.34, c = 10.25 Å, β = 90.82°. Space group $P2_1/c$ was deduced from systematic absences ($h0l$, $l \neq 2n$; $0k0$, $k \neq 2n$). The structure solved in this space group consists of pairs of centrosymmetrically related $(\eta^5\text{-}C_5H_5)_2Zr$ units with relative orientation and Zr—Zr separation observed for $[\eta^5\text{-}(C_5H_5)_2ZrH_2]_2$ (4). This suggests that the two units of the dimer are held by a similar pair of bridging hydrides. In the present structure the non-bridging hydrides are replaced by silyl groups. One of the C_5H_5 groups is severely disordered and the electron density for the Si—CH_3 group is more consistent with half occupancy at the two sites of the dimer. However, there is no disordering of the Si atoms corresponding to reflection through the plane perpendicular to the Si—Zr—Zr—Si plane, indicating that the crystal contains a single diastereomer. The present level of refinement (R = 12) does not allow an interpretation of the disorder in terms of superimposed ordered chemical units. Attempts to resolve this difficulty are continuing.

The kinetics of the direct chlorination of cyclopentanone (cp) and cyclohexanone (ch) in carbon tetrachloride, catalyzed by hydrogen chloride, was studied. The rate of chlorination, measured by flow and stopped-flow techniques, is zero order in chlorine; the order in cp and ch increases from 1 at [cp] and [ch] of 0.01 *M* concentration to 2 at concentrations of 1 *M*. This is explained by self-association of the ketones in carbon tetrachloride solutions. The order in hydrogen chloride is 1. Since this compound is one of the products, the reaction is *autocatalytic*. Deuterium isotope effects and the kinetic data strongly point to a mechanism in which the oxygen-protonated *monomeric* ketone is α-carbon deprotonated in a rate-determining step. This step, which is catalyzed by the bases cp or ch, respectively, leads to the corresponding enol as intermediate. The enol is then chlorinated very rapidly. In addition to the chloro ketone, very reactive chloride anions are formed. A small fraction of these anions deprotonate α- or α′-carbon atoms of the oxygen-conjugate acid of the monochloro ketone. The remainder are captured by HCl to form energetically more favored Cl--$(HCl)_n$ complexes with $n = 1, 2$, or 3. This explains why, even at low conversions of the ketones, substantial amounts of the various dichloro isomers are formed in addition to monochloro products. A rate expression is derived, which excellently describes the experimentally obtained rates of chlorination of cp and ch over a range of reaction rates of more than three decades.

EIZE J. STAMHUIS, HENK MAATMAN, HENK STINISSEN et GEERT E. H. JOOSTEN. Can. J. Chem. **64**, 1681 (1986).

Opérant dans le tétrachlorure de carbone, on a étudié la cinétique de la chloration directe, catalysée par le chlorure d'hydrogène, de la cyclopentanone (cp) et de la cyclohexanone (ch). Les vitesses de chloration, mesurées par des techniques de flux et de flux stoppés, sont d'ordre zéro en chlore alors que l'ordre en cp et en ch augmente de 1 (lorsque les concentrations de ces cétones sont égales à 0,01 *M*) à 2 (lorsque ces concentrations sont égales à 1 *M*). On explique cette observation par une auto-association des cétones dans des solutions dans le tétrachlorure de carbone. L'ordre en chlorure d'hydrogène est égal à 1. Puisque le chlorure d'hydrogène est un des produits, on doit classer la réaction comme *autocatalysique*. Les effets isotopiques du deutérium ainsi que les données cinétiques suggèrent fortement un mécanisme impliquant, dans l'étape qui détermine la vitesse, la déprotonation du carbone-α d'une cétone *monomère* protonée par l'oxygène. Cette étape, qui est catalysée respectivement par les bases cp et ch, conduit aux énols correspondants, comme intermédiaires. L'énol est alors chloré très rapidement. Une petite fraction de ces anions déprotone les atomes de carbones-α et -α′ de l'acide conjugé de l'oxygène de la cétone monochlorée. Le reste est capturé par le HCl pour former des complexes Cl--$(HCl)_n$ ($n = 1$, 2 et 3) qui sont plus favorisés du point de vue énergétique. Ceci explique pourquoi, même à des taux de conversions en cétones très faibles, il se forme des quantités substantielles de diverses cétones dichlorées aux côtés des produits monochlorés. On a dérivé une expression pour les vitesses qui décrit d'une façon excellente les vitesses expérimentales de chloration des cétones cp et ch, à des taux de réaction s'étalant sur trois ordres de grandeur.

[Traduit par la revue]

In polar media the acid-catalyzed halogenation of ketones usually proceeds by a rate-determining base-catalyzed α-carbon deprotonation of the oxygen-conjugate acid (1*a*). A reactive enol is produced that rapidly is halogenated in a subsequent step, according to Scheme 1. As far as aqueous and other polar

[1] $$—COCH_2— + HA \leftrightarrows —\overset{+}{C}OHCH_2— + A^-$$

[2] $$—\overset{+}{C}OHCH_2— + B \rightarrow —C(OH)=CH— + HB^+ \text{ (slow)}$$

[3] $$—C(OH)=CH— + Hal_2 \rightarrow —COCHHal + HHal \text{ (fast)}$$

HA : general acid
B : general base
Hal_2 : halogen

SCHEME 1

protic solvents are concerned, the mechanism of the reaction of Scheme 1, as well as the identity of the catalytic species HA and B, are quite well known (1*b*, 2, 3*a*). However, the direct halogenation of ketones under acidic conditions in inert solvents of low dielectric constant appears to be significantly more complicated (3*b*, 4, 5). Although acid–base catalysis is clearly demonstrated (4), the experimental results obtained so far do not permit a general description of the mechanism involved in the reaction (3*b*). Assuming a prototropic isomerization in non-polar aprotic solvents analogous to that in aqueous solutions, it has been suggested that the second proton transfer involves another ketone molecule acting as the basic species. This would result in a higher kinetic order than the first in the substrate (1*c*). Actually such a catalytic action is proposed by Boyer and de Aguirre (6). They studied the indirect bromination of cyclohexanone in benzene by *N*-bromosuccinimide, catalyzed by chloro acetic acids. However, the contribution of the reaction catalyzed by the ketone relative to those of other basic species was small and the mechanism could not be established.

The interpretation of the kinetic results of the direct halogenation of ketones is further complicated by a rather low selectivity of the monohalogenated product, even at deficient amounts of the halogen (7), and further by the partial self-association of the ketone molecules in solvents of low dielectric constant (8) and the *autocatalytic* nature of the reaction by the production of hydrogen halide as acid catalyst. To obtain more insight into the factors that determine the course of this type of reaction, a study is made of the hydrogen chloride catalyzed direct chlorination of cyclopentanone (cp) and cyclohexanone (ch) in carbon

tetrachloride under homogeneous conditions. In this paper we present the results of the kinetic measurements. In order to explain the kinetic data, the selectivity of the chlorination to the various products is also investigated. A kinetic rate equation is derived that quantitatively describes the experimental results, taking into account the partial self-association of the ketone molecules. Combining the kinetic data with the values of the primary kinetic deuterium isotope effects, obtained from the rates of chlorination of ch and of 2,2,6,6-tetradeuteriocyclohexanone (2,2,6,6-ch-d_4) using in each case HCl and DCl as catalysts, makes it possible to determine a mechanism for the reactions involved that is consistent with the experimental results.

Experimental

Materials

Chlorine and hydrogen chloride were obtained from Matheson, purity >99.5 and 99.0%, respectively. Carbon tetrachloride: Merck, Pro Analyse, purity >99.8%. The ch and cp (Merck, Zur Synthese, purity 99%) were distilled at reduced pressure (3.4 and 2.7 kPa, respectively). Fractions between 357 and 358 K for ch and 303 and 304 K for cp were collected for use. It is necessary to maintain a reduced pressure during the distillation of the ketones to prevent thermal dimerization and subsequent formation of the corresponding hydroxyketones. These compounds would interfere in the experiments since they are much more reactive towards chlorine than the starting ketones themselves. Distillation at atmospheric pressure is not recommended because it leads very easily to the formation of hydroxyketones, in concentrations of more than 500 ppm, during the time that the condensed liquid film cools down.

2,2,6,6-ch-d_4 was synthesized from ch and D_2O with DCl and D_3PO_4 as catalysts (9); bp 338 K at 4.1 kPa. The ir spectrum was identical with that given by the Aldrich ir catalog (10). The degree of deuteration was 96% as determined by mass spectroscopy. DCl was generated by the action of D_2O on benzoyl chloride at 373 K (11) and dissolved in carbon tetrachloride. Entrainment of benzoyl chloride did not occur, as was shown by ^{1}H nmr and glc. 2-Chlorocyclohexanone (2-mcch) and 2-chlorocyclopentanone (2-mccp) were obtained from Aldrich (purity >98%) and distilled at 1.3 kPa and 1.6 kPa, respectively. Fractions between 355 and 357 K and 346 and 348 K, respectively, were collected for use.

Analytical techniques

Gas–liquid chromatographic (glc) analyses were performed on a Perkin–Elmer 900 gas–liquid chromatograph, provided with a TCD and an FID detector. For hplc analysis a DuPont model 820 was used, equipped with a Kipp automatic injection system and a Tracor 970 A adjustable wavelength scanning uv detector. The glc and hplc instruments were connected with a Spectra Physics Autolab IV system for peak integration. The uv spectra were recorded on a Zeiss PMQII spectrophotometer and ir spectra were measured on a Perkin–Elmer 457. Mass and ^{1}H nmr spectra were recorded on an AEI-MS9 and a JEOL-C-60 AL, respectively (Department of Organic Chemistry). The chlorinated products, present in the reaction mixtures, were separated by hplc. Detection was performed by uv at 310 nm and 290 nm for the chlorinated cyclopentanones and cyclohexanones, respectively. Identification of the dichloro compounds was carried out by ir, mass spectrometry, and ^{1}H nmr after separation by glc and trapping of the pure compounds. The spectra were in accordance with published data (12, 13).

Titration of chlorine and hydrogen chloride

Samples of carbon tetrachloride, containing Cl_2 and HCl, were analysed for Cl_2 by adding them to an aqueous solution of 0.1 *N* KI. The heterogeneous mixture was stirred vigorously and titrated with 0.1 or 0.01 *N* aqueous thiosulphate. Starch was used as end point indicator. The mixture was then analysed for HCl by titration with 0.1 or 0.01 *N* aqueous sodium hydroxide, using Methyl Red as indicator. The latter titration did not interfere with that for Cl_2, as was thoroughly checked.

Kinetics and instrumentation

The kinetics of the chlorination of ch and cp was measured by a continuous flow technique and by a stopped-flow method (apparatus from Aminco Morrow). In both cases a dilute solution of the ketone in carbon tetrachloride and a dilute solution of chlorine and hydrogen chloride in carbon tetrachloride were rapidly mixed. The flow rate used in the continuous flow technique was always sufficiently high to ensure turbulent flow. The residence time distribution in the reactor was calculated to be negligible (14). The reactor volume, measured from the mixing chamber (a T-joint) to the middle of the transmission cell, was varied between 0.3×10^{-6} and 0.4×10^{-6} m^3. The internal diameter of the reaction tube was 1.5×10^{-3} m. Flow rates used were 3.2×10^{-6} to 1.2×10^{-5} m^3 s^{-1}. Therefore plug flow was assumed. Resulting reaction times ranged from 100 to 500 ms. The conversion of chlorine was determined by measuring the extinction of chlorine at $\lambda = 345$ nm (ε_{Cl_2}: 8200 m^3 kmol^{-1} m^{-1}). A crucial point in both techniques is to realize a very small ratio between the mixing time (t_m) of the two solutions and the reaction or residence time (τ). In our experiments t_m/τ was always smaller than 0.01. The mixing time is thus negligible. Reaction samples were taken and analysed for chlorinated ketones as described in the materials section. The conversion of the ketones was always less than 10%, in most cases even less than 5% to prevent autocatalytic effects. The reaction rates measured by the continuous flow technique and those by the stopped-flow method agreed within the experimental reproducibility. The self- or auto-association of ch and cp in carbon tetrachloride was determined by freezing point depression measurements (15). The apparent molecular mass, $\bar{M}_w$, can be related to the value of the fraction, α, of the ketone existing as monomer by

$$[4] \qquad \bar{M}_w = 2M_w/(1 + \alpha)$$

From α the association constant, K_A, was calculated by

$$[5] \qquad K_A = \frac{[\text{dimer ketone}]}{[\text{monomer ketone}]^2} = \frac{(1 - \alpha)}{2\alpha^2[X]_0}$$

$[X]_0$ being the total ketone concentration. It is assumed that the ratio of the concentrations of trimer ketone and dimers is negligible. (In Appendix I an equation is derived for the calculation of α).

Results and discussion

Reaction products

The direct acid-catalyzed chlorination of ketones does not usually proceed with high selectivity to the monochloro compounds (2). It may be expected that the formation of mono- and di-chlorinated compounds takes place consecutively and that the amount of higher chlorinated products only becomes substantial at appreciable fractional conversions of the ketone. However, as has been proven in the chlorination of 4-*tert*-butylcyclohexanone in carbon tetrachloride at 274–278 K, the monochloro ketone is not necessarily the precursor of the *cis*,*trans*-2,6-dichloro-4-*tert*-butylcyclohexanone (7). If a comparable reaction takes place, e.g. the chlorination of unsubstituted alicyclic ketones, the presence of dichlorinated products may be expected, even at low fractional conversions of the ketones. As a consequence, a correct interpretation of the kinetic results is only possible in connection with a known product distribution. Therefore, the selectivity to the distinct chlorinated ketones was studied at various concentrations of chlorine, hydrogen chloride, and ketone.

The selectivity $S(Y)$ of the chlorinated ketone, Y, is defined as

$$[6] \qquad S(Y) = \frac{[Y]}{[\text{mccp}] + [g\text{-2,2-dccp}] + [c\text{-2,5-dccp}] + [t\text{-2,5-dccp}]}$$

where Y: relevant chlorinated ketone; mccp: 2-chlorocyclopen-

tanone; *g*-2,2-dccp: *gem*-2,2-dichlorocyclopentanone; *c*-2,5-dccp: *cis*-2,5-dichlorocyclopentanone; and *t*-2,5-dccp: *trans*-2,5-dichlorocyclopentanone.

A similar expression holds for the selectivity of the chlorinated cyclohexanones. The selectivities of the different chlorinated products, obtained at conversions (η_x) of the ketone (X) up to 18%, are summarized in Tables 1–3.

Even at fractional conversions of cp that are lower than 3%, S(2-mccp) was found to be at most 86%. At higher ketone conversions S(2-mccp) decreases. Although the dichlorination does lead mainly to approximately equal amounts of *cis*- and *trans*-2,5-dichlorocyclopentanone, slight but not negligible amounts of the *gem*-2,2-dccp isomer are formed (Table 1). The product distribution obtained in the chlorination of ch in a conversion range of 1.8–19% is summarized in Tables 4 and 5.

The data of these tables show a maximum selectivity of 2-chlorocyclohexanone (2-mcch) of 81%. Although *gem*-2,2-dichlorocyclohexanone and *cis*-2,6-dcch could be detected, the concentrations were in most cases too low for a quantitative analysis. As might be expected, the product distribution did not vary when a time lag (up to a few days) was introduced between moment of reaction and analysis (5).

Kinetics

During the chlorination of ch and cp a linear decrease of the concentration of chlorine with increasing reaction time was observed up to conversions of chlorine of more than 90%, indicating a zero-order dependence on chlorine. The influence of the concentration of hydrogen chloride on the rate of chlorination of ketones was measured at several hydrogen chloride concentrations ranging from 10^{-2} to $10^{-1}\ M$. To prevent autocatalysis by hydrogen chloride, care was taken to avoid a substantial increase in its concentration during an experiment. In most cases the ratio of the concentrations of ketone and chlorine had a value of at least 20. Nevertheless, in the evaluation of the reaction order of hydrogen chloride a logarithmic mean value of initial and final concentration of this compound was used.

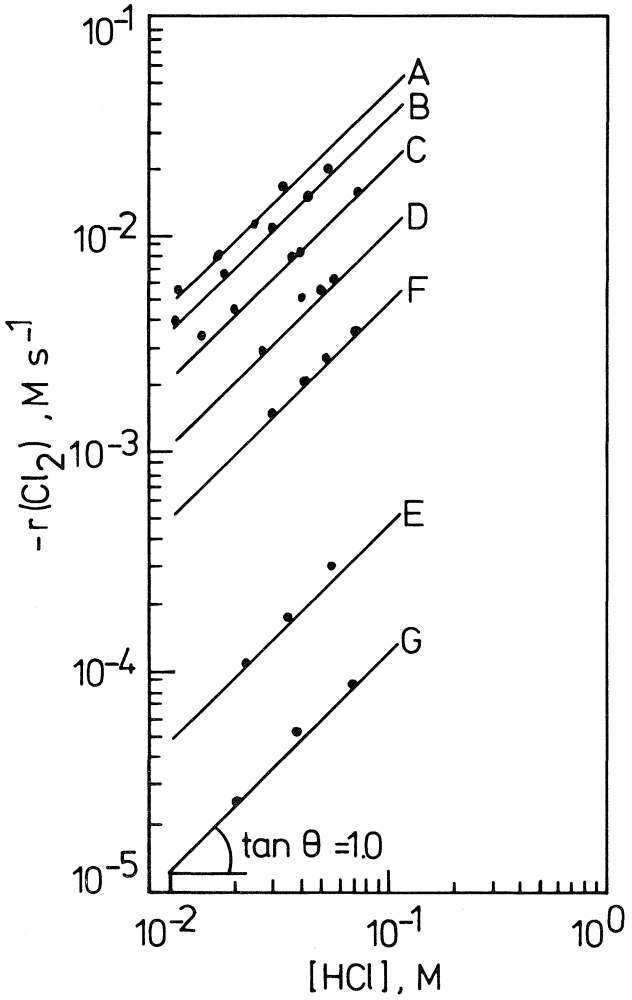

FIG. 1. The influence of the concentration of hydrogen chloride on the rate of chlorination of cp at 298 K. Ketone concentrations (in M): A: 2.00; B: 1.50; C: 1.00; D: 0.50; E: 0.25; F: 0.064; G: 0.032.

in hydrogen chloride (Fig. 2). From the experimental data for the determination of the order in hydrogen chloride at various ketone concentration levels, the dependence of the rate of reaction on the ketone concentration was calculated. This dependence is shown in Figs. 3 and 4. At low concentrations the reaction order is nearly 2 and at high concentrations it approximates 1.

So far, the zero order in chlorine points to a mechanism that is in part analogous to that of the chlorination in aqueous solutions. This is supported by the observation that the zero order in chlorine changes to first order at very low ($<2 \times 10^{-4}\ M$) concentrations of chlorine. It is therefore reasonable to assume that the chlorination step (at concentrations $>2 \times 10^{-4}\ M$) is a relatively very rapid process, but that another reaction earlier in the sequence is rate determining. However, the kinetic data presented so far are not sufficient to establish which reaction is rate determining.

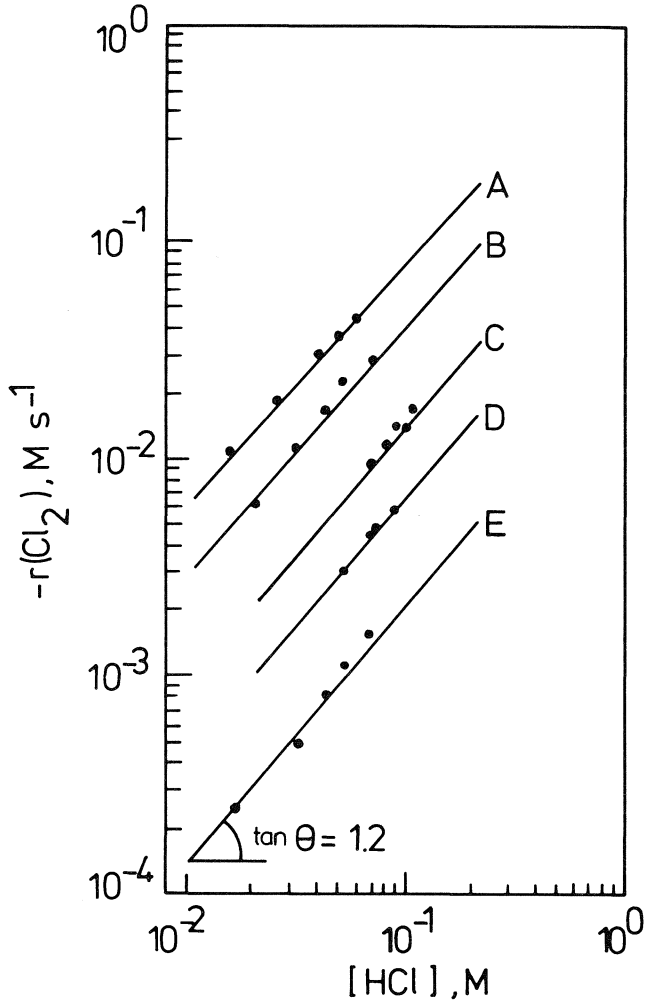

FIG. 2. The influence of the concentration of hydrogen chloride on the rate of chlorination of ch at 294 K. Ketone concentrations (in M): A: 1.00; B: 0.50; C: 0.24; D: 0.100; E: 0.050.

The self-association of cp and ch

The dependence of the reaction order of the ketone on the ketone concentration may be explained by self-association of the ketone molecules in carbon tetrachloride. Evidence for this self-association was obtained from measurements of the freezing point depression of ketone solutions in CCl_4. The apparent molecular weight of the ketones thus determined was always much larger than that of the monomers. More accurate values of the association constants $K_{A,cp}$ and $K_{A,ch}$ than those determined from freezing point measurements are obtained by fitting a derived expression for the reaction rates, given below, with the experimental reaction rates, since for both compounds a large number of reaction rates, determined over a wide range of ketone and hydrogen chloride concentrations, are available. This results in $K_{A,cp} = 3\ M^{-1}$ at 298 K and $K_{A,ch} = 4\ M^{-1}$ at 294 K. The self-association of cp and ch in carbon tetrachloride may be ascribed to a dipole–dipole interaction of the carbonyl group.

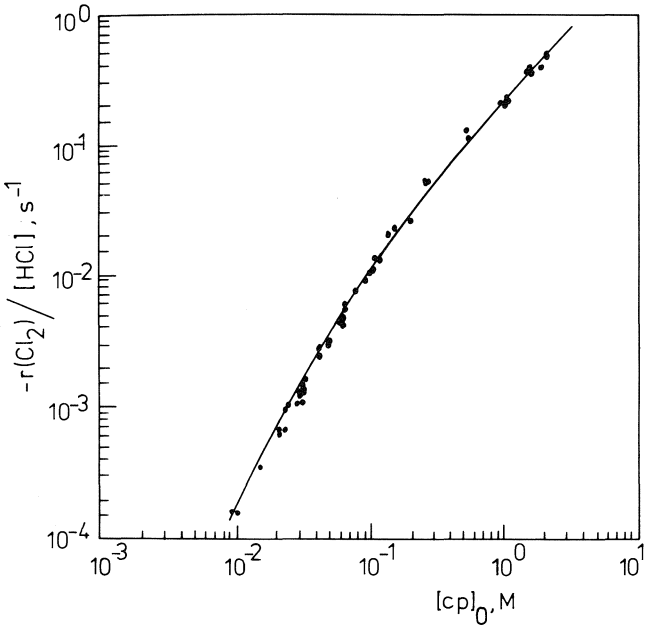

FIG. 3. The influence of $[cp]_0$ on the rate of chlorination at 298 K. Experimental values (●); the smooth curve is calculated with eq. [18] and the constants from Table 8.

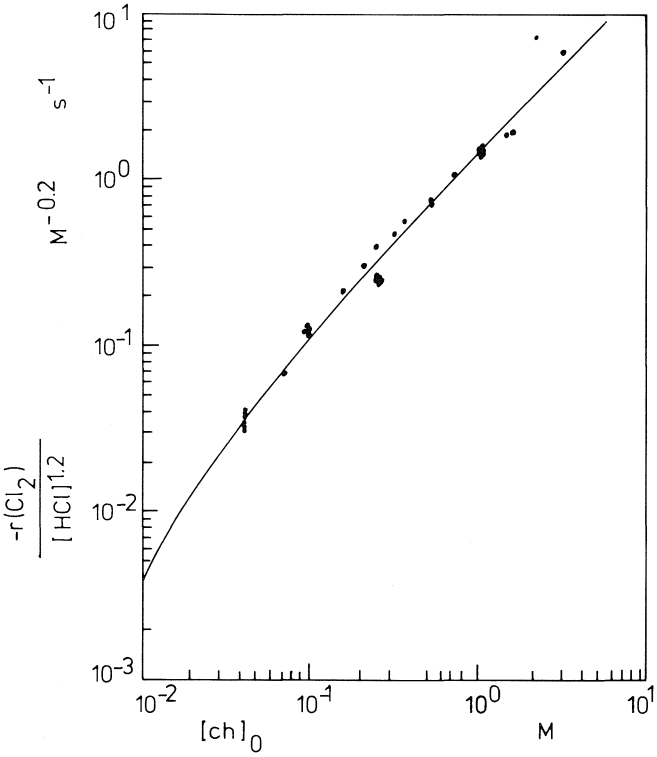

FIG. 4. The influence of [ch] on the rate of chlorination at 294 K. Experimental (●); the smooth curve is calculated with eq. [18] and the constants from Table 8.

Kinetic isotope effects of the chlorination of cyclohexanone in carbon tetrachloride

The kinetic results, given so far, are not sufficient to obtain a reliable mechanism for the hydrogen chloride catalyzed chlorination of cp and ch in carbon tetrachloride. Therefore the primary deuterium isotope effects were determined. Rates of chlorination of ch and of 2,2,6,6-ch-d_4 (cd) were measured,

TABLE 6. Rate constants of the chlorination of cyclohexanone (ch) and 2,2,6,6-cyclohexanone-d_4 (cd), catalyzed by HCl and DCl. [HCl] = 0.05–0.08 M, [DCl] = 0.05–0.07 M, $[Cl_2]_0 <$ 0.010 M, T = 294 K; [ch] and [cd] in M. For [ch] and [cd] = 0.1, k in $M^{-1.9}$ s^{-1}; for [ch] and [cd] = 0.5, k = $M^{-1.2}$ s^{-1}

0.5	1.9	3.7	0.52	0.78

using in both cases HCl as well as DCl as catalyst. Scheme 2 shows the combinations and the corresponding reaction rate constants.

[7] $\text{ch} + Cl_2 \xrightarrow[k_{ch, HCl}]{HCl} \text{products}$

[8] $\text{ch} + Cl_2 \xrightarrow[k_{ch, DCl}]{DCl} \text{products}$

[9] $\text{cd} + Cl_2 \xrightarrow[k_{cd, HCl}]{HCl} \text{products}$

[10] $\text{cd} + Cl_2 \xrightarrow[k_{cd, DCl}]{DCl} \text{products}$

SCHEME 2

On account of the varying order in ch, the experiments were carried out at two ketone concentrations, one in the region of reaction order approaching two and one in the first-order region. The reaction rate constants $k_{x,z}$ (x = ch, cd; z = HCl, DCl) were calculated from the kinetic expression:

[11] $$-r(Cl_2) = k_{x,z}[x]^n[z]^p$$

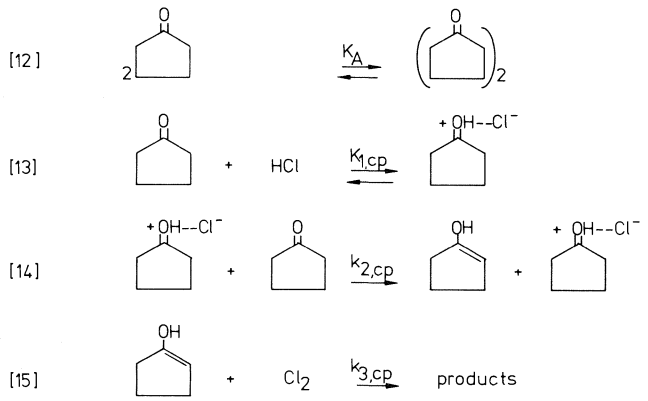
where $-r(Cl_2)$: rate of production of chlorine, M s^{-1}, with the following ketone or deuterated ketone concentrations and reaction orders

$$[x] = 0.1\ M \quad n = 1.7 \quad p = 1.2$$

$$[x] = 0.5\ M \quad n = 1.0 \quad p = 1.2$$

The values of the rate constants are summarized in Table 6. The primary (catalyst) kinetic isotope effects, $k_{ch, HCl}/k_{ch, DCl}$ and $k_{cd, HCl}/k_{cd, DCl}$, derived from Table 6, are approximately 0.5 and 0.6, respectively.

The primary (substrate) kinetic isotope effects $k_{ch, HCl}/k_{cd, HCl}$ and $k_{ch, DCl}/k_{cd, DCl}$ range between 3.7 and 7.0. Combination of the two sets of primary isotope effects strongly points to a base-catalyzed rate-determining proton abstraction from the α-carbon atom of the carbonyl-oxygen protonated ketone molecule, leading to the corresponding enol. The enol is subsequently chlorinated rapidly as long as enough chlorine is present, thus explaining the observed zero order in chlorine. The values of the primary kinetic isotope effects derived from Table 6 for the proton abstraction from the α-carbon atom at low and at high ketone concentrations are, though not equal, of the same order of magnitude. This leads to the conclusion that at both concentrations the rate-determining step is the same. All the experimental data presented so far strongly point to a mechanism that is in part analogous to that of the acid-catalyzed chlorination of ketones in aqueous solution. However, the mechanism is more complicated, as indicated by the varying order in ketone. This varying order in ketone may be explained



SCHEME 3

by assuming self-association of the ketones in the apolar solvent carbon tetrachloride.

The first step in the chlorination is the protonation of the carbonyl group by hydrogen chloride. In principle the monomer as well as the dimer can be protonated, but as the base strength of the carbonyl groups of the dimer may be expected to be lower by the dipole–dipole interaction, it is reasonable to assume that the monomer will be protonated preferentially and therefore be the reactive species in the chlorination.

The acid-catalyzed halogenation and enolization of ketones does not only show acid catalysis, but proceeds by a combined acid–base catalyzed step. In aqueous solution the base can be water or the basic component of the buffer system. In apolar aprotic media it is not immediately clear which species, present in the solution, acts as base. In the next section, evidence will be given that the ketone molecule itself acts as basic catalyst.

Proposed reaction scheme

A proposed reaction mechanism for the hydrogen chloride catalyzed chlorination of cp in carbon tetrachloride is presented in Scheme 3. An analogous scheme applies to the chlorination of ch. In step [14] the monomeric ketone acts as base.

From Scheme 3 a kinetic expression for the rate of reaction of chlorine can be derived.

$$[16] \quad -r(\mathrm{Cl_2}) = \frac{[2 - S(\mathrm{Y})]}{S(\mathrm{Y})} K_1 k_2 [\mathrm{cp}]^2 [\mathrm{HCl}]$$

In eq. [16] [cp] is unknown due to the dimerization. An expression for [cp] in terms of the total ketone concentration $[\mathrm{cp}]_0$ and the equilibrium constant K_A of the self-association can be derived, see Appendix I. This leads to

$$[17] \quad [\mathrm{cp}] = \frac{-1 + \sqrt{(1 + 8K_A[\mathrm{cp}]_0)}}{4K_A}$$

Substitution of eq. [17] in eq. [16] results in:

$$[18] \quad -r(\mathrm{Cl_2}) = \frac{[2 - S(\mathrm{Y})]}{S(\mathrm{Y})} K_1 k_2 \frac{\{-1 + \sqrt{(1 + 8K_A[\mathrm{cp}]_0)}\}^2}{16K_A^2} [\mathrm{HCl}]$$

It is clear that this rate expression shows the desired varying order in ketone. When

$$[19] \quad K_A[\mathrm{cp}]_0 \ll 1, \quad -r(\mathrm{Cl_2}) \sim [\mathrm{cp}]_0^2[\mathrm{HCl}]$$

$$[20] \quad K_A[\mathrm{cp}]_0 \gg 1, \quad -r(\mathrm{Cl_2}) \sim [\mathrm{cp}]_0[\mathrm{HCl}]$$

Intermediate values of $K_A[\mathrm{cp}]_0$ give reaction orders in ketone between 1 and 2. Fitting the derived expression to the experimental reaction rates yields the equilibrium constant of the association K_A and the concentration independent factor K_1k_2 in eq. [18]. The value of K_1k_2 can be interpreted as the overall reaction rate under conditions of $\alpha \rightarrow 1$ (see Appendix I).

TABLE 7. Equilibrium constants of the self-association of cp and ch, and the overall reaction rate constants at low ketone concentrations, derived from the chlorination experiments

Ketone	Temperature (K)	K_A (M^{-1})	K_1k_2 $M^{-(p+1)}\,s^{-1}$
cp*	298	3	1.6
ch*	294	4	15.5

*Order in hydrogen chloride is p. For cp, p = 1.04; for ch, p = 1.2.

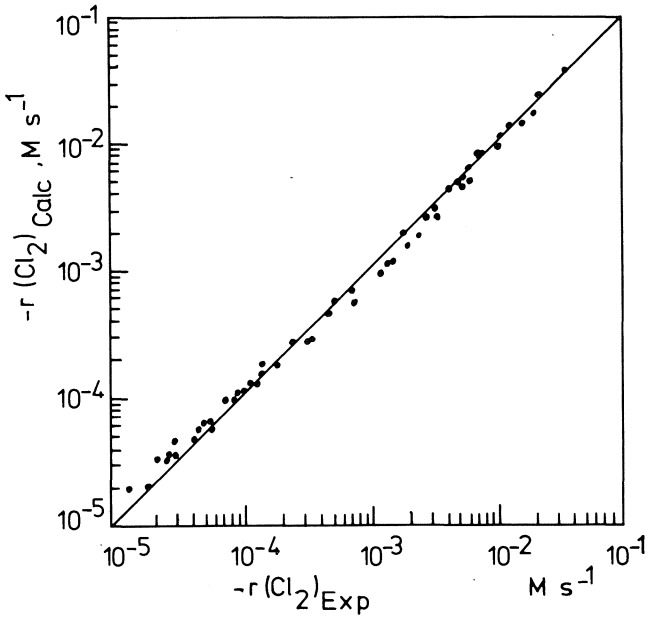


FIG. 5. Comparison between calculated (eq. [18], S (2-mccp) = 86%, constants from Table 8) and experimental rates of chlorination of cp. T = 298 K.

Analogous equations as derived for cp also apply to ch. Table 7 summarizes the values of K_A and K_1k_2 for cp and ch.

In Figs. 5 and 6 a comparison between the experimental reaction rates and those calculated on the basis of Scheme 3 and eq. [18] is presented. The experimental and calculated data agree excellently for both ketones over a range of reaction rates of more than *three* decades. This lends credit to the concept of a partial association of the polar ketone molecules in carbon tetrachloride and also strongly indicates that the proposed mechanism as shown by the reactions of Scheme 3 is correct.

The deprotonation of the α-carbon is rate determining and is catalyzed by the ketone molecule, acting as base. The proposed mechanism explains also that the experimental order in the ketone is 2 in the concentration range of the ketone where the self-association plays a minor role, i.e. for [cp] and [ch] < 0.1 M. More evidence on this point will be given in a following paper on the chlorination of the 2-chlorocycloketones.

As far as the rate-determining base-catalyzed deprotonation is concerned, as represented by eq. [14], the only other basic species present as potential catalyst, besides the ketone mole-

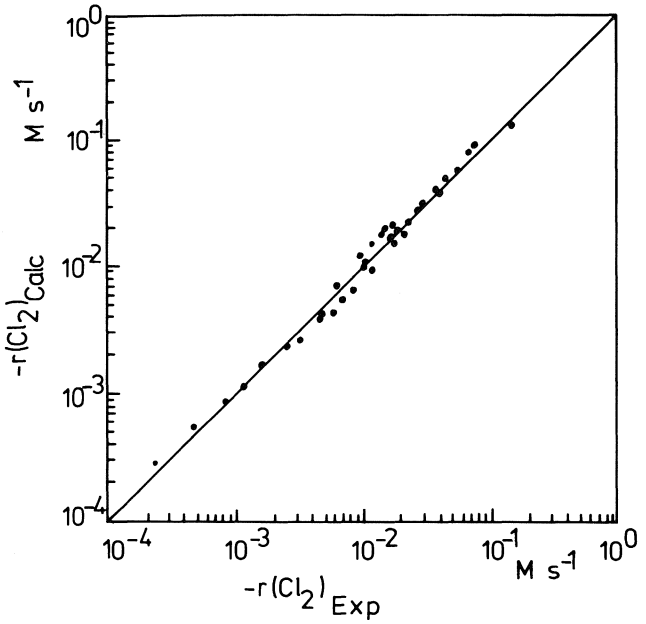

FIG. 6. Comparison between calculated (eq. [18], S (2-mcch) = 81%, constants from Table 8) and experimental rates of chlorination of ch. T = 294 K.

cule, would be the chloride anion. However, it is very unlikely that its concentration will be of any significance in this apolar medium. The maximal concentration would be in the order of that of the protonated ketone, which is very small. Besides, free Cl^- ions will be captured by HCl. Quantum mechanical calculations show a gain in energy of 129.3 kJ mol^{-1} by the formation of a homoconjugated complex $Cl^-...HCl$, a further gain of 79 kJ mol^{-1} for complexation with a second HCl molecule (linear configuration), and another 67.5 kJ mol^{-1} when a third HCl molecule enters the complex (equilateral configuration with Cl^- in the center).[6]

Though in these calculations no allowance was made for entropy and solvent effects, a rapid complexation of the free chloride anions by HCl molecules in this inert medium seems very likely. It may be expected that the basic properties of the $Cl^-...(HCl)_n$ complexes will be less than that of the free chloride anion. A significant contribution of chloride anion catalysis to the rate-determining step of eq. [14] may therefore be rejected. As mentioned above, the selectivity, S(Y), of the 2-chloro ketones never exceeds 86% and even at very low fractional conversions of the ketone a mixture of the three isomeric dichloro ketones is formed. The rate of chlorination of the 2-chloro ketones is much smaller than that of the unsubstituted compounds (16). Therefore a normal consecutive chlorination of the monochloro ketone can be excluded. A possible explanation may be that some of the incipient chloride anions formed in the chlorination of the enolic double bond will, before being captured by an HCl molecule to form a $Cl^-...(HCl)_n$ complex, attack an α- or α′-carbon hydrogen, leading to an enol as precursor of a dichloro compound. This process will in principle not stop after the introduction of two chlorine atoms and indeed 2,2,5-trichlorocyclopentanone is detected (Table 1). The observation that, besides *cis*- and *trans*-2,5-dccp, *gem*-2,2-dccp is also formed and that the presence of small amounts of *gem*-2,2-dcch could be detected cannot be explained by the mechanism proposed by Teo and Warnhoff (7). They studied the direct chlorination of 4-*tert*-butylcyclohexanone. Besides the *cis*- and *trans*-2-chloro ketones, *cis,trans*-2,6-dichloro-4-*tert*-butylcyclohexanone was also formed. The authors concluded that the latter compound was the result of a concerted dichlorination of the starting ketone. Such a mechanism excludes the formation of a *gem*-2,2-dichloro ketone. However, from Tables 1 and 2 it is clear that *gem*-2,2-dccp is actually formed and at a rate much larger than experimentally obtained in the chlorination of 2-mccp, even when the latter reaction is catalyzed (eq. [14]) by the stronger base cp instead of 2-mccp, as will be shown in the following paper in this series. We therefore believe that in the chlorination of cp and ch a rapid consecutive reaction catalyzed by the chloride anion, rather than a concerted mechanism, is responsible for the formation of substantial amounts of one or more of the dichloro isomers. This is shown in Scheme 4 for cp. The species that is formed as intermediate and is converted into the dichlorinated product may be regarded as an intimate ion pair.

The relative reactivities of cyclopentanone and cyclohexanone

From Table 7 it can be concluded that the ratio of the overall rate constants for ch and cp is about 10. Since the values of K_1 and k_2 are not known separately, it is hard to tell whether the high value of this ratio should be ascribed to the difference in basicity of the ketones (eq. [13]) or to the difference in acidity of the α-hydrogen atoms (eq. [14]). Campbell and Edward (17) have measured the basicities of ch and cp in concentrated sulphuric acid and obtained pK values of −6.8 and −7.5, respectively. The higher basicity of ch not only means a higher concentation of the oxygen-protonated species relative to that of cp but also a relative increase in reactivity of the deprotonation of the α-carbon atoms by the action of the ketone base.

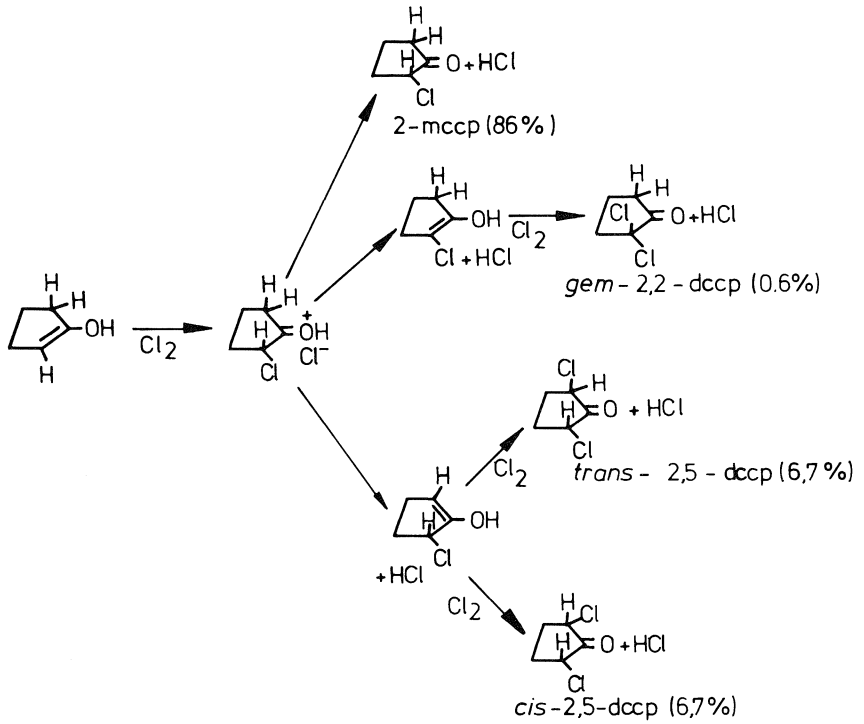
The ratio of the cis- *and* trans-*dichloro compounds formed*

As mentioned before, the chlorination of cp gives nearly equal amounts of *cis*- and *trans*-2,5-dccp, whereas *trans*-2,6-dcch is formed almost exclusively in the chlorination of ch. This can be understood by considering the conformation of the reactive chloro enols of both ketones. A model of 5-chloro-1-cyclopenten-1-ol shows that this enol is nearly flat and that the chlorine atom lies almost in the plane of the ring. Therefore the steric hindrance for the attack of molecular chlorine on the double bond from above or below the ring may be expected to be approximately the same, the *trans* attack being slightly favoured. In the 6-chloro-1-cyclohexen-1-ol molecule the Cl atom takes a much more pronounced axial position (13), leading to a much larger steric hindrance for an approach of a chlorine molecule from the *cis* position. Therefore virtually only *trans*-2,6-dcch is formed. Dang Quoc-Quan (13) reports that the *cis* isomer is thermodynamically the more stable isomer. However, equilibration of the isomerization only occurs at an appreciable rate above 360 K in acidic media. In our experiments virtually no *trans–cis* conversion was observed, as shown by analysis of samples of reaction mixtures even after several days of storage.

The influence of the temperature

In the reaction rate expression (eq. [18]) the overall reaction rate constant is compounded from several contributions. The

[6]Quantum mechanical calculations with an extended basis set on the $Cl^-...(HCl)_n$ complex, with n = 1, 2, and 3, were carried out by Prof. Dr. W. C. Nieuwpoort and Mrs. A. van den Bergh–van Dop, Dept. of Chemical Physics, The State University of Groningen, The Netherlands. For n = 1, 2, the complexes were assumed to be linear, for n = 3, the HCl molecules were assumed to be arranged around the central chloride ion in one plane at angles of 120°.



SCHEME 4

relative importance of these contributions varies with the concentration of the ketone. Each contribution probably has a different dependence on the temperature. Therefore we may expect that the measured activation energy of the overall reaction will vary with the ketone concentration. The apparent activation energy was therefore measured at two ketone concentrations [X]:

(*i*) At low ketone concentration, where the order of ketone is nearly 2. In this region eq. [18] degenerates to

$$[21] \quad -r(Cl_2) = \frac{[2 - S(Y)]}{S(Y)} K_1 k_2 [X]_0^2 [HCl] = \frac{[2 - S(Y)]}{S(Y)} k_{exp} [X]_0^2 [HCl]$$

(*ii*) At ketone concentrations of 0.5 *M* and more, where the order in ketone is 1, eq. [18] becomes

$$[22] \quad -r(Cl_2) = \frac{[2 - S(Y)]}{S(Y)} \frac{K_1 k_2}{2K_A} [X]_0 [HCl] = \frac{[2 - S(Y)]}{S(Y)} k_{exp} [X]_0 [HCl]$$

The experimentally determined activation energy, calculated from the rates of chlorination at 6 temperatures in the range of 279–314 K, was 15 kJ mol^{-1} at low and 25 kJ mol^{-1} at higher ($\geq$0.5 *M*) ketone concentrations for both cp and ch. The experimental rate constants, k_{exp}, are presented in Fig. 7.

The difference between the enthalpy values at low and high ketone concentrations may be ascribed to the influence of the temperature on the equilibrium constant of the self-association of the ketone molecules, K_A, the $-\Delta H_A^0$ for the self-association being 10 kJ mol^{-1}. This value is rather close to that of 12 kJ mol^{-1} determined for both the enthalpy of association of acetone in hexadecane (18) and the enthalpy of association of nitrobenzene in carbon tetrachloride (19). Arrhenius plots of the compounded reaction rate constants $K_1 k_2$ calculated from eq. [18] and corrected for the temperature dependence of K_A show

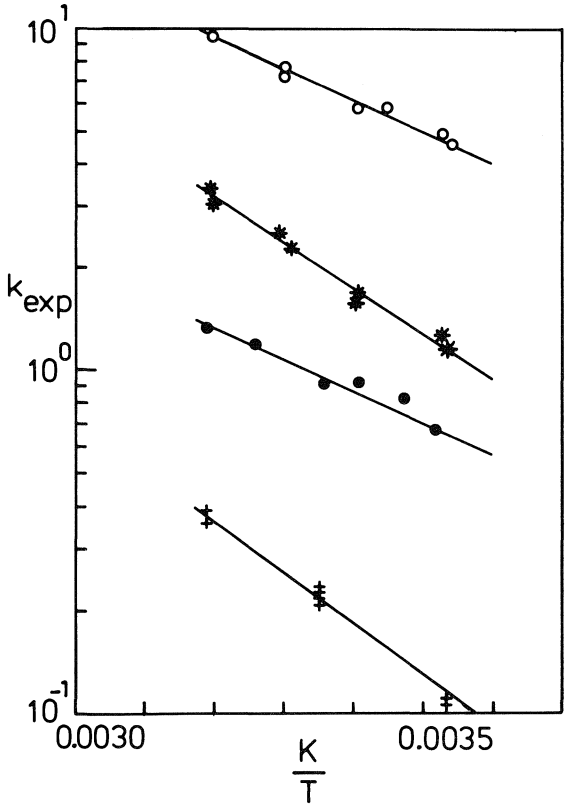


FIG. 7. The Arrhenius plots of the chlorination of cyclopentanone and cyclohexanone in carbon tetrachloride solutions at different ketone concentrations; ●, [cp] = 0.053 *M* (eq. [21]); +, [cp] = 0.50 *M* (eq. [22]); ○, [ch] = 0.10 *M* (eq. [21]); *, [ch] = 0.47 *M* (eq. [22]).

$K_1 k_2$ for cp as well as ch to be indeed independent of the ketone concentration, Fig. 8.

Values of activation energy, Arrhenius frequency factors, and enthalpy of the self-association are summarized in Table 8. The resemblance of the values of the enthalpy for the self-

association of cp and ch to those of acetone and nitrobenzene and the fact that the compounded reaction rate constants are independent of the ketone concentration lend credibility to the proposed reaction mechanism as presented in Scheme 3.

In the following paper the kinetics and mechanism of the hydrogen chloride catalyzed chlorination of 2-mcch and 2-mccp in carbon tetrachloride will be described.

Appendix I

The concentration of cp in solutions of carbon tetrachloride

The dimerization of cyclopentanone in carbon tetrachloride is represented by

[A-1] $2\,cp \overset{K_A}{\leftrightarrows} (cp)_2$

K_A is defined by eq. [5]. From this equation the fraction of the total ketone present in the monomeric form, $\alpha = [cp]/[cp]_0$, is obtained in terms of K_A and the total ketone concentration, $[cp]_0$:

$$[A\text{-}2] \quad \alpha = \frac{-1 + \sqrt{(1 + 8K_A[cp]_0)}}{4K_A[cp]_0}$$

Only the positive root has physical significance, resulting in the following expression for the concentration of the monomeric species:

$$[A\text{-}3] \quad [cp] = \frac{-1 + \sqrt{(1 + 8K_A[cp]_0)}}{4K_A}$$

A similar expression can be derived for the concentration of monomeric cyclohexanone in carbon tetrachloride.

Reactions of alicyclic ketones in carbon tetrachloride. II. Kinetics of the chlorination of 2-chlorocyclopentanone and 2-chlorocyclohexanone, catalyzed by hydrogen chloride

EIZE J. STAMHUIS,[1] HENK MAATMAN,[2] AND GEERT E. H. JOOSTEN[3]

EIZE J. STAMHUIS, HENK MAATMAN, and GEERT E. H. JOOSTEN. Can. J. Chem. **64**, 1690 (1986).

The kinetics of the direct chlorination of 2-chlorocyclopentanone (2-mccp) and 2-chlorocyclohexanone (2-mcch) in carbon tetrachloride, catalyzed by hydrogen chloride, were studied. Reaction products are all the possible 2,2-, 2,5-, and 2,6-dichloro compounds. The ratios depend on the concentrations of the monochloro compound and hydrogen chloride. Surprisingly, even at conversions of the monochloro compound as low as 2%, 2,2,5-trichlorocyclopentanone and 2,2,6-trichlorocyclohexanone, respectively, are also formed. The chlorination reaction of both monochloro ketones shows zero order in chlorine. The order in hydrogen chloride is 1.3. The order in 2-mccp and 2-mcch varies somewhat with the concentration of the ketone and was found to be roughly 1.7. The variation in reaction order is explained by a partial self-association of the ketones. The ketones act as substrates as well as basic catalysts in the rate-determining α- or α′-carbon deprotonation. General base catalysis is clearly demonstrated by a strong increase in the rate of chlorination of 2-mccp upon addition of cyclopentanone (cp) to the reaction mixture, which agrees with the mechanism as presented in a previous paper. Kinetic equations derived from the reaction models for the "separate" and "mixed" ketone chlorinations accurately describe the observed rates of the chlorination of 2-mccp and 2-mcch in the concentration range of 0.04–1.0 M.

EIZE J. STAMHUIS, HENK MAATMAN et GEERT E. H. JOOSTEN. Can. J. Chem. **64**, 1690 (1986).

Opérant dans le tétrachlorure de carbone, on a étudié la cinétique de la chloration directe, catalysée par le chlorure d'hydrogène, des chloro-2 cyclopentanone (2-mccp) et cyclohexanone (2-mcch). Les produits de la réaction correspondent à tous les produits possibles pour les disubstitutions en -2,2, -2,5 et -2,6. Les rapports varient avec les concentrations initiales de composé monochloré et de chlorure d'hydrogène. Il est surprenant de noter, à des taux de transformation du dérivé monochloré aussi bas que 2%, qu'il y a aussi formation, selon le cas, de trichloro-2,2,5 cyclopentanone ainsi que de trichloro-2,2,6 cyclohexanone. Par rapport au chlore, l'ordre de la réaction de chloration des deux cétones monochlorées est égal à zéro. Par rapport au chlorure d'hydrogène, il est égal à 1,3. Par rapport aux cétones 2-mccp et 2-mcch, l'ordre varie en fonction de la concentration des cétones; il s'établit approximativement à 1,7. On explique cette variation de l'ordre par rapport aux cétones en fonction d'une auto-association partielle des cétones. Les cétones agissent comme substrats ainsi que comme catalyseurs basiques dans la déprotonation des carbones α et α′ qui détermine la vitesse de la réaction. On a facilement mis en évidence une catalyse générale des bases en notant la grande augmentation de la vitesse de chloration de la 2-mccp par addition de cyclopentanone (cp) au milieu réactionnel; cette observation est en accord avec le mécanisme proposé dans notre travail antérieur. À des concentrations allant de 0,04 à 1,0 *M*, les équations cinétiques que l'on peut dériver des modèles réactionnels proposés pour des réactions de chlorations "séparées" et "mélangées" des cétones décrivent adéquatement les vitesses observées pour la chloration des cétones 2-mccp et 2-mcch.

[Traduit par la revue]

Introduction

In a previous paper the kinetics of the chlorination of cyclopentanone (cp) and cyclohexanone (ch) in carbon tetrachloride, catalyzed by hydrogen chloride, are described (1). A kinetic model is developed that is consistent with the experimental results over a broad range of concentrations of both ketones. A mechanism is proposed, which explains the kinetic results.

As to the product distribution, it was found experimentally that even at very low fractional conversions of the ketone, besides the 2-monochloro products, considerable amounts of the three isomeric dichloro ketones are also formed. This could not be explained by a normal consecutive chlorination of the monochloro ketones. To obtain more insight into the reactions involved, the kinetics of the chlorination of 2-chlorocyclopentanone (2-mccp) and 2-chlorocyclohexanone (2-mcch) in carbon tetrachloride, catalyzed by hydrogen chloride, were studied.

Experimental

Materials

Cyclopentanone and cyclohexanone were purified as reported in the previous paper (1). 2-Chlorocyclopentanone (Merck), purity >98%, was distilled and the fraction 346–348 K (1.6 kPa) was collected and used for the experiments. 2-Chlorocyclohexanone (Aldrich), purity >98%, was distilled and the fraction 355–357 K (1.3 kPa) was collected. Suppliers and specifications of chlorine, hydrogen chloride, and carbon tetrachloride are the same as reported in the previous paper (1).

Kinetic methods

The chlorination reactions were carried out in a thermostated ultraviolet transmission cell of 10×10^{-6} m^3 with a light path length of 2×10^{-2} m, equipped with a magnetic stirrer and placed in a Zeiss PMQ II spectrophotometer. Kinetic runs were carried out by rapidly mixing a solution of hydrogen chloride and chlorine in CCl_4, with a solution of 2-chloro ketone and hydrogen chloride in CCl_4. The concentration of chlorine was subsequently followed as a function of time by measuring the extinction of an optimal wavelength of 336 nm ($\varepsilon_{Cl_2} = 4200\ M^{-1}\ m^{-1}$).

Initial chlorine concentrations were determined by titration before mixing and from the extinction of the reaction mixture at time $t = 0$. Afterwards the mass balance on the chlorination products was calculated. The balance always agreed with 4%. All products were

analyzed by hplc. In some cases a stopped-flow technique was used as described in the preceding paper (1).

Results and discussion

Product distribution

After each kinetic run of the chlorination of 2-mccp the reaction mixture was analyzed quantitatively. In all experiments, including those at fractional conversions of 2-mccp down to 2%, some 2,2,5-trichlorocyclopentanone (2,2,5-tccp) was formed. In the chlorination of 2-mcch similar results were obtained. From the analytical results the selectivities, $S(Z)$, to the individual di- and trichlorinated ketones, (Z), were calculated according to

$$S(Z) = \frac{[Z]}{[gem\text{-}2,2\text{-dccp}] + [cis\text{-}2,5\text{-dccp}] + [trans\text{-}2,5\text{-dccp}] + [2,5,5\text{-tccp}]}$$

with *gem*-2,2-dccp: *gem*-2,2-dichlorocyclopentanone; *cis*-2,5-dccp: *cis*-2,5-dichlorocyclopentanone; *trans*-2,5-dccp: *trans*-2,5-dichlorocyclopentanone; and 2,5,5-tccp: 2,5,5-trichlorocyclopentanone.

The experimental isomer distributions obtained in the chlorination of 2-mccp at two conversions, η, of the starting ketone, and at several initial concentrations of the reactants, are summarized in Table 1. The content of *gem*-2,2-dccp decreases with increasing 2-mccp concentrations. The same applies to the ratio of *cis*-2,5-dccp to *trans*-2,5-dccp, although to a much lesser extent.

The observed selectivities will be discussed further on in this paper.

Kinetics

The experiments carried out in the temperature range of 284–314 K show a zero reaction order in chlorine. Figures 1 and 2 give the rate of disappearance of chlorine vs. the concentration of hydrogen chloride at several concentrations of 2-mccp and 2-mcch, respectively.

In view of the *autocatalytic* nature of the reaction, the chlorination was always carried out up to only a few percent conversion of the ketone to avoid a substantial increase in the concentration of hydrogen chloride. If necessary, corrections were made for the hydrogen chloride formed. From Figs. 1 and 2 an order in hydrogen chloride of 1.3 for both ketones can be calculated. From the rates at various ketone concentrations the order in monochloro ketone was determined to be roughly 1.7. Just as in the chlorination of the unsubstituted ketones, this value is not constant over the entire concentration range.

Figures 3 and 4 show the experimental results (points) and the calculated rates (drawn lines) based upon the kinetic model, which is given below.

Kinetic model

The observed variation of the reaction order of the monochloro ketones with the ketone concentrations as shown in Figs. 3 and 4 is reasonable in the light of the proposed mechanism for the chlorination of cyclopentanone and cyclohexanone as presented in the previous paper (1). This variation in order is brought about by a partial self-association of the monochloro ketones. Analogous to the reaction model of the chlorination of the parent ketones the rate expression is:

$$[1] \quad -r(Cl_2) = \frac{(2 - S_d)}{S_d} K_1 k_2 \times \left[\frac{-1 + \sqrt{1 + 8K_A[Y]_0}}{4K_A}\right]^2 [HCl]^{1.3}$$

Y: 2-mccp, 2-mcch; K_1: equilibrium constant of the ketone-oxygen protonation given by eq. [3] in Scheme 2; k_2: rate constant of the rate determining α- or α′-carbon deprotonation of the oxygen-protonated ketone (substrate) by the same ketone acting as base; K_A: equilibrium constant of the self-association of Y; and S_d: selectivity of the chlorination to the combined dichloro compounds. The values of the parameters as determined from the experimental results by a least-squares method are summarized in Table 2.

The calculated rates of chlorination obtained by substituting the parameters of Table 2 in eq. [1] agree well with the experimental rates of reaction (drawn curves in Figs. 3 and 4).

The values of the association constants K_A of the monochloro compounds in carbon tetrachloride are considerably lower than those of the parent ketones. This is the reason for the smaller variation in the reaction order in the monochloro ketones over the experimental range of concentrations compared to those of the parent ketones.

The influence of the temperature on the rate of chlorination of 2-mccp, measured at ketone concentrations of 0.10 and 0.23 M, is in fact composed of a contribution of the compounded chlorination reaction rate constant K_1k_2 and of the self-association of the monochloro ketone as represented by the term $(-1 + \sqrt{1 + 8\,K_A[Y]_0})^2/16\,K_A^2$ in eq. [1]. Correcting for the

latter contribution, assuming an enthalpy of self-association ($-\Delta H_A^0$) of 10 kJ mol^{-1} as found for cp and ch (1), the compounded rate constant K_1k_2 at various temperatures could be calculated and its temperature dependence expressed in an Arrhenius equation. The value of the activation energy, E_a(2-mccp), of the chlorination reaction is found to be 22 kJ mol^{-1} and the pre-exponential factor 900 $M^{-2.3}$ s^{-1}.

As might be concluded from the presence of trichloro compounds in the reaction mixture, part of the monochloro ketones is rapidly chlorinated to products containing two more chlorine atoms than the original reactant. For the parent ketones a similar behaviour was observed (1). However, the extent of this rapid consecutive reaction is smaller for the monochloro compounds, leading to about 5% of the trichloro ketones. Analogous to the explanation given in the previous paper for the formation of dichloro ketones directly from cp and ch, part of the oxygen-protonated dichloro compound formed by the chlorination of the monochloro ketone forms an intimate ion pair with a very reactive chlorine anion. This ion pair will subsequently lead to dichloro enol molecules as precursors of the trichloro ketone, according to Scheme 1.

This process must compete with an oxygen deprotonation of the dichloro compound by probably the same chloro anion. The lower reactivity and the smaller number of the remaining α-hydrogen atoms in the dichloro ketones with respect to the 2-chloro compounds are most probably responsible for the fact that in the chlorination of 2-mccp and 2-mcch only 5% trichloro ketones are formed, whereas in the chlorination of cp and ch approximately 17% of the dichloro derivatives are produced.

TABLE 2. Equilibrium constants of the self-association, K_A, of 2-mccp and 2-mcch, and the compounded reaction rate constant of the chlorination at 294 K

Ketone	K_A (M^{-1})	K_1k_2 ($M^{-2.3}$ s^{-1})
2-mccp	0.5	0.10
2-mcch	0.5	0.011

Both the unsubstituted ketones and the monochloro derivatives show similar behaviour regarding the chloride base-catalyzed rapid consecutive chlorination. It may therefore be expected that this reaction is not limited to this class of ketones, but will occur quite generally in the acid-catalyzed direct chlorination of ketones in apolar solvents. It may well be the main reason for the generally observed low selectivities of desired products in the direct halogenation of aldehydes and ketones.

The chlorination of 2-chlorocyclopentanone, catalyzed by cyclopentanone

The kinetic results for the chlorination of cp, 2-mccp, ch, and 2-mcch, obtained so far, permit the calculation of the selectivities to the mono-, di-, and trichlorinated products over a large range of fractional ketone conversions. At high conversions of the unsubsituted ketones the calculated values of the selectivities to the monochlorinated products were found to be much higher than those obtained experimentally, indicating more complicated kinetics than expected. The kinetic measure-

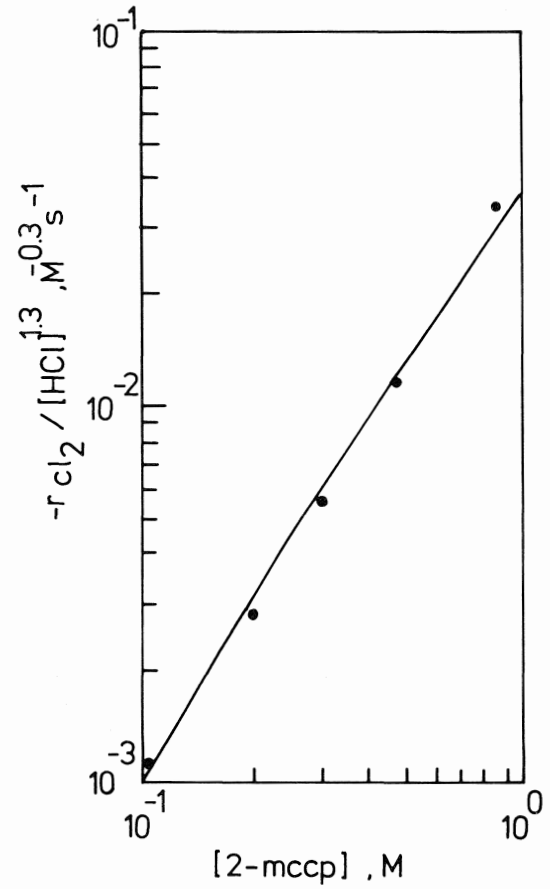

FIG. 3. The influence of the concentration of 2-mccp on the rate of chlorination at 294 K. Experimental (●); the smooth curve is calculated with eq. [1] and the constants from Table 2.

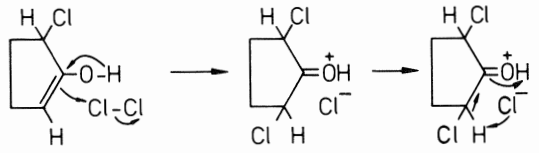

SCHEME 1

ments described thus far could be explained by a mechanism in which the ketone molecule is not only the substrate but also a base catalyst. This was confirmed by the results of two sets of primary kinetic isotope effects for ch (1). This raises the question whether addition of unsubstituted ketone to reaction mixtures containing 2-monochloro ketone would demonstrate base catalysis by the unsubstituted ketone in the proton removal from an α- or α′-carbon atom of the 2-chloro ketone on the one hand, and base catalysis by the 2-monochloro compound in the chlorination of the unsubstituted ketone on the other hand, thus explaining the deviations between experimental and calculated selectivities. Closer inspection shows that base catalysis by the 2-monochloro compound probably is negligible relative to that by the unsubstituted ketone: the pK_A values of the monochloro ketones, and thus their basicities, are significantly lower than those of the unsubstituted ketones, the difference being 2–3 pK_A units (2–4). The base catalysis by the parent ketone in the chlorination of the monochloro compound may be significant, however. This would lead to a considerable decrease in selectivity to the monochloro product in the chlorination of cp or

*The mean value of $K_{1,Y}k_{2,Y,X}$ is 0.39 ± 0.17 (standard deviation).

Based on Scheme 2, the rate of disappearance of chlorine in the chlorination of the monochloro ketone in a ketone – monochloro ketone mixture is given by

$$[7]\quad -r(Cl_2) = \frac{(2 - S_z)}{S_z} \times K_{1,Y}k_{2,Y,X}\left[\frac{-1 + \sqrt{1 + 8K_{A,Y}[Y]_0}}{4K_{A,Y}}\right] \times \left[\frac{-1 + \sqrt{1 + 8K_{A,X}[X]_0}}{4K_{A,X}}\right][HCl]$$

S_z: selectivity to the dichloro ketones; X: cp or ch; Y: 2-mccp or 2-mcch; $[X]_0$: total concentration of the unsubstituted ketone X; $[Y]_0$: total concentration of the monochloro ketone Y; $K_{1,Y}k_{2,Y,X}$: compounded reaction rate constant, based on Scheme 2, with X the unsubstitued ketone, here as base catalyst, and Y the monochloro ketone, here as substrate; in $M^{-2}\ s^{-1}$.

In an actual reaction mixture the rate of chlorine consumption will be larger as, parallel with the reactions given in Scheme 2, the chlorination of cp catalyzed by cp and of 2-mccp catalyzed by 2-mccp will also take place.

To determine the value of $K_{1,mccp}k_{2,mccp,cp}$, a number of experiments were carried out in which 2-mccp was chlorinated in the presence of cp. The results are presented in Table 3. The rates of chlorination of cp catalyzed by cp, and of 2-mccp catalyzed by 2-mccp, were subtracted from the observed rates. From the resulting difference, the compounded rate constant, $K_{1,mccp}k_{2,mccp,cp}$, was calculated, using eq. [7]. Thus a value of $0.39 \pm 0.17\ M^{-2}\ s^{-1}$ was obtained at a temperature of 294 K.

As well as self-association of the ketones, one may expect association of cp and 2-mccp molecules. By using a geometric mean value of $K_{A,X,Y}$ for this "cross-association," the greatest difference in the calculated[5] selectivity to 2-mccp with and without this kind of association was only 2%, even at a total ketone concentration of $2.5\ M$. The impact of the cross-association on the results of the mixed ketone experiments was therefore neglected.

Table 4 gives the values of the compounded reaction rate constant for the various combinations of substrate and base catalyst. The estimated values in Table 4 were obtained as follows. The difference in the values of the compounded rate constant for cases III and IV can be ascribed to the different catalytic activities of the bases acting in both cases. The relative activity of the bases is therefore $0.39/0.1 = 3.9$. If it be assumed that the ratio of the catalytic activities of the bases in cases I and II is the same, a value of $1.6/3.9 \approx 0.4$ is obtained for the rate constant in case II.[6]

A similar reasoning was applied in estimating the constant in case VI. The ratio of the catalytic activities of the unsubstituted and monosubstituted ketones as base is 3.9 for cp and approximately 150 for ch (comparison between cases III and IV, VII and VIII).

[5]As calculated from a computer simulation of a number of chlorination experiments, carried out in a trickle-bed reactor at 293 K.

[6]The rate-determining step in the chlorination of the ketones studied is expressed by eq. [5]. To a first approximation, this rate depends on the concentrations of substrate and catalyst, the acidity of the α-carbon hydrogen, which is removed, the basicity (nucleophilicity) of the catalyst-base, and other effects like steric hindrance in the activated complex. To estimate the value of the compounded rate constant for case II, these effects were taken into account qualitatively. As to the steric hindrance, a proportional increase in the series I–IV of Table 4 was assumed.

TABLE 4. The measured and estimated reaction rate constants based on the mechanism presented in Scheme 2. $K_{A,cp} = 3\ M^{-1}$, $K_{A,ch} = 4\ M^{-1}$, $K_{A,2\text{-mccp}} = K_{a,2\text{-mcch}} = 0.5\ M^{-1}$

Case	Substrate	Base catalyst	Compounded rate constant	Value compounded rate constant ($M^{-2}\ s^{-1}$)

*Estimated value.
†Estimated from computer simulations of chlorination experiments in a trickle-bed reactor.

In aqueous media a decrease of 2–3 pK_A units was found for the first chlorine atom introduced (2). It may be expected that such a decrease in basicity would result in ratios of these overall rate constants much larger than those experimentally obtained. However, as is well known, large differences in basicities as found in aqueous media diminish in an apolar solvent like carbon tetrachloride. This is brought about by strong ion-pair formation (5).

It is striking that the ratio of the overall rate constants of chlorination of the unsubstituted and monosubstituted ketones is 4 for cp (cases I and III) and 10 for ch (cases V and VII), in those cases that the unsubstituted ketone acts as basic catalyst. That these ratios are considerably larger than 1 is probably due to the lower basicities of the monochloro derivatives and to the smaller number of α-carbon and α′-carbon hydrogens available in the latter compounds with respect to the unsubstituted ketones. The extra decrease in reactivity of 2-mcch relative to 2-mccp with a factor of 2.5 might be ascribed to the exceptional position of the chlorine atom in 2-mcch. When dissolved in hexane, carbon tetrachloride, or iso-octane, this position is preferentially axial as a consequence of the electrostatic repulsion between the dipoles of the carbonyl group and the carbon chlorine in the equatorial position (6, 7), despite an increase in steric hindrance by the interaction of this α-carbon chlorine with the α′-axial hydrogen. Energetically, the hydrogen most favorable for enolization is this α′-carbon hydrogen, leading to 6-chloro-1-cyclohexen-1-ol. Just as in 2-mcch, the chlorine atom in this intermediate also takes a very pronounced axial position (6), leading to a much larger steric hindrance for an approach of a chlorine molecule from the *cis* position in the subsequent step. Therefore, virtually only *trans*-2,6-dichlorocyclohexanone is formed, as is indeed observed. One may expect that this route is only slightly influenced by the type of basic catalyst used. The selectivities to the dichlorocyclohexanones in the chlorination of ch catalyzed by the chloride anions in the intimate ion-pair mechanism can then also be understood, and indeed *trans*-2,6-dcch is formed almost exclusively (ref. 1, Tables 4 and 5).

Very likely the preferential axial position of the α-chlorine in 2-mcch in apolar media results in a lower basicity of the carbonyl group for this ketone with respect to 2-mccp. This explains the large difference in the ratios of the compounded rate constants for cases III and IV, and VII and VIII, respectively.

The selectivities S(*Z*)

In contrast to the 6-chloro-1-cyclohexen-1-ol molecule, a model of 5-chloro-1-cyclopenten-1-ol shows that this enol is nearly flat. The position of the chlorine atom is almost in the plane of the ring, *trans* attack of the chlorine molecule being slightly favored. Therefore a ratio of *S*(*trans*-2,5-dccp) and *S*(*cis*-2,5-dccp) of slightly larger than one may be expected in the chlorination of 2-mccp. Table 1 shows this to be actually the case. As was observed earlier (8), *S*(*gem*-2,2-dccp) appears to be dependent on the concentrations of the reagents. Table 1 shows that *S*(*gem*-2,2-dccp) decreases almost linearly with increasing concentrations of both 2-mccp and hydrogen chloride. Although the data are not sufficient to draw pertinent conclusions, this selectivity may well be related to the dielectric constant of the reaction mixture. At increasing concentrations of 2-mccp and (or) hydrogen chloride the dielectric constant will increase. It may be expected that the repulsion of the carbonyl and α-C—Cl dipoles will decrease with increasing dielectric constant of the medium. If acid–base catalyzed enolization is favoured by a planar configuration of the carbonyl group and the α-carbon–hydrogen bond, an increase in *S*(*gem*-2,2-dccp) at decreasing dielectric constant may indeed be expected. For at low dielectric constant the α-carbon chlorine is forced into the axial position and the α-carbon hydrogen then turns into the plane of the C=O group.

It should be mentioned that virtually no *cis–trans* conversion takes place after the reaction, as was proven by analysis of samples of the reaction mixtures, even after several days of storage at reaction temperatures. This is in agreement with observations by others (see ref. 6, p. 12, and ref. 8).

Conclusions

It is clear that the direct chlorination of the cyclic ketones in carbon tetrachloride, catalyzed by hydrogen chloride, is much more complicated than expected on the basis of literature data on chlorination reactions in polar media. This is mainly due to the fact that the substrate and products themselves also act as basic catalysts in the reaction. It may be pointed out that, actually, more reactions occur than described in this contribution. Although not kinetically investigated, batch experiments with ch always show the formation of small amounts of 2,2,6,6-tetrachlorocyclohexanone, as long as ch is present. This indicates a ch catalyzed enolization of the dichloro- and, to

a small extent, of the trichlorocyclohexanone. Besides, very small amounts of the tetrasubstituted compound may also be formed in the rapid consecutive chloride-anion catalyzed enolization of the oxygen-protonated dichloro ketones. Similar results were obtained in the chlorination of cp.

It should be mentioned that chlorination of ch and cp with excess of chlorine leads to a mixture of α,α'-chlorinated products, containing on the average not more than 2.3–2.5 chlorine atoms per ketone molecule. High conversions to 2,2,6,6-tetrachlorocyclohexanone are possible, using an organic base like collidine as catalyst (9).

Received January 10, 1986

GEORGE R. CLARK, CLIFTON E. F. RICKARD, and MICHAEL J. TAYLOR. Can. J. Chem. **64**, 1697 (1986).

The preparation, crystal structure, and vibrational spectra of the title compound are reported. The compound crystallizes in the triclinic space group $P\bar{1}$, with $a = 7.386(2)$, $b = 8.637(1)$, $c = 16.546(2)$ Å, $\alpha = 97.40(1)°$, $\beta = 95.51(2)°$, $\gamma = 112.91(2)°$, $V = 951.6$ Å^3, $\rho_{obs} = 2.43$ g cm^{-3}, $Z = 2$, $\rho_{calcd} = 2.424$ g cm^{-3} (MoK_α, $\lambda = 0.71069$ Å). The structure was solved by direct methods and electron density maps, and refined by full-matrix least squares to the final $R = 0.038$ for 3343 observed reflections. The structure consists of *N,N,N′,N′*-tetramethylpiperazonium cations containing a six-membered C_4N_2 heterocycle, $InBr_5(OH_2)^{2-}$ anions, and additional H_2O solvent molecules. Infrared and Raman spectral bands of the $InBr_5(OH_2)^{2-}$ complex are assigned on the basis of C_{4v} skeletal symmetry, and the H_2O molecule of crystallization is also detected spectroscopically.

GEORGE R. CLARK, CLIFTON E. F. RICKARD et MICHAEL J. TAYLOR. Can. J. Chem. **64**, 1697 (1986).

On rapporte la préparation, la structure cristalline et les spectres vibrationnels du composé mentionné dans le titre. Le composé cristallise dans le groupe d'espace triclinique, $P\bar{1}$, avec $a = 7,386(2)$, $b = 8,637(1)$ et $c = 16,546(2)$ Å, $\alpha = 97,40(1)$, $\beta = 95,51(2)$ et $\gamma = 112,91(2)°$, $V = 951,6$ Å^3, $\rho_{obs} = 2,43$ g cm^{-3}, $Z = 2$, $\rho_{calcd} = 2,424$ g cm^{-3} (MoK_α, $\lambda = 0,71069$ Å). On a résolu la structure par des méthodes directes et des cartes de densités électroniques et on l'a raffinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur de $R = 0,038$ pour 3343 réflexions observées. La structure comporte des cations *N,N,N′,N′*-tétraméthylpipérazonium contenant un hétérocycle à six chaînons C_4N_2, des anions $InBr_5(OH_2)^{2-}$ et des molécules additionnelles d'eau de solvation. On a attribué les bandes observées dans les spectres ir et Raman du complexe $InBr_5(OH_2)^{2-}$ sur la base d'une symétrie du squelette C_{4v}; la spectroscopie permet aussi de détecter la molécule d'eau de cristallisation.

[Traduit par la revue]

Introduction

Heterocyclic dipositive cations, which are easily prepared by reaction of *N,N,N′,N′*-tetramethyl-1,2-ethanediamine (tmen) with methylene dihalides or 1,2-dihalogenoalkanes, may be used as counterions for the isolation of complex anions, especially those possessing a double negative charge (1). Here we report structural investigations of the compound 1,1,4,4-tetramethylpiperazonium aquopentabromoindate monohydrate, $(C_8H_{20}N_2)[InBr_5(H_2O)].H_2O$, **1**, obtained as crystals from an aqueous solution in which a mixture of indium bromide complexes is believed to exist (2).

The anion in **1** is $InBr_5(OH_2)^{2-}$ and its characterisation completes the series of six-coordinate indium halide complex anions $InX_n(OH_2)_{6-n}^{3-n}$ (X = Cl or Br; $n = 4$–6) for which crystallographic and spectroscopic data are available (3). Also revealed are the dimensions of the *N,N,N′,N′*-tetramethylpiperazonium dication, containing a six-membered C_4N_2 heterocycle, which may be compared with those of the analogous five-membered ring imidazolidinium dication (from tmen and CH_2Cl_2), the structure of which was determined recently (4).

Experimental

Preparative, analytical, and spectroscopic aspects

Aqueous solutions of indium bromide were prepared by dissolving the metal in concentrated HBr, by dissolving $InBr_3$ in water, or by the addition of KBr to $In(NO_3)_3$ solution (3:1 KBr to $In(NO_3)_3$). 1,1,4,4-Tetramethylpiperazonium dibromide, prepared from tmen and 1,2-dibromoethane (1), was added in aqueous solution so as to afford a slight excess based on the quantity of In^{3+}. Crystalline products formed on mixing the solutions. Larger, well-shaped crystals for the present study were obtained by evaporation of a solution from which an initial crop had already been obtained. These were collected and dried by contact with filter paper. *Anal.* calcd. for $(C_8H_{20}N_2)InBr_5.2H_2O$: C 13.83, H 3.48, N 4.03; found: C 14.14, H 3.50, N 4.32.

[1]To whom all correspondence should be addressed.

Raman spectra were recorded with a Jasco R300 spectrometer, using Ar^+ laser excitation (488 or 514 nm) from a Coherent Radiation CR4 source operating at 200 mW. Infrared spectra were measured using a Perkin-Elmer 597 spectrometer for the range 4000–200 cm^{-1}, and in the far-infrared (400–40 cm^{-1}) using a Grubb-Parsons Cube MkII interferometer linked to an IBM PC microcomputer. The low-frequency spectra indicated the presence of an indium bromide complex anion (5). In some samples two intense ν(In—Br) Raman peaks were seen near 170 cm^{-1}, separated by ca. 5 cm^{-1}, and small shifts (less than 10 cm^{-1}) between one sample and another were noticed in the position of several bands due to the cation, particularly the rocking modes. These effects are probably associated with minor conformational changes in the ions concerned. In an attempt to eliminate this factor, care was taken to select the material for X-ray and spectroscopic analysis from the same batch of crystals.

X-ray studies

Crystals of the title compound are colourless prisms. A crystal with approximate dimensions 0.23 × 0.18 × 0.13 mm was affixed to the end of a glass fibre and positioned on a Enraf-Nonius CAD-4 diffractometer. Accurate unit cell parameters were derived from a least-squares fit to the setting angles of 25 high-θ reflections widely dispersed through reciprocal space. The diffraction pattern contained no systematic absences in a triclinic distribution, and the space group was deduced to be $P\bar{1}$ rather than $P1$ on the basis of intensity statistics. The data were corrected for Lorentz and polarization effects, and scaled to allow for isotropic decay of intensity standards (maximum decay 10%). Absorption corrections were from empirical curves derived from azimuthal scans, with maximum and minimum correction factors being 0.9992 and 0.6749, respectively (6). The crystal density was measured by flotation in CH_2Br_2/*c*-hexane mixtures.

The positions of the indium and bromine atoms were obtained by direct methods using the SHELX program (7), and the lighter atoms were found in a subsequent electron density map. No attempt was made to locate hydrogen atoms. The structure was refined anisotropically by full-matrix least squares to convergence at $R = 0.038$ and $R_w = 0.043$ for 3343 unique observed reflections. The function minimised during least-squares calculations was $\Sigma w(|F_o| - |F_c|)^2$, with $w = 1/[\sigma^2(F)$

$+ gF^2]$ and final g of 2.606×10^{-3}. $S = [\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2} = 0.748$. The maximum residual electron density in a final difference map (0.93 e Å^{-3}) was a spurious peak close to the indium atom position. Structure determination and refinement were performed on the University of Auckland IBM 4341 computer.

Details of the crystal, intensity data collection, and structure refinement are summarized in Table 1. Atomic positions and equivalent isotropic temperature factors are given in Table 2. Anisotropic thermal parameters, and tables of observed and calculated structure factor amplitudes, are available as Supplementary Data.[2]

Figure 1 shows the packing within the centrosymmetric unit cell. Figure 2 gives the cation with the atomic numbering scheme for C and N atoms, and Fig. 3 shows the $InBr_5(OH_2)^{2-}$ anion.

Results and discussion

Preparative aspects

Aqueous solutions of indium chloride or bromide are known to contain mixtures of complex anions, including species with water molecules coordinated to the metal (2, 8, 9). A variety of solids can be crystallised from these solutions by use of metal or alkylammonium cations, and include examples in which additional halide as well as a complex anion is present, e.g. $(MeNH_3)_4InBr_7$ contains Br^- and $InBr_6^{3-}$ ions (5, 10). Our objective was to see whether the use of a bulky dication would facilitate the isolation of a dianion from the mixture present in a indium bromide solution. $(Me_4N)_2InBr_5$, prepared by Tuck *et al.* (5), appears from spectroscopic evidence, to contain $InBr_4^-$ and Br^- ions. With the Me_4N^+ cation, the chloride system can furnish either $(Me_4N)_2[InCl_5]$ or $(Me_4N)_2[InCl_5(H_2O)]$ depending on the reaction medium (5). We find that indium bromide solutions to which the $Me_2N(C_2H_4)_2NMe_2^{2+}$ cation is added yield a crystalline product, and the position of ν(In—Br) bands in Raman and ir spectra indicates that a five- or six-coordinate indium complex is present. A crystal of this compound was selected for X-ray examination and the same product was investigated spectroscopically.

Structural studies

The crystal structure of **1** consists of discrete dipositive cations, $InBr_5(OH_2)^{2-}$ complex anions, and an additional H_2O solvent molecule which is linked to the coordinated water molecule of the anion by hydrogen bonding (Fig. 1). The separation between the oxygen atoms of the H_2O molecules is 2.79 Å, which suggests a hydrogen bond length of ca. 1.8 Å, a usual value. A "difference" Fourier map shows electron density along the O---O vector connecting the two water molecules, but fails to locate the proton precisely. All other interatomic distances involving the second water molecule and O or Br atoms are in excess of 3.3 Å, so that further bond formation is ruled out. The crystals of **1** are stable in the atmosphere at room temperature but become cloudy on the surface when in contact with acetone or alcohol, probably through loss of the solvent molecule from the lattice.

Figure 2 shows the structure of one of the two crystallographically distinct dications, the six-membered rings of which adopt a regular chair conformation. Bond distances and angles are given in Table 3. Note that the atomic numbering for the second dication is N(2) and C(5)—C(8). The C—N bond

lengths, in the range 1.50–1.53 Å, are normal values for quaternary nitrogen and are similar to those of the 1,1,3,3-tetramethylimidazolidinium dication (4). This latter species, the five-membered ring cyclic cation derived from tmen and a methylene dihalide, has a short C—C distance of 1.48 Å. In the present six-membered ring the C—C distance is larger, 1.533 Å, and is slightly greater than the corresponding bond length in piperazine (1.527 Å) or 1,4-dimethylpiperazine (1.521 Å) (11). These two molecules have C—N bonds of 1.45–1.47 Å: those of the present heterocycle are significantly longer, with C—N(ring) distances which average 1.507 Å, and are similar to those found in the tetraamidopiperazonium dication, which has C—N(ring) distances of 1.510 and 1.513 Å and a C—C distance of 1.521 Å (12).

The structure of the $InBr_5(OH_2)^{2-}$ anion is shown in Fig. 3, with bond lengths and angles in Table 4. The average In—Br distance, 2.644 Å, comes between those of $InBr_4(OH_2)_2^-$ and $InBr_6^{3-}$, which are 2.613 Å (13) and 2.670 Å (14), respec-

tively. Six-coordinate aquochloro complexes of indium also show an increase in bond length with increased charge on the anion (15).

For $InBr_5(OH_2)^{2-}$, the In—O distance of 2.344 Å makes this the longest indium–oxygen bond so far measured, exceeding the values of 2.224 Å in the chloride analogue $InCl_5(OH_2)^{2-}$ (16), 2.261 Å in $InBr_4(OH_2)_2^-$ (13), and 2.15 Å in $In(OH_2)_6^{3+}$ (17). A value of 2.287 Å has been estimated for the In—O distance in $(NH_4)_2[InBr_5(H_2O)]$ from an analysis of the single crystal ^{115}In nqr spectrum (18). The greater In—O distance of the present structure may be due in part to the effect of hydrogen bonding to the additional water molecule. Inspection of the bond angles of the present complex reveals a significant displacement of atoms Br(1)—Br(4) towards oxygen, the average of the set of Br—In—O angles being 85.6°. At the same time In—Br(2) and In—Br(4) bonds are noticeably shorter than the other three In—Br bonds, and close in length to those of $InBr_4(OH_2)_2^-$, but we can see no obvious explanation for this.

Vibrational spectroscopy

In the vibrational spectra of crystalline samples, bands due to the $Me_2N(C_2H_4)_2NMe_2^{2+}$ cation are readily identified by comparison with our measurements of the tetramethylpiperazonium halide salts in the solid state or in solution. These are reported and the assignment of the spectrum of this species is considered elsewhere (1). Remaining features are attributable to the $InBr_5(OH_2)^{2-}$ complex anion, and to the second water molecule which accompanies it in the crystal. Table 5 shows that the present spectrum closely resembles that of $Cs_2InBr_5(OH_2)$, reported by Adams and Lock (19) in a survey of some aquohalogeno complexes. Vibrational modes of the $InBr_5O$ unit, according to the idealised point group symmetry of C_{4v}, form the representation $4A_1 + 2B_1 + B_2 + 4E$ in which all species are Raman-active and A_1 and E species are also infrared-active, so that 8 of the 11 fundamentals should appear in both spectra. All these modes are anticipated to occur in the region below 400 cm^{-1}, with symmetric In—Br stretching expected to be close to the value of 172 cm^{-1} in $(MeNH_3)_4InBr_7$ which contains the octahedral $InBr_6^{3-}$ anion (5). The previous reports of $InBr_5(OH_2)^{2-}$ (9, 19, 20) did not give a detailed assignment. Our assignment in Table 5 is supported by comparison with the closely similar vibrational spectrum of $SbBr_5(OEt_2)$ which has a coordination sphere isoelectronic with $InBr_5O$ (21), and also takes advantage of single crystal Raman spectroscopy of the chloro complex $InCl_5(OH_2)^{2-}$ in the Cs^+ (22) and K^+ (16) salts. The infrared and Raman spectra of $InBr_5(OH_2)^{2-}$ are in reasonable agreement with predictions for C_{4v} symmetry. In particular we note that, although the pattern of In—Br bond lengths indicates that the structure is closer to

C_{2v} than C_{4v} symmetry, the spectrum does not approach the number of bands (21 Raman, 19 ir) required by the lower symmetry. In contrast to the case of $K_2InCl_5(OH_2)$ (16), we observe no factor group splitting attributable to coupling within the centrosymmetric cell. This is not surprising since the bulky tetramethylpiperazonium cations will serve to isolate the anions from one another.

Six modes of $InBr_5(OH_2)^{2-}$ should involve the water molecule coordinated to indium. ν(In—O), which was tentatively located between 260 and 320 cm^{-1} in previous work (19, 20), is probably masked by a cation band at 275 cm^{-1}. A lower value, compared with 300–350 cm^{-1} in $InCl_5(OH_2)^{2-}$ salts (16, 19, 22), is matched by a significant increase in the In—O bond length from 2.224(9) Å in $InCl_5(OH_2)^{2-}$ (16) to 2.344(5) Å in $InBr_5(OH_2)^{2-}$. Other vibrations, namely the stretching, bending, rocking, and wagging modes of the coordinated water molecule, give rise to broad bands which are generally strong in ir and very weak in Raman spectra. All of these excepting the wagging mode are observed and readily assigned as in Table 5. The δ(HOH) bend has been noted as a useful indication of the purity of specimens of aquohalogen complexes since it is very sharp and has a characteristic frequency, e.g., 1576 cm^{-1} for salts containing $InBr_5(OH_2)^{2-}$ (19). With this criterion, and by comparison with the ir spectrum of $Cs_2[InBr_5(H_2O)]$ (19), the ν(O—H) and δ(HOH) frequencies belonging to the complex anion can be distinguished from those of the uncoordinated water molecule within the crystal, which are also assigned in Table 5. For this solvent molecule, ν(O—H) stretching is observed as a broad band, centred at the relatively low frequency of 3280 cm^{-1}, in accordance with the presence of hydrogen bonding which is also deduced from the crystallographic findings.

Phosphoryl to carbonyl migration of amino groups in mixed anhydrides

JILL SYMES AND TOMASZ A. MODRO[1]

Department of Organic Chemistry, University of Cape Town, Rondebosch 7700, South Africa

Received January 23, 1986

JILL SYMES and TOMASZ A. MODRO. Can. J. Chem. **64**, 1702 (1986).

Mixed anhydrides derived from carboxylic and amidophosphoric acids, $(RO)(R'_2N)P(O)OC(O)R''$ (**1**), undergo unimolecular fragmentation yielding carboxyamides, $R''C(O)NR'_2$, and metaphosphate esters, $ROPO_2$. The mechanism of the amino group transfer was studied for substrate **1***a* (**1**, R = R′ = Me; R″ = Ph); solvent as well as substituent effects indicate little (if any) charge development in the transition state. The effects of solvents and Lewis acids on the reaction rate and the activation parameters determined for **1***a* can be explained best in terms of stabilizing interactions with either carboxyamide or metaphosphate being formed in the course of reaction. The transfer of a functional group from one acyl center to another was investigated for other anhydride systems and the relative contributions of the fragmentation vs. disproportionation of substrates are discussed.

JILL SYMES et TOMASZ A. MODRO. Can. J. Chem. **64**, 1702 (1986).

Les anhydrides mixtes, $(RO)(R'_2N)P(O)OC(O)R''$ (**1**), obtenus à partir d'acides carboxyliques et d'acides amidophosphoriques subissent des fragmentations unimoléculaires conduisant aux carboxyamides, $R''C(O)NR'_2$, et aux esters métaphosphates, $ROPO_2$. On a étudié le mécanisme de transfert du groupement aminé dans le substrat **1***a* (**1**, R = R′ = Me; R″ = Ph); les effets de solvant ainsi que les effets de substituant indiquent qu'il n'y a que peu (s'il en existe) de développement de charge dans l'état de transition. Dans le cas du composé **1***a*, on a déterminé les effets des solvants et des acides de Lewis sur les vitesses de réaction et sur les paramètres d'activation; les meilleures explications pour ces résultats sont basées sur les interactions stabilisantes qui se forment au cours de la réaction soit avec le carboxyamide ou le métaphosphate. On a étudié le transfert d'un groupement fonctionnel d'un centre acyle à un autre dans d'autres systèmes d'anhydrides et on discute des contributions relatives à la fragmentation des substrats par rapport à leur disproportionation.

[Traduit par la revue]

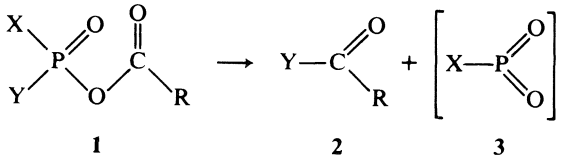
The ability of a functional group, such as alkyl ester OR, to migrate from one phosphoryl centre to another in a phosphoric anhydride was noticed as early as 1914 (1), when the formation of trialkyl phosphates was found to occur on thermal decomposition of tetraalkyl pyrophosphates. Reorganisation between structural units in an anhydride system was confirmed in later studies (2) on the polyphosphate esters with insecticidal properties. In the case of mixed anhydrides of dialkylphosphoric and carboxylic acids the major reaction is the disproportionation to a pair of symmetrical anhydrides; the reaction has been used (3) as a synthetic route to tetraalkyl pyrophosphates. It was reported, however (3), that when the mixed anhydrides contained a dialkylamide group, a considerable quantity of *N,N*-dialkylcarboxyamide was also formed, e.g.:

$$(Me_2N)_2P(O)OC(O)Me \xrightarrow{\Delta} Me{-}C(O)NMe_2$$

SCHEME 1

In consequence, acyl phosphates can undergo fragmentation according to two independent pathways; (*i*) the (necessarily) bimolecular disproportionation to symmetrical anhydrides; (*ii*) the fragmentation (possibly unimolecular) occurring within the anhydride framework and involving the transfer of a functional group from the phosphoryl to the adjacent acyl centre. The stoichiometry of this fragmentation (Scheme 2) requires reduction of the coordination number of phosphorus and the formation of (besides the carboxyderivative **2**) the metaphosphate-type product **3**.

While the phosphoramidate function shows high migratory reactivity in mixed anhydrides (see Scheme 1), N-substituted pyrophosphoramides of the Schradan type appear to be thermally stable (4). Thermal disproportionation leading to symmetrical anhydrides is characteristic of dialkylacyl phosphates (2), but mixed carboxylic–dihalophosphoric anhydrides, $RC(O)OP(O)X_2$



1 **2** **3**

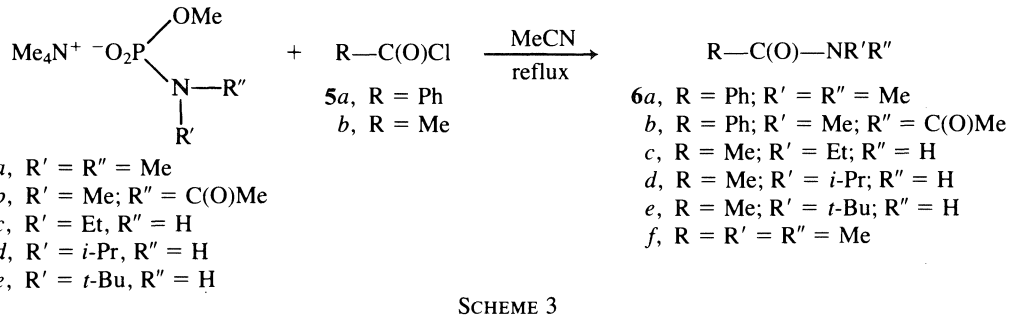
SCHEME 2

(X = F, Cl) yield upon distillation acyl halides RC(O)X (5). It seems, therefore, that the migratory aptitude of a group bonded to phosphorus in an anhydride system is a complex function of the nature of both the migrating group and the acceptor acyl centre. Although the chemistry of acyl phosphates has been extensively investigated with respect to their reactivity towards nucleophiles (6), no systematic studies have been carried out on the fragmentations of these diacyl systems under non-nucleophilic conditions. In this paper we report our results on the rearrangement of phosphoric–carboxylic anhydrides containing a phosphoramidate group (**1**, Y = NRR′).

Results and discussion

We have reported recently (7) that the reaction between tetramethylammonium salts of N-substituted methylphosphoramidic acids **4***a,b*, with benzoyl chloride (**5***a*) results in a facile and quantitative conversion to the corresponding N-substituted benzamide derivatives, **6***a,b* (Scheme 3). In the present work we extended this reaction to substrates containing secondary phosphoramidate functions (**4***c,d,e*) and found that they react smoothly with acetyl chloride yielding the corresponding acetamides (**6***c,d,e*). The obvious implication of Scheme 3 is that the initial reaction between **4** and **5** results in the formation of the mixed phosphoric–carboxylic anhydrides (**1**, R = Ph, Me; X = OMe; Y = NR′R″), which subsequently rearrange according to Scheme 2, yielding the carboxyamides **2** (Y = NR′R″). We therefore concentrated our further investigation on a selected pair of substrates (**4***a*, **5***a*) to demonstrate the

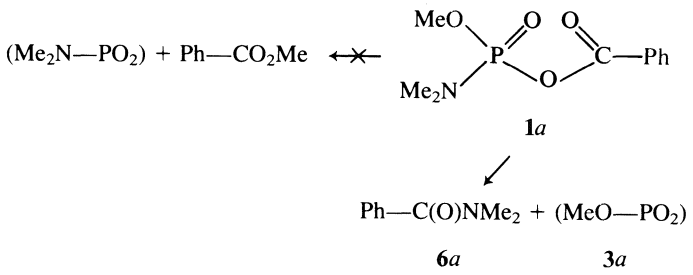
[1]Author to whom correspondence should be addressed.



SCHEME 3

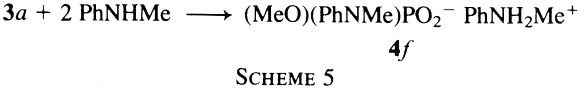
intermediate formation of the anhydride **1***a* (**1**, R = Ph; X = OMe; Y = NMe_2) and to study the mechanism of its fragmentation.

When **4***a* and **5***a* are allowed to react at room temperature, the only product obtained (after filtration of $Me_4N^+Cl^-$) is the expected mixed anhydride **1***a*. Although this compound can be stored in a refrigerator for several weeks, it decomposes slowly at room temperature, yielding *N*,*N*-dimethylbenzamide (**6***a*) and the polymeric, phosphorus-containing material, probably a product of self-condensation of methyl metaphosphate (**3***a*, X = OMe). The fragmentation can easily be followed by ^{1}H nmr spectroscopy due to the disappearance of the *N*-methyl signal of the P(O)NMe_2 group in **1***a* (δ 2.80, d, J_{HP} 11 Hz), and the appearance of the *N*-methyl signal of **6***a* (δ 3.0, br s). Under no circumstances were we able to detect any formation of methyl benzoate, i.e. a product expected from the migration of the OMe group in **1***a* rather than the NMe_2 group to the benzoyl carbon atom (Scheme 4).



SCHEME 4

If the fragmentation of **1***a* presented in Scheme 4 is a unimolecular process, it yields initially **3***a* in its monomeric form. In order to obtain evidence for the formation of "free" **3***a*, we carried out the trapping experiment described by Clapp and Westheimer (8), involving phosphorylation of *N*-methylaniline by the metaphosphate species (Scheme 5). When **1***a* was heated at 50°C in CD_3CN in the presence of 2.5 mol-equivalents of *N*-methylaniline for 60 h, the ^{1}H nmr of the solution revealed complete disappearance of the substrate and the formation (in addition to **6***a*) of the salt **4***f* whose spectroscopic features were identical to those reported in the literature (8).



SCHEME 5

Rate measurements

The changes in the ^{1}H nmr spectra of solutions of **1***a* that accompany its conversion to **6***a* (Scheme 3) could also be employed in determination of the rates of fragmentation. As can be seen from Table 1, which shows the effect of substrate concentration on the rate of fragmentation, the reaction follows first-order kinetics.

TABLE 1. Rates of formation of **2***a* from **1***a* at 68.0°C

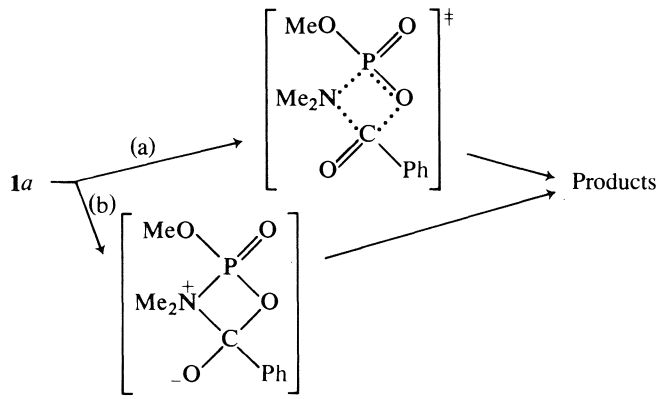
[a]Calculated according to the first- and second-order rate law, respectively.

The unimolecular collapse of anhydrides **1** may proceed according to a variety of mechanistic patterns, from a fully concerted pathway to the stepwise mechanism, involving a charge-separated intermediate. These two extreme cases are presented for **1***a* in Scheme 6. To provide experimental evidence for the "concerted" or "charge-separated" type of mechanism of fragmentation, we measured the rates of P → C dimethylamine group transfer in **1***a* as a function of reaction medium, temperature, catalyst, and substituents introduced to the benzene ring.



SCHEME 6

Table 2 lists rate constants obtained for fragmentation of **1***a* (Scheme 4) in four solvents and at different temperatures. Because of the rapid solvolysis of the anhydride linkage in **1**, the choice of reaction media was obviously limited to non-hydroxylic solvents, and because of the kinetic method, only deuterated solvents were used. The accuracy of the kinetic measurements is not very high. There are at least two reasons for the relatively poor reproducibility of the individual k_1 values. Firstly, since the formation of **6***a* is slow (typical value for $t_{\frac{1}{2}}$ is at least 1 week), it is difficult to exclude participation of any competing reactions for **1***a*, such as nucleophilic cleavage of the anhydride system, or the disproportionation process. Secondly,

1*c*	Cl	2.2
1*d*	NO_2	2.4

fragmentation of **1***a* is subject to the catalytic effect of a variety of species (*vide infra*), so traces of impurities present in the substrate or in the reaction medium can affect the reaction rate. The general trend for the medium effects on reaction rate can, nevertheless, be obtained; the rate of fragmentation decreases in the following order of solvents employed: $CD_3CN > (CD_3)_2CO \approx CDCl_3 > CCl_4$. The variations in the k_1 values are, however, small (the maximum value of k_{rel}, $k_{CD_3CN}/k_{CCl_4} \approx 13$) and the observed order of reactivities follows only approximately the usual (9) solvent polarity scales. The small effect of solvents on the rate of fragmentation of **1***a* would support the mechanism involving the isopolar transition state (Scheme 6, path a). For comparison, a concerted fragmentation of 3-methyl-2,5-dihydrothiophen-1,1-dioxide shows almost negligible dependance on solvent change ($k_{sulfolane}/k_{n\text{-decane}} = 1.8$) (10), while the thermolysis of α-chlorobenzyl methyl ether, involving formation of the chloride–oxocarbonium ion pair, is subject to a dramatic solvent effect ($k_{CH_3CN}/k_{CCl_4} = 166\,000$) (11). Additional support for the mechanism involving little (if any) charge development in the transition state for the fragmentation was obtained from the substituent effects on the reaction rate (Table 3). Not only does substitution involving a change of 1.05 σ units (substrates **1***d* and **1***b*) result in merely a 1.7-fold variation in the rate, but the observed order of reactivities does not reflect the electron-donating or -withdrawing properties of substituents Z.[2] In the absence of any correlation of k_1 values with substituent constants σ_z, we attribute small variations in reaction rate listed in Table 3 to solvation effects of substituents Z, which can possibly influence the conformational flexibility of the anhydride system **1**, necessary for the amino group transfer to occur.

During the initial experiments on the fragmentation reaction it had been noted that the rate of benzamide formation depended on the presence of other species, e.g. the unreacted acyl chloride used for the preparation of **1**. We have determined the effect of added benzoyl chloride on the rate of fragmentation of pure **1***a*, and have supported the data by demonstrating the catalytic effect of another Lewis acid, iodine, on the reaction rate. The results are given in Table 4.

[a]Correlation coefficient for the slope of the ln k_1 *vs.* 10^3 $1/T$ plot.

In our opinion, the most plausible explanation for the catalytic effects presented in Table 4 is the stabilizing interaction between the added Lewis acid and the incipient benzamide molecule being formed via the transition state depicted in Scheme 6 (path a). The equilibrium constants for complexation of a variety of covalent halide compounds and carboxylic amides are of the order of $K = 10^2$–10^3 (13), and the formation of the adduct of **6***a* with iodine in CCl_4 at 25°C was found to be accompanied by a free energy change of −0.8 kcal/mol (14).

Rate data included in Table 2 enabled us to calculate activation parameters for the fragmentation of **1***a* in three solvents ($CDCl_3$, acetone-d_6, CD_3CN) (Table 5); the accuracy of the kinetic measurements in CCl_4 was too low to prepare a reliable Arrhenius plot.

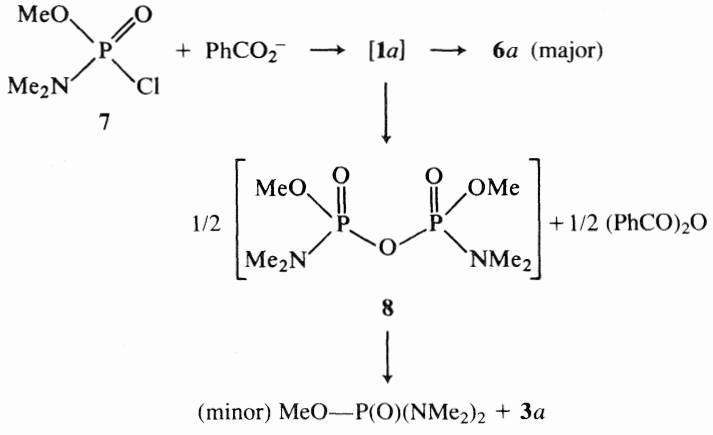
It can be seen from Table 5 that the decrease in the enthalpy of activation on moving from chloroform to acetone is largely compensated by the unfavourable change in activation entropy, resulting in small and ill-defined solvent effects on the reaction rate. The observed variations in the $\Delta S^{\ddagger}$ values indicate that in the chloroform–acetonitrile–acetone series a higher degree of solvent organisation is achieved in the transition state (relative to the initial state). We attribute these entropy changes to increasing nucleophilic solvation of the incipient methyl metaphosphate, effectively "freezing out" solvent molecules. Metaphosphate species are highly electrophilic by virtue of their readily accessible σ* and π* unoccupied orbitals (15), and their donor–acceptor interactions with solvents such as acetonitrile, as well as electrophile–nucleophile reactivity with respect to ketones, are well documented (16). Since ketones are stronger bases than nitriles, both in terms of HBA (17) and Brønsted (18) basicity, they also may be expected to interact more strongly than nitriles with such a powerful Lewis acid as $MeOPO_2$. As a result, activation entropy for NMe_2 group transfer is not far from zero for the poorly solvated transition state in $CDCl_3$ (and similar in magnitude to that obtained for thermal α,β-elimination of alkyl acetates (19)), but is highly negative in

[2]It may be noted at this point that the addition of semicarbazide (N-nucleophile) to aromatic aldehydes follows the Hammett equation with ρ = 0.9 (12).

acetone, where solvent molecules become involved in nucleophilic solvation of the metaphosphate formed. Solvent effects on the magnitude of the free enthalpy of activation are, however, large; $\Delta H^{\neq}$ is reduced by half when chloroform is replaced by acetone, and the intermediate value was obtained in acetonitrile. This result indicates that some polarity in the transition state (or intermediate) may be responsible for the observed dependence of $\Delta H^{\neq}$ on solvent polarity.[3] The order of the decrease in the $\Delta H^{\neq}$ values (Table 5) does not follow, however, the polarity of solvents involved, which increases in the order: chloroform < acetone < acetonitrile (9). This suggests that specific rather than general solvent effects operate in the transition state, with acetone being most effective in stabilizing the incipient metaphosphate product. It seems therefore that solvent effects on the activation parameters of the fragmentation are based on Lewis acid–base rather than dipole–dipole interactions.

In summary, we believe that the reaction represented in Scheme 4 probably does not involve significant charge development in the transition state (in the sense of distinct addition–elimination steps as shown in pathway b, Scheme 6), but is subject to both Lewis acid catalysis and nucleophilic solvation effects as a consequence of the nature of the reaction products.

Mixed anhydrides **1**, used as precursors for carboxyamides **6** (Scheme 3) were prepared by condensation of phosphate salts with carboxylic acid chlorides. The same anhydrides and, consequently, the same fragmentation products could be obtained by treating carboxylic salts with the corresponding phosphorochloridates. We have prepared **1***a* by the latter route, and decomposed it *in situ* to the expected product **6***a*. In this case, however, the reaction mixture contained small quantities of a new product that was absent in previous experiments, and which was subsequently identified as methyl *N,N,N',N'*-tetramethylphosphorodiamidate (**9**). The formation of this product can only be explained by partial disproportionation of **1***a* to benzoic anhydride and the pyrophosphoric diester diamide **8**, which then undergoes fragmentation with NMe_2 group transfer from one phosphoryl centre to another, yielding diamidoester **9** (Scheme 7).

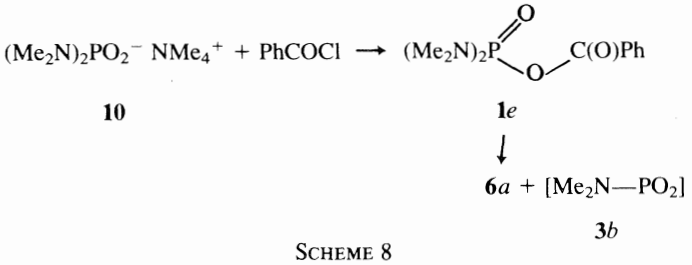


SCHEME 7

This result indicates that the selectivity in the non-nucleophilic cleavage (fragmentation vs. disproportionation) of the mixed anhydrides of the type **1** can be a sensitive function of reaction conditions and (or) the composition of the reaction mixture.

Related systems

Fragmentation represented in Scheme 2 has also been confirmed for anhydrides derived from diamidophosphoric acid. Mixed anhydride **1***e* (**1**, R = Ph; X = Y = NMe_2) has been prepared from benzoyl chloride and the tetramethylammonium salt of tetramethyldiamidophosphoric acid (**10**) and was found to yield, upon heating, benzamide (**6***a*), in a manner analogous to that of **1***a* (Scheme 8).



SCHEME 8

Reactivity of **1***e* relative to that of **1***a* is given in Table 6. The observed rate enhancement can be attributed to the greater stability (21) of the nitrogen-substituted metaphosphate systems, as compared with the PO_3-type species; such a difference should also be reflected in the transition states leading to products **3***a* and **3***b*, respectively.

In mixed anhydrides derived from dialkylphosphates (**1**, X = Y = OR), no migration of an alkoxy group OR from phosphoryl to carbonyl functions was observed. Dimethylbenzoyl phosphate **1***f* (**1**, R = Ph; X = Y = OMe), prepared either by condensation of dimethyl phosphorochloridate with benzoate anion (22) or from benzoyl chloride and dimethyl phosphate salt, disproportionated thermally to benzoic anhydride and tetramethyl pyrophosphate, but no methyl benzoate could be detected within the accuracy of ^1H nmr spectroscopy and tlc (thin-layer chromatography). Similarly, dimethylacetyl phosphate **1***g* (**1**, R = Me; X = Y = OMe), prepared from trimethyl phosphate and acetyl chloride (23), could be distilled, but upon storing at room temperature for a period of 6 months yielded significant quantities of acetyl anhydride and tetramethyl pyrophosphate with no evidence for any methyl acetate formed.

It seems, therefore, that the migratory (phosphoryl to carbonyl) aptitude of an amino group in a mixed anhydride system is much higher than that of an alkoxy substituent. Simple calculations, based on the magnitudes of the energies of the bonds being broken or formed during the fragmentation, show that the bond-energy changes that accompany amino group migration are ca. 18 kcal mol^{-1} more favourable than those expected for the OR group transfer. This difference could be responsible for shifting the reactivity of mixed anhydrides of the

[3]MO calculations on the fragmentation represented in Scheme 2 (**1**, X, Y = NH_2, OH; R = H) are currently being carried out (20). Although the results confirm in principle the concerted mechanism with no distinct intermediate occurring along the reaction coordinate, dipole moments calculated for the substrate, transition states, and products indicate some charge separation in the course of the reaction.

1*a*–**1***e* type towards the intramolecular amino group transfer rather than the bimolecular disproportionation reaction.

Experimental

Melting points (uncorrected) were determined on a Fisher–Johns apparatus. The ^{1}H nmr spectra were recorded on 60-MHz Varian EM 360 and 100-MHz Varian XL 100 spectrometers with TMS or DDS as internal standards. Aluminium-backed silica gel plates (Merck, Kieselgel 60 F_{254}) were used for tlc. Gas chromatography (gc) was performed on a gas chromatography Q Carlo Erba 4200 instrument using a 2-m column packed with 3% silicone SE-30 (G.C. Grade), and He as a carrier gas; FID, injection and detection temperature 250°C; ethyl benzoate as internal standard. Analyses for C, H, and N were carried out at the University of Cape Town. All solvents and commercial reagents were dried and purified by conventional means before use.

Materials

Dimethylphosphorochloridate was prepared from PCl_3, MeOH, and SO_2Cl_2 (24); 63%, bp 45°C (2 Torr) (lit. (24) bp 55–57°C (2–3 Torr) (1 Torr = 133.3 Pa)); ^{1}H nmr ($CDCl_3$) δ: 3.98 (d, J_{HP} 14 Hz). Methyl-*N*,*N*-dimethylphosphoroamidochloridate (**7**) was prepared from methylphosphorodichloridate and two equivalents of dimethylamine in ether with cooling in Dry Ice. Oil (69%); ^{1}H nmr ($CDCl_3$) δ: 2.72 (6H, d, J_{HP} 13 Hz, NMe_2), 3.85 (3H, d, J_{HP} 15 Hz, OMe). Tetramethylphosphorodiamidochloridate was prepared from $POCl_3$ and four equivalents of dimethylamine (25); 88%, bp 70–72°C (0.6 Torr) (lit. (25) bp 79–82°C (0.6 Torr)); ^{1}H nmr ($CDCl_3$) δ: 2.70 (d, J_{HP} 13 Hz). Dimethyl-*N*,*N*-dimethylphosphoramidate was prepared from dimethylphosphorochloridate and two equivalents of dimethylamine (26); 71%, bp 33°C (0.2 Torr) (lit. (26) bp 72°C (11 Torr)); ^{1}H nmr ($CDCl_3$) δ: 2.75 (6H, d, J_{HP} 10 Hz, NMe_2), 3.72 (6H, d, J_{HP} 11 Hz, OMe). Methyl-*N*,*N*,*N*′,*N*′-tetramethylphosphorodiamidate was prepared from the diamidochloridate and sodium methoxide in methanol; 44%, bp 46–48°C (0.5 Torr); ^{1}H nmr ($CDCl_3$) δ: 2.65 (12H, d, J_{HP} 10 Hz, NMe_2), 3.60 (3H, d, J_{HP} 11 Hz, OMe). Dimethyl-*N*-alkylphosphoramidates, $(MeO)_2P(O)NHR$, were prepared from dimethylphosphorochloridate and two equivalents of the corresponding amine in ether. After filtration, ethereal solutions were washed with water and dried, the solvent removed, and the products were used in further steps without purification; ^{1}H nmr ($CDCl_3$), R = Et, δ: 1.12 (3H, t, J_{HH} 7 Hz, β-Me), 2.97 (3H, m, CH_2 and N-H), 3.66 (6H, d, J_{HP} 11 Hz, OMe); R = i-Pr, δ: 1.18 (6H, d, J_{HH} 7 Hz, β-Me), 3.30 (1H, m, CH), 3.69 (6H, d, J_{HP} 12 Hz, OMe); R = *t*-Bu, δ: 1.28 (9H, s, β-Me), 3.70 (6H, d, J_{HP} 11 Hz, OMe).

Tetramethylammonium phosphates **4***a*,*c*,*d*,*e*, and $(MeO)_2PO_2^-$ NMe_4^+ were prepared according to the following procedure: 0.013 mol of a substrate was dissolved in 8 mL of dry acetonitrile and 14.5 mL of 5.4 *M* solution of trimethylamine in dry acetonitrile (ca. 6 mol-equivalents) were added. The solution was sealed in a glass tube and heated at 80°C overnight. After cooling, the precipitate was filtered off, washed quickly with cold, dry acetonitrile, and stored in a desiccator over P_4O_{10}. **4***a*: 76% (very hygroscopic); ^{1}H nmr (D_2O) δ: 2.60 (6H, d, J_{HP} 8 Hz, NMe_2), 3.21 (12H, s, NMe_4^+), 3.51 (3H, d, J_{HP} 10 Hz, OMe). *Anal.* calcd. for $C_7H_{21}N_2O_3P$: C 39.6, H 9.9, N 13.2%; found: C 39.1, H 9.9, N 14.3%. **4***c*, ^{1}H nmr (D_2O) δ: 1.09 (3H, t, J_{HH} 7 Hz, β-Me), 2.82 (2H, m, CH_2), 3.18 (12H, s, NMe_4^+), 3.45 (3H, d, J_{HP} 10 Hz, OMe). **4***d*, ^{1}H nmr (D_2O) δ: 1.09 (6H, d, J_{HH} 3 Hz, β-Me), 2.88 (1H, m, CH), 3.15 (12H, s, NMe_4^+), 3.75 (3H, d, J_{HP} 11 Hz, OMe). **4***e*, ^{1}H nmr (D_2O) δ: 1.25 (9H, s, β-Me), 3.20 (12H, s, NMe_4^+), 3.70 (3H, d, J_{HP} 11 Hz, OMe). $(MeO)_2PO_2^-$ NMe_4^+: 64% (as a monohydrate); ^{1}H nmr (D_2O) δ: 3.18 (12H, s, NMe_4^+), 3.55 (6H, d, J_{HP} 11 Hz, OMe).

Salt **10** could not be prepared in the same way since the starting methyl-*N*,*N*,*N*′,*N*′-tetramethylphosphorodiamidate proved unreactive towards demethylation by trimethylamine. **10** was prepared in the following way: $(Me_2N)_2P(O)Cl$ (0.022 mol) was added slowly with cooling and stirring to the aqueous solution of two mol-equivalents of tetramethylammonium hydroxide. Stirring was continued for 3 h, water was removed under reduced pressure, and the residue was dried by adding three times 20 mL of benzene and distilling to dryness. The final product consisted of equimolar quantities of **10** and NMe_4^+ Cl^-; 99.5%; ^{1}H nmr (D_2O) δ: 2.50 (12H, d, J_{HP} 10 Hz, PNMe), 3.10 (24H, s, NMe_4^+). *Anal.* calcd. for $C_{12}N_{36}N_4O_2PCl$: C 43.0, H 10.8, N 16.7%; found: C 42.5, H 11.1, N 15.7%. This product was used for the synthesis of **1***e* without further purification.

6*a* was prepared by adding benzoyl chloride to the solution of the equimolar quantity of dimethylammonium chloride in water containing three equivalents of NaOH, extracting with benzene, and removing benzene under reduced pressure; 85%; mp 40–42°C; ^{1}H nmr ($CDCl_3$) δ: 3.00 (6H, br s, NMe_2), 7.35 (5H, s, Ph). *Anal.* calcd. for $C_9H_{11}NO$: C 72.5, H 7.4, N 9.4%; found: C 72.6, H 7.4, N 9.4%. **6***f* was prepared by adding acetyl chloride to the solution of ca. 2.5 mol-equivalents of dimethylamine in ether, leaving the solution overnight, filtering, removing ether, and distilling the crude product; 20%; bp 34°C (0.2 Torr); ^{1}H nmr ($CDCl_3$) δ: 2.09 (3H, s, MeCO), 2.98 (6H, d, NMe_2). *Anal.* calcd. for C_4H_9ON: C 55.2, H 10.3, N 16.1%; found: C 54.6, H 10.3, N 15.8%.

Formation of amides **6** from salts **4** and acid chlorides **5** (Scheme 3): 1 mmol of **5** was added to a suspension of 1 mmol of **4** in 12 mL of dry acetonitrile and the mixture was stirred and heated under reflux for 4 h. After cooling, the white precipitate ($NMe_4^+Cl^-$) and glassy material (presumably polymeric methyl metaphosphate) were removed by filtration, washed with acetonitrile, and the solvent removed under reduced pressure. Examination of the residue by ^{1}H nmr ($CDCl_3$), tlc, or gc indicated that amides **6** were the only products present. Individual products were identified by comparison with authentic samples or by comparing their ^{1}H nmr spectra with those reported in the literature (27).

Synthesis of mixed anhydrides **1**

1*a*: **4***a* (3.5 mmol) was suspended in dry acetonitrile (20 mL) and a solution of **5***a* (2.6 mmol) in acetonitrile (20 mL) was added dropwise with stirring at room temperature. Stirring was continued for 3 h, dry CCl_4 (10 mL) was added, the mixture was filtered, and the solvent was removed under reduced pressure. CCl_4 (10 mL) was added, the mixture filtered again, and solvent removed. The resultant product was stored in the refrigerator; 93% (based on **5***a*); oil; ^{1}H nmr ($CDCl_3$) δ: 2.80 (6H, d, J_{HP} 11 Hz, NMe_2), 3.90 (3H, d, J_{HP} 12 Hz, OMe), 7.45 (3H, m, *m*+*p* arom.), 8.10 (2H, m, *o*-arom.). *Anal.* calcd. for $C_{10}H_{14}NO_4P$: C 49.4, H 5.8, N 5.8%; found: C 49.2, H 5.9, N 5.8%. Anhydrides **1***b*–**1***f* were prepared in the analogous way. **1***b*: oil; ^{1}H nmr ($CDCl_3$) δ: 2.75 (6H, d, J_{HP} 11 Hz, NMe_2), 3.85 (3H, s, C-OMe), 3.88 (3H, d, J_{HP} 11 Hz, P-OMe), 6.95 (2H, d, J_{HH} 10 Hz, 3,5-H_2), 8.05 (2H, d, J_{HH} 10 Hz, 2,6-H_2). *Anal.* calcd. for $C_{11}H_{16}NO_5P$: C 48.4, H 5.9, N 5.1%; found: C 47.8, H 6.2, N 5.1%. **1***c*: solid; ^{1}H nmr ($CDCl_3$) δ: 2.78 (6H, d, J_{HP} 11 Hz, NMe_2), 3.85 (3H, d, J_{HP} 12 Hz, OMe), 7.35 and 8.00 (2 × 2H, d, J_{HH} 10 Hz, 3,5-H_2 and 2,6-H_2). *Anal.* calcd. for $C_{10}H_{13}NO_4ClP$: C 43.2, H 4.7, N 5.0%; found: C 43.2, H 4.8, N 5.2%. **1***d*: solid; ^{1}H nmr ($CDCl_3$) δ: 2.80 (6H, d, J_{HP} 11 Hz, NMe_2), 3.92 (3H, d, J_{HP} 12 Hz, OMe), 8.33 (4H, m, arom.-H). *Anal.* calcd. for $C_{10}H_{13}N_2O_6P$: C 41.7, H 4.5, N 9.7%; found: C 41.8, H 4.8, N 9.8%. **1***e*: oil; ^{1}H nmr ($CDCl_3$) δ: 2.85 (12H, d, J_{HP} 11 Hz, NMe_2), 7.60 (3H, m, *m*+*p* arom.), 8.20 (2H, m, *o*-arom.). Since **1***e* always contained small quantities of $NMe_4^+Cl^-$, no satisfactory analysis was obtained for this product. **1***f*: oil; ^{1}H nmr ($CDCl_3$) δ: 3.95 (6H, d, J_{HP} 12 Hz, OMe), 7.45 (3H, m, *m*+*p* arom.), 8.10 (2H, m, *o*-arom.). *Anal.* calcd. for $C_{10}H_{11}O_5P$: C 47.0, H 4.8%; found: C 45.8, H 4.8%.

Reaction of **3**a *with* N-*methylaniline* (Scheme 5)

1*a* (20 μL) and *N*-methylaniline (22 μL) were dissolved in CD_3CN (0.4 mL) in the nmr tube; the tube was sealed and heated in a water bath at 50°C for 59 h. The final spectrum showed complete disappearance of **1***a* and the presence of signals expected for **6***a* and the salt **4***f*. Products **6***a* and **4***f* were identified by comparing the ^{1}H nmr spectrum of the reaction solution with the ^{1}H nmr characteristics of **6***a* obtained for the authentic sample of this compound, and of **4***f*, as reported in the literature (8). **6***a*, δ: 3.05 (6H, br s), 7.40 (5H, s). **4***f*, δ: 2.90 (3H, s,

NMe^+), 3.20 (3H, d, J_{HP} 9 Hz, P-NMe), 3.70 (3H, d, J_{HP} 11 Hz, OMe), 7.20 (10H, m, 2 × Ph) (lit. (8) δ: 2.9 (3H, s), 3.2 (3H, d, J_{HP} 8 Hz), 3.7 (3H, d, J_{HP} 12 Hz), 7.3 (10H, m)).

Reaction of ***7*** *with benzoic acid* (Scheme 7)

A solution of **7** (13 mmol) in acetonitrile (30 mL) and ether (10 mL) was added dropwise with stirring and cooling to a solution of benzoic acid (10 mmol), triethylamine (6 mmol), and DMF (10 mmol) in acetonitrile (30 mL). The mixture was then heated under reflux for 1 h, ether (50 mL) was added, the mixture was filtered, and solvents were removed under reduced pressure. The oily product was dissolved in chloroform (35 mL), washed with water (3 × 20 mL), dried, and evaporated under reduced pressure. The ^{1}H nmr of the product indicated the presence of ***6a*** (δ 3.05, 6H, br s; 7.4–8.1, 5H, m) and another, phosphorus-containing product (δ 2.68, 12H, d, *J* 10 Hz; 3.68, 3H, d, *J* 11 Hz). The product was separated by gc yielding **9** (9%, t_R 4.6 min) and ***6a*** (58%, t_R 9.7 min), which were identified by comparison with authentic samples.

Reaction of ***10*** *with* ***5****a* (Scheme 8)

10 (9.8 mmol) was suspended in dry acetonitrile (10 mL) and a solution of ***5a*** (6.6 mmol) in acetonitrile (15 mL) was added dropwise with stirring. The mixture was then heated under reflux for 4 h, cooled, filtered, and the solvent removed under reduced pressure. The resultant solid product was recrystallized from petroleum ether (bp 30–40°C) and identified as ***6a***; mp 39–41°C. When the reaction was carried out at room temperature and aliquots (4 mL) were withdrawn at intervals and worked up as before, the intermediate formation of ***1e*** was demonstrated by ^{1}H nmr spectroscopy (δ 2.80, 12H, d, J_{HP} 11 Hz, NMe_2).

Reaction of $(MeO)_2PO_2^-$ *with* ***5****a*

Tetramethylammonium dimethylphosphate (1.5 mmol) was suspended in dry acetonitrile (15 mL) and ***5a*** (1.55 mmol) in acetonitrile (15 mL) was added with stirring at room temperature. Stirring was then continued at room temperature for 3.5 h with removal of aliquots (4 mL) at various times; all aliquots were filtered, evaporated under reduced pressure, and the residue examined by ^{1}H nmr spectroscopy ($CDCl_3$). After carrying out the reaction for 3.5 h at room temperature, the mixture was heated under reflux for 4 h, again with removal of aliquots, which were worked up as before. Spectra obtained before heating showed the appearance of a new product (δ 3.99, d, J_{HP} 10 Hz), identified as dimethylbenzoyl phosphate. After 1 h of heating under reflux, however, this product had disappeared almost entirely and a new product had appeared (δ 3.72, d, J_{HP} 10 Hz), and remained unchanged over the period of further heating. This product was identified as tetramethyl pyrophosphate. No methyl benzoate or trimethyl phosphate were found in the reaction mixture, as demonstrated by the addition of authentic samples. The mixture of dimethylbenzoyl phosphate and tetramethyl phosphate was also obtained when dimethyl phosphorochloridate was allowed to react with benzoic acid in acetonitrile in the presence of triethylamine and DMF and the product distilled under reduced pressure (bp 120–125°C (0.5 Torr)).

Reaction of trimethyl phosphate with ***5****b*

Trimethyl phosphate (0.113 mol), ***5b*** (0.073 mol), and triethylamine (2 drops) were heated at 56–58°C for 12 h (23). Distillation of the product yielded dimethylacetyl phosphate; bp 68–71°C (0.2 Torr); ^{1}H nmr ($CDCl_3$) δ: 2.20 (3H, s, C-Me), 3.90 (6H, d, J_{HP} 11.5 Hz, OMe). The ^{1}H nmr of this product, recorded after 6 months of standing at room temperature, showed that marked changes had taken place: new signals appeared at δ 2.08 (s) and δ 3.78 (d, J_{HP} 10 Hz). These signals were assigned to acetic anhydride and tetramethyl pyrophosphate, as confirmed by addition of authentic samples. Again, no methyl acetate or trimethyl phosphate could be detected in the reaction mixture.

Rate measurements

In a typical run, mixed anhydride (20 μL) was dissolved in deuterated solvent (0.4 mL) in an nmr tube, and the tube was sealed and incubated in a thermostatted water bath of the required temperature. Progress of reaction was monitored periodically by ^{1}H nmr: the amount of carboxyamide product present at various times was calculated as a percentage by determining the ratio

$$X(\%) = \frac{100A}{A + B}$$

where A = increment (per proton) for the carboxyamide measured from integration of the $C(O)NMe_2$ signal at δ ca. 3.0 (in mm/H); and B = increment (per proton) for the anhydride substrate measured from integration of the $P(O)NMe_2$ signal at δ ca. 2.75 (mm/H). The value of $X(\%)$ was then substituted into the first-order rate law term:

$$k_1 t = \ln\left(\frac{100}{100 - X}\right)$$

Reactions were followed to ca. 70% completion. All runs gave linear plots with r values of 0.990–0.995.

Since the rates of fragmentation are sensitive to the presence of various substances (see Discussion), great care was taken to make certain that the rate constants used for determination of relative reactivity, solvent or catalytic effects, and temperature effects were obtained, as far as possible, under identical conditions. For example, the Arrhenius plots (Table 2) were obtained for each solvent by carrying out all kinetic measurements simultaneously and using the same sample of ***1a*** and the same bottle of solvent. Similarly, the effect of catalyst (Table 4) was measured using the same sample of ***1a*** for all runs, and the effect of substituents (Table 3) was determined using the same $CDCl_3$ as a solvent.

Contraction de cycle dans la substitution d'un triflate osidique

ANNIE GROUILLER

Service de chimie biologique de l'Institut national des sciences appliquées de Lyon, Bâtiment 406, 20 Avenue A. Einstein, 69621 Villeurbanne CEDEX, France

Reçu le 4 novembre 1985

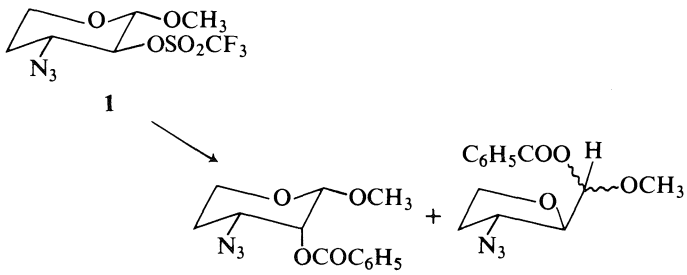
ANNIE GROUILLER. Can. J. Chem. **64**, 1709 (1986).

La substitution nucléophile par le benzoate de sodium du trifluorométhanesulfonate en 2 de l'azido-3 (ou du *O*-benzoyl-3) désoxy-4 α-DL-*thréo*-pentopyrannoside de méthyle (**1** ou **4**) procède avec une contraction du cycle pyrannose en cycle furannose, en C-2. Cette contraction n'est nullement observée lors d'une substitution avec l'azoture de lithium.

ANNIE GROUILLER. Can. J. Chem. **64**, 1709 (1986).

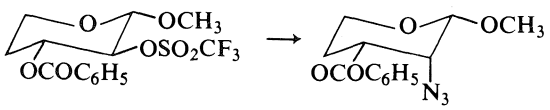
Benzoate displacement of the 2-triflyl derivative of methyl 3-azido or 3-*O*-benzoyl-4-deoxy-α-DL-*threo*-pentopyranoside (**1** or **4**) occurs with a pyranose to furanose contraction reaction at C-2. This contraction is not observed with an azido displacement.

Différentes contractions du cycle pyrannosique en cycle furannosique ont été récemment observées lors de la substitution nucléophile de sulfonates (1) ou au cours de leur désulfonyloxylation réductive (2). Nous-mêmes, dans le cadre d'un programme de synthèse d'azido-nucléosides à squelette désoxy-pentopyrannosyle (3), nous avions observé (4) que le traitement par le benzoate de sodium de l'anomère α de l'azido-3 didésoxy-3,4 *O*-trifluorométhanesulfonyle-2-DL-*thréo*-pentopyrannoside de méthyle (**1**) conduisait à un mélange de deux composés : le dérivé benzoylé attendu **2** de substitution et en quantité prépondérante le produit **3** de contraction du cycle pyrannose en cycle furannose.[1]



1 **2** **3**

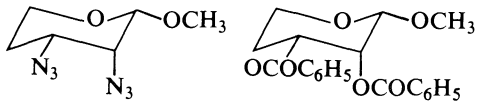
Ce résultat avait été interprété comme provenant d'une part de l'encombrement stérique dû aux conformations équatoriales des groupements méthoxyle et azido, d'autre part de la relation antipériplanaire qui existait entre la liaison C-1/oxygène hétérocyclique et celle C-2/sulfonate. Par la suite, nous avons constaté (5) que le triflate **4**, traité dans les mêmes conditions par de l'azoture de lithium ne donnait naissance qu'à la formation du produit de substitution **5**. Or la configuration et la conformation des deux triflates **1** et **4** étaient la même. Seules changeaient la nature du groupement porté par le sucre en position 3 et celle du nucléophile utilisé.



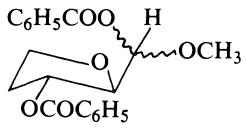
4 **5**

Pour discerner quel était le facteur déterminant, nous avons alors traité, toujours dans les mêmes conditions, d'une part l'azido-sucre **1** par l'azoture de lithium, d'autre part le benzoate **4** par le benzoate de sodium: dans le premier cas nous n'observons pas de contraction de cycle, mais que la formation du dérivé diazido de substitution **6**; dans le second cas, à côté du dibenzoate **7**, le produit de contraction de cycle **8** est formé dans un rapport de 3:2,5. Ces différents composés ont été purifiés et séparés par chromatographie sur colonne de gel de silice. Ils ont été identifiés d'après leur spectre de masse et leurs spectres de rmn du proton et du carbone 13.

Nous pouvons alors conclure que contrairement à l'hypothèse émise précédemment par nous (4) et par d'autres auteurs (6) pour expliquer cette contraction de cycle, l'attaque intramoléculaire du nucléophile par l'arrière du cycle sur le carbone 2 n'est pas dûe à la conformation de la molécule, mais à la nature du nucléophile utilisé : elle a lieu aussi bien avec le radical azido qu'avec le groupement benzoyle en position 3 équatoriale, à condition que le nucléophile utilisé soit le benzoate de sodium et non l'azoture de lithium. Généralement, la substitution S_N2 de



6 **7**



8

sulfonates en 2 de pyrannosides par des nucléophiles chargés est difficile et bien souvent impossible à cause d'un alignement défavorable des dipôles formés dans l'état de transition (7), sauf si le sulfonate est un triflate, excellent nucléofuge (8). Cependant, dans le cas de l'ion benzoate qui présente une concentration plus élevée en charge négative que l'ion azoture, l'attaque d'un triflate selon un mécanisme S_N2 est peut-être plus difficile qu'avec N_3^- : un déplacement interne (ou une contraction de cycle) peut alors entrer en compétition ou même devenir l'évènement principal.

Ces produits de contraction de cycle nous ouvrent une voie intéressante à la synthèse de C-nucléosides.

Partie expérimentale

Appareils et méthodes

La purification des composés a été réalisée par chromatographie sur gel de silice (Kieselgel 60 F_{254}, Merck 10757). Les spectres de rmn ont été enregistrés par le Service de rmn de la Faculté de Pharmacie de

[1]Tous nos composés sont racémiques; les formules représentent un seul énantiomère.

Marseille à 200 MHz pour ^1H et 50,3 MHz pour ^{13}C. Les déplacements chimiques sont exprimés en ppm, le tétraméthylsilane étant pris comme référence zéro. Les spectres de masse ont été obtenus en ionisation chimique (NH_3) par le Service Central d'Analyse du CNRS à Solaize.

Protocole général

Une solution de triflate (1,66 mmol) dans de l'hexaméthylphosphoramide (40 mL) est chauffée 5 h à 90°C avec 1,5 équiv. d'azoture de lithium (130 mg) ou de benzoate de sodium (360 mg). Le mélange réactionnel est versé sur de l'eau (50 mL) et extrait par de l'éther (200 mL). La phase organique est séchée sur sulfate de magnésium et évaporée sous pression réduite. Le résidue obtenu est purifié par chromatographie sur colonne sèche de gel de silice.

*Diazido-2,3 tridésoxy-2,3,4 α-DL-*érythro *pentopyrannoside de méthyle (**6**)*

Huile à partir de **1** (4) et d'azoture de lithium; rendement, 71%; R_f 0,68 (acétate d'éthyle – hexane, 1:1); ^1H rmn ($CDCl_3$) δ : 4,43 (d, $J_{1,2}$ = 2,0 Hz, H-1), 4,15–4,0 (sext, $J_{3,4a}$ = 3,6, $J_{3,4b}$ = 11 Hz, H-3), 3,73 (q, $J_{2,3}$ = 3,6 Hz, H-2), 3,67–3,38 (m, H-5a,b), 2,10–1,72 (m, H-4a,b); ^{13}C rmn ($CDCl_3$) δ : 100,8 (C-1), 61,1 (C-2), 60,3 (C-5), 58,3 (OCH_3), 58,0 (C-3), 26,3 (C-4); sm *m/e* : 216 (MNH_4^+).

An MNDO study of dipyridopyrazinium and relation cations: instability of certain fused heteroaromatic dications with two bridgehead nitrogens

JEFFREY G. EAVES, DAVID PARKER,[1] AND NIGEL RUDGEWICK-BROWN
Department of Chemistry, University of Durham, South Road, Durham DH1 3LE, U.K.

Received February 3, 1986

JEFFREY G. EAVES, DAVID PARKER, and NIGEL RUDGEWICK-BROWN. Can. J. Chem. **64**, 1711 (1986).

MNDO calculations are reported for the series of closed shell aromatic and heteroaromatic molecules and cations **1** to **7**. The 14π dipyrido-dications **1***a* and **2***a* are considerably less stable than their dihydro-analogues **1***b* and **2***b* and perhaps should not be considered to be "aromatic" cations.

JEFFREY G. EAVES, DAVID PARKER et NIGEL RUDGEWICK-BROWN. Can. J. Chem. **64**, 1711 (1986).

On rapporte des calculs MNDO effectués sur la série des molécules et des cations aromatiques et hétéroaromatiques **1** à **7** à couches fermées. Les dipyridodications **1***a* et **2***a* à 14 électrons π sont beaucoup moins stables que leurs analogues dihydro **1***b* et **2***b*; on ne devrait peut-être pas les considérer comme des cations "aromatiques".

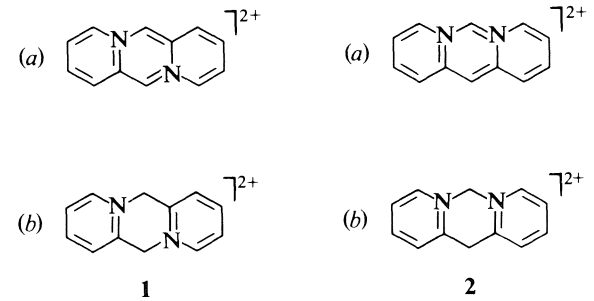
[Traduit par la revue]

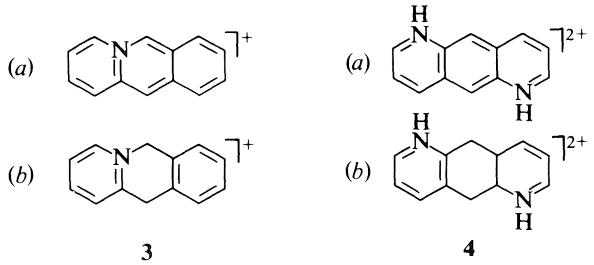
Introduction

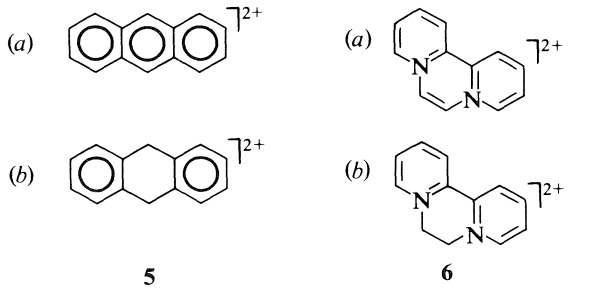
The series of condensed heteroaromatic systems which incorporates pyridinium cations has been studied in detail, mainly as a result of the herbicidal activity of certain derivatives (1). More recently, dipyridinium cations have been shown to be components of a novel class of organic metals (2). However, the dipyrido[1,2-*a*:1′,2′-*d*]pyrazinium ring system, **1**, and the related pyrimidinium cation **2** have been relatively poorly studied (3, 4). We have recently been studying the structure and reactivity of some dipyridopyrazinium cations (4). During the course of this work it became apparent that the putative aromatic cations **1***a* and **2***a* had not been defined. These dications are of particular interest as they may be expected to accept an electron readily, forming stable radical cations, as required for efficient herbicidal action. There was a need therefore to assess the relative stability of these dications compared to their dihydro-analogues, **1***b* and **2***b*, relating this to a series of mono- and dications of comparable structure, **3** to **7**. This series was chosen in order to compare the effect of varying overall charge, π-electron number and the location of the nitrogen atoms (i.e. at bridgehead positions or otherwise).[2] The cations selected include the commercial herbicide "diquat" **6***b* (5), and its dehydro-analogue **6***a* both of which are well-defined dications. The 12π anthracene dication, **5***a*, is also included. It has been characterised electrochemically recently (6) and was shown to be highly unstable with a life-time of the order of seconds at −50°C in liquid sulphur dioxide.

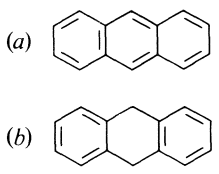
Discussion and results

A series of geometry optimised MNDO molecular orbital calculations has been undertaken in order to compare the relative stability of **1***a* and **2***a* and their dihydro analogues, **1***b* and **2***b*, to the related aromatic and heteroaromatic systems **3** to **7**. The calculations were carried out using Dewar's MNDO program (9) with the aid of a CDC 7600 or an IBM 370/168 computer. The geometric parameters were optimised and the appropriate point-group symmetry of **1** to **7** was utilised where necessary. It was therefore assumed that the aromatic species **1***a* to **7***a* were flat.









[1]To whom all correspondence should be addressed.

[2]Some of these systems have been examined previously using a semi-empirical PPP-SCFMO method (7, 8).

TABLE 1. MNDO calculated gas-phase enthalpies of formation[a] (kcal mol^{-1})

	ΔH_f^θ (**1***a*–**7***a*)	ΔH_f^θ/dihydro analogue (**1***b*–**7***b*)	$\delta(\Delta H_f^\theta)_{calcd}$ **n**(*a*) − (*b*)
1	495.8	457.5	+38.3
2	496.8	458.2	+38.6
3	225.3	204.6	+20.7
4	451.6	429.9	+21.7
5	504.8	544.4	−39.6
6	483.5	463.3	+20.2
7[b]	58.9 (55.2)	37.8 (38.2)	+21.1 (17.0)

[a]The mean absolute error in values has been calculated to be 7.2 kcal mol^{-1} for cationic systems and 6.3 kcal mol^{-1} for neutrals (9).
[b]Experimental value is given in parentheses (10).

(i) Heats of formation

In Table 1 the calculated gas-phase enthalpies of formation for the "aromatic" systems **1***a* to **7***a* are compared with the values for the corresponding dihydro systems, **1***b* to **7***b*. A striking feature of this comparison is the high *difference* in heats of formation ($(\delta\Delta H_{f\,calcd}^\theta)$, column 3) for **1** and **2** (38.5 kcal mol^{-1}) compared to **3**, **4**, **6**, and **7** where the difference averages 20.9 kcal mol^{-1}. The heats of formation for the pyrazinium and pyrimidinium dications **1***a* and **2***a* and the anthracene dication **5***a* are quite similar, despite the fact that the former are formally 14π aromatic dications and the latter is an anti-aromatic 12π system. This suggests that **1***a* and **2***a* are uniquely unstable within the series considered. The calculated difference in enthalpy of formation for **6***a* and **6***b* is 20.2 kcal mol^{-1}, in line with **3**, **4**, **6**, and **7** but in contrast to **1** and **2**. It would seem that the instability of **1***a* and **2***a* is not simply associated with the occurrence of two bridgehead nitrogens, as occurs also in **6***a* and **6***b*.

In the case of anthracene, experimental and calculated heats of formation may be compared (10). Both sets of values fall within the mean error of the calculation, as expected for such simple molecules (9). Finally it is worth noting that the conjugated 12π dication **5***a*, is notably more stable than its (5+5)π dihydro analogue, **5***b*. In the latter case the dication may be considered as two independent 5π aryl cations in which the positive charge is localised within each of the outer rings.

(ii) Molecular geometries and frontier orbital energies

For the series **1***a* to **7***a* it was expedient to assume that the cations and molecules were flat with the appropriate point-group

TABLE 2. Selected frontier molecular orbitals[a]

Compound	HOMO (energy/eV)	NHOMO (energy/eV)	LUMO (energy/eV)
1*a*	−16·5 	−18·4 	−10·3 2*a*	−16·6 	−18·1 	−10·1 3*a*	−12·4 	−13·6 	−5·5 4*a*	−16·7 	−17·5 	−9·5 5*a*	−17·2 	−17·5 	−11·3 6*a*	−17·6 	−17·7 	−9·7 6*b*	−17·5 	−18·7 	−9·6 7*a*	−8·0 	−9·0 	−0·8

symmetries.[3] For the dihydro-systems **1***b*, **2***b*, **3***b*, **4***b*, **6***b*, and **7***b* the central ring is calculated to be non-planar with dihedral angles between the planes of the two aromatic rings of 148, 149, 141, 153, 10, and 141°, respectively. The experimental values from the reported X-ray structures of **1***b* (4), **6***b* (11), and **7***b* (12) are 141, 20, and 145° showing reasonable agreement bearing in mind the perturbing influence on cation molecular geometry of nearest anions (4, 11) and crystal packing effects. Generally, the calculated and experimental bond lengths show good agreement.

The C(1)—C(9) bond length for the central ring of the "diquat" derivative **6***a* is calculated to be 1.36 Å in close agreement with both the experimental value of 1.35 Å and the commonly accepted bond length for an isolated alkene bond of 1.34 Å. This correlation suggests that the bond is perhaps best regarded as olefinic rather than aromatic in character. This is similar to the behaviour of the C(9)—C(10) double bond in phenanthrenes, although this point was overlooked by workers dicussing the crystal structure of **6***b* (5).

(iii) Charge distribution and frontier molecular orbitals.

Within the heteroaromatic rings of the dihydro systems **1***b*, **2***b*, **3***b*, **4***b*, and **6***b*, a pronounced $+/-$ alternation of net atomic charge density is consistently found. This may be associated with effective *delocalisation* of charge around the pyridinium ring. Such charge alternation is also found for the two outer rings in **6***a*: indeed the calculated values accord closely with those of **6***b*. This suggests that in **6***a* the positive charge is not effectively delocalised into the central ring and that **6***a* effectively behaves like **6***b* with a linking, but only weakly conjugating double bond. In the 14π systems **3***a* and **4***a*, such charge alternation is also observed in each heterocyclic ring.

Effective charge delocalization, as evidenced by this $+/-$ charge alternation, *does not* occur to such an extent with **1***a*, **2***a*, and **5***a*. In these three systems, there is a localization of charge on the ring atoms, which presumably must destabilise the system, raising its overall energy (as evidenced by their high heats of formation with respect to the dihydro analogues, Table 1). Again it is worth noting that the anthracene dication is behaving in a similar manner to the putative aromatic systems **1***a* and **2***a*. Further insight into the relative stability of these systems comes from an examination of their frontier molecular orbitals, Table 2. Examination of the calculated eigenvector matrix gives the atomic orbital coefficients for each molecular orbital from which the pictorial MO's shown in Table 2 have been simply derived. Inspection of Table 2 reveals that in the two highest-occupied MO's of **1***a*, **2***a*, and **5***a*, no π orbital overlap through the central ring occurs. This presumably may be related to the lack of charge delocalisation discussed above. In contrast, effective π-orbital overlap through the central ring is consistently observed in the HOMO or NHOMO for **3***a*, **4***a*, and **7***a*.

Given the similarity of **1***a* and **2***a* to the 12π anthracene dication **5***a*, it is tempting to speculate that they may not reasonably be termed "aromatic", despite the fact that they formally contain 14π-electrons in a conjugated, cyclic array. Their inherent instability, as manifested by the high differential heat of formation with respect to their dihydro-analogues, the lack of effective charge delocalisation around the ring and by the fact that they have eluded preparation, clearly sets them apart from the related systems considered in this study.

[3]Tables of frontier orbital energies, molecular bond lengths, and atomic charge densities are available from the authors, on request.

Kinetic and equilibrium studies of the σ-adduct forming reactions of 1,3,5-trinitrobenzene and picryl chloride with some carbon bases

MICHAEL R. CRAMPTON, TERENCE P. KEE, AND JENNIFER R. WILCOCK
Department of Chemistry, Durham University, Durham, DH1 3LE, England

Received February 19, 1986

MICHAEL R. CRAMPTON, TERENCE P. KEE, and JENNIFER R. WILCOCK. Can. J. Chem. **64**, 1714 (1986).

Reaction of 1,3,5-trinitrobenzene (TNB) with the malononitrile anion in methanol yields a carbon-bonded σ-adduct, (**3**). Ionisation of the remaining exocyclic hydrogen is favourable and yields the dianion (**4**). The initial reaction of 1-chloro-2,4,6-trinitrobenzene similarly occurs at an unsubstituted ring position, but is followed by slower nucleophilic attack at the 1-position yielding the substituted product. A major difference in the reaction of the ethyl malononitrile anion with TNB is that the adduct formed (**11**) has no readily dissociable proton. Hence, here, conversion to the carbon-bonded adduct is less favourable. Kinetic and equilibrium data are reported for these reactions and are compared with data for adduct formation involving methoxide ions.

MICHAEL R. CRAMPTON, TERENCE P. KEE et JENNIFER R. WILCOCK. Can. J. Chem. **64**, 1714 (1986).

La réaction du trinitro-1,3,5 benzène (TNB) avec l'anion malononitrile, dans le méthanol, conduit à un produit conduisant à la formation d'un adduit-σ lié à un carbone (**3**). L'ionisation de l'hydrogène exocyclique résiduel est favorable et conduit au dianion **4**. La réaction initiale du chloro-1 trinitro-2,4,6 benzène se produit de la même manière à la position non-substituée du cycle; toutefois, elle est suivie d'une attaque nucléophile plus lente au niveau de la position 1 qui conduit au produit substitué. Une différence importante dans la réaction de l'anion éthylmalononitrile avec le TNB est que l'adduit qui se forme, **11**, ne porte pas de proton dissociable. Alors, sa conversion en un adduit lié par le carbone est moins favorable. On rapporte les données cinétiques et d'équilibre de ces réactions et on les compare avec les données obtenues pour la formation d'adduits impliquant les ions méthylates.

[Traduit par la revue]

Many carbon-bonded σ-adducts have been characterised from the reactions of activated aromatic molecules with carbon bases (1, 2). However, relatively few kinetic studies of these systems have been reported, due in part to the difficulty of generating the nucleophiles under conditions suitable for such studies. A notable exception here is the work of Kaválek, Štěrba, and co-workers which showed that carbanions generated from malonic acid derivatives were suitable nucleophiles (3–5).

In this paper we report kinetic and equilibrium data for the reactions of malononitrile anion with 1,3,5-trinitrobenzene and with picryl chloride (1-chloro-2,4,6-trinitrobenzene) in methanol, and equilibrium data for reaction of the ethyl malononitrile anion with 1,3,5-trinitrobenzene. The results are important in that the equilibrium constants give a measure of the carbon basicities of the nucleophiles (thermodynamic affinity for carbon) while the rate constants measure their nucleophilicity and nucleofugality. There is current interest in the comparison of these quantities for different types of nucleophile, and in different types of reaction (6, 7).

Results and discussion

Acidities of malononitrile and ethyl malononitrile in methanol

The pK_a of malononitrile in water is reported (7–10) as 11.2. Carbanions were generated in methanol, as shown in reaction [1], by reaction of (**1**, R = H, Et) with methoxide ions. Values of K_{CH} determined spectrophotometrically are in Tables 1 and 2. These values are related by eq. [2] to K_a, the acid dissociation constants of the carbon acids and K_M, the autoprotolysis constant of methanol. Since the value (11) for pK_M is 16.92 we obtain values for pK_a in methanol for (**1**, R = H) of 14.14 and for (**1**, R = Et) of 15.60. The acid weakening effect of the ethyl group may be attributed partially to its polar effect and partially to steric inhibition of solvation of the anion (11).

$$[1]\quad \underset{\mathbf{1}}{RCH(CN)_2} + MeO^- \overset{K_{CH}}{\rightleftharpoons} \underset{\mathbf{2}}{RC(CN)_2^-}$$

$$[2]\quad K_{CH} = K_a/K_M$$

[b]Absorption is due to carbanion. These are initial values determined by stopped flow spectrophotometry. Values correspond to cell of 1 cm path length.
[c]Calculated as $(A - 0.01)/(1.49 - A)[NaOMe]_{eq}$ where A represents absorbance.

Reaction of malononitrile anion with 1,3,5-trinitrobenzene (TNB)

Our results are best interpreted by Scheme 1 which allows for the reaction of TNB with methoxide ions to produce **5**. This reaction, which is known to be very rapid on the stopped-flow timescale (12) and for which K_{OMe} has (13) the value 17 L mol^{-1}, was minimized by working with [MeO$^-$] ≤ 0.01 M. In all cases the fraction of substrate present in the form of **5** *at equilibrium* was negligibly small. The visible spectrum of the TNB-malononitrile adduct present at equilibrium had λ_{max} at ca. 450 nm with a shoulder at longer wavelength and was typical of 1:1 adducts of TNB with carbon bases (2). However, small variations of spectral shape were observed depending on the residual concentration of methoxide ions and provide evidence

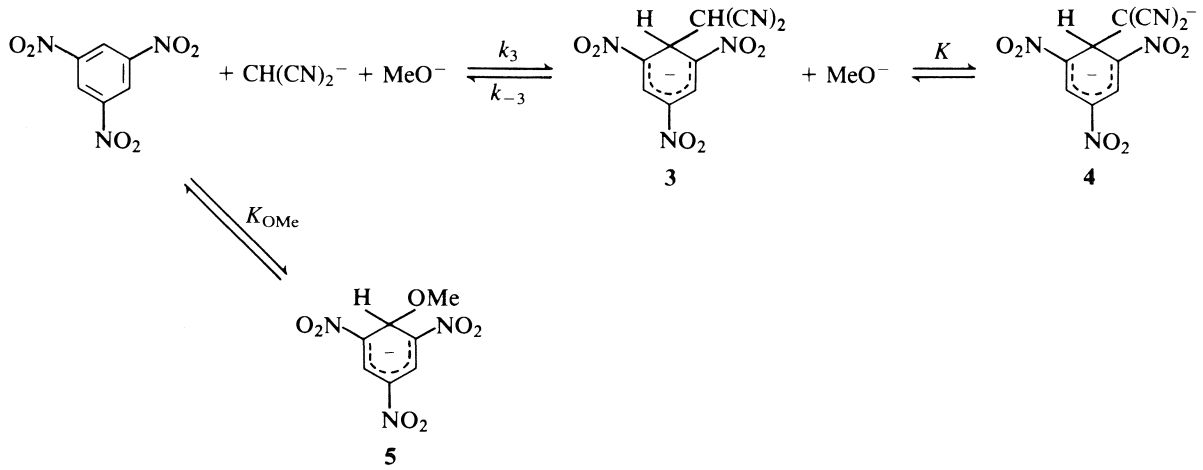

SCHEME 1

for the ionisation **3** ⇌ **4**. With [MeO$^-$] > 10^{-3} M, the spectrum had λ_{max} 460 nm, 520 (sh) and is attributed to the dianion **4**, while with [MeO$^-$] < 10^{-4} M (in buffer solutions) the spectrum showed λ_{max} 440 nm, 525 sh indicating the predominance of **3**. It is to be expected that the adduct **3** should be a stronger acid than malononitrile since it is known that the $C_6H_2(NO_2)_3^-$ group, although negatively charged, is electron withdrawing relative to hydrogen (14, 15).

Kinetic measurements were made by stopped-flow spectrophotometry, one syringe containing a mixture of TNB and malononitrile in methanol and the other a solution of sodium methoxide in methanol. We worked with concentrations [NaOMe] ≫ [malononitrile] ≫ [TNB] and a single first order process was observed in the visible region. Rate constants are in Table 3. The proton transfers involving the formation of the malononitrile anion, and the equilibration of **3** and **4** are expected to be fast on the stopped-flow time-scale (16). On that basis, and allowing for the rapid equilibrium formation of **5** we obtain eq. [3]

$$[3] \quad k_{obs} = \frac{k_3[CH(CN)_2^-]}{1 + K_{OMe}[MeO^-]} + \frac{k_{-3}}{1 + K[MeO^-]}$$

where K is the equilibrium constant for reaction of **3** with methoxide ions to give **4**. Plots, in Fig. 1, at constant methoxide concentration of k_{obs} versus $[CH(CN)_2^-]/(1 + K_{OMe}[MeO^-])$ were linear. The slopes gave a value for k_3 of $(3 \pm 0.5) \times 10^5$ L mol^{-1} s^{-1}. The values of the intercepts are inversely proportional to the sodium methoxide concentration, indicating that the condition $K[MeO^-] \gg 1$ applies, and giving a value for k_{-3}/K of 0.26 ± 0.02 mol L^{-1} s^{-1}. Hence we obtain a value for $K_3K(= k_3K/k_{-3})$ of $(1.1 \pm 0.3) \times 10^6$ L^2 mol^{-2}.

In order to separate the values of K_3 and K it was necessary to work in solutions containing very low concentrations of methoxide ions. This was achieved by using buffer solutions prepared from 4-bromophenol, whose pK_a value in methanol is known (11) to be 13.61. Equilibrium absorbances obtained using conventional spectrophotometry were measured at λ_{max} and also at 550 nm and are reported in Table 4. Because of the fairly fast decomposition reaction these are the values extrapolated to zero time. We define the equilibrium constant, K_{obs}, by eq. [4] where A is the measured absorbance and A_∞ is the value corresponding to complete conversion of TNB to adduct. If the reasonable assumption is made that the extinction coefficients of **3** and **4** at λ_{max} are the same then it is readily shown that K_{obs} is related to K_3 and K by eq. [5].

$$[4] \quad K_{obs} = \frac{A}{(A_\infty - A)} \cdot \frac{1}{[CH(CN)_2^-]}$$

[a]Concentration is 2×10^{-4} *M*.
[b]Residual methoxide concentration in 4-bromophenol/4-bromophenoxide buffers. Since the concentrations of buffer components (ca. 0.1 *M*) were not in a very large excess of the malononitrile concentration, a correction has been applied for depletion of base by formation of malononitrile anion. Ionic strength was maintained at 0.01 *M*.
[c]Calculated from eq. [1] using a value for K_{CH} of 600 L mol^{-1}.
[d]The extinction coefficients were determined to be 2.5×10^4 L mol^{-1} cm^{-1} at λ_{max}, and 1.15×10^4 L mol^{-1} cm^{-1} at 550 nm. These measurements were made using large excesses of [malononitrile] and [methoxide] over [TNB].

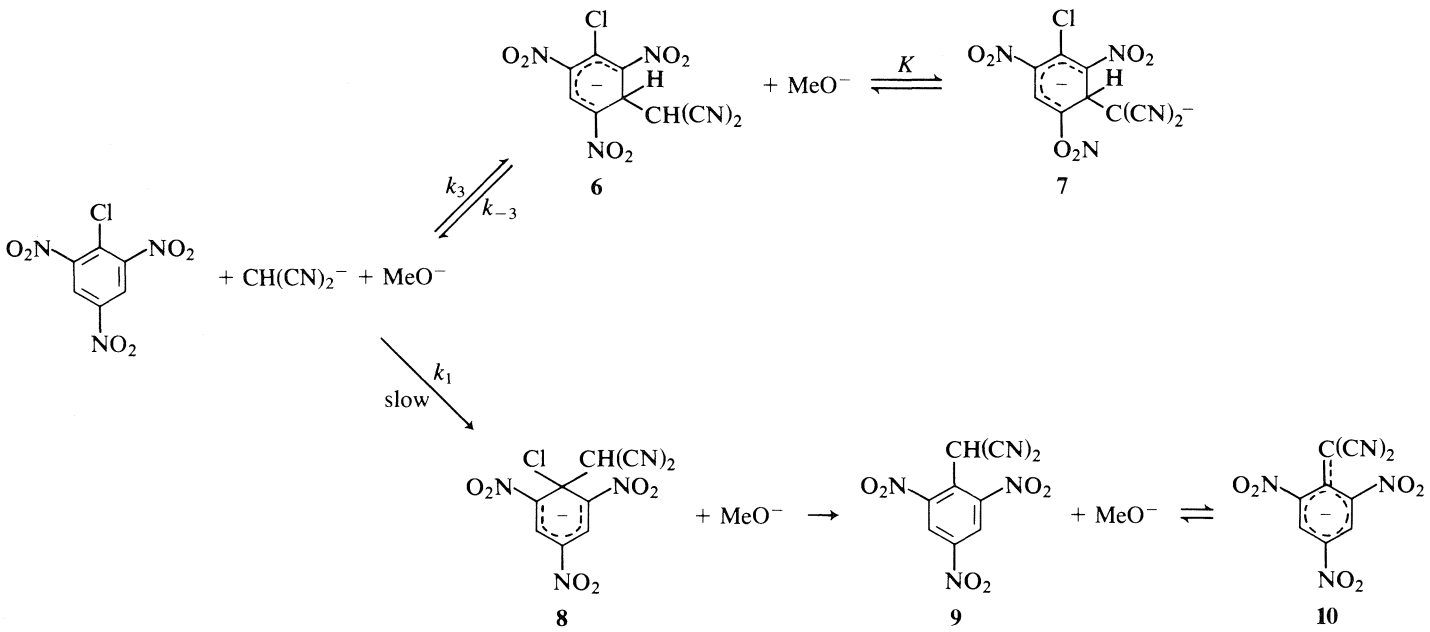
[5] $K_{obs} = K_3(1 + K[MeO^-]$

A plot, Fig. 2, of K_{obs} versus methoxide concentration gave values for K_3 of 37 L mol^{-1} (intercept) and for K of 2.1×10^4 L mol^{-1} (slope/intercept). Similar treatment of the data at 550 nm yielded values for K_3 of 42 L mol^{-1} and for K of 1.9×10^4 L mol^{-1}. The slopes of these plots give a value for the product K_3K of 8×10^5 L^2 mol^{-2}, in reasonable accord with that obtained from the kinetic measurements.

We now have two ways of calculating the value for k_{-3}. From the knowledge that the value of k_{-3}/K is 0.26 mol L^{-1} s^{-1} and the known value for K we obtain a value of 5500 ± 1000 s^{-1}. The second value, obtained from k_3/K_3, is 7500 ± 2000 s^{-1}. Our preferred value is 6500 ± 2000 s^{-1}.

