$C_2H_2^{+\cdot}$ and $C_4H_2^{+\cdot}$ appeared as the major product ions in this reaction. Formation of CN^+ and C_3N^+ is endothermic in this case. An abundance of secondary ion chemistry was observed since both of the primary product ions are reactive towards acetylene. We have established in separate experiments that $C_2H_2^{+\cdot}$ gives rise to $C_4H_2^{+\cdot}$, $C_4H_3^+$, and $C_4H_4^{+\cdot}$, which in turn add acetylene to give rise to the corresponding adduct ions. All of these conversions were observed to be initiated by the reaction of $(HC_3N)^{+\cdot}$ with acetylene. The $C_4H_3^+$ ion generated from $C_2H_2^{+\cdot}$, which also reacts further with acetylene, could not be distinguished with our mass spectrometer from $(HC_3N)^{+\cdot}$. Therefore it is conceivable that the decay of the ion at m/z = 51 provides only a lower limit to the rate constant of the primary reaction.

OCS

The predominant reaction observed with carbonyl sulphide was charge transfer, and the $(OCS)^{+\cdot}$ product ion reacted further to add one molecule of carbonyl sulphide. A minor channel was observed that corresponds to sulphur atom abstraction and so leads to the incorporation of sulphur into the cyanoacetylene ion. No reaction was observed with the $H_2C_3N^+$ ion that was also present initially. This is not surprising since proton transfer is endothermic in this case.

C_2H_4

$C_2H_4^{+\cdot}$ was the predominant product with ethylene and it rapidly reacted further to establish $C_3H_5^+$ and the adduct $(C_2H_4)_2^{+\cdot}$. The minor channel leading to the formation of $H_2C_3N^+$ corresponds to the transfer of a hydrogen atom.

C_4H_2

Charge transfer was the predominant reaction observed with diacetylene. The production of C_3N^+, which could not be distinguished with our mass spectrometer from $C_4H_2^{+\cdot}$, is endothermic. The $C_4H_2^{+\cdot}$ reacted further to form the adduct $C_4H_2^{+\cdot} \cdot C_4H_2$ as well as some $C_6H_2^{+\cdot}$. This latter reaction has been studied in separate experiments in more detail and will be reported elsewhere. It was also interesting to note that the $H_2C_3N^+$ reacted quite rapidly with diacetylene to add one molecule, while the addition of a second molecule was noted to be at least ten times slower. At 0.33 Torr of helium and a concentration of 1.1 × 10^{16} helium atoms cm^{-3} the apparent bimolecular rate constant for addition of the first molecule of diacetylene was (8.7 ± 2.6) × 10^{-10} cm^3 $molecule^{-1}$ s^{-1}. This is close to the collision limit and probably reflects the formation of a strong hydrogen bond in the adduct. Bonding of the second diacetylene molecule would then be much less favourable and lead to a much lower rate of adduct formation.

Discussion and conclusions

The efficiency of the hydrogenation of ionized cyanoacetylene by H atom transfer from H_2 according to reaction [1] has been established in the experiments reported here to be less than 0.05% at 296 K. The hydrogen atom transfer is more than 30 kcal mol^{-1} exothermic but its low efficiency suggests that it has a positive activation energy. Consequently it may not contribute significantly to the formation of $H_2C_3N^+$ at the much lower temperatures found in interstellar gas clouds. The reactions with CH_4 and H_2O provide more efficient routes for the hydrogenation of ionized cyanoacetylene and so may be more suited to the eventual synthesis of cyanoacetylene by reactions [2] and [3]. Of course other reactions operate in interstellar gas clouds to establish $H_2C_3N^+$ without $HC_3N^{+\cdot}$ as a precursor, such as, for example, the reaction of $C_3H_3^+$ with N atoms (2, 3) and the reaction of $C_2H_2^{+\cdot}$ with HCN (5).

Also, we have shown that proton transfer from ionized cyanoacetylene to carbon monoxide does not occur at room temperature and so is not a viable reaction in models of the chemistry of interstellar clouds. We have observed a slow addition reaction in a few tenths of a Torr of helium to form what may be the isocyanate ion, H—C≡C—C·=N⁺=C=O, but it is uncertain to what degree this happens in interstellar clouds in which radiative association would be the only means of stabilizing the adduct ion.

The reaction of ionized cyanoacetylene with carbonyl sulphide also has interesting implications for interstellar chemistry. The $(HC_3NS)^{+\cdot}$ ion formed in 20% of the reaction at room temperature is a potential source of ·S—C≡C—C≡N or :C=C=C=N—S·, which may be formed by the recombination of $(HC_3NS)^{+\cdot}$ with electrons.

The failure to observe significant amounts of proton transfer with any of the neutral reagents is curious. The proton affinities of the neutral molecules chosen as reagents span a range from 101 for H_2 to 184 kcal mol^{-1} for cyanoacetylene (14,15). The

proton affinity of $(C_3N)^{\bullet}$ can be calculated to be 140 kcal mol^{-1} from the known heats of formation of ionized cyanoacetylene, the proton, and the $(C_3N)^{\bullet}$ radical. The latter is based on the appearance potential of CN^- from dicyanoacetylene (16) and appears to be reliable. The proton affiinity of $(C_3N)^{\bullet}$ is therefore less than that for CO (142), OCS (151), C_2H_2 (153), C_2H_4 (163), H_2O (166), HCN (171), C_4H_2 (180), and HC_3N (184), where the proton affinity is given in parentheses in kcal mol^{-1}. Yet the proton transfer observed with any of these molecules was at most 5% of the total reaction pathway.

Charge transfer, H atom transfer, and adduct formation were the alternate channels that appeared to compete successfully with proton transfer. The recombination energy of $(HC_3N)^{+\bullet}$ is 11.60 eV, which exceeds the ionization energy of the molecules C_4H_2 (10.17), C_2H_4 (10.5), OCS (11.18), and C_2H_2 (11.41). Charge transfer is therefore exothermic and indeed was observed to be a predominant reaction channel for each of these four molecules. For the reaction with C_2H_2 the ultimate formation of the charge transfer product is minor but we speculate that $C_2H_2^{+\bullet}$ in part also reacts with HC_3N before the products separate to produce $C_4H_2^{+\bullet}$. We have shown in a separate study that this latter reaction proceeds readily when $C_2H_2^{+\bullet}$ is produced by electron impact from acetylene (17).

The hydrogen atom affinity of ionized cyanoacetylene is at least 10 kcal mol^{-1} higher than the homolytic X—H bond energy of any of the molecules of type XH chosen as reagents in this study. Yet hydrogen atom transfer was observed not to compete effectively with charge transfer when the latter was also exothermic, as for the reactions with ethylene, acetylene, and diacetylene. Also it did not compete significantly with adduct formation for the reactions with HCN and HC_3N. In fact, only for the reactions with H_2, CH_4, and H_2O was hydrogen atom transfer observed to compete effectively with other reaction channels.

We suggest that both the curious failure of proton transfer and the discriminating behaviour of hydrogen atom transfer may be accounted for by steric constraints that could operate at close separations because of the electrostatic interaction between the cyanoacetylene ion and the reacting molecule. Preferential attack at the nitrogen end of the lengthy $(H—C{\equiv}C—C{\equiv}N)^{+\bullet}$ ion would put the proton "out of reach" of the reacting molecule and so prevent proton transfer. Also, for hydrogen atom transfer, the hydrogen atom in the reacting molecule may become "out of reach" of the ion, depending on the length and preferred alignment of the reacting molecule. This is likely to be the case with HCN and HC_3N, for example. These strong dipoles are likely to approach the positive ion preferentially with their negative nitrogen end. Azine type N—N bonding would then be possible if the nitrogen end of the ion is the site of attack. The high rates of association observed for the reactions with HCN and HC_3N are consistent with this kind of chemical bond formation. The linkages may be the type shown in [8] and [9].

[8] $H—C{\equiv}C—C^{\bullet}{=}N—N{=}C^{+}—H$

[9] $H—C{\equiv}C—C^{\bullet}{=}N—N{=}C^{+}—C{\equiv}C—H$

Adduct formation was not observed with H_2, H_2O, and CH_4 because the hydrogen atom in these molecules is easily "within reach." Adduct formation was also not observed with C_2H_2, C_2H_4, and C_4H_2. In these cases charge transfer is preferred because of the relatively low ionization potentials of these molecules.

The association of cyanoacetylene molecules with ionized cyanoacetylene has also just recently been observed by Buckley *et al.* in an ICR (Ion Cyclotron Resonance) and a high pressure photoionization mass spectrometer (18). The apparent bimolecular rate constant that was reported for the addition of the first molecule in the ICR at a total pressure of 10^{-6} Torr is surprisingly large, $k = 7.4 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}, and close to the value obtained at the much higher pressures of the SIFT experiments reported here. High rates of association under SIFT conditions are normally attributable to the formation of strongly bound adducts stabilized by collision with the buffer gas atoms. In this case, however, the almost equally high specific rate observed at the much lower pressures of the ICR suggests that this stabilization may proceed by the emission of a photon and so implies a truly bimolecular radiative association reaction. Buckley *et al.* (18) have also proposed several bonding possibilities for the association reaction other than the azine-like linkage discussed earlier. They have pointed out that C—C bonding could lead to an ion of type [10] while C—N bonding may result in an ion of type [11]. These alternatives are attractive in that addition of a second molecule of cyanoacetylene to these dimer ions can lead to some interesting cyclic structures (18).

Received June 26, 1985

S. FLISZÁR, G. CARDINAL, and N. A. BAYKARA. Charge distributions and chemical effects. XL. Chemical bonds in benzenoid hydrocarbons. Can. J. Chem. **64**, 404 (1986).

Benzenoid hydrocarbons were examined using a bond energy scheme featuring the role of atomic charges. The latter were conveniently deduced from appropriate correlations between theoretical results and ^{13}C nuclear magnetic resonance shifts. Atomization energies calculated in this manner agree with their experimental counterparts to within 0.36 kcal mol^{-1} (average deviation). It appears that benzenoid hydrocarbons can be efficiently described in terms of *local* charge density properties. In the absence of any distinctive specific feature characterizing benzenoids, this particular description of chemical bonds ultimately results in a unifying genealogy smoothly relating to one another the various possible types of CC and CH bonds which are formed by sp^2 and sp^3 carbons.

S. FLISZÁR, G. CARDINAL et N. A. BAYKARA. Charge distributions and chemical effects. XL. Chemical bonds in benzenoid hydrocarbons. Can. J. Chem. **64**, 404 (1986).

Utilisant un schéma d'énergie de liaison comportant le rôle des charges atomiques, on a étudié des hycrocarbures benzènoïdes. On peut facilement déduire les charges atomiques des corrélations appropriées entre les résultats théoriques et les déplacements chimiques du ^{13}C en rmn. Les énergies d'atomisation calculées de cette manière sont en accord, dans des limites de 0,36 kcal mol^{-1} (déviation moyenne). Il semble que les hydrocarbures benzènoïdes peuvent être décrits d'une manière efficace en fonction des propriétés de densité de charge *locale*. En l'absence de caractéristiques spécifiques distinctives des benzènoïdes, cette description particulière des liaisons chimiques resulte finalement en un généalogie reliant l'un à l'autre les divers types possibles de liaisons CC et CH formées par les carbones sp^2 et sp^3.