Reaction of malononitrile anion with picryl chloride

Mixing solutions in methanol of picryl chloride (1-chloro-2,4,6-trinitrobenzene) and malononitrile in the presence of base produced a transient red colour, which we take to signify σ-adduct formation, followed by a strong permanent yellow colour λ_{max} 442 nm, ϵ 2.5×10^4 L mol^{-1} cm^{-1} which may be attributed to the substitution product. There is very strong evidence (1, 2, 17, 18) that nucleophilic attack at unsubstituted positions of picryl chloride is a considerably faster process than is attack at the chloro-substituted position. Hence we interpret the reactions by Scheme 2. Here the initially observed σ-adduct is **6** which in the presence of methoxide will be present largely in the ionised form **7**. The rate-determining step in the substitution reaction is expected (1, 2) to be formation of the intermediate **8**



SCHEME 2

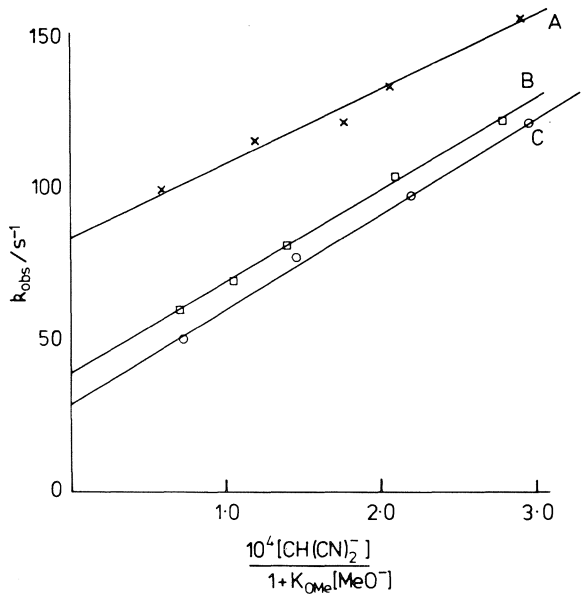


FIG. 1. Plots of k_{obs} versus $10^4[CH(CN)_2^-]/(1 + K_{OMe}[MeO^-])$ for solutions containing the following concentrations of sodium methoxide in methanol: *A*, 0.003 mol L^{-1}; *B*, 0.006 mol L^{-1}; *C*, 0.010 mol L^{-1}.

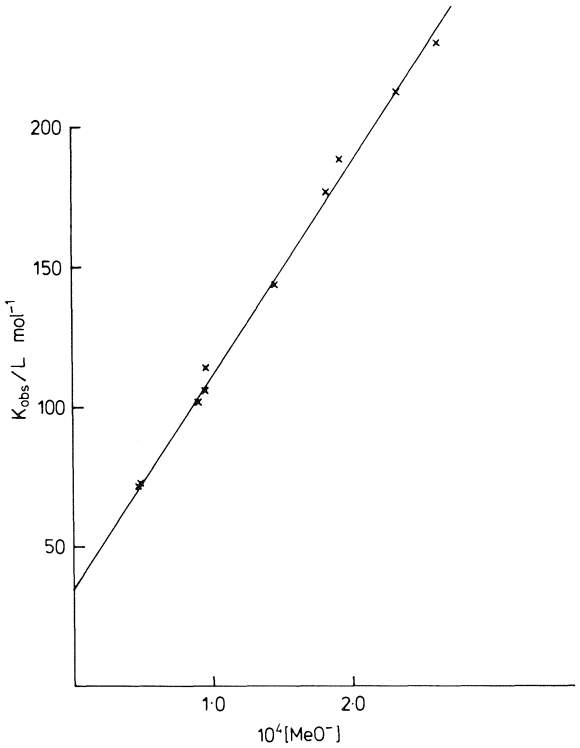

FIG. 2. Plot according to eq. [5] for the reaction of TNB with malononitrile in buffer solutions. Data at λ_{max}.

which will then rapidly expel chloride ion to yield **9**. In the presence of base **9** is expected (19, 20) to be largely ionised to **10**.

Kinetic measurements, made by stopped-flow spectrophotometry under first-order conditions, showed the presence of two well-separated processes. The rate expression for the fast process which is colour forming at 526 nm and may be identified with formation of **7** is similar to eq. [3] for reaction of TNB. However, since here methoxide attack at the 3-position may be neglected (the equilibrium constant is known (21) to have the low value of 2.6 L mol^{-1}) we obtain eq. [6]. It is readily shown

$$[6] \quad k_{fast} = k_3[CH(CN)_2^-] + \frac{k_{-3}}{1 + K[MeO^-]}$$

$$[7] \quad k_{slow} = \frac{k_1[CH(CN)_2^-]}{1 + K_3[CH(CN)_2^-] + KK_3[CH(CN)_2^-][MeO^-]}$$

that the rate expression appropriate for the slow process, colour fading at 526 nm, is eq. [7].

Data are presented in Table 5. A plot of k_{fast} versus $[CH(CN)_2^-]$ was linear with slope, k_3, 3×10^4 L mol^{-1} s^{-1} and intercept $k_{-3}/(1 + K[MeO^-])$ of 22 ± 2 s^{-1}. We expect the value of K for ionisation of **6** to be rather similar to the value for ionisation of the TNB adduct (3), since the negative charge

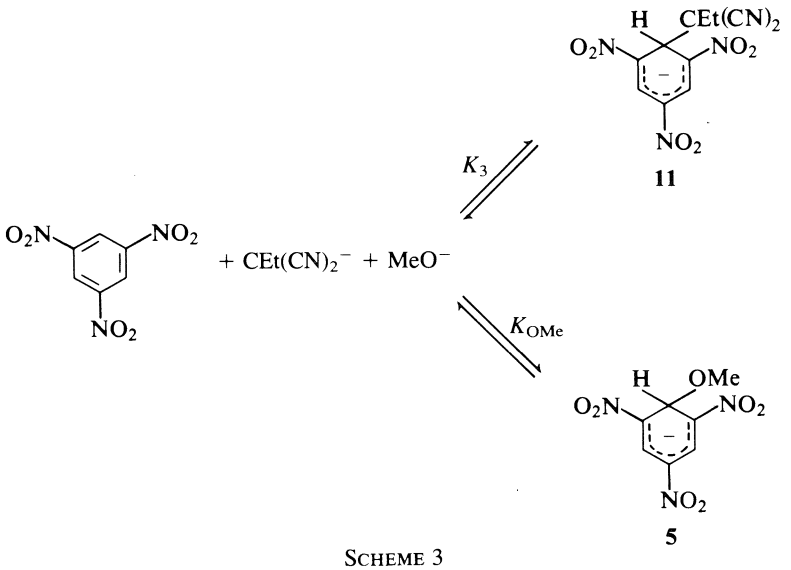
[e]Calculated from eq. [7] with k_1 1.75×10^3 L mol^{-1} s^{-1}, and KK_3, 1.4×10^5 L^2 mol^{-1}. Account was taken of the depletion of methoxide concentration in the formation of the malononitrile anion.



SCHEME 3

produced can not be directly delocalised into the ring. Assuming a value for *K* of 2×10^4 L mol^{-1}, as found for the TNB–adduct, we obtain a value for k_{-3} of 4400 s^{-1}. From the rate of the slower reaction we obtain a value for k_1 of 1.75×10^3 L mol^{-1} s^{-1}.

In a study of the reaction of picryl chloride with diethyl malonate Leffek and Matinopoulos-Scordou (20) observed a σ-adduct which they thought was the intermediate on the substitution pathway. It is worth noting that, in the present case, the assumption that the observed adduct has structure **8** leads to the conclusion that expulsion of chloride is slower by at least three orders of magnitude than is expulsion of the malononitrile anion. We think this is unlikely.

It is of interest to compare, Table 6, the data for picryl chloride with that for TNB. The pattern is very similar to that previously observed with oxygen bases. Thus the value of K_3 for picryl chloride is ca. six times smaller than the value for TNB (the corresponding ratios for reaction with methoxide ions (21) and with hydroxide ions (18, 22) are 6.5 and 5, respectively) and this change is due largely to a decrease in the value of k_3 while values of k_{-3} are similar. The value of k_1 for attack at the 1-position of picryl chloride is ca. 20 times lower than that for attack at the unsubstituted 3-position and ca. 200 times lower than that for attack at ring-positions of TNB. The origins of these effects have been discussed recently (22).

Reaction of ethylmalononitrile anion with TNB

Visible spectra indicate the rapid formation of a mixture of the carbon-bonded adduct (**11**) with λ_{max} 430 nm (ε, 2.5×10^4 L mol^{-1} cm^{-1}), 520 nm and the methoxide adduct (**5**),

TABLE 6. Comparison of rate and equilibrium constants for reaction of (**2**, R = H) with TNB and with picryl chloride

	Value	
Parameter	TNB	Picryl chloride
k_3/L mol^{-1} s^{-1}	3×10^5	3×10^4
k_{-3}/s^{-1}	6500	4400
K_3/L mol^{-1}	40	7
k_1/L mol^{-1} s^{-1}	—	1.75×10^3

λ_{max} 420, 490 nm (Scheme 3). A very much slower reaction gives a species probably a di-adduct (2, 3), with a single absorption in the visible region (490 nm).

A major difference from the reaction with (**2**, R = H) is that here the adduct formed, **11**, has no readily dissociable proton. Hence the favourable ionisation equilibrium, **3** ⇌ **4**, observed with the corresponding malononitrile adduct is absent. As a result conversion of TNB to the carbon-bonded adduct is considerably reduced and formation, at equilibrium, of the methoxide adduct **5** can more readily compete. To minimize this latter pathway we kept the concentration of ethyl malononitrile in large excess of the methoxide concentration. Equilibrium optical densities were measured at 430 nm and at 550 nm and are in Table 7. After correction of the values at 430 nm for the contribution due to **5** we obtain a value for K_{CH} of 33 ±

5 L mol^{-1}. The data at 550 nm, where **5** shows very small absorption, lead to an identical value for K_{CH}.

Comparison of equilibrium and kinetic data

Values obtained in the present work are collected in Table 8 and are compared with some values from the literature. Values of K_3 give a measure of the carbon basicities (24, 25) of the nucleophiles, as judged by the σ-adduct forming reaction with TNB, while values of k_3 measure nucleophilicities, and k_{-3} nucleofugalities. The results show that the effect of the ethyl group in enhancing the proton basicity of the ethylmalononitrile anion relative to the malononitrile anion is not carried through in the σ-adduct forming reaction. This may reasonably be attributed to the destabilising effect of steric crowding in the adduct **11**, which is formed by reaction of the trisubstituted carbanion at a somewhat hindered site (26).

The K_3 values show that the carbon basicity towards TNB of $CH(CN)_2^-$ is greater than that of methoxide by a factor of ca. 2. However, after taking account of the pK_a difference between the two bases we obtain a ratio of ca. 10^3. This is consistent with other observations which show that carbon bases have considerably higher carbon basicities than oxygen bases of similar proton basicity (7, 25). The data in Table 8 also indicate the enhanced carbon basicities, relative to methoxide, of cyanide ion and of sulphur bases.

The value of k_3 for $CH(CN)_2^-$ is ca. 40 times larger than the corresponding value for MeO^- while the ratio for k_{-3} values is ca. 20. This is in accord with results of Bernasconi *et al.* (7) which show that relatively low intrinsic barriers may be expected for reactions involving delocalised cyano-substituted carbanions. The relatively high nucleofugality of the malononitrile anion observed here is paralleled in carbonyl-forming elimination reactions (7), but contrasts with the low nucleofugality expected in olefin-forming reaction (6, 7). In the latter class of reactions the cyanide ion is found (6) to be an extremely poor leaving group with a nucleofugality at least six orders of magnitude lower than that of methoxide ion. Our results show that expulsion of cyanide from the TNB adduct is slower than the corresponding expulsion of methoxide by a factor of ca. 4000. This, while confirming the poor leaving group ability of the cyanide ion, suggests that the range of nucleofugalities to be expected in σ-adduct decompositions may be lower than observed in olefin-forming eliminations.

Experimental

1,3,5-Trinitrobenzene, 1-chloro-2,4,6-trinitrobenzene, malononitrile, and 4-bromophenol were purified commercial specimens. Ethyl malononitrile was prepared from ethyl malonic acid in three stages. In the first stage di-esterification was accomplished by refluxing in ethanol-containing sulphuric acid. Reaction of the di-ester with aqueous ammonia yielded the di-amide which was dehydrated by refluxing from phosphorus pentoxide. The product was purified immediately before use by prep-scale gas chromatography. The ^{1}H nmr spectrum showed bands at δ 4.70 (t, 7 Hz), 2.0 (pentet, 7 Hz),

1.10 (t, 7 Hz). Mr. J. Banks is thanked for this preparation. Solutions of alkali-metal methoxides were prepared by dissolving clean sodium or potassium in AnalaR methanol under nitrogen. Cloudiness in the resulting solutions was removed on centrifugation. Concentrations were determined by titration with standardised acid. The AnalaR methanol used as solvent was de-gassed before use.

Ultraviolet/visible spectra were measured using a Pye-Unicam SP8-100 recording spectrometer of a Hi-Tech SF3L stopped-flow instrument. The latter instrument was used for kinetic studies which were made under first order conditions. Quoted rate coefficients are the mean of at least five determinations and are precise to ±5%.

Received January 30, 1986

HENRYK PIEKARSKI and GUS SOMSEN. Can. J. Chem. **64**, 1721 (1986).

Enthalpies of solution of urea in binary mixtures of isopropanol, *s*-butanol, and ethoxyethanol with water have been measured at high water content. Those in the binaries isopropanol + water and ethoxyethanol + water show endothermic maxima at 8 and 4 mol% alkanol, respectively. Enthalpic pair interaction coefficients are calculated for the interactions between urea and the alkanols and discussed in connection with these coefficients for interactions between urea and other nonelectrolytes and between *N,N*-dimethylformamide and several nonelectrolytes. The enthalpic pair interaction coefficients correlate linearly with the heat capacity change on hydration of the nonelectrolytes and with the enthalpy of hydrophobic hydration of the alkanols.

HENRYK PIEKARSKI et GUS SOMSEN. Can. J. Chem. **64**, 1721 (1986).

Opérant dans des mélanges contenant une forte proportion d'eau, on a déterminé les enthalpies de solution de l'urée dans des mélanges binaires d'isopropanol, de *s*-butanol et d'éthoxyéthanol avec de l'eau. Les solutions dans des mélanges binaires d'isopropanol + eau et éthoxyéthanol + eau présentent respectivement des maxima endothermiques à 8 et à 4 mol% d'alcanol. On a calculé les coefficients d'interaction des paires enthalpiques pour les interactions entre l'urée et les alcanols et on en discute en relation avec les mêmes coefficients pour les interactions entre l'urée et d'autres non-électrolytes et entre le *N,N*-diméthylformamide et plusieurs non-électrolytes. Il existe une corrélation linéaire entre les coefficients d'interaction des paires enthalpiques et les changements de capacité calorifique lors de l'hydratation des non-électrolytes ainsi qu'avec l'enthalpie de l'hydratation hydrophobe des alcanols.

[Traduit par la revue]

Introduction

Much attention has recently been devoted to the so called "enthalpic pair interaction coefficients" h_{xy} of solutes in dilute solutions. These coefficients are regarded as a measure of the heat effect (i.e. the enthalpy of interaction) when two solute particles approach each other. Enthalpic interaction coefficients can be obtained from enthalpies of dilution (interactions between similar solutes) and enthalpies of mixing or of dissolution leading to three-component systems (interactions between dissimilar solutes) (1–3). The theoretical calculation of pair interaction coefficients by statistical mechanical methods has been performed by several authors (1, 4, 5), but has to face the problem that the results are sensitive to subtle details in the adopted potentials of mean force of the solute particles. In another line of approach the attention has been focussed on the interpretation of qualitative and quantitative variations of the interaction coefficients within groups of more or less related compounds (2, 3, 6–15). The group additivity concept developed by Savage and Wood (6) to correlate enthalpic pair interaction coefficients of a wide range of nonelectrolytes (mainly alcohols, polyhydroxy compounds, and amides) in water has been found to be very useful in predicting unknown values. A similar group additivity concept was employed by Heuvelsland, De Visser, and Somsen (16) to the analysis of interactions in systems containing ionic solutes (tetraalkylammonium bromides) in water as well as in the nonaqueous solvent *N,N*-dimethylformamide (DMF). Also the enthalpic interaction coefficients for NaI–alcohol pairs in aqueous solution appeared to be a sum of group contributions (17).

In a previous paper of one of the present authors (H.P., ref 17) the enthalpic pair interaction coefficients were analyzed in terms of correlations between h_{xy} and other properties of the solutes. In this way it seemed possible to find which interaction in the investigated aqueous systems gives the leading contribution to h_{xy}. All systems contained one electrolyte (NaI) with different nonelectrolytes. Simple correlations were found between h_{xy} (NaI–nonelectrolyte) in water and the molecular polarizability (α) of the nonelectrolyte as well as its Kosower acidity parameter (Z). However, the correlations are not general and hold only for groups of related compounds. The aim of this study is to explore the possibilities for a more general correlation of pair interaction coefficients with solute properties, using solutes with different molecular structure. The systems DMF–nonelectrolyte and urea–nonelectrolyte both in aqueous solution were selected for this purpose since there are many data in the literature concerning the pair interaction coefficients in these systems (2, 6, 9, 13, 14, 18). In order to enlarge the number of data for our analysis, we have determined experimentally some additional h_{xy} values for urea–nonelectrolyte interactions by measuring the enthalpies of solution of urea (U) in aqueous solutions of isopropanol (*i*-PrOH), *s*-butanol (*s*-BuOH), and ethoxyethanol (EEtOH).

Experimental

Urea, purissimum (POCh, Gliwice, Poland) was recrystallized from doubly distilled water and dried under vacuum for several days at 330 K. Isopropanol, analytically pure (POCh Gliwice, Poland), *s*-butanol, A.R. (Reanal, Hungary), and ethoxyethanol, analytically pure (Loba Chemie), were purified and dried by standard methods (19). Solutions of the alcohols in water were prepared by weight.

Enthalpies of solution of urea in the different solvent mixtures were measured in an isoperibol type calorimeter. The spherical glass calorimetric vessel with a capacity of 100 cm^3 was equipped with a calibration heater, stainless steel stirrer, and two thermistors as temperature sensors. Small glass ampoules containing the substance to

be dissolved can be attached to the stirrer. The dissolution process was initiated by crushing the ampoule against the bottom of the calorimetric vessel. The thermistors were connected to a multivibrator system which generates a rectangular wave. Its frequency changes correspond to changes of the temperature of the calorimeter. The frequency was measured by means of a digital frequencymeter type PFL-21 (Kabid, Poland). Its sensitivity of ±1 Hz corresponds to a temperature change of about 2×10^{-5} K. The calorimeter resides in a hermetically closed brass jacket with a capacity of about 1 dm^3 within a water thermostat. The temperature stability of the thermostat was better than 1×10^{-3} K.

Results

The final concentration of the urea solutions ranged from 0.006 to 0.015 mol dm^{-3}. No concentration dependence (outside the error limits) of the enthalpies of solution was observed and consequently the measured enthalpies were regarded as those at infinite dilution ΔH^{∞}_{sol}.

The values of ΔH^{∞}_{sol} for urea in aqueous solutions of *i*-PrOH, *s*-BuOH, and EEtOH at 298.15 K are listed in Table 1. The dissolution enthalpy of urea in water obtained by us (15.29 ± 0.03 kJ mol^{-1}) is in very good agreement with literature data: 15.28 kJ mol^{-1} (20), 15.29 kJ mol^{-1} (21), 15.30 kJ mol^{-1} (2), 15.31 kJ mol^{-1} (22).

Discussion

Enthalpies of solution

The enthalpies of solution of urea in the mixtures of water with isopropanol, *s*-butanol, and ethoxyethanol are plotted in Fig. 1 as a function of the mole percentage of the organic component. The curves representing the enthalpies of solution for urea in water + *i*-PrOH and water + EEtOH exhibit maxima at low alcohol contents. A similar extremum in ΔH^{∞}_{sol} has been observed in the urea – water – tertiary butanol system studied by Desnoyers *et al.* (2), as well as in all electrolyte–water–alkanol systems studied thus far. When it is assumed that these maxima are related to structure-making or -stabilizing effects of the alkanols when they are added to water (23–26), it appears that such effect is larger for the more globular solute *i*-PrOH than for the longer and non-branched molecule EEtOH.

Enthalpic pair interaction coefficients

From the enthalpy of solution data we have calculated the enthalpic pair interaction coefficients h_{xy} for the interaction urea–nonelectrolyte in water. The method of calculation has

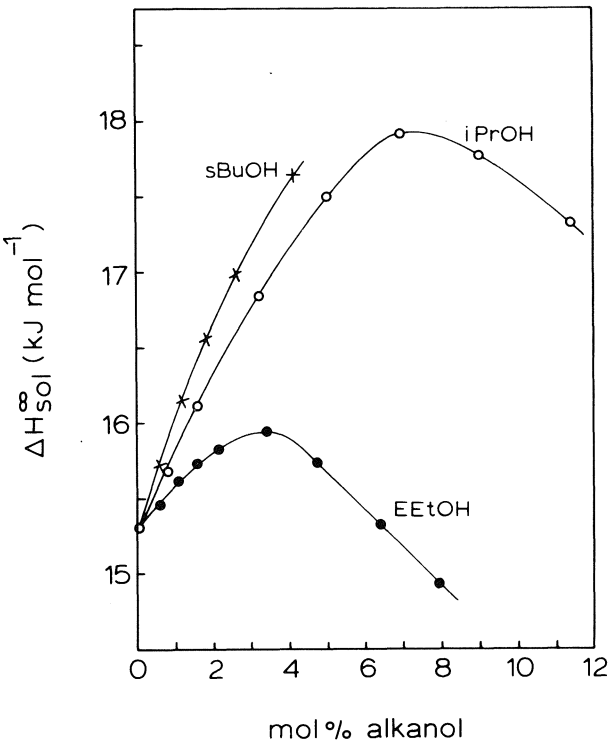

FIG. 1. Enthalpies of solution of urea in mixtures of water with isopropanol (*i*-PrOH), *s*-butanol (*s*-BuOH), and ethoxyethanol (EEtOH) vs. mol% of the nonaqueous component.

been described previously (17) and the results are given in Table 2. In Table 2 are collected also a number of values obtained in other investigations on urea–nonelectrolyte and DMF–nonelectrolyte interactions. There are a few general trends in the h_{xy} values. In all cases where interaction coefficients with DMF and with urea are known, the coefficients involving an interaction with DMF are more positive than those corresponding to an interaction with urea. Also, the interaction coefficients with DMF as well as with urea become more positive when the co-solute carries more or larger alkyl groups.

The interaction between molecules in aqueous solution leads to modification of the hydration structures (co-spheres) around the molecules. Due to an overlap of co-spheres some of the hydration water molecules may change their spatial arrangement from the co-sphere structure to a structure typical for bulk water (1, 28, 29). For correlation with enthalpic coefficients it may therefore be appropriate to pay attention to functions that are known to be sensitive to structural changes in solution. The entropy of hydration ΔS_h, probably the best function for this purpose, is only known in a few cases for the systems investigated here. Another function exhibiting comparable behaviour with respect to structural changes in solution as the entropy is the heat capacity (30). In order to reflect the contribution of the solvent to the total partial molar heat capacity of the solute, we have used values relative to the molar heat capacity in the gaseous state, i.e. heat capacities of transfer defined by

$$\delta C_p = \bar{C}^{\infty}_{p,2} - C^{g}_{p,m}$$

in which $\bar{C}^{\infty}_{p,2}$ is the partial molar heat capacity of a solute at infinite dilution in water and $C^{g}_{p,m}$ is the molar heat capacity of the same solute in the vapour phase. Values of δC_p are

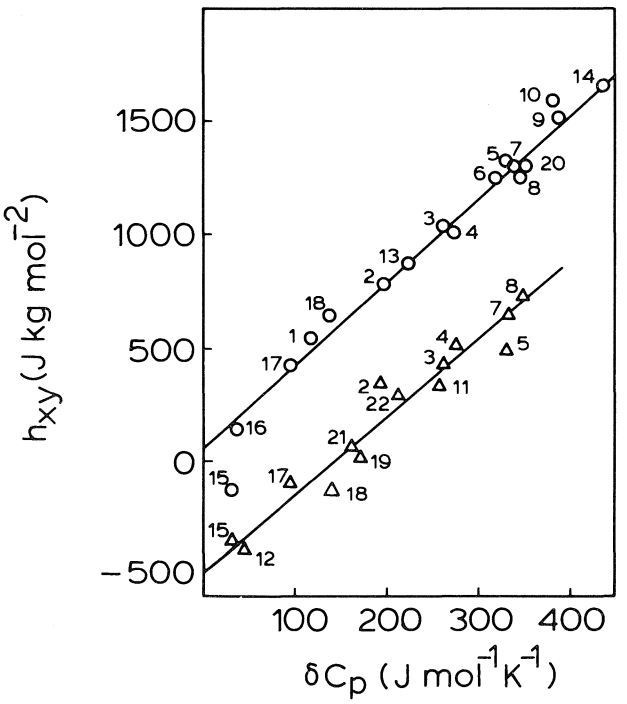

FIG. 2. The dependence of the enthalpic pair interaction coefficients h_{xy} for DMF–nonelectrolyte (circles) and urea–nonelectrolyte (triangles) interactions on the heat capacity of transfer ($\bar{C}_{p,2} - C_{p,m}$) of the nonelectrolyte from vapour phase to high dilution in water. The numbers correspond to those given in Table 2.

given in a compilation of Cabani *et al.* (31). The relation of the pair interaction coefficients h_{xy} for pairs: DMF–nonelectrolyte Y, and for pairs urea–nonelectrolyte Y with δC_p is presented in Fig. 2. As can be seen in this figure, there is a good linear correlation for interactions with DMF as well as for interactions with urea. The slope of the line correlating δC_p with h_{xy} values for pairs DMF–nonelectrolyte is 3.63 ± 0.12 kg mol^{-1} K^{-1}; that for pairs urea–nonelectrolyte amounts to 3.25 ± 0.22 kg mol^{-1} K^{-1}.

Values of h_{xy} will depend primarily on three effects: (*a*) the hydration of a separate molecule X; (*b*) the hydration of a separate molecule Y; and (*c*) the interaction between molecules X and Y when they approach each other. For a given particle X effect *a* will be constant. The linear dependences of h_{xy} for a given X with a hydration property of the varying co-solute Y, as found in Fig. 2, strongly suggests that effect *b* is more important than effect *c*. The two separate lines obtained in Fig. 2 demonstrate that h_{xy} is also determined by the difference in hydration between DMF and urea molecules (effect *a*). Since the slopes of the lines are approximately equal, it may be concluded that the cosphere overlap of the different co-solutes with DMF changes in the same way as that with urea. Again specific effects (*c*) seem to be of minor importance. However, they may be present in some cases. For instance, the deviations of the h_{xy} value for the DMF–urea interaction from both linear relations in Fig. 2 may well be due to this, since they are both far beyond the experimental uncertainty.

In water, part of the co-solutes given in Fig. 2 are hydrophobically hydrated. As a measure for their hydrophobicity the enthalpy of hydrophobic hydration Hb(W) of the nonelectrolyte may be adopted which is defined by De Visser and Somsen (32) and evaluated for the alcohols by Rouw (14). In the h_{xy} values would depend mainly on the hydrophobic hydration effect, a simple correlation between h_{xy} and Hb(W) should be expected. Figure 3 shows a plot of h_{xy} for DMF–alkanol interactions and for urea–alkanol interactions vs. Hb(W) of the alkanol. The good linear correlation for these systems confirms the conclusion about the influence of the hydration of the co-solute drawn above.

Values of h_{xy} for urea–nonelectrolyte interactions may also be compared with those for NaI–nonelectrolyte interaction published recently (17). Figure 4 shows that there is a good correlation between the two series of values. The slope of the line correlating these data is close to unity (0.99 ± 0.07). Hence,

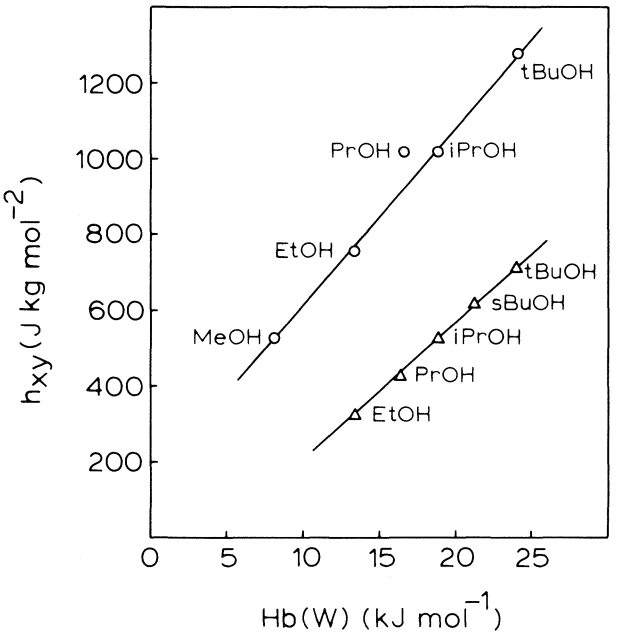

FIG. 3. The correlation between the hydrophobic hydration enthalpy Hb(W) of alkanols and the enthalpic pair interaction coefficients h_{xy} for DMF–alkanol and urea–alkanol pairs.

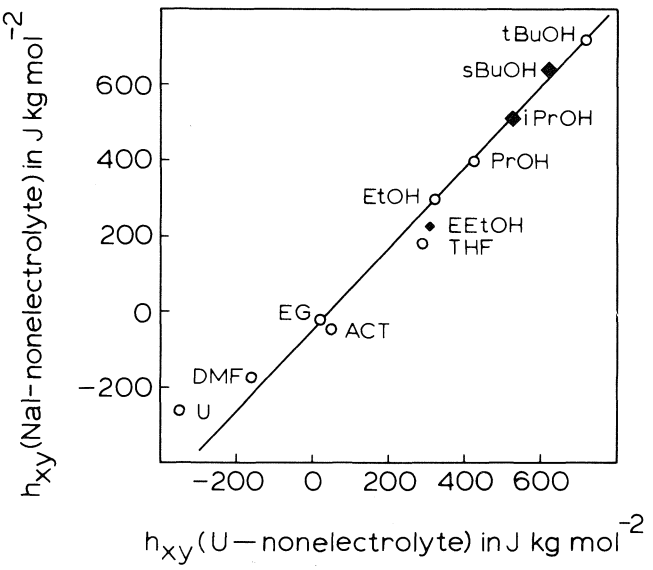

FIG. 4. The correlation between the enthalpic pair interaction coefficients h_{xy} for urea–nonelectrolyte pairs and for the NaI–nonelectrolyte pairs. EG = ethylene glycol; ACT = acetonitrile; THF = tetrahydrofuran; ◆: our data (the dimensions refer to the error limits); ○: literature data.

from the point of view of enthalpic pair interaction coefficients, the differences between urea–nonelectrolyte and electrolyte–-nonelectrolyte are predominantly quantitative. Probably there is some similarity in the hydration of urea and ionic solutes. The urea molecule has proton-donor and proton-acceptor as well as electron-donor and electron-acceptor properties. For this reason it might interact in a way comparable to that for cations and anions.

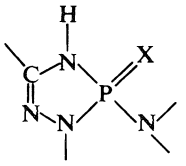
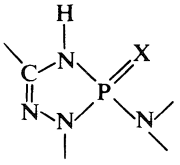
Les amines réagissent sur les triazaphospholes-1,2,4,3 substitués en 2,5 pour conduire à des composés d'addition en 1,2 selon une réaction équilibrée. Cet équilibre est mis en évidence d'une part par abaissement de la température, d'autre part par voie chimique : l'addition de soufre, de sélénium ou d'azoture (X) déplace entièrement l'équilibre vers le composé d'addition 1,2 :



Les grandeurs thermodynamiques associées à cet équilibre ont été déterminées dans quelques cas.

MARIE-THÉRÈSE BOISDON, LUCIEN LOPEZ, CHRISTIAN MALAVAUD, JEAN BARRANS, ABDELAZIZ CHABANE, and RAYMONDE MATHIS. Can. J. Chem. **64**, 1725 (1986).

The oxidation of 2,5-disubstituted 1,2,4,3-triazaphospholes with amines gives 1,2 addition products by an equilibrium reaction. This equilibrium has been proved by temperature lowering and also by chemical reaction: addition of sulfur, selenium, or azide (X) shifts the equilibrium to the 1,2 addition products:



The thermodynamical parameters associated with this equilibrium have been determinated in some cases.

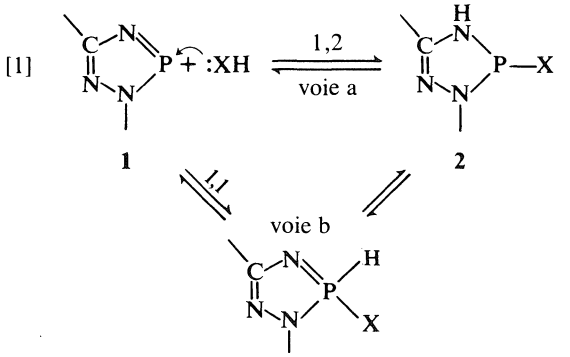
Introduction

Nous avons observé au laboratoire (1) que les triazaphospholes-1,2,4,3 substitués en 2,5 par des groupements alkyles ou phényles **1** réagissent avec les amines primaires et secondaires pour conduire à des amino-3 triazaphospholines **2** suivant une réaction réversible. Deux types de réaction étaient envisagés : *voie a* : la simple addition 1,2; et *voie b*: une addition 1,1 suivie d'un réarrangement.

La rmn (résonance magnétique nucléaire) à température variable n'a pas permis de mettre en évidence la présence d'un groupement P—H; néanmoins nous ne pouvons pas exclure la voie b.

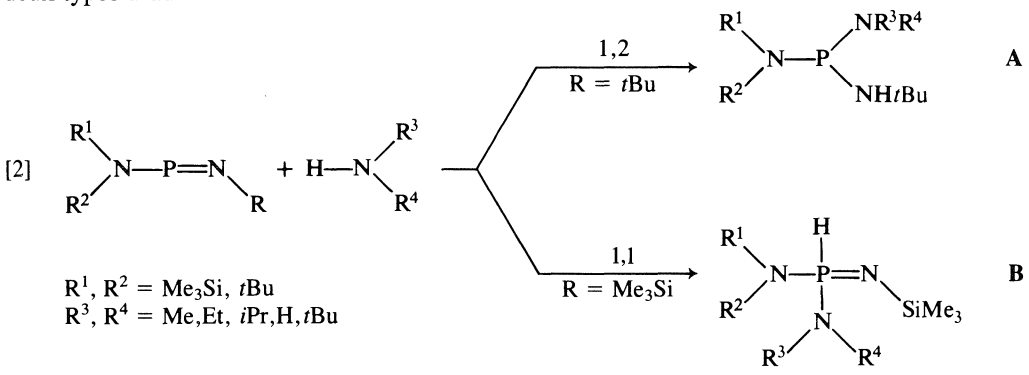
En effet des travaux récents d'addition d'amine sur des phosphazènes acycliques (2) ont conduit à l'observation des

[1]



1. Auteur à qui adresser toute correspondance.

deux types d'addition suivant la nature du reste R :



Les auteurs considérent que la formation de **A** ou de **B** est liée à des effets stériques et électroniques. Dans le cas particulier de l'aniline, et lorsque R = $SiMe_3$, il y a *équilibre* entre les formes **A** et **B**. Lorsque l'encombrement est trop grand autour de l'atome de phosphore, la réaction n'a pas lieu; par exemple, la diisopropylamine ne réagit pas lorsque R = *t*Bu.

Nous avons repris l'étude de l'addition oxydante d'amine sur les dérivés **1** en diversifiant les amines et les restes portés par le composé phosphoré (tableau 1).

Ce travail comportera deux parties : 1. Mise en évidence de l'équilibre [1] par abaissement de la température avec détermination des paramètres thermodynamiques et étude des facteurs de l'équilibre. 2. Déplacement de l'équilibre par voie chimique et étude des dérivés formés **3**, **4** et **5**.

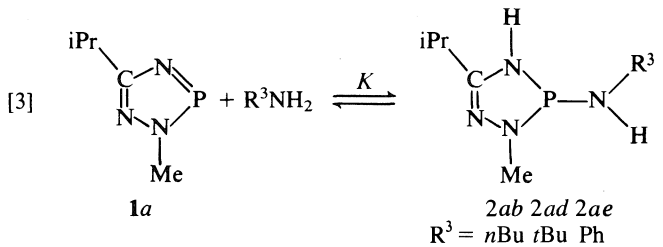
I. Étude thermodynamique de l'équilibre

Influence de la nature de l'amine

Nous avons tenté de détecter la présence éventuelle du composé d'addition 1,1 en utilisant des amines silylées et en opérant, dans certains cas, à basse température (addition des réactifs vers −50°C). Dans tous les cas, le seul produit observé a été l'amino-3 triazaphospholine-1,2,4,3 **2**.

L'abaissement de la température du mélange réactionnel a permis d'observer la formation d'adduits avec l'aniline, la tertiobutylamine ou l'ammoniac, qui nous avaient semblé initialement inactives sur les Me-2 triazaphospholes-1,2,4,3 (1).

Une étude thermodynamique de l'équilibre suivant :



a été faite par rmn de ^{31}P sur des mélanges stoechiométriques en solution dans le toluène. L'établissement de l'équilibre est rapide; il est atteint en moins de 2 min à température ordinaire, de 10 min à −50°C.

Les résultats des mesures sont rassemblés sur la figure 1 et dans le tableau 2.

La constante de l'équilibre dépend notamment de la force de la nouvelle liaison P—N formée. C'est ainsi qu'avec l'aniline moins basique (pK_b = 9,37) que la *n*-butylamine (pK_b = 3,23),

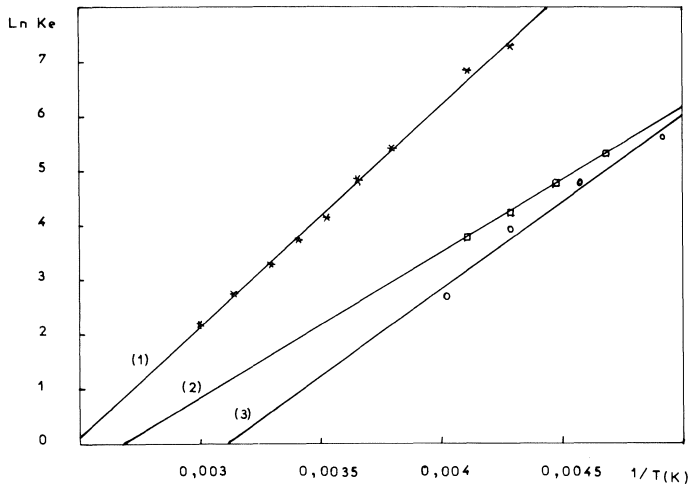


FIG. 1. Variation de la constante de l'équilibre [3] en fonction de la température (solvant : toluène). * **1***a* + $nBuNH_2$; □ **1***a* + $tBuNH_2$; ○ **1***a* + $PhNH_2$.

(3), le doublet de l'azote déjà engagé dans la conjugaison avec le phényle n'est pas disponible pour renforcer la liaison P—N par retrocoordination. On a bien : $K(n\text{Bu}) > K(\text{Ph})$. Par ailleurs avec la tertiobutylamine (pK_b = 3,17), de basicité comparable à celle de la *n*-butylamine, le produit formé est destabilisé par une gêne stérique entre le groupement *t*Bu et le groupement méthyle porté par l'azote N2 du cycle ($K(n\text{Bu}) > K(t\text{Bu})$).

Influence du solvant

Les solvants basiques (DMSO, pyridine) favorisent la formation des dérivés **2**. Dans l'équilibre : **1***c* + $nBuNH_2 \rightleftharpoons$ **2***cb*, la constante K_{308} est environ dix fois plus élevée dans le DMSO que dans le toluène et six fois plus dans la pyridine que dans le toluène (K_{308} (tol.) = 3,8; K_{308} (DMSO) = 75; K_{308} (pyr.) = 22). Le solvant basique doit stabiliser le composé P^{III} formé, par solvatation de l'hydrogène très acide (4) lié à l'azote N4 du cycle.

ex.:  **3***cb*

Cette stabilisation a été observée dans l'étude de l'équilibre (5) :

[4] 
Influence du substituant R^2 du triazaphosphole

On observe un déplacement de l'équilibre vers la formation de l'amino-3 triazaphospholine lorsque R^2 = Ph (**1***d*) par rapport aux cas où R^2 = Me (**1***a*, **1***b*, **1***c*) (Tableau 3).

La présence d'un groupement phényle en position 2 doit favoriser la conjugaison avec le cycle triazaphospholine et renforcer l'interaction $p\pi$–$d\pi$ entre l'azote exocyclique et le phosphore. Ces effets stabilisent l'aminotriazaphospholine.

Lorsque R^2 = $SiMe_3$, l'effet (−*I*) du silicium se traduit sur le triazaphosphole **1***e* par un déblindage du signal de rmn de ^{31}P ($\Delta\delta$ ^{31}P = +24 ppm). L'accroissement de l'électrophilie du phosphore doit favoriser l'addition d'amines. En fait, on obtient le même pourcentage de P^{III} qu'avec **1***c* (R^2 = Me) par suite de l'encombrement stérique du groupement $SiMe_3$.

Étude par rmn de ^{31}P des triazaphospholines **2**

Déplacements chimiques

Les déplacements chimiques observés en rmn de ^{31}P sont faibles (50–80 ppm) par rapport à ceux donnés généralement dans la littérature pour les tris(amino)phosphines et les amino-3 diazaphospholidines-1,3,2 (80–120 ppm) (2*a*, 6, 7). Toutefois les amino-3 tetrazaphospholines-1,2,4,5,3 (8) ont des déplacements chimiques encore plus faibles (~35 ppm).

Isomérie de rotation

De nombreuses études ont été faites sur la conformation stéréodynamique de mono, bis ou tris(amino)phosphines et d'aminodiazaphospholidines-1,3,2 s'appuyant sur des expériences de rmn de ^1H et ^{13}C à température variable (9–11) et sur

*Plusieurs composés.

des déterminations de structures par diffraction des rayons X (11*b* et 12). Dans tous les composés cycliques étudiés, l'atome d'azote exocyclique est hybridé en sp^2, et lorsque la rotation autour de la liaison P—N(*exo*) est bloquée, on observe en rmn des valeurs très différentes des constantes de couplage du phosphore avec les carbones ou les protons des substituants portés par cet azote exocyclique (tableau 4).

Dans les amino-3 triazaphospholines-1,2,4,3 **2**, on observe à la température ordinaire un seul signal en rmn de ^{31}P, même pour $R^3 \neq R^4$; de plus les protons méthyléniques du composé **2***cc* ($R^3 = CH_2C_6H_5$) restent équivalents même à −70°C, ce qui implique une rotation rapide autour de la liaison P—N(*exo*).

Remarquons que lorsque l'azote exocyclique porte des groupements encombrants (R^3 = *t*Bu ou $SiMe_3$), on observe à basse température un dédoublement du signal de rmn de ^{31}P. Pour **2***ad* (tol., T.O. (température ordinaire)) : δ ^{31}P = 63,7; à −70°C δ ^{31}P = 66,0 (75%) et 56,2 (25%). En supposant les populations des deux sites égales, on a calculé la barrière à la rotation autour de P—N(*exo*) : $\Delta G^{\ddagger}$ = 41,8 kJ mol^{-1}. Cette valeur est voisine de celle obtenue dans le cas de la diisopropylamino-2 diméthyl-3 diazaphospholidine-1,3,2 (tableau 4).

L'étude des spectres de rmn de ^{15}N de ces différents composés donne une valeur de $J_{PN(exo)}$ particulièrement élevée (80–100 Hz) (tableau 4), correspondant à un fort caractère *s* de la liaison P—N.

L'ensemble de ces résultats : (*i*) faible valeur de δ ^{31}P, (*ii*) rotation restreinte autour de la liaison P—N, et (*iii*) valeur élevée du couplage, $^1J_{PN(exo)}$, s'explique par une rétrocoordination $p\pi$–$d\pi$ entre N(*exo*) et P dans le plan du cycle et nous permet d'envisager pour les amino-3 triazaphospholines une structure autour de l'atome de phosphore comparable à celle des amino-3 tétrazaphospholènes-1,2,4,5,3 (8*a*).

II. Mise en évidence par voie chimique de l'équilibre [3]

La formation de triazaphospholine dans un mélange stoechiométrique de triazaphosphole et d'amine à température ambiante a été également prouvée par des réactions secondaires sur le composé du phosphore tricoordonné, qui déplacent totalement l'équilibre précédent. C'est ainsi que le soufre, le sélénium, les azotures réagissent facilement sur les mélanges pour donner des composés du phosphore tétracoordonné pentavalent (tableau 1).

1. Dérivés soufrés (thioaminotriazaphospholines) 3

On peut envisager deux voies d'accès aux composés du phosphore tétracoordonné pentavalent :

[5]

*Référence NO_2Me.

En effet le soufre réagit à température ambiante sur les dérivés de l'aminophosphazène —N—P=N— (13), et bien que l'atome de phosphore des triazaphospholes soit beaucoup moins nucléophile que celui des aminophosphazènes, on ne peut éliminer le second chemin de réaction.

De plus nous avons observé récemment que le soufre réagissait sur les triazaphospholes dans la pyridine après plusieurs heures de chauffage à 105°C (par exemple δ ^{31}P (**6***d*) = 39,8); compte tenu de cette faible réactivité, on peut penser que les vitesses de réaction par ces deux voies sont très différentes et que la première doît être beaucoup plus grande.

La réaction est totale, souvent exothermique; elle conduit à des composés solides, peu solubles dans les solvants organiques hydrocarbonés mais très solubles dans l'acétone et la pyridine.

L'ammoniac conduit à une nouvelle famille de thiophosphoramides, particulièrement stables vis-à-vis de l'eau lorsque R^2 = Ph (il faut plus de 24 h à 35°C pour hydrolyser complètement le composé **3***da*).

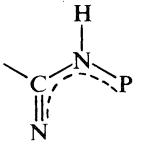
Caractéristiques de résonance magnétique nucléaire

Les déplacements chimiques en rmn de ^{31}P sont peu différents de ceux des triazaphospholines correspondantes. Ils se situent autour de 65 ppm pour R^2, R^3, R^4 aliphatiques, et autour de 55 ppm pour R^2 ou R^3 = Ph. Ces grandeurs sont comparables à celles de la littérature pour un environnement comparable de l'atome de phosphore (6).

En rmn de ^1H, les signaux correspondant aux groupements NH endo- et exocycliques sont nettement distincts : δ NH(*endo*) = 10,5–11,8 ppm dans la pyridine et δ N(*exo*) = 6,5–7 ppm. Un léger abaissement de température est souvent nécessaire pour observer les couplages proton–phosphore, dont les grandeurs sont également très différentes : $^2J_{PNH(endo)}$ = 17–21 Hz et $^2J_{PNH(exo)}$ = 5–7,2 Hz sauf pour $R^3 = CH_2Ph$ ($^2J_{PNH(exo)}$ = 21,2 Hz pour **3***cc* et 20 Hz pour **3***dc*) et pour R^3 = *t*Bu et Ph ($^2J_{PNH(exo)}$ = 18 Hz pour **3***cd*, **3***ce*, **3***dd* et **3***de*).

Caractéristiques infrarouges

Nous avons observé essentiellement les vibrateurs NH de ces composés, à l'état solide et en solution dans CCl_4. Les valeurs observées, en accord avec les donnés de la littérature (4, 7, 14, 15), confirment le caractère particulièrement acide du proton porté par l'azote endocyclique N4, et la forte délocalisation électronique dans l'enchaînement :



2. Dérivés séléniés

Le sélénium a été également utilisé pour mettre en évidence l'équilibre étudié. Sa plus grande réactivité sur les composés du phosphore tricoordonné a permis d'obtenir plus rapidement

certains dérivés, notamment avec la tertiobutylamine. Toutefois avec la diphénylamine, la réaction reste incomplète.

Les produits formés cristallisent très rapidement dans le toluène et sont ensuite très peu solubles et oxydables. On peut noter l'échange sélénium–oxygène dans le DMSO. Ainsi **4***cb* en solution dans le DMSO conduit à l'oxyde de triazaphospholine correspondant de même déplacement chimique (δ ^{31}P = 20,45 ppm) que le produit d'oxydation directe par l'ozone de **3***cc*. Un tel échange n'a pas lieu avec les dérivés soufrés (R^2 = Me).

Les déplacements chimiques de rmn de ^{31}P des dérivés séléniés sont inférieurs d'une dizaine de ppm à ceux des dérivés soufrés homologues. Dans certains composés, on a pu noter le couplage $^1J_{PSe}$(~850 Hz) grâce aux bandes satellites dues à ^{77}Se (16).

3. Addition d'azotures

Alors que les azotures sont inactifs sur les triazaphospholes à température ordinaire, ils réagissent très facilement sur les amino-3 triazaphospholines avec départ d'azote pour conduire aux amino-3 imino-3 triazaphospholines-1,2,4,3. Ils permettent donc, comme le soufre et le sélénium, de déplacer entièrement l'équilibre. Par précipitation par l'éther, on isole des poudres blanches dont la stabilité dépend du reste amino. Il peut y avoir dimérisation par ouverture de la liaison P=NR, comme cela a été observé au laboratoire sur les iminophospholanes à cycle dioxa, oxaza ou diaza (17).

Conclusion

Malgré la variété des substituants portés par le triazaphosphole et l'amine, nous n'avons jamais détecté la présence de composés d'addition 1,1, même en opérant à basse température et en utilisant des substituants silylés donnant des environnements voisins de ceux de E. Niecke (8*a*) et V. D. Romanenko (2*a*). On peut donc conclure que l'addition d'amine sur les triazaphospholes par la voie **B** est peu probable ou en tout cas nettement défavorisée.

La rmn de ^{31}P à température variable nous a permis de voir que cette addition est générale et équilibrée, de mesurer les constantes d'équilibre pour divers réactifs et de déterminer la valeur de la barrière à la rotation P—N(*exo*) pour R = *t*Bu. Cette liaison a un caractère double partiel que confirme la valeur élevée du couplage $^1J_{P^{15}N}$.

La réaction qui présente une enthalpie libre standard négative est défavorisée par les amines peu basiques ou encombrées. Inversement, on favorise la formation de l'aminotriazaphospholine en substituant l'azote N2 du cycle par un groupement phényle.

Dans certains cas où l'addition de l'amine ou de l'ammoniac est très défavorisée, l'introduction de soufre, de sélénium ou d'azoture permet l'addition totale avec formation du composé du phosphore tétracoordonné. L'action de l'ammoniac sur les triazaphospholes en présence de soufre est une méthode simple d'obtention des thiodihydroamino-3 phospholines, permettant de caractériser la présence de σ^2-λ^3-phosphazènes.

Dans les thiotriazaphospholines, le proton porté par l'azote N4 du cycle est particulièrement acide et peut donner lieu à des réactions de substitution.

Partie expérimentale

Les spectres de rmn ont été enregistrés : d'une part sur spectrographe Perkin–Elmer R32 (onde continue (υ_0 = 90 MHz) (sans lock) pour ^1H; FT (calculateur Nicolet TT7) (sans lock) pour ^{31}P) et d'autre part sur spectrographe Brüker WM 250 (pour ^{13}C (υ_0 = 62,83 MHz) réf. int. TMS; pour ^{15}N (υ_0 = 25,34 MHz) réf. ext. NO_2Me en présence de triacétylacétonate de chrome (0,08 mol L^{-1}) (NS = 57 000)).

L'étude spectrométrique infrarouge a été réalisée à l'aide d'un spectrographe PERKIN–ELMER, modèle 125, à double faisceau, sur les échantillons à l'état pur dispersés dans une pastille de bromure de potassium (~1,5 mg dans 150 mg de KBr), ou en solution dans des cuves de 10 cm pour CCl_4.

Les spectres de masse on été obtenus par impact électronique sous 75 eV sur spectromètre quadripolaire RIBER modèle QML-SI.

Triazaphospholines 2

La plupart des amino-3 H-4 triazaphospholines-1,2,4,3 substituées en 2,5 **2**, ont été observées par rmn de ^{31}P dans le mélange réactionnel (toluène) à l'équilibre soit à température ordinaire (T.O.) (33°C), soit à basse température. **2***aa* (−30°C) : 65,8; **2***ab* (T.O.) : 66,5; **2***ac* (T.O.) : 67; **2***ad* (−30°C) : 63,7 et (−70°C) : 66,0 et 56,2 (3:1) coalescence à −50°C; **2***ae* (−20°C) : 57,1 et (−30°C) : 66,1 et 54,3 (1:15); **2***ag* (T.O.) : 77,9; **2***ba* (−30°C) : 69,1; **2***bf* (T.O.) : 65,0; **2***bg* (T.O.) : 70,2; **2***ca* : (−30°C) : 66,1; **2***cb* (T.O.) : 69,8; **2***cc* 69,2; **2***cd* (−30°C) : 66,4; **2***ce* (−30°C) : 55,4; **2***ch* (T.O.) : 82,6; **2***cj* (T.O.) : 78,8; **2***ch* (T.O.) : 79,5; **2***cp* (T.O.) : 77 et (−30°C) 81,9 et 76,8 (1:3); **2***cq* (−30°C) : 65 et (−70°C) 67,3 et 57,3 (2:1) coalescence à −45°C; **2***cm* (−30°C); 87; **2***db* (T.O.) : 65,5 ($^2J_{PH}$ = 31,5); **2***dc* (T.O.) : 65,0 ($^2J_{PH}$ = 34); **2***dd* (T.O.) : 61,5 ($^2J_{PH}$ = 16 et 33); **2***de* (T.O.) : 59,7; **2***dm* (T.O.) : 65,5; **2***dk* (T.O.) : 70,4 ($^2J_{PH}$ = 38); **2***dr* (−25°C) : 75; **2***ea* (T.O.) : 71,3; **2***eb* (T.O.) : 68,9.

2*cn* Méthode A (7) : On mélange 10 mmol de morpholine dissoute dans 10 mL de benzène anhydre et 10 mmol de triazaphosphole en solution dans 20 mL de benzène. La réaction est exothermique. On concentre la solution obtenue sous le vide de la trompe à eau. Le produit formé cristallise plus ou moins vite. Il est recristallisé dans le benzène sous atmosphère inerte car il est hygroscopique et oxydable à l'air; *F* (benzène) 63°C; ν_{NH} (KBr) : 3300, 3200 cm^{-1}; ν_{NH} (sol.) (4); δ ^{31}P (tol. + pyr.) : 78,5; δ H(C_6D_6) : 8,1 et 7,32 (2H et 3H, m, Ph), 3,25 (3H, d, $^3J_{HP}$ = 8,0, NMe), 2,65 et 3,4 (4H, m, $(CH_2)_4$). *Anal.* calc. pour $C_{12}H_{17}N_4PO$: C 54,59; H 6,49; N 21,22; P 11,76; tr. : C 53,67; H 6,44; N 20,67; P 11,48.

2*dn* Méthode A : *F* (benzène) 128°C; ν_{NH} (sol.) (4); δ ^{31}P (pyr.) : 77; δ H(C_6H_6) : 8,1, 7,75 et 7,3 (2H, 2H, 6H, m, 2Ph), 3,3 et 2,8 (8H, m, $(CH_2)_4$). *Anal.* calc. pour $C_{17}H_{19}N_4PO$: C 62,63; H 5,87; N 17,19; P 9,52; tr. : C 61,79; H 5,97; N 16,70; P 9,39.

Thiotriazaphospholines (3)

3*aa* Méthode B : 20 mmol de triazaphosphole **1***a*, dissoutes dans 5 mL de toluène sec, sont ajoutées à la quantité stoechiométrique de soufre élementaire. On fait barboter un courant d'ammoniac sec jusqu'à disparition du soufre. Il se produit un net échauffement et au bout d'une ou deux minutes, le produit formé cristallise sous forme d'une poudre blanche qui est filtrée, lavée plusieurs fois à l'hexane et séchée sur P_2O_5 sous pression réduite; *F* (hexane) 151–152°C; ν_{NH} (KBr) : 3392, 3250, 3205–3310; (CCl_4) : 3496 et 3388; (NH_2) : 3452 dissym. Sulphur cation chemistry in a fuel-rich, CH_4–O_2 flame with OCS additive

NICHOLAS S. KARELLAS AND JOHN M. GOODINGS

Department of Chemistry and Centre for Research in Experimental Space Science, York University, 4700 Keele Street, Downsview, Ont., Canada M3J 1P3

Received February 17, 1986

NICHOLAS S. KARELLAS and JOHN M. GOODINGS. Can. J. Chem. **64**, 1733 (1986).

A fuel-rich, methane–oxygen, premixed flame at atmospheric pressure was doped with 0.2 mol% of OCS. More than 40 different sulphurous cations were observed in the mass range < 100 u by sampling the flame into a flame-ion mass spectrometer. Ion concentration profiles along the flame axis are presented, together with mass spectra at fixed points in the flame. In the reaction zone, primary sulphur ions CH_xS^+ (x = 1, 3, 5) undergo extensive ion–molecule reactions (association and condensation) with CH_4/CH_3, C_2H_2, and OCS to form a considerable variety of secondary sulphurous cations. Just downstream of the reaction zone, the ion chemistry is somewhat different; it appears to be dominated by reactions of primary sulphur ions including H_xS^+ (x = 0–3) with C_2H_2 present as an intermediate. A few ions (H_xS^+, OS^+, S_2^+) persist throughout the burnt gas region in equilibrium with the natural flame ions CHO^+ and H_3O^+. These sulphurous cation signals show the evolution of the sulphur chemistry, both ionic and neutral, through the flame reaction zone into the burnt gas downstream where H_2S, not SO_2, is the major product in fuel-rich combustion.

NICHOLAS S. KARELLAS and JOHN M. GOODINGS. Can. J. Chem. **64**, 1733 (1986).

Une flamme pré-mélangée de méthane/oxygène, riche en combustible, a été dopée avec 0,2 mol% de OCS. En procédant à un échantillonage de la flamme dans un spectromètre de masse, on a détecté plus de 40 de cations différents, de masse inférieure à 100 unités, qui contiennent du soufre. On présente les courbes des concentrations ioniques en fonction de l'axe de la flamme ainsi que les spectres de masse à des points définis de la flamme. Dans la zone de la réaction, les ions sulfurés primaires, CH_xS^+ dans lesquels x = 1, 3 et 5, subissent des réactions ion/molécules importantes (association et condensation) avec la paire CH_4/CH_3, le C_2H_2 et le OCS; il y a ainsi formation d'une variété importante de cations sulfurés secondaires. Juste après la zone réactionnelle, la chimie des ions est un peu différente; elle semble être dominée par des réactions des ions sulfurés primaires, y compris H_xS^+ (x = 0–3), avec le C_2H_2 qui est présent comme intermédiaire. Quelques ions (H_xS^+, OS^+ et S_2^+) sont présents partout dans le région des gaz ayant subi la combustion et ils sont en équilibre avec les ions normaux de la flamme, comme le CHO^+ et le H_3O^+. Ces signaux dus à des cations sulfurés démontrent l'évolution de la chimie du soufre, tant ionique que neutre, de la zone réactionnelle de la flamme à celle des gaz formés après la combustion; dans toutes ces zones, c'est le H_2S et non pas le SO_2 qui est le produit majeur de la combustion dans des mélanges riches en combustible.

Introduction

Gaseous sulphur compounds are poured into the atmosphere mainly by stationary plants for electrical power generation, space heating, smelting, paper making and sulphuric acid manufacture. The effects of both short-range and long-range transport of sulphur pollutants are increasingly recognized in connection with respiratory diseases, acid rain, and general environmental damage, both urban and rural. At the same time, detection methods for pollutants of many types have improved dramatically in the past 20 years, particularly with regard to specificity (1). A great deal of the sulphur pollution arises from combustion processes; coal is the fuel most likely to have a high sulphur content.

Any hydrocarbon flame contains a wide variety of natural ions, both positive and negative. If sulphur is present in the flame in whatever form, it will be chemically ionized to give sulphurous anions and cations. These can serve as a probe of the sulphur chemistry if the ion chemistry is reasonably well understood. The ions present in a flame at atmospheric pressure can be sampled through a nozzle into a flame-ion mass spectrometer. The method is advantageous because all types of sulphur ions can be detected with equal facility, ion identification is highly specific in the chemically complex flame environment, and all regions of the flame can be probed including the reaction zone where the sulphur chemistry originates upstream. Two such studies of sulphurous negative ions have already been completed in which a fuel-rich, CH_4–O_2 flame was doped with 0.2 mol% first of OCS (2), and then with H_2S and SO_2 for comparison with OCS (3). The types of sulphurous anions detected were relatively few (S^-, HS^-, OS^-, O_2S^-, O_3S^-, HO_3S^-, $CH_3O^-.O_2S$, O_4S^-, HO_4S^-) and were essentially confined to the flame reaction zone.

The present study involves observations of sulphurous positive ions in the same fuel-rich, CH_4–O_2 flame, again doped with 0.2 mol% of OCS. Typical ion concentration profiles measured along the flame axis are presented. Obviously, the chemical ionization (CI) processes for positive ions are different, and more than five times as many cations as anions were detected at mass numbers below 100 u. This considerable variety of cations was measured for presentation by taking mass spectra at three different points in the flame. The sulphurous cation chemistry can be understood in terms of addition and condensation reactions of primary sulphur ions with the CH_4 fuel (or CH_3 radicals derived from it), with C_2H_2 present as a major intermediate, and with S atoms supplied directly by the OCS additive. It is significant that a number of the sulphur cations, unlike most of the anions, can be detected everywhere in the flame; in the reaction zone, downstream of it, and also throughout the burnt gas region.

Experimental

All of the ion concentration measurements were performed on the same CH_4–O_2 flame of fuel-rich composition (equivalence ratio ϕ = 2.15) whose ion chemistry we have studied extensively in the past (4, 5). It was of the laminar premixed type with a conical luminous reaction zone (height ≃ 5 mm, base diameter ≃ 3 mm, thickness ≃ 0.3 mm) to facilitate ionic sampling along the flame axis into the mass spectrometer. The flame has a burnt gas velocity of approximately 1 m s^{-1} and an adiabatic flame temperature of 2460 K, although the measured temperature of the equilibrium burnt gas was close to 2200 K. The flame was stabilized at atmospheric pressure on a simple,

tubular, quartz burner (2.3 mm id) surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. Provision was made to add 0.2 mol% of OCS to the premixed gas in exactly the same way as was done previously for the sulphurous anion studies (2). The additive could be introduced or removed without altering the flame. All gases were used straight from the cylinders without further purification (CH_4 > 99.0%, O_2 > 99.6%, Ar > 99.9%, OCS > 97.5%). The burner was mounted on a motor-driven carriage with accurate alignment of the flame axis with the sampling orifice of the mass spectrometer. The calibrated burner drive provided spatial resolution of ±0.02 mm along the flame axis (designated z) for measurements of ion concentration profiles.

The flame-ion mass spectrometer has been described previously in detail (4). The flame burned against a 60°, conical, chromium, sampling nozzle of orifice diameter ca. 0.1 mm mounted in a water-cooled flange of the type described by Hayhurst and Telford (6). The sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday collector connected to a vibrating reed electrometer having a grid-leak resistance of 10^{10} ohms. The ion signal magnitudes in the figures are quoted in volts based on the detected ion current passing through 10^{10} ohms. The mass spectra shown below have been corrected for mass discrimination in the filter against ions of high m/e measured at high resolving power. The dynamic range of sensitivity of the apparatus is five orders of magnitude.

A method has been described (4) involving a relatively sharp minimum in the pressure profile of the sampled gas for locating a reproducible origin ($z = 0$) in the *flame* (not referred to the burner). It corresponds to the downstream edge of the luminous reaction zone on the flame axis. In this way, a family of ion profiles at different mass numbers m/e can be accurately overlaid on the distance scale z. It is also an important consideration, when comparing mass spectra at a fixed point on the flame axis with and without OCS additive, to be able to return to the same point on the flame axis.

Neutral sulphur chemistry

Approximate concentration profiles for the important neutral species appropriate to our flame are given in Fig. 1 adapted from Hastie's studies of a similar fuel-rich flame (7). The profiles reflect our use of an argon shield to suppress the secondary downstream combustion region which is evident in Hastie's work. Figure 1 shows the expected fall of CH_4 and O_2 through the reaction zone, and the rapid rise of the major neutral products H_2, CO, and H_2O as well as H atoms; the HO concentration actually overshoots its equilibrium value in this region. Because of the relatively weak C—S bond, OCS is an efficient donor of S atoms in reaction with a variety of flame species. Thus, when OCS is added to the premixed gas, the following series of reactions might be expected to be balanced, or nearly so, in the flame reaction zone; relevant data are given in Table 1 drawn from Westley's compilation of recommended rate constants for combustion reactions (8)

[1] $OCS + H \rightleftharpoons HS + CO$

[2] $HS + H_2 \rightleftharpoons H_2S + H$

[3] $H_2S + HO \rightleftharpoons HS + H_2O$

[4] $HS + H \rightleftharpoons S + H_2$

[5] $S + HO \rightleftharpoons OS + H$

[6] $OS + HO \rightleftharpoons O_2S + H$

Combined with a balanced reaction not involving sulphur species

[7] $H_2O + H \rightleftharpoons HO + H_2$

the overall net reaction of [1] to [7] is

[8] $OCS + 2HO \rightleftharpoons O_2S + CO + H_2$

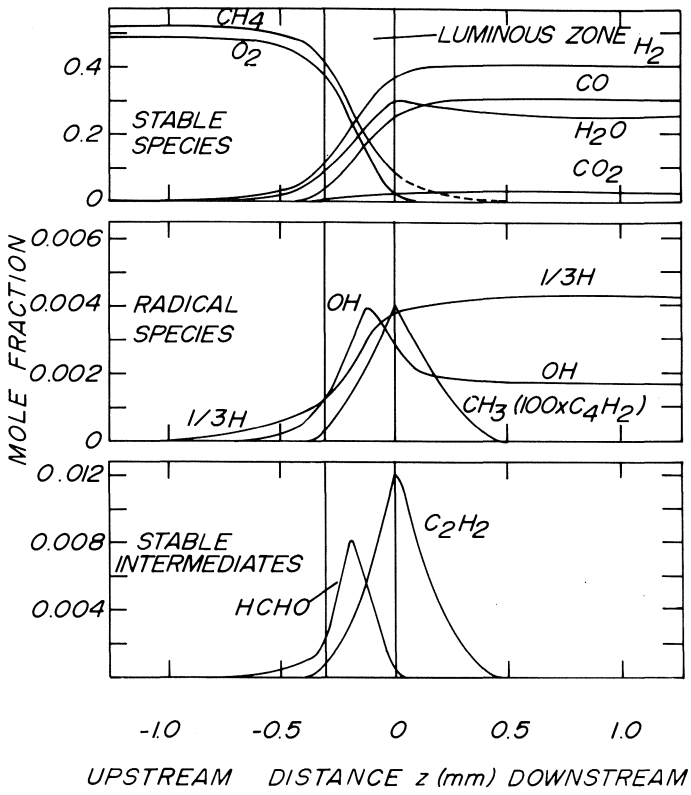

FIG. 1. Approximate concentration profiles for important neutral species adapted from Hastie's studies of a similar fuel-rich flame.

Because of the HO radical overshoot, O_2S and OS will be enhanced in the flame reaction zone, particularly when reactions involving molecular oxygen are considered

[9] $S + O_2 \rightleftharpoons OS + O$

[10] $OS + O_2 \rightleftharpoons O_2S + O$

before the oxidant is consumed. This will not be the case downstream, however, since the concentrations of CO and H_2 continue to rise, whilst that of HO falls to its equilibrium value. In addition, minor reactions can lead to diatomic sulphur

[11] $S + OCS\ (HS, OS) \rightleftharpoons S_2 + CO\ (H, O)$

In any event, a variety of sulphurous neutrals (e.g. S, HS, H_2S, OS, O_2S, S_2) will be present in the reaction zone of this fuel-rich flame.

Well downstream in the equilibrium burnt gas, the identity of the original sulphur additive is, of course, lost and only the quantity of sulphur present is important. For this flame, exactly 0.2 mol% of OCS in the premixed unburnt gas translates into 0.1285 mol% of sulphur species in the burnt gas; that is, each mole of unburnt reagents combusts to give 1.556 mol of products. Equilibrium concentrations of various sulphur species in the burnt gas can be found from calculated equilibrium constants for reactions [1] to [6] and also [11] to [13]

[12] $CS + HO \rightleftharpoons HS + CO$

[13] $CS + OCS \rightleftharpoons CS_2 + CO$

All the necessary standard free energies of formation at 2200 K are listed in JANAF Tables (11). For a few minor species (e.g. HO_2S), thermodynamic data are not available. The equilibrium concentrations of nine sulphur species, and also those of the important non-sulphurous neutrals, are given in Table 2. The figures show the preponderance of H_2S over O_2S in this

fuel-rich flame, and also the relatively high concentrations of HS and OS. Species involving C—S bonds are very minor.

Results

Sulphur cation profiles

The effect on the total positive ion profile of adding 0.2 mol% of OCS is shown in Fig. 2. The ion signal was enhanced in the reaction zone, located upstream of $z = 0$ (negative z in Fig. 2) and, to a lesser extent, downstream in the burnt gas but the peak value remained unchanged within experimental error. Profiles of individual ionic species which showed a change with the addition of OCS were measured in the mass range 32–100 u. Broadly speaking, these profiles were of four types. A number of them, particularly those at high mass numbers, showed a relatively sharp peak in the reaction zone; Fig. 3 gives an example at 77 u. Others exhibited a fairly broad maximum just downstream of the reaction zone before tailing out into the burnt gas; Fig. 4 at 47 u is a typical example.

A third group of ions, of which Fig. 5 at 59 u is typical, showed both effects; namely, a fairly sharp peak in the reaction zone and a broader one downstream. A fourth group is comprised of a few distinctive profiles like that given in Fig. 6 at 48 u which showed an even broader maximum further downstream with the signal persisting throughout the burnt gas; in the case of Fig. 6, a sulphur peak was also noted in the flame reaction zone. In all, sulphurous cation signals, many of them large, were observed at 47 mass numbers below 100 u. This behaviour is in marked contrast to the sulphurous anion signals studied previously with OCS additive in the same flame (2) which were attributable to just nine negative ion species.

Mass spectra

In order to organize this large quantity of data for presentation, mass spectra were recorded at three distinct positions on the flame axis. These three positions could be accurately reproduced with and without OCS additive with the aid of the profiles shown in Fig. 7. The first position is defined in the flame reaction zone at the peak of the profile at 43 u corresponding to $z = -0.15$ mm. This profile, due to protonated ketene, CH_2COH^+, is the largest ion signal present in the reaction zone and is a very useful marker because its peak position does not change when OCS is added to the flame. Mass spectra recorded at this position are shown in Figs. 8 and 9. The solid lines were measured with OCS present and the dashed lines with OCS

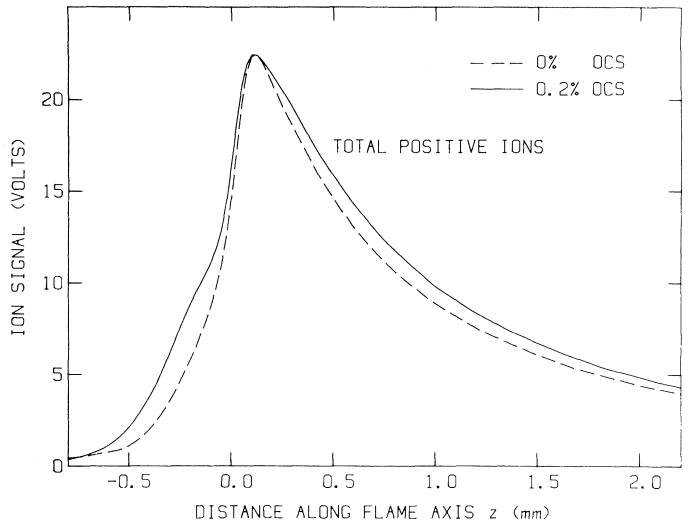

FIG. 2. Total positive ion profiles with, and without, 0.2 mol% of OCS additive. The flame reaction zone is located upstream of $z = 0$.

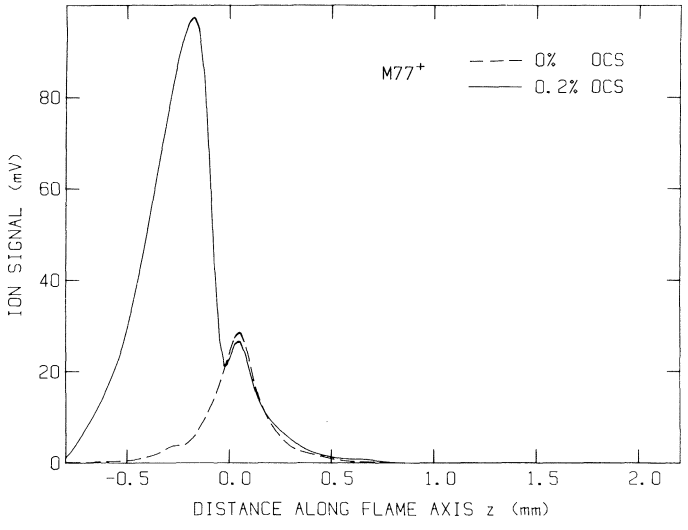

FIG. 3. Typical sulphurous cation profile with 0.2 mol% of OCS additive showing a concentration peak in the flame reaction zone; this example at 77 u is due to CHS_2^+. The dashed profile was measured with OCS absent.

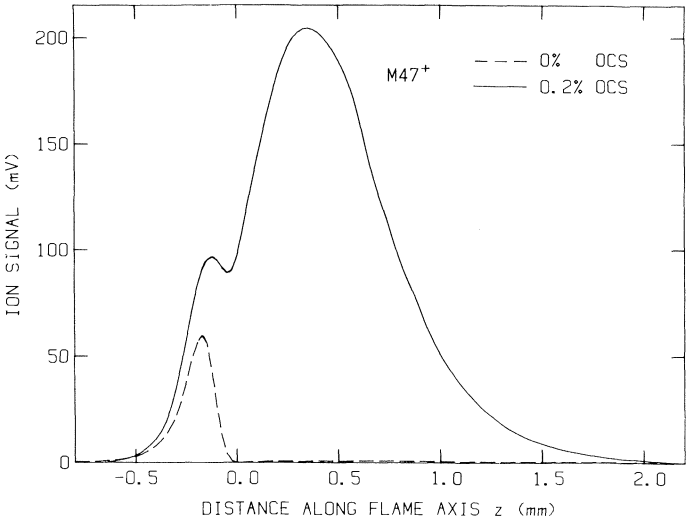

FIG. 4. Typical sulphurous cation profile with 0.2 mol% of OCS additive showing a fairly broad maximum just downstream of the flame reaction zone; this example at 47 u is due to CH_3S^+. The dashed profile was measured with OCS absent.

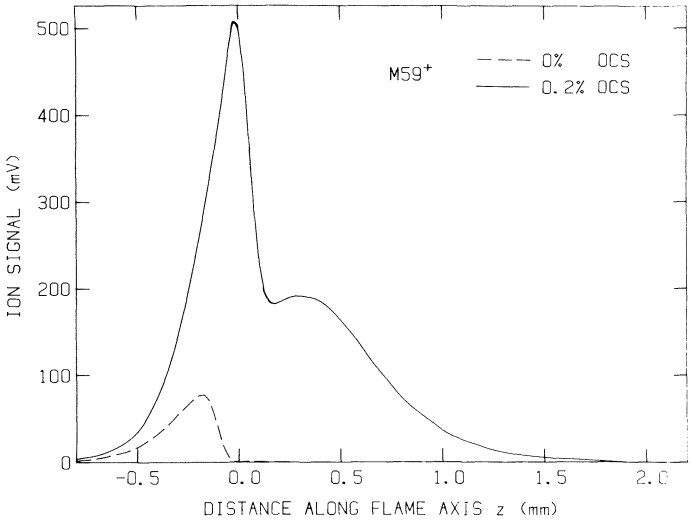

FIG. 5. Typical sulphurous cation profile with 0.2 mol% of OCS additive showing maxima both in the flame reaction zone and just downstream of it; this example at 59 u is due to $C_2H_3S^+$. The dashed profile was measured with OCS absent.

absent. For clarity, the spectra are divided up between Fig. 8 where sulphurous cations are involved, and Fig. 9 where the ion signals decrease or show little change with OCS addition.

The second position is defined at $z = 0.2$ mm on the flame axis in the vicinity of the broad profile maxima. It is designated 0.15 mm downstream of the very large $C_3H_3^+$ profile peak at 39 u which occurs at $z = 0.05$ mm as shown in Fig. 7. Although the $C_3H_3^+$ peak decreased somewhat in magnitude with the addition of OCS, it is a useful marker because the peak position does not shift. Mass spectra recorded at this position are given in Figs. 10 and 11. The data are presented in exactly the same way as those for Figs. 8 and 9.

Further downstream in Fig. 7, the very broad maximum of the persistent H_3O^+ profile at 19 u decreased and shifted considerably with OCS addition, and is not a useful marker. Thus, a third position is defined at $z = 0.5$ mm downstream, still with reference to the $C_3H_3^+$ profile peak as a marker. Figure 12 gives the mass spectra of sulphurous cations recorded at this position whose profiles persist far downstream throughout the burnt gas like H_3O^+ in Fig. 7 or OS^+ at 48 u in Fig. 6.

Discussion

Sulphurous cations may form in a number of ways. From Fig. 2, the total ion signal is appreciably higher in the flame reaction zone when OCS is present. One possible explanation is the existence of a new chemi-ionization source reaction involving sulphur such as

[14] $CH + S \rightarrow CHS^+ + e^- \qquad \Delta H^0 = 38$

(Standard heats of reaction ΔH^0 are given in kcal mol^{-1} at 298 K.) This is analogous to the established fundamental ionization reaction in hydrocarbon flames (12)

[15] $CH + O \rightarrow CHO^+ + e^- \qquad \Delta H^0 = -5$

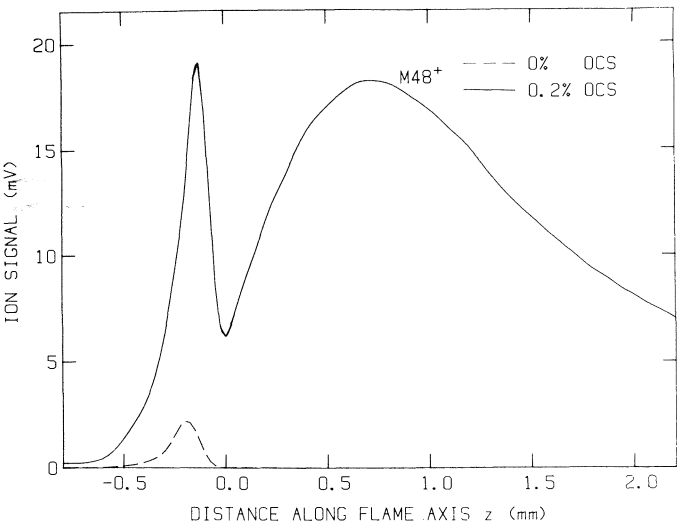

FIG. 6. Typical sulphurous cation profile with 0.2 mol% of OCS additive showing a broad maximum downstream in the flame which persists throughout the burnt gas region. This example at 48 u is due to OS^+; the additional peak in the reaction zone probably represents CH_4S^+. The dashed profile was measured with OCS absent.

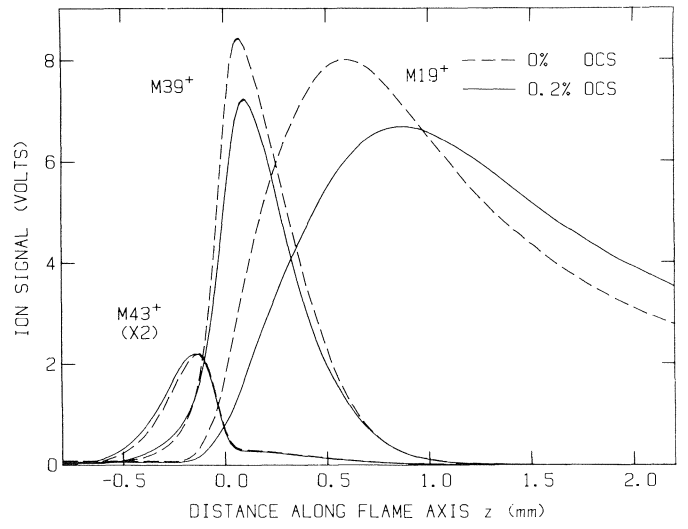

FIG. 7. Major non-sulphurous positive ion profiles with, and without, 0.2 mol% of OCS additive used to locate position markers on the flame axis. The ions represent $C_2H_3O^+$ at 43 u in the reaction zone, $C_3H_3^+$ at 39 u just downstream of it, and H_3O^+ at 19 u which persists throughout the burnt gas region.

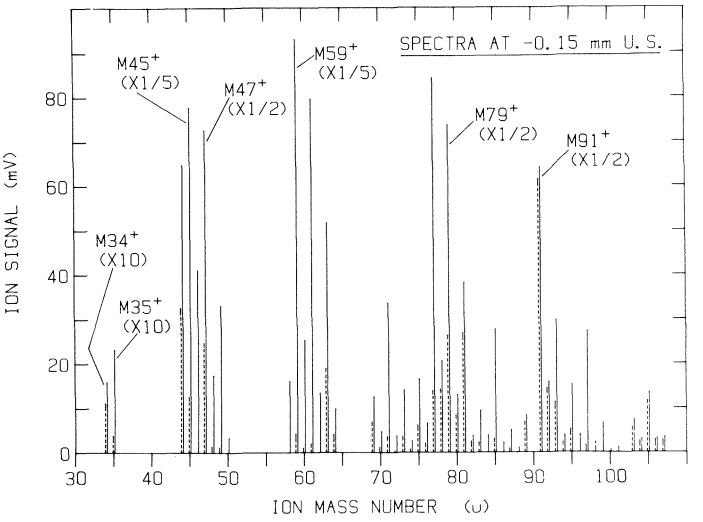
However, reaction [14] is an unlikely process because it is considerably endothermic, and also because the CHS^+ profile (not shown) did not commence as far upstream as many profiles of other ionic species. An alternative explanation might be a decreased rate of ion recombination when the flame is doped with OCS. At the present time, we do not have a satisfactory explanation of the enhanced total ion signal in the flame reaction zone, but further work is in progress to clarify the situation.

If chemi-ionization involving sulphur is not a major mechanism, the first sulphur ions to appear in the flame, which we shall designate here as primary sulphur ions, must result from ion–molecule reactions of natural flame ions with sulphurous neutrals. The most obvious example is the formation of $CHOS^+$ at 61 u by exothermic proton transfer from CHO^+ to the OCS additive



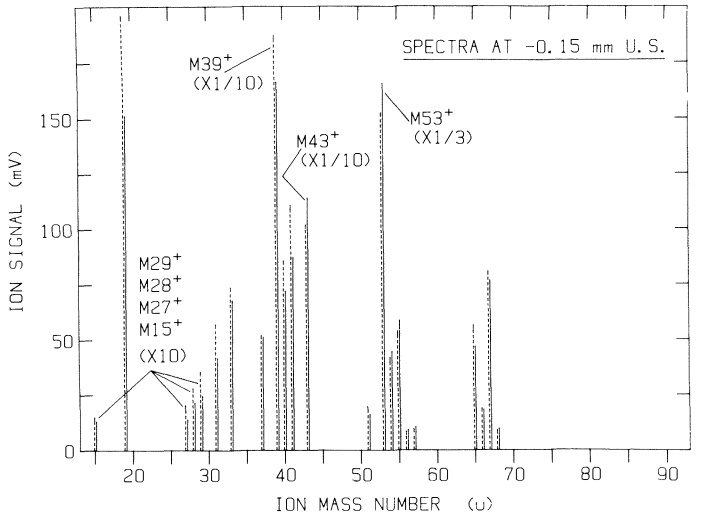


FIG. 8. Mass spectra measured in the reaction zone both with (solid lines) and without (dashed lines) OCS additive emphasizing sulphurous cations.

FIG. 9. Mass spectra measured in the reaction zone both with (solid lines) and without (dashed lines) OCS additive emphasizing non-sulphurous cations.

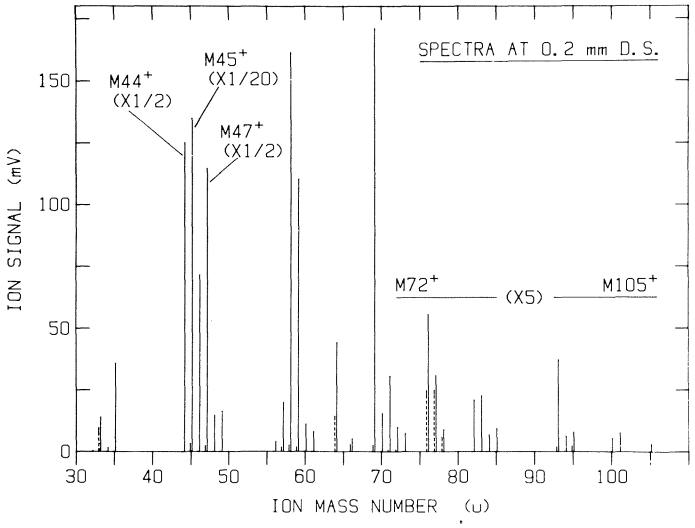
[16] $CHO^+ + OCS \rightarrow CHOS^+ + CO \qquad \Delta H^0 = -9$

Data for a number of relevant ion–molecule reactions involving sulphurous species like reaction [16] are given in Table 3 which is based mainly on Albritton's compilation (13). Not surprisingly, the $CHOS^+$ profile (not shown) was observed to commence very far upstream in the flame reaction zone. In addition, secondary sulphurous cations can form with comparatively large rates of production if primary sulphur ions react with major flame neutrals.

It will become apparent that the downstream sulphur ion chemistry at $z = 0.2$ mm exemplified by Fig. 10 is a simpler case of the ion chemistry in the reaction zone. For this reason, the downstream spectra will be discussed first before proceeding to Fig. 8.

Downstream sulphurous ion chemistry

Figure 13 is a simplified version of the mass spectra shown in Fig. 10 giving just the differences in signal magnitudes due to



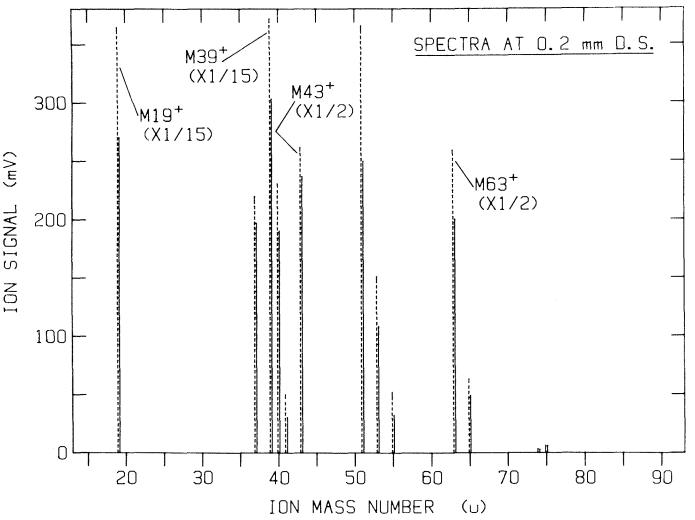


FIG. 10. Mass spectra measured just downstream of the reaction zone both with (solid lines) and without (dashed lines) OCS additive emphasizing sulphurous cations.

FIG. 11. Mass spectra measured just downstream of the reaction zone both with (solid lines) and without (dashed lines) OCS additive emphasizing non-sulphurous cations.

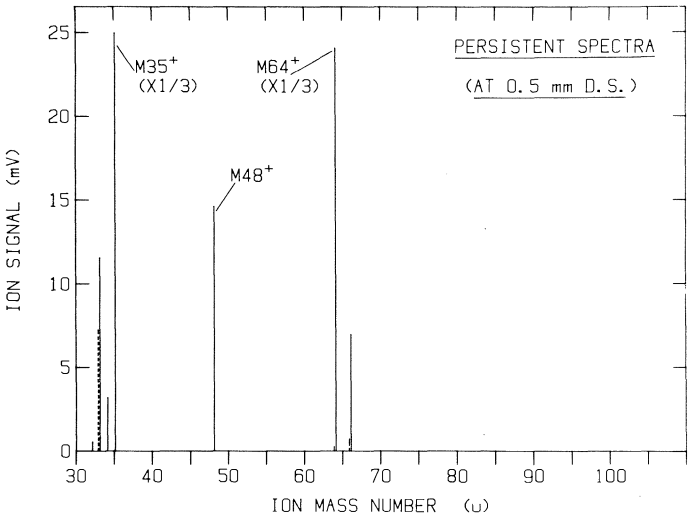

FIG. 12. Mass spectra measured at $z = 0.5$ mm both with (solid lines) and without (dashed lines) OCS additive of those sulphurous cations whose profiles persist throughout the burnt gas region.

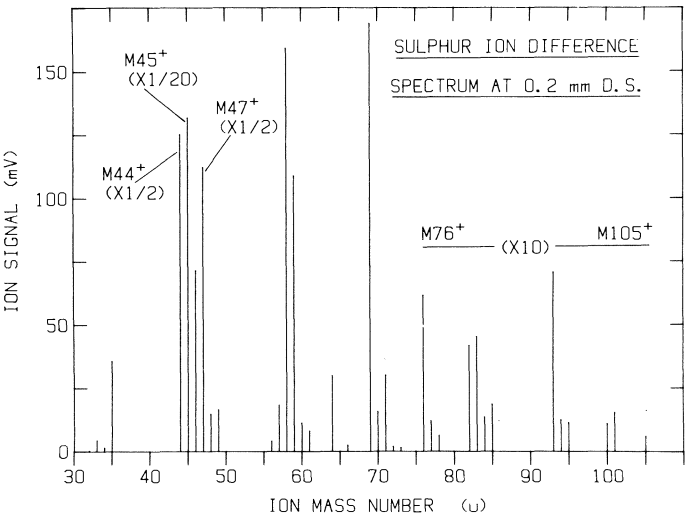

FIG. 13. Difference mass spectrum of just the sulphurous cation signals measured just downstream of the flame reaction zone.

sulphur cations at $z = 0.2$ mm downstream. The ions at 33–35 u can arise from protonated S, HS, and H_2S whose proton affinities (PA's) are fairly high. Table 4 lists the PA's of a number of sulphur species and also those of their oxygen analogues for comparison purposes; the values are taken from the recent compilation of Lias *et al.* (19). For a given pair, it is significant that the sulphur value is higher than the oxygen one in every case. The tiny S^+ ion signal at 32 u can arise by H atom stripping of HS^+

[17] $HS^+ + H\ (HO) \rightarrow S^+ + H_2\ (H_2O) \qquad \Delta H^0 = -20\ (-35)$

since the concentrations of H and HO will be near their equilibrium values 0.2 mm downstream. Similar H atom stripping reactions are exothermic for the $H_2S^+ \rightarrow HS^+$ and $H_3S^+ \rightarrow H_2S^+$ conversions as well.

The next group of ions in the mass range 44–49 u is comprised of CH_xS^+ ($x = 0$–3) and probably OS^+ and HOS^+. The large signals observed at 45 and 47 u may derive in part from proton transfer to CS and HCHS (thioformaldehyde) whose PA's given in Table 4 are high. Otherwise, a number of possible reactions leading to CHS^+ and CH_3S^+ have been measured at room temperature, and are listed in Table 3. For example, there is a series of reactions of CH_x^+ ($x = 0$–3) ions with H_2S

[18] $C^+ + H_2S \rightarrow CHS^+ + H \qquad \Delta H^0 = -127$
$\rightarrow H_2S^+ + C \qquad \Delta H^0 = -19$

[19] $CH^+ + H_2S \rightarrow CHS^+ + H_2 \qquad \Delta H^0 = -137$
$\rightarrow H_3S^+ + C \qquad \Delta H^0 = -23$

[20] $CH_2^+ + H_2S \rightarrow CHS^+ + H + H_2 \qquad \Delta H^0 = -29$
$\rightarrow CH_3S^+ + H \qquad \Delta H^0 = -75$
$\rightarrow H_3S^+ + CH \qquad \Delta H^0 = 4$

[21] $CH_3^+ + H_2S \rightarrow CH_3S^+ + H_2 \qquad \Delta H^0 = -54$

and a similar series involving CH_x^+ with OCS. At 48 and 49 u, OS^+ and HOS^+ are favoured over CH_4S^+ and CH_5S^+.

Although the PA of CH_3SH given in Table 4 is high, and presumably that of the CH_3S radical also, these species are more likely to be found in the reaction zone and not downstream. On the other hand, the downstream concentration of OS even at z = 0.2 mm will be relatively high tending towards the calculated value given in Table 2. Although PA(OS) is not known, proton transfer to form HOS^+ followed by H atom stripping to give OS^+ is the most logical mechanism. Further support for this hypothesis comes from Fig. 12 where a sulphur profile at 48 u, undoubtedly OS^+, was observed to persist far downstream throughout the burnt gas.

The signal at 64 u is due to S_2^+, not O_2S^+, since the peak height at 66 u is 8.5% of that at 64 u in keeping with the natural abundance of the ^{34}S isotope of 4.22%. The group of ions observed at 76–78 u appears to represent $CH_xS_2^+$ (x = 0–2) disulphide ions. The ion with x = 1 at 77 u amounts to protonated carbon disulphide for which the H atom stripping reactions

[22] $CHS_2^+ + H(HO) \rightarrow CS_2^+ + H_2(H_2O) \qquad \Delta H^0 = -18\,(-33)$

are exothermic (20). Similarly, the signal at 78 u probably results from H atom stripping of $CH_3S_2^+$ at 79 u. Better evidence for CHS_2^+ and $CH_3S_2^+$ at 77 and 79 u comes from Figs. 3 and 8 in the flame reaction zone where the measured signals are much larger. The profiles of both ions were observed to commence very far upstream like that of $HCOS^+$.

The next step in the explanation comes from Hastie's neutral profiles (7) shown in Fig. 1. He observed the formation of acetylene as an intermediate having a peak concentration > 1% near the downstream edge of the reaction zone. Flame-ion evidence for acetylene comes from the very large $C_3H_3^+$ peak shown in Fig. 7 at the same position in our flame; C_2H_2 is the neutral reagent for the formation of $C_3H_3^+$ (4, 21). Acetylene is the key ingredient. All the other high-mass ions in Fig. 13 are explicable in terms of ion–molecule reactions of C_2H_2 with the ion groups at 32–35, 44–49, and 76–78 u. Acetylene is known to participate in ion-molecule association/condensation reactions (4, 22–24) of the types

[23] $$X^+ + C_2H_2 \xrightarrow{M} \begin{cases} C_2H_2X^+ \\ \rightarrow C_2HX^+ + H \\ \rightarrow C_2X^+ + H_2 \end{cases}$$

where M is a third body. Downstream in the flame where the H and HO concentrations are high, the C_2X^+ product is favoured because $C_2H_2X^+$ and C_2HX^+ are subject to H atom stripping. In general, the expected mechanism for secondary sulphurous ion formation is the addition of 24–26 mass units to ions of lower mass. Thus, acetylene addition to the H_xS^+ (x = 0–3) ions at 32–35 u produces the ion groups at 57–61 and 82–85 u. In particular, the large ion signals 35 → 59 → 83 differ by 24 u except that the peak at 58 u is greater than that at 59 u. (Note that the reverse is true in the reaction zone, Fig. 8.) However, H atom stripping of protonated thioketene at 59 u should be exothermic such that the larger signal at 58 u is not surprising

[24] $C_2H_3S^+ + H(HO) \rightarrow C_2H_2S^+ + H_2(H_2O)$

That reaction [24] would be exothermic stems from the fact that the oxygen analogue of the reaction involving protonated ketene is thermoneutral

[25] $C_2H_3O^+ + H \rightarrow C_2H_2O^+ + H_2 \qquad \Delta H^0 = 0.4$

Although PA(CH_2CS) is slightly greater than PA(CH_2CO) in Table 4, the ionization energy IE(CH_2CS) should be at least 1 eV less than IE(CH_2CO) = 9.614 eV (20), and the exothermicity of reaction [24] follows.

In the same way, acetylene addition to the $CH_xS^+/OS^+/HOS^+$ group of ions at 44–49 u produces the ion groups at 69–73 u and 93–95 u. In particular, the large ion signals in each group, 45 → 69 → 93, differ by 24 u. Also, the addition of acetylene to the $CH_xS_2^+$ ions grouped at 76–78 u accounts for the signals observed at 100, 101, and even 105 (i.e. $CH_3S_2^+$ + 26 u). In summary, three groups of protonated primary ions modified by H atom stripping plus acetylene addition/condensation reactions account for essentially all of the sulphurous cations observed in Fig. 13. An exception is S_2^+ which will be discussed further in the next section.

Persistent downstream ion profiles

Figure 12 is a mass spectrum of sulphurous cations whose profiles persist far downstream throughout the burnt gas like those shown for OS^+ and H_3O^+ in Figs. 6 and 7, respectively. The CHO^+ profile (not shown) is similar in this fuel-rich flame, and is indicative of a proton transfer equilibrium with H_3O^+

[26] $CHO^+ + H_2O \rightleftharpoons H_3O^+ + CO \qquad \Delta H^0 = -24.6$

(ΔH^0 values are quoted for the forward direction.) In the same way, all of the sulphurous ions represented in Fig. 12 (S^+, HS^+, H_2S^+, H_3S^+, OS^+, S_2^+) must come into equilibrium with H_3O^+ and CHO^+ downstream. The four H_xS^+ (x = 0–3) ions can be formed by proton transfer reactions involving H_3O^+

[27] $H_3O^+ + H_2S \rightleftharpoons H_3S^+ + H_2O \qquad \Delta H^0 = -3.7$

[28] $H_3O^+ + HS \rightleftharpoons H_2S^+ + H_2O \qquad \Delta H^0 = 2$

[29] $H_3O^+ + S \rightleftharpoons HS^+ + H_2O \qquad \Delta H^0 = 8.2$

in combination with the H atom stripping reactions

[30] $H_3S^+ + H(HO) \rightleftharpoons H_2S^+ + H_2(H_2O) \qquad \Delta H^0 = -6\,(-21)$

[31] $H_2S^+ + H(HO) \rightleftharpoons HS^+ + H_2(H_2O) \qquad \Delta H^0 = -14\,(-29)$

[17] $HS^+ + H(HO) \rightleftharpoons S^+ + H_2(H_2O) \qquad \Delta H^0 = -20\,(-35)$

which are exothermic in every case. For the latter three reactions, the rates of the endothermic back reactions are aided by the high equilibrium concentrations of H_2 and H_2O quoted in Table 2. But H_2S^+, HS^+, and S^+ are, of course, ionized H_2S, HS, and S which have ionization energies (IE's) of 10.47, 10.41, and 10.36 eV, respectively (20, 25). These IE's are all slightly higher than those of OS (10.31 eV) and S_2 (9.37 eV) such that OS^+ and S_2^+ could be formed by exothermic charge transfer processes; for example

[32] $H_2S^+ + OS \rightleftharpoons OS^+ + H_2S \qquad \Delta H^0 = -3$

Table 3 lists rate constants for a number of fast reactions which link these ions together and increase the rate of attainment of equilibrium; for example

[33] $OS^+ + H_2S \rightleftharpoons S_2^+ + H_2O \qquad \Delta H^0 = -47$

Thus, persistent ion signals are found in the burnt gas involving reasonably abundant sulphur neutrals (see Table 2) whose PA's are relatively high, and/or whose IE's are relatively low.

In principle, some of the ion–molecule reactions involving sulphurous species might be used to determine equilibrium constants K in the burnt gas. For example, reaction [27] yields

[34] $$K_{27} = \frac{[H_2O]}{[H_2S]} \times \frac{[H_3S^+]}{[H_3O^+]}$$

in terms of calculated neutral concentrations given in Table 2 and the measured ion signal ratio. Hence, $\Delta G^0 = -RT \ln K$ for

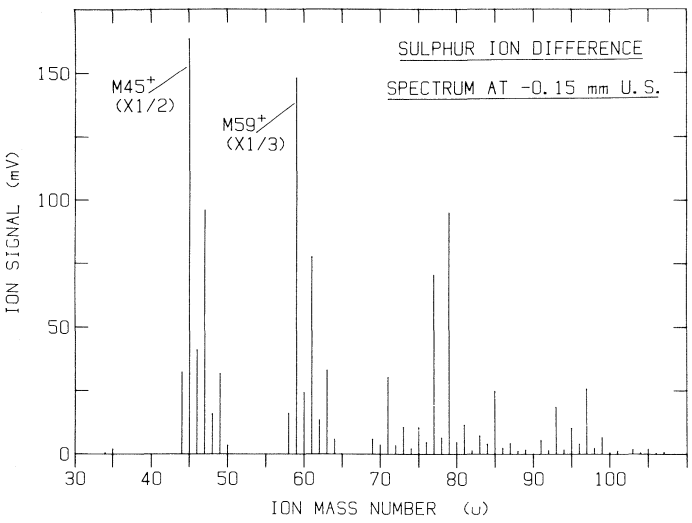

FIG. 14. Difference mass spectrum of just the sulphurous cation signals measured in the flame reaction zone.

such a reaction can be determined at the flame temperature provided that equilibrium is attained. We intend to consider some of these quantitative aspects in a future publication.

Sulphur ions in the reaction zone

Figure 14 is a simplified version of the mass spectra shown in Fig. 8 giving just the differences in signal magnitudes due to sulphur cations at $z = -0.15$ mm upstream in the reaction zone. Clearly the sulphur ion chemistry is more complicated than that shown in Fig. 13 for the downstream region. Here, the aim will be to high-light the main features without attempting to explain every peak. Thus, the explanation will concentrate on the larger ion signals having odd mass numbers recognizing that the ions of even mass can generally be produced by H atom stripping reactions.

In what respects is the reaction zone chemically different from the downstream region? Hastie's neutral profiles in Fig. 1 show the rise of formaldehyde as an intermediate whose concentration reaches a peak value of approximately 0.8 mol%. In addition, the acetylene concentration rises steadily through the reaction zone, and also that of methyl radicals from the decay of the methane fuel. Finally, the OCS additive retains its identity and serves as a donor of S atoms in reactions with other ions, giving CO as a neutral product.

In the first place, Fig. 14 shows that the H_xS^+ ($x = 0$–3) ion signals are much smaller than those measured downstream. This is partly due to the fact that the concentrations of S, HS, and H_2S have not yet reached their downstream equilibrium values. In addition, the PA's of all three neutrals given in Table 4 are less than that of formaldehyde; Table 3 indicates that the proton transfer reaction

$$[35] \quad H_3S^+ + HCHO \rightarrow CH_3O^+ + H_2S \qquad \Delta H^0 = -1.5$$

has a very high rate constant at room temperature (16). Although H_3S^+ does not react with CH_4 (17) it might well do so with CH_3 radicals

$$[36] \quad H_3S^+ + CH_3 \rightarrow CH_5S^+ + H \qquad \Delta H^0 = 0$$

at the flame temperature.

For the next ion group, let us focus attention primarily on the ion signals at 45, 47, and 49 u. Sources of the first two ions, CHS^+ and CH_3S^+, are given in Table 3 involving reactions of the CH_x^+ ($x = 0$–3) ions with OCS rather than with H_2S given

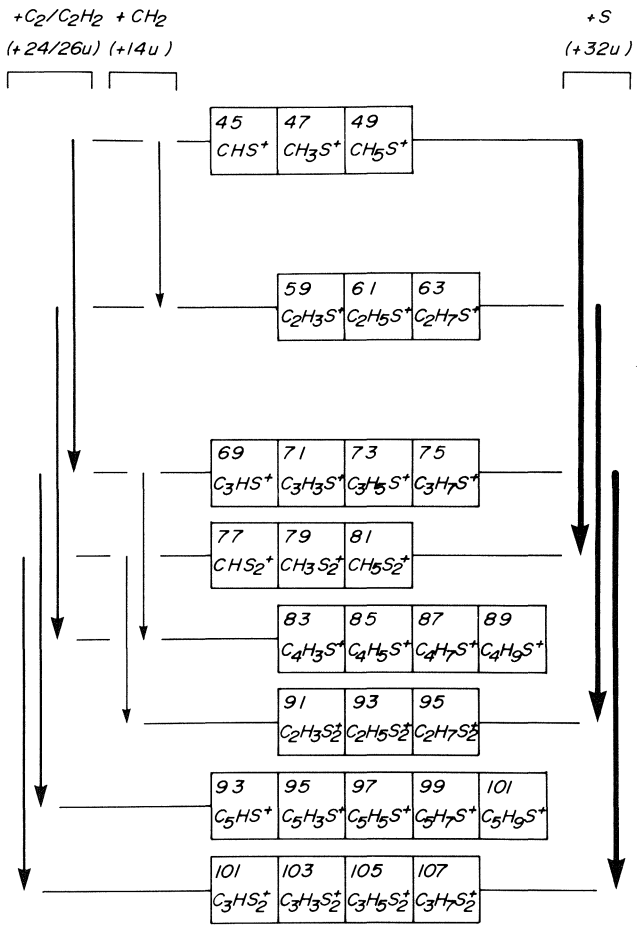

FIG. 15. Reaction flow diagram of the sulphurous ion chemistry in the flame reaction zone showing reactions of primary sulphur ions with C_2H_2, CH_4/CH_3, and with the OCS additive.

previously for the downstream region (reactions [18] to [21]). The ion at 49 u is likely to be CH_5S^+ rather than HOS^+ in the reaction zone. It might arise via reaction [36] or, if the mercaptan CH_3SH is present, by proton transfer since PA(CH_3SH) is high (see Table 4).

We are suggesting that these three CH_xS^+ ($x = 1, 3, 5$) ions in reactions with CH_4/CH_3, C_2H_2, and OCS are the primary reagents for essentially all the major sulphurous cations observed at higher mass numbers in Fig. 14. Thus, reactions with CH_4/CH_3 will result in the addition of a methylene group to the parent ion increasing its mass by 14 u

$$[37] \quad C_nH_mS^+ + CH_4\ (CH_3) \rightarrow C_{n+1}H_{m+2}S^+ + H_2\ (H)$$

Acetylene will add in much the same way as discussed previously for the downstream region

$$[38] \quad C_nH_mS^+ + C_2H_2 \xrightarrow{M} C_{n+2}H_{m+2}S^+ \rightarrow C_{n+2}H_mS^+ + H_2$$

except that the lower temperature of the reaction zone might be expected to favour the first channel; i.e., acetylene reactions will increase the parent mass by 26 or 24 u. Finally, reactions with OCS will add sulphur giving a mass increase of 32 u

$$[39] \quad CH_xS^+ + OCS \rightarrow CH_xS_2^+ + CO \qquad (x = 1, 3, 5)$$

The anomalously large signal at 79 u might involve $(CH_3)_2SOH^+$ as well as $CH_3S_2^+$ since PA(dimethylsulphoxide) = 211.3 kcal mol^{-1} is so high. Figure 15 presents a reaction scheme which closely follows the observations of the sulphurous cations given in

Fig. 14. In particular, the preservation of the relative signal magnitudes for the CH_xS^+ ($x = 1, 3, 5,$) ion triad at higher mass numbers should be noted. In general, H atom stripping is not observed to occur to the same extent as was the case downstream; the concentration of H atoms has not yet reached its equilibrium value upstream in the flame reaction zone.

Conclusions

When a fuel-rich, CH_4–O_2 flame is doped with 0.2 mol% of OCS, a number of conclusions can be drawn about the involvement of the sulphur additive in the flame chemistry as inferred from observations of flame cations.

(*1*) A great variety of different sulphurous cations has been detected at roughly half the mass numbers below 100 u.

(*2*) Concentration profiles of sulphurous ions measured along the flame axis show three characteristic shapes or combinations of them; fairly sharp peaks in the reaction zone, broader maxima just downstream of it, or even broader maxima still further downstream with ion signals which persist throughout the burnt gas.

(*3*) Upstream in the reaction zone, the CH_xS^+ ($x = 1, 3, 5$) ions are the major sulphurous ions to be formed first. Essentially all the rest of the sulphurous cations are secondary ions formed by addition (i.e. association) or condensation reactions of CH_xS^+ with (*a*) CH_4/CH_3, (*b*) C_2H_2, or (*c*) S from the OCS additive.

(*4*) Just downstream of the reaction zone, the primary sulphurous cations are H_xS^+ ($x = 0$–3) in addition to CH_xS^+ and possibly OS^+/HOS^+ as well. Essentially all the rest of the sulphur ions in this flame region can be explained by reactions of the primary cations with just C_2H_2, although ions of even mass number can be produced by H atom stripping reactions with H and HO.

(*5*) The few sulphur ions which persist throughout the burnt gas (H_xS^+ ($x = 0$–3), OS^+ and S_2^+) must be equilibrated with the natural flame ions CHO^+ and H_3O^+. These signals may be useful analytically for downstream sulphur determinations of H_2S, HS, OS, and S_2, but a cation link with O_2S is not immediately apparent.

(*6*) In the burnt gas region of this fuel-rich flame, equilibrium calculations show that H_2S accounts for about half, and HS nearly one quarter, of the total sulphur present; OS and O_2S amount to about 10% each. For fuel-rich combustion in general, it is of interest to know just where, and if, H_2S is subsequently oxidized to O_2S.

(*7*) The OCS additive is a very effective donor of S atoms in reaction with either ions or neutral species present in the flame.

(*8*) From observations of mass spectra, it is apparent that the sulphur cation chemistry closely mimics the oxygen cation chemistry with a separation of 16 mass units. Comparatively large sulphur ion signals are obtained from a small concentration of additive because the proton affinities of the sulphur species are larger, and ionization energies are smaller, than those of their oxygen analogues.

(*9*) When compared with previous studies of sulphurous negative ions (2, 3), it is clear that a much greater variety of sulphurous positive ions was observed. This bears out the general contention that electron-deficient cations are better candidates for molecular growth by condensation reactions than are electron-rich anions.

GÉRARD BEINERT et MITCHELL A. WINNIK. Can. J. Chem. **64**, 1743 (1986).

Dans le but d'étudier la formation d'exciplexes intramoléculaires, nous avons préparé comme intermédiaires de synthèse des polystyrènes qui portent quantitativement à l'une des extrémités de la chaîne une fonction alcool, et à l'autre le groupe *N*,*N*-diméthylaminophényle. Ce groupe chromophore a été introduit dans le polymère par amorçage de la polymérisation anionique du styrène au moyen d'une solution contenant du potassio-1 (*N*,*N*-diméthylamino-4)phényl-1 éthane. En desactivant ensuite le polymère «vivant» par de l'oxiranne, on obtient la fonction alcool. Une méthode simple de préparation de cet amorceur consiste à faire réagir un excès de potassium sur une solution d'éthoxy-1 (*N*,*N*-diméthylamino-4)phényl-1 éthane dans le THF. Malgré son instabilité relative, cette solution se présente comme un amorceur efficace de la polymérisation du styrène.

GÉRARD BEINERT and MITCHELL A. WINNIK. Can. J. Chem. **64**, 1743 (1986).

To prepare polymers carrying a donor chromophore at one end and an acceptor chromophore at the other, anionic initiators carrying the 4-*N*,*N*-dimethylaminophenyl group were synthesized by two different methods. These polymers were needed for the purpose of studying intramolecular cyclization via observation of exciplex formation. It was established that metal cleavage of appropriately substituted ethers was the most advantageous way to synthesize these functionalized initiators. These compounds proved very reactive toward styrene, yielding quantitatively polymers bearing 4-(*N*,*N*-dimethylaminophenyl) groups at one end of the chain. At the other end of the chain, induced deactivation of the "living" sites by means of oxirane created a hydroxy function that could be used in a later step to attach various other groups. Attachment of pyrene to this end would lead to a system in which intramolecular exciplex formation could occur.

Introduction

La dynamique de cyclisation de chaînes macromoléculaires par formation intramoléculaire de complexes de type excimère ou exciplexe suscite depuis quelques années un vif intérêt (1). Pour réaliser de telles études, il est nécessaire de disposer de polymères linéaires—et si possible bien définis—portant des fonctions aux extrémités de leur chaîne. Dans le cas des exciplexes qui nous occupe ici, les deux fonctions doivent être de nature différente, l'une ayant un caractère donneur, l'autre accepteur d'électrons. Nous avons choisi la fonction *N*,*N*-diméthylamino-4 phényle (DAP) comme groupe donneur. Le présent article a pour objet de décrire la préparation de polystyrènes portant cette fonction à une extrémité de leur chaîne, l'autre étant dotée d'une fonction alcool susceptible de servir ultérieurement de point d'ancrage pour différents groupes chromophores de type accepteur.

L'objectif que nous nous sommes fixé implique l'utilisation d'un amorceur anionique comportant la fonction DAP afin de pouvoir utiliser l'oxiranne pour la formation de la fonction hydroxy à l'autre extrémité de la chaîne.

Nous avons donc conçu deux méthodes permettant de préparer des composés organo-métalliques fonctionnalisés par le groupe en question et nous avons étudié le comportement de ces composés en tant qu'amorceurs de la polymérisation anionique du styrène.

On sait en effet que la polymérisation anionique sans transfert, ni terminaison, constitue une méthode de choix pour la préparation de polymères de masse molaire déterminée et de faible polymolécularité, et pour la fonctionnalisation des extrémités de chaîne par désactivation sélective à l'aide d'un réactif approprié. L'objectif visé pourrait donc être atteint s'il s'avère possible d'amorcer la polymérisation du styrène par un composé organo-métallique portant la fonction DAP, et si la désactivation par l'oxiranne conduit effectivement à une fonction OH à l'autre extrémité de la chaîne (schéma 1) : l'action du chlorure de (pyrényl-1)-4 butyryle sur cette dernière devrait en effet permettre d'accéder à des chaînes polymères portant des fonctions différentes à leurs extrémités, et susceptibles de conduire à la formation d'exciplexes intramoléculaires.

Résultats et discussions

Il semble établi que le groupe *N*,*N*-diméthylamino n'entraîne pas de réactions parasites en polymérisation anionique. Par exemple Worsfold (2) a obtenu des polystyrènes marqués quantitativement à l'une des extrémités de leur chaîne en amorçant la polymérisation du styrène par le lithio-1 (*N*,*N*-diméthyl)amino-3 propane.

Le problème consiste donc à préparer un amorceur organo-métallique portant la fonction DAP. Deux voies s'offrent à nous : (*i*) la réaction d'addition d'un composé organo-métallique R^-M^+ sur le (*N*,*N*-diméthylamino-4)isopropényl benzène (DAB) dans des conditions choisies de façon à éviter la polymérisation intempestive de ce monomère; et (*ii*) la réaction de clivage par le potassium d'un éther comportant un groupe DAP.

Méthode procédant par addition

Le (*N*,*N*-diméthylamino-4)isopropényl benzène a été préparé selon la méthode de Seymour et Wolfstirn (3). La réaction d'addition d'un composé organo-métallique sur un dérivé de l'α-méthylstyrène ne peut se produire de façon satisfaisante que si le caractère nucléophile de l'organo-métallique est très accusé. C'est pourquoi nous avons choisi les trois composés suivants : le *sec*-butyllithium (*s*BuLi), le potassio-2 phényl-2 propane (PIK) et le potassio-1 phényl-1 éthane (PEK), dont

1. Révision reçue le 2 avril 1986.

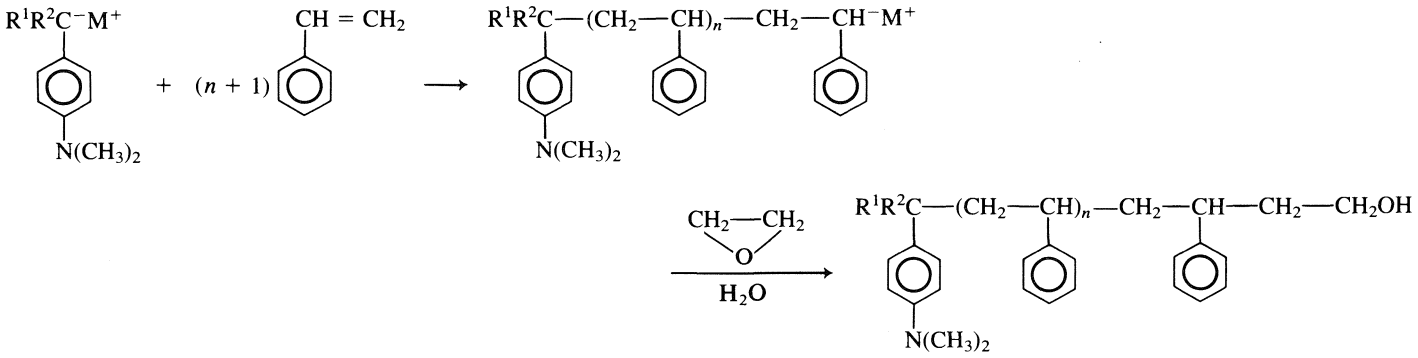

SCHÉMA 1

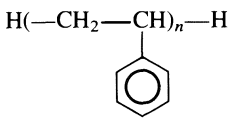
l'efficacité en tant qu'amorceurs n'est plus à démontrer. Le dernier mentionné a été utilisé en particulier pour la synthèse de polystyrènes de structure «idéale» ne comportant aucun groupe étranger au polymère (4) ainsi que pour la synthèse de copolymères séquencés polystyrène–polyoxyéthylène.



Le potassio-1 phényl-1 éthane peut être obtenu selon le procédé de Benkeser *et al.* (6) qui consiste à métaller l'éthylbenzène par un alkyl-potassium. Une méthode plus facile consiste à traiter une solution de bis(phényl-1 éthyl)éther dans le THF par du potassium. Cette réaction, étudiée par Gillman et McNinch (7) dans le cas du lithium, est transposable au potassium et conduit à une solution d'amorceur efficace pour la polymérisation du styrène (8). Il faut noter que, dans le cas qui nous occupe, la présence de phényl-1 éthanolate de potassium, qui se forme simultanément, n'est pas gênante.

La réaction d'addition a été conduite à 50°C dans le benzène, dans le cas du *s*BuLi, et à 25°C dans le THF pour les deux autres composés organo-métalliques. La solution est agitée pendant 2 h. On ajoute ensuite le styrène goutte à goutte, puis l'oxiranne destiné à la formation de fonctions hydroxyle. Il faut noter à cet égard que lorsque le potassium est le contre-ion, il est impératif d'opérer à une température suffisamment basse pour qu'un seul motif —CH_2—CH_2—O— se fixe en bout de chaîne, et que la polymérisation de l'oxiranne ne puisse avoir lieu.

Les résultats de nos essais sont rassemblés au tableau 1, et appellent quelques commentaires :

Pour vérifier le taux de fixation du groupe DAP en bout de chaîne, nous avons comparé entre elles les valeurs de la masse molaire moyenne en nombre $\bar{M}_n$ obtenue par chromatographie liquide d'exclusion (SEC) et de la masse molaire calculée à partir de l'absorption du chromophore, en faisant l'hypothèse que chaque chaîne porte *une* telle fonction, $\bar{M}_{uv}$. Nous avons supposé que le coefficient d'absorption molaire ε du groupe DAP est égal à celui d'un composé modèle : le *N*,*N*-diméthyl-amino-4 *tert*-butyl benzène que nous avons préparé au laboratoire (9) par alkylation de l'amino-4 *tert*-butyl benzène. La valeur de ε que nous avons trouvée à 300 nm est de 2 530 L mol^{-1} cm^{-1}, cette mesure étant effectuée sur un mélange d'isomères *para* (96,7%) et *ortho* (3,2%) caractérisé par chromatographie en phase gazeuse. Le point d'ébullition du composé modèle est de 121°C sous 1 600 Pa.

Il apparait dans le tableau 1 que les valeurs du rapport $\bar{M}_n/\bar{M}_{uv}$ sont dans tous les cas inférieures à l'unité. Cela peut s'expliquer par la lenteur de la réaction d'addition de R^-M^+ sur le DAB. Il faut noter que les conditions de concentration et de température n'étaient pas propices à la polymérisation du DAB. Par conséquent, la fonctionnalisation incomplète ne peut résulter que de la présence d'amorceur résiduel non fonctionnel (*s*BuLi, PIK, PEK) qui a participé à l'amorçage de la polymérisation du styrène.

Méthode procédant par clivage

La réaction déjà mentionnée de clivage du bis(phényl-1 éthyl)éther par le potassium nous a incité à avoir recours à une méthode semblable pour la synthèse du potassio-1 (*N*,*N*-diméthylamino-4)phényl-1 éthane. La synthèse de l'éther correspondant, le bis[(*N*,*N*-diméthylamino-4)phényl-1 éthyl]éther, et de l'éther dissymétrique, le (*N*,*N*-diméthylamino-4)phényl-1 éthyl éthyl éther, sont originales, le rendement étant bien meilleur dans le second cas.

La réaction de clivage s'effectue en milieu THF à −20°C, avec un excès de potassium. Le milieu réactionnel devient rouge foncé et contient alors un amorceur de polymérisation efficace, qui doit être consommé (schéma 2) dans les heures qui suivent, car sa stabilité n'est par très élevée. Même conservée à −20°C la solution évolue, sa viscosité s'accroît et son utilisation devient hasardeuse. Par contre, conservée à −75°C, elle est utilisable pendant une semaine.

Nous avons constaté que le dosage classique des sites actifs par l'acétanilide conduit dans ce cas à des résultats erronés. Il suffit en effet de 0,5 molécule d'acétanilide pour titrer un site organo-métallique. Ce résultat peut surprendre, mais il est reproductible, et peut être lié au caractère fortement nucléophile d'un carbanion benzylique substitué en *para* par un groupe donneur.

Les résultats des expériences de polymérisation effectuées à l'aide des solutions d'amorceur fonctionnel obtenues par clivage d'éther figurent au tableau 2. Comme précédemment, le taux de fonctionnalisation réalisé par amorçage a été déterminé par le rapport $\bar{M}_n/\bar{M}_{uv}$. Le composé modèle que nous avons utilisé pour la détermination du coefficient d'absorption molaire ε est ici le *N*,*N*-diméthylamino-4 isopropyl benzène préparé par

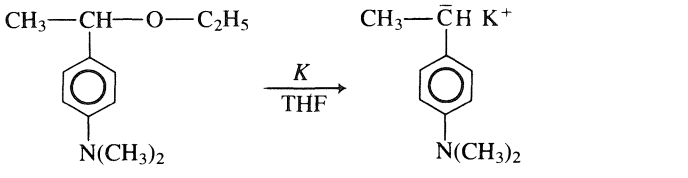


SCHÉMA 2

TABLEAU 1. Conditions expérimentales et résultats de la polymérisation amorcée par DAB

Amorceur	Solvant	T_{am} (°C)	Durée (h)	$T_{pol.}$ (°C)	$\bar{M}_n$ (g mol^{-1})	$\bar{M}_{uv}$ (g mol^{-1})	$\bar{M}_n/\bar{M}_{uv}$
DAB + *s*BuLi	Benzène	50	2	50	21 000	65 000	0,32
DAB + PIK	THF	25	2	−65	18 000	70 500	0,25
DAB + PEK	THF	25	4	−65	25 000	52 600	0,48

T_{am} : température à laquelle on prépare la solution d'amorceur; durée : temps durant lequel on laisse réagir le DAB sur l'organoalcalin R^-M^+; $T_{pol.}$: température à laquelle s'effectue la polymérisation du styrène; $\bar{M}_n$: masse molaire moyenne en nombre déterminée par chromatographie liquide d'exclusion; $\bar{M}_{uv}$: masse molaire moyenne déterminé par spectrométrie uv.

TABLEAU 2. Masse molaire des polymères préparés par la méthode procédant par clivage

$\bar{M}_n$ (g mol^{-1})	$\bar{M}_w$ (g mol^{-1})	$\bar{M}_{uv}$ (g mol^{-1})	$\bar{M}_w/\bar{M}_n$	$\bar{M}_n/\bar{M}_{uv}$
3 250	3 600	3 270	1,11	0,99
4 770	5 300	4 370	1,11	1,09
7 700	9 200	7 440	1,19	1,03
11 400	12 300	11 800	1,09	0,97
18 600	19 900	14 850	1,07	1,25
22 800	23 900	18 200	1,05	1,25
28 300	32 100	24 100	1,13	1,17
61 000	67 000	45 000	1,10	1,36
124 000	138 000	97 000	1,11	1,28

$\bar{M}_n$, $\bar{M}_w$: masse molaire moyenne en nombre et en poids déterminée par chromatographie liquide d'exclusion; $\bar{M}_{uv}$: masse molaire moyenne déterminée par spectrométrie uv.

réaction de deux molécules d'iodure de méthylmagnésium sur la *N,N*-diméthylamino-4 bénzaldehyde selon la méthode de Sachs (10, 11). Le produit brut est purifié par distillation, puis par chromatographie liquide sur silice, l'éluant étant le benzène, et enfin par redistillation. Son point d'ébullition se situe à 64°C sous 30 Pa. Le coefficient d'absorption molaire mesuré en solution dans le THF est de $\varepsilon = 2\,050$ L mol^{-1} cm^{-1} à 304 nm.

D'autre part, l'étude des chromatogrammes d'exclusion (SEC) permet d'évaluer la polymolécularité des échantillons, liée elle aussi à l'efficacité de l'amorceur.

En vue de s'assurer que des adsorptions imputables aux groupes fonctionnels ne conduisent pas à des valeurs erronées des masses molaires déterminées par SEC, nous avons comparé sur quelques échantillons les masses molaires moyennes en poids $\bar{M}_w$ et $\bar{M}_{ddl}$ déterminées par SEC et par diffusion de la lumière. Nous avons aussi vérifié que l'incrément d'indice de réfraction dn/dc du polystyrène fonctionnalisé est le même que celui du polystyrène classique soit 0,186 mL g^{-1} à 632 nm dans le THF. Ces valeurs figurent au tableau 3. Les écarts relevables ne sont pas supérieurs aux erreurs de mesures habituelles.

Bien que nos essais couvrent un large domaine de masses molaires, on peut considérer que la méthode proposée donne entière satisfaction. En effet, les valeurs de $\bar{M}_n/\bar{M}_{uv}$ voisines de l'unité attestent une fonctionnalisation quantitative. Les valeurs plus élevées sont probablement dues à des espèces chromophores résiduelles retenues par le polymère.

Dans le tableau 4 figure l'évolution de $\bar{M}_{uv}$ en fonction du nombre des précipitations d'un polymère; les variations observées étayent notre hypothèse.

Le tableau 5 rassemble les caractéristiques des produits isolés lors d'un essai spécial qui avait pour objectif la préparation d'un polymère fonctionnel de très faible masse molaire. Ce test supplémentaire d'efficacité de l'amorceur fonctionnel a pleinement confirmé les conclusions antérieures.

Partie expérimentale

Toutes les opérations mettant en oeuvre un carbanion ont été effectuées sous une légère surpression d'argon dans un appareillage étanche désormais classique.

Le THF est séché sur KOH, puis distillé sur fil de sodium; il est redistillé sur complexe benzophénone–sodium dans une ampoule étanche, puis conservé sous argon. Le styrène est séché sur $CaCl_2$, puis distillé sur fil de sodium. L'oxiranne est dégazé, puis distillé sur fil de sodium. Les mesures de SEC ont été réalisées sur un appareil équipé de 3 colonnes Shodex A 801, A 802 et A 803, la détection étant assurée par un réfractomètre différentiel Waters.

Les déterminations spectrophotométriques uv ont été effectuées sur un appareil Beckman Acta V.

(N,N-Diméthylamino-4)phényl-1 éthyl éthyl éther

Dans un ballon muni d'un décanteur de type Dean et Stark, on porte à ébullition durant 24 h 700 mL de benzène, 300 mL d'éthanol, 100 g (0,61 mole) de (*N,N*-diméthylamino-4)phényl-1 éthanol (10, 11) et 0,50 g d'acide *p*-toluène sulfonique. Après refroidissement, on ajoute 10 mL d'une solution de méthanolate de sodium (0,4 mol L^{-1}) dans du méthanol. On évapore les solvants, on redissout le produit dans 500 mL d'éther, puis on lave et on sèche sur sulfate de sodium. Enfin on évapore l'éther et on distille le résidu (115 g). On recueille 80 g. Eb. : 80–85°C (200 Pa). On conserve le produit sous argon.

Amorceur

On place 10 g (0,25 mol) de potassium dans 100 mL de THF, puis on abaisse la température à −20°C. On ajoute ensuite 10 mL (0,10 mol) de (*N,N*-diméthylamino-4)phényl-1 éthyl éthyl éther (éthoxy-1 (*N,N*-diméthylamino-4)phényl-1 éthane). La solution devient rapidement rouge. On maintient l'agitation la nuit. Dosée par l'acétanilide, la concentration en sites carbanioniques de cette solution est 0,34 mol L^{-1}.

Polymérisation du styrène

Exemple 1

À 250 mL de THF maintenu à −70°C on ajoute goutte à goutte 9 mL d'une solution de l'amorceur à une concentration de 0,34 mol L^{-1}. On ajoute ensuite goutte à goutte 25 g de styrène. La température croît rapidement à −40°C. Quand elle revient à −70°C, on ajoute 2 mL d'oxiranne, puis on enlève le bain réfrigérant. La décoloration du milieu réactionnel n'est pas immédiate. Quand elle se produit, vers −50°C, on ajoute successivement un peu de méthanol, 1 mL d'acide chlorhydrique, puis 2 mL d'ammoniaque. On filtre la solution pour éliminer le KCl, puis on précipite le polymère par 2 L de méthanol. On dissout et reprécipite le polymère avec les mêmes volumes de THF et de méthanol. Rendement quantitatif : $\bar{M}_n = 7\,700$ g mol^{-1}; $\bar{M}_w = 9\,200$ g mol^{-1}, $\bar{M}_{uv} = 7\,440$ g mol^{-1}.

Exemple 2

À 250 mL de THF maintenu à −70°C on ajoute 70 mL d'une solution d'amorceur de concentration 0,48 mL L^{-1}. On ajoute ensuite goutte à goutte 25 g de styrène. La température croît jusqu'à −50°C. On ajoute alors 5 mL d'oxiranne puis on enlève le bain réfrigérant. Après

TABLEAU 4. Évolution de la masse molaire moyenne en fonction du nombre des precipitations

Nombre des précipitations	$\bar{M}_{uv}$ (g mol^{-1})
1	69 000
2	99 000
3	102 300
4	103 300
5	105 200

$\bar{M}_{uv}$: mass molaire moyenne déterminé par spectrométrie uv.

TABLEAU 5. Caractéristiques du polymère de faible mass molaire

	M_n (g mol^{-1})	M_w (g mol^{-1})	M_{uv} (g mol^{-1})	$\bar{M}_w/\bar{M}_n$	$\bar{M}_n/\bar{M}_{uv}$	O % (*c*)	O % (*t*)
F 1	3 220	3 820	3 260	1,19	0,99	0,49	0,60
F 2	1 990	2 200	1 600	1,11	1,24	0,80	1,11

$\bar{M}_n$, $\bar{M}_w$: masse molaire moyenne en nombre et en poids déterminée par chromatographie liquide d'exclusion; $\bar{M}_{uv}$: masse molaire moyenne déterminée par spectrometrie uv; O % (*c*) : taux en oxygène calculé, soit le rapport $16/\bar{M}_n$; O % (*t*) : taux en oxygène déterminé par analyse chimique élémentaire.

décoloration du milieu réactionnel, à −30°C, on introduit 7 mL d'acide chlorhydrique puis 9 mL d'ammoniaque. On filtre la solution pour éliminer le KCl, puis on précipite le polymère par 4 L de méthanol. On filtre 11,5 g de polymère. Ce produit est dissous dans 50 mL de THF puis reprécipité par 1 L de méthanol contenant 2 mL d'ammoniaque. Enfin on filtre 10,5 g (F 1) de polymère.

Les filtrats sont alors rassemblés. On évapore les solvants, redissout le résidue dans 150 mL de benzène, agite la solution avec un peu de gel de silice, filtre, puis précipite le polymère par un mélange de 2 L de méthanol, 200 mL d'eau et 2 mL d'ammoniaque. Ce polymère est d'aspect collant. On le redissout dans 10 mL de benzène. Après lyophilisation, on obtient 6,9 g (F 2) de polymère sous forme poudreuse.

Conclusion

L'action du potassium sur une solution de (*N*,*N*-diméthylamino-4)phényl-1 éthyl éthyl éther conduit à un composé organo-métallique qui est un amorceur anionique efficace agissant par addition. Lorsqu'on provoque la polymérisation du styrène par cette solution d'amorceur, et lorsqu'on fait réagir ensuite de l'oxiranne sur les sites carbanioniques, on obtient un polymère portant à l'une des extrémités de sa chaîne le groupe *N*,*N*-diméthylamino-4 phényle et à l'autre extrémité la fonction alcoolate.

Remerciements

Les auteurs expriment leurs vifs remerciements à M. F. Isel pour l'aide efficace qu'il leur a apportée dans la réalisation de ce travail.

Utilisation de l'*ortho*-tolidine pour l'étude des réactions des halogénates et halogénites[1]

GUY SCHMITZ ET HENRI ROOZE

Université libre de Bruxelles, Faculté des sciences appliquées, 50 avenue F. Roosevelt, 1050 Bruxelles, Belgique

Reçu le 29 janvier 1986

GUY SCHMITZ et HENRI ROOZE. Can. J. Chem. **64**, 1747 (1986).

Nous avons montré précédemment, que l'*ortho*-tolidine simplifie fortement l'étude cinétique des réactions redox du chlorite en réagissant avec des produits intermédiaires et en supprimant des réactions secondaires. Cette étude établit la validité de la méthode dans le cas de réactions du bromate. Pour la réaction bromate–bromure elle donne la loi classique d'ordre quatre avec $k = 1{,}54\ M^{-3}\ s^{-1}$ en milieu perchlorique de force ionique 1 *M* à 25°C, et une constante d'acidité de l'acide bromique valant 2,9. Cette méthode est ensuite utilisée pour étudier la réaction entre le bromate et le chlorite, réaction complexe en absence d'*ortho*-tolidine. On obtient la loi cinétique

$$-\frac{d[BrO_3^-]}{dt} = k[BrO_3^-][HClO_2][H^+]$$

avec $k = 0{,}83 + 0{,}76\ [H^+]$ dans les mêmes conditions. Si $[H^+] = 0{,}1\ M$ l'énergie d'activation apparente vaut 47,4 kJ/mol.

GUY SCHMITZ and HENRI ROOZE. Can. J. Chem. **64**, 1747 (1986).

We have shown previously that *ortho*-tolidine greatly simplifies the kinetic study of redox reactions of chlorite by reacting with intermediate products and eliminating side reactions. The present study shows the validity of the method in the case of bromate reactions. For the bromate–bromide reaction it gives the classical fourth-order rate law with $k = 1.54\ M^{-3}\ s^{-1}$ in perchloric acid solutions at 25°C and 1 *M* ionic strength, and an acidity constant of bromic acid of 2.9. This method is then used to study the reaction between bromate and chlorite, a complex reaction in the absence of *ortho*-tolidine. The rate law is

$$-\frac{d[BrO_3^-]}{dt} = k[BrO_3^-][HClO_2][H^+]$$

with $k = 0.83 + 0.76\ [H^+]$ in the same conditions. If $[H^+] = 0.1\ M$ the apparent activation energy is 47.4 kJ/mol.

Introduction

L'*ortho*-tolidine (biphényl-4,4′ diamino-3,3′ diméthyl) permet d'obtenir simplement et avec précision les caractéristiques cinétiques de nombreuses réactions redox des halogénates et halogénites. Nous avons discuté antérieurement ses propriétés et les avons mises à profit pour étudier la cinétique de la dismutation du chlorite catalysée par les ions Cl^- (1) et par le fer (2).

En résumé, ni le chlorate ni le chlorite n'oxydent l'*ortho*-tolidine avec une vitesse mesurable. Par contre le chlore, l'acide hypochloreux et le dioxyde de chlore l'oxydent extrêmement rapidement. Le produit de son oxydation présente, si le pH est inférieur à 2,5, une bande d'absorption intense ayant son maximum à 440 nm. Les absorbances mesurées sont reproductibles et, si la concentration en *ortho*-tolidine n'est pas trop élevée, suffisamment stables pour permettre des mesures très précises. Nous avons généralement utilisé des concentrations inférieures à $5 \times 10^{-4}\ M$.

L'élimination de produits intermédiaires des réactions étudiées simplifie leurs mécanismes et le coefficient d'absorption molaire élevé de l'*ortho*-tolidine oxydée, 59 700 $M^{-1}\ cm^{-1}$, permet une mesure aisée de leurs vitesses initiales. Nous montrons dans cet article que cette méthode est également utile pour étudier des réactions du bromate, en particulier la réaction bromate–chlorite.

Technique expérimentale

Les solutions de chlorite de sodium sont préparées à partir de chlorite commercial purifié par trois recristallisations successives. Elles sont conservées dans le noir en milieu légèrement basique et standardisées par iodométrie. Elles restent stables pendant plusieurs jours et donnent des résultats reproductibles. Le bromate de la qualité «pour analyses» est recristallisé, les traces de bromure qu'il contient pouvant influencer certains résultats. L'acidité est fixée avec de l'acide perchlorique et la force ionique avec du perchlorate de sodium «pour analyses», utilisés sans purification supplémentaire.

Les réactifs, conservés dans un thermostat, sont mélangés rapidement et transférés dans la cuvette thermostatisée d'un spectrophotomètre Beckman DBGT. Sauf précision contraire, la température est maintenue à 25 ± 0,1°C. Les conditions expérimentales sont toujours telles que l'on mesure des vitesses initiales. En enregistrant, en fonction du temps, l'absorbance à 440 nm due à l'oxydation de l'*ortho*-tolidine, on obtient des droites dont les pentes donnent ces vitesses. La linéarité des enregistrements est importante car elle assure qu'au cours d'une mesure on peut négliger la dégradation de l'*ortho*-tolidine oxydée. Nous abrégerons la formule de l'*ortho*-tolidine en NH_2RNH_2 et celle de sa forme oxydée en NHRNH.

$$\frac{d[NHRNH]}{dt} = \frac{1}{59700}\frac{dA}{dt} \qquad (M/s)$$

Réaction de l'*ortho*-tolidine avec le brome

L'*ortho*-tolidine est oxydée extrêmement rapidement par le brome suivant [1]. Nous avons obtenu le même maximum d'absorbance à 440 nm avec le même coefficient d'absorption molaire que dans le cas du chlore (cf. fig. 1). Comme dans ce cas le pH doit être inférieur à 2,5 et il est préférable de limiter la concentration en *ortho*-tolidine à $5 \times 10^{-4}\ M$. Avec un excès de Br_2 on obtient $[NHRNH] = [NH_2RNH_2]_0$ ce qui montre que l'*ortho*-tolidine n'est pas bromée.

[1] $\quad NH_2RNH_2 + Br_2 \rightarrow NHRNH + 2Br^- + 2H^+$

En milieux très acides (1 *M* en $HClO_4$) ou avec des concentrations en Br^- supérieures à $10^{-2}\ M$ nous avons obtenu des rapports $[NHRNH]/[Br_2]_0$ inférieurs à 1. Ceci ne résulte pas de la réversibilité de la réaction [1] (nous avons vérifié que Br^- ne réduit pas NHRNH) mais probablement de traces

1. Article n°4 de la série «Mécanisme des réactions du chlorite et du dioxyde de chlore.»

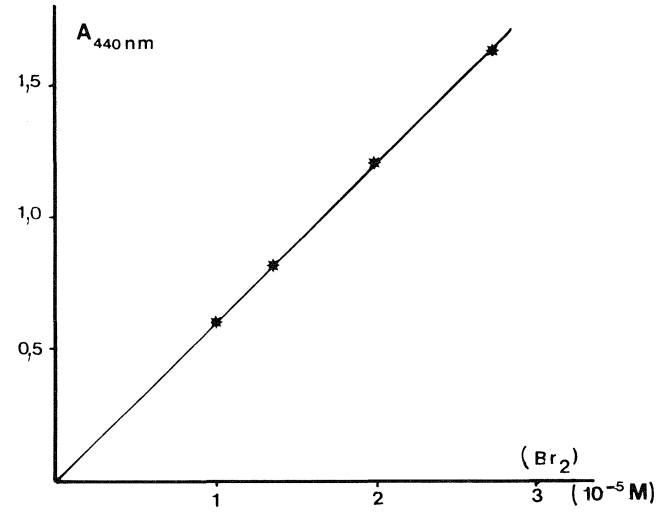

FIG. 1. Réaction de l'*ortho*-tolidine avec le brome. $[NH_2RNH_2] = 5 \times 10^{-5}\ M$; $[HClO_4] = 0{,}02\ M$.

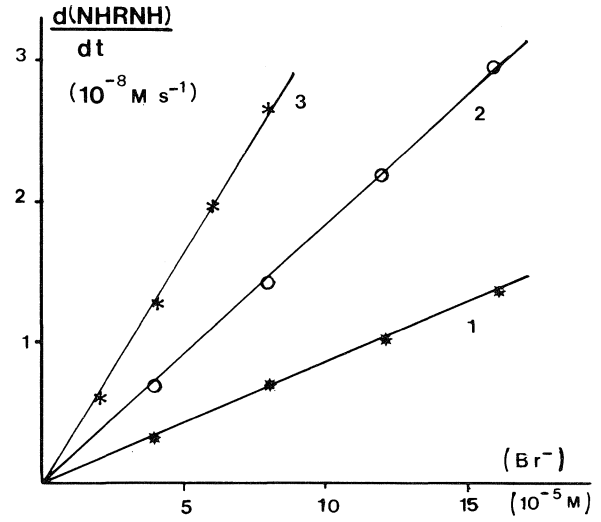

FIG. 2. Réaction bromate–bromure. $[NH_2RNH_2] = 10^{-4}\ M$. $[HClO_4] = 0{,}203$, $[NaBrO_3] = 5 \times 10^{-4}\ M$ (1); $[HClO_4] = 0{,}203$, $[NaBrO_3] = 10^{-3}\ M$ (2); $[HClO_4] = 0{,}406$, $[NaBrO_3] = 5 \times 10^{-4}\ M$ (3).

d'impuretés oxydables dans les réactifs. Par exemple, l'addition préalable d'un peu d'iodure réduit la quantité de NHRNH formée : une fraction du brome oxyde l'iodure en iode et celui-ci n'oxyde pas l'*ortho*-tolidine. Un tel effet peut fausser le dosage du brome par l'*ortho*-tolidine mais pas nos mesures cinétiques : après oxydation de ces impuretés la vitesse de formation de NHRNH devient bien proportionnelle à la vitesse de réaction. Quoi qu'il en soit, ce qui constitue la garantie finale de la validité de nos mesures est la linéarité des enregistrements de l'absorbance en fonction du temps. Les vitesses sont déduites des pentes de ces droites et indépendantes du temps zéro.

Cinétique de la réaction bromate–bromure en présence d'*ortho*-tolidine

L'*ortho*-tolidine n'est pas oxydée directement par le bromate avec une vitesse mesurable. La très faible vitesse d'oxydation que l'on peut parfois observer dépend de la pureté des réactifs. Il faut en particulier éliminer les traces d'halogénures dans le bromate.

Dans une solution acide de bromate et de bromure on obtient la réaction classique [2].

$$[2] \quad BrO_3^- + 5Br^- + 6H^+ \rightarrow 3Br_2 + 3H_2O$$

En présence d'*ortho*-tolidine le brome ainsi formé réagit rapidement suivant [1] et l'on obtient globalement [3].

$$[3] \quad BrO_3^- + 3NH_2RNH_2 \rightarrow Br^- + 3NHRNH + 3H_2O$$

L'étude de cette réaction nous a permis d'une part de confirmer la validité de la méthode à l'*ortho*-tolidine dans le cas des réactions du bromate, d'autre part de préciser l'effet du pH sur la réaction [2] en milieux très acides.

La réaction [2] obéit à la loi cinétique [4] (3–8).

$$[4] \quad -\frac{d[BrO_3^-]}{dt} = k_4[BrO_3^-][Br^-][H^+]^2$$

En présence d'*ortho*-tolidine l'étape déterminante reste la même et on déduit de [3] :

$$\frac{d[NHRNH]}{dt} = 3\,k_4[BrO_3^-][Br^-][H^+]^2$$

Nos mesures de vitesses initiales de formation de l'*ortho*-tolidine oxydée sont en parfait accord avec cette loi. Quelques résultats montrant l'ordre 1 par rapport au bromure sont repris sur la figure 2. Nous avons également vérifié l'ordre 1 par rapport au bromate (10^{-4}–$10^{-3}\ M$). Les vitesses sont indépendantes de la concentration de l'*ortho*-tolidine (10^{-4} ou $4 \times 10^{-4}\ M$). Elles diminuent si la force ionique I augmente, comme observé dans les travaux antérieurs. Avec $[HClO_4] = 0{,}1\ M$ et $[NaClO_4]$ variable, nous avons obtenu des vitesses dans les rapports 1,52:1,03:1,00 respectivement pour $I = 0{,}1$, 0,5 et 1,0 M.

TABLEAU 1. Réaction bromate–bromure

$[HClO_4]$ (M)	k_{exp} ($M^{-3}\ s^{-1}$)	k_4 ($M^{-3}\ s^{-1}$)
0,102	1,55 ± 0,04(7)	1,60
0,203	1,38 ± 0,03(9)	1,48
0,203	1,46 ± 0,04(8)	1,56
0,406	1,30 ± 0,07(8)	1,48
0,813	1,23 ± 0,03(11)	1,57

$T = 25°C$, $I = 1\ M$. Les nombres de mesures sont indiqués entre parenthèses, les erreurs correspondent aux écarts-types.

Les valeurs des constantes cinétiques obtenues pour différentes acidités, avec une force ionique fixée à 1 M, sont indiquées dans le tableau 1. La colonne k_{exp} donne les valeurs de k_4 calculées en prenant pour $[BrO_3^-]$ la concentration totale en bromate. On constate que k_{exp} diminue lorsque l'acidité augmente. Ceci s'explique par l'équilibre [5].

$$[5] \quad BrO_3^- + H^+ = BrO_3H$$

Soient $[NaBrO_3]$ la concentration totale en bromate et K_a la constante d'acidité de l'acide bromique.

$$[BrO_3^-] = \frac{K_a}{K_a + [H^+]}[NaBrO_3]$$

$$k_4 = \left[1 + \frac{[H^+]}{K_a}\right] k_{exp}$$

En prenant $K_a = 2{,}9\ M^{-1}$ on obtient des valeurs de k_4 indépendantes de l'acidité. Elles sont indiquées dans le tableau 1 et donnent en moyenne :

$$k_4 = 1{,}54\ M^{-3}\ s^{-1} \qquad (T = 25°C,\ I = 1\ M)$$

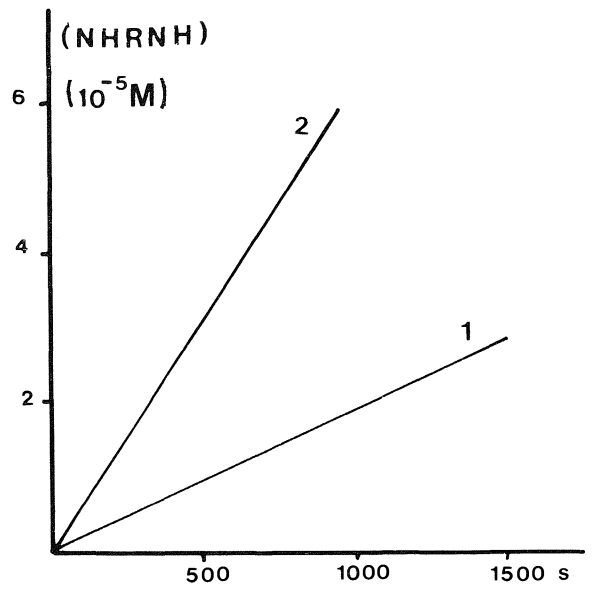

FIG. 3. Réaction bromate–chlorite. $[NH_2RNH_2] = 10^{-4}\,M$. $[HClO_4] = 0{,}102$, $[NaClO_2] = 1{,}24 \times 10^{-5}$, $[NaBrO_3] = 5 \times 10^{-3}\,M$ (1); $[HClO_4] = 0{,}404$, $[NaClO_2] = 1{,}00 \times 10^{-5}$, $[NaBrO_3] = 5 \times 10^{-3}\,M$ (2).

L'effet de l'équilibre [5] n'était pas apparu dans les travaux antérieurs car l'acidité, soit était trop faible pour qu'il apparaisse, soit avait varié parallèlement à la force ionique et l'effet de celle-ci était dominant. La valeur adoptée de K_a est tout à fait raisonnable et se compare favorablement à une estimation antérieure : $pK_a = 0{,}7$ (9). Les valeurs antérieures de k_4 permettant une comparaison avec la nôtre sont 2,32 et 1,18 pour $I = 1\,M$ (4, 6) et 1,86 pour $I = 0{,}8\,M$ (8).

Cinétique de la réaction bromate–chlorite en présence d'*ortho*-tolidine

Cette réaction présente un intéret particulier d'une part dans le cadre du mécanisme de réactions périodiques (10), d'autre part parce que sa première étape correspond à l'échange d'un seul électron au contraire des réactions classiques halogénates–halogénures.

Lorsqu'on mélange des solutions de bromate et de chlorite on obtient un système dont l'évolution aussi bien stoechiométrique que cinétique est très complexe. La première étape est [6].

[6] $BrO_3^- + HClO_2 + H^+ \rightarrow BrO_2 + ClO_2 + H_2O$

Le BrO_2 et le ClO_2 peuvent ensuite réagir de diverses manières. Thompson (11) a étudié cette réaction en présence d'alcool allylique qui, en captant le produit intermédiaire HOBr, élimine certaines complications. Cependant, même ainsi la stoechiométrie dépend des conditions expérimentales. Par contre, en présence d'*ortho*-tolidine on obtient simplement la stoechiométrie [7].

[7] $BrO_3^- + 3NH_2RNH_2 \rightarrow Br^- + 3NHRNH + 3H_2O$

Les expériences de la figure 3 montrent que le chlorite n'est pas consommé : la vitesse est inchangée alors que l'on a oxydé une quantité d'*ortho*-tolidine nettement supérieure à la quantité de chlorite introduite. L'expérience (2) a été faite en présence de 5×10^{-5} ion g/L d'Ag^+ pour éliminer l'effet des ions Br^- produits par [7] qui sinon apparaîtrait aux conversions élevées. Par contre, lors de toutes les expériences ci-après, les conversions sont restées suffisamment faibles (quelques pourcents) pour que cet effet soit négligeable. Rappelons que nos conditions expérimentales sont toujours telles que les enregistrements d'absorbances en fonction du temps soient linéaires et que l'on mesure des vitesses initiales.

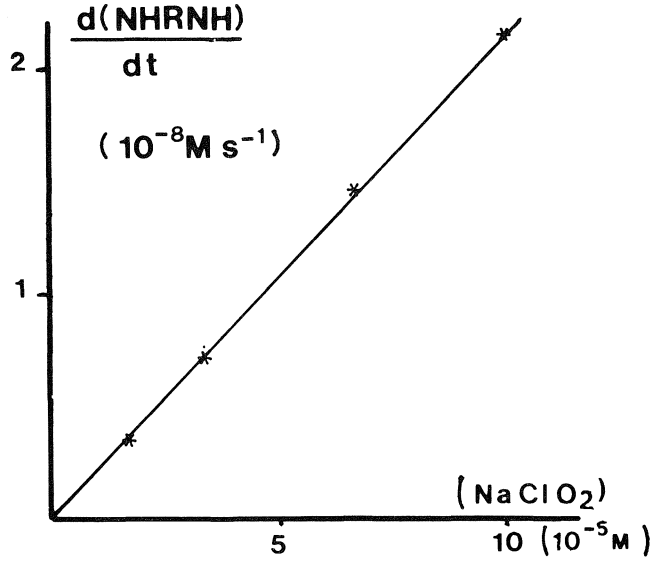

FIG. 4. Réaction bromate–chlorite. $[HClO_4] = 0{,}102$, $[NaBrO_3] = 10^{-3}$, $[NH_2RNH_2] = 10^{-4}\,M$, $I = 1\,M$, $T = 25°C$.

La simplification du mécanisme se comprend aisément. La première étape reste [6] car l'*ortho*-tolidine ne réagit ni avec le bromate ni avec le chlorite. Ensuite nous savons qu'elle est oxydée très rapidement par le ClO_2 suivant [8].

[8] $2ClO_2 + NH_2RNH_2 \rightarrow 2HClO_2 + NHRNH$

Le BrO_2 formé par [6] pourrait de même être réduit par l'*ortho*-tolidine en $HBrO_2$. Cependant celui-ci ne peut pas s'accumuler dans le système et, quel que soit le mécanisme de la réduction, on obtient la réaction globale [9].

[9] $2BrO_2 + 5NH_2RNH_2 \rightarrow 2Br^- + 2H^+ + 5NHRNH + 4H_2O$

En combinant [6], [8] et [9] on obtient [7], et

$$\frac{d[NHRNH]}{dt} = 3r_6$$

1. Résultats à 25°C et I = *0,1–1* M

Les figures 4 et 5 donnent quelques exemples de nos mesures établissant l'ordre 1 par rapport au bromate et au chlorite. L'ensemble des résultats obtenus est résumé dans le tableau 2. Les constantes k_{exp} sont définies par

$$\frac{d[NHRNH]}{dt} = k_{exp}[NaBrO_3][NaClO_2][H^+] + r_{Fe}$$

où $[NaBrO_3]$ et $[NaClO_2]$ désignent les concentrations totales et r_{Fe} la vitesse de la catalyse par le fer de l'oxydation de l'*ortho*-tolidine par le chlorite (2). Après purification des réactifs cette correction reste assez faible, généralement moins de 5%, pour permettre une détermination précise de k_{exp}. Soient K_{a1} et K_{a2} les constantes d'acidité de $HBrO_3$ et de $HClO_2$. Posons

$$r_6 = k_6[BrO_3^-][HClO_2][H^+]$$

On obtient

$$k_{exp} = 3\frac{K_{a1}}{K_{a1} + [H^+]}\frac{[H^+]}{K_{a2} + [H^+]}k_6$$

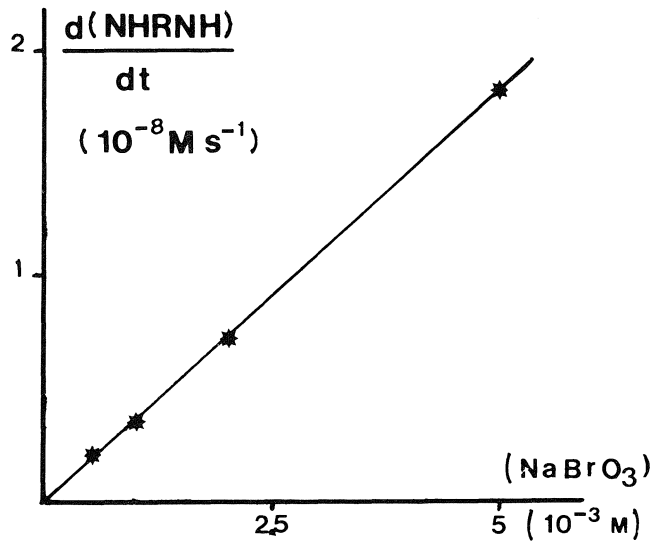

FIG. 5. Réaction bromate–chlorite. $[HClO_4] = 0{,}102$, $[NaClO_2] = 1{,}69 \times 10^{-5}$, $[NH_2RNH_2] = 10^{-4}\ M$, $I = 1\ M$, $T = 25°C$.

TABLEAU 2. Réaction bromate–chlorite

$[HClO_4]$ (M)	$[NaBrO_3]$ (M) $\times 10^3$	$[NaClO_2]$ (M) $\times 10^4$	k_{exp} ($M^{-2}\ s^{-1}$)	k_6 ($M^{-2}\ s^{-1}$)

0,10[a]	0,5–5	0,24	3,00 ± 0,09(8)	1,23
0,10	1	0,17–1,0	2,08 ± 0,04(8)	0,89
0,10	0,5–5	0,17	2,12 ± 0,06(8)	0,91
0,20	1	0,17	2,44(2)	0,97
0,30	1	0,17	2,65(2)	1,05
0,40	1	0,17	2,90(2)	1,17
0,10	1	0,40–1,6	2,14 ± 0,07(6)	0,92
0,10	0,5–5	0,40	2,15 ± 0,11(15)	0,92
0,20	1	0,40	2,47(2)	0,99
0,30	1	0,40	2,56(2)	1,02
0,40	1	0,40	2,80(2)	1,13

$T = 25°C$; $I = 1\ M$.
[a] $I = 0{,}1\ M$.
[b] Vérification de l'invariance de la vitesse pour $[NH_2RNH_2] = 5 \times 10^{-5} - 5 \times 10^{-4}\ M$. Les nombres de mesures sont indiqués entre parenthèses, les erreurs correspondent aux écarts-type.

Les valeurs de K_{a2} ont été mesurées par Hong et Rapson (12) en fonction de la force ionique. Ils ont obtenu $K_{a2} = 1{,}74 \times 10^{-2}$ pour $I = 0{,}1\ M$ et $2{,}4 \times 10^{-2}$ pour $I = 1\ M$. La valeur de K_{a1} pour $I = 1\ M$ a été déduite de notre étude de la réaction bromate–bromure. Si elle varie en fonction de la force ionique comme K_{a2} on obtient $K_{a1} = 2{,}1$ pour $I = 0{,}1\ M$. Le choix de cette constante n'influence quasi pas le calcul de k_6.

Quelques mesures faites à des forces ioniques comprises entre 0,1 et 1 M avec $[HClO_4] = 0{,}1\ M$ indiquent que k_{exp} varie à peu près comme l'inverse de K_{a2}, c'est-à-dire comme γ_{HClO_2}.

L'examen du tableau 2 montre que k_6 augmente avec l'acidité. Thompson (11) avait obtenu :

$$r_6 = k_6[BrO_3^-][HClO_2][H^+]^{1,2}$$

Nous verrons que, tenant compte de K_{a1} et K_{a2}, ses résultats comme les nôtres se laissent mieux représenter par :

$$r_6 = (k_6' + k_6''[H^+])[BrO_3^-][HClO_2][H^+]$$

TABLEAU 3. Réaction bromate–chlorite. Effet de la température

T (°C)	k_{exp} ($M^{-2}\ s^{-1}$)
33,3	5,04 ± 0,35(7)
25,0	2,98 (Tableau 2)
17,5	1,81 ± 0,10(6)
3,4	0,67 ± 0,04(11)

$[HClO_4] = 0{,}1$; $[NaClO_2] = 2{,}2 \times 10^{-5}\ M$; $[NaBrO_3] = 5 \times 10^{-4} - 0{,}01\ M$; $I = 0{,}1\ M$.

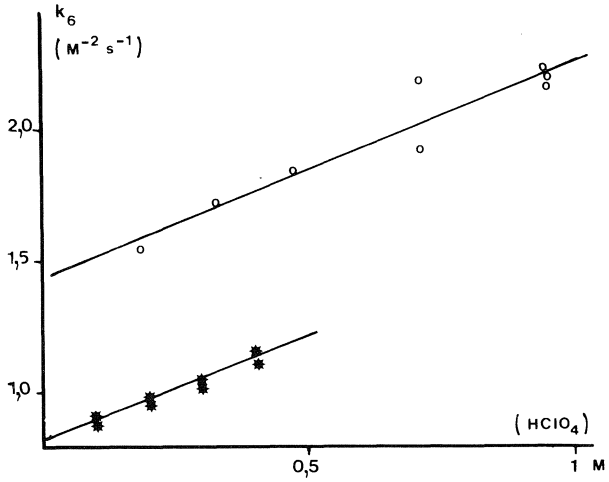

FIG. 6. Constantes cinétiques de la réaction bromate–chlorite à 25°C. Comparaison de nos valeurs (*) pour $I = 1\ M$ avec celles de Thompson (o) pour $I = 1{,}93\ M$.

2. Effet de la température, I = *0,1* M

Nos mesures de k_{exp} à différentes températures sont résumées dans le tableau 3. On en déduit une énergie d'activation de 47,4 kJ/mol. Comme k_{exp} dépend de l'acidité cette valeur n'est en toute rigueur valable que pour l'acidité à laquelle elle a été déterminée, soit $[HClO_4] = 0{,}1\ M$. Remarquons cependant que Thompson a obtenu une valeur pratiquement identique, 47,7 kJ/mol, pour $[HClO_4] = 1{,}92\ M$.

Conclusion et discussion

Pour discuter le mécanisme de réactions complexes, telles que les réactions périodiques, il est souhaitable de connaître les constantes cinétiques de leurs composantes. La méthode à l'*ortho*-tolidine permet de mesurer simplement et avec précision certaines de ces constantes.

Nous avons confirmé la validité de cette méthode dans le cas de réactions du bromate et déterminé la constante d'acidité de l'acide bromique. Nous l'avons ensuite utilisée pour mesurer la vitesse de l'étape déterminante de la réaction bromate–chlorite.

Pour interpréter l'effet de $[H^+]$ sur la vitesse de cette réaction il faut tenir compte des constantes d'acidité de l'acide chloreux et de l'acide bromique. La figure 6 montre que la variation de k_6 en fonction de $[H^+]$ est linéaire : $k_6 = 0{,}83 + 0{,}76[H^+]$. Cette figure reprend également les valeurs de k_6 déduites des mesures de Thompson (11), en remarquant que ses constantes k_a correspondent, avec nos notations, à $k_{exp}[H^+]/3$. Elles sont compatibles avec les nôtres, compte tenu de la différence de force ionique et des incertitudes affectant les mesures en absence d'*ortho*-tolidine. Cette variation de k_6 peut, par exemple, être interprétée par [5], [10], [11] et [12].

[10] $HBrO_3 + H^+ = BrO_2^+, H_2O$

[11] $BrO_2^+, H_2O + ClO_2^- \rightarrow BrO_2 + ClO_2 + H_2O$

[12] $BrO_2^+, H_2O + HClO_2 \rightarrow BrO_2 + ClO_2 + H_2O + H^+$

On obtient ainsi $k_6 = k_{11}K_{10}K_{a2}/K_{a1} + k_{12}K_{10}[H^+]/K_{a1}$.

Des calculs MS-Xα d'orbitales moléculaires ont été réalisés pour les dianions $B_{12}H_{12}^{2-}$ et $B_9C_2H_{11}^{2-}$. Leurs structures électroniques sont discutées en relation avec les distributions de charge de groupe. Cette étude conduit à une hiérarchie des sites d'attaque électrophile dans l'ion dicarbollyle, le bore opposé à la liaison C—C dans la face pentagonale étant le site le plus favorable.

ANNICK GOURSOT, EDOUARD PÉNIGAULT, HENRY CHERMETTE, and JOSEPH G. FRIPIAT. Can. J. Chem. **64**, 1752 (1986).

MS-Xα molecular orbital calculations have been performed on the dianions $B_{12}H_{12}^{2-}$ and $B_9C_2H_{11}^{2-}$. Their electronic structures are discussed in terms of group charge distributions. For the dicarbollide ion, this study indicates a most probable electrophilic attack on the boron site opposite to the C—C bond, on the pentagonal face.

La nature originale des liaisons chimiques que le bore est susceptible d'établir, tant avec lui-même qu'avec des hétéroéléments, favorise la formation d'unités structurales polyédriques, qui peuvent être complètes ou fragmentaires (1*a*). Une unité complète, ou structure *closo*, est décrite par un polyèdre dont toute face est trigonale et tout sommet occupé par un bore ou un hétéroélément. Toute structure fragmentaire dite *nido*, dérive formellement d'une structure *closo*, par élimination de l'un des sommets du polyèdre de référence.

Le dianion du dodécaborane ($B_{12}H_{12}^{2-}$) est l'archétype d'une structure *closo* régulière. Les B occupent les sommets d'un icosaèdre (fig. 1a) dont les 20 faces sont des triangles équilatéraux égaux (groupe de symétries I_h). Les métallocarboranes $(B_9C_2H_{11})_2M$, ou complexes bis-dicarbollyle du métal M de transition, ont une structure comptant deux unités icosaédriques irrégulières, qui sont opposées par un sommet commun occupé par M. Le ligand intervenant dans ces complexes est l'ion dicarbollyle $B_9C_2H_{11}^{2-}$, qui a une structure *nido* dérivant de l'icosaèdre. En dehors de ses faces trigonales, le polyèdre résultant comporte une face qui s'appuie sur 5 sommets sensiblement coplanaires (2), deux d'entre eux étant occupés par un carbone (fig. 1b). La nature des interactions métal–ligand dans les complexes $(B_9C_2H_{11})_2M$ en fait des complexes sandwich présentant une analogie marquée avec les métallocènes (3).

Il a été montré, antérieurement, que la méthode d'orbitales moléculaires SCF-MS-Xα conduit à une description satisfaisante de la structure électronique de divers composés sandwich, qu'il s'agisse de métallocènes (4) ou de complexes bis-aryle du chrome (5). Dans la perspective d'étudier divers métallocarboranes sandwich, nous avons effectué, dans un premier temps, l'étude Xα des structures électroniques de l'ion (3)-1,2-dicarbollyle et de son précurseur formel, $B_{12}H_{12}^{2-}$. En fait, la référence à $B_{12}H_{12}^{2-}$ vaut pour de nombreux autres composés à déficience électronique (boranes, hétéroboranes et dérivés), c'est-à-dire des composés dont le nombre total d'électrons de valence est inférieur à celui des orbitales atomiques (OA) de valence. À notre connaissance, la littérature ne rapporte pas d'étude d'orbitales moléculaires (OM) concernant l'ion dicarbollyle. Il en va différemment de $B_{12}H_{12}^{2-}$ et son étude Xα élargit le champ des comparaisons entre modèles issus de méthodes différentes. Jusqu'à maintenant, la méthode Xα a été rarement sollicitée pour étudier des édifices polyatomiques déficients en électrons (6). De nouvelles exploitations du modèle Xα offrent donc, aussi, l'intérêt de pouvoir contribuer à mieux faire apprécier l'étendue de sa fiabilité.

Géometrie et paramètres de calcul

La géométrie de $B_{12}H_{12}^{2-}$ (groupe I_h) est issue de la structure radiocristallographique de son sel dipotassique (7), le premier à avoir été isolé (8). Toute distance entre 2 B voisins de la cage icosaédrique régulière est de 1,775 Å, tandis que la longueur de toute liaison B—H est 1,07 Å.

La géométrie de l'ion (3)-1,2-dicarbollyle est tirée d'un étude radiocristallographique du complexe sandwich neutre $(B_9C_2H_{11})_2Ni$ (9). Pour rendre le modèle compatible avec l'existence d'un miroir, de légères corrections sont apportées aux positions atomiques. Ce miroir est le seul élément de symétrie du modèle (group C_s) et se confond avec le plan médiateur de la liaison C—C. Hormis B4 et B7, voisins des C sur la face pentagonale (fig. 1b), les éléments B occupent certains sommets d'un icosaèdre régulier. La distance séparant 2 éléments B voisins et occupant de tels sites, ainsi que les distances entre B8 et ses autres plus proches voisins (B4 et B7), s'identifient à la moyenne (1,785 Å) des distances expérimentales homologues, dans les 2 cages du complexe sandwich de référence. Tout élément H est positionné à l'extérieur de la cage, sur la demi-droite issue du centre de l'icosaèdre régulier cité et passant par l'élément, B ou C, auquel il est lié. Toute distance B—H ou C—H est confondue, dans le modèle, avec la moyenne (respectivement 1,08 ou 0,94 Å) des distances expérimentales de même nature. Le plan contenant les 5 voisins B de

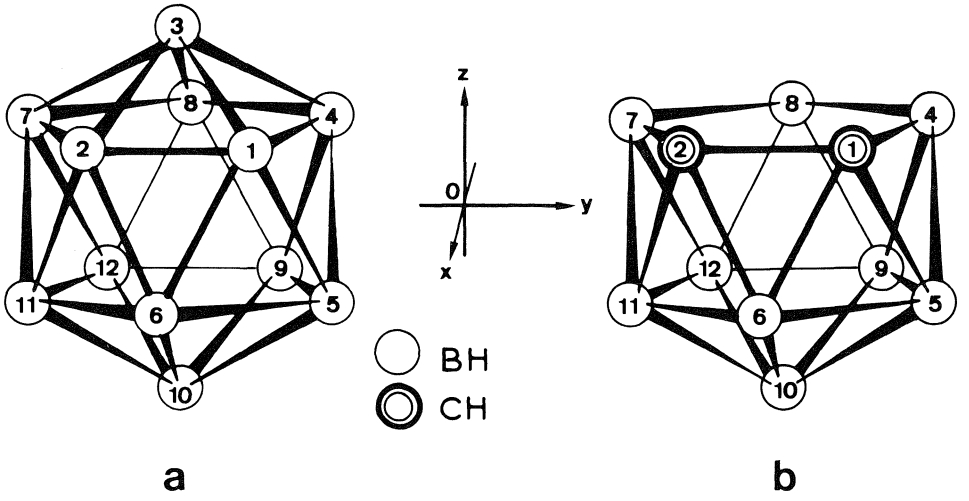

FIG. 1. Structures schématiques (a) de $B_{12}H_{12}^{2-}$ et (b) de l'ion (3)-1,2-dicarbollyle avec numérotation conventionnelle (22, 3) des groupes BH et CH.

B10 (fig. 1b) fait, avec la face pentagonale de l'ion dicarbollyle, un angle dièdre de 1,5°. Les éléments de la face pentagonale, les plus proches du plan des 5 B, sont C1 et C2, l'arête C1—C2 étant parallèle à ce plan. Les valeurs des autres distances interatomiques du modèle sont mentionnées dans un schéma topologique (fig. 2).

La version standard de la méthode SCF-MS-Xα (10) est utilisée sans orientation des spins. Le procédé de l'état de transition de Slater (11) sert à la détermination des énergies d'excitation de $B_{12}H_{12}^{2-}$. Pour les 2 dianions, le critère d'auto-cohérence du potentiel final est meilleur que 10^{-3}.

Les paramètres MS-Xα sont rassemblés dans le tableau 1. Le procédé non empirique de Norman (12) a été utilisé pour définir les sphères atomiques, de sorte que les sphères de 2 éléments directement liés soient sécantes. Dans le modèle de $B_{12}H_{12}^{2-}$, tout rayon atomique est pris égal à 88% du rayon de la sphère qui renfermerait le même nombre d'électrons que l'atome neutre, dans la superposition des densités atomiques. Pour l'ion dicarbollyle, les rayons atomiques r_C et $r_{H(C)}$ sont calculés selon le mode précédent et les rayons r_B et $r_{H(B)}$ sont identifiés à ceux retenus pour $B_{12}H_{12}^{2-}$. Les valeurs des paramètres d'échange de B (0,76531) et C (0,75928) sont celles optimalisées par Schwarz (13). Le paramètre d'échange de H (0,77725) est celui proposé par Slater (14). La moyenne des valeurs atomiques, pondérée par le nombre d'atomes, est adoptée pour les régions interatomique (Int.) et extramoléculaire (Ext.). La sphère circonscrite aux sphères atomiques constitue, par sa surface, la limite commune à ces 2 régions. Elle sert aussi de sphère de Watson (15) dont la charge (+2,5 pour chaque dianion) simule l'environnement et assure le signe négatif aux premiers niveaux énergétiques virtuels.

Dans tous les calculs rapportés, les ondes multiples de la région extramoléculaire sont développés sur une base d'ondes correspondant à $l \leqslant 4$ pour $B_{12}H_{12}^{2-}$ et $l \leqslant 3$ pour $B_9C_2H_{11}^{2-}$. Dans les sphères atomiques des deux dianions, les valeurs limites de l sont zéro pour H et 1 pour B et C.

Résultats et discussion

Le tableau 2 rassemble le type de symétrie, la population, la répartition de la charge et l'énergie en rydbergs (1 Ry = 0,5 ua = 13,6 eV), pour toute OM occupée et les 4 OM virtuelles les plus basses, dans l'état fondamental de $B_{12}H_{12}^{2-}$. Les énergies

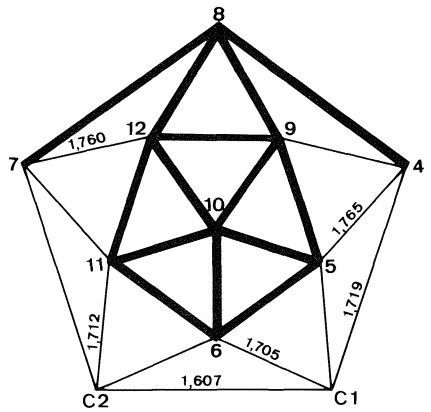

FIG. 2. Distances interatomiques (en Å) dans la cage de l'ion (3)-1,2-dicarbollyle, tout trait renforcé désignant une distance B—B de 1,785 Å.

TABLEAU 1. Paramètres MS-Xα (rayons atomiques en ua) des dianions $B_{12}H_{12}^{2-}$ et $B_9C_2H_{11}^{2-}$

$\alpha_{int} = \alpha_{ext}$	0,77128	0,77073

des OM de valence occupées, calculées par 2 méthodes semi-empiriques à champ auto-cohérent (ou SCF), sont rappelées dans un but de comparaison. Il s'agit des méthodes PRDDO et MNDO, respectivement utilisées par Lipscomb (1*b*) et par Dewar et McKee (16).

L'OM occupée la plus haute (ou HOMO) est $1g_u$. Elle est dégénérée d'ordre 4 et saturée par 8 électrons, conformément au diamagnétisme de $B_{12}H_{12}^{2-}$ (17). Pour des raisons de symétrie, les OA participant à l'HOMO sont exclusivement des orbitales p des éléments B, de sorte que $1g_u$ est non liante vis-à-vis de B—H. En revanche, $1g_u$ décrit des interactions B—B liantes qui contribuent à la cohésion de la cage.

TABLEAU 2. Niveaux d'énergie et distribution de charge de $B_{12}H_{12}^{2-}$ à l'état fondamental; (*a*) réf. 1*b*, (*b*) réf. 16, (*c*) nos résultats

					Distribution de charge (en %)

$1s$B	24	−14,4		−13,18	100				

L'OM virtuelle la plus basse (ou LUMO) est $3a_g$. Elle est très diffuse, ainsi que les 2 OM virtuelles ($3t_{1u}$ et $3h_g$) qui la suivent dans l'échelle des énergies croissantes. Ces 3 premières OM virtuelles sont non liantes. Elles sont presque exclusivement localisées dans les régions extramoléculaire (pour la plus grande part) et interatomique. Les OA engagées dans l'OM virtuelle suivante ($1g_g$) sont, pour des raisons de symétrie, exclusivement des orbitales *p* des éléments B. L'OM $1g_g$ est antiliante et elle est localisée, essentiellement et pour parts sensiblement égales, dans les sphères atomiques B et dans la région interatomique.

La hiérarchie énergétique qualitative des OM de valence occupées est, à l'exception de l'inversion des niveaux $1h_g$ et $2a_g$, la même que celle établie par les auteurs cités précédemment. En fait, cette inversion n'a pas vraiment de signification, les 2 niveaux Xα concernés étant si proches (0,005 Ry) qu'ils sont assimilables à des niveaux fortuitement dégénérés. D'une méthode de calcul à l'autre, la seule comparaison énergétique qui soit significative, concerne les écarts entre niveaux. L'ensemble des distances énergétiques successives séparant les 5 niveaux occupés les plus hauts, définis par les calculs PRDDO et MNDO, est en assez bond accord avec le calcul Xα, le meilleur accord concernant les résultats PRDDO (1*b*). Par ailleurs, la méthode PRDDO et, plus encore, la méthode MNDO, conduisent à une beaucoup plus grande stabilisation relative des bas niveaux de valence ($1h_g$, $1t_{1u}$, $1a_g$), que ne le fait la méthode Xα. Il s'ensuit que les écarts successifs Xα, entre ces niveaux, sont systématiquement et très nettement inférieurs à ceux calculés par les 2 autres méthodes.

L'écart énergétique entre LUMO et HOMO est remarquable par son importance (0,52 Ry = 7,07 eV). Il est compatible avec diverses observations expérimentales (17), en particulier avec la très grande stabilité polarographique de $B_{12}H_{12}^{2-}$, tant vis-à-vis de l'oxydation que de la réduction. Par ailleurs, le spectre d'absorption uv–visible ne présente qu'une queue de bande, située à la limite (200 nm) du domaine exploré. Un calcul Xα concernant les transitions permises par symétrie, situe un maximum d'absorption à 165 nm pour la transition de moindre énergie HOMO → LUMO et à 150 nm pour la transition $1g_u \rightarrow 1g_g$.

Lipscomb (18) utilise des liaisons covalentes multicentriques pour rendre compte de la cohésion de la cage icosaédrique de $B_{12}H_{12}^{2-}$. Deux types de liaison sont distingués dans ce modèle : toute liaison B—H est classiquement covalente tandis que toute liaison B—B est électroniquement déficiente, vis-à-vis du schéma covalent traditionnel. L'extension de ce modèle à l'ensemble des boranes de structure *closo* ou *nido* et à leurs dérivés isoélectroniques (en particulier les carboranes) a permis de dégager des règles empiriques, qui relient le type structural de la cage polyédrique à son nombre de paires électroniques liantes. Ces règles ont reçu récemment une démonstration rigoureuse (19) et s'énoncent comme suit. Les liaisons dans le squelette polyédrique d'un borane *closo* $B_nH_n^{2-}$ ($n > 4$) sont assurées par $n + 1$ paires électroniques liantes, tandis que $n + 2$ paires sont nécessaires s'il s'agit d'un borane *nido* $B_nH_n^{4-}$ (ou, en particulier, d'un carborane isoélectronique). Compte tenu des électrons engagés dans les *n* liaisons covalentes B—H (et C—H dans un carborane), c'est au total $2n + 1$ et $2n + 2$ paires électroniques liantes, qui interviennent respectivement dans les structures *closo* et *nido*. Toutes les OM de valence occupées de $B_{12}H_{12}^{2-}$ étant liantes, leur population électronique totale (soit 50e) est donc conforme à la règle spécifique aux structures *closo*.

L'examen du tableau 2 montre que les OM de valence peuplées, à l'exception de $1g_u$ et $1t_{2u}$, décrivent à la fois des interactions B–B et des interactions B–H. Pour des raisons de symétrie, l'HOMO $1g_u$ est exclusivement concernée par les premières et l'OM $1t_{2u}$ par les secondes.

Les orbitales *p* des B participent à toute OM de valence peuplée et contribuent (sauf dans $1t_{2u}$) de manière prépondérante à l'ensemble des interactions B–B, qui font de $B_{12}H_{12}^{2-}$ un véritable cluster moléculaire. La plus grande part des interactions B–B est décrite par les 2 OM de plus basse énergie ($1a_g$ et $1t_{1u}$ où les orbitales des B sont à caractère *s* largement dominant) et par les 3 OM de plus haute énergie ($2t_{1u}$, $2h_g$, $1g_u$ à caractère *p* pratiquement exclusif). Toutefois, l'OM $2t_{1u}$ rend compte aussi d'interactions B–H qui sont sensiblement de même importance que les interactions B–B. Les niveaux se situant entre les 2 domaines à forte interactions B–B, correspondent à une prédominance marquée (voire exclusive pour $1t_{2u}$) des interactions B–H.

Il est possible d'obtenir une image de la configuration

électronique des éléments B et H, dans $B_{12}H_{12}^{2-}$, en attribuant la charge de la région interatomique, à la fois aux sphères atomiques B et H, et la charge de la région extramoléculaire, exclusivement aux sphères atomiques H. Ces répartitions sont faites, pour toute OM, proportionnellement aux charges des sphères atomiques et conduisent aux configurations électroniques suivantes : $2s^{0,91}\ 2p^{2,09}$ pour B et $1s^{1,17}$ pour H. Il en résulte une charge nette nulle sur B, la charge formelle (−0,17) de tout groupe BH étant portée par H. Un autre mode de répartition de la charge de la région extramoléculaire consisterait à l'attribuer, comme celle de la région interatomique, à la fois aux sphères B et H. Eu égard à la faible population électronique (0,71e) de la région extramoléculaire, les configurations électroniques précédentes n'en seraient pas affectées de manière sensible. En effet, d'un mode de calcul à l'autre, la plus grande différence concernant les populations d'un même sous-couche atomique est inférieure au seuil de signification (0,05).

Le tableau 3 regroupe le type de symétrie, l'énergie et la répartition de la charge de quelques OM de l'ion (3)-1,2-dicarbollyle, dans son état fondamental. Il s'agit, d'une part, d'OM peuplées (les 4 les plus basses en énergie et les 9 les plus hautes) et, d'autre part, d'OM virtuelles (les 2 les plus basses en énergie et l'OM $14a''$). Toutes les OM peuplées sont saturées par 2e et sont liantes, conformément à la règle de dénombrement des paires électroniques liantes dans une structure *nido*.

La filiation structurale formelle de $B_{12}H_{12}^{2-}$ à l'ion dicarbollyle, ne s'accompagne que d'une diminution de 2 électrons de valence. Cette situation est favorable à la recherche de corrélations entre les niveaux d'énergie des 2 dianions. A cet effet, il faut considérer l'abaissement de symétrie $I_h \rightarrow C_s$ et les applications suivantes concernant les représentations irréductibles de I_h, sous-tendues par les OM de $B_{12}H_{12}^{2-}$:

$$A_g \rightarrow A' \qquad T_{1u}\ (\text{ou } T_{2u}) \rightarrow 2A' + A''$$

$$H_g \rightarrow 3A' + 2A'' \qquad G_g\ (\text{ou } G_u) \rightarrow 2A' + 2A''$$

Le premier niveau de valence occupé de $B_{12}H_{12}^{2-}$ ($1a_g$) correspond à celui ($1a'$) de l'ion dicarbollyle. Au-delà de ces niveaux et dans le sens des énergies croissantes, il est possible de faire correspondre à tout niveau dégénéré d'ordre n de $B_{12}H_{12}^{2-}$, une séquence de n niveaux consécutifs de l'ion dicarbollyle, sans qu'il y ait recouvrement des domaines énergétiques de 2 séquences adjacentes. Dans cette démarche, la dégénérescence fortuite des niveaux $2a_g$ et $1h_g$ de $B_{12}H_{12}^{2-}$ conduit à les confondre en un niveau unique qui serait dégénéré d'ordre 6. En ce qui concerne l'HOMO $1g_u$ de $B_{12}H_{12}^{2-}$, il lui correspond dans l'ion dicarbollyle, une séquence comportant les 3 niveaux occupés les plus hauts en énergie ($8a''$, $9a''$, $15a'$) ainsi que la LUMO $16a'$.

Dans l'échelle des énergies croissantes, toutes les OM virtuelles de l'ion dicarbollyle jusqu'au niveau $14a''$ exclu, sont diffuses, essentiellement dans la région extramoléculaire. L'OM $14a''$ rend compte, exclusivement, d'interactions antiliantes entre des OA p des éléments de la cage polyédrique, à l'exception de B10. La contribution au niveau $14a''$ des éléments appartenant à la face pentagonale est d'environ 2 fois celle des autres éléments de la cage et la participation la plus grande concerne les OA p_z des C. C'est par l'intermédiaire de l'OM virtuelle $14a''$ que se ferait, dans un complexe métallique, un éventuel don électronique en retour du métal au ligand.

Le niveau énergétique de l'HOMO est plus élevé dans l'ion dicarbollyle (−0,484 Ry) que dans $B_{12}H_{12}^{2-}$ (−0,637 Ry). L'écart énergétique LUMO–HOMO est important dans le

TABLEAU 3. Energie et répartition de la charge de quelques OM de $B_9C_2H_{11}^{2-}$, à l'état fondamental (le niveau occupé le plus haut en énergie est $15a'$, saturé par 2 électrons)

	BH 10	0,89	2,12	1,19	−0,01	−0,19	−0,20

premier dianion (0,29 Ry = 3,94 eV) mais il est nettement inférieur à l'écart homologue dans le second (0,52 Ry = 7,07 eV). Par ailleurs, la distance énergétique séparant la LUMO du plus bas niveau de valence peuplé est sensiblement la même dans les 2 dianions (19,6 eV pour l'ion dicarbollyle et 19 eV pour $B_{12}H_{12}^{2-}$).

Le tableau 3 révèle une quasi-dégénérescence des 2 niveaux occupés de plus haute énergie ($9a''$ et $15a'$), séparés de seulement 0,004 Ry = 0,05 eV. Dans ces conditions, il n'est pas étonnant que l'ordre énergétique relatif de ces 2 niveaux soit susceptible de s'inverser, selon la méthode d'orbitales moléculaires retenue. Ainsi, une étude MNDO de divers carboranes (20) signale, sans autre détail, que la symétrie de l'HOMO de l'ion dicarbollyle est de type a''. La même étude est beaucoup plus explicite en ce qui concerne $B_9C_2H_{13}$, isoélectronique de l'ion dicarbollyle. Dans ce carborane neutre, les 2 niveaux peuplés les plus hauts en énergie sont distants de 0,62 eV et sont, par ordre d'énergie croissante, $15a'$ et $9a''$ (HOMO).

Les contributions moyennes des sphères atomiques, à la charge des 3 niveaux occupés de plus haute énergie ($8a''$, $9a''$ et $15a'$) de l'ion dicarbollyle, sont les plus importantes pour les éléments définissant la face pentagonale. Par atome, les contributions sont croissantes dans l'ordre : C1, C2 < B4, B7 < B8. La nature des composantes relatives à ces atomes, dans les 3 OM considérées, privilégie la présence des électrons dans des régions sensiblement axées sur les 5 arêtes fictives issues du sommet vacant n°3 de la structure *nido* (fig. 1). Les 4 niveaux occupés, énergétiquement les plus proches des précédents (c'est-à-dire $6a''$, $7a''$, $13a'$ et $14a'$), s'en distinguent très nettement par leur distribution de charge. Ce sont les contributions des éléments hors de la face pentagonale de la cage, qui y sont largement majoritaires. Il en résulte que les OM jouant le rôle primordial dans l'établissement d'une liaison π de coordination, entre un métal de transition et l'ion dicarbollyle (donneur de 3 doublets électroniques), sont les 3 occupées les plus hautes en énergie.

Les interactions B–H interviennent dans tous les niveaux de valence de l'ion dicarbollyle, à l'exception du premier ($1a'$). Toutefois, la somme des contributions aux interactions B–H, des 2 niveaux suivant $1a'$ (c'est-à-dire $1a''$ et $2a'$) et des 4 niveaux les plus hauts en énergie (c'est-à-dire $14a'$, $8a''$, $9a''$, $15a'$) n'atteint pas 5%. Les interactions B–H prédominent dans la suite des 9 niveaux (dont 3 de type de symétrie a'') comprise entre $5a'$ (−1,094 Ry) et $10a'$ (−0,840 Ry). Les interactions B–H sont quasi exclusives dans les 3 niveaux médians ($7a'$, $4a''$, $8a'$) de cette suite.

Les interactions C–H sont assurées dans une proportion voisine de 4/5 par les 6 OM de valence les plus basses en énergie, les 2 premières ($1a'$, $1a''$) décrivant à elles seules presque la moitié de ces interactions.

Les interactions entre éléments du squelette polyédrique sont présentes dans tous les niveaux sauf les 3 remarqués précédemment ($7a'$, $4a''$, $8a'$). En s'écartant de ces niveaux et quel que soit le sens de variation de l'énergie, les interactions croissent rapidement dans la cage polyédrique, pour devenir majoritaires dans deux ensembles de niveaux. Il s'agit des 4 niveaux de plus basse énergie, où les électrons engagés ont un caractère s dominant, et des 9 niveaux les plus élevés à caractère p quasi exclusif.

Le tableau 4 rapporte les configurations électroniques des éléments de l'ion dicarbollyle et les charges nettes qui en résultent. À titre de référence, les grandeurs homologues de $B_{12}H_{12}^{2-}$ sont aussi rappelées. Le mode de calcul utilisé pour l'ion dicarbollyle est le même que celui développé pour $B_{12}H_{12}^{2-}$. La remarque concernant l'influence du mode de calcul sur la configuration électronique des éléments de $B_{12}H_{12}^{2-}$, demeure valable pour l'ion dicarbollyle. La faible population électronique (0,60e) de la région extramoléculaire de l'ion dicarbollyle, conduit aux mêmes conclusions. Quant aux charges nettes de groupe, d'un mode de calcul à l'autre, elles se reproduisent à 0,01 près, c'est-à-dire très largement en-deçà du seuil de signification.

Lipscomb et coll. (21) on fait une étude PRDDO de l'ion $C_2B_9H_{12}^-$, isoélectronique de l'ion dicarbollyle. En adoptant les hypothèses qui sous-tendent cette étude, il est possible de dégager quelques tendances concernant la réactivité de l'ion dicarbollyle. D'après ces auteurs, les processus réactionnels ioniques seraient contrôlés par les charges nettes de groupe, plutôt que par la distribution de charge dans les niveaux occupés de plus haute énergie. Cette distribution, en revanche, régirait les processus réactionnels covalents. Compte tenu du seuil de signification, la population électronique de l'OA $2s$ de B se conserve pratiquement d'un groupe BH à l'autre. Il en est de même de la population électronique de l'OA $1s$ de H. La valeur moyenne pondérée de la première (0,88) et celle de la seconde (1,18), sont pratiquement confondues avec les grandeurs homologues de $B_{12}H_{12}^{2-}$ (respectivement 0,91 et 1,17). C'est donc, exclusivement, la population de l'OA $2p$ de B qui, en créant des différences de charge nette d'un groupe à l'autre, est susceptible d'induire une réactivité sélective. Ainsi, une attaque électrophile devrait se faire préférentiellement sur le site B8 (chargé −0,15 et le plus éloigné des C sur la face pentagonale).

Quant à une attaque nucléophile, si elle est possible, elle interviendrait en priorité sur les sites B6 ou B5, 11 (chargés +0,08 ou +0,06 et les plus proches des C en dehors de la face pentagonale). La reconnaissance expérimentale de ces sites privilégiés d'attaque, prouverait que les états réactifs de transition de l'ion dicarbollyle, dépendent principalement de la distribution statistique de charge, à l'état fondamental.

Il convient de souligner que les contributions de C et H à la charge nette de groupe sont très peu différentes, de sorte que les liaisons C—H sont pratiquement apolaires. Il en est de même de la liaison B—H du groupe 8. En revanche, les liaisons B—H des groupes 5, 11 et 6 ont une polarité accrue par rapport à toute liaison B—H de $B_{12}H_{12}^{2-}$. Il devrait en résulter une accentuation du caractère hydrure, pour les groupes concernés. Quant aux autres liaisons B—H de l'ion dicarbollyle, elles ont sensiblement la même polarité que dans $B_{12}H_{12}^{2-}$.

En conclusion, les analyses comparées des fonctions d'onde Xα de $B_{12}H_{12}^{2-}$ et $B_9C_2H_{11}^{2-}$ et des distributions de charge qui en résultent ont permis d'apprécier l'important effet de polarisation induit par les C. Cet effet est vraisemblablement le facteur essentiel de la stabilité de la structure *nido* de l'ion dicarbollyle. L'absence d'effet analogue dans un ion $B_{11}H_{11}^{4-}$, qui serait de même structure et isoélectronique du précédent, peut faire douter de son existence tandis que sa mise en évidence expérimentale reste à établir.

Thioether complexes of tungsten hexacarbonyl

C. Robert Lucas

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received October 9, 1985[1]

C. Robert Lucas. Can. J. Chem. **64**, 1758 (1986).

The preparation of a series of organic and organometallic thioethers R_3MSR' (M = C, Si, Ge, or Sn) is reported. From these, several new compounds of type **1** are synthesized, some of which contain *para*-substituted aryl functions for R and R′. In hexane solution in the carbonyl stretching region of the ir and in the uv there is evidence for a degree of multiple bonding, at least in the M—S—W—CO portion of these molecules. Multiple bonding extending into aromatic R or R′ is small or non-existent and cannot be assessed precisely because of spontaneous decomposition of the complexes. All the complexes undergo a thermally initiated decomposition, the ease of which depends on the nature of R, R′, and M. The unusual W(I) thiolate *cis*-$[(CO)_4W\text{-}\mu\text{-}SR']_2$ is the thermal decomposition product.

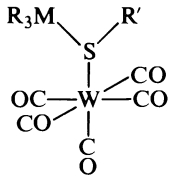
C. Robert Lucas. Can. J. Chem. **64**, 1758 (1986).

On rapporte la préparation d'une série de thioéthers R_3MSR' (M = C, Si, Ge ou Sn) organiques et organométalliques. En partant de ceux-ci, on a synthétisé plusieurs nouveaux composés du type **1**; dans certains de ces composés, R et R′ représentent quelquefois des fonctions aryles substituées en position *para*. La région carbonyle des spectres ir, mesurés solution dans l'hexane, ainsi que les spectres uv suggèrent qu'il existe un certain degré de liaisons multiples, au moins dans la portion M—S—W—CO de ces molécules. Par ailleurs, il n'y a que peu ou pas d'extension de cette liaison multiple dans les portions aromatiques R et R′; de plus, on ne peut pas en déterminer d'une façon précise l'étendue à cause de la décomposition spontanée des complexes. Tous les complexes subissent une décomposition initiée thermiquement et la facilité de cette réaction dépend de la nature de R, R′ et de M. The thiolate inhabituel du W(1), $[(CO)_4W\text{-}\mu\text{-}SR']_2$-*cis*, est le produit de la décomposition thermique.

[Traduit par la revue]

Introduction

It has been shown (1) that in complexes of type **1** the presence of a degree of multiple bonding between M and S, S and W, and W and CO can be detected by ir spectroscopy when M = Si, Ge, or Sn. It is of interest to know whether this can be detected by other physical methods, whether it extends into R and R′ if they are aromatic, and whether the multiple bonding has any



1

significant impact on the structure or chemical properties of the molecule.

Experimental

Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; nmr, Varian EM 360 or Bruker WP80 FT; mass spectra, VG Micromass 7070HS, uv, Cary Model 17. Analyses were performed by Canadian Microanalytical Service Ltd.

Ligands

All thiols and halides were obtained commercially except for *para*-$CF_3—C_6H_4—SH$, (*para*-Cl—$C_6H_4)_3GeCl$, (*para*-MeO—$C_6H_4)_3GeCl$, and (*para*-$CF_3—C_6H_4)_3GeCl$.

para-$CF_3—C_6H_4$-*SH*

To a mixture of concentrated HCl (10 mL) and ice (10 g) was added dropwise $CH_3—C_6H_4—NH_2$ (8.0 g, 6.3 mL, 50 mmol) at −4°C. To this was added dropwise a solution of $NaNO_2$ (3.7 g, 55 mmol) in H_2O (9 mL) also at −4°C. The cold diazonium salt solution was added dropwise to a solution of $KS_2COC_2H_5$ (9.4 g, 60 mmol) in H_2O (12 mL) at 45°C and stirred for 4 h. The solution was poured over chopped ice and the layers separated. The aqueous layer was extracted with ether (3 × 40 mL) and the extracts added to the organic layer which was then washed with 10% Na_2CO_3 and H_2O before being dried over $CaCl_2$. Volatiles were removed in vacuum, 95% ethanol (35 mL) was added to the residue and the mixture refluxed under an atmosphere of dry nitrogen while K_2CO_3 (12.2 g, 88 mmol) was added in small portions at a rate to maintain boiling. The mixture was refluxed overnight under an inert atmosphere. Water (75 mL) was added and the mixture extracted with ether (3 × 40 mL). The extracts were washed with 10% Na_2CO_3 (3 × 50 mL) and the washings were added to the aqueous phase previously separated which was then acidified to pH 3 with concentrated HCl and extracted with ether (3 × 40 mL). The extracts were dried over $CaCl_2$ and distilled. The product was an evil smelling oil boiling at 57°C at 8 mm Hg. Yield 1.4 g (16%).

(para-*Cl—*$C_6H_4)_3GeCl$, (para-*MeO—*$C_6H_4)_3GeCl$, *and* (para-*$CF_3—C_6H_4)_3GeCl$*

These compounds which are required for the preparation described below were obtained from the appropriate aryl bromide and $GeCl_4$ via a Grignard reaction in tetrahydrofuran and were used subsequently without isolation.

$Pb(SR)_2$

Lead mercaptides were obtained by stirring overnight stoichiometric mixtures of lead(II) acetate trihydrate and the appropriate thiols in 50% ethanol/water. The yellow precipitates were removed, washed several times with water and then alcohol, and dried in vacuum. Yields are typically >95%.

Me_3SiSPh, Me_3GeSPh, Ph_3CSPh, Ph_3GeSPh, (para-*Cl—*$C_6H_4)_3GeSPh$ (para-*MeO—*$C_6H_4)_3GeSPh$, (para-*$CF_3—C_6H_4)_3GeSPh$,* para-*Cl—*$C_6H_4—S—SiMe_3$, para-*MeO—*$C_6H_4—S—SiMe_3$, para-*$CF_3—C_6H_4—S—SiMe_3$*

These compounds were prepared by suspending $Pb(SR)_2$ (10 mmol) and the appropriate halide (20 mmol) in tetrahydrofuran (100 mL) and refluxing the mixture with stirring under an inert atmosphere until the suspended solids had turned white. Solids and solvent were removed to obtain crude products. Those that were mobile oils were distilled at reduced pressures under an inert atmosphere while those that were solids were recrystallized from benzene/hexane or were chromatographed in benzene/hexane on Florisil before being recrystallized.

Me_3SnSPh and Ph_3SnSPh

These compounds were prepared in tetrahydrofuran from stoichio-

[1]Revision received April 15, 1986.

metric mixtures of the appropriate organometal halide and thiophenol in presence of pyridine as a base. The solvent was removed under reduced pressure and the white crystalline products purified by recrystallization from benzene/hexane.

Ph_3SiSPh[2]

Diazabicyclo[2.2.2]octane (DABCO) (2.2 g, 20 mmol) was dissolved in dry toluene (15 mL) and thiophenol (2.2 g, 2.1 mL, 20 mmol) was added dropwise. The suspension was stirred for 2 h under a $CaCl_2$ drying tube and then filtered. The residue was dried under vacuum. Yield 3.1 g (70%) of DABCO.HSPh. Mp 95–97°C.

DABCO.HSPh (3.1 g, 14 mmol) and Ph_3SiCl (4.1 g, 14 mmol) were suspended in dry benzene (50 mL) and stirred under a $CaCl_2$ drying tube for 5 days. The suspension was filtered and the filtrate was concentrated under reduced pressure until a nearly colourless oil remained which crystallized on standing and from hexane.

(para-Cl—C_6H_4)$_3$CSPh and (para-MeO—C_6H_4)$_3$CSPh

Both compounds were obtained from the appropriate aryl bromide via its Grignard reagent which was first used with CO_2 to form the carboxylic acid and its methyl ester and then the tertiary carbinol by addition of the Grignard reagent to the methyl ester.

Thus, *para*-MeO—C_6H_4COOMe (6.6 g, 41.5 mmol) in dry tetrahydrofuran (25 mL) was added dropwise with stirring to MeO—C_6H_4—MgBr (125 mmol) in tetrahydrofuran (150 mL) and the mixture refluxed overnight. To this was added dropwise a saturated solution of NH_4Cl (20 mL) and water (40 mL). The mixture was stirred until two layers developed at which time they were separated and the aqueous layer washed with ether (3 × 50 mL). The washings were added to the organic layer which was then treated with 5% HCl, 10% $NaHCO_3$ and H_2O, and finally dried over $CaCl_2$. The solvent was removed to leave (MeO—C_6H_4)$_3$COH as an orange oil. Yield 6.0 g (41%).

The carbinol (3.5 g, 10 mmol) was suspended in dry ether (50 mL) containing PhSH (2.2 g, 2.0 mL, 20 mmol) and concentrated H_2SO_4 (0.3 mL) was added. The mixture was stirred for 24 h under a drying tube. Sodium hydroxide (1.0 mol/L, 35 mL) was added and the mixture stirred vigorously. The aqueous layer was separated and washed with CH_2Cl_2 (2 × 50 mL). All organic phases were combined, filtered through celite, and dried over $CaCl_2$. The solvent was removed to give a sticky yellow solid which was dissolved in benzene and chromatographed on Florisil to produce an off-white solid. Yield 2.2 g (50%).

(*para*-Cl—C_6H_4)$_3$CSPh was obtained similarly.

Complexes

A general method for the preparation of the type **1** complexes has been reported (1) with typical yields of 30%.

Mass spectra of the freshly prepared complexes did not show molecular ion peaks except for (Me_3GeSPh)$W(CO)_5$ and [(Cl—C_6H_4)$_3$GeSPh]$W(CO)_5$. Spectra of the other complexes consisted of peaks corresponding to $[ligand]^+$, $[R_3M]^+$, $[R'S]^+$, $[W(CO)_n]^+$ (n = 1–4), and ligand fragments.

cis-*[(OC)$_4$W-μ-SPh]$_2$*

Tungsten hexacarbonyl (5.3 g, 15 mmol) was dissolved in dry tetrahydrofuran (200 mL) in a Pyrex flask fitted with a double surface condenser, a magnetic stirrer, and a gas dispersion inlet tube. The top of the condenser was connected to an oil bubbler and the solution was irradiated for 4 h with a 100 W uv lamp while stirring and passing a stream of nitrogen bubbles through the solution. The lamp was switched off and Ph_3SiSPh (5.5 g, 15 mmol) dissolved in dry, degassed tetrahydrofuran (50 mL) was added under an inert atmosphere. The solution was refluxed for 24 h. Solvent was removed in vacuum and the residue extracted with hexane until the extracts were nearly colourless. The extracts were concentrated and chromatographed on Florisil using hexane as eluant. The first material to be removed is a green, non-terminal carbonyl substance which is followed by $W(CO)_6$, *cis*-[$(OC)_4W$-μ-SPh]$_2$, (Ph_3SiSPh)$W(CO)_5$, and $Ph_3SiSiPh_3$. The green *cis*-[$(OC)_4W$-μ-SPh]$_2$ was separated from its solvent, placed in a sublimer, and some $W(CO)_6$ removed by sublimation at 40°C and 0.1 mm Hg. The residue was recrystallized from hexane. Yield 1.3 g (22%). Mp 93°C (decomp). Mass spectrum: parent ion m/e = 810 not seen. Fragments with high abundance have m/e = 405, 268, 240, and 109 corresponding to $[(OC)_4WSPh]^+$, $[W(CO)_n]^+$ (n = 2–4) and $[PhS]^+$. *Anal.* calcd. for $C_{20}H_{10}O_8S_2W_2$: C 29.65, H 1.24, W 45.39; found C 29.72, H 1.96, W 45.50.

[2]A previously reported preparation of this compound, in our hands, gave no Ph_3SiSPh. However, the physical properties of Ph_3SiSPh prepared as described above agree with those previously reported (2).

Results and discussion

Many of the ligands employed in this study were obtained by the lead mercaptide process originally reported by Abel (3) as a method for (alkylthio)trimethylsilanes.

The lead mercaptides were prepared by precipitation from alcoholic solutions containing thiol and lead acetate trihydrate.

The thiols are available commercially or can be prepared easily from a diazonium salt and potassium ethyl xanthate.

The preferred route to R_3MSR' (M = C, R = substituted phenyl), however, starts from *para*-substituted aryl bromides and involves conversion of their Grignard reagents into methyl esters to which more Grignard is added forming tertiary carbinols. The carbinols are converted to thioethers by treatment with PhSH in the presence of mineral acid.

In two cases, neither of the routes already discussed is appropriate. Tertiary butyl chloride does not react with $Pb(SPh)_2$ even after 3 days in refluxing tetrahydrofuran and treatment of it with PhSH in the presence of a base leads only to isobutene. To prepare Me_3CSPh, addition of PhSH to isobutene in the presence of H_2SO_4 is the preferred route (4).

The lead mercaptide method also fails to yield Ph_3SiSPh. That compound can be obtained, however, from mixtures of PhSH and Ph_3SiCl in presence of the special base diazabicyclo[2.2.2]octane.

Some properties of the thioethers are listed in Table 1. All act as monodentate ligands to transition metals and we have already described some of their complexes (1).

In that earlier study, we examined several compounds of type **1** in hydrocarbon solution by vibrational spectroscopy in the carbonyl stretching region. Data from that and from the present studies (Table 2) were treated according to Cotton and Kraihanzel (5) to obtain approximate carbonyl stretching force constants and then by Graham's method (6) to obtain $\Delta\sigma$ and $\Delta\pi$ factors. Results are in Table 2 and are displayed graphically in Fig. 1 which also shows that all R_3MSR' ligands lie between triphenylphosphine and pyridine and near acetonitrile in terms of their σ-donor/π-acceptor abilities.

As will be discussed below, many of the complexes undergo a spontaneous decomposition to a *cis*-disubstituted carbonyl system which has ir and Raman absorptions in the same region as the B_1 mode of the type **1** complexes. Consequently, the type **1** complexes reported here which were not reported in our earlier study cannot be isolated in an analytically pure state. Furthermore, the frequency of their B_1 modes cannot be determined with precision due to the presence of overlapping bands from the decomposition product. Nonetheless, the other three bands expected for a molecule with C_{4v} local symmetry are well resolved and are sufficient to calculate all constants and the frequency of the partially obscured B_1 mode (Table 2) (7).

Reproducibility of the spectra is such that the probable error in the measured frequencies is <1 cm^{-1}. The effect of such an error is to introduce uncertainties of less than ± 0.07 for $\Delta\pi$ and ± 0.09 for $\Delta\sigma$ (Fig. 1).

The spectra appear as predicted by theory (7). The signifi-

cance of the force constants and Graham parameters has been discussed previously (1) and while the absolute values of the force constants may be disputed, differences between them for a series of closely related compounds are generally accepted as meaningful (8). As previously demonstrated (1), there is a relationship between the relative σ- and π-bonding abilities of the ligands and the nature of R and M in them. This relationship can be detected by vibrational spectroscopy and rationalized in terms of the electron density on sulfur which is affected both by the electronegativity of groups bound to sulfur and by the extent of $p\pi \rightarrow d\pi$ S → M bonding.

To determine whether vibrational spectroscopy can also detect changes in the carbonyls caused by *para*-substituents in aromatic R or R′, the substituents —CF_3, —Cl, —H, and —OMe, covering a range of electron-donating and -withdrawing abilities, indicated by their Hammett σ-values, were introduced. There is, however, no change within experimental error (Fig. 1), in the σ- and π-bonding ability of the ligands as their *para*-substituents are altered. This is not surprising when M = C in R_3MSR' since the absence of *d* orbitals on M prevents transmission of electronic effects except through the σ bonds. Thus, the influence of the *para*-substituents should diminish

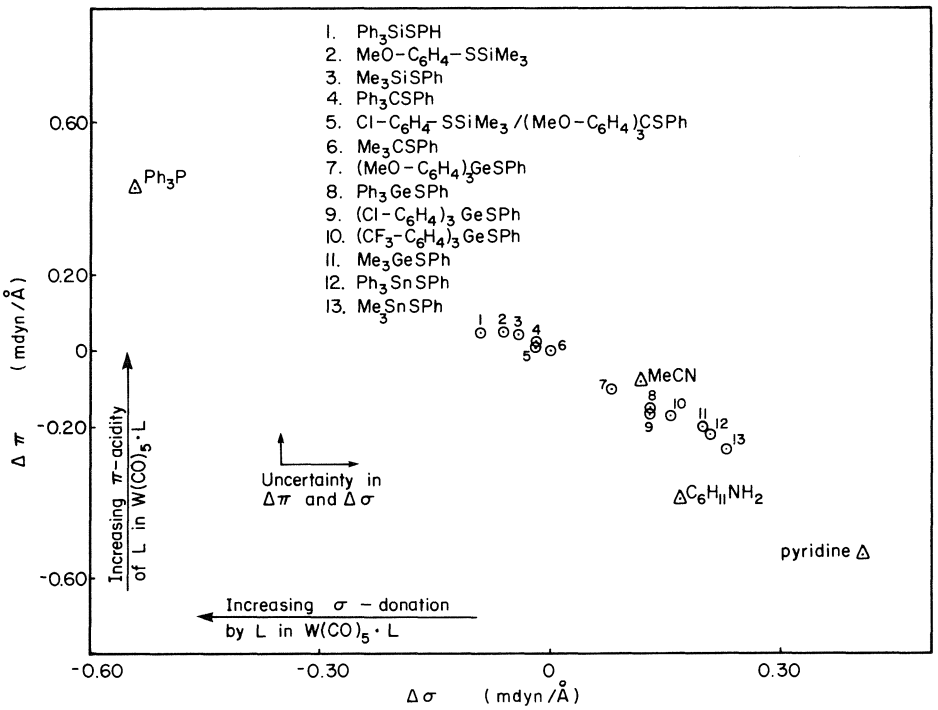

FIG. 1. Graham parameters for $W(CO)_5 \cdot L$ as a function of L: ⊙, data from this work; △, data from cotton (refs. 23 and 24) for comparison.

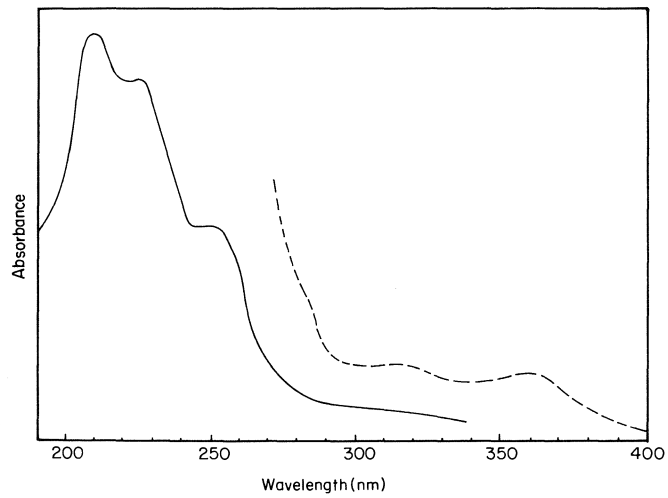

FIG. 2. Electronic spectrum of $W(CO)_5(Ph_3GeSPh)$: — $\sim 10^{-5}$ mol/L; --- $\sim 10^{-4}$ mol/L in hexane at room temperature.

rapidly with distance from the ring, becoming undetectably small over the four bonds to the carbonyls. This explanation probably reasonably describes the situation for the germanium–thioether complexes too because the extent of Ge—S π-bonding is small as has been shown in X-ray (9) and spectroscopic (1) studies.

When the *para*-substituent is on R′, however, it lies one bond closer to the carbonyls and to the sulfur atom and a greater effect might therefore be expected. That no significant change was detected is probably due to the fact that the uncertainty in Δσ and Δπ (discussed above) is larger than the changes caused by varying the *para*-substituent. This is consistent with the relatively small changes in Δσ and Δπ observed when R is changed from methyl to phenyl in these systems.

In an attempt to develop a more sensitive assessment of electronic effects, the uv spectra of some of the complexes

Ph_3CSPh	235
Me_3GeSPh	220
Ph_3GeSPh	224
Me_3SnSPh	212
Ph_3SnSPh	215

were examined. A typical spectrum (Fig. 2) consists of a series of moderately intense metal-to-ligand charge transfer bands between 200 and 260 nm and two much weaker *d*–*d* transitions between 300 and 400 nm. One of the charge transfer bands is particularly sensitive to the nature of the ligand and moves as the ligand is changed (Table 3). By analogy with other $W(CO)_5L$ species, this band is assigned to a tungsten-to-thioether transition involving essentially *d* orbitals on both tungsten and sulfur (10).

If the sulfur *d*-orbital energies are affected by both the electro-negativity and by the extent of π-bonding to adjacent atoms or groups as discussed above, the energy of this charge transfer band should be affected also, assuming a reasonably constant energy for the tungsten orbitals. That such is indeed the case is illustrated in Fig. 3. As the groups attached to sulfur are changed in such a manner as to lower the electron density on sulfur (1), the π acidity of the ligand increases as the tungsten and sulfur *d* orbitals become closer in energy.

As noted earlier several of the type **1** complexes spontaneously decompose and their electronic spectra are uninterpretable due to overlapping bands. The decompositions, which can be represented in general by reaction [1], are thermally but not photochemically induced, their ease being sensitive to the nature of R and R′, with some occurring even in the solid state.

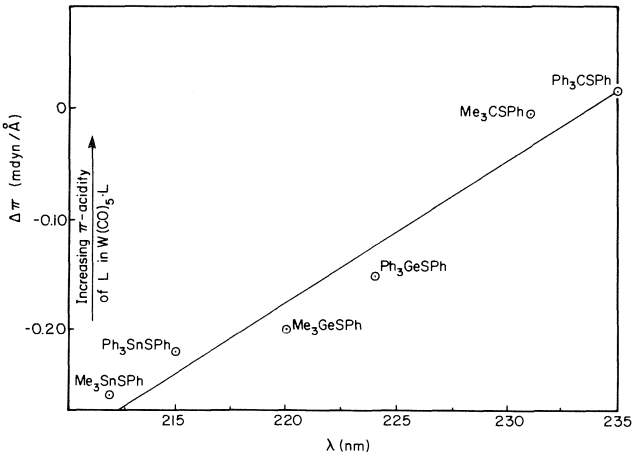

FIG. 3. π-acidity of L in $W(CO)_5 \cdot L$ vs. tungsten-to-thioether charge transfer wavelength.

[1] $2W(CO)_5(R_3MSR') \xrightarrow{\Delta} [W(CO)_4(SR')]_2 + (R_3M)_2$

For example, when R_3MSR' = $(Cl—C_6H_4)_3CSPh$ or $Me_3SiS—C_6H_4—CF_3$, the decomposition is so rapid that the type **1** complexes cannot be detected even in freshly prepared hexane extracts of the crude reaction products. By contrast, when R_3MSR' = Ph_3GeSPh, significant decomposition can only be accomplished by refluxing overnight. Irradiation of the same solution at room temperature for a similar period gives only small amounts of the desired products. Exactly which features of the ligand control the ease with which the decompositions proceed is not clear although when M = Si or when R or R′ are substituted phenyl, the decompositions seem to occur more readily.

Hexane solutions of the unusual W(I) thiolates which are products of these decompositions have ir spectra in the carbonyl stretching region consisting of four bands. For $W_2(CO)_8(SPh)_2$, these occur at 2038(s), 1979(m), 1973(m), and 1964(vs) cm^{-1}. Such spectra are consistent with a *cis*-disubstituted structure with C_{2v} local symmetry. Based on intensity arguments (11), the highest energy band can be assigned to the A_1 mode involving *trans* carbonyls and the lowest energy band to the B_1 mode. Since the *trans* force constant, k_1, must be less than the *cis* force constant, k_2 (5), there is only one satisfactory assignment of the two bands of intermediate frequency. Thus, the A_1 mode involving the *cis* carbonyls occurs at 1979 cm^{-1} and the B_2 mode occurs at 1973 cm^{-1}. Force constants obtained using these assignments are k_1 = 15.93, k_2 = 16.01, and k_i = 0.22 mdyn/Å.

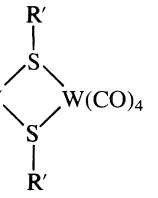
Preliminary structural studies by X-ray methods (12) have confirmed the *cis*-disubstituted nature of the compound when R′ = Ph and that it is dimeric as indicated in reaction [1]. These studies also show that the W—W distance of 297.2(1) pm is substantially less than the 344 pm predicted from previously reported covalent radii (13).[3] Furthermore, the angles at S are acute while those at tungsten are obtuse. These observations suggest the presence of a W—W bond which is consistent with the appearance of a narrow phenyl multiplet 7.3 ppm from TMS in the ^1H nmr spectrum. In the absence of a W—W bond, some broadening or shift of the signal due to paramagnetism of a formally W(I) species might be expected. Analogous compounds of Group VI metals are rare, but $[Mo_2(SBu^t)_2(CO)_8]$ (14) is structurally similar and is also diamagnetic.

No study of the decomposition mechanism has been undertaken, but certain observations point to processes for which precedent exists. Thus, one could envisage the following stages occurring within the mechanism.

[2] $W(CO)_5(R_3MSR') \rightarrow W(CO)_5SR' + (1/2)(R_3M)_2$

[3] $W(CO)_5SR' \rightarrow W(CO)_4SR' + CO$

[4] $2W(CO)_4SR' \rightarrow (OC)_4W(SR')_2W(CO)_4$



Reaction [2] involves cleavage of an M—S bond which has been demonstrated, at least in the case of M = Si, to be a facile process for the free ligand even under mild conditions (3, 15). Furthermore, there is evidence to suggest that when the ligand is coordinated, the central metal can assist in an M—S cleavage (16). The next stage (reaction [3]) requires loss of a *cis* carbonyl which could occur as a result of a *cis* labilizing process such as has been observed in related systems (17) and finally, reaction [4] involves dimerization similar to that observed for related complexes of Ru and W (18–21).

A structural study of Ge—S and Sn—S bonds in organometallic thioethers (9) found no shortening in the M—S bonds compared to the calculated lengths (22) and concluded that M—S multiple bonding was not structurally significant in these compounds. From our evidence, it would appear (Fig. 1) that the significance of M—S multiple bonding is greatest when M = Si and diminishes considerably when M = Ge or Sn. An X-ray study of Ph_3SiSPh was therefore undertaken (12) and the Si—S bond was found to have a length of 215.6(2) pm. This represents a shortening of >4 pm compared to the calculated length (22).

In conclusion, the effects of M—S multiple bonding in organometallic thioethers can be detected by both ir and uv spectroscopy. Such bonding diminishes in magnitude from Si through Ge to Sn, having structural significance only when M = Si and even then the M—S bond is cleaved with ease in the complexes. Whether multiple bonding extends into aromatic R and R′ cannot be determined with certainty although if such bonding exists it must be small.

ipso Nitration. XXVIII.[1] Nitration of 4-substituted toluenes: 1,2 adducts[2]

ALFRED FISCHER,[3] DEBORAH L. FYLES, GEORGE N. HENDERSON, AND SUMIT RAY MAHASAY
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received February 10, 1986

ALFRED FISCHER, DEBORAH L. FYLES, GEORGE N. HENDERSON, and SUMIT RAY MAHASAY. Can. J. Chem. **64**, 1764 (1986).

Nitration of 4-acetamido-, 4-chloro-, and 4-methoxy-toluene in acetic anhydride gives in each case a *cis* 1,2 nitronium acetate adduct in addition to the nitro substitution product(s). Nitration of 4-fluorotoluene gives a pair of diastereomeric 1,4 nitronium acetate adducts and the *cis* 1,2 adduct.

ALFRED FISCHER, DEBORAH L. FYLES, GEORGE N. HENDERSON et SUMIT RAY MAHASAY. Can. J. Chem. **64**, 1764 (1986).

En plus de conduire à la formation de produits substitués par un groupement nitro, la nitration des acétamido-4, chloro-4 et méthoxy-4 toluènes effectuée dans l'anhydride acétique conduit aussi, dans chaque cas, à la formation d'un adduit nitronium acétate-1,2-*cis*. Lors de la nitration du fluoro-4 toluène, il y a formation de l'adduit 1,2-*cis* ainsi que d'une paire d'adduits nitronium acétates-1,4 diastéréoisomères.

[Traduit par la revue]

Nitration in acetic anhydride of aromatic compounds in which a substituted position is activated often leads to the formation of nitronium acetate adducts in which the nitro group is attached to the activated substituted site (3, 4). There are many examples in the polymethylbenzenes and *p*-alkyltoluenes (5–11). In these reactions the nitration of *p-tert*-butyltoluene appears anomalous in that it gives both 1,2 and 1,4 adducts (12), whereas only a pair of diastereomeric 1,4 adducts is formed in all of the other cases. In this paper we describe the nitration of 4-X-toluenes (X = F, Cl, OMe, NHCOMe) leading, in each case, to the formation of a 1,2 adduct and, in the case of 4-fluorotoluene, to a pair of diastereomeric 1,4 adducts. In a previous paper we described the structure and stereochemistry of the adduct formed on the nitration of 4-bromotoluene (1). Nitration of 4-bromo- and 4-methoxytoluene has been investigated previously by Clemens *et al.* (13). They obtained 4-methyl-4-nitrocyclohexadienone from both substrates and did not detect the formation of dienes.[4]

Results and discussion

Nitrations were carried out under conditions that led to optimum yields of the adducts and which were determined by carrying out preliminary reactions on a 0.5-mmol scale and following the reactions by nuclear magnetic resonance spectroscopy (^{1}H nmr). For preparative nitrations the reaction temperature was −40°C and trifluoroacetic anhydride was added to increase the activity of the nitrating mixture (4) in the cases of the less reactive substrates (X = F, Cl, I, NHAc). Reaction mixtures were neutralized by the addition of aqueous ammonia at low temperature or by addition to cold aqueous sodium bicarbonate followed by stirring for 1.5 h. Generally the composition of the reaction product isolated after work-up was the same as that present in the reaction mixture prior to work-up. The adduct from 4-chlorotoluene, like that from 4-bromotoluene (1), was crystallized directly from the reaction product. In the cases of the other substituted toluenes the product mixtures were separated by chromatography. The adduct from 4-acetamidotoluene was particularly labile, undergoing aromatization even at −20°C. However, it was obtained pure following two successive chromatographic separations at −78°C. The adducts from 4-fluorotoluene were also reactive, being subject to autocatalytic acid-catalysed loss of the elements of acetyl fluoride to form first 4-methyl-4-nitrocyclohexa-2,5-dienone, which in turn rearranged to 4-methyl-2-nitrophenol (15).

As in the case of 4-bromotoluene, 4-chlorotoluene gave an adduct and two substitution products, whereas the methoxy and acetamidotoluenes gave only the adduct and the 3-nitro derivative (Table 1). Nitration of 4-fluorotoluene was strikingly different from that of 4-bromo- and 4-chlorotoluene in that the major product was the 1,4 adduct (81%) obtained as a pair of

[4]The ^{1}H nmr spectrum of 4-methyl-4-nitrocyclohexa-2,5-dienone that they reported (δ: 1.95, 5.66, 6.53 ppm) differs significantly from that reported by Myhre and co-workers (14) (1.96, 6.35, 7.15 ppm). When we repeated the nitration of 4-bromotoluene under the conditions described (13), we observed diene but not dienone in the reaction mixture and only 40% of the 4-bromotoluene reacted. Pure samples of the dienone have been characterized unambiguously by various workers and its formation at higher temperatures from 4-methylanisole is now well established.

diastereomers. Only a small amount (8%) of 1,2 adduct was formed and no nitro substitution product was observed. Some 4-methyl-4-nitrocyclohexadienone was also obtained (11%) but, since this is a product of further reaction of the dienes (*vide supra*), it is likely that it was not formed as a primary reaction product. Nitration of 4-iodotoluene gave a very small amount of adduct (<10%), which was not isolated. The predominant product was 4-nitrotoluene, accompanied by the liberation of iodine. Substitution product(s) was also formed. Nitration of 4-(*N*,*N*-dimethylamino)toluene gave nitroaromatic product and no adduct was observed. Attempted nitration of 4-(*N*-methylamino)toluene resulted in the formation of the anilide. Nitration of 4-(*N*-methylacetamido)toluene gave an adduct that did not survive the work-up procedure.Nitration of 4-acetoxytoluene (4-methylphenyl acetate) gave the dienone, as previously observed (14), but no diene, even at −60°C.

Structure and spectra of the adducts

The structures of the dienes **1**, **2**, **3**, **4**, and **5** were initially assigned on the basis of spectral information. Elemental analyses are consistent with the addition of acetyl nitrate to the substrate aromatic. Such addition is confirmed by the infrared spectra, which exhibit strong absorptions around 1750 (for $OCOCH_3$) and 1550 cm^{-1} (for NO_2). The ultraviolet spectra (λ_{max} = 257–271 nm, $\varepsilon = 350\ m^2\ mol^{-1}$) show that the dienes are conjugated, since isolated double bonds absorb below 253 nm (21). There are three arrangements of conjugated double bonds that can be derived from addition to a 4-substituted toluene. Using the enumeration of toluene,[5] these may be described a 1,3-diene, a 1,5-diene, and a 2,4-diene. In the 1,3-diene both sp^3 carbon atoms have an attached hydrogen atom. However, the ^{13}C nmr spectra (Table 2) indicate that there is one sp^3 carbon atom with an attached hydrogen atom (δ_C = 70 ppm, doublet splitting in the gated spectrum J = 150 Hz), and one sp^3 carbon atom with no attached hydrogen (δ_C = 87 ppm, singlet in the gated spectrum). Moreover, this structure cannot account for the 10-Hz splitting in the ^1H nmr spectra (Table 3), which points to the presence of adjacent vinylic protons. In the 1,5-diene structure the variable substituent (4-X) is attached to an sp^3 carbon that has no attached hydrogen (either the nitro or the acetate group must also be attached to this carbon). However, in the ^{13}C nmr spectra the position of the fully substituted sp^3 carbon absorption is relatively invariant (δ_C = 87 ppm), which points to a constant substitution pattern. Correspondingly, the sp^2 carbon that has no attached hydrogen has widely ranging absorption (δ_C = 122.6–159.4 ppm) consistent with the 4-X substituent being located at this carbon. Only the 2,4-diene structure is consistent with the position of the absorptions of these two carbon atoms.

[5]The toluene enumeration is used in Table 1. The other tables use the appropriate enumeration for the cyclohexadienyl acetates.

The nitro group must be located at position 1 because the chemical shift of the fully substituted carbon (δ_C = 87 ppm) is the same as that of the sp^3 carbon of 4-methyl-4-nitrocyclohexa-2,5-dieone to which are attached the nitro and methyl groups. The acetate group is thus at position 6. In the case of diene **1** an X-ray crystal structure determination confirmed the structure assigned on the basis of the spectral data and gave the stereochemistry, the nitro and acetate groups being *cis* to each other (1). It seems reasonable to conclude that the 1,2 addition of acetyl nitrate, which is stereoselective in all of the substrates investigated and which is also stereoselective in the case of 4-*tert*-butyltoluene (12), is in all cases a *syn* addition. Shift reagent studies applied to the two members of a pair of diastereomeric adducts have been used to determine the stereochemistry of 1,4-adducts in which the acetate group is secondary (22), but the method could not be applied to the 1,2-dienes obtained in this work since a pure sample of the second diastereomer was not generally available.

Other features of the nmr spectra of the 1,2 adducts are as follows (enumeration now follows that exemplified in 3-chloro-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate). In the ^1H nmr the methyl group protons resonate at 1.8 ppm and the acetate methyl protons resonate at 2.0 ppm. The protons of the methoxy group of diene **4** are at 3.60 ppm and those of the acetamido methyl group in diene **5** at 2.10 ppm. The absorptions of the 1 and 2 protons were distinguished from those of the 4 and 5 protons by the 6-Hz coupling of the former as compared with the 10-Hz coupling of the latter. The individual assignments of the absorptions of the 1 and 2 protons were made on the basis that the 1-proton absorption should be essentially invariant in position, and is therefore the absorption at 5.5 ppm, whereas the 2-proton absorption should be affected by the variation of the 3-substituent, which is vinylic to it, and thus this absorption ranges from 5.0 to 6.5 ppm. These assignments were confirmed in the cases of dienes **1** and **2** by selective proton decoupling of the 1-H from the C-1 in the ^{13}C spectra. The assignments of the 4 and 5 protons were made on the basis of long range coupling constants. Thus, in **2** the 1-H is coupled to one of 4-H and 5-H (J = 1.6 Hz) and 2-H is coupled to the other (J = 2.0 Hz). The four-bond 1,5 and 2,4 couplings should be larger than the five-bond 1,4 and 2,5 couplings and the 4-H and 5-H were assigned to reflect this. In the dienes **1** and **2** there is in addition a small 2,5 coupling (J = 0.6 Hz). Decoupling experiments were carried out on dienes **1** and **2**. In **1** the 1-H absorption appeared as a doublet of doublets (J = 6.2 Hz and 1.8 Hz). The 2-H absorption appeared as a doublet of a doublet of a doublet (J = 6.2 Hz, 1.8 Hz, 0.6 Hz). Irradiation of 1-H (5.45 ppm) caused the large coupling in 2-H to disappear, and the smallest coupling disappeared when the 5-H was irradiated (6.45 ppm). The 5-H absorption itself appeared as a doublet of a doublet of a doublet (J = 10.2 Hz, 1.8 Hz, 0.6 Hz), which collapsed to a doublet of a doublet (J = 10.2 Hz and 0.6 Hz) when the 1-H was irradiated. The 4-H absorption appeared as a doublet of a doublet (J = 10.2 Hz and 1.8 Hz). Similar observations were made on **2**. In diene **3** the signal due to 2-H is shifted upfield and it overlaps with the peak of the 1-H (5.6 ppm). Addition of the shift reagent tris-(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III) (Eu([$^2H_9$]fod)$_3$) separated the 1-H peak from that of 2-H and allowed the coupling constants to be determined. The 2-H signal is shifted even further upfield in **4** (to 4.97 ppm). The five-bond coupling between 2-H and 5-H is absent in **3** and **4**.

The ^1H nmr spectrum of **5** is temperature dependent, the

[a]Very broad.

greatest variation being exhibited by the N-H followed by the 2-H and 4-H (Table 4). The C—N bond of an amide has partial double bond character, as a consequence of the amide group resonance, and hence rotation about the carbonyl nitrogen bond is hindered. In monosubstituted amides the rotamers differ in energy and therefore participate unequally in the thermal equilibrium. For N-alkyl compounds the predominant planar rotamer is the one with the alkyl groups (attached to the N and C=O) *anti* to each other (23). In the case of diene **5** such geometry gives rise to two limiting structures, **5***i* and **5***ii*, differing by rotation about the diene-N bond. In *i* the 2-H and in *ii* the 4-H lies in the deshielding zone of the carbonyl group. The chemical shifts of these protons thus vary with the relative orientation of the carbonyl group and their values at a particular temperature will be determined by the weighted average of the populations of rotamers *i* and *ii* in the equilibrium. From Table 4 it can be seen that the signal of 2-H shifts upfield and that of 4-H shifts downfield with increase in temperature. This suggests that structure *ii* is favored with increase in temperature, and that structure *i* is thermodynamically favored over *ii*.

The ^{13}C spectra of dienes **1** and **2** had two peaks due to methyl carbons, of which the lower field signal (δ_C = 23 ppm) was twice the intensity of the other (δ_C = 20 ppm). In the single frequency decoupled ^{13}C spectrum, obtained by irradiating the protons on the acetyl methyl group (δ = 1.95 ppm), the lower field signal (23 ppm) appeared as a quartet whereas the higher field signal became a singlet. This allowed the assignment of the lower field signal with the higher intensity to the ring methyl and the higher field signal as the acetyl methyl. The methyl signals are relatively invariant throughout the series and this assignment also applies to **3**, **4**, and **5**. The signal at C-2 was assigned on the basis of the effect of the substituent attached to the adjacent C-3; in all compounds this was expected to move the C-2 peak to higher fields and thus the highest field signal of the peaks attributable to C-2, C-4, and C-5 was assigned to C-2. The trends in the shifts of the C-2 and C-3 atoms in dienes **1**–**6** parallel those reported for the β and α carbons, respectively, of the monosubstituted ethylenes (24, 25), confirming the assignments (Table 5). The assignments of C-4 and C-5 were made on the basis of single frequency decoupling of the splitting by the protons attached to each carbon in the case of diene **4** and by the C-5 proton in other cases. As would be expected, the C-4 signal is more affected by the adjacent substituent than is the signal of the more remote C-5 (Tables 2 and 5). Furthermore, the relative shifts for the C-4 atoms parallel those for the C-2 atoms with the magnitudes of the relative shifts attenuated, reflecting the lower bond order for the 3–4 bond compared with the 2–3 bond. The

relative shifts for C-5 do not parallel those for C-2 and C-4. In the case of diene **3** the fluorine–carbon coupling, largest at C-3 and decreasing with increase of the separation of the carbon and the fluorine, supports the assignments made.

The structures of the 1,4 dienes **7***a* and **7***b* were also established by spectral studies. The presence of nitro and ester groups is evident from the ir. The symmetry apparent in both the ^1H and ^{13}C spectra clearly demonstrates that these must be 1,4 adducts and this is confirmed by the absence of strong uv absorption above 250 nm (the weak absorption, $<30\ m^2\ mol^{-1}$, is probably from an impurity). The 1,2 adduct from *p-tert*-butyltoluene has the C-1 absorption (toluene enumeration) at lower field (88 ppm) than does the 1,4 adduct (85 ppm). Correspondingly, in **3** the absorption is at lower field (87.9 ppm) than in **7***b* (83.2 ppm). In **7***b* the absorptions of 2-H and 3-H, and C-2 and C-3, and in **7***a* of 2-H and 3-H, were assigned in accordance with the expectation that the fluorine–proton 3-bond coupling should be larger than the 4-bond coupling and the fluorine–carbon 2-bond coupling should be larger than the 3-bond coupling. Addition of Eu([$^2H_9$]fod)$_3$ moved the CH_3 protons of **7***b* downfield to a greater extent (relative slope 0.17) than the corresponding protons of **7***a* (0.125). This indicates that **7***a* is the *E* isomer (from *syn* addition) and **7***b* the *Z* (*anti* addition).

Reactivities and positional selectivities of 4-substituted toluenes

The conditions required for nitration reflect the relative reactivities of the aromatic compounds. A longer reaction time, a higher mole-proportion of nitrating agent, a higher temperature, and the presence of trifluoroacetic anhydride (4) are required for deactivated substrates. Based on these features, the substrates belonging to the 4-X-toluene series can be arranged in order of decreasing reactivity as: OMe > (*t*-Bu, F) > Cl > Br > NHAc. The lower reactivity of the acetamido compound is unexpected as it is known to be a stronger activating group than alkyl and halogen substituents. The apparent anomaly could be a consequence of the lower solubility of the substrate in the reaction mixture. Since solid acetanilide was added to the nitrating agent, the reaction medium was heterogeneous at the early stages of the reaction and the effective concentration of the aromatic in solution would have been less than calculated.

The reactivities of the different ring positions of the *p*-disubstituted benzenes can be calculated from the partial rate factors for nitration of the appropriate monosubstituted benzenes in acetic anhydride, using the assumption of additivity of the logarithms of these factors.[6] Partial rate factors for nitration of toluene in acetic anhydride are known for all positions including the *ipso* position (16). Partial rate factors for other monosubstituted benzenes are known for the *ortho*, *meta*, and *para* positions but not for the *ipso* position. An estimate of the relative partial rate factor at the *ipso* position of chlorobenzene can be derived from data for the nitration of chloromesitylene (26). The ratio of adduct (with nitro *ipso* to chloro) to 2-chloro-4-nitro-1,3,5-trimethylbenzene is 21:73 and this gives the partial rate factor ratio of 21:36.5, i.e. the position *ipso* to chlorine is 60% as reactive as the *meta* position. Thus, using the known $o_f:m_f:p_f$ (18), the relative partial rate factors for chlorobenzene are $i_f:o_f:m_f:p_f$ = 0.6:33:1.0:154, from which

[6]Absolute values of the partial rate factors are not required. The relative yields of the nitration products obtained from a monosubstituted benzene (the isomer distribution), with each yield being divided by the number of positions in the substrate giving rise to that product on nitration, gives the relative partial rate factors.

TABLE 5. Relative ^{13}C chemical shifts for 3-X-6-methyl-6-nitrocyclohexa-2,4-dienyl acetates and for X-ethylenes[a]

	Chemical shifts, ppm					
X	C-2	C-3	C-4	C-5	C-α	C-β
Br	3.9	−11.0	1.7	−0.9	−10.5	4.7
F	−19.9	25.8	−6.0	2.1	21.6	−28.9
OMe	−30.3	21.6	−3.4	−1.0	27.0	−31.9
NHAc	−15.5	0.7	−3.4	−0.3	3.9	−23.1
t-Bu	−5.1	13.9	−1.1	−2.5	23.6	−7.6

[a]The reference compound is the chloro derivative. Data for X-ethylenes from refs. 24 and 25.

the calculated product distribution on nitration of 4-chlorotoluene is as shown in Table 1. The yield of *m*-nitrochlorobenzene obtained on nitration of chlorobenzene is quite small and thus the partial rate factor for *meta* (and thus *ipso*) nitration is subject to significant error and the results should be interpreted semiquantitatively at best. Nevertheless the calculation correctly predicts that the adduct with nitro *ipso* to methyl should be the major product, that there should be very little adduct with nitro *ipso* to chlorine (none was found), and that both nitro-4-chlorotoluenes should be obtained (although less 2-nitro than 3-nitro is predicted, whereas the opposite was found). Analogous data are not available to estimate the factors for nitration *ipso* to the other substituents. However, it seems reasonable to assume that such *ipso* partial rate factors, like that for chloro, are small since adducts with nitro *ipso* to these substituents were not observed. Calculated and observed product distributions are shown in Table 1. 4-Fluorotoluene is predicted to give, almost completely, *ipso* adduct, as was observed. 4-Bromotoluene, like 4-chlorotoluene, is predicted and found to give the adduct as the major product as well as observable amounts of both nitrobromotoluenes. 4-Iodotoluene is also predicted to give mainly adduct (with nitro *ipso* to methyl) and lesser but significant amounts of both nitro substitution products. Less than 0.2% of nitrodeiodination occurs on the nitration of iodobenzene (27), from which it may be calculated that not more than 2% of nitrodeiodination should occur in 4-nitrotoluene (Table 1). Here observation is in conflict with prediction since the extent of nitration *ipso* to methyl is small and that *ipso* to iodine, as measured by the formation of 4-nitrotoluene, is large. Nitrosodeiodination may account for the formation of 4-nitrotoluene as the major nitration product. This is known to be the process by which apparent nitrodeiodination occurs in the nitration of very reactive iodoaromatics, although such cases involve substrates rather more reactive than 4-iodotoluene (19*b*). 4-Methoxytoluene and 4-acetamidotoluene, for which the methoxy and acetamido groups are known to be particularly strongly *ortho* directing (and very weakly *meta* directing) in acetic anhydride (19*c*), give, as predicted, only the 3-nitro substitution product in addition to the *ipso* product, the latter predicted and found to be the smaller component. Nitration of 4-methoxytoluene in 46–80% sulphuric acid gives 4-methyl-2-nitrophenol (38%) and 4-methoxy-3-nitrotoluene (62%) (28). *ipso* Nitration and capture of the *ipso* cation by water, followed by loss of methanol, gives the dienone, which rearranges to the nitrocresol. The constant yield of the nitrocresol over the wide range of acidity implies that all of the *ipso* cation is captured in up to 80% sulphuric acid. The extent of capture is similar to that directly observed

in acetic anhydride (30%). The nitration of 4-bromo- and 4-chlorotoluene has been investigated in 63–85% sulphuric acid (29). In both cases there is competition between capture of the *ipso*-nitrocyclohexadienyl cation by water and its rearrangement to (ultimately) the 4-halo-2-nitrotoluene. The data imply that there is a significant amount of attack *ipso* to methyl in the two halotoluenes, but they do not provide a quantitative measure of the extent of this reaction as is obtained from our studies.

Regioselectivity in nucleophilic trapping

A striking feature of the nitration of 4-substituted toluenes is the change in the preference for 1,2 versus 1,4 adduct formation with change in the 4-substituent. It is known that formation of the adduct is subject to kinetic control (30) and thus it is the energetics of the transition states for trapping of the *ipso* cation that determine the preferred adduct. It is plausible that the greater formation of 1,2 adduct in the case of *p-tert*-butyltoluene is the consequence of a steric effect since in the series of 4-alkyltoluenes (alkyl = Me, Et, i-Pr, *t*-Bu) it is only in the last case that 1,2 adduct is obtained and the alkyl groups should have very similar electronic effects, but markedly different steric effects. However, the same explanation cannot be invoked to account for the formation of 1,2 adduct in the cases of the other substituents since none of these should have a large steric effect and most should be more similar to methyl than to *tert*-butyl. On the other hand, it is not apparent that an explanation can be found in terms of the electronic effects of the 4-substituents since, in terms of inductive effects as measured by σ_I (31), the order of electron-donating ability is Me > OMe > Br > Cl > F and, in terms of resonance effects (σ^+_R (31)) OMe > F > Cl > Br > Me. Neither order, nor the order of the sums, groups fluoro with methyl and accounts for the fact that these substituents promote 1,4 adduct formation.

Ab initio molecular orbital calculations carried out by Birch *et al.* indicate that the 4-substituted 1,2-dihydrobenzene is of lower energy than the 4-substituted 1,4-dihydrobenzene over a range of substituents (32). This supports the conclusion that adduct formation is subject to kinetic control since under equilibrium conditions the 1,2 adduct should be favoured for all substituents. The 1,4 adducts from those 4-substituted toluenes in which the substituent is a nucleofuge should undergo a facile elimination of this group as an acetyl derivative to form the dienone directly. However, dienone formation was not observed except in the case of 4-fluorotoluene. Thus the absence of the 1,4 adduct in the products from other 4-substituted toluenes cannot be attributed to its conversion to the dienone.

Experimental

Melting points are uncorrected and were determined on a Büchi SMP-20 melting point apparatus. Infrared spectra, calibrated with polystyrene, were recorded on a Perkin Elmer 283 spectrometer. Observations were made on potassium bromide discs for solids and on thin films between sodium chloride plates for liquids. Proton nuclear magnetic resonance spectra were recorded on Perkin Elmer R-12B (60 MHz), Perkin Elmer R-32 (90 MHz), or Brüker WM 250 (250 MHz) spectrometers. The nmr spectra of nitration reaction mixtures were recorded with the acetic anhydride peak at 2.15 ppm as the lock signal. For all other solutions either tetramethylsilane (90 MHz) or the solvent deuterium signal (250 MHz) was used as the lock signal. The ^{13}C nmr spectra were obtained with a Nicolet TT-14 spectrometer (15.1 MHz) or the Brüker WM 250 spectrometer (62.9 MHz), using solutions in $CDCl_3$ with TMS as the internal standard. Ultraviolet spectra were recorded on a Beckman DU-8 spectrophotometer using methanol or methylene chloride as solvent. For high performance liquid chromatography (hplc) a Varian 5000 liquid chromatograph (analytical) and a Waters Prep LC system (preparative) were used. Elemental analysis was performed by Canadian Microanalytical Service Ltd., Vancouver, British Columbia.

4-Chlorotoluene and *p*-methylanisole were from Eastman. 4-Fluorotoluene was from Aldrich. 4-Iodotoluene was from ICN Pharmaceuticals. *p*-Acetotoluidide (4-acetamidotoluene) was prepared from *p*-toluidine (J. T. Baker), and *N*-methyl-*p*-acetotoluidide (4-(*N*-methylacetamido)toluene) from *N*-methyl-*p*-toluidine (Eastman), following Vogel's procedure for acetanilide (33).

Acetic anhydride was certified ACS from Fisher. Trifluoroacetic anhydride was Aldrich gold label (99 + %). Fuming nitric acid (Fisher, 300 cm^3) was purified by distilling from urea (10 g) and sulphuric acid (500 cm^3) at below 40°C and stored at −25°C.

Solvents for chromatography including pentane (reagent, Fisher), ether (Fisher), and petroleum ether (reagent, Fisher) were dried over sodium and distilled before use. Silica gel (60–200 mesh, Davison Commercial grade H), neutral alumina (Brockman Activity I), and alumina (80–200 mesh, Fisher) deactivated with 3% (v/v) distilled water were used for chromatography. Anhydrous magnesium sulphate was used to dry solutions in organic solvents.

Nitration of 4-chlorotoluene

A nitrating mixture was prepared by the careful addition of acetic anhydride (75 g, 0.75 mmol), with stirring, to freshly distilled nitric acid (18.9 g, 0.3 mmol) at −78°C. The mixture was then warmed to 0°C, stirred for 15 min at 0°C, and cooled to −40°C. Trifluoroacetic anhydride (20.8 g, 0.15 mmol) was then slowly added to the mixture at −40°C. A solution of 4-chlorotoluene (18.99 g, 0.15 mol) in acetic anhydride (15 g, 0.15 mol) was added dropwise over 30 min to the stirred nitrating mixture at −40°C. Stirring was continued for 1 h at −40°C and the mixture was then cooled to −78°C and poured into ether (80 cm^3) at −78°C. Ammonium hydroxide (450 cm^3, 28%) was added in small portions to the stirred mixture and stirring was continued for an additional 1 h while the mixture warmed to ambient temperature. The ether layer was separated and the residue was washed with ether (400 cm^3). The combined ether solution was washed with cold water (4 × 300 cm^3) and dried. Removal of ether on the rotovapor at 15°C yielded a brown oil (31 g). The ^1H nmr spectrum of the crude mixture indicated the presence of (*Z*)-3-chloro-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**2**) (70%), 4-chloro-3-nitrotoluene (13%), and 4-chloro-2-nitrotoluene (17%). Crystallization from ether–pentane (500 cm^3, 1:4) at −20°C afforded crude **2** (12 g), which on recrystallization gave colorless crystals, mp 49–50°C; ir (KBr): 1740 and 1230 ($OCOCH_3$), 1555 and 1375 (NO_2) cm^{-1}; uv (CH_3OH): 263 nm (390 m^2 mol^{-1}); ^1H nmr (250 MHz, $CDCl_3$): Table 3; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_9H_{10}NO_4Cl$: C 46.61, H 4.29, N 5.92; found: C 46.67, H 4.35, N 6.05.

Nitration of 4-fluorotoluene

4-Fluorotoluene (12.4 g, 0.13 mol) was nitrated in a mixture of acetic anhydride (0.55 mol), trifluoroacetic anhydride (0.05 mol), and nitric acid (0.20 mol) following the general procedure described for 4-chlorotoluene. The ^1H nmr spectrum of the reaction mixture showed it to be a mixture of 1,4 diene (81%), 1,2 diene (8%), and 4-methyl-4-nitrocyclohexadienone (11%). On work-up a red-yellow oil was obtained, which contained 1,4 diene (73%), 1,2 diene (8%), and dienone (19%); hplc of the oil with 70% ether-pentane eluent gave a mixture of dienes (17.9 g) in the first fraction and the dienone (2.66 g) in the second. The ratio of 1,4 to 1,2 diene was 9:1. Further chromatography of the diene mixture using 50% ether–pentane as solvent gave a mixture of 1,2 and 1,4 dienes in the first fraction and (*Z*)-1-fluoro-4-methyl-4-nitrocyclohexa-2,5-dienyl acetate (**7***b*) (8.9 g, 32% yield) in the second. Diene **7***b* was isolated as a red oil and had uv (CH_2Cl_2): 269 nm (28 m^2 mol^{-1}); ir (film) 1765 and 1220 ($OCOCH_3$), 1550 and 1365 (NO_2) cm^{-1}; ^1H nmr (270 MHz, $CDCl_3$) δ: 1.81 (s, 3, 4-C*H*$_3$), 2.08 (s, 3, OCOC*H*$_3$), 6.34 (dd, 2, 2-*H* and 6-*H*), 6.49 (dd, 2, 3-*H* and 5-*H*) ppm, J_{23} = 10.5, $J_{2,1\text{-F}}$ = 5.0, $J_{3,1\text{-F}}$ = 0.7 Hz; ^{13}C nmr (15.1 MHz, $CDCl_3$, 0°C) δ_C: 21.7 (OCO*C*H$_3$), 25.4 (J_{CF} = 3.7 Hz, 4-*C*H$_3$), 83.2 (J_{CF} = 3.7 Hz, *C*-4), 102.6 (J_{CF} =

206.4 Hz, *C*-1), 126.1 (J_{CF} = 27.4 Hz, *C*-2, *C*-6), 132.2 (J_{CF} = 9.8 Hz, *C*-3, *C*-5), 167 (J_{CF} = 1.8 Hz, O*C*OCH$_3$) ppm.

The mixture of dienes was triturated with a solution of 25% ether–pentane and gave crystals of (*E*)-1-fluoro-4-methyl-4-nitrocyclohexa-2,5-dienyl acetate (**7***a*) (1.1 g, 4% yield). On recrystallization from ether–pentane **7***a* had mp 45–47°C; uv (CH_2Cl_2): 280 nm (8 m^2 mol^{-1}); ir (KBr): 1750 and 1210 (OCOCH$_3$), 1555 and 1350 (NO_2) cm^{-1}; ^{1}H nmr ($CDCl_3$, 0°C) δ: 1.81 (s, 3, 4-C*H*$_3$), 2.09 (s, 3, OCOC*H*$_3$), 6.49 (d, 4, 2-*H*, 3-*H*, 5-*H*, 6-*H*) ppm, J_{23} = 10 Hz, $J_{2\text{-H,F}}$ = 4 Hz, the coupling constants were determined after addition of the shift reagent Eu(fod)$_3$ to separate the chemical shifts of the overlapping peaks. Diene **7***a* readily decomposed to 4-methyl-4-nitrocyclohexadienone.

The solution from the trituration contained a mixture of equal amounts of 1,2 diene and 1,4 diene. The mixture was chromatographed using 25% ether–pentane as solvent. The first fraction contained the 1,2 diene and 4-methyl-2-nitrophenol (a decomposition product via the dienone). 3-Fluoro-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**3**) was crystallized from the mixture. Recrystallization from ether–pentane gave colourless crystals, mp 45.5–47°C, uv (CH_2Cl_2): 256.5 nm (394 m^2 mol^{-1}); ir (KBr): 1745 and 1230 (OCOCH$_3$), 1555 and 1375 (NO_2) cm^{-1}; ^{1}H nmr (270 MHz, $CDCl_3$) δ: 1.82 (s, 3, 6-C*H*$_3$), 1.98 (s, 3, OCOC*H*$_3$), 5.57 (m, 2, 1-*H* and 2-*H*), 6.03 (ddd, 1, 4-*H*), 6.64 (ddd, 1, 5-*H*) ppm, J_{12} = 6, J_{15} = 1, $J_{1,3\text{-F}}$ = 5, J_{24} = 2, $J_{2,3\text{-F}}$ = 6, J_{45} = 10.5, $J_{4,3\text{-F}}$ = 6, $J_{5,3\text{-F}}$ = 5 Hz, addition of the shift reagent separated the overlapping peaks at 5.57 ppm and allowed the determination of the coupling constants between the 1-H, 2-H and 3-F; ^{13}C nmr (15.1 MHz, $CDCl_3$, 0°C) δ$_C$: 20.9 (OCO*C*H$_3$), 23.4 (6-*C*H$_3$), 73.1 (J_{CF} = 12.6 Hz, *C*-1), 87.9 (*C*-6), 98.2 (J_{CF} = 19.5 Hz, *C*-2), 120.1 (J_{CF} = 37.1 Hz, *C*-4), 131.5 (J_{CF} = 9.9 Hz, *C*-5), 159.4 (J_{CF} = 259.7 Hz, C-3), 169.4 (O*C*OCH$_3$) ppm. *Anal.* calcd. for $C_9H_{10}NO_4F$: C 50.24, H 4.68, N 6.51; found: C 50.58, H 4.69, N 6.45.

Nitration of 4-methylanisole

A solution of 4-methylanisole (54.6 g, 0.445 mol) in acetic anhydride (45.4 g, 0.445 mol) was added dropwise with stirring at −40°C over 30 min to a nitrating mixture prepared from nitric acid (56 g, 0.89 mol) and acetic anhydride (182 g, 1.78 mol). After complete addition, the mixture was stirred for 30 min at −40°C, then transferred into a three-necked 3-dm^3 round-bottom flask fitted with a mechanical stirrer, a low temperature thermometer, and an ammonia condenser, and containing 1.5 dm^3 ether at −78°C. Ammonia was condensed into the mixture until the temperature, which had risen to −60°C, fell again to −78°C. The mixture was then alkaline to litmus. Excess ammonia was removed on the aspirator while the temperature rose to 0°C over a period of 60 min. The mixture was then neutral to litmus. The ether layer was decanted into a separating funnel and the residue was washed with more ether (750 cm^3). The combined ether solution was washed with cold water (4 × 500 cm^3) and dried. Removal of the ether at 15°C yielded a reddish brown oil (80 g). The ^{1}H nmr spectrum of this mixture showed the composition as (*Z*)-3-methoxy-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**4**) (30%) and 4-methyl-2-nitroanisole (70%). Crystallization from ether–pentane mixture at −20°C afforded, in three successive crops, crude diene **4** (26 g). On recrystallization, colorless crystals of **4** were obtained, mp 101.5–103.5°C; ir (KBr): 1735 and 1235 (OCOCH$_3$), 1545 and 1370 (NO_2), 1450 (OCH$_3$) cm^{-1}; uv (CH_2Cl_2): 271.3 nm (290 m^2 mol^{-1}); ^{1}H nmr ($CDCl_3$, 250 MHz): Table 3; ^{13}C nmr ($CDCl_3$, 62.9 MHz): Table 2. *Anal.* calcd. for $C_{10}H_{13}NO_5$: C 52.86, H 5.77, N 6.16; found: C 53.00, H 5.94, N 6.14.

Nitration of 4-acetamidotoluene

Finely powdered 4-acetamidotoluene (1.49 g, 10 mmol) was added to a nitrating mixture prepared from nitric acid (3.15 g, 50 mmol), acetic anhydride (15 g, 150 mmol), and trifluoroacetic anhydride (2.1 g, 10 mmol) at −40°C. The mixture was stirred at −40°C for 2 h, cooled to −78°C, and added to ether (500 cm^3) at −78°C. Ammonium hydroxide (100 cm^3, 28%) was added slowly, with stirring, and stirring was continued for an additional 2 h at −78°C. The ether layer was decanted and stored at −78°C. The residue was dissolved in cold water (250 cm^3), transferred to a separating funnel containing ether previously cooled to −20°C, and extracted. The combined ether solution was quickly washed with cold brine (4 × 250 cm^3), dried at −78°C, and filtered, through a jacketed filtering funnel maintained at −78°C, into a 1-dm^3 round-bottom flask cooled to −78°C. The ether was removed on a rotovapor connected to a high vacuum pump via a Dry Ice condenser followed by three liquid nitrogen traps. The evaporation flask was maintained at −40°C. The ^{1}H nmr spectrum of the yellow residue (2 g), taken at −40°C, indicated the presence of (*Z*)-3-acetamido-6-methyl-6-nitrocyclohexa-2,4-dienyl acetate (**5**) (35%) and 4-methyl-2-nitroacetanilide (65%). The mixture was chromatographed on activated silica gel (mesh size 60–200, 75 g) contained in a jacketed filtering funnel cooled to −78°C. Solvent used as eluent was cooled under nitrogen, in a jacketed dropping funnel, to −78°C. All fractions were collected in flasks cooled to −78°C, and evaporated below −40°C. Elution, first with 60% ether – petroleum ether and then with 80% ether – petroleum ether, gave 4-methyl-2-nitroacetanilide, mp 95–96°C (lit. (34) mp 96°C); ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.22 (s, 3, C*H*$_3$), 2.32 (s, 3, NHCOC*H*$_3$), 7.38 (dd, 1, 5-*H*), 7.92 (d, 1, 3-*H*), 8.54 (d, 1, 6-*H*), 10.12 (s, 1, N*H*) ppm, J_{35} = 1.85, J_{56} = 8.70 Hz; ^{13}C nmr (62.9 MHz, $CDCl_3$) δ$_C$: 20.5 (*C*H$_3$), 25.5 (NHCO*C*H$_3$), 122.2 (*C*-6), 125.5 (*C*-3), 132.5 (*C*-4), 133.5 (*C*-1), 136.4 (*C*-2), 136.8 (*C*-5), 168.9 (NH*C*OCH$_3$). The 90% ether – petroleum ether fraction contained 30% of the nitrotoluidide and 70% of **5**. The mixture (500 mg) was rechromatographed on silica gel (75 g) under the same conditions. Pure diene **5** was eluted in the 100% ether fraction and was characterized by nmr, Tables 2 and 3.

Nitration of other substrates

4-Iodotoluene was nitrated under conditions similar to those used for 4-chlorotoluene. The substrate was insoluble in acetic anhydride at −40°C. At 0°C 4-nitrotoluene was the major product but other substitution products were also apparent in the nmr. Iodine was present in the solution. When the reaction was carried out using methylene chloride to dissolve the iodotoluene, some small peaks were present in the diene region of the spectrum in addition to the peaks of the aromatic nitro products.

4-(*N*-methylacetamido)toluene was nitrated with nitric acid in acetic anhydride and trifluoroacetic anhydride at −40°C. Up to 30% of diene was observed by nmr, in addition to substitution product. The diene disappeared when the temperature was raised to 0°C. The diene also did not survive when the reaction mixture at −40°C was worked up.

4-(*N*,*N*-dimethylamino)toluene was nitrated at −40°C in acetic anhydride containing 1 mol proportion of nitric acid. Only substitution product was formed.

4-Methylphenyl acetate was nitrated with nitric acid in acetic anhydride at −40°C and also at −60°C but only 4-methyl-4-nitrocyclohexa-2,5-dienone was observed.

N-methyl-*p*-toluidine was reacted with nitric acid in acetic anhydride at −40°C but only acetylation occurred.

Substrates for the differentiation of the *N*-acetylglucosaminyltransferases. Synthesis of βDGlcNAc(1→2)αDMan(1→6)βDMan and βDGlcNAc(1→2)αDMan(1→6)[αDMan(1→3)]βDMan glycosides

S. Hasan Tahir and Ole Hindsgaul[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 14, 1986

S. Hasan Tahir and Ole Hindsgaul. Can. J. Chem. **64**, 1771 (1986).

The trisaccharide βDGlcNAc(1→2)αDMan(1→6)βDMan (**2**) and the tetrasaccharide βDGlcNAc(1→2)αDMan(1→6)[αDMan(1→3)]βDMan (**3**) have been chemically synthesized as their 8-methoxycarbonyloctyl glycosides. Compounds **2** and **3**, both partial structures of naturally occurring asparagine linked oligosaccharides, are designed to function as selective substrates in *N*-acetylglucosaminyltransferase assays.

S. Hasan Tahir and Ole Hindsgaul. Can. J. Chem. **64**, 1771 (1986).

Faisant appel à des méthodes chimiques, on a synthétisé le trisaccharide β-DGlcNAc(1→2)αDMan(1→6)βDMan **2** ainsi que le tétrasaccharide β-DGlcNAc(1→2)αDMan(1→6)[αDMan(1→3)]βDMan **3**, tous les deux sous la forme de leur glycosides méthoxycarbonyl-8 octyles. Les composés **2** et **3**, qui sont des fractions d'asparagine qui l'on retrouve naturellement liée à des oligosaccharides, ont été préparés pour servir de substrats sélectifs dans des études sur la *N*-acétylglucosaminyltransférase.

[Traduit par la revue]

Introduction

About ten years ago, evidence began to accumulate that the carbohydrate structures of cell-surface glycoproteins and glycolipids became dramatically altered during both normal and abnormal cellular development (1–4). Consistent changes in cell-surface carbohydrate structures have now been shown to accompany the development of human melanoma, neuroblastoma, and colorectal, gastric, and pancreatic carcinoma (5). The occurrence of large fucosylated highly-branched glycopeptides is in fact one of the most reproducible correlates with the malignant transformation of cells (6). The functional significance, if any, of these cell-surface structural changes is not at all clear but these aberrant carbohydrate structures are attracting a great deal of clinical interest as potential tumor markers. The structures of many of these "tumor-associated" carbohydrates have been elucidated in recent years and major research efforts have gone into the production of the corresponding tumor-specific monoclonal antibodies (4, 7).

In 1984 Yamashita *et al.* (6) compared the carbohydrate structures of the membrane N-linked glycoproteins of baby hamster kidney (BHK) cells and their polyoma transformant (Py-BHK). They found that while the transformed cells synthesized the same (approximately 20) structures as did the normal cells, they produced more of the larger, more highly branched oligosaccharides. They proposed that the changes in the relative proportions of the cell-surface oligosaccharides observed on transformation could be explained by the elevation in the activity of a single enzyme, a glycosyltransferase, termed *N*-acetyl-β-D-glucosaminyltransferase V (GlcNAc-transferase V, GnT V), and subsequently showed (8) that the GnT V activity in Py-BHK cells was in fact elevated two-fold when compared with untransformed cells. This work (6, 8) therefore suggests that the activity of a single glycosyltransferase can, in itself, serve as a tumor marker. The detection of a change in a single specific enzymatic activity may be far simpler than the characterization and quantification of a highly heterogeneous mixture of cell-surface carbohydrate structures produced *as a result* of this single enzymatic change.

At least 7 different GlcNAc-transferases are known to be involved in the biosynthesis of the asparagine-linked oligosaccharides (6, 8–10). All of these enzymes use UDP-GlcNAc as the glycosyl donor and the difference between them lies in their specificity for different acceptor structures. To simplify the assay procedures for measuring these individual glycosyltransferase activities we have embarked on a synthetic program to provide carbohydrate structures that we expect will be substrates for only single preselected enzymes. Such substrates might include oligosaccharides where cross-reacting sugar residues are completely absent or where the interfering hydroxyl groups that might be acted on by other GlcNAc transferases are masked by either *O*-methylation or deoxygenation. This latter approach has recently (11, 12) been successfully applied in the differentiation of two competing α-L-fucosyltransferases in serum. To be truly useful, such substrates and their glycosylated products should also be amenable to simple rapid isolation from the incubation mixtures of cell extracts or fluids that contain the glycosyltransferase activities being assayed.

To test the practicability of this approach we chose to attempt the preparation of substrates selective for GnT V, since this glycosyltransferase is already attracting interest as a potential tumor marker. The heptasaccharide **1** (Fig. 1) is known to be a substrate for GnT V (as well as for other glycosyltransferases) and has been used to assay this enzyme. Recent work (13–17), from the laboratory of Lemieux, on the molecular basis for the binding of oligosaccharides by monoclonal antibodies and lectins strongly suggested that proteins were not likely to require carbohydrate surfaces much larger than that of a trisaccharide for faithful recognition. We expected that this situation might also hold true for the enzymatic specificity of glycosyltransferases and therefore envisioned the trisaccharide βDGlcNAc(1→2)αDMan(1→6)βDManOR (**2**) as a likely acceptor for GnT V. Our rationale for the choice of **2** can be seen in Fig. 1 where the structure of the natural heptasaccharide acceptor **1** is also shown. We set forth, therefore, to synthesize **2**, which contains the reactive target hydroxyl group acted on by the enzyme and one sugar residue on either side of the α-D-mannose residue bearing this hydroxyl group. Since we did not know whether this structure incorporated sufficient features for recognition by GnT V, the synthesis was planned in a way that also allowed the preparation of the tetrasaccharide **3**, which is closer in structure

[1]Author to whom correspondence may be addressed.

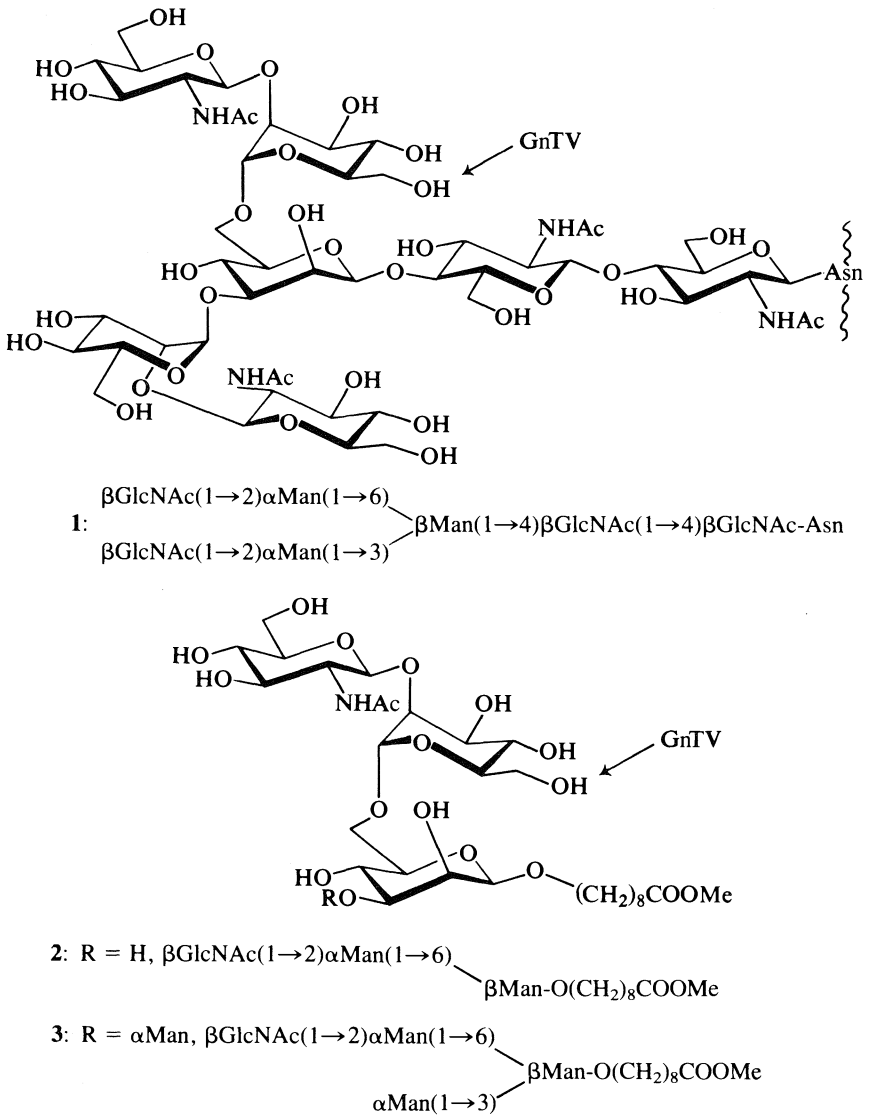

FIG. 1. A heptasaccharide acceptor (**1**) for GlcNAc-transferase V (GnT V) compared with the structures of the proposed synthetic acceptors **2** and **3**. The bold arrows show the primary hydroxyl group to which GnT V transfers an *N*-acetyl-β-D-glucosaminyl residue.

to the natural acceptor **1**. To facilitate the isolation of our glycosylated substrates from their enzymatic incubation mixtures, we elected to prepare **2** and **3** as their 8-methoxycarbonyloctyl glycosides (18), since inclusion of this hydrophobic group should facilitate adsorption on reverse phase (C-18) chromatography supports. This "linking arm" might also be used for the preparation of synthetic glycoconjugates.

Results and discussion

A retrosynthetic analysis of the target structures **2** and **3** suggested, as the key intermediate, the trisaccharide precursor **4**, which was protected in a manner to allow the selective liberation of the hydroxyl group at C-3 of the β-D-mannopyranosyl residue for subsequent glycosylation by **5**. A straightforward route to **4** from the glycosyl bromides **6**, **7**, and **8** was then apparent. Compounds **5** (19), **6** (20), and **7** (21) have already been described. A synthetic route to **8** was therefore required.

Methyl 4,6-*O*-benzylidene-α-D-mannopyranoside (**9**) was selectively allylated (22), via its 2,3-*O*-dibutylstannylidene derivative, to provide the 3-*O*-allyl derivative **10** in 82% yield. Benzylation of **10** then furnished the 2-*O*-benzyl derivative **11** in 90% yield. Reductive cleavage of the benzylidene group in **11** using $LiAlH_4$–$AlCl_3$, according to Liptak *et al.* (23), gave the 4-*O*-benzyl (**12**) and 6-*O*-benzyl (**13**) derivatives, in the ratio of 7:1, in a combined yield of 86%. Reaction of **12** with acetic anhydride in pyridine provided the 6-*O*-acetyl derivative **14**, which was acetolyzed (24) using acetic anhydride in the presence of a catalytic amount of sulfuric acid to afford 1,6-di-*O*-acetyl-3-*O*-allyl-2,4-di-*O*-benzyl-α-D-mannopyranose (**15**) in 77% yield.

Reaction of the diacetate **15** in dichloromethane, at 0°C, with hydrogen bromide that was dried by passage through a calcium sulfate column led to the formation of the glycosyl bromide **8** in essentially quantitative yield. When **15** was allowed to react with HBr gas introduced directly from the cylinder without passage through calcium sulfate, the thin-layer chromatogram (tlc) of the reaction mixture showed the presence of two products, the minor being the desired bromide **8**. The major product **16** had a slightly lower mobility in tlc. The ^1H nmr spectrum of the mixture of **8** and **16** indicated **16** to be the

hydrobromination product of **8**, namely, 6-*O*-acetyl-2,4-di-*O*-benzyl-3-*O*-(3-bromopropyl)-α-D-mannopyranosyl bromide. This structural assignment was made to account for the observation of a triplet for two protons at δ 3.688 ($BrCH_2CH_2CH_2O$), a multiplet for two protons at δ 3.510 for $BrCH_2CH_2CH_2O$, and a two-proton multiplet at δ 2.119 for $BrCH_2CH_2CH_2O$. The ratio of **16** to **8** was determined to be 4:1 from this ^1H nmr spectrum.

Reaction of the glycosyl bromide **8** and 8-methoxycarbonyl-octanol according to Paulsen and Lockhoff (25), in the presence of an insoluble catalyst prepared by precipitation of silver silicate on aluminum oxide, provided a mixture of the β and α mannosides **17** (50–60%), which could not be separated chromatographically. That **17** was a mixture of the α and β glycosides was evident from the ^1H nmr spectrum, which showed a signal at δ 4.365 for H-1 of the β anomer and a doublet ($J_{1,2}$ = 2.0 Hz) at δ 4.824 for H-1 of the corresponding α anomer. The β:α ratio of this mixture, determined by integration of these signals in the ^1H nmr spectrum of **17**, was found to vary with the temperature of the reaction. At −78°C, the β and α anomers were produced in a 6:1 ratio, while at the higher temperatures of −20 and 0°C the ratios of β to α anomers were 4.3:1 and 3.5:1 respectively.

Treatment of the α/β mixture **17** with sodium methoxide in methanol effected the removal of the acetyl groups to provide **18**(β) and **19**(α), which could now be separated by column chromatography on silver nitrate impregnated silica gel. The ^{13}C nmr spectrum of the β glycoside **18** showed the signal for C-1 at 101.69 ppm ($J_{C\text{-}1,H\text{-}1}$ = 153.6 Hz) while the corresponding α anomer **19** showed C-1 at 98.25 ppm ($J_{C\text{-}1,H\text{-}1}$ = 168.2 Hz), in accord with the empirical rules formulated by

Bock and Pedersen (26) for the dependence of the one-bond C—H coupling on the anomeric configuration of pyranosides.

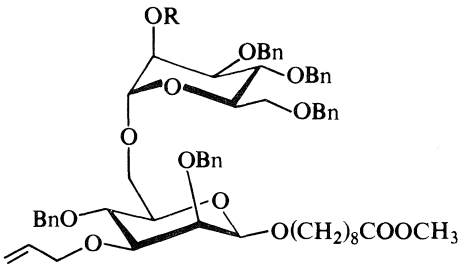
Condensation of the alcohol **18** and 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl bromide (21) (**7**) using mercuric bromide and mercuric cyanide as promoters and acetonitrile as solvent furnished the α-linked disaccharide **20** in 77% yield. The resonances for both anomeric protons were observed in the ^{1}H nmr spectrum, at δ 4.911 ($J_{1',2'}$ = 2.0 Hz) and 4.334 ($J_{1,2} \approx 1$ Hz), while the ^{1}H-coupled ^{13}C nmr spectrum showed a doublet each for C-1 and C-1′ at δ 104.64 ($J_{C\text{-}1,H\text{-}1}$ = 154.7 Hz) and 97.77 ($J_{C\text{-}1',H\text{-}1'}$ = 170.4 Hz) respectively. One-bond C—H coupling constants of these magnitudes require the presence of the β and α glycosidic linkages as assigned (26).

Reaction of **20** with sodium methoxide in dry methanol provided the alcohol **21**, which was glycosylated with 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (20) (**6**) according to Paulsen *et al.* (27), providing the trisaccharide **4** in 76% yield after chromatographic purification. The anomeric configuration of the newly introduced glycosyl residue was evident from the ^{1}H nmr spectrum of **4**, which showed a doublet at δ 5.573 ($J_{1'',2''}$ = 8.5 Hz) for H-1″. Isomerization of the allyl ether in **4** using tristriphenylphosphinerhodium(I) chloride (28), followed by hydrolysis of the resulting prop-1-enyl ether in the presence of mercuric chloride and mercuric oxide, then afforded the trisaccharide alcohol **22** in 85% yield.

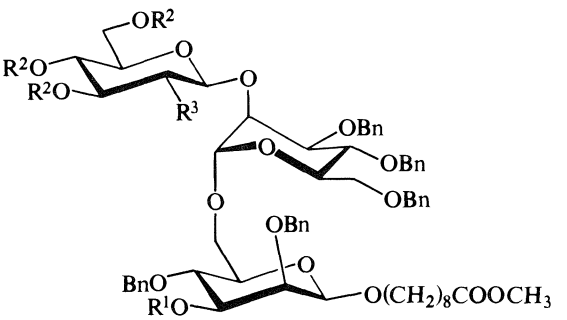
Deacetylation of **22** using sodium methoxide in methanol led to the quantitative formation of **23**. Removal of the phthalimido group from **23**, and subsequent *N*-acetylation of the free amine as described by Bundle and Josephson (29), provided the acetyl derivative **24** in an overall yield of 60%. No evidence of attack at the 8-methoxycarbonyloctyl ester was obtained.

Finally, hydrogenolytic cleavage of the benzyl protecting groups of **24** using 5% palladium-on-charcoal as the catalyst, in 98% ethanol, furnished the target trisaccharide **2**, which was purified by size-exclusion chromatography on Bio-Gel P-2. Compound **2** was obtained as a white lyophilized powder in 85% yield.

Preparation of the tetrasaccharide **3** required the addition of an α-D-mannopyranosyl unit to the free 3-hydroxyl group of **22**, followed by deprotection. Reaction of **22** with 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide (19) (**5**) promoted by mercuric bromide and mercuric cyanide in dichloromethane, in the presence of 4 Å molecular sieves, gave the tetrasaccharide **25** in 65% yield. The anomeric configuration of the newly introduced mannopyranosyl unit of **34** was evident from its nmr spectra, where the signal for an additional anomeric proton

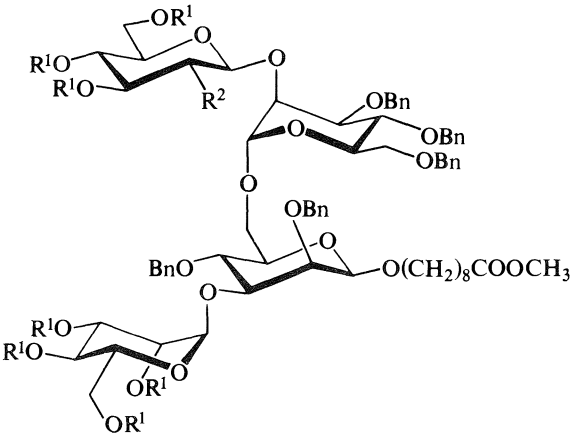


20 R = Ac
21 R = H



4 R^1 = CH_2CHCH_2, R^2 = Ac, R^3 = NPhth
22 R^1 = H, R^2 = Ac, R^3 = NPhth
23 R^1 = H, R^2 = H, R^3 = NPhth
24 R^1 = H, R^2 = H, R^3 = NHAc

appeared at δ 5.018 ($J_{1',2'} \approx 2$ Hz). The ^{13}C nmr spectrum showed the presence of four anomeric carbons: δ 101.95, $J_{C\text{-}1,H\text{-}1}$ = 152 ± 2 Hz; 97.64, $J_{C\text{-}1'',H\text{-}1''}$ = 170 ± 2 Hz; 96.60, $J_{C\text{-}1''',H\text{-}1'''}$ = 165 ± 2 Hz; and the new signal for the peracetylated α-linked mannose at δ 99.83, $J_{C\text{-}1',H\text{-}1'}$ = 169 ± 2 Hz.



25 R^1 = Ac, R^2 = NPhth
26 R^1 = Ac, R^2 = NHAc

Conversion of **25** to **26** was effected in three steps without characterization of the intermediates involved. Deacetylation of **25** with sodium methoxide in methanol gave a white foam, which was refluxed with hydrazine in methanol to generate the free amine that, on treatment with acetic anhydride in pyridine, gave the peracetylated product **26** in 63% yield. Attempted *N*-acetylation of the intermediate free amine, obtained in the second step of the above sequence using acetic anhydride in methanol–water (1:1), gave a very polar hydroxylated derivative that proved difficult to purify by silica gel chromatography. Removal of the *O*-acetyl and *O*-benzyl protecting groups of **26** was accomplished by treatment with sodium methoxide in

methanol followed by hydrogenolysis over 5% palladium-on-charcoal. Filtration of the crude product through a column of Bio-Gel P-2 afforded the target tetrasaccharide **3** as a white lyophilized powder in a total yield of 85%.

The trisaccharide **2** is indeed an acceptor specific for GlcNAc-transferase V and detects the expected increase in activity of this enzyme on Rous sarcoma transformation of BHK cells. The tetrasaccharide **3** is a substrate for GlcNAc-transferase V and at least one other BHK GlcNAc-transferase. These results will be reported in detail elsewhere.[2]

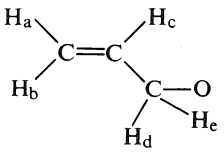
Experimental

All solvents and reagents used were reagent grade and, in cases where further purification was required, standard procedures (30) were followed. Mercuric bromide was not purified before use. All solid reactants for glycosylation were dried overnight over phosphorus pentaoxide in a high vacuum prior to use. Solution transfers where anhydrous conditions were required were done under nitrogen using standard syringe techniques (31). Molecular sieves were purchased from BDH Chemicals, and the ratio of alcohol to molecular sieves in glycosylation was between 1:5 and 1:10 by weight.

Thin-layer chromatograms (tlc) were performed on precoated silica gel 60-F254 plates (E. Merck, Darmstadt) and visualized by quenching of fluorescence and (or) by charring after spraying with 5% sulfuric acid in ethanol. For flash chromatography (32) 40–63 μm (400–230 mesh) silica gel 60 (E. Merck No. 9385) and distilled solvents were used, and the ratio of silica gel to compound was in the range 50:1–100:1. Solvents were removed on a rotary evaporator under the vacuum of a water aspirator with bath temperatures of 40°C or lower. For gel filtration, Bio-Gel P-2 (200–400 mesh) (Bio-Rad Laboratories, Richmond, California, USA) was used.

Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded at either 400 MHz (Bruker WH-400) or 360 MHz (Bruker WM-360) with either tetramethylsilane (δ 0 in $CDCl_3$) or acetone (δ 2.225 in D_2O) as internal standard at ambient temperature. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were recorded at either 100.62 MHz (Bruker WH-400) or 90.56 MHz (Bruker WM-360) with either external tetramethylsilane (δ 0 in $CDCl_3$) or external 1,4-dioxane (δ 67.4 in D_2O) as reference standard. ^{1}H chemical shifts and coupling constants are reported as if they were first order. Assignments of ^{13}C resonances are tentative. Optical rotations were determined on a Perkin–Elmer 241 polarimeter in a 1-dm cell at ambient temperature (23 ± 1°C).

Protons of the allyl group present in the compounds described in this work were designated as H_a, H_b, H_c, H_d, and H_e as defined below. These protons generally showed the same coupling constants and thus the same multiplicity pattern in all the compounds examined and only the chemical shifts varied. The observed coupling constants were:



H_a, dddd, $J_{a,c}$ = 10.5 Hz, $J_{a,d}$ = 1.5 ± 0.5 Hz, $J_{a,e}$ = 1.5 ± 0.5 Hz, $J_{a,b}$ = 1.5 ± 0.5 Hz; H_b, dddd, $J_{b,c}$ = 17.0 Hz, $J_{b,d}$ = 1.5 ± 0.5 Hz, $J_{b,e}$ = 1.5 ± 0.5 Hz, $J_{a,b}$ = 1.5 ± 0.5 Hz; H_c, dddd, $J_{b,c}$ = 17.0 Hz, $J_{a,c}$ = 10.5 Hz, $J_{c,d}$ = 5.5 Hz, $J_{c,e}$ = 5.5 Hz; H_d, dddd, $J_{d,e}$ = 13.5 Hz, $J_{c,d}$ = 5.5 Hz, $J_{b,d}$ = 1.5 ± 0.5 Hz, $J_{a,d}$ = 1.5 ± 0.5 Hz; H_e, dddd, $J_{d,e}$ = 13.5 Hz, $J_{c,e}$ = 5.5 Hz, $J_{a,e}$ = 1.5 ± 0.5 Hz, $J_{b,e}$ = 1.5 ± 0.5 Hz.

*Methyl 3-*O*-allyl-2-*O*-benzyl-4,6-*O*-benzylidene-α-*D*-mannopyranoside (**11**)*

To a solution of methyl 3-*O*-allyl-4,6-*O*-benzylidene-α-D-mannopyranoside (22) (**10**) (13.60 g; 42.24 mmol) in dry benzene (500 mL) were added sodium hydride (about 80% dispersion in oil; 2.02 g) and benzyl bromide (7.55 mL; 63.35 mmol). The mixture was refluxed under nitrogen atmosphere for 16 h. After the mixture had cooled to room temperature, the excess of sodium hydride was decomposed by the addition of methanol (250 mL); then water (500 mL) was added. The organic layer was separated, washed with water, dried ($MgSO_4$), filtered, and concentrated. Purification of the major product could be achieved by gradient flash chromatography employing a mixture of hexane and ethyl acetate (the ratio of hexane – ethyl acetate was changed from 50:1 to 2:1 during elution). Finally **11** was obtained as a yellow oil (15.73 g; 90%); $[\alpha]_D$ +33.0° (*c* 1.4, chloroform); R_f 0.35 (hexane – ethyl acetate, 10:1); ^{1}H nmr ($CDCl_3$) δ: 7.505–7.259 (10H, arom.), 5.901 (1H, H_c allyl), 5.609 (s, 1H, $C_6H_5CHO_2$), 5.294 (1H, H_b allyl), 5.146 (1H, H_a allyl), 4.843 (d, 1H, J_{gem} = 12.0 Hz, C_6H_5CHHO), 4.725 (d, 1H, J_{gem} = 12.0 Hz, C_6H_5CHHO), 4.681 (d, 1H, $J_{1,2}$ = 2.0 Hz, H-1), 4.294–4.208 (2H, H_d allyl (δ 4.268) and H-6e (δ 4.244, dd, $J_{6a,6e}$ = 10.5 Hz, $J_{5,6a}$ = 4.5 Hz)), 4.185 (dd, 1H, $J_{6a,6e}$ = 10.0 Hz, $J_{5,6a}$ = 10.0 Hz, H-6a), 4.104 (1H, H_e allyl), 3.885–3.834 (2H, H-3 and H-4), 3.818 (dd, 1H, $J_{2,3}$ = 3.2 Hz, $J_{1,2}$ = 2.0 Hz, H-2), 3.761 (dd, 1H, $J_{4,5}$ = 10.0 Hz, $J_{5,6a}$ = 10.0 Hz, $J_{5,6e}$ = 4.5 Hz, H-5), 3.310 (s, 3H, CH_3O); ^{13}C nmr δ: 138.18, 137.72 (quat. arom.), 135.0 (CH_2=$CHCH_2O$), 128.64, 128.00, 127.87, 127.59, 125.00 (tert. arom.), 116.32 (CH_2=$CHCH_2O$), 101.43, 100.52 (C-1 and $C_6H_5CHO_2$), 79.09 (C-4), 76.47, 76.03 (C-2 and C-3), 73.56 ($C_6H_5CH_2O$), 68.79 (CH_2=$CHCH_2O$), 64.03 (C-6), 54.67 (C-5), 29.57 (CH_3O). *Anal.* calcd. for $C_{24}H_{28}O_6$: C 69.89, H 6.84; found: C 69.67, H 6.94.

*Methyl 3-*O*-allyl-2,4-di-*O*-benzyl-α-*D*-mannopyranoside (**12**) and methyl 3-*O*-allyl-2,6-di-*O*-benzyl-α-*D*-mannopyranoside (**13**)*

To a stirred solution of **11** (14.27 g; 34.59 mmol) in 1:1 diethyl ether – dichloromethane (300 mL) was added, portionwise, $LiAlH_4$ (3.95 g; 103.9 mmol) and the mixture was slowly heated to the boiling point. To the refluxing solution was added $AlCl_3$ (13.85 g; 103.9 mmol) in diethyl ether (150 mL) over a period of 70 min, when tlc indicated the absence of starting material. The mixture was cooled and the excess of $LiAlH_4$ was decomposed with ethyl acetate (75 mL), and $Al(OH)_3$ was precipitated by the addition of water (75 mL). After dilution with ether (400 mL), the organic layer was separated from the aqueous layer, which was back-extracted with ether (150 mL). The combined ether extracts were washed with water (3 × 150 mL), dried ($MgSO_4$), and concentrated to an oily residue, which tlc indicated to be a mixture of two compounds. The separation of these two products was achieved by flash chromatography using hexane – ethyl acetate (3:1) as eluent. Evaporation of the early fractions provided the minor product **13** (1.69 g) as an oil; $[\alpha]_D$ −6.25° (*c* 1.04, chloroform); R_f 0.47 (hexane – ethyl acetate, 2:1); ^{1}H nmr ($CDCl_3$) δ: 7.39–7.25 (10H, arom.), 5.906 (1H, H_c allyl), 5.283 (1H, H_b allyl), 5.185 (1H, H_a allyl), 4.778 (d, 1H, $J_{1,2}$ = 2.0 Hz, H-1), 4.730–4.665 (AB, 2H, J_{gem} = 12.0 Hz, $C_6H_5CH_2O$), 4.655–4.583 (AB, 2H, J_{gem} = 12.0 Hz, $C_6H_5CH_2O$), 4.070–3.938 (3H, H_d and H_e allyl overlapping with H-4 (δ 4.004, ddd, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 9.0 Hz, $J_{4,OH}$ = 2.0 Hz, simplified to dd with J_{OH} being absent on D_2O exchange)), 3.830–3.704 (4H, H-2, H-5, H-6a, and H-6b), 3.596 (dd, 1H, $J_{3,4}$ = 9.5 Hz, $J_{2,3}$ = 3.0 Hz, H-3), 3.354 (s, 3H, CH_3O), 2.578 (d, 1H, $J_{4,OH}$ = 2.0 Hz, D_2O exchangeable, 4-OH); ^{13}C nmr ($CDCl_3$) δ: 138.40, 138.37 (quat. arom.), 134.76 (CH_2=$CHCH_2O$), 128.37, 127.88, 127.66, 127.56 (tert. arom.), 117.22 (CH_2=$CHCH_2O$), 99.40 (C-1), 79.41 (C-3), 73.79 (C-2), 73.65, 72.78 ($C_6H_5CH_2O$), 71.58 (C-5), 70.73 (CH_2=$CHCH_2O$), 70.66 (C-6), 67.96 (C-4), 54.99 (CH_3O). *Anal.* calcd. for $C_{24}H_{30}O_6$: C 69.55, H 7.30; found: C 69.67, H 7.35.

Evaporation of the later fractions gave the major product **12** (10.78 g) as an oil; $[\alpha]_D$ +48.25° (*c* 0.97, chloroform); R_f 0.35 (hexane – ethyl acetate, 2:1); ^{1}H nmr ($CDCl_3$) δ: 7.42–7.24 (10H, arom.), 5.950 (1H, H_c allyl), 5.326 (1H, H_b allyl), 5.180 (1H, H_a allyl), 4.936 (d, 1H, J_{gem} = 11.0 Hz, C_6H_5CHHO), 4.813 (d, 1H, J_{gem} = 12.5 Hz, C_6H_5CHHO), 4.709–4.688 (2H, C_6H_5CHHO (δ 4.709, d, J_{gem} = 12.5 Hz) overlapping with H-1 (δ 4.690, d, $J_{1,2}$ = 2 Hz)), 4.638 (d, 1H, J_{gem} = 11.0 Hz, C_6H_5CHHO), 4.146–4.064 (2H, H_d and H_e allyl), 3.913 (dd, 1H, $J_{3,4}$ = 9.5 Hz, $J_{4,5}$ = 9.5 Hz,

*Methyl 6-O-acetyl-3-O-allyl-2,4-di-O-benzyl-α-D-mannopyranoside (**14**)*

To a solution of **12** (10.30 g; 24.85 mmol) in dry pyridine (100 mL) was added acetic anhydride (7.5 mL; 79.54 mmol). The mixture was stirred under nitrogen atmosphere at room temperature overnight. The excess of acetic anhydride was decomposed by dropwise addition of ethanol (5 mL) to the ice-cold reaction mixture, and dichloromethane (300 mL) and water (250 mL) were then added. The aqueous layer was separated and back-extracted with dichloromethane (100 mL). The combined dichloromethane extracts were washed with 1 *N* aqueous HCl and saturated aqueous sodium bicarbonate. The organic phase was dried ($MgSO_4$), filtered, and evaporated under reduced pressure to give **14** (11.06 g; 98%) as a chromatographically pure oil; $[\alpha]_D$ +42.91° (*c* 1.03, chloroform); R_f 0.45 (hexane – ethyl acetate, 3:1); ^1H nmr ($CDCl_3$) δ: 7.41–7.25 (10H, arom.), 5.920 (1H, H_c allyl), 5.309 (1H, H_b allyl), 5.169 (1H, H_a allyl), 4.910 (d, 1H, J_{gem} = 11.0 Hz, C_6H_5CHHO), 4.778–4.691 (3H, $C_6H_5CH_2O$ (δ 4.778–4.691, AB, J_{gem} = 11.0 Hz) overlapping with H-1 (δ 4.718, d, $J_{1,2}$ = 2.0 Hz)), 4.561 (d, 1H, J_{gem} = 11.0 Hz, C_6H_5CHHO), 4.348–4.268 (2 × dd, 2H, $J_{6a,6b}$ = 12.0 Hz, $J_{5,6a}$ = 3.0 Hz, $J_{5,6b}$ = 5.0 Hz, H-6a and H-6b), 4.119–4.025 (2H, H_d and H_e allyl), 3.844 (dd, 1H, $J_{3,4}$ = 9.0 Hz, $J_{4,5}$ = 9.5 Hz, H-4), 3.781–3.706 (3H, H-3 (δ 3.766, $J_{2,3}$ = 3.5 Hz, $J_{3,4}$ = 9.5 Hz), H-2 (δ 3.743, $J_{1,2}$ = 2.0 Hz, $J_{2,3}$ = 3.5 Hz), and H-5), 3.31 (s, 3H, CH_3O), 2.05 (s, 3H, $OCOCH_3$); ^{13}C nmr ($CDCl_3$) δ: 170.80 ($OCOCH_3$), 138.34 (quat. arom.), 134.85 (CH_2=$CHCH_2O$), 128.36, 128.29, 128.08, 127.70, 127.60 (tert. arom.), 116.70 (CH_2=$CHCH_2O$), 99.10 (C-1), 79.89 (C-3), 75.07 ($C_6H_5CH_2O$), 74.50, 74.58 (C-2 and C-4), 72.66 ($C_6H_5CH_2O$), 70.98 (CH_2=$CHCH_2O$), 69.98 (C-5), 63.63 (C-6), 54.73 (CH_3O), 20.81 ($OCOCH_3$). *Anal.* calcd. for $C_{26}H_{32}O_7$: C 68.40, H 7.07; found: C 68.39, H 7.09.

*1,6-Di-O-acetyl-3-O-allyl-2,4-di-O-benzyl-α-D-mannopyranose (**15**)*

A solution of concentrated sulfuric acid (0.22 mL) in acetic anhydride (7.68 mL) was added dropwise to a solution of **14** (8.77 g; 19.65 mmol) in acetic anhydride (40 mL) at 0°C over 10 min. The mixture was stirred at 0°C for 25 min and at room temperature for 20 min. Then the reaction mixture was poured into dichloromethane (1 L) and ice-cold water (1 L) containing sodium bicarbonate, and the resulting mixture was stirred at room temperature for 30 min. The organic and aqueous layers were separated, and the aqueous layer was extracted with dichloromethane (500 mL). The dichloromethane solutions were combined and then washed with saturated aqueous sodium carbonate and water. Finally the organic phase was dried (Na_2SO_4), filtered, and concentrated. The residual syrup was purified by flash chromatography using hexane – ethyl acetate as eluent, the ratio of hexane to ethyl acetate being varied from 6:1 to 3:1 during elution. Removal of solvent from the early fractions provided the title compound as an oil (7.35 g; 77% yield); $[\alpha]_D$ +37.85 (*c* 0.93, chloroform); R_f 0.56 (hexane – ethyl acetate, 3:1); ^1H nmr ($CDCl_3$) δ: 7.431–7.273 (10H, arom.), 6.195 (d, 1H, $J_{1,2}$ = 2.0 Hz, H-1), 5.923 (1H, H_c allyl), 5.315 (1H, H_b allyl), 5.200 (1H, H_a allyl), 4.935 (d, 1H, J_{gem} = 10.5 Hz, C_6H_5CHHO), 4.840–4.766 (AB, 2H, J_{gem} = 12.0 Hz, $C_6H_5CH_2O$), 4.621 (d, 1H, J_{gem} = 10.5 Hz, C_6H_5CHHO), 4.384–4.310 (2 × dd, 2H, H-6a and H-6b), 4.095 (ddd, 2H, CH_2=$CHCH_2O$), 3.973 (dd, 1H, $J_{3,4}$ = 10.0 Hz, $J_{4,5}$ = 10.0 Hz, H-4), 3.893 (ddd, 1H, $J_{4,5}$ = 10.0 Hz, $J_{5,6a}$ = 4.0 Hz, $J_{5,6b}$ = 3.0 Hz, H-5), 3.814, 3.785 (2 dd, 2H, $J_{3,4}$ = 10.0 Hz, $J_{2,3}$ = 3.0 Hz, $J_{1,2}$ = 2.0 Hz, H-3 and H-2 respectively), 2.055 (s, 6H, $OCOCH_3$ × 2); ^{13}C nmr ($CDCl_3$) δ: 170.82, 168.82 ($OCOCH_3$), 138.08, 137.87 (quat. arom.), 134.68 (H_2C=$CHCH_2O$), 128.50, 128.40, 128.24, 127.93, 127.88, 127.83 (tert. arom), 117.04 (H_2C=$CHCH_2O$), 91.79 (C-1), 79.17 (C-3), 75.36 ($C_6H_5CH_2O$), 73.89, 73.39 (C-2 and C-4), 72.53 ($C_6H_5CH_2O$), 72.41 (C-5), 71.09 (H_2C=$CHCH_2O$), 63.24 (C-6), 20.98, 20.85 ($OCOCH_3$). *Anal.* calcd. for $C_{27}H_{32}O_8$: C 66.93, H 6.66; found: C 66.78, H 6.74.

*6-O-Acetyl-3-O-allyl-2,4-di-O-benzyl-α-D-mannopyranosyl bromide (**8**)*

Hydrogen bromide gas was passed for 30 min through a tube of calcium sulfate into a solution of **15** (5.80 g; 11.97 mmol) in dry dichloromethane (300 mL) at 0°C. The solution was then taken to dryness and the by-product acetic acid removed by evaporation of toluene (100 mL) from the residue (twice). Finally **8** was obtained as an oil, a portion of which was purified for elemental and nmr spectral analysis by flash chromatography using hexane – ethyl acetate (3:1) as eluent; $[\alpha]_D$ +133.08° (*c* 0.91, chloroform); R_f 0.60 (hexane – ethyl acetate, 3:1); ^1H nmr ($CDCl_3$) δ: 7.42–7.30 (10H, arom.), 6.444 (d, 1H, $J_{1,2}$ = 1.5 Hz, H-1), 5.936 (1H, H_c allyl), 5.350 (1H, H_b allyl), 5.233 (1H, H_a allyl), 5.955 (d, 1H, J_{gem} = 10.5 Hz, C_6H_5CHHO), 4.788–4.718 (AB, 2H, J_{gem} = 12.5 Hz, $C_6H_5CH_2O$), 4.613 (d, 1H, J_{gem} = 10.5 Hz, C_6H_5CHHO), 4.388–4.058 (2H, H-6a and H-6b), 4.243 (dd, 1H, $J_{3,4}$ = 9.0 Hz, $J_{2,3}$ = 3.0 Hz, H-3), 4.116 (d, 2H, *J* = 5 Hz, CH_2=$CHCH_2O$), 4.016–3.935 (3H, H-2 (δ 4.011, dd, $J_{2,3}$ = 3.0 Hz, $J_{1,2}$ = 1.5 Hz), H-4 and H-5), 2.065 (s, 3H, $OCOCH_3$); ^{13}C nmr ($CDCl_3$) δ: 170.57 ($OCOCH_3$), 137.90, 137.55 (quat. arom.), 134.37 (CH_2=$CHCH_2O$), 128.63, 128.44, 128.14, 127.97, 127.87, 127.73 (tert. arom.), 117.38 (CH_2=$CHCH_2O$), 87.41 (C-1), 78.41 (C-3), 78.31, 74.31, 73.57 (C-2, C-4, and C-5), 75.30, 72.89 ($C_6H_5CH_2O$), 71.21 (CH_2=$CHCH_2O$), 62.39 (C-6), 20.72 ($OCOCH_3$). *Anal.* calcd. for $C_{25}H_{29}O_6Br$: C 59.41, H 5.78, Br 15.81; found: C 59.48, H 5.82, Br 16.17.

*8-Methoxycarbonyloctyl 6-O-acetyl-3-O-allyl-2,4-di-O-benzyl-β-D-mannopyranoside (**17β**) and 8-methoxycarbonyloctyl 6-O-acetyl-3-O-allyl-2,4-di-O-benzyl-α-D-mannopyranoside (**17α**)*

8-Methoxycarbonyoctanol (18) (7.50 g; 39.89 mmol) and silver silicate/alumina (16.50 g) in dry dichloromethane (100 mL) were stirred at room temperature for 1 h. To the above mixture, which was cooled to −78°C, was added dropwise, with stirring, a solution of **8** (7.44 g; 14.72 mmol) in dry dichloromethane (75 mL) and stirring was continued for 2.5 h at −78°C, and for 10 h at room temperature. The mixture was diluted with dichloromethane (100 mL) and filtered through Celite. The filtrate was washed with water, dried (Na_2SO_4), and concentrated to a syrup that was purified by flash chromatography, using hexane – ethyl acetate (4.5:1) as eluent. A chromatographically inseparable 6:1 mixture of the β and α mannosides **17** was obtained as an oil (5.14 g; total yield 57%); ^1H nmr ($CDCl_3$) δ: 4.824 (d, $J_{1,2}$ = 1.5 Hz, H-1α), 4.365 (d, $J_{1,2} \approx 0.5$ Hz, H-1β), 2.059 (s, $OCOCH_3\alpha$), 2.050 (s, $OCOCH_3\beta$).

*8-Methoxycarbonyloctyl 3-O-allyl-2,4-di-O-benzyl-β-D-mannopyranoside (**18**) and 8-methoxycarbonyloctyl 3-O-allyl-2,4-di-O-benzyl-α-D-mannopyranoside (**19**)*

The mixture of α and β anomers **17** described above (4.39 g; 7.17 mmol) was dissolved in dry methanol (200 mL) containing a trace of sodium methoxide, and the resulting solution was stirred at room temperature overnight. Neutralization with Amberlite IR-120(H) resin followed by the removal of the resin and evaporation provided an oily residue (4.10 g) whose tlc on silica gel impregnated with silver nitrate showed it to be a mixture of two compounds. Purification of these two products was accomplished by flash chromatography on silver nitrate-impregnated silica gel (prepared by mixing silica gel (40–63 μm) with 17% by weight of finely powdered silver nitrate) using hexane – ethyl acetate as eluent, the ratio of hexane to ethyl acetate being decreased from 7:1 to 2:1 during elution. Evaporation of early fractions furnished the α anomer **19** (0.19 g) as an oil; $[\alpha]_D$ +30.8° (*c* 0.75, chloroform); ^1H nmr ($CDCl_3$) δ: 7.42–7.27 (10H, arom.), 5.965 (1H, H_c allyl),

5.345 (1H, H_b allyl), 5.194 (1H, H_a allyl), 4.945 (d, 1H, J_{gem} = 11.0 Hz, C_6H_5CHHO), 4.843–4.788 (2H, C_6H_5CHHO (δ 4.828, d, J_{gem} = 12.0 Hz) and H-1 (δ 4.790, d, $J_{1,2}$ = 2.0 Hz), 4.724 (d, 1H, J_{gem} = 12.0 Hz, C_6H_5CHHO), 4.655 (d, 1H, J_{gem} = 11.0 Hz, C_6H_5CHHO), 4.138 (br d, 2H, H_d and H_e allyl), 3.923 (dd, 1H, $J_{4,5}$ = 9.5 Hz, $J_{3,4}$ = 9.5 Hz, H-4), 3.870–3.579 (9H, H-2, H-3, H-5, H-6a, H-6b, $OCHHCH_2$, and OCH_3 (δ 3.665, s)), 3.329 (dt, 1H, J_{gem} = 9.0 Hz, J_{vic} = 6.5 Hz, $OCHHCH_2$), 2.303 (t, 2H, CH_2COOCH_3, J = 7.5 Hz), 2.098 (br s, 1H, D_2O exchangeable, OH), 1.620 (m, 2H, aliphatic), 1.510 (m, 2H, aliphatic), 1.29 (br s, 8H, remaining aliphatic); ^{13}C nmr ($CDCl_3$) δ: 174.15 ($COOCH_3$), 138.48, 138.43 (quat. arom.), 134.95 (CH_2=$CHCH_2O$), 128.35, 128.29, 128.07, 127.72, 127.67, 127.58 (tert. arom.), 116.47 (CH_2=$CHCH_2O$), 98.25 (C-1), 79.98 (C-3), 75.18 ($C_6H_5CH_2O$), 75.04, 75.01 (C-3 and C-4), 72.88 ($C_6H_5CH_2O$), 72.08 (C-5), 71.07 (CH_2=$CHCH_2O$), 67.61 (OCH_2CH_2), 62.46 (C-6), 51.33 ($COOCH_3$), 34.01 (CH_2COOCH_3), 29.32, 29.11, 29.06, 29.01, 25.99, 24.85 (aliphatic). *Anal.* calcd. for $C_{33}H_{46}O_8$: C 69.45, H 8.12; found: C 69.27, H 8.26.

Further elution provided a mixture of α and β anomers (0.9 g) which were in the ratio of 1:3 (α:β) by ^{1}H nmr.

Evaporation of the later fractions afforded the β anomer **18** (2.89 g) as an oil; $[\alpha]_D$ −51.33 (*c* 0.9, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.49–7.29 (10H, arom.), 5.893 (1H, H_c allyl), 5.288 (1H, H_b allyl), 5.17 (1H, H_a allyl), 4.969–4.858 (3H, $C_6H_5CH_2O$ (δ 4.969–4.800, AB, J_{gem} = 12.5 Hz) and C_6H_5CHHO (4.935, d, J_{gem} = 10.5 Hz)), 4.624 (d, 1H, J_{gem} = 10.5 Hz, C_6H_5CHHO), 4.408 (d, 1H, J = 1 Hz, H-1), 4.024–3.828 (6H, H-2, H-4, H-6a, $OCHHCH_2$, and CH_2=$CHCH_2O$), 3.763 (ddd, 1H, $J_{6a,6b}$ = 12.0 Hz, $J_{5,6b}$ = 6.0 Hz, $J_{6b,OH}$ = 6.0 Hz, simplified to dd with $J_{6b,OH}$ being absent on D_2O exchange, H-6b), 3.688 (s, 3H, OCH_3), 3.444–3.386 (2H, H-3 and $OCHHCH_2$), 3.316 (dt, 1H, $J_{4,5}$ = 9.5 Hz, $J_{5,6b}$ = 6.0 Hz, $J_{5,6a}$ = 3.0 Hz, H-5), 2.330 (t, 2H, CH_2COOCH_3, J = 7.5 Hz), 2.140 (t, 1H, $J_{6a,OH}$ = 6.0 Hz, $J_{6b,OH}$ = 6.0 Hz, D_2O exchangeable, OH), 1.670–1.628 (4H, aliphatic), 1.345 (8H, remaining aliphatic); ^{13}C nmr ($CDCl_3$) δ: 174.50 ($COOCH_3$), 138.66, 138.36 (quat. arom.), 134.70 (CH_2=$CHCH_2O$), 128.37, 128.28, 128.11, 128.03, 127.73, 127.37 (tert. arom.), 116.75 (CH_2=$CHCH_2O$), 101.69 (C-1, $J_{C\text{-}1,H\text{-}1}$ = 153.6 Hz), 82.33 (C-3), 75.77, 74.88, 73.90 (C-2, C-4, and C-5), 75.18, 73.86 ($C_6H_5CH_2O$), 70.58, 70.12 (CH_2=$CHCH_2O$ and OCH_2CH_2), 62.63 (C-6), 51.36 ($COOCH_3$), 34.04 (CH_2COOCH_3), 29.63, 29.16, 29.04, 26.01, 24.89 (aliphatic). *Anal.* calcd. for $C_{33}H_{46}O_8$: C 69.45, H 8.12; found: C 69.41, H 8.13.

*8-Methoxycarbonyloctyl 6-O-(2-O-acetyl-3,4,6-tri-O-benzyl-α-D-mannopyranosyl)-3-O-allyl-2,4-di-O-benzyl-β-D-mannopyranoside (**20**)*

To a solution of **18** (2.89 g; 5.06 mmol) in dry acetonitrile (60 mL) containing 4 Å molecular sieves were added, sequentially, mercuric bromide (2.19 g; 6.07 mmol), mercuric cyanide (1.53 g; 6.07 mmol), and a solution of 2-*O*-acetyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl bromide (21) (**7**) in dry acetonitrile (25 mL), which had been freshly prepared from 3,4,6-tri-*O*-benzyl-1,2-*O*-(methoxyethylidene)-β-D-mannopyranose (3.07 g; 6.07 mmol). The reaction mixture was stirred at room temperature for 1 h, and the mixture was then filtered through Celite. Evaporation of the solvent gave an oily residue, which was extracted 3 times with dichloromethane. The extracts were combined and washed successively with saturated aqueous potassium chloride, saturated aqueous sodium bicarbonate, water, and brine. The organic layer was dried (Na_2SO_4), filtered, and evaporated to dryness. The resulting oil was purified by flash chromatography using hexane–ethyl acetate (4:1) as eluent to provide the title compound as a syrup (4.07 g; 77%); $[\alpha]_D$ −6.07° (*c* 1.22, chloroform); R_f 0.3 (hexane–ethyl acetate, 3:1); ^{1}H nmr ($CDCl_3$) δ: 7.47–7.10 (25H, arom.), 5.86 (1H, H_c allyl), 5.459 (dd, 1H, $J_{2',3'}$ = 3.0 Hz, $J_{1',2'}$ = 2.0 Hz, H-2'), 5.270 (1H, H_b allyl), 5.159 (1H, H_a allyl), 4.980–4.825 (5H, H-1' (δ 4.911) and 4 × C_6H_5CHHO (d, J_{gem} = 11.0–12.5 Hz)), 4.680–4.650 (2d overlapping, 2H, J_{gem} = 10.5 and 12.0 Hz, $C_6H_5CH_2O$), 4.513–4.408 (4 × d, 4H, J_{gem} = 11.0–12.0 Hz, $C_6H_5CH_2O$), 4.334 (s, 1H, H-1), 3.930–3.590 (15H, $COOCH_3$ (δ 3.66), H-2, H-4, H-6a, H-6b, H-3', H-4', H-5', H-6a', H-6b', CH_2=$CHCH_2O$ and $OCHHCH_2$), 3.410–3.315 (3H, H-3, H-5, and $OCHHCH_2$), 2.283 (t, 2H, J = 7.5 Hz, CH_2COOCH_3), 2.133 (s, 3H, $OCOCH_3$), 1.620–1.513 (4H, aliphatic), 1.335–1.240 (8H, remaining aliphatic); ^{13}C nmr ($CDCl_3$) δ: 174.08 ($COOCH_3$), 170.12 ($OCOCH_3$), 139.00, 138.80, 138.53, 138.46, 138.05 (quat. arom.), 134.79 (CH_2=$CHCH_2O$), 128.27, 128.19, 128.13, 128.10, 127.97, 127.77, 127.70, 127.59, 127.54, 127.50, 127.38, 127.29, 127.23 (tert. arom.), 116.67 (CH_2=$CHCH_2O$), 101.64 (C-1, $J_{C\text{-}1,H\text{-}1}$ = 154.7 Hz), 97.77 (C-1', $J_{C\text{-}1',H\text{-}1'}$ = 170.4 Hz), 82.56 (C-3), 77.94 (C-3'), 74.80, 74.37, 73.91 (C-2, C-4, C-5, and C-4'), 71.36 (C-5'), 68.67 (C-2'), 74.91, 73.71, 73.30, 71.51 ($C_6H_5CH_2O$ × 5), 70.43, 69.79 (CH_2=$CHCH_2O$ and OCH_2CH_2), 68.98 (C-6'), 67.06 (C-6), 51.26 ($COOCH_3$), 34.05 (CH_2COOCH_3), 29.65, 29.23, 29.16, 29.07, 26.09, 24.92 (aliphatic), 20.99 ($OCOCH_3$). *Anal.* calcd. for $C_{62}H_{76}O_{14}$: C 71.24, H 7.33; found: 71.09, H 7.46.

*8-Methoxycarbonyloctyl 3-O-allyl-2,4-di-O-benzyl-6-O-(3,4,6-tri-O-benzyl-α-D-mannopyranosyl)-β-D-mannopyranoside (**21**)*

The disaccharide **20** (2.88 g; 2.76 mmol) was de-*O*-acetylated as described for the preparation of **18**. After removal of the resin by filtration the solvent was evaporated to afford **21** as chromatographically pure oil (2.73 g; 99%); $[\alpha]_D$ +3.13° (*c* 1.34, chloroform); R_f 0.32 (hexane–acetone, 3:1); ^{1}H nmr ($CDCl_3$) δ: 7.48–7.14 (25H, arom.), 5.883 (1H, H_c allyl), 5.288 (1H, H_b allyl), 5.170 (1H, H_a allyl), 5.258 (br s, 1H, $J_{1',2'} \leq 2$ Hz, H-1'), 4.968–4.795 (4 × d, 4H, J_{gem} = 11.0 and 12.5 Hz, $C_6H_5CH_2O$), 4.644–4.438 (6 × d, 6H, J_{gem} = 11.0–12.0 Hz, $C_6H_5CH_2O$), 4.335 (s, 1H, $J_{1,2} \leq 1$ Hz, H-1), 4.128 (br s, 1H, H-2'), 4.038–3.593 (15H, OCH_3 (δ 3.655, s), H-2, H-4, H-6a, H-6b, H-3', H-4', H-5', H-6a', H-6b', $OCHHCH_2$, and CH_2=$CHCH_2O$), 3.423–3.320 (3H, H-3, H-5, and $OCHHCH_2$), 2.355 (br s, 1H, D_2O exchangeable, OH), 2.284 (t, 2H, J = 7.5 Hz, CH_2COOCH_3), 1.59 (4H, aliphatic), 1.28 (8H, remaining aliphatic); ^{13}C nmr ($CDCl_3$) δ: 173.86 ($COOCH_3$), 139.04, 138.73, 138.59, 138.44, 138.03 (quat. arom.), 134.86 (CH_2=$CHCH_2O$), 128.49, 128.36, 128.29, 128.24, 128.07, 127.99, 127.89, 127.78, 127.62, 127.48, 127.40 (tert. arom.), 116.84 (CH_2=$CHCH_2O$), 101.73 (C-1), 99.77 (C-1'), 82.47 (C-3), 79.69 (C-3'), 75.24, 74.61, 74.36, 74.06 (C-3, C-4, C-5, and C-4'), 75.07, 74.94, 73.88, 73.41, 71.48 ($C_6H_5CH_2O$), 71.07 (C-5'), 70.54, 69.88 (CH_2=$CHCH_2O$ and OCH_2CH_2), 69.03 (C-6'), 68.01 (C-2'), 66.65 (C-6), 51.43 ($COOCH_3$), 34.12 (CH_2COOCH_3), 29.72, 29.29, 29.25, 29.14, 26.15, 24.99 (aliphatic). *Anal.* calcd. for $C_{60}H_{74}O_{13}$: C 71.83, H 7.44; found: C 71.59; H 7.31.

*8-Methoxycarbonyloctyl 6-O-[2-O-(3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranosyl]-3-O-allyl-2,4-di-O-benzyl-β-D-mannopyranoside (**4**)*

To a solution of **21** (2.73 g; 2.73 mmol) in dry dichloromethane (75 mL) were added silver triflate (7.0 g; 27.25 mmol), *sym*-collidine (3.6 mL, 27.25 mmol), and 4 Å molecular sieves. To the resulting mixture, cooled to −50°C, was added dropwise a solution of 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide (20) (**6**) (2.30 g; 2.60 mmol) in dry dichloromethane (25 mL). The above mixture was stirred at −50°C for 15 min and then allowed to warm to room temperature over a period of 1 h. The tlc of the mixture revealed the presence of unreacted alcohol **21** (~30%). The reaction mixture was again cooled to −50°C and a solution of the bromide **6** (2.30 g; 2.60 mmol) in dry dichloromethane (25 mL) was added dropwise. After stirring at −50°C for 15 min, the mixture was allowed to attain room temperature, while stirring, over 1 h, by which time tlc showed the complete disappearance of **21**. The mixture was diluted with dichloromethane, and then filtered through Celite. The filtrate was washed sequentially with ice water, ice-cold 1 *N* HCl, and saturated aqueous sodium bicarbonate. The organic phase was dried (Na_2SO_4), filtered, and evaporated. The residual oil was purified by flash chromatography using hexane–acetone (3:1) as eluent to provide the title compound as a syrup (2.92 g; 76%); $[\alpha_D$ −23.04° (*c* 1.02, chloroform); R_f 0.17 (hexane–acetone, 3:1); ^{1}H nmr ($CDCl_3$) δ: 7.86–7.04 (29H, arom.), 5.901–5.790 (2H, H_c allyl and H-3" (δ 5.815, $J_{3'',4''}$

Compound **23** (0.43 g; 0.34 mmol) in methanol (25 mL) containing hydrazine hydrate (0.14 mL of an 85% solution; 2.6 mmol) was refluxed for 12 h. The tlc showed the presence of the starting material in the reaction mixture. Therefore more hydrazine hydrate (0.07 mL of an 85% solution, 1.3 mmol) was added, the mixture was refluxed for another 4 h, and the solution was then taken to dryness. The residue was dissolved in methanol–water (1:1, 15 mL) and acetic anhydride (1 mL) was added. The resulting solution was stirred at room temperature for 2 h. Removal of solvent gave a white solid, which was purified by flash chromatography using dichloromethane–methanol (12:1) as eluent. Pure **24** was obtained as a white foam (0.24 g; 60%) $[\alpha]_D$ −20.46° (*c* 0.88, chloroform); R_f 0.61 (dichloromethane–methanol, 10:1); ^{1}H nmr ($CDCl_3$) δ: 7.42–7.16 (25H, arom.), 5.90–5.65 (br s, 1H, NH, D_2O exchangeable), 5.053 (d, 1H, J_{gem} = 12.0 Hz, C_6H_5CHHO), 4.913–4.825 (3H, $C_6H_5CH_2O$ (2 × d, J_{gem} = 11.0 Hz) and H-1' (δ 4.910, d, $J_{1',2'}$ = 2.0 Hz)), 4.743 (d, 1H, J_{gem} = 12.0 Hz, C_6H_5CHHO), 4.688–4.574 (3H, H-1'' and $C_6H_5CH_2O$) (2 × d, J_{gem} = 12.0 Hz)), 4.488–4.325 (5H, H-1 (δ 4.435) and $C_6H_5CH_2O$ (4 × d, J_{gem} = 12.0 and 11.0 Hz)), 4.253 (t, 1H, H-2'), 3.995–3.293 (23H, H-2, H-3, H-4, H-5, H-6a, H-6b, H-3', H-4', H-5', H-6a', H-6b', H-2'', H-3'', H-4'', H-5'', H-6a'', H-6b'', OH, OCH_2CH_2, and OCH_3 (δ 3.643, s)), 3.00–2.65 (br s, 2H, D_2O exchangeable, OH), 2.501 (d, 1H, $J_{3,OH}$ = 9.0 Hz, D_2O exchangeable, 3-OH), 2.276 (t, 2H, J = 7.0 Hz, CH_2COOCH_3), 1.840 (s, 3H, $NHCOCH_3$), 1.64–1.52 (4H,

8-Methoxycarbonyloctyl 6-O-[2-O-(3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranosyl]-3-O-(2,3,4,6-tetra-O-acetyl-α-D-mannopyranosyl)-2,4-di-O-benzyl-β-D-mannopyranoside (25)

To a solution of the alcohol **22** (504 mg; 0.371 mmol) in dry acetonitrile (10 mL) containing 4 Å molecular sieves were added sequentially mercuric bromide (1.416 g; 3.93 mmol) and mercuric cyanide (988 mg; 3.95 mmol). To the resulting mixture was added a solution of 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide (19) (**5**) (0.915 g; 2.23 mmol) in dry acetonitrile (5 mL) in five portions with an interval of 30 min between additions, and the reaction mixture was strired for 2 h. Evaporation of the solvent gave an oily residue, which was extracted three times with dichloromethane. The organic extracts were combined and washed with saturated aqueous potassium chloride, saturated aqueous sodium bicarbonate, water, and brine. The dried organic layer (Na_2SO_4) was evaporated to give a foamy residue, which was purified by flash chromatography using toluene – ethyl acetate (3:1) as eluent. The title compound was obtained as a white foam (0.405 g; 65%); $[\alpha]_D$ +4.41° (*c* 0.98, chloroform); R_f 0.25 (toluene – ethyl acetate, 3:1); ^{1}H nmr ($CDCl_3$) δ: 7.88–7.02 (29H, arom.), 5.811 (dd, 1H, $J_{3''',4'''}$ = 10.0 Hz, $J_{2''',3'''}$ = 9.0 Hz, H-3‴), 5.574 (d, 1H, $J_{1''',2'''}$ = 8.5 Hz, H-1‴), 5.391–5.349 (2H, $J_{2',3'}$ = 3.0 Hz, H-2′ and H-3′), 5.240–5.094 (4H, H-4′, H-4‴, C_6H_5CHHO, and H-1 (δ 5.094) $J_{3',4'} = J_{4',5'}$ = 9.5 Hz, $J_{3''',4'''} = J_{4''',5'''}$ = 9.5 Hz), 4.893–4.750 (3H, J_{gem} = 11.5 Hz, and 13.0 Hz, 3 × C_6H_5CHHO), 4.696 (d, 1H, $J_{1'',2''}$ = 1.5 Hz, H-1″), 4.539–4.448 (2H, H-2‴ (δ 4.515, dd, $J_{1''',2'''}$ = 8.5 Hz, $J_{2''',3'''}$ = 10.5 Hz) and C_6H_5CHHO (J_{gem} = 11.5 Hz)), 4.440–4.284 (6H, H-1 (δ 4.440), H-2″ (δ 4.375, dd, $J_{1'',2''}$ = 2.0 Hz, $J_{2'',3''}$ = 2.0 Hz), H-6a‴, and 3 × C_6H_5CHHO (J_{gem} = 11.0 and 11.5 Hz)), 4.121 (dd, 1H, $J_{6a''',6b'''}$ = 12.0 Hz, $J_{5''',6b'''}$ = 1.5 Hz, H-6b‴), 4.098–3.235 (21H, H-2, H-3, H-4, H-5, H-6a, H-6b, H-5′, H-6a′, H-6b′, H-3″, H-4″, H-5″, H-6a″, H-5‴, OCH_2CH_2, $C_6H_5CH_2O$, OCH_3 (δ 3.674)), 2.953 (dd, 1H, $J_{6a'',6b''}$ = 10.5 Hz, $J_{5'',6''}$ = 6.0 Hz, H-6b″), 2.313 (t, 2H, *J* = 7.5 Hz, CH_2COOCH_3), 2.059–2.000 (6s, 18H, $OCOCH_3$ × 6), 1.868 (s, 3H, $OCOCH_3$), 1.74–1.54 (4H, aliphatic), 1.46–1.20 (8H, remaining aliphatic); ^{13}C nmr ($CDCl_3$) δ: 174.11 ($COOCH_3$), 170.58, 170.21, 170.06, 169.65, 169.47, 169.44, 169.35 ($OCOCH_3$ and phthalimido carbonyl), 138.75, 138.46, 137.73, 137.61 (phthalimido quat. arom.), 133.90 (phthalimido tert. arom.), 128.82, 128.46, 128.36, 128.15, 128.08, 128.03, 127.87, 127.54, 127.47, 127.36, 127.28, 127.18 (benzyl tert. arom.), 123.31 (phthalimido tert. arom.), 101.95 (C-1, $J_{C\text{-}1,H\text{-}1}$ = 152 ± 2 Hz), 99.83 (C-1′, $J_{C\text{-}1',H\text{-}1'}$ = 169 ± 2 Hz), 97.62 (C-1″, $J_{C\text{-}1'',H\text{-}1''}$ = 170 ± 2 Hz), 96.60 (C-1‴, $J_{C\text{-}1''',H\text{-}1'''}$ = 165 ± 2 Hz), 81.25, 76.29, 74.78, 74.48, 74.17, 72.90, 72.03, 71.80, 70.73, 69.33, 69.15, 68.98, 68.93, 65.94 (C-2, C-3, C-4, C-5, C-2′, C-3′, C-4′, C-5′, C-2″, C-3″, C-4″, C-5″, C-3‴, C-4‴, and C-5‴), 74.68, 74.58, 73.71, 72.52, 70.43 ($C_6H_5CH_2O$), 70.11 (OCH_2CH_2), 69.62 (C-6″), 66.29 (C-6), 62.44, 62.32 (C-6′ and C-6‴), 54.37 (C-2‴), 51.34 ($COOCH_3$), 34.02 (CH_2COOCH_3), 29.66, 29.27, 29.19, 29.07, 26.10, 24.89 (aliphatic), 20.69, 20.56, 20.40 ($OCOCH_3$). *Anal.* calcd. for $C_{91}H_{107}N_1O_{31}$: C 63.89, H 6.30, N 0.82; found: C 63.45, H 6.31, N 0.82.

8-Methoxycarbonyloctyl 6-O-[2-O-(3,4,6-tri-O-acetyl-2-acetamido-2-deoxy-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranosyl]-3-O-[2,3,4,6-tetra-O-acetyl-α-D-mannopyranosyl]-2,4-di-O-benzyl-β-D-mannopyranoside (26)

Compound **25** (260 mg; 0.15 mmol) was de-*O*-acetylated as described for the preparation of **18** to provide a foamy solid that was dissolved in methanol (10 mL). To this solution was added hydrazine hydrate (0.4 mL of an 85% solution, 7.43 mmol) and the mixture was refluxed for 1 h. Removal of solvent gave a white residue from which traces of hydrazine were removed by evaporation of methanol (twice). The product was then dissolved in pyridine (3.5 mL) and acetic anhydride (3.5 mL), and stirred overnight at room temperature. Excess acetic anhydride was decomposed by dropwise addition of ethanol to the reaction mixture at 0°C, to which was then added dichloromethane and water. The aqueous layer was separated and back-extracted with more dichloromethane and the combined dichloromethane layers were washed with 1 *N* aqueous HCl and saturated aqueous sodium bicarbonate. The organic phase was dried (Na_2SO_4), filtered, and evaporated to give a foamy solid, which was purified by flash chromatography using hexane – ethyl acetate – ethanol (20:20:1) as eluent. Pure **26** was obtained as a white foam (154 mg; 62%) $[\alpha]_D$ +11.23 (*c* 1.18, chloroform); R_f 0.3 (hexane – ethyl acetate – ethanol, 20:20:1); ^{1}H nmr ($CDCl_3$) δ: 7.70–7.12 (25H, arom.), 5.613–5.523 (2H, H-3′‴ (δ 5.588) and NH (δ 5.533, d, *J* = 7.5 Hz)), 5.405–5.340 (2H, H-2′ (δ 5.399, dd, $J_{2',3'}$ = 3.5 Hz, $J_{1',2'}$ = 1.5 Hz) and H-3′ (δ 5.358, dd, $J_{3',4'}$ = 10.0 Hz, $J_{2',3'}$ = 3.5 Hz)), 5.213–4.990 (5H, H-4′ (δ 5.188, dd, $J_{4',5'}$ = 10.0 Hz, $J_{3',4'}$ = 10.0 Hz), C_6H_5CHHO (δ 5.133, d, J_{gem} = 13.0 Hz), H-1′ (δ 5.100), H-1‴ (δ 5.074, d, $J_{1''',2'''}$ = 8.5 Hz), and H-4‴ (δ 5.015, dd, $J_{4''',5'''}$ = 10.0 Hz, $J_{3''',4'''}$ = 10.0 Hz)), 4.905–4.765 (4H, H-1″ (δ 4.850, d, $J_{1'',2''}$ = 2.5 Hz) and 3 × C_6H_5CHHO (J_{gem} = 11.5–13.0 Hz)), 4.575–4.530 (2H, J_{gem} = 11.5 Hz and 12.0 Hz, $C_6H_5CH_2O$), 4.466–4.228 (6H, H-1 (δ 4.466), 3 × C_6H_5CHHO (J_{gem} = 12.0 Hz), H-2″ (δ 4.288, br s), H-6a‴ (δ 4.250, dd, $J_{6a''',6b'''}$ = 12.5 Hz, $J_{5''',6a'''}$ = 5.0 Hz)), 4.119–3.300 (13H, H-6b‴ (δ 4.100, dd, $J_{6a''',6b'''}$ = 12.0 Hz, $J_{5''',6b'''}$ = 2.0 Hz), H-2, H-3, H-4, H-5, H-6a, H-6b, H-5′, H-6a′, H-6b′, H-3″, H-4″, H-5″, H-6a″, H-6b″, H-2‴, H-5‴, OCH_2CH_2, and OCH_3 (δ 3.665)), 2.305 (t, 2H, CH_2COOCH_3, *J* = 7.5 Hz), 2.048–1.993 (21H, 7 × $OCOCH_3$), 1.779 (s, 3H, $NHCOCH_3$), 1.67–1.52 (4H, aliphatic), 1.40–1.14 (8H, remaining aliphatic); ^{13}C nmr ($CDCl_3$) δ: 174.22 ($COOCH_3$), 171.03, 170.70, 170.33, 170.15, 169.84, 169.59, 165.54 ($OCOCH_3$ and acetamido carbonyl), 138.71, 138.46, 137.91, 137.73 (quat.

arom.), 128.55, 128.50, 128.45, 128.37, 128.27, 128.22, 127.94, 127.87, 127.72, 127.61, 127.51, 127.41, 127.34 (tert. arom.), 101.90 (C-1), 99.83 (C-1′), 98.35 (C-1″), 98.09 (C-1‴), 81.09, 76.97, 76.52, 74.93, 74.48, 74.37, 73.57, 72.02, 71.61, 69.33, 69.20, 69.11, 68.90, 65.88 (C-2, C-3, C-4, C-5, C-2′, C-3′, C-4′, C-5′, C-2″, C-3″, C-4″, C-5″, C-3‴, C-4‴, and C-5‴), 74.93, 74.66, 73.74, 73.03, 70.77 ($C_6H_5CH_2O$), 70.59 (OCH_2CH_2), 69.27 (C-6″), 66.37 (C-6), 62.42 (C-6′ and C-6‴), 55.90 (C-2‴), 51.45 ($COOCH_3$), 34.07 (CH_2COOCH_3), 29.66, 29.33, 29.25, 29.14, 26.08, 24.94 (aliphatic), 23.27 ($NHCOCH_3$), 20.76, 20.68 ($OCOCH_3$). *Anal.* calcd. for $C_{85}H_{107}N_1O_{30}$: C 62.91, H 6.65, N 0.86; found: C 63.05, H 6.67, N 0.83.