[Traduit par le journal]

Introduction

This study describes benzenoid hydrocarbons. It considers the role of electronic charges in chemical bonding and leads to reasonably accurate energy calculations using atomic charges deduced from ^{13}C nmr shifts. Moreover, it offers a vivid insight into the nature of chemical bonds.

The expression

$$[1] \quad \epsilon_{ij} = \epsilon^0_{ij} + a_{ij}\Delta q_i + a_{jk}\Delta q_j$$

indicates how their energies depend on the charges of the bond-forming atoms (1–3): ϵ^0_{ij} is for a reference bond with net charges q^0_i and q^0_j at atoms i and j, respectively, whereas ϵ_{ij} corresponds to modified charges, $q_i = q^0_i + \Delta q_i$ and $q_j = q^0_j + \Delta q_j$. The a_{ij} and a_{ji} parameters, "measuring" the changes in bond energy accompanying unit charge variations at atoms i and j, respectively, are discussed further below, as well as the ϵ^0_{ij}'s. Finally, the sum[1]

$$[2] \quad \Delta E^*_a \simeq \sum_{i<j} \epsilon_{ij}$$

is a valid approximation for the atomization energy of a molecule at its potential minimum. Indeed, the formula

$$[3] \quad \Delta E^*_a \simeq \Sigma\epsilon^0_{ij} + \Sigma_i\Sigma_j a_{ij}\Delta q_i$$

has proven accurate in over 130 comparisons between calculated and experimental energies (Fig. 1).

Equation [3] indicates the steps involved in these energy calculations. We begin with a description of the appropriate a_{ij} and ϵ^0_{ij} parameters, which will be conveniently tabulated. Next, we discuss the derivation of the required Δq_i charges, with the help of ^{13}C nmr shifts. Then it becomes a simple matter of assembling the pieces in order to deduce ΔE^*_a and,

[1]The omitted nonbonded contributions can safely be neglected in a first approximation (1–3).

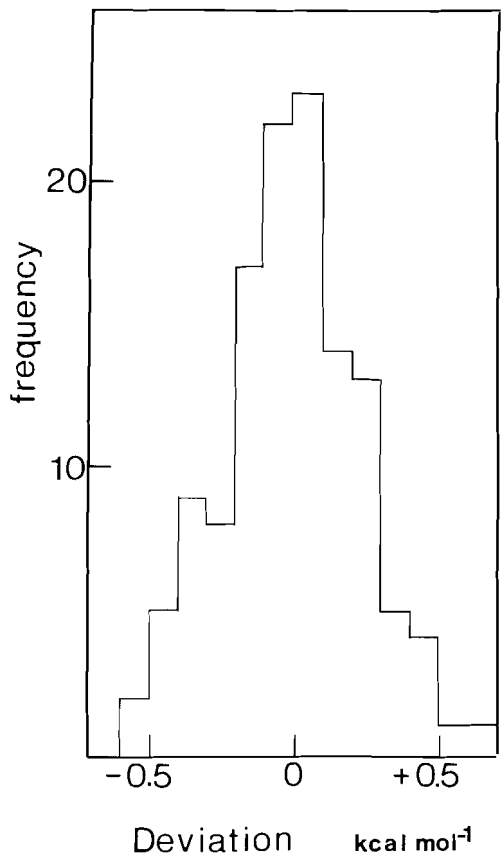

FIG. 1. Frequency of deviations between calculated and experimental atomization energies. This error distribution survey covers alkanes (1, 2) (including cycloalkanes constructed from chair and (or) boat cyclohexane rings), simple ethylenic (4) and polyunsaturated hydrocarbons (5), both conjugated and nonconjugated, as well as ethers, aldehydes, and ketones (6). The average deviation is ~0.23 kcal mol^{-1}.

TABLE 1. Most frequently used a_{ij} values[a], from eq. [4]

Bond	i—j	R_{ij} (Å)	a_{ij} (kcal mol^{-1} me^{-1})
1	C(Ar)—C(Ar)	1.40	$a_{CC}^{\sigma,\pi} = -0.358$
2	C(sp^3)—C(sp^3)	1.53	$a_{CC} = -0.488$
3	C(Ar)—H	1.08	$a_{CH}^{\sigma,\pi} = -0.083$
4	C(sp^3)—H	1.08	$a_{CH} = -0.247$
5	H—C	1.08	$a_{HC} = -0.632$
6	C(Ar)—C(sp^3)	1.53	$a_{CC}^{\sigma} = -0.450$
7	C(Ar)—H	1.08	$a_{CH}^{\sigma} = -0.210$
8	C=C (C_2H_4)	1.34	$a_{CC}^{\sigma,\pi} = -0.183$
9	C(sp^2)—C(sp^3)	1.53	$a_{CC}^{\sigma,\pi} = 0.275$
10	C(sp^2)—H	1.08	$a_{CH}^{\sigma,\pi} = 0.454$

[a]The values indicated $a_{ij}^{\sigma,\pi}$ are expressed for total ($\sigma + \pi$) electronic charges, eq. [5]; a_{ij}^{σ} refers to changes in σ electrons only. The results 2, 4, and 5 are from refs. 1 and 2; 8–10, describing ethylenic carbons, are from refs. 2 and 4.

therefrom, the corresponding enthalpies of formation, ΔH_f^0 (gas, 298.15 K).

Calculation of the a_{ij} *parameters*

The appropriate expression is (1, 2)

$$[4]\quad a_{ij} = \frac{3/7}{\nu_i K_i^{mol}}\left[\left(\frac{\partial E_i^{vs}}{\partial N_i}\right)^0 - \frac{1}{2}\left(\frac{\partial^2 E_i^{vs}}{\partial N_i^2}\right)^0 \Delta q_i\right] - \frac{3}{7} Z_j^{eff}\langle r_{ij}^{-1}\rangle^0$$

where Z^{eff} are effective nuclear charges (7–9) (e.g., 4 for C), ν_i = number of atoms attached to i, and $\langle r_{ij}^{-1}\rangle^0$ is the average inverse distance between the N_i electrons of atom i and the nucleus of atom j. K_i^{mol} is $\frac{1}{2}$ for H and 0.4287 for C (1, 2, 10). The factor $\frac{3}{7}$ translates nuclear-electronic into total (potential + kinetic) energy changes (1, 2, 10, 11). The derivatives of the appropriate valence state energy of atom i, E_i^{vs}, follow from SCF-Xα calculations (Appendix I). The second-order term being negligible for hydrogen and carbon, all the a_{ij}'s used in this work can be treated as constants. The most frequently occurring values are indicated in Table 1.

With sp^2 carbons, whose charges vary at both the σ and π levels, the $a_{ij}\Delta q_i$ term becomes $a_{ij}^{\sigma}\Delta q_i^{\sigma} + a_{ij}^{\pi}\Delta q_i^{\pi}$; a_{ij} is thus the weighted average of a_{ij}^{σ} and a_{ij}^{π} (2). Taking advantage of the relationship (12) $\Delta q_i^{\sigma} = m\Delta q_i^{\pi}$, this average is (4)

$$[5]\quad a_{ij} = (ma_{ij}^{\sigma} + a_{ij}^{\pi})/(1 + m)$$

For nonsubstituted aromatic carbons, it is found that $m \simeq -0.812$ (Appendix II); substitution (e.g. with a methyl group) changes m to ~ -0.90. For ethylenic carbons, $m = -0.955$ (4, 5). Equations [4] and [5] sum up the calculation of the a_{ij}'s.

Reference bond energies, ϵ_{ij}^0

The reference bonds ϵ_1–ϵ_5 (Table 2) were described earlier (1–3). Additional, frequently occurring reference energies are conveniently deduced with the help of the function[2] (1, 2, 13)

$$[6]\quad F = -\frac{3}{7}\sum_i\sum_j Z_i^{eff} q_j(\langle r_{ij}^{-1}\rangle - \langle r_{ij}^{-1}\rangle^0) - \frac{3}{7} \times \sum_i\sum_j Z_i^{eff} Z_j^{eff}[(R_{ij}^{-1}) - (R_{ij}^{-1})^0 - (\langle r_{ij}^{-1}\rangle - \langle r_{ij}^{-1}\rangle^0)]$$

which contains information regarding orbital shapes and internuclear distances, R_{ij}. This function is part of ΔE_a^* and nonzero if actual $\langle r_{ij}^{-1}\rangle$ and (or) R_{ij} parameters differ from those assumed in the definition of any ϵ_{ij}^0 included in $\Sigma\epsilon_{ij}^0$. (This situation arises, for example, if ethylene is constructed with ethane CH reference bonds.) In contrast, *when the* e_{ij}^0*'s are properly chosen, results derived from eq. [3] show that* $F \simeq 0$ *is a valid approximation*[3] (cf. Fig. 1), hence the merits of defining suitable ϵ_{ij}^0's. This is achieved by modifying ϵ_{ij}^0's deduced for $\langle r_{ij}^{-1}\rangle^0$ and $(R_{ij}^{-1})^0$ into values corresponding to $\langle r_{ij}^{-1}\rangle$ and (R_{ij}^{-1}), as requested by eq. [6].[4] Changes in reference charges, if desired, are made with the help of eq. [1]. Thus we deduce, for example, the ethylene and benzene CH bonds from that of ethane, or CC single bonds like those in biphenyl, *cis*-stilbene, etc., from that of ethane.

While a unified new genealogy of chemical bonds surfaces with eq. [6], the pivotal question rests here with our approximate way of applying it in a possibly rough, but certainly simple, scheme satisfying chemical intuition. The underlying hypotheses and detailed numerical examples illustrating the use of eq. [6] are given in Appendix III. These hypotheses are eventually going to be put on trial in extensive comparisons with experimental results. With the set of reference bond energies indicated in Table 2, F is ~0 again, and energy calculations can be made in a straightforward manner using eq. [3].

Charge calculations

Net charges of alkane carbon atoms are conveniently deduced from the remarkably accurate relationship (1, 2, 15)

$$[7]\quad \Delta q_C = -0.148\,\delta^{C_2H_6}\,\text{me}$$

where the ^{13}C nmr shift, $\delta^{C_2H_6}$ (ppm), and $\Delta q_C = q_C - q_C^0(C_2H_6)$ are expressed with reference to ethane. Similarly, for ethylenic sp^2 carbons we use (4)

$$[8]\quad \Delta q_C = 0.15\,\delta^{C_2H_4}\,\text{me}$$

where the nmr shifts, $\delta^{C_2H_4}$ and $\Delta q_C = q_C - q^0{}_C(C_2H_4)$ are expressed taking ethylene as reference. Finally, for aromatic carbons we use (Appendix II)

$$[9]\quad \Delta q_C = 1.20\,\delta^{C_6H_6}\,\text{me}$$

where both Δq_C and $\delta^{C_6H_6}$ are taken with reference to the benzene carbon atom. Note that eqs. [8] and [9] are for total ($\sigma + \pi$) net charges. These results serve two purposes, namely, the calculation of individual $a_{ij}\Delta q_i$ terms and that of the total net charge on all carbon atoms. The latter is obtained from a sum of

[2]The quantities appearing in eq. [6] are defined in terms of a suitable partitioning of the molecular electron density into atomic contributions, ρ_i, and of the equilibrium coordinates, r_i, of the nuclei, i.e.,

$$\int \frac{\rho_i(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{r}_i|}\,d\boldsymbol{r} = N_i\langle r_i^{-1}\rangle \text{ with } \int \rho_i(\boldsymbol{r})\,d\boldsymbol{r} = N_i$$

$$\int \frac{\rho_i(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{r}_i|}\,d\boldsymbol{r} = N_j\langle r_{ij}^{-1}\rangle \text{ with } \int \rho_j(\boldsymbol{r})\,d\boldsymbol{r} = N_j$$

The superscript zero indicates the corresponding expressions for the reference molecule.