8-Methoxycarbonyloctyl 6-O-[2-O-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-α-D-mannopyranosyl]-3-O-(α-D-mannopyranosyl)-β-D-mannopyranoside (3)

Compound **35** (111 mg; 0.07 mmol) was de-*O*-acetylated as described for the preparation of **18** to provide a foamy solid (89 mg), which was dissolved in 98% ethanol (17 mL) and hydrogenolyzed over 5% palladium-on-charcoal (180 mg) at atmospheric pressure for 5 days. Processing, as described for **2**, gave **3** as a white amorphous solid (51 mg; 85%) following lyophilization; $[\alpha]_D$ +6.48° (*c* 0.91, water); R_f 0.28 (dichloromethane–methanol–water, 10:6:1); ^{1}H nmr (D_2O) δ: 5.104 (1H, $J_{1',2'}$ = 2.0 Hz, H-1′), 4.918 (1H, $J_{1'',2''}$ = 1.8 Hz, H-1″), 4.671 (1H, $J_{1,2} \leq$ 0.8 Hz, H-1), 4.579 (d, 1H, $J_{1''',2'''}$ = 8.0 Hz, H-1‴), 4.139 (2H, H-2 and H-2″), 4.065 (dd, 1H, $J_{2',3'}$ = 3.0 Hz, $J_{1'',2''}$ = 1.5 Hz, H-2′), 4.018–3.445 (26H, H-3′ (δ 3.891, $J_{3',4'}$ = 10.0 Hz, $J_{2',3'}$ = 3.0 Hz), H-3″ (δ 3.843, $J_{3'',4''}$ = 9.5 Hz, $J_{2'',3''}$ = 3.0 Hz), H-3 (δ 3.728, $J_{3,4}$ = 9.5 Hz), H-2‴ (δ 3.705), OCH_3 (δ 3.688, s), H-4, H-5, H-6a, H-6b, H-4′, H-5′, H-6a′, H-6b′, H-4″, H-5″, H-6a″, H-6b″, H-3‴, H-4‴, H-5‴, H-6a‴, H-6b‴, and OCH_2CH_2), 2.388 (t, 2H, CH_2COOCH_3, *J* = 7.5 Hz), 2.055 (s, 3H, $NHCOCH_3$), 1.66–1.50 (4H, aliphatic), 1.40–1.20 (8H, remaining aliphatic). The above ^{1}H nmr assignments were confirmed by homonuclear decoupling; ^{13}C nmr (D_2O) δ: 178.76 ($COOCH_3$), 175.66 ($NHCOCH_3$), 103.22 (C-1′, $J_{C\text{-}1',H\text{-}1'}$ = 172.0 Hz), 100.69 (C-1, $J_{C\text{-}1,H\text{-}1}$ = 159.1 Hz), 100.40 (C-1‴, $J_{C\text{-}1''',H\text{-}1'''}$ = 159.1 Hz), 97.61 (C-1″, $J_{C\text{-}1'',H\text{-}1''}$ = 169.3 Hz), 81.65, 77.14, 76.70, 75.12, 74.24, 74.18, 73.70, 71.24, 71.16, 70.94, 70.80, 70.49, 68.17, 67.67, 66.63 (C-2, C-3, C-4, C-5, C-2′, C-3′, C-4′, C-5′, C-2″, C-3″, C-4″, C-5″, C-3‴, C-4‴, and C-5‴), 70.99 (OCH_2CH_2), 66.63 (C-6), 62.49, 61.86, 61.51 (C-6′, C-6″, and C-6‴), 56.25 (C-2‴), 52.95 ($COOCH_3$), 34.59 (CH_2COOCH_3), 29.50, 29.11, 29.07, 28.99, 25.86, 25.15 (aliphatic), 23.22 ($NHCOCH_3$).

The addition of electrophiles on ester enolates containing an oxygen in the β-position. A stereoelectronically controlled reaction

MAURICE CARON,[1] TAKESHI KAWAMATA, LUC RUEST, PIERRE SOUCY, AND PIERRE DESLONGCHAMPS[2]

Laboratoire de synthèse organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received February 6, 1986

MAURICE CARON, TAKESHI KAWAMATA, LUC RUEST, PIERRE SOUCY, and PIERRE DESLONGCHAMPS. Can. J. Chem. **64**, 1781 (1986).

The enolate anion derived from spiro ketal methyl esters (**1**, **3**, and **4**) reacts with various electrophiles (PhSeBr, Ch_3I, O_2, I_2, $(CH_3S)_2$, and $(PhS)_2$) to yield as the major product, the isomer resulting from an equatorial approach of the electrophilic reagent. This stereochemically controlled reaction is discussed in terms of stereoelectronic effects that increase the electron density of the α face of the enolate anion.

MAURICE CARON, TAKESHI KAWAMATA, LUC RUEST, PIERRE SOUCY et PIERRE DESLONGCHAMPS. Can. J. Chem. **64**, 1781 (1986).

L'anion énolate d'esters méthyliques de spirocétal (**1**, **3** et **4**) réagit avec divers électrophiles (PhSeBr, CH_3I, O_2, I_2, $(CH_3S)_2$ et $(PhS)_2$) et donne, comme produit principal, l'isomère résultant d'une approche équatoriale de l'agent électrophilique. La stéréochimie de la réaction est discutée en tenant compte d'effets stéréoélectroniques qui augmentent la densité électronique de la face α de l'anion énolate.

In the course of our recent work on the formal total synthesis of erythromycin A (1), it was observed that the lithium ester enolate derived from spiroketal ester **1** (mixture of equatorial and axial isomers) (Scheme 1) gave, on reaction with phenylselenenyl bromide (2), a mixture of the isomeric phenylselenide esters **2***a* and **2***b* in a 12:88 ratio. The major formation of **2***b* was rationalized by invoking a stereoelectronic effect (3) that would favor an equatorial approach of phenylselenenyl bromide on the ester enolate intermediate.

To verify the generality of this process, we have studied the reactivity of the ester enolates derived from **3** and **4** with a variety of electrophilic reagents (C_6H_5SeBr, O_2, I_2, CH_3I, $(CH_3S)_2$, and $(C_6H_5S)_2$). We wish to report this work.

The synthesis of spiroketals **3**[3] and **4**[3] is depicted in Scheme 2. The lactone **8**,[4] a common intermediate for the preparation of **3** and **4**, was obtained from the Michael addition of dimethyl malonate on methyl methacrylate (→ **7**) followed by an aldol condensation with paraformaldehyde. The tetrahydropyranyl ether **9** of 3-butynol was prepared. The tetrahydropyranyl ether **11** of 5-hexyn-3-ol (**10**) was also obtained as shown. The lithium acetylides of **9** and that of **11** were then prepared and reacted with lactone **8** to give the hemiketals **12** and **13** respectively (4). Catalytic hydrogenation of **12** and **13** gave the corresponding saturated hemiketals **14** and **15**, which were cyclized under acidic conditions to give respectively spiroketal diesters **16** and **17** (5).

Decarbomethoxylation of spiroketal diester **16** with lithium chloride in wet dimethyl sulfoxide (6) gave a 83:17 mixture of axial and equatorial spiroketal monoester **3**, which could be separated by chromatography. Similarly, decarbomethoxylation of spiroketal diester **17** gave a 80:20 mixture of axial and equatorial monoester **4**. The epimers of **4** can also be obtained pure by chromatography. The enolates of **3** and **4** were generated (LDA in THF) starting from their respective axial and equatorial epimeric mixtures. The results obtained from the reaction of these two enolates with the various electrophiles are described in the experimental part and are summarized in Table 1.

In each case, the various equatorial and axial isomers obtained (**5***a*–*b* and **6***a*–*b*) were separated and obtained pure by chromatography. The assignment of configuration for the isomeric phenyl selenides **5***a* and **5***b* (E = PhSe) and for the methylated products **5***a* and **5***b* (E = Me) was rigorously established by finding the relative proportion of the equatorial and the axial isomer under equilibrating conditions. These two sets of isomers can be equilibrated under acidic conditions via the formation of tetrasubstituted dihydropyran intermediate. Indeed, under these conditions, isomer **5***a* can be converted via spiroketal opening into the mirror image of **5***b*. Equilibration of the phenyl selenides **5***a* and **5***b* (E = PhSe) gave a 25:75 ratio, and the major isomer was assigned as the equatorial isomer **5***b* because a PhSe is a larger group than a carbomethoxy. Similarly, equilibration of the methylated products **5***a* and **5***b* (E = CH_3) gave a 36:64 ratio, where the slightly major isomer was assigned as the equatorial isomer **5***b* on the basis that a methyl is slightly larger than a carbomethoxy group (7). This assignment was also confirmed by ^{13}C nmr analyses, which showed that for product **5***a* (E = CH_3) the carbon at position 4 appears as expected at higher field (33.9 ppm) than for compound **5***b* (E = CH_3) (36.6 ppm) due to a 1,3 diaxial interaction with axial methyl at position 2 (5).

In both isomeric series, ^1H nmr studies also showed (5) that the methoxy group of an axial ester always appears at a lower field that that of the equatorial one, and that the axial proton at position 4 is strongly deshielded by the axial substituent E (see Table 2). The configurational assignment for the isomeric compounds **2***a* and **2***b* and **6***a* and **6***b* (E = PhSe, OH, I, CH_3, CH_3S, and Phs) was established by spectral analysis by comparison with compounds **5***a* and **5***b* (E = PhSe and CH_3).

The results described in Table 1 show a very large preference for the formation of the equatorial isomer and it is unlikely that such a stereochemical control would be due only to steric effect.

[3]As these 1,7-dioxaspiro[5.5]undecane compounds are, in fact, the ketal derivatives of 1,9-dihydroxy-5-nonanone, we used the aliphatic chain numbering as indicated in structure **1**.

[4]Lactone **8** served also as a key intermediate in our formal total synthesis of erythromycin A (1).

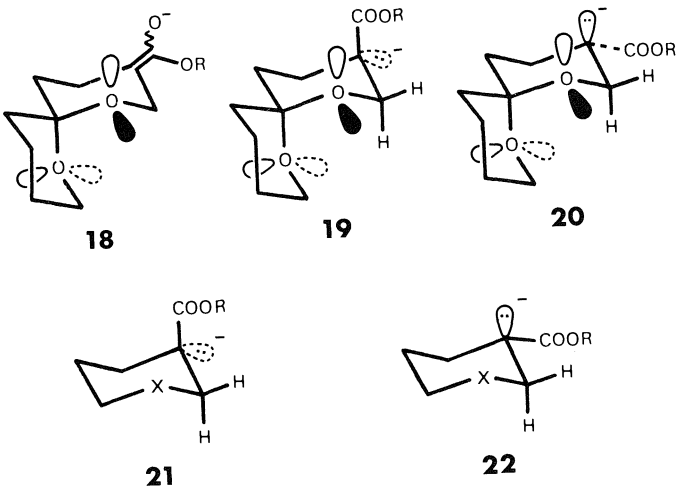
We have suggested[5] that the observed selectivity might be a consequence of a stereoelectronic effect that renders the electron density on the α face of the enolate ester greater than that of the β face because the enolate anion **18** (Scheme 3) would be closer to the sp_3-hybridized equatorial anion **19** (a hybrid of **18** and **19**) than to the axial anion **20**. This would be due to the fact that the equatorial anion **19** is more stable, thus more important as a limiting structure, than the axial anion **20**. In the equatorial anion **19**, the carbon electron pair is antiperiplanar to the polar C—O bond; an additional stabilization due to the electronic delocalization resulting from the overlap of this electron pair with the antibonding orbital of that C—O bond is thus possible (n_C–σ^*_{O-C} overlap). This stereoelectronic effect is equivalent to the anomeric effect, except for the fact that the electron pair is on a carbon rather than an oxygen atom.

Krapcho and Dundulis (8) have reported the alkylation with methyl iodide of the enolate ester anion of methyl-4-*tert*-butylcyclohexane carboxylate. They have also studied the alkylation of methyl 2-methyl- and 3-methyl-cyclohexane carboxylate. In all cases, the major alkylated product was the "equatorial" isomer (84, 80, and 90% respectively) resulting from an equatorial approach of the alkylating agent.

Very similar results are thus obtained with the spiroketal and the cyclohexane methyl esters. Thus, the introduction of an oxygen in the cyclohexane ring does not influence much the axial:equatorial product ratio and one may simply conclude that steric rather than stereoelectronic factors govern the course of these reactions.



SCHEME 3

It is, however, also possible that the anion **21** (X = CH_2) is better stabilized than the anion **22** (X = CH_2) because a n_C–σ^*_{C-C} overlap in the former would be better than a n_C–σ^*_{H-C} overlap in the latter, and that the alkylation of cyclohexane ester would also be governed by stereoelectronic factors (9). When X = O, the electronic delocalization in anion **21** must, however, be more important than when Y = CH_2 and, on that basis, the former should produce more of the equatorial alkylated product than the latter. On the other hand, replacing a CH_2 group by an oxygen atom decreases the steric repulsion for the axial approach and more axial alkylated product should be formed. Thus, when X = O, the stereoelectronic and steric effects are favoring competing processes and must cancel each other. Consequently, the result observed with spiro ketal ester is similar to that found in cyclohexane ester.

In conclusion, the results that we are reporting cannot be considered as a clear demonstration that stereoelectronic effects play an important role in the alkylation of enolate ester having an oxygen atom in the β position because they can be rationalized either by a combination of steric and stereoelectronic effects or by steric effects only. Subsequent to this study, it was discovered that the influence of stereoelectronic effects can be observed very clearly by studying the relative rate of deprotonation of isomeric esters. This work is reported in the following article (10).

Experimental

The ir spectra were taken on a Perkin–Elmer 257 spectrophotometer. Proton nmr spectra were recorded on a Bruker WP-60 or Bruker WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublet; t, triplet; m, multiplet; and br, broad. Chemical shifts are reported in δ values relative to tetramethylsilane or chloroform as internal standard. Carbon nuclear magnetic resonance spectra were recorded on a Bruker HX-90 instrument. Mass spectra were obtained on Hitachi–Perkin–Elmer RMU-6A and Micromass ZAB-2F machines. Melting points were determined on a Buchi M-50 apparatus and are uncorrected. Ether, tetrahydrofuran, and 1,2-dimethoxyethane were dried by distilling over sodium benzophenone whereas benzene, dimethyl sulfoxide, and amines were distilled over calcium hydride. Anhydrous sodium sulfate was used as the drying agent in working up reactions. For flash

[5]See pages 283–284 in ref. 3*a*.

chromatography, Merck Kiesel gel 60 (230–400 mesh A.S.T.M.) was used. Thin-layer chromatography was performed using silica gel 60 F-250.

Triester 7

Dimethylmalonate (343 g, 2.6 mol) was added with stirring to a solution of sodium (12 g, 0.5 mol) in anhydrous methanol (800 mL) under nitrogen. A solution of methyl methacrylate (200 g, 2.0 mol) in methanol (150 mL) was then added and the mixture was refluxed for 9 h. The mixture was then concentrated by removal of methanol. The residue was dissolved in ether (600 mL), washed with hydrochloric acid (0.1 *N*, 3 × 20 mL), water (3 × 20 mL), and brine. The organic layer was dried over sodium sulfate, filtered, and the solvent was evaporated. The crude product was distilled under reduced pressure to give triester **7** (356 g, 76%); bp 100–102°C, 0.7 Torr (1 Torr = 133.3 Pa); ir ($CHCl_3$): 1735 and 1440 cm^{-1}; nmr ($CDCl_3$) δ: 3.73, 3.72, and 3.67 (three s, 3 × —OCH_3), 3.41 (1H, t, J = 6.0 Hz, —$HC(CO_2CH_3)_2$), 2.17 (3H, m, CH_2 and CH—CH_3), 1.18 (3H, d, J = 6.5 Hz, CH_3); *Mol. Wt.* (ms) calcd. for $C_{10}H_{16}O_6 - OCH_3$: m/e 201.0762; found: m/e 201.0751.

Lactone diester 8

Triester **7** (168 g, 0.72 mol) in dry benzene (500 mL) was added dropwise under nitrogen to a stirred suspension of sodium hydride (4.69 g, 0.19 mol) in dry benzene (200 mL). After the sodium hydride had disappeared, paraformaldehyde (54 g, 1.8 mol) was added and the mixture stirred for 3.5 h. The reaction mixture was then filtered, and washed with dilute hydrochloric acid (0.1 *N*, 3 × 200 mL) and water (2 × 200 mL). The extract was dried, filtered, and the solvent evaporated. The residue was purified either by distillation (bp 142–144°C, 0.4 Torr) or by hplc techniques (elution with toluene – ethyl acetate 9:1) to give lactone diester **8** (103 g, 62%); ir ($CHCl_3$): 1750, 1440, and 1260 cm^{-1}; nmr ($CDCl_3$) δ: 4.77 and 4.50 (2H, AB system, J_{AB} = 12 Hz, OCH_2), 3.78 (6H, s, 2 × OCH_3), 2.50 (3H, m, CH_2 and $CHCH_3$), 1.27 (3H, d, J = 6.1 Hz, CH_3); ms m/e: 230. *Mol. wt.* (ms) calcd. for $C_{10}H_{14}O_6$: m/e 230.0789; found: m/e 230.0789.

Hemiketal 12

To a stirred solution of acetylene **9** (10.2 g, 66 mmol) in tetrahydrofuran (75 mL) was added *n*-butyllithium (41.5 mL of 1.6 *M* solution in hexane, 66 mmol) at −78°C under nitrogen. After 30 min, a solution of lactone diester **8** (15.1 g, 66 mmol) was added and the mixture was stirred at −78°C for 45 min. A saturated solution of ammonium chloride was added and the mixture was extracted with ether (4 × 100 mL). The combined organic layers were dried and the solvents were evaporated to leave a crude product (21 g, 83%), which was not purified; ir ($CHCl_3$): 3580, 3400, 2180, 1740, 1260; nmr ($CDCl_3$) δ: 4.63 (1H, br t, O_2CH), 4.48 (1H, dd, J_{AB} = 12 Hz, J_w = 2 Hz) and 4.15 (1H, d, J_{AB} = 12 Hz) [$OCH_2C(CO_2CH_3)_2$], 3.7 (10H, m, 2 × CH_2O and 2 × OCH_3), 2.60 (3H, $CHCH_3$ and $CH_2C{\equiv}C$), 1.9–1.1 (8H, m, 4 × CH_2), 1.07 (3H, d, J = 6 Hz, CH_3); ms m/e: 366 ($M^+ - H_2O$).

Saturated hemiketal 14

A solution of acetylenic hemiketal **12** (828 mg, 2.16 mmol) in methanol (15 mL) was stirred under hydrogen with palladium-on-charcoal catalyst (5%, 43 mg) for 2 h. The solution was then filtered and methanol was evaporated to give crude saturated hemiketal **14** (807 mg, 96%), which was used without any further purification; ir ($CHCl_3$): 3600, 3440, 1740, 1260 cm^{-1}; nmr ($CDCl_3$) δ: 4.54 (1H, br t, O_2CH), 4.16 (2H, s, $OCH_2C(CO_2CH_3)_2$), 3.75 and 3.67 (6H, 2 s, 2 × OCH_3), 3.8–3.1 (4H, m, 2 × OCH_2), 2.32–1.57 (15H, m), 0.94 (3H, d, J = 6.0 Hz, CH_3); ms m/e: 370 ($M^+ - H_2O$).

Spiroketal diester 16

A solution of saturated hemiketal **14** (4.47 g, 12.27 mmol) in tetrahydrofuran (60 mL) was stirred with hydrochloric acid (1 *N*, 20 mL) for 2 h at 45°C. The mixture was then concentrated under vacuum and extracted with ether (3 × 30 mL). The organic layers were combined, dried, filtered, and the solvent was evaporated. The crude product was then refluxed in benzene (100 mL, Dean–Stark) with *p*-toluenesulfonic acid (200 mg) for 12 h. It was then purified by column chromatography on silica gel with hexane – ethyl acetate (3:2) as the solvent to give spiroketal diester **16** (see footnote 3) (2.49 g, 71%); mp 75–76°C; ir ($CHCl_3$): 1725, 1260 cm^{-1}; nmr ($CDCl_3$) δ: 4.21 (1H, dd, J_{AB} = 12 Hz, J_w = 1.9 Hz, H_{eq}-C1), 3.87 (1H, d, J_{AB} = 12 Hz, H_{ax}-C1), 3.78 (3H, s, OCH_3), 3.69 (3H, s, OCH_3), 3.7–3.5 (2H, m, H_2-C9), 2.3–1.1 (9H, m), 0.92 (3H, d, J = 6.1 Hz, CH_3). *Mol. Wt.* (ms) calcd. for $C_{14}H_{22}O_6$: m/e 286.1416; found: m/e 286.1426.

5-Hexyn-3-ol (10) (11)

To a mechanically stirred suspension of magnesium (48 g, 1.97 g-at.) and mercuric chloride (0.5 g, 1.8 mmol) in anhydrous ether (500 mL) was added under nitrogen a small quantity of propargyl bromide (8 g, 6 mL, 67.2 mmol). When the exothermic reaction started, the reaction mixture was cooled at −20°C (inner temperature). Then a solution of propargyl bromide (134 g, 1.13 mol, 100 mL) and propanal (53 g, 0.91 mol, 65.8 mL) in ether (500 mL) was added dropwise over a period of 3 h. The grey mixture was stirred at room temperature for 5 h, then cooled at 0°C, hydrolyzed with a saturated ammonium chloride solution (500 mL), and extracted with ether (4 × 500 mL). The combined organic layers were dried, filtered, and evaporated to an oil that was distilled under reduced pressure to yield pure 5-hexyn-3-ol (**10**) (67.5 g, 76%); bp 64°C, 25 Torr (lit. (11) bp 44°C, 10 Torr); ir ($CHCl_3$): 3580, 3460, 3310, 2100; nmr ($CDCl_3$) δ: 3.65 (1H, sextuplet, J = 6 Hz, H-C3), 2.40 (3H, m, H_2-C4 and OH), 2.05 (1H, t, H-C6), 1.58 (2H, m, H_2-C2), 0.96 (3H, t, J = 6.3 Hz, CH_3).

Tetrahydropyranyl ether 11

To a mixture of 5-hexyn-3-ol (**10**) (66.17 g, 0.67 mol) and freshly distilled dihydropyran (57.16 g, 0.67 mol) was added, with stirring, undistilled phosphorous trichloride (8 drops). After 4 h at 25°C, the mixture was diluted with ether (600 mL), washed with dilute sodium hydroxide solution (0.1 *N*, 2 × 250 mL), and the organic layer was dried, filtered, and evaporated. The crude product was distilled to give compound **11** (112.7 g, 92%); bp 79°C, 4.4 Torr; ir ($CHCl_3$): 3310, 2100, 1200–1040; nmr ($CDCl_3$) δ: 4.78 and 4.66 (1H, two br t, O_2CH), 3.66 (3H, m, H-C3 and OCH_2), 2.40 (2H, m, H_2-C4), 1.96 (1H, m, H-C6), 1.66 (8H, m, 4 × CH_2), 0.91 (3H, m, CH_3). *Mol. Wt.* (ms) calcd. for $C_{11}H_{17}O_2$: m/e 181.1228 ($M^+ - H$); found: m/e 181.1233.

Hemiketal 13

The preparation of this hemiketal was done as for hemiketal **12** (*vide supra*) with the following quantities: acetylene **11** (25.6 g, 141 mmol) in tetrahydrofuran (200 mL), *n*-butyllithium (88 mL, 1.6 *M*, 141 mmol), and lactone diester **8** (32.4 g, 141 mmol) in tetrahydrofuran (200 mL). The crude product (54.7 g, 94%) was not purified; ir ($CHCl_3$): 3600, 2210, 1740, 1260 cm^{-1}; nmr ($CDCl_3$) δ: 4.77 and 4.65 (1H, two br t, O_2CH), 4.51 (1H, dd, J_{AB} = 2 Hz) and 4.15 (1H, d, J_{AB} = 12 Hz) [$OCH_2C(CO_2CH_3)_2$], 3.75 (9H, m, CH_2O, H-COTHP, 2 × OCH_3), 2.51 (2H, m, H_2C—C═), 1.8–1.0 (10H, m), 0.98 (6H, m, 2 × CH_3); ms m/e: 395 ($M^+ - OH$).

Saturated hemiketal 15

A solution of acetylenic hemiketal **13** (25 g, 60.7 mmol) in methanol (250 mL) was hydrogenated over 10% Pd/C catalyst (1.5 g) for 2 h. After filtration of the mixture, the solvent was evaporated to leave a crude product **15** (24.6 g, 97%) that was not purified; ir ($CHCl_3$): 3600, 1740, 1240 cm^{-1}; nmr ($CDCl_3$) δ: 4.62 (1H, br t, O_2CH), 4.17 (2H, s, $OCH_2C(CO_2CH_3)_2$), 3.76–3.2 (9H, m, CH_2O, HCOTHP, 2 × OCH_3), 2.5–1.2 (17H), 0.92 (6H, m, 2 × CH_3).

Spiroketal diester 17

A solution of saturated hemiketal **15** (1.51 g, 3.65 mmol) in tetrahydrofuran (40 mL) was stirred with hydrochloric acid (1 *N*, 15 mL) for 4 h at 25°C. Water (10 mL) was then added and the mixture was extracted with ether (3 × 25 mL). The organic layer was dried, filtered, and the solvents were evaporated. The crude product was then refluxed in benzene (30 mL) with *p*-toluenesulfonic acid (85 mg, 7% w/w) for 12 h. The solvent was then evaporated and the residue

was purified by chromatography on silica gel (hexane – ethyl acetate, 9:1) to give spiroketal **17** (see footnote 3) (568 mg, 50%); ir ($CHCl_3$): 1735, 1260 cm^{-1}; nmr ($CDCl_3$) δ: 4.16 (1H, dd, J_{AB} = 11 Hz, J_w = 1.9 Hz, H_{eq}-C1), 3.87 (1H, d, J_{AB} = 11 Hz, H_{ax}-C1), 3.78 (3H, s, OCH_3), 3.70 (3H, s, OCH_3), 3.35 (1H, m, H-C9), 2.2–1.0 (11H, m), 0.90 (3H, t, J = 7 Hz, H_3-C11), 0.87 (3H, d, J = 6.5 Hz, H_3C-C4); ms m/e: 314 (M^+).

Spiroketal ***1***

Synthesis of this spiroketal has been reported elsewhere (1).

Decarboalkoxylation

(a) Spiroketal monoesters ***3*** *axial and equatorial*

A solution of diester **16** (2.34 g, 8.18 mmol), lithium chloride (694 mg, 16.9 mmol), and water (147 μL, 8.1 mmol) in dimethylsulfoxide (12 mL) was heated under nitrogen at 160°C for 1 h 40 min. The solvent was then evaporated under reduced pressure and the crude product was chromatographed on silica gel (hexane–ether 75:25) to give a mixture (1.64 g, 88%) of monoesters **3** (axial CO_2Me:equatorial CO_2Me 83:17, nmr integration of H-C2); ms m/e: 228 (M^+). A small quantity of the mixture was separated by preparative thin-layer chromatography.

Equatorial monoester **3** (less polar): ir ($CHCl_3$): 1735, 1250, 1150, 1070 cm^{-1}; nmr ($CDCl_3$) δ: 3.78 (1H, ddd, J_{AB} = 11 Hz, $J_{e,e}$ = 4.7 Hz, J_w = 1.6 Hz, H_{eq}-Cl), 3.66 (3H, s, OCH_3), 3.66 (1H, dd, J_{AB} = $J_{a,a}$ = 11 Hz, H_{ax}-C1), 3.63 (2H, m, H_2-C9), 2.75–2.60 (1H, m, H_{ax}-C2), 1.88–1.2 (8H, m), 1.54 (1H, m, H-C4), 0.94 (3H, d, J = 6.6 Hz, CH_3).

Axial monoester **3** (more polar): ir ($CHCl_3$): 1735, 1260, 1150, 1050 cm^{-1}; nmr ($CDCl_3$) δ: 4.07 (1H, dd, J_{AB} = 12 Hz, $J_{e,e}$ = 3 Hz, J_w = 2 Hz, H_{eq}-C1), 3.78 (1H, dd, J_{AB} = 12 Hz, $J_{a,e}$ = 3.4 Hz, H_{ax}-C1), 3.73 (3H, s, OCH_3), 3.62 (2H, m, H_2-C9), 2.55–2.42 (1H, narrow m, H_{eq}-C2), 2.0–1.1 (9H, m), 0.94 (3H, d, J = 6 Hz, CH_3).

(b) Spiroketal monoester ***4*** *axial and equatorial*

This reaction was done as for compound **3** with the following quantities: diester **17** (7.6 g, 24.2 mmol), dimethylsulfoxide (35 mL), lithium chloride (2.05 g, 48.4 mmol), and water (435 μL, 24.2 mmol). The purified monoesters (4.9 g, 79%, axial ester:equatorial ester 80:20, nmr integration of H-C2) were characterized on small scale, after separation by preparative thin-layer chromatography (hexane:ether, 85:15); ms m/e: 256 (M^+).

Equatorial monoester **4** (less polar): ir ($CHCl_3$): 1730, 1250, 1030 cm^{-1}; nmr ($CDCl_3$) δ: 3.74 (1H, ddd, J_{AB} = 11.1 Hz, $J_{e,a}$ = 4.9 Hz, J_w = 1.5 Hz, H_{eq}-C1), 3.63 (1H, dd, J_{AB} = $J_{a,a}$ = 11.1 Hz, H_{ax}-C1), 3.66 (3H, s, OCH_3), 3.44 (1H, m, H-C9), 2.66 (1H, heptet, H_{ax}-C2), 1.9–1.0 (11H, m), 0.93 (3H, t, J = 7.4 Hz, H_3-C11), 0.92 (3H, d, J = 6.6 Hz, H_3C-C4).

Axial monoester **4** (more polar): ir ($CHCl_3$): 1725, 1250, 1070 cm^{-1}; nmr ($CDCl_3$) δ: 4.00 (1H, ddd, J_{AB} = 11.3 Hz, $J_{e,e}$ = J_w = 1.7 Hz, H_{eq}-C1), 3.78 (1H, dd, J_{AB} = 11.3 Hz, $J_{a,e}$ = 3.4 Hz, H_{ax}-C1), 3.72 (3H, s, OCH_3), 3.43 (1H, m, H-C9), 2.47 (1H, narrow m, H_{eq}-C2), 1.95–1.0 (11H, m), 0.94 (3H, t, J = 7.4 Hz, H_3-C11), 0.89 (3H, d, J = 6.3 Hz, H_3C-C4).

Phenylselenide formation

(i) From spiroketal monoester ***3***

To a stirred solution of dry diisopropylamine (985 mg, 1.36 mL, 9.73 mmol) in dry tetrahydrofuran (15 mL) was added, under argon at −20°C, a solution of *n*-butyllithium (6.08 mL, 1.6 *M* in hexane, 9.73 mmol). After 10 min, to the cooled mixture (−78°C) was added dropwise a solution of monoester **3** (760 mg, 3.33 mmol) in tetrahydrofuran (15 mL). After 10 min at −78°C, the mixture was warmed at −50°C for 10 min and then cooled again at −78°C; then was added, via a cannula, a solution of phenylselenenyl bromide (9.73 mmol) freshly prepared at 0°C by the addition of bromine (249 μL, 4.86 mmol) to a solution of diphenyldiselenide (1.52 g, 4.86 mmol) in tetrahydrofuran (20 mL). The mixture was stirred 45 min at −78°C then hydrolyzed by the addition of saturated ammonium chloride solution (5 mL), and extracted with methylene chloride (3 × 120 mL). The combined organic layers were dried, filtered, and the solvents evaporated. Filtration of the extract on silica gel (hexane–ether, 3:1) afforded a purified mixture (880 mg, 69%) of selenides ***5a*** and *b* (10:90, E = PhSe—), which were separated by flash chromatography with hexane–ether (9:1) as a solvent.

Axial selenide ***5a*** (E = PhSe—) (less polar): ir ($CHCl_3$): 1720, 1440, 1260, 1070, 1030; nmr ($CDCl_3$) δ: 7.60 (2H), and 7.34 (3H) (two m, Ar-H), 3.80 (1H, d, J_{AB} = 12.7 Hz, H_{ax}-C1), 3.73 (1H, dd, J_{AB} = 12.7 Hz, J_w = 1.7 Hz, H_{eq}-C1), 3.58 (2H, m, H_2-C9), 3.51 (3H, s, OCH_3), 2.14 (2H, m, H_{eq}-C3 and H-C4), 1.92–1.1 (8H, m), 0.94 (3H, d, J = 6.8 Hz, CH_3). *Mol. Wt.* (ms) calcd. for $C_{18}H_{24}O_4Se$: m/e 384.0839; found: m/e 384.0835.

Equatorial selenide ***5b*** (E = PhSe) (more polar): mp 60–61°C; ir ($CHCl_3$): 1725, 1440, 1320, 1240, 1120, 1080, 1050; nmr ($CHCl_3$) δ: 7.57 (2H) and 7.33 (3H) (two m, Ar-H), 4.02 (1H, dd, J_{AB} = 11 Hz, J_w = 2.7 Hz, H_{eq}-C1), 3.85 (1H, d, J_{AB} = 11 Hz, H_{ax}-C1), 3.63 (2H, m, H_2-C9), 3.55 (3H, s, OCH_3), 2.13 (1H, ddd, J_{AB} = 12.7 Hz, $J_{e,a}$ = 4.0 Hz, J_w = 2.7 Hz, H_{eq}-C3), 1.82 (1H, dd, J_{AB} = $J_{a,a}$ = 12 Hz, H_{ax}-C3), 1.8–1.2 (7H, m), 0.89 (3H, d, J = 6.7 Hz); ms m/e: 384 (M^+).

Acid treatment of equatorial selenide ***5*** b (E = PhSe)

To a solution of equatorial selenide (34 mg, 0.088 mmol) in benzene (10 mL) was added *p*-toluenesulfonic acid (10 mg) and the mixture was refluxed (Dean–Stark) for 6 h under argon. The solvent was then evaporated and the residue filtered on silica gel to give a mixture (34 mg) of selenides ***5a*** and *b* (E = PhSe) (respectively 25:75, nmr integration).

(ii) From spiroketal monoester ***4***

Selenides ***6a*** and *b* (E = PhSe) were prepared exactly as selenides ***5a*** and *b* (*vide supra*) from the following quantity of monoester **4**: 170 mg, 0.66 mmol. Separation of the purified mixture (211 mg, 77%) led to axial (25 mg, 12%, less polar) and equatorial (186 mg, 88%, more polar) selenides ***6a*** and *b* (E = PhSe).

Axial selenide ***6a***: ir ($CHCl_3$): 1720, 1440, 1260, 1055, 1025; nmr ($CDCl_3$) δ: 7.59 (2H) and 7.32 (3H) (two m, Ar-H), 3.76 (1H, d, J_{AB} = 12 Hz, H_{ax}-C1), 3.70 (1H, dd, J_{AB} = 12 Hz, J_w = 1.7 Hz, H_{eq}-C1), 3.51 (3H, s, OCH_3), 3.43 (2H, m, H_2-C9), 2.16 (1H, m, H_{ax}-C4), 1.90 (1H, dd, J_{AB} = 14.3 Hz, $J_{a,a}$ = 11.7 Hz, H_{ax}-C3), 1.78 (1H, ddd, J_{AB} = 14.3 Hz, $J_{e,a}$ = 4.7 Hz, J_w = 1.7 Hz, H_{eq}-C3), 2.0–1.0 (8H, m), 0.93 (3H, d, J = 6.8 Hz, H_3C-C4), 0.87 (3H, t, J = 7.4 Hz, H_3-C11). *Mol. Wt.* (ms) calcd. for $C_{20}H_{28}O_4Se$: 412.1151; found: 412.1165.

Equatorial selenide ***6b***: ir ($CHCl_3$): 1720, 1440, 1240, 1160, 1110, 1070, 1005; nmr ($CDCl_3$) δ: 7.56 (2H) and 7.35 (3H) (two m, Ar-H), 4.00 (1H, dd, J_{AB} = 11 Hz, J_w = 2.7 Hz, H_{eq}-C1), 3.81 (1H, d, J_{AB} = 11 Hz, H_{ax}-C1), 3.57 (3H, s, OCH_3) 3.41 (1H, m, H-C9), 2.13 (1H, ddd, J_{AB} = 12.6 Hz, $J_{e,a}$ = 3.8 Hz, J_w = 2.7 Hz, H_{eq}-C3), 1.85 (1H, dd, J_{AB} = $J_{a,a}$ = 12.6 Hz, H_{ax}-C3), 1.85–1.0 (8H, m), 0.94 (3H, t, J = 7.3 Hz, H_3-C11), 0.87 (1H, d, J = 6.6 Hz, H_3C-C4); ms m/e: 412 (M^+).

(iii) From spiroketal monoester ***1*** [6]

To a stirred solution of dry cyclohexyl isopropylamine (2.88 mL, 15.8 mmol) in dry dimethoxyethane (DME) (10 mL) at −20°C was added under argon *n*-butyllithium (7.48 mL, 1.85 *M* in hexane, 13.8 mmol). After 10 min, to the mixture cooled at −78°C was added, via a cannula, a solution of monoester **1** (625 mg, 1.978 mmol) in DME (20 mL). The mixture was stirred 30 min at −78°C and 10 min at −50°C; then at −78°C was added a solution of phenylselenenyl bromide freshly prepared at 0°C by the addition of bromine (404 μL, 7.87 mmol) to a solution of diphenyldiselenide (2.451 g, 7.86 mmol) in DME (20 mL). After the addition, the mixture was stirred 1 h at −78°C, then hydrolyzed by the addition of saturated ammonium chloride solution (5 mL) and extracted with methylene chloride (3 × 120 mL). The combined organic layers were dried, filtered, and the solvents evaporated. Filtration of the extract on silica gel (hexane–ether, 3:1) afforded a purified mixture (854 mg, 92%) of selenides ***2a***

[6]The synthesis of compound **1** has been reported elsewhere (1).

Hydroxylation of spiroketal monoester **4**

Anion derivative of spiroketal monoester **4** was prepared as previously described (*vide supra*, starting from 180 mg, 0.70 mmol of ester). Then, at −78°C, dry oxygen was slowly bubbled through the solution for a period of 1 h after which time dimethylsulfide (1 mL) was added. The mixture was warmed to room temperature, shaken with a slightly (pH 5) acidic potassium iodide solution (becomes brown), and extracted with methylene chloride (4 × 20 mL). The extract was washed with aqueous sodium thiosulfate solution, dried, filtered, and the solvent were evaporated. The crude extract was purified by flash chromatography (hexane–ether, 75:25) to give starting material **4** (22 mg, 12%), equatorial hydroxy-ester **6***b* (E = OH) (less polar, 122 mg, 64%), and axial hydroxy-ester **6***a* (E = OH) (more polar, 22 mg, 11.5%).

Equatorial hydroxy-ester **6***b*: ir ($CHCl_3$): 3580, 3520, 1720, 1440, 1240, 1055, 1045, 1020, 1010 cm^{-1}; nmr ($CDCl_3$) δ: 3.81 (3H, s, OCH_3), 3.70 (1H, dd, J_{AB} = 11 Hz, J_w = 2.1 Hz, H_{eq}-C1), 3.52 (1H, d, J_{AB} = 11 Hz, H_{ax}-C1), 3.42 (1H, m, H-C9), 2.79 (1H, s, OH), 1.91 (1H, m, H-C4), 1.88 (1H, ddd, J_{AB} = 12.7 Hz, $J_{e,a}$ = 3.9 Hz, J_w = 2.1 Hz, H_{eq}-C3), 1.79 (1H, dd, J_{AB} = $J_{a,a}$ = 12.7 Hz, H_{ax}-C3), 1.75–1.05 (8H, m), 0.94 (3H, t, J = 7.4 Hz, H_{ax}-C11), 0.92 (3H, d, J = 6.2 Hz, H_3C-C4). *Mol. Methyl derivative formation

From spiroketal monoester **3**

To a solution of anion derivative at −78°C prepared as described (*vide supra*) from spiroketal monoester **3** (75 mg, 0.33 mmol) was added methyl iodide (125 μL, 2.0 mmol) in tetrahydrofuran (1 mL). The mixture was stirred 30 min at −78°C, hydrolyzed with ammonium chloride solution, and extracted with methylene chloride (4 × 20 mL). The crude product was filtered on silica gel to give a mixture (71 mg, 90%) of **5***a* (E = CH_3) and **5***b* (E = CH_3) in a ratio of 14:86 (nmr integration of methoxy groups). Each compound was characterized after separation by thin-layer chromatography (hexane:ether, 9:1).

Axial methyl derivative **5***a* (less polar): ir ($CHCl_3$): 1725, 1165 cm^{-1}; nmr ($CDCl_3$) δ: 3.83 (1H, dd, J_{AB} = 11 Hz, J_w = 0.4 Hz vs. H_3C-C2, H_{ax}-C1), 3.68 (3H, s, OCH_3), 3.63 (1H, m, H_2-C9), 3.43 (1H, dd, J_{AB} = 11 Hz, J_w = 2.4 Hz, H_{eq}-Cl), 1.9–1.2 (9H, m), 1.34 (3H, s, H_3C-C2), 0.93 (3H, d, J = 6.5 Hz, H_3C-C4); nmr ^{13}C: 176.78 (CO_2), 96.99 (C5), 64.01 (C1), 60.5 (C9), 51.68 (OCH_3), 41.86 (C2), 35.60 (C6), 33.90 (C4), 31.40 (CH_3-C2), 25.15 (C8), 19.96 (C3), 18.60 (C7), 16.30 (CH_3-C4); ms *m/e*: 242.

Equatorial methyl derivative **5***b* (more polar): ir ($CHCl_3$): 1725, 1165 cm^{-1}; nmr ($CDCl_3$) δ: 3.95 (1H, dd, J_{AB} = 11.2, J_w = 2.8 Hz, H_{eq}-C1), 3.71 (3H, s, OCH_3), 3.59 (2H, m, H_2-C9), 3.36 (1H, d, J_{AB} = 11.2 Hz, H_{ax}-C1), 2.02–1.2 (9H, m), 1.03 (3H, s, H_3C-C2), 0.89 (3H, d, J = 6.7 Hz, CH_3-C4); nmr ^{13}C: 176.78 (CO_2), 97.10 (C5), 65.50 (C1), 60.60 (C9), 51.97 (OCH_3), 43.44 (C2), 36.60 (C4), 36.10 (C6), 31.21 (CH_3-C2), 25.20 (C8), 22.89 (C3), 18.50 (C7), 16.40 (CH_3-C4); ms *m/e*: 242.

From spiroketal monoester **4**

To a solution of anion derivative at −78°C prepared as described previously from spiroketal monoester **4** (170 mg, 0.664 mmol) (*vide supra*) was added dropwise a solution of methyl iodide (250 μL, 4.01 mmol) in tetrahydrofuran (2 mL). The mixture was stirred 30 min at −78°C, then hydrolyzed with ammonium chloride solution and extracted with methylene chloride (4 × 20 mL). The crude product was purified by flash chromatography (hexane:ether, 9:1) to give axial derivative **6***a* (E = CH_3) (19 mg, 11%, less polar) and equatorial derivative **6***b* (E = CH_3) (160 mg, 89%, more polar).

Axial methyl derivative **6***a*: ir ($CHCl_3$): 1725, 1295, 1250, 1130, 1068, 1050 cm^{-1}; nmr ($CDCl_3$) δ: 3.81 (1H, dd, J_{AB} = 11.1 Hz, J_w = 0.4 Hz vs. H_3C-C2, H_{ax}-C1), 3.67 (3H, s, OCH_3), 3.45 (1H, m, H-C9), 3.37 (1H, dd, J_{AB} = 11.1 Hz, J_w = 2.5 Hz, H_{eq}-C1), 1.91 (1H, dd, J_{AB} = $J_{a,a}$ = 12.6 Hz, H_{ax}-C3), 1.72 (1H, m, H_{eq}-C3), 1.9–1.1 (9H, m), 1.34 (3H, s, H_3C-C2), 0.93 (3H, t, J = 7.4 Hz, H_3-C11), 0.90 (3H, d, J = 6.6 Hz, H_3C-C4). *Mol. Wt.* (ms) calcd. for $C_{15}H_{26}O_4$: 270.1831; found: 270.1835.

Equatorial methyl derivative **6***b*: ir ($CHCl_3$): 1725, 1250, 1170, 1115, 1060, 1052 cm^{-1}; nmr ($CDCl_3$) δ: 3.93 (1H, dd, J_{AB} = 11.1 Hz, J_w = 2.7 Hz, H_{eq}-C1), 3.71 (3H, s, OCH_3), 3.41 (1H, m, H-C9), 3.34 (1H, d, J_{AB} = 11.1 Hz, H_{ax}-C1), 1.94 (1H, ddd, J_{AB} = 12.6 Hz, $J_{e,a}$ = 3.3 Hz, J_w = 2.7 Hz, H_{eq}-C3), 1.90–1.05 (9H, m), 1.45 (1H, dd, J_{AB} = $J_{a,a}$ = 12.6 Hz, H_{ax}-C3), 1.03 (3H, s, H_3C-C2), 0.94 (3H, t, J = 7.4 Hz, H_3-C11), 0.89 (3H, d, J = 6.6 Hz, H_3C-C4); ms *m/e*: 270 (M^+).

Acid treatment of equatorial methyl derivative **5**b (E = CH_3)

To a solution of equatorial methyl derivative **5***b* (15 mg, 0.062 mmol) in benzene (10 mL) was added *p*-toluenesulfonic acid (5 mg) and the mixture was refluxed (Dean–Stark) for 6 h under argon. Benzene was evaporated and the residue was filtered on silica gel to give a mixture

(14 mg) of methyl derivatives **5***a* and **5***b* (E = CH_3) in the proportion 36:64 respectively (nmr integration, OCH_3).

Methyl sulfide derivatives **6**a *and* **6**b (E = SCH_3)

To a solution of anion derivative, at −78°C, prepared as described previously from spiroketal monoester **4** (169 mg, 0.66 mmol) (*vide supra*), was added dropwise a solution of dimethyldisulfide (171 μL, 1.9 mmol) in tetrahydrofuran (2 mL). The mixture was stirred 30 min at −78°C, then hydrolyzed with ammonium chloride and extracted with methylene chloride (4 × 25 mL). The crude product was purified by flash chromatography (hexane:ether, 9:1) to give axial thiomethyl ester **6***a* (E = SCH_3) (1.5 mg, 0.7%, less polar) and equatorial thiomethyl ester **6***b* (E = SCH_3) (195 mg, 98%, more polar).

Axial sulfide derivative **6***a*: ir ($CHCl_3$): 1720, 1440, 1260, 1110, 1005 cm^{-1}; nmr ($CDCl_3$) δ: 3.80 (1H, d, J_{AB} = 12.4 Hz, H_{ax}-C1), 3.74 (3H, s, OCH_3), 3.69 (1H, dd, J_{AB} = 12.4 Hz, J_w = 2.4 Hz, H_{eq}-C1), 3.45 (1H, m, H-C9), 2.05 (1H, m, H-C4), 2.05 (3H, s, SCH_3), 2.01 (1H, m, H_{eq}-C3), 1.97 (1H, dd, J_{AB} = $J_{a,a}$ = 12.1 Hz, H_{ax}-C3), 1.90–1.0 (9H, m), 0.93 (3H, d, J = 6.3 Hz, H_3C-C4), 0.90 (3H, t, J = 7.4 Hz, H_3-C11). *Mol. Wt.* (ms) calcd. for $C_{15}H_{26}O_4S$: 302.1550; found: 302.1550.

Equatorial sulfide derivative **6***b*: ir ($CHCl_3$): 1725, 1460, 1440, 1320, 1240, 1075, 1015 cm^{-1}; nmr ($CDCl_3$) δ: 4.09 (1H, dd, J_{AB} = 10.9 Hz, J_w = 2.8 Hz, H_{eq}-C1), 3.80 (3H, s, OCH_3), 3.61 (1H, d, J_{AB} = 10.9 Hz, H_{ax}-C1), 3.45 (1H, m, H-C9), 2.13 (1H, ddd, J_{AB} = 12.4 Hz, $J_{e,a}$ = 3.4 Hz, J_w = 2.8 Hz, H_{eq}-C3), 2.07 (3H, s, SCH_3), 1.80 (1H, m, H-C4), 1.74 (1H, dd, J_{AB} = $J_{a,a}$ = 12.4 Hz, H_{ax}-C3), 1.86–1.02 (8H, m), 0.95 (3H, t, J = 7.3 Hz, H_3-C11), 0.92 (3H, d, J = 6.5 Hz, H_3C-C4); ms *m/e*: 302 (M^+).

Phenyl sulfide derivatives **6**a *and* **6**b (E = PhS)

To a solution of anion derivative, at −78°C, prepared as described from spiroketal monoester **4** (162 mg, 0.633 mmol) (*vide supra*) was added dropwise a solution of diphenyldisulfide (413 mg, 1.89 mmol) in tetrahydrofuran (2 mL). The mixture was stirred for 30 min at −78°C, then hydrolyzed with ammonium chloride solution and extracted with methylene chloride (4 × 25 mL). The crude product was purified by flash chromatography (hexane:ether, 92:8) to give axial thiophenyl ester **6***a* (E = PhS) (1.5 mg, 0.6%, less polar) and equatorial thiophenyl ester **6***b* (E = PhS) (216 mg, 94%, more polar).

Study on the enolization of alkylation of *cis* and *trans* 2-*tert*-5-X-1,3-dioxanes (X = CO_2CH_3, CHO, COPh, NO_2, and CN). Evidence for stereoelectronic control

ALEXIS NDIBWAMI[1] AND PIERRE DESLONGCHAMPS

Laboratoire de synthèse organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received February 6, 1986

ALEXIS NDIBWAMI and PIERRE DESLONGCHAMPS. Can. J. Chem. **64**, 1788 (1986).

Alkylation of 2-*tert*-butyl-5-X-1,3-dioxanes (X = CO_2CH_3, COPh, and NO_2) was studied. Products resulting from an equatorial approach of the alkylating agent are preferentially formed when X = CO_2CH_3 and NO_2. Also, the *cis* isomers that have an equatorial hydrogen at C-5 were found to deprotonate at a faster rate than the *trans* isomers when X = CO_2CH_3, COPh, CHO, and CN. These results are compared with those obtained with methyl 2-*tert*-butyl cyclohexane carboxylate and are interpreted by taking into account stereoelectronic principles.

ALEXIS NDIBWAMI et PIERRE DESLONGCHAMPS. Can. J. Chem. **64**, 1788 (1986).

On a étudié l'alkylation des *tert*-butyl-2 X-5 dioxannes-1,3 (X = CO_2CH_3, COPh et NO_2). Les produits résultant d'une approche équatoriale d'un agent alkylant sont préférentiellement formés quand X = CO_2CH_3 et NO_2. Également, les isomères *cis* ayant un hydrogène équatorial en position 5 se déprotonent plus rapidement que les isomères *trans* quand X = CO_2CH_3, COPh, CHO et CN. Ces résultats sont comparés avec ceux obtenus avec le *tert*-butyl-4 carbométhoxy-1 cyclohexane et sont interprétés en tenant compte des principes du contrôle stéréoélectronique.

In the course of our investigation on the formal total synthesis of erythromycin A (1), it was found that the reaction of various electrophiles with the lithium enolate of spiroketal esters such as **1** (Scheme 1) gave the product **3**, having the E group in the equatorial position, as the major isomer (2, 3). We have suggested (2, 3) that this high selectivity might be due to the fact that, for stereoelectronic reasons caused by the presence of the ring oxygen, the electron density of the α face of the ester enolate **2** might be greater than that of the β face. This would be due to the fact that the enolate structure would correspond to a hybrid of enolates **4** and **5**, and that the other possible limiting structure **6** would not be important because it is energetically less favorable than **5**, in which the carbon electron pair is properly aligned to be delocalized in the antibonding orbital of the polar C—O bond (n_C–$\sigma^*_{O—C}$ overlap). As a result, the product resulting from an equatorial approach of the electrophile would be preferentially observed.

This stereoelectronic effect should also exist and likely be more important when two oxygens are present in the same ring, as in 1,3-dioxanes that have an enolizable functional group at C-5. Banks has recently obtained evidence in this respect by reporting (4) the decarboethoxylation of 1,3-dioxane diester **7**, which proceeds with high stereochemical control yielding a mixture of *cis* and *trans* monoesters **8** and **9** in an 87:13 ratio. Thus protonation of the enol ester intermediate that is produced in the decarboethoxylation of 1,3-dioxane diester **7** takes place preferably from the equatorial face, yielding the *cis* isomer **8**. In contrast, he observed that the decarboethoxylation of the corresponding cyclohexane diester **10** was not selective, yielding a ~1:1 ratio of *cis* and *trans* ethyl esters **11** and **12**.

Banks has explained the stereoselectivity in the decarboethoxylation of 1,3-dioxanes on the basis of the work of Klein (5): "attack on the intermediate carbanion **13** (Scheme 1) should be preferentially from the equatorial direction. The HOMO of this carbanion has antibonding interactions on its upper face of the axial non-bonding electron pair on the ring oxygens, producing an accumulation of electron density below the plane of the intermediate." This is an interesting theoretical explanation but our explanation based on the above stereoelectronic effect is also quite attractive.

To further study this problem, we have prepared and studied the alkylation and the relative rate of deprotonation of the *cis* and *trans* isomers of 2-*tert*-butyl-5-X-1,3-dioxane (X = CO_2CH_3, CHO, COPh, CN, and NO_2). We wish to report this work, which is discussed by taking into account stereoelectronic principles.

Results and discussion

Synthesis of starting materials

Formaldehyde was condensed with dimethyl malonate according to the method of Gault and Roesch (6) to give dimethyl bishydroxymethylmalonate (**14**) in 78% yield (Scheme 2). Acetalization (7) of **14** with pivalaldehyde gave the diester **15** (99% yield). Using the method of Krapcho and Weimasster (8), decarbomethoxylation of **15** gave a result similar to that previously observed by Banks (4) with diethyl ester, i.e. 80% yield of a mixture in a 89:11 ratio of *cis* and *trans* methyl esters **17** and **18**. Epimerization of this mixture with sodium methoxide in methanol gave 16.5 and 83.5% of esters **17** and **18** respectively. These two isomers can be separated by chromatography. The more stable isomer **18** was assigned the *trans* configuration and this was confirmed by ^{1}H nmr spectroscopy. In the *cis* isomer **17**, the hydrogen at C-5 shows a septet ($J_{ee} = J_{ea} = 1.3$ Hz) at 2.28 ppm, whereas in the *trans* isomer **18** the same hydrogen appears as a triplet of triplets at 2.94 ppm, with a large coupling constant ($J_{aa} = 11.2$ Hz). The axial orientation of the C-5 hydrogen in ester **18** is characterized by the large coupling constant and also by a low field chemical shift (2.94 ppm), which must be caused by the deshielding of the two axial electron pairs on the oxygen atoms of the dioxane ring.

Reduction of the mixture of esters **17** and **18** with lithium aluminium hydride (9) gave the corresponding mixture of epimeric alcohols, which was oxidized with pyridinium chlorochromate (10) to a nonseparable mixture of aldehydes **19** and **20**. Starting with pure ester **17** gave a mixture of aldehydes **19** and **20** in a 94:6 ratio, whereas pure ester **18** yielded the same products in a 25:75 ratio. Grignard reaction on a mixture of

aldehydes **19** and **20** with phenyl magnesium bromide (11) followed by oxidation with pyridinium chlorochromate gave a mixture (ratio 85:15) of phenyl ketones **21** and **22** that can be separated by chromatography.

The *cis* and *trans* nitriles **23** and **24**, which can be obtained pure by chromatography, were prepared by treating a mixture of isomeric esters **17** and **18** with dimethylaluminium amide (12).

Treatment of nitromethane with paraformaldehyde in tetrahydrofuran–hexamethylphosphoramide (5:1) yielded the bishydroxymethylnitromethane (**16**) in 25% yield. Condensation of **16** with pivalaldehyde gave a mixture (ratio 93:7) of *cis* and *trans* nitro 1,3-dioxanes **25** and **26**, which can be obtained pure by chromatography. Finally, catalytic hydrogenation of 4-*tert*-butyl benzoic acid with platinum oxide gave the corresponding cyclohexane carboxylic acids (13), which on esterification with diazomethane yielded a mixture (74:26) of *cis* and *trans* methyl 4-*tert*-butylcyclohexane carboxylates **27** and **28**. Pure samples of each isomer were obtained by a careful chromatography.

Equilibration

The relative stability of the *cis* and the *trans* isomers of 2-*tert*-butyl-1,3-dioxanes having a functional group X at C-5 was determined by equilibration under basic conditions (CH_3ONa, CH_3OH). The isomeric nitro dioxanes **25** and **26** failed to undergo epimerization under the basic conditions used, the equilibration was carried out under acidic conditions (*p*-TSOH, benzene, reflux) presumably via acetal opening and reclosure. The results are the following: the *cis*:*trans* ratio is 16:84 for X = $COOCH_3$, 18:82 for X = COPh, ~50:50 for X = CHO, 75:25 for X = CN, and 63:37 for X = NO_2. Thus, the *trans* isomer (having an equatorial X group) is more stable when the X group is large (X = COOMe, COPh). No discrimination was observed for the smaller CHO group. The *cis* isomer is more stable when X = CN and NO_2, and the preferred axial orientation for these groups has been previously explained (14) on the basis of solvation, orbital interaction, and charge attraction (for NO_2).

Alkylation

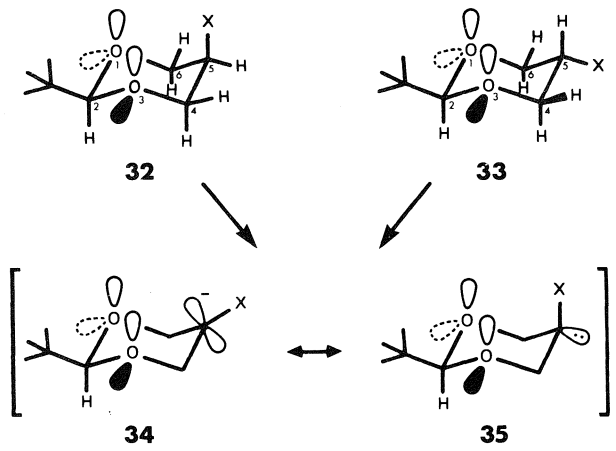
Alkylation was carried out for 2-*tert*-butyl-5-X-1,3-dioxane (X = $COOCH_3$, COPh, and NO_2). The results are summarized in Table 1, which contains also the alkylation of methyl 4-*tert*-butylcyclohexane carboxylate recently reported by Krapcho and Dundulis (15).

The enolates of the methyl esters and phenyl ketones were generated with lithium diisopropyl amide (LDA) at −78°C in tetrahydrofuran or dimethoxyethane and alkylated with methyl iodide and allyl bromide. The enolate of the 5-nitro-1,3-dioxanes was produced with sodium hydride.

The rather high stereochemical control in the alkylation of the enolate ester of 1,3-dioxane (more than 95% of isomer **29** (X = $COOCH_3$, R = CH_3 or allyl)) is the result of an equatorial approach of the alkylating agent and it strongly supports the hypothesis of stereoelectronic control. On the other hand, the very poor selectivity observed with the phenyl ketone (even less than the cyclohexane methyl esters) indicates no stereoelectronic control. In this case, the enolate ion is more stable and thus much less reactive, since it is conjugated with an aromatic ring. This important additional stabilization may render the stereoelectronic effects caused by the ring oxygen comparatively less important at the transition state level because the activation energy of this alkylation process must be higher by comparison with that of the ester enolate. This explanation is also in agreement with the fact that in a reaction having a lower energy of activation, i.e. the deprotonation of the phenyl ketone (or the reverse process), the influence of stereoelectronic effects is then clearly observed (*vide infra*).

Attempts to alkylate the anion of nitro 1,3-dioxanes with methyl iodide or allyl bromide led to starting material and nonidentified products. Alkylation with *p*-nitrobenzyl bromide gave an 80:20 ratio of the "equatorial" and "axial" products **29** and **30** in 62% yield. A secondary product, the enol ether **31** (8% yield), which comes from the elimination of HNO_2 from the alkylated product, was also isolated from this reaction (16). The formation of C-alkylated products is, however, the result of an O-alkylation followed by an intramolecular rearrangement that might be a radical process (17). It is therefore difficult to appreciate the contribution of stereoelectronic effects in this case. However, it was found that quenching the nitro enolate with deuterium oxide led exclusively to the *cis* product **29** (X = NO_2, R = D) having a deuterium atom in the equatorial position.

In conclusion, this limited study indicates that stereoelec-



SCHEME 3

tronic factors may play a determining role only in the alkylation of the 1,3-dioxane ester. The specific equatorial protonation of the nitro enolate suggested, however, that the protonation of enolate or the reverse process, i.e. deprotonation, might be more appropriate processes to show the importance of stereoelectronic effects in the reactivity of enolates with electrophiles.

Deprotonation

If stereoelectronic effects are important at the transition state level for deprotonation, the *cis* isomer with an equatorial hydrogen at C-5 (Scheme 3) ought to be more readily deprotonated than the *trans* isomer, which has an axial hydrogen at C-5. In the *cis* isomers **32**, the equatorial C5—H bond to be broken is antiperiplanar to the polar C4—O3 and C6—O1 bonds, whereas in **33** the axial C5—H bond is antiperiplanar to the nonpolar axial C4—H and C6—H bonds. So, in **32**, the electron pair orbital of the equatorial C5—H bond can be delocalized by an interaction with the antibonding orbital (σ^*) of two polar C—O bonds. This electronic delocalization should therefore increase the acidity of the equatorial C-5 hydrogen, and deprotonation of the *cis* isomer **32** (to give the corresponding enolate anion, which should be a hybrid of **34** and **35**) should proceed at a faster rate than that of the *trans* isomer **33**.

The relative rate of deprotonation of the *cis* and *trans* isomers of 5-*tert*-butyl-1,3-dioxanes (X = $COOCH_3$, COPh, CHO, and CN) is shown in Table 2. Deprotonation of *cis* and *trans* methyl 2-*tert*-butyl cyclohexane carboxylate (**27** and **28**) was also measured. The analysis was made by comparing the time required to achieve 50% of deprotonation in each isomer. This was done by treating each isomer with sodium methoxide in methanol-O-*d* and the reaction was followed by ^1H nmr (250 MHz) spectroscopy. Aliquots were taken until the signal for the proton at C-5 had disappeared. A curve of the percentage of starting material versus time was drawn, from which the time that corresponds to 50% of deprotonation was determined ($t_{\frac{1}{2}}$). The 250-MHz ^1H nmr analysis showed clearly that in the dioxane series (X = $COOCH_3$, COPh, CHO, and CN), starting either with the *cis* or the *trans* isomers, only the *cis* monodeuterated isomers **36** were produced first, and the *trans* monodeuterated isomers **37** appeared slowly and became important only after a long period of time, indicating a large preference for an equatorial protonation of the anion.

The results show that the *cis* isomers are much more acidic than the *trans* isomers, when X = $COOCH_3$, COPh, and CHO, and on that basis, clearly, stereoelectronic effects must play a determining role in the relative acidity of these compounds. The

TABLE 2. Rate of deprotonation and deuterium incorporation

28	*trans*	CH_2	$COOCH_3$	25°C	>8 days

cis nitrile is deprotonated at a slightly faster rate than the *trans* isomer and both are less acidic than the corresponding esters. Thus the type of stereoelectronic effects discussed above does not play a dominant role with nitriles. The *cis* methyl *tert*-butyl cyclohexane carboxylate **27** is also deprotonated at a slightly faster rate than the *trans* isomer **28**, but this can be due to steric effect only or to a combination of steric and less important stereoelectronic effects (due to overlap of the carbon electron pair with the C—C and C—H σ^* antibonding orbital (3)).

The isomeric cyclohexane esters are, however, much less acidic than the corresponding 1,3-dioxane esters, and this striking result indicates that the replacement of two methylene groups by two oxygen atoms in the cyclohexane ring has an enormous influence. This must be due to the inductive effect of the oxygen atoms, which increase the acidity of both the equatorial and axial hydrogen at C-5. The *cis* isomer would, however, be more acidic because in this isomer the equatorial C5—H bond is appropriately aligned in space (antiperiplanar to the C—O bonds) for an additional electronic delocalization.

We have already described that the enolate of the 5-nitro 1,3-dioxanes is protonated exclusively from the equatorial side. It can therefore be concluded that the protonation and deprotonation of 1,3-dioxanes having a functional group at C-5 take place with a very high degree of stereochemical control, and that these results can be taken as evidence that stereoelectronic effects play a key role in these processes.

Experimental

The infrared (ir) spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nuclear magnetic resonance (^1H nmr) spectra were recorded on a Bruker WP-60, a Bruker WP-80, or a Bruker WM-250 instrument. Chemical shifts are reported in δ values (ppm) relative to tetramethylsilane or chloroform as internal standard.

Carbon nuclear magnetic resonance (^{13}C nmr) spectra were recorded on a Bruker WM-250 instrument. Melting points were determined on a Rinco M-50 apparatus, and are not corrected. Gas–liquid chromatography (glc) analysis was done on a Varian Aerograph 2868 or a Gas Chromatograph 5710A. The mass spectra (ms) were recorded on a VG Micromass ZAB-1F mass spectrometer.

Reactions were carried out under nitrogen or argon. Anhydrous magnesium sulfate was used as the drying agent in work-up of reactions.

*Dimethyl bishydroxymethylmalonate (**14**)*

To a mixture of potassium carbonate (1.25 g, 9 mmol) in water (4 mL) and 37% formalin (125 mL, 1.66 mol) was added methylmalonate (87.5 mL, 0.76 mol) in portions of 10 mL with agitation in a cold water bath. The solution was stirred at room temperature for 1 h, then a saturated aqueous solution of ammonium sulfate was added and the mixture extracted with ether. The aqueous layer was saturated with solid ammonium sulfate, and extracted again with ether followed by ethyl acetate. Drying and evaporation of the combined organic layers gave the diol **14** (115.6 g, 78%) after crystallization in ethyl acetate; mp 77–78°C; ir ($CHCl_3$): 3570, 3020, 2960, 1730, and 1040 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.11 (4H, s, —CH_2OH), 3.79 (6H, s, —OCH_3), 2.85 (2H, br, —OH).

*2-tert-Butyl-1,3-dioxane-5,5-dicarboxylic acid dimethyl diester (**15**)*

Pivalaldehyde (12 mL, 0.11 mol), diol **14** (19.2 g, 0.1 mol), *p*-toluenesulfonic acid (0.8 g), and benzene (70 mL) were placed in a flask equipped with a Dean–Stark trap. The reaction mixture was kept at reflux temperature for 4 h, after which approximately 1.6 mL of water was removed. After cooling at room temperature, anhydrous sodium acetate (0.7 g) was added and the mixture stirred for 20 min. After filtration, the solution was diluted with ether and washed three times with water. Drying and evaporation of the organic phase gave pure diester **15** (25.8 g, 99%), which crystallized in hexane – ethyl acetate (2:8); mp 79°C; ir ($CHCl_3$): 3020, 2960, and 1735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.7 (2H, d of t, J = 11.46 Hz, 1.45 Hz, —OCH_2—, equatorial protons), 4.10 (1H, s, C2-H), 3.88 (2H, d of t, J = 11.46 Hz, 1.45 Hz, —OCH_2—, axial protons), 3.83 (3H, s, —OCH_3, axial ester), 3.71 (3H, s, —OCH_3, equatorial ester), 0.87 (9H, s, *tert*-butyl).

Cis *and* trans *2-tert-butyl-1,3-dioxane-5-carboxylic acid methyl esters (**17** and **18**)*

Lithium chloride (0.848 g, 20 mmol), water (0.54 g, 30 mmol), and diester **15** (2.6 g, 10 mmol) in 25 mL of dimethyl sulfoxide were mixed in a flask that was heated on an oil bath at 140–145°C for 4 h. The cooled solution was then poured into ice water, saturated with sodium chloride, extracted with hexane (5 × 30 mL), and the combined organic layers dried. An aliquot was analyzed by glc (column 5 ft × $\frac{1}{4}$ in. 5% FFAP on Chromosorb W; 60–80 mesh, 180°C), and showed 89% of *cis* isomer **17** and 11% of *trans* isomer **18**. Separation on silica gel with 5% ethyl acetate – hexane gave isomers **17** (1.44 g) and **18** (180 mg) in 80% combined yield. Cis *isomer **17**:* mp 35°C; ir ($CHCl_3$): 3000–2860 and 1735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.59 (2H, d of q, J = 11.8 Hz, 2.7 Hz, 1.4 Hz, —OCH_2—, equatorial protons), 4.12 (1H, s, C2-H), 3.84 (2H, d of q, J = 11.8 Hz, 3.1 Hz, 1.4 Hz, —OCH_2—, axial protons), 3.79 (3H, s, —OCH_3), 2.28 (1H, sept, J = 1.4 Hz, C5-H), 0.88 (9H, s, *tert*-butyl). Trans *isomer **18**:* mp 50–51°C; ir ($CHCl_3$): 3020–2880 and 1735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.37 (2H, apparent d of d of d, J = 11.7 Hz, 4.8 Hz, 1.4 Hz, —OCH_2—, equatorial protons), 4.03 (1H, s, C2-H), 3.75 (2H, apaprent d of d of d, J = 12.4 Hz, 10.5 Hz, 1.5 Hz, —OCH_2—, axial protons), 3.68 (3H, s, —OCH_3), 2.94 (1H, t of t, J = 12.3 Hz, 11.2 Hz, 4.7 Hz, C5-H), 0.91 (9H, s, *tert*-butyl).

Cis *and* trans *2-tert-butyl-5-formyl-1,3-dioxanes (**19** and **20**)*

Esters **17** and **18** (89:11 mixture) (2.63 g, 13 mmol) in ether (20 mL) were added during 1 h with stirring to a suspension of lithium aluminium hydride (2 g, 54 mmol) in ether (80 mL) at 0°C. The reaction mixture was stirred for an additional half-hour at room temperature. Saturated aqueous sodium sulfate solution (20 mL) was added at −40°C, and the mixture was poured into a saturated aqueous ammonium chloride solution (100 mL) and extracted with ether. The aqueous layer was filtered and the solution extracted with methylene chloride. The combined organic layers were dried and the solvents evaporated to afford, after flash chromatography with 40% ethyl acetate – hexane, 1.8 g (80%) of alcohol. Pyridinium chlorochromate (3.12 g, 14.5 mmol) and powdered molecular sieves 3 Å (3.35 g) were suspended in methylene chloride (50 mL). The above alcohol (1.68 g, 9.64 mmol) in methylene chloride (10 mL) was added and the reaction mixture stirred at room temperature for 1 h, then diluted with ether and filtered on Florisil. This afforded after evaporation a mixture of aldehydes **19** and **20** (1.39 g, 84%). A pure analytical sample of isomer **19** was obtained by fractional crystallization. *Isomer **19**:* mp 44–45°C; ir ($CHCl_3$): 2960, 2920, 2860, 1725, and 1150 cm^{-1}. ^1H nmr ($CDCl_3$) δ: 9.96 (1H, d, J = 0.7 Hz, —CHO), 4.55 (2H, d of t, J = 10.6 Hz, 1.4 Hz, —OCH_2—, equatorial protons), 4.15 (1H, s, C2-H), 3.95 (2H, d of m, J = 11 Hz, —OCH_2—, axial protons), 2.04 (1H, sept, J = 1.3 Hz, C5-H), 0.86 (9H, s, *tert*-butyl). *Isomer **20**:* ^1H nmr ($CDCl_3$) δ: 9.60 (1H, d, J = 1 Hz, —CHO), 4.34 (2H, d of d of d, J = 11.8 Hz, 4.7 Hz, 1.5 Hz, —OCH_2—, equatorial protons), 4.00 (1H, s, C2-H), 3.71 (2H, apparent t of d, J = 13 Hz, 10.5 Hz, 1.5 Hz, —OCH_2—, axial protons), 3.03 (1H, t of t of d, J = 13 Hz, 11 Hz, 4.7 Hz, 1.2 Hz, C5-H), 0.89 (9H, s, *tert*-butyl).

Cis *and* trans *2-tert-butyl-5-phenylketone-1,3-dioxanes (**21** and **22**)*

To a stirred solution of phenylmagnesium bromide (2.96 mL, 2.9 *M* in ether, 8.58 mmol) in ether (40 mL) at 0°C was added dropwise a solution of a mixture of aldehydes **19** and **20** (738 mg, 4.29 mmol) in anhydrous ether (5 mL). The reaction mixture was stirred for an additional 2 h at 0°C. Water (10 mL) was added, and the reaction mixture was allowed to warm to room temperature and then extracted with ether. The organic layer was dried and the ether evaporated to give, after flash chromatography with 20% ethyl acetate – hexane, 1.04 g (97%) of alcohol. Pyridinium chlorochromate (1.734 g, 8 mmol) and powdered molecular sieves 3 Å (2 g) were suspended in methylene chloride (150 mL). The above benzyl alcohol (1 g, 4 mmol) in methylene chloride (10 mL) was added and the mixture stirred at room temperature for 8 h. The solution was diluted with ether and filtered on Florisil. Separation on silica gel (1% acetone–chloroform) gave isomer **21** (85%) and isomer **22** (15%) (862 mg, 86.5% yield). *Isomer **21**:* mp 158–159°C; ir ($CHCl_3$): 3010, 2960, 2860, 1690, 1600, and 1150 cm^{-1}; ^1H nmr ($CDCl_3$): δ: 7.80–7.48 (5H, m, —C_6H_5), 4.58 (2H, d of q, J = 10.5 Hz, 1.3 Hz, —OCH_2—, equatorial protons), 4.14 (1H, s, C2-H), 4.05 (2H, d of d of t, J = 11.1 Hz, 3.7 Hz, 1.5 Hz, —OCH_2—, axial protons), 3.1 (1H, m, C5-H), 0.87 (9H, s, *tert*-butyl). *Isomer **22**:* mp 101–102°C; ^1H nmr ($CDCl_3$) δ: 7.97–7.50 (5H, m, —C_6H_5), 4.31 (2H, d of d of d, J = 11 Hz, 4.3 Hz, 1.8 Hz, —OCH_2—, equatorial protons), 4.13 (1H, s, C2-H), 3.93 (m, C5-H and —OCH_2—, axial protons), 0.94 (9H, s, *tert*-butyl).

Cis *and* trans *2-tert-butyl-5-cyano-1,3-dioxanes (**23** and **24**)*

Preparation of a solution of dimethylaluminium amide

To a solution of trimethylaluminium (15 mL, 2 *M* in toluene) in dry methylene chloride (5 mL) was added excess of ammonia (~10 mL) distilled from sodium. When the addition of ammonia was complete, the solution was stirred at room temperature until no more gas evolution. This makes an approximately 1.5 *M* solution of dimethylaluminium amide. A solution of a mixture of esters **17** and **18** (101 mg, 0.5 mmol) in dry xylene (20 mL) was treated with dimethylaluminium amide (700 μL, 1.05 mmol). The mixture was refluxed for 20 h, then cooled and treated with water (10 mL). The aqueous layer was extracted with ethyl acetate. The combined organic layers were dried and the solvents were evaporated under reduced pressure to give *cis* nitrile **23** (41.4%) and *trans* nitrile **24** (13%), after separation on silica gel with 5% ethyl acetate – benzene. *Isomer **33**:* mp 100–101°C; ir ($CHCl_3$): 2980, 2860, and 2245 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.30 (2H, d of q, J = 11.9 Hz, 1.4 Hz, —OCH_2—, equatorial protons), 4.12 (1H, s, C2-H), 3.86 (2H, d of q, J = 11.6 Hz, 2.7 Hz, 1.3 Hz, —OCH_2—, axial protons), 2.57 (1H, sept, J = 1.3 Hz, C5-H), 0.94

(9H, singlet, *tert*-butyl). *Isomer **24**:* mp 118–119°C; ^{1}H nmr ($CDCl_3$) δ: 4.36 (2H, d of d, J = 11.5 Hz, 4.7 Hz, 1.5 Hz, —OCH_2—, equatorial protons), 4.10 (s, C2-H), 3.79 (2H, d of d of d, J = 12 Hz, 11.4 Hz, 1.5 Hz, —OCH_2—, axial protons), 3.03 (1H, t of t, J = 11.2 Hz, 4.7 Hz, C5-H), 0.88 (9H, s, *tert*-butyl).

*Bishydroxymethylnitromethane **16***

n-Butyllithium (19 mL, 1.56 *M* in hexane, 28.9 mmol) was added to a solution of nitromethane (780 μL, 14.43 mmol) in tetrahydrofuran–hexamethylphosphoramide (5:1). The mixture was stirred for 1 h at −78°C, then paraformaldehyde (1 g) was added in one portion and the reaction mixture was heated to room temperature and refluxed for 2 h. After cooling, saturated aqueous ammonium sulfate solution was added and the mixture extracted with ethyl acetate. The aqueous layer was saturated with solid ammonium sulfate and extracted again with ethyl acetate. The combined organic layers were dried and the solvents evaporated to give diol **16** (446 mg, 25.5%); ^{1}H nmr (acetone-d_6) δ: 4.86 (1H, quint, J = 5.9 Hz, CH), 4.56 (2H, br s, OH), 4.00 (4H, d, J = 5.9 Hz, CH_2).

Cis *and* trans 2-tert-*butyl-5-nitro-1,3-dioxanes (**25** and **26**)*

Pivaldehyde (380 μL, 3.5 mmol), trimethyl orthoformate (328 μL, 3 mmol), diol **16** (332 mg, 2.74 mmol), and *p*-toluenesulfonic acid (24 mg) in benzene (100 mL) were refluxed in a flask equipped with a condenser and a Dean–Stark trap. After 5 h the mixture was cooled and sodium acetate was added. After filtration, the solution was diluted with ether and washed with water. The organic layer was dried and the solvents evaporated. Flash chromatography with 40% ethyl acetate – hexane gave *cis* isomer **25** (308 mg, 59.5%) and *trans* isomer **26** (23.5 mg, 4.5%). *Isomer **25**:* mp 112–113°C; ir ($CHCl_3$): 2960, 1555, and 1150 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.88 (2H, d of q, J = 11.8 Hz, 1.3 Hz, —OCH_2—, equatorial protons), 4.18 (1H, s, C2-H), 4.13 (1H, sept, J = 1.3 Hz, C5-H), 4.03 (2H, d of q, J = 11.8 Hz, 1.3 Hz, —OCH_2—, axial protons), 0.87 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 107.95 (C2), 77.45 (C5), 66.25 (C4, C6), 35 (C^{IV} of *tert*-butyl), 24.27 (CH_3 of *tert*-butyl); ms *m/e* (CI methane): 190 (MH^+), 143 (M − NO_2), 132 (M − $C(CH_3)_3$). *Isomer **26**:* ^{1}H nmr ($CDCl_3$) δ: 4.68 (1H, sept, J = 5 Hz, C5-H), 4.55 (2H, d of d of d, J = 11 Hz, 5.1 Hz, 1.5 Hz, —OCH_2—, equatorial protons), 4.07 (1H, s, C2-H), 3.98 (2H, d of d of d, J = 10.7 Hz, 1.4 Hz, —OCH_2—, axial protons), 0.90 (9H, s, *tert*-butyl).

Cis *and* trans *methyl 4*-tert-*butyl cyclohexane carboxylates (**27** and **28**)*

4-*tert*-Butyl benzoic acid (1 g, 5.6 mmol) and platinum oxide (112 mg) were suspended in glacial acetic acid (5 mL) in a hydrogenation apparatus. The mixture, mechanically stirred, was allowed to hydrogenate under hydrogen atmosphere (50 psi (1 psi = 6.9 kPa)) for 3 h at room temperature. The catalyst was removed by filtration and acetic acid evaporated. The resulting crude acid was dissolved in ether and diazomethane added dropwise at 0°C until the yellow coloration persisted. Ether was evaporated to give a mixture (74:26 as shown by glc) of *cis* and *trans* isomers **27** and **28** in a 95% overall yield. Analytically pure samples of each isomer were obtained by flash chromatography with 4% ethyl acetate – benzene. *Isomer **27**:* ir ($CHCl_3$): 2960, 2870, and 1740 cm^{-1}: ^{1}H nmr ($CDCl_3$) δ: 3.68 (3H, s, —OCH_3), 2.62 (1H, m, C1-H), 2.20–1.42 (4H, m, —CH_2—, equatorial protons), 1.60–1.10 (5H, m, C4-H and —CH_2—, axial protons), 0.82 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 175.59, 51.22, 47.96, 38.91, 32.40, 27.96, 27.36, and 23.79. *Isomer **28**:* ^{1}H nmr ($CDCl_3$) δ: 3.65 (3H, s, —OCH_3), 2.20 (1H, t of t, J = 12.6 Hz, 11.2 Hz, 3.7 Hz, C1-H), 2.14 (4H, m, —CH_2—, equatorial protons), 1.85–0.99 (5H, m, C4-H and —CH_2—, axial protons), 0.84 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 176.6, 51.3, 47.38, 43.43, 32.33, 29.52, 27.41, and 26.55.

2-tert-*Butyl-5-carbomethoxy-5-methyl-1,3-dioxanes (**29** and **30**)*

n-Butyllithium (900 μL, 1.7 *M* in hexane, 1.5 mmol) was added to a solution of diisopropylamine (210 μL, 1.5 mmol) in anhydrous tetrahydrofuran (10 mL) at 0°C and the mixture stirred for 30 min. The temperature was lowered to −78°C and ester **17** (89:11 mixture with isomer **18**) (101 mg, 0.5 mmol) in anhydrous tetrahydrofuran (1 mL) was added via a cannula. The reaction mixture was stirred for 1 h and methyl iodide (130 μL, 2 mmol) was added. The stirring was continued at −78°C for 30 min (reaction monitored by thin-layer chromatography). Saturated aqueous ammonium chloride solution (5 mL) was added and the mixture stirred at room temperature. The solution was extracted with ether, the organic layer washed with saturated aqueous sodium thiosulfate solution, dried, and the ether was evaporated. Gas–liquid chromatographic analysis showed methyl equatorial isomer **29** (98%) and methyl axial isomer **30** (2%) in 70% yield. The isomers were separated by flash chromatography with 20% ethyl acetate – hexane. *Isomer **29**:* mp 93–94°C; ir ($CHCl_3$): 2990–2860, 1738, and 1130–1100 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.47 (2H, d, J = 11.2 Hz, —OCH_2—, equatorial protons), 4.06 (1H, s, C2-H), 3.76 (3H, s, —OCH_3), 3.37 (2H, d, J = 11.3 Hz, —OCH_2—, axial protons), 0.94 (3H, s, —CH_3), 0.87 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 174.86 (C=O), 107.67 (C2), 73.27 (C4, C6), 52.06 (—OCH_3), 42.4 (C5), 34.74 (C^{IV} of *tert*-butyl), 24.48 (CH_3 of *tert*-butyl), 17.57 (CH_3). *Isomer **30**:* mp 56–57°C; ir ($CHCl_3$): 3020–2880, 1730, and 1100 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.01 (1H, s, C2-H), 3.91 (2H) and 3.83 (2H) (two doublets, J_{AB} = 11.1 Hz, —OCH_2—), 3.67 (3H, s, —OCH_3), 1.45 (3H, s, —CH_3), 0.92 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 174.01 (C=O), 107.8 (C2), 72.15 (C4, C6), 51.74 (—OCH_3), 41.01 (C5), 34.75 (C^{IV} of *tert*-butyl), 24.53 (CH_3 of *tert*-butyl), 18.97 (CH_3).

2-tert-*Butyl-5-allyl-5-carbomethoxy-1,3-dioxanes (**29** and **30**)*

n-Butyllithium (900 μL, 1.5 mmol) was added to a solution of diisopropylamine (210 μL, 1.5 mmol) in anhydrous dimethoxyethane at 0°C and the mixture stirred for 45 min. Ester **17** (89:11 mixture with isomer **18**) (101 mg, 0.5 mmol) was added at −78°C via a cannula. The solution was stirred for 1.5 h and allyl bromide (170 μL, 2 mmol) was added. The stirring was continued at −78°C for an additional 1.5 h, after which the mixture was warmed to room temperature. Saturated aqueous ammonium chloride solution (5 mL) was added and the solution extracted with ether. The organic layer was dried and the ether evaporated to give (after purification on silica gel with 20% ethyl acetate – hexane) a mixture (80 mg, 66%) of allyl equatorial isomer **29** (95%) and allyl axial isomer **30** (5%) as determined by glc. Pure analytical samples of each isomer were obtained by preparative gas–liquid chromatography at 130°C. *Isomer **29**:* ir ($CHCl_3$): 3080, 2960, 1730, 1640, and 1125 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.60 (1H, m, olefinic proton), 5.03 (2H, m, olefinic protons), 4.45 (2H, d, J = 11.3 Hz, —OCH_2—, equatorial protons), 4.01 (1H, s, C2-H), 3.71 (3H, s, —OCH_3), 3.40 (2H, d, J = 11.3 Hz, —OCH_2—, axial protons), 2.02 (2H, d, J = 7.1 Hz, —CH_2—CH=CH_2), 0.83 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 173.58 (C=O), 131.14 (—CH=), 118.76 (=CH_2), 107.83 (C2), 72.20 (C4, C6), 51.88 (—OCH_3), 45.93 (C5), 37.1 (—CH_2—), 34.75 (C^{IV} of *tert*-butyl), 24.46 (CH_3 of *tert*-butyl). *Isomer **30**:* ^{1}H nmr ($CDCl_3$) δ: 6.00–4.90 (3H, m, olefinic protons), 4.17 (1H, s, C2-H), 4.01 (3.84 (4H, apparent doublet, J = 10 Hz, —OCH_2—), 3.66 (3H, s, —OCH_3), 2.68 (2H, d, J = 7 Hz, —CH_2—CH=), 0.92 (9H, s, *tert*-butyl); ^{13}C nmr ($CDCl_3$) δ: 172.68 (C=O), 133.13 (—CH=), 118.72 (=CH_2), 107.78 (C2), 70.13 (C4, C6), 51.54 (—OCH_3), 44.7 (C5), 35.97 (—CH_2—), 34.73 (C^{IV} of *tert*-butyl), 24.44 (—CH_3 of *tert*-butyl).

2-tert-*Butyl-5-methyl-5-phenylketone-1,3-dioxanes (**29** and **30**)*

n-Butyllithium (228 μL, 1.55 *M* in hexane) was added to a solution of diisopropylamine (51 μL, 0.35 mmol) in anhydrous tetrahydrofuran (5 mL) at 0°C and the mixture stirred for 1 h, after which the temperature was lowered to −78°C. Phenylketone **21** (35 mg, 0.14 mmol) in anhydrous tetrahydrofuran (3 mL) was added via a cannula and the reaction mixture stirred for 2 h. Methyl iodide (46 μL) was added at −78°C and the reaction stirred at this temperature for 2 h and at room temperature for 14 h. Saturated aqueous ammonium chloride solution (1 mL) was added and the solution extracted with ether. The organic layer was washed with saturated aqueous sodium thiosulfate solution, dried, and the solvents were evaporated. This gave, after flash chromatography with 20% ethyl acetate – hexane, methyl equatorial isomer **29** (50%) and methyl axial isomer **30** (50%) in 65% yield.

Isomer ***29****:* mp 148–149°C; ^{1}H nmr ($CDCl_3$) δ: 7.51 (5H, m, —C_6H_5), 4.71 (2H, d, J = 11 Hz, —OCH_2—, equatorial protons), 4.14 (1H, s, C2-H), 3.47 (2H, d, J = 11 Hz, —OCH_2—, axial protons), 1.07 (3H, s, —CH_3), 0.87 (9H, s, *tert*-butyl); ms *m/e*: 261 (M − H), 247 (M − CH_3), 205 (M − $C(CH_3)_3$). *Isomer* ***30****:* ^{1}H nmr ($CDCl_3$) δ: 7.66–7.49 (5H, m, —C_6H_5), 4.23 (2H, d, J = 11.1 Hz, —OCH_2—, equatorial protons), 4.02 (1H, s, C2-H), 3.86 (2H, d, J = 11 Hz, —OCH_2—, axial protons), 1.68 (3H, s, —CH_3), 0.94 (9H, s, *tert*-butyl); ms *m/e*: 261 (M − H), 247 (M − CH_3), 205 (M − $C(CH_3)_3$).

*2-*tert*-Butyl-5-allyl-5-phenylketone-1,3-dioxanes (****29*** *and* ***30****)*

n-Butyllithium (2.2 mL, 1.55 *M* in hexane) was added to a solution of diisopropylamine (486 μL, 3.4 mmol) in anhydrous tetrahydrofuran (5 mL) at 0°C and the mixture stirred for 1 h, then cooled to −78°C. Phenylketone **21** (280 mg, 1.125 mmol) in anhydrous tetrahydrofuran (5 mL) was added and stirring continued for 2.5 h. Allyl bromide (382.5 μL, 4.5 mmol) was added and the mixture allowed to stir at room temperature for 24 h. After habitual work-up and purification on silica gel with 1% acetone–chloroform, a mixture (202 mg, 61%) of allyl equatorial isomer **29** (60%) and allyl axial isomer **30** (40%) (determined by glc) was isolated. Analytically pure samples were obtained by careful fractional crystallization in hexane. *Isomer* ***29****:* ^{1}H nmr ($CDCl_3$) δ: 7.5 (5H, m, —C_6H_5), 6.5 (3H, m, olefinic protons), 4.71 (2H, apparent doublet, J = 11.6 Hz, —OCH_2—, equatorial protons), 4.13 (1H, s, C2-H), 3.54 (2H, apparent doublet, J = 11.7 Hz, —OCH_2—, axial protons), 2.22 (2H, d, J = 6.5 Hz, —CH_2—CH=), 0.86 (9H, s, *tert*-butyl); ms *m/e*: 288 (M), 231 (M − $C(CH_3)_3$). *Isomer* ***30****:* ^{1}H nmr ($CDCl_3$) δ: 7.50 (5H, m, —C_6H_5), 6.50 (3H, m, olefinic protons), 4.37 (2H, apparent doublet, J = 11.8 Hz, —OCH_2—, equatorial protons), 4.03 (1H, s, C2-H), 3.82 (2H, apparent doublet, —OCH_2—, axial protons), 3.00 (2H, d, J = 7 Hz, —CH_2—CH=), 0.94 (9H, s, *tert*-butyl).

*2-*tert*-Butyl-5-nitro-5-*p*-nitrobenzyl-1,3-dioxanes (****29*** *and* ***30****)*

To sodium hydride (washed from oil with hexane) (16 mg) suspended in anhydrous tetrahydrofuran – dimethylformamide (2:1) (3 mL) was added, at 0°C, nitrodioxane **25** (47.3 mg, 0.25 mmol) in tetrahydrofuran (0.5 mL). The mixture was stirred at room temperature for 1 h, and *p*-nitrobenzyl bromide (108 mg, 0.5 mmol) in tetrahydrofuran (1 mL) was added. The reaction was stirred at room temperature for an additional 2 h. Saturated aqueous ammonium chloride solution was added and the mixture was extracted with ether, the organic layer dried, and the ether evaporated. Separation on silica gel with 4% ethyl acetate – hexane afforded equatorial isomer **29** (49%) and axial isomer **30** (13%). Compound **31** (8%) resulting from elimination of HNO_2 was also isolated. *Isomer* ***29****:* ir ($CHCl_3$) δ: 8.18, 7.30 (4H, m, —C_6H_4—), 4.21 (2H, d of t, J = 10.1 Hz, 1.5 Hz, —OCH_2—, equatorial protons), 4.12 (1H, s, C2-H), 3.93 (2H, d of t, J = 11.6 Hz, 1.5 Hz, —OCH_2—, axial protons), 3.61 (2H, s, —CH_2—$C_6H_4NO_2$), 1.00 (9H, s, *tert*-butyl); ms *m/e*: 323 (M − H), 267 (M − $C(CH_3)_3$). *Isomer* ***30****:* ir ($CHCl_3$): 3020, 2960, 1660, 1520, 1350, and 1130 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 8.21 (2H, d, J = 8.8 Hz, —$C_6H_4NO_2$), 7.47 (2H, d, J = 8.8 Hz, —$C_6H_4NO_2$), 5.15 (2H, s, —CH_2—$C_6H_4NO_2$), 5.15 and 4.46 (2 × 1H, d of t, J = 15.6 Hz, 14.2 Hz, 1.1 Hz, —OCH_2—, equatorial protons), 4.26 (2H, apparent triplet of triplet, J = 14.8 Hz, 14 Hz, 1.1 Hz, —OCH_2—, axial protons), 4.23 (1H, s, C2-H), 0.92 (9H, s, *tert*-butyl). *Compound* ***31****:* ir ($CHCl_3$): 3010, 2960, 2920, 1600, 1520, and 1100 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 8.20 (2H, d, J = 6.8 Hz, —$C_6H_4NO_2$), 7.27 (2H, d, J = 7.1 Hz, —$C_6H_4NO_2$), 6.45 (1H, s, —OCH=), 4.85 (2H, d, J = 13.4 Hz, —OCH_2—), 4.48 (2H, s, —CH_2—$C_6H_4NO_2$), 4.30 (1H, s, C2-H), 0.92 (9H, s, *tert*-butyl); ms *m/e*: 276 (M − H), 220 (M − $C(CH_3)_3$).

Deuterium incorporation, typical example

Sodium metal (6 mg, 0.25 mmol) was dissolved in methanol-O-*d* (2 mL), and ester **17** (50.5 mg, 0.25 mmol) in methanol-O-*d* (2 mL) was added in one portion. Aliquots (250 μL each) were taken at 1, 5, 15, 30, 45 min, and more, quenched by saturated aqueous ammonium chloride solution, and extracted with ether. The organic layer was dried and the ether evaporated. The residue was dissolved in $CDCl_3$ and analyzed (250 MHz ^{1}H nmr).

Study of photocatalytic reaction of methanol with water over Rh-, and Pd-loaded TiO_2 catalysts. The role of added alkali metal cations

SHUICHI NAITO

Research Centre for Spectrochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-Ku, Tokyo, 113, Japan

Received January 31, 1986

SHUICHI NAITO. Can. J. Chem. **64**, 1795 (1986).

The product selectivity of the photocatalytic reaction of methanol with water is changed drastically by the addition of alkali metal cations to Rh- and Pd-loaded TiO_2 catalysts. Over alkali metal cation free catalysts, the main products are 1:1 ratio of H_2 and dimethoxymethane, which is replaced with H_2, methyl formate, and CO_2 over alkali metal cation added catalysts. The role of added alkali metal cations is the stabilization of the reaction intermediate as adsorbed formate instead of adsorbed formaldehyde, which causes the selectivity change from dimethoxymethane to methyl formate.

SHUICHI NAITO. Can. J. Chem. **64**, 1795 (1986).

Lors de la réaction photocatalytique du methanol et de l'eau, la sélectivité des produits change d'une façon drastique par l'addition de cations de métaux alcalins aux catalyseurs de TiO_2 saturés de Rh ou de Pd. Avec des catalyseurs ne contenant pas de cations de métaux alcalins, les produits principaux sont le H_2 et le diméthoxyméthane dans un rapport de 1:1; lorsque des cations de métaux alcalins sont ajoutés aux catalyseurs, les produits il y a formation de H_2, de formate de méthyle et de CO_2. Les cation des métaux alcalins qui sont ajoutés stabilisent l'intermédiaire réactionnel sous la forme d'une formate plutôt que de formaldéhyde adsorbé et ceci provoque le changement de sélectivieé du diméthoxyméthane vers le formate de méthyle.

[Traduit par la revue]

Extensive studies have been carried out to discover effective photocatalysts which convert solar energy into useful chemical compounds. Although many catalytic systems have been reported so far, they are mainly concerned with the efficiency of the photon energy conversion, and the control of the selectivity of the photoreaction has not attracted much attention. For instance, platinized titanium dioxide catalyzes many photoreactions including the decomposition of water (1–4), but the role of platinum tends to be recognized as an electron collector to receive electrons from the conduction band of TiO_2 and reduce the reactants. From the viewpoint of heterogeneous catalysis, it is interesting to modify these electron transfer sites and control the reaction selectivity.

Recently, we have reported that addition of alkali metal cations to Rh-, Pd-, and Pt-loaded TiO_2 catalysts can change the products selectivity of the photoreaction of methanol with water (5). The effect of alkali metal cation was remarkable and the main products changed drastically from H_2 and dimethoxymethane over Rh/TiO_2 to H_2, methyl formate, and CO_2 over $Rh–Na/TiO_2$. In this report, the role of the added alkali metal cations was studied in detail, by comparing the kinetic behaviour of alkali metal cation added catalysts with that of the catalysts free of alkali metal cations.

Experimental

The catalysts were prepared by a conventional impregnation method of precursor salts (5 wt%) onto TiO_2 powder (Aerosil P-25). For catalysts free of alkali metal cations, $RhCl_3$ and $(NH_4)_2PdCl_4$ were used as precursors. To add alkali metal cations, M_3RhCl_6 and M_2PdCl_4 (M = Li, Na, and Rb) type salts were employed.

The pretreatment of the catalysts was carried out as follows: 1 g of the catalyst was spread on the flat bottom of a quartz reaction cell (the area of the exposed catalyst was ca. 30 cm^2 and its depth was 1–2 mm), which was connected to a closed gas circulation system (total volume = ca. 305 cm^3). After evacuation at room temperature, the catalyst was reduced under 40 kPa of H_2 at 773 K for 20 h. Formed water was gathered in the liquid nitrogen cold trap of the circulation system. The dispersion of the reduced catalyst was determined by H_2 adsorption at room temperature (Rh/TiO_2 and $Rh–Na/TiO_2$ catalysts, 30–40% dispersion; and Pd/TiO_2 and $Pd–Na/TiO_2$ catalysts, 5–10% dispersion). The reduced catalyst exhibited photocatalytic activity for the reaction of methanol with water, but the rate was slow and not reproducible. To obtain constant activities, the catalyst was then oxidized under 40 kPa of O_2 at 573 K for 2 h prior to the photoreaction.

The reaction was carried out in the closed gas circulation system mentioned above. A mixture of methanol and water vapour was introduced in the system and the catalyst was irradiated by a 500 W Xe lamp (Ushio UXL500D) through the flat bottom of the reaction cell. In the reaction at room temperature, the reaction cell was air-cooled from the side and kept at 308 K in a stationary state under irradiation. For experiments on the determination of activation energy, the temperature was controlled by putting a bottom-opened furnace around the reaction cell. The products were analyzed by gas chromatography at certain intervals. For H_2 analysis, molecular sieve 13X column was used with Ar carrier at room temperature and for other products, Porapak Q column was used with He carrier at elevated temperatures. The identification of the products was performed by means of mass spectroscopy (UTI 100) as well as infrared spectroscopy (JASCO IRA-2) after the separation of each component by gas chromatography.

Results

Photoreaction over Rh/TiO_2 and Pd/TiO_2 catalysts

When a mixture of methanol and water vapour was introduced onto Rh/TiO_2 or Pd/TiO_2 catalyst under irradiation, a 1:1 ratio of H_2 and dimethoxymethane was formed as shown in Fig. 1. After 6 h, the irradiation was stopped and the reaction mixture was circulated in the closed system overnight without irradiation. No increase of H_2 and dimethoxymethane was observed during the dark reaction. When the catalyst was irradiated again, formation of H_2 and dimethoxymethane was restarted with similar rates as before. To study the dependence of the reaction rate upon the light intensity over Rh/TiO_2, the intensity of the Xe lamp was reduced to 40% using neutral density filter. The initial rates of H_2 and dimethoxymethane formation were changed from 0.074 and 0.082 mmol h^{-1} to 0.030 and 0.032 mmol h^{-1}, respectively. These results indicate that the reaction rates are proportional to the light intensity. The temperature dependence of the reaction was also examined over Rh/TiO_2 and Pd/TiO_2 catalysts. The results in Fig. 2 demonstrate that the rates of H_2 and dimethoxymethane formation were independent of the reaction temperature up to 368 K. Accordingly, it is strongly suggested that the photo-

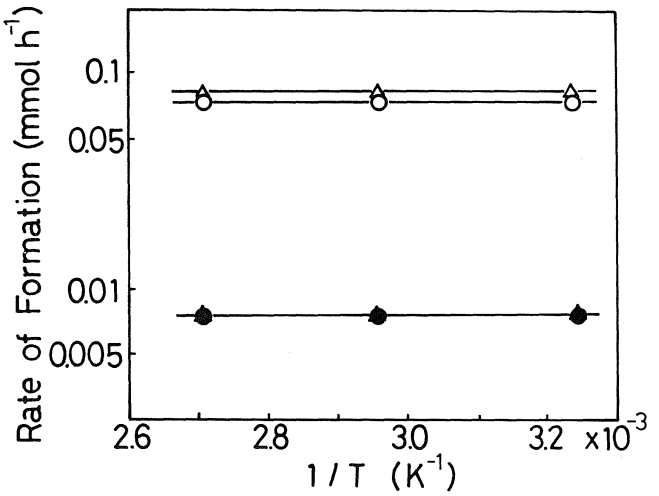

FIG. 2. Temperature dependence of the initial rate of the photocatalytic reaction of methanol with water over Rh/TiO_2 and Pd/TiO_2. (P_{H_2O} = 0.7 kPa, P_{CH_3OH} = 9.0 kPa): ○, H_2 (Rh); △, dimethoxymethane (Rh); ●, H_2 (Pd); ▲, dimethoxymethane (Pd).

excitation of the catalyst is involved in the rate-determining step of this reaction.

The pressure dependence of the reaction rate was examined over Rh/TiO_2 catalyst as shown in Fig. 3. Almost 1:1 ratio of H_2 and dimethoxymethane was formed at any pressure, but the dependency upon the partial pressures of water and methanol was different. In the case of water vapour lower than 1.5 kPa, the rate was proportional to the water pressure and reached a plateau abruptly at higher pressures. No such plateau was observed in the case of methanol, and the rate was of 0.5 order with respect to the partial pressure of methanol up to 15 kPa.

In order to study the role of water, the reaction with pure methanol vapour was attempted on Rh/TiO_2. It was recognized that the rate of H_2 evolution was very slow in the absence of water. This result was supported by the extrapolation to zero pressure of the water pressure dependence in Fig. 3, which shows almost zero rates for H_2 and dimethoxymethane formation.

Photoreaction over Rh–Na/TiO_2 and Pd–Na/TiO_2 catalysts

When a mixture of methanol and water vapour was introduced onto Rh–Na/TiO_2 catalyst under irradiation, H_2, methyl formate, and CO_2 were formed instead of dimethoxymethane as shown in Fig. 4. The ratio of formed products was almost constant during the reaction (in the case of Fig. 4, the ratio was H_2:$HCOOCH_3$:CO_2 = 9:3:1). Similar results were obtained over Pd–Na/TiO_2 catalyst. The dependency of the reaction rate upon the light intensity was studied over Rh–Na/TiO_2 by reducing the intensity of the Xe lamp with neutral filter. When the intensity was reduced to 40%, the initial rate of H_2 formation was changed from 0.082 mmol h^{-1} to 0.030 mmol h^{-1}, indicating almost proportional dependency. The initial rates of methyl formate and CO_2 formation were also changed from 0.016 and 0.008 mmol h^{-1} to 0.006 and 0.003 mmol h^{-1}, respectively.

The temperature dependence of the reaction was examined over Rh–Na/TiO_2 catalyst as shown in Fig. 5. The rate of H_2 formation was slightly dependent on the reaction temperature, and the apparent activation energy was measured as 4 kcal mol^{-1}. The rate of methyl formate formation decreased considerably

Open symbols: dependence of P_{H_2O} (P_{CH_3OH} = 9.0 kPa): ○, H_2; ○, methyl formate; □, CO_2. Closed symbols: dependence P_{CH_3OH} (P_{H_2O} = 0.7 kPa): ●, H_2; ●, methyl formate; ■, CO_2.

at higher temperatures. At the same time, the rate of CO_2 formation increased significantly with temperature, indicating the successive formation of these two products. The rates of CO_2 and methyl formate formation also depend on the alkali metal cations employed. As summarized in Table 1, over sodium- and rubidium-added catalysts, methyl formate was formed in higher amounts than CO_2, but over lithium-added catalyst, CO_2 was the main product even at room temperature.

The pressure dependence of the reaction was examined over $Rh–Na/TiO_2$ catalyst. As for the partial pressure of water, a dependency similar to the one observed in the case of Rh/TiO_2 was obtained. As shown in Fig. 6, the rate of H_2 formation was proportional to the partial pressure of water below 2 kPa, and reached a plateau at higher pressures. The variation of the CO_2 formation rate was similar to the one of H_2 (reaction order = 0.9), but for methyl formate a lower order than in the case of other products (reaction order = 0.6) was observed. The dependence was quite opposite in the case of methanol partial pressure. The reaction order was unity for methyl formate formation, but 0.6 for H_2 and CO_2 formations. The reaction scarcely proceeded when only methanol vapour was introduced on $Rh–Na/TiO_2$ or $Pd–Na/TiO_2$, which is consistent with the result of pressure dependence in Fig. 6.

Discussion

As shown in Figs. 1 and 4, the reaction of CH_3OH with H_2O did not proceed at all without irradiation over Rh-loaded TiO_2 catalyst. No reaction was observed either under dark or irradiation over Rh-loaded SiO_2 catalyst. These results indicate that photoexcitation of TiO_2 is indispensable to initiate the reaction.

[1] $TiO_2 + h\nu \rightarrow e^- + h^+$

Separated electrons and holes diffuse to the different active sites, where they react with H^+ and reducing agents to form

H_2 and oxidized products. In the present reaction, both water and methanol can be reducing agents. But the direct reaction between methanol and holes seems to be negligible on Rh and Pd catalysts, because the photoreaction did not proceed when pure methanol vapour was introduced over these catalysts as mentioned already. Moreover, Figs. 3 and 6 indicate the first order dependence of the reaction rates upon the partial pressure of water on both alkali metal cation added and free catalysts. Accordingly it is reasonable to suppose the photodissociation of weakly physisorbed water molecules to form OH radical as the first step of the reaction:

[2] $H_2O(a) + h^+ \rightarrow H^+(a) + \cdot OH(a)$

[3] $H^+(a) + e^- \rightarrow (1/2)H_2$ (on Rh or Pd)

The existence of such hydroxyl radical on TiO_2 under irradiation has been identified by Jaegar and Bard (6). The rate of H_2 formation was proportional to the light intensity and very little dependent on the reaction temperature. These facts suggest that the rate determining step of this reaction exists in reactions [1] to [3].

Over alkali metal cation free catalysts of Rh and Pd, the main products were H_2 and dimethoxymethane, and their molar ratio was 1:1 under the reaction conditions investigated. This result strongly suggests that the following reactions proceed over these catalysts:

[4] $CH_3OH + \cdot OH(a) \rightarrow HCHO(a) + H_2O + (1/2)H_2$

[5] $HCHO(a) + 2CH_3OH(a) \rightarrow CH_2(OCH_3)_2 + H_2O$

Reaction [4] is the oxidation of adsorbed methanol with OH radical to form adsorbed formaldehyde. Because formaldehyde was not detected at all in the gas phase during the reaction, reaction [5] to form dimethoxymethane should be fast. Actually, when a mixture of formaldehyde and methanol vapour was introduced on these catalysts, rapid formation of dimethoxymethane was observed even under the dark condition as summarized in Table 1.

When alkali metal cations were added to these catalysts, the product selectivity changed drastically and the formation of dimethoxymethane was not observed any more. But when a mixture of formaldehyde and methanol vapour was introduced over alkali metal cation added catalysts under the dark condition, dimethoxymethane was formed rapidly (Table 1). These results suggest that adsorbed formate may be formed directly from methanol under irradiation, without going via formaldehyde.

Similar effect of alkali metal cation addition has been reported on the selective formation of methanol from $CO–H_2$ reaction over similar catalysts. By adding sodium cation to Pd/SiO_2, the rate of methanol formation was accelerated more than 30 times compared to sodium-free catalyst (7). When formaldehyde, methanol, or $CO–H_2$ mixture was introduced over sodium added $Pd–Na/SiO_2$ catalyst, formation of adsorbed formate was observed by infrared spectroscopy, but no such infrared band was observed in the case of sodium cation free Pd/SiO_2 catalyst (8). From the tracer experiments using ^{13}CO and $C^{18}O$, it was demonstrated that active sites for methanol formation contain some surface oxygen O(s) which can stabilize reaction intermediate as formate, and alkali metal cations are effective for the preservation of such surface oxygen (9).

If we can postulate the existence of such surface structure for the alkali metal added catalysts in the present study, following reaction schemes can be proposed:

[6] $CH_3OH + \cdot OH(a) + O(s) \rightarrow HCOO(a) + H_2O + H_2$

[7] $HCOO(a) + \cdot OH(a) \rightarrow HCOOH(a) + O(s)$

[8] $HCOOH(a) + CH_3OH \rightarrow HCOOCH_3 + H_2O$

[9] $HCOOH(a) + \cdot OH(a) \rightarrow H_2O + CO_2 + (1/2)H_2$

Reaction [6] is the oxidation of adsorbed methanol with OH radical, which is similar to reaction [4]. But by the aid of surface oxygen O(s), formate is formed instead of formaldehyde. Stabilized formate may have a chance to be oxidized with another OH radical as shown in reaction [7]. Because no formic acid was detected in the gas phase during the reaction, reaction [8] should be fast, which could be confirmed by the introduction of methanol and formic acid vapour onto these catalysts (Table 1). From the results of Fig. 6, reaction [8] seems to show the first order dependence on the partial pressure of methanol suggesting the participation of weakly adsorbed methanol in this process. At room temperature, this step is much faster than step [9], but at higher temperatures, reaction [9] becomes a main step as indicated in Fig. 5.

By summing up reactions [1] to [9] formally, the following equations can be obtained for each product:

[10] $3CH_3OH \rightarrow H_2 + CH_2(OCH_3)_2 + H_2O$

[11] $2CH_3OH \rightarrow 2H_2 + HCOOCH_3$

[12] $CH_3OH + H_2O \rightarrow 3H_2 + CO_2$

From these equations it is easy to estimate the stoichiometry of the reaction. Equation [10] indicates the formation of H_2 and dimethoxymethane with a 1:1 ratio, which is the case on alkali metal cation free catalysts. Equations [11] and [12] suggest the formation of two hydrogen molecules per methyl formate, and three hydrogen molecules per CO_2 molecule over alkali metal cation added catalysts. Accordingly, if the reactions proposed above are correct, the following relation should be valid between the amounts of formed H_2, methyl formate, and CO_2:

[13] $[H_2] = 2[HCOOCH_3] + 3[CO_2]$

Calculated results according to eq. [13] were summarized in Table 1, which indicates that the proposed reaction schemes are consistent with the experimental results.

In the case of $Pd–Na/SiO_2$ catalyst, it was recognized that active sites for methanol formation may exist only in the vicinity of the palladium metal particle on the support, and their number is rather small (a few percent of the palladium atoms on the surface) (9). This situation seems to be also true in the present study. From the preparation method, it is supposed that formed surface structures are not uniform in both alkali metal cation added and free catalysts. Nevertheless, the effect of alkali metal cation addition was clear and caused a drastic change of the product selectivity over Rh and Pd catalysts, which strongly suggests the specificty of the active sites. As reported already (5), the photocatalytic behaviour of Pt/TiO_2 was considerably different from that of Rh or Pd catalysts in the photoreaction of methanol with water. The effect of alkali metal cation addition was not so clear over Pt/TiO_2, where methyl formate was formed even on the catalyst free of alkali metal cations. It has been also reported that in the case of $Pt–K/TiO_2$ catalyst (2 wt%, prepared by the photodecomposition of K_2PtCl_6), H_2 evolution was observed when only methanol vapour was introduced under irradiation (10, 11). This result suggests the existence of the direct reaction between holes and methanol, which was not the case on Rh and Pd catalysts. The explanation of the different catalytic behaviour with different metals or preparation methods is not clear at present, but they also suggest

the possibility of the selectivity control of the photocatalytic reactions by modifying the structures and chemical properties of the active sites.

A general plan is outlined for disconnection of the polyene macrolides, which is aimed at achieving their syntheses, as well as facilitating the determination of their absolute configurations. The plan is exemplified by amphotericin B, **I**, the only family member of known absolute configuration. The major chiral component is a 20-carbon chain, **III**, which upon further retrosynthetic disconnection leads to three subunits, two of which correspond to the dideoxy hexoses **IV** and **V**. Although these are formally mirror images, they are best represented as the 3,4-dideoxyhexopyranoside, **1**, and the 3,5-dideoxyfuranose, **2**. Syntheses of **1** and **2** from readily available starting materials are described.

DAVID LIANG, HENRY W. PAULS, BERT FRASER-REID, MICHAEL GEORGES, AZEEZ M. MUBARAK et SŁAWOMIR JAROSZ. Can. J. Chem. **64**, 1800 (1986).

On présente un plan général de démembrement des macrolides polyéniques qui a pour but d'en réaliser la synthèse ainsi que de faciliter la détermination de leurs configurations absolues. Utilisant comme exemple l'amphotéricine B, le seul membre de la famille dont la configuration soit connue, on démontre comment le plan peut être opérationalisé. Le composant chiral principal est une chaîne à 20 atomes de carbone, **III**, qui conduit à trois sous-unités par un démembrement rétrosynthétique; deux de ces sous-unités correspondent aux didéoxy hexoses **IV** and **V**. Même si ces sous-unités sont formellement des images mirroirs, leurs meilleures représentations sont le didéoxy-3,4 hexopyrannoside **1** et le diéoxy-3,5 furannose **2**. On décrit les synthèses des composés **1** et **2** à partir de produits de départ facilement accessibles.

[Traduit par la revue]

Introduction

The polyene macrolides comprise a group of approximately 100 members (1), some of which have been in widespread clinical use for over 30 years, mainly for the treatment of yeast and candida infections (2–4), but also as antitumor agents (5) and in prostate therapy (6). Their skeleta are characteristically divided into a conjugated polyene chain (7) (from which the family name is derived), and an array that contains secondary hydroxyl groups in (almost) regular 1,3 relationships. The latter stereochemical feature currently attracts considerable attention (8).

In spite of the remarkable profile based on their clinical importance and unique structural features, the absolute stereochemistry is known for only one member, amphotericin B (**I**), which has yielded a crystalline derivative (9). However, in general, these antibiotics are amorphous, and their sensitivity to a wide variety of chemical reagents, as well as to light, renders chemical proof of structure very difficult. Synthetic activity has been remarkably light in comparison with other types of macrolides; however, the studies spearheaded by Masamune and co-workers (10), Nicolaou and Uenishi (11), Brooks *et al.* (12), and Floyd *et al.* (13) deserve particular note.

Our laboratory has been developing a general program on the polyene macrolides, which should facilitate proof of their structures and stereochemistry, relative and absolute, by a combination of degradative and synthetic studies. Our plans are necessarily based on the only member whose structure is known with certainty, that of amphotericin B, **I**, but there are several structural features that **I** shares with other polyene macrolides, which suggest that a general plan for degradation and (or) synthesis should be possible.

Retrosynthetic analysis

Logical points of disconnection of **I** are termini of the polyene chain (bonds **a** and **b**), and the lactone (bond **c**). The subunits thereby obtained are hexose **II**, and the uronic acid **III**. The regions of the latter designated **d** and **e** do not contain any contiguous chiral centers, and hence are logical sites for further retrosynthetic disconnections, resulting in segments **X**, **Y**, and **Z**.

Segment X

A plausible synthon for segment **X** is the 2,4-dideoxyhexose **IV**, which is conveniently represented as the methyl α-D-pyranoside, **1**.

Segment Y

Interestingly, a synthon for this segment is **V**, which, being the mirror image of **IV**, leads to the pyranoside **V***a*. However, pursuit of this analysis would require the use of an L-sugar, which would be uneconomical for a major synthetic undertaking. A more acceptable chiron (14) is the 3,5-dideoxyfura-

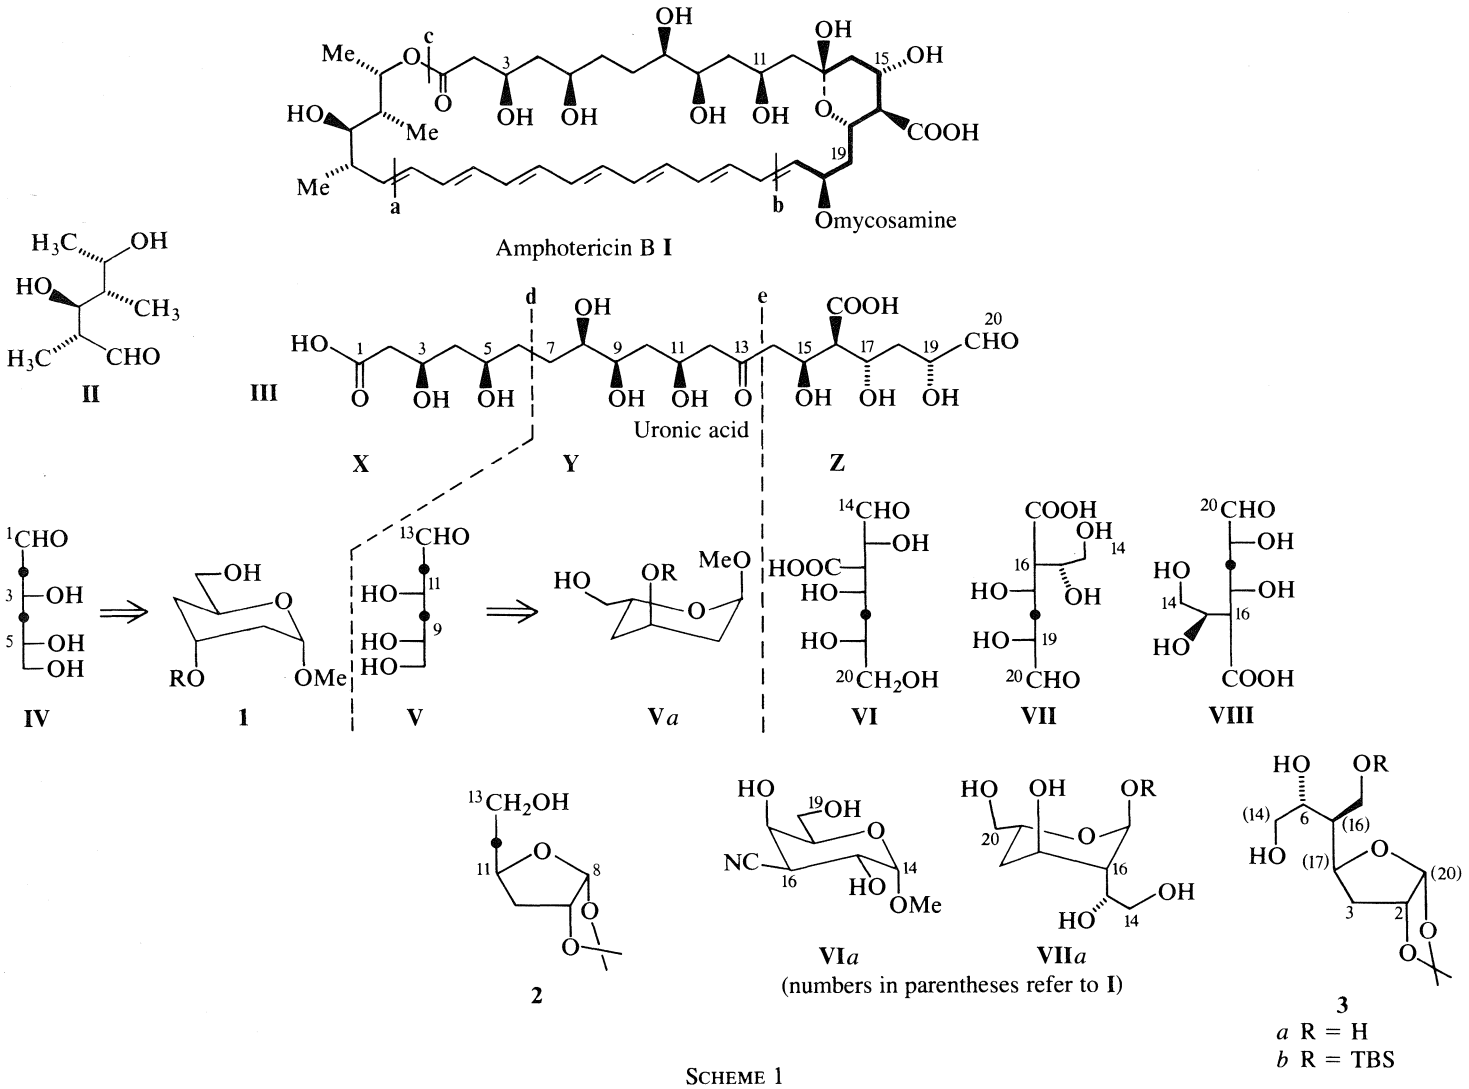


SCHEME 1

nose **2**, whose relationship to 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, **6***a*, is readily appreciated.

Segment Z

The C14—C15 portion is by far the most challenging, and its importance stems from the fact that the hemiketal feature that it represents (shown in heavy lines in **I**) is also found in most polyene macrolides (7). Thus this synthon could find general use in the synthesis of members of this family of macrolides.

The Fisher projections **VI**, **VII**, and **VIII** suggest three possible synthons for this segment. Structure **VI** initially seemed attractive since one approach would be via a 3-*C*-cyano sugar, such as **VI***a*, and although such compounds have been prepared by Guthrie and co-workers (15, 16) and ourselves (17), our preliminary explorations of this avenue did not prove promising.

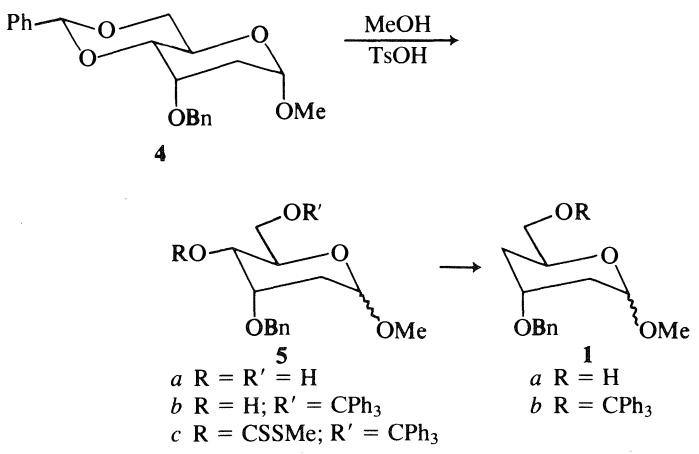
In the case of **VII** and **VIII**, the C-15 stereocenter is "off template" and hence its stereocontrolled formation and verification present special challenges, as noted by us elsewhere (18). Synthon **III** correlates with the L-sugar **VII***a* and was therefore rejected for the reasons discussed above in connection with segment **Y**. Attention was therefore focused on VIII, which correlates with the furanose **3**.

Strategies for connecting the segments, such as olefination procedures and nucleophilic displacements, have been widely utilized in syntheses of macrolides from sugar precursors (14).

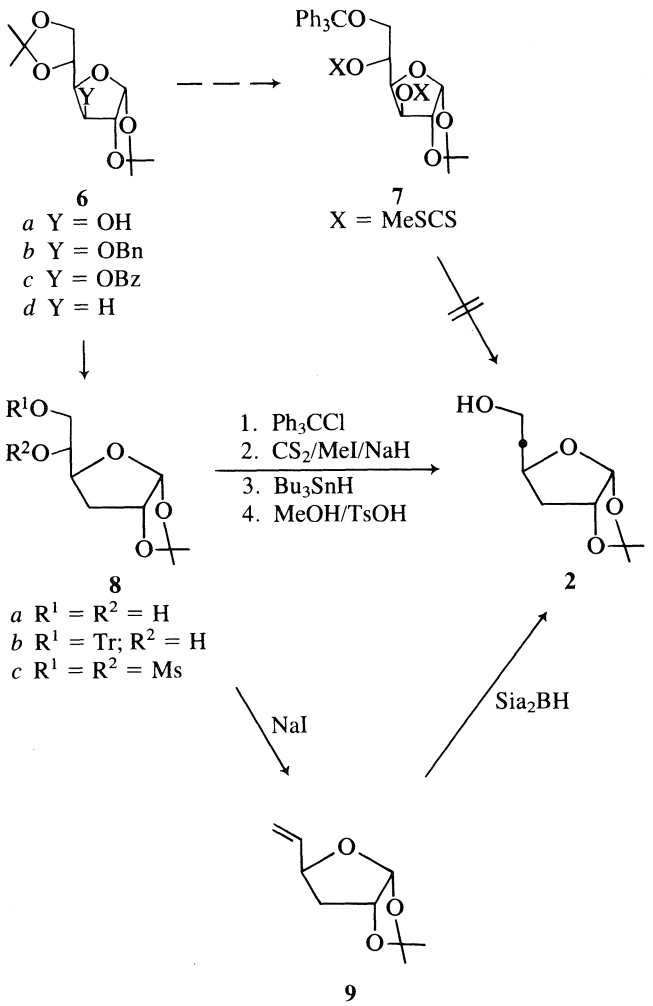
Synthetic studies

Chiron 1

This subunit was prepared routinely from the readily obtained 2-deoxy pyranoside **4** (19), by use of a variation of the procedure of Prugh and Deanna (20*b*). In our hands, unfortunately, acidic hydrolysis of the 4,6-*O*-benzylidene ring could not be accomplished without concomitant anomerisation, leading to



SCHEME 2



SCHEME 3

the α,β mixture **5***a*. Deoxygenation of the alcohol **5***b* was effected by the classical Barton–McCombie (21) procedure.

Chiron 2

The chiron **V** is a 3,5-dideoxy hexose and it seemed most expedient to remove the C-3 and C-5 oxygens simultaneously. However, we were unable to effect double deoxygenation of several doubly activated derivatives **7** (e.g. X = SO_2R, SCimidazoyl, SCSMe) by a variety of procedures. The product in each case was a complex mixture.

The deoxygenations therefore had to be done separately, and the logical starting point was the well-known 3-deoxy derivative **6***d* (21, 22), prepared most conveniently from **6***a* by the Barton procedure (21). Selective hydrolysis of **6***d* afforded the diol **8***a* (21, 22) and the tritylated derivative there of **8***b* was then subjected to the Barton deoxygenation followed by hydrolysis. However, the overall yield of **2** from **8***a* obtained by this route was 60% and so an alternative route was examined.

A more satisfactory yield (~80%) was achieved by hydroboration (23) of the alkene **9**. Of various procedures (24) tested for the preparation of this olefin, the reductive elimination of vicinal disulfonates, originated by Jones and Thomson (24*a*), proved to be the most convenient.

Chiron 3

In our first approach to the synthesis, we had hoped to make use of the alcohol **8***b*. Thus oxidation to **10** and a Horner–Emmons reaction afforded a 4:1 mixture (^{1}H nmr estimate) of the geometric isomers **11***a*. Reduction with DIBAL (diisobutylaluminum hydride) gave the allylic alcohols **11***b*, and hydroboration then led to **12** in excellent overall yield. However, the latter was obtained as a mixture of diastereomers of undetermined composition, as indeed as to be expected in view of the fact that the olefinic precursor, **11***b*, was a mixture of geometric isomers.

The uncertainty about the C-5 and C-6 configurations of **12** was a major problem for us. Our preliminary studies had suggested that, with C-5 alkenes such as **11***b*, the presence of a bulky substituent at C-3 could be used to control the facial selectivity of electrophilic additions. According to this observation, the desired C-5 and C-6 configurations of **3** could *both* be achieved, by ensuring that addition to the C-5 alkene occurred from the *re–re* face of a (*Z*) olefin such as **15**. The corresponding (*E*) olefin, **16**, would give the correct C-5, but incorrect C-6, configuration.

Stereoselective formation of a (*Z*) olefin therefore became the first requirement. The known diol **13***a* (25) was converted into ketone **14** by routine transformations. It was found that reaction with trimethylphosphonoacetate gave an inseparable 6:1 mixture of **15***a* and **16**. However, the corresponding Wittig reagent, carbomethoxymethylenetriphenylphosphorane, afforded **15***a* exclusively. Assignment of structure to these geometric isomers followed from the fact that treatment of each isomer with fluoride ion gave the hydroxyester **15***b* and the butenolide **17**, respectively, based upon their ir (infrared) and ^{1}H nmr spectral characteristics. Compound **15***b*, therefore, had the desired (*Z*) configuration, and hydrogenation over palladium gave two products that were assigned as the hydroxyester **18** and lactone **19***a* since, upon treatment of the mixture with *p*-toluenesulfonic acid for 6 h at room temperature, the more polar component was gradually transformed quantitatively into the less polar product, i.e. **18** → **19***a*.

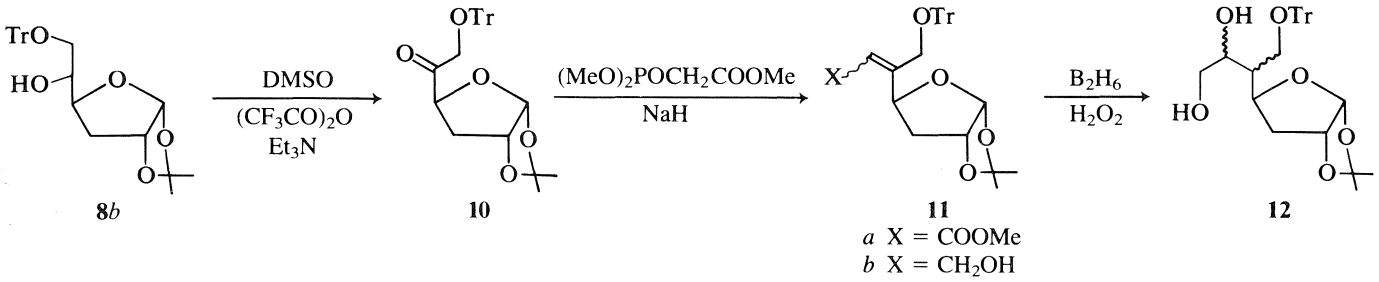
A timely publication by Redlich and Neumann (26) also reported stereocontrolling effects on the hydrogenation of C-5 alkenes and, on the basis of these observations, the C-5 configuration of the lactone was tentatively assigned as shown in **19***a*. This assignment was subsequently established by X-ray analysis of a transformation product (27), and it was therefore apparent that hydrogenation of the double bond of **15** was favored from the *re–re* face. We then hoped to extend this selectivity to hydroboration.

The allylic alcohol **20***a* was obtained by DIBAL reduction of **15***a*, and upon hydroboration a 5:3 mixture of compounds **21** and **22***a* was formed. The structures of these compounds were established as follows. Firstly **21** was treated with thiocarbonyldiimidazole to give the thionocarbonate **23**, which was then reduced with tri-*n*-butyltin hydride according to the Barton–Subramanian procedure (28) to give **22***a*. The latter was hydrogenated over palladium in the presence of formic acid, and the resulting triol **22***b* was acetylated directly to give triacetate **22***c*.

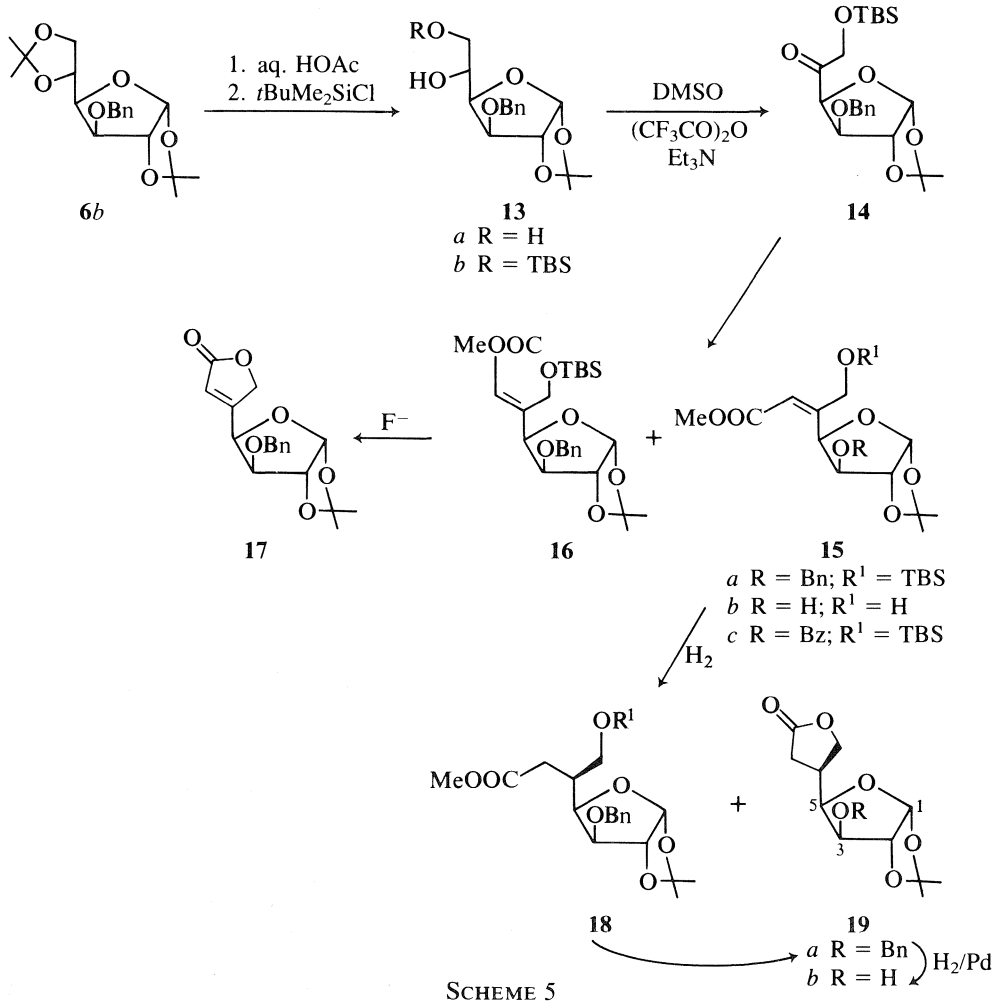
Secondly, compound **19***a* was correlated with **22***c* by hydrogenolysis to give the hydroxylactone **19***b*, which upon reduction and acetylation gave the triacetate **22***c*.

These correlations indicated that the C-5 configurations in **19** and **21** were the same. Given (a) the *Z* configuration of **20** and (b) the mechanism of hydroboration (29), the C-6 hydroxyl configuration must therefore be as shown in **21**.

However, the high proportion of the by-product, **22***a*, was intolerable. This abnormal course of hydroboration responsible for its formation has been observed previously, and the mechanism that has been proposed is shown below (30). It is



SCHEME 4



SCHEME 5

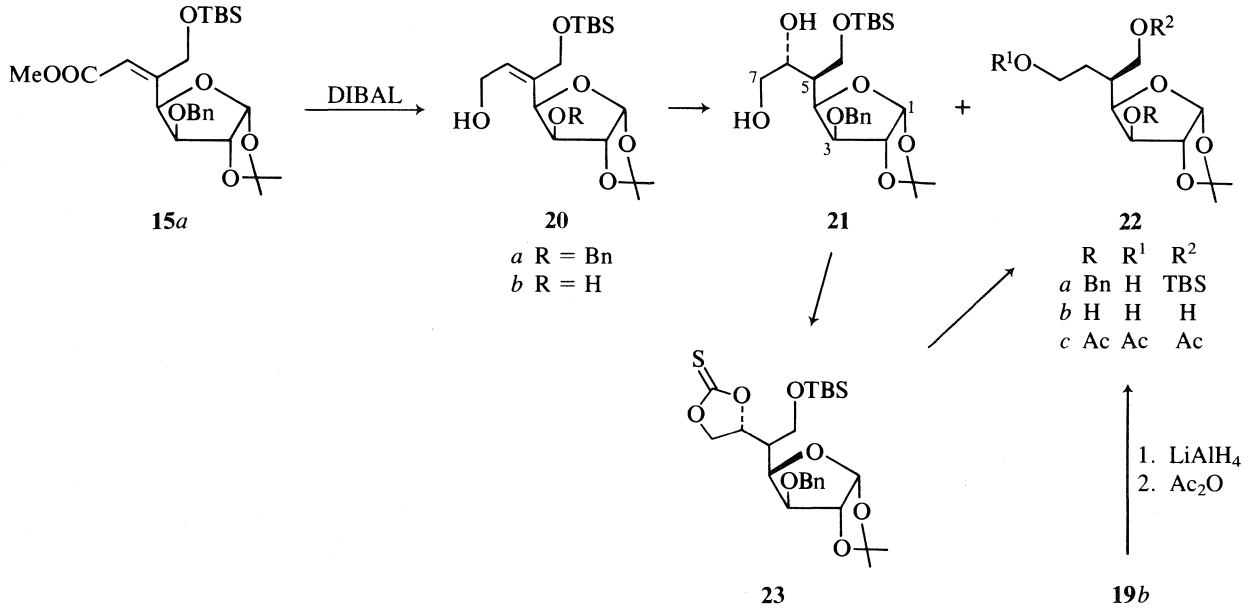
also known that this abnormal reaction can be suppressed by the use of dialkyl boranes, and in the light of this information, the protocol outlined in Scheme 7 was developed.

The germ of the idea (31) was that the reaction of a hindered borane with diol **20**b *would give the bis-boronate ester* **24**. *The bulky C-3 substituent of the latter should insure stereocontrolled approach from the* re–re *face of the double bond, and the bulky C-7 ester should suppress the formation of the abnormal product (such as* **22**). The starting material was the previously described benzoate **15***c* (27) from which **20***b* was readily obtained. Addition of disiamylborane did cause the rapid formation of a less polar product (tlc) presumed to be **24**; however, subsequent reaction was slow and upon work-up the starting material **20***b* was substantially recovered.

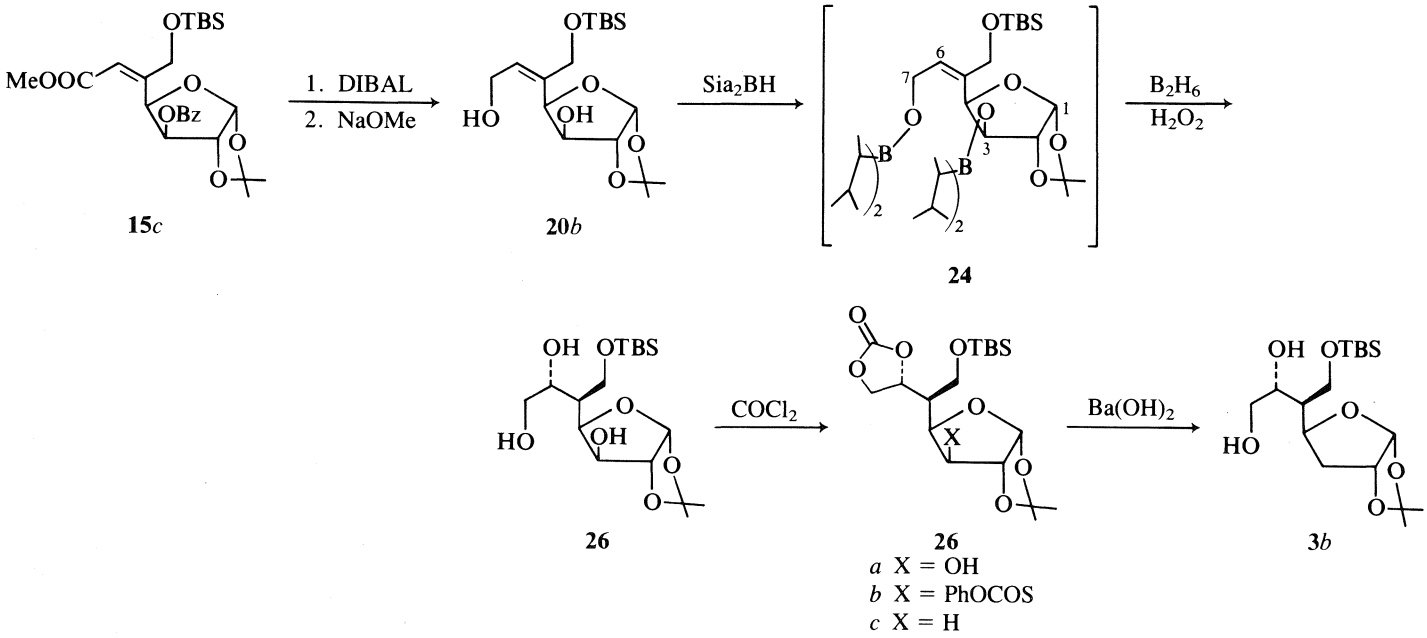
It emerged that the preferred reaction course was to allow **20***b* to stand with five equivalents of disiamylborane for 2 h at −78°C, whereupon complete formation of **24** was evident (tlc). Excess diborane was then added and the mixture was allowed to stand at room temperature, further additions of diborane being made if it was deemed necessary (tlc evidence). After the standard oxidative work-up, the triol **25** was isolated in 80% yield.

To prepare C-3 for deoxygenation selectively, triol **25** was treated with phosgene, which afforded the carbonate **26***a* in near quantitative yield. The Robbins variation (32) of the Barton–McCombie (21) reaction was then applied, affording **26***b* and **26***c* in 82 and 90% yields respectively.

Saponification of the carbonate group then afforded the diol **3***b*. From the numbering sequence shown (see Scheme 1), it is clear that **3***b* is a promising chiron for the hemiketal moiety of



SCHEME 6



SCHEME 7

the polyene macrolides. The compound has been obtained with complete stereoselectivity, and the various functional groups are distinctively differentiated in order to facilitate docking with the other subunits. Studies in this direction are underway and will be reported in due course.

Experimental

General

Melting points were determined in capillary tubes using a Buchi Model 510 melting point apparatus and are uncorrected. Elemental analyses were performed by M-H-W Laboratories, Phoenix, Arizona. The ir spectra were recorded on Perkin–Elmer models 297 and 298 using sodium chloride cells and chloroform as solvent for solids, or sodium chloride plates for thin films of liquids or syrups. Optical rotations were determined at the sodium D line using a Perkin–Elmer 241 polarimeter. ^{1}H nmr spectra were determined on the following spectrometers: Varian EM-360A, Bruker NR-80, Varian XL-100, Varian XL 200, Bruker WM-250, or Bruker-WH-400. Unless otherwise stated the solvent was $CDCl_3$ with internal tetramethylsilane as the standard. The coupling constants were verified by homonuclear decoupling experiments. For the purpose of ^{1}H nmr interpretation, compound structures have been numbered in the schemes. Low resolution mass spectra were obtained using a Hitachi/Perkin–Elmer RMH-2 instrument, and high resolution mass spectra (hrms) were performed at the Research Triangle Park, North Carolina, with a VG7070F instrument. The progress of all reactions was monitored by thin-layer chromatography (tlc), which was performed on aluminum plates precoated with silica gel HF-254 (0.2-mm layers) containing a fluorescent indicator (Merck, 5539), with detection by uv (254 nm), charring with sulfuric acid spray, or charring with a solution of ammonium molybdate(VI) tetrahydrate (12.5 g) and cerium(IV) sulfate tetrahydrate (5.0 g) in 10% aqueous sulfuric acid (500 mL). Flash chromatography was performed using Kiesselgel 60 (230–400 mesh, E. Merck).

*Methyl 3-O-benzyl-2-deoxy-6-O-triphenylmethyl-α,β-D-*ribo*-hexopyranoside (5b)*

A solution of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranoside, **4** (19) (140 g, 0.39 mol), in $CHCl_3$ (700 mL) and

MeOH (700 mL) containing *p*-toluenesulfonic acid (5 g) was refluxed for 3 h. After cooling, the solution was neutralized with triethylamine (5 mL), concentrated *in vacuo*, and the oily residue was chromatographed on silica gel (400 g). Elution with cyclohexane – ethyl acetate (2:1) and EtOAc gave diol **5***a* (84.9 g, 80.5%) as an oil. The material was dissolved in methylene chloride (500 mL) containing triethylamine (70 mL) and triphenylmethyl chloride (87.3 g, 0.31 mmol) and *N,N*-dimethylaminopyridine (2 g) were added. After 15 h stirring at room temperature, the reaction mixture was evaporated *in vacuo*, diluted with ethyl acetate, washed with aqueous saturated NH_4Cl, NaCl, and $NaHCO_3$ solutions, then chromatographed on a silica gel column (1.5 kg). Elution with EtOAc–C_6H_{12} (1:4) gave 140 g (87%) of **5***b* as a syrupy, inseparable mixture of anomers. $[\alpha]_D^{20}$ + 37.3° (*c* 1.1, chloroform); ν_{max} (film): 3510 (OH) cm^{-1}; ^1H nmr (60 MHz) δ: 1.50–2.60 (m, 3H, H-2a, H-2e, OH), 3.42 (s, 3H, OCH_3), 3.20–4.20 (m, 5H, H-3, H-4, H-5, H-6a, H-6b), 4.55 (q, 2H, OCH_2Ph), 4.6 (m, 1H, H-1), 7.00–7.75 (m, 20H, OCH_2Ph, CPh_3). *Anal.* calcd. for $C_{33}H_{34}O_5$: C 77.62, H 6.71; found: C 77.38, H 6.56.

*Methyl 3-*O*-benzyl-2-deoxy-4-*O*-[(methylthio)thiocarbonyl]-6-*O*-triphenylmethyl-α,β-*D*-*ribo*-hexopyranoside (**5**c)*

To a suspension of NaH (12 g, oil free) in tetrahydrofuran (500 mL) was added a solution of compound **5***a* (128 g, 0.25 mol) in tetrahydrofuran (800 mL), and imidazole (1.2 g). The mixture was refluxed for 3 h under argon, and then carbon disulfide (75 mL) was added gradually. After 30 min under reflux methyl iodide (75 mL) was added gradually and, after an additional 2 h, the reaction mixture was cooled and quenched with acetic acid (40 mL), diluted with ethyl acetate, and washed with 3% dilute HCl, $NaHCO_3$, and NaCl solutions, then dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo*. The residue was purified by flash silica gel chromatography to give 140 g (95%) of the thiocarbonate **5***c* as a yellow syrup; R_f 0.54 (15% ethyl acetate – petroleum ether) for the β isomer, 0.44 for the α isomer; ^1H nmr (60 MHz, $CDCl_3$) for the α isomer, δ: 1.66–2.20 (m, 2H, H-2a, H-2e), 2.30 (s, 3H, SCH_3), 2.96–3.34 (m, 2H, H-6, H-6), 3.38 (s, 3H, OMe), 3.96–4.32 (m, 2H, H-3, H-5), 4.50 (s, 2H, $PhCH_2O$), 4.74 (br s, 1H, H-1), 5.86 (dd, 1H, $J_{4,5}$ = 9.6 Hz, $J_{3,4}$ = 4.0 Hz, H-4), 6.93–7.90 (m, 20H, $PhCH_2O$, Ph_3C); for the β isomer, δ: 1.50–2.20 (m, 2H, H-2a, H-2e), 2.34 (s, 3H, SMe), 2.90–3.22 (m, 2H, H-6, H-6), 3.42 (s, 3H, OMe), 4.06–4.35 (m, 2H, H-3, H-5), 4.46 (s, 2H, $PhCH_2O$), 4.78 (dd, 1H, $J_{1,2a}$ = 8.0 Hz, $J_{1,2e}$ = 3.0 Hz, H-1), 5.90 (dd, 1H, $J_{4,5}$ = 9.0 Hz, $J_{3,4}$ = 4.0 Hz, H-4), 6.90–7.70 (m, 20H, $PhCH_2O$, Ph_3C). *Anal.* calcd. for $C_{35}H_{36}O_5S_2$: C 69.97, H 6.04; found: C 69.42, H 6.12.

*Methyl 3-*O*-benzyl-2,4-dideoxy-α,β-*D*-*erythro*-hexopyranoside (**1**a)*

The crude oily xanthate **5***a* (140 g) was dissolved in toluene (1 L) containing 2,2-azobis(2-methylpropionitrile) (250 mg). The solution was added to tributyltin hydride (100 mL) in toluene (0.5 L). The mixture was boiled under argon for 24 h. Additional tributyltin hydride (50 mL) was added, and reflux was continued for 24 h. Concentration *in vacuo* gave a crude mixture, which was diluted with *n*-hexane (150 mL) and extracted with acetonitrile (100 mL × 2). The acetonitrile layer was concentrated *in vacuo*, and chromatographed on a silica gel column. Elution with cyclohexane – ethyl acetate (4:1) gave 120 g of material, which was assumed to be the tritylated derivative **1***b*. To the crude substance was added, directly, methanol (2.5 L) containing *p*-toluenesulfonic acid (5 g), and the mixture was stirred at room temperature for 6 h. The solution was then neutralized with triethylamine (10 mL), concentrated *in vacuo*, and chromatographed on a silica gel column. Elution with cyclohexane – ethyl acetate (4:1, then 1:1) gave 44 g (68%) of the anomeric mixture **1***a*; R_f 0.16 (30% ethyl acetate – petroleum ether); ^1H nmr (60 MHz) δ: 1.20–2.38 (m, 4H, H-2, H-4), 2.80 (br s, 1H, OH), 3.53 (s, 3H, OMe), 3.34–4.25 (m, 4H, H-3, H-5, H-6, H-6′), 4.55 (s, 2H, $PhCH_2$), 4.78 (dd, 1H, $J_{1,2e}$ = 2.0 Hz, $J_{1,2a}$ = 10 Hz, H-1), 7.35 (s, 5H, Ph). *Anal.* calcd. for $C_{14}H_{20}O_4$: C 66.64, H 7.99; found: C 65.80, H 7.89.

*3-Deoxy-1,2-*O*-isopropylidene-6-*O*-triphenylmethyl-α-*D*-hexofuranose (**8**b)*

A mixture of 3-deoxy-1,2-*O*-isopropylidene-α-D-*ribo*-hexofuranose, **8***a* (21, 22) (10.2 g, 50 mmol), triphenylmethyl chloride (14.6 g, 52.5 mmol), and *N,N*-dimethylaminopyridine (500 mg) was dissolved dimethylformamide (120 mL) and stirred at room temperature for 20 h. The reaction mixture was poured into ice water (100 mL) and then extracted with dichloromethane (3 × 200 mL). The combined organic extracts were washed with saturated ammonium chloride solution, water, and brine, dried (Na_2SO_4), and concentrated *in vacuo*. Flash chromatography of the residue afforded 19.6 g (88%) of **8***b*; R_f 0.50 (30% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −15.8° (*c* 1.0, $CHCl_3$); ^1H nmr (80 MHz, $CDCl_3$) δ: 1.32, 1.52 (s, s, 6H, $C(CH_3)_2$), 1.67–2.55 (m, 3H, H-3, H-3′, OH, D_2O exchange), 3.22 (m, 1H, H-5), 3.74–4.50 (m, 3H, H-4, H-6, H-6′), 4.70 (t, 1H, *J* = 3.7 Hz, H-2), 5.78 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1). *Anal.* calcd. for $C_{28}H_{30}O_5$: C 75.31, H 6.77; found: C 75.44, H 6.67.

*3,5,6-Trideoxy-1,2-*O*-isopropylidene-α-D-*erythro*-hex-5-enofuranose (**9**)*

To a solution of the diol **8***a* (78 g, 0.382 mol) in tetrahydrofuran (400 mL) and pyridine (180 mL) was added methylsulfonyl chloride (131 g, 1.146 mol). The mixture was refluxed for 1.5 h and, after cooling, was concentrated *in vacuo*, diluted with ethyl acetate, washed with dilute solutions of HCl, $NaHCO_3$, and NaCl, then dried ($MgSO_4$). Evaporation gave a crude oil that was chromatographed on silica gel to yield compound **8***c* as a crystalline solid (46 g, 33.4%). The material was dissolved directly in butanone (1 L), sodium iodide (60 g, 0.4 mol) was added, and the solution was boiled under reflux overnight. The reaction mixture was diluted with diethyl ether, and washed with solutions of sodium thiosulfate, $NaHCO_3$, and NaCl. After drying over $MgSO_4$, the solution was concentrated *in vacuo* and the residue distilled at 45°C (1 Torr (1 Torr = 133.3 Pa)) to give **9** (15 g, 88%) as an oil; R_f 0.83 (50% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −38.7° (*c* 1.0, $CHCl_3$); ^1H nmr (80 MHz) δ: 1.38, 1.58 (s, s, 6H, $C(CH_3)_2$), 1.60–1.86 (m, 1H, H-3), 2.22 (dd, 1H, *J* = 4.6 Hz, H-3β), 4.66 (m, 1H, H-4), 4.78 (t, 1H, *J* = 3.7 Hz, H-2), 5.14, 5.26, and 5.46 (m, 2H, H-6, H-6′), 5.88 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 5.92 (m, 1H, H-5). *Anal.* calcd. for $C_9H_{14}O_3$: C 63.51, H 8.29; found: C 63.47, H 8.26.

*3,5-Dideoxy-1,2-*O*-isopropylidene-α-D-*erythro*-hexofuranose (**2**)*

(a) Deoxygenation and detritylation of compound **8***b* (646 mg, 13.4 mmol) was carried out as described above for **5***b* → **5***c* → **1***a*. The product **2** (337 mg), obtained in 70% overall yield from **8***b*, was isolated as a colorless oil by chromatography.

(b) To a solution of disiamylborane (4.8 mmol) in tetrahydrofuran was added, dropwise, a solution of **9** (540 mg, 3.18 mmol) in tetrahydrofuran (5 mL) at 0°C under argon. After stirring at room temperature for 3 h, water (1 mL) was added dropwise at 0°C to destroy the excess of the reagent. The reaction mixture was oxidized by addition of 3 *N* sodium hydroxide (2 mL) in one portion and then 30% hydrogen peroxide (2 mL) dropwise, while maintaining the temperature at 20–25°C. After stirring for another 3 h at room temperature, the aqueous phase was saturated with sodium chloride. The tetrahydrofuran phase was separated and the aqueous layer was extracted with ether. The combined organic layers were dried ($MgSO_4$) and concentrated *in vacuo* and the excess water was removed azeotropically with toluene. Flash chromatography afforded compound **2** (537 mg, 90%) as a colorless syrup; R_f 0.20 (50% ethyl acetate – hexane); $[\alpha]_D^{23}$ −8.0° (*c* 1.05, chloroform); ^1H nmr (80 MHz) δ: 1.28, 1.48 (s, s, 6H, $C(CH_3)_2$), 1.60–2.35 (m, 5H, H-3, H-3′, H-5, H-5′, OH, D_2O exchange), 3.75 (m, 2H, H-6, H-6′), 4.33 (m, 1H, H-4), 4.68 (t, 1H, *J* = 3.7 Hz, H-2), 5.78 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1). *Anal.* calcd. for $C_9H_{16}O_4$: C 57.43, H 8.57; found: C 57.21, H 8.61.

*3-Deoxy-1,2-*O*-isopropylidene-6-*O*-triphenylmethyl-α-*D*-erythro-hexofuran-5-ulose (**10**)*

To a solution of dry dimethylsulfoxide (3.9 mL) in dichloromethane (50 mL), trifluoroacetic anhydride (5.8 mL) was added dropwise at −78°C under an argon atmosphere. After 15 min a solution of **8***b* (6.1 g, 13.7 mmol) in dichloromethane (60 mL) was added dropwise over a period of 45 min, and after another hour triethylamine (12 mL) was added dropwise, and the resulting solution was warmed up to

room temperature. The reaction solution was diluted with 200 mL of dichloromethane and then washed with saturated sodium bicarbonate, water, and brine, dried (Na_2SO_4), then concentrated *in vacuo*. Flash chromatography gave 5.8 g (96%) of ketone **10** as a syrup; R_f 0.42 (15% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −1.33° (*c* 1.0, chloroform); ν_{max} ($CHCl_3$): 3000, 1730 cm^{-1}; ^1H nmr (60 MHz) δ: 1.15, 1.35 (s, s, 6H, $C(CH_3)_2$), 1.60 (dd, 1H, J = 4.0 Hz, J = 13.0 Hz, H-3α), 2.20 (dd, 1H, J = 4.0 Hz, H-3β), 3.90 (s, 2H, H-6, H-6′), 4.50 (t, 1H, J = 4.0 Hz, H-2), 4.62 (dd, 1H, J = 5.0 Hz, H-5), 5.62 (d, 1H, J = 4.0 Hz, H-1), 7.20 (m, 15H, Ph_3C). *Anal.* calcd. for $C_{28}H_{28}O_5$: C 75.65, H 6.35; found: C 75.59, H 6.31.

*Methyl 3,5,6-trideoxy-5-*C*-triphenylmethyloxy-1,2-*O*-isopropylidene-α-*D*-*erythro*-hept-5-(*E*,*Z*)-enofuranosyluronate (**11**a)*

To a suspension of 1.0 g (20.8 mmol) of 50% sodium hydride dispersion (prewashed with hexane) in dry benzene (60 mL) was added trimethylphosphonoacetate (2.6 g, 14.3 mmol) at room temperature under an argon atmosphere. After stirring at 35°C for 1 h, a solution of **10** (5.8 g, 13.06 mmol) in dry benzene (60 mL) was added to the reaction flask dropwise at room temperature. After stirring for 2 days the solution was diluted with ether and processed in the usual way. Flash chromatography gave 5.6 g (86%) of **11***a* as an inseparable 4:1 mixture of geometric isomers (based upon the integration of the methoxy peaks); R_f 0.58 (30% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −33° (*c* 1.0, chloroform); ν_{max} ($CHCl_3$): 3000, 1710 (C=O), 1450 cm^{-1}; ^1H nmr (80 MHz) δ: 1.30, 1.58 (s, s, 6H, $C(CH_3)_2$), 1.50 (m, 1H, H-3), 2.53 (dd, 1H, J = 5.0 Hz, J = 13.0 Hz, H-3β), 3.80 (s, 3H, OCH_3), 4.00 (AB, 2H, J = 11.0 Hz, Δδ = 0.13 ppm, H-5, H-5′), 4.64 (t, 1H, J = 3.7 Hz, H-2), 5.63 (d, 1H, J = 3.7 Hz, H-1), 5.84 (dd, 1H, J = 4.4 Hz, J = 5.0 Hz, H-4), 6.45 (m, 1H, H-6), 7.32 (m, 15H, Ph_3C). *Anal.* calcd. for $C_{31}H_{32}O_6$: C 74.38, H 6.44; found: C 74.34, H 6.20.

*3,5,6-Trideoxy-5-*C*-triphenylmethyloxy-1,2-*O*-isopropylidene-α-*D*-*erythro*-hept-5-(*E*,*Z*)-enofuranose (**11**b)*

To a solution of **11***a* (3.5 g, 7 mmol) in diethyl ether, disobutylaluminum hydride (21 mL, 1.0 *M* in toluene) was added dropwise at 0°C under an argon atmosphere. After 4 h, 1 mL of water was added slowly at 0°C, followed by 1 mL of 15% aqueous sodium hydroxide and 3 mL of water. The inorganic salts were removed by filtration and the residue was rinsed with diethyl ether. The combined filtrates were dried ($MgSO_4$) and then concentrated *in vacuo*. Flash chromatography afforded 2.64 g (80%) of the allylic alcohol **11***b* as a white amorphous solid, mp 104–106°C (from ether – petroleum ether); R_f 0.29 (30% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −18.4° (*c* 1.0, chloroform); ^1H nmr (80 MHz) δ: 1.18, 1.38 (s, s, 6H, $C(CH_3)_2$), 1.66–2.20 (m, 3H, H-3, H-3′, OH, D_2O exchange), 3.52 (br s, 2H, H-5, H-5′), 4.16 (d, 2H, J = 7.0 Hz, H-7, H-7′), 4.52 (t, 1H, J = 3.7 Hz, H-2), 4.84 (dd, 1H, J = 4.4 Hz, J = 5.0 Hz, H-4), 5.58 (d, 1H, J = 3.7 Hz, H-1), 5.94 (t, 1H, J = 7.0 Hz, H-6), 7.35 (m, 15H, Ph_3C). *Anal.* calcd. for $C_{30}H_{32}O_5$: C 76.25, H 6.82; found: C 76.06, H 6.61.

*Hydroboration of compound **11**b*

To a solution of diborane (16 mL, 1.0 *M* in tetrahydrofuran), which had been cooled to 0°C, was added a solution of **11***b* (2.5 g, 5.3 mmol) in tetrahydrofuran (20 mL) dropwise over a period of 1 h under an argon atmosphere. After 6 h, 1 mL of water was added slowly, followed by addition of 6 mL of 3 *N* aqueous sodium hydroxide and 6 mL of 30% hydrogen peroxide, maintaining the temperature at 20–25°C. After stirring for another 3 h at room temperature, the aqueous phase was saturated with sodium chloride. The tetrahydrofuran phase was separated and the aqueous layer was extracted with diethyl ether. The combined organic layers were dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The excess of water was removed azeotropically with toluene, after which flash chromatography afforded **12** (2.3 g, 90%) as an amorphous solid; R_f 0.26 (50% ethyl acetate – petroleum ether); ^1H nmr (60 MHz) δ: 1.30, 1.50 (s, s, 6H, $C(CH_3)_2$), 1.70–2.24 (m, 3H, H-3′, H-5), 2.50–3.80 (m, 8H, H-4, H-6, H-7, H-7′, H-5, H-5′, 2 × OH), 4.68 (m, 1H, H-2), 5.75 (br d, 1H, H-1), 7.40 (m, 15H, Ph_3C). *Anal.* calcd. for $C_{30}H_{34}O_6$: C 73.45, H 6.98; found: C 73.38, H 6.93.

*3-*O*-Benzyl-6-*O*-tert-butyldimethylsilyl-1,2-*O*-isopropylidene-α-*D*-glucofuranose (**13**b)*

To a solution of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**13***a*) (25) (17.4 g, 56.13 mmol), *N*,*N*-dimethylaminopyridine (1.0 g), and trimethylamine (23 mL) in dichloromethane (250 mL) was added *tert*-butyl-dimethylsilyl chloride (8.46 g, 56.13 mmol) at room temperature under an argon atmosphere. After 20 h the reaction mixture was poured into 100 mL of ice water, extracted with dichloromethane, and processed in the usual way to give **13***b* (23.1 g, 97%) as a colorless syrup; R_f 0.41 (15% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −24.2° (*c* 1.0, chloroform); ^1H nmr (80 MHz) δ: 0.03 (s, 6H, $SiMe_2$), 0.89 (s, 9H, *t*BuSi), 1.30, 1.46 (s, s, 6H, $C(CH_3)_2$), 2.62 (d, 1H, J = 5.5 Hz, OH), 3.68–4.20 (m, 5H, H-3, H-4, H-5, H-6, H-6′), 4.57 (d, 1H, J = 3.7 Hz, H-2), 4.66 (s, 2H, $PhCH_2$), 5.89 (d, 1H, J = 3.7 Hz, H-1), 7.33 (s, 5H, Ph). *Anal.* calcd. for $C_{22}H_{36}O_6Si$: C 62.23, H 8.55; found: C 62.31, H 8.64.

*3-*O*-Benzyl-6-*O*-tert-butyldimethylsilyl-1,2-*O*-isopropylidene-α-*D*-xylo-hexofuran-5-ulose (**14**)*

Compound **13***b* (23.1 g, 54.48 mmol) was oxidized as described above for **8***b* → **10**. The product **14** (20.7 g, 90%) was a colorless syrup; R_f 0.41 (15% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −91.98° (*c* 1.87, chloroform); ν_{max} ($CHCl_3$): 2950, 1740 (C=O), 1460 cm^{-1}; ^1H nmr (80 MHz) δ: 0.04 (s, 6H, $SiMe_2$), 0.90 (s, 9H, *t*BuSi), 1.30, 1.48 (s, s, 6H, $C(CH_3)_2$), 4.37 (d, 1H, $J_{3,4}$ = 3.5 Hz, H-3), 4.48 (s, 2H, H-6, H-6′), 4.52 (d, 2H, J = 3.5 Hz, $PhCH_2$), 4.58 (d, 1H, $J_{3,4}$ = 3.5 Hz, H-4), 4.88 (d, 1H, J = 3.7 Hz, H-2), 6.02 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 7.25 (s, 5H, Ph). *Anal.* calcd. for $C_{22}H_{34}O_6Si$: C 62.53, H 8.11; found: C 62.62, H 8.15.

*Methyl 3-*O*-benzyl-5-*C*-(tert-butyldimethylsilyloxymethyl)-5,6-dideoxy-1,2-*O*-isopropylidene-α-*D*-xylo-hept-5-(*Z*)-enofuranosyluranote (**15**a)*

A solution of **14** (16 g, 37.9 mmol) and carbomethoxymethylenetriphenylphosphorane (16 g, 50 mmol), in dry acetonitrile (50 mL) under argon, was refluxed for 2 h. Work-up in the usual way afforded **15***a* (15.2 g, 84%) after chromatography; R_f 0.63 (20% ethyl ether – petroleum ether); ν_{max} ($CHCl_3$): 2950, 1740 (C=O, unsaturated ester), 1660 cm^{-1}; ^1H nmr (80 MHz) δ: 0.05 (s, 6H, $SiMe_2$), 0.92 (s, 9H, *t*BuSi), 1.31, 1.50 (s, s, 6H, $C(CH_3)_2$), 3.62 (s, 3H, OCH_3), 4.35–4.73 (m, 6H, H-2, H-3, H-5, H-5′, $PhCH_2$), 5.86 (m, 1H, H-6), 5.95 (d, 1H, $J_{1,2}$ = 3.7 Hz, H-1), 6.17 (m, 1H, H-4), 7.30 (s, 5H, Ph). *Anal.* calcd. for $C_{25}H_{38}O_7Si$: C 62.73, H 8.00; found: C 62.70, H 7.96.