[3]The first part is small because atomic net charges are small (e.g., <0.0351 e for sp^3 and ~0.007 e for ethylenic sp^2 carbons) and because small changes in electron populations are unlikely to modify their center of charge to any significant extent. The second part, in square brackets, is obviously zero for spherically symmetric electron clouds or small if the centers of electronic charge move along with the nuclei during small changes in internuclear distances.

[4]For example, eq. [6] predicts $F = -2.39$ kcal mol^{-1} for an ethylenic CH bond and -4.80 kcal mol^{-1} for a CC single bond formed by an ethylenic carbon (4, 5, 13, 14). Systematic inclusion of these results in the ϵ_{ij}^0's corresponding to these bonds takes care of F. Figure 1 includes ~50 olefins calculated in this manner.

TABLE 2. Frequently used reference bond energies[a]

Bond	i—j	Type	R_{ij} (Å)	Reference charge (me) i	Reference charge (me) j	ϵ_{ij}^0(kcal mol^{-1})
1	C—C	sp^3—sp^3	1.53	35.1	35.1	69.633
2	C=C	sp^2—sp^2	1.34	7.7	7.7	139.27
3	C—C	sp^2—sp^2	1.46	7.7	7.7	89.70
4	C:::C	Ar—Ar	1.40	14.8	14.8	114.21
5	C—H	sp^3—H	1.08	35.1	−11.7	106.806
6	C—C	Ar—Ar	1.40	14.8	14.8	91.56
7	C—C	Ar—sp^3	1.53	14.8	35.1	79.30
8	C—C	Ar—sp^2(nc)	1.49	14.8	7.7	86.89
9	C—C	Ar—sp^2(c)	1.48	14.8	7.7	90.40
10	C—C	sp^2—sp^3	1.53	7.7	35.1	77.70
11	C—H	Ar—H	1.08	14.8	−11.7	111.58
12	C—H	sp^2—H	1.08	7.7	−11.7	110.68

[a]Bond 8 is nonconjugated, 9 is conjugated, Ar = aromatic C atom, sp^2 indicates an ethylenic carbon. The following ϵ_{ij}^0's are taken from previous work: 1, 5 (1), 2, 10, 12 (4) and 3 (5). Bonds 1, 3, and 5 were used for deducing 6–12. The reference charge selected for benzene, 14.8 me, is discussed in Appendix II.

all Δq_i's to which are added 35.1 me for each sp^3 carbon, 14.8 me for each aromatic, and 7.7 me for each ethylenic sp^2 carbon of the molecule. This gives the sum Σq_C and $\Sigma q_H = -\Sigma q_C$. The reference for hydrogen being taken in all cases at −11.7 me, it follows that

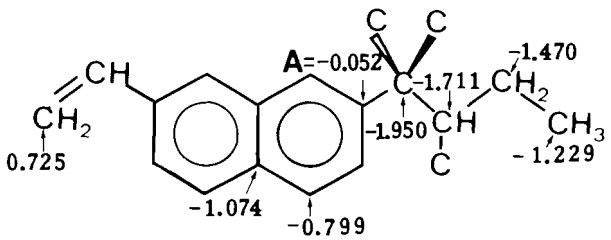
[10] $\Sigma\Delta q_H = -\Sigma q_C + 11.8\, n_H$ me

where n_H is the number of hydrogen atoms. This concludes the derivation of the charges required in the forthcoming energy calculations.

The calculation of atomization energies, ΔE_a^*

We can now apply eq. [3]. The calculation of $\Sigma\epsilon_{ij}^0$ is straightforward, using Table 2. There is one point to be mentioned. The aromatic CC bond, ϵ_4, represents, so to speak, the average between a single and double bond as they are found in benzenoid structures: it is the CC bond of benzene. It is counted twice the number of double bonds one can write using classical Kekulé structures. The remaining CC bonds (e.g., 1 in naphthalene, 2 in anthracene, etc.) are treated as C(sp^2)—C(sp^2) single bonds—bond ϵ_6 in Table 2.

As regards the evaluation of $\Sigma_i\Sigma_j a_{ij}\Delta q_i$, first we calculate $\Sigma_j a_{ij}$ for each carbon atom, using Table 1. These sums are conveniently displayed in structure **I**. Next, we calculate the corresponding Δq_C's and form the product $\Delta q_i\Sigma_j a_{ij} = \Sigma_j a_{ij}\Delta q_i$ for each carbon, as in the example given in Table 3. The sum of these atomic terms over all carbon centers i yields the



I

Sum of the a_{ij} terms for the various types of atoms, $\Sigma_j a_{ij}$, in kcal mol^{-1} me^{-1}.

TABLE 3. Calculation of $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ (kcal mol^{-1}) for 2-methylnaphthalene, using the a_{ij}'s of Table 1 and eqs. [7] and [9][a]

Atom	δ	Δq	$\Sigma_j a_{ij}$	$\Sigma_j a_{ij}\Delta q_i$
1	−1.5	−1.80	−0.799	1.438
2	6.8		(−0.052)	−0.354
3	−0.45	−0.54	−0.799	0.431

CH_3	16.35	−2.42	−1.229	2.974
$\Sigma\Delta q_H$		−61.88	−0.632	39.108

[a]The δ's are relative to benzene (1–10) and to ethane for the methyl carbon. From the Δq_c's (me), counting 14.8 me for each aromatic carbon and 35.1 me for the sp^3 reference, it is Σq_C = 178.88 and $\Sigma\Delta q_H = -178.88 - 10(-11.7)$ me. Note the contribution of C—2, $-0.052\,\delta = -0.354$ kcal mol^{-1}. The sum of all the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$'s yields 40.11 kcal mol^{-1}, ready for use in eq. [3].

corresponding part of $\Sigma_i\Sigma_j a_{ij}\Delta q_i$. Finally, we calculate $\Sigma\Delta q_H$ and add $-0.632\ \Sigma\Delta q_H$ to the previous sum. This is now $\Sigma_i\Sigma_j a_{ij}\Delta q_i$, ready for use in eq. [3].

There is one case which is treated in a slightly different manner, with no loss in simplicity, that of an aromatic carbon attached to a non-aromatic carbon. Its contribution is $-0.052\ \delta^{C_6H_6}$ kcal mol^{-1}. This carbon is taken at 14.8 me in the computation of Σq_C. The reason for this approach stems from a situation of small differences between large numbers (explained in Appendix IV) arising in the evaluation of $\Sigma_j a_{ij}$.

In closing, let us mention a simple formula for nonsubstituted aromatic hydrocarbons, taking care of $\Sigma\Delta q_H$ by charge normalization and using the a_{ij}'s of Table 1, as well as eq. [9]. It is, indeed, readily deduced that

$$\Sigma_i\Sigma_j a_{ij}\Delta q_i = -0.33\,\Sigma N_{CC}\delta^{C_6H_6} + 0.46\,\Sigma\Delta^{C_6H_6} + 0.632\,(14.8\,n_C - 11.7\,n_H)$$

where N_{CC} = number of CC bonds formed by the carbon whose

TABLE 4. Energy calculations of selected planar benzenoid hydrocarbons, using ^{13}C nmr shifts (kcal mol^{-1})[a]

Molecule	$\Sigma N_{CC}\delta$	$\Sigma\delta$	$\Sigma_i\Sigma_j a_{ij}\Delta q_i$	$\Sigma\epsilon_{ij}^0$	ΔE_a^*
Benzene	0	0	11.76	1354.74	1366.50

Anthracene	50.1	17.6	48.57	2900.26	2948.83
Phenanthrene	−4.5	−8.0	54.81	2900.26	2955.07
Pyrene	−30.2	−17.1	77.81	3217.84	3295.65
Benz[*a*]anthracene	17.3	−0.7	73.60	3673.02	3746.62

[a]The average deviation between these calculated atomization energies and their experimental counterparts is 0.23 kcal mol^{-1} (see Table 5). The sources of the nmr shifts are indicated at the bottom of Table 5.

nmr shift is $\delta^{C_6H_6}$, n_C = number of C atoms, and n_H = number of H atoms in the molecule. Selected numerical examples are indicated in Table 4.

Now is the proper time to look at thermochemical results in order to assess the validity of our approach toward solving eq. [3].

Results

Most of the benzenoid hydrocarbons for which both the enthalpy of formation, ΔH_f^0 (gas, 298.15), and the carbon-13 nmr spectrum are experimentally known were examined in the present work. While experimental ΔH_f^0 results are typically reported with an error of 0.3–1.0 kcal mol^{-1}, independent measurements from different laboratories often differ from one another by much more than this. Pyrene, for example, is reported by Cox and Pilcher (16) with $\Delta H_f^0(g) = 49.94 \pm 0.64$, contrasting with the result cited by Kao and Allinger (17), 51.59 kcal mol^{-1}. Whenever reasonable, critically selected data given by Cox and Pilcher (16) were used. The structures of some of the compounds investigated here are shown in Fig. 2.

In order to offer valid comparisons with theoretical results, we must first deduce "experimental" atomization energies from enthalpies of formation, zero-point and heat-content energies, ZPE + $H_T - H_0$, and from the enthalpies of formation of the atoms, $\Delta H_f^0(A)$. The latter are taken from the literature (18), namely, $\Delta H_f^0(C) = 170.89$ and $\Delta H_f^0(H) = 52.09$ kcal mol^{-1} at 298.15 K. The appropriate equation is, for nonlinear molecules,

$$[11] \quad \Delta E_a^* = \sum_i n_i \left[\Delta H_f^0(A_i) - \frac{5}{2} RT \right] + \text{ZPE} + H_T - H_0 - \Delta H_f^0$$

Vibrational energy data are scarce, however, for the molecules considered in this study. Fortunately they can be constructed to a good approximation by means of additivity rules (2), e.g., ZPE + $H_T - H_0 \simeq 33.35 + 18.213\ (n-2) - 0.343\ n_{br}$ for a mono-olefin with n carbons and n_{br} = number of branchings, or ZPE + $H_T - H_0 \simeq 55.19 + 18.213\ (n-4) - 0.343\ n_{br}$ kcal mol^{-1} for diolefins (5). Similar equations are also found to apply in other homologous series of compounds, e.g., alkanes and cycloalkanes, ethers, and carbonyl compounds (2). Along these lines, we use the following formula for alkyl substitution, based on the experimental ZPE + $H_T - H_0$ value (66.22 kcal mol^{-1}) deduced for benzene in the harmonic oscillator approximation (2):

$$\text{ZPE} + H_T - H_0 = 66.22 + 18.21\, n - 0.343\, n_{br}$$

where n is the number of alkyl carbon atoms. Molecules like 9,10-dihydroanthracene or 1,2,3,4-tetrahydronaphthalene were treated in similar manner. In these situations, attention must be given to a lowering of ZPE + $H_T - H_0$ by 11.5 kcal mol^{-1} accompanying the loss of a pair of hydrogen atoms and by $\sim RT/2 = 0.296$ kcal mol^{-1} for each hindered rotation in cyclic compounds (2, 19). Moreover, the condensation of two fragments involves a correction of $4RT = 2.37$ kcal mol^{-1} because this term is included in the $H_T - H_0$ part of each molecule used as fragment and should not be counted twice in the final product. For example, the ZPE + $H_T - H_0$ value of 9,10-dihydroanthracene is obtained from dimethylbenzene ($66.22 + 2 \times 18.21$) and benzene, less 2×11.5, less $4RT$, and less $4RT/2$ kcal mol^{-1}. This type of estimate usually carries an uncertainty not exceeding 0.2 kcal mol^{-1}. Styrene, for example, can be constructed from benzene and ethylene to give ZPE + $H_T - H_0 = 66.22 + 33.35 - 11.5 - 4RT = 85.70$ kcal mol^{-1}.

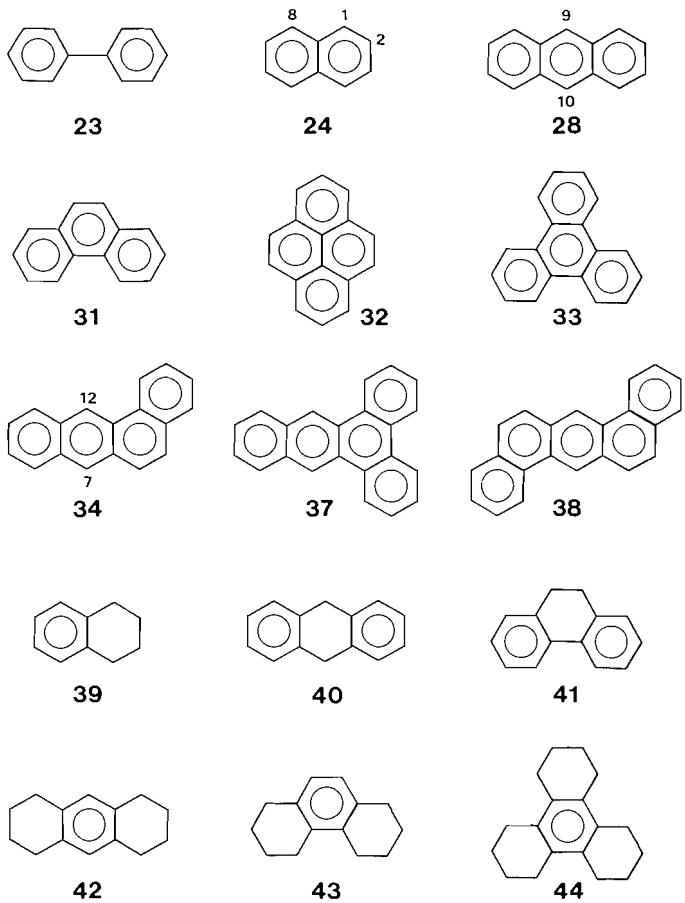

FIG. 2. A selection of molecules examined in this work. The numbering corresponds to that indicated in Table 5.

[a]The experimental ΔH_f^0 results for **1–8**, **14–21**, **23**, **28**, **31**, **33**, **36**, and **40** are "selected values" reported in ref. 16. The results for **9–13** are given in ref. 24, that of **22** in ref. 25, and those of **24–26** in ref. 26. The value indicated for **32** is taken from ref. 27, **34** is reported in ref. 17, and **39** is taken from ref. 28. The ZPE + $H_T - H_0$ result given for **31** was deduced from a vibrational analysis described in ref. 29, in the harmonic oscillator approximation. The carbon-13 nmr spectra are from ref. 30 (**2–13**), ref. 31 (**14–19**), and from ref. 32 (**20**, **23**, **39–44**); **21** and **22** are from ref. 33; **24**, **31**, **32** from ref. 34; and **28** is from ref. 35; **25**, **26** are given in ref. 36; **27** is from ref. 37; and **29**, **30**, **34–38** are from ref. 38; **33** is described in ref. 39. In order to minimize possible solvent effects, whenever possible measurements made in benzene were selected.

From the vibrational spectrum of styrene (20), on the other hand, we find in the harmonic oscillator approximation that ZPE = 80.96 and $H_T - H_0 = 4.84$, for a total of 85.80 kcal mol^{-1}. Similarly, using ZPE + $H_T - H_0$ = 88.82 + 5.08 = 94.90 kcal mol^{-1} for naphthalene, deduced from its vibrational spectrum (21), we add to it the difference, 28.68 kcal mol^{-1}, between naphthalene and benzene, thus obtaining an estimate of 123.6 kcal mol^{-1} for anthracene. The same procedure is used for the higher homologues as well. Finally, using the fundamental frequencies of pyrene (22), we obtain (in the harmonic oscillator approximation) ZPE = 125.94, $H_T - H_0 = 7.11$, for a total of 133.05 kcal mol^{-1}.

While, of course, additional spectroscopic information would be welcome, we feel that the uncertainties affecting present estimates of ZPE + $H_T - H_0$ energies should not be blamed for possible discrepancies between calculated and observed ΔE_a^* (or ΔH_f^0) energies. With this in mind, we can now proceed with comparisons involving experimental enthal-

pies of formation (Table 5). In the absence of experimental results, predicted ΔH_f^0 values are indicated in parentheses. Two ΔE_a^* results listed in the column reporting "experimental values" are in parentheses: these are theoretical results offered for comparison, deduced from enthalpies of formation calculated by Dewar and de Llano (23).

Discussion

The average deviation between calculated and experimental energies is 0.36 kcal mol^{-1} for a collection of 35 benzenoid compounds. This result does not include 7,12-dimethylbenz-[*a*]anthracene: the discrepancy of ~16 kcal mol^{-1} between theory and experiment is in all likelihood due in part to an error in the latter. Although certainly real, steric interactions involving the methyl group in position 12 are probably not so severe as to cause a destabilization exceeding that found in 1,8-dimethylnaphthalene and 4,5-dimethylphenanthrene—molecules which are discussed further below.

At this stage it seems safe to conclude that the agreement between theory and experiment supports the general ideas underlying our energy analysis. On the other hand, the quality of this agreement should not be used to hide the limitations of our approach. These are best revealed by the following examples. *Trans*-stilbene was treated as a planar system and the C(sp^2)—Ph bonds were accordingly derived on the basis of a conjugated sp^2—sp^2 single bond (Appendix III, example 6). While the molecular structure of *trans*-stilbene appears to be approximately planar in the solid state (40), its gas phase structure is found to be nonplanar (41). However, the potential curve for energy vs. the dihedral angle is very shallow and the calculated energy barrier corresponding to the C_i conformation is only about 0.5 kcal mol^{-1} (17). Both these results and our calculation suggest that in *trans*-stilbene there is no great energy difference between conjugation and hyperconjugative stabilization of the sp^2—sp^2 single bond[5] but it is also clear that in this particular situation it could not be assumed *a priori* that our treatment would lead to a valid result, as it did. The case of *cis*-stilbene is clear-cut. Electron diffraction data (43) point to a C_2 symmetry in the gas phase and a structure that may be described as having a propeller-like conformation with phenyl groups rotated ca. 43° about the C—Ph bonds. The latter were thus treated as nonconjugated bonds: ϵ_s = 86.89 kcal mol^{-1} was deduced for R_{CC} = 1.49 Å, which is the experimental bond length (43). Similarly, the gas phase value (44) for the torsional angle about the central bond of biphenyl, 41.6°, and its bond length, R = 1.49 Å (17, 45), suggest that the central bond should be treated like a nonconjugated CC single bond, thus giving ϵ_{CC} = 88.68 kcal mol^{-1}. Finally, the same situation arises with triphenylene (**33**) which is significantly nonplanar (17, 46). The bonds joining the "external" rings to one another were thus calculated at ϵ_{CC} = 88.45 kcal mol^{-1} for R = 1.46 Å, following the approach used for biphenyl. It is clear that some advance knowledge is necessary in our calculations, namely, as regards planarity (or lack of it) of the benzenoid skeleton.

As an additional example, consider 4,5-dimethylphenanthrene. Using the ^{13}C nmr spectrum measured by Stothers *et al.* (47), we deduce ΔH_f^0 = 36.8 kcal mol^{-1} assuming planarity. Closely neighboring methyl groups which are separated by five bonds in the molecular skeleton, however, result in chiral nonplanar conformations (48). Modeling, where appropriate, the CC bonds on those described for biphenyl and *cis*-stilbene, we predict ΔH_f^0 = 47.8 for the nonplanar form, in acceptable accord with the reported value (16), 46.26 ± 1.46 kcal mol^{-1}, a result which is self-explanatory. Equally instructive examples are offered by dimethylnaphthalene isomers. With the substituents in the 1,8 position, our calculation yields ΔE_a^* = 2748.6 kcal mol^{-1} for the planar form, in error with respect to its experimental counterpart,[6] 2745.0 kcal mol^{-1}. The thermochemical stability is overestimated by ~3.6 kcal mol^{-1}, thus suggesting a possible loss of conjugation in this molecule which, as a matter of fact, is known to suffer considerable distortion from the normal naphthalene geometry (50). Indeed, a calculation following the lines described above for biphenyl and nonplanar 4,5-dimethylphenanthrene agrees with experiment. In contrast, 2,6-dimethylnaphthalene can safely be assumed to retain the planar geometry of naphthalene. The result deduced for this form, ΔE_a^* = 2751.3, agrees well with the experimental value,[6] 2751.0 kcal mol^{-1}. These examples illustrate possible applications of energy analyses based on ^{13}C spectra in problems regarding the origin of molecular stability, namely, as regards partial suppression of conjugation accompanying deformations of a benzenoid skeleton.

These examples are also there to remind us that our theory differs in its nature from variational calculations and thus lacks the flexibility of the latter, capable of predicting geometries as well as energies. Indeed, our approach applies only to molecules at equilibrium; in turn, it illustrates efficiently the role of local charges, namely, the way they affect chemical bonds. It is certainly gratifying to recognize how intimately bonds of different types are related to one another, e.g., the CH bonds of ethane, ethylene, and benzene or the CC single bonds of ethane, toluene, *cis*-stilbene, and biphenyl. Minor uncertainties plaguing numerical applications should not obscure the fundamental simplicity of the arguments describing bond energies in terms of local charges. The general concepts developed here, capable of describing chemical bonds in a unifying picture encompassing well-diversified situations, are more relevant, in our opinion, than the precision of the calculations supporting these views. At the present level, residual uncertainties resulting from occasional computational approximations are of the order of those affecting experimental results and are not of the sort that could threaten the essence of the basic ideas underlying our description of molecular energies.

While, of course, our approach does not have the potential of true density functional theory based on the Hohenberg–Kohn theorem (51), it offers at least a conceptually related, simple, and instructive solution when both local charges and nuclear positions are given for a ground-state molecule at equilibrium. At this relatively modest level, it becomes clear that the theory of chemistry and of the chemical bond are in essence a theory of electron density, a fact which can now be described in simple terms for a great variety of organic molecules.