*5-*C*-Hydroxymethyl-5,6-dideoxy-1,2-*O*-isopropylidene-α-*D*-gluco-heptofuranuronic 1′,7-lactone (**19**b)*

To a solution of **15***a* (5.0 g, 10 mmol) in methanol (50 mL) was added ammonium fluoride (0.75 g, 20 mmol) in water (4 mL). The reaction mixture was refluxed for 3 h, cooled, and the methanol removed *in vacuo*. A solution of the residue (**15***b*) in benzene (100 mL) was hydrogenated over 5% platinum on carbon at a starting pressure of 500 psi (1 psi = 6.9 kPa). After 45 min the catalyst was removed by filtration and the filtrate was concentrated *in vacuo* to yield an oil that showed two components (tlc) assigned as **18** and **19***a*. To a solution of the oil in diethyl ether (100 mL) was added *p*-toluenesulfonic acid (120 mg, 0.6 mmol), and after 6 h at 23°C the reaction mixture was quenched with triethylamine, washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to afford 3.4 g (96%) of **19***a*. Debenzylation by hydrogenolysis (10% Pd/C) in ethanol was carried out in the usual way, to give **19***b* (1.9 g, 79%) as a crystalline material, mp 138–139°C; R_f 0.44 (5% methanol – methylene chloride); $[\alpha]_D^{20}$ −47.9° (*c* 0.4, chloroform); ν_{max} ($CHCl_3$): 3400 (hydrogen bonded OH), 2910, 1775 (lactone) cm^{-1}; ^1H nmr (400 MHz) δ: 1.31 (s, 3H, CCH_3), 1.49 (s, 3H, CCH_3), 1.57 (s, 1H, OH), 2.70 (ddd, 2H, H-7, H-7′), 3.00 (q, J = 8.0 Hz, 1H, H-5), 4.09–4.17 (m, 3H, H-3, H-6, H-6′), 4.46 (dd, J = 8.0 Hz, 1H, H-4), 4.50 (d, J = 3.7 Hz, 1H, H-2), 5.91 (d, J = 3.7 Hz, 1H, H-1). *Anal.* calcd. for $C_{11}H_{16}O_6$: C 54.09, H 6.60; found: C 54.14, H 6.76.

*3-O-Benzyl-5-C-(*tert*-butyldimethylsiloxymethyl)-5,6-dideoxy-1,2-O-isopropylidene-α-D-*xylo*-hept-5-(Z)-enofuranose (**20**a)*

Reduction of **15***a* (15.0 g, 31.4 mmol) with diisobutylaluminum hydride was carried out as described above for **11***a* → **11***b*. The product **20***a* (11.6 g, 82%) was a syrup; R_f 0.54 (50% ether – petroleum ether); ^{1}H nmr (80 MHz) δ: 0.05 (s, 6H, $SiMe_2$), 0.90 (s, 9H, *t*BuSi), 1.32, 1.48 (s, s, 6H, $C(CH_3)_2$), 1.75 (t, 1H, J = 5.4 Hz, OH), 3.92 (d, 1H, $J_{3,4}$ = 3.3 Hz, H-3), 4.00–4.28 (m, 4H, two H-7, two H-5′), 4.54 (d, 2H, J = 2.7 Hz, $PhCH_2$), 4.58 (d, 1H, J = 3.7 Hz, H-2), 4.92 (br d, 1H, J = 3.3 Hz, H-4), 5.94 (d and m, 2H, $J_{1,2}$ = 3.7 Hz, H-1, H-6; overlapping), 7.29 (s, 5H, Ph). *Anal.* calcd. for $C_{24}H_{38}O_6Si$: C 63.97, H 8.50; found: C 63.86, H 8.57.

*Hydroboration of compound **20**a (formation of compounds **15** and **16**a)*

Hydroboration of **20***a* (1.72 g, 3.78 mmol) was carried out as described for **11***b* → **12**. Flash chromatography of the product gave **21** (500 mg) and **22***a* (283 mg). For **21**: R_f 0.41 (50% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −42.8° (*c* 0.90, chloroform); ^{1}H nmr (250 MHz) δ: 0.03 (d, 6H, J = 10.4 Hz, $SiMe_2$), 0.80 (s, 9H, *t*BuSi), 1.28, 1.44 (s, s, 6H, $C(CH_3)_2$), 2.20 (m, 1H, H-5), 2.70 (br s, 2H, two OH, D_2O exchange), 3.47 (dd, 1H, $J_{6,7a}$ = 4.3 Hz, J_{gem} = 11.3 Hz, H-7a), 3.70 (d, 2H, J = 5.0 Hz, two H-5′), 3.75 (dd, 1H, $J_{6,7b}$ = 3.0 Hz, J_{gem} = 11.3 Hz, H-7b), 3.84 (d, 1H, $J_{3,4}$ = 2.5 Hz, H-3), 3.98 (m, 1H, H-6), 4.32 (dd, 1H, $J_{3,4}$ = 2.5 Hz, J = 11.3 Hz, H-4), 4.54 (ABq, 2H, J = 11.3 Hz, PhCH_2), 4.60 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-2), 5.90 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1), 7.30 (m, 5H, Ph). *Anal.* calcd. for $C_{24}H_{40}O_7Si$: C 61.51, H 8.60; found: C 61.36, H 8.83.

For **22***a*: R_f 0.67 (50% ethyl acetate – petroleum ether); ^{1}H nmr (250 MHz) δ: 0.03 (d, 6H, $SiMe_2$), 0.82 (s, 9H, *t*BuSi), 1.30, 1.45 (s, s, 6H, $C(CH_3)_2$), 1.82 (m, 2H, two H-6), 2.16 (m, 1H, H-5), 3.40 (dd, 1H, $J_{5,5'a}$ = 5.0 Hz, J_{gem} = 10.0 Hz, H-5′a), 3.56 (dd, 1H, $J_{5,5'b}$ = 2.5 Hz, J_{gem} = 10.0 Hz, H-5′b), 3.69 (t, 2H, J = 5.5 Hz, two H-7), 3.82 (d, 1H, $J_{3,4}$ = 2.5 Hz, H-3), 4.12 (dd and s, 2H, $J_{3,4}$ = 2.5 Hz, $J_{4,5}$ = 10.0 Hz, H-4, OH, D_2O exchange), 4.55 (ABq, 2H, J = 10.0 Hz, PhCH_2), 4.60 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-2), 5.88 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1), 7.28 (m, 5H, Ph). *Anal.* calcd. for $C_{24}H_{40}O_6Si$: C 63.68, H 8.91; found: C 63.56, H 8.83.

*5-C-Acetoxymethyl-3,7-di-O-acetyl-5,6-dideoxy-1,2-O-isopropylidene-α-D-*gluco*-heptofuranose (**22**c)*

(a) Lactone **19***b* (0.123 g, 0.543 mmol) was dissolved in dry ether (25 mL), cooled in an ice water bath, and treated with lithium aluminum hydride (0.067 g, 1.76 mmol). The reaction mixture was warmed to room temperature and stirred, with the exclusion of moisture, for 1 h. Excess lithium aluminum hydride was destroyed with water and the solvent was removed. The residue (**22***b*) was dissolved in dry pyridine (30 mL) and treated with excess acetic anhydride (5 mL) for 1.5 h at room temperature. Work-up in the usual way afforded **22***c* (0.156 g, 76%); R_f 0.40 (50% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −13.6° (*c* 1.1, $CHCl_3$); ^{1}H nmr (250 MHz) δ: 1.28, 1.48 (two s, 2 × 3H, $O_2C(CH_3)_2$), 1.74, 1.97–2.06 (two m, 2H, H-6a, H-6b), 2.01, 2.03, 2.09 (three s, 3 × 3H, 3 × $OCOCH_3$), 2.15 (m, 1H, H-5), 3.91–4.26 (m, 5H, H-4, H-7a, H-7b, H-1′a, H-1′b), 4.46 (d, 1H, H-2, $J_{1,2}$ = 3.7 Hz), 5.14 (d, 1H, H-3, $J_{3,4}$ = 3.2 Hz), 5.84 (d, 1H, H-1). *Anal.* calcd. for $C_{17}H_{26}O_9$: C 54.54, H 7.00; found: C 54.36, H 6.86.

(b) A mixture of compound **21** (530 mg, 1.08 mmol) and 1,1′-thiocarbonyldiimidazole (228 mg, 1.3 mmol) in 20 mL of dry tetrahydrofuran was refluxed under an argon atmosphere for 1 h. The reaction solution was partitioned between diethyl ether (50 mL) and cold 2 *N* hydrochloric acid (10 mL). The organic layer was separated, washed with water and brine, dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo* to give 518 mg (90%) of crude thionocarbonate **23**. A portion of the crude thionocarbonate (388 mg, 0.72 mmol), in tri-*n*-butyltin hydride (424 g, 1.44 mmol), and a catalytic amount of 1,1′-azobis(isobutyronitrile) in 20 mL of dry toluene was added to refluxing toluene over 10 min. After refluxing 3 h the mixture was treated with 5 mL of 10% aqueous sodium hydroxide at 40°C for 12 h. Work-up with the standard processing and flash chromatography provided pure compound **22***a*. A portion of the material (162 mg, 0.36 mmol), a catalytic amount of 10% palladium on activated carbon, and a few drops of 88% aqueous formic acid in 10 mL of methanol were stirred at room temperature under a hydrogen atmosphere. After 6 h the reaction mixture was filtered and evaporated *in vacuo*. The crude residue (**22***b*) was acetylated using the standard procedure, then treated with acetic anhydride and pyridine, to yield compound **22***c* (121 mg, 90%) whose physical properties were identical with those of the material described in part (a).

*5-C-(*tert*-Butyldimethylsiloxymethyl)-5,6-dideoxy-1,2-O-isopropylidene-α-D-*xylo*-hept-5-(Z)-enofuranose (**20**b)*

To a solution of 4.1 g (8.1 mmol) of the ester **15***c* (27) in 100 mL of dry toluene was added 24 mL of 1 *M* diisobutylaluminum hydride in toluene at 0°C, dropwise, over a period of 20 min under an argon atmosphere. After 3 h, tlc indicated that most of the starting material had been consumed. The reaction was quenched by addition of water at 0°C followed by 15% aqueous sodium hydroxide (1 mL) and water (3 mL). After vigorous stirring at room temperature for a few minutes, the white inorganic salts were removed by filtration, the residue was rinsed several times with ethyl acetate, and the combined filtrates were dried over anhydrous magnesium sulfate. The residue from evaporation was dissolved in dry methanol (100 mL) and then treated with a catalytic amount of sodium methoxide at room temperature. The saponification was monitored by tlc and, upon completion, the reaction mixture was poured into ice water and extracted with dichloromethane. The combined extracts were washed with cold dilute hydrochloric acid, saturated sodium bicarbonate, water, and brine, dried over anhydrous sodium sulfate, filtered, and concentrated *in vacuo*. The residue was purified by flash chromatography to give 2.1 g (72%) of pure diol **20***b* as a colorless syrup; R_f 0.45 (50% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −38.4° (*c* 1.0, chloroform); ^{1}H nmr (80 MHz) δ: 0.08 (s, 6H, $SiMe_2$), 0.88 (s, 9H, *t*BuSi), 1.28, 1.45 (s, s, 6H, $C(CH_3)_2$), 2.48 (br s, 1H, OH), 3.80–4.46 (m, 6H, H-3, H-7, H-7′, H-5, H-5′, OH), 4.52 (d, 1H, J = 3.7 Hz, H-2), 5.03 (br s, 1H, H-4), 5.88 (m, 2H, $J_{1,2}$ = 3.7 Hz, H-1, H-6). *Anal.* calcd. for $C_{17}H_{32}O_6Si$: C 56.64, H 8.95; found: C 56.73, H 8.93.

*5-C-(*tert*-Butyldimethylsiloxymethyl)-5-deoxy-1,2-O-isopropylidene-L-*glycero*-α-D-*gluco*-heptofuranose (**25**)*

To a solution of disiamylborane (38 mmol) in dry tetrahydrofuran was added a solution of diol **20***b* (2.65 g, 7.36 mmol) in dry tetrahydrofuran (45 mL) at −78°C under an argon atmosphere, dropwise, over a period of 45 min. After stirring at −78°C for 2 h, the temperature was raised to −20°C, on the assumption (tlc evidence) that the formation of **24** was optional. A solution of 1 *M* borane in tetrahydrofuran (46 mL) was then added dropwise over a period of 45 min and the reaction mixture was stirred at room temperature for 16 h. Further portions of borane solution were added if necessary (tlc evidence). The reaction was quenched by addition of water (2 mL) to destroy the excess of borane, followed by 3 *N* sodium hydroxide and 30% hydrogen peroxide (30 mL of each) at 0°C. After vigorous stirring at room temperature for 6 h, the mixture was saturated with sodium chloride. The tetrahydrofuran phase was separated and the aqueous phase was extracted with ethyl acetate. The combined organic extracts were dried over anhydrous magnesium sulfate, filtered, and concentrated *in vacuo*. Excess water was removed azeotropically with toluene several times. The resulting residue was purified by flash chromatography to afford 2.22 g (80%) of pure triol **25** as a colorless syrup; R_f 0.21 (50% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ +7.8° (*c* 0.97, chloroform); ^{1}H nmr (250 MHz) δ: 0.06 (s, 6H, $SiMe_2$), 0.88 (s, 9H, *t*BuSi), 1.28, 1.47 (s, s, 6H, $C(CH_3)_2$), 2.14 (m, 2H, H-5, OH, D_2O exchange), 2.92 (br s, 1H, OH, D_2O exchange), 3.35 (br s, 1H, OH, D_2O exchange), 3.57–3.83 (m, 4H, H-3, H-6, H-5, H-5′), 3.86 (dd, 1H, $J_{3,4}$ = 2.5 Hz, J = 11.3 Hz, H-4), 4.13 (m, 2H, H-7, H-7′), 4.52 (d, 1H, J = 4.2 Hz, H-2), 5.88 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1). *Anal.* calcd. for $C_{17}H_{34}O_7Si$: C 53.94, H 9.12; found: C 53.76, H 9.05.

*5-C-(*tert*-Butyldimethylsiloxymethyl)-5-deoxy-1,2-O-isopropylidene-L-*glycero*-α-D-*gluco*-heptofuranose-6,7-carbonate (**26**a)*

To a stirred solution of triol **25** (1.14 g, 3.0 mmol) in dry dichloromethane (70 mL) and dry pyridine (35 mL) was added dropwise

14.4 mL of 12.5% phosgene in toluene at 0°C under an argon atmosphere over a period of 20 min. After 1 h the reaction was poured into 50 mL of ice water and then extracted with dichloromethane (2 × 50 mL). The combined organic extracts were washed with cold dilute hydrochloric acid, water, and brine, and dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The residue was purified by flash chromatography to give **26***a* (1.1 g, 90%) as a colorless syrup; R_f 0.64 (50% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ +10.7° (*c* 1.47, chloroform); ν_{max} ($CHCl_3$): 3450 (OH), 2950, 2900, 1880 (C=O, cyclic carbonate) cm^{-1}; ^1H nmr (250 MHz) δ: 0.05 (s, 6H, $SiMe_2$), 0.85 (s, 9H, *t*BuSi), 1.27, 1.45 (s, s, 6H, $C(CH_3)_2$), 2.32 (m, 1H, H-5), 3.17 (br s, 1H, OH, D_2O exchange), 3.68 (dd, 1H, $J_{5,5'a}$ = 7.5 Hz, J_{gem} = 10.0 Hz, H-5′a), 3.90 (dd, 1H, $J_{5,5'b}$ = 2.5 Hz, J_{gem} = 10.0 Hz, H-5′b), 4.04 (dd, 1H, $J_{3,4}$ = 2.5 Hz, $J_{4,5}$ = 10.0 Hz, H-4), 4.18 (d, 1H, *J* = 2.5 Hz, H-3), 4.35 (t, 1H, *J* = 8.8 Hz, H-7a), 4.50 (d, 1H, *J* = 4.2 Hz, H-2), 4.61 (dd, 1H, *J* = 7.5 Hz, *J* = 10.0 Hz, H-7b), 4.76 (q, 1H, $J_{5,6}$ = $J_{6,7a}$ = 8.8 Hz, H-6), 5.82 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1). *Anal.* calcd. for $C_{18}H_{32}O_8Si$: C 53.44, H 7.97; found: C 53.43, H 8.00.

5-C-(tert-*Butyldimethylsiloxymethyl)-5-deoxy-1,2*-O-*isopropylidene-3*-O-*phenoxythiocarbonyl-L*-glycero-α-*D*-gluco-*heptofuranose-6,7-carbonate (**26**b)*

To a solution of the alcohol **26***a* (1.1 g, 2.7 mmol) and a catalytic amount of *N,N*-dimethylaminopyridine (~10 mg) in dry dichloromethane (50 mL) and dry pyridine (2 mL) was added phenyl chlorothionocarbonate (0.62 mL, 4.5 mmol) at room temperature under an argon atmosphere. After 3 h another more phenyl chlorothionocarbonate (0.2 mL) was added and the reaction was monitored by tlc. The reaction mixture was poured into 10 mL of ice water and extracted with 3 × 20 mL of dichloromethane. The combined organic extracts were washed with cold dilute hydrochloric acid, water, and brine, and dried over anhydrous sodium sulfate, filtered, and concentrated *in vacuo*. Flash chromatography gave **26***b* (1.2 g, 82%) as a yellow syrup; R_f 0.50 (50% ethyl acetate – hexane); $[\alpha]_D^{23}$ +9.4° (*c* 0.98, chloroform); ν_{max} ($CHCl_3$): 2950, 2900, 1800 (C=O), 1580, 1480 cm^{-1}; ^1H nmr (250 MHz) δ: 0.06 (d, 6H, $SiMe_2$), 0.88 (s, 9H, *t*BuSi), 1.31, 1.50 (s, s, 6H, $C(CH_3)_2$), 2.30 (ttt, 1H, *J* = 2.9 Hz, *J* = 9.8 Hz, H-5), 3.63 (dd, 1H, *J* = 3.3 Hz, J_{gem} = 10.8 Hz, H-5′a), 3.96 (dd, 1H, *J* = 3.3 Hz, J_{gem} = 10.8 Hz, H-5′b), 4.38 (t, 1H, *J* = 8.8 Hz, H-7a), 4.49 (dd, 1H, $J_{3,4}$ = 2.9 Hz, $J_{4,5}$ = 9.8 Hz, H-4), 4.62 (dd, 1H, *J* = 7.8 Hz, *J* = 8.8 Hz, H-7b), 4.72 (d, 1H, *J* = 4.2 Hz, H-2), 4.96 (q, 1H, *J* = 7.8 Hz, H-6), 5.64 (d, 1H, $J_{3,4}$ = 2.9 Hz, H-3), 5.92 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1), 7.05–7.50 (m, 5H, Ph). *Anal.* calcd. for $C_{25}H_{36}O_9SSi$: C 55.53, H 6.71, S 5.93; found: C 55.61, H 6.50, S 6.15.

5-C-(tert-*Butyldimethylsiloxymethyl)-3,5-dideoxy-1,2*-O-*isopropylidene-β-L*-talo-*heptofuranose-6,7-carbonate (**26**c)*

A mixture of compound **26***b* (1.2 g, 2.22 mmol), tri-*n*-butyltin hydride (0.9 mL, 3.33 mmol) and 2,2′-azobis(2-methylpropionitrile) (30 mg) in toluene (40 mL) was heated to reflux under an argon atmosphere. After 3 h the reaction mixture was cooled to room temperature and then concentrated *in vacuo*. Flash chromatography afforded compound **26***c* (775 mg, 90%) as a colorless syrup; R_f 0.15 (30% ethyl acetate – hexane); $[\alpha]_D^{23}$ +1.9° (*c* 1.35, chloroform); ν_{max} ($CHCl_3$): 3000, 1800 (C=O, cyclic carbonate), 1500 cm^{-1}; ^1H nmr (250 MHz) δ: 0.04 (s, 6H, $SiMe_2$), 0.88 (s, 9H, *t*BuSi), 1.29, 1.46 (s, s, 6H, $C(CH_3)_2$), 1.55 (m, 1H, H-3α), 1.80 (m, 1H, H-5), 2.25 (dd, 1H, $J_{2,3\beta}$ = $J_{3\beta,4}$ = 4.2 Hz, J_{gem} = 13.0 Hz, H-3α), 3.67 (dd, 1H, *J* = 3.1 Hz, J_{gem} = 10.2 Hz, H-5′a), 3.91 (dd, 1H, *J* = 3.1 Hz, J_{gem} = 10.2 Hz, H-5′b), 4.25 (ddd, 1H, $J_{3\beta,4}$ = 4.2 Hz, $J_{4,5}$ = 10.2 Hz, H-4), 4.38 (t, 1H, *J* = 9.3 Hz, H-7a), 4.62 (t, 1H, *J* = 8.3 Hz, H-7b), 4.70 (t, 1H, $J_{1,2}$ = $J_{2,3\beta}$ = 4.2 Hz, H-2), 4.90 (q, 1H, *J* = 8.3 Hz, H-6), 5.74 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1). *Anal.* calcd. for $C_{18}H_{32}O_7Si$: C 55.64, H 8.30; found: C 55.81, H 8.36.

5-C-(tert-*Butyldimethylsiloxymethyl)-3,5-deoxy-1,2*-O-*isopropylidene-β-L*-talo-*heptofuranose (**3**b)*

To a stirred solution of the carbonate **26***c* (215 mg, 0.56 mmol) in 215 mL of a water–methanol–tetrahydrofuran (1:1:1) mixture was added barium hydroxide octahydrate (100 mg). After stirring at room temperature for 30 min, the reaction mixture was neutralized with a stream of carbon dioxide gas, and then extracted with 3 × 20 mL of ethyl acetate. The combined organic extracts were dried over anhydrous magnesium sulfate, filtered, and concentrated *in vacuo*. Flash chromatography gave diol **3***b* (197 mg, 98%) as a colorless syrup; R_f 0.13 (30% ethyl acetate – petroleum ether); $[\alpha]_D^{23}$ −9.8° (*c* 1.25, chloroform); ^1H nmr (250 MHz) δ: 0.06 (s, 6H, $SiMe_2$), 0.88 (s, 9H, *t*BuSi), 1.28, 1.48 (s, s, 6H, $C(CH_3)_2$), 1.57 (m, 1H, H-3β), 1.82 (m, 1H, H-5), 2.15 (dd, 1H, $J_{2,3\beta}$ = $J_{3\beta,4}$ = 4.2 Hz, J_{gem} = 13.0 Hz, H-3β), 2.70 (dd, 1H, *J* = 6.3 Hz, *J* = 8.3 Hz, OH, D_2O exchange), 3.21 (d, 1H, *J* = 6.3 Hz, OH, D_2O exchange), 3.65–3.83 (m, 4H, two H-5′, H-7, H-7′), 3.93 (m, 1H, H-6), 4.32 (m, 1H, H-4), 4.71 (t, 1H, $J_{1,2}$ = $J_{2,3\beta}$ = 4.2 Hz, H-2), 5.78 (d, 1H, $J_{1,2}$ = 4.2 Hz, H-1). *Anal.* calcd. for $C_{17}H_{34}O_6Si$: C 56.32, H 9.45; found: C 56.32, H 9.31.

Electron transport in dense gases: limitations on the Ioffe-Regel and Mott criteria[1]

NORMAN GEE AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 2, 1986

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **64**, 1810 (1986).

In the gas phase, the Ioffe–Regel criterion that electron transport becomes modified when the mean free path equals the electron wavelength ($L = \lambda$) applies clearly only to helium and hydrogen, which have a net repulsive interaction with electrons. The Mott criterion, that when $L = \lambda/2\pi$ the electron is in a localized state, also applies to these two gases. The two criteria are less effective for molecules that have net attractive interactions with the electrons, because the interactions are not simply additive. They are not useful for xenon gas. The criteria are also assessed for: (*a*) several highly polarizable, spherical and nonspherical molecules; (*b*) polar molecules; (*c*) nitrogen and carbon dioxide, which form transient anions.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **64**, 1810 (1986).

En phase gazeuse, le critère de Ioffe–Regel, selon lequel le transport d'électrons est modifié lorsque le parcours libre moyen est égal à la longueur d'onde de l'électron ($L = \lambda$), ne s'applique clairement que dans les cas de l'hélium et de l'hydrogène qui possèdent une interaction répulsive nette vis-à-vis les électrons. Le critère de Mott, selon lequel l'électron est dans un état localisé lorsque $L = \lambda/2\pi$, s'applique aussi à ces deux gaz. Dans les cas des molécules qui possèdent des interactions attractives pour les électrons, ces deux critères sont moins efficaces parce que les interactions ne sont alors pas additives. Ils ne sont pas utiles pour le xénone à l'état gazeux. On a aussi évalué ces critères pour : (*a*) plusieurs molécules hautement polarisables, sphériques et non-sphériques; (*b*) des molécules polaires et (*c*) pour l'azote et le dioxyde de carbone qui forment des anions transitoires.

[Traduit par la revue]

Introduction

In a gas at low densities the mobility μ of electrons is inversely proportional to the number density n of the gas, so:

[1] $$n\mu = \text{constant}$$

At sufficiently high densities $n\mu$ may either decrease (1–6) or increase (4–7) with increasing n, depending on the properties of the molecules and on n and the temperature T (4–6). There is no universal agreement about the causes of the changes in $n\mu$.

The effects of gas density on $n\mu$ are interpreted in terms of multibody scattering. What has come to be known as the Ioffe–Regel criterion for multibody scattering is often employed. Unfortunately there is confusion in the literature about the Ioffe–Regel criterion. The present work attempts to clarify the terminology, and to assess the applicability of the Ioffe–Regel criterion in a wide variety of gases.

2. Ioffe–Regel criteria

In 1960 Ioffe and Regel, in an article about amorphous and liquid semiconductors (8), discussed the limits of applicability of common theories of electronic conduction. The theories included assumptions about the mean velocity $\langle v \rangle$ and mean free path L of the electrons. Ioffe and Regel compared the magnitude of L with the average wavelength λ_T of the (nearly) free electrons and the average interatomic or intermolecular distance a of the medium.

The value of L can be obtained from the mobility of thermal, nearly free electrons by (from eqs. [13] and [17] in ref. 6*b*):

[2] $$L = \frac{1}{n\sigma_{ave}} = \frac{3}{e}\left(\frac{\pi m k_B T}{8}\right)^{1/2}\mu$$
$$= 4.17 \times 10^{-8}\, T^{1/2}\mu$$

where $\sigma_{ave} = \langle v \rangle / \langle v/\sigma_m \rangle$ is the momentum transfer cross section averaged over the Maxwellian velocity distribution, e and m are the electronic charge and mass, respectively, and k_B is Boltzmann's constant. The unit for L is m and for μ is (m^2/V s). At 300 K eq. [2] gives

[3] $$L = 7.2 \times 10^{-7}\,\mu$$

which agrees with Ioffe and Regel's room temperature value $L \approx 10^{-6}\,\mu(m^*/m_0)^{1/2}$, where the effective mass ratio m^*/m_0 is unity in the gas at low and moderate densities.

In many gases at $n \approx 1 \times 10^{26}$ molecules/m^3 electron mobilities at 300 K are of the order of 0.1 m^2/V s, so $L \approx 10^{-7}$ m. The value of a at this density is $\sim 10^{-9}$ m. The average de Broglie wavelength of the electron at this temperature is $\sim 10^{-8}$ m. Thus $L > \lambda_T > a$. By increasing n one decreases L as n^{-1}, and decreases a as $n^{-1/3}$; λ_T is varied for nearly free electrons by changing T.

Free forward motion with a mean velocity $\langle v \rangle$ only occurs over the mean distance L. Therefore Ioffe and Regel suggested that when L becomes smaller than λ_T "the concept of velocity of the charge carriers loses its meaning" (8). This means a modification of μ, but does not imply localization. However, when L calculated from eq. [3] has a value less than a "the mechanism of mobility itself must be altogether different, and the concept of mean free path has no meaning" (8). The value of L cannot in reality be less than a, so when eq. [3] indicates $L < a$ the electron must be in a localized state, and it migrates by hopping from site to site in a probabilistic manner. Equation [3] then does not apply.

The conditions, (*a*) $L \approx \lambda_T$ and (*b*) $L \approx a$, have been taken to depict multibody scattering and electron localization, respectively. The latter seems clear enough. The former is obscured by the wide variety of treatments of the average electron wavelength (8–18). The different treatments cause differences up to *eleven-fold* in the predicted densities where multibody scattering should become important (see Appendix 1). This large factor of eleven is made up of a factor of $6.3 = 2\pi$, caused by confusing wavelength λ with $\lambda/2\pi = \lambda\!\!\!^{-}$, and a factor of 1.8 caused by different methods of averaging over the Maxwellian velocity distribution. For the largest portion, 6.3-fold, it is convenient to distinguish by name λ, which is the distance over which the phase of the wave changes by one cycle, and $\lambda\!\!\!^{-}$, which is the distance over which the phase of the wave changes by one radian. Hence, λ is the *wavelength* and $\lambda\!\!\!^{-}$ is the *radianlength* (19). The names are useful in the visualization (20) of the processes.

For averaging λ over the Maxwellian velocity distribution we

[1]Assisted financially by the Natural Sciences and Engineering Research Council of Canada.

favor the 3-dimensional model and the inverse velocity, since $\lambda = h/mv$. Hence, the average wavelength and radianlength of electrons at temperature T are taken as

[4] wavelength $\lambda_T = h\langle v_{3d}^{-1}\rangle/m$
$$= h\left(\frac{2}{\pi m k_B T}\right)^{1/2}$$
$$= 1.49 \times 10^{-7}\, T^{-1/2}$$

[5] radianlength $\lambda\!\!\!^{-}_T = \hbar\langle v_{3d}^{-1}\rangle/m$
$$= 2.37 \times 10^{-8}\, T^{-1/2}$$

The one dimensional $\langle v_{1d}^{-1}\rangle$ equals infinity and cannot be used.

Mott changed the Ioffe–Regel criterion, although he did not change the name. Mott's criterion was that when L equals the "wavelength", $h/[2\pi(mk_BT)^{1/2}]$, the electron cannot be in a nearly free state, so it is in a localized state (11). As noted in Appendix 1, $h/[2\pi(mk_BT)^{1/2}]$ is a radianlength rather than a wavelength, so Mott's criterion is $L \approx \lambda\!\!\!^{-}_T$. Mott's is sort of a combination of the Ioffe–Regel criteria (*a*) and (*b*) and we call it the Mott criterion of localization.

3. Application of Ioffe–Regel $L \approx \lambda_T$, Mott $L \approx \lambda_T$, and $L \approx 2\lambda_T$

Iakubov (21) set out to quantify the Ioffe–Regel criterion (*a*), but actually used that of Mott. For the wavelength he used a formula for radianlength equivalent to (see Appendix 1)

[6] $\lambda\!\!\!^{-}_T = \hbar/m\alpha_{3d}$

where $\alpha_{3d} = (2k_BT/m)^{1/2}$ is the most probable speed. Iakubov suggested that for short range (repulsive) electron–atom interactions the "quantum interference" at high gas densities increased the effective collision frequency ν_{ef} of the electrons:

[7] $$\nu_{ef} = \nu\left(1 + \frac{\lambda\!\!\!^{-}_T}{L}\right)$$
$$= \nu(1 + \lambda\!\!\!^{-}_T n\sigma_{ave})$$

The mobility is inversely proportional to ν_{ef}:

[8] $$\mu \approx e/(m\nu_{ef})$$
$$\approx e/[m\nu(1 + \lambda\!\!\!^{-}_T n\sigma_{ave})]$$
$$= \mu_0/(1 + \lambda\!\!\!^{-}_T n\sigma_{ave})$$

When the deviation of μ_0 is small, $\lambda\!\!\!^{-}_T n\sigma_{ave} \ll 1$, eq. [8] is approximately

[9] $\mu/\mu_0 \approx (1 - \lambda\!\!\!^{-}_T n\sigma_{ave})$

Equation [9] empirically fits the density dependence of μ/μ_0 down to 0.4 in helium and hydrogen gases (13, 22). As it is also similar to Mott's localization criterion, its use is appealing. However, its derivation by way of eq. [8] is restricted to $\lambda\!\!\!^{-}_T n\sigma_{ave} \ll 1$. The choice of radianlength rather than wavelength as the parameter is related to the final localized state. The radianlength is a Bohr-type radius of a localized electron state, and the inverse radianlength is the exponential decay parameter of a Schrödinger-type ground state ($e^{-r/\lambda\!\!\!^{-}}$). For example, the hydrogen atom Bohr radius a_0 is a radianlength.

Atrazhev and Iakubov (15) apparently decided that a localized electron requires a space $2\lambda\!\!\!^{-}_T$ in dimension, which is a Bohr-type diameter. They modified eq. [9] to

[10] $\mu/\mu_0 = (1 - 2\lambda\!\!\!^{-}_T n\sigma_{ave})$

However, there is no general agreement about whether the factor in front of $\lambda\!\!\!^{-}_T$ should be exactly 2 (13, 22). This, in combination with the variety of methods of averaging the speed to obtain $\lambda\!\!\!^{-}_T$ (see Appendix 1) leaves flexibility in the equation.

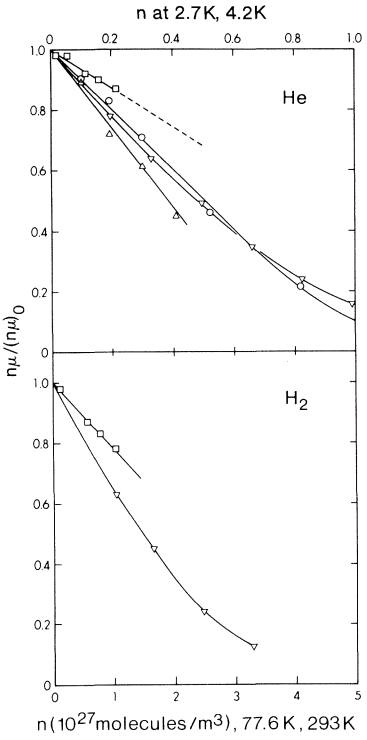

FIG. 1. Reduction of density normalized mobility $n\mu$ with increasing gas density n at several constant temperatures. He: △, 2.70 K, ref. 13; ○, 4.2 K, ref. 13; ▽, 77.6 K, ref. 24; □, ~293 K, data in ref. 2 extrapolated to zero field and normalized to the n = 10 and 28 (10^{25} molecules/m^3) results (see text). H_2: ▽, 77.6 K, ref. 24; □, ~293 K, ref. 2. The points were calculated from experimental data in the cited references.

Equation [10], like eq. [9], is related to the Mott criterion, not to that of Ioffe and Regel.

The Ioffe–Regel criterion means that when $L \approx \lambda$, $n\mu$ should be somewhat different than when $L \gg \lambda$ (8). When the electron–molecule interaction is repulsive (as when the molecule is nonpolar and has a very small polarizability) $n\mu$ decreases (negative effect) (15). When the electron–molecule interaction is attractive (as when the molecule is nonpolar and has a large polarizability) $n\mu$ increases (positive effect) (15). When the molecules are strongly polar the electron–molecule interaction is attractive and one might expect a positive effect, but a negative effect is observed (14, 17). These behaviors are quantitatively examined in the following sections.

(a) Molecules with low polarizability

Helium and hydrogen have small polarizabilities (23) and serve to illustrate the negative Ioffe–Regel effect (24). The condition

[11] $L = \lambda_T$

corresponds to

[12] $$\frac{1}{n\sigma_{ave}} = \frac{h}{m}\langle v_{3d}^{-1}\rangle$$

From eqs. [2] and [4], eq. [11] is satisfied at the Ioffe–Regel density:

[13] $n_{IR} = 0.28\,T(n\mu)_0$

where $(n\mu)_0$ is the low density value of $n\mu$ at temperature T. Thus the value of n_{IR} is extrapolated from low density behavior.

In helium over a hundred-fold range of temperatures, from 2.7 to 293 K, the value of $(n\mu)_{IR}/(n\mu)_0$ is 0.72 ± 0.02 (Fig. 1

[a]Mean polarizability $\bar{\alpha}$ and dipole moment $\mathcal{D}$, ref. 23. $\bar{\alpha}$ has SI units C m^2/V. To retain the familiar units m^3, we list $\bar{\alpha}/4\pi\epsilon_0$.
[b]T_c and n_c are the temperature and density of the critical fluid.
[c]Values from the references in parentheses indicated.
[d]Equation [13].
[e]Obtained from plots such as those in Fig. 1, constructed from data in refs. for $(n\mu)$, unless otherwise indicated. $n_{2\chi} = \pi n_{IR}$ and $n_{\chi} = 2\pi n_{IR}$.
[f]From $n\mu = 103 \times 10^{25}$ molecules/m V s at 87 K and $n = 21 \times 10^{27}$ molecules/m^3 (ref. 29), multiplied by the ratio of $(\chi_T/T^{3/2})^{-1}$ values at 149 and 87 K (ref. 31). At this density the isothermal compressibility $\chi_T = 1.4 \times 10^{-4}$ atm^{-1} at 149 K, and 2.2×10^{-4} atm^{-1} at 87 K (ref. 32). Thus $(n\mu)_{\chi} = 72 \times 10^{25}$ molecules/m V s at 149 K.
[g]From data in ref. 37*c*.
[h]±10%, extrapolated from data in ref. 7.
[i]Values slightly less than unity are caused by quasilocalization of electrons by density fluctuations in the gas.
[j]Values much less than unity are caused by the formation of localized states in the liquid.
[k]Using high density data from ref. 42.

and Table 1). The constancy of $(n\mu)_{IR}/(n\mu)_0$ over a hundredfold range of temperature confirms the validity of the Ioffe–Regel concept in helium.

In Fig. 1, the electrons in helium at 293 K were still slightly epithermal at the lowest field strength used (9×10^{-24} V m^2/molecule); the plots of drift velocity against field strength did not reach a slope of unity (2), in agreement with recent measurements in the same field range (25). Furthermore, Grünberg (2) evidently normalized his results at $n = 10$ and 28 (10^{25} molecules/m^3) to the $(n\mu)_0$ values of Crompton and co-workers (26), whereas in the denser gases used by Grünberg $n\mu$ should have been 1% and 3% lower, respectively. The points at 293 K were obtained by extrapolating Grünberg's data to zero field, assigning the average of the expected values $n\mu/(n\mu)_0 = 0.98$ to the equal sets at $n = 10$ and 28 (10^{25} molecules/m^3), and measuring the ratios at higher densities relative to that.

In hydrogen at 77.6 and 293 K the value of $(n\mu)_{IR}/(n\mu)_0$ is 0.72 ± 0.01 (Fig. 1 and Table 1). The behavior is the same as that in helium. The transient electron capture mechanism suggested by Frommhold (27) involving resonance with a rotational state of the molecule is therefore not the cause of the decrease of $n\mu$ in hydrogen. The decrease is caused by the constructive interference of the repulsive interactions of the electron with more than one molecule at a time, in accord with the Ioffe–Regel concept that electron transport is modified when $L \approx \lambda\!\!\!^{-}_T$.

Equation [10] predicts localization at

$$[14] \quad L = 2\lambda\!\!\!^{-}_T$$

where $\lambda\!\!\!^{-}_T$ is given by eq. [5]. If all the electrons had the same energy and if the scatterers were regularly spaced, a mean free path equal to $2\lambda\!\!\!^{-}$ should imply that a relatively completely localized state of the electrons had been formed. In a Maxwellian system ~30% of the electrons have $\lambda\!\!\!^{-} < \lambda\!\!\!^{-}_T$. Furthermore the scatterers are randomly distributed in space. At the density $n_{2\lambda}$ that satisfies eq. [14] the ratio $(n\mu)_{2\lambda}/(n\mu)_0$ is 0.17 in helium at 4.2 K and 0.27 ± 0.02 in helium and hydrogen at 77.6 K (Table 1). This is consistent with the $L = 2\lambda\!\!\!^{-}$ criterion of localization.

Mott's statement (11) that L cannot be smaller than $\lambda\!\!\!^{-}$ is commonly represented by saying that when

$$[15] \quad L = \lambda\!\!\!^{-}_T$$

the electron is in a localized state. In helium at a density that fulfills eq. [15], the experimental value of $(n\mu)_{\lambda}/(n\mu)_0$ is 1.34×10^{-4} at 4.2 K and 0.035 at 77.6 K (Table 1). In hydrogen at 77.6 K the ratio is 0.025. The electrons are localised. However, since $\lambda\!\!\!^{-}_T$ is the average of a wide distribution of values, the condition (15) is well past the threshold of localization and probably has less theoretical significance than condition [14].

Furthermore, the Ioffe–Regel condition (*b*), $L \approx a$, is well past the localization threshold.

(b) Molecules with larger polarizability

The preceding discussion applies to molecules that have a net repulsive interaction with the electrons. Molecules that have a large enough polarizability, such as argon and methane, have a net attractive interaction with thermal ($\lesssim$0.1 eV) electrons. In such gases the simultaneous interactions of an electron with more than one molecule at a time interfere destructively, so $n\mu$ increases in the multibody scattering regime (7, 15, 28).

In low density argon at 297 K the density normalized mobility is $(n\mu)_0 = 1.3 \times 10^{26}$ molecules/m V s (29). The value of n_{IR} is therefore 10.8×10^{27} molecules/m^3, which is 11% below the density where the mobility maximum occurs (30). Although 297 K is well above the highest temperature (158 K) used at this density, the results (30) indicate that in the supercritical gas at 297 K one would have $(n\mu)_{IR} > 1.6 \times 10^{27}$ molecules/m V s. Thus $(n\mu)_{IR}/(n\mu)_0 > 12$ (Table 1). Values of the ratio much greater than unity indicate that the electrons are in a conduction band.

TABLE 2. Electron scattering cross sections, dilute gas

Gas	T (K)	σ_{ave} (10^{-20} m^2) Obsd	Pol[a]	Obsd/Pol
Xe	145	63 (4)	249	0.25
	297	44 (4)	174	0.25
CH_4	150	7.8 (35)	200	0.04
	297	4.0 (35)	140	0.03
Ar	149	2.5 (29)	157	0.02
	297	1.1 (29)	111	0.01

[a]Equation [18].

At lower temperatures the values of $(n\mu)_0$ and n_{IR} are smaller, and the mobility ratio is smaller: at 149 K, $(n\mu)_{IR}/(n\mu)_0 = 1.6$ (Table 1). However, at the highest density $n_{2\lambda}$ the ratio is $(n\mu)_{2\lambda}/(n\mu)_0 = 16$ (Table 1). The still higher density $n_{\lambda} = 21 \times 10^{27}$ molecules/m^3 at 149 K is the density of liquid argon at its normal boiling point, 87 K. We used the model of Cohen and Lekner (31) and the isothermal compressibilities of the liquid at 87 and 149 K (32) to calculate the value of $(n\mu)_{\lambda}$ at 149 K from the value of $n\mu$ at the same density at 87 K (29). The resulting $(n\mu)_{\lambda}/(n\mu)_0 = 9$ is smaller than the lower density value $(n\mu)_{2\lambda}/(n\mu)_0 = 16$, because of the density dependence of the scattering length (33).

In methane (34, 35) the effects at n_{IR} and $n_{2\lambda}$ are smaller than in argon, and in xenon (4) they are smaller still (Table 1). This result is contrary to the initial expectation that the positive effect would be more pronounced at larger polarizabilities. It is the polarizability that determines whether the Ioffe–Regel effect is negative or positive (15).

The contribution of the polarization interaction to electron scattering by Xe, CH_4, and Ar can be assessed by comparison of σ_{ave} with that expected from the polarization potential. The scattering cross section expected from the polarization potential is (36)

$$[16] \quad \sigma_{pol} = \left(\frac{2.21\pi e}{4\pi\epsilon_0}\right)\left(\frac{\bar{\alpha}}{mv^2}\right)^{1/2}$$

Thus

$$[17] \quad \sigma_{pol,ave} = \langle v\rangle/\langle v/\sigma_{pol}\rangle = \left(\frac{2.21\pi e}{4\pi\epsilon_0}\right)\left(\frac{\bar{\alpha}}{m}\right)^{1/2}\frac{\langle v\rangle}{\langle v^2\rangle}$$

For a Maxwellian distribution of electrons at temperature T,

$$[18] \quad \sigma_{pol,ave} = 0.0150(\bar{\alpha}/4\pi\epsilon_0 T)^{1/2}$$

where σ is in m^2 and $\bar{\alpha}/4\pi\epsilon_0$ is in m^3 (the SI units of α are C m^2/V). The observed σ_{ave} of Xe is only 25% of $\sigma_{pol,ave}$, while those of CH_4 and Ar are only 4% and 2%, respectively (Table 2). Most of the electron–molecule attractive polarization interaction is cancelled by the short range Pauli repulsion

[d]Equation [13].
[e]Obtained from plots such as those in Fig. 1, constructed from data in the refs. for $(n\mu)_0$, unless otherwise indicated. $n_{2\lambda} = \pi n_{IR}$ and $n_\lambda = 2\pi n_{IR}$.

between the electron and the filled valence electron shells of these molecules.

However, electron scattering is strong enough in low density xenon gas that n_{IR} corresponds to only ~10 atm pressure at 297 K; there is no enhancement of $n\mu$. Scarcely any enhancement of $n\mu$ occurs even at the 6.3 times higher density n_λ in xenon (Table 1). At much higher densities, $\sim 10 n_\lambda \approx 1$–2 ($10^{28}$ molecules/m^3), the value of $n\mu/(n\mu)_0$ is enormous, ~1000 (4). There is a large density effect, but it is not related to the Ioffe–Regel criterion.

If the positive Ioffe–Regel effect in argon and methane is indeed due to the density dependence of an attractive electron–molecule interaction (15), it should be at least as prominent in xenon. The absence of the effect in xenon suggests that the theoretical interpretation of the effects in argon and methane be reopened.

Recent attempts by Polischuk to explain the behavior in xenon and other gases are discussed in Appendix 2.

(c) Electron attachment

Nitrogen is a nonpolar molecule with an average polarizability similar to that of argon. The values of $(n\mu)_0$ at low temperatures are also similar in the two gases (Table 1) (29, 37). One might therefore expect similar values of $(n\mu)_{IR}/(n\mu)_0$ in nitrogen and argon at low temperatures. In fact the ratios are very different. In argon the ratio is greater than unity. In nitrogen it is smaller than unity, and even smaller than those in helium and hydrogen, which repel the electrons (Table 1). The deviation of $(n\mu)_{IR}/(n\mu)_0$ from unity is twice as great in nitrogen as in helium and hydrogen, and the deviation of $(n\mu)_{2\lambda}/(n\mu)_0$ is 100 times as great (Table 1). The behavior in nitrogen is explained by transient attachment of electrons to nitrogen molecules in the dense gas (37*a*).

Similarly, carbon dioxide can be compared to methane. They are nonpolar and have the same mean polarizability. The Ioffe–Regel ratio $(n\mu)_{IR}/(n\mu)_0$ is unity or slightly smaller in carbon dioxide, while in methane it is unity or greater. At higher densities the ratio $n\mu/(n\mu)_0$ becomes much smaller than unity in carbon dioxide and much larger than unity in methane (Table 1). Transient attachment of electrons occurs in dense carbon dioxide gas (3, 38, 39).

The Ioffe–Regel and Mott criteria should not be applied when electron attachment occurs.

(d) Nonspherical alkanes

There might be a small enhancement of $n\mu$ due to the Ioffe–Regel effect in ethane (40, 41), propane (5, 6, 42), and *n*-butane (6), but it is obscured by the decrease of $n\mu$ caused by quasilocalization (6, 40) under the conditions of experiment (Table 1). Heating the gas decreases the magnitude of the density fluctuations and therefore decreases the extent of quasilocalization; the value of $(n\mu)_{IR}/(n\mu)_0$ in ethane and propane increased to ≥ 1.0 (Table 1).

The $L = 2\lambda$ criterion applies to formation of localized states in the dense fluids; $(n\mu)_{2\lambda}/(n\mu)_0 \approx 0.1$ (Table 1).

There is an extensive literature about localized states of electrons in liquid, nonspherical hydrocarbons. The subject does not require discussion here. Example references are 5, 6, 40–42, and works cited therein.

(e) Polar compounds

The scattering cross sections of highly polar molecules for low energy ($\lesssim 0.1$ eV) electrons are large. The values of $(n\mu)_0$ are correspondingly low (compare values in Table 3 with those

in Table 1). The electron–dipole interaction is attractive and one might expect the Ioffe–Regel effect to be positive. However, it is slightly negative; $(n\mu)_{IR}/(n\mu)_0 = 0.9$ in dimethyl ether (43), methylamine (44), ammonia (10, 17, 44), methanol (6*b*), and water (9). The ratio in ammonia remains 0.9 over a two-fold range of temperature, 300–600 K (Table 3).

At the three-fold higher density $n_{2\lambda}$ the value of $(n\mu)_{2\lambda}/(n\mu)_0$ has only been reduced to 0.7, similar to $(n\mu)_{IR}/(n\mu)_0$ in the repulsive-interaction gases helium and hydrogen. At the still higher density n_λ a large degree of electron localization has still not been achieved (Table 3).

Polischuk's recent treatment of the behavior in water vapour (45*b*) is discussed in Appendix 2.

The scattering interaction does not change in a simple manner with density. Simple criteria such as those of Ioffe and Regel (8) and of Mott (11) are only of qualitative use in these gases. The criteria were devised for electron behavior in condensed phase semiconductors, where the internal electronic structure can change a lot from one material to another, but the density does not change much.

5. Conclusions

(*a*) The Ioffe–Regel criterion that $n\mu$ changes when $L \leq \lambda$ and the Mott criterion that $L \approx \lambda$ corresponds to a localized state of the electron, apply to gas density effects in helium and hydrogen, which have a net repulsive interaction with electrons.

(*b*) The Ioffe–Regel and Mott criteria are not useful when transient attachment of electrons occurs, nor when the molecules are highly polar.

(*c*) The positive Ioffe–Regel effect is not present in xenon, which brings into question the explanation of the effects in argon and methane.

Appendix 1. Wavelength and radianlength

Each of the following eight formulas have been used to calculate the *wavelength* of electrons at temperature T; h is Planck's constant.

[*i*] $h(\pi/8mk_BT)^{1/2}$

This corresponds to the 7×10^{-9} m at room temperature given in ref. 8, and to $\langle k \rangle^{-1} = \langle \lambda^{-1} \rangle^{-1}$ in refs. 9 and 10.

[*ii*] $h(3/2mk_BT)^{1/2}$

This was incorrectly attributed to Ioffe and Regel (8) by Mott (11).

[*iii*] $h/[2\pi(mk_BT)^{1/2}]$

This corresponds to the 3×10^{-9} m at 100 K given in ref. 11.

[*iv*] $h/(mk_BT)^{1/2}$ (ref. 12)

[*v*] $h/(2\pi mk_BT)^{1/2}$ (refs. 12–14)

[*vi*] $h/[2\pi(2mk_BT)^{1/2}]$ (refs. 15–17)

The temperature in ref. 15 was used as an energy, so it

included k_B.

[*vii*] $h/(2mk_BT)^{1/2}$ (ref. 18)

[*viii*] $h/(8\pi mk_BT)^{1/2}$

This form is obtained when the empirical factor $\alpha = 1/2$, obtained by fitting a model to electron behavior in helium gas (13), is included where it seems to belong, in the wavelength factor.

The wavelengths estimated at a given T by these formulas can differ up to 11-fold, [*ii*]/[*vi*]. The differences are caused by different definitions of wavelength and different averaging procedures for the velocity.

Although all of the above formulas were called wavelength or average de Broglie wavelength by the authors cited, formulas [*iii*], [*vi*], and [*viii*] are actually for $\lambda\!\!\!^{-} = \lambda/2\pi$, which is 6.3-fold smaller than a wavelength. $\lambda\!\!\!^{-}$ is a *radianlength* (19). The radianlength is the counterpart of the *angular velocity* ω (radian/s). Angular velocity has been burdened with a number of imprecise names such as angular frequency, circular frequency, frequency, and radian frequency. The *frequency* ν (cycle/s) of a wave or oscillation is $\omega/2\pi$. In attempts to visualize wavelike properties of particles it is important to distinguish between wavelength and radianlength, and between frequency and angular velocity. The visualization of processes and concepts is of great utility, and will be more widely used in the future (20).

There are also differences between formulas [*i*] to [*viii*] due to the use of one dimensional ($1d$) or 3-dimensional ($3d$) speeds, and different types of averages over the Maxwellian distribution. The relevant $1d$ averages are

[*ix*] $\langle v_{1d}\rangle = (2k_BT/\pi m)^{1/2}$

[*x*] $\langle v_{1d}^2\rangle^{1/2} = (k_BT/m)^{1/2}$

while the $3d$ averages include

[*xi*] $\langle v_{3d}\rangle = (8k_BT/\pi m)^{1/2} = 2\langle v_{1d}\rangle$

[*xii*] $\langle v_{3d}^{-1}\rangle^{-1} = (\pi kT/2m)^{1/2}$

[*xiii*] $\langle v_{3d}^{-2}\rangle^{-1/2} = (k_BT/m)^{1/2} = \langle v_{1d}^2\rangle^{1/2}$

and the most probable speed

[*xiv*] $\alpha_{3d} = (2k_BT/m)^{1/2}$

The formulas therefore represent the following:

[i] wavelength$_{3d}$ $\lambda_{T,3d} = h/m\langle v_{3d}\rangle$
or half wavelength$_{1d}$ $\lambda_{T,1d}/2 = h/2m\langle v_{1d}\rangle$

[ii] approximate wavelength$_{1d} \approx h/m\langle v_{1d}\rangle$
or 2× wavelength$_{3d} \approx 2h/m\langle v_{3d}\rangle$

[iii] radianlength $\lambda\!\!\!^{-}_T = \hbar\langle v_{3d}^{-2}\rangle^{1/2}/m = \hbar/m\langle v_{1d}^2\rangle^{1/2}$

[iv] wavelength $= h\langle v_{3d}^{-2}\rangle^{1/2}/m = h/m\langle v_{1d}^2\rangle^{1/2}$

[v] $2\times$ radianlength$_{1d} = 2\hbar/m\langle v_{1d}\rangle$
or $4\times$ radianlength$_{3d} = 4\hbar/m\langle v_{3d}\rangle$

[vi] radianlength $= \hbar/m\alpha_{3d}$

[vii] wavelength $= h/m\alpha_{3d}$

[viii] radianlength$_{1d} = \hbar/m\langle v_{1d}\rangle$
or $2\times$ radianlength$_{3d} = 2\hbar/m\langle v_{3d}\rangle$

Equations [4] and [5] are preferred to the above eight in the dense gas context.

Appendix 2. Recent attempts

Polischuk, who was a co-worker of Iakubov, has recently made interesting attempts to explain the density dependence of $n\mu$ in xenon (45*a*) and in polar gases (45*b*). Although he made progress beyond earlier attempts, his work is obscured by the same language problems discussed in Appendix 1. There are other difficulties that deserve comment.

The density effect in nitrogen was classed with those in helium and hydrogen (45*a*, *b*), whereas the effect in nitrogen is due to electron capture (Table 1).

Models that use $\hbar = 1$, $h = 1$, $c = 1$ or $k_B = 1$ eliminate visualization of the physical processes. The ideas being advanced are then trapped behind jargon barriers and are not easily available to a broad audience. Polischuk used $\hbar = 1$ and $k_B = 1$, but in eq. [15] of ref. 45*b* he inserted $\hbar$ "which demonstrates the quantum nature of the density effect". His equation is quite complicated, but it is equivalent to the above eq. [7] multiplied by 0.5; $\Gamma = 0.5\nu$. However, he did not explain why the attractive electron–dipole potential should produce a negative rather than a positive effect of density on $n\mu$. Equation [3] of ref. 45*b* is simply the Altshuler cross section (46).

For nonpolar scatterers, Polischuk argued that the r_0 which occurs in terms such as $\alpha e^2/2(r_0^2 + r^2)^2$ is not simply a fitting parameter (45*a*), although it is simply that (33). He suggested that "r_0 can be estimated by the sizes of the outer electronic shell of the atom and by the effective radius of hard spheres". But he used values of r_0 for argon and xenon that were only 37% of the hard sphere radii estimated from the solid phase (29). A calculated curve for μ/μ_0 against xenon density is shown in Fig. 2 of ref. 45*a*, but values of the equation parameters are lacking. In particular, the values of the chemical potential and mobility threshold energy are needed at each density. Furthermore, electron quasilocalization and the drastic effect of temperature on it (4) were ignored.

The demicellization temperature of potassium *n*-octanoate in deuterium oxide as estimated from ^{1}H and ^{13}C nuclear magnetic resonance spectra

M. A. DESANDO AND L. W. REEVES

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received December 28, 1984[1]

M. A. DESANDO and L. W. REEVES. Can. J. Chem. **64**, 1817 (1986).

Measurements of the proton nmr peak positions and carbon-13 nmr chemical shifts as a function of concentration and of temperature estimate the demicellization temperature to be in the range ca. 115–227°C for potassium *n*-octanoate in deuterium oxide at concentrations around the critical micelle concentration.

M. A. DESANDO et L. W. REEVES. Can. J. Chem. **64**, 1817 (1986).

Opérant dans de l'oxyde de deutérium, à diverses températures et à diverses concentrations, on a mesuré les positions des bandes dans les spectres rmn du ^{1}H et du ^{13}C de l'octanoate de potassium; sur la base de ces résultats, on a évalué que la température de démicellisation, à des concentrations proches de la concentration micellaire critique, se situe entre 115 et 227°C.

[Traduit par la revue]

Introduction

Potassium *n*-octanoate in deuterium oxide ($^{2}H_2O$), as with aqueous solutions of other fatty acid salts, can form normal micelles (1–3) above the Krafft point (3) of the surfactant. Whereas considerable information is available on the properties of surfactant solutions around room temperature, very little is known on the behaviour of micelle-forming systems at high temperatures, especially above the boiling point of the solvent.

A study was therefore undertaken to obtain data on the nature of a simple two-component surfactant system, namely, potassium *n*-octanoate in $^{2}H_2O$, over a wide temperature range (29–154°C). The nmr method is a suitable one for the characterization of the species present in solution, and has the advantage over many other techniques of providing information on the environments and interactions of different parts of the molecule. It is possible to correlate spectral parameters such as resonance peak position to changes in the properties of the surfactant aggregates with variations in temperature.

There is substantial evidence from a number of experimental techniques that surfactants with a short alkyl chain ($\leq$8 carbon atoms) form small aggregates in water around room temperature (4). Sodium *n*-octanoate, for instance, self-associates into micelles with a mean aggregation number in the range 4–15 at temperatures around 25°C (5–7). Small micelles would be expected to be less stable than large ones, which would have stronger interactions among the larger more hydrophobic alkyl chains of the surfactant. Short-chain surfactants therefore tend to micellize via multiple equilibria (8, 9), whereas the self-association of long-chain surfactants may be described by a cooperative process where the monomer $\rightleftharpoons$ micelle equilibrium is dominant (1, 10). The micellization process of potassium *n*-octanoate in $^{2}H_2O$ is in contrast to that for long-chain surfactants that can form large micelles, e.g., 50–100 monomers per micelle (4).

The chemical nature of the surfactant, whether nonionic or ionic, bears on the variation of the critical micelle concentration (c.m.c), and hence the micelle stability, with temperature. Inherent in the c.m.c. value is a reflection of the ease of formation of the micelles, i.e., it has a dependence on the free energy of micellization (1, 4, 8, 10). A system that approaches thermal demicellization should, therefore, display an increase in the c.m.c. value at high temperatures. Indeed, the few experimental studies at elevated temperatures do show a monotonic increase of the c.m.c. with temperature. Consider, for instance, the works of Evans and Wightman (11) on cetyltrimethylammonium bromide, and Kunieda and Shinoda (12) on dioctadecyldimethylammonium chloride in water. These researchers were able to measure c.m.c. values at 166 and 200°C, respectively, which suggest that micelles exist at high temperatures. A theoretical treatment by Poland and Scheraga (13, 14) relates micelle stability to the hydrophobic character of the surfactant, e.g., alkyl chain length, and the c.m.c. They have calculated the temperature variation of the micelle size and, for a nonionic surfactant, demonstrate how micelles may not exist above a certain temperature.

From the literature data (1, 4, 11–18), a few basic features appear on the effects of temperature on micelle formation: (*i*) the c.m.c. possesses a parabolic-type variation with temperature, with the minimum usually around 25°C for ionic surfactants; and (*ii*) the size of ionic micelles appears to decrease with increasing temperature. Much information, however, is lacking on how temperature affects the self-association of surfactant amphiphiles.

One of the prime objectives of this study is, therefore, to observe the effects of high temperature on micellization, and subsequently to determine at which temperatures demicellization occurs, that is, the temperature above which micelle formation is not favoured.

Research on a simple micelle system will provide valuable information on temperature effects, which may be applied to lyotropic mesophases (19, 20), industrial processes involving surfactants (21), and to chemical evolution (22). Potassium *n*-octanoate was chosen for this work for the following reasons: (*i*) alkali metal salts of fatty acids do not decompose appreciably at higher temperatures; (*ii*) it has a high critical micelle concentration (c.m.c. ~0.30–0.40 *m* at ca. 25–35°C) (23), which allows for easier determination of the range of concentrations where most of the surfactant is in the micellar state; and (*iii*) it appears to form rather small micelles that are likely to disintegrate more completely at a lower temperature, and thus facilitate the detection of the demicellization temperature.

Experimental

Potassium *n*-octanoate was synthesized from the equimolar reaction of *n*-octanoic acid (Aldrich 99.5+%) with potassium hydroxide (Baker A.R.) in absolute ethanol, followed by several recrystallizations from absolute ethanol and rigorous drying *in vacuo*.

[1]Revision received April 11, 1986.

TABLE 1. Carbon-13 nmr chemical shifts (relative to external hexamethyldisiloxane) for the carbon atoms (numbered as position away from the CO_2^-) of potassium *n*-octanoate in the monomeric (δ_m) and micellar (δ_M) states in ^2H_2O

Potassium *n*-octanoate (from laboratory stock) was washed several times with ethyl acetate and then dried *in vacuo* over $CaCl_2$ for a few days. Ethylene glycol (Baker A.R.) was refluxed over anhydrous sodium sulfate, distilled several times in dry nitrogen, and was then immediately sealed in an nmr tube.

Surfactant solutions of molal and, in a few cases, of molar concentrations (at 29°C) in ^2H_2O (99.8 atom %; Merck, Sharp and Dohme) were placed in the outer tubes of 5 or 10 mm od Wilmad precision coaxial nmr cells, with tetramethylsilane (TMS) (MSD Isotopes) in CCl_4 (~1% v/v) as the external reference for proton nmr spectra and neat hexamethyldisiloxane (Aldrich) for carbon-13 nmr spectra. Solutions for proton nmr spectra above 72°C were sealed in 5 mm od thick-wall nmr tubes. All resonance peak positions (in ppm) are relative to the external reference set to 0 ppm in the 1.88-T magnetic field of a Bruker WP-80 nmr spectrometer.

Variable temperature, natural abundance carbon-13 nmr spectra, with heteronuclear broad-band decoupling, were recorded at 20.12 MHz on the WP-80 spectrometer, and at 30°C and 62.95 MHz, with power gated decoupling, on a Bruker AM-250 nmr spectrometer.

Samples were allowed to attain thermal equilibrium, as confirmed from spectra taken over a period of time until constant values of resonance peak positions were observed (ca. 15–20 min at 29°C). In the case of high temperature measurements, the samples were preheated in a constant temperature bath to the desired temperature. In most cases, two or three proton nmr spectra were recorded for each sample. A typical uncertainty in the proton resonance peak position is ±0.003 ppm and the mean variation of the carbon-13 chemical shift for several measurements at 20.12 MHz is ±0.012 ppm. At 80 MHz the coupled spectra are second order, and so the term, peak position, has been applied to the proton nmr signals.

The temperature inside the 5-mm ^1H nmr probehead was determined from the equation of the line of best fit (from linear regression analysis) to the plot of frequency difference between the resonance peaks of neat ethylene glycol against observed temperature. The observed temperature was determined from measurements of the melting points of eight organic solids in a manner similar to that of Yamamoto and Yanagisawa (24). Melting points measured on a Meltemp block-heater type of apparatus were correlated to those determined from plots of spectral intensity versus the temperature set on a calibrated B-ST 100/700 temperature controller. At temperatures around and above the boiling point of ^2H_2O (101.4°C) it was necessary to use either degassed ^2H_2O – chlorosulfonic acid or ^2H_2O – sulfuric acid mixtures as the deuterium lock agents in the outer tubes of the coaxial nmr cells that contained the ethylene glycol.

Measurements of the relative intensities and areas of the proton resonance peaks as a function of concentration and temperature revealed that any evaporation of the solvent above 127°C resulted in a small change in concentration of the surfactant of the order of 10%. Corrections were not applied for bulk magnetic susceptibility in the coaxial samples as this was determined to be a small effect (25–27).

Results

The observed nmr peak is a weight average signal whose position (δ_{obs}) is dependent on the species present in solution; thus $\delta_{obs} = \Sigma(iC_i\delta_i)/C_T$, where the peak position (δ_i) and concentration (C_i) are for the species composed of i monomers, and C_T is the total surfactant concentration. Extrapolation of the δ_{obs} versus C_T curve to $C_T = 0$, i.e., infinite dilution, yields the δ_i value for the unassociated monomer (δ_m). Also, extrapolation of the δ_{obs} versus C_T^{-1} curve to infinite concentration ($C_T^{-1} \rightarrow O$) provides the value for the micellar state (δ_M) (26). The difference, $\Delta\delta = \delta_M - \delta_m$, is therefore a measure of the change in environment of a proton or set of magnetically equivalent protons upon entering the micellar state. In the case of ^{13}C nuclei, other factors may contribute to the chemical shift, notably, hybridization, and inductive and steric effects (28). Representative plots of δ_{obs} versus C_T^{-1} (Figs. 1 and 2) are given. Table 1 lists the carbon-13 nmr δ_m and δ_M values at different temperatures.

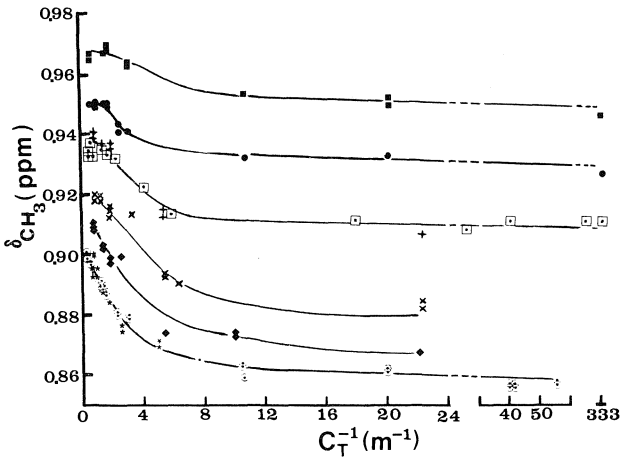

FIG. 1. Proton resonance peak position for the methyl group versus reciprocal total molal concentration of potassium *n*-octanoate in ^2H_2O; ⊙, 31°C; *, 32°C; ◆, 37°C, ×, 44°C; ⊡, 52°C; +, 54°C; ●, 61°C; ■, 72°C.

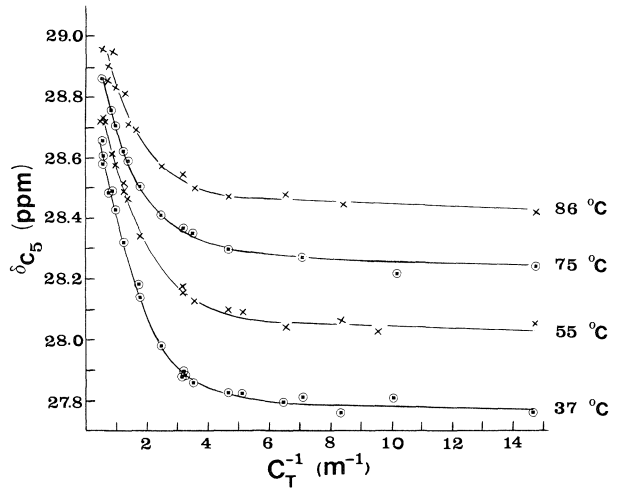

FIG. 2. Carbon-13 nmr chemical shift for the C_5 carbon atom versus reciprocal total molal concentration of potassium *n*-octanoate in ^2H_2O at different temperatures.

When TMS was not employed as an external reference, the difference in peak position, $\Delta\nu = \nu(\alpha\text{-}CH_2) - \nu(CH_3)$ was taken. The position of the centre peak of the resonance multiplet was used as $\nu(\alpha\text{-}CH_2)$. Plots of $\Delta\nu$ versus C_T yield the values ($\Delta\nu_m$) for the monomers at $C_T \rightarrow 0$ and the minima values in the plots of $\Delta\nu$ versus log C_T^{-1} (Fig. 3) were taken for the micellar state ($\Delta\nu_M$).

Critical micelle concentrations were determined from the intersection point, calculated from the equations of the lines (from linear regression analyses) of limiting slope in the plots of carbon-13 nmr chemical shift versus C_T^{-1}.

Discussion

The variations of the proton nmr peak positions as a function of the total potassium *n*-octanoate concentration in ^2H_2O are consistent with the model of normal micelle formation. For example, the difference in peak position ($\Delta\delta$) between the micellar and monomeric states is least for the α-CH_2 protons and increases with distance from the CO_2^- K^+ moiety (see Fig. 4). Over the temperature range 29–72°C the $\Delta\delta(CH_3)$ value is ca. 1.5–3.1 times larger than the $\Delta\delta(\alpha\text{-}CH_2)$ value and is in line with the fact that the methyl groups constitute the core of the

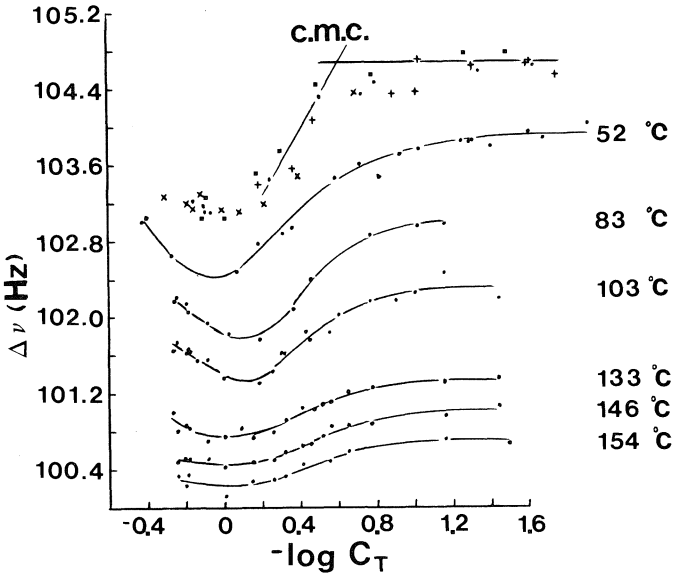

FIG. 3. Difference in peak positions ($\Delta\nu$) between the α-CH_2 and CH_3 resonances versus total molal concentration of potassium *n*-octanoate in ^2H_2O at different temperatures; ■, 29°C; +, 31°C; ×, 32°C; ●, 35°C.

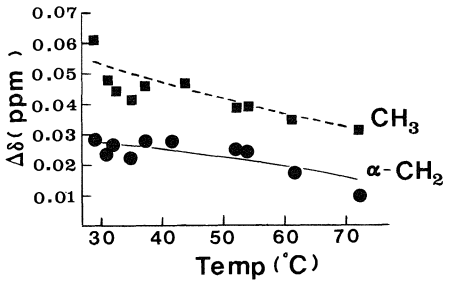

FIG. 4. Difference in proton resonance peak position ($\Delta\delta$) between the micellar and monomeric states for potassium *n*-octanoate in ^2H_2O at different temperatures (--- calculated from a computer generated least-squares fit (WATFIV LEAST).

micelle, whereas the methylene groups adjacent to the polar head groups of the amphiphile are near the surface of the micelle and, therefore, are subject to a substantial degree of hydration (29, 30). In fact, Halle and Carlström (29) have reported that fewer than two CH_2 groups of an amphiphile molecule are hydrated in the micelles of potassium *n*-octanoate in ^2H_2O at 28°C. At high temperatures the micelles are expected to be less stable and more hydrated. Enhanced dissociation of the micelles would lead the monomers to reside in a hydrated environment for longer periods of time, as is reflected in the decrease of $\Delta\delta$ with temperature over the range 29–72°C (Fig. 4).

Above ca. 70°C the volatility of the TMS in CCl_4 solution made it necessary to internally reference the peaks, e.g., the difference in peak position ($\Delta\nu$) between the α-CH_2 and CH_3 proton nmr signals was measured. Just as the characteristic peak positions, δ_m and δ_M, for the monomer and micelle, respectively, yield $\Delta\delta$, so the differences, $\delta_m(\alpha\text{-}CH_2) - \delta_m(CH_3) = \Delta\nu_m$ and $\delta_M(\alpha\text{-}CH_2) - \delta_M(CH_3) = \Delta\nu_m$, provide $\nu_M - \nu_m = \Delta(\Delta\nu)$. Micellization is also indicated from the discontinuity in the concentration dependence of $\Delta\nu$ at the c.m.c. (Fig. 3). The c.m.c. value from the $\Delta\nu$ versus log C_T^{-1} plot is similar to that from the proton nmr peak positions and the carbon-13 nmr chemical shifts (e.g., c.m.c. $\approx$ 0.30 *m* at 29°C (lit. (23) c.m.c. $\approx$ 0.30–0.40 *m* at ca. 25–35°C)). The latter are accepted

†Value at which the data extrapolate to the demicellization temperature, within the experimental error in $\Delta\delta$.

experimental parameters for the determination of c.m.c. values (26, 31). It is also worth noting that the shape of the $\Delta\nu$ versus log C_T^{-1} plot differs from that of δ versus C_T^{-1}, and this may be attributed to the different rates at which $\delta(\alpha\text{-}CH_2)$ and $\delta(CH_3)$ vary with the total surfactant concentration. The minimum position in the $\Delta\nu$ versus log C_T^{-1} plots is in all cases above the c.m.c., and has been chosen as an experimental $\Delta\nu_M$ value for the micelles. Intrinsically, the $\Delta\nu$ parameter behaves in an analogous manner to its parent parameter, δ, as reflected in the decrease in amplitude of both the δ and $\Delta\nu$ versus C_T^{-1} plots with temperature (Fig. 1 and 3).

A third parameter that affords information on demicellization phenomena is the ^{13}C nmr chemical shift. Because the ^{13}C nmr spectra are first order, it is possible to map the $\Delta\delta$ values as a function of position in the alkyl chain (Fig. 5). In contrast to the results from proton nmr spectra, the $\Delta\delta$ values from the ^{13}C spectra are higher for carbon atoms in the middle of the alkyl chain (see Fig. 5). One may explain the foregoing effect on the basis that carbon-13 chemical shifts are sensitive to conformational changes, e.g., *trans* ⇌ *gauche* rotational isomerism, with the *trans* rotamer being favoured in the micellar state (15, 16, 29). Elevation of the temperature will enhance rotations around the C—C bonds, and consequently alter the relative populations of the amphiphiles in the different rotameric states. Furthermore, conformational changes coupled with increased translational motion will weaken the hydrophobic bonding and thereby reduce the micelle stability. Increased temperature should thus induce a change in the ^{13}C nmr chemical shift, as observed from the plot of $\Delta\delta$ as a function of position along the alkyl chain (Fig. 5).

Collectively, the results from the variable temperature ^1H and ^{13}C nmr spectra suggest that potassium *n*-octanoate self-associates over a wide temperature range, 29°C to at least 103°C, and perhaps as high as 154°C. Also, the experimental results comply with a process that involves the dominance of complex processes, e.g., multiple equilibria, as exemplified by the enhanced curvature of the δ versus C_T^{-1} plot (Fig. 1) at the high temperatures. If a simple monomer ⇌ micelle equilibrium reaction exists, then the nmr peak position, or chemical shifts, as a function of C_T^{-1} will generate two straight lines ($\delta = \delta_M + (C_m/C_T)(\delta_m - \delta_M)$), which intersect at the critical micelle concentration (26). Deviations from ideal behaviour result in curved δ versus C_T^{-1} plots with larger radii of curvature for cases where the aggregates are small in size and the dominant mode of self-association is via multiple equilibria. From Figs. 1 and 3 it is obvious that the amplitude of the plots decreases and the curves tend toward the monomer line ($\delta = \delta_m$ and $\Delta\nu = \Delta\nu_m$) as the temperature increases.

Upon demicellization, surfactant monomers would be the predominant species in solution, and so the observed chemical shift would be that for the nonassociated amphiphiles, e.g., δ_m and $\Delta\nu_m$. This feature allows an estimate to be made of the demicellization temperature (DMT), for as the system tends toward the DMT, the micellar δ_M and $\Delta\nu_M$ values would, in effect, become more similar to the monomer δ_m and $\Delta\nu_m$ values (see Figs. 1–3 and 6). Two methods have been used to estimate the DMT from the ^1H nmr data, one by solving equations of the lines of δ and $\Delta\nu$ versus temperature (e.g. Fig. 6) of the monomers and micelles, for their intersection point, and the other from the temperature at which $\Delta\delta = 0$ and $\Delta(\Delta\nu) = 0$. The δ and $\Delta\delta$ data gave a DMT of ca. 127–157°C and the $\Delta\delta$ and $\Delta(\Delta\nu)$ data yielded a DMT of ca. 227°C.

The demicellization of potassium *n*-octanoate in deuterium oxide is well illustrated from the decrease in amplitude of the carbon-13 nmr $\Delta\delta$ as a function of position in the alkyl chain with increasing temperature (Fig. 5). Estimates of the DMT (115–199°C; see Table 2), from linear extrapolation of the ^{13}C nmr data to $\Delta\delta = 0$, are similar to the values (127–227°C) from the proton nmr experiments.

Although the DMT values must be considered as rough estimates, they do show some interesting and important features. In all cases the DMT (115–227°C) is above the boiling point of the solvent and in most cases is near or above the iceberg point of water (160°C) (32). Iceberg formation in water results from restructuring of the water molecules around hydrophobic entities (11, 32). This results in a change in entropy and has been attributed as a factor that affects the micellization process (1, 11). It is also significant that self-association of the surfactant into small aggregates exists above

the boiling point of ^2H_2O, where substantial changes in the bulk structure of the solvent occur.

It is not unreasonable that the demicellization temperature is above ca. 115°C. Consider the following: it is well established that alkali metal monoalkyl carboxylates with six to eight carbon atoms form small aggregates (16) in water above the c.m.c. Whereas potassium *n*-octanoate self-associates with up to ~10 monomers per micelle (29), it is questionable whether the hexanoate salt, with less than five monomers per aggregate, forms proper micelles, although it does display a c.m.c. at ca. 1.6 mol dm^{-3} at 25°C (23). Sodium pentanoate forms even smaller aggregates, dimers and trimers, and does not show a marked discontinuity in the physical parameter – concentration plot (33), although a c.m.c. has been assigned at 2.4 mol dm^{-3} at 20°C (23). A very short-chain amphiphile, such as sodium butyrate, exhibits little or no aggregation, as revealed from proton spin-lattice relaxation studies (33).

Some measure of the size of the micelles may be gained from a plot of log C_m versus log $(C_T - C_m)$, which is based on the single-step equilibrium model, where C_m is the concentration of unassociated monomers (34). The proton nmr data yield mean aggregation numbers ($\bar{n}$) in the range 3–6 monomers per micelle at 31°C and $\bar{n} \sim 2$ at 72°C, whereas the carbon-13 data give $\bar{n} \sim 9$ at 37°C and $\bar{n} \sim 4$ at 55°C. The $\bar{n}$ values should be considered as approximate, owing to the possibility of multiple equilibria and a polydispersity of aggregate sizes. Persson *et al.* (5) have determined similar $\bar{n}$ values of ~4–5 and 10–11 for sodium *n*-octanoate in ^2H_2O at 25°C.

The experimental results are in line with evidence that suggests small micelles form via multiple equilibria (18, 35), and with the quasielastic light scattering data of Mazer *et al.* (35), which reveal a decrease in the size of micelles with an increase in temperature over the range 10–85°C, for sodium dodecyl sulfate with sodium chloride in water. The aggregates formed by the alkali metal alkanoate surfactants should be very small at the high temperatures where the c.m.c. increases rapidly.

Both experimental and theoretical studies favour a parabolic or quadratic variation of the c.m.c. with temperature, the minimum value for ionic surfactants being around 25°C. From this work the c.m.c. (see Table 3) is observed to increase from ca. 0.30 *m* at 30°C to ca. 0.40 *m* at 86°C. These values are similar to those from the conductivity studies, by White and Benson, on potassium *n*-octanoate in water (36, 37). Even though the present work uses deuterium oxide as the solvent, it has been shown that ^2H_2O depresses the c.m.c. by only a small amount relative to the value in water (38).

One other point to be explored in the relation of the c.m.c. to micellization is the rate at which it changes with temperature. Literature data on the long-chain surfactants, tetradecyltrimethylammonium bromide (11) and dioctadecyldimethylammonium chloride (12) in water, reveal that the c.m.c. rises rapidly above 100°C. These results support the view that micellization becomes difficult above the boiling point of the solvent.

Finally, consider the fact that the binding energy of small micelles is less than that for large ones, and they would, therefore, be expected to demicellize at a lower temperature. The DMT for potassium *n*-octanoate corresponds to *RT* values of 3.2–4.2 kJ mol^{-1}, which are similar to the heat of dimerization of *n*-octanoic acid in water (ΔH_D = 4 kJ mol^{-1}) (39). It is consequently not unreasonable that the demicellization temperature of potassium *n*-octanoate in ^2H_2O at concentrations around the c.m.c. is in the range ca. 115–227°C, where surfactant dimers and monomers would be the predominant species in solution.

Conclusion

The experimental results from proton and carbon-13 nmr spectra provide the following information: (*i*) potassium *n*-octanoate forms aggregates over a wide temperature range, 29–154°C, and above the boiling point of deuterium oxide; (*ii*) complex or multiple equilibria appear to dominate the self-association process of the surfactant at high temperatures; and (*iii*) estimates of the demicellization temperature are in the range ~115 ≤ DMT ≤ 227°C where micelle formation is not favoured.

The effects of high temperatures (29–123°C) on critical micelle concentrations in solutions of potassium *n*-octanoate in deuterium oxide: A nuclear magnetic resonance study

M. A. DESANDO AND L. W. REEVES

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received September 9, 1985[1]

M. A. DESANDO and L. W. REEVES. Can. J. Chem. **64**, 1823 (1986).

Critical micelle concentrations have been determined for potassium *n*-octanoate in deuterium oxide over a wide temperature range, 29–123°C, from the concentration dependence of proton nmr spectral parameters (peak positions, and vicinal splitting values of the α-CH_2 multiplet) and carbon-13 nmr chemical shifts. The c.m.c. varies from ca. 0.30 *m* at ca. 30°C to ca. 0.50 *m* at ca. 120°C and is at a minimum (0.30–0.35 *m*) in the temperature range ca. 30–50°C. $^{23}Na^+$ spin-lattice relaxation times reveal that a co-counterion (Na^+) different from that of the surfactant counterion (K^+) reflects the micellization process. A second critical micelle concentration has been observed around 1.0 *m* at ca. 30°C.

M. A. DESANDO et L. W. REEVES. Can. J. Chem. **64**, 1823 (1986).

Opérant dans l'oxyde de deutérium et à des températures aliant de 29 à 123°C et en se basant sur la variation des paramètres spectraux de la rmn du ^1H (déplacements chimiques et constantes de couplages vicinaux du multiplet du α-CH_2) et du ^{13}C (déplacements chimiques) avec la concentration, on a déterminé les concentrations micellaires critiques de l'octanoate de potassium. Ces c.m.c. varient d'environ 0,30 *m* à 30°C à environ 0,50 *m* à 120°C; elles passent par un minimum (0,30–0,35 *m*) dans l'intervalle de température de 30 à 50°C. Les temps de relaxation spin-réseau du $^{23}Na^+$ révèlent que la présence d'un contre-ion (Na^+) différent de celui présent dans les surfactants (K^+) se réflète dans le processus de micellisation. À 30°C, on a aussi observé une deuxième concentration micellaire critique autour de 1,0 *m*.

[Traduit par la revue]

Introduction

Amphiphiles of fatty acid salts are known to form normal micelles in water (1–5) around room temperature. Whereas considerable study has been done on the properties of surfactant solutions around the critical micelle concentration (c.m.c.), relatively little research has been performed on micelles at high temperatures and at high surfactant concentrations. There is uncertainty as to the nature of the changes that occur in the micelles as surfactant is added to the solution above the c.m.c, and at temperatures near and above the boiling point of water.

The critical micelle concentration is a fundamental parameter in the characterization of surfactant solutions, for it indicates the usually narrow range of concentrations separating the limits below which most of the surfactant is in the monomeric state and above which virtually all additional surfactant enters the micellar state (6). This definition has been subject to controversy as has been the concept of a c.m.c. A number of theories have been advanced to explain the occurrence of a critical micelle concentration (1, 6–9). The usefulness of c.m.c. values in the study of micelle formation, however, cannot be argued. For example, the variation of the c.m.c. with temperature can provide thermodynamic data and information on the nature of the surfactant self-association process.

In light of the importance of the c.m.c parameter, it is surprising that few studies have been carried out on its variation over a wide temperature range, which extends above the boiling point of water (10, 11). Research on surfactant systems is relevant to the industrial processes, e.g., the temperature for optimum detergency, and to biological phenomena such as temperature effects on membranes and the origin of life on the primitive earth.

It has been suggested that a second critical micelle concentration (c.m.c.$^{\#2}$) exists at concentrations higher than the critical micelle concentration (12–17). Some researchers believe that the c.m.c.$^{\#2}$ arises from a sphere-to-rod transition of the micelle geometry (16). Others attribute the c.m.c.$^{\#2}$ to a distortion of the micelles owing to increased binding of the counterions (ion condensation) and hence enhanced hydration of the micelles (13). Another explanation for the second critical concentration is that it occurs where the aggregates gain positional order because of increased electrical repulsions among the micelles (14). It has even been advanced that the changes in micelle structure at the c.m.c.$^{\#2}$ are so subtle that a very sensitive technique such as position annihilation is required to detect it (13).

The prime objective of the present work is therefore to study a simple ionic surfactant system, viz., potassium *n*-octanoate in ^2H_2O, by multinuclear nmr spectroscopy with a view to obtaining information on the temperature dependence of critical micelle concentrations.

Experimental

Potassium *n*-octanoate was prepared by neutralizing *n*-octanoic acid (Aldrich 99.5 + %) with an equimolar quantity of potassium hydroxide (Baker A.R.) in absolute ethanol. The product was recrystallized several times from absolute alcohol and rigorously dried *in vacuo*. Potassium *n*-octanoate (from laboratory stock) was washed several times with ethyl acetate to remove any residual acid, and was then dried *in vacuo* over anhydrous $CaCl_2$ for several days. Sodium chloride (Baker A.R.) was used without further purification. Ethylene glycol (Baker A.R.) was dried over anhydrous sodium sulfate during reflux in dry nitrogen gas prior to several distillations. Deuterium oxide (99.8 at.%) was purchased from Merck, Sharp & Dohme. The absence of recrystallizing solvents in potassium *n*-octanoate and water in ethylene glycol was checked from carbon-13 and proton nmr spectra.

Solutions of potassium *n*-octanoate in ^2H_2O were of molal concentration, except for those at 29°C, which were of molar concentration, and were contained in the outer tubes of thin-wall 5 mm od coaxial nmr cells (Wilmad WGS-5B1). Tetramethylsilane (TMS) in CCl_4 (~1 v/v) was used as the external reference in the inner tube of the nmr cell for proton spectra. Above 72°C the samples for proton spectra were contained in sealed thick-wall 5 mm od nmr tubes, without a reference material.

Proton nmr peak positions were measured relative to external TMS set to zero ppm on an 80-MHz (1.88-T field) Bruker WP-80 nmr spectrometer equipped with a PTS 160 frequency synthesizer and a B-ST 100/700 variable temperature controller. A typical uncertainty in

[1]Revision received April 11, 1986.

the proton nmr peak position is ±0.003 ppm. Corrections were not applied for bulk diamagnetic susceptibility in the coaxial samples, as no appreciable difference in peak position was noticed when the inner cell was present. The undecoupled proton nmr spectra are second order, and so the term, peak position, has been applied to the data.

$^{23}Na^+$ spin-lattice relaxation times were measured by the application of a $(\pi-\tau-\pi/2)_n$ pulse sequence via the inversion–recovery method at a frequency of 20.13 MHz at 29°C.

The temperature inside the ^1H probehead was measured from the linear equation for the difference in peak position of the ethylene glycol resonances as a function of observed temperature. The method employed to determine the observed temperature was similar to that of Yamamoto and Yamagisawa (18), and involved measurements of the melting points of eight organic solids, first on a Meltemp melting point apparatus and then on the nmr spectrometer. Ethylene glycol was sealed in the inner tube of a coaxial cell and the ^2H-lock agents (^2H_2O; ($^2H_2O/HSO_3Cl$ or $^2H_2O/H_2SO_4$ at ≥101°C)) in the outer tube.

Natural abundance, broad-band decoupled carbon-13 nmr spectra were recorded at 20.12 MHz on the Bruker WP-80 spectrometer, and power gated, broad-band decoupled carbon-13 nmr spectra, at 62.95 MHz and 30°C, on an AM-250 Bruker nmr spectrometer with a superconducting magnet. The ^{13}C nmr chemical shifts are relative to external hexamethyldisiloxane (98+%, Ald), and have a mean variation of ±0.012 ppm for several measurements.

Results

In accord with a single-step equilibrium model of micellization (monomer ⇌ micelle) the resonance peak position or chemical shift (δ) as a function of total surfactant concentration (C_T) can be expressed as:

$$[1] \quad \delta = \delta_M + [c.m.c.(\delta_m - \delta_M)]/C_T$$

where the subscripts m and M refer to the monomer and micelle, respectively (19). Inherent in the above equation is the condition that a plot of δ versus C_T^{-1} will consist of two straight lines that intersect at the critical micelle concentration (c.m.c). Factors such as multiple equilibria, polydispersity of micelle size, small aggregates, and structural transformations of the micelles may induce a degree of curvature in the δ versus C_T^{-1} plot, which increases as the system deviates from the simple equilibrium model. Modifications of eq. [1] have been formulated to consider ion-pair dissociation, but these have little effect on the shape of the curve (19).

Almost any physical property that varies with the degree of association of a solute will display a change in magnitude as the solute concentration is altered. Whether an abrupt change or discontinuity occurs at a certain concentration, e.g., the c.m.c., depends on the rate of change of the property (P) being observed. At the c.m.c., for example, d^3P/dC_T^3 is zero (20).

The c.m.c. values were determined, using linear regression analysis, from the intersection point of the lines of limiting slope of the spectral parameter (δ, $^3J_{HH}$, and T_1) versus the reciprocal of the total surfactant concentration C_T^{-1}) (Figs. 1–4). A low limit for the monomer line was set from the extrapolated value of the parameter–concentration curve to infinite dilution. The uncertainty in the c.m.c. value may be as high as ±0.05 m.

Although nmr chemical shifts (19) and spin-lattice relaxation times (21) have been used to determine c.m.c. values, the indirect nuclear spin–spin splitting value ($^3J_{HH}$) has not received much attention. The average vicinal proton ($H_1C_1C_2H_2$) splitting ($^3J_{H_1H_2}$) has been related empirically to the dihedral angle between the protons, by the Karplus equations for the ethanic molecules (22). Determinations of the $^3J_{HH}$ values, which are weight averaged ($^3J_{HH} = \Sigma x_i {}^3J_{HH_i}$; $^3J_{HH_i}$ is the splitting value for the species of mole fraction, X_i), for the monomeric and

micellar states, give an indication of conformational changes in the surfactant ion pair, and possibly counterion binding upon micellization.

Spin-lattice relaxation times (T_1) were determined from the variation of the magnetization (M_z) along the z laboratory axis and thus the spectral intensity, as a function of the relaxation delay time between the π and $\pi/2$ pulses (23).

$$[2] \quad \ln (M_0 - M_z) = \ln (2M_0) - (t/T_1)$$

M_0 is the equilibrium magnetization before decay, $M_0 = -M_z$ at time $t = 0$.

Measurement of the c.m.c. value at different temperatures, from the various parameters (Table 1), allows for the calculation of thermodynamic quantities, such as the free energy (ΔG_{mic}), enthalpy (ΔH_{mic}), and entropy ΔS_{mic} of micellization, from a van't Hoff type of relation (10, 20, 24, 25):

$$[3] \quad \Delta G_{mic} = \Delta H_{mic} - T\Delta S_{mic} = \bar{n}(2 - \beta)RT \ln X_{c.m.c.}$$

In eq. [3] $\bar{n}$ is the mean aggregation number, $0 \leq \beta \leq 1$ ($\beta = 0$ for an electrically neutral micelle) is the degree of ionization of the micelle, and $X_{c.m.c.}$ is the c.m.c. in mole fraction units.

Discussion

It is observed from the plots of the proton resonance peak positions and carbon-13 nmr chemical shifts against the reciprocal of the total surfactant concentration that each of the different sets of magnetically equivalent nuclei reflects the micellization process, even the solvent (Fig. 1). Micellization is therefore a bulk phenomenon and is experienced by every part of the system. Although the water resonance signal has received some attention (26, 27), few studies have focussed on the alkyl group protons for the determination of the c.m.c. value. There are differences in the literature as to the extent of change in chemical shifts that the CH_3 and CH_2 protons experience as a function of the total surfactant concentration. Some researchers state that the alkyl proton resonances display little or no variation in chemical shift upon micelle formation (26–28). Odberg *et al.*, on the other hand, were able to determine c.m.c. values for the short-chain alkanoates from the alkyl proton nmr chemical shifts and differences in chemical shifts (29). Also, Fendler *et al.* observed appreciable changes in the chemical shifts of the CH_3 and CH_2 proton resonance signals of hexylammonium propionate in ^2H_2O (30).

One significant outcome of this study is that micellization is reflected in the abrupt change of the vicinal splitting value ($^3J_{HH}$) of the α-CH_2 protons around the c.m.c. (cf. c.m.c. from

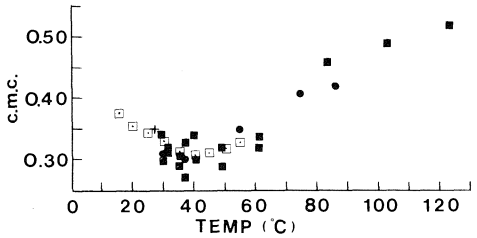

FIG. 5. Critical micelle concentration values (c.m.c. in mol kg^{-1}) at different temperatures for potassium *n*-octanoate in ^2H_2O: ■, from proton, and ●, from carbon-13 nmr spectral parameters (Table 1); ⊡, refs. 6, 24, and 51.

*Potassium *n*-octanoate:NaCl (3:1 mole:mole) in ^2H_2O.

^{13}C nmr chemical shifts; see Fig. 3 and Table 1). Notice how the splitting values, at many temperatures, increase from ca. 7 Hz in the monomeric state to ca. 8 Hz in the micellar condition (Table 2). The variation of the $^3J_{HH}$ values may be accounted for by conformational changes around the headgroup and (or) increased binding of the cations to the micelles.

In the cases where NaCl is added in a 1:3 molar ratio to potassium *n*-octanoate in deuterium oxide the c.m.c. is obtained from the $^{23}Na^+$ spin-lattice relaxation time (Fig. 1), and agrees with that from the other parameters (see Table 1). Lindman *et al.* demonstrated, for binary solutions, the application of $^{23}Na^+$ spin-lattice relaxation times to the measurement of the c.m.c. (15, 31, 32). Clearly, the third component (electrolyte) experiences the formation of micelles. Exchange reactions of the type: $K^+Oc^- + Na^+ \rightleftharpoons Na^+Oc^- + K^+$ (Oc^- is *n*-octanoate) lead, in effect, to a mixed micelle. An indication of the interaction of the sodium cations with the micelles is forwarded by the $^{23}Na^+$ spin-lattice relaxation times (T_1) of the ternary solutions. At infinite dilution, the fact that T_1 ($\sim 4.6 \times 10^{-2}$ s) is ca. 40 times greater than the value $T_1 \sim 1.1 \times 10^{-3}$ s, in the micellar state, suggests enhanced interactions of the Na^+ with the *n*-octanoate ion. The former value compares to $T_1 \sim 4.1 \times 10^{-2}$ s for a solution of 0.25 molar NaCl in ^2H_2O and a literature value (33) of 5.0×10^{-2} s for a dilute solution of NaCl in water at 25°C.

A further indication of the effect of added electrolyte may be gained from the difference in peak position ($\Delta\delta$) between the micellar and monomeric states. When sodium chloride is present, $\Delta\delta$ increases by ca. 16% for the CH_3 protons as compared to ca. 77% for the α-CH_2 protons. These results suggest that although there are additional interactions among the hydrocarbon tails owing to the large size of the aggregates, there are also appreciable changes at the micelle surface. The decrease in the c.m.c. at 31°C from ca. 0.30 *m* to ca. 0.20 *m*, upon the addition of NaCl, testifies to the formation of large micelles.

Simple electrolytes, as well as high surfactant concentrations, are known to induce changes in the size and shape of micelles (2, 16, 34–49). However, the concentrations associated with the above phenomena, and the exact nature of the changes in the micellar solution, are not well understood. Above the c.m.c. a second critical micelle concentration may exist where the micelles undergo processes such as: (*i*) sphere (or globule)-to-rod transitions; (*ii*) increased hydration and binding of the counterions (ion condensation) (31); and (*iii*) greater positional order (14).

A second critical micelle concentration (c.m.c.$^{\#2}$) does in fact appear at ca. 1.0 *m* potassium *n*-octanoate in deuterium oxide (see Figs. 2 and 4). Statistically, the data may be correlated to two lines, one below and one above ca. 1.0 *m* potassium *n*-octanoate, as reflected in the correlation coefficient (Fig. 4). When the ^{13}C nmr data of Persson *et al.* (48), for sodium *n*-octanoate in ^2H_2O, are plotted along with the ^{13}C and ^1H nmr results from this work, the discontinuity around 1.0 *m* surfactant is quite obvious. Furthermore, when NaCl is added to the surfactant solutions, the second critical micelle concentration is again observed around 1.0 *m* potassium *n*-octanoate (Fig. 2).

Other cases in which researchers have utilized proton chemical shifts to detect a second critical micelle concentration are for potassium and sodium *n*-hexanoate at a 2 molar concentration in water (29). Gustavsson and Lindman reported a second break, at ca. 1.2 *m*, in the plot of $^{23}Na^+$ spin-lattice relaxation time versus total sodium *n*-octanoate concentration in ^2H_2O, along with an increase in the ratio of counterion to surfactant in the micelles (32). Aqueous solutions of cetylpyridinium chloride (16) and potassium oleate (17) display a second critical micelle concentration at around 10% by weight of surfactant, as compared to ca. 18% by weight for potassium *n*-octanoate in ^2H_2O from this study.

The variations of the spectral parameters with surfactant concentration suggest a progressive buildup of the micelles, via multiple equilibria reactions. If a monomer $\rightleftharpoons$ micelle equilibrium process is dominant, then a sharp transition point would be observed and the plot of δ versus concentration would generate two intersecting lines according to eq. [1]. Explicit in eq. [1] is the assumption that C_m = c.m.c., i.e., a constant monomer concentration above the c.m.c. If the number of free monomers changes with the total surfactant concentration there will be deviations from linearity in the plot of δ versus C_T^{-1}. There is experimental evidence that the unassociated monomer concentration decreases above the critical micelle concentration (50). Should there be a transition from spherical micelles (SM) to say globular, disk, cylindrical, or rod-shaped micelles (CM), then, for an equilibrium of the kind sphere $\rightleftharpoons$ rod, the nmr peak

position as a function of total surfactant concentration may take the form:

$$[4] \quad \delta = \delta_{CM} + \frac{\text{c.m.c.}^{\#2}}{C_T}(\delta_{SM} - \delta_{CM}); \quad \text{c.m.c.}^{\#2} = C_{SM}$$

assuming that all of the solute is in the two forms of micelles, i.e., no unassociated monomer. The presence of monomers would result in an expression of the form

$$[5] \quad \delta = (C_m\delta_m + \bar{n}C_{SM}\delta_{SM} + \bar{n}'C_{CM}\delta_{CM})/C_T$$

If $C_m \sim$ c.m.c. and $C_{SM} \sim$ c.m.c.$^{\#2}$, then

$$[6] \quad \delta = (\text{c.m.c.}\,\delta_m + \bar{n}\,\text{c.m.c.}^{\#2}\delta_{SM} + \bar{n}'C_{CM}\delta_{CM})/C_T$$

The total surfactant concentration can be expressed as

$$[7] \quad C_T = C_m + \bar{n}C_{SM} + \bar{n}'C_{CM} = \text{c.m.c.} + \bar{n}\,\text{c.m.c.}^{\#2} + n'C_{CM}$$

therefore,

$$[8] \quad C_{CM} = (C_T - \text{c.m.c.} - \bar{n}\,\text{c.m.c.}^{\#2})/\bar{n}'$$

Substitution of eq. [8] into eq. [6] and rearrangement yields

$$[9] \quad \delta = \delta_{CM} + \{[\text{c.m.c.}(\delta_m - \delta_{CM}) + \bar{n}\,\text{c.m.c.}^{\#2}(\delta_{SM} - \delta_{CM})]/C_T\}$$

When $\delta_{SM} = \delta_{CM}$ the above equation reduces to eq. [1] and two intersecting lines are observed in the plot of δ versus C_T^{-1}.

From the plots of δ against C_T^{-1} it is observed that the slope above the second transition point is less than that above the c.m.c.; thus from eqs. [1] and [9] one may infer:

$$[10] \quad \text{c.m.c.}(\delta_m - \delta_{SM}) > \text{c.m.c.}(\delta_m - \delta_{CM}) + \bar{n}\,\text{c.m.c.}^{\#2}(\delta_{SM} - \delta_{CM})$$

Other factors that may induce a change in the slope of the δ versus C_T^{-1} plot, above the c.m.c., are the concentration of the monomer and the size of the micelles. Notice in eqs. [6] and [9] that if C_m ($C_m \sim$ c.m.c.), $\bar{n}$, and $\bar{n}'$ vary with the total surfactant concentration then the slope will change. There is experimental evidence that the monomer concentration is at a maximum at the c.m.c. and that a polydispersity of aggregate sizes exists (50). If the $\bar{n}$ and $\bar{n}'$ values vary at different concentrations then slightly different δ_{SM} and δ_{CM} values would also be expected.

An expression ($\log C_m + \log nK = n \log (C_T - C_m)$; n is the mean aggregation number and K is the equilibrium constant) based on a single-step equilibrium model affords a rough estimate of the size of the micelles (46, 47). The average slope of the $\log C_m$ versus $\log (C_T - C_m)$ plot yields $\bar{n}$ in the range 3–6 monomers per micelle at 31°C from ^{1}H nmr spectra, and $n \sim 9$ at 37°C from ^{13}C nmr experiments. Literature values for sodium n-octanoate are $\bar{n} = 4$ to $\bar{n} = 15$ (48, 50). Some papers quote two $\bar{n}$ values for sodium n-octanoate, depending on the concentration interval studied (48). It is therefore very important that one understands the type of micelle present in a certain concentration interval and, therefore, the critical micelle concentrations, to interpret data on micelle systems.

Measurements of the c.m.c. values at temperatures in the range 29–123°C give additional information on the nature of micelle formation, in particular, the thermodynamics. Some ionic surfactants exhibit a minimum in the c.m.c. around room temperature, whereas for some nonionic and betaine surfactants the c.m.c. decreases with an increase in temperature (5). Critical micelle concentrations for bivalent metal alkyl sulfates appear to be independent of the temperature.

In the case of potassium n-octanoate in ^2H_2O, the c.m.c. shows little change, ca. 0.30–0.35 m, in the temperature range ca. 30–50°C and is at a minimum around 30–50°C, and then increases to ca. 0.52 m at 123°C. White and Benson observed a minimum in the c.m.c. of potassium n-octanoate plus a slight excess of KOH in water at 35°C, from conductivity measurements (24).

Analysis of the temperature variation of the c.m.c. allows for the determination of the enthalpy and entropy of micellization (eq. [3]). Mean aggregation numbers of 5–10 monomers per micelle and a degree of micelle ionization of $\beta = 0.7$–0.8 (from ref. 24) were applied in the calculations. The plot of ln c.m.c. (in mole fraction units) versus the reciprocal of the temperature yields $-101 \lesssim \Delta H_{mic} \lesssim -47$ kJ mol^{-1} and $117 \lesssim \Delta S_{mic} \lesssim 234$ J K^{-1} mol^{-1} above ~55°C. A decrease in the size of the micelles to dimers and trimers yields $-30 \lesssim \Delta H_{mic} \lesssim -19$ kJ mol^{-1}. The observed ΔH values compare with $\Delta H \sim -4$ to -12 kJ mol^{-1} at 45–55°C, from the conductivity data of White and Benson for potassium n-octanoate + KOH in water (24). Use of the van't Hoff relation for the derivation of enthalpies of micellization from c.m.c. values has been criticized on the basis that it assumes a temperature invariant micelle size, and the only reliable values are from conductivity experiments (24, 25). The ΔH_{mic} values do, however, indicate an exothermic process above ~55°C.

A factor that must be considered in the interpretation of the thermal dependence of the c.m.c. is the presence of the second critical micelle concentration. Boussaha and Ache demonstrated, using the positron annihilation technique, that the second critical micelle concentration for sodium n-octanoate/n-pentanol/H_2O decreases with increasing temperature (13). Mazer *et al.* determined, calorimetrically, the enthalpy for the process at the second critical concentration to be -1.74 ± 0.15 kJ mol^{-1}, for sodium dodecyl sulfate plus 0.6 molar sodium chloride in water (34). The aforementioned results imply subtle changes in the micelles at the second critical micelle concentration, yet appreciable changes in the nmr spectral parameters are noticed (Figs. 2 and 4).

Caution is advised in the study of micellization over wide temperature and surfactant concentration ranges, where both a critical micelle concentration and a second critical concentration occur and may vary at different rates with a change in temperature. Care should be taken to correlate the concentration dependence of a physical property on the total surfactant concentration to the proper critical micelle concentration, and to analyze the parameter–concentration plot over the appropriate range of concentrations associated with each phenomenon.

Conclusion

The study of micellization in potassium n-octanoate in deuterium oxide, over wide concentration and temperature intervals, reveals the following features:

(*i*) Proton nmr spectral parameters (peak position, and the vicinal splitting value of the α-CH_2 protons) yield the c.m.c. and the second critical micelle concentration, and the results are found to agree with those from carbon-13 nmr chemical shifts.

(*ii*) The c.m.c. shows little variation (ca. 0.30–0.35 m) with temperature in the range ca. 30–60°C, is at a minimum around 30–50°C, and increases up to ca. 0.52 m at 123°C (see Fig. 5).

(*iii*) A second critical micelle concentration exists around 1.0 *m* potassium *n*-octanoate in deuterium oxide at ca. 30–40°C.

Received July 16, 1984[2]

CARMEN ESTEBAN-CALDERON, MARTÍN MARTINEZ-RIPOLL, SEVERINO GARCÍA-BLANCO, FERNANDO TEMPRANO, and JOSÉ GONZALO RODRIGUEZ. Can. J. Chem. **64**, 1829 (1986).

The structures of cyclohexan[*b*]indole *N*-β-propionic acid (**1**) and cyclooctan[*b*]indole *N*-β-propionic acid (**2**) have been determined by X-ray methods. The conformational populations of their *N*-β-propionic chains have been determined in solution by ^{1}H nmr analyses. Crystals of **1** are triclinic, space group $P\bar{1}$, with a = 12.3562(4), b = 11.0727(3), c = 10.2050(4) Å, α = 108.519(3), β = 83.941(3), γ = 104.826(3)°, and Z = 4. Crystals of **2** are monoclinic, space group $P2_1/c$, with a = 5.636(1), b = 18.937(3), c = 13.976(4) Å, β = 98.84(3)°, and Z = 4. In both structures, the molecules are linked forming dimers through centrosymmetric H bonds. In solution the *trans* conformation of the chain is the preferred one in both compounds and increases with dilution until a constant value is reached.

CARMEN ESTEBAN-CALDERON, MARTÍN MARTINEZ-RIPOLL, SEVERINO GARCÍA-BLANCO, FERNANDO TEMPRANO et JOSÉ GONZALO RODRIGUEZ. Can. J. Chem. **64**, 1829 (1986).

On a déterminé par cristallographie de rayons-X les structures des acides cyclohexan[*b*]indole (**1**) et cyclooctan[*b*]indole (**2**) *N*-β-propioniques et les populations conformationelles de la chaine *N*-β-propionique en solution par rmn ^{1}H. Les cristaux de l'acide **1** sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$ avec a = 12,3562(4), b = 11,0727(3), c = 10,2050(4) Å, α = 108,519(3), β = 83,941(3), γ = 104,826(3)° et Z = 4. Les cristaux de l'acide **2** sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 5,636(1), b = 18,937(3), c = 13,976(4) Å, β = 98,84(3)° et Z = 4. L'empaquetement moleculaire presente des dimeres avec des liaisons hydrogènes vers les centres d'inversion. En solution, la conformation *trans* est la préférée en **1** et **2** et elle augmente avec la dilution jusqu'à un valeur constante.

[Traduit par la revue]

Cycloalkan[*b*]indole *N*-β-propionic acids are potential anti-inflammatory drugs, structurally related to Indomethazin. Moreover, the *N*-γ-aminopropyl derivatives of the cycloalkan[*b*]indoles have antidepressant action.[3] Structures of this type of compound are analyzed to correlate the sizes of the cycloalkane rings with their particular action. The conformational analysis of the *N*-β-propionic acid chain in solution is also interesting, to verify the implication of the bulk of cycloalkane ring versus the conformational equilibrium of the chain.

Experimental

Synthesis

Cyclohexan[b]indole and cyclooctan[b]indole

These compounds were synthesized by thermal reaction (in ethylene glycol) of the phenylhydrazone of the cyclohexanone, 90%, mp 114–115°C, and of the phenylhydrazone of the cyclooctanone, 88%, mp 72–73°C, respectively.

Acids **1** and **2** were prepared by addition of acrylonitrile to an ethereal solution of sodium hydride with the respective cycloalkan[*b*]indole, followed by nitrile hydrolysis and recrystallization; 48%, mp 113–116°C for **1** and 52%, mp 134–135°C for **2**. Crystals of **1** and **2** were formed by slow evaporation at 5°C of an ethanolic solution.

X-ray structure determination

Compound 1

$C_{15}H_{19}O_2N$ Mr = 245.4

V = 1279.4(1) Å^3, D_c = 1.27 g cm^{-3}, $F(000)$ = 527, θ_{max} = 60°, prismatic colorless crystals, 0.25 × 0.20 × 0.10 mm.

Compound 2

$C_{17}H_{21}O_2N$ Mr = 271.4

V = 1474(1) Å^3, D_c = 1.22 g cm^{-3}, $F(000)$ = 584, θ_{max} = 65°, prismatic colorless crystals, 0.20 × 0.15 × 0.10 mm.

A four-circle automatic Pw 1100 diffractometer with graphite monochromated CuKα radiation (λ = 1.5418 Å) and ω/2θ scan were used to collect the intensities of 3792 independent reflections for **1** and 2705 for **2**. Cell constants, as given in the abstract, were obtained by least-squares fit of 30 reflections with high angles, measured for both positive and negative Bragg angles. Two standard reflections, monitored every 90 min, showed no crystal decomposition. In reducing the data, Lorentz and polarization factors were applied, but no corrections for absorption were made. 2639 reflections for **1** and 1658 for **2** were considered as observed with the criterion $I > 3\sigma(I)$.

Both structures were solved using MULTAN (1). The usual sequence of isotropic and anisotropic refinement was followed, after which all H atoms were located on difference maps. A weighting scheme of the type $w = w_1 \cdot w_2$ was used to prevent bias on $\langle w \cdot \Delta^2 F \rangle$ vs. $\langle F_o \rangle$ and vs. $\langle \sin\theta/\lambda \rangle$, with $w_1 = K/(a + b|F_o| + c|F_o|^2)^2$ and $w_2 = 1/(d + e \sin\theta/\lambda)$ (2). Final full-matrix (3) anisotropic weighted refinement (isotropic fixed parameters for H atoms) gave the discrepancy indices R = 0.050, $R\omega$ = 0.054 for **1** and R = 0.047, $R\omega$ = 0.056 for **2**. Scattering factors for neutral atoms (4) were used in both cases. Final atomic parameters are shown in Tables 1 and 2.[4]

Bond lengths, bond angles, least-squares planes, and torsional angles for **1** and **2** are given in Tables 3–10. The atomic labelling for both compounds is shown in Figs. 1((*a*) and (*b*)) and 2.

Discussion

Cyclohexan[b]indole N-*β-propionic acid* ***1***

The bond lengths and bond angles in the two independent molecules can be analyzed together. The average of the C(sp^2)—C(sp^2) indole nucleus distances are 1.398(6) in molecule 1 and 1.397(6) Å in molecule 2. The common fused bonds C(12)—C(13) = 1.361(6) and C(22)—C(23) = 1.357(5) Å are the shortest distances, the C(13)—C(14A) = 1.427(6) and C(23)—C(24A) = 1.423(6) Å being the longest ones within the pyrrole rings. N(11)—C(12) = 1.393(4), N(21)—C(22) = 1.395(5) and N(11)—C(17A) = 1.381(6), N(21)—C(27A) = 1.389(5) Å are between single and double bond lengths, although the latter are slightly shorter than the former. The indole fragment is planar within experimental error, Table 5.

The average of the C(sp^3)—C(sp^3) cyclohexene ring is 1.530(7) (here only molecule 1 is considered), while C(sp^3)—C(sp^2) bond lengths are 1.499(6) Å in molecule 1 and 1.500(6) Å in molecule 2. Moreover, bond lengths C(13)—C(111) = 1.511(5) and C(12)—C(18) = 1.487(7) Å within the cyclohexane ring of molecule 1 are differently affected by the electronegative N(11)—C(12) bond. Similar differences were observed in molecule 2, 1.508(6) vs. 1.492(6) Å.

The cyclohexene ring in molecule 1 is in a half-chair conformation, which seems the most stable from inspection of mechanical models, and it is the only one observed in the crystal structures (5).

Conformation of the cyclohexene ring in molecule 2 cannot be properly analyzed because of a disorder problem affecting the atoms C(29) and C(210). The electron density profiles for C(29) and C(210) are very broad, having maxima corresponding to the coordinates where those atoms were located. The temperature factors of these two atoms and the fact that only one H atom appears attached to each of them, confirms a disorder in which the atomic positions found are actually the average of the positions given by two different "half-chair" conformations.

Conformational site exchange in the liquid state is assumed to proceed via a "boat" intermediate conformation. The energy barrier has been calculated by dynamic nmr to be 22.6 kJ/mol for partially deuterated cyclohexene (6). Cyclohexene on the indole ring should be examined, but care must be exercised in extrapolating the conclusions to cyclohexene derivatives, since the torsional barrier in the C—C bond adjoining the pyrrole ring is close to zero. These energy requirements for the conformational equilibrium through a boat intermediate seem not to be present in 2 in the solid state, and thus alternative "half-chair" conformers in the crystal can be considered as contributing to the disorder.

The *N*-β-propionic chains of both molecules show *gauche* conformations (Fig. 1). The molecules are packed forming dimers through centrosymmetric hydrogen bonds, their geometrical features being presented in Table 3.

Cyclooctan[b]indole N-*β-propionic acid* ***2***

The average of the C(sp^2)—C(sp^2) bond lengths within the indole nucleus is 1.395(3) Å. This molecule shows identical relationships between bond distances, in the pyrrole ring, to the ones reported above for the cyclohexan[*b*]indole. The average of the C(sp^3)—C(sp^3) bond lengths in the cyclooctene ring is

agreement with those appearing in 3-methylindole (7) and iprindole (8).

While "boat-chair" and "crown" conformations have been experimentally found for the cyclooctane ring in X-ray structure determinations (5), there are only a few examples of a cyclooctene ring in the crystallographic literature. The preferred conformation of a cylooctene system is not known with certainty. The most stable conformation was calculated to be an unsymmetrical structure related to the cylooctane "boat–chair" (9). The *cis* cyclooctene ring shows a twisted boat conformation in this compound under investigation. The torsional angles defining the conformation of this ring are given in Table 10. They are in good agreement with those reported for iprindole (8) and for the *cis*-9,9-dimethyl-9-azoniabicyclo[6,1,0]nonane ion (10).

The *N*-β-propionic chain in Fig. 2 shows the fully extended *trans* conformation. The molecular packing of this compound is also due to centrosymmetric hydrogen bonds, forming dimers (Table 7).

Conformational ^1H nmr analysis

An interesting aspect of the present investigation is the conformational analysis of the *N*-β-propionic chain in **1** and **2**, since this may well be relevant to the mode of action of these compounds.

[a]ΔE in kcal mol^{-1}; $N/2$ (Hz) = J_{AB}.

chloroform solution, to observe the influence of the bulky cycloalkane substitution and of dilution on the conformational equilibrium populations of the *N*-β-propionic acid chain. Thus, cyclopentan-, cylclohexan- (**1**), cycloheptan-, and cyclooctan[*b*]indole (**2**) *N*-β-propionic acids show, in all cases, two triplet signals of A_2B_2 type for the two methylenes of the chain, a complex multiplet of the methylenes of the cycloalkane ring, and a low-field half broadened signal due to the long range coupling with the aromatic protons.

Newman representations of the staggered conformers are shown in Fig. 3. The two *gauche* forms are mirror images and hence of equal energy. The observed value of J_{AB} is then simply obtained as the weighted average of the values in the *trans* (J_t) and *gauche* (J_g) conformations according to a method previously reported (11), with

$$J_{AB} = n_g J_g + n_t J_t$$

$$n_g + n_t = 1$$

$$\Delta E = E_g - E_t = RT \ln 2(J_{AB} - J_g)/(J_t - J_{AB})$$

where n_t and n_g are the populations of the *trans* and *gauche* conformers respectively, ΔE being the excess of energy (strictly free energy) of the *gauche* form. J_t and J_g are experimental values observed in compounds that are entirely in the *trans* (8.68 Hz) and *gauche* (5.38 Hz) conformations, respectively (11). Thus, n_g, n_t, and ΔE can be deduced for the cycloalkan[*b*]indole *N*-β-propionic acids and are given in Table 11. It is remarkable that the conformational equilibrium of the chain of the cycloalkan[*b*]indole *N*-β-propionic acids in solution is displaced to the *trans* conformation, and this is more evident with the bulk of the cycloalkane. Moreover, this equilibrium in all cases remains practically constant with dilution.

Preparation of 2,2-diaryl-1-picrylhydrazyls using potassium permanganate

K. C. BROWN AND J. A. WEIL[1]

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received March 26, 1986

K. C. BROWN and J. A. WEIL. Can. J. Chem. **64**, 1836 (1986).

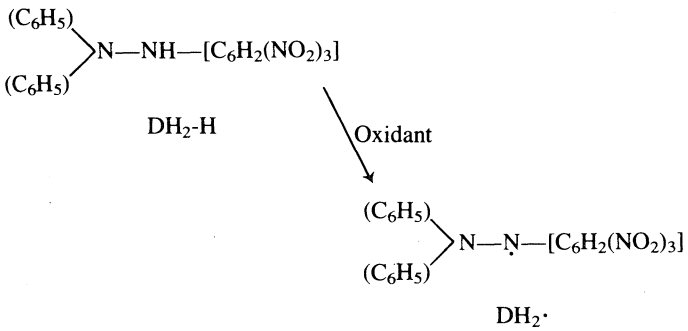
Potassium permanganate is used as a reagent for the oxidation of various 2,2-diaryl-1-picrylhydrazines to their corresponding hydrazyls. Thin-layer chromatography indicates complete oxidation of the hydrazine to free radical, unlike the case with PbO_2 (the most widely used oxidant for this purpose). Several other advantages over previous oxidants used to produce the hydrazyls are offered.

K. C. BROWN et J. A. WEIL. Can. J. Chem. **64**, 1836 (1986).

On utilise le permanganate de potassium comme réactif pour effectuer l'oxydation de diverses diaryl-2,2 picryl-1 hydrazines en hydrazyles correspondants. La chromatographie en couches minces indique que l'oxydation de l'hydrazine en radical libre est complète; ce résultat diffère de ceux obtenus avec le PbO_2 qui est l'oxydant le plus fréquemment utilisé à cette fin. Cette méthode offre aussi plusieurs autres avantages par rapport aux oxydants utilisés antérieurement pour produire des hydrazyles.

[Traduit par la revue]

As part of our continuing investigations into the chemistry of 2,2-diphenyl-1-picrylhydrazyl radical ($DH_2\cdot$) and related substituted hydrazyl radicals (1), we have found that $KMnO_4$ is very efficient at oxidizing the parent hydrazines to their corresponding hydrazyls. Typically:



In the past, the most common oxidant for this purpose has been lead dioxide (2). Other oxidants used include benzoyl peroxide (3), oxygen (4), chromium oxides (5), and other radicals (6), although none of these has been used on a preparative scale. $DH_2\cdot$ has also been observed (7) to form electrochemically from DH_2-H. Until now, there appear to have been no reports of the above reaction using $KMnO_4$ as the oxidizing agent.

We have found that, although 2,2-diphenyl-1-picrylhydrazyl is produced in high yield using PbO_2, 2,2-di(*p*-nitrophenyl)-1-picrylhydrazyl ($D(NO_2)_2\cdot$) is not similarly produced in high yield, and that here considerable starting material is left. We attribute this to the fact that $D(NO_2)_2\cdot$ is less stable relative to its hydrazine than is $DH_2\cdot$: a solution of $D(NO_2)_2\cdot$ will revert immediately to $D(NO_2)_2$-H if DH_2-H is added, with formation of $DH_2\cdot$ (8). Moreover, a mixture of $D(NO_2)_2\cdot$ and $D(NO_2)_2$-H is quite difficult to purify. These compounds, unlike $DH_2\cdot$ and DH_2-H, cannot be easily passed through a preparative chromatography column since they are tenaciously adsorbed on the column material even when a highly polar solvent is used as the eluant. It is thus preferable in this case to attempt a crystallization directly from the crude product.

The consequence of these observations was a search for a stronger oxidant for $D(NO_2)_2$-H. Lead tetraacetate was found to be a suitably strong oxidant but presented purification problems. It is highly soluble in most organic solvents and therefore any excess is carried along with the hydrazyl produced, remaining in solution with it. The preparation of specially activated lead dioxide for the purpose of these oxidations is well known (2, 9), but, although it is very efficient at oxidizing hydrazines (2*c*), again this presents problems associated with its preparation and purification.

It was decided that solid $KMnO_4$ used with tetra-*n*-butylammonium bromide (TBAB) phase-transfer catalyst (10) might provide the requisite oxidation power. Here, any excess $KMnO_4$ and the reduced Mn compounds (chiefly MnO_2, presumably) are in the solid phase and therefore easily separated from the products by filtration, and the phase-transfer catalyst is used only in small amounts and is not difficult to separate from the products by crystallization.

Table 1 shows the results of the oxidation of DH_2-H and of some related hydrazines with this method. The extent of reaction can be followed by periodic thin-layer chromatography analysis. Generally only two spots will appear on the plate, those of the hydrazine and the corresponding hydrazyl, making the method simple and useful. Side reactions were noted in some cases but these may be largely avoided by careful attention to the extent of reaction, stopping the reaction when starting material is no longer evident on the tlc plate. The potassium permanganate must be freshly ground, as it was noted that $KMnO_4$ that had been ground and left on the bench for some time lost some of its oxidizing power. This is not surprising since photolytic decomposition of $KMnO_4$ is known to occur (11). There is evidence that $KMnO_4$ will not dissolve unaided in dichloromethane and benzene, the solvents used in this study: when $KMnO_4$ is stirred with dichloromethane or benzene for several hours and then filtered, the solution has no characteristic purple color, indicating that the potassium permanganate does not dissolve. On the other hand, when a small quantity of phase-transfer catalyst is added and the same steps are taken, the filtered solution is deeply purple in color, as with "purple benzene" (10). It was noted, however, that solid $KMnO_4$ alone (no TBAB) will effect oxidation of DH_2-H to $DH_2\cdot$ (Table 1), and presents the added benefit of even easier purification. In this case the reaction is heterogeneous and presumably takes place on the surface of the $KMnO_4$ particles. With or without TBAB present, the rate of oxidation is affected only to a minor extent by stirring; even an unstirred solution of DH_2-H with solid $KMnO_4$ will show complete formation of $DH_2\cdot$, in approximately twice the time observed for a stirred solution. The mole

ratio of $KMnO_4$ to DH_2-H required for complete oxidation is approximately 3:1, compared to 10:1 for PbO_2 as found by Laederich and Traynard (12).

Usually, when oxidation of a hydrazine is done with PbO_2, anhydrous sodium sulfate is added (2*a*) as a drying agent to prevent reduction of the hydrazyl back to its parent hydrazine by the H_2O produced as a by-product of the reaction:

$$PbO_2 + 2H^+ + 2e^- \rightarrow PbO + H_2O$$

This does not appear to be necessary for oxidations using permanganate. It is known that for the permanganate oxidation of β,γ-unsaturated alcohols (13), water is essential to the reaction: without H_2O in the manganese coordination shell, the oxidation does not proceed. In the present case, however, it was shown that the oxidation proceeds equally well with either off-the-shelf or with dried $KMnO_4$ and solvent. If MnO_2 is formed, then there must be water formed as well:

$$MnO_4^- + 4H^+ + 3e^- \rightarrow MnO_2 + 2H_2O$$

It may be then that any H_2O generated is taken up by the MnO_2 or is in the coordination shell of the excess MnO_4^- present, and is unavailable for reduction of the hydrazyl radicals.

In aqueous solution, the permanganate ion is known to react with atomic hydrogen (14) generated by pulse radiolysis to make MnO_4^{-2} and H^+. The ion $HMnO_4^-$ has been postulated by Webster and Halpern (15) to form during the reaction between permanganate and molecular hydrogen, catalysed by Ag^+. In the present case, a possible first step of the reaction may be abstraction of a hydrogen atom from the hydrazine to form the hydrazyl and hydrogen manganate anion, followed by disproportionation of the latter. That manganate is not likely to be present in large quantities at any stage was shown by an experiment in which finely powdered $BaMnO_4$ in dichloromethane (no TBAB) was found to oxidize DH_2-H to $DH_2\cdot$. This oxidant appears to be virtually as efficient as $KMnO_4$ under the conditions of this study. On the other hand, no oxidation product was observed when DH_2-H was stirred with MnO_2, suggesting that the manganese ends up in the +4 oxidation state. This possibility was investigated by epr (electron paramagnetic resonance) spectroscopy. No signal attributable to manganate or to Mn^{+2} was observed in the frozen reaction vessel containing DH_2-H and $KMnO_4$ in dichloromethane (~30 K); MnO_2, which is antiferromagnetic at this temperature (16), was not observed under these conditions.

It was decided, to further our knowledge about the reaction mechanism, to investigate oxidation of the potassium salt ($DH_2^-K^+$) of DH_2-H with $KMnO_4$. This compound was previously reported to be oxidizable to $DH_2\cdot$ by PbO_2 (17). Using $KMnO_4$, $DH_2\cdot$ was indeed produced (although not in as great yield as for the corresponding hydrazine). This result suggests that, at least here, the first step of the oxidation is a one-electron transfer to permanganate.

Finally, we may note that the use of $KMnO_4$ holds two advantages over PbO_2 and other lead oxidants: its low cost and its relatively low toxicity. The price of potassium permanganate is about one third that of lead dioxide (based on comparable grades of each compound available from Aldrich Chemical Co.) and the acceptable level of manganese in air is approximately 5 mg/m^3 compared with that of 0.2 mg/m^3 for lead (18).

Experimental

2,2-Diphenyl-1-picrylhydrazyl from DH_2-H using $KMnO_4$/TBAB

DH_2-H (1 g) in 100 mL of dichloromethane was oxidized using 5.5 g of $KMnO_4$ and 50 mg of tetra-*n*-butylammonium bromide. The finely ground potassium permanganate was added in increments of 1 g at 15-min intervals with stirring. After each addition of the oxidant, a sample of the solution was taken for tlc analysis on a silica gel 60 plate developed in toluene: DH_2-H, R_f 0.32; $DH_2\cdot$, R_f 0.27.

When DH_2-H was no longer observed, the solution was filtered, the solvent was evaporated, and the crude solid was crystallized from benzene – petroleum ether (1:1). The melting point must be taken carefully since solvent of crystallization is invariably associated with $DH_2\cdot$. The technique used here was to put a sample of the crystals onto a microscope cover plate and then, using a Fisher–Johns melting point apparatus, slowly raise the temperature to ~110°C to drive off the solvent. Then the temperature was slowly raised to 135°C, the melting point being generally observed towards the end of this range. See Table 1 for yield and melting point.

2,2-Diphenyl-1-picrylhydrazyl from DH_2-H using $KMnO_4$

Exactly the same procedure was used as above except that no phase-transfer catalyst was used.

N-Picryl-9-aminocarbazyl from N-picryl-9-aminocarbazole using $KMnO_4$

The procedure was identical to that for $DH_2\cdot$ using $KMnO_4$ without TBAB; however, it was noted that some starting material was left after

the addition of all of the $KMnO_4$. Tetra-*n*-butylammonium bromide (50 mg) was added to the solution of the incompletely oxidized *N*-picryl-9-aminocarbazole and a tlc plate developed after 15 min. All of the starting material was seen to have disappeared. Table 1 gives the yield and melting point of the crude product.

*2,2-Di(*p*-nitrophenyl)-1-picrylhydrazyl from $D(NO_2)_2$-H using $KMnO_4$*

$D(NO_2)_2$-H, prepared by the method of Weil, Sane, and Kinkade (8), was oxidized by $KMnO_4$ in the same way as DH_2-H.

*Preparation of 1-(*N,N*-diphenylhydrazono)-2,4,6-trinitrobenzenide ($DH_2^-K^+$)*

This compound was prepared by the method used by Weil and Janusonis (17).

Calculations of yields for $D(NO_2)_2\cdot$ and $D'H_2\cdot$

$D(NO_2)_2\cdot$ and $D'H_2\cdot$ are unstable in solution and tend to abstract hydrogen from the solvent if left for long periods of time. For this reason, crystallization of these compounds was not attempted. In all cases of reaction of the parent hydrazines of these two compounds with $KMnO_4$, the tlc plate showed no evidence of any hydrazine left after allowing the appropriate time for reaction. Thus the crude yield was reported. However, in the case of the oxidation of these hydrazines by PbO_2, there was always a considerable amount of starting material left over and the yield of radical was determined using the fact that $D(NO_2)_2\cdot$ and $D'H_2\cdot$ will readily and quickly abstract a hydrogen atom from DH_2-H (8) producing $DH_2\cdot$, which may be then determined spectrophotometrically.

Acknowledgements

This research was carried out under the auspices of the Natural Sciences and Engineering Research Council of Canada. We thank Mr. R. S. Dickson for his help with some of the epr experiments and Professor D. G. Lee of the University of Regina for a sample of $BaMnO_4$.

A. MARTIN DE P. NICHOLAS and RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 1839 (1986).

The temperature dependence of nitrogen-14 nuclear magnetic resonance (nmr) spin-lattice relaxation times (T_1) for dilute aqueous solutions of the linear triatomic anions, $SeCN^-$, SCN^-, OCN^-, and N_3^-, is investigated in the temperature range 3–80°C. These nmr relaxation times (T_1) yield rotational correlation times, τ_{2R}, for the reorientation of the C_∞ symmetry axis in these anions. The observed nonlinear dependence of log $T_1(^{14}N)$ on temperature suggests that the rotations of the anions are coupled to the transport properties of water. For the thiocyanate anion the nmr correlation times are compared with those obtained previously from Raman spectroscopic data and Rayleigh scattering results. ^{17}O T_2 and ^{14}N T_1 measurements for the NCO^- anion are used along with *ab initio* calculations to estimate the ^{17}O nuclear quadrupolar coupling constant in this ion.

A. MARTIN DE P. NICHOLAS et RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 1839 (1986).

Opérant à des températures allant de 3 à 80°C, on a étudié la variation des temps de relaxation spin/réseau (T_1), en rmn du ^{14}N, pour des solutions aqueuses diluées des anions linéaires triatomiques, $SeCN^-$, SCN^-, OCN^- et N_3^-. En utilisant ces temps de relaxation (T_1), on a pu obtenir les temps de corrélation rotationnelle (τ_{2R}) pour la réorientation de l'axe de symétrie C_∞ de ces anions. On a observé que la relation entre la température et le log $T_1(^{14}N)$ n'est pas linéaire et ce résultat suggère que les rotations des anions sont couplées avec les propriétés de transport de l'eau. Dans le cas de l'anion thiocyanate, on a comparé les temps de corrélation rmn avec ceux obtenus antérieurement pour les données de spectrométrie Raman et avec les résultats de diffraction Rayleigh. Dans le but d'évaluer la constante de couplage quadrupolaire nucléaire du NCO^-, on utilise des calculs *ab initio* de concert avec des mesures de $T_2(^{17}O)$ et de $T_1(^{14}N)$ effectuées sur cet ion.

[Traduit par la revue]

Introduction

A variety of spectroscopic techniques have been used to obtain a large body of information on rotations of molecules and ions in condensed phases (1–3). However, relatively little work of this kind has been reported for anions in aqueous solution (4), and in particular for linear ions, where information is available only for the thiocyanate anion (4, 5). Furthermore, the results for SCN^- obtained from Raman spectroscopy and Rayleigh scattering experiments, where the derived correlation times are partly influenced by vibrational relaxation processes and orientational cross-correlations, respectively, are not in agreement (4). Thus it is desirable to obtain nuclear magnetic relaxation data, which are free from such influences (6), in order to investigate further the rotations of linear anions in aqueous solution.

Recently, we have shown the strength of the nmr technique in studying rotations of the nitrate and carbonate anions in aqueous solution (7). Here we apply this method to a group of linear triatomic anions, $SeCN^-$, SCN^-, OCN^-, and N_3^- by studying the temperature dependence of the relaxation rates of the quadrupolar nucleus ^{14}N at anion concentrations of approximately 1 molar. A few ^{14}N T_1 measurements of more dilute solutions are carried out to investigate the importance of ion pairing in these systems. In addition, the rotational correlation times obtained for the dilute solutions are discussed in terms of a hydrodynamic model (7).

Theory

Both ^{14}N ($Q = 0.0195 \times 10^{-28}$ m^2) (8*a*) and ^{17}O ($Q = -0.026 \times 10^{-28}$ m^2) (8*b*) are quadrupolar nuclei that are expected to relax entirely by the quadrupolar mechanism (6). Under conditions of extreme narrowing, the rate of relaxation (R_1) of a quadrupolar nucleus of spin I, in an axially symmetric environment, is given by eq. [1] (6):

$$[1] \quad R_1 = 1/T_1 = \frac{3\pi^2}{10}\,\frac{2I+3}{I^2(2I-1)}(e^2qQ/h)^2\tau_{2R}$$

where e^2qQ/h is the nuclear quadrupolar coupling constant (QCC), and τ_{2R} is the rotational correlation time. Quadrupolar coupling constants for ions in the solid state are available from either nuclear quadrupole resonance (nqr) or nmr experiments (9). Assuming the validity of these values in solution, one can derive rotational correlation times for these ions from the nmr data using eq. [1].

Experimental

All nmr measurements were performed on a Nicolet 360 NB (B_0 = 8.48 T) using a broad-band variable temperature 10-mm probe. The temperature was maintained with an accuracy of ±2 K by a nitrogen gas flow. The transmitter frequency was adjusted so that the transmitter was centred on the resonance of interest and spin-lattice relaxation times were measured by the inversion recovery pulse sequence (IRCA), which uses compensating pulses (10). The $\pi/2$ pulse widths were 50–60 μs. Typically, 16 scans at each variable delay, D_1, in the IRCA experiment were carried out in the ^{14}N relaxation experiments. About 120 000 scans were required in the natural abundance ^{17}O T_2 measurement of the isocyanate anion. The resulting S/N in the $D_1 = \infty$ measurements was about 100:1 for the ^{14}N and approximately 30:1 for the ^{17}O spectrum of the isocyanate anion. All T_1 values were calculated from peak heights obtained at 12 or more different D_1 values, using a nonlinear three-parameter least-squares fitting procedure available on the Nicolet software (11).

Solutions of the chalcogencyanates and the azide were prepared by weighing out appropriate amounts of laboratory reagent grade chemicals and diluting with distilled water volumetrically. The thiocyanate anion concentration was determined by titration with $AgNO_3$ using K_2CrO_4 as indicator (12).

[b]An average of the values obtained using the T_1's of the central and terminal nitrogens.

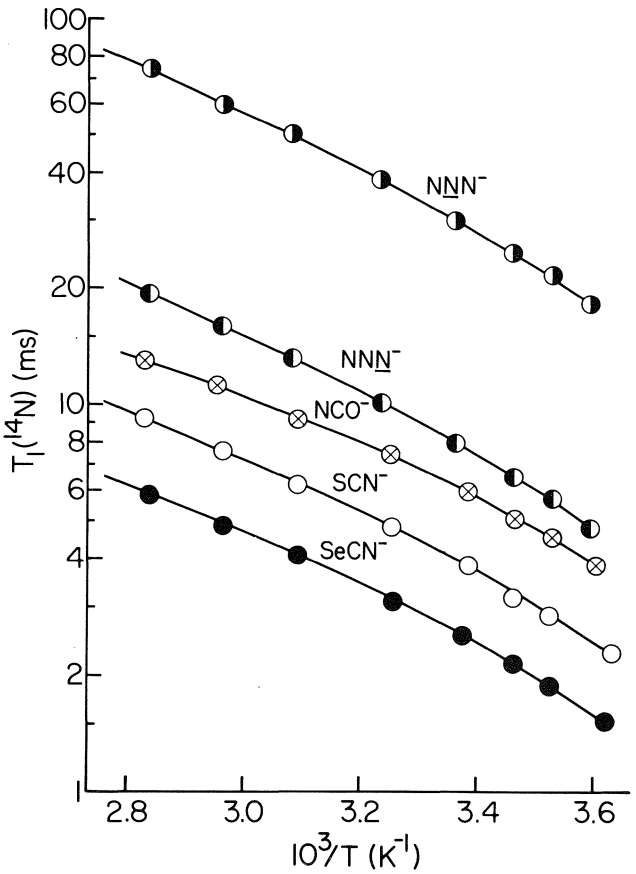

FIG. 1. A. plot of log ($T_1(^{14}N)$) versus $1/T$ for approximately 1 molar aqueous solutions of linear triatomic anions. Note that, for the NCO^- anion, values shown are $T_1/10$.

NaOCN, and NaN_3 are given in Tables 1–4, respectively, and also illustrated in Fig. 1 by a plot of the logarithm of T_1 with the inverse of the absolute temperature.

A comparison of the T_1 values for the chalcogencyanates at any given temperature shows a decrease down the group from OCN^- to $SeCN^-$. This trend is a result of an increase in the ^{14}N QCC and (or) a decrease in the rates of anion reorientation on going from OCN^- to $SeCN^-$. While the order $SeCN^- > SCN^- > OCN^-$ is expected for τ_{2R} on the basis of the size of the anion (*vide infra*), one cannot *a priori* predict the variation of the ^{14}N QCC in these ions because the interpretation of a QCC in terms of the overall electronic distribution is not straightforward (13). Since N_3^- and the NCO^- anions are similar in size, any difference in their T_1's should be predominantly due to the relative magnitude of their respective QCCs.

Rotational correlation times for the $SeCN^-$ and SCN^- were calculated using eq. [1], taking ^{14}N QCC of 2.846 and 2.432 MHz, respectively, obtained from previous nqr results (14). Although the effective values of QCC for $SeCN^-$ and SCN^- in aqueous solution may differ from those obtained in the

solid state by nqr, we anticipate that the solvent effects result in a systematic error in the QCCs. That is, if QCC(SCN^{-}) increases by 5% on going from solid KNCS to aqueous solution, then QCC($SeCN^{-}$) is also expected to increase by approximately the same amount. The implication is that although the τ_{2R} values in Tables 1 and 2 may have significant errors (e.g. ±15%) we expect the relative error to be much smaller (±5%). The consistently larger τ_{2R} values obtained for $SeCN^{-}$ compared to those obtained for SCN^{-} at any given temperature are probably significant. In the absence of an experimental QCC for OCN^{-}, we have used a theoretical value of 0.71 MHz obtained from a high level *ab initio* calculation near the Hartree–Fock limit (13), to derive τ_{2R} values for this ion. In the azide anion two estimates of τ_{2R} were derived from the T_1 data using the QCC values of 1.79 and 1.028 MHz, respectively, for the terminal and central nitrogens; these values were obtained from solid-state nmr experiments (15). The correlation times derived from the nmr T_1 data of the central nucleus were ca. 20% lower than those for the terminal nucleus. These τ_{2R} values were different because the effective QCC values in solution are probably slightly different from those in the solid state. The average of τ_{2R} (terminal) and τ_{2R} (central) at each temperature is given in column 4 of Table 4.

The τ_{2R} values determined by the nmr method are the same rotational correlation times probed previously by Raman spectroscopy and Rayleigh light scattering experiments. For the thiocyanate anion the nmr τ_{2R} values are in good agreement with the corresponding Raman data (4), especially at the higher temperatures. At 30°C, the lowest of these temperatures investigated in the Raman study, τ_{2R} (Raman) = 2.0 ps, while τ_{2R} (nmr) = 2.5 ps; both results pertain to 1 M aqueous solutions of NaSCN. Comparing the nmr results with the Rayleigh scattering data (5), we find the τ_{2R} (nmr) values are slightly shorter (ca. 30%) than the τ_{2R} (Rayleigh) values (e.g., for an infinitely dilute aqueous solution of SCN^{-} at 20°C, τ_{2R} (nmr) = 3.0 ± 0.4 ps, while τ_{2R} (Rayleigh) = 4.2 ± 0.2 ps).

Figure 1 shows that the plot of $\log(^{14}N(T_1))$ versus $1/T$, where T is the absolute temperature, is nonlinear for all the anions studied. As discussed previously in our study of the nitrate anion (7), this behaviour may arise for a variety of reasons. First the equilibrium constant for the association of these anions with the cation may be temperature dependent. However, because a comparison of the correlation times for the 1 M and 0.1 M solutions shows a relatively small variation ranging from 10 to 20% (Tables 1–5), ion pairing does not appear to be important. This is supported by results obtained by other techniques (4, 5).

A second possibility is that the anion rotations are coupled to those of the solvent. It is well known that nmr relaxation data and other transport properties of water can not be fitted to a single exponential (i.e., a single E_a value in eq. [2]) over the

$$[2] \quad \ln T_1 = -(E_a/RT) + \text{constant}$$

entire liquid range (16). In the temperature range 0–25°C and 35–80°C, proton relaxation data for water are well described by eq. [2], with E_a values of 4.6 and 3.3 kcal mol^{-1} respectively for the low and high temperature regions (16*a*, *b*). This is usually ascribed to cooperative behaviour (16*c*). For each of the anions studied here, we have carried out the same arbitrary evaluation of E_a in the low and high temperature regions (see Table 6). Values for the nitrate anion are presented for comparison. From the data in Table 6 it is apparent that the same general behaviour is observed for all ions. This suggests that the anion rotations involve a breaking of the water "structure". Furthermore, the observed linearity in the plots of τ_{2R} vs. η/T (correlation coefficient, r = 0.998–0.999, where η is the solvent viscosity, for the anions considered here) provides evidence for the coupling of the rotations of these linear anions with the transport properties of water (7) (*vide infra*). A plot of τ_{2R} vs. η/T for 0.1 M NaSCN is illustrated in Fig. 2.

For the thiocyanate anion the average activation energy, E_a = 3.6 ± 0.2 kcal mol^{-1}, from the nmr data (1 M NaSCN) is in fair agreement with the value of 3.0 kcal mol^{-1} obtained in the Rayleigh scattering study of 1.8 M NH_4SCN (5). Essentially the same activation energy was determined for a 6.0 M solution of NH_4SCN (5) and τ_{2R} values at any given temperature and solute concentration appeared to be the same for NH_4SCN and KSCN solutions. From the Raman data (4) on 1.0 M NaSCN at

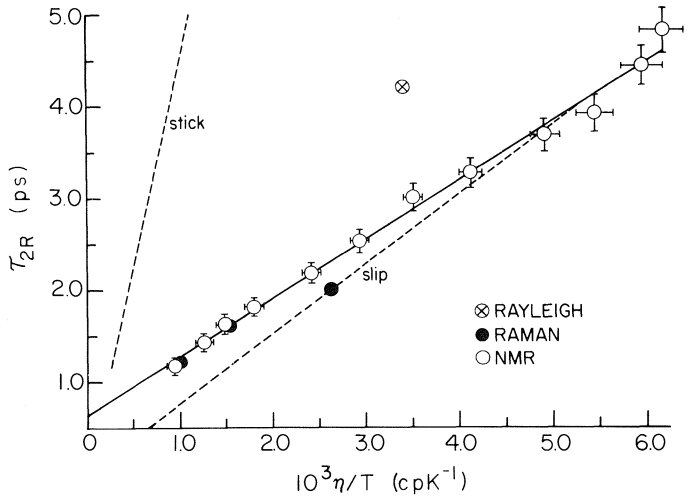

FIG. 2. A plot of τ_{2R} (nmr) versus η/T for an aqueous solution of 0.1 *M* NaSCN ($r = 0.995$). The Raman τ_{2R} values correspond to a 1 *M* solution and the Rayleigh scattering value is at infinite dilution.

30, 55, and 80°C, $E_a = 2.2 \pm 0.3$ kcal mol^{-1}, in fair agreement with the value obtained in this study, 3.0 ± 0.1 kcal mol^{-1}, over the same temperature range.

Finally, we have assumed the QCC to be independent of temperature. Clearly, the vibrationally averaged QCC will be temperature dependent (9); however, such effects are expected to be small in the temperature range investigated. Also we would like to point out that it is not a trivial procedure to correct for such effects in solution.

Next, we investigate further the effect of the medium on the rotation of these ions by considering a hydrodynamic model.

(b) The hydrodynamic rotation of anions

In the hydrodynamic model of molecular rotation (17, 18) the rotational correlation time is given by eq. [3],

$$[3] \quad \tau_{2R} = \eta V f C / k_B T$$

where V is the molecular volume of the anion, f is a shape factor that accounts for the deviation of the ion from spherical symmetry, C is an empirical parameter that accounts for the variable boundary conditions, and k_B is the Boltzmann constant. When the parameters f and C are both set equal to unity, eq. [3] reduces to the familiar Stokes–Einstein–Debye equation originally derived for a sphere (17).

The anions investigated in this study were assumed to be prolate spheroids and the value of f was calculated using eq. [4] (18),

$$[4] \quad f = \frac{(2/3)(1 - x^4)}{[(2 - x^2)x^2 \ln\{(1 + (1 - x^2)^{1/2})/x\}/(1 - x^2)^{1/2}] - x^2}$$

where $x\,(= b/a)$ is the axial ratio of the ellipsoid. For the anions investigated here, the major semiaxis (a) was estimated to be half the total sum of the bond lengths (19) and the van der Waals radii of the terminal atoms. The minor semiaxis (b) was assumed to be equal to the van der Waals radius of the largest atom. The van der Waals radii for Se, S, O, and N were assumed to be 1.95, 1.85, 1.60, and 1.70 Å, respectively. These values are taken to be 0.1 Å larger than the corresponding values in the neutral atoms (20) because of the partial negative charge on the terminal atoms. The assumed values of a and b for each anion are given in Table 5.

The two extreme boundary conditions are the so-called stick boundary condition ($C = 1$) and the slip boundary, where C is a minimum dependent on the shape of the solute (18*a*).

$$[5] \quad C_{slip} = 1 - f^{(-2/3)}$$

For the anions investigated here C_{slip} falls in the range 0.15–0.17; for a perfect sphere $C_{slip} = 0$. An observed "C" value of 1 implies a strong interaction between solute and solvent. For example, recently, Masuda, Sano, and Yamatera (21) have found that rotations of the phosphate anion obey the stick boundary condition. Under the slip boundary condition the only frictional resistance to rotation results from solvent displacement as the solute molecules rotate. Previous workers (4, 5) have found that rotations of the SCN^- anion are best described by the slip boundary condition.

To compare observed nmr rotational correlation times with those calculated under the slip and stick boundary conditions we studied all ions at 0.1 *M*, so that ion pairing will be negligible and the viscosity of the solution can be approximated to that of water. The rotational correlation times derived from the nmr data using eq. [1] are compared with the τ_{2R} values for the "stick" and "slip" boundary conditions in Table 5.

From the data in Table 5 we find that the value of C for all the anions investigated in this study is 0.2, just slightly larger than C_{slip}. The implication is that interactions between these anions and water is rather weak. This statement is not inconsistent with the activation energies reported above in section (*a*). As these prolate ellipsoidal shaped anions rotate they must, because of their shape, displace solvent and, in doing so, break water structure; hence the observed activation energies for anion rotation parallel those observed for water reorientation (i.e., rotations of the solute molecules are coupled to those of the solvent). Rotations of the perchlorate anion in aqueous solution are also described best by the slip boundary condition ($C = 0.03$). However, in this case, since the anion is approximately spherical, rotational correlation times are shorter and the activation energy is only 2.2 kcal mol^{-1} (21). The divalent sulphate anion is also approximately spherical; however, because of its charge it interacts more strongly with water ($C = 0.21$) and $E_a = 3.1$ kcal mol^{-1} (21).

One important basic assumption in applying any hydrodynamic model is that the solvent must appear as a continuum (17); that is, the solute molecule should be large compared to the size of the solvent molecule (18). Also we must assume that the solute molecules undergo small-step rotational diffusion (this assumption appears justified for SCN^- (4)). Because of these assumptions any attempt at interpretation of C values obtained in this and other related studies is at best qualitative. The importance of measuring experimental C values or related empirical parameters to assess solute–solvent interactions has been recently discussed by Zwanzig and Harrison (22).

(c) The ^{17}O quadrupolar coupling constant in the isocyanate anion

(i) The nmr method

In the extreme narrowing limit the spin–spin and spin-lattice relaxation times of quadrupolar nuclei are equal (6):

$$[6] \quad T_1 = T_2 = 1/\pi\nu_{1/2}$$

For the isocyanate anion both ^{17}O and ^{14}N relaxation rates are related to the same correlation time. Hence, by substituting values of $I = 5/2$ and 1, for ^{17}O and ^{14}N, respectively, from eqs. [1] and [6]:

TABLE 7. *Ab initio* calculations of the oxygen-17 nuclear quadrupolar coupling constant in the isocyanate anion

Basis set	EFG/au	QCC/MHz
STO-3G	−1.5280	9.34
4-31G	−1.0191	6.23
6-31G	−1.0460	6.39
6-31G*	−0.8833	5.40
⟨9S,5P⟩	−1.0246	6.26

[7] $1/T_2(^{17}O) = 8(QCC(^{17}O))^2/\{125(QCC(^{14}N))^2T_1(^{14}N)\}$

At 25°C, for a 1.0 *M* NaNCO aqueous solution in 10% D_2O, we find the ^{17}O line width ($\nu_{1/2}$) to be $<40 \pm 3$ Hz, corresponding to $T_2(^{17}O) > 8 \pm 1$ ms. The absence of any previous reports of $\delta(^{17}O)$ for NCO^- (23) may be due to the close proximity of the ^{17}O resonance of this ion to that of water (42.6 ± 1 ppm to high frequency). Substitution of $T_2(^{17}O) > 8 \pm 1$ ms, $T_1(^{14}N) = 62 \pm 3$ ms, and $QCC(^{14}N) = 0.71$ MHz in eq. [7] gives an upper limit of 7.8 ± 1 MHz for the ^{17}O quadrupolar coupling constant in the isocyanate anion.

Next we compare the ^{17}O QCC derived from the nmr relaxation data with the corresponding value obtained using *ab initio* calculations.

(ii) The ab initio *method*

Calculation of nuclear quadrupolar coupling constants from electric field gradients (EFGs) requires a knowledge of the value of the quadrupole moment (Q) of ^{17}O. The uncertainty in this Q value will be one source of error in the derived QCC (8*b*). We have used the $Q(^{17}O)$ value recommended by Fuller (8*b*) after a critical analysis of the available data.

EFGs were computed by performing *ab initio* molecular orbital (MO) calculations at a variety of levels using the program GAUSSIAN 76 (24*a*) appended by a version of the properties package of GAUSSIAN 79 (24*b*) adapted to run on the CDC 170-730 computer at Dalhousie University. The EFGs of NCO^- ($C_{\infty v}$, $r_{NC} = 1.21$ Å, and $r_{CO} = 1.13$ Å) (21) calculated using the STO-3G, 4-31G, 6-31G, and 6-31G* basis sets (25) and the Huzinaga ⟨9S,5P⟩ basis set (26) are given in Table 7. The results in this table indicate that the *ab initio* calculations yield QCCs smaller than those derived from the nmr method for all the extended basis sets. However, previous studies (7, 27) on a variety of molecules indicate that ^{17}O QCCs derived from *ab initio* theory using comparable basis sets are too large by ca. 10–20%. Assuming the calculated values in Table 7 are too large, these calculations suggest an ^{17}O QCC of ca. 5 MHz in NCO^-. From a comparison of the estimates of the QCC by the two methods and a consideration of the uncertainty in the data, we propose a ^{17}O QCC of 6 ± 2 MHz in the isocyanate anion. This estimate is reasonable when compared to the values of 8.1 ± 0.5 and 7 ± 0.5 MHz for oxygen-17 singly coordinated and doubly bonded to carbon in *N*-methylsydnone (28) and the bicarbonate anion (29), respectively, and other reported QCCs (23).

Conclusions

We have applied nmr relaxation techniques to study the temperature dependence of rotations of linear triatomic anions in dilute aqueous solution. Rotational correlation times for the rotation of the C_∞ symmetry axis in the thiocyanate anion are intermediate to those obtained from Rayleigh scattering and Raman spectroscopy. The logarithm of the quadrupolar spin-lattice relaxation time is found to vary nonlinearly with the inverse of temperature. This is attributed to a coupling of the rotations of these linear anions with those of the solvent water. An analysis of these rotations in terms of a hydrodynamic model indicates that anion reorientation is governed by slip boundary conditions in all cases.

We feel that the largest error in the nmr rotational correlation times results from the assumption that solid state and (or) gas phase QCCs are valid in solution. The nmr technique has the advantage in that relatively dilute solutions can be easily studied. Also, for a more accurate description of the temperature dependence of τ_{2R} data the effect of vibrational averaging on EFGs should probably be considered.

The fact that two quadrupolar relaxation rates can be related to the same correlation time in NCO^- without assuming any specific rotational model permits an estimate of the ^{17}O QCC in this ion to be made by nmr spectroscopy. Accurate ^{14}N and (or) ^{17}O nqr data for NCO^- would lead to more reliable rotational correlation times for this ion.

Acknowledgements

All nmr spectra were obtained at the Atlantic Regional NMR centre, Dalhousie University. We are grateful to the Natural Sciences and Engineering Research Council of Canada for financial support in helping establish and maintain this centre and for an operating grant (R.E.W.). Zn(II)–D-(−)-penicillamine complexes in aqueous solution. Zn-67 nuclear magnetic resonance study

ALFRED DELVILLE[1] AND CHRISTIAN DETELLIER[2]

Ottawa–Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, Ont., Canada K1N 9B4

Received September 4, 1985[3]

ALFRED DELVILLE and CHRISTIAN DETELLIER. Can. J. Chem. **64**, 1845 (1986).

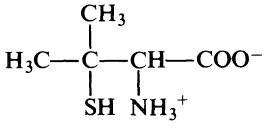
D-(−)-Penicillamine interactions with Zn(II) have been studied in aqueous solutions as a function of pH, penicillamine concentration, and temperature, using Zn-67 nuclear magnetic resonance. Longitudinal and transverse relaxation rate measurements show the presence in solution of complexes in fast exchange with the aquated Zn(II) cation, and belonging to the extreme narrowing regime. Using equilibrium constant values from the literature, the relaxation behaviour was modelled. Characteristic Zn-67 line width values for the two complexes Zn(Pen) (ν = (6200 ± 500) Hz) and $[Zn(Pen\,H)]^+$ (ν = (6000 ± 1000) Hz) were found. Equality of the two values is in agreement with zinc chelation by the sulfhydryl and the amino groups.

ALFRED DELVILLE et CHRISTIAN DETELLIER. Can. J. Chem. **64**, 1845 (1986).

L'étude de la complexation du Zn(II) par la D-(−)-pénicillamine a été effectuée en solutions aqueuses en fonction du pH, de la concentration en pénicillamine et de la température, à l'aide de la résonance magnétique nucléaire du Zn-67. Les mesures des temps de relaxation longitudinal et transverse montrent la présence en solution de complexes en échange rapide avec le cation $Zn(II)_{aq}$. Les résonances de ces complexes obéissent aux conditions de rétrécissement extrême. À l'aide de valeurs de constantes d'équilibre tirées de la littérature, une modélisation de la relaxation observée a fourni des largeurs de raie caractéristiques des complexes Zn(Pen) (ν = (6200 ± 500) Hz) et $[Zn(Pen\,H)]^+$ (ν = (6000 ± 1000) Hz). Ces valeurs sont en accord avec une chélation du zinc par les groupements sulfhydryle et amino.

Introduction

D-(−)-Penicillamine (**1**, H_2Pen) is a powerful ligand for transition metal cations (1–12). It acts as a bidentate or tridentate ligand, taking advantage of the coordination ability of



1

its amino, sulfhydryl, and carboxylic groups. The diversity of the possible ligation sites together with their protonation pattern make this small molecule a versatile ligation system. The pK_a values of $(H_3Pen)^+$ are $pK_1 = 1.92$; $pK_2 = 8.00$; $pK_3 = 10.74$ (25.0°C; 0.1 *M* KNO_3) (5), where pK_2 and pK_3 are composite macroscopic constants. These values corroborate previous similar determinations (3). The values of the equilibrium constants for the formation of complexes between the penicillamine dianion and transition metal cations show the effectiveness of this molecule to capture Cd(II) or Hg(II), for example ($\log \beta_1$ = 11.5 and 18.9; $\log \beta_2$ = 19.5 and 25.0 for Cd(II) and Hg(II) respectively) (5). In addition to the 1:1 and 1:2 complexes, diverse protonated complexes or polynuclear species coexist in solution (4, 7). Penicillamine has been used in the treatment of metal poisoning (13–18), can chelate excess copper responsible for the blocking of nerve impulses in Wilson's disease (19, 20), is an effective drug in rheumatoid arthritis (21–23), idiopathic pulmonary fibrosis (24), and scleroderma (25), and its copper complex possesses some anti-inflammatory properties (26).

In that context, the study of the complexes formed between Zn(II) and penicillamine is of interest since, for example, they interfere with the removal of toxic mercury, cadmium, or lead (5). Some unwanted side effects could originate in the complexation of essential zinc (27). X-ray photoelectron spectroscopy results (1) support a structure for the 1:2 complex in the solid state in which one penicillamine moiety acts as a monodentate carboxylate ligand and the second penicillamine is coordinated to zinc through the sulfhydryl and the amino groups. In solution, a structure in which the two penicillamine molecules act as bidentate ligands is more probable, the two sites of ligation being the sulfhydryl and the amino groups (2, 11, 14, 23, 28). The coordination could possibly involve the carboxylic group at lower pH range (6). The X-ray structure of dibromo-bis(D-penicillamine)Zn(II) isolated from an acidic solution (pH 2) has been recently published: penicillamine behaves as a monodentate ligand with the deprotonated carboxylate group as the binding site (29). Formation constants for the Zn(Pen) and $[Zn(Pen)_2]^{2-}$ complexes are $\log \beta_1 = 9.38$ and $\log \beta_2 = 19.39$ respectively (μ = 0.12, 25°C) (3). The order of magnitude of these values is corroborated by other works (4–6). Since $K_2 > K_1$, for a sufficiently high ligand concentration the major species in solution are aquated Zn(II) and $[Zn(Pen)_2]^{2-}$ (4–6). Consequently, until now, the structure of the 1:1 complex in solution has been only rarely discussed.

To better define the nature and the structure of these complexes in solution, we have undertaken a Zn-67 nuclear magnetic resonance study of the system Zn(II)–penicillamine in water at different pH values. The only nmr active isotope of zinc, Zn-67 (spin 5/2) is a quadrupolar nucleus endowed with a poor receptivity (0.665 with respect to C-13) due to its low natural abundance (4.11%) and its low gyromagnetic ratio (1.6737×10^3 rad s^{-1} G^{-1}) (30). So far, only a few studies have involved this nucleus (31–38). Given the high biological importance of zinc, and the inability to use other spectroscopic techniques directly, the development of Zn-67 nmr is of prime significance.

We show in this paper that Zn-67 nmr can be used to study the complexation of Zn(II) by penicillamine in relatively dilute conditions (0.10 *M*). We work in conditions where Zn(II) is in

large excess compared to penicillamine and consequently where the 1:1 complex is in excess compared to the 1:2 complex. We give an estimate of the characteristic relaxation rates for the complexes Zn(Pen) and $[Zn(Pen\,H)]^+$.

Experimental

$Zn(NO_3)_2 \cdot 6H_2O$ (Baker) and D-(−)-penicillamine (Aldrich) were used without further purification. The zinc concentration was checked by EDTA titration and the pH was adjusted by addition of small amounts of concentrated NaOH or H_2SO_4. The pH meter (Corning 155) was calibrated with buffer solutions at pH 7.00 ± 0.01 and 4.00 ± 0.01. The precision of the pH measurements was better than 0.02 pH units.

The nmr spectra were recorded on a Varian XL-300 spectrometer operating at the frequency of 18.768 MHz. The 90° pulse width was 91 μs. Typically, the acquisition time was 10 ms for a 1-ms transverse relaxation time. No weighting functions were applied to the FID, which was Fourier transformed with zero filling. All measurements at room temperature were made on 16-mm spinning tubes, and on 10-mm spinning tubes at variable temperatures. Solvent was a mixture of D_2O/H_2O (20:80) to provide a deuterium lock. No correction was made to pH values for the use of 20% D_2O. Chemical shifts were measured with reference to a 1.0 *M* $Zn(NO_3)_2$ solution (pH = 4.47). Sample temperatures were measured with a copper–constantan thermocouple dipped into the non-spinning tube. The precision of the temperature reading was estimated to be ±0.5°C. To attenuate the acoustic ringing of the probe (39) we used the pulse sequence ACOUSTIC (40): —(90°, x – ACQ^+ – Dl – 180°, $x - \tau - 90°$, x – ACQ^- – Dl – 90°, x – ACQ^+ – Dl – 180°, $-x - \tau - 90°$, x – $ACQ^-\rightarrow_n$ (40, 41), which was available as the standard program ACOUST on the XL-300. In the case of a quadrupolar nucleus, the delay D1 can be set to short values or zero, since the acquisition time permits a full relaxation of the magnetization. The delay τ is the crucial parameter for a successful result. With our instrumentation (Varian XL-300) we found 100 μs to be a good compromise, with the use of a delay time (100–200 μs) between the end of the 90° pulse and the beginning of the acquisition. To obtain an acceptable base line in the case of the routine pulse sequence —(90° – $ACQ\rightarrow_n$, this delay would have been 1 ms, an unacceptable value for a rapidly relaxing quadrupolar nucleus. Typical conditions were as follows (given for 0.10 *M* Zn(II) and 0.10 *M* penicillamine at pH 3.0): acquisition time = 0.02 s; delay Dl = 0.01 s; delay between 90° pulse and acquisition = 100 μs; total experiment time was less than 1 h (112 000 transients); signal on noise ratio = 50; line width = (140 ± 10) Hz.

Transverse relaxation times were directly determined from a linewidth measurement. We have checked that the measured line width was independent of the delay time between the 90° pulse and the beginning of the acquisition. All spectra had a Lorentzian line shape. Longitudinal relaxation times were measured with the sequence $-(-180° - \tau - 90° - ACQ\rightarrow_n$, with at least ten τ comprised between 0 and 20 times T_1. T_1 was calculated by a nonlinear regression on three parameters (42). Typical conditions were as follows (given for 0.20 *M* Zn(II), 6×10^{-3} *M* penicillamine, pH 3.5): acquisition time = 0.05 s; delay between 90° pulse and acquisition = 200 μs; ten values of τ between 0.2 ms and 160 ms; the total experiment time was less than 1 h; 3000 transients for each spectrum; T_1^{-1} = (92 ± 5) Hz.

Results

Transverse relaxation times

Table 1 gives the line width at half-height ($\nu_{1/2}$) of the Zn-67 signal as a function of the ratio ρ = $[H_2$ Pen$]/[Zn(II)]$ for different pH, at (21 ± 1)°C. The line width of a 0.1 *M* $Zn(NO_3)_2$ aqueous solution is (25 ± 2) Hz, which is in good agreement with previously published values (31, 33). The line width of the latter solution did not vary significantly with changes in pH. However, small amounts of added penicillamine have a considerable effect on the observed line width: for ρ = 0.1, $\nu_{1/2}$ = 44 Hz (pH = 3.1), 60 Hz (pH = 4.0), 360 Hz (pH = 5.0), 460 Hz[4] (pH = 6.2). This trend corresponds to the diminution of the relative percentage of the aquated Zn(II) cation when the pH increases (6). This is similar to the result obtained recently by Kohnlein *et al.* (33) for a 1 *m* $ZnSO_4$ solution in the presence of increasing amounts of sodium citrate (0–80 m*m*). In the case of a ratio ρ = [citrate]/[Zn(II)] = 0.1, the value of the reported line width was twice that measured from a 1 *m* Zn(II) solution. We have been limited in our investigations by the formation of precipitates for ratios [Pen]/[Zn(II)] bigger than the ones indicated in Table 1.

TABLE 1. Zn-67 bandwidth at half height ($\nu_{1/2}$) as a function of pH and of ρ = [penicillamine]/[Zn(II)] ratios. $[Zn(NO_3)_2]$ = 0.10 *M*

Under non-extreme narrowing conditions, the relaxation of a spin 5/2 nucleus is characterized by three exponential decays (43). In all the cases studied here only one Lorentzian line was observed, which can be the result of extreme narrowing conditions, where all three components of the relaxation are identical ($\omega^2\tau_c^2 \ll 1$), or of very fast relaxation for two of the three components. We can simply test which of these two hypotheses is valid by varying the waiting time between the 90° pulse and the acquisition. If the observed resonance were superposed upon one or two other broad resonances, variation of that waiting time should affect the observed line width. This is not observed: the measured line width is independent of the waiting time. A better test is given by the comparison between T_2 and T_1:T_2 = T_1 under extreme narrowing conditions. Moreover, an equality of T_2 and T_1 would show the absence of a chemical exchange contribution to the transverse relaxation time (44–46). This test will be considered in the next section.

Since the observed broadening could be due to an exchange

[4]Interpolated value.

process between aquated Zn(II) and penicillamine–Zn(II) complexes, we have tested this hypothesis by temperature measurements. Ln (T_2^{-1}) increases linearly with an increase of T^{-1} for 0.2 M $Zn(NO_3)_2$, in the absence of any penicillamine. This behaviour was expected on the basis of the high value of the Zn-67 quadrupole moment (0.15×10^{-28} m^2), which makes the quadrupolar mechanism of relaxation very effective.

In the presence of penicillamine, the order of magnitude of T_2^{-1} does not change dramatically with temperature for a given pH: $4.9 < \ln T_2^{-1} < 5.1$ at pH 3.4; $6.2 < \ln T_2^{-1} < 6.6$ at pH 5.0; $6.4 < \ln T_2^{-1} < 7.3$ at pH 6.4. Line widths in the range 0.7–1.4 kHz are found at pH 5.0 and 6.4. This order of magnitude is accompanied by large errors, precluding any precise analysis of the data. However, the observation that the order of magnitude of the line widths is constant for a given pH is a good indication that there is no chemical exchange contribution to the transverse relaxation time.

Longitudinal relaxation times

Table 2 shows Zn-67 longitudinal and transverse relaxation rates at different pH and for different ratios ρ = [Pen]/[Zn(II)] of 0.2 M zinc nitrate solutions. A measure of the inhomogeneity contribution to T_2 is obtained from the difference between T_2^{-1} and T_1^{-1} for the 0.2 M $Zn(NO_3)_2$ solution (pH = 5.61) and is 17 ± 14 Hz. Given the inhomogeneity contribution, one observes an equality between T_2^{-1} and T_1^{-1} for all the cases studied: the system obeys the extreme narrowing condition. Moreover, the equality of T_2 and T_1 excludes the possibility of an exchange contribution to the transverse relaxation time.

Chemical shifts

Zn-67 chemical shifts are sensitive to the nature of the counterion in concentrated solutions, spanning a range of 300 ppm from iodide to cyanide (34), and are also quite sensitive to the nature of the solvent (31). However, within the limits of experimental error, we did not observe any measurable chemical shifts of the Zn-67 signal with increasing concentrations of penicillamine. We will come back to this point in the discussion.

We have carried out exploratory measurements on a 0.1 M $Zn(NO_3)_2$ solution at pH ≃ 13.5. A single resonance line was observed at (205 ± 5) ppm with reference to 1.0 M $Zn(NO_3)_2$ (pH 4.47); the line width was (200 ± 30) Hz. We attribute this resonance to the zincate anion, $Zn(OH)_4^{2-}$, whose chemical shift is in the range oberved for other tetracoordinated anionic zinc derivatives: $ZnBr_4^{2-}$ (δ = 169 ppm), $ZnCl_4^{2-}$ (δ = 253 ppm) (34).

Modelling

The observed relaxation rate can be described by a fast exchange and is the result of the average of all the possible contributions originating from the different complexes in fast equilibrium. This is reflected in eq. [1], which is valid under the condition that the rate constant for dissociation is small compared to the inverse of the correlation time for the complexed species (47). This condition is fulfilled, given the high values of the equilibrium constants for the formation of the various complexes (see below). To derive the characteristic line widths for some complexes, we have used the formation constants of the Zn(II)–penicillamine complexes that have been determined in the literature (5, 6). The following zinc-containing species have been considered: Zn(Pen) ($\log \beta_{110} = 9.66$); $[Zn(Pen)_2]^{2-}$ ($\log \beta_{120} = 19.39$); $[Zn(Pen\ H)]^+$ ($\log \beta_{111} = 14.8$); $[Zn(Pen)_2H]^-$ ($\log \beta_{121} = 25.23$); $[Zn(Pen)_2H_2]$ ($\log \beta_{122} = 30.65$), in addition to the protonated forms of penicillamine: $(Pen\ H)^-$ ($\log \beta_{011} = 10.658$); $Pen\ H_2$ ($\log \beta_{012} = 7.932 + \log \beta_{011}$); $(Pen\ H_3)^+$ ($\log \beta_{013} = 1.90 + \log \beta_{012}$) (6). For each pH value and total Zn(II) and penicillamine concentrations (Table 1), $[Pen^{2-}]$ was calculated from a third degree equation solved by an iterative Newton–Gauss procedure. The observed line width was then fitted following eq. [1]

$$[1]\quad (\nu_{1/2})_{obs}\cdot[Zn(II)]_T = \nu_0[Zn(II)_{aq}] + \nu_1[Zn(Pen)] + \nu_2[Zn(Pen)_2^{2-}] + \nu_3[Zn(Pen\ H)^+] + \nu_4[Zn(Pen_2H)^-] + \nu_5[Zn(Pen)_2H_2]$$

where $[Zn(II)]_T$ is the total Zn(II) concentration, $[Zn(II)_{aq}]$ the concentration of aquated Zn(II), $[Zn(Pen)_iH_j]$ the concentrations of the different complexes, and ν_0 was experimentally determined (Table 1). Figure 1 shows the result of the fittings. Each fitting was effected independently for each pH value. However, a simultaneous fitting on the four pH curves did not give significantly different results. At pH 6.0, only two species are major: $Zn(II)_{aq}$ and Zn(Pen). We can determine in these conditions a characteristic line width for the complex Zn(Pen) with a good precision: $\nu_{1/2}$ = (6200 ± 500) Hz. At pH = 3.0, two major species are also present: $Zn(II)_{aq}$ and $Zn(Pen\ H)^+$ for which we determine a characteristic line width $\nu_{1/2}$ = (6000 ± 1000) Hz. At intermediate pH, more species strongly influence the fitting procedure and the characteristic line widths for the various complexes could be determined only with large errors. Unfortunately, at the Zn(II) concentrations used we were limited in the quantity of added penicillamine by the insolubility of complexes of the type $Zn(Pen)_2H_j$ (j = 0–2).

Discussion

All the spectra studied belong to the extreme narrowing regime. This is in good agreement with the fact that only monomeric chemical species are formed in the Zn(II)–penicillamine system (4, 7). The equality between T_1 and T_2 rules out the possibility of an exchange contribution to the transverse relaxation rate. Using equilibrium constant data from the literature (6), the characteristic line widths for two complexes were determined: Zn(Pen): (6200 ± 500) Hz and $(Zn\ Pen\ H)^+$: (6000 ± 1000) Hz. The finding of an equality between the two values supports the structure accepted for the solution state: coordination through the sulfhydryl and amino groups (3). The possibility of a coordination involving the carboxylic group in

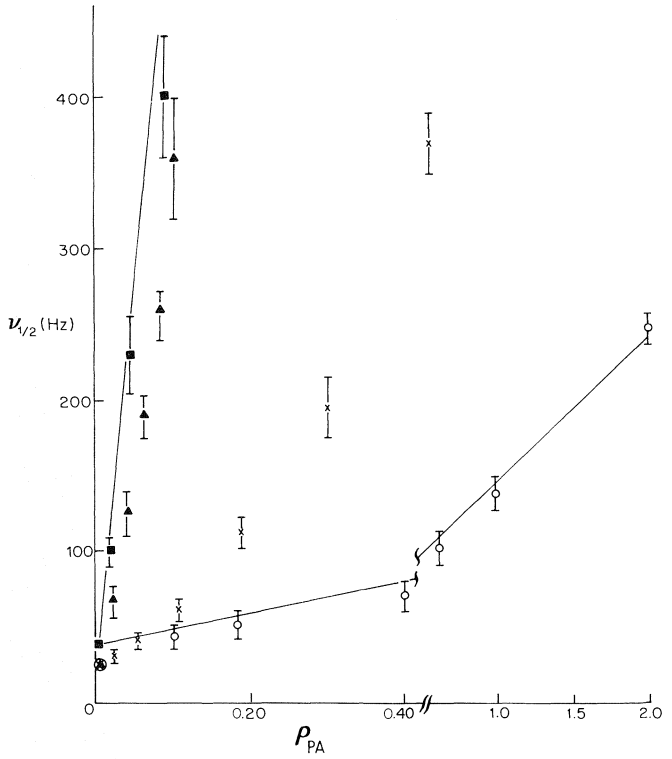

FIG. 1. Zn-67 line width variation as a function of the ratio ρ [penicillamine]/[Zn(II)], at different pH values. $[Zn(NO_3)_2]$ = 0.10 *M*. (○): pH ≃ 3; (×) pH ≃ 4; (▲) pH ≃ 5; (■) pH ≃ 6 (see Table 1 for precise pH values). The points are experimental and the curves are calculated (see text).

the lower pH range had been proposed (6). Our results at pH 3 and 6 strongly suggest a structure involving only sulfhydryl and amino groups in the chelation of Zn(II), in such a manner that the site of protonation of the complex is the non-coordinated carboxylic group. This protonation has a minor influence on the electric field gradient at the Zn(II) site, which is reflected in the similarity of the characteristic relaxation rates for Zn(Pen) and $Zn(Pen\,H)^+$. Of course, these conclusions are valid under the assumption that the equilibrium model used is fully correct. Morever, we have likened proton activities to concentrations. In the case of ionic strength constancy, this approximation results in a systematic error. In the case of our study, the initial ionic strength of the Zn(II) solution (0.3) is progressively reduced with the addition of penicillamine. However, since in our study the population of complexed Zn(II) is always lower than 14%, we have preferred not to introduce any activity correction (48).

A highly asymmetric environment for complexed Zn(II) is suggested by the high value (6000 Hz) of the characteristic line widths of the complexes. Under extreme narrowing conditions, the relaxation rates of a spin 5/2 nucleus is given by:

$$[2]\quad \frac{1}{T_2} = \frac{12\pi^2}{125}\left(\frac{e^2qQ}{h}\right)\tau_q\left(1+\frac{\eta^2}{3}\right)$$

where $\chi = e^2qQ/h$ is the quadrupolar coupling constant (NQCC), η the asymmetry factor, and τ_q the correlation time responsible for the quadrupolar relaxation. A correlation time has been determined by N-14 nmr for penicillamine 0.2 *M* in aqueous solution: τ_q(N-14) = (34 ± 9) ps (49). Knowing that the complex involves only one penicillamine molecule, we make the approximation that τ_q(Zn-67) of Zn(Pen) equals τ_q(N-14) of (Pen) and, neglecting the asymmetry factor η, we obtain an estimate of χ, the quadrupolar coupling constant: χ = (13 ± 5) MHz. This appears to be the first proposed Zn-67 quadrupolar coupling constant value in solution and is valid only under the assumptions of the double nuclear spin method (50, 51). It can be compared with the published value of the Zn-67 quadrupolar coupling constant in Zn metal determined by nuclear quadrupole resonance: 13.620 MHz (52).

Zn-67 chemical shifts are known to span a large range of values and one expects them to be very sensitive to the nature of the first coordination sphere of Zn(II). Consequently, one would expect to observe a large chemical shift variation when Zn(II) is complexed by penicillamine. However, we have an apparent contradiction here since, within the limits of experimental error, the observed Zn-67 chemical shift does not show any variation outside a 1-ppm range. To resolve this apparent contradiction two facts have to be stressed. First, large line width variations are observed: for a ratio ρ = 0.14 and $[Zn(II)]_T$ = 0.10 *M*, $\nu_{1/2}$ = 710 ± 150 Hz. Under these conditions chemical shifts can hardly be measured with a better precision than 3 ppm, and any expected chemical shift variation is accompanied by a large increase of the experimental error on its measurement. Second, in the conditions mentioned of ρ = 0.14 and $[Zn(II)]_T$ = 0.10 *M*, one can calculate (6) that only 9% of the total zinc is the 1:1 complex Zn(Pen), when less than 2% is $[Zn(Pen)_2]^{2-}$ or $[Zn(Pen\,H)]^+$, the quantity of $[Zn(Pen)_2\,H]^-$ being negligible. A chemical shift variation of 3 ppm, the error limit, would correspond to a characteristic chemical shift for the complex of the order of 30 ppm. For a 1 molal $ZnSO_4$ solution in the presence of a 10 m*m* citrate solution a shift of 0.55 ppm to lower frequency has been reported, which would lead to a maximum value of 55 ppm for the complex Zn(II)–citrate (33).

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

Received September 26, 1985[1]

A. KOLL, M. ROSPENK, L. SOBCZYK, and T. GŁOWIAK. Can. J. Chem. **64**, 1850 (1986).

The crystals of 2-(*N*,*N*-diethylamino-*N*-oxymethyl)-4,6-dichlorophenol chosen as a representative of the Mannich base *N*-oxides were found to be monoclinic, $P2_1/c$ space group, with $a = 11.729(3)$, $b = 16.232(4)$, $c = 13.689(3)$ Å, $\beta = 107.37(3)°$, and $Z = 8$. The structure solved by the direct method was refined to $R = 0.033$ for 3170 independent reflections. Two slightly different molecules denoted as **A** and **B** in the unit cell with very short (2.42 and 2.40 Å) OHO intramolecular hydrogen bonds were detected. Both a X-ray diffraction study and the ir and uv spectra indicate a symmetric type of bridge in this compound.

A. KOLL, M. ROSPENK, L. SOBCZYK et T. GŁOWIAK. Can. J. Chem. **64**, 1850 (1986).

On a trouvé que les cristaux du (*N*,*N*-diéthylamino *N*-oxy méthyl)-2 dichloro-4,6 phénol, qui ont été choisi comme représentatifs des *N*-oxydes des bases de Mannich, sont monocliniques, avec un groupe d'espace $P2_1/c$ et $a = 11,729(3)$, $b = 16,232(4)$ et $c = 13,689(3)$ Å, $\beta = 107,37(3)°$ et $Z = 8$. On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à une valeur de $R = 0,033$ pour 3170 réflexions indépendantes. On a détecté deux molécules légèrement différentes, **A** et **B**, dans chaque maille unitaire; on a aussi noté l'existence de liaisons hydrogènes intramoléculaires OHO très courtes (2,42 et 2,40 Å). Tant l'étude par diffraction des rayons-X que les spectres ir et uv suggèrent la présence d'un pont de type symétrique dans ce composé.

[Traduit par la revue]

Introduction

The *ortho* Mannich bases show an interesting example of intramolecular hydrogen bonds as analogues of intermolecular bonds between parent phenols and amines (1–3). These bonds possess all of the spectroscopic features typical of intermolecular bonds and are characterized by a rigid conformation and high stability. It seemed interesting to undertake a study of the behaviour of *N*-oxides of *ortho* Mannich bases. One could expect that in this case strong intramolecular OH...O hydrogen bonds would be formed. However, in the crystalline state one cannot exclude the possibility of breaking of intramolecular, and the formation of intermolecular bonds as in 2-(*N*,*N*-diethylaminomethyl)-4-nitrophenol where proton transfer and the creation of dimeric ionic structures take place (4). As a subject of our study we selected 2-(*N*,*N*-diethylamino-*N*-oxymethyl)-4,6-dichlorophenol (**1**), in which the proton–donor capability of the phenolic group is distinctly pronounced.

Experimental

The *N*-oxides of *ortho* Mannich bases were synthesized by oxidation of the bases in Perhydrol. The crystals of compound **1** were grown from water–ethanol solutions; mp, 146–147°C. Density of crystals was measured by flotation method in $CCl_4/C_2H_4Cl_2$ solution.

The ir spectra were recorded on a Perkin-Elmer spectrophotometer type 180 and a Carl-Zeiss Jena Specord 75 IR Spectrophotometer. The uv spectra were studied by using a Carl-Zeiss Jena Specord UV Vis Spectrophotometer.

The space group and approximate unit-cell dimensions were determined from rotation and Weissenberg photographs. The diffraction data for a crystal with dimensions 0.45 × 0.50 × 0.50 mm were collected with MoK_α radiation on a Syntex $P2_1$ four-circle diffractometer with a graphite monochromator. The lattice parameters and orientation matrix used from data collection were obtained from the least-squares refinement of 15 reflections ($19° < 2\theta < 29°$). All diffraction data were collected at room temperature by the θ–2θ scan technique, to $2\theta = 50.0°$. Two check reflections measured after each 50 reflections indicated no decomposition. The raw intensity data were corrected for Lorentz and polarization effects, but not for absorption and extinction.

TABLE 1. Summary of data collection and processing parameters

Space group	$P2_1/c$
Cell constants	$a = 11.729(3)$ Å
	$b = 16.232(4)$
	$c = 13.689(3)$
	$\beta = 107.37(3)°$
	$V = 2487.3$ Å^3
Molecular formula	$C_{11}H_{15}NO_2Cl_2$
Molecular weight	264.2
Molecules per cell	$Z = 8$
Density	$D_m = 1.40(1)$ g cm^{-3}
	$D_c = 1.41$
Absorption coefficient (MoK_α)	$\mu = 5.1$ cm^{-1}
Unique data collected	4389
Data with $I > 4\sigma(I)$	3170
Total variables	409
$R = \Sigma(\lvert F_o\rvert - \lvert F_c\rvert)/\Sigma\lvert F_o\rvert$	0.033
$R_w = [\Sigma w(F_o - F_c)^2/\Sigma w(F_o)^2]^{1/2}$	0.032
$S = [\Sigma w(F_o - F_c)^2/(n - p)]^{1/2}$	2.742
Final $\Delta\sigma$	±0.2 eÅ^3
Final $(\Delta/\sigma)_{max}$	0.02 for non-H atoms
	0.13 for H atoms

The structure was solved by the direct phase determination method using the program MULTAN (1974 Syntex version of program in ref. 5) and refined by a full-matrix least-squares technique. The non-hydrogen atoms were recognized from an *E*-map (calculated for the starting set having the highest combined FOM of 3.0) and the Fourier synthesis. The positions of all hydrogen atoms were determined from the difference Fourier synthesis. Several cycles of refinement of coordinates and thermal parameters (anisotropic for non-hydrogen and isotropic for hydrogen atoms) reduced the *R* value to 0.033 and R_w to 0.032 for the 3170 significant independent reflections with $F > 8.0\sigma(F)$. The minimized function was $\Sigma w(\lvert F_o\rvert - \lvert F_c\rvert)^2$ with $w = 1/\sigma^2(F)$. Neutral atomic scattering factors for all atoms were taken from a standard source (6) while all calculations were performed on NOVA 1200 minicomputer with the SYNTEX XTL/STLE struc-

ture determination system (7). The data collection and processing parameters are summarized in Table 1. Positional parameters together with the B_{eq} values for non-hydrogen atoms, and B_{iso} for bridge hydrogen atoms for both types of molecules are given in Table 2. The bond lengths, bond angles, and torsion angles are given in Tables 3, 4, and 5, respectively.[2]

Results and discussion

In the unit cell there are two slightly different types of molecules, denoted by **A** and **B**, with very short intramolecular hydrogen bonds, 2.425(3) and 2.407(3) Å, respectively. A drawing of the packing in the unit cell is presented in Fig. 1. The structure of molecules and atom numbering are shown in Fig. 2. The difference between molecules **A** and **B** arises from the packing effects and consists mainly in the torsional angle N—O(2)—H—O(1) and the localization of the bridge hydrogen atom.

One should use some caution about the localization of the hydrogen atoms in the bridges. It seems particularly strange that for a slightly shorter bridge (molecules of type **B**) the refinement gives an asymmetric position of the proton, although it is markedly displaced to the centre of the bridge. Nevertheless, the results obtained seem to confirm very short hydrogen bonds of the symmetric type (8), though from a chemical point of

[2]Supplementary tables containing hydrogen atoms parameters, anisotropic temperature factors and structure factor amplitudes may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

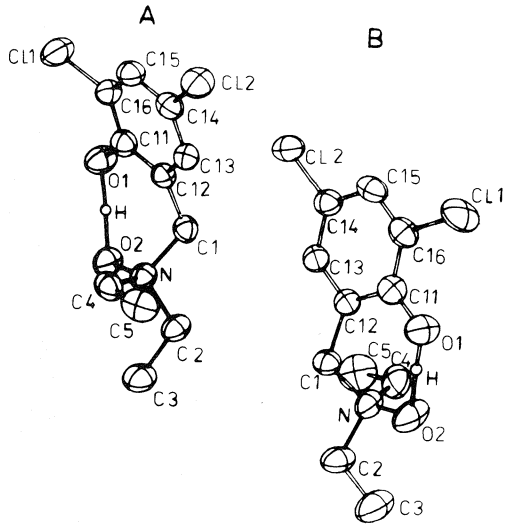

FIG. 2. Schematic representation of molecules **A** and **B**.

view both oxygen bridge atoms possess a different character. Usually, in such situation, asymmetric hydrogen bonds are formed in which the proton is attached to either the proton donor atom or to the proton acceptor (proton transfer ion-pair).

The "symmetric" character of the bridges is clearly reflected in other bond lengths, particularly in the C—O distance. From the Bavoux *et al.* data (9–13) it follows that the average C—O bond length in dichlorophenols equals 1.378(9) Å. In phenolates this bond length undergoes a substantial lowering. Thus, for aniline pentachlorophenolate (14), *N*-methylmorpholine pentabromophenolate (15), and 2-(*N*,*N*-dimethylaminomethyl)-4-nitrophenol (4), it equals to 1.287(13), 1.275(20), and 1.283(3) Å, respectively. In the case of picrates (16) the C—O bond becomes very short, 1.248(1) Å, but this is partly due to a strong mesomeric interaction with nitro groups. Thus, the C—O length of 1.328(3) and 1.319(4) found in this paper for molecules **A** and **B**, respectively, is half-way between the two limited phenolic and phenolate states. Much less sensitive and less informative is the length of N—O bond. For morpholine (17) and trimethylamine (18) *N*-oxides, it is equal to 1.391(3) and 1.388(5) Å, while for trimethylamine *N*-oxide hydrochloride (19) it is 1.425(11) Å. The difference between the two limiting cases, namely, N—O and N—$\overset{+}{O}$H, is reflected in the bond length by 0.04 Å only. Nevertheless, the value of 1.407(3) Å found in this paper could confirm the central proton density distribution within the OHO bridge.

TABLE 6. Position of the long wave-length band of **1** in various solvents (cm^{-1})

Solvent	Wave-length
CCl_4	32 100
Cyclohexane	32 500
Diethyl ether	32 100
DMSO	32 300
Acetonitrile	32 250
$CHCl_3$	32 200
CH_2Cl_2	32 250
Methanol	32 400
Isopenthanol	32 600
Water	33 250
HCl 0.01 *N*	34 000
NaOH 0.01 *N*	31 000

Infrared spectra

The ir spectrum of the investigated compound[2] is typical of very short OHO bridges of the symmetric type (8). One observes a broad intense band over the 400–1800 cm^{-1} frequency range with a maximum at about 900–1000 cm^{-1}. No absorption above 1800 cm^{-1} was found which could be assigned to the bridge protonic vibrations. Also, the isotopic effect seems to confirm very short hydrogen bonds of the symmetric type. The comparison of the ODO and OHO systems shows that the centre of gravity of the broad band in the fingerprint region does not change after deuteration. It means that $\nu_{OHO}/\nu_{ODO} \approx 1$, which is reported for very short OHO bonds (8). One can also notice that the protonic band undergoes some broadening after deuteration without substantial change of the integrated intensity. This is possibly due to some elongation and, thus, to some weakening of the bridge which occurs in the case of short hydrogen bonds (20). In strongly polar solvents the solubility of **1** was high enough to allow the recording of the ir spectra in solution.[2] The position of the maximum of the protonic band was found to remain practically unchanged; however, the long and short wave-length wings appears. This phenomenon seems to be due to both the fluctuations of the bridge conformation (21) and the fluctuations of the electric field around the bridge (22) arising from collisions with the polar solvent molecules.

Ultraviolet spectra

The particular stability of the OHO hydrogen bonds in *N*-oxide of Mannich base is very well reflected in the uv

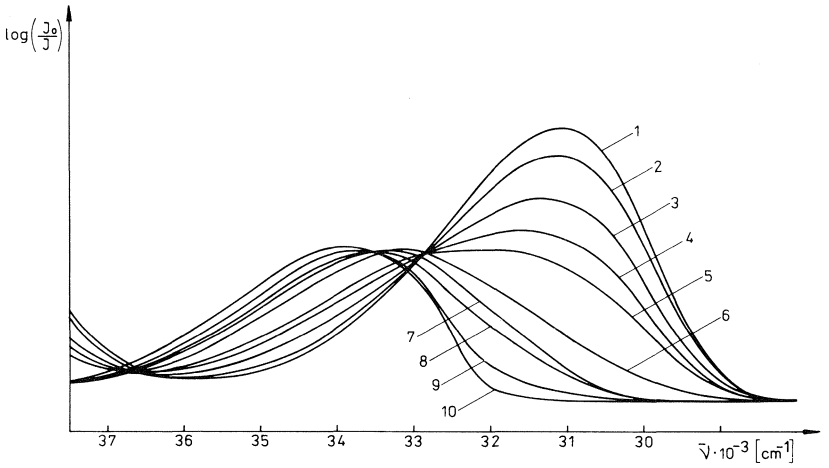

FIG. 3. Ultraviolet absorption spectra of **1** at various pH: 11.1 (*1*), 9.9 (*2*), 9.4 (*3*), 9.0 (*4*), 8.87 (*5*), 8.16 (*6*), 5.14 (*7*), 4.15 (*8*), 2.4 (*9*), and in 1 *N* HCl (*10*).

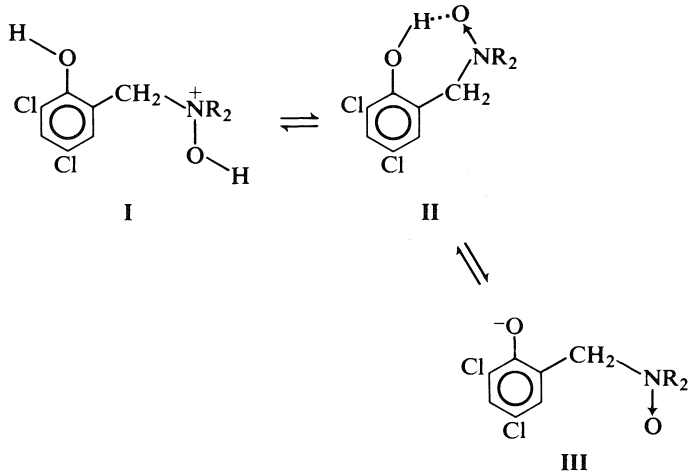
spectrum of this compound. Firstly, there is well reflected from the position of the long wave-length phenolic band in various solvents. In Table 6 the ν_{max} values are collected for various solvents and compared with those for ionic states in HCl and NaOH solutions. Except in H_2O, ν_{max} remains almost constant, with irregular oscillations depending on the donor–acceptor properties of the solvents. The average ν_{max} value is located exactly at midway between the values for the NaOH (phenolate anion) and HCl (protonized broken bridge) solutions. A special situation occurs in water, where ν_{max} = 33 250 cm^{-1}, i.e. the band is markedly shifted towards the position for protonized species. The results of the effect of the pH on the uv spectra are interesting since they reflect the stability of the intramolecular OHO hydrogen bonds. From the dependence of absorption curves on pH (Fig. 3) and particularly from the dependence of the extinction at 32 000 cm^{-1} (Fig. 4) the following equilibria are clearly visualized:



The stabilizing character of the hydrogen bonds causes drastic changes in the acidity and basicity of the interacting groups, as expressed by their pK values. As may be seen in Fig. 4, they undergo a substantial shift in comparison with the respective phenol and *N*-oxide, extending the stability range of the unionized form of Mannich base *N*-oxide. 2,6-Dichlorophenol (pK_a = 7.9 (23)) and tribenzylamine *N*-oxide (pK_a = 4.78 (24)) have been taken as reference compounds. They are

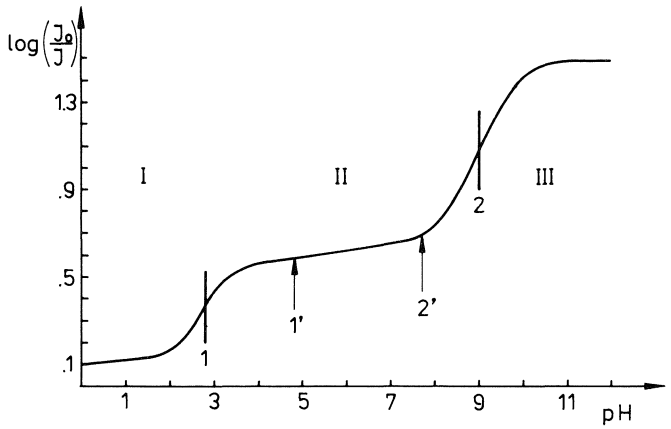


FIG. 4. Dependence of extinction at 3200 cm^{-1} on pH. The arrows correspond to pK_a values for 2,4-dichlorophenol (23) and tribenzylamine *N*-oxide (24).

indicated by arrows in Fig. 4. The hydrogen bond effect is similar here to that observed in dicarboxylic acids and diamines (25).

It is worth noticing that the acid–base behaviour of the Mannich base *N*-oxide is quite different from that of the Mannich base itself, in which the intramolecular OH...N hydrogen bond is formed. In water solution this bond is broken and the hydrated zwitter-ion is formed. The detachment of a proton from the protonized amine group occurs in alkaline solutions. In the Mannich base *N*-oxide the basicity of the *N*-oxide group is much less than for the respective amine group but, in spite of that, the hydrogen bond stability is considerably higher.

Received February 12, 1986

W. KLIEGEL, L. PREU, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **64**, 1855 (1986).

The title compound was prepared according to the literature in order to determine whether it has a bicyclic cage structure resulting from intramolecular O → B coordination or a monocyclic boronate structure incorporating a trigonal planar boron atom. Crystals of 5-methyl-5-nitro-2-phenyl-1,3-dioxa-2-boracyclohexane are orthorhombic, a = 17.2358(4), b = 6.5007(2), c = 9.9225(3) Å, Z = 4, space group *Pnam*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.064 and R_w = 0.070 for 798 reflections with $I \geq 3\sigma(I)$. The molecule actually has C_1 symmetry but, in the solid state, is located at a site of crystallographic C_s symmetry. In order to maintain the apparent mirror symmetry the nitro oxygen atoms are disordered over two mirror-related rotational positions around the C(2)—N bond. The molecule was found to have a monocyclic boronate structure, in agreement with earlier predictions. The six-membered heterocyclic ring has a "semi-planar" conformation. Bond distances and angles are normal.

W. KLIEGEL, L. PREU, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **64**, 1855 (1986).

Dans le but de déterminer si le composé mentionné dans le titre possède une structure bicyclique en cage résultant d'une coordination intramoléculaire O → B ou une structure boronate monocyclique incorporant un atome de bore plan trigonal, on a préparé ce composé en suivant les indications fournies dans la littérature. Les cristaux du méthyl-5 nitro-5 phényl-2 dioxa-1,3 bora-2 cyclohexane sont orthorhombiques, avec a = 17,2358(4), b = 6,5007(2) et c = 9,9225(3) Å, Z= 4 et groupe d'espace *Pnam*. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,064 et R_w = 0,070 pour 798 réflexions avec $I \geq 3\sigma(I)$. La molécule possède une symétrie C_1; toutefois, à l'état solide, elle se situe dans un site cristallographique C_s. Dans le but de maintenir une symétrie apparente dans un miroir, les oxygènes des groupements nitro occupent des positions désordonnées par rapport à deux positions rotationnelles symétriques par rapport à un miroir et résultant d'une rotation autour de la liaison C(2)—N. On a trouvé que la molécule possède une structure boronate monocyclique et ce résultat est en accord avec des prédictions antérieures. L'hétérocycle à six chaînons existe dans une conformation «semi-planaire». Les distances des liaisons ainsi que les angles sont normaux.

[Traduit par la revue]

Introduction

It has been shown by X-ray structure analysis (1) that phenylboronates of bis(hydroxyalkyl)nitrones can have either a bicyclic structure **1** (resulting from intramolecular O → B coordination) or a monocyclic structure **3** (stabilized by O—B $pp(\pi)$ back donation within the trigonal planar boronate system). It was thus of interest to determine whether the phenylboronate of a 2-nitro-1,3-propanediol would possess an analogous bicyclic cage structure **2** or a monocyclic bidentate structure **4**. The "semi-planar" form **4**, with an "axial" nitro group, has been suggested by Urbanski *et al.* (2) for the phenylboronates of 2-alkyl-2-nitro-1,3-propanediols on the basis of calculated and experimentally determined dipole moments. It is noteworthy that these nitro derivatives were found to be more stable than other cyclic phenylboronates with respect to hydrolytic agents (3). This finding would also be consistent with intramolecular O → B coordination leading to a shielded sp^3 boron center. The existence of intramolecular hydrogen bonding in nitroalkanols is well established (4–8). If the "chelated" protons of a nitroalkanol such as 2-methyl-2-nitro-1,3-propanediol were to be replaced by the (formal) dication PhB^{2+} (generated from phenylboronic acid), the chelate **2** could be formed. Similarly, a tridentate nitrone ligand led to the chelate **1** (1) and a tridentate *N*-oxide ligand gave a bicyclic chelate with the same basic ring skeleton (9). For an unambiguous decision between the two possible structures, the phenylboron chelate **2** or the phenylboronate **4**, an X-ray crystallographic analysis of the compound has been carried out.

Experimental

*5-Methyl-5-nitro-2-phenyl-1,3-dioxa-2-boracyclohexane, **4***

The title compound was prepared according to the literature (ref. 3, method A) and was recrystallized from acetone. Mp. 147–148°C, lit. 148–150°C. *Anal.* calcd. for $C_{10}H_{12}BNO_4$: C 54.34, H 5.47, N 6.34; found: C 53.86, H 5.46, N 6.36. ^{1}H nmr ($CDCl_3$/TMS): δ (ppm) =

[1]Part XXIII, ref. 27.

1.53 (s, CH_3), 4.07 and 4.75 (AB system, J = 11 Hz, 2 OCH_2), 7.15–7.85 (m, C_6H_5).

X-ray crystallographic analysis

A crystal bounded by the seven faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.08, ±(0 0 1), 0.20, (0 1 1), 0.25, (0 1 −1), 0.22, (0 −1 0), 0.25 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 80–100°) measured on a diffractometer with Cu-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 1.540562, $\lambda(K\alpha_2)$ = 1.544390 Å). Crystal data at 22°C are:

$C_{10}H_{12}BNO_4$ fw = 221.0

Orthorhombic, a = 17.2358(4), b = 6.5007(2), c = 9.9225(3) Å, V = 1111.77(5) Å^3, Z = 4, ρ_c = 1.320 Mg m^{-3}, $F(000)$ = 464, μ(Cu-$K\alpha$) = 7.99 cm^{-1}. Absent reflections: $0kl$, $k + l$ odd, and $h0l$, h odd, space group *Pnam* (non-standard setting of *Pnma*, D_{2h}^{16}, No. 62, equivalent positions: ±(x, y, z; ½ + x, ½ − y, z; −x, −y, ½ + z; ½ − x, ½ + y, ½ + z)) from structure analysis.

Intensities were measured with graphite-monochromated Cu-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.34–10.06° min^{-1} over a range of (0.80 + 0.15 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (10, 11). Transmission factors ranged from 0.742 to 0.880 for 168 integration points. Of the 1213 independent reflections measured, 798 (65.8%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The systematic absences allow space groups *Pna*2$_1$ or *Pnam*, the latter being indicated by the E-statistics. The structure was solved by direct methods, all non-hydrogen atoms of the molecule (which has crystallographically imposed mirror symmetry) being positioned from an E-map. Hydrogen atoms were positioned from a subsequent difference map. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic, and the hydrogen atoms with isotropic, thermal parameters. The R value at this point was 0.088. The large U_{22} value obtained for the oxygen atom of the nitro group (O(2)) suggested possible disorder or that the actual space group may be *Pna*2$_1$. Attempts to refine the structure in the lower symmetry space group did not resolve this problem and were thwarted by high correlation coefficients. Refinement of the structure was completed with disordered nitro oxygen atoms, O(2) and O(3), being refined with anisotropic thermal parameters and occupancy factors fixed at 0.5. The scattering factors of ref. 12 were used for non-hydrogen atoms and those of ref. 13 for hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley-Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (14–16). The final value of g was 0.49(23) × 10^4. Convergence was reached at R = 0.064 and R_w = 0.070 for 798 reflections with $I \geq 3\sigma(I)$. For all 1213 reflections R = 0.093. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.13σ, respectively. The mean error in an observation of unit weight was 3.044. A final difference map showed maximum fluctuations of −0.35 to +0.22 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 5,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

†Occupancy factor 0.5.

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (17). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0032 and, excluding the nitro oxygen atoms, 0.0017 Å^2. The structural subunits $PhBO_2$ and C(1–3), N, and O(1) (along with their mirror-related counterparts) were analysed separately (rms ΔU_{ij} = 0.0042 and 0.0017 Å^2, respectively). The appropriate bond distances have been corrected for libration (17, 18), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformation of heterocyclic ring are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

Results and discussion

The crystal structure of 5-methyl-5-nitro-2-phenyl-1,3-dioxa-2-boracyclohexane consists of discrete molecules, all intermolecular distances being greater than the sums of van der Waals radii. The molecule actually has C_1 symmetry but, in the solid state, is located at a site of crystallographic C_s symmetry. In order to maintain the apparent mirror symmetry the nitro oxygen atoms are disordered over two mirror-related rotational positions around the C(2)—N bond.

The observed structure **4** (see Fig. 1) corresponds to that deduced by Urbanski *et al.* (2) as being the most probable one with a calculated dipole moment of μ = 4.35 D in good agreement with the experimental value of 4.25 D. The intra-

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

*Primed atoms have coordinates related to those in Table 1 by the symmetry operation $x, y, \frac{1}{2} - z$.

molecular contacts between the nitro oxygen atoms and the boron atom are clearly too long for coordinative interaction (B—O(2) = 3.46(1), B—O(3) = 3.89(1) Å). The *pp*(π) back donation from the two oxygen atoms to boron in the phenylboronate system is energetically favored over intramolecular O → B coordination involving a nitro group oxygen atom which would force the cycloboronate ring into a boat conformation (formula **2**).

The six-membered heterocyclic ring adopts a "semi-planar" conformation with C(2) displaced from the approximate plane of the other five atoms and the nitro group in a pseudo-axial position. This conformation has been predicted on the basis of nmr (19–22) and dipole moment studies (2, 19), and has been verified by X-ray structure analyses (ref. 1 and references therein). The overall geometry of the 1,3-dioxa-2-boracyclohexane ring in **4** is very similar to that of compound **3** (1). The

TABLE 4. Intra-annular torsion angles (deg) standard deviations in parentheses*

Atoms	Value (deg)

O(1)—C(1)—C(2)—C(1)′	48.7(4)

*Symmetry-related torsion angles have the opposite sign.

partial π-bond character of the O—B bonds is demonstrated by the short O—B distance of 1.371(2) Å. The relatively short B—C bond of 1.567(5) Å is indicative of some π-interaction between the sp^2 boron atom and the aromatic system. Both O—B and B—C distances are in good agreement with those observed for **3** and related compounds (ref. 1 and references therein). The C—N bond in **4** (1.552(4) Å) is significantly longer than the corresponding distance of 1.528(3) Å in **3**, whereas the N—O bonds of the nitro group (1.217(8) and 1.143(11) Å) in **4** are considerably shorter than the N—O bond of the nitrone group in **3** (1.291(2) Å). This reflects the more pronounced (partial) double bond character of the N—O bond in the nitro compound **4**. The longer of the two N—O bonds in **4** is in the range 1.190–1.230 Å normally observed for nitro groups (23–25). The anomalously short N—O(3) distance of 1.143(11) Å is most likely an artifact of thermal motion and/or disorder although an inequality of the two N—O bond lengths could arise as a result of differences between the two nitro oxygen atoms with respect to intramolecular non-bonded interactions (O(2)···C(1) = 2.66(1), O(2)···O(1) = 2.95(1), and O(2)···C(3) = 3.31(1) Å vs. O(3)···C(1)′ = 2.76(1), O(3)···O(1)′ = 3.34(1), and O(3)···C(3) = 2.93(1) Å). The geometrical distortion of the phenyl ring is as expected (ref. 26 and references therein). The phenyl ring is planar within experimental error while the boronate and nitro groups are slightly, but significantly, non-planar (B and N are displaced 0.017(4) and 0.015(3) Å, respectively, from the planes of their substituents). The dihedral angle between the normals to the phenyl and boronate mean planes is 1.6(4)°.

Received February 13, 1986

TED SCHAEFER, JAMES PEELING, GLENN H. PENNER, and ALBERTA LEMIRE. Can. J. Chem. **64**, 1859 (1986).

Unlike their counterparts in anisole or toluene derivatives, the six-bond spin–spin coupling constants between *para* ring protons or ^{19}F nuclei and protons or ^{13}C nuclei in the sidechain of derivatives of benzaldehyde, acetophenone, and benzophenone can apparently contain components of opposite sign, at least for the fluorine derivatives. The σ–π components are much smaller in magnitude than in toluene derivatives, leading to very small or unobservable coupling constants. Consequently they are of limited use in conformational analysis. INDO MO FPT computations and their modifications are examined as to the reasons for the small σ–π magnitudes. Although the spin polarizability of the 2*pz* orbital on oxygen appears to play an important role in the transmission of nuclear spin state information, the computations do not account for a ^{19}F coupling mechanism that appears to be significant for planar conformations. On the other hand, spin–spin coupling constants over five formal bonds to *meta* protons are sizeable and stereospecific.

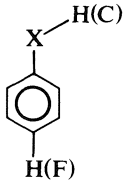
TED SCHAEFER, JAMES PEELING, GLENN H. PENNER et ALBERTA LEMIRE. Can. J. Chem. **64**, 1859 (1986).

Contrairement à leurs contreparties dans les dérivés de l'anisole ou du toluène, les constantes de couplage spin–spin à travers six liaisons, entre les protons du cycle en position *para* ou les noyaux de ^{19}F et les protons ou les noyaux de ^{13}C de la chaîne latérale des dérivés du benzaldéhyde, de l'acétophénone et de la benzophénone peuvent apparemment contenir des composants de signes opposés, au moins dans les dérivés fluorés. Les constituants σ–π ont une intensité inférieure à celle des dérivés du toluène conduisant ainsi à des constantes de couplage très faibles qu'on ne peut observer. En conséquence, ces constantes sont très peu utiles dans l'analyse conformationnelle. On a utilisé des calculs INDO OM FPT ainsi que leurs modifications pour déterminer les causes des faibles intensités des constituants σ–π. Bien que la polarisabilité du spin de l'orbitale 2*pz* de l'oxygène semble jouer un rôle important dans la transmission de l'information sur l'état du spin nucléaire, les calculs ne tiennent pas compte du mécanisme de couplage du ^{19}F qui semble être important dans les conformations planes. Par ailleurs, les constantes de couplage spin–spin à travers cinq liaisons formelles par rapport aux protons en position *meta* sont quantifiables et stéréospécifiques.

[Traduit par la revue]

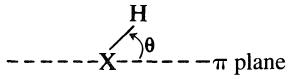
Introduction

Long-range spin–spin coupling constants between ring protons or fluorine nuclei and α protons on the sidechain in benzene derivatives are valuable indicators of conformational preferences and of the potentials governing internal rotation about the C(1)—X bond in **1** (1–3). In particular, it appears that



1

$^6J(^1H,^1H)$ and $^6J(^1H,^{19}F)$ are proportional to $\sin^2\theta$, where θ is the angle by which the X—H bond twists out of the benzene plane, as in **2** (1). The proportionality constant is $^6J_{90}$, the value



2

of ^6J when θ is 90°. The mechanism of coupling therefore involves the σ–π interaction between the σ electrons in the sidechain and the π electrons of the ring. If $^6J_{90}$ is known, then $\langle\sin^2\theta\rangle$ is derivable from the observed ^6J and this expectation value is related to the preferred conformation and the barrier to rotation about the C—X bond (2).

It also appears that $^6J(^1H,^{13}C)$ and $^6J(^{13}C,^{19}F)$ are σ–π couplings, the ^{13}C nucleus being situated in the sidechain, when $X = CH_2$, CH, or C with sp^2 hybridization (4, 5) or when X = O (6). In such compounds $^6J(^{13}C,^{19}F)$ is particularly easy to measure under conditions of ^1H decoupling and is therefore a convenient conformational indicator.

In this paper, attempts to measure $^6J(^1H,^{13}C) \equiv {}^6J(H,C)$ and $^6J(^{13}C,^{19}F) \equiv {}^6J(C,F)$ are described for compounds in which X is a carbonyl group, C=O. It turns out that the σ–π mechanism is relatively inefficient and some modified INDO MO FPT calculations are examined as to the reasons for its absence. Comparisons are made with $^6J(H,F)$ in 4-fluorobenzaldehyde. These indicate a coupling mechanism giving rise to negative six-bond couplings in planar conformations.

Experimental

All compounds, except for acetophenone-β-^{13}C, 2,6-dichloroacetophenone-β-^{13}C, and 4-fluorophenyl-*tert*-butyl ketone came from Aldrich Chemical Co. The second of these was prepared from 2,6-dichlorobenzaldehyde (Frinton) by treatment with ^{13}C-methyl magnesium iodide in ether (7), prepared from ^{13}C enriched CH_3I (Merck, Sharpe and Dohme), followed by oxidation of the alcohol with pyridinium chlorochromate (Aldrich). The unenriched product followed in the obvious way. Acetophenone-β-^{13}C was prepared from benzaldehyde in a similar way. The 4-fluorophenyl-*tert*-butyl ketone

$^4J_{35}$	1.332(3)	Root mean square deviation	0.009

[a]In Hz to high frequency of internal TMS.
[b]Not included in the iterative analysis.
[c]Numbers in parentheses are standard deviations in the last significant figure.
[d]Couplings of 0.06 Hz between methyl and *ortho* ring protons were observed but no couplings from ^{13}C to *ortho* or *para* protons. Line widths for these peaks were no larger than the peaks from the *meta* protons.

was obtained from 1-bromo-4-fluorobenzene (Aldrich) and *tert*-butylcyanide via the Grignard reagent (8). These compounds were identified by means of ^{1}H and ^{13}C nmr spectra.

The ^{13}C nmr spectra for most of the compounds were accumulated on a WH90 FFT nmr spectrometer under conditions of broadband ^{1}H decoupling at a probe temperature of 305 K. The ^{13}C nmr spectra of the methyl carbon nuclei of the acetyl groups in 2,6-dichloroacetophenone and 2,6-dimethoxyacetophenone were acquired with the INEPT (9) pulse sequence, as described recently (4). The ^{1}H nmr spectra of acetophenone-β-^{13}C and of its 2,6-dichloro derivative were recorded on an AM300 nmr spectrometer at a probe temperature of 300 K. All nmr samples were degassed by the freeze–pump–thaw technique and were flame-sealed. Solvents and concentrations are given below.

Molecular orbital computations were performed on an Amdahl 470/V8 computer system and employed MONSTERGAUSS (10), INDO MO FPT (11), and its modified version FINDO (12).

Results and discussion

Spectral data

Table 1 presents the spectral parameters obtained from a NUMARIT (13) analysis of the ^{1}H nmr spectrum of acetophenone-β-^{13}C. A similar analysis of the ^{1}H nmr spectrum of a 5 mol% solution of 2,6-dichloroacetophenone-β-^{13}C in acetone-d_6 gave ^6J(H-4,C) as −0.136(7) Hz and ^5J(H-3,C) as 0.131(5) Hz, the signs being determined by weak multiple irradiation procedures.

In Table 2 are found the ^{13}C chemical shifts and J(C,F) values for 4-fluorophenyl-*tert*-butyl ketone in acetone solution. ^nJ(C,F) for n = 1–4 are very similar for all 4-fluorophenyl compounds and are not reproduced here. Relevant ^6J(C,F) values, those involving the ^{13}C nucleus directly bonded to the carbonyl group, were ±0.132(7) Hz for 4-fluoroacetophenone (25% v/v in acetone-d_6), ±0.087(9) Hz for 4-fluoropropiophenone (30% v/v in acetone-d_6), <0.05 Hz for 4-fluorobenzophenone (25% v/v in acetone-d_6), and <0.07 Hz for 4,4′-difluorobenzophenone (35% v/v in acetone-d_6).

No ^6J(C,F) was observable for 4-fluoro-β-chloroacetophenone nor for pentafluoroacetophenone as a 30% v/v solution in acetone-d_6, although couplings of 2.41(2) and 0.33(2) Hz were measured from the methyl ^{13}C nucleus to the *ortho* and *meta* ^{19}F nuclei, respectively, in the latter compound.

For a 50% v/v solution of 2,6-dimethoxyacetophenone in acetone-d_6, the INEPT spectrum of the acetyl methyl ^{13}C nucleus yielded a ^6J(H-4,C) of ±0.12 ± 0.02 Hz. A similar experiment on unenriched 2,6-dichloroacetophenone gave ^6J(H-4,^{13}C) as ±0.12 ± 0.02 Hz.

TABLE 2. The ^{13}C nmr parameters of 4-fluorophenyl-*tert*-butyl ketone as a 50 v/v% solution in acetone-d_6 at 22.639 MHz and 305 K

Parameter	Value	Parameter	Value
$\delta(CH_3)$	29.08[a]	^1J(C,F)[b]	−250.39
δ(C)	45.21	^2J	21.81
δ(C=O)	207.27	^3J	8.77
δ_1	136.07	^4J	3.31
δ_2	132.32	^5J[c]	<0.05
δ_3	116.44	^6J[c]	<0.05
δ_4	165.62	^7J[c]	<0.04

[a]The chemical shifts were measured relative to the resonance peak of the methyl ^{13}C nuclei in acetone-d_6 and were converted to δ values by addition of 29.8 ppm.
[b]The spin–spin coupling constants have an uncertainty of ca. 0.1 Hz for ^nJ (n = 1–4).
[c]These couplings must be very small, the line width at half height being 0.08 Hz for ^{13}C=O and 0.07 Hz for the methine carbon.

The small magnitudes of ^{6}J(^{1}H,^{13}C) and ^{6}J(^{13}C,^{19}F)

In solution, the free energy of activation for rotation about the exocyclic C_{sp^2}—C_{sp^2} bond in acetophenone is 22.4 kJ/mol (14). Our STO 3G MO computations with geometry optimization indicate a planar ground state and, to within 3%, a twofold barrier to rotation for the acetyl group. Because the barrier to rotation is large compared to thermal energies at 300 K, the absence (Table 1) of ^6J(H,C) is possibly reconcilable with a σ–π mechanism since $\langle \sin^2 \theta \rangle$ is 0.06. If $^6J_{90}$(H,C) is about −0.6 Hz, as in ethylbenzene (4), then the observed ^6J(H,C) should be about −0.04 Hz and may have escaped detection. Some other techniques (15–17) do agree that acetophenone is planar in the ground state.

Turning to 2,6-dichloroacetophenone, ^6J(H,C) is −0.136(7) Hz. Geometry-optimized STO 3G MO computations find the θ = 90° conformation (acetyl plane perpendicular to the benzene plane) as 47.0 kJ/mol more stable than the planar conformation. If this number is correct, then ^6J(H,C) at θ = 90° is −0.14 Hz, compared to (−)0.63 Hz for the corresponding coupling in anisole (6) and (−)0.6$_2$ Hz in ethyl benzene (4). It is true that θ has been estimated as 28° from ^{13}C nmr chemical shifts (18). However, for 2,4,6-trimethylacetophenone a variety of techniques yield various θ values (19, 20), ranging from 50 to 90°. In our opinion, the expectation value of θ cannot be far from 90° in 2,6-dichloroacetophenone. In 2,6-dimethoxyacetophenone,

^6J(H,C) has the same magnitude as in the 2,6-dichloro derivative, the ^{13}C nmr chemical shift suggesting θ as 40° in the former (18).

Because the hyperfine coupling parameter, Q_{CF}, is much larger in magnitude than Q_{CH}, these quantities giving the efficiency of the transfer of spin state information from the π to the σ electrons at the *para* position, measurements of ^6J(C,F) were made on a number of 4-fluorophenyl ketones. In the acetophenone derivative, ^6J(C,F) is ±0.132(7) Hz. The free energy barrier to internal rotation in this compound in solution is 24.7 kJ/mol (14), higher than for acetophenone itself because of increased conjugation across the exocyclic C_{sp^2}—C_{sp^2} bond. In 4-fluoropropiophenone, ^6J(C,F) is ± 0.087(9) Hz and sinks to <0.05 Hz in 4-fluorophenyl-*tert*-butyl ketone (Table 2). In the absence of the fluorine substituent, this compound has been estimated to have $25° \leq \theta \leq 63°$ by different physical techniques (21).

^6J(C,F) at θ = 90° is near 1.5 Hz in anisole derivatives (6) and near 1.3 Hz (5) in 4-fluorophenyl-R (R = CH_2CH_3, $CH(CH_3)_2$, and $C(CH_3)_3$). If ^6J(C,F) at θ = 90° were similar in magnitude in acetophenone derivatives, then a θ of 45° would imply a ^6J(C,F) of at least 0.6 Hz. Yet ^6J(C,F) is absent in 4-fluorophenyl-*tert*-butyl ketone and in pentafluoroacetophenone, for which ⟨θ⟩ may well be as large as 40° (22). Furthermore, ^6J(C,F) is also absent in benzophenone derivatives, for which θ values are about 50° (23). ^6J(C,F) in 4,4′-difluorophenylmethane has a θ dependence very similar to that in 4-fluorophenyl ethane (5), implying similar σ–π parameters for sp^2 and sp^3 carbon atoms at the end of the coupling path.

INDO MO FPT computations

Such computations reproduce the $\sin^2\theta$ dependence of ^6J(H,C) and ^6J(C,F) in anisole derivatives, for example (6). Thus, ^6J(H,C) is computed as $-0.63\sin^2\theta$ in anisole, rather close to the magnitude of 0.62_5 Hz observed in 2,6-dibromoanisole and the 0.64 Hz for ^7J(H,C) in 4-methyl-2,6-dibromoanisole (equality in magnitudes of ^6J(H,C) and ^7J(H,C) is expected for a σ–π mechanism). For ^6J(C,F) the maximum value is computed as too small (6), in line with expectations (1).

In Table 3, computed ^6J(H,C) values as a function of θ are given for a standard geometry (24) of acetophenone. As for similar calculations on anisole (6), the methyl group is rotated as θ increases to keep two H—H_{ortho} distances equal (correlated motion).

When no off-diagonal Fock matrix elements are neglected (3, 12, 25, 26) and no orbitals are restricted (3, 12, 27), the results for ^6J(H,C) indicate a finite value at θ = 0° *and* that its magnitude changes very little as θ goes towards 90° (column A).[2] Qualitatively, the computed increase in magnitude of 0.07 Hz agrees with the −0.14 Hz observed in 2,6-dichloroacetophenone. The finite computed value at 0° then arises from an inadequacy of the INDO MO parameterization.

When the Fock elements between orbitals in the methyl group and the *oxygen* atom and those in the phenyl group are set to zero, the computed ^6J(H,C) values (column B) change very little, implying that such "through-space" or proximate coupling pathways are unimportant.[3] Column B therefore yields the coupling pathway via the orbitals on the carbonyl carbon atom.

If, in addition, the Fock elements involving the 2*pz* orbitals on the carbonyl and the *ipso* carbon atoms are eliminated, ^6J(H,C) drops to zero for all θ. Therefore the implied coupling pathway goes via the partial double bond (conjugation).

On the other hand, restriction of the development of spin polarization in the 2*pz* orbital on oxygen (column D) entails a vanishing ^6J(H,C) for the planar conformer and a maximum magnitude for the perpendicular form. Comparison with column A suggest that the remarkable computed nonzero coupling for the planar conformation arises from an increased polarization of the 2*pz* orbital on the carbonyl carbon atom caused by the spin polarizability of the C=O bond. Note that no such coupling is actually observed in acetophenone (Table 1).

However this may be, in practical terms ^6J(H,C) is not very useful as an indicator of preferred conformations and barriers to rotation about the C_{sp^2}—C_{sp^2}(O) bond in aromatic ketones. Simply put, the carbonyl group acts as a barrier to transfer of nuclear spin state information via a σ–π mechanism.

The INDO MO FPT computations for ^6J(C,F) gave results parallel to those for ^6J(H,C) and are not reproduced here. The theoretical results do not account for the observation of a ^6J(C,F) in acetophenone and its absence in the *tert*-butyl ketone derivative, that is, the decrease in magnitude for nonplanar conformations.

TABLE 3. Some computed $^6J(^1H,^{13}C)$ values in Hz for the methyl ^{13}C nucleus in acetophenone

	$^6J(^1H,^{13}C)$

[a]The angle of twist about the exocyclic C_{sp^2}—C_{sp^2} bond of length 1.46 Å. The methyl group lies in plane for θ = 0°, one of its C—H bonds lying in plane and pointing away from the benzene ring. As θ increases the methyl group twists so as to keep two of its H—H (*ortho*) distances equal (correlated motion).

[b]A standard INDO MO FPT computation.

[c]All off-diagonal Fock elements are set to zero if they involve interactions between orbitals on the ring and orbitals on the oxygen atom and the methyl group, i.e., "through-space" interactions are minimized.

[d]In addition to footnote *c*, the Fock elements involving the 2*pz* orbitals on the *ipso* and carbonyl carbon atoms are forced to vanish.

[e]In addition to footnote *c*, the 2*pz* orbital on the oxygen atom is restricted, i.e., is not allowed to develop spin polarization.

Comparisons with ^{n}J(*H,CHO*) *in benzaldehyde*

A recent precise and unpublished analysis in this laboratory of the ^{1}H nmr spectrum of benzaldehyde in acetone-d_6 solution yielded ^6J(*H,CHO*) as −0.013(1) Hz. In other words, there was no significant coupling, this number being a consequence of the least-squares analysis procedure. Because the internal barrier to rotation in benzaldehyde in solution is greater than 30 kJ/mol (27–31), this result could again be interpreted as arising from the very small $\langle\sin^2\theta\rangle$. The INDO MO FPT computation gives ^6J(*H,CHO*) as −0.29 Hz for θ = 0° (3), implying that this number represents an inadequacy in the

[2]Use of the geometry-optimized STO 3G MO geometries yielded computed ^6J(H,C) values which changed between −0.22 and −0.30 Hz as θ increased from 0 to 90°.

[3]For a fuller discussion of procedures designed to investigate coupling pathways, see ref. 3.

theory, as apparently is also true for the computation of ^6J(H,C) in acetophenone above.

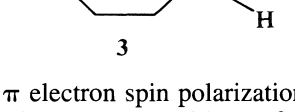
In 2,6-dichlorobenzaldehyde in acetone-d_6 solution we find $^6J(H,CHO)$ as −0.135(3) Hz. A geometry-optimized STO 3G MO computation of the barrier yields $V(\theta)/\text{kJ mol}^{-1} = 2.7(1)\sin^2\theta - 2.8(1)\sin^2 2\theta$ for the internal rotational potential. In other words, the minimum energy occurs near $\theta = 40°$ and the potential is relatively flat. This potential implies a $\langle\sin^2\theta\rangle$ of 0.41 at 300 K. Then $^6J(H,CHO)$ at $\theta = 90°$ would be −0.33 Hz, very much smaller in magnitude than the ^6J(H,H) of −1.2 Hz at $\theta = 90°$ in toluene (32) or the −1.0 Hz in thiophenol (33). Furthermore, at $\theta = 0°$, ^6J(H,C) in ethylbenzene is near (−)0.6 Hz. The ratio of ^6J(H,H) in toluene and ^6J(H,C) in ethylbenzene is 0.52. If a similar ratio holds for $^6J(H,CHO)$ in benzaldehyde and ^6J(H,C) in acetophenone at $\theta = 90°$, then the latter coupling should be -0.33×0.52 or −0.17 Hz. It is observed as −0.14 Hz in 2,6-dichloroacetophenone. These comparisons again illustrate the ability of the carbonyl group to hinder transmission of spin state information via a σ−π mechanism.

By way of contrast, the σ electron pathways are not hindered, but enhanced. Thus, $^5J(H,CHO)$ is 0.430(1) Hz in benzaldehyde and is the average of *cis* and *trans* coupling paths. If $^5J(H,CHO)$ follows a $\sin^2(\theta/2)$ relationship, then $^5J(trans) \equiv {}^5J_{180} = 0.86$ Hz. This can be compared to a $^5J_{180}$ of 0.32 Hz in toluene (32, 34). Using the factor of 0.52 above, ^5J(H,C) in acetophenone follows as 0.22 Hz, as observed (Table 1). In 2,6-dichlorobenzaldehyde, $^5J(H,CHO)$ is 0.403(2) Hz. If $^5J(H,CHO)$ is a pure σ coupling, then it must be the same in benzaldehyde and its 2,6-dichloro derivative because $\langle\sin^2(\theta/2)\rangle$ will be 0.5 in both molecules. The values differ by 0.03 Hz in the two molecules. The difference between the ^5J(H,C) values in acetophenone and 2,6-dichloroacetophenone is rather larger, however.

^{6}J(CHO,F) in 4-fluorobenzaldehyde

The internal rotational barrier in 4-fluorobenzaldehyde in solution is about 34 kJ/mol (14, 35), so that a σ−π mechanism for $^6J(CHO,F)$ should result in a very small, *positive* number. Instead, it is −0.442(3) Hz (36). The INDO MO FPT values for this coupling are positive (36). Clearly, another mechanism is responsible. In view of the remarks above concerning the non-transmission of spin state information via the σ−π mechanism, the negative $^6J(CHO,F)$ must be attributed to a mechanism represented by ionic structure **3**.

$Q_{C(O)H} < 0$
$Q_{CF} > 0$



3

In **3** the arrows represent π electron spin polarizations in 2*pz* π-type orbitals on the carbon atoms. Evidence for such a structure comes from hyperfine fields observed in certain paramagnetic nickel(II) aminotropeneimineate derivatives (37), which show that the hyperfine coupling parameter, Q_{CH}, for an aldehydic group attached to a π electron system is negative, unlike the effective Q_{CH} for a methyl group, which is really a Q_{CCH} originating in a θ dependent hyperconjugative interaction.

The fluorine substituent would facilitate the coupling mechanism described by **3** because, being a π electron donor, it would increase the conjugation across the exocyclic C_{sp^2}—C_{sp^2} bond.

This line of evidence implies that ^6J(C,F) in 4-fluoroacetophenone is also negative (a tricky heteronuclear sign determination experiment is implied by the small magnitudes of the couplings). The observed magnitude of 0.13 Hz is qualitatively in agreement with such a mechanism, being smaller than $^6J(CHO,F)$ in the benzaldehyde derivative.

Now, as the carbonyl group twists out-of-plane, the mechanism represented by **3** becomes less effective, perhaps going as $\cos^2\theta$, and the σ−π (hyperconjugative) increases, going as $\sin^2\theta$. The two contributions to ^6J(C,F) are of opposite sign and, depending on their relative magnitudes, can lead to a vanishing coupling for some nonzero θ value, presumably accounting for the vanishing ^6J(C,F) in the nonplanar *tert*-butyl ketone and benzophenone derivatives above. It remains to be seen whether mechanism **3** helps to account for the vanishing ^5J(C,F). It would give a positive contribution to this coupling involving the carbonyl carbon nucleus.[4]

It may be noted that ^6J(C,F) for the ^{13}C nucleus of the methyl group in 4-fluoro-α-methylstyrene appears to be a σ−π coupling and is estimated to have a maximum magnitude of 1.1 Hz at $\sigma = 90°$ (5). Of course, an ionic structure analogous to **3** is not expected to be important for styrene.

If this line of argument is correct, it follows that the INDO MO FPT method does not account for a coupling mechanism of type **3**.

Furthermore, $^6J(H,CHO)$ is of insignificant magnitude in benzaldehyde. Because its internal barrier to rotation is so large, the σ−π mechanism is inoperative ($\langle\sin^2\theta\rangle \sim 0.04$ and ^6J at 90° is perhaps −0.33 Hz). However, mechanism **3**, if as efficient as in 4-fluorobenzaldehyde, would imply a coupling of about +0.2 Hz ($-Q_{CF} \sim 2Q_{CH}$). Its absence in benzaldehyde must then mean that mechanism **3** is not effective because it demands a larger conjugation across the C_{sp^2}—C_{sp^2} double bond, as large as in the 4-fluoro derivative.

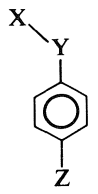
Estimates of ^{6}J(CHO,F) and ^{6}J(C,F) at $\theta = 90°$

Assume that these couplings can be written as $^6J_0^\pi\langle\cos^2\theta\rangle + {}^6J_{90}^{\sigma,\pi}\langle\sin^2\theta\rangle$ where $^6J_0^\pi$ is negative and arises from a π mechanism of type **3**, while $^6J_{90}^{\sigma,\pi}$ is the σ−π or hyperconjugative interaction. On the basis of birefringence measurements, θ has been estimated as 28 ± 6° in pentafluorobenzaldehyde. $^6J(CHO,F)$ for the latter is −0.243(5) Hz in acetone solution (38). A barrier of 34 kJ/mol in 4-fluorobenzaldehyde implies a $\langle\sin^2\theta\rangle$ of about 0.045. The actual Kerr constants for the pentafluoro derivative (39) imply a $\langle\sin^2\theta\rangle$ of 0.233. The implied equations in $^6J^\pi$ and $^6J^{\sigma,\pi}$ yield $^6J_{90}^{\sigma,\pi}$ as 0.56 Hz and $^6J_0^\pi$ as −0.49 Hz. In view of the relatively large uncertainties in the $\langle\sin^2\theta\rangle$ values, write $^5J(CHO,F)/\text{Hz} = -0.5 + 1.1\langle\sin^2\theta\rangle$, where the $\cos^2\theta$ term has been absorbed. Note that $^6J_{90}^{\sigma,\pi}(H,CHO)$ was estimated as −0.33 Hz above. The corresponding $^6J_{90}$(H,H) in toluene is −1.20 Hz (32) and $^6J_{90}$(H,F) in 4-fluorotoluene is 2.28 Hz (40), yielding a ratio of −0.53, similar to the ratio (−0.55) of the corresponding numbers here deduced for benzaldehyde and 4-fluorobenzaldehyde.

This treatment implies that $^6J(CHO,F)$ should vanish in 4-fluorobenzaldehyde derivatives when $\langle\sin^2\theta\rangle \sim 0.5$, that is for a zero barrier, and should become positive and sizeable as $\langle\sin^2\theta\rangle$ approaches unity. Unfortunately, it is difficult to twist an aldehydic function substantially out-of-plane, as shown by the θ of 27° in 9-anthracene-carbaldehyde (41). The synthesis of 2,6-diX-4-fluorobenzaldehyde derivatives (X large and polar) is indicated.

Turning to ^6J(C,F) in the fluorophenyl ketone derivatives,

[4]In the 4-fluorophenyl ketones $^5J(C{=}O,F)$ was not observable. In 4-fluorophenyl methane ^5J(C,F) has a magnitude of 0.73 Hz (5) and is 0.59 Hz in 4-fluorostyrene (5). The striking modification of coupling magnitudes caused by the carbonyl moiety is again evident.



$^6J_{90}^{\sigma,\pi}$/Hz	X	Y	Z
−1.2	H	CH_2	H
−0.3	H	C=O	H
−0.6	C	CH_2	H
-0.1_4	C	C=O	H
2.3	H	CH_2	F
0.6	H	C=O	F
1.3	C	CH_2	F
0.3	C	C=O	F

SCHEME 1

the latest θ value for *tert*-butyl phenyl ketone is 49 ± 5° (21), while that for pentafluoroacetophenone is 41° (22). In both compounds ^6J(C,F) is unobservable. Assume θ as 45°, therefore. Combined with a barrier of 24.7 kJ/mol in 4-fluoroacetophenone, for which $\langle \sin^2 \theta \rangle$ is therefore near 0.05 and ^6J(C,F) is 0.13 Hz, assumed negative here, one derives $^6J_0^{\pi}$ as -0.1_6 Hz and $^6J_{90}^{\pi}$ as 0.3_0 Hz. These are clearly very rough estimates, although it is true that $^6J_{90}^{\sigma,\pi}$, as expected, is roughly twice as large in magnitude as $^6J_{90}^{\sigma,\pi}$ for the ^6J(H,C) in 2,6-dichloroacetophenone above.

Summary and conclusions

The σ−π contributions to spin–spin couplings over six bonds between *para* protons or ^{19}F nuclei, and protons or ^{13}C nuclei, in the sidechain of benzaldehyde and phenyl ketones are only about 25% of those in toluene derivatives. The relative magnitudes are given in Scheme 1. In addition, the six-bond couplings to ^{19}F nuclei contain substantial negative components in planar conformations. In consequence, the utility of these coupling parameters in conformational analysis is very limited as compared with those in toluene, anisole, and thioanisole derivatives. By way of contrast, σ electron couplings over five bonds to *meta* ring protons are not reduced in magnitude by the intervening carbonyl group (36, 42).

As a referee has noted, for a given Y, there is a fairly constant ratio between the above coupling constants that involve protons and those that involve ^{13}C nuclei. This is reasonable if both coupling constants are dependent on a σ−π mechanism. Similar ratios are known for couplings over two, three, and four bonds (43). The $^6J_{90}$ values when Y is C=O are derived on the assumption that the *ortho* substituents do not strongly perturb the σ−π coupling mechanism. This assumption is substantiated for Y = CH_2 (4) and, in view of the data above, appears a sensible one when Y is C=O.

Oxydoréduction photochimique et thermique entre le chrome(VI) et un acide α aminé (glycine, alanine, hydroxyproline et méthionine)

M. Bolte, B. Robert et J. Lemaire

Laboratoire de photochimie moléculaire et macromoléculaire de l'Université de Clermont-Ferrand II Unité associée au Centre national de la recherche scientifique n° 433 B.P. 45, 63170 Aubière, France

Reçu le 31 janvier 1986

M. Bolte, B. Robert et J. Lemaire. Can. J. Chem. **64**, 1864 (1986).

L'oxydoréduction thermique ou photochimique, qui intervient entre le chrome(VI) et différents acides aminés, conduit quantitativement à la formation de chrome(III), avec apparition intermédiare de chrome(V). Il n'apparaît pas de preuve spectrale de la formation à l'état fondamental d'un complexe entre $HCrO_4^-$ et l'acide aminé. La réduction thermique de $HCrO_4^-$ met en jeu l'acide aminé protoné $NH_3^+—CH(COOH)—R$ et nécessite la présence d'ions H^+. La photo-oxydoréduction fait intervenir $HCrO_4^-$, qui est la seule entité absorbante. $[HCrO_4^-]^*$ réagit ensuite avec l'acide aminé présent dans la solution. Le rendement quantique de réduction du chrome(VI) en chrome(III) est proportionnel à la concentration en acide aminé et indépendant du pH dans le domaine d'existence de $HCrO_4^-$.

M. Bolte, B. Robert, and J. Lemaire. Can. J. Chem. **64**, 1864 (1986).

Photochemical and thermal oxidation that occurs between chromium(VI) and various amino acids leads quantitatively to chromium(III). Spectroscopic studies rule out the formation of a chromium(VI) – amino acid complex in the ground state. Thermal oxidoreduction involves $HCrO_4^-$, the protonated amino acid $NH_3^+—CH(COOH)—R$, and H^+ ions. Chromium(V) appears to be an intermediate species in the reaction. $HCrO_4^-$ is the only absorbing compound and the photochemical chromium(VI) reduction proceeds through a reaction between $[HCrO_4^-]^*$ and the amino acid. Chromium(V) is the primary product of the charge transfer reaction. Reduction quantum yields are proportional to the amino acid concentration and pH independent in the $HCrO_4^-$ existence range.

Introduction

La modification de réseaux macromoléculaires par l'introduction de composés de coordination et leur exposition à la lumière est une technique couramment utilisée en photogravure. Ainsi, l'insolubilisation de la gélatine (1), de la cellulose (1) ou de l'alcool polyvinylique (2) peut être provoquée par des réticulations photo-induites par du bichromate de potassium. Une revue complète sur la gélatine bichromatée, matériau photosensible, et ses applications a été faite par D. Meyerhofer (3). Il nous est apparu important d'essayer d'élucider les mécanismes mis en jeu lors de la photo-oxydoréduction, qui intervient entre le chrome(VI) et un substrat réducteur. Dans un premier travail, l'acrylamide a été la substance oxydable étudiée (4). Ainsi, alors qu'il n'apparaît pas de complexation entre $HCrO_4^-$ et l'acrylamide à l'état fondamental, on provoque par excitation dans une transition propre de $HCrO_4^-$ la polymérisation du monomère vinylique. La réaction entre le chrome(VI) et l'acrylamide, qui intervient à l'état excité, conduit à la formation de chrome(V) et d'un radical amorceur de polymérisation.

Dans le présent travail, nous avons examiné les processus d'oxydoréduction photochimique et thermique, intervenant entre le chrome(VI) et différents acides aminés, principaux constituants de la chaîne peptidique de la gélatine : la glycine, l'alanine, l'hydroxyproline et la méthionine. L'étude préliminaire concernant la glycine et le chrome(VI) a fait l'objet d'une note (5).

Partie expérimentale

I. Réactifs utilisés

Le chromate de potassium, le bichromate d'ammonium ou de potassium sont des produits Fluka purum.

$CrCl_3 \cdot 6H_2O$, la glycine, l'alanine, l'hydroxyproline et la méthionine sont des produits Fluka puriss.

II. Préparation des solutions

Les solutions de sels de chrome(VI) ont une concentration en chrome comprise entre 5×10^{-4} *M* et 10^{-3} *M*. Elles sont extrêmement stables à l'inverse des solutions d'acide aminé, dont la durée d'utilisation ne peut excéder quelques jours.

Le pH, ajusté au moyen de HCl ou $HClO_4$, est mesuré avec un pH mètre Orion 811.

La désoxygénation des solutions est réalisée par un bullage d'argon pendant 30 min.

Les irradiations à 365 nm ont été réalisées à l'aide d'une lampe à vapeur de mercure «haute pression» associée à un monochromateur Bausch et Lomb. Le faisceau obtenu est parallèle et le réacteur est une cuve de quartz ronde de trajet optique 1 cm. L'intensité incidente, déterminée par actinométrie avec le ferrioxalate de potassium, est de l'ordre de 3×10^{15} photons $cm^{-2}\,s^{-1}$.

III. Méthodes d'analyse

Les spectres d'absorption uv–visible ont été enregistrés sur un spectrophotomètre Cary 118 C et sur un spectrophotomètre Perkin Elmer 554. La correction de l'effet thermique a été faite en analysant simultanément une solution irradiée et la même solution gardée à l'obscurité.

Les mesures rpe (résonance paramagnétique électronique) ont été réalisées sur un spectromètre Bruker ER 200 D bande X (ν = 9,21 GHz), fréquence des modulations 100 kHz, phase 90°. Les irradiations polychromatiques dans la cavité du spectromètre rpe ont été faites au moyen d'une lampe Hanovia Xe–Hg 1000 W. Le facteur de Landé *g* a été déterminé par rapport au DPPH (diphényl picryl hydrazyle) utilisé comme standard.

Résultats expérimentaux

Le chrome(VI), dans une solution aqueuse de bichromate d'ammonium de concentration comprise entre 10^{-3} et 10^{-4} *M* à pH inférieur à 5 se trouve à 85% sous forme $HCrO_4^-$ (6). Son spectre d'absorption uv–visible présente deux maximums à 263 et 352 nm et un épaulement à 440 nm. L'addition à une solution aqueuse de $HCrO_4^-$ de quantités croissantes de glycine,

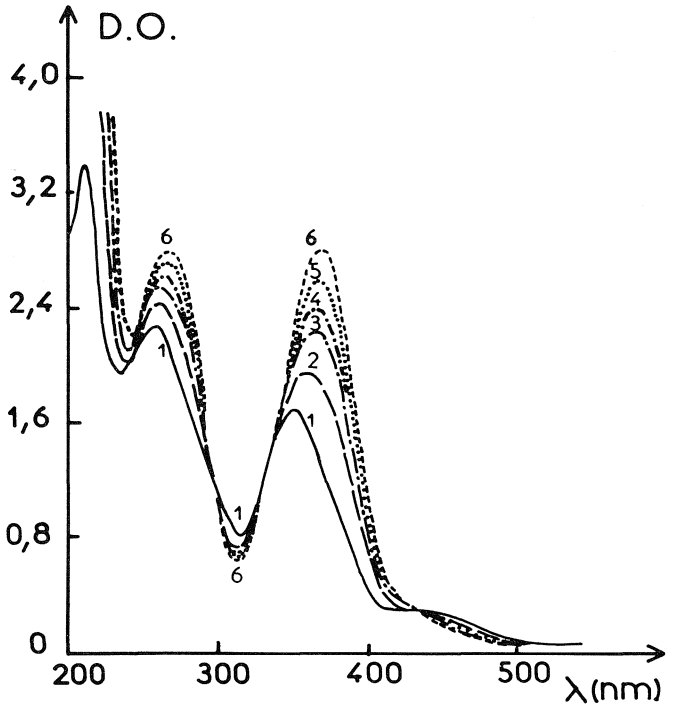

FIG. 1. Spectres d'absorption uv–visible de solutions de bichromate ((Cr(VI) = $10^{-3}M$) en présence de glycine en concentration c croissante (1, c = 0; 2, c = 0,35 M; 3, c = 0,75 M; 4, c = 1 M; 5, c = 1,3 M; 6, c = 1,68 M).

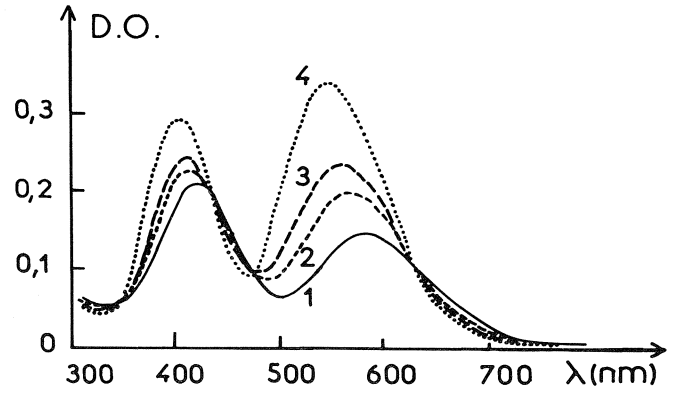

FIG. 2. Évolution spectroscopique d'une solution de chrome(III) ($c = 10^{-2}M$) et de glycine (c = 1 M) en fonction du temps (1, t = 0; 2, t = 1 jour; 3, t = 2 jours; 4, t = 8 jours).

alanine, hydroxyproline ou méthionine, provoque le déplacement vers le rouge du maximum à 352 nm, ainsi que la diminution de l'absorption à 440 nm (fig. 1). Cette modification spectrale est accompagnée d'une augmentation de pH. Si le pH est maintenu inférieur ou égal à 4, l'addition d'acide aminé ne modifie pas le spectre uv–visible de $HCrO_4^-$.

Le chrome(III), sous forme $Cr(H_2O)_6^{3+}$, stable dans l'eau dans le domaine 1,5 < pH < 5, présente deux maximums dans le visible à 415 et 582 nm (ε = 13 M^{-1} cm^{-1}). L'addition d'acide aminé provoque un lent déplacement des maximums vers les courtes longueurs d'onde (fig. 2). En fin de réaction, pour une solution molaire en glycine et $10^{-2}M$ en chrome(III), on observe deux maximums à 390 et 526 nm ($\varepsilon = 80\,M^{-1}$ cm^{-1}). Cette évolution traduit la substitution progressive de l'eau par l'acide aminé.

À 350 nm, le coefficient d'extinction molaire du chrome(III) est négligeable devant celui du chrome(VI). Les cinétiques de disparition du chrome(VI) peuvent être suivies par spectroscopie uv–visible à 352 nm, maximum d'absorption de l'espèce $HCrO_4^-$.

TABLEAU 1. Constantes de vitesse de réduction du chrome(VI) en fonction du pH

	pH	k_0 (min^{-1})
[Méthionine]	1,1	0,344
0,05 M	1,5	0,155
[Cr(VI)]	1,65	0,087
7,25 × $10^{-4}M$	1,83	0,057
	2,27	0,015
	2,80	0,006

Evolution thermique

Laissées à l'obscurité et à température ordinaire, des solutions aqueuses de chrome(VI) et d'acide aminé peuvent évoluer avec le temps. Ainsi, en milieu acide, on note la disparition de la couleur jaune de départ et l'apparition en fin de réaction d'une très faible coloration violette. L'absorption à 350 et 440 nm, due à $HCrO_4^-$, décroît régulièrement, tandis qu'apparaissent deux maximums à 390 et 525 nm. La vitesse de ce phénomène, observée pour tous les acides aminés, dépend de l'acide aminé étudié et du pH. Très lente avec la glycine, la disparition du chrome est beaucoup plus rapide avec la méthionine. L'influence des différents paramètres, pH, concentration en acide aminé et chrome(VI), a été étudiée dans le cas de la méthionine.

Les réactions ont systématiquement été réalisées avec un excès de méthionine par rapport au chrome(VI). La disparition du chrome(VI) à pH = 2,8 suit une loi du premier ordre en fonction du temps, si le rapport méthionine/Cr(VI) est supérieur ou égal à 15. De plus, à cette condition, la vitesse initiale est proportionnelle à la concentration en méthionine. La disparition du chrome(VI) est également du premier ordre par rapport au temps dans un domaine de pH compris entre 1 et 3. À pH supérieur, il apparaît une déviation.

Nous avons également calculé les valeurs de vitesse initiale lorsque le pH varie en dessous de la valeur du pK_I de la méthionine égal à 2,28 (7). Il apparaît une relation de proportionnalité directe entre la vitesse initiale et la concentration en ions H^+. Le tableau 1 regroupe les constantes de vitesse à différents pH. Dans nos conditions expérimentales, il n'y a pas de modification notable de pH en cours de réaction.

Dans le cas de la glycine, les constantes de vitesse sont extrêmement faibles, souvent difficilement déterminables avec une bonne précision. Nous avons cependant évalué la valeur de la constante de vitesse en milieu relativement acide et en présence d'un très gros excès de glycine. Soit :

$$[\text{glycine}] = 0{,}5\,M$$
$$\text{pH} = 1{,}5$$
$$[\text{Cr(VI)}] = 7{,}25 \times 10^{-4}\,M$$
$$k_0 \simeq 1{,}5 \times 10^{-4}\ \text{min}^{-1}$$

Considérant la proportionnalité qui existe entre k_0 et la concentration en acide aminé, le rapport des constantes de vitesse entre la méthionine et la glycine est de l'ordre de 10^4. La réaction thermique en présence d'alanine est du même ordre que

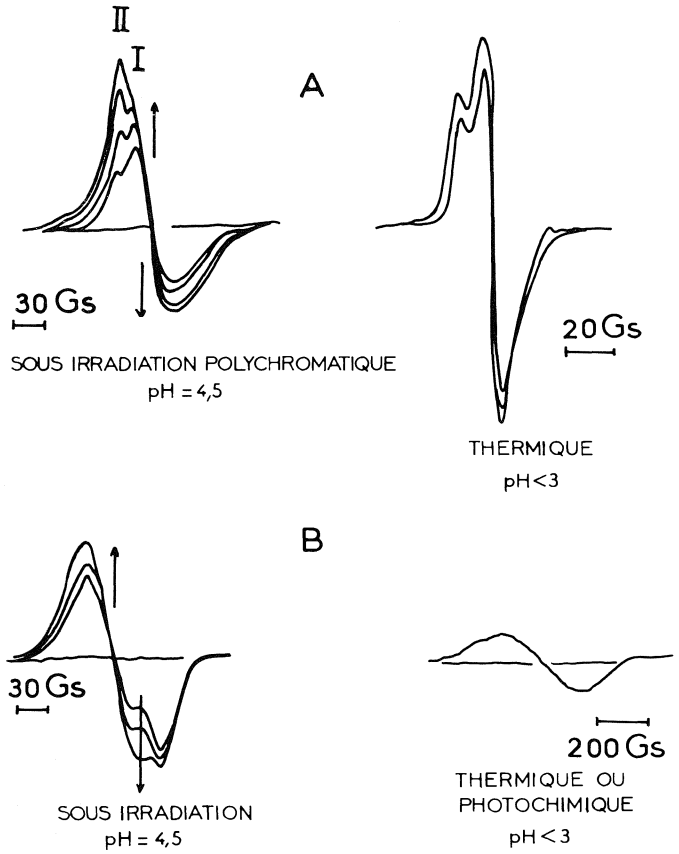

FIG. 3. Spectres rpe de solutions congelées (−30°C) de : A : glycine + chrome(VI); B : méthionine + chrome(VI).

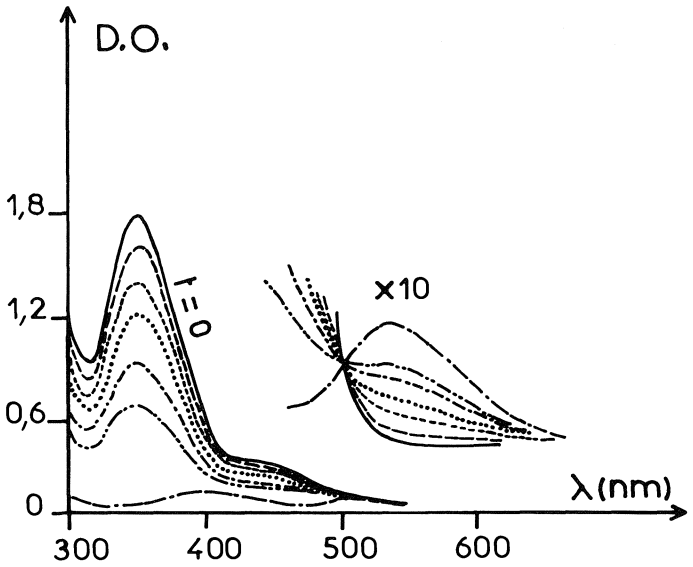

FIG. 4. Évolution du spectre uv–visible d'une solution de bichromate en présence de glycine, pH = 4, sous irradiation à 365 nm.

TABLEAU 2. Rendement quantique de réduction du chrome(VI) en présence de méthionine à λ = 365 nm

Méthionine pH = 4	$\phi^0_{Cr(VI)\rightarrow Cr(III)}$	
0,0125 *M*	$3,9 \times 10^{-3}$	
0,025 *M*	$6,4 \times 10^{-3}$	
0,05 *M*	13×10^{-3}	Cr(VI) = $7,25 \times 10^{-4}$ *M*
0,115 *M*	28×10^{-3}	
0,166 *M*	48×10^{-3}	

celle observée en présence de glycine, tandis que l'hydroxyproline possède un caractère réducteur intermédiaire.

Étude en résonance paramagnétique électronique

À température ordinaire, on n'observe aucun signal pour des solutions aqueuses Cr(VI)–glycine ou méthionine. C'est également le cas en matrice solide (solution congelée à −30°C) à pH supérieur à 3,5. Par contre, à pH inférieur, un ou plusieurs signaux apparaissent, caractéristiques du système étudié : avec la glycine, il apparaît deux signaux intenses de largeur respective 7,5 et 15 Gs (g = 1,9795 et g = 1,9824) et dont les intensités augmentent, puis diminuent avec la même vitesse. Par contre, leur intensité relative dépend des conditions expérimentales. Après complète transformation, on observe un signal faible et de grande largeur de bande ($\Delta G \simeq 160$ Gs).

Avec la méthionine, on observe directement un signal faible de grande largeur de bande ($\Delta G \simeq 320$ Gs). Ce signal augmente très lentement à −30°C. La figure 3 regroupe l'ensemble des signaux rpe étudiés.

Comportement photochimique

L'irradiation d'une solution [Cr(VI)] = $7,25 \times 10^{-4}$ *M* et [acide aminé] = 1 *M*, dont le pH est environ 5, provoque une augmentation de pH. La photoréaction est pratiquement arrêtée dès que le pH atteint une valeur de 6,5. La consommation d'ions H^+ ne peut être imputée à la réaction thermique, car la vitesse d'une telle réaction est nulle dans cette zone de pH. Les manipulations ont donc été réalisées à pH compris entre 1,5 et 4,5, le pH étant ajusté avec $HClO_4$ ou HCl. Au delà de pH = 1,5, la réaction thermique devient trop importante et rend imprécise la détermination des rendements quantiques. Les expériences faites en milieu aéré ou désoxygéné montrent que l'oxygène n'a pas d'influence sur les valeurs des rendements quantiques.

Les rendements quantiques de réduction du chrome(VI) sous excitation à 365 nm ont été déterminés en présence de glycine, alanine, hydroxyproline et méthionine à pH = 4. Lors de l'irradiation, on observe la diminution de l'absorption à 352 et 440 nm, la présence d'un point isobestique à 500 nm, ainsi que l'apparition de deux absorptions à 390 et 525 nm (fig. 4). La diminution de densité optique est parfaitement linéaire en début de photoréaction. Lorsque l'irradiation est maintenue, on observe la disparition presque complète du chrome(VI) : il reste en fin d'expérience environ 2% du chrome(VI) de départ.

Les courbes A de la figure 5 donnent la variation du rendement quantique initial de réduction en fonction du pH. Après correction de l'oxydoréduction thermique, réalisée pour la glycine et la méthionine, le rendement quantique apparaît indépendant du pH dans le domaine 1,5–4,5 (courbes B de la figure 5). Dans ce domaine de pH, le rendement quantique est directement proportionnel à la concentration en acide aminé. Les tableaux 2 et 3 regroupent l'ensemble des rendements quantiques obtenus.

Spectroscopie rpe sous irradiation

L'étude a été faite sous irradiation polychromatique avec des

TABLEAU 3. Rendement quantique de réduction du chrome(VI) par excitation à 365 nm

[Acide aminé] = 0,1 *M*, pH = 4	Structure	$\Phi_{Cr(VI)\rightarrow Cr(III)}$
Glycine	$NH_2—CH_2COOH$	$0{,}24 \times 10^{-3}$
Alanine	$CH_3CH(NH_2)—COOH$	$0{,}36 \times 10^{-3}$
Hydroxyproline		$2{,}40 \times 10^{-3}$
Méthionine	$CH_3—S—(CH_2)_2—CH(NH_2)COOH$	25×10^{-3}

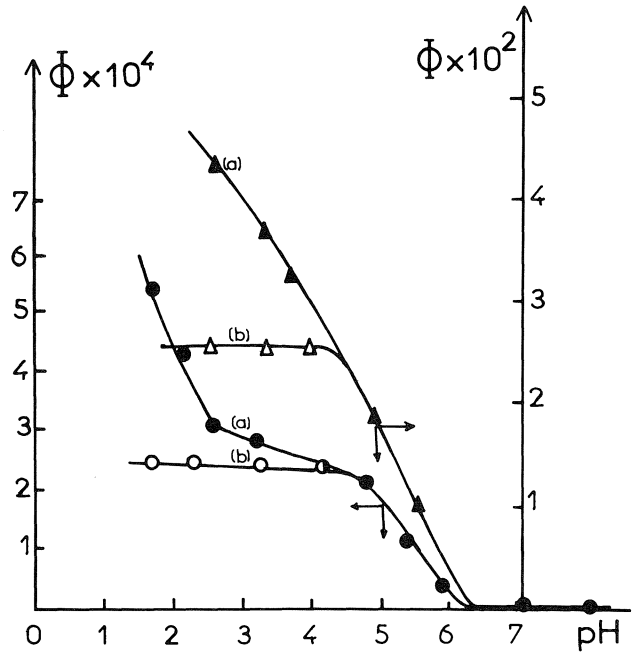

FIG. 5. Rendements quantiques de réduction du chrome(VI) par la glycine (0,1 *M*) et la méthionine (0,1 *M*) (○ : glycine; △ : méthionine); a : ϕ apparent; b : Φ corrigé de l'effet thermique.

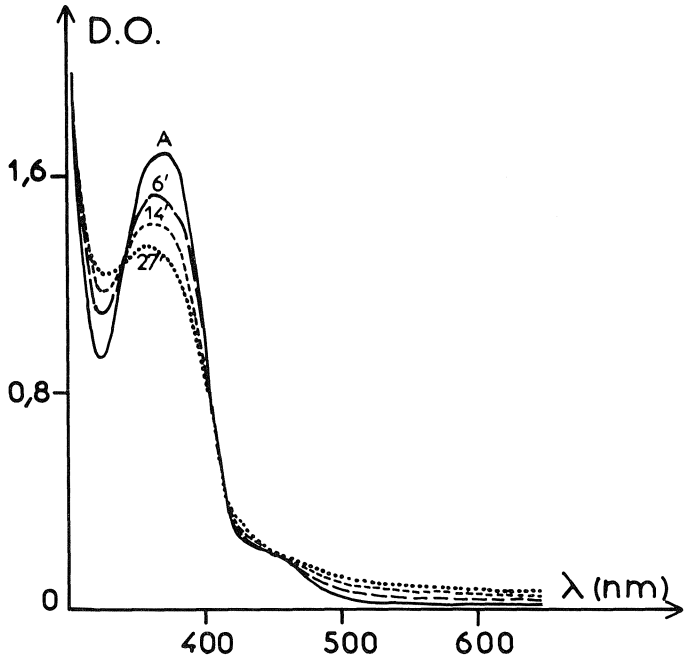

FIG. 6. Évolution spectrale d'un film de gélatine imprégné de bichromate sous irradiation à 365 nm.

solutions liquides (23°C) ou congelées (−30°C) de chrome(VI) en présence de méthionine (0,1 *M*) ou de glycine (1 *M*). À température ordinaire, on observe uniquement et pour de longues irradiations un signal faible et de très grande largeur de bande ($\Delta G \simeq 160$ Gs). En matrice solide, à −30°C, il faut différencier les systèmes et les conditions :

(*i*) Pour le système chrome(VI)–glycine et à pH = 4,5, deux signaux apparaissent à $g = 1{,}9765$ et $g = 1{,}9746$. Leur intensité relative varie avec le temps d'irradiation (fig. 3), le signal I ($\Delta G = 23$ Gs) apparaît dans un premier temps, puis décroît tandis que le signal II ($\Delta G = 30$ Gs) augmente, atteint un maximum, puis décroît très lentement. À pH inférieur à 3, on observe dès le début les deux signaux décrits lors de l'étude thermique ($g = 1{,}9795$ et $g = 1{,}9824$). L'irradiation provoque leur disparition au profit de deux autres signaux analogues ($g = 1{,}9765$ et $g = 1{,}9746$) déplacés vers les champs forts. Pour des irradiations prolongées, on voit apparaître un très faible signal de $\Delta G = 160$ Gs.

(*ii*) Pour le système chrome(VI)–méthionine à pH = 4,5, pH auquel le phénomène thermique ne masque pas le phénomène photochimique, on a, sous irradiation, un spectre rpe analogue à celui obtenu avec la glycine : deux signaux de largeur respective 13 et 26 Gs, dont l'intensité relative varie en cours d'irradiation. À pH inférieur à 3, la réaction thermique provoque l'apparition d'un signal faible et de très grande largeur de bande ($\Delta G = 300$ Gs). L'irradiation en accélère la formation.

Cas particulier de la gélatine

Un film de gélatine, d'épaisseur environ 40 μm, est trempé dans une solution de bichromate de potassium à 5% en poids, pendant 5 min. L'imprégnation de chrome(VI) conduit à une concentration de l'ordre de 0,35 *M*, déterminée par spectroscopie uv–visible. Le spectre rpe d'un film fraîchement préparé ne présente aucun signal. Par contre, avec le temps, il apparaît un signal intense ($\Delta G = 17{,}5$ Gs). Photochimiquement, il apparaît également un signal analogue, mais déplacé vers les champs forts. Pour des irradiations prolongées, on a également apparition d'un signal faible de $\Delta G = 160$ Gs. L'évolution du spectre d'absorption d'un film imprégné de chrome(VI) a été suivie sous irradiation à 365 nm (fig. 6). Il apparaît deux points isobestiques à 340 et 432 nm. Le spectre ΔD.O. $= f(\lambda)$ présente deux maximums à 320 et 424 nm, et un à environ 520 nm (fig. 7).

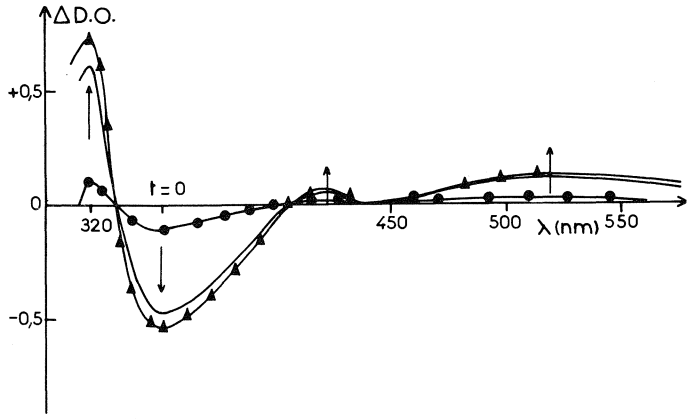

FIG. 7. $\Delta D.O. = f(\lambda)$: variation de la densité optique du film de gélatine imprégné de bichromate sous irradiation à 365 nm.

Discussion

Un certain nombre de résultats et les considérations qui en découlent concernent à la fois les phénomènes thermiques et photochimiques. Nous présentons donc dans la première partie de la discussion un ensemble de points communs aux deux types d'activation.

La méthionine $NH_2—CH(COOH)—(CH_2)_2—S—CH_3$ existe sous forme protonée $NH_3^+—CH(COOH)—(CH_2)_2—S—CH_3$ à pH inférieur à pK_I, ou zwitterionique $NH_3^+—CH(COO^-)—(CH_2)_2—S—CH_3$ à pH supérieur à pK_I, avec $pK_I = 2{,}28$ (7). Le pK de déprotonation du groupement NH_3^+ est en dehors de notre domaine d'études ($pK_{II} = 9$).

Il n'y a apparemment pas de complexation entre Cr(VI) et l'acide aminé à l'état fondamental. La réduction thermique ou photochimique de $HCrO_4^-$ par les acides aminés conduit au chrome(III), comme le montre l'évolution spectrale. La présence de maximums à 390 et 525 nm implique que le complexe obtenu soit, non pas le chrome(III) hexahydraté $Cr(H_2O)_6^{3+}$, mais le chrome(III) complexé par l'acide aminé. Étant donné la faible vitesse de substitution de l'eau par un acide aminé, le complexe chrome(III) – acide aminé s'établit obligatoirement au cours du processus d'oxydoréduction. À pH supérieur, CrO_4^{2-} est la seule espèce présente en solution. Le dianion s'avère une espèce non réductible par les acides aminés dans nos conditions expérimentales.

Les signaux obtenus en rpe dépendent des conditions expérimentales, quel que soit le type d'activation, thermique ou photochimique. Si l'acide aminé est très réducteur, si le milieu est très acide et (ou) à température ordinaire, l'oxydoréduction est très rapide et on observe seulement le stade ultime de la réaction, le chrome(III) hexacoordonné caractérisé par un signal faible et de très grande largeur de bande. Dans des conditions moins favorables à l'oxydoréduction (pouvoir réducteur inférieur, pH supérieur ou milieu rigide ...), on observe un signal intense que, parmi les états de valence du chrome, seul le chrome(V) en d^1 peut présenter. Le chrome(VI) est diamagnétique, le chrome(IV) avec deux électrons non appariés ne présente un signal qu'à très basse température et le chrome(III) présente un signal faible déjà décrit. Les différents signaux observés thermiquement ou photochimiquement correspondent à des environnements du chrome(V) différents selon les conditions (nature de l'acide aminé, concentrations respectives et pH).

Les expériences réalisées avec la gélatine nous ont permis de corréler le signal rpe et le spectre uv. On observe une espèce dont le spectre d'absorption est analogue à celui calculé par Srinivasan et Rocek (8), pour le complexe de chrome(V) résultant de la réduction thermique du chrome(VI) par l'acide oxalique. Ces auteurs observent un maximum à 320 nm et une différence d'absorption ($\varepsilon Cr(V) - \varepsilon Cr(VI)$) maximum à 425 nm et importante au delà de 520 nm. Par ailleurs, ils signalent l'apparition de deux signaux rpe analogues aux signaux que nous observons.

Le chrome(V) apparaît donc comme un produit primaire de l'oxydoréduction thermique ou photochimique entre le chrome(VI) et les acides aminés étudiés. En effet, l'hypothèse souvent admise (9–11), selon laquelle le chrome(V) résulte de la réaction du chrome(VI) de départ sur le chrome(IV), produit primaire d'une oxydation à deux électrons est hautement

[1] $Cr(VI) + Cr(IV) \rightleftharpoons 2Cr(V)$

improbable. Rahman et Rocek (12) ont montré que la constante de vitesse de la réaction [1] en solution aqueuse est très faible. L'équilibre est donc très fortement déplacé vers la gauche.

Il est à remarquer que la gélatine support solide permet de mettre en évidence le chrome(V) dans des conditions de température où, en solution, seul le chrome(III) final peut être observé.

Oxydoréduction thermique chrome(VI) – acide aminé

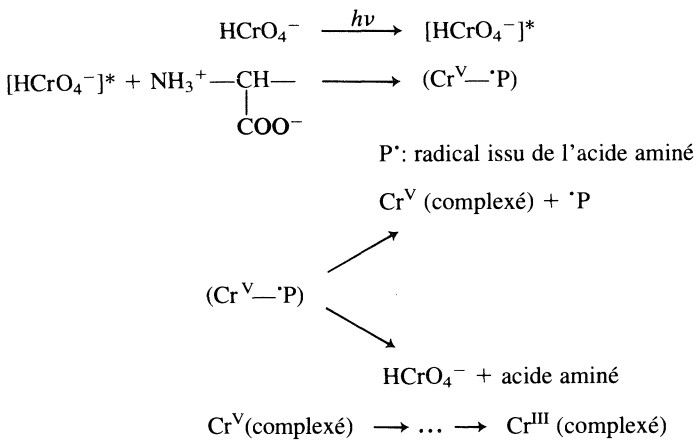
L'étude de la réduction thermique du chrome(VI) montre que la constante de vitesse dépend de la concentration en ions H^+ et en méthionine. La disparition du chrome(VI) ne suit plus une loi du premier ordre si le pH est trop élevé et (ou) si la concentration en réducteur est faible. Par ailleurs, dans ces conditions, la réduction est extrêmement lente donc difficilement analysable avec une bonne précision.

À $pH < pK_I$ où la méthionine est majoritairement sous forme protonée, la constante de vitesse varie proportionnellement à la concentration en ions H^+. La réduction du chrome(VI) par la méthionine est donc une réaction faisant intervenir trois composants $HCrO_4^-$, H^+ et $NH_3^+—CH(COOH)—(CH_2)_2—S—CH_3$; étant donné l'excès de méthionine présent dans la solution, la réaction est en fait contrôlée par les ions H^+. Les conclusions sont analogues avec les autres acides aminés étudiés.

Réaction photochimique

Comme indiqué précédemment, l'unique espèce absorbante est $HCrO_4^-$: une excitation à 365 nm correspond à une transition à caractère de transfert de charge du ligand oxygène vers le chrome(VI). $[HCrO_4^-]^*$ réagit ensuite avec l'acide aminé présent sous forme zwitterionique; la vitesse de réaction contrôle l'ensemble du mécanisme comme le prouvent les rendements quantiques proportionnels à la concentration en acide aminé. Le chrome(V) formé par transfer puis séparation des charges est réduit en chrome(III) par un mécanisme de réaction en cage qui maintient la complexation entre le centre métallique et l'acide aminé. On ne note aucune influence du pH sur le rendement quantique dans le domaine d'existence de $HCrO_4^-$, alors que la photoréduction consomme des ions H^+.

La photoréaction peut être schématisée de la façon suivante :



La formation d'un radical a été mise en évidence lors de l'étude de l'oxydation de l'acide oxalique par le chrome(VI) (10), ainsi que par nous-mêmes lors de l'étude de la polymérisation de l'acrylamide photo-amorcée par $HCrO_4^-$ (4).

Étant donné que nous travaillons à faible degré d'avancement (<10%), nous négligeons l'absorption de la lumière par le chrome(V) qui conduirait au chrome(III).

En conclusion, thermiquement ou photochimiquement, la vitesse de la réaction d'oxydoréduction entre le chrome(VI) et la glycine, l'alanine, l'hydroxyproline ou la méthionine est proportionnelle à la concentration en réducteur. Cependant, les résultats divergent quant à l'influence du pH. La réaction thermique nécessite un milieu relativement acide, afin de fournir les ions H^+ nécessaires à la réaction et à la protonation de l'acide aminé; elle est pratiquement inexistante à pH = 4. Au contraire, la réaction photochimique possède un rendement quantique indépendant du pH dans le domaine d'existence de $HCrO_4^-$ et permet ainsi de travailler à des pH où la réaction thermique est inefficace. La réaction est ainsi contrôlée par la lumière sans réaction thermique parasite, ce qui rend possible la photogravure.

Synthesis and structural studies of rhodium complexes of phosphorus—sulfur ligands

DAVID G. DICK AND DOUGLAS W. STEPHAN[1]
Department of Chemistry, University of Windsor, Ont., Canada, N9B 3P4

Received October 1, 1985[2]

DAVID G. DICK and DOUGLAS W. STEPHAN. Can. J. Chem. **64**, 1870 (1986).

Rhodium complexes of the phosphorus—sulfur ligands, 2-diphenylphosphinoethyl methyl sulfide (MeSP), **1**, and 2-diphenylphosphinothiophene (PTH), **2**, have been prepared and studied by single crystal X-ray diffraction methods. $[Rh(MeSP)_2]BF_4 \cdot H_2O$, **3**, crystallizes in the space group $P2_1/n$ with a = 16.939(6) Å, b = 17.152(5) Å, c = 12.049(9) Å, β = 106.50(4)°, and Z = 4. The MeSP ligands chelate to Rh yielding a distorted square-planar geometry. The disposition of the methyl groups on the *cis* sulfur atoms is transoid. Average Rh—P and Rh—S bond distances were found to be 2.225(3) and 2.347(3) Å, respectively. $[Rh(PTH)_2(COD)]BF_4$, **4**, crystallizes in the space group Cc with a = 15.862(2) Å, b = 15.112(3) Å, c = 16.029(3) Å, β = 103.32(1)°, and Z = 4. The Rh atom in **4** also has essentially a square-planar coordination geometry. **2** does not chelate but rather is monohapto through phosphorus. Rh—P distances of 2.319(3) and 2.378(3) Å and Rh—C distances of 2.17(1), 2.22(1), 2.24(1), and 2.27(1) Å were found. The small variations in the Rh—P and Rh—C bonds distances appear to be a result of steric interactions between **2** and the COD ligand.

DAVID G. DICK et DOUGLAS W. STEPHAN. Can. J. Chem. **64**, 1870 (1986).

On a préparé des complexes de rhodium des ligands phosphore–soufre : le diphényl-2 phosphinoéthyle sulfure de méthyle (PSMe), **1** et le diphényl-2 phosphinothiophène (PTH) **2**, et on les a étudiés par diffraction de rayons X sur un monocristal. Le complexe de $[Rh(PSMe)_2]BF_4 \cdot H_2O$, **3**, cristallise dans le groupe d'espace $P2_1/n$ avec a = 16,939(6) Å, b = 17,152(5) Å, c = 12,049(4) Å, β = 106,50(9)° et Z = 4. Le ligand PSMe chélaté au Rh donne une géométrie carré plan déformée. Les groupes méthyle situés sur l'atome de soufre en position *cis* sont transoides. On a trouvé des distances moyennes de liaison Rh—P et Rh—S de 2,225(3) et 2,347(3) Å respectivement. Le complexe $[Rh(PTH)_2(COD)]BF_4$, **4** cristallise dans le groupe d'espace Cc avec a = 15,862(2) Å, b = 15,112(3) Å, c = 10,029(3) Å, β = 103,32(1)° et Z = 4. L'atome de Rh du composé **4** également a essentiellement une géométrie de coordination carré-plan. Le composé **2** ne chélate pas mais il est plutôt monohapto à travers l'atome de phosphore. Les longueurs de liaison Rh—P sont de 2,319(2) et 2,378(3) Å et celles de la liaison Rh—C sont de 2,17(1), 2,22(1), 2,24(1) et 2,27(1) Å. Les faibles variations observées dans les longueurs de liaison Rh—P et Rh—C se révèlent être le résultat d'interactions stériques entre le composé **2** et le ligand COD.

[Traduit par la revue]

Introduction

Over the past ten years increasing attention has focused on ligands containing both phosphorus and sulfur (1–18). Such ligands are of interest because they can exist in either monohapto or dihapto forms. For example, in Mo, Rh, and Ir complexes (7–12), the ligand 2-diphenylphosphinoethyl methyl sulfide (MeSP), **1**, exhibits dihapto coordination. However, reactivity studies of the complex $[Rh(MeSP)_2]BF_4$ suggest that the sulfur end of **1** is easily displaced yielding a monohapto ligand (10, 12). In comparison, Rh, Co, and Ni complexes of the ligand, 2-diphenylphosphinothiophene (PTH), **2**, have been reported in which **2** is proposed to coordinate only through phosphorus (15, 16). In our continuing interest (17–19) in such dissymmetric ligands, we have prepared and characterized by X-ray crystallography Rh complexes of both **1** and **2**. These structural studies confirm the dihapto and monohapto coordination modes of **1** and **2** in the complexes $[Rh(MeSP)_2]BF_4$, **3**, and $[Rh(PTH)_2(COD)]BF_4$, **4**, respectively. The results of these studies are presented and discussed herein.

Experimental

All preparations were done under an atmosphere of dry O_2-free N_2. Solvents were reagent grade and were degassed by the freeze–thaw method at least three times prior to use. $^{31}P\{^1H\}$ nmr spectra were recorded on a Nicolet GN-300 spectrometer located at Wayne State University, operating at 121.5 MHz with broad band proton decoupling. The ^{31}P chemical shifts are reported relative to external 85% H_3PO_4. Combustion analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario. $[(COD)_2Rh]BF_4$, diphenylphosphinoethanethiol and 2-diphenylphosphinothiophene (PTH), **2**, were prepared by literature methods (20–22). Chlorodiphenylphosphine and 2-iodothiophene were purchased from the Aldrich Chemical Co.

Preparation of 2-diphenylphosphinoethyl methyl sulfide, (MeSP), 1

A solution consisting of 4.33 g (17.6 mmol) of the phosphine thiol, $HSCH_2CH_2PPh_2$, was prepared using 150 mL of THF. A solution of 1.6 *M* *n*-butyl lithium (11.0 mL, 17.6 mmol) in anhydrous diethyl ether was then added followed by dropwise addition of iodomethane (2.50 g, 17.6 mmol). The lithium iodide was extracted from the reaction mixture with water. The THF layer was dried over $MgSO_4$ and the solvent removed under vacuum, leaving a pale yellow oil. This subsequently crystallized *in vacuo* to give white needles (2.43 g, 53% yield). The product may be recrystallized from methanol by addition of diethyl ether. Comparison of the ^{31}P and ^1H nmr parameters to those already reported for **1** confirm the formulation of this product (9, 13).

Preparation of $[Rh(MeSP)_2]BF_4 \cdot H_2O$, 3

A solution of $[Rh(COD)_2]BF_4$ (0.334 g, 0.823 mmol) was prepared in approximately 15 mL of CH_2Cl_2. The ligand, **1** (0.430 g, 1.65 mmol), was dissolved in a small amount (approximately 3 mL) of the same solvent and added to the Rh complex. *n*-Hexane was allowed to diffuse into the yellow reaction mixture. The product, $[Rh(MeSP)_2]BF_4 \cdot H_2O$, crystallized as yellow needles (0.44 g, 70% yield). $^{31}P\{^1H\}$ nmr (CH_2Cl_2) δ (ppm): 65.4 (d) $J_{Rh—P}$ = 160.5 Hz. *Anal.* calcd. for $C_{30}H_{36}BF_4OP_2RhS_2$: C 49.47, H 4.98; found: C 50.59, H 4.92.

Preparation of $[Rh(PTH)_2(COD)]BF_4$, 4

A solution of $[Rh(COD)_2]BF_4$ (60 mg, 0.148 mmol) was prepared in approximately 5 mL of CH_2Cl_2. To this was added **2** (79 mg, 0.295 mmol) in 1 mL of the same solvent. The solution immediately takes on a yellow–orange color. Diffusion of *n*-hexane into this solution precipitated an orange crystalline product (93 mg, 75% yield). $^{31}P\{^1H\}$ nmr (CH_2Cl_2) δ (ppm): 17.7 (d), $J_{Rh—P}$ = 147.1 Hz. *Anal.* calcd. for $C_{40}H_{38}BF_4P_2RhS_2$: C 57.57, H 4.59; found: C 56.82, H 4.78.

X-ray data collection and reduction

Yellow crystals of **3** were obtained by vapor diffusion of diethyl ether into a CH_2Cl_2 solution of **3**. Orange crystals of **4** were obtained by diffusion of *n*-hexane into a CH_2Cl_2 solution of **4**. Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation. The initial orientation matrix for each crystal was obtained from 15 machine-created reflections selected from rotation photographs. These data were used to determine the crystal systems. Partial rotation photographs around each axis were consistent with a monoclinic crystal system in each case. Ultimately, 40 high-angle reflections ($15° < 2\theta < 31°$) for **3** and 30 high-angle reflections for **4** ($15° < 2\theta < 36°$) were used to obtain the final lattice parameters and the orientation matrices. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed extinctions were consistent with the space group $P2_1/n$ for **3** and Cc or $C2/c$ for **4**. Successful refinement later confirmed the space group as Cc for **4**. $\pm h, +k, +l$ data were collected in one shell ($4.5° < 2\theta < 45°$) for both **3** and **4**. Three standard reflections were recorded every 197 reflections. Their intensities showed no statistically significant change over the duration of data collection. The data were processed using the SHELX-76 program package on the computing facilities at the University of Windsor. A total of 2950 reflections for **3** and 2459 reflections for **4** with $F_o^2 > 3\sigma F_o^2$ were used in the refinements. In both cases the absorption coefficients were small ($\mu < 7$ cm^{-1}). The complexity of the crystal faces of **3** precluded accurate indexing. To check for absorption effects psi-scans were recorded for **3**. The average deviation from the mean intensity was less than 2.0% of the mean thus no absorption correction was applied to the data for **3**. For **4**, in which the crystal dimensions were distinctly anisotropic, the crystal faces were indexed, measured and an analytical absorption correction applied to the data. The maximum and minimum absorption corrections applied were 1.247 and 1.578, while the average correction was 1.343.

Structure solutions and refinements

Non-hydrogen atomic scattering factors were taken from the literature (23). The Rh atom positions were determined using the heavy atom (Patterson) method. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. Refinement was carried out by using full-matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/\sigma^2(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. The refinement of **4** confirmed the space group as Cc. In the final cycles of refinement for each structure, the Rh, S, and P atoms were assigned anisotropic temperature factors. The methylene and methyl carbon atoms of **3** and the COD carbon atoms of **4** were also assigned anisotropic thermal parameters. The remaining non-hydrogen atoms were described by isotropic temperature factors. The phenyl-ring geometries were constrained to those of regular hexagons with C—C bond lengths of 1.39 Å. Hydrogen atom positions were allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which the hydrogen is bonded. The hydrogens of the methyl groups of **3** were treated as rigid rotors. In all cases the hydrogen atom contributions were calculated but not refined. In both refinements disorder of the BF_4 moieties were apparent thus the geometries of BF_4 groups were constrained to those of tetrahedra with B—F bond distances of 1.28 Å. Difference map calculations suggested the presence of a two orientation disorder of the BF_4 group in **3**. After refinement of positional and site occupancy factors the best model for **3** was found to involve two orientations of the BF_4, centered at the same site, each with a 0.5 occupancy. For **4**, no simple multi-site disorder model was evident from the difference map analyses, thus a single constrained group with isotropic atoms was ultimately used. The final values of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o||$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$ are given in Table 1. Refinement of the inverted

model was of **4** performed. The R and R_w increased to 0.0688 and 0.0756, respectively. Using the Hamilton R factor test, the initial solution was confirmed to be the correct enantiomorph at a greater than 95% confidence level. The maximum Δ/σ on any of the parameters in the final cycles of refinement was 0.005 for **3** and 0.008 for **4**. Final difference Fourier map calculations showed no peaks of chemical significance; the largest peak was 1.35 electrons/Å^3 for **3** and was associated with the water molecule, while the largest peak for **4** was 1.5 electrons/Å^3 associated with C62. The following data are tabulated: positional parameters (Table 2); selected bond distances and angles (Table 3). Thermal parameters (Table S1), Hydrogen atom parameters (Table S2), and values of $10|F_o|$ and $10|F_c|$ (Table S3) have been deposited as supplementary material.[3]

Results and discussion

Reaction of CH_3I with the thiolate anion, $Ph_2PCH_2CH_2S^-$, yielded the previously reported ligand, **1** (10). This synthetic method is a convenient alternative to the known route. The

second P—S ligand, **2**, was prepared by the published method (17). Reaction of the ligands, **1** and **2**, with $[Rh(COD)_2]BF_4$ gave yellow and orange rhodium complexes, respectively. In the case of **1**, the $^{31}P\{^1H\}$ nmr spectrum of the complex shows a doublet at 65.4 ppm. The Rh—P coupling constant is 160.5 Hz. These data were identical to those recently reported for the complex, $[Rh(MeSP)_2]BF_4$, **3** (9). Analytical data suggest that there is a molecule of H_2O per Rh atom in the crystal lattice. A similar reaction with ligand **2** gives an orange rhodium complex. $^{31}P\{^1H\}$ nmr as well as analytical data are consistent with the formulation $[Rh(PTH)_2(COD)]BF_4$, **4**. The upfield shift of the phosphorus resonance (17.7 ppm) and the Rh—P coupling constant of 147.1 Hz are consistent with phosphorus nuclei *trans* to COD (24).

Structural studies

Confirmation of the formulation as well as structural details of the Rh complexes **3** and **4** are obtained from crystallographic investigations. The study of compound **3** clearly shows that the crystal lattice is built from unit cells each containing discrete cations, anions, and waters of crystallization. The closest non-bonded approach between anion and cation is 2.501 Å (F3···H1C), while the closest approach between adjacent cations is 2.612 Å (H1A···H2B). The closest approach between the water molecule of crystallization and either the cation or the anion is 2.967 Å (O···H5A). Selected bond distances and angles are given in Table 3. An ORTEP drawing of the cation of **3** is shown in Fig. 1. The geometry of the Rh is essentially square planar with two phosphorus and two sulfur atoms comprising the coordination sphere. The Rh—P and Rh—S

bond distances average 2.225(3) and 2.348(3) Å and are typical (25, 26). The MeSP ligands form puckered five-membered chelate rings with the Rh. The bite angles average 85.8(6)°, a typical value for five-membered chelate rings (27). The disposition of the methyl groups on the *cis* sulfur atoms is transoid. The phenyl rings on the phosphorus atom adopt pseudo-axial and pseudo-equatorial positions. The two equatorial phenyl rings (C21—C26 and C41—C46) are almost parallel as the angle between the planes is only 8.16°. The average distance between these phenyl rings is 3.39 Å. This type of phenyl ring alignment for adjacent phenyl—phosphine groups has been observed in other structures (28).

The crystallographic study of **4** shows that the crystal is made up of unit cells containing discrete anions and cations. The closest non-bonded approach between anion and cation is 2.483 Å (F2···H24). The closest approach between adjacent cations is 2.389 Å (H14···H63). The interatomic distances and angles are included in Table 3. An ORTEP drawing of the cation of **4** is shown in Fig. 2. The geometry of the Rh is essentially square planar; two phosphorus atoms and the midpoints of the two carbon—carbon double bonds of the COD moiety complete the coordination sphere. The COD moiety binds to the Rh such that the Rh—C1 and Rh—C6 distances average 2.19(2) Å while Rh—C2 and Rh—C5 distances average 2.26(2) Å. In addition, the Rh—P1 bond length (2.378 Å) is slightly longer than the Rh—P2 bond length (2.319 Å). It is noteworthy that the closest approach of H5 or H6 to any of the rings on P1 is 2.357 Å (H5···H56), while for H1 or H2, the closest approach to the rings on P2 is 2.396 Å (H1···C11). Thus the slight lengthening of the Rh—C5, Rh—C6, and Rh—P1 bond lengths may serve to alleviate some of the steric interactions between the phosphine substituents and the COD ligand. The S atoms of the thiophene groups are not oriented to allow coordination to Rh. The intramolecular Rh···S distances are 4.828 and 5.099 Å while the closest intermolecular Rh···S distance is 7.085 Å (Rh···S1), thus confirming the monohapto nature of **2** in **4**. Once again, the phenyl groups on the adjacent phosphines are oriented such that two of the rings (C31—C36 and C61—C66) are almost parallel; the angle between the planes is 12.47°. The average distance between these phenyl rings is 3.45 Å. This situation is similar to that observed in **3** and other species (28).

The structures of the complexes described herein confirm two

possible coordination modes for phosphorus—sulfur ligands. The MeSP ligands in **3** form chelate rings (dihapto), while the PTH ligands in **4** coordinate only through phosphorus (monohapto). These modes of coordination have been proposed for **1** and **2** as well as related ligands (7–16). The monohapto nature of **2** may be attributed to the substantial strain involved in the formation of a four-membered chelate ring. In addition, the donor capability of the thiophene sulfur atom of **2** is certainly poorer than that of the thioether sulfur in **1**.

MARIE-CLAUDE CORBEIL, ANDRÉ L. BEAUCHAMP, SERGE ALEX, and RODRIGUE SAVOIE. Can. J. Chem. **64**, 1876 (1986).

The complexes $(CH_3Hg)Gly$, (CH_3Hg)(L-Ala), and (CH_3Hg)(DL-Ala) were prepared by reacting CH_3HgOH with glycine (HGly) and alanine (HAla). Crystals of (CH_3Hg)(DL-Ala) are monoclinic, space group $P2_1/c$, $a = 9.460(2)$, $b = 8.794(2)$, $c = 8.723(2)$ Å, $\beta = 97.49(2)°$, $Z = 4$. The structure was refined on 935 MoKα reflections to $R = 0.042$. The complex results from displacement of an alanine NH_3^+ proton by the CH_3Hg^+ ion, which is linearly bonded to the $—NH_2$ group. An intramolecular Hg...O contact of 2.63 Å is also formed with a carboxylate oxygen. The Raman and infrared spectra of solid $(CH_3Hg)Gly$ and (CH_3Hg)(L-Ala) are compared with those of the ligands. Raman spectra of aqueous solutions at different pH indicate that the NH_2-bonded structure is retained in solution, although no complexation via the carboxylate occurs.

MARIE-CLAUDE CORBEIL, ANDRÉ L. BEAUCHAMP, SERGE ALEX et RODRIGUE SAVOIE. Can. J. Chem. **64**, 1876 (1986).

Les complexes $(CH_3Hg)Gly$, (CH_3Hg)(L-Ala) et (CH_3Hg)(DL-Ala) ont été préparés par réaction de CH_3HgOH avec la glycine (HGly) et l'alanine (HAla). Les cristaux de (CH_3Hg)(DL-Ala) sont monocliniques, de groupe spatial $P2_1/c$, $a = 9{,}460(2)$, $b = 8{,}794(2)$, $c = 8{,}723(2)$ Å, $\beta = 97{,}49(2)°$, $Z = 4$. La structure a été affinée au moyen de 935 réflexions MoKα jusqu'à $R = 0{,}042$. Dans ce complexe, un proton du groupement NH_3^+ de l'alanine est déplacé par l'ion CH_3Hg^+, qui se trouve linéairement coordonné au groupe NH_2. Un oxygène du groupe carboxylate établit également un contact intramoléculaire Hg...O de 2,63 Å. Les spectres Raman et infrarouges de $(CH_3Hg)Gly$ et (CH_3Hg)(L-Ala) à l'état solide sont comparés à ceux des ligands libres. Les spectres Raman de solutions aqueuses à différents pH indiquent que la liaison avec le groupe NH_2 persiste en solution, aucune complexation avec le groupe carboxylate n'ayant cependant pu être décelée.

Introduction

Our laboratories have undertaken a series of studies on the interaction of the CH_3Hg^+ ion with amino acids and small peptides, both in the solid state and in solution, with the aim of better understanding the behaviour of this cation with respect to polypeptides and proteins. In a recent paper (1), we have reported that the CH_3Hg^+ ion coordinates first to the $—NH_2$ lone pair of glycylglycine, in agreement with earlier observations by Rabenstein and co-workers (2) for other amino acids. We have also found that a second CH_3Hg^+ ion binds to a carboxylate oxygen in solid $[(CH_3Hg)_2Glygly]ClO_4$ (1). The very intense Raman bands observed between 450 and 575 cm^{-1} for the Hg—ligand stretching vibrations were particularly useful in distinguishing between these two different types of bonding.

Concurrently with the above study, 1:1 complexes with glycine (HGly) and alanine (HAla) were isolated which, judging from the Hg—ligand stretching regions in Raman, seemed to show different binding sites.[3] Indeed, whereas $(CH_3Hg)Gly$ produced a strong signal at the position expected for the Hg—N stretching vibration, the analogous band for $(CH_3Hg)Ala$ occurred in the region where the ν(Hg—O) band had been observed for the glycylglycine compound (1). As these amino acids were not expected to react differently, we decided to examine these two systems in greater detail.

[2]Revision received April 25, 1985.

[3]Symbols for the various forms of the ligands are as follows: neutral zwitterionic forms: HGly and HAla; monoanions, Gly^- and Ala^-; monocations, H_2Gly^+ and H_2Ala^+.

Experimental section

Reagents and techniques

Glycine and alanine (both from Fisher Scientific) were used without further purification. The source of CH_3Hg^+ ions was the hydroxide CH_3HgOH (1 *M* aqueous solution from Alfa Inorganics).

The CH_3Hg^+ ion was analyzed potentiometrically by titration with KCl in ethanol (Ag/AgCl indicator electrode) (3). The concentrations of the solutions studied by Raman spectroscopy (4–16% w/w) are indicated for each of the spectra presented below, the pH being adjusted in each case with either NaOH or HNO_3 (4 *N*).

Raman spectroscopy

The Raman spectra, generally excited by the 514.5 nm line from a Spectra Physics Model 165 argon ion laser, were recorded on a Spex Model 1400 microcomputer-controlled spectrometer. The 488.0 nm line was used for the $(CH_3Hg)Gly$ crystals. The samples were contained in capillary tubes which, in the case of the highly light-sensitive solid complexes, were mounted on a motor shaft and rotated at high speed in the laser beam. Even so, the laser power at the sample had to be kept very low (~25 mW) in order to prevent sample decomposition. The various solutions, contained in sealed capillaries mounted in a copper block maintained at 10°C, were studied at a laser power of 200 mW at the sample. The spectra were typically recorded at 5 cm^{-1} spectral slit width, with a 2 s integration time at each 2 cm^{-1} frequency increment.

Infrared spectroscopy

The ir spectra were recorded as KBr pellets with a Digilab FTS-15 C/D Fourier-transform spectrophotometer equipped with a Globar source and a wide-band mercury cadmium telluride detector (Infrared Associates, New Brunswick, NJ). Typically, 100 interferograms of 4096 points recorded with an optical velocity of 1.2 cm s^{-1} and maximum optical retardation of 0.5 cm were co-added, apodized with a boxcar function, and Fourier transformed with four levels of zero filling

resulting in a spectral resolution of 2 cm^{-1}. The apparatus was purged with nitrogen during the experiment.

Nuclear magnetic resonance spectroscopy

The ^1H nmr spectra were obtained with a Bruker WH-90 spectrometer. The internal references used ($\delta = 0$) were TMS for DMSO-d_6 solutions or DSS for D_2O solutions. The solvents used were Silanor DMSO-d_6 (Merck, Sharp and Dohme Canada, 99.5% isotopic purity) and D_2O (Cambridge Isotope Lab., 99.83% isotopic purity).

Preparations

[(CH$_3$Hg)Gly]

Glycine (1 mmol, 75 mg) was dissolved in 1.0 mL of 1 *M* aqueous CH_3HgOH. Absolute ethanol (1 mL) and dimethylformamide (9 mL) were added. After a few hours at room temperature and in open air (hood), thin colorless platelets were obtained. Yield: 100 mg (33%). *Anal.* calcd. for $C_3H_7HgNO_2$: C 12.44, H 2.44, N 4.84; found: C 12.55, H 2.57, N 4.86. ^1H nmr (in D_2O): 3.69 (2H, s, CH_2), 0.86 (3H, s, CH_3Hg), $^2J(^1H—^{199}Hg)$ = 216 Hz; (in DMSO-d_6): 5.09 (2H, s, br, NH_2), 3.26 (2H, s, CH_2), 0.60 (3H, s, CH_3Hg), $^2J(^1H—^{199}Hg)$ = 208 Hz.

[(CH$_3$Hg)(DL-Ala)]

Prepared from DL-alanine by the same method as above, with addition of 2 mL of absolute ethanol and 8 mL of dimethylformamide. Colorless platelets precipitated after a few days. Yield: 100 mg (30%). ^1H nmr (in D_2O): 4.17 (1H, q, CH), 1.45 (3H, d, CH_3), 0.89 (3H, s, CH_3Hg), $^2J(^1H—^{199}Hg)$ = 215 Hz; (in DMSO-d_6): 5.05 (2H, s, br, NH_2), 3.70 (1H, q, CH), 1.24 (3H, d, CH_3), 0.63 (3H, s, CH_3Hg), $^2J(^1H—^{199}Hg)$ = 207 Hz. A crystal from this homogeneous crystalline sample was used for X-ray work.

[(CH$_3$Hg)(L-Ala)]

Prepared as above from L-alanine. The ^1H nmr data were identical with those of the DL-isomer. *Anal.* calcd. for $C_4H_9NO_2Hg$: C 15.82, H 2.99, N 4.61; found: C 16.04, H 3.01, N 4.60.

Crystal data

$C_4H_9HgNO_2$ fw = 303.71

Monoclinic, $P2_1/c$, $a = 9.460(2)$, $b = 8.794(2)$, $c = 8.723(2)$ Å, $\beta = 97.49(2)°$, $V = 719.2$ Å^3, $Z = 4$, $D_c = 2.804$ g cm^{-3}, λ(MoK$\bar{\alpha}$) = 0.71069 Å (graphite monochromator), μ(MoKα) = 213.0 cm^{-1}, T = 293 K.

Crystallographic measurements and structure determination

The crystal used for X-ray work had dimensions 0.045 × 0.188 × 0.168 mm^3. The space group and initial cell parameters were determined from precession and cone-axis photographs. Space group $P2_1/c$ was uniquely defined from the systematic absences ($0k0$, $k \neq 2n$; $h0l$, $l \neq 2n$). Accurate cell parameters and intensity data were obtained with an Enraf-Nonius CAD4 diffractometer, as described elsewhere (4). Three standard reflections monitored during the experiment showed that the crystal slowly decomposed in the X-ray beam, their intensities having decreased by 15% over the 2½ days of data collection. This decay was considered at the data reduction stage. A total of 1015 hkl and hkl reflections were measured, within a sphere limited by 2θ = 45°. After rejection of 80 systematic absences, the data set consisted of 935 independent reflections, of which 660 were used to solve the structure ($I > 3.0\sigma(I)$). The data were corrected for absorption (Gaussian integration, grid 8 × 8 × 8, transmission range: 0.074–0.392), polarization, and the Lorentz effect.

The structure was solved by the heavy-atom and refined on $|F_o|$ by full-matrix least squares. The Hg atom was located from a Patterson map and the remaining non-hydrogen atoms were found on the difference Fourier (ΔF) map phased on Hg. Isotropic refinement converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.052$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.064$. The hydrogen atoms on the amino and methine groups were fixed at ideal positions (C—H = 0.95 Å, N—H = 0.87 Å, B_{iso} = 4 Å^2). Their parameters were not refined, but the coordinates were recalculated after each cycle. The hydrogens of the methyl groups were neglected. Anisotropic refinement of all non-hydrogen atoms converged to $R = 0.042$ and $R_w = 0.049$. The goodness-to-fit ratio was 1.82. The highest residuals on the final ΔF map (±|1.2–2.0| e Å^{-3}) were all around the Hg atom. The general background was below ±1.0 e Å^3. The refined coordinates and equivalent isotropic temperature factors are listed in Table 1.[4] The temperature factor of C(1) is relatively large. Mercury-bound methyl groups often exhibit high thermal motion, which sometimes includes rotational disordering of the methyl group about the Hg—CH_3 bond. This results in larger esd's for C(1), but does not affect the overall structure.

The scattering curves were from standard sources (5). The f' and f'' contributions of Hg to anomalous dispersion were included in structure factor calculation (6). The programs used are listed elsewhere (7).

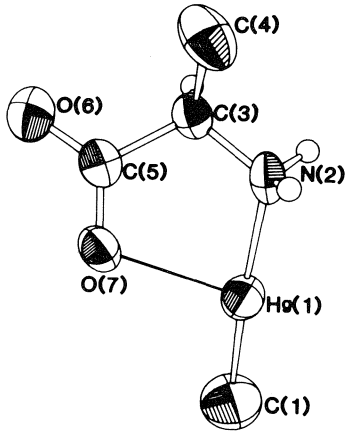

FIG. 1. Drawing of the (CH_3Hg)(DL-Ala) molecule, with the numbering scheme used. Thermal ellipsoids correspond to 50% probability. The methyl hydrogens were not found, the others are shown as small spheres of arbitrary size. The single line corresponds to the intramolecular Hg...O contact.

Results and discussion

Description of the structure

The [(CH_3Hg)Ala] complex is represented in Fig. 1 with the atom symbols used. Interatomic distances and bond angles are listed in Table 2.

The CH_3Hg^+ ion has replaced one of the ammonium protons of alanine, as anticipated from the higher affinity of mercury for amino than carboxylate groups. The Hg atom shows a

[4]The supplementary material includes lists of refined temperature factors, coordinates of hydrogen atoms, atom-to-plane distances and structure factor amplitudes. Complete set of material may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

linear coordination (C(1)—Hg(1)—N(2) = 175.6(9)°), and the Hg—N(2) distance (2.14(2) Å) is similar to those reported for this type of complex (1, 8–10). Besides the strong Hg—CH_3 and Hg—NH_2 bonds, there is an intramolecular contact between mercury and the carboxylate oxygen O(7) at 2.63(1) Å (Table 3). Contacts of this type have been found for other compounds, namely in the 1:1 tyrosine (8) and the 1:1 methionine (10) complexes. In the 1:1 and 2:1 complexes with glycylglycine (1), the amino-bonded CH_3Hg^+ group also establishes a contact with the amide oxygen, but the distances (2.71(1) and 2.82(2) Å, respectively) are greater.

Light-atom positions cannot be determined precisely in the presence of the heavy atom. Considering the high esd's, complexation seems to leave the bond lengths and angles of DL-alanine unchanged (11), although the conformation is modified. In free alanine, the chain is not planar, the N—C—C—O torsion angle being 17°. In the complex, this same angle is 2(2)°, and the $NCCO_2$ chain is nearly planar. However, the CH_3Hg^+ group does not lie in this plane. The Hg—N(2)—C(3)—C(5) torsion angle of 33(2)° probably results from the intramolecular Hg—carboxylate contact mentioned above.

Each molecule is held in the lattice by six neighbors with which it forms hydrogen bonds and Hg...O contacts (Fig. 2 and Table 3). Both amino hydrogens participate in moderately strong N—H...O(7) hydrogen bonds of 2.88(2) Å with two different complex molecules (12). On the other hand, each Hg atom forms intermolecular contacts of 2.92(1) and 3.05(1) Å, respectively, with free carboxylate oxygens O(6) in two different molecules. These Hg...O(6) contacts are found at 90 ± 22° from the H_3C—Hg and Hg—N bonds, as usual.

The hydrogen bonds and Hg...O contacts generate layers parallel to the *bc* plane, with the complex molecules oriented roughly perpendicular to the layer (Fig. 2). As a result, the layer surface consists mainly of methyl groups from alanine and the CH_3Hg^+ groups. Cohesion between the layers is mainly due to normal van der Waals contacts between these methyl groups.

Vibrational spectroscopy

The vibrational spectra of glycine and alanine are well documented (13–15). Most of the assignments used in this work for the free ligands are those proposed by Machida and co-workers (13, 14).

The present X-ray work shows that one of the NH_3^+ protons of alanine is displaced by a CH_3Hg^+ ion in the (CH_3Hg)(DL-

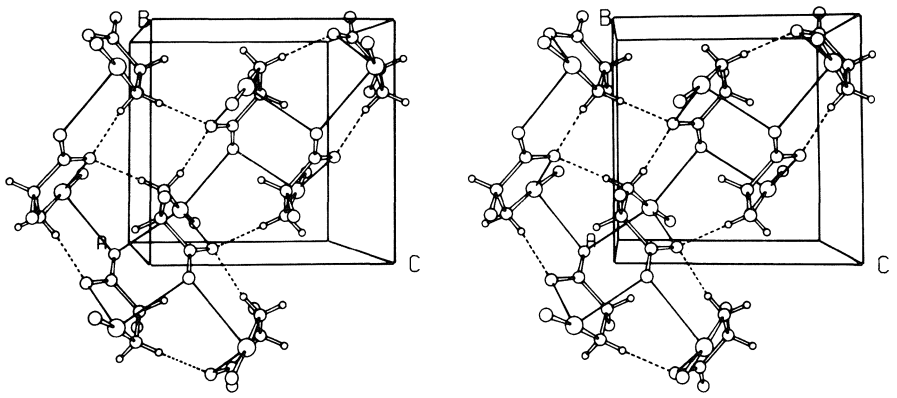

FIG. 2. Stereoview of the unit cell of (CH_3Hg)(DL-Ala). The atoms are shown as spheres of arbitrary sizes (large for Hg), and they can be identified by comparison with Fig. 1. Single lines correspond to Hg...O contacts and dashed lines to hydrogen bonds.

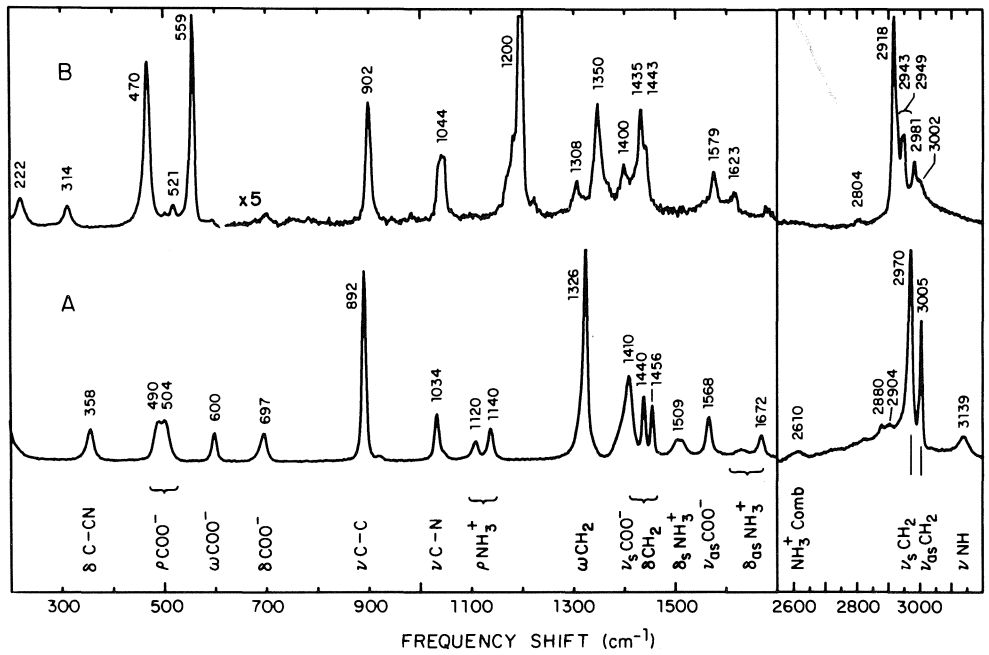

FIG. 3. Raman spectra of glycine (*A*) and its (CH_3Hg)Gly complex (*B*) in the solid state.

Ala) complex, with only secondary interaction between Hg and a carboxyl oxygen. The very close similarity of the Raman and infrared spectra for this compound and (CH_3Hg)(L-Ala) indicates that both have identical structures. The same type of binding probably also occurs in (CH_3Hg)Gly.

Although the vibrational spectra of many glycine and alanine chelates have been analyzed (16–21), the only vibrational study on a complex showing unidentate coordination via $—NH_2$ is that of Kieft and Nakamoto for $Pt(NH_3)_2(Gly)_2$ (22). Our discussion on metal—ligand vibrations is based on earlier work on mercury complexes with amino acids and purines (1, 10, 17, 23).

(CH_3Hg)Gly, solid state

The Raman spectra of glycine and its methylmercury complex, both in the solid state, are compared in Fig. 3. The infrared results are given in Fig. 8 (supplementary material) and Table 4.

The CH_3Hg^+ group in the complex is detected from various characteristic features (1, 10, 24). The $\nu_s(CH_3)$ and $\delta_s(CH_3)$ modes produce strong bands at ~2920 and ~1200 cm^{-1} in the Raman. The broad infrared absorption at ~800 cm^{-1} for the $\rho(CH_3)$ mode is also readily detected. The Hg—C stretching vibration at ~560 cm^{-1}, weak in the infrared, gives rise to the strongest line in the Raman spectrum. This same region contains the Hg—ligand stretching vibration whose high intensity in the Raman is due to the polarizability of mercury. This band and, to a lesser extent, the $\delta(CH_3)$ vibration are sensitive to the type of bonding. They will be used hereafter to identify the coordination site in the amino acid.

The glycine bands arising from the $—NH_3^+$ group are affected by complexation, since proton substitution leads to a $—NH_2(HgCH_3)^+$ unit. The broad ν(N—H) band of glycine at 3139 cm^{-1} disappears in the Raman spectrum for the complex, whereas the infrared counterpart at 3180 cm^{-1} is shifted upward. Complexation also removes from the Raman spectrum of glycine a broad combination band at 2610 cm^{-1} involving the NH_3^+ group (25). The $\delta(NH_3^+)$ bands (1672, 1620, and 1509 cm^{-1}) are replaced by a single $\delta(NH_2)$ mode, which is reported to occur in the 1600–1610 cm^{-1} range for various metal chelates (18). It is probably observed here as a weak band

at 1623 cm^{-1} in the Raman and a shoulder at ~1606 cm^{-1} in the infrared, although band assignments to the $\delta(NH_2)$ and $\nu_a(CO_2^-)$ modes in this region are not unambiguous (20, 26). The τ, ω, and ρ modes of the coordinated NH_2 groups are weak and metal-sensitive (18, 22, 26). The assignments proposed in Table 4 lie in the ranges previously reported.

Deprotonation of the $—NH_3^+$ group also affects vibrations mainly located in the C—H bonds. The Raman spectrum of glycine shows two well-defined ν(C—H) bands at 3005 and 2970 cm^{-1}, which are both shifted by −20 cm^{-1} in $(CH_3Hg)Gly$. The $\omega(CH_2)$ band of glycine at 1326 cm^{-1} occurs at 1350 cm^{-1} in the complex. Similar shifts have been proposed by Krishnan and Plane (16) as diagnostics for the complexation of zinc to the deprotonated form of glycine.

The $(CH_3Hg)Gly$ bands at 902 (ν(C—C)) and 1044 cm^{-1} (ν(C—N)) are shifted by +10 cm^{-1} with respect to free glycine. These bands are sensitive to perturbations in charge distribution caused by changes of ionization or substitution on terminal groups. In the case of glycine, for instance, they occur at 899/968 cm^{-1} for Gly^-, 896/1027 cm^{-1} for HGly, 869/1042 cm^{-1} for H_2Gly^+ (27), and 912/1048 cm^{-1} for glycylglycine (28). As to the vibrations originating from the

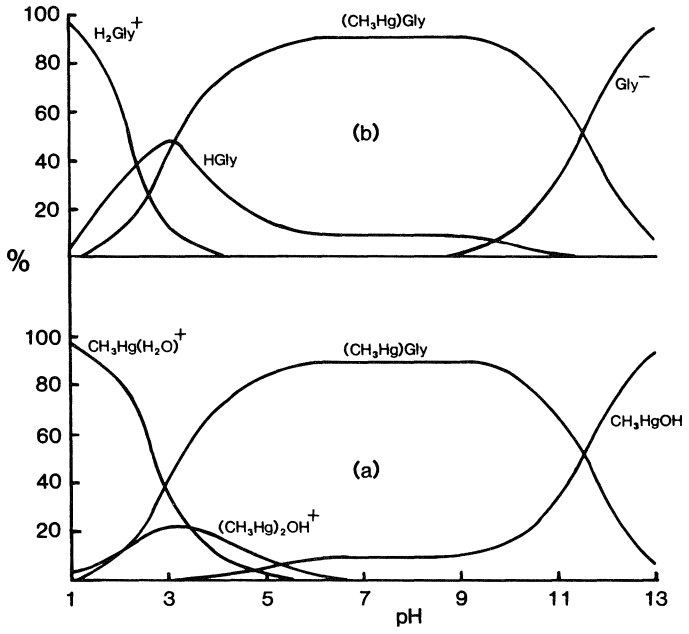

FIG. 4. Distribution curves of CH_3Hg^+ (*a*) and glycine (*b*) as a function of pH for a mixture of CH_3Hg^+ (0.2 *M*) and glycine (0.2 *M*). Calculated from literature values of equilibrium constants (see text).

$—CO_2^-$ group, they are not greatly modified in the complex, in agreement with the absence of strong coordinative Hg—O interactions.

Although the spectral modifications discussed so far indicate that the CH_3Hg^+ group is present and the $—NH_3^+$ group of glycine is deprotonated, they provide only indirect evidence that mercury is actually bound to nitrogen. In this respect, the 400–600 cm^{-1} region of the Raman spectrum is more informative. The two strongest Raman signals are observed at 559 cm^{-1} (ν(Hg—C) band mentioned above) and at 470 cm^{-1}. The latter is assigned to the ν(Hg—N) vibration. It occurs at the same position in the Raman spectra of CH_3Hg^+ complexes of glycylglycine (1) and at 464 cm^{-1} for the Hg^{2-}–glycine system (17). The relatively strong Raman line at 222 cm^{-1} is probably due to a C—Hg—N deformation motion.

$(CH_3Hg)Gly$, aqueous solutions

The equilibrium constant for the formation of $(CH_3Hg)Gly$ has been determined by Rabenstein and co-workers (2):

$$CH_3Hg^+ + Gly^- \rightleftharpoons (CH_3Hg)Gly \qquad \log K = 7.88\ (2)$$

In addition, glycine participates in two acid–base equilibria,

$$H_2Gly^+ \rightleftharpoons HGly + H^+ \qquad \log k_a = -2.35\ (29)$$

$$HGly \rightleftharpoons Gly^- + H^+ \qquad \log k_a = -9.78\ (29)$$

where the CH_3Hg^+ cation can be involved in two acid–base and condensation reactions:

$$CH_3Hg^+ \overset{H_2O}{\rightleftharpoons} CH_3HgOH + H^+ \qquad \log K = -4.63\ (2)$$

$$2CH_3Hg^+ \overset{H_2O}{\rightleftharpoons} (CH_3Hg)_2OH^+ + H^+ \qquad \log K = -2.37\ (2)$$

These constants were used to calculate the distribution curves represented in Fig. 4. The trimer $(CH_3Hg)_3O^+$ known to exist at high concentrations (30) can be neglected at the concentration level used here.

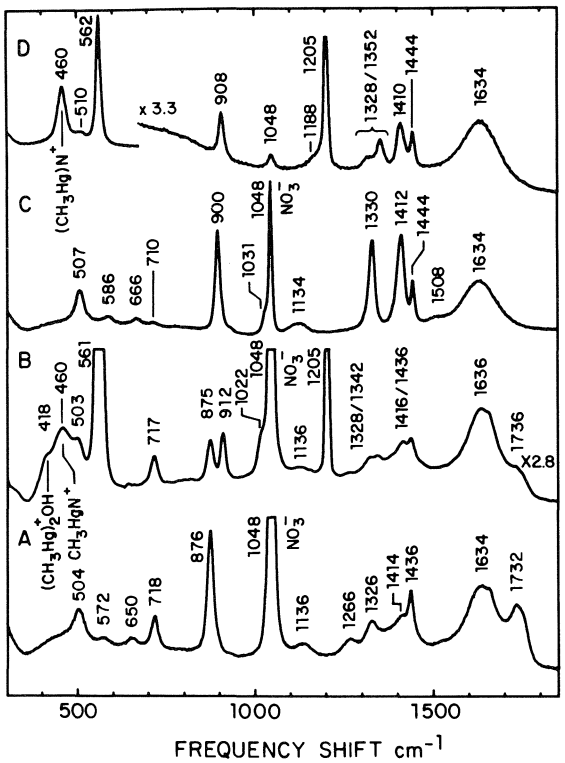

FIG. 5. Raman spectra of glycine and the (CH_3Hg)Gly complex in aqueous solutions: glycine 8% (w/w), pH 1 (*A*); (CH_3Hg)Gly 4% (w/w), pH 2 (*B*); glycine 8% (w/w), pH 7.8 (*C*); (CH_3Hg)Gly 4% (w/w), dissolved in H_2O (*D*).

These curves indicate that dissociation of (CH_3Hg)Gly should be <5% between pH 5 and 10.5. Accordingly, no free glycine can be detected from the Raman spectra of a water solution of solid (CH_3Hg)Gly or of a 1:1 mixture of CH_3HgOH and glycine at pH 7 (Fig. 5, spectra *C* and *D*). For instance, only one strong band is observed for the ν(C—C) mode at 908 cm^{-1}, whereas free HGly, which possesses a strong and sharp band at 900 cm^{-1}, should show a shoulder or even a resolved peak if it were present in appreciable amounts. The presence of large quantities of free methylmercury can also be discarded. At pH 7, free methylmercury would consist of ~50% of CH_3HgOH, which should produce a strong band at 510 cm^{-1} due to ν(Hg—OH) and a shoulder on the ν(Hg—C) band at 560 cm^{-1}.

Furthermore, the spectra at pH 7 and 10 are found to be identical, and in the latter case, the 510 cm^{-1} band should be very strong, since free methylmercury should exist completely as CH_3HgOH molecules. The strong bands assigned to the CH_3Hg^+ group for the solid complex occur at almost the same positions for the solution (ν(Hg—N) = 460 cm^{-1}, ν(Hg—C) = 562 cm^{-1}, $\delta(CH_3)$ = 1205 cm^{-1}), in agreement with the same binding being present in solution and in the solid state. It is noteworthy that the $\nu_s(CO_2^-)$ and $\rho(CO_2^-)$ bands (1410 and 510 cm^{-1}, respectively) occur at the same position as for aqueous HGly, which is consistent with the presence of a free carboxylate group in both cases. This holds true even in the presence of a two-fold excess of CH_3Hg^+, thereby indicating that a second CH_3Hg^+ ion does not coordinate to the free carboxylate end of the NH_2-bonded (CH_3Hg)Gly complex.

Acidic solutions (1:1 and 2:1 CH_3Hg^+:Gly ratios) were also examined for possible binding to the carboxylate end of glycine.

The spectra of glycine and of a 1:1 CH_3Hg^+:glycine mixture are shown in Fig. 5 (spectra *A* and *B*). The Raman lines for H_2Gly^+ have been listed earlier (31). The ν(C—C) band for the H_2Gly^+ form occurs at 876 cm^{-1}. A band is also observed at this position for the 1:1 mixture, together with the sharp (CH_3Hg)Gly peak at 912 cm^{-1} discussed above. Therefore, H_2Gly^+ and (CH_3Hg)Gly appear to be the only forms of glycine present in appreciable amounts under these conditions. According to the distribution curves (Fig. 4), complexation to an extent of ~20% should occur at pH 2. The free methylmercury should exist as monomeric CH_3Hg^+ and dimeric $(CH_3Hg)_2OH^+$ in roughly equal amounts. These two species and (CH_3Hg)Gly have their ν(Hg—C) and $\delta(CH_3(Hg))$ bands almost at the same positions, but they show differences in the 450–500 cm^{-1} region. The observed spectrum (Fig. 5, spectrum *B*) is consistent with the presence of some (CH_3Hg)Gly, characterized by a sharp ν(Hg—N) band at 460 cm^{-1}, whereas the uncomplexed methylmercury as monomer and dimer produces much weaker and broader bands at 455 and 418 cm^{-1}, respectively.

There is no evidence for species with the CH_3Hg^+ ion bonded to glycine via the carboxylate group. This type of coordination was found to produce ν(Hg—O) and ν(Hg—C) bands at 536 and 572 cm^{-1}, respectively, for $[(CH_3Hg)_2Glygly]ClO_4$ (1).

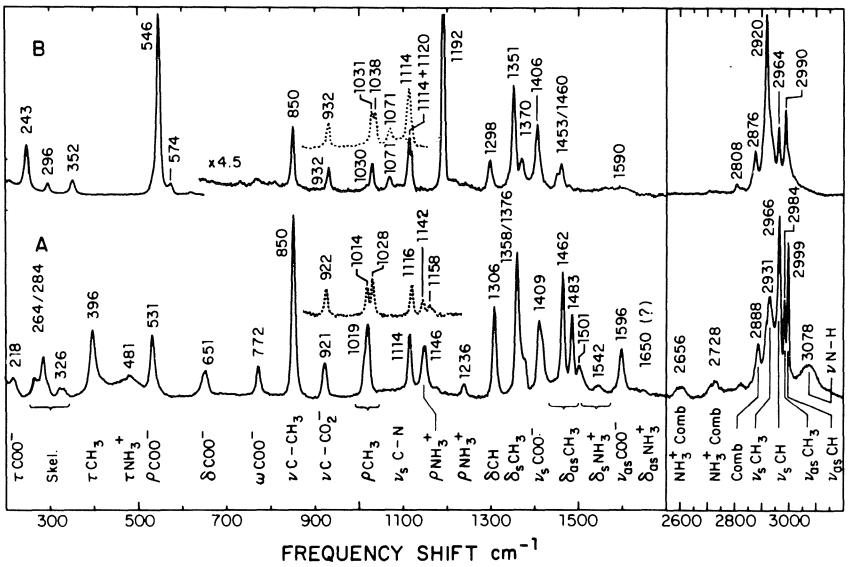

FIG. 6. Raman spectra of L-alanine (*A*) and its CH_3Hg^+ complex (*B*) in the solid state. The dotted lines correspond to the compounds with DL-alanine.

The very weak band at 503 cm^{-1} in the spectrum of the 1:1 mixture (Fig. 5, curve *B*) originates from $\rho(CO_2^-)$ motion of H_2Gly^+ (31), and the absence of nearby bands for ν(Hg—O) and of splitting in the ν(Hg—C) band indicates that no O-bonded complexes are appreciably formed.

(CH_3Hg)(L-Ala), solid state

The Raman spectra of solid L-alanine and (CH_3Hg)(L-Ala) are shown in Fig. 6 (spectra A and B). The infrared results are provided in Fig. 9 (supplementary material) and Table 5.

The spectra of (CH_3Hg)(L-Ala) include the characteristic bands of the CH_3Hg^+ unit, namely at 2920 (ν, ir, R), 1195 (δ, ir, R), and 809 cm^{-1} (ρ, ir) (1, 24). The strong Raman line observed at 546 cm^{-1} could be due to the ν(Hg—C) vibration, but assignment is not so straightforward as for the glycine complex (*vide infra*).

Evidence for $—NH_3^+$ deprotonation arises, as in the case of glycine, from the disappearance of the bands originating from this group, to be replaced by those of the coordinated $—NH_2$ group. The $\delta(NH_2)$ and $\nu_a(CO_2)$ vibrations are close together at ~1575 cm^{-1} and they cannot be individually assigned with certainty (19–21). Segnini and co-workers (21) have reported that the bands at 1230 and 1120 cm^{-1}, removed by NH_2 deuteration for a number of alanine complexes, originate from the twisting and wagging modes, respectively. By comparison, the broad absorption at ~1226 cm^{-1} in infrared is assigned to the NH_2 twisting mode, whereas the wagging mode is believed to produce the sharp infrared peak at 1032 cm^{-1}. According to the same authors, the NH_2 rocking mode occurs at ~780 cm^{-1} in several complexes. It is probably located at ~809 cm^{-1} here.

The carboxylate ν_a, ν_s, ω, and ρ modes undergo only minimal shifts by complexation, whereas the $\delta(CO_2^-)$ band at 650 cm^{-1} is displaced by −32 cm^{-1} in (CH_3Hg)(L-Ala). This reflects changes in the environment of the $—CO_2^-$ group, which remains uncoordinated in the complex. Several other shifts of 5–15 cm^{-1} are found for bands located in the C—C(CH_3)—N portion of the ligand, namely for the δ(C—H), ν(C—CO_2^-) and $\rho(CH_3)$ modes (Table 5).

On the basis of the results obtained with (CH_3Hg)Gly, we

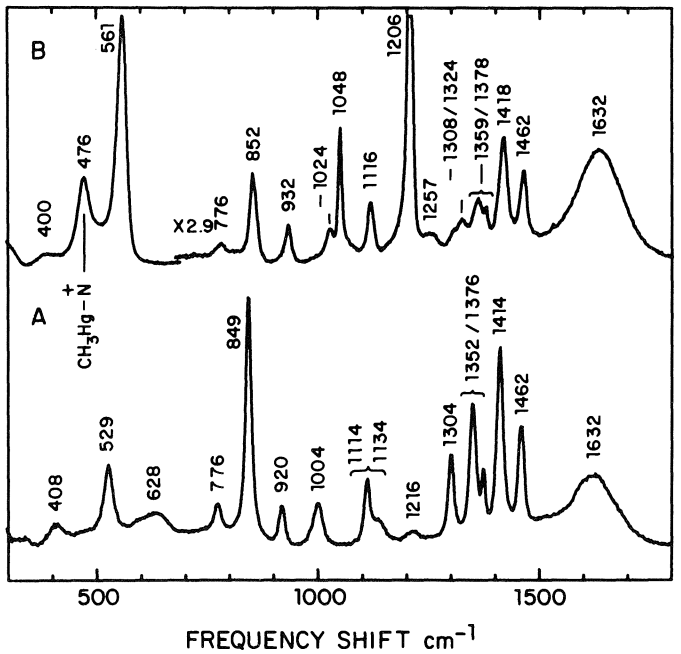

FIG. 7. Raman spectra of aqueous solutions of L-alanine, 16% (w/w), pH 6 (*A*) and (CH_3Hg)(L-Ala), 8% (w/w), pH 6 (*B*).

anticipated that the ν(Hg—N) and ν(Hg—C) vibrations would produce strong Raman lines at ~460 and ~560 cm^{-1}, respectively. However, the solid showed only one strong line at 546 cm^{-1} and a very weak band at 574 cm^{-1}. If we dissolve this neutral (CH_3Hg)Ala complex in water, we effectively obtain the expected pair of strong Raman lines (*vide infra*). When the solvent is then removed, the initial solid spectrum (Fig. 6) is restored.

We were first tempted to conclude that the CH_3Hg^+ group could be both amino- and carboxylate-bonded in this compound, as we had already observed for $[(CH_3Hg)_2Glygly]ClO_4$ a vibration at 536 cm^{-1} which was assigned to ν(Hg—O) motion (1). However, since it is known from the X-ray work

that the metal is bonded only to the nitrogen end, we assume that no discrimination can be made in this case between ν(Hg—N) and ν(Hg—C) for the solid, probably because of specific intra- and intermolecular interactions. A similar behavior has been noted by Wong and co-workers (10) for (DL-methioninato)methylmercury(II), in which the contacts with Hg are comparable with those found here for the alanine complex. However, the lack of crystal structures on a large enough sample of related systems precludes further discussion for the moment.

(CH_3Hg)(L-Ala), aqueous solutions

The pk_a values of alanine (2.35, 9.87) (29) are close to those of glycine, and both amino acids should form CH_3Hg^+ complexes of comparable stability. Therefore, the distribution curves of Fig. 4 should also apply to the CH_3Hg^+–alanine system.

A series of Raman spectra at various pH is consistent with the same reaction pattern found for glycine. The spectra of a solution of (CH_3Hg)(L-Ala) and of a 1:1 mixture of CH_3HgOH and alanine at pH 7 (which are identical) (Fig. 7, spectrum *B*) provide no evidence for appreciable dissociation of the complex. The presence of free ligand would be detectable in the ν(C—CO_2) region, where the band appears at 932 cm^{-1} for the complex and at 920 cm^{-1} for HAla. The complex and the free ligand also differ in two other regions: the $\rho(CO_2)$ mode produces a medium band at 529 cm^{-1} for HAla, but no detectable band for the complex, whereas the δ(C—H) band at 1304 cm^{-1} is strong for HAla, but much weaker for the complex. No free ligand could be detected from these three regions. The presence of significant amount of free methylmercury is also ruled out by inspection of the 450–500 cm^{-1} region, as in the case of glycine. On the other hand, the presence of (CH_3Hg)Ala is deduced from the clear ν(Hg—N) band observed at 476 cm^{-1}.

In acidic media (pH < 3.5), the complex is progressively destroyed as the pH is decreased, while the cationic H_2Ala^+ species becomes increasingly important (31). In all these cases, the spectra (not shown) could be satisfactorily explained by assuming superposed contributions from HAla and H_2Ala^+ (whose proportions depend on pH), (CH_3Hg)Ala and free methylmercury (as monomeric and dimeric species). Even with excess CH_3Hg^+ and at any pH, it has not been possible to detect binding to the carboxylate group in this system.