Appendix I

The $\partial E/\partial N$ derivatives were obtained from LCAO-Xα calculations by means of the programs developed by Dunlap *et al.* (52). Huzinaga's (9*s*5*p*) basis (53) was used for ground-state carbon. Hydrogen was described by a (5*s*) basis obtained from Dunning's (3*s*) basis set (54). In the LCAO-Xα method it is necessary to fit the charge density and the exchange potentials to sets of auxiliary Hermite gaussian functions. The Xα exchange potentials were fitted to the auxiliary functions following the criterion given by Dunlap *et al.* (52), i.e.,

$$\int \rho(\widetilde{\rho^{1/3}})\,d\tau = \int (\widetilde{\rho^{1/3}})^4\,d\tau$$

TABLE A1. $(\partial E/\partial N)_\pi$ and $(\partial E/\partial N)_\sigma$ values (au) for use in eq. [4][a]

Molecule	Orbital	$(\partial E/\partial N)$, au		
		α_{HF}	$\alpha_{expt.}$	Selected
Benzene	π	−0.259	−0.264	−0.262
	σ	−0.372	−0.379	−0.375
Ethylene	π	−0.244	−0.248	−0.246
	σ	−0.373	−0.378	−0.375

[a]Additional results are reported in refs. 1 and 2.

where the tilde represents a fitted quantity. The sampling points for the exchange potentials were determined by taking each tenth point of the Herman–Skillman radial mesh (55) and an angular mesh consisting of the twelve vertices of a regular icosahedron (56). The auxiliary functions were selected as suggested by Dunlap *et al.* (52) for first-row diatomics: *s*-type functions were employed for the charge density fit, having orbital exponents twice those of the corresponding *s*-type gaussians used for the orbital basis. Five orbital exponents (5.0, 2.0, 0.6, 0.3, 0.1) were used for *p*-type functions. The exponents of every other *p* function used in the orbital basis were doubled to construct *d*-type Hermite gaussians for fitting the Coulomb potential. Bond-centered auxiliary *s* functions were also used, as suggested by Dunlap *et al.* (52). For the fit to the exchange potential, orbital exponents were taken at one-third of those of the corresponding charge density auxiliaries.

In LCAO-Xα calculations of heteronuclear systems one meets with the problem of choosing a single α value for the whole system because, contrasting with the Scattered Wave Method (57), the possibility of assigning different α values to different regions of space no longer exists. The general attitude has been to use the Kohn–Sham value of 2/3 or 0.7 in such situations. For a significant collection of organic molecules, on the other hand, we have found (58) that experimental atomization energies are well reproduced with an α value taken as an average of α_{ij}'s defined for the individual bonds, i.e.,

$$\alpha_{ij} = 1/2\,(\alpha_A + \alpha_B)$$

where (i, j) is a bond between centres A and B. The individual α_A's can be chosen following Schwarz (59), from a fit with Hartree–Fock values, or, else, from a fit with experimental energies of ground-state atoms (58). Selection of the latter α_A's yields atomization energies that are closer to their experimental counterparts (within a few kcal mol^{-1}) than the corresponding results deduced from the α_{HF} values given by Schwarz (59). The results are indicated in Table A1. The last column reports the $(\partial E/\partial N)$ values used in applications of eq. [4].

Appendix II

STO-3G charge analyses, following Pople's recipe (60) and Mulliken's scheme (61), are reported in Table A2, as well as the pertinent ^{13}C nmr shifts. Taking the σ–π separation, $\Delta q = \Delta q^\sigma + \Delta q^\pi$, into account as well as the relationships $\Delta q^\sigma = m\Delta q^\pi$, $\delta = c^\sigma \Delta q^\sigma + c^\pi \Delta q^\pi$ and $(d\delta/dq^\pi) = 157$ ppm/e (2, 12), we deduce $\delta = 0.835\,\Delta q + 178.66$ (ppm from TMS) and, hence, $\Delta q = 1.2\,\delta$ and $m = -0.812$. These results are admittedly crude. Extensive numerical analyses, however, such as those reported in Table 4, gave no reason for revision.

Mulliken's analysis involves a half-and-half partitioning of overlap populations. While charges of like C atoms (i.e., atoms forming the same type and number of bonds) are valid in comparisons involving them, lifting the constraint of halving overlap terms between dissimilar atoms becomes a must in realistic evaluations of absolute atomic charges (1, 2, 15). For benzene, we are presently unable to lift this constraint: hence the following approaches toward an estimate for the carbon net charge of benzene.

TABLE A2. Atomic charges (me) and ^{13}C nmr shifts (ppm from TMS) of selected benzenoid hydrocarbons[a]

Molecule	Atom	Net charge	δ
Benzene		−60.1	128.5
Naphthalene	C—1	−60.1	128.3
	C—2	−62.9	126.1
Anthracene	C—1	−57.9	130.3
	C—2	−62.6	125.7
	C—9	−56.0	132.8
Phenanthrene	C—1	−59.1	129.1
	C—2	−63.0	126.9
	C—3	−62.2	126.9
	C—4	−63.1	123.2
	C—9	−62.6	127.5

[a]Geometries were taken from electron diffraction studies of benzene (62), naphthalene (63), and anthracene (64) and from a neutron diffraction study of phenanthrene (65). The shift vs. charge correlation is generally acceptable. Atom C-4 of phenanthrene exhibits the largest deviation. The difference between calculated and experimental energies of phenanthrene is 0.76, using the shift value, and −0.34 kcal mol^{-1} using the charge result, while the reported experimental uncertainty is ±1.1 kcal mol^{-1}, a situation frustrating dedication to accuracy.

(*i*) The ^{13}C nmr shift of the methyl carbon in toluene, δ 21.3 ppm from TMS (32), gives $q_C = 32.77$ me, from eq. [7]. Using the correlation between methyl-C and methyl-H net charges (2), the latter are estimated at −12.38 me in toluene. The toluene CH_3 group is, in this approximation, 4.37 me negative. On the other hand, H replacing CH_3 (under otherwise identical conditions) is 9.05 me more negative than the latter (2). In this estimate, the benzene hydrogen should be negative by 13.4 me and, hence, $q_C(C_6H_6) \simeq 13.4$ me. This, of course, is a rough estimate. Now we look at an entirely different approach.

(*ii*) Applying eq. [2] to the benzene CH bond with ϵ^0_{11}, a_5, a_7, and $q^B_C = -q^B_H$ gives $\epsilon_{CH} = 107.29 + 0.422\,q^B_C$ kcal mol^{-1}, where the benzene carbon net charge, q^B_C, is now left as an unknown. Six of these CH bonds plus six CC bonds add up to give $\Delta E^*_a = 1366.5$ kcal mol^{-1}. Estimates of the CC bond energy based on SCF potentials at the nuclei (1–3) indicate that ϵ_{CC} is 1.62–1.65 times the CC bond energy of ethane, $\epsilon^0_1 = 69.633$ kcal mol^{-1}. With the ratio 1.62 there results $q^B_C = 18.1$ me; for 1.65 it is $q^B_C = 13.2$ me. Extensive numerical analyses involving all the experimental data included in Table 5 suggest that the ratio ~1.64 (giving ϵ_4) with $q^B_C = 14.8$ me represents a valid estimate. In this analysis, the uncertainty about q^B_C is unlikely to exceed 2 me. Finally, current work on graphite (to be published) shows that the uncertainty about $q^B_C = 14.8$ me is probably less than 1 me.

Appendix III

Approximate but valid estimates of eq. [6] can be obtained in a simple way. They are rooted in the following hypotheses (13). For CC and CH bonds involving sp^3 carbons, $\langle r^{-1}_{ij} \rangle$ is

adequately approximated by the inverse of the appropriate internuclear distance (1), a simplifying hypothesis that locates the centers of σ charges at their respective nuclear positions. Similarly, the charge centroids of aromatic carbons are taken at their nuclear positions. The situation differs with ethylenic sp^2 carbons because their overlapping $2p$ electrons forming a π bond shift their respective charge centroids inwards (4, 5, 13, 14). A simple recipe for single bonds formed by an ethylenic carbon j is as follows. (*i*) The centroid of the $(N_j - 1)$ σ electrons of ethylene (taken as reference) is located at its nuclear position. (*ii*) The "effective" distance of a bonded nucleus i (C or H) from the $2p$ electron of j is 0.02 Å larger than R_{ij}. (*iii*) Our estimate of the average inverse distance between the N_j electrons of the sp^2 carbon and nucleus i is thus

$$\langle r_{ij}^{-1}\rangle \simeq 0.529\,[(N_j - 1)R_{ij}^{-1} + (R_{ij} + 0.02)^{-1}]/N_j \text{ au}$$

ready for use in eq. [6]. This recipe, offered as a convenient replacement for equivalent but involved SCF analyses[7] of charge centroids (13), has proven accurate. Indeed, for a collection of ~50 olefins calculated in this approximation, the average deviation between theoretical and experimental atomization energies is ~0.25 kcal mol^{-1} (4, 5). Note that these considerations do not concern the benzenoid structures themselves, but only the ethylenic parts in molecules like styrene, stilbene, etc., reported here for the sake of completeness.

The numerical examples worked out below illustrate the use of eqs. [2] and [6] in the derivation of suitable reference bond energies, ϵ_{ij}^0. The conversion factors 1 bohr = 0.529 Å and 1 hartree = 627.51 kcal mol^{-1} were used. All a_{ij}'s are expressed in kcal mol^{-1} me^{-1} units and the energies in kcal mol^{-1}. The numbering of the a_{ij} and ϵ_{ij}^0 parameters is that indicated in Tables 1 and 2. The reference carbon net charges are (in 10^{-3} e units) 35.1 (C_2H_6), 7.7 (C_2H_4) and 14.8 (C_6H_6).

Example 1. Let us first apply the recipe given for $\langle r_{ij}^{-1}\rangle$ when j is an ethylenic C atom, with $N_i = 3.9923$ e. For a C_i—C_i single bond ($R = R^0 = 1.53$ Å) we find $\langle r_{ij}^{-1}\rangle = 0.34463$ au and $F = -4.80$ kcal mol^{-1}. For a CH bond ($R = R^0 = 1.08$ A) we find $\langle r_{ij}^{-1}\rangle = 0.48758$ au and $F = -2.39$ kcal mol^{-1}. These F values are incorporated in the new ϵ_{ij}^0's describing CC and CH bonds formed by ethylenic sp^2 carbons, as shown below.

Example 2. Starting with the ethane CC bond, ϵ_1^0, we construct the $C_j(sp^2)$—$C_i(sp^3)$ bond, ϵ_{10}, with $R_{CC} = 1.53$ Å, $q_j = 7.7$, and $q_i = 35.1$ me. The change from 35.1 to 7.7 me (using the average of $a_2 = -0.488$ and $\alpha_6 = -0.450$) modifies ϵ_1^0 to give $\epsilon_{CC} = 82.49$; adding $F = -4.80$, one obtains 77.7 for ϵ_{10}. Similarly, starting now with the ethane CH bond, ϵ_5, the change from 35.1 to 7.7 me at the C atom (using the average of $a_4 = -0.247$ and $a_7 = -0.210$ in eq. [2] leads to $\epsilon_{CH} = 113.07$; with $F = -2.39$, it follows that $\epsilon_{12} = 110.68$ for the $C(sp^2)$—H reference bond (13).

Example 3. For aromatic carbons, we keep the centers of charge as in the bond described above, $\epsilon_{CC} = 82.49$, hence $F = 0$. To obtain ϵ_7, we start with this result and modify the charge from 7.7 to 14.8 me, using $a_6 = -0.450$. Thus, $\epsilon_7 = 82.49 - 0.450\,(14.8–7.7) = 79.30$. Similarly, the 113.07 result quoted above leads to $\epsilon_{11} = 113.07 - 0.210\,(14.8–7.7) = 111.58$.