Conclusion

The crystal structure of (CH_3Hg)(DL-Ala) shows that the soft Hg atom binds to the NH_2 end of this amino acid, in preference to the carboxylate oxygens, which are much harder sites. Raman spectroscopy provides evidence that the metal is also bonded to the NH_2 lone pair in the solid (CH_3Hg)Gly complex. Raman studies in aqueous solutions show that the NH_2-bonded structure is retained in solution in the pH interval 3.5–10. Rabenstein and co-workers (2) also interpreted their ^1H nmr data for the CH_3Hg–glycine system in terms of a similar amino-bonded complex. However, the presence of a minor carboxylate-bonded species and tautomeric equilibrium between these two isomeric forms could not be dismissed, since fast exchange in this system would lead to signal averaging in nmr. Our results in Raman spectroscopy, which has a much faster time scale, indicate that such an equilibrium does not exist to any appreciable extent, and that (CH_3Hg)Gly and (CH_3Hg)Ala are the only species present under these conditions.

Received January 27, 1986

DANNY P. C. MCGEE and JOHN C. MARTIN. Can. J. Chem. **64**, 1885 (1986).

A high yielding, one-pot method for the preparation of 2′,3′-secoguanosines **5** and **6** by treatment of 5′-deoxyguanosine (**4**) and guanosine (**2**), respectively, with sodium periodate and then sodium borohydride is described. The final products **5** and **6** were purified from contaminating salts by passage of the reaction mixture over a column of activated charcoal. An additional acyclic derivative **14** was prepared in racemic form by an approach involving a novel condensation reaction. Alkylation of N^2,9-diacetylguanine (**8**) with 2,3-dichlorotetrahydrofuran (**7**) resulted in selective *N*-9 alkylation to give adduct **9***a*. Compound **9***a* was deacylated with ammonium hydroxide to give **10**, which was monomethoxytritylated to **11**. Elimination of hydrogen chloride from **11** using potassium *tert*-butoxide afforded **12**, which was reacted with OsO_4–$NaIO_4$ followed by treatment with $NaBH_4$ to give **13**, which was then deprotected with acid to **14**. Compounds **5**, **6**, **14**, and **16** were tested in vitro against herpes simplex virus types 1 and 2 and were found to be inactive.

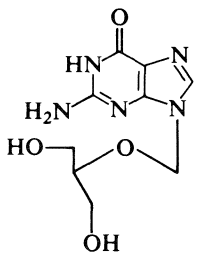
DANNY P. C. MCGEE and JOHN C. MARTIN. Can. J. Chem. **64**, 1885 (1986).

On décrit une méthode de préparation dans un récipient unique qui conduit aux séco-2′,3′ guanosines **5** et **6** avec d'excellents rendements. Cette méthode utilise respectivement la déoxy-5′ guanosine (**4**) et la guanosine (**2**) que l'on traite successivement par le périodate de sodium et le borohydrure de sodium. Le désalage sur une colonne de charbon actif conduit aux produits **5** et **6** à l'état pur. On a en outre préparé un dérivé acyclique racémique **14** en faisant appel à une nouvelle réaction de condensation. L'alkylation sélective de la N^2-diacétyl-9 guanine (**8**) avec le dichloro-2,3 tétrahydrofuranne (**7**) conduit au produit d'addition **9***a* alkylé sélectivement sur l'azote en position 9. La désacylation du composé **9***a* par l'hydroxyde d'ammonium conduit au composé **10** qui, par monométhoxytritylation, donne le composé **11**. Ce dernier, traité par le *tert*-butylate de potassium, libère du chlorure d'hydrogène et conduit au composé **12** dont la réaction avec le mélange OsO_4–$NaIO_4$, suivie d'un traitement par le $NaBH_4$, conduit au composé **13** que l'on déprotège avec de l'acide pour obtenir le composé **14**. On a effectué des essais in vitro avec les composés **5**, **6**, **14** et **16** sur les virus simplex de l'herpes de type 1 et 2. Ces composés sont inactifs.

[Traduit par la revue]

Investigators faced with the task of discovering effective antiviral agents have often turned to nucleosides and analogues thereof for solutions (1). One such compound recently reported by several groups (2), 9-[(1,3-dihydroxy-2-propoxy)methyl]guanine (**1**, DHPG), is visualized as an acyclic analogue of 2′-deoxyguanosine and is highly effective against herpes simplex virus types 1 (HSV-1) and 2 (HSV-2), as well as Epstein–Barr virus and human cytomegalovirus (3).

As a result of the demonstrated activity of DHPG (**1**), we elected to synthesize a number of related acyclic nucleoside analogues that retain a 2′-hydroxymethyl group and thus more closely resemble guanosine in structure. We selected as represented members of this class 2′,3′-secoguanosine (**6**), 5′-deoxy-2′,3′-secoguanosine (**5**), (*R*,*S*)-9-[1-(2-hydroxyethoxy)-2-hydroxyethyl]guanine (**14**), and 9-(β-(D,L)-*erythro*-furanosyl)guanine (**16**). It should be noted that a cursory disclosure of the antiherpes virus activity of compounds **6** and **14** has previously appeared (2*e*).



1

Results and discussion

As a general approach to the acyclic analogues **5**, **6**, and **14** we wished to make use of a one-pot reaction sequence using $NaIO_4$ and then $NaBH_4$ on suitably derivatized 2′,3′-dihydroxypentofuranosyl guanines (**2**, **4**, **15**). The action of $NaIO_4$ on unprotected nucleosides is well known; the resulting dialdehydes (4) exist as a complex mixture of hydrates, and are generally not isolated as such but converted to the respective acylic triols by the action of $NaBH_4$. The purification of the acyclic triols from the residual salts is difficult and has usually been limited to the use of ion-exchange chromatography (4) from which the acyclic nucleosides are often obtained as foams or lyophilized powders. Thus, difficulty in obtaining reasonable quantities of acyclic nucleosides via these procedures has generally limited their use to biochemical/enzymatic studies (5), leaving the chemistry (6) of such derivatives relatively untouched. Alternatively, the synthesis of a few acyclic derivatives in this system has been accomplished using 5′-protected nucleosides as starting material (6).

Recently, two improved approaches to secoguanosines have been published (7). Lerner has described a procedure in which the crude product reaction mixture, after treatment with $NaIO_4$ and then $NaBH_4$, is exhaustively acetylated and a triacetate derivative is isolated in 38% yield. Deacetylation gave **6** (7*a*). Alternatively, Bessodes and Antonakis (7*b*) have used polymer bound reagents so that reagent salts are simply removed by filtration. We have found, *inter alia*, that activated charcoal can be used to desalt the final reaction mixture, effectively removing the iodate and borate salts, to afford crystalline **6** directly in 67% yield. This was accomplished by neutralization of the crude reaction mixture to pH 7 and then passing the resulting solution

G = 9-guaninyl; (a) $P(Ph)_3$, I_2, imidazole, *N*-methyl-2-pyrrolidinone; (b) 10% Pd/C, H_2, 60°C, in H_2O/EtOH; (c) $NaIO_4$, 3 h, then $NaBH_4$, charcoal chromatography

SCHEME 1

over a column of the charcoal.[3] The column was first eluted with water to remove the salts. The desired product **6** was then eluted with 3% NH_4OH in 1:1 ethanol/water.

With this method in hand our approach to **5** (Scheme 1) proceeded in a straightforward manner. Iodination of unprotected guanosine using triphenylphosphine–iodine–imidazole (8) proceeded exceptionally well in *N*-methyl-2-pyrrolidinone as solvent to afford crystalline 5′-deoxy-5′-iodoguanosine (**3**) in 69% yield after simple dilution of the reaction mixture with dichloromethane and water. The high selectivity of this reaction is attributable both to the *in situ* protection of the 2′- and 3′-hydroxyls as a cyclic oxyphosphorane intermediate (9) and to the rate enhancement associated with the use of *N*-methyl-2-pyrrolidinone as reaction solvent. The iodide **3** was catalytically reduced with 10% Pd/C to give 5′-deoxyguanosine (**4**) (10) in 47% yield. The vicinal diol functionality of **4** was oxidized using sodium periodate and the resulting dialdehyde was reduced directly to **5** using sodium borohydride. The above reaction mixture was then desalted using activated charcoal to afford 5′-deoxy-2′,3′-secoguanosine (**5**) in 87% yield.

The initial steps in the synthesis of analogue **14** (Scheme 2) are conceptually similar to an approach taken by others for the synthesis of substituted tetrahydro-2-furanyl analogues of 5-fluorouracil (11) (Ftorafur) and guanine (12). The preparation of a similar analogue of adenine, (*R*,*S*)-9-[1-(2-hydroxyethoxy)-2-hydroxyethyl]adenine, has been described (13) via the reaction of 2-alkyl-1,3-dioxolane with trimethylsilyl iodide, and subsequent coupling of the resultant alkyl iodide with a purine base. A number of thio analogues related to **14** and **16** have also been reported (14).

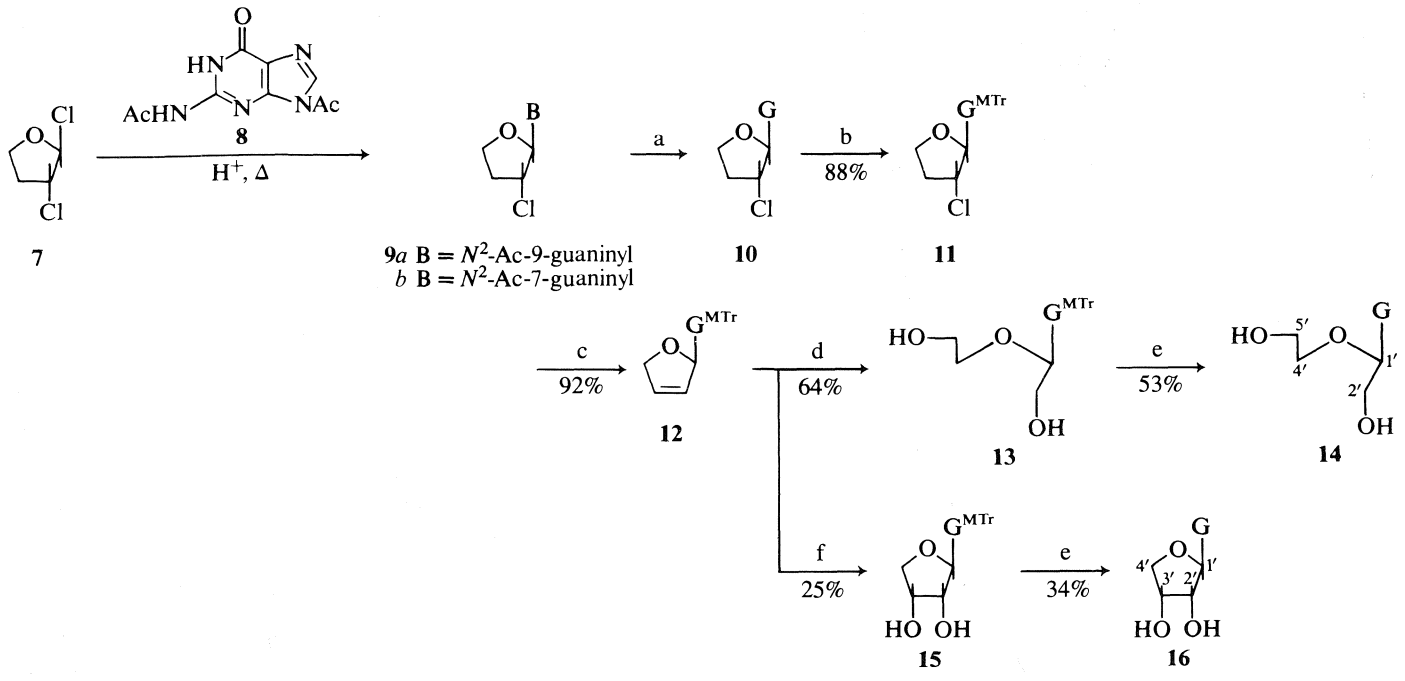
The outcome of the coupling of N^2,9-diacetylguanine (**8**) (15) with *trans*-2,3-dichlorotetrahydrofuran[4] (**7**) (16) in a fusion reaction was variable, resulting in the production of either a mixture of *N*-9 and *N*-7 alkylated guanines (**9***a*, *b*) in low yield or, in other cases, a near quantitative conversion to the *N*-9 isomer (**9***a*). The position of alkylation of the guanine nucleus for adducts **9***a*, *b* was determined on the basis of their characteristic uv spectra. The assigned 1′,2′-*trans* relative stereochemistry[5] (17) is consistent with the small coupling constants in the ^1H nmr ($J_{1',2'} = 1.7$ Hz) and is circumstantially corroborated by the subsequent transformation of derivative **11** to afford **12**. Due to the poor solubility of adduct **9** it was generally more convenient to treat the crude reaction mixture containing only **9***a* directly with methanolic ammonium hydroxide to obtain **10** in 59% yield from diacetylguanine. Reaction of **10** with monomethoxytrityl chloride in pyridine gave **11**, which was freely soluble in several organic solvents. Heating a toluene–pyridine solution of **11** with potassium *tert*-butoxide at 75°C for 1 h gave **12** in 92% yield. The elimination proved sensitive to both solvent and temperature where, for example, the reaction of **11** with potassium *tert*-butoxide in tetramethylene sulfone at 100°C quickly led to elimination of the purine to produce N^2-monomethoxytritylguanine. This alternative product is a useful form of protected guanine and is currently being studied in our laboratory as a building block for nucleoside synthesis.

The *cis* hydroxylation of **12** using potassium permanganate afforded **15** in 25% yield, which we assume had a 1′,2′-*trans* orientation due to steric hindrance (18) associated with a β face approach. Deprotection of **15** with aqueous acetic acid gave analogue **16** in 34% yield. The 1′,2′-*trans* orientation assigned to analogues **15** and **16** is consistent with the small coupling ($J_{1',2'} < 0.3$ Hz) observed for the 2′,3′-isopropylidene of **16**. The observed $\Delta\delta$ of 0.13 ppm for the methyls of the isopropylidene of **16** falls short of the generalizations proposed by Imbach and co-workers for ribonucleosides (19). Alternatively, analogue **14** can best be prepared directly from **12** by reaction with catalytic osmium tetroxide and sodium periodate to produce the dialdehyde intermediate, which was reduced with sodium borohydride to give **13** in 64% yield after silica gel chromatography. Deprotection of **13** with acid afforded analogue **14** in 53% yield.

[3]Neutralization to pH 7 prior to charcoal chromatography is not deemed essential. For example, reaction of adenosine as described above, with omission of the neutralization step, afforded 2′,3′-secoadenosine, which crystallized from ethanol, 2.65 g (53%); mp 139–140°C.

[4]The 2,3-dichlorotetrahydrofuran produced by the action of chlorine gas on tetrahydrofuran at 0–10°C was a single isomer; ^1H nmr δ: 6.23 (s, 1H, H-2), 4.64 (ddd, J = 0, 1, 5.6 Hz, 1H, H-3), 4.35 (dd, J = 5.4, 9.1 Hz, 2-H, H-5), 2.83, 2.25 (m, 2H, H-4).

[5]For convenience, we adopted a "ribose-like" numbering of the tetrahydrofuranyl moiety when said is coupled to a purine base, i.e., structure **16**.



(a) NH_4OH, MeOH; (b) MTr-Cl, TEA, pyridine; (c) *t*-BuOK, pyridine, toluene, 80°C, 1 h; (d) OsO_4, $NaIO_4$, MeOH, then $NaBH_4$; (e) 80% aqueous HOAc, 50°C, 16 h; (f) $KMnO_4$, H_2O, acetone

SCHEME 2

Preliminary in vitro testing of compounds **5**, **6**, **14**, and **16** showed them to be inactive against herpes simplex virus types 1 and 2.

Experimental

Nuclear magnetic resonance spectra were recorded on samples dissolved in deuteriodimethyl sulfoxide unless otherwise stated and chemical shifts are reported in parts per million downfield from internal tetramethylsilane. The compounds described are viewed as nucleoside analogues and for convenience the peak assignments are numbered according to a ribose-like representation. Spectroscopic data and elemental analyses were obtained by Syntex Analytical Research. All chromatographic purifications were carried out on Merck Silica Gel 60. Charcoal used was commercially available from Aldrich (nucleotide desalting grade). Alternatively, Sigma charcoal C-3014 could be used with a resultant small decrease in product recovery. Melting points were determined on a hot stage microscope and are corrected.

*5′-Deoxy-5′-iodoguanosine (**3**)*

Iodine (40.2 g, 158 mmol) was added over 5 min to a magnetically stirred suspension of guanosine hydrate (15.0 g, 50 mmol), triphenylphosphine (43.2 g, 165 mmol), and imidazole (22.5 g, 331 mmol) in *N*-methyl-2-pyrrolidinone (200 mL) at room temperature. During the addition complete dissolution occurred and the solution warmed to 60°C. The solution cooled back to room temperature and after 3 h was diluted with dichloromethane (2 L) and water (0.6 L). A white crystalline solid separated from solution and was collected by filtration to give 13.53 g (69%) of **3**: mp 190–200°C (dec.) (lit. (8*b*) mp 192–216°C (dec.); $[\alpha]_D$ −26.9° (*c* 1.1, Me_2SO); uv λ_{max} (0.1 *N* HCl): sh 278 nm (ε 7 320), 258 (10 800); (0.1 *N* NaOH): 266 (11 800), 260 (11 500); ^1H nmr δ: 10.67 (s, br, 1H, NH), 7.93 (s, 1H, H-8), 6.50 (s, br, 2H, NH_2), 5.72 (d, J = 6 Hz, 1H, H-1′), 5.56 (s, br, 1H, OH), 5.38 (s, br, 1H, OH), 4.63 (m, 1H, H-2′), 4.08 (s, br, 1H, H-3′), 3.95 (m, 1H, H-4′), 3.57 and 3.42 (ABX, J_{AB} = 10 Hz, J_{AX} = 6 Hz, J_{BX} = 7 Hz, 2H, H-5′); ^{13}C nmr (75.453 MHz) δ: 156.63 (C-6), 153.59 (C-2), 151.32 (C-4), 135.74 (C-8), 116.70 (C-5), 86.57 (C-1′), 83.62 (C-4′), 73.02 (C-2′), 72.65 (C-3′), 7.91 (C-5′). *Anal.* calcd. for $C_{10}H_{12}N_5O_4I$ (393.14): C 30.55, H 3.08, N 17.81; found: C 30.38, H 2.97, N 17.62.

*5′-Deoxyguanosine (**4**)*

A magnetically stirred suspension of **3** (12.83 g, 32.6 mmol) and 10% Pd/C (10 g) in water (300 mL) plus ethanol (300 mL) was heated at 60°C under 1 atm (1 atm = 101.3 kPa) of hydrogen gas for 8 h, filtered through Celite, and then evaporated to a volume of 400 mL. The solution was applied to a charcoal column (100 g) and eluted with water (3.5 L). The product was then eluted with 2% NH_4OH in 1:1 water/ethanol. Selected fractions were evaporated to dryness and the solid residue crystallized from water to give 4.14 g (47%) of **4**: mp 222–223°C (lit. (9) mp 226–228°C uncorrected); $[\alpha]_D$ −42.5 (*c* 1.4, Me_2SO); uv λ_{max} (0.1 *N* HCl): sh 278 nm (ε 8 200), 257 (12 000); (0.1 *N* NaOH): 267 (10 200), 257 (10 000); ^1H nmr δ: 10.73 (s, br, 1H, NH), 8.02 (s, 1H, H-8), 6.53 (s, br, 2H, NH_2), 5.67 (d, J = 5 Hz, 1H, H-1′), 4.46 (dd, J = 5 Hz, 1H, H-2′), 3.90 (m, 2H, H-3′, H-4′), 1.29 (d, J = 6 Hz, 3H, H-5′). *Anal.* calcd. for $C_{10}H_{13}N_5O_4$ (267.25): C 44.94, H 4.90, N 26.21; found: C 44.66, H 4.94, N 26.11.

*5′-Deoxy-2′,3′-secoguanosine (**5**)*

$NaIO_4$ (3.12 g, 14.6 mmol) was added to a mechanically stirred suspension of **4** (3.0 g, 11.2 mmol) in water (150 mL) at room temperature. After 3 h, $NaBH_4$ (0.70 g, 18.5 mmol) was added. After an additional 1.5 h, the pH was reduced from 9.5 to 7.0 with concentrated HCl. The solution was applied to a carbon column (30 g), and the column was eluted with water (2.5 L). The product was eluted with 3% NH_4OH in 1:1 water/ethanol. Selected fractions were concentrated to a yellow solid, which was crystallized from water/ethanol to give 2.63 g (87%) of **5**: mp >300°C; $[\alpha]_D$ 31.3 (*c* 1, Me_2SO); uv λ_{max} (0.1 *N* HCl): sh 278 nm (ε 8 050), 256 (11 900); (0.1 *N* NaOH), 266 (10 700), 257 (10 500); ^1H nmr δ: 10.6 (s, br, 1H, NH), 7.79 (s, 1H, H-8), 6.46 (s, br, 2H, NH_2), 5.63 (t, 1H, H-1′), 5.14 (t, br, 1H, OH), 4.74 (t, br, 1H, OH), 3.83, 3.79 (ABX, after D_2O, J = 6, 11 Hz, 2H, H-2′), 3.55 (tq, 1H, H-4′), 3.39 (d, J = 5.1 Hz, 2H, H-3′), 0.82 (d, J = 6.8 Hz, 3H, CH_3); ^{13}C nmr (22.62 MHz) δ: 156.89 (C-6), 153.67 (C-2), 151.49 (C-4), 135.66 (C-8), 116.48 (C-5), 83.51 (C-1′), 75.65 (C-4′), 64.62 (C-3′), 62.22 (C-2′), 17.36 (C-5′). *Anal.* calcd. for $C_{10}H_{15}N_5O_4 \cdot 0.33\,H_2O$ (275.20): C 43.63, H 5.74, N 25.44; found: C 43.74, H 5.74, N 25.48.

*2′,3′-Secoguanosine (**6**)*

$NaIO_4$ (5.56 g, 26 mmol) was added to a mechanically stirred

suspension of guanosine hydrate (6.03 g, 20 mmol) in water (200 mL) at room temperature. After 2 h, $NaBH_4$ (2.0 g, 53 mmol) was added. After an additional 1 h, the pH was reduced from 8.5 to 7.0 with concentrated HCl. The solution was applied to a carbon column (50 g), and the column was eluted with water (2 L). The product was then eluted with 3% concentrated NH_4OH in 1:1 water/ethanol. Selected fractions were concentrated to a yellow solid, which was crystallized from water/ethanol to give 3.82 g (67%) of **6**: mp 263–265°C (lit. (*7a*) mp 215–220°C); $[\alpha]_D$ 31.4° (*c* 1, 0.1 *N* NaOH); uv λ_{max} (0.1 *N* HCl): sh 277 nm (ε 8 200), 255 (12 200); (0.1 *N* NaOH): 266 (11 200), 257 (11 000); ^{1}H nmr δ: 7.70 (s, 1H, H-8), 6.94 (s, br, 2H, NH_2), 5.65 (t, 1H, J = 5.6 Hz, H-1′), 4.60 (br, 3H, OH), 3.80, 3.77 (ABX, 2H, J = 5, 11 Hz, H-2′), 3.56, 3.47 (ABX, 2H, J = 4, 12 Hz, H-5′), 3.42 (m, 1H, H-4′), 3.24, 3.22 (ABX, 2H, J = 6, 12 Hz, H-3′); ^{13}C nmr (22.62 MHz) δ: 163.16 (C-6), 158.02 (C-2), 151.88 (C-4), 134.26 (C-8), 116.90 (C-5), 83.06 (C-1′), 79.61 (C-4′), 62.35 (C-2′), 60.82, 60.56 (C-3′, C-5′). *Anal.* calcd. for $C_{10}H_{15}N_5O_5$ (285.26): C 42.11, H 5.30, N 24.55; found: C 42.20, H 5.35, N 24.45.

trans-N^2-*Acetyl-9-(3-chlorotetrahydofuran-2-yl)guanine (**9**a)*

A mixture of freshly distilled **7** (9.6 g, 68 mmol), N^2,9-diacetylguanine (**8**) (13 g, 55 mmol), bis(*p*-nitrophenyl)phosphate (120 mg, 0.35 mmol), and dimethylformamide (10 mL) was heated for 1 h at 90–95°C, then left for 16 h at room temperature. The reaction mixture was then suspended in 12% methanol/dichloromethane and filtered free of insolubles. The filtrate was evaporated to a dark oil, which was chromatographed (5% methanol/dichloromethane) to give, in order of elution, 2.2 g (10.9%) of the N-7 isomer, **9***b*, obtained as a powder: mp 200–202°C; uv λ_{max} (methanol): 264 nm (ε 13 600); ^{1}H nmr δ: 12.2 (s, br, 1H, NH), 11.64 (s, br, 1H, NH), 8.29 (s, 1H, H-8), 6.36 (d, J = 1.8 Hz, 1H, H-1′), 4.96 (m, 1H, H-2′), 4.55, 4.22 (ABXY, 2H, J_{AB} = J_{AX} = 8.2 Hz, J_{AY} = 3.2 Hz, J_{BX} = 7.6 Hz, J_{BY} = 8.2 Hz, H-4′), 2.51, 2.26 (m, 2H, H-3′), 2.17 (s, 3H, $COCH_3$); ^{13}C nmr (22.62 MHz) δ: 173.50 (*C*OCH_3), 157 (C-6), 152.57 (C-2), 147.30 (C-4), 141.68 (C-8), 110.50 (C-5), 92.68 (C-1′), 68.50 (C-4′), 32.41 (C-3′), 23.67 (CO*C*H_3). *Anal.* calcd. for $C_{11}H_{12}N_5O_3Cl$ (297.70): C 44.38, H 4.06, N 23.52, Cl 11.91; found: C 44.38, H 4.09, N 23.32, Cl 11.83, followed by 2.4 g (11%) of the N-9 isomer **9***a*, which was crystallized from dimethylformamide: mp 205–206°C; uv λ_{max} (methanol): sh 278 nm (ε 9 800), 259 (13 600); ^{1}H nmr δ: 12.07, 11.71 (s, br, 2H, NH), 8.09 (s, 1H, H-8), 6.12 (d, J = 1.7 Hz, 1H, H-1′), 5.01 (m, 1H, H-2′), 4.47, 4.19 (ABXY, 2H, J_{AB} = J_{AX} = 8.2 Hz, J_{AY} = 2.4 Hz, J_{BX} = 6.8 Hz, J_{BY} = 8.4 Hz, H-4′), 2.73, 2.29 (m, 2H, H-3′), 2.19 (s, 3H, $COCH_3$); ^{13}C nmr (22.62 MHz) δ: 173.66 (*C*OCH_3), 154.81 (C-6), 147.95, 147.85 (C-2, C-4), 137.19 (C-8), 120.51 (C-5), 90.77 (C-1′), 68.30 (C-4′), 60.76 (C-2′), 33.41 (C-3′), 23.73 (CO*C*H_3). *Anal.* calcd. for $C_{11}H_{12}N_5O_3Cl$ (297.70): C 44.38, H 4.06, N 23.52, Cl 11.91; found: C 44.36, H 4.26, N 23.72, Cl 11.99.

trans-*9-(3-Chlorotetrahydrofuran-2-yl)guanine (**10**)*

A mixture of freshly distilled **7** (13 g, 92.3 mmol), N^2,9-diacetylguanine (20 g, 85.1 mmol), bis(*p*-nitrophenyl)phosphate (30 mg), and sulfolane (25 mL) was heated for 16 h at 100°C, then cooled. The resultant mass was treated with concentrated NH_4OH (50 mL) in methanol (170 mL) for 21 h and the solid that had formed was isolated by filtration, washed twice with acetone, and dried to give 13 g (59.7%) of **10**. An analytical sample was obtained by crystallization from DMSO/ethanol: mp >300°C (dec.); uv λ_{max} (0.1 *N* HCl): sh 278 nm (ε 9 000), 255 (11 700); (0.1 *N* NaOH): 265 (11 300), 257 (11 100); ^{1}H nmr δ: 10.94 (s, br, 1H, NH), 8.06 (s, 1H, H-8), 6.25 (s, br, 2H, NH_2), 6.25 (d, J = 1.9 Hz, 1H, H-1′), 4.94 (m, 1H, H-2′), 4.40, 4.16 (ABXY, 2H, H-4′), 2.48, 2.23 (m, 2H, H-3′); ^{13}C nmr (22.62 MHz) δ: 156.79 (C-6), 153.87 (C-2), 150.58 (C-4), 134.88 (C-8), 116.94 (C-5), 90.31 (C-1′), 67.94 (C-4′), 60.56 (C-2′), 33.65 (C-3′). *Anal.* calcd. for $C_9H_{10}N_5O_2Cl$ (255.66): C 42.28, H 3.94, N 27.39, Cl 13.87; found: C 42.38, H 3.90, N 27.20, Cl 13.62.

trans-N^2-(p-*Anisyldiphenylmethyl)-9-(3-chlorotetrahydrofuran-2-yl)guanine (**11**)*

A mixture of **10** (14.7 g, 57.5 mmol), *p*-anisylchlorodiphenylmethane (19.5 g, 63.1 mmol), and triethylamine (20 mL) in pyridine (100 mL) was stirred for 16 h at room temperature, then evaporated to a slurry. The residue was redissolved in dichloromethane and partitioned twice with H_2O; the organic phase was dried over $MgSO_4$ and evaporated to a foam. Redissolution in ethyl acetate deposited 26.8 g (88.7%) of **11** as a white crystalline mass: mp 183–184°C; uv λ_{max} (methanol): sh 277 nm (ε 13 100), 261 (14 800); ^{1}H nmr δ: 10.67 (s, br, 1H, NH), 7.74 (s, br, 1H, NH), 7.69 (s, 1H, H-8), 7.25–7.15, 6.98 (m, 14H, aromatic), 5.53 (d, J = 3.1 Hz, 1H, H-1′), 4.42 (m, 1H, H-2′), 3.82 (m, 2H, H-4′), 3.73 (s, 3H, CH_3), 2.07, 1.89 (m, 2H, H-3′); ^{13}C nmr (75.453 MHz) δ: 157.80 (C-6), 156.26 (MTr), 150.85 (C-2), 148.39 (C-4), 144.78, 144.54, 136.49, 129.65, 128.32, 127.59, 126.61, 112.92 (MTr), 136.56 (C-8), 117.99 (C-5), 90.98 (C-1′), 69.84 (MTr), 67.36 (C-4′), 58.67 (C-2′), 54.95 (OCH_3), 33.83 (C-3′). *Anal.* calcd. for $C_{29}H_{26}N_5O_3Cl$ (528.01): C 65.97, H 4.96, N 13.26, Cl 6.71; found: C 65.94, H 5.08, N 13.41, Cl 6.79.

(R,S)-N^2-(p-*Anisyldiphenylmethyl)-9-(2,5-dihydrofuran-2-yl)guanine (**12**)*

To **11** (20.2 g, 38.4 mmol) and potassium *tert*-butoxide (19.5 g, 173.7 mmol) was added a mixture of pyridine (10 mL), 1,2-dimethoxyethane (10 mL), and toluene (180 mL). The resulting mixture was heated for 1 h at 75°C (monitored with $KMnO_4$ spray), then cooled and partitioned directly with H_2O (1×), and the aqueous phase was back washed with dichloromethane (800 mL). The combined organic phase was washed with H_2O (1×), dried ($MgSO_4$), and then evaporated to give 17.4 g (92%) of **12** as a yellow foam. An analytical sample was obtained as a white powder by precipitating a dichloromethane solution of **12** with ether: mp 203–205°C; uv λ_{max} (methanol): sh 276 nm (ε 14 000), 261 (15 700), 234 (16 300); ^{1}H nmr δ: 10.63 (s, br, 1H, NH), 7.63 (s, br, 1H, NH), 7.54 (s, 1H, H-8), 7.29–7.33 (m, 10H, aromatic), 7.30, 6.87 (AB, J = 8.9 Hz, 4H, aromatic), 6.23 (dd, $J_{1',2'}$ = 6.1 Hz, $J_{1',3'}$ = 1.5 Hz, 1H, H-1′), 6.12 (m, 1H, H-3′), 5.56 (m, 1H, H-2′), 4.53, 4.46 ($J_{4',4''}$ = 11 Hz, $J_{4',3'}$ = 5 Hz, $J_{4'',3'}$ = 1.9 Hz, $J_{4',2'}$ = 1.5 Hz, $J_{4'',2'}$ ≃ 0, 2H, H-4′), 3.71 (s, 3H, OCH_3); ^{13}C nmr (75.453 MHz) δ: 157.69 (C-6), 156.38 (MTr), 150.84 (C-2), 148.83 (C-4), 144.90, 144.77, 136.74, 129.80, 128.41, 128.35, 127.51, 126.44, 112.84 (MTr), 135.33 (C-8), 132.57 (C-2′), 123.53 (C-3′), 117.27 (C-5), 88.40 (C-1′), 74.88 (C-4′), 69.82 (MTr), 54.93 (OCH_3). *Anal.* calcd. for $C_{29}H_{25}N_5O_3$ (491.55): C 70.86, H 5.12, N 14.25; found: C 70.98, H 5.13, N 14.04.

N^2-(p-*Anisyldiphenylmethyl)-9-(β-(DL)*-erythro-*furanosyl)guanine (**15**)*

A solution of $KMnO_4$ (3.4 g, 21.5 mmol) in H_2O (mL) was added over 5 min with vigorous stirring to a solution of **12** (10.8 g, 21.9 mmol) in acetone (100 mL): H_2O (40 mL). The reaction mixture was then filtered through Celite and partially evaporated. The residue was redissolved in CH_2Cl_2 and washed with H_2O (2×), the organic phase dried over $MgSO_4$ and evaporated. The resulting oil was chromatographed (5% methanol/CH_2Cl_2) to give 2.85 g (25%) of **15** as a powder from ether: mp 180–181°C; uv λ_{max} (methanol): sh 278 nm (ε 10 300), 260 (11 300); ^{1}H nmr δ: 10.64 (s, br, 1H, NH), 7.68 (s, 1H, H-8), 7.62 (s, br, 1H, NH), 7.31–7.2 (m, 10H, aromatic), 7.27, 6.87 (AB, 4H, J = 8.9 Hz, aromatic), 5.28 (d, J = 6.6 Hz, 1H, H-1′), 4.94, 4.90 (d, J = 6.9, 3.5 Hz, 2H, OH), 4.03 (after D_2O added, dd, J = 6.6, 4.4 Hz, 1H, H-2′), 3.72 (s, 3H, OCH_3), 3.61 (s, br, 1H, H-3′), 3.29 (s, br, 1H, H-4′); ^{13}C nmr (75.453 MHz) δ: 157.74 (C-6), 156.36 (MTr), 150.59 (C-2), 148.87 (C-4), 138.39 (C-8), 144.86, 144.64, 136.62, 129.60, 128.22, 127.61, 126.56, 112.94 (MTr), 118.72 (C-5), 89.06 (C-1′), 73.23, 73.13 (C-2′, C-4′), 70.38 (C-3′), 69.81 (MTr), 54.95 (OCH_3). *Anal.* calcd. for $C_{29}H_{27}N_5O_5$ (525.56): C 66.27, H 5.18, N 13.32; found: C 66.33, H 5.20, N 13.48.

9-(β-(DL)-erythro-*furanosyl)guanine (**16**)*

A solution of **15** (400 mg, 0.76 mmol) in 80% acetic acid was heated for 16 h at 50°C, then evaporated. The residue was first triturated with acetone and then crystallized from ethanol/H_2O to afford **16** (65 mg, 34%). Recrystallization from hot H_2O gave the analytical sample: mp >230°C (dec.); uv λ_{max} (H_2O): sh 274 nm (ε 8 190), 253 (11 700); ^{1}H nmr δ: 10.62 (s, br, 1H, NH), 7.89 (s, 1H, H-8), 6.44 (s, br, 2H, NH_2), 5.66 (d, J = 6.7 Hz, 1H, H-1′), 5.41 (d, J = 6.3 Hz, 1H, OH),

5.12 (d, J = 3.7 Hz, 1H, OH), 4.63 (after D_2O added, dd, J = 4.7, 6.7 Hz, 1H, H-2′), 4.30, 3.75 (ABX, J_{AB} = 10 Hz, J_{AX} = 3.6 Hz, J_{BX} = 1.6 Hz, 2H, H-4′), 4.20 (m, 1H, H-3′). *Anal.* calcd. for $C_9H_{11}N_5O_4 \cdot H_2O$ (271.23): C 39.85, H 4.83, N 25.82; found: C 39.79, H 4.85, N 25.82.

*(R,S)-N²-(p-Anisyldiphenylmethyl)-9-[1-(2-hydroxyethoxy)-2-hydroxyethyl]guanine (**13**)*

To a solution of **12** (6.3 g, 12.8 mmol) in methanol (150 mL)/H_2O (20 mL) was added $NaIO_4$ (6 g, 28 mmol) followed by a solution of OsO_4 (5 mL) (0.5 g OsO_4 in 100 mL *tert*-butanol). The suspension was stirred for 3 h at room temperature, after which time $NaBH_4$ (1.7 g, 44.9 mmol) was added, stirring was continued for 10 min, and then the reaction mixture was partially evaporated. The resulting residue was redissolved in chloroform and washed with H_2O (1×) followed by dilute Na_2CO_3 (1×), and the organic phase was dried over $MgSO_4$ and evaporated to a brown oil. The oil was chromatographed (5–10% methanol/dichloromethane) to afford 4.3 g (64%) of **13** as a foam: uv λ_{max} (methanol): sh 277 nm (ϵ 14 500), 261 (16 000), 235 (16 900); ^{1}H nmr δ: 10.57 (s, br, 1H, NH), 7.69 (s, 1H, H-8), 7.63 (s, br, 1H, NH), 7.29 (m, 10H, aromatic), 7.19, 6.86 (AB, 4H, J = 8.9 Hz, aromatic), 4.97 (t, J = 5 Hz, 1H, OH), 4.79 (t, J = 6 Hz, 1H, H-1′), 3.72 (s, 3H, OCH_3), 3.48 (dd, J = 5, 6 Hz, 2H, H-2′), 3.24 (dt, 2H, H-5′), 2.93 (t, J = 4 Hz, 2H, H-4′); ^{13}C nmr (75.453 MHz) δ: 159.12 (C-6), 157.48 (MTr), 152.59 (C-2), 150.14 (C-4), 145.49, 145.38, 137.26, 129.90, 128.45, 127.30, 126.12, 112.64 (MTr), 134.86 (C-8), 116.78 (C-5), 83.37 (C-1′), 70.30 (MTr), 69.52 (C-4′), 61.67, 59.60 (C-2′, C-5′), 54.87 (OCH_3). *Anal.* calcd. for $C_{29}H_{29}N_5O_5 \cdot H_2O$ (545.59): C 63.84, H 5.72, N 12.84; found: C 63.83, H 5.77, N 12.80.

*(R,S)-9-[1-(2-Hydroxyethoxy)-2-hydroxyethyl]guanine (**14**)*

A solution of **13** (4.3 g, 8.1 mmol) in 80% aqueous acetic acid (50 mL) was heated for 4.5 h at 70°C, then cooled to room temperature (1 h) and evaporated. The residue was co-evaporated with ethanol (2×) and crystallized from methanol/H_2O to afford in 2 crops 1.1 g (53%) of **14**: mp >300°C; uv λ_{max} (0.1 *N* HCl): sh 278 nm (ϵ 8 020), 255 (12 100); (0.1 *N* NaOH): 265 (10 800), 254 (10 600); ^{1}H nmr δ: 10.61 (s, br, 1H, NH), 7.79 (s, 1H, H-8), 6.46 (s, br, 2H, NH_2), 5.46 (t, J = 5.9 Hz, 1H, H-1′), 5.16 (t, J = 6 Hz, 1H, 2′-OH), 4.63 (t, J = 5.2 Hz, 1H, 3′-OH), 3.81 (dd, 2H, J = 5.9, 4.8 Hz, H-2′), 3.46 (dt, 2H, H-5′), 3.32 (t, J = 6 Hz, 2H, H-4′); ^{13}C nmr (75.453 MHz) δ: 156.78 (C-6), 153.58 (C-2), 151.60 (C-4), 135.60 (C-8), 116.32 (C-5), 83.97 (C-1′), 70.12 (C-4′), 61.88, 59.68 (C-5′, C-2′). *Anal.* calcd. for $C_9H_{13}N_5O_4$ (255.23): C 42.35, H 5.13, N 27.44; found: C 42.07, H 4.98, N 27.46.

Catalysis of ring expansion of 1-methylcyclopropylmethanol to 1-methylcyclobutanol by rhodium(I)

J. Thomas Burton and Richard J. Puddephatt[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 14, 1986

J. Thomas Burton and Richard J. Puddephatt. Can. J. Chem. **64**, 1890 (1986).

Stoichiometric reaction between $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ and $CH_2CH_2CHCMe_2OPNB$, OPNB = 4-nitrobenzoate, gave $[Rh_2(\mu\text{-}OPNB)_2(CO)_4]$ and $Me_2C{=}CHCH_2CH_2Cl$. The complex $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ in acetone solution catalyzes the ring expansion of $CH_2CH_2CMeCH_2OH$ to give $CH_2CH_2CH_2CMeOH$, and experiments with labelled derivatives indicate that the rhodium complex acts as a Lewis acid. The reaction is zero order in cyclopropyl derivative but second order in catalyst concentration. The equilibrium constant for the reaction is 21 at 40°C and a mechanism is proposed.

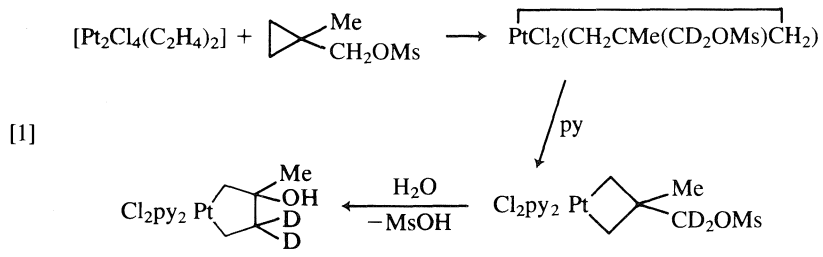
J. Thomas Burton et Richard J. Puddephatt. Can. J. Chem. **64**, 1890 (1986).

La réaction stoïchiométrique du $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ et du $CH_2CH_2CHCMe_2OPNB$ (OPNB = nitro-4 benzoate) conduit au $[Rh_2(\mu\text{-}OPNB)_2(CO)_4]$ et au $Me_2C{=}CHCH_2CH_2Cl$. En solution dans l'acétone, le complexe $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ catalyse l'extension de cycle du $CH_2CH_2CMeCH_2OH$ qui conduit au $CH_2CH_2CH_2CMeOH$; des expériences avec des dérivés marqués indiquent que le complexe de rhodium agit comme un acide de Lewis. La réaction est d'ordre zéro en dérivé cyclopropyle; toutefois, elle est d'ordre deux par rapport au catalyseur. A 40°C, la constante d'équilibre de la réaction est égale à 21 et on propose un mécanisme.

[Traduit par la revue]

Introduction

We have been interested in the reactions of cyclopropylmethanol and its derivatives with platinum complexes (1–3). In favorable cases, platinacyclobutanes have been isolated and subsequent solvolysis gave platinacyclopentanols (for example, reaction [1], OMs = mesylate, py = pyridine)



[1]

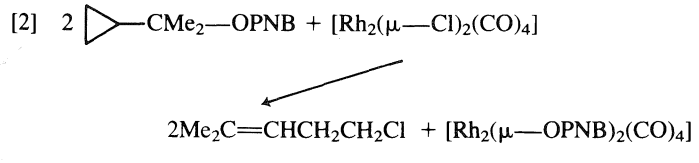
Since $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ is known to react with cyclopropanes to give rhodacyclobutanes (4), which may then undergo further interesting reactions (5–7), attempts were made to develop rhodium chemistry analogous to reaction [1]. The results of this study are described below.

Results

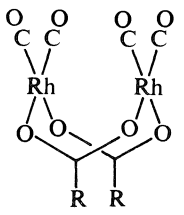
In no case did reaction of a derivative of cyclopropylmethanol give organorhodium complexes of the type expected by analogy with reaction [1]. However, new reactions were observed in two cases.

*Reaction with 2-cyclopropyl-2-propyl-*p*-nitrobenzoate*

In this case a stoichiometric reaction occurred according to reaction [2] (OPNB = *p*-nitrobenzoate)



The rhodium complex precipitated from the reaction mixture as a blue–black crystalline solid, which dissolves in organic solvents such as dichloromethane to give orange solutions. Similar carboxylate bridged complexes are known and are also dichroic (8, 9). They have the structure **1**. The organic product was identified by its ^1H and ^{13}C nmr spectra and was formed quantitatively. The reaction is stoichiometric and the rhodium-containing product did not react with $c\text{-}C_3H_5CMe_2OPNB$.



1

This organic product is not expected on the basis of the solvolysis of the cyclopropyl precursor which gives only unrearranged 2-cyclopropyl-2-propanol and no alkene products (11). However, it is known that magnesium halides in refluxing ether can effect a similar reaction to that in reaction [2] (10). These precedents do not aid an understanding of the mechanism of reaction [2], in particular whether the rhodium centre is involved in the cyclopropyl ring opening step.

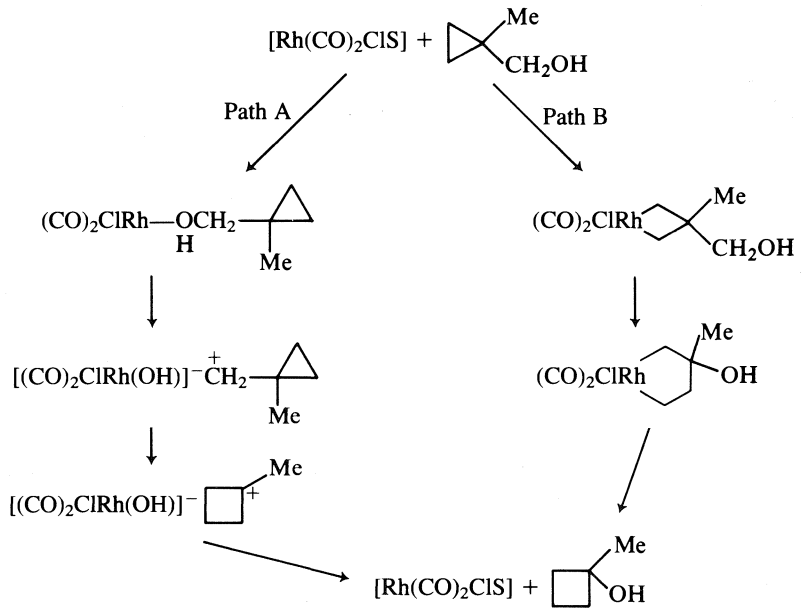

SCHEME 1

Reaction with 1-methylcyclopropylmethanol

It was found that $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ in acetone solution at 40°C catalyzes the ring expansion of 1-methylcyclopropylmethanol according to reaction [3].

[3] 
This ring expansion occurred under mild conditions and was easily monitored by nmr in acetone-d_6 solution. The reaction did not proceed to completion but reached an equilibrium with the equilibrium constant at 40°C for reaction [3] equal to 21. This corresponds to a free energy change, ΔG, of -1.9 kcal mol^{-1} for the reaction. This is fairly close to the value expected from the difference in ring strain between cyclopropane and cyclobutane, which would predict $\Delta H = 26.4\text{–}27.6 = -1.2$ kcal mol^{-1}. We have not measured the changes in K for reaction [3] with temperature and so ΔH for reaction [3] is not known. Despite the large numbers of studies of ring expansions analogous to reaction [3], there appear to be very few systems where it is possible to determine the equilibrium constants (12). In this case, integration of the signals due to the methyl protons of starting material and product, at $\delta = 1.22$ and 1.40 ppm, respectively, when the reaction had reached equilibrium gave an accurate measure of K. No other compounds could be detected by nmr in these reactions. The ring expansion can be catalyzed by acid at 100°C (12), but no ring expansion occurred using acid catalysts CF_3CO_2H or HCl at 40°C. The catalyst is therefore clearly the rhodium complex, which could be recovered unchanged at the end of the reaction.

Two possible mechanisms for the rhodium-catalyzed reaction are shown in Scheme 1. In path A, which has many precedents in organic systems (13), the rhodium acts only as a Lewis acid and the ring expansion involves carbocation intermediates whereas, path B, rhodacyclobutane intermediates are proposed and the mechanism is based on the platinum chemistry of reaction [1] (1, 2).

It has been shown that hydrolysis of $[Cl_2py_2\overline{PtCH_2CMe(CD_2OMs)CH_2}]$ is selective and gives very largely $[Cl_2py_2\overline{PtCH_2CMe(OH)CD_2CH_2}]$, reaction [1] (1, 2, 13), whereas general methylene scrambling occurs within the cyclopropylmethyl cation (14). It seemed likely therefore that different distributions of deuterium label would be seen between the products of hydrolysis of $\overline{CH_2CH_2CMe(CD_2OMs)}$ and rhodium-catalyzed ring expansion of $\overline{CH_2CH_2CMe(CD_2OH)}$ if path B was correct whereas the same distribution of deuterium label would be observed if path A was correct. When these experiments were carried out, the same distribution of deuterium label was observed, the products being $\overline{CH_2CH_2CD_2CMe(OH)}$, 65%, and $CH_2CD_2CH_2CMe(OH)$, 35%, in each case. This strongly suggested that path A, or some similar pathway in which the rhodium acts as a powerful Lewis acid, was correct. Further evidence against path B was obtained by conducting the isomerization reaction under CO pressure. Rhodacyclobutanes are known to undergo rapid CO insertion, and any such intermediates should therefore be trapped under these conditions (15). However, the reaction proceeded in the usual way under these conditions (reaction [3]), the only complication being the conversion of some of the catalyst to $[Rh_6(CO)_{16}]$.

The complex $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ in acetone solution is very largely present as the acetone complex (reaction [4], S = acetone) (16).

[4] $[Rh_2(\mu\text{-}Cl)_2(CO)_4] + 2S \rightleftharpoons 2cis\text{-}[RhCl(CO)_2S]$

The reaction according to path A should therefore follow overall second order kinetics, first order in both $[RhCl(CO)_2S]$ and in cyclopropane derivative. A kinetic study was carried out at 40°C, with monitoring by ^{1}H nmr. Unexpectedly, for a given kinetic run, the order with respect to cyclopropane derivative was close to zero, and the zero order rate constants for runs with varying concentrations of $[RhCl(CO)_2S]$ were approximately proportional to $[RhCl(CO)_2S]^2$, Fig. 1.

The kinetic data are interpreted in terms of the mechanism of reactions [5] and [6]

[5] $2cis\text{-}[RhCl(CO)_2S] \xrightarrow{\text{slow}}$ "A"

[6] "A" + $\overline{CH_2CH_2CMe(CH_2OH)} \xrightarrow{\text{fast}} 2cis\text{-}[RhCl(CO)_2S] + \overline{CH_2CH_2CH_2CMe(OH)}$

The nature of the species "A" is obscure since it is not formed in spectroscopically detectable concentration. One possibility is

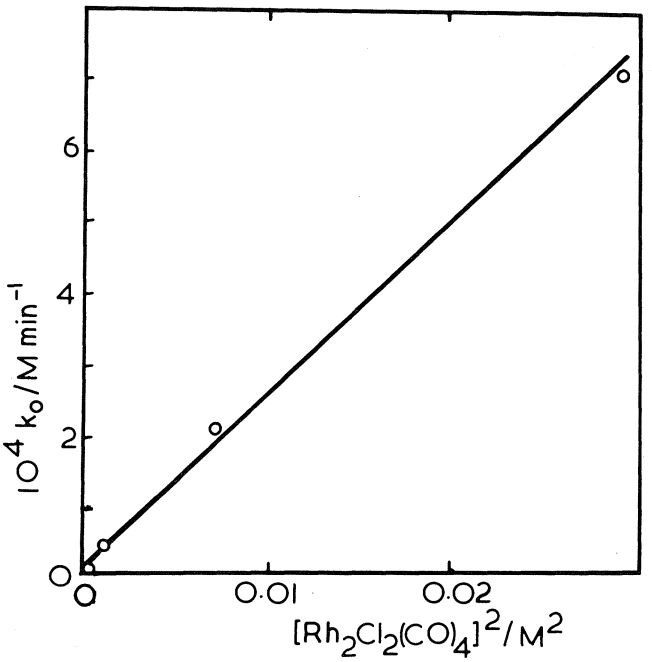

FIG. 1. Plot of observed zero order rate constants ($k_0/M\ min^{-1}$) for the rhodium-catalyzed ring expansion versus the square of the catalyst concentration.

that it might be *cis*-$[Rh(CO)_2S_2]^+$ *cis*-$[RhCl_2(CO)_2]^-$, with the cation acting as a strong Lewis acid. Alternatively it could be a dinuclear complex with a single μ-Cl bridge, which should also be a stronger Lewis acid than *cis*-$[RhCl(CO)_2S]$. Such complexes with two labile centres, could also interact with the cyclopropyl group and facilitate ring expansion. The ability of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ to act as a Lewis acid, including its use in catalysis of other reactions of strained ring compounds, has been noted previously (17–19).

The observed kinetic behaviour was unexpected but may be used to rationalize the fact that the catalyzed ring expansion of reaction [3] is very sensitive to solvent. Thus effective catalysis was not observed using chloroform solvent, when the catalysis is present as the dimer $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$, or in neat 1-methylcyclopropylmethanol, when the catalyst is probably present as *cis*-$[RhCl(CO)_2S]$, S = 1-methylcyclopropylmethanol.

Experimental

^1H and ^{13}C nmr spectra were recorded using a Varian XL100 or Varian XL200 spectrometer, and chemical shifts are quoted with respect to TMS. $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ was prepared by the literature method and was purified by vacuum sublimation (20), and cyclopropane derivatives were prepared as described previously (13).

Reaction with $CH_2CH_2CHCMe_2CH_2O_2CC_6H_4NO_2$

2-Cyclopropyl-2-propyl-4-nitrobenzoate (0.258 mmol) was added to a solution of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ (0.129 mmol) in acetone-d_6 (2 mL). The solution became dark red in colour and a blue–black precipitate formed. This was removed by filtration, dried under a vacuum, and identified as $[Rh_2(\mu\text{-}O_2CC_6H_4NO_2)_2(CO)_4]$. Yield 70%; mp 209–210°C; ir (Nujol): 2076, 2021 (ν(CO)); 1605, 1555 ($\nu(CO)_2$). ^1H nmr: δ = 8.34 (*m*, C_6H_4). *Anal.* calcd. for $C_{18}H_8N_2O_{12}Rh_2$: C 33.25, H 1.2, N 4.3. Found: 33.5, H 1.9, N 4.2. The organic product was identified as $(C^1H^1{}_3)_2C^2{=}C^3H^3C^4H^4{}_2C^5H^5{}_2Cl$ by comparison of the ^1H and ^{13}C nmr spectra with those of an authentic sample (21). ^1H: δ = 1.63 (*s*, H^1); 1.69 (*s*, H^1); 5.17 (*t*, $J(H^3H^4)$ = 7, H^3); 2.44 (*q*, $J(H^3H^4) = J(H^4H^5)$ = 7, H^4); 3.53 (*t*, $J(H^4H^5)$ = 7, H^5). ^{13}C: δ = 25.8, 17.8 (C^1H_3); 135.1 (C^2); 121.2 (C^3H); 32.2 (C^4H_2); 45.1 (C^5H_2).

Reaction with $CH_2CH_2CMeCH_2OH$

In a typical experiment, a solution of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ (1.71×10^{-2} *M*) and $CH_2CH_2CMeCH_2OH$ (1.71×10^{-1} *M*) in acetone-d_6 (0.6 mL) in an nmr tube was thermostated at 40°C and nmr spectra were recorded periodically until no further change occurred. The product was identified as $C^1H_2C^2H_2C^3H_2C^4Me^5OH$ by its ^1H and ^{13}C nmr spectra (18). ^1H: δ = 1.40 (*s*, CH_3); 1.5–2.3 (*m*, cyclobutyl CH_2 protons). ^{13}C: δ = 38.4 (C^1, C^3); 12.2 (C^2); 72.5 (C^4); 27.2 (C^5). The rate was monitored by integration of the resonances due to the CH_3 groups of the starting material and product. At the end of the reaction, $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ was recovered from the solution and identified by ir.

Reaction with $CH_2CH_2CMeCD_2OH$

A solution of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ (0.103 mmol) and CH_2CH_2C-$MeCD_2OH$ (0.556 mmol) in acetone-d_6 (0.6 mL) was allowed to react until there was no further change in the nmr spectrum. The volatiles were then distilled on the vacuum line into a clean nmr tube and the ^{13}C nmr spectrum of the 1-methylcyclobutanol-d_6 was recorded. The residue was identified as $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ by ir.

For comparison, a sample of $CH_2CH_2CMe(CD_2OMs)$, OMs = methanesulfonate (3.41 mmol), was hydrolyzed in aqueous acetone (15 mL), 60% v/v) at 40°C in the presence of $CaCO_3$ (34 mmol) for 90 min. The mixture was extracted with pentane (10 mL) and then pentane–ether (3 × 3 mL, 1:1 mixture). The solvent was removed from the dried combined organic extracts to give 1-methylcyclobutanol-d_2, and the ^{13}C nmr spectrum of this product (50 mg) in acetone-d_6 (0.6 mL) was recorded.

The relative intensities of ^{13}C resonances in the above two samples were the same, and both were estimated to contain $CH_2CH_2CD_2CMe(OH)$, 65%, and $CH_2CD_2CH_2CMe(OH)$, 35%, by comparison of the spectra with that of $CH_2CH_2CH_2CMe(OH)$, recorded using identical conditions.

Iodo-bridged complexes of platinum(II) and synthesis of *cis* mixed-amine platinum(II) compounds

F. D. ROCHON AND P. C. KONG

Département de chimie, Université du Québec à Montréal, C.P. 8888, succ. A, Montréal, Qué., Canada H3C 3P8

Received October 1, 1985[1]

F. D. ROCHON and P. C. KONG. Can. J. Chem. **64**, 1894 (1986).

Iodo-bridged platinum(II) dimers, $[Pt(L)I_2]_2$ with ligands (L) containing nitrogen as the donor atom, have been synthesized from the reactions of *cis*-$[Pt(L)_2I_2]$ with perchloric acid. The dimers can be cleaved in aqueous media by a second nitrogen ligand to produce isometrically pure *cis*-$[Pt(L)(L')I_2]$. These compounds can finally be converted to the chloro or carboxylato compounds by precipitating the iodo ligands with a silver salt and adding KCl or a carboxylate salt. Several compounds of the types *cis*-$[Pt(L)(L')Cl_2]$ and *cis*-[Pt(L)(L')(dicarboxylate)] were thus prepared. A few dimers of the type [(L)(L')Pt(tetracarboxylate)Pt(L)(L')] were also synthesized.

F. D. ROCHON et P. C. KONG. Can. J. Chem. **64**, 1894 (1986).

Des complexes de platine(II) à ponts iodés $[Pt(L)I_2]_2$ avec des ligands à atomes donneurs azotés, ont été synthétisés par la réaction entre *cis*-$[Pt(L)_2I_2]$ et l'acide perchlorique. L'ouverture des dimères a été réalisée en milieu aqueux par un autre ligand azoté (L') et des complexes isomériquement purs, *cis*-$[Pt(L)(L')I_2]$ ont été isolés. Ces derniers composés peuvent être transformés en composés chlorés ou carboxylates, par précipitation des ligands iodés avec un sel d'argent et l'ajout de KCl ou un sel carboxylate. Plusieurs complexes de types *cis*-$[Pt(L)(L')Cl_2]$ et *cis*-[Pt(L)(L')(dicarboxylate)] ont ainsi été préparés. De plus, quelques dimères de type [(L)(L')Pt(tétracarboxylate)Pt(L)(L')] ont été synthétisés.

Introduction

Iodo-bridged platinum(II) dimers $[Pt(L)I_2]_2$ containing nitrogen as the donor atom are not known and there are no methods in the literature that could lead to their synthesis. Iodo dimers with phosphine (1) or sulfoxide (2) ligands have been reported, but these two methods cannot be used to prepare amine iodo dimers.

Chloro-bridged dimers of piperidine, aniline, and pyridine derivatives have been reported (3–7). Courtot *et al.* (5) synthesized a chloro-bridged dimer with a very bulky amine, *t*-butylamine but were unable to prepare dimers with smaller amines since their method of synthesis is limited. They used the following photochemical method:

$$[Pt(L)(olefin)Cl_2] \xrightarrow[\substack{CHCl_3 \text{ or} \\ CHCl_3/\text{pentane}}]{h\nu} [Pt(L)Cl_2]_2$$

When L = is a simple amine R—NH_2 (R ≠ *t*-butyl) the starting material $[Pt(L)(olefin)Cl_2]$ is not soluble in $CHCl_3$ or $CHCl_3$/pentane and the dimers cannot be synthesized.

The halide dimers are important compounds because they can be the starting material for the preparation of mixed-ligand complexes, $[Pt(L)(L')X_2]$. Indeed, the dimers can be cleaved with several types of molecules (L') and depending on L, L', and the conditions of reactions, will produce *cis* or *trans* compounds. We have been trying for several years to prepare mixed-amine compounds of the type *cis*-$[Pt(L)(L')X_2]$ in view of increasing the screening range for antitumor properties of platinum compounds. We have now developed a general method to synthesize iodo-bridged dimers with amines. The method can also be used to prepare dimers with NH_3, pyridine derivatives, and probably any nitrogen ligand. This method will be discussed below.

The iodo dimers can be cleaved by several type of ligands (L'). The results obtained when L' = amine ≠ L will be discussed, along with the experimental conditions which are important for obtaining isomerically pure *cis* isomers.

Very few mixed-amine Pt(II) compounds have been reported. Braddock *et al.* (8) and Hydes (9) prepared a few compounds by the following method:

$$K[Pt(NH_3)Cl_3] + \text{amine} \rightarrow \textit{cis}\text{-}[Pt(NH_3)(am)Cl_2]$$

The method is limited to L = NH_3 and the yields are very low (<8%). $K[Pt(amine)Cl_3]$ cannot be prepared with the presently published method. We have published a method to produce $K[Pt(py)Cl_3]$ where py = pyridine derivatives (10), but the method cannot be used with amines. We have tried reacting $K[Pt(py)Cl_3]$ with amines in order to obtain *cis*-$[Pt(am)(py)Cl_2]$. But the yields are very low because of the formation of several ionic by-products and decomposed products.

The synthesis of mixed-amine compounds from the cleavage of the iodo dimers is a very important method at the moment, since *cis*-$[Pt(L)(L')I_2]$ can be the starting material for several other mixed-amine complexes. We have synthesized several chloro compounds, *cis*-$[Pt(L)(L')Cl_2]$, eight of which were sent to the National Cancer Institute (U.S.A.) for antitumor testing (11). Carboxylate (especially bidentate) compounds, *cis*-$[Pt(L)(L')(carboxylate)_2]$, have also been synthesized. Carboxylate platinum(II) compounds are less toxic and more soluble than the corresponding chloro analogues. Therefore they seem to be quite promising, since these compounds also have good antitumor activities. We have also synthesized carboxylate dimers by the same method, using a tetracarboxylate salt. These will be discussed below.

Experimental

Microanalyses were done by Galbraith Laboratories Inc., Knoxville. Melting points were measured on a Fisher-Johns apparatus. Infrared spectra were measured in Nujol on a P.E. 621 spectrometer.

K_2PtCl_4 was purchased from Strem Chemicals and Johnson Matthey Inc. and recrystallized from water. Most chemicals were bought from Aldrich. All the platinum complexes were dried at 60°C under vacuum in the presence of P_2O_5.

Synthesis of cis-*[Pt(L)$_2$I$_2$]*

A K_2PtI_4 solution was obtained by mixing K_2PtCl_4 (0.415 g in 5 mL H_2O) and KI (0.67 g in 5 mL H_2O) for 5 min. *cis*-$[Pt(L)_2I_2]$ (L = amine or other nitrogen ligand) was synthesized according to

[1]Revision received April 29, 1986.

Dhara's method (12) from the aqueous reaction of K_2PtI_4 and L. Yield: quantitative. A table of the elemental analysis of a few compounds has been deposited.[2]

Iodo-bridged complexes [Pt(L)I$_2$]$_2$

cis-[Pt(L)$_2$I$_2$] (2 mmol) was mixed with 10 mL of perchloric acid 0.67 *M*. Water (30 mL) was added to the mixture which was left at room temperature overnight. (Ethanol (30 mL) can also be added, instead of water, to the mixture which is left at room temperature for 4–6 h.) When L = pyridine derivative, slight heating to ~50°C is necessary. The reddish or brownish precipitate is filtered off, washed with water or 1:1 mixture of ethanol–water, and dried under vacuum. Yield: 80–90%, except for L = NH_3 (60%).

Compounds with NH_3, methylamine, ethylamine, isopropylamine, *t*-butylamine, dimethylamine, diethylamine, cyclopropylamine, cyclobutylamine, cyclopentylamine, pyridine, and ethanolamine have been synthesized and characterized.[2]

cis-*[Pt(L)(L′)I$_2$]$_2$*

The iodo dimer [Pt(L)I$_2$]$_2$ (1 mmol) was mixed with an excess of L′ (1.5–2.5×) (or 4 mL of 1 *M* ammonium hydroxide for L′ = NH_3) in 25 mL of water. The mixture was left at room temperature for about 6 h or overnight. The colour of the resulting mixture was bright yellow. The precipitate *cis*-[Pt(L)(L′)I$_2$] was filtered, washed with water, and dried under vacuum over P_2O_5. Yield: almost quantitative.[2]

cis-*[Pt(L)(L′)Cl$_2$]*

cis-[Pt(L)(L′)I$_2$] (1 mmol) was stirred with 1.8 mmol of $AgNO_3$ in 20 mL of water for 10 h or overnight in the dark. The AgI precipitate was removed by filtration and 1–2 drops of NaCl (0.5 *M*) was added to the filtrate. If a precipitate (AgCl) appeared immediately it was filtered out after 10 min and again 1 drop of NaCl was added to the filtrate. The procedure was repeated until there was no immediate precipitate after adding one drop of NaCl solution. When all the silver ions have been removed, solid NaCl or in aqueous solution was added to the filtrate. After a few hours, the mixture was evaporated to dryness, washed with a great quantity of cold water to remove $NaNO_3$ and NaCl completely. The pale yellow compounds, *cis*-[Pt(L)(L′)Cl$_2$] were dried under vacuum over P_2O_5. Yield: ~80%.

cis-*[Pt(L)(L′)(carboxylate)$_2$]*

cis-[Pt(L)(L′)I$_2$] (1 mmol) was reacted with $AgNO_3$ exactly as in the above procedure to prepare *cis*-[Pt(L)(L′)Cl$_2$]. When all the silver ions have been removed a slight excess of the sodium salt of the carboxylic acid was added to the filtrate. After 3–4 h, the mixture was evaporated to dryness and washed a few times with a minimum quantity of very cold water, since the product is slightly soluble in water. The white product was dried under vacuum over P_2O_5. Yield: ~80%.

Compounds with 1,1′-cyclobutanedicarboxylate, *trans*-1,2-cyclobutanedicarboxylate, *cis*- and *trans*-1,2-cyclohexanedicarboxylate were characterized.

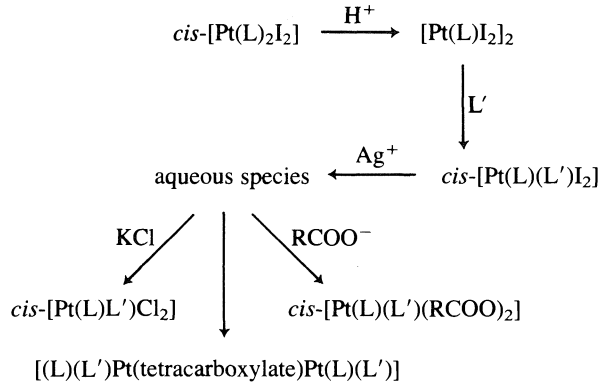
[(L)(L′)Pt(tetracarboxylate)Pt(L)(L′)]

cis-[Pt(L)(L′)I$_2$] (1 mmol) was treated with $AgNO_3$ exactly as in the procedure to prepare *cis*-[Pt(L)(L′)Cl$_2$]. After the complete removal of the silver ions, slightly more than 0.5 mmol of the tetracarboxylate sodium salt was added to the clear filtrate. After 3–4 h, the mixture was evaporated to dryness and washed with cold water. The white product was dried under vacuum over P_2O_5. Yield: ~80%.

Compounds with 1,2,4,5-benzenetetracarboxylate and 1,1′,3,3′-cyclobutanetetracarboxylate were characterized.[2]

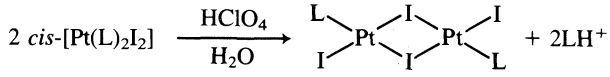
Results and discussion

The general method which we have developed to synthesize *cis* mixed-amine platinum(II) compounds is shown below.



The complexes *cis*-[Pt(L)$_2$I$_2$], where L = amine, were first prepared according to Dhara's method (12) who synthesized *cis*-[Pt(NH_3)$_2$I$_2$] from the reaction of K_2PtI_4 and NH_3 in water. Since *cis*-[Pt(L)$_2$I$_2$] is completely insoluble in water, it will precipitate immediately, preventing the formation of by-products. The yields are quantitative.

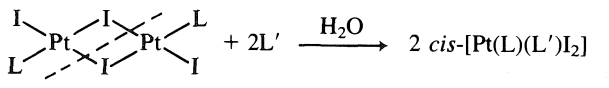
Iodo-bridged dimers were then synthesized from the reaction of *cis*-[Pt(L)$_2$I$_2$] with perchloric acid. In these conditions, one amine is protonated. The formation of aquo species is limited because of the strength of the Pt—I bonds and the equilibrium is shifted towards the formation of the iodo-bridged compound since the dimer is insoluble in the reaction medium.



Other acids can be used, but for most amines, perchloric acid was found preferable. The dimerisation reaction was done for most amines, at room temperature in aqueous media, overnight. For some ligands like isopropylamine, the reaction is slower, and it can be accelerated by the addition of ethanol. For the pyridine derivatives, heating at ~50°C is necessary to obtain good yields. The formation of the dimer can be seen by the appearance of a reddish or brownish precipitate, which can then be removed by filtration and washed with water or ethanol. The yields are almost quantitative except for L = NH_3 (60%). Compounds with NH_3, with primary, secondary, and tertiary amines, with pyridine and with 2-aminoethanol were synthesized.[2]

Results of the chemical analyses carried out on some of the compounds have shown the composition [Pt(L)I$_2$]$_2$.[2] The infrared spectra were measured between 4000 and 200 cm^{-1} and confirmed the presence of coordinated amines. The stretching ν(Pt—I) vibrations absorb below 200 cm^{-1} and were not observed as expected. Thus, the configuration of the dimer could not be determined although platinum(II) dimers are very often centrosymmetric. The *trans* configuration is therefore expected as in the chloro-bridged dimer [Pt(2,6-lutidine)Cl$_2$]$_2$ (7). We have tried to prepare adequate crystals for X-ray diffraction, in order to determine the crystal structure of one of the iodo-bridged dimers but have not been successful as yet.

The iodo-bridged dimers can be cleaved with a second nitrogen ligand (L′) in aqueous media to give bright yellow *cis*-[Pt(L)(L′)I$_2$]. Under theses conditions, no isomerisation occurs, since *cis*-[Pt(L)(L′)I$_2$] is very insoluble in water.



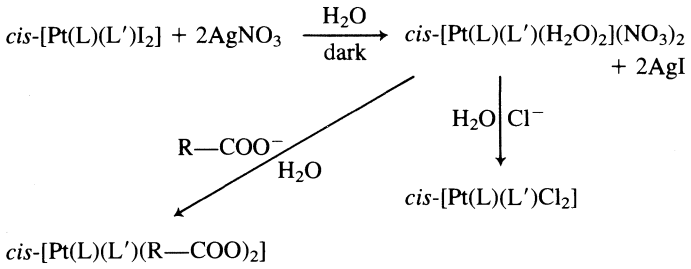
[2]Lists of the results of the elemental analysis, the decomposition points, and the main infrared bands of all the different types of platinum(II) complexes may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Since only *cis*-[Pt(L)(L′)I_2] is obtained from the bridge splitting of the dimer, we can come to the conclusion that the dimer was the *trans* isomer, since the cleavage of a *cis* isomer would produce a mixture of isomers [Pt(L)(L′)I_2]. The cleaved Pt—I bonds are those in *trans* position to the iodide ligands, as predicted by the *trans* effect ($I^- > RNH_2$).

The yield of the reaction is almost quantitative. This reaction cannot be done in organic solvents, since *cis*-[Pt(L)(L′)I_2] may dissolve and isomerise to produce the *trans* compounds, as already observed for the complexes *cis*-[Pt(L)$_2X_2$] (13–17). The results of the chemical analyses on a few iodo compounds have confirmed the expected composition. The ir spectra were measured but again do not give much information on the structure of the compounds.

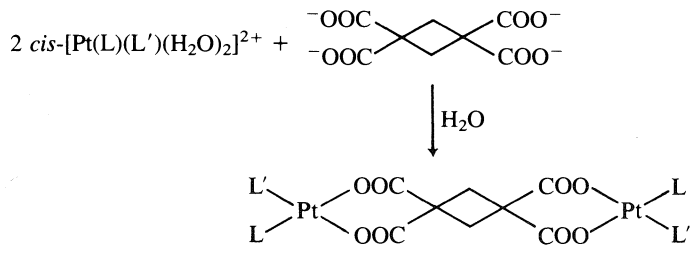
When synthesizing compounds of the type *cis*-[Pt(amine)-(NH_3)I_2], it is preferable to start with the amine (L = amine, L′ = NH_3) since the NH_3 dimer is slightly more difficult to obtain and the yield is lower.

The synthesis of mixed-amine compounds *cis*-[Pt(L)(L′)I_2] is important especially in relation to the synthesis of potential new platinum anti-cancer drugs. Compounds with almost any combination of nitrogen ligands can now be synthesized and tested systematically for antitumor acivity. These iodo compounds can be converted to the more active chloro or carboxylato complexes by the following reactions:



This is a modification of Dhara's method to synthesize *cis*-[Pt(NH_3)$_2Cl_2$] from *cis*-[Pt(NH_3)$_2I_2$] (12). The iodide ions are removed by precipitating with a silver salt in the dark. A slight excess of the platinum compound is used in order to prevent an excess of silver ions. The latter has to be completely removed before the precipitation of the platinum complex. After the complete removal of the silver ions, the sodium salt of the carboxylic acid or NaCl is added to the filtrate to precipitate the appropriate complex. The results of the chemical analysis done on the synthesized compounds have confirmed the expected composition.[2]

Dimeric species were also prepared with tetracarboxylate ligands by adding the sodium salt of the ligand to the aqueous species as follows:



Compounds with 1,1′,3,3′-cyclobutanetetracarboxylate, *cis,cis,cis,cis*-1,2,3,4-cyclopentanetetracarboxylate and 1,2,4,5-benzenetetracarboxylate were prepared.

Usually, infrared spectroscopy is a good method to identify the configuration of the dichloro platinum(II) compounds. Both symmetric and asymmetric ν(Pt—Cl) are active in ir for the *cis* compound, while only the asymmetric mode of the *trans* compound is active in ir. But sometimes there is coincidence of the two bands in the Pt—Cl stretch region for the *cis* isomer. For example, *cis*-[Pt(cyclobutylamine)$_2Cl_2$] showed one ν(Pt—Cl) at 311 cm^{-1}, while the *trans* isomer showed also one band but at slightly higher wave number (333 cm^{-1}). These assignments were confirmed by structure determination of the two compounds (14). These authors suggested that for this type of compounds, band position is more important for determining the configuration of the compound than the number of bands.

For the mixed amines compounds, we have observed that depending on the ligands, some compounds show two bands while others show only one large band. For example, *cis*-[Pt(cyclopropylamine)(NH_3)Cl_2] and *cis*-[Pt(cyclopropylamine)(CH_3NH_2)Cl_2] showed two ν(Pt—Cl) bands at 327, 316 and 312, 308 cm^{-1}, respectively, while *cis*-[Pt(L)(NH_3)Cl_3] where L = isopropylamine (310 cm^{-1}), cyclobutylamine (320 cm^{-1}), and cyclopentylamine (318 cm^{-1}) showed only one ν(Pt—Cl) band. More than one ν(Pt—Cl) was also observed for *cis*-[Pt(cyclopropylamine)$_2Cl_2$] (18). Therefore infrared spectroscopy should be used with great care when determining the configuration of the dichloroplatinum(II) compounds. The configuration of *cis*-[Pt(cyclobutylamine)(NH_3)Cl_2] and *cis*-[Pt(cyclopentylamine)(NH_3)Cl_2] were confirmed by crystal structure determinations (19, 20).

Reactions of *cis*-[Pt(sulfoxide)$_2$Cl$_2$] with silver salts and synthesis of hydroxo-bridged platinum(II) complexes with sulfoxides

FERNANDE D. ROCHON, PI-CHANG KONG, AND LOUISE GIRARD

Département de chimie, Université du Québec à Montréal, C.P. 8888, succ. A, Montréal (Qué.), Canada H3C 3P8

Received August 8, 1985[1]

FERNANDE D. ROCHON, PI-CHANG KONG, and LOUISE GIRARD. Can. J. Chem. **64**, 1897 (1986).

Platinum(II) compounds of the type *cis*-[Pt(L)$_2$X$_2$] where L = tetramethylenesulfoxide (TMSO), ethylmethylsulfoxide (EMSO), di-*n*-propylsulfoxide (DPSO), benzylmethylsulfoxide (BMSO), and dibenzylsulfoxide (DBSO) and X = Cl^- and I^- have been synthesized. The reactions of these compounds with a silver salt were studied in aqueous solution. Monomers of the type *cis*-[Pt(L)$_2$(ClO$_4$)$_2$] (L = TMSO, EMSO, and DBSO), *cis*-[Pt(EMSO)$_2$(SO$_4$)] and hydroxy-bridged oligomers were isolated. Dimers, *cis*-[Pt(L)$_2$(OH)]$_2$(NO$_3$)$_2$ (L = TMSO, DPSO), and *cis*-[Pt(EMSO)$_2$(OH)]$_2$SO$_4$ and possibly a trimer (*cis*-[Pt(EMSO)$_2$(OH)]$_3$)$_2$(SO$_4$)$_3$ were characterized. The compounds were studied by infrared spectroscopy and by ^{1}H nmr.

FERNANDE D. ROCHON, PI-CHANG KONG et LOUISE GIRARD. Can. J. Chem. **64**, 1897 (1986).

Des complexes de platine(II), *cis*-[Pt(L)$_2$X$_2$] où L = tétraméthylènesulfoxyde (TMSO), éthylméthylsulfoxyde (EMSO), di-*n*-propylsulfoxyde (DPSO), benzylméthylsulfoxyde (BMSO) et dibenzylsulfoxyde (DBSO) et X = Cl^- et I^- ont été synthétisés. La réaction de ces composés avec un sel d'argent a été étudiée en solution aqueuse. Des monomères de types *cis*-[Pt(L)$_2$(ClO$_4$)$_2$] (L = TMSO, EMSO et DBSO), *cis*-[Pt(EMSO)$_2$(SO$_4$)] ainsi que des oligomères à ponts hydroxo ont été isolés. Les dimères *cis*-[Pt(L)$_2$(OH)]$_2$(NO$_3$)$_2$ (L = TMSO, DPSO) et *cis*-[Pt(EMSO)$_2$(OH)]$_2$SO$_4$ et possiblement un trimère (*cis*-[Pt(EMSO)$_2$(OH)]$_3$)$_2$(SO$_4$)$_3$ ont été caractérisés. Les complexes ont été étudiés par spectroscopie infrarouge et par rmn protonique.

Introduction

Sulfoxide ligands have two potential donor sites but the preference of Pt(II) for the sulfur donor site is well known and all reported neutral complexes are exclusively sulfur bonded in the solid state (1). Platinum, being a soft metal, does not form strong bonds with oxygen unless it is deprotonated or partly ionized as in DMF.

When K_2PtCl_4 reacts with a sulfoxide ligand (L), *trans*-[Pt(L)$_2$Cl$_2$] is probably first formed and is eventually isomerized to the *cis* configuration (2). There are three factors affecting the formation and the stability of the two isomers. First, the *trans* effect of sulfoxide ligands is fairly large. Therefore the *trans* isomer should be first formed. The second factor is the enhanced $(d-d)\pi$ bonding which is more effective in the *cis* geometry (1) and finally the steric hindrance between two large ligands in *cis* position. In the Pd(II) complexes, the enhanced $(d-d)\pi$ bonding in the *cis* geometry is probably not sufficient to overcome the interligand repulsions which are larger in the *cis* configuration, and all the compounds have the *trans* structure. In the corresponding Pt(II) complexes $(d-d)\pi$ bonding is apparently more effective and *cis* structures are obtained for all the complexes except with a very sterically demanding ligand like diisoamylsulfoxide (1).

The synthesis of *cis*-[Pt(L)$_2$Cl$_2$] where L = tetramethylenesulfoxide (TMSO), di-*n*-propylsulfoxide (DPSO), benzylmethylsulfoxide (BMSO), and dibenzylsulfoxide (DBSO) has been reported (1, 3). But we have found that the published method does not produce isomerically pure compounds especially for bulky groups like DPSO, BMSO, and DBSO. For example, the aqueous reaction between K_2PtCl_4 with DPSO will produce in the first 10 min yellow insoluble *trans*-[Pt(DPSO)$_2$Cl$_2$] which has to be filtered out in order to obtain isomerically pure, very pale yellow coloured *cis*-[Pt(DPSO)$_2$Cl$_2$]. The formation of *trans*-[Pt(DPSO)$_2$Cl$_2$] in the few first minutes has already been observed (2). We have therefore modified the published methods in order to obtain pure *cis*-[Pt(L)$_2$Cl$_2$]. *Cis* and *trans*-compounds can be identified by their stretching Pt—Cl vibrations. Since some of the ligands (L) absorb in this region the corresponding iodo compounds were synthesized to confirm the ν(Pt—Cl) assignments. Compounds with ethylmethylsulfoxide (EMSO) were also synthesized since *cis*-[Pt(EMSO)$_2$Cl$_2$] has not yet been reported.

These compounds were well characterized since they were the starting material for a study of their reactions with a silver salt to prepare oligomeric species. Dimeric species of DMSO has been recently synthesized (4). The crystal structure of a hydroxo-bridged platinum compounds [(DMSO)$_2$Pt(OH)$_2$Pt(DMSO)$_2$](ClO$_4$)$_2$, isolated from an aqueous solution of *cis*-[Pt(DMSO)$_4$](ClO$_4$)$_2$ (two O-bonded and two S-bonded DMSO (1)) was recently reported (4). However, this method was found to be inadequate for the synthesis of dimers with other sulfoxides. We have developed a new method involving the precipitation of the chloride ligands of *cis*-[Pt(L)$_2$Cl$_2$] with a silver salt. The method is similar to the one used to prepare amine hydroxo-bridged oligomers (5, 6). Usually, sulfoxide and amine platinum complexes behave quite differently. But we found that in this case, reactions were very similar. This study of the reactions of *cis*-[Pt(L)$_2$X$_2$] (X = Cl^- or I^-) with several silver salts is described below.

Experimental

Elemental analyses were done by Galbraith Inc. The infrared spectra were measured as Nujol mulls on a P.E. 621 spectrometer. A 60 MHz Varian EM 360C was used to record the ^{1}H nmr spectra. The reactions with silver salts were done in the dark. Special care was taken with silver perchlorate, since it is explosive when mixed with combustible material. However, it was not considered a potential hazard when used in the following experiments.

cis-*[Pt(EMSO)$_2$Cl$_2$]*

An aqueous solution (volume 15 mL) containing 3 mmol of purified K_2PtCl_4 and 9 mmol EMSO was stirred overnight. The white precipitate was filtered, washed with water, ethanol, and ether, and then dried. The yield can be increased by concentrating the filtrate to 10 mL and letting the solution stand at room temperature. After a few days, the crystals were filtered, washed with water, ethanol, ether, and then dried. Total yield: 67%, mp 126°C. *Anal.* calcd.: C 16.00, H 3.58; found: C 16.26, H 3.83.

[1]Revision received May 6, 1986.

cis-*[Pt(DPSO)$_2$Cl$_2$]*

A 40 mL aqueous solution containing 2 mmol of K_2PtCl_4 and 4.4 mmol DPSO was stirred for 15 min. The mixture was filtered and the filtrate was stirred overnight at room temperature. The very pale yellow precipitate was filtered, washed with hot water, ethanol, and ether, and then dried. Yield: 70%, mp 105°C. *Anal.* calcd.: C 26.97, H 5.28; found: C 27.07, H 5.25.

cis-*[Pt(TMSO)$_2$Cl$_2$]*

An aqueous solution (15 mL) containing 3 mmol of purified K_2PtCl_4 and 6.6 mmol TMSO was stirred at room temperature for 18 h. The white precipitate was filtered, washed with a great quantity of hot water, and dried. Yield: 90%, mp 194°C. *Anal.* calcd.: C 20.26, H 3.40; found: C 20.33, H 3.39.

cis-*[Pt(BMSO)$_2$Cl$_2$]*

Method 1: BMSO (6 mmol, finely powdered) were added to an aqueous solution containing 3 mmol of K_2PtCl_4. The mixture was stirred at room temperature for 48 h and then filtered. The precipitate was washed with hot water, ethanol, and ether, and then dried. The yellow compound was dissolved in DMF and stirred for 3–4 days. The DMF was then evaporated, and the residue dissolved in acetone. Ether was added to the solution and the pale yellow precipitate filtered and dried. Yield: 67%, mp 140°C (lit. (3) 141–143°C). *Anal.* calcd.: C 33.45, H 3.51; found: C 33.41, H 3.58.

Method 2: BMSO (6 mmol) and K_2PtCl_4 (3 mmol) were dissolved in 40 mL of DMF. The mixture was stirred for 3 days and heated at 70°C for 5 h each day. The DMF was evaporated at reduced pressure at 40°C. The product was washed with ether, ethanol, and water, and then dried. Yield: 60%.

cis-*[Pt(DBSO)$_2$Cl$_2$]*

This compound was prepared by the methods described for *cis*-[Pt(BMSO)$_2$Cl$_2$]. Yield: 70% (method 1), mp 141°C (lit. (3) 142°C). *Anal.* calcd.: C 46.28, H 3.88, Cl 9.76; found: C 45.92, H 3.86, Cl 10.09.

cis-*[Pt(L)$_2$I$_2$] L = TMSO, EMSO, DBSO*

KI (4 mmol) was added to 1 mmol of K_2PtCl_4 dissolved in 15 mL H_2O. After stirring for 4 min, 2 mmol of L were added and the mixture was stirred in the dark for 24 h. The compound was filtered, washed with hot water, ethanol, ether, and then dried. Yield: ~80%. *Anal.* calcd. for *cis*-[Pt(EMSO)$_2$I$_2$]: C 11.38, H 2.55; found: C 11.26, H 2.64.

cis-*[Pt(EMSO)$_2$(ClO$_4$)$_2$]·2H$_2$O*

cis-[Pt(EMSO)$_2$Cl$_2$] (1.325 mmol) and $AgClO_4$ (2.650 mmol) were mixed together in 15 mL H_2O. After 24 h of stirring, AgCl was filtered out. The pH of the filtrate which was about 1.5 was raised to 6.5 with NaOH. The solution was concentrated avoiding precipitation of the products. The solution was then passed through "Sephadex G-25" in order to eliminate $NaClO_4$. The solution was then evaporated to dryness and the product dissolved in acetone. Ether was then added to precipitate the compound which was filtered and dried to yield a white hygroscopic compound. Yield: 30%, mp 160°C. *Anal.* calcd.: C 11.73, H 3.26, S 10.42; found: C 11.56, H 2.92, S 9.93.

cis-*[Pt(TMSO)$_2$(ClO$_4$)$_2$]·H$_2$O*

cis-[Pt(TMSO)$_2$Cl$_2$] (0.752 mmol) and $AgClO_4$ (1.504 mmol) were stirred together in water for 24 h and then filtered to remove AgCl. The filtrate was neutralized with KOH and evaporated to dryness. The residue was dissolved in acetone and filtered to remove $KClO_4$. The acetone filtrate was evaporated to dryness, washed with ether, and dried. A pale yellow hygroscopic compound was obtained. Yield: 30%, mp 100°C. *Anal.* calcd.: C 15.05, H 3.13, S 10.03; found: C 15.46, H 2.77, S 9.97.

cis-*[Pt(BMSO)$_2$(ClO$_4$)$_2$]*

cis-[Pt(BMSO)$_2$I$_2$] (0.263 mmol) and $AgClO_4$ (0.526 mmol) were mixed together in a H_2O–ethanol mixture. After stirring for 4 days, ethanol was evaporated and AgI filtered out. The filtrate was concentrated and refrigerated. The white precipitate was filtered, washed with very cold water, and dried. Yield: 30%, mp 135–140°C. *Anal.* calcd.: C 27.35, H 2.85, S 9.12; found: C 27.62, H 2.89, S 8.76.

cis-*[Pt(EMSO)$_2$SO$_4$]*

cis-[Pt(EMSO)$_2$Cl$_2$] (1.870 mmol) and Ag_2SO_4 (1.870 mmol) were mixed together in 15 mL H_2O. The mixture was stirred overnight and filtered to remove AgCl. Ethanol (5 mL) was added to the filtrate which was then evaporated to dryness. The white product was washed with ethanol, ether, and dried. Yield: 90%, mp 125°C.

cis-*[(TMSO)$_2$Pt(OH)$_2$Pt(TMSO)$_2$](NO$_3$)$_2$*

cis-[Pt(TMSO)$_2$Cl$_2$] (3 mmol) was suspended in 20 mL of water. Slightly less than 6 mmol of $AgNO_3$ dissolved in water were added to the above suspension and the mixture was stirred in the dark for 24 h. The precipitate (AgCl) was filtered and the excess $AgNO_3$ (if present) was precipitated with 0.5 *M* NaCl. The pH of the filtrate (about 1.5) was increased to 6.5 with a 1 *M* NaOH. The solution was maintained at 40°C for a few days until crystallization occurred. Very pale yellow crystals were obtained upon filtration. Yield: 30%, mp 170°C. *Anal.* calcd.: C 19.92, H 3.55, O 19.90, N 2.90; found: C 19.87, H 3.72, O 19.25, N 2.58.

cis-*[(DPSO)$_2$Pt(OH)$_2$Pt(DPSO)$_2$](NO$_3$)$_2$*

The above method was used. The mixture was stirred in the dark for 48 h (instead of 24 h). Yield: 83%, mp 145°C. *Anal.* calcd.: C 26.56, H 5.39, O 17.69; found: C 26.24, H 5.17, O 17.29.

cis-*[(EMSO)$_2$Pt(OH)$_2$Pt(EMSO)$_2$]SO$_4$ and* (cis-*[Pt(EMSO)$_2$(OH)]$_3$)$_2$-(SO$_4$)$_3$*

cis-[Pt(EMSO)$_2$Cl$_2$] (4 mmol) was mixed with slightly less than 4 mmol of Ag_2SO_4 in 15 mL H_2O. The mixture was stirred for 24 h and the AgCl formed was then filtered. The pH of the solution (1.4) was raised to 6.5 with $Ba(OH)_2$. The mixture was stirred at room temperature overnight. (Heating at 40°C overnight will increase the proportion of the trimer.) The precipitate ($BaSO_4$) was then filtered and the filtrate evaporated to dryness under vacuum at 40°C. About 5–10 mL of absolute ethanol were added to the dry product to dissolve the yellow trimer. The white dimer, insoluble in ethanol, was filtered and dried. Yield: 33%, mp 115°C.

The ethanol filtrate was evaporated to dryness. Ether was added to the product which was filtered and dried. The yellow compound is believed to be a trimer. Yield: 32%, mp 195°C (dec.).

The yield of the dimer can be increase by reducing the heating to a minimum throughout the preparation procedure while the yield of the trimer can be increased by heating the aqueous mixture for several hours at 40°C. *Anal.* calcd. for [(EMSO)$_2$Pt(OH)$_2$Pt(EMSO)$_2$]SO$_4$: C 16.22, H 3.85, O 18.00; found: C 15.48, H 4.17, O 17.39. *Anal.* calcd. for ([Pt(EMSO)$_2$OH]$_3$)$_2$(SO$_4$)$_3$: C 16.22, H 3.85, S 18.04; found: C 15.70, H 3.74, S 18.84.

Results and discussion

Complexes cis-*[Pt(L)$_2$X$_2$]*

Five complexes of this type were synthesized. Four of these compounds (L = TMSO, DPSO (1), BMSO, and DBSO (3)) have been reported as yellow crystals. We have modified the method used by these authors and we have isolated pure *cis* compounds which are white or very pale yellow in colour. The yellow compounds are believed to be the *trans* complexes which are formed at the beginning of the reaction. If the *trans* compounds stay in solution, they will isomerize to give the thermodynamically more stable *cis* species. If they precipitate, a mixture of *cis* and *trans* compounds will be obtained. To obtain pure *cis*-compounds, the reaction can be done in a solvent like DMF (BMSO and DBSO) or the first formed *trans* compounds can be filtered out. We were able to isolate pure *trans*-[Pt(BMSO)$_2$Cl$_2$] which is yellow. The infrared spectrum showed one ν(Pt—Cl) at 349 cm^{-1}. All *cis* compounds showed two ν(Pt—Cl) vibrations (Table 1).

All *cis*-[Pt(L)$_2$Cl$_2$] compounds showed a ν(S—O) vibration

TABLE 1. Main infrared bands of the $[Pt(L)_2X_2]$ complexes (cm^{-1})

Compound	ν(S—O)	ν(Pt—Cl)	Other bands (500–300 cm^{-1})
TMSO	1020s		326m
cis-$[Pt(TMSO)_2Cl_2]$	1150s, 1134s, 1119s	336s, 320s	515m, 368s, 335sh
cis-$[Pt(TMSO)_2I_2]$	1135s, 1125s		368m

cis-$[Pt(DBSO)_2I_2]$	1100s		476s, 410m, 405m, 353w

at a frequency higher than that in the free ligand, confirming that the binding site is the sulfur atom (3) (Table 1). The infrared spectra of the iodo compounds confirmed the ν(Pt—Cl) assignments since some of the ligands absorb in that region.

A crystal structure determination of *cis*-$[Pt(TMSO)_2Cl_2]$ (7) and *cis*-$[Pt(DPSO)_2Cl_2]$ (8) confirmed the configuration of the complexes and the binding site of the ligands.

Reactions of cis-*[Pt(L)$_2$Cl$_2$] with AgClO$_4$*

Rochon, Kong, and Melanson (4) have synthesized a DMSO dimer by the following method:

$$cis\text{-}[Pt(DMSO)_2Cl_2] + 2AgClO_4 \xrightarrow{DMSO} cis\text{-}[Pt(DMSO)_4](ClO_4)_2 + 2AgCl\downarrow$$
$$\xrightarrow{H_2O\downarrow} [(DMSO)_2Pt(OH)_2Pt(DMSO)_2](ClO_4)_2$$

DMSO was used as solvent and as ligand. We have tried this method with other sulfoxides (L) using DMF as solvent. But we have found the method inadequate. We have then tried the reaction in aqueous medium. Compounds of the type $[Pt(L)_2(ClO_4)_2]$ were isolated (L = EMSO, TMSO, and BMSO).

$$cis\text{-}[Pt(L)_2Cl_2] + 2AgClO_4 \xrightarrow{H_2O} cis\text{-}[Pt(L)_2(ClO_4)_2] + 2AgCl\downarrow$$

The results of the elemental analyses showed that some of the compounds were hydrated even after drying under vacuum (see Experimental section). The coordination of the perchlorate ion to the platinum atom in the solid state can be determined by infrared spectroscopy. Group theory predicts one large band ν_3(Cl—O) in the region 1150–1030 cm^{-1} for ionic ClO_4^- (T_d) and two bands for coordinated monodentate ClO_4^- (C_{3v}) (9). *cis*-$[Pt(DMSO)_2(OH)]_2(ClO_4)_2$ showed one ν_3 at 1076 cm^{-1} while $[Pt(BMSO)_2(ClO_4)_2]$ showed two bands at 1130 and 1094 cm^{-1}. The infrared spectra of $[Pt(TMSO)_2(ClO_4)_2].2H_2O$ and $[Pt(EMSO)_2(ClO_4)_2].H_2O$ showed the presence of water.

Conductivity measurements of *cis*-$[Pt(EMSO)_2(ClO_4)_2].2H_2O$ showed that the compound is hydrolyzed in aqueous solution. The value found immediately after dissolving the compound in water was 182 and 229 Ω^{-1} cm^2 mol^{-1} after 24 h, indicating the presence of close to three ions (10). The different hydrolysed species could be *cis*-$[Pt(EMSO)_2(H_2O)_2](ClO_4)_2$, *cis*-$[Pt(EMSO)_2(H_2O)(OH)](ClO_4)$, and possibly some dimeric species *cis*-$[Pt(EMSO)_2(OH)]_2(ClO_4)_2$. Perchlorate in aqueous solution does not coordinate to platinum as shown by ^{195}Pt nmr (11).

Attempts to isolate oligomeric species by neutralizing the resulting aqueous solution of *cis*-$[Pt(L)_2(ClO_4)_2]$ were not successful.

Reactions with AgNO$_3$

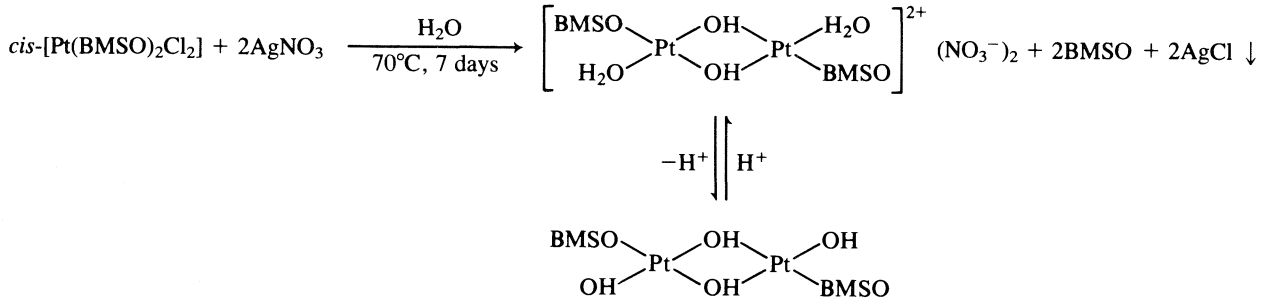
The reactions between *cis*-$[Pt(L)_2Cl_2]$, (where L = TMSO and DPSO) and $AgNO_3$ produced dimeric species $[Pt(L)_2(OH)]_2(NO_3)_2$. Nitrate dimers seem easier to crystallize than perchlorate dimers. The synthetic method is shown in Fig. 1. The reaction is slower for L = DPSO but the yield is higher (80% and 35% for L = TMSO).

The quantity of $AgNO_3$ is critical since an excess will decompose the complexes. The mixture of *cis*-$[Pt(L)_2Cl_2]$ and $AgNO_3$ in water is stirred for 24 h (48 h for DPSO) in the dark before filtering the AgCl. The pH is then about 1.5. NaOH (1 *M*) is added until the pH is 6.5 to increase the proportion of monoaquo–monohydroxo species in order to favor dimerisation. The solution is kept at 40°C for 3–4 days and crystallization occurs. The method of separation is based on solubility differences of the species in solution. The dimer crystallizes first, but it is quite soluble in water. The dimer containing DPSO is less soluble and is therefore easier to separate than the TMSO analogue. A series of forced crystallizations can increase the yield of the TMSO dimer. During this process, a very pale yellow compound is first obtained. Later, a darker compound believed to be a trimer can be isolated. The crystal structure analysis of *cis*-$[Pt(TMSO)_2OH]_2(NO_3)_2$ has confirmed the structure (12). The cation contains a centre of symmetry.

The molar conductivities were measured in aqueous solutions. The results showed the presence of three ionic species. The experimental values were 238 Ω^{-1} cm^2 for *cis*-$[Pt(TMSO)_2OH]_2(NO_3)_2$ and 236 Ω^{-1} cm^2 for *cis*-$[Pt(DPSO)_2OH]_2(NO_3)_2$.

The nitrate salt of the EMSO dimer could not be isolated. This compound is very soluble and could not be separated from $NaNO_3$ produced upon neutralisation with NaOH.

The reactions of *cis*-$[Pt(BMSO)_2Cl_2]$ and *cis*-$[Pt(DBSO)_2Cl_2]$ with $AgNO_3$ are very different probably for steric reasons. The reaction is very slow ($\approx$1 week) and must be initiated by heating. The product of the reaction is also different from the expected dimer. About half of the sulfoxide molecules were found free after the reaction. The pH of the solution after the reaction was acidic indicating the presence of deprotonated hydroxo species. The product is very soluble in acidic media but precipitates when the solution is neutralized. Therefore the complex is probably ionic in acidic media but neutral at pH > 7. The preliminary results seem to suggest the following reactions:



The infrared spectrum of the neutral compound showed the presence of O—H vibrations but no ionic or coordinated NO_3^-.

Several attempts to synthesize dimers *cis*-$[Pt(BMSO)_2(OH)]_2^{2+}$ were not successful. The close proximity of two very bulky sulfoxide ligands which contain phenyl groups situated above and below the platinum plane, might prevent the expected dimerisation. The platinum atom will prefer to lose a sulfoxide ligand to reduce the steric hindrance and dimerisation can then occur. The complex *cis*-$[Pt(DBSO)_2Cl_2]$, which is even more bulky, will react similarly with $AgNO_3$, but slower.

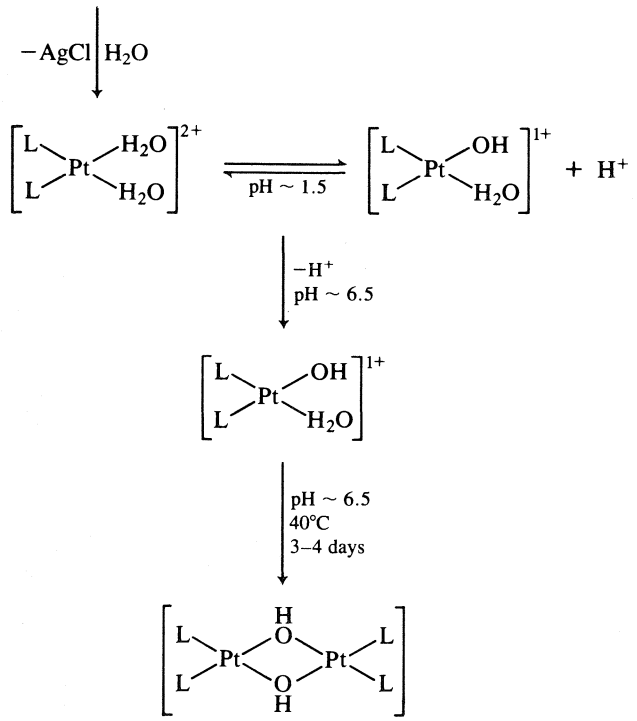


FIG. 1. Synthetic method for hydroxy-bridged dimers.

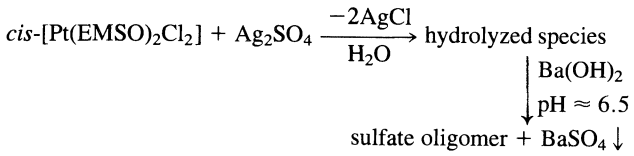
Reactions with Ag_2SO_4

The method developed to synthesize the EMSO dimer involve the following reactions:



The complex *cis*-$[Pt(EMSO)_2Cl_2]$ reacts in water with Ag_2SO_4. After 24 h, AgCl is filtered out. The pH of the solution is 1.4 and is raised to 6.5 with $Ba(OH)_2$. The next day, the barium sulfate is filtered out. The filtrate contains the hydroxo dimer and probably some trimeric species. If it is desired to increase the proportion of the trimer, the mixture can be heated at 40°C for several hours before filtering the $BaSO_4$. The dimer and the trimer can be separated with ethanol. The white dimer is insoluble in ethanol while the trimer is soluble. After evaporating the ethanol, the trimer can be recovered with ether. This complex is dark yellow. The dimer can be obtained pure, while the trimer is more difficult to purify. Both compounds are very soluble in water and are difficult to recrystallize. The results of the element analyses of the two compounds are shown in the Experimental section. The trimer might contain some higher oligomers.

Conductance measurements do not give any informations on the different oligomeric species for this type of compounds. The molar conductivities depend on the molecular weights which change with the different oligomers.

The dimeric species were confirmed by ^{195}Pt nmr which gave a signal at $\delta = -2887$ ppm which is 259 ppm higher (lower field) than *cis*-$[Pt(EMSO)_2(H_2O)_2]$ as expected. The trimer showed a weak and broad signal at −2906 ppm (13).

^1H nmr and ir spectra

The ^1H nmr spectra of the oligomeric species were measured in D_2O. The results are shown in Table 2. The α protons in the complexes have been shifted to lower field by 0.56 to 0.73 ppm

TABLE 2. ^{1}H nmr of the oligomers (δ(ppm))

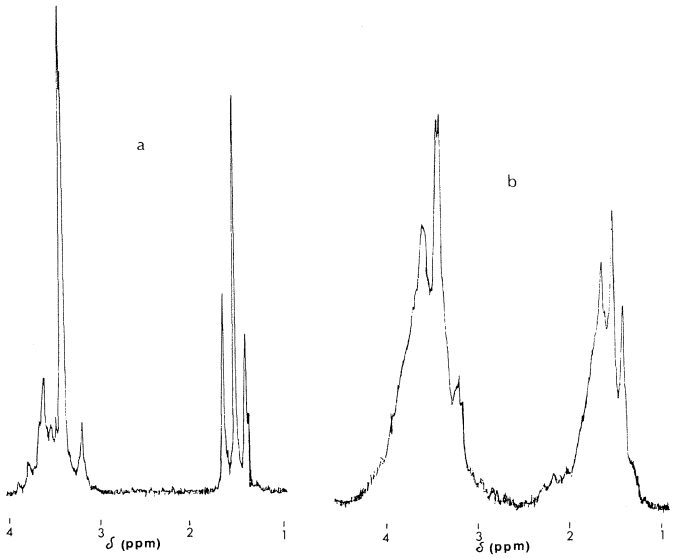

FIG. 2. ^{1}H nmr spectra of (*a*) the dimer [Pt(EMSO)$_2$OH]$_2$SO$_4$ and (*b*) the trimer.

upon complexation. These values show the great influence of Pt on its environment. This influence is still important on the protons in β and even γ (DPSO) positions. The smaller influence of Pt on Hβ of TMSO (Δδ = 0.03 ppm) can be explained by the cyclic nature of the ligand, since the β protons cannot approach the Pt atom as much as those in aliphatic ligands.

The dimer and trimer of EMSO have similar chemical shifts, but the peaks are much broader for the trimer (Fig. 2). The widening of the peaks can be explained by different conformations of the cation which is stereochemically non-rigid in solution as observed for the ammine trimer [(NH$_3$)$_2$Pt(OH)]$_3^{3+}$ (6). The EMSO trimer might contain some small quantities of the dimeric compound.

The EMSO complexes contain chiral sulfur centers, so that diastereoisomers may coexist as oberved for *cis*-[Pt(CH$_3$SOCH$_2$C$_6$H$_5$)$_2$Cl$_2$] (3) which showed, in chloroform solution, two CH$_3$—S resonances separated by 0.14 ppm. There seem to be two very close CH$_3$—S resonances for the EMSO dimer and trimer (Fig. 2). The separation between the two peaks is only 0.02 ppm. Therefore, two forms might coexist in aqueous solution. The ^{195}Pt—H^1 satellites of the CH$_3$—S resonances are well defined in the spectrum of the dimeric compound (Fig. 2*a*). The ^{195}Pt—H^1 coupling constant is 26 Hz and compares well with the values found in *cis*-[Pt(DMSO)$_2$Cl$_2$] (23 Hz), in *cis*-[Pt(CH$_3$SOCH$_2$C$_6$H$_5$)$_2$Cl$_2$] (22.5 Hz), and in [Pt(CH$_3$SOCH(CH$_3$)$_2$)$_2$Cl$_2$] (23 Hz) (3).

The monomeric compound *cis*-[Pt(EMSO)$_2$SO$_4$] also contains two chiral centers with the possibility of the coexistence of *dl* and *meso* forms. But the nmr spectrum of the compound is consistent with the presence of one form, since a single CH$_3$—S resonance was observed. Only one CH$_3$—S resonance was also observed for *cis*-[Pt(CH$_3$SOCH(CH$_3$)$_2$)$_2$Cl$_2$] in chloroform solution (3). The ^{195}Pt nmr spectrum of *cis*-[Pt(EMSO)$_2$SO$_4$] showed that the compound is hydrolysed in aqueous solution (13). The two main species are *cis*-[Pt(EMSO)$_2$(SO$_4$)(H$_2$O)] and *cis*-[Pt(EMSO)$_2$(H$_2$O)$_2$]$^{2+}$. A small quantity of the dimeric compound was also observed.

Infrared spectroscopy is an important method to identify the different synthesized species. Monomers are characterized in the solid state by coordinated NO_3^- or SO_4^{2-}, while these are ionic in oligomers. Ionic NO_3^- (D_{3h}) has four vibrational modes, three are ir active, two of which are more intense (9). These were observed at 1360 and ≈825 cm^{-1} (Table 3) for the TMSO and DPSO dimers. Therefore these two compounds contain ionic nitrate ions. Ionic SO_4^{2-} (T_d) has two vibrations active in infrared (ν_3 and ν_4) while chelating bidentate sulfate with lower symmetry (C_{2v}) has all degenerated modes separated (9). All the modes are infrared-active. The main bands of the three EMSO sulfate compounds are listed in Table 3. These results show that the dimer and the trimer contain ionic sulfate ions while the monomer contains coordinated SO_4^{2-}. Three ν_3 and three ν_4 bands have been identified indicating C_{2v} symmetry for the monomer. The ν_3 vibrations appear at higher frequencies indicating chelating bidentate SO_4^{2-} rather than a bridged bidentate complex (9). A unidentate SO_4^{2-} (C_{3v}) complex would show two ν_3 and two ν_4 vibrations. Therefore

TABLE 3. Mean infrared bands of the bridged-hydroxy oligomers

Assignment	TMSO	DPSO
ν_2 ionic nitrate	826s	822m
ν_3 ionic nitrate	1355vs	1360vs
ν(S—O)	1138vs	1140vs
ν(Pt—O), ν(Pt—S), and skeletal vibrations below 600 cm^{-1}	568s	537s
	534m	512s
	374s	442s
	346w	392w
	272w	285m
	257m	

	EMSO		
Assignment	Monomer	Dimer	Trimer
$\nu_3SO_4^{2-}$ ionic + ν(S—O)		1125s,br	1100s,br
$\nu_4SO_4^{2-}$ ionic		620s	615s
$\nu_1SO_4^{2-}$ bidentate	940s		
$\nu_2SO_4^{2-}$ bidentate	512m		
$\nu_3SO_4^{2-}$ bidentate	1265vs		
	1130vs		
	1050s		
$\nu_4SO_4^{2-}$ bidentate	663m		
	622m		
	586m		
ν(Pt—O), ν(Pt—S), and skeletal vibrations below 600 cm^{-1}	430m	550s	540m
	376w	505m	505m
	300w	425s	430s
		380m	375m
		292m	305w

we can conclude that the structure of the monomer is *cis*-[Pt(EMSO)$_2$(SO$_4$)] and the dimer and trimer contain ionic sulfates.

Reaction of sodium hydride in tetrahydrofuran with the hydrogen-bonded phosphinito complex, $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$, gives a solution of the salt, $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$, which is a precusor to synthesis of other bimetallic derivatives, $[PtCl(PEt_3)\{(\mu\text{-}PPh_2O)_2Q\}]^{n+}$: n = 0, Q = Rh(COD) or Ir(COD); n = 1, Q = $Pd(PEt_3)_2$ or $Pt(PEt_3)_2$. Detailed ^{31}P and ^{195}Pt nmr studies are reported for these and related examples including a titanium complex (n = 0, Q = $Ti(acac)Cl_2$) synthesised by direct reaction of $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ with $[TiCl_2(acac)_2]$. The diplatinum complex, $[Cl(PEt_3)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$ crystallizes in the monoclinic space group $P2_1/n$, with a = 13.018(2), b = 34.205(9), c = 11.279(2) Å, β = 91.71(2)°. A complete X-ray diffraction study shows that the two platinum centres are significantly non-planar and are linked by the phosphinito ligands to form a six-membered ring in a boat conformation with phosphorus and oxygen atoms forming the prows of the boat.

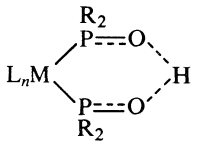
DAVID ERIC BERRY, KATHRYN ANNE BEVERIDGE, JANE BROWNING, GORDON WILLIAM BUSHNELL et KEITH ROGER DIXON. Can. J. Chem. **64**, 1903 (1986).

La réaction de l'hydrure de sodium, dans le tétrahydrofuranne, avec les complexes phosphinito suivants ayant des liaisons hydrogènes $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ conduit à une solution de sel de $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$ qui est un précurseur dans la synthèse d'autres dérivés bimétalliques comme $[PtCl(PEt_3)\{(\mu\text{-}PPh_2O)_2Q\}]^{n+}$ dans lesquels n = 0, Q = Rh(COD) ou Ir(COD); n = 1, Q = $Pd(PEt_3)_2$ ou $Pt(PEt_3)_2$. On rapporte les études détaillées de la rmn du ^{31}P et du ^{195}Pt de ces complexes et des complexes apparentés, y compris un complexe de titane (n = 0, Q = $Ti(acac)Cl_2$) préparé par la réaction directe du $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ avec le $[TiCl_2(acac)_2]$. Le double complexe de platine $[Cl(PEt_3)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$ cristallise dans le groupe d'espace monoclinique $P2_1/n$ avec a = 13,018(2), b = 34,205(9), c = 11,279(2) Å et β = 91,71(2)°. Les études par diffraction des rayons X révèlent que les deux centres Pt ne sont pas plans et se lient aux ligands phosphinito pour former un cycle à six chaînons dans une conformation bateau avec les atomes d'oxygène et de phosphore en positions de proue.

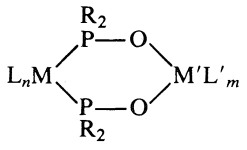
[Traduit par la revue]

Introduction

The coordination chemistry of organophosphites is notable for the large variety of possible products occasioned by the reactivity of the P—OR bond. We have summarized the literature relating to this area in two recent papers and have also discussed the formation of P—O complexes via hydrolysis of coordinated chlorophosphines (1, 2). A particularly interesting and widely studied class of complexes is exemplified by structure **I**.



I



II

Hydrogen bonded ring systems of this type are formed in many reactions of secondary phosphites and are also the most usual final outcome of hydrolyses of *cis*-$M(PR_2Cl)_2$ fragments. They have been studied by many research groups (3) and examples are known for a wide range of transition metals including Mn (4), Cr (5), Mo (5–7), W (5), Ru (8, 9), Rh (10), Ir (11), Ni (12), Pd (13–16), and Pt (13–15). X-ray diffraction studies (4, 7, 9, 10, 17–19) have shown O---O distances in the range 2.38–2.43 Å and the hydrogen bonds have been generally assumed to be symmetrical. However, it is interesting that the only two crystal structures (4, 9) which explicitly locate the hydrogen atom have shown asymmetrical hydrogen bonds despite the short O—O distances. Values less than 2.5 Å are normally considered indicative of symmetrical hydrogen bonds (19).

The hydrogen bonded proton of structure **I** is readily removed by a variety of bases and this leads to an extensive coordination chemistry in which the anion derived from **I** may be regarded as an analogue of acetylacetonate (acac). Coordination compounds have been reported in which the proton is replaced by the non-metals B (6, 8, 11, 20–22), Si (20), and P (5), and by a wide range of metals, including Na (6), Zn (12, 21, 22), Al, Tl (12), V (11, 12, 20, 23), Mn (23), Co (11, 12, 21–24), Ni, Cu (21–23), U (21, 22, 25), and Th (21, 22). The chemistry is interesting as a potential route to mixed metal chain oligomers having different metal ions in specific sites (21, 22), one site being "soft" in character and the other "hard", and also as a route to studies of reactivity of proximate metal centres. As we have noted above, the hydrogen bonded ring systems **I** are structurally well-characterized but despite the large number of known metal derivatives only two X-ray diffraction studies are available, the uranium complex, $[(\eta\text{-}C_5H_5)Ni\{\mu\text{-}P(OMe)_2O\}_2)_4U]$ (25) and, very recently, a relatively low accuracy (R_w = 11.4%) cobalt structure, $[\{(Et_2NS_2)Pt(\mu\text{-}PPh_2O)_2\}_2Co]$ (24, 26).

In the present paper we describe syntheses and ^{31}P and ^{195}Pt nmr studies of Ti, Pd, Pt, Rh, and Ir complexes of the type I ligand $[(Et_3P)ClPt(PPh_2O)_2]^-$. With the exception of the Ti complex, these differ from previous examples in that M′ in structure **II** is a "soft" metal. A structural study of

[1]To whom all correspondence should be addressed.

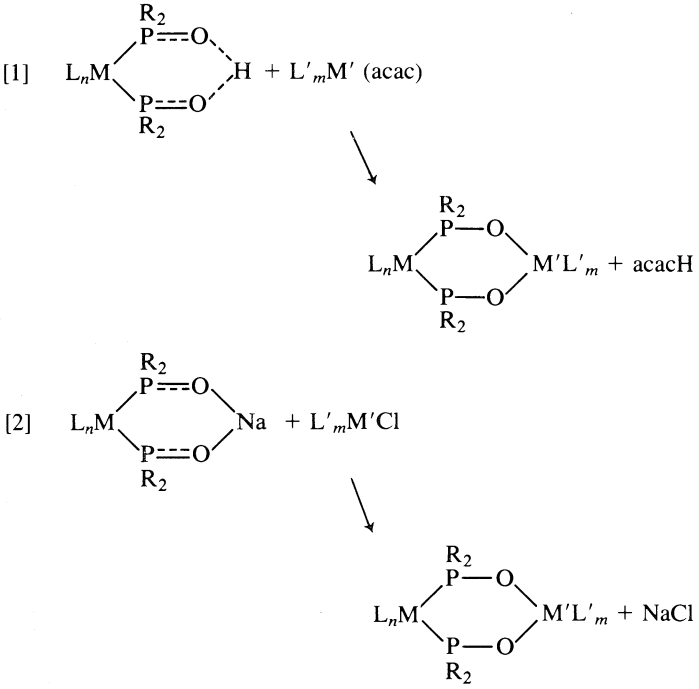
the platinum complex, $[(Et_3P)ClPt(\mu\text{-}PPh_2O)_2Pt(PEt_2)_2][BF_4]$ (**III**) is reported.

Results and discussion

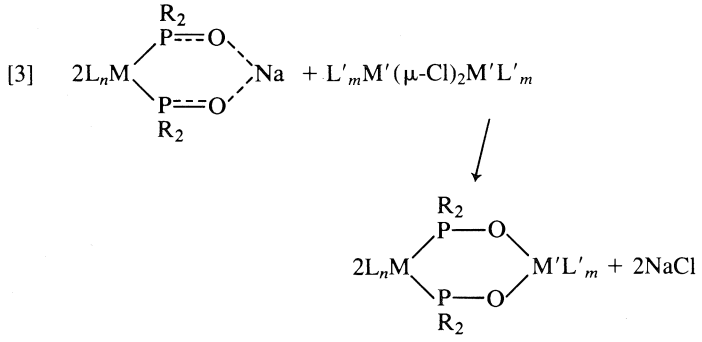
(A) Synthesis

The complexes discussed below were characterized primarily by the ^{31}P nmr spectra discussed in the next section. ^{195}Pt spectra were also recorded as given in the Experimental section and in all cases show coupling constants and multiplicities as expected from the ^{31}P spectra. ^1H spectra served mainly to confirm the ratios of aryl, alkoxy, and alkyl protons.

If complexes of type **I** are regarded as analogues of acetylacetone (acacH) then two simple routes to their coordination complexes are available.

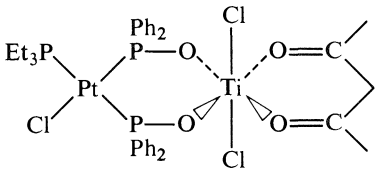


In practice, since reaction [2] requires an expansion of the coordination shell of M′, we have found a variant using cleavage of a double chloride bridge to be more useful. Thus:

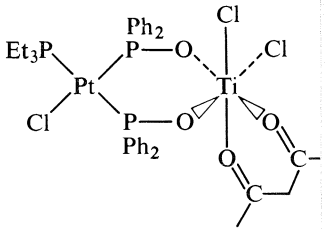


Solutions of $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$ are readily prepared by heating the known complex, $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ (15), with excess sodium hydride under reflux in tetrahydrofuran. Reactions of this solution with the chloride bridged complexes, $[Pt_2Cl_2(PEt_3)_4]^{2+}$ or $[Rh_2Cl_2(COD)_2]$ proceed under mild conditions according to reaction [3] to give, respectively, $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2]^+$ or $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Rh(COD)]$. Palladium and iridium analogues, $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pd(PEt_3)_2]^+$ or $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Ir(COD)]$ can be similarly prepared. As a check on the analogy with acetylacetone we also reacted $[Pt_2Cl_2(PEt_3)_4]^{2+}$ with Na(acac) to give $[Pt(acac)(PEt_3)_2]^{2+}$, the expected product according to reaction [3].

The products from an acac displacement reaction similar to reaction [1] were more problematical. Reaction of $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ with $[TiCl_2(acac)_2]$ gave a principal product analysing as $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2TiCl_2(acac)]$.



IV



V

There are five possible isomers of this formulation since the complex can be *trans* (structure **IV**) or *cis* (structure **V**). There are two possible *cis* structures (with transposition of the Cl and PEt_3 ligands) and each of these is chiral. The ^{31}P nmr of the main product is very similar to that of the other complexes described above except that the resonances for the bridging PPh_2O resonances are doubled indicating the presence of two isomers. The centreband resonances for the PEt_3 ligands of the two isomers are not resolved but some resolution is seen in the ^{195}Pt sidebands. A third product showing another very similar spectrum but in which the PEt_3 resonances were also significantly chemically shifted was observed in the supernatant liquids from the reaction. These observations suggest that the principal (less soluble) product consists of a racemic mixture of the two possible *cis* isomers (**V**), and the other (more soluble) product is probably the *trans* isomer (**IV**), but it is clear that we cannot be certain of these assignments. Data for all three products are given in Table 1 but spectra for the more soluble component were poor and only the parameters for the PEt_3 group could be determined with confidence.

In the course of our preliminary studies for the above work we also prepared several analogues of $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$. Bridge cleavage reactions of $[Pt_2(\mu\text{-}Cl)_2\{(PPh_2O)H\}_2]$ with tertiary phosphines and phosphites gave $[PtCl(L)\{(PPh_2O)_2H\}]$, L = PBu^n_3, $P(OMe)_3$, or $P(OPh)_3$, and reaction of $(EtO)_2P(O)H$ with $[Pt_2Cl_4(PEt_3)_2]$ gave $[PtCl(PEt_3)\{(P(OEt)_2O)_2H\}]$.

In their 1978 review of phosphinite and phosphite chemistry (3), Roundhill, Sperline, and Beaulieu noted an unusual and little studied substitution reaction in which $[Pt\{(PPh_2O)_2H\}_2]$ is converted to $[Pt\{(PPh_2O)(P(OPh)_2)H\}_2]$ by reaction with $P(OPh)_3$. The reaction of $P(OMe)_3$ with $[Pt_2(\mu\text{-}Cl)_2\{(PPh_2O)H\}_2]$ provides a further example of this type of process. As noted above, use of two molar equivalents of $P(OMe)_3$ gives $[PtCl\{P(OMe)_3\}\{(PPh_2O)_2H\}]$, but if excess phosphite is used then the product is complex **VI**. In contrast to the example reported previously (3), we found no evidence for a corresponding reaction with excess $P(OPh)_3$.

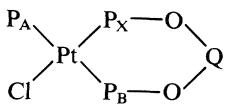
[a]Present work.
[b]Data from ref. 20.
[c]Data from ref. 29.
[d]Data from ref. 14. These workers used P_4O_6 as a phosphorus reference and we have converted the shifts assuming that P_4O_6 is at +113 ppm relative to 85% H_3PO_4.
[e]Platinum-195 parameters for this complex are given in the Experimental section.
[f]24.3 MHz in dichloromethane solution.
[g]24.3 MHz in tetrahydrofuran solution.
[h]101.3 MHz in deuterochloroform solution.
[i]Not resolved.
[j]The *cis*-PEt_3 groups in "Q" appeared as an NM quartet. All P—P and Pt—P couplings through the oxygen were smaller than the instrument resolution.
[k]δ(N) 41.65, δ(M) 39.43 ppm; ^2J(NM) −26.6 Hz.
[l]δ(N) 8.28, δ(M) 5.51 ppm; ^2J(NM) −25.2, ^1J(Pt—P_N) 3683, ^1J(Pt—P_M) 3716 Hz.
[m]δ(N) 39.44, δ(M) 38.00 ppm; ^2J(NM) −27.4 Hz.
[n]Three isomers were observed for this complex. Their significance is discussed in the text.
[o]Chemical shifts (δ) are quoted in parts per million relative to 85% H_3PO_4. Except as indicated, all shifts were positive. Coupling constants (*J*) are in Hz and their signs are discussed in the text.

(B) ^{31}P nuclear magnetic resonance spectra

Most of the complexes studied in this work are of the general type illustrated by structure **VII**:



VII

Proton decoupled ^{31}P nmr spectra of these complexes can usually be analyzed in the ABX spin system as defined in **VII**, and exhibit ^{195}Pt sidebands belonging to the ABMX spin system. This designation is somewhat unusual in that the chemical shift difference between A and B is often greater than that between B and X; but it is the large *trans* coupling between A and B which determines the spin system. Most of the spectra are sufficiently close to first order that the analyses present no special problems and a typical spectrum has been illustrated in a previous paper (20). However, in the present work we have improved the reliability of the parameters by computer simulation and refinement of all spectra, thereby avoiding the assumption of first order character made by previous authors.

For many of the complexes, we had available spectra at both 24.3 and 101.3 MHz and the non-first order character of the lower frequency spectra provided some information on signs of coupling constants. The details varied from compound to compound, but the procedure adopted for $[PtCl\{P(OMe)_3\}\{(PPh_2O)_2H\}]$ is illustrative of the internal checks for consistency which were applied in all cases. At 101.3 MHz the spectrum of $[PtCl\{P(OMe)_3\}\{(PPh_2O)_2H\}]$ was essentially first order. At 24.3 Mz the centre bands were an ABC spin system but the ^{195}Pt sidebands allowed ABMX analysis. Refinement of the sidebands with all possible sign combinations for J_{AX} and J_{BX} showed that only like signs gave satisfactory refinements with magnitudes in agreement with those obtained from the 101.3 MHz spectrum. Moreover, only negative signs for these parameters were able to predict the appearance of the ABC centre bands. The large *trans* coupling, J_{AB}, and all the platinum–phosphorus coupling were assumed to be positive on the basis of previous literature results (27, 28).

The parameters derived from these analyses are collected in Table 1 together with literature data for comparison. In general the parameters follow well established trends and require little comment. Thus $J(Pt—P_B)$ and $J(Pt—P_X)$ reflect the *trans*-influences of the Et_3P and Cl ligands; a difference which is also apparent in the Pt—P bonds lengths discussed below. Also the various coupling constants depend as expected on the electronegativity of the substituents, with larger magnitudes where either or both atoms carry alkoxy or aryloxy substituents. There is, however, one interesting trend associated with the variation of the group Q. Changing from a hydrogen bonded proton to a sodium ion causes shielding of P_B and P_X and increases in $J(Pt—P_B)$, $J(Pt—P_X)$, and $J(P_A—P_B)$. All of these changes are consistent with greater electron density in the sigma bonds of the $Pt(PR_2O)_2$ unit. At the same time the slightly strengthened $Pt—P_B$ bond exerts an increased *trans* influence causing a decrease in $J(Pt—P_A)$ and deshielding of P_A. When Q is a group containing a less electropositive metal (Rh, Ir, Pd, or Pt) the changes relative to the protonated species are similar but generally smaller in magnitude than those for sodium. When Q contains boron or silicon the changes are of small magnitude and erratic in direction. These trends can all be rationalised by increasing polarising power of the group Q in the sequence: electropositive metals < electronegative metals < non-metals and hydrogen. The data for the titanium complexes fit into this sequence (assuming Ti(IV) to be strongly polarising) except for a large deshielding of P_B and P_X, a perturbation which could be a result of the very different six-coordinate geometry of these complexes.

$[Pt\{(PPh_2O)(P(OMe)_2O)H\}_2]$

In principle the ^{31}P spectrum of this complex should belong to the AA′BB′ spin system as shown in structure **VI**, but in practice $J(AA')$ and $J(BB')$ are both *trans* phosphine couplings which are expected to be large and significantly different in magnitude because of the different substituents. Also it is likely that $J(AB) \simeq J(AB')$ since *cis* couplings show very little variation (see Table 1). Either of these two conditions could lead to the deceptively simple A_2B_2 spectrum (30) shown in Fig. 1. Computer refinement and simulation gave the following parameters:

$\delta(P_A)$ +82.11, $\delta(P_B)$ +85.14 ppm. $J(Pt—P_A)$ 2463, $J(Pt—P_B)$ 3324 Hz. $(1/2)\{J(AB) + J(AB')\}$ 38.4 Hz.

Comparison of these parameters with those for $[Pt\{(PPh_2O)_2H\}_2]$, $\delta(P)$ +72.5 ppm, $J(Pt—P)$ 2467 Hz (25), and $[Pt\{(P(OMe)_2O)_2H\}_2]$, $\delta(P)$ +89.2 ppm, $J(Pt—P)$ 3456 Hz (24), makes it clear that P_A above is the PPh_2O group and P_B is $P(OMe)_2O$ as shown in **VI**.

The spectrum of **VI** is also interesting as a further example showing significantly different centre bands and ^{195}Pt sidebands (31). As Figure 1 shows, the low field sideband is first order A_2X_2, the centre band is a weakly coupled A_2B_2 pattern, and the upfield sideband is strongly coupled A_2B_2. These differences are caused by the effective chemical shifts introduced into the sidebands by the different magnitudes of $J(Pt—P_A)$ and $J(Pt—P_B)$ (31).

*(c) Structure of $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$ (**III**)*

The atomic labelling scheme and the structure of a single molecule are shown in Fig. 2. Fractional atomic coordinates and isotropic temperature parameters, bond lengths, and bond angles are collected in Tables 2–4, and the following tables have been deposited: anisotropic temperature factors, structure factors, selected intermolecular distances, and mean plane information.[2]

The structure of $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$ consists of two nominally square-planar platinum centres linked by a pair of P—O bridges to form a six-membered ring. There is asymmetry at both ends of the molecule, Cl versus PEt_3 at Pt(1) and differing conformations of PEt_3 at Pt(2), and the coordination geometry around both platinums is considerably distorted. The angles seem to reflect the most obvious considerations of ligand size and the constraints imposed by the ring structure. Thus, around Pt(1) all the angles are compressed (84.1–88.6°) except for P(2)—Pt(1)—P(3) (102.0(2)°), whereas around Pt(2) it is the angle between the terminal PEt_3 groups which is opened (98.5(2)°) and the others compressed (85.2–90.4°). Both sets of atoms bonded to Pt are distinctly non-planar ($\chi^2 = \Sigma p^2/\sigma(p)^2 = 7906$ at Pt(1), 116 at Pt(2)), but the distortion at Pt(1) is much larger and may be due to a significant intramolecular interaction between PEt_3 containing P(3) and the adjacent phenyl ring.

[2]Copies of these tables may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

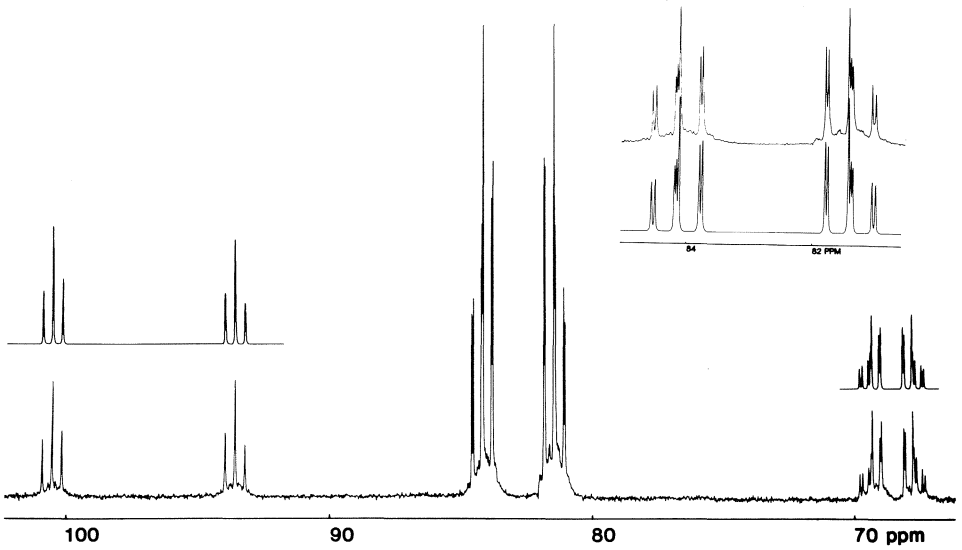


FIG. 1. $^{31}P\{^1H\}$ nuclear magnetic resonance spectrum of $[Pt\{(PPh_2O)(P(OMe)_2O)H\}_2]$. The main figure shows the complete spectrum with computer simulations of the ^{195}Pt sidebands (upper traces). The inset is an expansion of the centre band with a computer simulation (lower trace).

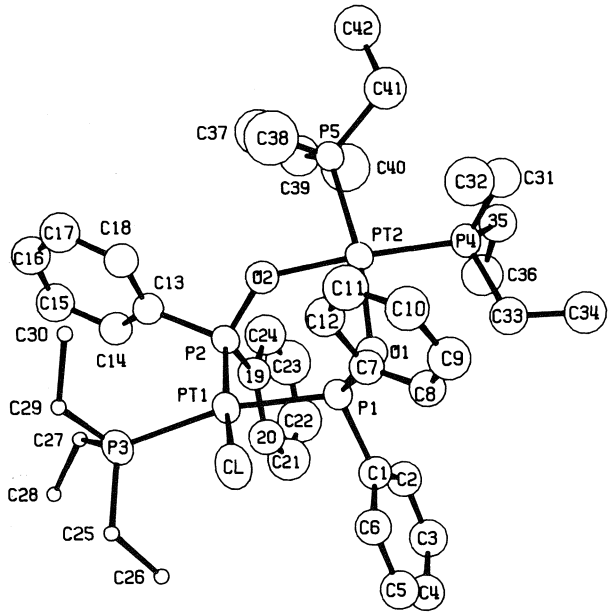

FIG. 2. ORTEP plot of compound **III**, $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$. Thermal ellipsoids scaled to enclose 50% probability.

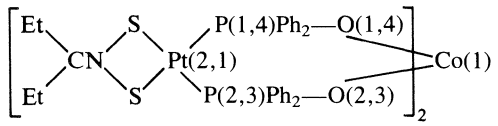
The bond lengths involving Pt(1) and the P—O lengths in the six-membered ring are all closely similar to those observed previously in $[Pt\{(P(OMe)_2O\}_2)BF_2\}_2]$ (32) and $[Cl(Et_3P)Pt(PPh_2O)_2BF_2]$ (33). The Pt(2)—P(4), 2.226(5) Å, and Pt(2)—P(5), 2.253(5) Å, bonds are relatively short (34, 35), consistent with the expected small *trans*-influence of oxygen ligands. The shorter length is similar to the Pt—P bonds (ave. 2.235 Å) in the dihydroxy bridged cation, $[Pt_2(OH)_2(PEt_3)_4]^{2+}$ (36). The Pt(2)—O lengths in **III**, 2.057(10) and 2.087(11) Å, are also close to those in the hydroxy bridged cation, ave. 2.133 Å.

The most interesting structural feature concerns the conformation of the six-membered ring. Our previous study of $[Pt\{(P(OMe)_2O\}_2)BF_2\}_2]$ showed a chair conformation, with a roughly planar P_2O_2 unit forming the seat, and we noted that the geometry of the MP_2O_2 fragment was relatively unaffected by substitution of BF_2 for H (32). In the present structure substitution by platinum changes the ring to a boat conformation, either because of the P(3)Et_3---phenyl interaction or because of the need to accommodate a second ~90° angle within the ring. Also the non-bonded O(1)---O(2) distance increases from the 2.38–2.43 Å in the BF_2 and H derivatives (4, 7, 9, 10, 17–19, 32) to 2.822(14) Å in **III**. The boat is not the obvious one having the Pt atoms at the prows, but rather that with P(2) and O(1) at the prows. Referring to Fig. 2, the Pt(1)—P(1) and O(2)—Pt(2) vectors are approximately parallel and the four atoms involved are all within 0.061 Å of the unweighted least-squares plane through the four atoms. The prows of the boat, P(2) and O(1), are, respectively, −0.780(4) and −0.658(9) Å below this plane. The torsion angle across the ring, O(1)—P(1)---P(2)—O(2) is 47.6(5)°. The coordination planes of Pt(1) and Pt(2) are incorporated into the ring in similar ways, being set at respective dihedral angles of 26.4 and 18.4° to the Pt(1), P(1), Pt(2), O(2) plane. It is interesting that the only other related structure involving two metal centres, compound **VIII** (24, 26), can be described in a similar way.[3]



VIII

Using the revised coordinates given by Marsh (26),[3] we calculate that the unweighted least-squares plane through Pt(2,1), Co(1), O(2,3), and P(1,4) has a maximum perpendicular deviation of 0.153 Å leaving O(1,4) and P(2,3), respectively, 0.14(2) and 0.825(8) Å out-of-plane in boat conformation. The phenyl ring positions on P(2,3) resemble those on our P(2). The more obvious unweighted least-squares plane through P(1,4), P(2,3), O(1,4), and O(2,3), has a marginally worse maximum

[3]The double numbering in **VIII** results from the fact that the structure was refined in a less symmetric space group (24).

TABLE 2. Fractional atomic coordinates and temperature parameters[a]

Atom	x/a	y/b	z/c	U_{iso}	Atom	x/a	y/b	z/c	U_{iso}

[a]Estimated standard deviations are given in parentheses. Coordinates $\times 10^n$ where $n = 5, 3, 3$ for Pt, B, F and $n = 4$ ortherwise. Temperature parameters $\times 10^n$ where $n = 4$ for Pt and $n = 3$ otherwise. U_{eq} (the equivalent isotropic temperature parameter) $= (1/3)\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* (a_i \cdot a_j)$. Primed values indicate that U_{eq} is given. $T = \exp[-(8\pi^2 U_{iso} \sin^2\theta/\lambda^2)]$.

deviation of 0.174 Å, passes almost exactly through Co(1), and leaves Pt(2,1) 0.957 Å out-of-plane. The transannular torsion angle O(1,4)—P(1,4)---P(2,3)—O(2,3) is 25(1)°.

We conclude that the less obvious description brings out the structural similarity between the two compounds well, and is a better description in both cases although only marginally so for the cobalt compound. In agreement with this, the possible causative steric interactions are less severe in the cobalt case and there is also no need to accommodate a second small angle since the cobalt is tetrahedral.

Experimental section

(a) Synthetic and spectroscopic studies

Data relating to the characterization of the complexes are given in the tables, the Results section, and in the preparative descriptions below. Microanalysis was by the Canadian Microanalytical Service, Vancouver, B.C., Canada. ^{31}P nuclear magnetic resonance spectra were recorded in appropriate solvents (Table 1) at either 24.3 MHz using a Nicolet TT14 Fourier transform spectrometer with a Varian HA60 magnet and an external C_6D_6 lock signal or at 101.3 MHz using a Bruker WP250 Fourier transform spectrometer locked to the solvent deuterium resonance. ^{195}Pt spectra were recorded at 53.5 MHz in $CDCl_3$ solution using the Bruker instrument. For both nuclei protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. ^{31}P chemical shifts were measured relative to external $P(OMe)_3$ and are reported in ppm relative to 85% H_3PO_4 using a conversion factor of +141 ppm. ^{195}Pt chemical shifts are reported in ppm relative to $\Xi(^{195}Pt) = 21.4$ MHz (37). Positive values are downfield of the references. ^1H spectra were recorded at 60 MHz in $CDCl_3$ solution using the Nicolet instrument and chemical shifts were measured relative to internal $Si(CH_3)_4$ reference. Simulated nmr spectra were calculated on an IBM 3031 computer and plotted on a Calcomp 1039 plotter. The programs used were a locally constructed package based on the UEAITR and NMRPLOT programs from the literature (38, 39).

All operations were carried out at ambient temperature (ca. 25°C) under an atmosphere of dry nitrogen using standard Schlenk tube techniques. Solvents were dried by reflux over appropriate reagents (calcium hydride for dichloromethane, molecular sieves for acetone, and potassium/benzophenone for diethyl ether, tetrahydrofuran, toluene, benzene, and hexane) and were distilled under nitrogen prior to use. Recrystallizations from solvent pairs were by dissolution of the complex in the first solvent (using about double the volume required for complete solution) followed by dropwise addition of sufficient second solvent to cause turbidity at ambient temperature. Crystallization was then completed either by continued very slow dropwise addition of the second solvent or, in those cases where a temperature is indicated in the detailed descriptions below, by setting the mixture aside at a reduced temperature.

Sodium acetylacetonate (40), $[Ti(acac)_2Cl_2]$ (41), $[Pt_2Cl_2\{(PPh_2O)H\}_2]$ (15), $[Pt_2Cl_4(PEt_3)_2]$ (42), $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ (43), $[Pd_2Cl_2(PEt_3)_4][ClO_4]_2$ (43), $[Rh_2Cl_2(COD)_2]$ (44), $[Ir_2Cl_2(COD)_2]$ (45), $[PdCl(PEt_3)\{(PPh_2O)_2H\}]$ (15), and $[PdCl(PEt_3)\{(PPh_2O)_2BF_2\}]$ (20), were prepared as previously described.

[Pt(acac)(PEt$_3$)$_2$][BF$_4$]

A slurry of sodium acetylacetonate (0.036 g, 0.30 mmol) in acetone was added to a stirred solution of $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ (0.163 g, 0.15 mmol) in acetone (20 mL). After 15 min the solvent was removed *in vacuo* and the residue dissolved in dichloromethane and stirred vigorously with an aqueous solution of $NaBF_4$. The organic layer was separated, the solvent removed *in vacuo* and the residue recrystallized from tetrahydrofuran/diethyl ether at −20°C to yield

*Estimated standard deviations are given in parentheses.

$[Pt(acac)(PEt_3)_2][BF_4]$ as colourless crystals (0.165 g, 0.27 mmol). *Anal.* calcd. for $C_{17}H_{37}BF_4O_2P_2Pt$: C 33.1, H 6.04; found: C 33.1, H 5.99; nmr: $\delta(^{31}P)$ +5.33 ppm in CH_2Cl_2, ^1J(Pt—P) 3586 Hz; $\delta(^{195}Pt)$ +407.78 ppm (t, Ξ 21.408726 MHz).

[PtClL{(PPh$_2$O)$_2$H}], L = PEt$_3$, PBu$^n_3$, P(OMe)$_3$, or P(OPh)$_3$

These complexes were prepared by similar methods to that described previously for the L = PEt_3 complex (15). For example; PBu^n_3 (0.08 mL, 0.32 mmol) was added dropwise to a stirred suspension of $[Pt_2Cl_2\{(PPh_2O)H\}_2]$ (0.20 g, 0.16 mmol) in acetone (20 mL). A clear solution resulted almost immediately and the solvent was removed *in vacuo* to leave a colourless oil which was crystallized from benzene/pentane. Recrystallization by the same method gave $[PtCl(PBu^n_3)\{(PPh_2O)_2H\}]$ (0.223 g, 0.27 mmol) as white crystals. *Anal.* calcd. for $C_{36}H_{48}ClO_2P_3Pt$: C 51.7, H 5.79; found: C 51.8, H 5.63. ^{195}Pt nmr: δ −70.75 ppm (ddd, Ξ 21.398486 MHz).

L = P(OMe)$_3$. Anal. calcd. for $C_{27}H_{30}ClO_5P_3Pt$: C 42.8, H 3.99; found: C 42.7, H 3.83. mp 163–166°C; nmr: $\delta(^1H)$ ~7.5 (m, 20H, Ph), 3.48 ppm (d with ^{195}Pt sidebands, ^3J(PH) 11 Hz, ^4J(PtH) 112 Hz, 9H, Me); $\delta(^{195}Pt)$ −54.29 ppm (ddd, Ξ 21.398838 MHz).

L = P(OPh)$_3$. Anal. calcd. for $C_{42}H_{36}ClO_5P_3Pt$: C 53.4, H 3.84; found: C 52.5, H 3.81. ^{195}Pt nmr: δ −56.43 ppm (ddd, Ξ 21.398792 MHz).

[Pt{(PPh$_2$O)(P(OMe)$_2$O)H}$_2$]

This complex was prepared as colourless crystals by the same procedure described above for $[PtCl\{P(OMe)_3\}\{(PPh_2O)_2H\}]$ except that an excess of $P(OMe)_3$ (ca. 0.5 mmol) and an extended reaction time (18 h) were employed. It could also be made by reaction of equimolar quantities of $P(OMe)_3$ and $[PtCl\{P(OMe)_3\}\{(PPh_2O)_2H\}]$ in acetone. *Anal.* calcd. for $C_{28}H_{34}O_8P_4Pt$: C 41.1, H 4.19; found: C 41.1, H 4.20. mp 216–218°C; nmr: $\delta(^1H)$ ~7.5 (m, 20H, Ph), 2.94 ppm (t with ^{195}Pt sidebands, $(1/2)\{^3J(PH) + {}^5J(PH)\}$ 5.5 Hz, ^5J(PtH) 66 Hz, 12H, Me); $\delta(^{195}Pt)$ −492.25 ppm (tt, Ξ 21.398466 MHz).

[PtCl(PEt$_3$){(P(OEt)$_2$O)$_2$H}]

A slight excess of $(EtO)_2P(O)H$ (0.4 mL, 3 mmol) was added dropwise to a stirred solution of $[Pt_2Cl_4(PEt_3)_2]$ (0.5 g, 0.65 mmol) in dichloromethane (20 mL). The reaction mixture was warmed to 50°C for 2 h and then stirred at 25°C for 18 h. Removal of solvent and excess diethylphosphite *in vacuo* gave $[PtCl(PEt_3)\{(P(OEt)_2O)_2H\}]$ as yellowish crystals which were identified by ^{31}P nmr spectroscopy (see Table 1).

[Cl(Et$_3$P)Pt(PPh$_2$O)$_2$BF$_2$]

This complex was prepared for nmr experiments by the reaction of $BF_3 \cdot OEt_2$ with $[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ as previously described (5). ^{195}Pt nmr: δ −134.93 ppm (ddd, Ξ 21.397113 MHz).

[Cl(Et$_3$P)Pt(μ-PPh$_2$O)$_2$Ti(acac)Cl$_2$]

A solution of $[Pt_2Cl_2\{(PPh_2O)_2H\}_2]$ (0.10 g, 0.13 mmol) in dichloromethane (10 mL) was added dropwise to a stirred solution of $[Ti(acac)_2Cl_2]$ (0.04 g, 0.13 mmol) in the same solvent (10 mL). After 2 h the solvent was removed *in vacuo*. The residue was washed with diethyl ether followed by toluene and recrystallized from dichloromethane/diethyl ether to give $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Ti(acac)Cl_2]$ as orange–yellow crystals. *Anal.* calcd. for $C_{35}H_{42}Cl_3O_4P_3PtTi.(1/2)CH_2Cl_2$: C 42.2, H 4.29; found: C 42.4, H 4.19. mp 227–228°C.

^{31}P nmr spectra of this product showed the presence of two isomers and a third isomer was seen in the spectrum of the toluene extract (see Results and discussion section).

[PtCl(PEt$_3$){(PPh$_2$O)$_2$Na}]

$[PtCl(PEt_3)\{(PPh_2O)_2H\}]$ (ca. 0.2 mmol) was heated under reflux in tetrahydrofuran (20 mL) for 15 min with a 2–3 fold excess of NaH (ca. 0.5 mmol as a dispersion in mineral oil). The mixture was filtered to yield a clear yellow solution of $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$. The solution was then used as a reagent in the following four preparations:

1. [Cl(Et$_3$P)Pt(μ-PPh$_2$O)$_2$Pt(PEt$_3$)$_2$][BF$_4$]

A suspension of $[Pt_2Cl_2(PEt_3)_4][BF_4]_2$ (0.10 g, 0.09 mmol) in tetrahydrofuran (10 mL) was added dropwise to a solution of $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$ (0.18 mmol) in the same solvent (20 mL) and the mixture was stirred for 3 h to give a clear, colourless solution. The solvent was removed *in vacuo* and the residue washed with diethyl ether and recrystallized from tetrahydrofuran/diethyl ether to give $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$ (0.16 g, 0.12 mmol) as colourless crystals. *Anal.* calcd. for $C_{42}H_{65}BClF_4O_2P_5Pt_2$: C 39.7, H 5.16; found: C 39.7, H 5.24. mp 223–225°C (dec.). ^{195}Pt nmr: δ +48.94 (ddd, Ξ 21.401047 MHz), +354.20 ppm (t, 21.407580 MHz).

2. [Cl(Et$_3$P)Pt(μ-PPh$_2$O)$_2$Pd(PEt$_3$)$_2$][ClO$_4$]

A procedure identical to *1* above but using $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$ (0.20 mmol) and $[Pd_2Cl_2(PEt_3)_4][ClO_4]_2$ (0.095 g, 0.10 mmol) gave $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pd(PEt_3)_2][ClO_4]$ (0.14 g, 0.12 mmol) as colourless crystals. *Anal.* calcd. for $C_{42}H_{65}Cl_2O_6P_5PdPt$: C 42.3, H 5.49; found C 42.6, H 5.59.

The analogous compound, $[Cl(Bu^n_3P)Pt(\mu\text{-}PPh_2O)_2Pd(PEt_3)_2][BF_4]$, was prepared on a small scale for nmr experiments by a similar procedure. ^{195}Pt nmr: δ +43.00 ppm (ddd, Ξ 21.400920 MHz).

3. [Cl(Et$_3$P)Pt(μ-PPh$_2$O)$_2$Rh(COD)]

A solution of $[Rh_2Cl_2(COD)_2]$ (0.049 g, 0.10 mmol) in tetrahydrofuran (10 mL) was added to a solution of $[PtCl(PEt_3)\{(PPh_2O)_2Na\}]$ (0.20 mmol) in the same solvent (20 mL). The reaction mixture was stirred for 8 h before filtration through Celite and removal of the solvent *in vacuo*. Extraction of the residue with diethyl ether and addition of hexane to the extract gave $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Rh(COD)]$ (0.06 g, 0.06 mmol) as yellow crystals. *Anal.* calcd. for $C_{38}H_{47}ClO_2P_3PtRh$: C 47.4, H 4.92; found: C 47.6, H 4.37. Dec. > 184°C.

4. [Cl(Et$_3$P)Pt(μ-PPh$_2$O)$_2$Ir(COD)]

A procedure identical to *3* above but using $[Ir_2Cl_2(COD)_2]$ in place of the Rh analogue gave an orange solution which was shown by ^{31}P nmr to contain mainly $[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Ir(COD)]$. Attempts to isolate a solid product resulted in decomposition.

(b) X-ray data collection

$[Cl(Et_3P)Pt(\mu\text{-}PPh_2O)_2Pt(PEt_3)_2][BF_4]$ (**III**) was prepared as des-

cribed above and a crystal suitable for study by X-ray diffraction was grown by vapour diffusion of diethyl ether into a solution of the complex in tetrahydrofuran. Preliminary photographic work was carried out with Weissenberg and precession cameras using Cu K_α radiation. After establishment of symmetry and an approximate unit cell the crystal was transferred to a Picker 4-circle diffractometer automated with a PDP11/10 computer and utilising Zr filtered Mo K_α radiation (λ = 0.71069 Å). The unit cell was refined by least-squares methods employing 10 pairs of centering measurements at $\pm 2\theta$ in the range $|2\theta|$ = 10–39°. The crystal was mounted approximately along the c axis. The crystal data at approximately 26°C were as follows:

$C_{42}H_{65}BClF_4O_2P_5Pt_2$ M_r = 1269.3

Monoclinic, space group $P2_1/n$, equivalent positions $x, y, z; -x, -y, -z; \frac{1}{2}+x, \frac{1}{2}-y, \frac{1}{2}+z; \frac{1}{2}-x, \frac{1}{2}+y, \frac{1}{2}-z$; a = 13.018(2), b = 34.205(9), c = 11.279(2) Å; β = 91.71(2)°; V(cell) = 5020(2) Å^3; D_m = 1.66 g cm^{-3} (flotation in $CCl_4/CHBr_3$), D_c = 1.68 g cm^{-3}; Z = 4; asymmetric unit = one molecule.

Intensity measurements were collected for two reciprocal space octants (h unrestricted, $k \geq 0$, $l \geq 0$) up to 2θ = 40°. A $\theta/2\theta$ step scan was used with 104 steps of 0.01° in 2θ, counting for 0.25 s per step. Background measurements were for 13 s at each end of the scan. Each batch of 50 reflections was preceded by the measurement of three standard reflections (0, 0, 6; 4, 0, 0; and 0, 10, 0;). The Lorentz and polarization factors were applied and each batch was scaled to maintain the sum of the standards constant. There was no evidence of sample decomposition during the data collection. Absorption corrections were applied with a numerical integration procedure utilizing a 10 × 8 × 14 Gaussian grid. The crystal shape was defined by perpendicular distances to crystal faces from a central origin as follows: ±{001},

0.2121 mm; ±{100}, 0.1183 mm; ±{010}, 0.0334 mm. The absorption coefficient was 61.18 cm^{-1} and the range of transmission factors 0.23–0.66.

(c) Structure solution and refinement

The structure was found and refined using the SHELX-76 program package (46), and illustrations were drawn using ORTEP (47). The atomic scattering factors used were for neutral atoms, with corrections for anomalous dispersion (48). The structure was solved by direct methods, developed by standard Fourier synthesis procedures using difference maps, and refined by the method of least squares minimising $\Sigma w\Delta^2$ where $\Delta = ||F_o| - |F_c||$. The weights were obtained from counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. Reflections for which $I < 2.5\sigma(I)$ were suppressed from the calculations and reflection (0,2,0), which was intense and at very low angle due to the length of the *b*-axis, was also omitted leaving 3813 of the initial 4680 independent measurements.

The PEt_3 group containing P(3) could not be determined in the same way as the other PEt_3 groups. This was attributed to disorder, but no double imaging of the group was obtained. The difficulty was mainly with two of the ethyl groups, C(27)—C(30), so the well behaved group C(25)—C(26) was used to help locate the other atoms. The following constraints (which did not entirely dominate the X-ray intensities) were applied:

P(3)—C(27), P(3)—C(29) = 1.820(1) Å

C(27)—C(28), C(29)—C(30) = 1.54(1) Å

C(25)—C(27), C(27)—C(29), C(29)—C(25) = 2.88(1) Å

Pt—C(27), Pt—C(29) = 3.517(10) Å

There were 269 parameters to be determined from 3813 independent observations. Hydrogen atoms were not located. All atoms heavier than fluorine were treated as vibrating anisotropically. Convergence was obtained with a maximum shift/esd ratio of 0.12 for the cation excluding the constrained PEt_3 ligand (1.66), and 0.29 for the BF_4^- anion. The residuals were $R = 0.0499$ and $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.0707$. The final difference map had a maximum of +1.9 e $Å^{-3}$ close to the disordered group and a minimum of −0.83 e $Å^{-3}$ but gave no indication that any material had been overlooked.

On décrit la synthèse l'acétamido-2 *O*-4-[(acétamido-2′ déoxy-2′ β-D-glucopyrannosyl) *O*-6-α-L-fucopyrannosyl] déoxy-2 β-D-glucopyrannoside de méthoxycarbonyloctyle, réalisée suivant le schéma 1, ainsi que son couplage avec l'albumine du sérum de boeuf et la poly-L-sérine. On a aussi préparé et partiellement caractérisé des antisérum de souris et de lapin du conjugé du ASB.

[Traduit par la revue]

Any success of contemporary cancer therapy depends heavily on early diagnosis of the disease, i.e. before a widespread invasion and dissemination occurs (1). Since clinical symptoms appear usually when the disease is in a relatively advanced stage, it is of importance to characterize reliable and easily detectable chemical markers (bio-, immuno-) of the onset of neoplasia and malignancy. It has been shown in numerous studies that unusual carbohydrate structures appear both in neoplasia and cancer (2–6). The carbohydrate structures in an appropriate form are usually immunogenic and consequently can be used for the preparation of antibodies which in turn can recognize the original carbohydrate structure. Appropriately modified or as such, the antibodies can serve as diagnostic reagents. The high specificity required can be best achieved by using in the immunization protocol a well-characterized, chemically pure, oligosaccharide antigen. In theory, such an antigen could be available from natural sources. These oligosaccharides are, however, obtainable from natural sources in minute quantities only, and their purity can never be assured entirely even after tedious and time-consuming purification procedures. Chemical synthesis eliminates these problems, and moreover allows to vary structural parameters as necessary for different uses. Since we have centered our attention on large bowel cancer, we have initiated a program of syntheses of oligosaccharide cancer markers associated with this particular site, and of studies of antibodies to these oligosaccharides.

One of the structures of interest is a class of oligosaccharide structures represented certain saccharide moieties of *N*-linked glycoproteins. A characteristic invariant basic structure of this class is portrayed in formula **1**. This structural element has been shown to exist in γ-glutamyltranspeptidase (in liver) and carcinoembryonic antigen (7, 8) in cancer but not in the absence of the disease. The "normal" oligosaccharides lack either *N*-acetylglucosamine or fucose or both (cf. underlined fragments in **1**). We have decided to synthesize **1** in two parts (cf. *a* and *b* in **1**), and investigate the immunochemistry of both fragments separately. This approach will help in the recognition and elimination of antibodies cross-reacting with the small fragments of **1** when the antibodies to the complete **1** are made.

In order to synthesize fragment *a* and link it to bovine serum albumin (and poly-L-lysine as an immunoadsorbent for immunoassays) we have modified a procedure employed previously for the synthesis of a methyl glycoside of the trisaccharide *a* (9). We have chosen to connect the trisaccharide with the carrier, i.e. bovine serum albumine, with a linker proposed by Lemieux *et al.* (10) and successfully used by others as well (11). Ethyl 9-hydroxynonanoate has been used in the first step (ref. 10; cf. Scheme 1) since it was easier to prepare it than a corresponding methyl ester. Its preparation involves diborane reduction of the free carboxyl group in a monoester of azelaic acid, and the methyl carboxylate is reduced to a significant extent whereas ethyl carboxylate is not. In the first Zemplén deacetylation, quantitative exchange to give the methyl ester occurs. Since the linker carries an alkali-labile methoxycarbonyl group, care had

1

to be taken to avoid any condition causing hydrolysis of this ester group. In practice it meant maintaining anhydrous conditions even more carefully than usual in most steps. Particularly difficult was the hydrazinolysis of the phthalimido protective group, since a number of conditions led to the hydrolysis of the ester group. Eventually, hydrazine acetate was found to be compatible with the presence of the ester group. Phthalimido protection of the amino function was used to avoid a potential problem of imidate formation (12) by an acetamido group in glycosylation reactions using strong promoters, as required for the formation of the 1,4 linkage in chitobiose. It has also been found that the simplest approach is to form a chitobiose derivative first, and to connect it with a fucosyl derivative (13) in the second stage. The reaction pathway is depicted in Schemes 1 and 2 which are self-explanatory. Acetylation after complete deprotection was found to be necessary for the purification of the trisaccharide since it allowed for easy chromatographic separation on silica gel. Not only did this chromatography remove unwanted by-products but also inorganic ions introduced during the hydrogenolysis of the benzyl groups. The inorganic ions caused unacceptable broadening of ^{1}H nmr signals (14).

We have found FAB mass spectrometry extremely useful for both identification and purity determination of synthetic intermediates. We report in this article *m/e* values for M-derived ions; the complete analysis, however, of the FAB mass spectra of compounds reported here, together with other carbohydrate intermediates, will be published elsewhere.

Finally, this trisaccharide ester was coupled to two different carrier molecules, bovine serum albumin (BSA) or poly-L-lysine, using a recent modification of the standard procedure (11). The trisaccharide ester **15***a* was first converted into the acyl hydrazide and subsequently, by treatment with dinitrogen tetroxide into the acyl azide which was then attached to BSA or poly-L-lysine. Quantitative determination (16) of incorporation by the colorimetric phenolsulphuric acid method showed incorporation of 10.5 molecules of carbohydrate per molecule of BSA and 1.9 carbohydrate molecules per poly-L-lysine molecule (mw_{ave} 16 000).

The synthetic antigen **15***b* was used to immunize (17) both rabbits and mice. The specificity of binding of rabbit antisera to the trisaccharide determinant **15***a* was determined in a preliminary fashion by competition analysis with various oligosaccharides using a solid-phase immunoassay (18) on the solid state substrate **15***c*. For detection of solid phase binding of the antibodies, ^{125}I-protein A was used. The binding specificity was expressed in terms of the molar concentrations of various oligosaccharides and their derivatives required to inhibit 50% of the binding of a non-saturating concentration of rabbit sera (2×10^{-4}) and the values found are summarized in Table 1. As can be seen from the Table 1, the only effective inhibitors were the trisaccharide derivatives **15**. Other segments of the structure **1** or its variations (cf. Table 1) did not exhibit any binding to the rabbit antibodies. Similar results were obtained with mice. The analysis of rabbit antisera and the biochemical characterization of the purified antibodies is in progress and will be published elsewhere.

Experimental

General methods

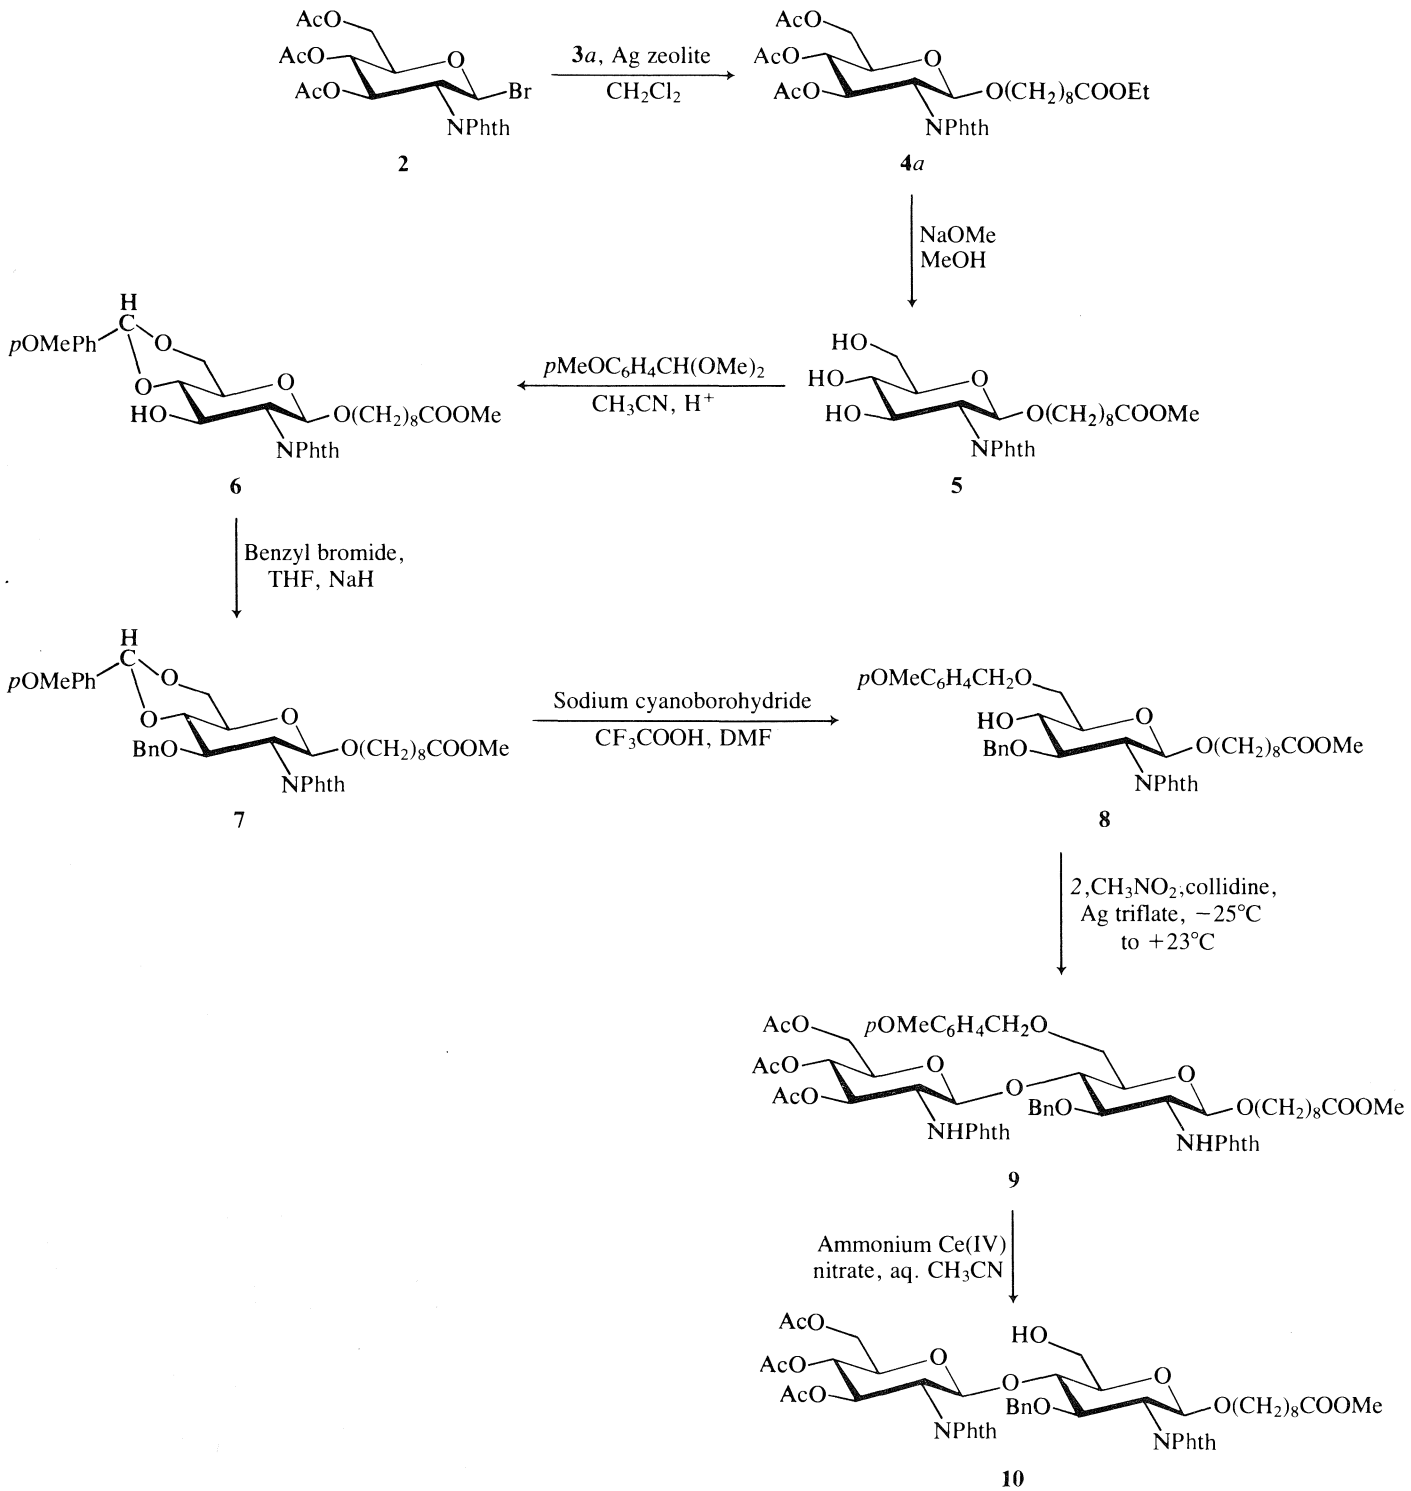
Melting points were determined on a Reichert Thermovar melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer polarimeter (Model 140) at 26 ± 1°C. Microanalyses were performed by the Microanalytical Laboratory Ltd., Markham, Ont. ^{1}H nmr spectra were recorded at 360 MHz with a Nicolet spectrometer at the Toronto Biomedical NMR Centre, University of Toronto (Director: Dr. A. A. Grey). They were obtained at 23 ± 2°C either in $CDCl_3$ containing 1% TMS as the internal standard or in D_2O (99.996%, Merck, Sharp, and Dohme) with acetone (0.1%, 2.225 ppm relative to internal DSS) as the internal standard. Infrared spectra were recorded with a Perkin-Elmer (Model 1430) Infrared Spectrometer, and calibrated at 1601 cm^{-1} of polystyrene film. FAB mass spectrometry was performed using thioglycerol matrix and ±NaOAc with a VG Analytical ZAB HF reversed geometry instrument (for general conditions, cf. ref. 19, and references therein) at the Institute of Physiological Chemistry, University of Bonn through the courtesy of Dr. H. Egge.

Thin layer chromatography (tlc) was performed on silica gel 60 F_{254} (Merck) plastic plates and visualized by quenching of ultraviolet fluorescence and (or) spraying with 50% aqueous sulfuric acid and heating at 100°C. Silica gel 60 (230–400 mesh; Merck) was used for flash column chromatography. All starting materials were dried overnight over KOH or P_2O_5 *in vacuo* prior to use. All solvents were distilled from appropriate drying agents. Unless stated otherwise, all reactions were carried out under anhydrous conditions and in an argon atmosphere. Solvents were removed at reduced pressures using a rotary evaporator at temperatures not exceeding 40°C.

*8-Ethoxycarbonyloctyl 3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (**4**a; 15)*

To a mixture of the bromide **2** (1.5 g, 3.01 mmol) and silver zeolite (1.5 g) in dry dichloromethane (9 mL) was added a solution of 8-ethoxycarbonyloctylalcohol (**3***a*; 0.73 g, 3.61 mmol) prepared according to ref. 10 in dichloromethane (9 mL) under stirring and protection from light at room temperature.[4] After 18 h, an additional amount of **3***a* (0.12 g, 0.60 mmol) in dichloromethane (2 mL) was

[4]This compound and some other intermediates were purchased from TRC (Toronto Research Chemicals), 4483 Chesswood Drive, Downsview, Ont., Canada M5J 2C3.



SCHEME 1

added and stirring in the dark was continued for 22 h. The mixture was then filtered through Celite, the Celite was washed with dichloromethane, the combined filtrates and washings (100 mL) were washed with cold aqueous sodium bicarbonate (100 mL) and water (2 × 50 mL), dried over Mg_2SO_4, and concentrated to give a light yellow syrup (2.13 g). The latter was subjected to chromatography on a silica gel column using hexane/ethyl acetate (3:1) to give slightly yellow syrupy **4***a* (1.0 g, 54%), R_f 0.42 (sixfold development in the above solvent mixture); $[\alpha]_D$ +21.2° (c. 1.3, $CHCl_3$); ir (neat) 1780, 1750, 1720 cm^{-1} (CO); ^1H nmr δ: 7.75–7.92 (m, 4H, $N[CO]_2C_6H_4$), 5.80 (dd, 1H, J = 10.7 and 9.1 Hz, H-3), 5.36 (d, 1H, J = 8.5 Hz, H-1), 5.19 (dd, 1H, J = 10.0 and 9.3 Hz, H-4), 4.29–4.37 (m, 2H, H-2 and H-6), 4.18 (dd, 1H, J = 12.3 and 2.3 Hz, H-6′), 4.13 (q, J = 7.1 Hz, OCH_2CH_3), 3.81–3.90 and 3.40–3.47 (2m, 3H, H-5, and $OCH_2(CH_2)_7$), 2.21 (t, 2H, J = 7.4 Hz, CH_2COOEt), 2.12, 2.04, 1.87 (3s, 9H, CH_3COO), 1.26 (t, 3H, J = 7.1 Hz, CH_2CH_3), 1.35–1.58 and 0.90–1.16 (2m, 12H, $[CH_2]_6$). *Anal.* calcd. for $C_{31}H_{41}NO_{12}$ (619.263): C 60.09, H 6.67, N 2.26; found: C 59.83, H 6.42, N 2.18. Molecular ions observed: $[MH]^+$ 620, $[MNa]^+$ 642.

*8-Methoxycarbonyloctyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-*D*-glucopyranoside (**4**b)*

To a mixture of the bromide **2** (0.5 g, 1.00 mmol) and silver zeolite (0.5 g) in dry dichloromethane (3 mL) was added a solution of

TABLE 1. Competition analyses of two rabbit sera raised against **15***b*[a]

Competitor[a]	C_{50} Rabbit 1	C_{50} Rabbit 2
15*b*	5×10^{-9}	7×10^{-9}
15*c*	6×10^{-7}	5×10^{-7}
16	1.4×10^{-5}	4×10^{-4}
17	3×10^{-4}	4×10^{-4}

[a]C_{50} is the molar concentration of carbohydrates and glycoconjugates required to inhibit 50% of the binding of a non-saturating concentration of rabbit sera (2×10^{-4}) using a solid phase immunoassay. The solid phase substrate was **15***c* and the detection of solid phase binding of antibodies was with ^{125}I-protein A. Compounds used in competition experiments were preincubated with the dilution of rabbit sera for 16 h in the presence of 1% BSA prior to the assay at 4°C. **16** is GlcNAcβ1,4(Fucα1,6)GlcNaCβ1,OMe; **17** is GlcNAcβ1,BSA. Other compounds tested were not effective competitors with $C_{50} > 10^{-3}$: GlcNAcβ1,4GlcNAcβ1,OBn (**18**); Fucα1,6GlcNAcβ1,OMe; Fucα1,4(Fucα1,6)GlcNAcβ1,OMe; Fucα1,3Galβ1,OMe; Fucα1,OMe; GlcNAcβ1,4GlcNAcβ1,OMe (9); Manα1,3Manα1,OMe; Manα1,6Manα1,OMe; Manα1,3(Manα1,6)Manα1,OMe (21); GlcNAcβ1,2Manα1,3(GlcNAcβ1,2-Manα1,6)Manβ1,4GlcNAcβ1,4GlcNAc; as well as purified oligosaccharides from fetuin, fibrinogen A1, and ovalbumin (these compounds were kindly provided by Dr. D. A. Cumming). Note that 3×10^{-2} of **18** for rabbit 2 was the next most effective concentration.

8-methoxycarbonyloctylalcohol (**3***b*; 0.24 g, 1.28 mmol) prepared according to ref. 10 in dichloromethane (3 mL) under stirring and protection from light at room temperature. After continued stirring for 19 h in dark, the mixture was filtered through Celite, the Celite was washed with dichloromethane, the combined filtrates and washings were washed with water (2 × 50 mL), dried over $MgSO_4$, and concentrated to give a light brown syrup (0.63 g) which was subjected to chromatography on a silica gel column using hexane/ethyl acetate (2:1) giving slightly yellow syrupy **4***b* (0.33 g, 54%), R_f 0.45 (four-fold development in the above solvent mixture); $[\alpha]_D$ +18.5° (c. 1.5, $CHCl_3$); ^{1}H nmr δ: 7.75–7.92 (m, 4H, N[CO]$_2$C$_6$*H*$_4$], 5.79 (dd, 1H, *J* = 10.7 and 9.1 Hz, H-3), 5.36 (d, 1H, *J* = 8.5 Hz, H-1), 5.18 (br t, 1H, *J* = 9.5 Hz, H-4), 4.27–4.37 (m, 2H, H-2 and H-6), 4.18 (dd, 1H, *J* = 12.2 and 2.3 Hz, H-6′), 3.80–3.90 and 3.39–3.47 (2m, 3H, H-5, and OC*H*$_2$(CH$_2$)$_7$), 3.68 (s, 3H, OC*H*$_3$), 2.23 (t, 2H, *J* = 7.5 Hz, C*H*$_2$COOMe), 2.12, 2.03, 1.87 (3s, 9H, C*H*$_3$COO), and 0.92–1.57 (m, 12H, [C*H*$_2$]$_6$). *Anal.* calcd. for $C_{30}H_{39}NO_{12}$ (605.247): C 59.50, H 6.49, N 2.31; found: C 59.71, H 6.61, N 2.28. Molecular ions observed: $[MH]^+$ 606, $[MNa]^+$ 628, $[MNH_4]^+$ 623.

*8-Methoxycarbonyloctyl 2-deoxy-2-phthalimido-β-D-glucopyranoside (**5**)*

Treatment of **4***a* (6.15 g, 9.94 mmol) in dry methanol (100 mL) with 1% sodium methoxide in methanol (100 mL) for 30 min, deionization with Dowex-1 (H^+, 37 mL, prewashed with methanol) at 0°C, addition of ethyl acetate (200 mL), filtration, and evaporation of the filtrate and of added toluene (150 mL) gave a thick syrup of **5** (4.77 g, 99%); R_f 0.43 (ethyl acetate); ir (neat): 3430 (OH), 1770, 1735, 1714 cm^{-1} (CO); ^{1}H nmr δ: 7.78 (m, 4H, N[CO]$_2$C$_6$*H*$_4$), 5.20 (d, 1H, *J* = 8.4 Hz, H-1), 3.66 (s, 3H, OC*H*$_3$), 2.22 (t, 2H, *J* = 7.5 Hz, C*H*$_2$COOCH$_3$). This product was used without further purification.

*8-Methoxycarbonyloctyl 2-deoxy-4,6-O-(4-methoxybenzylidene)-2-phthalimido-β-D-glucopyranoside (**6**)*

To a mixture of **5** (4.76 g, 9.94 mmol) and 4-methoxybenzaldehyde dimethyl acetal (3.3 mL, 19.9 mmol) in acetonitrile (150 mL) was added *p*-toluenesulfonic acid monohydrate (120 mg) (20). The reaction mixture was stirred at room temperature and with light exclusion for 50 min, then it was poured into water (300 mL) and the product was

extracted into diethyl ether (3 × 250 mL). The ethereal solution was washed with cold aqueous sodium bicarbonate (200 mL) and water (200 mL), dried over $MgSO_4$, and evaporated to a light brown syrup which was subjected to chromatography on a silica gel column in hexane/ethyl acetate (2:1) yielding **6** (3.81 g, 64%) as a pale yellow syrup, $[\alpha]_D$ −36.2° (c. 0.87, $CHCl_3$), R_f 0.22 (solvent as above); ir (neat): 3487 (OH), 1778, 1735, 1715 cm^{-1} (CO); ^1H nmr δ: 7.89 and 7.75 (m, 4H, $N[CO]_2C_6H_4$), 7.44 and 6.93 (2m, 4H, $C_6H_4OCH_3$), 5.53 (s, 1H, C_6H_5CH), 5.26 (d, 1H, J = 8.5 Hz, H-1), 4.63 (ddd, 1H, J = 10.4, 8.6, and 3.2 Hz, H-3), 4.38 (dd, 1H, J = 10.4 and 4.2 Hz, H-6), 4.24 (dd, 1H, J = 10.5 and 8.5, H-2), 3.81 (s, 3H, $C_6H_4OCH_3$), 3.66 (s, 3H, $COOCH_3$), 3.37–3.87 (m, 5H, H-4, H-5, H-6′, and $OCH_2[CH_2]_7$), 2.44 (d, 1H, J = 3.3 Hz, exchangeable with D_2O, OH), 2.23 (t, 2H, J = 7.4 Hz, CH_2COOMe), 0.90–1.54 (m, 12H, $(CH_2)_6$). *Anal.* calcd. for $C_{32}H_{39}NO_{10}$ (597.369): C 64.31, H 6.58, N 2.34; found: C 64.42, H 6.61, N 2.39. Molecular ions observed: $[MH]^+$ 598, $[MNa]^+$ 620.

8-Methoxycarbonyloctyl 3-O-benzyl-2-deoxy-4,6-O-(4-methoxybenzylidene)-2-phthalimido-β-D-glucopyranoside (7)

A mixture of **6** (3.63 g, 6.07 mmol) and benzyl bromide (14.3 mL, 121 mmol) in dry THF (20 mL) was added to solid sodium hydride (390 mg, 9.71 mmol, prewashed with dry hexane), and the resulting reaction mixture was stirred in the dark at room temperature for 4 h. Additional sodium hydride (180 mg, 4.48 mmol) was added and the reaction mixture stirred for another 17 h. Then it was diluted with ethyl acetate (50 mL), filtered through Celite, washed with ethyl acetate (3 × 50 mL), and the combined filtrate and washings were washed with water (300 mL). The organic layer was separated, the aqueous layer extracted with ethyl acetate, all organic extracts were combined, washed once again with water (200 mL), dried over $MgSO_4$, and evaporated to dryness. The residue was subjected to chromatography on a silica gel column with hexane/ethyl acetate (3:1) to give **7** (3.76 g, 90%) as colorless plates, mp 88–89°C (hexane/ethyl acetate), $[\alpha]_D$ +27.4° (c. 1.0, $CHCl_3$); R_f 0.37 (two-fold development, the same solvent as above); ir (neat): 1778, 1736, and 1716 cm^{-1} (CO); ^1H nmr δ: 5.58 (s, 1H, C_6H_5CH), 5.18 (d, 1H, J = 8.5 Hz, H-1), 4.78 (2d, 2H, J = 12.3 Hz, $C_6H_5CH_2$), 4.49 (2d, 2H, J = 12.3 Hz, $C_6H_5CH_2$), 3.82 (s, 3H, $C_6H_4OCH_3$), 3.66 (s, 3H, $COOCH_3$), 2.22 (t, 2H, J = 7.5 Hz, CH_2COOMe), 0.90–1.54 (m, 12H, $(CH_2)_6$). *Anal.* calcd. for $C_{39}H_{45}NO_{10}$ (687.445): C 68.11, H 6.60, N 2.04; found: C 68.33, H 6.65, N 2.18. Molecular ions observed: $[MH]^+$ 688, $[MNa]^+$ 710.

8-Methoxycarbonyloctyl 3-O-benzyl-2-deoxy-6-O-(4-methoxybenzyl)-2-phthalimido-β-D-glucopyranoside (8) (20)

A mixture of **7** (3.62 g, 5.27 mmol), sodium cyanoborohydride (1.66 g, 26.4 mmol), and powdered molecular sieve 3A (5 g) in *N,N*-dimethylformamide (DMF, 40 mL) was stirred for 15 min at room temperature, and a solution of trifluoroacetic acid (4 mL, 52.7 mmol) in DMF (35.7 mL) was then added; stirring was continued for 19 h and, after addition of further trifluoroacetic acid (3.8 mL, 50 mmol), for an additional 24 h. The mixture was then cooled to 0°C, diluted with ethyl acetate (50 mL) and methanol (5 mL), stirred for 5 min and filtered, and the residue was washed with ethyl acetate (3 × 50 mL). The combined filtrates were washed with cold water (200 mL), cold aqueous sodium bicarbonate (200 mL), and water (2 × 100 mL), dried over $MgSO_4$, and evaporated to dryness. Chromatography of the syrupy residue on a silica gel column with hexane/ethyl acetate (2:1) gave **8** (3.01 g, 83%); $[\alpha]_D$ +16.5° (c. 1.1, $CHCl_3$), R_f 0.36 (same solvent as above); ir (neat): 3487 (OH), 1778, 1737, and 1713 cm^{-1} (CO); ^1H nmr δ: 6.90–7.90 (m, 13H, $N[CO]_2C_6H_4$, $C_6H_4OCH_3$, and $C_6H_5CH_2$), 5.11 (d, 1H, J = 8.3 Hz, H-1), 4.75 (d, 1H, J = 12.2 Hz, C_6H_5CH), 4.50–4.60 (m, 3H, C_6H_5CH), 4.21 (dd, 1H, J = 10.7 and 8.3 Hz, H-3), 4.12 (dd, 1H, J = 10.7 and 8.3, H-2), 3.82 (s, 3H, $C_6H_4OCH_3$), 3.66 (s, 3H, $COOCH_3$), 3.26–3.85 (m, 6H, H-4, H-5, H-6, H-6′, and $OCH_2[CH_2]_7$), 3.02 (d, 1H, J = 2.4 Hz, exchangeable with D_2O, OH), 2.21 (t, 2H, J = 7.6 Hz, CH_2COOMe), 0.85–1.53 (m, 12H, $(CH_2)_6$). *Anal.* calcd. for $C_{39}H_{47}NO_{10}$ (689.320): C 67.91, H 6.87, N 2.03; found: C 67.83, H 6.64, N 1.97. Molecular ions observed: $[MH]^+$ 690, $[MNa]^+$ 712, $[MNH_4]^+$ 707.

8-Methoxycarbonyloctyl 3-O-benzyl-2-deoxy-6-O-(4-methoxybenzyl)-2-phthalimido-4-O-(3′,4′,6′-tri-O-acetyl-2′-deoxy-2′-phthalimido-β-D-glucopyranosyl)-β-D-glucopyranoside (9)

A mixture of **8** (323 mg, 0.469 mmol), collidine (0.26 mL, 1.92 mmol), dry nitromethane (1 mL), and silver triflate (482 mg, 1.87 mmol) was stirred at −25°C, and a solution of **2** (934 mg, 1.87 mmol) in dry nitromethane (1 mL) was added. After 30 min the mixture was warmed up slowly to room temperature, and stirring was continued for 4.5 h. Then the mixture was diluted with ethyl acetate (50 mL) and filtered through Celite, which was washed with ethyl acetate (3 × 20 mL), and the combined filtrates and washings were washed with cold water (100 mL), cold 1 *N* HCl (100 mL), cold aqueous sodium bicarbonate (100 mL), and again cold water (100 mL), and dried over $MgSO_4$. The residue obtained after solvent evaporation was subjected to chromatography on a silica gel column with hexane/ethyl acetate (3:2) and gave **9** (345 mg, 66%) as an amorphous solid, $[\alpha]_D$ +3.3° (c. 0.95, $CHCl_3$); R_f 0.30 (two-fold development in hexane/ethyl acetate 2:1); ir (neat) 1780, 1750, 1717 cm^{-1} (CO); ^1H nmr δ: 6.85–7.90 (m, 17H, $N[CO]_2C_6H_4$, $C_6H_4OCH_3$, and $C_6H_5CH_2$), 5.78 (dd, 1H, J = 10.7 and 9.1 Hz, H-3′), 5.49 (d, J = 8.4 Hz, H-1′), 5.11 (dd, 1H, J = 10.0 and 9.2 Hz, H-4′), 4.92 (d, 1H, J = 8.2 Hz, H-1), 4.82 (d, 1H, J = 12.6 Hz, $C_6H_5CH_2$), 4.46–4.49 (m, 3H, C_6H_5CH), 4.32 (dd, 1H, J = 10.7 and 8.4, H-2′), 3.83 (s, 3H, $C_6H_4OCH_3$), 3.65 (s, 3H, $COOCH_3$), 3.19–4.23 (m, 11H, H-2, H-3, H-4, H-5, 2H-6, H-5′, 2H-6′, and $OCH_2[CH_2]_7$), 2.19 (t, 2H, J = 7.5 Hz, CH_2COOMe), 2.01, 1.97, 1.85 (3s, 9H, CH_3COO), and 0.80–1.50 (m, 12H, $(CH_2)_6$). *Anal.* calcd. for $C_{59}H_{66}N_2O_{19}$ (1106.426): C 64.01, H 6.01, N 2.53; found: C 63.98, H 5.88, N 2.49. Molecular ions observed: $[MH]^+$ 1107, $[MNa]^+$ 1129, $[MNH_4]^+$ 1124.

*8-Methoxycarbonyloctyl 3-O-benzyl-2-deoxy-2-phthalimido-4-O-(3′,4′,6′-tri-O-acetyl-2′-deoxy-2′-phthalimido-β-D-glucopyranosyl)-β-D-glucopyranoside **10** (20)*

To a stirred solution of **9** (419 mg, 0.379 mmol) in acetonitrile/water (9:1, 1.5 mL) at 0°C was added ammonium cerium(IV) nitrate (415 mg, 0.758 mmol) and stirring was continued at 0°C for 10 min and then at room temperature for 45 min. The mixture was diluted with ethyl acetate (100 mL), washed with water (2 × 50 mL), dried with $MgSO_4$, and the solvent evaporated to a syrup which was subjected to chromatography on a silica gel column. Elution with hexane/ethyl acetate (3:1) gave unreacted **9** (24 mg, 6%), followed by **10** (319 mg, 86%) which was a colorless solid, mp 142.5–144.6°C (ethyl ether/hexane); $[\alpha]_D$ +10.3° (c. 1.1, $CHCl_3$); R_f 0.17 (ethyl ether/hexane, 1:1); ir (neat) 3485, 3525 (OH), 1777, 1750, and 1718 cm^{-1} (CO); ^1H nmr δ: 6.80–7.95 (m, 13H, $N[CO]_2C_6H_4$ and $C_6H_5CH_2$), 5.80 (dd, 1H, J = 10.6 and 9.1 Hz, H-3′), 5.65 (d, 1H, J = 8.3 Hz, H-1′), 5.16 (dd, 1H, J = 10.0 and 9.2 Hz, H-4′), 4.99 (d, 1H, J = 8.6 Hz, H-1), 4.86 (d, 1H, J = 12.7 Hz, $C_6H_5CH_2$), 4.46 (d, 1H, C_6H_5CH), 4.35 (dd, 1H, J = 10.6 and 8.3, H-2′), 3.65 (s, 3H, $COOCH_3$), 3.22–4.32 (m, 11H, H-2, H-3, H-4, H-5, 2H-6, H-5′, 2H-6′, and $OCH_2[CH_2]_7$), 2.19 (t, 2H, J = 7.5 Hz, CH_2COOMe), 2.00, 1.99, 1.84 (3s, 9H, CH_3COO), 1.73 (dd, 1H, J = 8.8 Hz and 4.3 Hz, exchangeable with D_2O, OH), and 0.80–1.50 (m, 12H, $(CH_2)_6$). *Anal.* calcd. for $C_{51}H_{58}N_2O_{18}$ (986.368): C 62.06, H 5.92, N 2.84; found: C 62.21, H 6.03, N 2.73. Molecular ions observed: $[MH]^+$ 987, $[MNa]^+$ 1009, $[MNH_4]^+$ 1004.

8-Methoxycarbonyloctyl 4-O-(3′,4′,6′-tri-O-acetyl-2′-deoxy-2′-phthalimido-β-D-glucopyranosyl)-6-O-(2″,3″,4″-tri-O-benzyl-α-L-fucopyranosyl)-3-O-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (11)

A mixture of **10** (312 mg, 0.315 mmol), tetraethylammonium bromide (1.32 g, 6.30 mmol), and powdered molecular sieve 4A (2.33 g) in dry dichloromethane (6 mL) was stirred in the dark at room temperature for 1 h. A solution of freshly prepared tri-*O*-benzyl-α-L-fucopyranosyl bromide (ref. 13*a*; 626 mg, 1.26 mmol) in dry dichloromethane (ref. 13*b*; 5 mL) was then added, and the reaction mixture was slowly stirred for 44 h. It was diluted with dichloromethane (60 mL) and filtered through Celite, which was washed with dichloromethane

(2 × 30 mL), and the combined filtrate and washings were washed with water (2 × 100 mL), dried over $MgSO_4$, and evaporated to give a syrupy residue that was subjected to chromatography on a silica gel column with hexane/ethyl acetate (2:1). Together with unreacted **10** (19 mg, 2%), **11** (347 mg, 79%) was obtained as an amorphous solid, $[\alpha]_D$ −51.9° (c. 1.0, $CHCl_3$); R_f 0.30 (two-fold development in the above solvent); ir (neat) 1779, 1750, and 1718 cm^{-1} (CO); ^1H nmr δ: 6.80–7.95 (m, 28H, $N(CO)_2C_6H_4$ and $C_6H_5CH_2$), 5.72 (dd, 1H, J = 10.7 and 9.2 Hz, H-3′), 5.63 (d, 1H, J = 8.4 Hz, H-1′), 5.09 (d, 1H, J = 3.3 Hz, H-1″), 4.91 (d, 1H, J = 8.3 Hz, H-1), 3.64 (s, 3H, $COOCH_3$), 2.19 (t, 2H, J = 7.5 Hz, CH_2COOMe), 1.91, 1.87, and 1.83 (3s, 9H, CH_3COO), and 1.04 (d, 3H, J = 6.5 Hz, H-6″). *Anal.* calcd. for $C_{78}H_{86}N_2O_{22}$ (1402.567): C 66.75, H 6.18, N 2.00; found: C 66.61, H 6.11, N 1.94. Molecular ions observed: $[MH]^+$ 1403, $[MNa]^+$ 1425, $[MNH_4]^+$ 1420.

*8-Methoxycarbonyloctyl 2-acetamido-4-*O*-(2′-acetamido-3′,4′,6′-tri-*O*-acetyl-2′-deoxy-β-*D*-glucopyranosyl)-3-*O*-benzyl-6-*O*-(2″,3″,4″-tri-*O*-benzyl-α-*L*-fucopyranosyl)-2-deoxy-β-*D*-glucopyranoside (**12**)*

A solution of **11** (591 mg, 0.422 mmol) and hydrazine acetate (1.17 g, 12.7 mmol) in dry methanol (20 mL) was boiled under reflux for 3 h, then another portion of hydrazine acetate (1.17 g, 12.7 mmol) was added and the refluxing continued for 4.5 h. After cooling, the reaction mixture was evaporated to dryness and treated with acetic anhydride (14 mL) in pyridine (15 mL) at room temperature for 19 h. The mixture was diluted with ethyl acetate (200 mL) and washed with cold water (100 mL), 1 *N* HCl (2 × 100 mL), and water (100 mL). The organic layer was dried over $MgSO_4$, the solvent evaporated, and the pale yellow solid residue was subjected to chromatography on silica gel using ethyl acetate/hexane (3:1), to give pure **12** (423 mg, 82%) as a colorless solid, mp 186–188°C; $[\alpha]_D$ −42.5° (c. 0.76, $CHCl_3$); R_f 0.12 (the above solvent); ir (neat) 3305 (NH), 1748 (COOR), and 1662 (CONH); ^1H nmr δ: 7.20–7.50 (m, 20H, $C_6H_5CH_2$), 6.22 (d, 1H, J = 9.4 Hz, N*H*), 5.56 (d, 1H, J = 8.7 Hz, N*H*), 5.00 (d, 1H, J = 9.6 Hz, H-1′), 4.66 (d, 1H, J = 2.5 Hz, H-1″), 4.43 (d, 1H, J = 6.9 Hz, H-1), 3.65 (s, 3H, $COOCH_3$), 2.28 (t, 2H, J = 7.5 Hz, CH_2COOMe), 2.03, 1.98, 1.94, 1.87, and 1.82 (5s, 15H, CH_3COO), 1.20–1.65 (m, 12H, $[CH_2]_6$), and 1.04 (d, 3H, J = 6.4 Hz, H-6″). *Anal.* calcd. for $C_{66}H_{86}N_2O_{20}$ (1226.577): C 64.59, H 7.06, N 2.28; found: C 64.67, H 7.20, N 2.33. Molecular ions observed: $[MH]^+$ 1227, $[MNa]^+$ 1249.

*8-Methoxycarbonyloctyl 2-acetamido-4-*O*-(2′-acetamido-3′,4′,6′-tri-*O*-acetyl-2′-deoxy-β-*D*-glucopyranosyl)-6-*O*-(α-*L*-fucopyranosyl)-2-deoxy-β-*D*-glucopyranoside (**13**)*

Hydrogenolysis of **12** (179 mg, 0.146 mmol) on 10% Pd/C in ethyl acetate/methanol (1:3, 20 mL) gave, after filtration through Celite and evaporation of the solvent, colorless **13** (118 mg, 94%), which was unstable on standing. R_f 0.40 (ethyl acetate/methanol, 5:1); ^1H nmr δ: 5.11 (t, 1H, J = 9.8 Hz, H-3′), 5.02 (t, 1H, J = 9.7 Hz, H-4′), 4.81 (d, 1H, J = 1.8 Hz, H-1″), 4.73 (d, 1H, J = 8.6 Hz, H-1′), 4.39 (d, 1H, J = 7.8 Hz, H-1), 3.67 (s, 3H, $COOCH_3$), 3.40–4.28 (m, 16H, H-2, H-3, H-4, H-5, 2H-6, H-2′, H-5′, 2H-6′, H-2″, H-3″, H-4″, H-5″, $CH_2[CH_2]_7$), 2.30 (t, 2H, J = 7.5 Hz, CH_2COOCH_3), 2.09, 2.02, 2.01, 2.00, and 1.96 (5s, 15H, CH_3COO), and 1.20–1.65 (m, 15H, H-6″ and $CH_2[CH_2]_6COOCH_3$).

*8-Methoxycarbonyloctyl 2-acetamido-4-*O*-(2′-acetamido-3′,4′,6′-tri-*O*-acetyl-2′-deoxy-β-*D*-glucopyranosyl)-6-*O*-(2″,3″,4″-tri-*O*-acetyl-α-*L*-fucopyranosyl)-3-*O*-acetyl-2-deoxy-β-*D*-glucopyranoside (**14**)*

Compound **13** (120 mg, 0.139 mmol) was treated with acetic anhydride (1.5 mL) in dry pyridine (2 mL) for 19 h. The reaction mixture was diluted with ethyl acetate (100 mL), washed with cold water (50 mL), 1 *N* HCl (2 × 50 mL), and water (50 mL), dried ($MgSO_4$), and evaporated to give a colorless, syrupy residue. The latter was subjected to chromatography on a silica gel column using ethyl acetate to give **14** (113 mg, 79%); $[\alpha]_D$ −69.2° (c. 1.0, $CHCl_3$); R_f 0.12 (ethyl acetate), 0.64 (ethyl acetate/methanol 9:1); ^1H nmr δ: 5.68 (d, 1H, J = 7.9 Hz, exchangeable with D_2O, N*H*), 5.60 (d, 1H, J = 8.6 Hz, exchangeable with D_2O, N*H*), 5.07 (d, 1H, J = 3.6 Hz, H-1″), 4.96 (d, 1H, J = 8.4 Hz, H-1′), 4.51 (d, 1H, J = 7.8 Hz, H-1), 4.30 (br, q, 1H, J = 6.2 Hz, H-5″), 3.66 (s, 3H, $COOCH_3$), 2.30 (t, 2H, J = 7.5 Hz, CH_2COOCH_3), 2.18, 2.15, 2.07, 2.01, 2.00, 1.96, and 1.91 (7s, 27H, CH_3COO), 1.28–1.61 (m, 12H, $CH_2[CH_2]_6CH_2COOCH_3$), and 1.13 (d, 3H, J = 6.4 Hz, H-6″). *Anal.* calcd. for $C_{46}H_{70}N_2O_{24}$ (1034.432): C 53.38, H 6.82, N 2.71; found: C 53.46, H 6.91, N 2.83. Molecular ions observed: $[MH]^+$ 1035, $[MNa]^+$ 1057.

*8-Methoxycarbonyloctyl 2-acetamido-4-*O*-(2′-acetamido-2′-deoxy-β-*D*-glucopyranosyl)-6-*O*-α-*L*-fucopyranosyl-2-deoxy-β-*D*-glucopyranoside (**15**a)*

Zemplén deacetylation of **14** (78 mg, 0.075 mmol) in methanol (2 mL) was performed as described for the preparation of **5**. The trisaccharide **15***a* (50 mg, 91%) was obtained as colorless solid, mp 283–286°C (aqueous ethanol), $[\alpha]_D$ −63.5° (c. 0.42, 50% aqueous ethanol); ^1H nmr δ: 4.90 (d, 1H, J = 3.8 Hz, H-1″), 4.64 (d, 1H, J = 8.4 Hz, H-1′), 4.49 (d, 1H, J = 7.8 Hz, H-1), 4.13 (br, t, 1H, J = 6.5 Hz, H-5″), 3.68 (s, 3H, $COOCH_3$), 3.40–3.95 (m, 17H, H-2, H-3, H-4, H-5, 2H-6, H-2′, H-3′, H-4′, H-5′, 2H-6′, H-2″, H-3″, H-4″, $OCH_2[CH_7]$), 2.39 (t, 2H, J = 7.4 Hz, CH_2COOCH_3), 2.08 and 2.03 (2s, 6H, CH_3COO), 1.58 and 1.30 (m, 12H, $CH_2[CH_2]_6CH_2COOCH_3$), and 1.23 (d, 3H, J = 6.6 Hz, H-6″). *Anal.* calcd. for $C_{32}H_{56}N_2O_{17}$ (740.358): C 51.88, H 7.62, N 3.78; found: C 51.92, H 7.83, N 3.88. Molecular ions observed: $[MH]^+$ 741, $[MNa]^+$ 763.

Hydrazide

Compound **15***a* (35 mg, 0.047 mmol) and hydrazine hydrate (1.6 mL) were stirred in dry ethanol (4.6 mL) at room temperature for 24 h. The mixture was evaporated to dryness, and the residue was evaporated from water (2 × 12 mL) to give the hydrazide as a colorless solid (36 mg) that was used in the next step without purification.

Coupling reaction with BSA

To a solution of the hydrazide (21 mg, 0.029 mmol) in DMF (0.4 mL) stirred at −40 to −30°C, was added a solution of dinitrogen tetroxide (11) in dichloromethane (0.46 *M*, 0.08 mL). Stirring was continued at −20 to −10°C for 45 min, then this solution was added to a buffered solution ($KHCO_3/Na_2B_4O_7$; pH 8.93; 9.4 mL) of bovine serum albumin (purified, 94 mg, 0.00145 mmol) under stirring at 0°C, and the stirring was continued for 25 h. The mixture was then dialyzed against water (5 × 100 mL) using an Amicon ultrafiltration cell (Model 402) equipped with a YM-10 membrane. After lyophilization, **15***b* (97 mg) was obtained as a colorless solid. The carbohydrate content was determined according to ref. 16 as 10.5 carbohydrate equiv. per BSA molecule.

Coupling reaction with poly-L-lysine

Hydrazide (17 mg, 0.023 mmol) was treated with dinitrogen tetroxide as in the previous reaction; however, instead of BSA, poly-L-lysine (mw 16 000); 96 mg, 0.006 mmol) in buffer (9.6 mL) at 0°C was used. After 44 h the reaction mixture was dialyzed against water (5 × 100 mL) using a YM-2 membrane, and lyophilized to give **15***c* as a pale yellow solid (47 mg). The incorporation level was determined as above as 1.9 carbohydrate equiv. per poly-L-lysine molecule.

Immunization protocol (17)

Rabbits were immunized subcutaneously with 200 μg of **15***b* (0.2 mL in 0.15 *M* NaCl) and equal volume of Freund's complete adjuvant at four sites at the back of the neck. Boosting immunizations were performed with the same amount of **15***b* and incomplete Freund's adjuvant weekly for 3 weeks. After a resting period of 2 weeks, the animals were again immunized with 400 μg of **15***b* in PBS (0.4 mL) in the ear vein, and blood samples were taken after 1 week.

Solid-phase radioimmunoassay (RIA) and competition analysis

The solid phase RIA was performed using 86-well acrylic plastic plates (Flow laboratories) that were incubated with **15***c* at 20 μg/mL

for 16 h at room temperature. Following washing in ST buffer (0.15 *M* NaCl, 0.01 *M* TRIS, pH 8), the plates were blocked with 0.5% gelatin in ST.

The solid-phase binding of rabbit sera was measured by incubating the plates for 4 h at room temperature with 50 mL rabbit sera diluted in 1% BSA-ST, washing in ST buffer, amplifying for 2 h with ^{125}I-protein A prepared according to ref. 18 (3×10^4 cpm/well). A non-saturating concentration of rabbit sera was determined for use in the competition analysis.

The compounds used in competition experiments prepared in our laboratories (9, 14, 21) were preincubated with this dilution of rabbit sera (2×10^{-4}) in 1% BSA-ST buffer for 16 h at 4°C. The residual activity was determined in the solid phase RIA, and the percent inhibition was calculated for a titration of the competitor.

Viscosities of dilute aqueous suspensions of montmorillonite and kaolinite clays[1]

KIM L. KASPERSKI, CHARLES T. HEPLER, AND LOREN G. HEPLER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 11, 1986

KIM L. KASPERSKI, CHARLES T. HEPLER, and LOREN G. HEPLER. Can. J. Chem. **64**, 1919 (1986).

We have measured viscosities and densities of dilute aqueous suspensions of Na-kaolinite (25°C), of Na-montmorillonite (25–55°C), and of mixtures of Na-kaolinite/Na-montmorillonite (25°C). Results of the measurements at 25°C have been analyzed in terms of the Einstein equation with conclusions that are consistent with previous knowledge that colloidal particles of these clays are non-spherical and that montmorillonite is a swelling clay. Viscosities of mixed clay systems are nearly consistent with a simple additivity model; the small non-additivities are in accord with previous evidence that relatively small montmorillonite particles are adsorbed on the surface of relatively large kaolinite particles. The effect of temperature on the viscosities of suspensions of montmorillonite is consistent with the idea that aggregation of clay particles diminishes with increasing temperature.

KIM L. KASPERSKI, CHARLES T. HEPLER et LOREN G. HEPLER. Can. J. Chem. **64**, 1919 (1986).

On a mesuré les viscosités et les densités de suspensions aqueuses diluées de kaolinite de sodium (25°C), de montmorillonite de sodium (25–55°C) et de mélanges de kaolinite de sodium/montmorillonite de sodium (25°C). On a analysé les résultats des mesures à 25°C en fonction de l'équation de Einstein et les conclusions sont en accord avec nos connaissances antérieures sur le fait que les particules colloïdales de ces argiles ne sont pas sphériques et que la montmorillonite est une argile qui se gonfle. Les viscosités des systèmes mixtes d'argiles sont en accord presque parfait avec un modèle simple d'additivité; les faibles différences à l'additivité sont en accord avec les données antérieures à l'effet que les particules relativement faibles de montmorillonite sont adsorbées sur la surface de particules relativement grosses de kaolinite. L'effet de la température sur les viscosités de suspensions de montmorillonite est en accord avec l'idée que l'aggrégation de particules d'argile diminue avec une augmentation de la température.

[Traduit par la revue]

Introduction

Colloidal suspensions of clays in water and aqueous solutions have been investigated in many ways, including many investigations of rheological properties. Because of applications in such fields as ceramics and drilling muds, most of these investigations have been concerned with concentrated suspensions in which non-Newtonian flow is important. There have been only a few investigations of the viscosities of dilute suspensions, in spite of their general theoretical importance and also their practical importance in such areas as enhanced oil recovery and water treatment. Our particular interest has been in the flow properties of dilute suspensions of clays, including investigations of mixed-clay systems that may be important in connection with problems involving oil sands tailings as well as to problems related to permeabilities in enhanced oil recovery.

As background for our research we cite a few previous investigations of viscosities of dilute suspensions of clays (1–6) and evidence for interesting and potentially important interactions of different kinds of clays with each other in dilute suspensions (7, 8).

Experimental

Materials

Well-characterized clay samples were obtained from the Source Clay Mineral Repository, Department of Geology, University of Missouri, Columbia, MO, U.S.A. The kaolinite (KGa-1) came from Washington County, GA, and the montmorillonite (SWy-1) came from Crook County, WY. Our preparations of Na-kaolinite and Na-montmorillonite for subsequent use followed procedures that have been described previously (9, 10).

Apparatus and methods

Densities of suspensions were obtained with glass pycnometers of 25 cm^3 nominal volume, which we calibrated at each temperature with distilled water. Uncertainties in most of our densities of clay suspensions are less than ± 0.0005 g cm^{-3}.

Cannon-Fenske glass viscometers (ASTM 25 and 50) from Fisher Scientific were calibrated with distilled water and with 0.010 *M* NaOH at each temperature. Flow times ranged from 1 to 20 min, as timed with a stopwatch; total timing uncertainties (due to the stopwatch and our response times) were about ± 0.1 s. At the low flow rates of our measurements, we had no complications due to non-Newtonian flow and were correspondingly unable to investigate the non-Newtonian rheology that becomes important at higher flow rates and for more concentrated suspensions (2, 3, 5, 11).

Particular care was taken with cleaning the viscometers between measurements, because of the tendency of clay particles to adhere to the walls of the capillaries of the viscometers, which was particularly troublesome with our most concentrated suspensions.

All measurements were done with pycnometers and viscometers suspended in a constant temperature water bath with temperature known to ± 0.01°C and stable to ± 0.005°C, as checked with a platinum resistance thermometer.

Results and calculations

Results of our measurements leading to densities and viscosities of suspensions of Na-kaolinite and Na-montmorillonite at 25.00°C are summarized in Tables 1 and 2, respectively, and illustrated in Fig. 1, which is based on eq. [8] that is presented later.

We want to calculate the volume fractions of dry clay in our various suspensions, which requires that we know the density of our solid dry clays. Previous investigations of similar clays have led to reported densities ranging from 2.4 to 2.8 g cm^{-3} for Na-montmorillonite (4, 5, 12, 13) and 2.58 to 2.63 g cm^{-3} for Na-kaolinite (12, 14). Largely because of the substantial range in reported densities for Na-montmorillonite, we use our densities of suspensions to obtain our own values for the densities of the dry clays we have used, as follows.

We begin by assuming that the volumes of clay (V_c) and water (V_w) are additive so that the volumes of suspensions (V_s)

[1]The first part of this research was done in the Department of Chemistry, University of Lethbridge, Lethbridge, Alta.

TABLE 1. Densities and viscosities of suspensions of Na-kaolinite in 0.010 *M* NaOH at 25.00°C

Wt.% clay	Density (g cm^{-3})	Viscosity (mPa s)	ϕ_d	$[(n - n_0)/\phi_d n_0]^a$
1.180	1.005	0.909	0.00453	4.2
2.017	1.010	0.920	0.00778	4.0
2.912	1.016	0.942	0.0113	5.0
3.787	1.021	0.956	0.0148	4.9

1.80	1.0083	3.031	6.98×10^{-3}	345
2.00	1.0095	3.622	7.77×10^{-3}	395
2.20	1.0109	4.767	8.55×10^{-3}	509

are given by

[1] $V_s = V_c + V_w$

Very accurate results reported by Low (13) provide support for the validity of eq. [1] to the level of accuracy that we require here. Some algebraic manipulations with eq. [1] and the definition of density lead to

[2] $d_c = [d_w d_s P]/[100(d_w - d_s) + d_s P]$

where d_c, d_s, and d_w represent the densities of dry clay, aqueous suspension, and water, respectively, and P represents the weight percent clay in the suspension. Because of the term $(d_w - d_s)$ in eq. [2] and the ± 0.0005 g cm^{-3} uncertainties in our values of d_s, this equation is useful only when applied to solutions more concentrated than about 1% clay. Our calculations with eq. [2] applied to densities of our suspensions lead to $d_c = 2.6 \pm 0.1$ g cm^{-3} for dry Na-kaolinite and the same value for dry Na-montmorillonite, in which ± 0.1 g cm^{-3} is our estimate of the *total* uncertainty due to our experimental results and the initial assumption that volumes are additive.

There is also another way to calculate d_c from our results. Solution chemists have found it useful to define "apparent molar" properties for solutions of small molecules and "apparent specific" properties for solutions of high molecular weight polymers, with the latter being appropriate to our problem. In similar fashion we define the apparent specific volume of clay (V_ϕ) as

[3] $V_\phi = (V_s - V_w)/m_c$

in which V_s represents the volume of a suspension containing a specified amount of water, V_w represents the volume of that same amount of water, and m_c represents the mass of dry clay in the suspension. Algebraic manipulations similar to those that led to eq. [2] lead to

[4] $V_\phi = [100(d_w - d_s)/(d_s d_w P)] + [1/d_w]$

in which the symbols have already been defined.

In eq. [4], just as in eq. [2], we have a $(d_w - d_s)$ term that limits useful calculations to suspensions containing more than about 1% clay. Calculations with data from Tables 1 and 2 in eq. [4] lead to $V_\phi = 0.387$ cm^3 g^{-1} for each of our clays. Since the reciprocal of V_ϕ is the density, we again obtain $d_c = 2.6$ g cm^{-3} for each of our clays. This value of d_c is *not* an independent confirmation of our identical value based on eq. [2] since our use of eq. [4] is also based on the implied validity of eq. [1].

Now we use the above $d_c = 2.6$ g cm^{-3} for dry clay as follows to obtain the volume fraction of dry clay in water (ϕ_d) that will be used in subsequent calculations with the Einstein equation. Choosing to consider 100 g of suspension, we obtain

[5] $\phi_d = V_c/V_s = P d_s/100 d_c$

Values of ϕ_d, the volume fraction of dry clay, are listed in Tables 1 and 2 for Na-kaolinite and Na-montmorillonite.

A simple way to start the analysis of viscosity data for suspensions is in terms of the Einstein equation, which we write

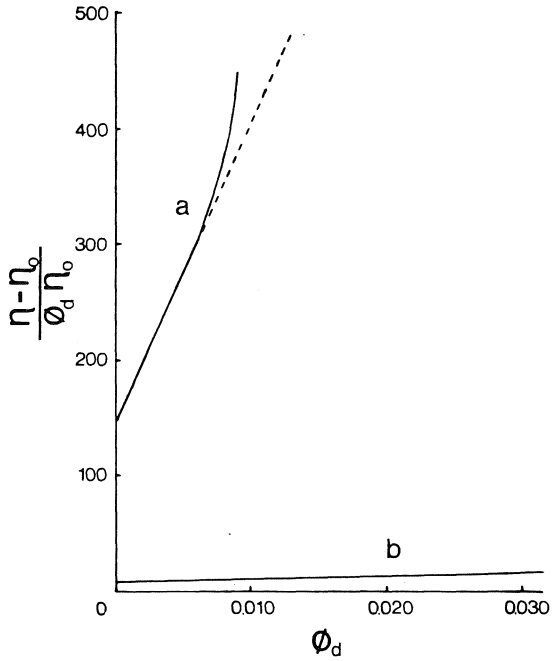

FIG. 1. Graphs of reduced viscosity ($(n - n_0)/\phi_d n_0$) against volume fraction of dry clay (ϕ_d) for montmorillonite (*a*) and kaolinite (*b*). The dashed line for montmorillonite is an extension of the straight line corresponding to $(AS)_m = 148$ and $(BS^2)_m = 2.6 \times 10^4$ and is drawn to show the deviation from linearity above a value of about 0.006 for ϕ_d.

TABLE 3. Densities and viscosities of 0.30 wt.% Na-montmorillonite in water at various temperatures

Temperature (°C)	Density (g cm^{-3})	Viscosity (mPa s)	ϕ_d	$[(n - n_0)/\phi_d n_0]$
25.0	0.9988	1.067	1.15×10^{-3}	173
35.0	0.9959	0.870	1.15×10^{-3}	182
45.0	0.9917	0.721	1.14×10^{-3}	184
55.0	0.9881	0.608	1.14×10^{-3}	181

TABLE 4. Densities and viscosities of 2.20 wt.% Na-montmorillonite in water at various temperatures

Temperature (°C)	Density (g cm^{-3})	Viscosity (mPa s)	ϕ_d	$[(n - n_0)/\phi_d n_0]$
25.0	1.0109	4.767	8.55×10^{-3}	509
35.0	1.0083	4.011	8.53×10^{-3}	536
45.0	1.0044	3.457	8.50×10^{-3}	565
55.0	0.9996	3.020	8.46×10^{-3}	590

as

[6] $(n - n_0)/n_0 = A\phi + B\phi^2 + \ldots$

In this equation n and n_0 represent the viscosities of the suspension and of the pure solvent, ϕ is the volume fraction of the suspended particles, and A and B are constants. It should be emphasized that ϕ refers to the volume fraction of clay particles as they exist in suspension; that is, ϕ refers to the volume fraction of swollen clay particles whereas it is the volume fraction of dry clay (ϕ_d) that we know and have listed in Tables 1 and 2. All we can do now is recognize that ϕ and ϕ_d are related by a "swelling factor" that we denote by S so that

[7] $\phi = S\phi_d$

Substitution of eq. [7] into eq. [6] and rearrangement leads to

[8] $(n - n_0)/\phi_d n_0 = (AS) + (BS^2)\phi_d + \ldots$

As suggested by this equation, we have calculated the values of the reduced viscosities, $[(n - n_0)/\phi_d n_0]$, that are listed in Tables 1 and 2 and have constructed graphs of these reduced viscosities against ϕ_d as in Fig. 1. Least-squares fits of eq. [8] to our experimental results lead to $(AS)_m = 148$ and $(BS^2)_m = 2.6 \times 10^4$ for Na-montmorillonite and to $(AS)_k = 3.5$ and $(BS^2)_k = 1.1 \times 10^2$ for Na-kaolinite, where the subscripts m and k refer to montmorillonite and kaolinite, respectively.

Einstein's original calculations showed that $A = 2.5$ for spherical particles. Subsequent calculations by others have shown that $A > 2.5$ for particles of non-spherical shape, such as the clays of present interest. Since it is known that montmorillonite is a swelling clay (14), we also know that $S_m > 1$. On the basis that $A_m > 2.5$ and $S_m > 1$, it is expected that $(AS)_m$ should be substantially greater than 2.5, as has indeed been found. Kaolinite, however, is not a swelling clay (15), so we expect the difference between $(AS)_k$ and 2.5 to be determined almost entirely by the non-spherical shape of the kaolinite particles.

More quantitative consideration of the magnitudes of A_m and S_m must be based on detailed considerations of the swelling of montmorillonite and on the related hydration of the clay particles in aqueous suspensions as well as on the shapes of the suspended (hydrated) particles. Although these matters are of general scientific interest and are also important in connection with many questions concerning the colloid chemistry of clays in aqueous systems, they extend beyond the realm of the present investigation and must be left as subjects for future investigations.

TABLE 5. Densities and viscosities of pure water at various temperatures

Temperature (°C)	Density (g cm^{-3})	Viscosity (mPa s)
25.0	0.99707	0.8904
35.0	0.99406	0.7194
45.0	0.99025	0.5960
55.0	0.98573	0.5040

The B term in eq. [6] and thence the BS^2 term in eq. [8] is partly determined by particle–particle interactions. Even allowing for the fact that $S_m > S_k$, the conclusion from our results that $(BS^2)_m \gg (BS^2)_k$ shows that particle–particle interactions are stronger in suspensions of montmorillonite (nearly neutral pH) than in suspensions of kaolinite (high pH) of similar concentrations.

Results obtained for the densities and viscosities of suspensions of Na-montmorillonite at several temperatures are given in Tables 3 and 4. Properties of distilled water used in our calculations are given in Table 5. The viscosities and densities decrease with increasing temperature, as expected. For dilute suspensions (0.30 wt.%) the reduced viscosity does not change significantly with temperature, as was also found by Wood, Granquist, and Krieger (1) for suspensions of attapulgite. However, for more concentrated suspensions (2.20 wt.%), the reduced viscosity increases with increasing temperature, which could be the result of a partial breakdown of relatively large nearly spherical structures to smaller less spherical structures, which can account qualitatively for the observed temperature dependence.

Because many natural environments contain mixtures of clays and earlier investigations (7, 8) have shown that there are specific interactions between different clays in aqueous suspen-

sions, we have measured viscosities of some dilute mixed clay systems. Our densities and viscosities of suspensions of mixtures of Na-kaolinite and Na-montmorillonite at five different total clay concentrations (0.25, 0.50, 0.75, 1.00, and 3.00 wt.%) were measured at 25.00°C, with results given in Tables 6–10.

We investigate the possible effects of kaolinite–montmorillonite specific interactions on viscosities by comparing our measured viscosities with those that can be predicted on the basis of a simple additivity principle. This comparison can be done in two ways.

One way to express additivity of viscosity effects is by way of

$$[9]\quad [(n - n_0)/n_0]_{mixture} = [(n - n_0)/n_0]_k + [(n - n_0)/n_0]_m$$

in which $[(n - n_0)/n_0]_k$ and $[(n - n_0)/n_0]_m$ are obtained from eq. [8] multiplied through by ϕ_d, using values of (AS), (BS^2), and ϕ_d appropriate to each component of the mixture. Comparison of results of these calculations with the measured viscosities shows that there are small (relative to uncertainties) deviations from additivity.

The other (effectively equivalent) way of testing our results for additivity is to use the viscosities of mixtures having the same ratio of (kaolinite/montmorillonite) in eq. [8] to permit

evalution of $(AS)_{mix}$ and $(BS^2)_{mix}$ for each (k/m) ratio. To the extent that a simple additivity principle is valid, these $(AS)_{mix}$ and $(BS^2)_{mix}$ values should vary linearly with composition from the values for pure kaolinite to those for pure montmorillonite. We have also found in this way that there are small (relative to uncertainties) deviations from additivity.

The deviations (just barely statistically significant) of viscosities of dilute suspensions of mixed clays from simple additivity justify a brief summary as follows. First, viscosities of dilute suspensions with (k/m) ratios larger than about 0.5 are slightly larger than predicted on the basis of additivity, while viscosities of suspensions with smaller (k/m) ratios are close to those

predicted on the basis of additivity. These observations are consistent with the idea that there are more or stronger particle–particle interactions in the mixed clay suspensions than in corresponding suspensions of single clays, but do not distinguish between adsorption of relatively small montmorillonite particles on the surfaces of relatively large kaolinite particles, as previously suggested (7, 8), and some other kinds of particle–particle interactions. In any case, it should be recognized that the effects of adsorption or other kinds of particle–particle interactions on viscosities of dilute suspensions are less than the effects on electrophoretic mobilities (8) and related ζ potentials.

The relative rate constants of oxygen, $O(^3P)$, atoms with different gaseous unsaturated compounds at room temperature

H. DESLAURIERS AND G. J. COLLIN[1]

Département des sciences fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Received January 28, 1986

H. DESLAURIERS and G. J. COLLIN. Can. J. Chem. **64**, 1925 (1986).

A simple method is proposed in order to measure the relative rate constants of the interactions between oxygen $O(^3P)$ atoms and unsaturated hydrocarbon. A 147 nm photolysis of air is used to produce the $O(^3P)$ atoms. In the presence of 1,2-butadiene, these oxygen atoms have a very clean reaction that gives rise to propylene formation. By including a suitable additive, and by looking at the formation of propene versus the [additive]/[1,2-butadiene] ratio, the absolute values of the various $O(^3P)$ + unsaturated hydrocarbon interactions can be evaluated. These rate constants increase with the number of substituents attached to the double bond. Moreover, a correlation between the total rate constants and ionization potentials is also observed.

H. DESLAURIERS et G. J. COLLIN. Can. J. Chem. **64**, 1925 (1986).

Une méthode relativement simple est proposée pour mesurer les constantes de vitesse relatives de l'interaction entre les atomes d'oxygène, $O(^3P)$, et une variété d'hydrocarbures insaturés. On utilise la photolyse de l'air à 147 nm pour générer les atomes d'oxygène. En présence de butadiène-1,2 ceux-ci conduisent à la formation de propène dans une réaction considérée comme quantitative. En ajoutant un autre additif, et en suivant la formation de propène avec le rapport [additif]/[butadiene-1,2], on peut estimer les valeurs absolues des différentes constantes de vitesse. Celles-ci ont été mesurées dans le cas de 19 additifs et croissent avec le nombre de substituents attachés à la double liaison. En outre, il existe une bonne corrélation entre les constantes de vitesse et les potentiels d'ionisation.

Introduction

In a recent paper from this laboratory, it was shown that a very clean reaction results from the mixture of oxygen atoms $O(^3P)$ with gaseous 1,2-butadiene: the products are carbon monoxide and propene (1):

[1] $CH_2{=}CH{=}CHCH_3 + O(^3P) \rightarrow CO + C_3H_6$

Thus, if a convenient source of oxygen atoms is available, the monitoring of either carbon monoxide or propene formation may be used to measure the relative rate constants of these atoms with different additives. The 147 nm photolysis of molecular oxygen appears to be a convenient source of such atoms (2). In fact, it is well known that, at this wave-length, molecular oxygen has a fairly high absorption coefficient (3), and the photo-excited molecule decomposes very quickly, giving rise to the formation of two oxygen atoms: one $O(^3P)$ and one $O(^1D)$ atom with a quantum yield of one (2). The fate of the $O(^1D)$ atom is straightforward: at room temperature it is deactivated to the $O(^3P)$ state by collision, provided that a suitable quencher is added to the reaction mixture. For example, molecular oxygen itself is a good quencher, as well as many others such as nitrogen, rare gases ... (4). Conversely, $O(^3P)$ atoms are not known to react or to disappear quickly in the presence of these gases.

[2] $O_2 + h\nu(147\text{ nm}) \rightarrow O(^3P) + O(^1D)$
$\phi = 1.0$

[3] $O(^1D) + O_2 \rightarrow O(^3P) + O_2$
$k_3 = 0.75 \times 10^{-10}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$ (4)

[4] $O(^1D) + N_2 \rightarrow O(^3P) + N_2$
$k_4 = 0.55 \times 10^{-10}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$ (4)

Thus, it is to be expected that the 147 nm photolysis of molecular oxygen is a clean source of $O(^3P)$ atoms with a quantum yield of 2.0. Since nitrogen is transparent when submitted to the 147 nm wave-length, air is also a good starting source for these $O(^3P)$ atoms. If small amounts of 1,2-butadiene are added to oxygen, a high propene quantum yield is measured: Φ(propene) $\cong$ 1.6–1.8 with a 1,2-butadiene/oxygen ratio lower than 0.05 (1). This paper relies on these interactions to explain the measurements of the relative rate constants of $O(^3P)$ atoms with different hydrocarbon compounds. In fact, by adding a few percentage points of a convenient compound to a mixture of air and 1,2-butadiene, a decrease in the propylene quantum yield may be expected and, from that decrease, one may have access to the relative rate constants. Of course, comparisons with literature values are also in order.

[1]To whom all correspondance should be addressed.

Experimental techniques

Most of the experimental techniques have already been described. In particular, the preparation of samples, photolytic as well as analytic procedures, and also actinometry, have been recently reported (5). Oxygen — research purity (99.98%) — (Matheson Gas Product Canada), and either Air zero — hydrocarbon content < 2 ppm — or extra dry (Liquid Carbonic), are used as received. The origin and the analysis of the starting hydrocarbon materials are indicated in Table 1.

All experiments were done at room temperature (293 ± 2 K) in a 1/2 liter Pyrex bulb. The photolytic times were generally 1 min and in some cases 3 to 5 min. The number of photon entering the cell was between 9 and 35 × 10^{13} photons per s. With these conditions the percentage of transformation of the hydrocarbon is equal to and generally much less than 0.12%.

Results

In all cases, the addition of small amounts of various unsaturated hydrocarbons to air:1,2-butadiene (485:0.75 Torr) mixtures, results in the decrease of propene quantum yield. Conversely, the photolysis of air:hydrocarbon mixtures does not produce propene Φ(propene) < 0.005 except in three cases which will be identified later. In the cases where no propene is formed in the absence of 1,2-butadiene, the following mechanism may be assumed: to reactions [1]–[4], reaction [5] must be added.

[5] $O(^3P) + RH \rightarrow$ products (no propene)

The steady-state approximation leads to the following relationship. Thus, the inverse of propene quantum yield

[a]American Petroleum Institute, Carnegie Mellon Inst.
[b]Phillips, Research Grade.
[c]Merck, Sharp, and Dohme of Canada.
[d]Some of the impurities may come from our analytical system.

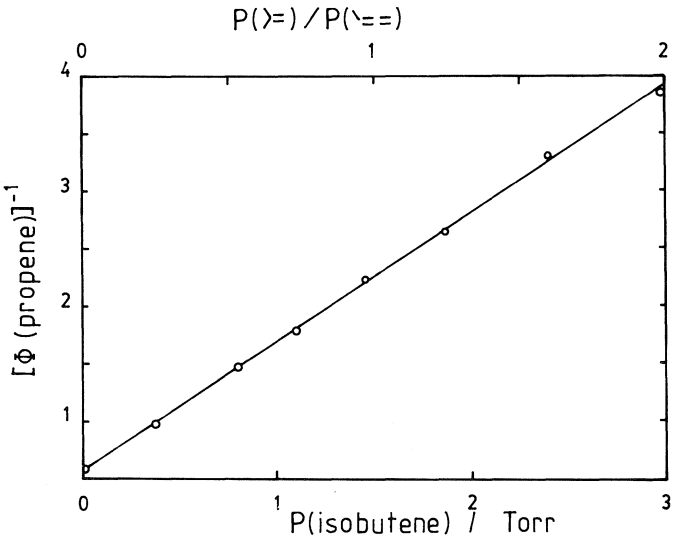

FIG. 1. The 147 nm photolysis of air:1,2-butadiene:isobutene (48:1.5:x Torr) mixtures. The inverse of the propene quantum yield versus the partial pressure of isobutene.

$$[\mathrm{I}] \qquad [\Phi(C_3H_6)]^{-1} = \frac{1}{2\phi} + \frac{k_5}{2k_1\phi}\frac{[RH]}{[1,2\text{-}C_4H_6]}$$

is a linear function of $[RH]/[1,2\text{-}C_4H_6]$ ratio. Figures 1–4 show the plot for expression [I] and for various added compounds. The analytic expressions are given in Table 2, and in each case the slope/intercept ratio gives the pertinent k_5/k_1 one. Using the $k_5[O(^3P)]$ [isobutene] as a standard, the absolute rate constant of $O(^3P)$ + 1,2-C_4H_6 interaction may be calculated (Fig. 1) and through the various k_5/k_1 ratios, each rate constant may be calculated (Table 2 and Fig. 2).

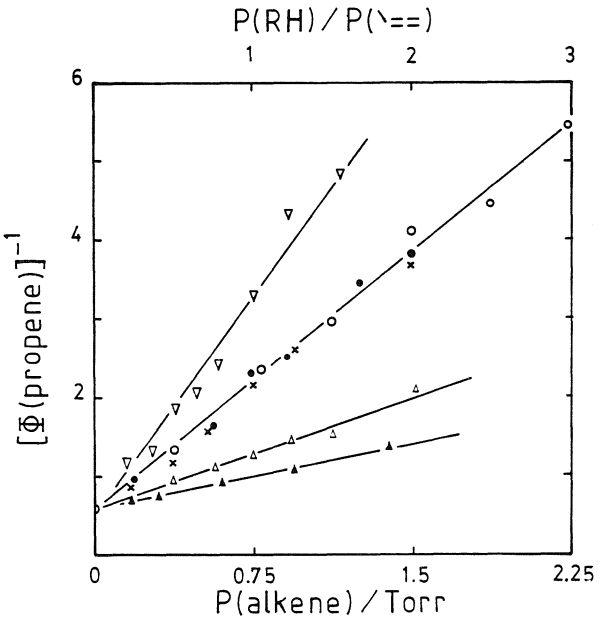

FIG. 2. The 147 nm photolysis of air:1,2-butadiene:alkene (485: 0.74:x Torr) mixtures. The inverse of the propene quantum yield in the presence of 1-pentene-d_1 (▲), 1,2-pentadiene (△), 2,3-pentadiene (×), 2-methyl-1-butene (●), *cis*-2-pentene (○), and 3-methyl-1,2-butadiene (▽).

In cases where the photolysis of air:hydrocarbon mixtures lead to propene, a correction must be applied to the above mechanism and the following process must be added:

[6] $O(^3P) + RH \rightarrow C_3H_6 + X$

In these cases, the steady-state treatment leads to the following equation:

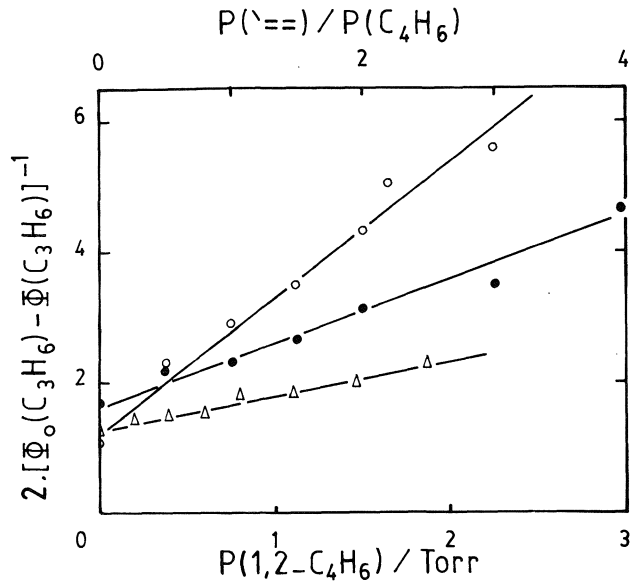

FIG. 3. The 147 nm photolysis of air:1,2-butadiene:C_4H_6 (485: x:0.75 Torr) mixtures. The inverse of the [Φ_0(propene) − Φ(propene)] values versus the 1,2-butadiene pressure in the presence of 1,3-butadiene (△), 2-butyne (●), and 1-butyne (○).

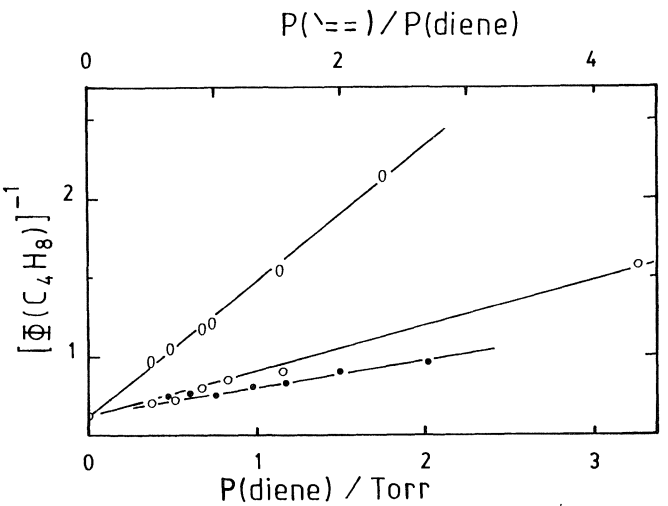

FIG. 4. The 147 nm photolysis of air:1,2-butadiene:C_5H_8 (485: 0.74:x Torr) mixtures. The inverse of Φ(isobutene) in the presence of 3-methyl-1,2-butadiene (●), Φ(2-butene) in the presence of 2,3-pentadiene (○), and Φ(1-butene) in the presence of 1,2-pentadiene (O).

$$[\text{II}] \quad \frac{2\phi}{\Phi_0(\text{Pe}) - \Phi(\text{Pe})} = \frac{k_6 + k_5}{k_5} + \frac{k_1[1,2\text{-}C_4H_6]}{k_5[\text{RH}]}$$

where Φ_O(Pe) is the propene quantum yield measured in the oxygen:1,2-butadiene mixture and Φ(Pe) that measured in various oxygen:1,2-butadiene:RH mixtures. Figure 3 shows the results obtained in the case of the C_4H_6 compounds, namely 1-butyne, 2-butyne, and 1,3-butadiene, and numerical results appear in Table 3.

Finally, some ultimate stable products formed in process [5] have been identified. For example, the photolysis of either the 1,2- and 2,3-pentadienes produce alkenes in a similar way as observed in 1,2-butadiene case.

[7] $O(^3P) + C_5H_8 \rightarrow C_4H_8 + CO$

TABLE 2. Relative rate constants of the $O(^3P)$ + RH reactions

RH	1^a / 2ϕ	k ($\times 10^{12}$ cm^3 molecule^{-1} s^{-1}) Literature (ref.)	This work
Isobutene	—	17.35[b] (6)	—
1,2-Butadiene	0.56_9	7.46 (7)	5.95 (0.25)[c]
1-Butene	0.59_8	3.98–4.00 (6–8)	4.14 (0.13)
1-Butene-d_8	0.59_5		3.93 (0.22)
1-Pentene-5-d_1	0.54_8	4.78 (9)	4.96 (0.28)

Cyclopentene	0.58_8	20.65 (10)	18.6 (1.0)
Cyclohexene	0.64_6	18.74 (10)	16.0 (1.4)
1,2-Pentadiene	0.57_8		7.58 (0.62)
2,3-Pentadiene	0.58_6		16.5 (0.70)
3-Methyl-1,2-butadiene	0.53_1	41.64 (7)	30.4 (2.2)
Isoprene	0.63_5		26.7 (2.2)

[a] The zero intercept of relationship [I]. Each correlation coefficient of the linear regression is higher than 0.988.
[b] This value is taken as a reference in this work.
[c] One standard deviation.

Taking processes [1]–[4] and [7], the steady state treatment leads to a relationship [III] similar to [I]:

$$[\text{III}] \quad \Phi[\text{alkene}]^{-1} = \frac{1}{2\phi} + \frac{k_1[1,2\text{-}C_4H_6]}{2\phi k_7[\text{diene}]}$$

Again the slope/intercept ratio gives the k_1/k_7 ratios (Fig. 4 and Table 4).

Discussion

Results shown in Tables 2–4 are in good agreement with values taken from literature (6–13). In a first approximation, the rate constant of the $O(^3P)$ + alkene interaction increases very quickly with the number of substituents attached to the double bond. However, some remarks must be made on the experimental system in order to determine its value.

The photolytic behavior of molecular oxygen at 147 nm is well established and, as such, does not need to be discussed. The first approximation comes from the conversion of oxygen $O(^1D)$ to $O(^3P)$ atoms. The rate constants for the $O(^1D)$ + alkene interactions are relatively large and larger than that of the $O(^1D)$ + O_2 or $O(^1D)$ + N_2 processes. For example, $k[O(^1D)$ + isobutene] = (4.4 ± 1.2) × 10^{-10} and $k[O(^1D)$ + *cis*-butene] = (8.7 ± 1.8) × 10^{-10} cm^3 molecule^{-1} s^{-1} (14). Thus, in mixtures described in Fig. 1, 25.5 and 70% of $O(^1D)$ atoms react with molecular oxygen and nitrogen, respectively: they are converted to $O(^3P)$ — processes [3] and [4]. Moreover, it may be assumed that the rate constants of the $O(^1D)$ + unsaturated hydrocarbon are not greater than the collision rate constant. Thus, the direct $O(^1D)$ + unsaturated hydrocarbon reactions involve less than 5% of $O(^1D)$ atoms.

Since the primary quantum yield of process [2] is one (2), the total $O(^3P)$ quantum yield must be 2.0. Thus, in the absence of any other additive, from process [1], the expected propene quantum yield must be 2.0. From Table 2, it appears that the inverse of the propene quantum yield at zero concentration of additive (relationship [I]) is 0.59 (σ = 0.04), and the

TABLE 3. Relative rate constants for the $O(^3P)$ + C_4H_6 interactions

[c]$(k_5+k_6)_{1,3\text{-butadiene}} = 20.7 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} (11).

TABLE 4. Products formed in the $O(^3P)$ + 1,2- or 2,3-diene interactions

Diene	Product	$\frac{1^a}{2\phi}$	$k_7{}^b$
1,2-Pentadiene	1-Butene	0.61	5.61 (0.52)
2,3-Pentadiene	2-Butene[c]	0.57	13.8 (1.5)
3-Methyl-1,2-butadiene	Isobutene	0.66	35.5 (3.2)

[a]Relationship [III].
[b]10^{-12} cm^3 molecule^{-1} s^{-1}, ( ): one standard deviation.
[c]*trans*/*cis*: 1.39 ± 0.01; 1-butene is also formed: 1-butene/$C_4H_8 \cong 3 \pm 1\%$.

Φ_0(propene) is rather 1.70. This difference may be explained on the basis of at least four reasons. First, there may be some recombination of the type (O + O + M → O_2 + M) in the reaction chamber, although the intensity of the photon beam is not too high. Moreover, some of the oxygen atoms may be absorbed either by the walls or the window of the reaction chamber. This phenomenon may be non-negligible for the less reactive unsaturated hydrocarbons. Of course part of the $O(^3P)$ + 1,2-butadiene interaction may lead to different compounds than propene + carbon monoxide. For example, traces of buten-2-one (1.7%), crotonaldehyde (1.1%), and methacrylaldehyde (0.3%) are observed (7). Moreover, although molecular oxygen has a high absorption coefficient, a small fraction of the incident beam is absorbed by 1,2-butadiene. In an air:1,2-butadiene (485:0.75 Torr), it may be estimated that 3 to 4% of the incident beam are absorbed directly by 1,2-butadiene (5). Finally, oxygen atoms are known to react with molecular oxygen to form ozone in the presence of a third body:

[8] $$O + O_2 \xrightarrow{(N_2)} O_3$$

and $k_8 = (7.57 \pm 1.72) \times 10^{-15}$ cm^3 molecule^{-1} s^{-1} at 298 K and 400 Torr of added nitrogen (15, 16). With these conditions, in the 1,2-butadiene:air mixtures (1.5:485 Torr), 7.3% of $O(^3P)$ atoms react with O_2. Obviously, this effect is attenuated by the addition of another hydrocarbon. Thus, the two last effects are probably responsible for a 10 ± 1% loss in the original budget of oxygen atoms. Of course a systematic error in the process of actinometry cannot be ruled out.

In the case where propene is also a product of the $O(^3P)$ + additive interaction, the kinetic system may distinguished between propene arising either from 1,2-butadiene or additive interaction (Table 3). From this reaction, the branching ratios have been evaluated in the case of 1-butyne, 2-butyne, and 1,3-butadiene. A branching ratio of 0.32 ± 0.05 has been measured in the case of 2-butyne for the formation of propene, and this value may be higher if carbon monoxide is considered (17).

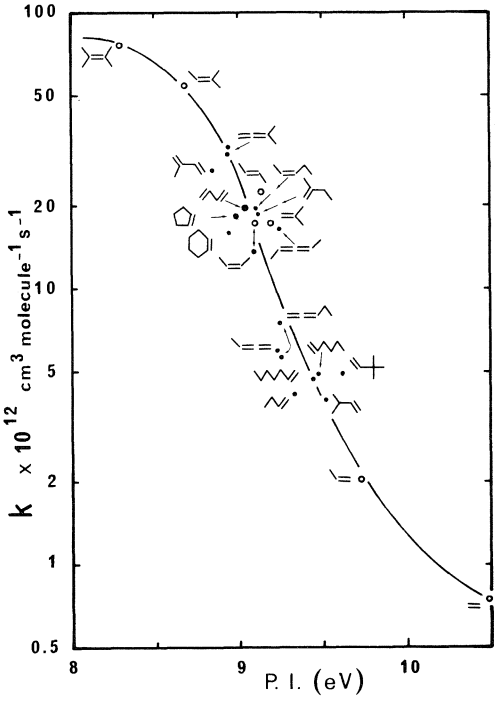

FIG. 5. Rate constants at room temperature as a function of ionization potential (19, 20). ●: this work; ○: ref. 6*b*.

Finally, the relative rate constant measured for processes [5] and [7] and reported in Table 2 and 4 must be compared. Of course process [7] is included in process [5] and k_7 must be smaller or equal to k_5. It may be said that more 60% of the $O(^3P)$ + 1,2-diene interaction results in alkene + carbon monoxyde formation.

Nothing can be said about the mechanism involved in the $O(^3P)$ + alkene reaction. However, the reaction is most likely an addition reaction rather than an abstraction of a hydrogen atom (6). This conclusion is supported by measurements of the relative rates of reaction of $O(^3P)$ atom with 1-butene and 1-butene-d_8 for which k_4/k_D is about 1.05 (Table 2), an isotope effect which is too small to be interpreted on the basis of a primary C—H bond scission. Finally, there is a correlation between the total rate constant and the electron donating property of the alkene molecules, as is illustrated in Fig. 5 where the rate constants are plotted against ionization potential. Similar trend was reported in the case of substituted benzenes (18).

Received March 7, 1986

IAN D. MCKAY and NICHOLAS C. PAYNE. Can. J. Chem. **64**, 1930 (1986).

The crystal structure and absolute configuration of (bicyclo[2.2.1]hepta-2,5-diene)[*N*,*N*-dimethyl-1(*R*)-(*o*-(bis(*tert*-butyl)phosphino)phenyl)ethylamine]rhodium(I) perchlorate, [Rh(*R*-dibutphos)(C_7H_8)]ClO_4, have been determined from three-dimensional X-ray data collected by counter methods. The complex crystallizes in the orthorhombic space group $P2_12_12_1$ with four formula units in a cell of dimensions a = 15.773(3), b = 18.660(4), and c = 8.990(3) Å. Full-matrix least-squares techniques on F, using 2257 reflections with $F > 1.5\sigma(F)$, were used to refine the structure to a final agreement factor of R_1 = 0.042. The cation displays a small tetrahedral distortion from square planar geometry (if the diene is viewed as a bidentate ligand) with Rh—P and Rh—N distances of 2.398(2) and 2.212(6) Å, respectively. The absolute configuration of the aminophosphine ligand was determined to be *R* by the Bijvoet method. The six-membered chelate ring adopts a δ twist-boat conformation with the methyl substituent of the chiral C atom axially disposed. Rh complexes of the aminophosphine ligand were shown to catalyze the homogeneous hydrosilation of prochiral ketones, but failed to produce an optical bias in any of systems investigated.

IAN D. MCKAY et NICHOLAS C. PAYNE. Can. J. Chem. **64**, 1930 (1986).

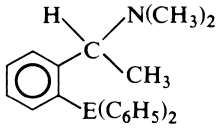
En se basant sur des données de diffraction des rayons-X tridimensionnelles, on a déterminé la structure cristalline et la configuration absolue du perchlorate du (bicyclo[2.2.1]heptadiène-2,5) [*N*,*N*-diméthyl (*o*-(bis(*tert*-butyl)phosphino)phényl)-1(*R*) éthylamine] rhodium(I), [Rh(*R*-dibutphos)(C_7H_8)]ClO_4. Le complexe cristallise dans le groupe d'espace orthorhombique $P2_12_12_1$, avec quatre molécules par cellule dont les dimensions sont a = 15,773(3), b = 18,660(4) et c = 8,990(3) Å. On a résolu la structure par la méthode des moindres carrés (matrice entière sur F) et on l'a affinée jusqu'à une valeur de R_1 = 0.042 en se basant sur 2257 réflexions avec $F > 1{,}5\sigma(F)$. Le cation existe dans un forme tétraédrique légèrement déformée de la géométrie plan carré (si l'on considère le diène comme un ligand bidentate) et les distances Rh—P et Rh—N sont respectivement égales à 2,398(2) et 2,212(6) Å. Utilisant la méthode de Bijvoet, on a déterminé que la configuration absolue du ligand aminophosphie est *R*. Le chélate à six chaînons adopte une conformation δ bateau déformé dans lequel le substituant méthyle de l'atome de carbone chiral est disposé dans la position axiale. On a démontré que les complexes de Rh avec l'aminophosphine catalysent l'hydrosilation homogène des cétones prochirales; toutefois, dans les systèmes étudiés, il n'y a pas de formation préférentielle de l'un des isomères optiques.

[Traduit par la revue]

Introduction

The use of chiral transition metal catalysts in the asymmetric, homogeneous hydrosilation of prochiral ketones to produce chiral silyl ethers is a topic which has been of interest to others (1–15) as well as ourselves (16, 17) in the last few years. Chiral silyl ethers can subsequently be hydrolyzed to the corresponding chiral alcohols.

In previous work (16), the ligand amphos (E = P) and its analog, amars (E = As), were prepared, and Rh(I) complexes of these species were investigated as possible hydrosilation catalysts (16, 17). Both complexes catalyzed the reaction, but whereas the amphos complex gave encouraging optical yields



(up to 72%), the amars analog showed no such optical induction. X-ray crystal structure analyses of the complexes [Rh(*S*-amars)(C_7H_8)]ClO_4 (16) and [Rh(*S*-amphos)(C_7H_8)]ClO_4 (17) were completed, and conformational analyses of the solution species were conducted (17) using variable temperature ^1H nmr spectroscopy and energy minimization calculations (Molecular Mechanics II, MM2) (18). An explanation for the observed difference in optical selectivity was suggested.

To further our work in this area we have synthesized the chiral ligand *N*,*N*-dimethyl-1-(*o*-(bis(*tert*-butyl)phosphino)phenyl)ethylamine, dibutphos, and prepared Rh complexes of dibutphos for use as hydrosilation catalysts. We report herein the results of these studies, and describe the single crystal X-ray structure determination of [Rh(*R*-dibutphos)(C_7H_8)]ClO_4, **I**.

Experimental

All syntheses and hydrosilation reactions were performed under a dry, O_2-free Ar atmosphere. ^1H nmr spectra were recorded on a Varian XL-200 spectrometer using $Si(CH_3)_4$ as a reference. ^{31}P nmr spectra were recorded on a Varian XL-300 spectrometer with $OP(OCH_3)_3$ as the reference. Rotations were recorded with a Rudolph polarimeter, model 80, at the sodium D line. Concentrations are given in g 100 mL^{-1}, path lengths in dm. Chemical analyses were performed by Guelph Chemical Laboratories, Guelph, Ont., Canada. $RhCl_3 \cdot xH_2O$ was purchased from Johnson Matthey Ltd. [$RhCl(C_2H_4)_2]_2$ (19) and [$Rh(C_7H_8)_2$] (20) were prepared via published routes.

Synthesis of (R)-o-(($t\text{-}C_4H_9)_2P)C_6H_4CHCH_3N(CH_3)_2 \cdot HCl$, (R-*dibutphos·HCl)*

(*R*)-*N*,*N*-Dimethyl-1-phenylethylamine was prepared from (*R*)-1-phenylethylamine by reaction with formaldehyde and formic acid (21). (*R*)-*N*,*N*-Dimethyl-1-phenylethylamine (20.0 mL) was dissolved in freshly distilled diethyl ether (50 mL) and cooled in a dry ice/acetone bath. *n*-BuLi (47.5 mL) in hexanes (2.6 *M*) was added, the cooling bath was removed and the mixture was stirred for 18 h. The mixture was cooled again and ($t\text{-}C_4H_9)_2PCl$ (22.0 mL) was added slowly. After removal of the cooling bath and stirring for 6 h, 50 mL of H_2O was added and the stirring continued for 1 h. The organic layer was separated and the aqueous phase extracted with diethyl ether (2 × 50 mL). The combined organic phases were dried over $MgSO_4$,

[a] ^1H nmr spectra were recorded using d-$CHCl_3$ solutions and TMS as a reference.
[b] ^{31}P nmr spectra for dibutphos·HCl and dibutphos were recorded using $CHCl_3$ solutions and $OP(OCH_3)_3$ as a reference. The spectrum of the Rh complex was recorded using CH_2Cl_2 as the solvent.
[c] Small amounts of deuterated solvents were added to serve as lock signals.

filtered, and excess gaseous HCl added. The white precipitate formed was washed with diethyl ether, and recrystallized from CH_2Cl_2/acetone to give 8.3 g (19%) of product. $[\alpha]_D^{20} = 7.4°$ ($CHCl_3$, $c = 0.53$, $l = 2.0$); mp = 241°C, dec. Elemental analyses were variable.

Synthesis of (S)-o-*((*t-$C_4H_9)_2P)C_6H_4CHCH_3N(CH_3)_2$·*HCl, (*S-*dibutphos·HCl)*

S-Dibutphos·HCl was prepared in an analogous fashion. $[\alpha]_D^{20} = 7.8°$ ($CHCl_3$, $c = 1.4$, $l = 2.0$); mp = 240°C, dec. Elemental analyses were variable.

Synthesis of (R)-o-*((*t-$C_4H_9)_2P)C_6H_4CHCH_3N(CH_3)_2$, (R-*dibutphos)*

R-Dibutphos·HCl (5.0 g) was stirred with excess NaOH in ethanol for 15 min. After filtration and solvent removal, the residue was dissolved in diethyl ether and filtered. The solvent was removed and the product was distilled under reduced pressure to yield 2.0 g of viscous liquid. $[\alpha]_D^{20} = 116.0°$ ($CHCl_3$, $c = 0.61$, $l = 2.0$); bp 140°C/1 mm. *Anal.* calcd. for $C_{18}H_{32}NP$: C 73.68, H 10.99, N 4.77; found: C 73.94, H 11.12, N 4.89.

Synthesis of (S)-o-*((*t-$C_4H_9)_2P)C_6H_4CHCH_3N(CH_3)_2$, (S-*dibutphos)*

In the same manner *S*-dibutphos was prepared. $[\alpha]_D^{20} = 119.6°$ ($CHCl_3$, $c = 0.93$, $l = 2.0$); bp 140°C/1 mm. *Anal.* calcd. for $C_{18}H_{32}NP$: C 73.68, H 10.99, N 4.77; found: C 74.41, H 11.15, N 5.84.

*Synthesis of [Rh(*R-*dibutphos)C*$_7H_8$*]ClO*$_4$*, I*

$[Rh(C_7H_8)_2]ClO_4$ (100 mg) and *R*-dibutphos (76 mg) were dissolved in 15 mL of 50/50 $CH_2Cl_2/CHCl_3$ and stirred for 15 min. After filtration and addition of several mL of hexanes, the mixture was left to stand at room temperature. Crystals formed rapidly and were recovered from solution within 4 h of reaction; mp 180–182°C dec. *Anal.* calcd. for $C_{25}H_{40}ClNO_4PRh$: C 51.07, H 6.86, N 2.38; found: C 50.13, H 6.78, N 2.37.

^1H and ^{31}P nmr data for the species above are summarized in Table 1.

Procedure for hydrosilation of ketones

The hydrosilation reactions were all performed as described below for acetophenone, with appropriate modifications. $[RhCl(C_2H_4)_2]_2$ (19) (20 mg) was dissolved in degassed benzene (3 mL). A solution of *R*-dibutphos in benzene (1.95 mL, 0.053 *M*) was then added from a syringe. $C_6H_5SiH(CH_3)_2$ (5.0 mL) was then added, followed by acetophenone (2.92 mL). The mixture was stirred for 7 days. Chemical yields were measured by ^1H nmr spectroscopy. The benzene was removed by distillation and the silyl-ether $(C_6H_5)CHCH_3OSi(CH_3)_2C_6H_5$ distilled under vacuum (127°C/2 mm). A total of 3.8 g of product was isolated. In each of the trials with 3,3-dimethyl-2-butanone and 2-butanone, using the silane $C_6H_5SiH(CH_3)_2$, the amount of product isolated was too small for an optical rotation measurement. In the remaining trials all optical rotations were zero within experimental error.

X-ray data collection and reduction

Orange crystals of **I** were prepared as described above. A photographic examination using Weissenberg and precession techniques showed the crystals to be orthorhombic, Laue symmetry *mmm*. Observation of the systematic absences $h00$ for h odd, $0k0$ for k odd, and $00l$ for l odd led to an unambiguous assignment of the acentric space group $P2_12_12_1$ (22). The crystal density was determined by neutral buoyancy in a mixture of 1,2-dibromoethane and hexanes.

A crystal, cleaved from a long needle, of approximate dimensions $0.36 \times 0.16 \times 0.07$ mm^3 was chosen for data collection. Eight crystal faces were identified by optical goniometry, and indices (001) assigned to the broken face. Faces {100} were prominent. The crystal dimensions were carefully measured with a filar microscope.

Intensity data were recorded on an Enraf-Nonius CAD4F diffractometer using an incident beam graphite monochromator. Cell parameters and an orientation matrix were obtained from refinement of 23 reflections with $15 < 2\theta < 25°$. ω-Scans of several intense, low angle reflections, recorded with a wide open counter, had an average width at half height of 0.16°. Crystal data and experimental conditions are summarized in Table 2. Variable scan rates within a maximum time per datum of 75 s were used in order to optimize counting statistics. A Zr foil attenuator was used for extremely strong reflections and three standard reflections were recorded every 2 h of X-ray exposure time. On average, the standard intensities decreased in a nearly linear fashion by 3.9% during the 66 h required to record 3408 reflections. Corrections for background, monochromator polarization, Lorentz, and polarization effects were applied to the data using the Enraf-Nonius Structure Determination Package running on a DEC PDP11/23+ computer (23). Standard deviations were assigned, based on counting statistics, and a linear decay correction and a Gaussian absorption correction were applied to the data (23). In all, 2075 reflections with $F > 3\sigma(F)$ were available.

TABLE 2. Summary of crystal data and experimental conditions

Compound	$C_{24}H_{40}ClNO_4PRh$ f.w. 587.93

Standard reflections	200, 080, 002

Structure solution and refinement

Positional parameters for the Rh and P atoms were obtained from a three dimensional Patterson sythesis. A series of least-squares refinements and difference Fourier syntheses were used to locate the remaining 31 non-H and 25 H atoms of the cation and anion. Refinement of atomic parameters was by full-matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factor amplitudes and w, the weighting factor, is given by $w = 4F_o^2/\sigma^2(F_o^2)$. Scattering factors used for non-H atoms were those for neutral atoms calculated by Cromer and Waber (22), those for H by Stewart *et al.* (24). The real and imaginary components of anomalous dispersion of Cromer (22) were included for all atoms.

In the final model the 26 non-H atoms, excluding those in the norbornadiene ligand, were refined with anisotropic thermal parameters. The seven C atoms in the norbornadiene ligand were refined with isotropic Debye factors. All 25 H atoms were located in a difference Fourier with peak heights ranging from 0.16(11) to 0.46(11) e Å^{-3}, and included in ideal positions (C—H = 0.90 Å; methyl C atoms, C—H = 0.95 Å) in calculations of F_c. H atom thermal parameters were 110% of the isotropic equivalent of those of the atoms to which they are bonded. No H parameters were refined, but all values were updated as refinement continued.

Since the absolute configuration of the ligand was known, the correct choice of hand could be made at the beginning of the analysis. In the final cycles of refinement, 2257 reflections with $F > 1.5\sigma(F)$ were used to refine 263 variables, with convergence at residuals of R_1 = 0.0420 and R_2 = 0.0494. In the final cycle all parameter shifts were less than 0.01σ, and, with a p value of 0.08 (25), the error in an observation of unit weight was 1.03 e. A total difference Fourier synthesis showed that the highest peak, at fractional coordinates (0.437, 0.328, 0.531), with an electron density of 0.61(9) e Å^{-3} is situated 0.72 Å from the Rh atom. A statistical analysis of R_1 and R_2 in terms of F_o, λ^{-1} sin θ, and classes of indices showed no unusual trends, indicating a satisfactory weighting scheme and the absence of significant secondary extinction.

Final positional and U equivalent thermal parameters are given in Table 3 for the non-H atoms. H atom parameters, anisotropic thermal parameters, root-mean-square amplitudes of vibration and structure amplitudes have been deposited.[2]

Confirmation of absolute configuration

The absolute configuration of the cation was confirmed by the Bijvoet absorption edge technique (26) using Cu Kα radiation (λ = 1.5418 Å), and the same crystal. Friedel pairs were recorded for a selection of structure amplitudes calculated from the final model and its enantiomorph for which $F_c(h\,k\,l)$ and $F_c(\bar{h}\,\bar{k}\,\bar{l})$ differed by more than 15%. The results are presented in Table SIV,[2] and indicate that the assignment based upon the ligand synthesis was correct.

est Rh...Rh and Cl...Cl distances of 8.253(1) and 8.140(3) Å respectively. The shortest Rh...Cl distance is 4.992(2) Å. The shortest non-bonded cation–anion contacts are O(3)...H3C(19) $(1 - x, \frac{1}{2} + y, \frac{3}{2} - z)$ of 2.51 Å and O(4)...HC(12) (x, y, z) of 2.62 Å. Between cations the closest contacts are H1C(7)...H1C(24) $(1 - x, -\frac{1}{2} + y, \frac{1}{2} - z)$ at 2.50 Å and H2C(23)...H2C(34) $(\frac{3}{2} - x, 1 - y, -\frac{1}{2} + z)$ at 2.56 Å. The perchlorate anions are well ordered, with Cl—O distances ranging from 1.368(11) to 1.406(9) Å and angles from 106.5(7) to 114.7(6)°.

A stereoview of the cation showing the atom numbering scheme for the norbornadiene ligand is given in Fig. 1 and a perspective drawing of the cation, less the norbornadiene ligand and showing the remainder of the numbering scheme, is presented in Fig. 2. Atoms are drawn as 50% probability thermal ellipsoids in both figures. Selected bond distances and bond angles are given in Table 4, and others have been deposited.[2]

The Rh atom is coordinated in a square-planar environment, with a slight tetrahedral distortion. The angle between the plane formed by the Rh, P, and N atoms and that formed by the Rh atom and M23 and M56, which are the midpoints of the alkene bonds, is 9.8°. The six-membered chelate ring adopts a twist boat conformation of absolute configuration δ, and the configuration of C(17) has been confirmed as *R*, as expected from the synthesis. The methyl substituent, C(18), is axially disposed with respect to the chelate ring. This arrangement has been shown to occur in order to minimize steric interactions between the methyl substituent, C(18), and H(15), the nearest neighbour

[d]Number in parentheses indicates the percentage of olefin formed due to β-elimination of siloxyalkyl intermediate.

on the phenyl ring in the chelate backbone (17). The N-methyl substituents then adopt corresponding staggered dispositions. All dimensions within the dibutphos ligand are normal, and they and other dimensions in the cation correspond well with those in related complexes (17, 27, 28). The geometry of the norbornadiene ligand is unexceptional (29–44). Weighted least-squares planes and selected torsion angles have been deposited as Tables SVI and SVII.[2]

Hydrosilation reactions

The results of hydrosilation reactions performed using the silanes dimethylphenylsilane and diphenylsilane, with each of the four ketones, acetophenone, 3,3-dimethyl-2-butanone, propiophenone, and 2-butanone, are presented in Table 5. Some trends are evident. The reactions in which diphenylsilane was used produced greater chemical yields in a shorter period of time than did those with dimethylphenylsilane. Use of dimethylphenylsilane resulted in the formation of only a silyl-ether as the product in each case, whereas trials with diphenylsilane produced two products, one being the silyl-ether (major product), and the other, an olefin, presumably resulting from β-elimination of a siloxyalkyl intermediate. We also note that, when dimethylphenylsilane was used, reactions with the dialkyl ketones gave markedly lower chemical yields than the reactions with the alkylaryl ketones. When diphenylsilane was used the reverse was seen, with the dialkyl ketones giving slightly higher chemical yields. In contrast to the results reported for catalytic systems based on the ligand amphos (16), the reactions described herein produced no measurable optical bias in the products. A possible explanation may be proposed from an examination of the structure of $[Rh(dibutphos)(C_7H_8)]ClO_4$ in the solid state. The *tert*-butyl groups on the dibutphos complex cannot produce an asymmetric coordination environment through a face-edge arrangement of phenyl rings, as was seen for the amphos complex. We had hoped that an equivalent asymmetric environment could result from a pseudo-axial/equatorial arrangement of the bulky *tert*-butyl groups in the metal-chelate unit, but such was not observed in the solid state. The tertiary C atoms of the *tert*-butyl groups, C(21) and C(31), are displaced from the plane of the Rh, P, and N atoms to a similar extent, by −1.331(8) and 1.716(8) Å, respectively. Thus, although the complex catalyzes the hydrosilation reaction, the dibutphos ligand does not induce an asymmetric environment for the incoming substrate molecule, and hence no optical induction results.

The oxidation of hydrogen peroxide by tris(polypyridine) complexes of osmium(III), iron(III), ruthenium(III), and nickel(III) in aqueous media

DONAL H. MACARTNEY

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received November 5, 1985

DONAL H. MACARTNEY. Can. J. Chem. **64**, 1936 (1986).

The stoichiometry and kinetics of the oxidation of hydrogen peroxide by tris(2,2′-bipyridine) and tris(4,4′-dimethyl-2,2′-bipyridine) complexes of osmium(III), iron(III), ruthenium(III), and nickel(III) were studied in acidic and neutral aqueous media at 25°C and $I = 0.50\ M$ ($LiCF_3SO_3$). The reaction $2M(bpy)_3^{3+} + H_2O_2 \rightarrow 2M(bpy)_3^{2+} + O_2 + 2H^+$ is observed with quantitative yields of dioxygen gas. The observed rate constants displayed an inverse acid dependence over the pH range 6.0–8.5; $k_{obsd} = k_1 + k_2K_1/[H^+]$, attributed to the oxidations of H_2O_2 (k_1) and HO_2^- (k_2). An application of the Marcus theory relationship to the cross-reaction data gave a self-exchange rate constant of 10^{-2}–$10^{-1}\ M^{-1}\ s^{-1}$ for the HO_2^-/HO_2 couple. The electron exchange rate constant is evaluated in terms of the inner-sphere and solvent reorganizational barriers and is compared to values reported for other small molecule couples. Rate and activation parameters for the reduction of the nickel(III) complexes by the hydroxide ion have been determined and are compared with the corresponding values for other metal tris(polypyridine) complexes.

DONAL H. MACARTNEY. Can. J. Chem. **64**, 1936 (1986).

Opérant en milieu aqueux acide ou neutre, à 25°C et à $I = 0{,}50\ M$ ($LiCF_3SO_3$), on a étudié la stoéchiométrie et la cinétique de l'oxydation du peroxyde d'hydrogène par les complexes de tris(bipyridine-2,2′) et tris(diméthyl-4,4′ bipyridine-2,2′) d'osmium(III), de fer(III), de ruthénium(III) et de nickel(III). On a observé que la réaction $2M(bpy)_3^{3+} + H_2O_2 \rightarrow 2M(bpy)_3^{2+} + O_2 + 2H^+$ se produit avec des rendements quantitatifs en dioxygène gazeux. Il existe une corrélation inverse entre les constantes de vitesse observées et la concentration d'acide dans l'intervalle de pH allant de 6,0 à 8,5; $k_{obs} = k_1 + k_2K_1/[H^+]$ et on attribue k_1 et k_2 respectivement à l'oxydation du H_2O_2 (k_1) et du HO_2^- (k_2). L'application de la relation de la théorie de Marcus aux données de la réaction d'échange donne une constante de vitesse d'auto-échange de 10^{-2}–$10^{-1}\ M^{-1}\ s^{-1}$ pour le couple HO_2^-/HO_2. On évalue la constante de vitesse d'échange de l'électron en fonction de la sphère interne et des barrières de réorganisation du solvant et on la compare aux valeurs rapportées pour d'autres couples de petites molécules. On a déterminé la vitesse et les paramètres d'activation de la réduction des complexes de nickel(III) par l'ion hydroxyde et on les compare aux valeurs correspondantes pour d'autres complexes tris(polypyridine) de métal.

[Traduit par la revue]

Introduction

The oxidation water to molecular oxygen involves the overall transfer of four electrons and four protons.

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^-$$

This reaction represents the net oxidation process in green plant photosynthesis (1) and is important in the transfer and storage of energy in many chemical and biochemical systems. The successive addition of electrons to molecular oxygen generates dioxygen intermediates such as the superoxide, $H_nO_2^{(n-1)+}$, and the peroxide, $H_nO_2^{(n-2)+}$, ions. The interconversions of the various dioxygen species and their affinities for metal complexes have been studied in considerable detail (2–5).

Hydrogen peroxide is usually regarded as an oxidant but may itself be oxidized by species such as Ce(IV), MnO_4^-, and Cl_2. With metal aquo ions such as Ce^{4+}(aq) (6), Tl^{3+}(aq) (7), Mn^{3+}(aq) (8), Ag^{3+}(aq) (9), and Co^{3+}(aq) (10) as oxidants the electron transfers occur by inner-sphere processes, involving $MOOH^{n+}$ intermediates and complicated by the proton dissociation equilibria of the metal ions. Outer-sphere oxidations of H_2O_2 by $Ag(bpy)_2^{2+}$ (11), $Ru(bpy)_3^{3+}$ (12), $(bpy)_2pyRuO^{2+}$ (13), and $Ni(bpy)_3^{3+}$ (14) have also been observed.

In this paper the results of systematic kinetic investigation of the oxidation of H_2O_2 and its conjugate base HO_2^- by tris(2,2′-bipyridine) and tris(4,4′-dimethyl-2,2′-bipyridine) complexes of osmium(III), iron(III), ruthenium(III), and nickel(III) in aqueous media are reported. These species are well characterized one-electron outer-sphere oxidants and the lack of proton equilibria associated with these complexes permits a differentiation between H_2O_2 and HO_2^- pathways. The Marcus relationship (15) has been employed to correlate the cross-reaction data and provide an estimate of the electron exchange rate constant for the HO_2^-/HO_2 couple. This exchange rate constant may be compared with values reported for other small molecule couples, such as O_2^-/O_2. A semi-classical model (16) for bimolecular electron transfer is used to evaluate the rate of electron exchange in HO_2^-/HO_2 in terms of inner-sphere and solvent reorganizational barriers. Kinetic and activation parameters are also reported for the spontaneous reduction of the nickel(III) complexes in basic aqueous solution and are compared with corresponding values for the Os(III), Fe(III), and Ru(III) complexes.

Experimental

Reagents

Trifluoromethanesulphonic acid (CF_3SO_3H, 3M Co.) was purified by distillation at reduced pressure. Dilute stock solutions of CF_3SO_3H were standardized by titration with sodium hydroxide. Solutions of $LiCF_3SO_3$ were prepared by the neutralization of CF_3SO_3H with recrystallized lithium carbonate. An aliquot of the solution was passed through a Dowex 50W-X2 column in the H^+ form and titrated with standardized base. Solutions of hydrogen peroxide (Mallinckrodt or Fisher, 30%, stabilizer free) were prepared with doubly distilled water, analyzed by titration with standardized permanganate, and used promptly.

The tris(2,2′-bipyridine) and tris(4,4′-dimethyl-2,2′-bipyridine) complexes of osmium(II) (17), iron(II) (18), ruthenium(II) (18), and nickel(II) (19) were prepared as perchlorate salts by reported procedures. The corresponding metal(III) complexes for Os, Fe, and Ru were synthesized by PbO_2 oxidation in 1 M H_2SO_4 followed by precipitation with excess sodium perchlorate. The nickel(III) complexes were prepared by electrochemical oxidation of the correspond-

ing nickel(II) salts in anhydrous acetonitrile (19, 20). The reactions of $M(bpy)_3^{3+}$ and $M(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$ with H_2O_2 were studied in 0.50 *M* CF_3SO_3H and in the pH range of 6.0 to 8.5. The pH was controlled by the use of 0.10 *M* tris and 0.025 *M* phosphate buffers with the ionic strength maintained at 0.50 *M* with $LiCF_3SO_3$. The buffered H_2O_2 solutions were mixed with metal complex solutions kept at pH 2 and the pH of the reaction mixture was measured immediately following the reaction. The spontaneous reductions of the nickel(III) complexes in basic aqueous solution were studied by mixing solutions of the Ni(III) complex in 10^{-3} *M* CF_3SO_3H with solutions of various $[OH^-]$, at an ionic strength of 0.50 *M* maintained using $LiCF_3SO_3$.

Kinetic experiments

Kinetic measurements were made using a Durrum D-110 stopped-flow apparatus or with slower reactions, Cary 17 and 210 spectrophotometers. All experiments were performed under pseudo-first-order conditions of an excess of hydrogen peroxide or hydroxide ion. The reactions involving the Os(III), Fe(III), Ru(III), and Ni(III) complexes were monitored at 480, 510, 460, and 400 nm, respectively. Plots of $\ln(A_t - A_\infty)$ or $\ln(A_\infty - A_t)$ against time were linear for at least three half-lives with first-order rate constants reproducible to within 5%. The temperature was maintained to within 0.1°C by means of an external water bath.

Oxygen analysis

Gas chromatography (Varian Series 1400 gas chromatograph, 2 m × ⅛ cm Molecular Sieve 5A column, argon carrier gas) was used to analyze for O_2 in the gas phase above a helium saturated reaction mix- as described previously (21). Equal volumes of 3×10^{-3} *M* H_2O_2 phosphate buffer and 2×10^{-3} *M* $M(bpy)_3^{3+}$ in 10^{-2} *M* H_2SO_4 mixed and stirred for 20 min before sampling. The observed peak ıts were corrected for any air leakage using the N_2 peak produced.

Results

The addition of an excess of hydrogen peroxide to neutral solutions of OsL_3^{3+}, FeL_3^{3+}, RuL_3^{3+}, and NiL_3^{3+} (L = bpy or $4,4'\text{-}(CH_3)_2bpy$) result in the rapid formation of products whose visible spectra resemble those of the corresponding ML_3^{2+} species. The expected stoichiometry for the two electron oxidation of hydrogen peroxide to molecular dioxygen by ML_3^{3+} was observed.

$$[1] \quad 2ML_3^{3+} + H_2O_2 \rightarrow 2ML_3^{2+} + O_2 + 2H^+$$

The yields of dioxygen gas based on this stoichiometry were as follows: for $Ni(bpy)_3^{3+}$, 98 ± 10%; $Ru(bpy)_3^{3+}$, 94 ± 10%; $Fe(bpy)_3^{3+}$, 95 ± 10%; and $Os(bpy)_3^{3+}$, 104 ± 10%.

Kinetic measurements of the oxidation of hydrogen peroxide by the ML_3^{3+} complexes were performed in acidic solution (0.5 *M* CF_3SO_3H) and in solutions buffered between pH 6.0 and 8.5 (I = 0.50 *M* $LiCF_3SO_3$). The reactions in 0.5 *M* CF_3SO_3H were slow and followed the rate law in eq. [2]

$$[2] \quad \frac{-d[ML_3^{3+}]}{2dt} = k_a[ML_3^{3+}][H_2O_2]$$

with the pseudo-first-order rate constant k_{obsd} displaying a first-order dependence on $[H_2O_2]$. The rate constants k_a are presented in Table 1. In the $Fe(bpy)_3^{3+}/H_2O_2$ reaction, the redox step is followed by acid hydrolysis of $Fe(bpy)_3^{2+}$. No reactions of H_2O_2 were observed at 25°C with the weaker oxidants $Os(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$, $Os(bpy)_3^{3+}$, or $Fe(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$. Rate constants have been reported previously for the oxidation of H_2O_2 by $Ru(bpy)_3^{3+}$ (4.2 M^{-1} s^{-1}, pH = 3, I = 1.00 *M* Na_2SO_4 (12)) and by $Ni(bpy)_3^{3+}$ (0.34 M^{-1} s^{-1}, I = 2.00 *M* $LiClO_4$ (14)). The discrepancies between these values and the present results are likely due to the different media and acid and ionic strengths employed in the kinetic experiments.

	7.17	4280	
	7.62	13600	
	7.86	23700	

At higher pH the oxidation of hydrogen peroxide by ML_3^{3+} is more rapid. Between 6.0 and 8.5 the observed rate constants (Table 1) displayed an inverse first-order dependence on the acid concentration as illustrated in Fig. 1 for the bipyridine complexes.

$$[3] \quad \frac{-d[ML_3^{3+}]}{2dt} = k_b[ML_3^{3+}][H_2O_2]/[H^+]$$

The negligible intercepts are consistent with the small rate constants observed in acidic solution. The rate constants k_b derived from the slopes of k against $[H^+]^{-1}$ are presented in Table 1.

Spontaneous reduction of tris(polypyridine)metal(III) com-

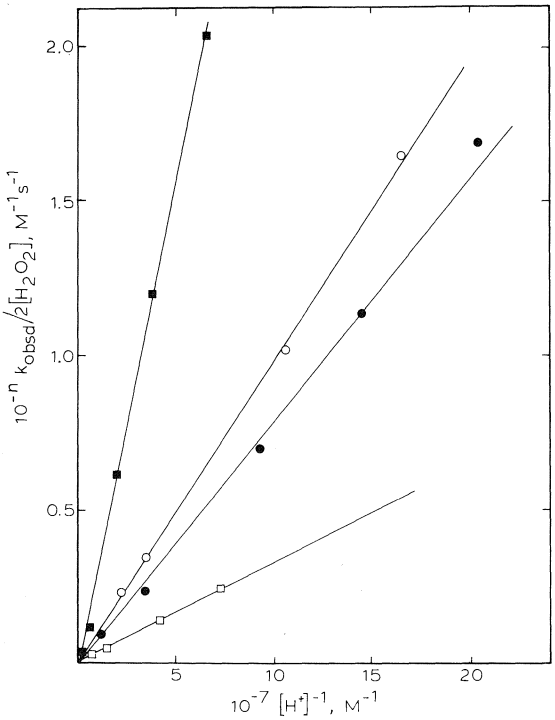

FIG. 1. Dependence of the observed rate constant on $[H^+]^{-1}$ for the reactions of $M(bpy)_3^{3+}$ with hydrogen peroxide: M = Os (n = 1) (●); M = Fe (n = 2) (○); M = Ru (n = 3) (■); M = Ni (n = 4) (□).

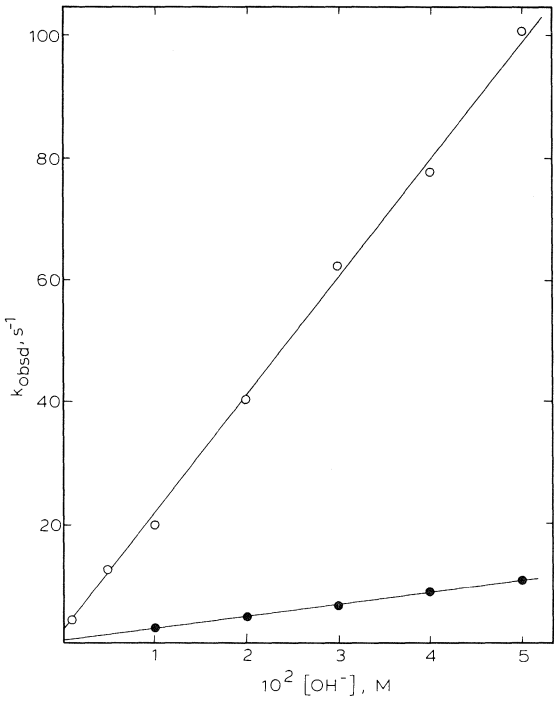

FIG. 2. Dependence of the observed rate constant on $[OH^-]$ for the reductions of $Ni(bpy)_3^{3+}$ (○) and $Ni(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$ (●) at 25°C and I = 0.50 M.

plexes also occurs in aqueous solution in the absence of hydrogen peroxide. The kinetics of the reduction of $Ni(bpy)_3^{3+}$ and $Ni(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$ in basic solution were studied at several temperatures. The pseudo-first-order rate constants were observed to have a first-order dependence on hydroxide ion concentration over the range $[OH^-]$ = 0.001–0.050 M, with small intercepts in plots of k against $[OH^-]$ (Fig. 2). The variation of k with ionic strength (Table 2) is consistent with the reaction between +3 and −1 charged species. The second-order rate constants and activation parameters for these reactions are presented in Table 2, along with the corresponding values (12, 22, 23) for $M(bpy)_3^{3+}$ complexes of Os(III), Fe(III), and Ru(III). The rate of reduction of these complexes by hydroxide ion is negligible compared to the rate of reduction by hydrogen peroxide in the pH range 6–9.

Discussion

The kinetic data for the reactions of metal(III) tris(polypyridine) complexes with hydrogen peroxide are consistent with a mechanism involving the reduction of ML_3^{3+} by both the

undissociated H_2O_2 and the peroxide anion HO_2^- (pK_1 = 11.86, $I = 0.50\ M$ (24)).

[4] $$H_2O_2 \overset{K_1}{\rightleftharpoons} HO_2^- + H^+$$

[5] $$M(bpy)_3^{3+} + H_2O_2 \xrightarrow{k_1} M(bpy)_3^{2+} + H_2O_2^+$$

[6] $$M(bpy)_3^{3+} + HO_2^- \xrightarrow{k_2} M(bpy)_3^{2+} + HO_2$$

The one-electron oxidation products, $H_2O_2^+$ and HO_2, are both acidic (Table 3) such that in the pH range 6–9, the superoxide ion would exist in the form O_2^-.

[7] $$M(bpy)_3^{3+} + O_2^- \xrightarrow{\text{fast}} M(bpy)_3^{2+} + O_2$$

The rate law for the one-electron oxidations of H_2O_2 and HO_2^- is given by eq. [8].

[8] $$-\frac{d[M(bpy)_3^{3+}]}{2dt} = \left(\frac{k_1 + k_2K_1/[H^+]}{1 + K_1/[H^+]}\right)[M(bpy)_3^{3+}][H_2O_2]$$

In the pH range 6–9 employed in this study $K_1 \ll [H^+]$ such that the observed second-order rate constant may be expressed as $k_{obsd} = 2\{k_1 + k_2K_1/[H^+]\}$ where $k_1 = k_a$ and $k_2 = k_b/K_1$ (eq. [3]). For the oxidants employed in this study reaction [5] is thermodynamically very unfavourable because of the high reduction potential of $H_2O_2^+$ (Table 3). The acid-independent pathway is likely more complicated than represented by k_1 and these values will not be used in further calculations. The rate constants specific to the HO_2^- pathway are presented in Table 4. A rate constant of $2.7 \times 10^7\ M^{-1}\ s^{-1}$ ($I = 1.00\ M\ Na_2SO_4$) has been reported for the $Ru(bpy)_3^{3+}/HO_2^-$ reaction (12), in good agreement with value from this study.

In the absence of hydrogen peroxide the nickel(III) tris(polypyridine) complexes are spontaneously reduced in aqueous solution, with a rate that is first-order in hydroxide ion concentration. Similar processes are observed with the analogous complexes of Os(III) (23), Fe(III) (22, 23), and Ru(III) (12, 21), and these reactions, especially with $Ru(bpy)_3^{3+}$, have been of much interest in regards to the catalysis of water photooxidation. There have been several mechanisms proposed for the $M(bpy)_3^{3+}/OH^-$ reactions (21, 30) and the products of reduction depend on a number of factors including pH, photocatalysis, and added cayalysts such as $Co^{2+}(aq)$. In the noncatalyzed thermal reductions of the $Ni(bpy)_3^{3+}$ complexes in basic solution there are two mechanisms which are suggested by the kinetic data: (*a*) the nucleophilic addition of H_2O or OH^- to a bipyridine carbon to form a pseudobase species and (*b*) formation of a free hydroxyl radical OH· and $Ni(bpy)_3^{2+}$. Both mechanisms are consistent with the $[OH^-]$ rate dependence and the increase in the rate constant as the oxidizing power of $M(bpy)_3^{3+}$ is increased. The latter mechanism may be more favourable with the nickel(III) complexes as the reduction potential of 1.89 V for the $OH\cdot/OH^-$ couple (31) would render the reaction energetically unfavourable for the complexes of the other metals. The former mechanism has received much support in the reactions of $Ru(bpy)_3^{3+}$ with OH^-, but further studies are clearly required to establish its applicability to the $Ni(bpy)_3^{3+}$ complexes. It is unlikely, owing to the lability of the $Ni(bpy)_3^{2+}$, that this complex would find use in the catalysis of water oxidation.

The rate constants for the oxidation of HO_2^- increase as the reduction potentials of the oxidants in the series is increased (Table 4). This trend is consistent with the Marcus theory relationship (15) for outer-sphere electron transfer reactions. The Marcus equation, which relates the rate and equilibrium constants for a cross-reaction to the self-exchange rate constants for the component reactants is given, in a modified form (16), by eqs. [9]–[12].

[9] $$k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2}W_{12}$$

where

[10] $$\ln f_{12} = \frac{[\ln K_{12} + (w_{12} - w_{21})/RT]^2}{4\left[\ln\left(\frac{k_{11}k_{22}}{A_{11}A_{22}}\right) + \left(\frac{w_{11} + w_{22}}{RT}\right)\right]}$$

[11] $$W_{12} = \exp\left[-(w_{12} + w_{21} - w_{11} - w_{22})/2RT\right]$$

[12] $$w_{ij} = \frac{z_iz_je^2}{D_s\sigma_{ij}(1 + \beta\sigma_{ij}I^{1/2})}$$

In these expressions w_{ij} is the work required to bring ions i and j (charges z_i and z_j) to the separation distance σ_{ij} (taken equal to the sum of a_i and a_j, the radii of ions i and j), $\beta = (8\pi Ne^2/1000D_skT)^{1/2}$, and D_s is the dielectric constant of the medium. The value of $A_{11}A_{22}$ for the ML_3^{3+}/HO_2^- reactions is $2 \times 10^{24}\ M^{-2}\ s^{-2}$, taking the radii of the metal tris(bipyridine) complexes and the peroxide anion to be 6.8 Å and 1.6 Å, respectively.

Equation [9] was used to determine the self-exchange rate constant for the HO_2^-/HO_2 couple from the cross-reaction data in Table 4. In order to calculate the constants K_{12} for the equilibria in eq. [6], the reduction potential of the HO_2/HO_2^- couple must be determined. This potential may be calculated (eq. [13]) using the proton equilibrium constants and formal electrode potentials found in Table 3.

[13] $$E^0(HO_2/HO_2^-) = E^0(O_2^-/HO_2^-) - 0.059pK_{r2}$$

The reduction potential of HO_2 from this calculation is 0.75 V. The reduction potential of the $H_2O_2^+$ is calculated to be ≥ 2.0 V using the HO_2/H_2O_2 potential and the value of $pK_{r1} < -10$

TABLE 4. Cross-reaction and self-exchange rate constants for reactions involving the HO_2^-/HO_2 couple; ionic strength in parentheses

Oxidant[a]	Reductant[a]	$E^{0\,b}$ (V)	$k_{22}{}^c$ (M^{-1} s^{-1})	k_2 (M^{-1} s^{-1})	$k_{11}{}^c$ (M^{-1} s^{-1})
$Os(dmbpy)_3^{3+}$	HO_2^-	0.66	$4.2 \times 10^8(0.1)^d$	$1.0 \times 10^3(0.5)$	1.1×10^{-2}
$Os(bpy)_3^{3+}$	HO_2^-	0.81	$4.2 \times 10^8(0.1)^d$	$6.0 \times 10^4(0.5)$	1.0×10^{-1}
$Fe(dmbpy)_3^{3+}$	HO_2^-	0.81	$3 \times 10^8(5.5)^e$	$2.7 \times 10^4(0.5)$	7.5×10^{-2}
$Fe(bpy)_3^{3+}$	HO_2^-	1.05	$3 \times 10^8(5.5)^e$	$7.1 \times 10^5(0.5)$	0.9×10^{-2}
$Ru(dmbpy)_3^{3+}$	HO_2^-	1.06	$4.2 \times 10^8(0.1)^f$	$1.3 \times 10^6(0.5)$	0.6×10^{-2}
$Ru(bpy)_3^{3+}$	HO_2^-	1.26	$4.2 \times 10^8(0.1)^f$	$2.4 \times 10^7(0.5)$	0.4×10^{-2}
$Ni(dmbpy)_3^{3+}$	HO_2^-	1.59	$1.5 \times 10^3(1.0)^g$	$3.3 \times 10^7(0.5)$	1.5×10^{-1}
$Ni(bpy)_3^{3+}$	HO_2^-	1.72	$1.5 \times 10^3(1.0)^g$	$2.4 \times 10^8(0.5)$	2.9×10^{-1}
$(bpy)_2pyRuOH^{2+}$	HO_2^-	0.85[h]	$10^7(0.1)^i$	$2.9 \times 10^3(0.1)^j$	0.4×10^{-2}
HO_2	O_2^-	−0.15	$10^2(1.0)^k$	$1.0 \times 10^8(0.1)^l$	6.3
HO_2	$Ru(NH_3)_5isn^{2+}$	0.39[m]	$4.7 \times 10^5(0.1)^n$	$9.1 \times 10^6(0.1)^o$	2.0
HO_2	$KFe(CN)_6^{3-}$	0.42[p]	$2.2 \times 10^3(0.02)^p$	$3.3 \times 10^4(0.02)^q$	3.2×10^{-1}
HO_2	$Mo(CN)_8^{4-}$	0.75[r]	$3 \times 10^4(0.0)^s$	$5.7 \times 10^4(0.5)^t$	53

[a]dmbpy = 4,4′-$(CH_3)_2$bpy, py = pyridine, isn = isonicotinamide.
[b]E^0 values for $ML_3^{3+/2+}$ measured in 0.50 M CF_3SO_3H.
[c]Self-exchange rate constants: k_{22} is for partner of HO_2^- or HO_2 in cross-reaction; k_{11} is for HO_2^-/HO_2 using eq. [9].
[d]k_{22} for $OsL_3^{2+/3+}$ is assumed to be the same as for $Ru(bpy)_3^{2+/3+}$.

suggested by Schwarz (26) for the $H_2O_2^+$ ion. The very high reduction potential for $H_2O_2^+$ explains the much reduced rate constantes for the oxidations of H_2O_2 compared with the rate constants for HO_2^-. The reduction potentials of the metal(III) polypyridine complexes were measured in trifluoromethanesulphonate media at an ionic strength of 0.50 M. The E^0 values, similar to the reported potentials in sulphate and perchlorate media (32), are presented in Table 4 along with the self-exchange rate constants for the $ML_3^{2+/3+}$ couples.

The application of eq. [9] to the cross-reaction data yields a k_{11} value for the HO_2^-/HO_2 couple in the range of 10^{-2}–10^{-1} M^{-1} s^{-1}. The plot of log $(k_{12}/(k_{11}k_{22})^{1/2}W_{12})$ against log $(K_{12}f_{12})^{1/2}$ in Fig. 3, with $k_{11} = 5 \times 10^{-2}$ M^{-1} s^{-1}, indicates that the Marcus correlation is applicable over a wide range of thermodynamic driving forces. Also included in Table 4 and Fig. 3 are data for several reactions involving the reduction of the HO_2 radical. The calculated k_{11} values for the HO_2^-/HO_2 couple determined from these systems are for the most part larger than the estimates from the HO_2^- reactions. A much larger variation in self-exchange rate constants derived from the application of the Marcus equation is seen in the O_2^-/O_2 couple, with values spread over the range 10^{-7}–10^6 M^{-1} s^{-1}. Espenson and co-workers (47) have suggested that this variation results from the considerable differences in the solvation characteristics of the superoxide anion and the dioxygen molecule. With the variety, in terms of size and charge, of the cross-reactants employed, the transition stat would vary substantially in regard to the extent of desolvatior the superoxide anion. The same behaviour, perhaps to a les extent, would thus be expected in other small molecule coupl such as HO_2^-/HO_2.

Considerable success in predicting the electron exchange ra constant for transition metal complex (48) and small molecu (49) couples has been achieved using a semi-classical model fo outer-sphere electron exchange reactions (16). In this model the rate constant for a bimolecular exchange k_{11} may be expressed as the product of a pre-equilibrium constant K_A, an effectiv nuclear frequency ν_n, and electronic and nuclear factors, and κ_n, respectively.

$$[14] \quad k_{11} = K_A \nu_n \kappa_{el} \kappa_n$$

The nuclear factor is related to the reorganization barrier t electron exchange and is comprised of terms for the inne sphere reorganization bond distances and angles (ΔG_{in}^*) and the outer-sphere reorganization of solvent polarization (ΔG_{out}^*),

$$[15] \quad \kappa_n = \Gamma_n \exp\left[-(\Delta G_{in}^* + \Delta G_{out}^*)/RT\right]$$

where Γ_n is the inner-sphere nuclear tunneling factor. The inner-sphere reorganization energy may be derived from a knowledge of the change in the equilibrium bond distances between the reduced and oxidized states (Δd_0) and the reduced force constants (f_i) of the intramolecular vibrations.

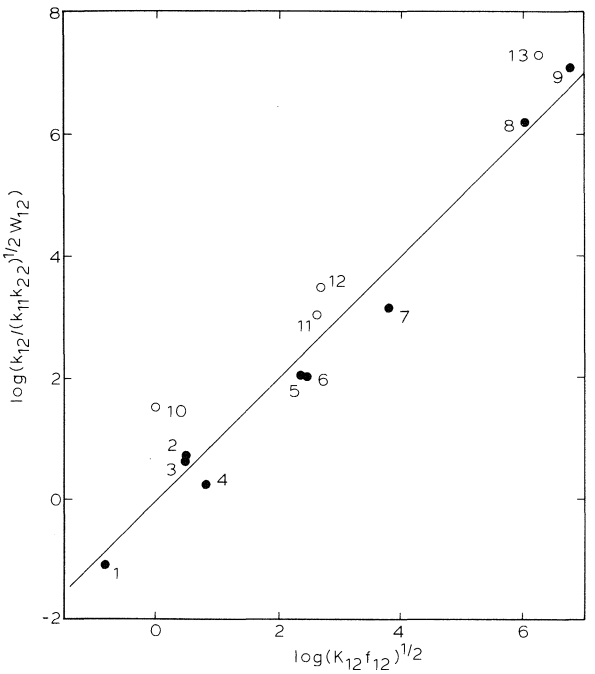

FIG. 3. Plot of log $(k_{12}/(k_{11}k_{22})^{1/2}W_{12})$ against log $(K_{12}f_{12})^{1/2}$ for the oxidation of HO_2^- by: (*1*) $Os(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$; (*2*) $Os(bpy_3^{3+}$; (*3*) $Fe(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$; (*4*) $(bpy)_2pyRuOH^{2+}$; (*5*) $Fe(bpy)_3^{3+}$; (*6*) $Ru(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$; (*7*) $Ru(bpy)_3^{3+}$; (*8*) $Ni(4,4'\text{-}(CH_3)_2bpy)_3^{3+}$; (*9*) $Ni(bpy)_3^{3+}$; and for the reduction of HO_2 by: (*10*) $Mo(CN)_8^{4-}$; (*11*) $KFe(CN)_6^{3-}$; (*12*) $Ru(NH_3)_5isn^{2+}$; (*13*) O_2^-. The points are calculated using k_{11} for $HO_2^-/HO_2 = 5 \times 10^{-2}\ M^{-1}\ s^{-1}$. Solid line has the theoretical slope of unity.

$$[16]\quad \Delta G_{in}^{*} = (1/2)\Sigma f_i(\Delta d_0/2)_i^2$$

The solvent reorganization energy may be calculated using eq. [17],

$$[17]\quad \Delta G_{out}^{*} = \frac{(\Delta e)^2}{4}\left(\frac{1}{2a_1}+\frac{1}{2a_2}-\frac{1}{r}\right)\left(\frac{1}{D_{op}}-\frac{1}{D_s}\right)$$

where r is the radius of the activated complex ($r = a_1 + a_2$), and D_{op} and D_s are the optical and static dielectric constants of the medium.

The addition of an electron to a π^* orbital in HO_2 to form HO_2^- increases the O—O bond distance from 1.33 Å to 1.49 Å (50, 51). Using O—O stretching force constants of 610 Nm^{-1} ($\nu_{O—O}$ = 1138 cm^{-1}) (52) for HO_2 and 360 Nm^{-1} ($\nu_{O—O}$ = 836 cm^{-1}) (53) for HO_2^-, an inner-sphere reorganization barrier of 4.2 kcal mol^{-1} is obtained. The radius of the HO_2^-/HO_2 activated complex is estimated to be ~3.2 Å, giving a solvent reorganization barrier of 14.1 kcal mol^{-1}. The nuclear tunneling factor (16) in most transition metal complex couples is close to unity as the M—L stretching frequencies are low. When $h\nu > kT$ (as in HO_2^-/HO_2, where ν = 964 cm^{-1}) the vibration modes which allow for nuclear reorganization cannot be fully populated by thermal excitations and electron exchange occurs to some degree by nuclear tunneling. Using Holstein's expression (54) a value of 8 for Γ_n was calculated for the HO_2^-/HO_2 couple. The estimate of ΔG_{in}^{*} is based on negligible contributions from changes in the O—H bond distance (<0.02 Å) and the OOH bond angle (~4°) in the HO_2^-/HO_2 couple (50). The nuclear factor (eq. [15]) is calculated to be 3.1×10^{-13}, and the nuclear frequency is $1.4 \times 10^{13}\ s^{-1}$. The pre-equilibrium constant is estimated to be 0.062 M^{-1} using a radius of 3.2 Å. For an adiabatic electron exchange ($\kappa_{el} = 1$) the semi-classical model predicts an exchange rate constant of $2.7 \times 10^{-1}\ M^{-1}\ s^{-1}$. This value is in reasonably good agreement with the rate constants derived from the cross-reaction data, although it is subject to the uncertainties associated with the assumptions made in its determination. One of these assumptions is that the radius of the activated complex is the sum of the hard-sphere radii of HO_2^- and HO_2. Estimates of the self-exchange rate constants or other small molecule couples, such as ClO_2^-/ClO_2 ($k_{11} = 1.6 \times 10^2\ M^{-1}\ s^{-1}$ (53)), NO_2^-/NO_2 ($k_{11} = 8.1 \times 10^{-3}\ M^{-1}\ s^{-1}$ (55)), and Br_2^-/Br_2 ($k_{11} = 10^2\ M^{-1}\ s^{-1}$ (29, 47, 56)), have been made from cross-reaction kinetic studies. Applications of classical and semi-classical models to these couples have invariably led to calculated radii which are ~1 Å larger than is predicted from the hard-sphere radii. This may imply an activated complex in which the reactants are not in close contact but are separated by solvent molecules originating from solvation of the anionic species in the couple. The variations in k_{11} for diatomic and triatomic molecules from cross-reaction data also suggest that the solvent reorganization barrier associated with the cross-reaction may differ substantially (higher or lower) from an average of the individual solvent reorganization barriers for the self-exchange reactions. Kinetic studies of the reactions of HO_2^- and HO_2 with additional outer-sphere cross reactants may help to clarify the energetics of electron exchange in this and other small molecule couples.

A method is proposed for the preparation of Ru/ZSM-5 catalysts using substituted and non-substituted ruthenocenes. To this end, the following complexes have been synthesized and characterized: dimethyl-1,1′; diphenyl-1,1′; dibenzoyl-1,1′, and monobenzoyl ruthenocene. Results of ESCA intensity ratio and ir of adsorbed pyridine show differences in the surface segregation of Ru as well as in the cationic exchange of Ru with Brønsted acid sites of the zeolite, when the catalyst is prepared using ring-substituted ruthenocene instead of ruthenocene itself. The binding energies of Ru $3d_{5/2}$ measured by ESCA are discussed.

G. LEMAY, S. KALIAGUINE, A. ADNOT, S. NAHAR, D.COZAK et J MONNIER. Can. J. Chem. **64**, 1943 (1986).

On propose une méthode de préparation des catalyseurs de type Ru/ZSM-5 utilisant des ruthenocènes substitués ou non. A cette fin, on a fait la synthèse et la caractérisation des complexes suivants: dimethyl-1,1′, dipenyl-1,1′, dibenzoyl-1,1′ et monobenzoyl ruthenocène. Des données sur les rapports d'intensités ESCA et sur l'analyse infrarouge de la pyridine adsorbée indiquent des différences relatives à la ségrégation superficielle du Ru ainsi qu'à l'échange de cations ruthenium avec les sites acides de Brønsted de la zéolithe, lorsque le catalyseur est préparé à l'aide de ruthenocène substitué au lieu de ruthenocène. Les énergies de liaisons de Ru $3d_{5/2}$ déterminées par ESCA sont discutées.

Organometallic complexes of transition metals have been systematically utilized in the preparation of model catalysts in which the transition metal is deposited on a support and the supported species retains some desirable properties of the complex (1). Among the properties being controlled are the state of dispersion and the size of metallic clusters (2), the oxidation state of the metal (3), the nature and number of organic ligands retained on the species (4), the number of its bonds to the support and to surrounding atoms like oxygen or sulfur, and its state of coordination (5).

In this paper, complexes of ruthenium have been used in an effort to control yet another property, namely the spatial distribution of the metal in a particle of zeolite used as the support. The ZSM-5 type zeolite used in this work has near-circular ten-oxygen ring pore openings with diameters in the 5.1 to 5.7 Å range (6). It is therefore expected that ruthenocene (ruthenium biscyclopentadienyl) with 4.6 Å ring diameter and 3.2–3.6 Å ring interplanar distance would diffuse freely in the ZSM-5 pores (7). However, 1,1′-disubstitution of bulky functional groups like phenyl or benzoyl should yield complexes with kinetic diameters higher than 5–6 Å, and diffusion in the ZSM-5 pores should be limited by steric constraints.

Therefore the following series of organometallic compounds have been synthesized and used in the preparation of ZSM-5 supported ruthenium catalysts: ruthenocene, dimethyl-1,1′ ruthenocene, diphenyl-1,1′ ruthenocene, and dibenzoyl-1,1′ ruthenocene.

This paper will be divided in two parts dealing, respectively, with the synthesis of these ring-substituted ruthenocenes and with the preparation and characterization of the Ru/ZSM5 catalysts.

Part I. Synthesis of ring-substituted ruthenocenes

Ruthenocene is known to have chemical properties and a structure similar to ferrocene. A preparative procedure for the synthesis of ruthenocene was proposed in 1961 by Bublitz, McEwen, and Klemberg (8). A much simpler procedure, giving a quantitative yield of ruthenocene was, however, suggested more recently by Pertici *et al.* (9). Based on this last method, we have been successful in synthesizing with improved yields two ruthenocene-derived compounds: dimethyl-1,1′ ruthenocene and diphenyl-1,1′ ruthenocene.

[1] $RuCl_3 \cdot 3H_2O$ —(R, ethanol)→ Ru(R)(R)

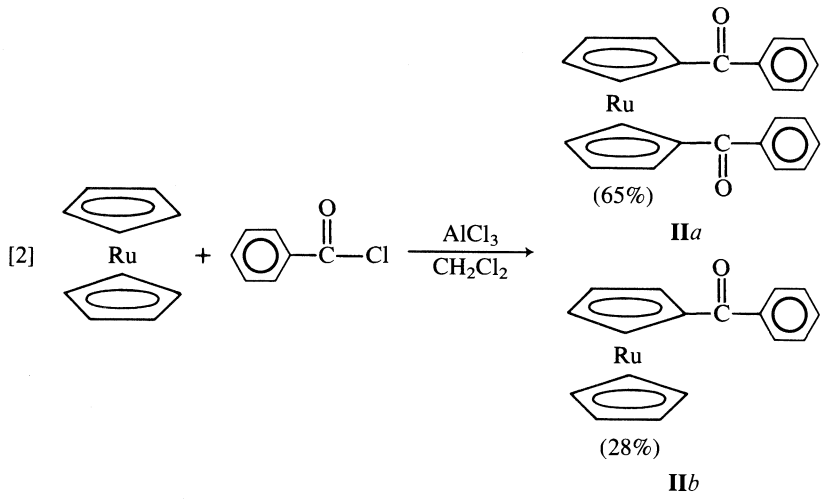
with (*a*) R = CH_3, (*b*) R = C_6H_5.

Dimethyl-1,1′ ruthenocene has been synthesized by Hofler and Schlögl (10). This procedure however is time consuming and complex, whereas with Pertici *et al.*'s technique the product is obtained in only one step in quantitative yield.

Before using this method for the preparation of diphenyl-1,1′ ruthenocene, we tried the reaction used by Pauson (11) for the production of diphenyl-1,1′ ferrocene. For this, we utilized anhydrous ruthenium trichloride ($RuCl_3$) instead of $FeCl_3$. No product was obtained after stirring for 24 h and therefore this technique was abandoned. Perhaps anhydrous ruthenium trichloride is too insoluble in organic solvents for this type of reaction.

The method of Pertici *et al.* requires, however, a large excess of phenylcyclopentadiene (PCP). The yield is high but a large excess of PCP with respect to hydrated ruthenium trichloride must be used.

No synthesis procedure could be found in the literature for dibenzoyl-1,1′ ruthenocene. Rosenblum and Woodword (12) in 1958, proposed a Friedel–Craft synthesis for dibenzoyl-1,1′ ferrocene. We therefore tried to apply this technique, starting from ruthenocene, and the results were satisfactory:



Some monobenzoyl ruthenocene (**II***b*) is necessarily produced in the course of this reaction since too large an excess of benzoyl chloride results in the formation of other nondesirable impurities. Ruthenocene, benzoyl ruthenocene (**II***b*), and dibenzoyl-1,1′ ruthenocene (**II***a*) can be well separated by column chromatography on silica gel. These ruthenocene compounds are air stable at room temperature. Davis and O'Reardon (13) have synthesized monobenzoyl ruthenocene (**II***b*) in order to perform a mass spectrometric comparative study with monobenzoyl ferrocene. They applied Hofler and Schlög's method, monobenzoyl ruthenocene being prepared by a technique similar to the one proposed for monoacetyl ruthenocene. This method involves several steps with the Friedel–Craft technique, the main product (**II***a*) can be obtained with a high yield by using 2 mol of benzoyl chloride per mole of ruthenocene. The technique is fast and simple.

It may be mentioned that Davis and O'Reardon did not give the characteristics of benzoyl ruthenocene except for the mass spectrum. We therefore report both nmr and ir spectra for this compound.

Experimental

Melting points were determined in capillary tubes using a Thomas–Hoover melting point apparatus and were not corrected. Infrared spectra were recorded with KBr wafers using a Beckman IR-4250 spectrometer calibrated with the 2851 and 1602 cm^{-1} bands of polystyrene. Samples for mass spectrometric analysis were prepared under purified nitrogen in sealed capillaries. Mass spectra (ms) were determined using a Hewlett-Packard 5992 GC/MS system. Proton nuclear magnetic resonance spectra were recorded using a 90 MHz Brucker HX-90 spectrometer or a 60 MHz Varian A60 instrument. Elemental C, H, N analyses were performed using a Hewlett-Packard F and M Scientific 185 analyzer.

Starting materials

Ruthenocene was synthesized using the method of Pertici *et al.* Phenylcyclopentadiene was produced according to the method of Pauson and purified by vacuum distillation. Methylcyclopentadiene was distilled immediately prior to use. Hydrated 2-cyclopentenone (lot No 8024 KL), metallic lithium (lot No 5320 LK), and anhydrous ruthenium trichloride (lot No 4431 KL) were from Aldrich chemicals and hydrated ruthenium chloride from Aesar Johnson Mattey Inc. (lot No 122783). Aluminium chloride (lot No 710047), benzoyl chloride (lot No 716475), and powdered zinc (lot No 733421) were bought from Fisher Scientific Ltd. All solvents were purified by distillation under purified nitrogen (Cu + molecular sieves).

*Preparation of dimethyl-1,1′ ruthenocene (**I**a)*

Hydrated ruthenium trichloride (5.00 g, 0.019 mol) is dissolved absolute ethanol (100 mL) under purified nitrogen and cooled to −70°C. Freshly distilled methylcyclopentadiene (100 mL) and powdered zinc (50 g) are then added to the solution. This mixture is slowly warmed up to room temperature while stirring. The reaction starts at −40°C. The mixture is stirred for 30 min after it reaches room temperature and is filtered in air. The solvent is then evaporated to dryness and dimethyl-1,1′ ruthenocene is extracted with pentane. The product is purified by column chromatography (silica gel, activity I, 20 cm) and eluted with pentane. Evaporation of the solvent yields light yellow crystals (4.9 g). Melting point: 56–57.5°C [lit. (3): 61–63°C]. *Anal.* calcd. for $C_{12}H_{14}Ru$: C 55.58, H 5.44, mw 259.32; found: C 55.28, H 5.83, ms 259 *m/z*. Ir (KBr): 1465 or 1445, 990 and 803 cm^{-1} (C_5H_4). ^1H nmr (60 MHz, CCl_4): δ 1.96 ppm (6H, s) CH_3, 4.4 ppm (8H, m) C_5H_4.

Preparation of diphenyl-1,1′ ruthenocene (***I***b)

Hydrated ruthenium trichloride (2.91 g, 0.0111 mol) is dissolved in absolute ethanol (60 mL) under purified nitrogen. The solution is cooled down to −70°C.

Freshly distilled phenylcyclopentadiene (9.50 g, 0.0668 mol) is dissolved in ethanol (125 mL) and added to the solution along with powdered zinc (29 g). With stirring, the mixture is slowly warmed to room temperature and kept stirring for 1 h. The mixture is then filtered in air and the solvent is evaporated to dryness. Diphenyl-1,1′ ruthenocene is extracted with cyclohexane (1.5 L) and purified by column chromatography (silica gel, activity I, 150 g) and eluted with cyclohexane. Evaporating the solvent yields 3.23 g of pure diphenyl-1,1′ ruthenocene which corresponds to a yield of 76%. The product can be purified either by recrystallization or by sublimation at 150°C, 10.01 Torr. Melting point: 162°C (benzene/petroleum ether). *Anal.* calcd. for $C_{22}H_{18}Ru$: C 68.91, H 4.73, mw 383.43; found: C 67.66, H 4.45, ms 384 *m/z*. Ir (KBr): 1603 [ν(C=C) of Ph], 1445, 995, and 800 cm^{-1} (C_5H_4). ^1H nmr (90 MHz, $CDCl_3$): δ 4.66 ppm (4H, m) and 5.0 ppm (4H, m) C_5H_4, 7.24 ppm (10H, s) C_6H_5.

*Preparation of dibenzoyl-1,1′ ruthenocene (**II**a)*

Ruthenocene (3 g, 0.013 mol) is added to a suspension of benzoyl chloride (3.66 g, 0.026 mol) and aluminum chloride (3.81 g, 0.0285 mol) in anhydrous dichloromethane (75 mL) under purified nitrogen. The mixture is heated to reflux for 2 h, hydrolyzed over ice, and extracted three times with dichloromethane. The extract is then washed with water and dried over magnesium sulfate. The solvent is then evaporated. Dibenzoyl-1,1′ ruthenocene crystallizes and is purified by recrystallization from a benzene/petroleum ether solution. **II***b* can be easily separated from **II***a* by column chromatography of the mother liquor over 100 g of silica gel by elution with benzene. Yields of

Part II. Preparation and characterization of Ru/ZSM-5

Experimental procedures

The catalysts reported in this study were prepared using ZSM-5 samples from the same batch as a support. This zeolite was synthesized according to the procedure described as method B′ by Gabelica *et al.* (14).

The sodium precursor was thoroughly washed under flowing distilled water and dried overnight at 130°C. It was then slowly heated under static air up to 500°C and maintained at this temperature for 15 h in order to decompose the organic base [TPA]Br. Then the Na^+ counter ions were exchanged with NH_4^+ ions in 1 *M* ammonium nitrate solution at 80°C, this operation being repeated three times. The ammonium form was then again thoroughly washed with distilled water, dried, and calcined at 550°C yielding the H form which was used as the support. This H-ZSM-5 has a Si/Al ratio of 36 and a sodium content lower than 0.01 wt%. Its X-ray diffraction pattern in characteristic of the ZSM-5 lattice (15) and shows a crystallinity very close to 100%.

The Ru/ZSM-5 catalysts were prepared according to the following original procedure: the zeolite and the solid ruthenocene compound were mixed in calculated proportions, ground in an agate mortar and introduced into a Pyrex tube. This tube was evacuated, sealed, and introduced in a furnace in which it was slowly heated to 500°C and kept for 24 h at this temperature. The recovered material was placed in a crucible and calcined for 5 h in air at 550°C. The ruthenium content of these solids was determined by X-ray fluorescence. X-ray diffraction spectra showed the pattern of RuO_2 superimposed on the one of ZSM-5. The ZSM-5 spectrum showed no alteration of the ZSM-5 crystallinity. The RuO_2 lines, even though not very intense, especially in the low Ru samples, showed almost no broadening over the experimental lines of a stoichiometric RuO_2 sample. This observation indicates the presence in all samples of RuO_2 particles larger than 300 Å.

The photoelectron spectra were recorded using a Vacuum Generators ESCALAB mark II instrument using an Al K_α X-ray source (1486.6 eV). The base pressure of the instrument is 5×10^{-11} Torr and during experiments the pressure was less than 10^{-8} Torr. The spectrometer energy scale was calibrated using both Au $4f_{7/2}$ (84.0 eV) and Ag $3d_{5/2}$ (368.3 eV). The Si 2*p* (103.3 eV) line was systematically used as an internal standard in obtaining the binding energies of ruthenium and other elements. The Ru/ZSM-5 samples were introduced in the spectrometer as powders pressed onto indium disks. No flood gun was utilized.

Infrared spectra of adsorbed pyridine were shown by Stencel *et al.* (16) to be of special value for Fe and Co/ZSM5 catalysts. The technique employed in this study involves preparing very thin wafers (10 mg in 13 cm wafers) and the use of a special movable ir cell which can be connected to a vacuum line. The wafer is preheated to 450°C in vacuum. Pyridine is adsorbed at room temperature and the wafer is heated overnight at 150°C in a vacuum better than 10^{-4} Torr in order to eliminate physisorbed pyridine. The ir spectrum is then recorded at room temperature on a Beckman model IR-4250 instrument.

Results and discussion

Table 1 shows results for the binding energies of several elements in our Ru/ZSM5 samples, calculated from the experimental values of the kinetic energy of photoelectrons E_k as:

$$[1] \quad E_B = h\nu - E_k - \Delta_c$$

where $h\nu$ is the energy of the incident photons and Δ_c a correction including the charging effect and calculated by referencing the energy scale to some known standard value. Table 1 gives the values of Δ_c obtained by adjusting the Si 2*p* level to a binding energy of 103.3 eV. A lower value is often

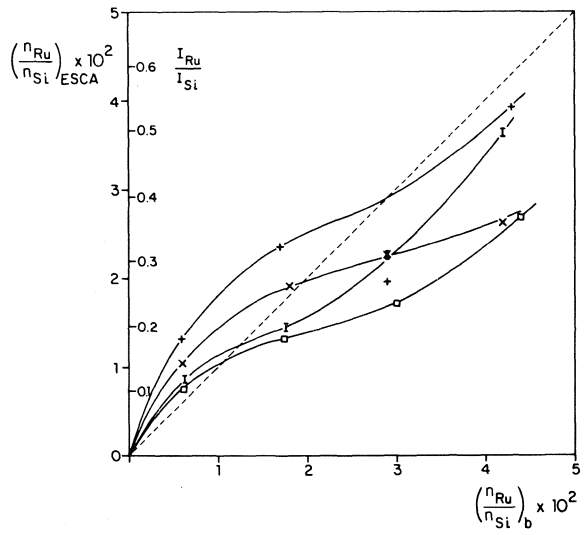

FIG. 1. ESCA intensity ratio (I_{Ru3d}/I_{Si2p}) and atomic ratio $(n_{Ru}/n_{Si})_{ESCA}$ as a function of bulk atomic ratio. □ ruthenocene, × dimethyl ruthenocene, + diphenyl ruthenocene, I dibenzoyl ruthenocene.

reported in the literature, for example 102.7 eV for Si $2p$ in silica gel, but it is our experience that for Si $2p$ in ZSM-5, the value of 103.3 eV is more appropriate. This is confirmed here by the correct position of the O_{1s} line obtained (532.55 ± 0.15 eV). The Al $2p$ line shows more scatter (74.9 to 75.6 eV and one point at 76.1 eV). The average value close to 75.2 eV is higher than the value quoted for Al $2p$ in Al_2O_3 (74.5 eV) but such a difference would be compatible with a more ionic character of the links of Al^{3+} to the zeolite lattice. The Ru $3d$ binding energy results will be discussed later on.

Figure 1 shows the results for the XPS intensity ratio Ru $3d$/Si $2p$ plotted as a function of the bulk atomic ratio $(n_{Ru}/n_{Si})_b$ calculated from X-ray fluorescence analytical results.

According to Kerkhoff and Moulijn (17) the XPS intensity ratio is given by

$$[2] \quad \left(\frac{I_{Ru}}{I_{Si}}\right)_{mono} = \left(\frac{n_{Ru}}{n_{Si}}\right)_b K$$

in the case of Ru being uniformly distributed within the pore lattice of the support. Moreover, for a monolayer dispersion of ruthenium, K can be calculated as:

$$[3] \quad K = \frac{D(E_{kRu})}{D(E_{kSi})} \frac{\sigma_{Ru}}{\sigma_{Si}} \frac{\beta_1}{2} \frac{(1 + e^{-\beta_2})}{(1 - e^{-\beta_2})}$$

In our case K was estimated using

$$[4] \quad \frac{D(E_{kRu})}{D(E_{kSi})} = \left(\frac{E_{kSi}}{E_{kRu}}\right)^{1/2}$$

σ_{Ru} and σ_{Si} being the photoelectron cross sections, as given by Scofield (18), and

$$[5] \quad \beta_1 = 2/\rho_s S_0 \lambda_{Si}$$
$$\beta_2 = 2/\rho_s S_0 \lambda_{Ru}$$

ρ_s and S_o are respectively the density and specific surface area of the support and λ_{Si}, λ_{Ru} the escape depths of Si and Ru photoelectrons from the support.

Deviations from the hypothesis of eq. [2] can be shown by comparing to $(n_{Ru}/n_{Si})_b$ the calculated values of:

$$[6] \quad (n_{Ru}/n_{Si})_{ESCA} = \left(\frac{I_{Ru}}{I_{Si}}\right)_{expt} \frac{1}{K}$$

Such a comparison is made in Fig. 1. When, as found for the lower Ru loadings, $(n_{Ru}/n_{Si})_{ESCA} > (n_{Ru}/n_{Si})_b$, the Ru content of the surface layers sensed by ESCA is higher than the average value. It can therefore be concluded from the results of Fig. 1 that superficial segregation is already present at Ru contents as low as 1%, and is more important for samples prepared from substituted than for non-substituted ruthenocene. At higher loadings the dispersion of Ru is decreased, K is no longer represented by eq. [3] and, as shown in ref. 17, mus decrease, yielding

$$\left(\frac{I_{Ru}}{I_{Si}}\right)_{expt} < \left(\frac{I_{Ru}}{I_{Si}}\right)_{mono}$$

or

$$\left(\frac{n_{Ru}}{n_{Si}}\right)_{ESCA} < \left(\frac{n_{Ru}}{n_{Si}}\right)_b$$

Nevertheless, ruthenocene-prepared catalysts show the lowest $(I_{Ru}/I_{Si})_{expt}$ whereas for diphenyl ruthenocene-prepared samples this ratio is the highest, indicating as expected, mor surface segregation in this last case.

Table 2 gives results for ir of adsorbed pyridine and in particular the ir absorbance ratio A_B/A_L, A_B and A_L corresponding to pyridine adsorbed on Brønsted and Lewis acid sites, respectively. This ratio is related to (B/L), the ratio of Brønsted to Lewis sites per unit cell:

$$[7] \quad (A_B/A_L) = (B/L) \times (\epsilon_B/\epsilon_L)$$

where ϵ_b and ϵ_L are extinction coefficients.

The ratio (ϵ_L/ϵ_B) has been measured in silica–alumina (19) and zeolites (20) and from the trend of these data with increasing Si/Al, it was suggested (21) that the value of $(\epsilon_L/\epsilon_B) = 1.5$ is appropriate for high silica zeolites. Applying eq. [7] to the support yields:

$$[8] \quad (B_z/L_z) = 3.75$$

Because the unit cell of the support is expressed as $Al_{2.6}Si_{93.4}O_{192}$, and the Lewis site in the zeolite is generated by dehydroxylation of two Brønsted sites:

$$[9] \quad B_z = 2.6 - 2L_z$$

Combining eqs. [8] and [9] yields $B_z = 1.7$, $L_z = 0.45$.

A rough estimate of the number of ruthenium ions exchanged per unit cell (Ru) can be obtained by combining eq. [7] with balances of acid sites, which, assuming arbitrarily the valence 2 for the exchanged ruthenium, may be written as:

$$[10] \quad L = 2(\text{Ru}) + L_z$$

$$[11] \quad B = B_z - 2(\text{Ru})$$

$$[12] \quad (\text{Ru}) = \frac{B_z - (\epsilon_L/\epsilon_B)(A_B/A_L)L_z}{2[1 + (\epsilon_L/\epsilon_B)(A_B/A_L)]}$$

These results expressed either as the number of unexchanged Brønsted sites or as the weight percent of exchanged ruthenium are given in Table 2.

Although these figures are not definitely established due to uncertainties in the valence state of exchanged ruthenium, they can nevertheless be used for comparison between the various catalysts.

Figure 2 allows such a comparison by showing the uncon-

TABLE 2. Infrared results of adsorbed pyridine

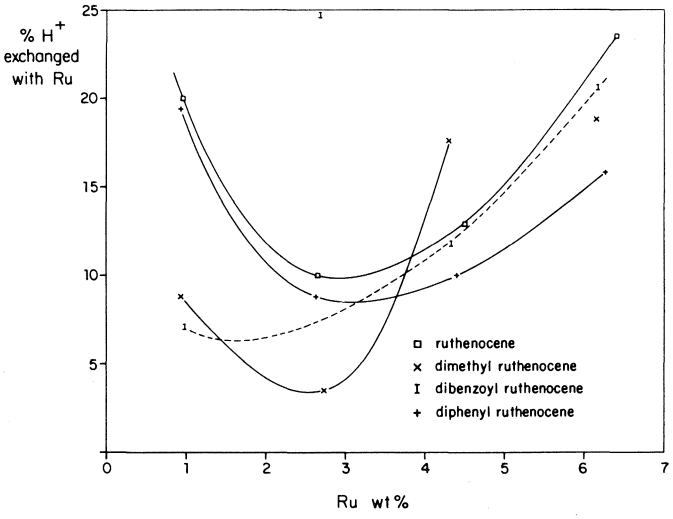

FIG. 2. Percent of Brønsted acid sites exchanged with Ru cations, as measured by ir of adsorbed pyridine.

verted percentage of Brønsted acid sites as a function of bulk ruthenium loadings.

The general trend of these curves shows a higher exchange of ruthenium when ruthenocene is used in the preparation, indicating more metal has penetrated the pore lattice in this case. This result is in agreement with the ESCA results reported in Fig. 1. Figure 2 shows that increasing the size of the ring substituent does not completely avoid the penetration of ruthenium. The curve for diphenyl ruthenocene for example is almost as high as the ruthenocene one. The initial decrease in exchanged Brønsted sites with increasing ruthenium loading may be explained by restrictions to the inward diffusion of ruthenium compounds due to an early formation of ruthenium plugs. This lower dispersion of the inside ruthenium is indeed compatible with the ESCA results in Fig. 1 at these low Ru loadings.

We may now proceed to the discussion of the Ru ESCA data of Table 1.

ESCA data for stoichiometric ruthenium compounds have been reported by Kim and Winograd (22) and by Folkesson (23). These data are presented in Table 3. Both authors agree on a value close to 280.0 eV for the binding energy of Ru $3d_{5/2}$ in Ru^0. Folkesson (23), however, mentions that this is about 1 eV higher than the values reported by Siegbahn. There is, however, a clear disagreement on the RuO_2 value. Kim and Winograd (22) discuss in details the difficulties in obtaining this value. They explain that the surface of a RuO_2 sample may contain species of higher oxides (RuO_3 and RuO_4) which are volatile. They show by ESCA that this species can be eliminated by heating at temperatures as low as 220°C and that in this process ruthenium metal appears on the surface. We believe that this process must be quite common on RuO_2 surfaces. We produced a sample of ruthenium oxide by calcination of $RuCl_3$ in air at 900°C. The X-ray diffraction pattern showed this sample was essentially RuO_2 but the spectrum of Ru metal was definitely apparent. The ESCA spectrum of this sample showed essentially a Ru^0 covered surface with a Ru $3d_{5/2}$ binding energy of 279.8 eV, with only a shoulder at 281.7 eV corresponding to RuO_2.

Therefore we believe that the ESCA data of Table 1 showing that for a large proportion of our samples the binding energy of Ru $3d_{5/2}$ is in the range 280.0 ± 0.3 eV correspond to a similar situation. Most of the ruthenium would therefore be in the form of RuO_2 microcrystals of diameter larger than 300 Å (as shown by XRD) located at the external surface of the ZSM-5 crystal, and having their surface covered with metallic ruthenium.

It is interesting to note in this regard that both Pedersen and Lunsford (24) and Tkatchenko *et al.* (25) find low Ru $3d_{5/2}$ binding energies for oxygen- or air-calcined samples of Ru Y catalysts. The last author reports for example values of 280.6, 280.7, 280.8, and 280.6 eV, respectively, for Ru metal and Ru Y heated at 400°C, 500°C in O_2 for 2.5 h and at 500°C in H_2 for 1.5 h. Therefore on these catalysts, just like on ours, it seems

TABLE 3. Binding energies of Ru $3d_{5/2}$ in ruthenium compounds

Oxidation state	Compound	Reference line	B.E. Ru $3d_{5/2}$ (eV)	Reference
0	Ru metal	Au $4f_{7/2}$ = 84.0 eV	280.0	22
4	RuO_2		280.7	22
4	RuO_2,XH_2O		281.4	22
6	RuO_3		282.5	22
8	RuO_4		283.3	22
0	Ru metal	Pt $4f_{7/2}$ = 71.1 eV	279.9	23
2	$Ru(NH_3)_5N_2Cl_2$		282.5	23
2	$Ru(NH_3)_5N_2Br_2$		280.5	23
2	$Ru(NH_3)_5N_2I_2$		282.2	23
3	$RuCl_3$		281.8	23
4	RuO_2		282.1	23

that Ru is essentially in the zero valence state in the surface zone sensed by ESCA, even in the calcined samples.

As shown by the ir results of Table 2, the exchanged ruthenium is only a minor fraction of total supported ruthenium in our samples. It is therefore not surprising that the ruthenium ions that exchanged with protons do not have a major effect on the ESCA spectra. It may at most be conjectured that the 0.5–0.6 eV higher Ru $3d_{5/2}$ binding energies observed for samples 129-A and 124-A compared to samples with higher loadings reflect the presence of cationic species with charges between 0 and +4.

Conclusion

Our investigation of the synthesis of ring-substituted ruthenocenes allowed us to propose improved methods for the syntheses of dimethyl and diphenyl-1,1′ ruthenocene which are derived from the procedure reported by Pertici *et al.* (9) for the synthesis of ruthenocene. An original method is also proposed for the synthesis of dibenzoyl-1,1′ ruthenocene in which monobenzoyl ruthenocene is obtained as a by-product. Complete chemical identifications of these four ruthenocenes are reported.

A new method based on the gas–solid interaction of these compounds with the H form of the zeolithe ZSM-5 has been used for the preparation of ZSM-5 supported ruthenium catalysts. The addition of ring substituents allows some control of the spatial distribution of ruthenium with respect to the limits of the ZSM-5 crystal. From the characterization of the catalysts by ESCA, XRD, and ir of adsorbed pyridine, three forms of ruthenium may be present in the calcined samples.

(*1*) RuO_2 particles with diameter larger than 300 Å, located on the external surface of the ZSM-5 crystals. Unexpectedly, the surface of these particles is covered with Ru^0.

(*2*) Ruthenium ions located in the ZSM-5 pore lattice and having partially exchanged the Brønsted acid sites. ESCA did not allow for a determination of the valence state of these ions which could be 1+, 2+, or 3+.

(*3*) Ruthenium oxide (likely RuO_2) with a particle size in the 5–10 Å range may also be present in the pore lattice. The presence of such plugging material is inferred from the variations in the content of exchanged ruthenium ions with bulk ruthenium loading.

Photochemical retro-aldol type reactions of nitrobenzyl derivatives. Mechanistic variations in the elimination of nitrobenzyl carbanions from nitrobenzyl derivatives on photolysis

PETER WAN[1] AND S. MURALIDHARAN
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 4, 1986

PETER WAN and S. MURALIDHARAN. Can. J. Chem. **64**, 1949 (1986).

The photochemical retro-aldol type reactions of several nitrobenzyl derivatives are reported. The reactions are observed only in aqueous solution with quantum efficiencies being pH dependent for several derivatives, consistent with the existence of several mechanistic pathways for reaction. The primary photochemical event is believed to involve the generation of a nitrobenzyl carbanion, which acts as a photolabile leaving group in these reactions, and the generation of an oxocarbocation (or oxocarbocation-derived) fragment.

PETER WAN et S. MURALIDHARAN. Can. J. Chem. **64**, 1949 (1986).

On a étudié les réactions photochimiques de type rétro-aldol de plusieurs dérivés nitrobenzyles. On n'a observé ces réactions qu'en solution aqueuse et les rendements quantiques dépendent souvent du pH. Ceci témoigne de l'existence de divers chemins réactionnels. On pense que la première réaction photochimique implique la formation d'un carbanion nitrobenzyle, agissant comme groupe photolabile ainsi que celle d'un fragment oxocarbocation (ou d'un dérivé d'oxocarbocation).