[7]Theoretical analyses, at the 4-31G level including polarization functions, account for over 80% of the results anticipated from empirical evaluations (13). Our recipe is, in principle, at the level of experimental accuracy.

Example 4. ϵ_7 was obtained from ϵ_1 by replacing one CH_3 of ethane by phenyl. The nonconjugated central bond of biphenyl is deduced from $2(\epsilon_7 - \epsilon_1) + \epsilon_1$ and $F = -0.29$, which reduces R from 1.53 to 1.49 Å with $q_C = 14.8$ me. The reference ϵ_8 (for a CC single bond, as in *cis*-stilbene) is deduced from ϵ_7 (R = 1.53 Å), which is reduced to 1.49 Å with $F = -5.40$. Using the average of a_2 and $a_{CC}^\sigma = -0.460$ (for 1.53 and 1.49 Å, respectively) for evaluating the change from 35.1 to 7.7 me at the sp^2 carbon, we find $\epsilon_8 = 79.30 - 5.40 + 12.99 = 86.89$.

Example 5. Here we begin with $\epsilon_3 = 89.70$ (a conjugated CC single bond formed by sp^2 carbons, as in 1,3-butadiene) (5) at its equilibrium distance, ~1.48 Å, and construct a C(Ar)—C(Ar) single bond modelled on benzene, with $R = 1.397$ Å. For $q_i = q_j = 7.7$ me, $F = 9.90$. Setting the charges at 14.8 me, using $a_{CC}^\sigma = -0.486$, reduces ϵ_{CC} by 6.90. The final result, 92.70, is in moderate agreement with its counterpart, 91.56, obtained from a numerical analysis of experimental data. Contrasting with the previous examples, this case illustrates a limitation of our simple evaluation of $\langle r_{ij}^{-1}\rangle$ for use in eq. [6].

Example 6. Taking now the above CC single bond, $\epsilon_6 = 91.56$, as input, we construct a CC single bond, $R = 1.445$ Å (66), like that found in styrene. The change from 1.397 to 1.445 Å translates into $F = -4.98$ with $q_i = q_j = 14.8$ me. Modification of the charge from 14.8 to 7.7 me at the ethylenic carbon, with $a_{CC}^\sigma = -0.472$, increases ϵ_{CC} by 3.35, thus giving $\epsilon = 89.93$. Similarly, for 1.48 Å (17) we find $\epsilon_9 = 90.40$ describing the C(Ar)—C(sp^2) reference bond, as in *trans*-stilbene.

Appendix IV

For an aromatic carbon linked to a non-aromatic carbon, $\Sigma_j a_{ij}$ is $2a_{CC}^{\sigma,\pi}(\text{Ar}) + a_{CC}^{\sigma,\pi}(\text{nAr})$, where $a_{CC}^{\sigma,\pi}(\text{Ar})$ is for the benzenic bond and $a_{CC}^{\sigma,\pi}(\text{nAr})$ for the bond formed with a non-aromatic carbon. The change in charge at the aromatic carbon is Δq_C (relative to benzene), contributing $\Delta q_C \Sigma_j a_{ij}$ to ΔE_a^*. On the other hand, this Δq_C is also part of Σq_C, hence, of $\Sigma \Delta q_H$, contributing $-\Delta q_C a_{HC}$. The total contribution of Δq_C is thus

$$[2a_{CC}^{\sigma,\pi}(\text{Ar}) + a_{CC}^{\sigma,\pi}(\text{nAr}) - a_{HC}]\Delta q_C$$

Of course, in this calculation, Δq_C must *not* be included in the evaluation of $\Sigma \Delta q_H$. Using eq. [5], as well as $\Delta q_C = (m + 1) \times \Delta q^\pi$ and $\delta = 157\ \Delta q^\pi$ (Appendix II), we find that the energy contributed by Δq_C is, in au,

$$m[2a_{CC}^{\sigma}(\text{Ar}) + a_{CC}^{\sigma}(\text{nAr}) - a_{HC}]\left(\frac{\delta}{157}\right) + [2a_{CC}^{\pi}(\text{Ar}) + a_{CC}^{\pi}(\text{nAr}) - a_{HC}]\left(\frac{\delta}{157}\right)$$

where δ is the ^{13}C shift relative to benzene. Inserting the appropriate a_{ij}'s (in au) gives the energy contributed by Δq_C, i.e., in kcal mol^{-1},

$$-(1.2562m + 1.1432)\left(\frac{627.51}{157}\right)\delta = -0.052\,\delta$$

for $m = -0.8997$. It is clear that the final result depends heavily on m, beyond the precision permitted by present SCF charge analyses. Inspection of molecules corresponding to this situation has consistently led to the −0.052 parameter. The corresponding m value, ~−0.90, seems intuitively reasonable when compared to −0.955 for ethylenic carbons (4) and to −0.812 for a benzenic carbon not engaged in a bond with a non-aromatic carbon.

The influence of ionic strength on the adsorption of azide ions on mercury electrodes

ARTUR J. MOTHEO, ERNESTO R. GONZALEZ,[1] AND LUIS A. AVACA
Instituto de Física e Química de São Carlos, Universidade de São Paulo, C.P. 369, São Carlos, SP, 13560 Brasil
Received April 1, 1985

ARTUR J. MOTHEO, ERNESTO R. GONZALEZ, and LUIS A. AVACA. Can. J. Chem. **64**, 413 (1986).

The adsorption of azide ions on mercury electrodes has been studied from constant ionic strength solutions of composition χ *M* NaN_3 + ($\mu - \chi$) *M* NaF with $\mu = 0.25$ and 0.5. Double layer parameters were obtained by taking into account the change in activity coefficients with solution composition. The results were analyzed together with those reported previously for $\mu = 0.95$, recalculated to take into account the change in activity coefficients. The influence of the ionic strength on the amount adsorbed, the properties of the inner layer, and the parameters of an adsorption isotherm for azide anions are discussed in terms of the electrostatic model of the double layer.

ARTUR J. MOTHEO, ERNESTO R. GONZALEZ et LUIS A. AVACA. Can. J. Chem. **64**, 413 (1986).

Opérant sur des solutions de force ionique constante et de composition χ *M* en NaN_3 + ($\mu - \chi$) *M* en NaF, avec $\mu = 0{,}25$ et 0,5, on a étudié l'adsorption des ions azotures sur des électrodes de mercure. On a obtenu les paramètres de double couche en tenant compte du changement des coefficients d'activité avec la composition des solutions. On a analysé ces résultats ainsi que ceux rapportés antérieurement pour $\mu = 0{,}95$ et recalculés pour tenir compte du changement dans les coefficients d'activité. On discute de l'influence de la force ionique sur la quantité de substance adsorbée, sur les propriétés de la couche interne et sur les paramètres de l'isotherme d'adsorption des ions azotures en fonction du modèle électrostatique de la double couche.
[Traduit par le journal]

Introduction

Because of its many advantages, most recent studies of adsorption of anions on mercury have been carried out in constant ionic strength solutions. A comparison with studies of the same anion in single salt solutions often showed differences in the amount adsorbed and, in some cases, in the double layer properties. Ions for which the adsorption is so strong that the adsorbed charge numerically exceeds the electrode charge, show higher specific adsorption in constant ionic strength solutions. Fawcett and McCarrick (1) showed this to be the case for iodide. More recently, the same situation was found in a study of thiocyanate adsorption at two different ionic strengths (2). A different behavior was found for ions that adsorb moderately. By comparing their results with a previous study by Payne (3), Fawcett and Sellan (4) concluded that for nitrate the adsorption increased with ionic strength at high concentrations of NO_3^- while the opposite situation was observed for low concentrations of NO_3^-.

In relation to the inner layer properties in constant ionic strength and single salt solutions, no differences were found for azide (5), and small ones for iodide (6), while widely differing behaviors were observed for chloride (7) and bromide (8). These results point to the necessity of detailed studies of the effect of the ionic strength on the double layer properties.

In a previous study on the adsorption of azide on mercury (5) at a constant ionic strength (μ) equal to 0.95, a comparison was made with the results in single salt solutions (9). This showed that the amount of N_3^- anions adsorbed depends on the ionic strength of the solution, but in both cases the same adsorption isotherm applies. Moreover, as mentioned above, the inner layer in single salt and mixed solutions seems to have the same characteristics. This is not a general case, so it is of interest to study the effect of the ionic strength on the adsorption of N_3^- in order to better understand the properties of the interface in the presence of this anion.

In the present work, the double layer properties of the system NaN_3 + NaF on mercury were studied at $\mu = 0.5$ and 0.25 and the results examined together with those obtained previously (5) for $\mu = 0.95$. In this work, the change of activity coefficients of the electrolytes with solution composition was taken into account so the double layer parameters for $\mu = 0.95$ were recalculated accordingly.

Experimental

Experimental details of the purification of reagents, electrochemical techniques for recording capacity–potential curves, and potentials of zero charge were given previously (5). Activity coefficients for NaN_3 were calculated as described below, from data obtained using the cell

[1] Na electrode/χ *M* NaCl + ($\mu - \chi$) *M* NaN_3/AgCl/Ag

The emf measurements were carried out with a Corning Electrometer 101, employing a Corning n° 476 210 electrode and an Ag/AgCl electrode prepared according to recommendations (10). All measurements were done at 25 ± 0.1°C.

Results and discussion

Capacity–potential curves

Figure 1 shows the capacity–potential curves for the system χ *M* NaN_3 + (0.25 − χ) *M* NaF. A similar set of curves was obtained for $\mu = 0.50$. The general features are the same as those observed previously (5) for $\mu = 0.95$ and resemble those of other halides and pseudo-halides (2, 7, 8). These systems differ from most oxyanions in the sense that no pronounced minimum is observed on the anodic side of the potential of zero charge (E_z). The base solution curve (μ *M* NaF) was integrated twice in the cathodic direction using the experimental value of E_z and taking for the surface tension at the potential of zero charge a reference value $\gamma_z^b = 0$ as integration constants. By back integration from $E = -1.65$ V of the remaining curves in each set, taking into account the influence of the variation of activity coefficients on the potential (see discussion in the next section), the values of $\Delta\gamma_z = \gamma_z^b - \gamma_z$ presented in Table 1 were obtained. A comparison of the values of $\Delta\gamma_z$ with those obtained for $\mu = 0.95$ (5) shows that this parameter has some dependence on the ionic strength only at high azide concentrations.

Change in activity coefficients with solution composition

As it was pointed out previously (1), in some constant ionic strength systems it becomes important to take into account the changes in activity coefficients with solution composition.

*Voltage vs. standard calomel electrode.

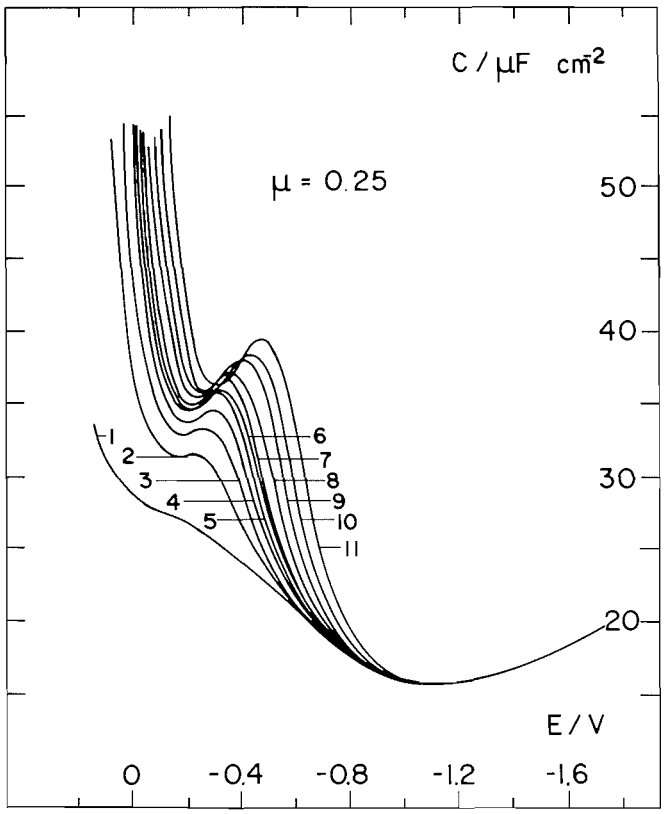

FIG. 1. Differential capacity of the double layer for a mercury electrode in aqueous χ *M* NaN_3 + (0.25 − χ) *M* NaF. χ = 0.0 (1), 0.001 (2), 0.0025 (3), 0.005 (4), 0.0075 (5), 0.01 (6), 0.015 (7), 0.025 (8), 0.05 (9), 0.1 (10), 0.25 (11).

As will be seen later, these affect the calculation of double layer parameters, in particular the specifically adsorbed charge determined by differentiation. Fawcett and McCarrick (1) took this into consideration for a system of two salts with a common cation, RA and RB, and at constant ionic strength, by introducing a parameter β defined as $\beta = d \ln \gamma_R/dx$, where γ_R is the activity coefficient of the cation and $x = C_{RA}/(C_{RA} + C_{RB})$. For such a system it is possible to write (11)

$$[2] \quad \frac{d \ln \gamma_{RA}}{dx} = \frac{1}{2}\left[\ln (\gamma^0_{RA})_\mu - \ln (\gamma^0_{RB})_\mu\right]$$

where γ_{RA} is the mean activity coefficient of the salt RA in the mixture, while the γ^0s are the corresponding values in single salt solutions at the same ionic strength of the mixture. This equation is derived from treatments based on a modified Debye–Hückel equation and does not take into account size effects (12).

For the system described, the activity coefficients of the anions γ_A and γ_B may be assumed to be independent of solution composition (12), so from eq. [2], the parameter β can be defined as

$$[3] \quad \beta = \frac{d \ln \gamma_R}{dx} = \ln (\gamma^0_{RA})_\mu - \ln (\gamma^0_{RB})_\mu$$

Thus, for NaN_3–NaF mixtures a β_1 will be introduced as:

$$[4] \quad \beta_1 = \ln \frac{(\gamma^0_{NaN_3})_\mu}{(\gamma^0_{NaF})_\mu}$$

Values of γ^0_{NaF} are available in the literature, but not those for $\gamma^0_{NaN_3}$. Attempts to measure these with a $Ag/AgN_3/N_3^-$ electrode were unsuccessful because of instability of the electrode. The alternative procedure of measuring β_1 directly using the cell

[5] Na electrode/χ *M* NaN_3 + ($\mu - \chi$) *M* NaF/F electrode

as described previously (1) also failed because the fluoride electrode was unstable in these solutions. The final procedure adopted here was to obtain the necessary values of $\gamma^0_{NaN_3}$ to be used in eq. [4] by the experimental determination of a β_2 defined as

$$[6] \quad \beta_2 = \ln \frac{(\gamma^0_{NaCl})_\mu}{(\gamma^0_{NaN_3})_\mu}$$

and corresponding to the mixtures NaCl–NaN_3 used in the cell described in the experimental section (eq. [1]). The Nernst equation for that cell is

$$[7] \quad \epsilon + \frac{RT}{F} \ln C_{Na} C_{Cl} = \epsilon_0 - \frac{RT}{F} \ln \gamma_{Na} \gamma_{Cl}$$

where ϵ_0 is the standard emf. Considering that at constant ionic strength γ_{Cl} is independent of composition (12), it follows that

$$[8] \quad \beta_2 = \frac{d \ln \gamma_{Na}}{dx} = -\frac{F}{RT}\frac{d}{dx}\left(\epsilon + \frac{RT}{F}\ln C_{Na}C_{Cl}\right)$$

The resulting values of β_2, together with the corresponding errors, were the following: -0.012 ± 0.003 for $\mu = 0.25$; -0.034 ± 0.006 for $\mu = 0.5$; and -0.0763 ± 0.0004 for $\mu = 0.95$. Introducing these values of β_2 and those of $(\gamma^0_{NaCl})_\mu$ from the literature (13) into eq. [6], the values of $\gamma^0_{NaN_3}$ were found to be 0.730, 0.705, and 0.709 for the ionic strengths 0.25, 0.5, and 0.95, respectively. It must be pointed out that owing to the form of eq. [6] the errors in β_2 represent at most a 1% uncertainty in the values of $\gamma^0_{NaN_3}$. Using those results in eq. [4] together with those of $(\gamma^0_{NaF})_\mu$ (13), the values of β_1 for the NaN_3–NaF mixtures were calculated as being 0.056, 0.109, and 0.208 for the ionic strengths 0.25, 0.5, and 0.95, respectively.

It is of interest to note that the values of $\gamma^0_{NaN_3}$ are very similar to those of γ^0_{NaSCN} (13). This justifies the approximation made by D'Alkaine *et al.* (9) in using values of γ^0_{NaSCN} in the work with NaN_3 in single salt solutions.

The adsorbed charge

Using the values presented in Table 1, capacity–potential curves were integrated twice to obtain the electrode charge density (q) and the surface tension (γ) as a function of potential, for each value of χ in each set. From these, Parsons' function $\xi_+ = qE_+ + \gamma$ was obtained. For this purpose, the experimental potential scale (E_R) was converted to a thermodynamic scale using the expression

$$[9] \quad dE_+ = dE_R - (\beta/f)\,dx$$

where $f = F/RT$. Values of the specifically adsorbed charge (q') due to N_3^- anions were then obtained at constant electrode charge from the expression

$$[10] \quad \frac{f}{1+\beta x}\left(\frac{\partial \xi_+}{\partial \ln \chi}\right)_q = q' + q^d_-\left(\frac{\beta x}{1+\beta x}\right)$$

where q^d_- is the anionic charge in the diffuse layer. In order to apply this equation, q^d_- was taken at first as being equal to $(RT\epsilon\mu/2\pi)^{1/2}$ and a value of q' calculated. By using diffuse layer theory, a new value of q^d_- was obtained. The procedure was then applied in an iterative way until the difference between two successive values of q' was less than 0.01 $\mu C\ cm^{-2}$. This calculation of q' was also applied to the experimental results obtained previously (5) for $\mu = 0.95$ because in that work the change of activity coefficients with solution composition was not taken into account. All the calculations described above were carried out with the use of computer programs.

If the influence of the change in activity coefficients is disregarded, values of q' are given by the simpler expression $q' = f(\partial \xi_+/\partial \ln \chi)_q$. A comparison with the more correct values obtained from eq. [10] shows that the correction is negligible for $\mu = 0.25$. For $\mu = 0.5$ and 0.95 differences are larger but they become significant only for the two highest values of χ.

For $\mu = 0.5$ and 0.25 the dependence of q' on q resembles that presented previously (5) for $\mu = 0.95$. The effect of the ionic strength on the adsorbed charge can be seen in Fig. 2 where the q' vs. q curves for three concentrations of N_3^- in the bulk are presented for each value of μ. For $\chi = 0.25$, it can be observed that q' increases with μ. This is because in this situation $|q'| > q$ and the potential at the outer Helmholtz plane

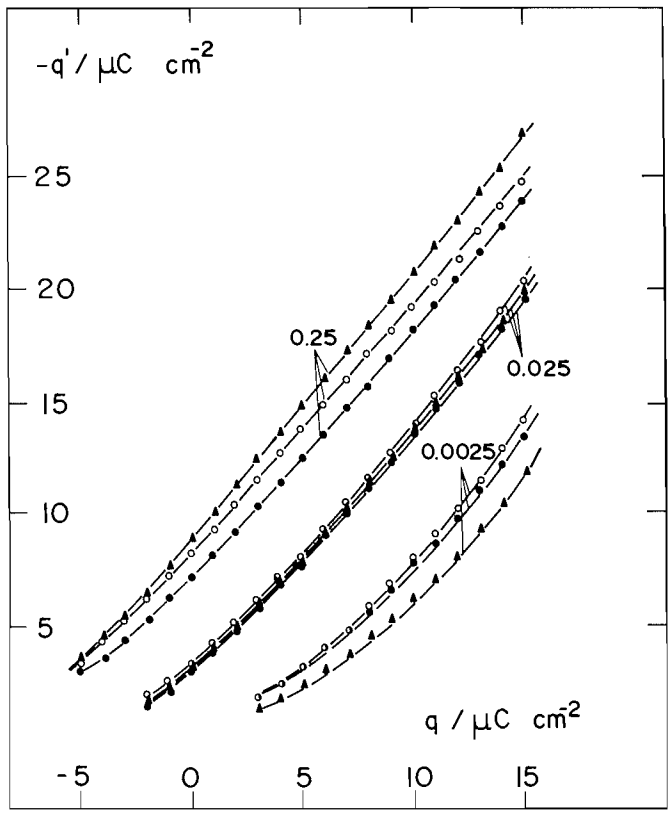

FIG. 2. Specifically adsorbed charge due to N_3^- anions on mercury for the ionic strengths 0.25 (●), 0.5 (○), and 0.95 (▲). Figures on the lines indicate the values of χ.

(oHp) ϕ_2 is negative. An increase of the ionic concentration in the diffuse layer makes ϕ_2 less negative, allowing larger values of q' to be attained. For $\chi = 0.0025$ the values for $\mu = 0.25$ and 0.5 are very close to each other and may be considered equal within experimental error. But those for $\mu = 0.95$ lie well below, indicating that for this value of χ the situation is reversed with respect to that for $\chi = 0.25$. Here, $|q'| < q$ and ϕ_2 is positive. An increase in the ionic concentration makes ϕ_2 less positive so q' decreases. An intermediate situation is observed for $\chi = 0.025$. This set of curves suggests that at some lower value of χ, for which ϕ_2 will approach a zero value, q' for a given concentration of NaN_3 will be independent of μ. The analysis done here in terms of electrostatic principles is quite straightforward; it has already been discussed in connection with the adsorption of SCN^- (2) and NO_3^- (4) but no results as illustrative as those in Fig. 2 were presented.

The inner layer properties

As usual, the properties of the inner layer will be analyzed in terms of plots of the potential drop across the inner layer (ϕ_{m-2}), obtained by subtracting the potential ϕ_2 of the oHp from the electrode potential, as a function of the adsorbed charge at constant q (Christie plots). Figure 3 shows the combined Christie plots for the three ionic strengths analyzed. The relevant region for the present system is that for $q > 0$, $|q'| > q$ and it is obvious that here the plots are independent of μ. This is in accordance with the fact that a previous comparison of the results for $\mu = 0.95$ (5) and single salt solutions (9) showed that the inner layer properties were the same in both systems. The slope of the plots seems to depend on μ when $q < 0$ and when $q > 0$ and $|q'| < q$. However, the reduced number of points and the larger errors

associated with low values of q' preclude the possibility of reaching definite conclusions. According to the classical model of the double layer, ϕ_{m-2} can be written

$$[11] \quad \phi_{m-2} = \frac{q}{K_{m2}} + \frac{q'}{K_{12}}$$

where K_{m2} is the integral capacity of the inner layer and K_{12} that between the inner Helmholtz plane (iHp) and the oHp. The slope of the Christie plots is then given by

$$[12] \quad \left(\frac{\partial\phi_{m-2}}{\partial q'}\right)_q = q\left(\frac{\partial 1/K_{m2}}{\partial q'}\right)_q + \frac{1}{K_{12}} + q'\left(\frac{\partial 1/K_{12}}{\partial q'}\right)_q$$

In the region where $q > 0$ and $|q'| > q$ the plots are linear and almost parallel, so that the two derivatives on the right-hand side of eq. [12] are zero and the slope is simply $1/K_{12}$. It must then be concluded that in this region K_{12} is independent of the ionic strength. This integral capacity can be written

$$[13] \quad K_{12} = \frac{\epsilon}{4\pi(x_2 - x_1)}$$

where ϵ is the permittivity of the inner layer, x_2 the distance from the metal to the oHp, and x_1 that between the metal and the iHp. Thus the conclusion above means that neither the ϵ profile nor the distances are affected by the ionic strength (unless they both vary in a compensating way, which is unlikely). This is not a general situation because in other cases, for example for the adsorption of SCN^- (2), the slope was found to be dependent on ionic strength. Figure 3 shows that in the region where $q \leq 0$ there is a definite tendency of the slope to increase with μ. This is a consequence of the weight of the points corresponding to the higher values of q'. Because the values of q' are small, it is unlikely that x_2 and (or) x_1 may be affected, so the smaller values of K_{12} for increasing μ are probably a consequence of a decreasing ϵ. This decrease in ϵ can be due to the fact that between the iHp and oHp more water is bound as the adsorbed charge and ionic concentration increase. Finally, in the region where $q > 0$ and $|q'| < q$ the effect of μ is not well defined, probably because q' is more inaccurate. Nevertheless, values of K_{12} are definitely larger. As already discussed (5), this is due to a replacement of Na^+ by F^- in the diffuse layer, which makes x_2 smaller.

The equivalent of eq. [13] for the integral capacity of the inner layer is $K_{m2} = \epsilon/4\pi x_2$. Then if a uniform value of the permittivity is assumed, the distance ratio $(x_2 - x_1)/x_2 = K_{m2}/K_{12}$ can be obtained. K_{12} and K_{m2} were calculated from the slope and the separation of the Christie plots, leading, in the region $q > 0$, to the average values $x_1/x_2 = 0.77$ for $|q'| > q$ and $x_1/x_2 = 0.86$ for $|q'| < q$. Because changes in x_1 are unlikely, these values show that the oHp is nearer the iHp when $|q'| < q$. Again this is due to the fact that the solvated F^- anion, which determines the diffuse layer charge in this region, has a smaller radius than the Na^+ cation (5).

The adsorption isotherm

According to the electrostatic model of the double layer and in the situation where discreteness-of-charge effects are estimated on the basis of the cutoff-disc model, the adsorption isotherm can be written (14, 15)

$$[14] \quad \ln(-q'/a_{N_3^-}) - \ln(q' - q_s') = \Phi + \frac{f}{K_{12}}q_s' + \frac{f}{K_{12}} \times \left(1 - g\frac{K_{m2}}{K_{m1}}\right)q' + f\phi_2$$

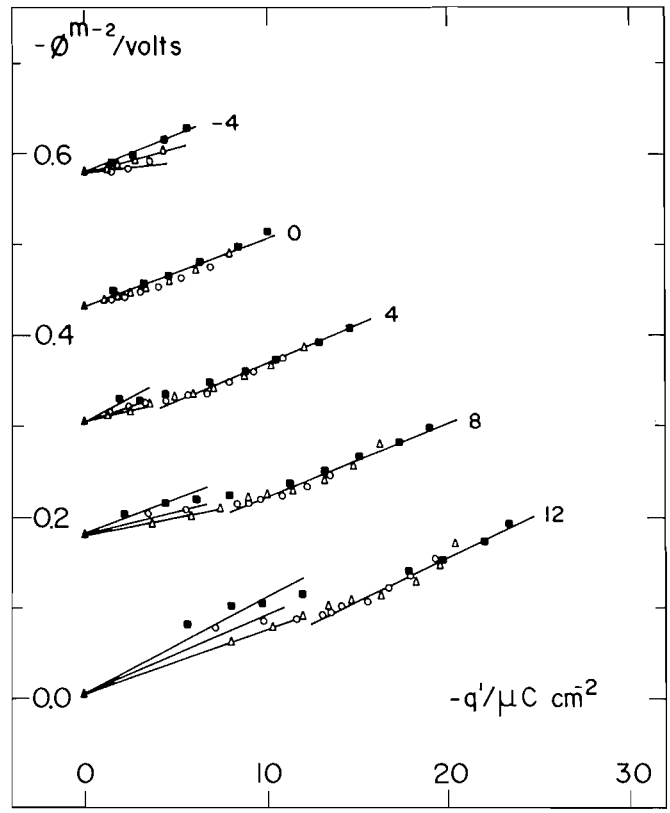

FIG. 3. Potential drop in the inner layer as a function of the specifically adsorbed charge due to N_3^- anions $\mu = 0.25$ (○), 0.5 (△), 0.95 (■). Figures on the lines indicate the electrode charge density in $\mu C\ cm^{-2}$. (▲) values correspond to the base solution.

where $a_{N_3^-}$ is the activity of N_3^- in the bulk, q_s' the maximum value of q', Φ a parameter related to the standard free energy of adsorption of an isolated particle, K_{m1} the integral capacity between the metal and the iHp, and g a dimensionless parameter related to the self-atmosphere potential of the adsorbed ion. As in previous cases (4, 16), the values of ϕ_2 are not large and can be approximated by the expression

$$[15] \quad f\phi_2 = \frac{q + q'}{A}$$

where $A = (RT\epsilon\mu/2\pi)^{1/2}$. Introducing eq. [15] into eq. [14] the result is

$$[16] \quad \ln(-q'/a_{N_3^-}) - \ln(q' - q_s') = \Phi + \left(\frac{f}{K_{12}} + \frac{1}{A}\right)q + \left(\frac{f}{K_{12}}\left(1 - g\frac{K_{m2}}{K_{m1}}\right) + \frac{1}{A}\right)q'$$

This isotherm was tested by plotting q' vs. $\ln(-q'/a_{N_3^-}) - \ln(q' - q_s')$ at constant q. Here it was assumed that the N_3^- anion adsorbs with the long axis perpendicular to the metal surface, giving for q_s' a value of 226 $\mu C\ cm^{-2}$. Figure 4 shows the results for $\mu = 0.25$. Plots with the same characteristics were obtained for $\mu = 0.5$ and 0.95. It is interesting to note that the isotherm plots present characteristics similar to those of the Christie plots. This statement is theoretically obvious but such a situation has not been apparent in experimental results presented for other systems. Figure 4 shows that straight lines are obtained for small values of q, but as q becomes larger it is apparent that there are two different slopes: one in the region $|q'| < q$ and

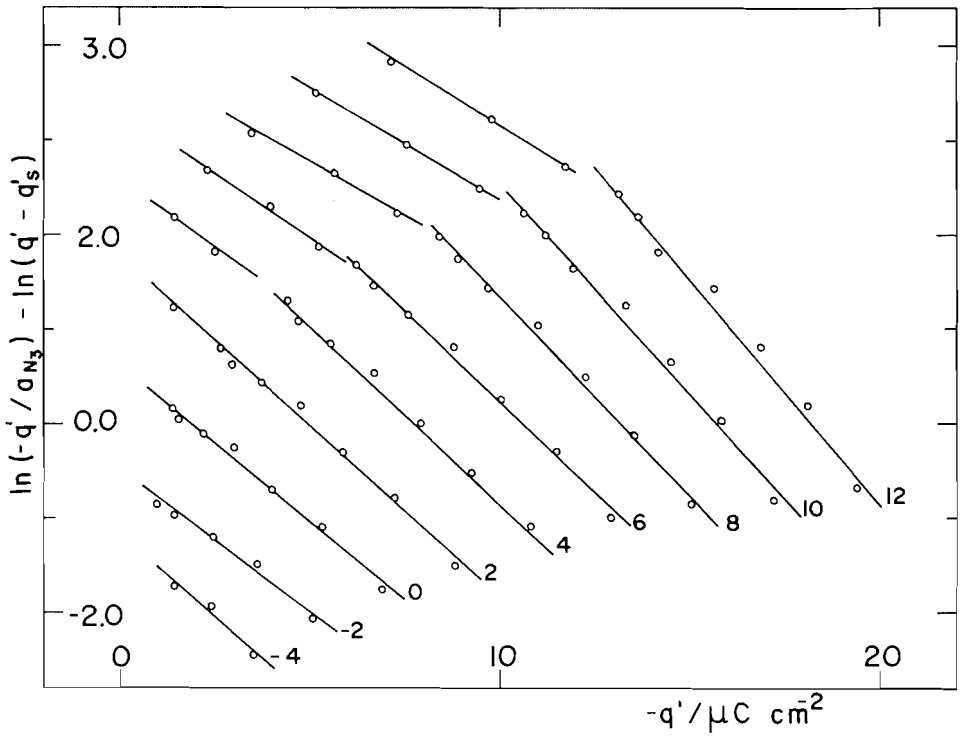

FIG. 4. Test of the adsorption isotherm (eq. [8]) for $\mu = 0.25$. Figures on the lines indicate the electrode charge density in $\mu C\ cm^{-2}$.

another one for $|q'| > q$. From the point of view of the isotherm parameters it is interesting to analyze the dependence of the parameter g on μ. This parameter was determined from slopes of plots like those in Fig. 4 using values of K_{m2} and K_{12} obtained from the corresponding Christie plots as described above. K_{m1} was evaluated from the relationship $K_{m2} = (1/K_{m1} + 1/K_{12})^{-1}$. In the region where $|q'| > q$, g depends somewhat on q but on average it was calcuated as being 1.14, 1.05, and 0.90 for the ionic strengths 0.25, 0.5, and 0.95, respectively. As discussed by Levine and Robinson (17, 18) g depends on the relative positions of the iHp and oHp and on the profile of variation of the permittivity of the inner layer with distance. As shown above, an increase in μ leads to an increase in q'. This increase is relatively small and unlikely to cause any alteration in the dimensions of the double layer. At the same time, an increase in μ means an increase in the ionic concentration in the diffuse layer. Thus there will be more bound water at the oHp and the permittivity in this region is likely to decrease. This may explain the fact that g decreases with increasing μ.

In the region where $|q'| < q$ the average values of g were 1.53, 1.30, and 1.13 for the ionic strengths 0.25, 0.5, and 0.95, respectively. Here g decreases with μ for the reasons just discussed. Also, it must be noted that the values of g are larger than those for the condition $|q'| > q$. The reason is again the fact that when F^- determines the diffuse layer charge the thickness of the inner layer is reduced. In other words, the oHp becomes nearer the iHp and consequently g increases (17, 18). The values of g obtained here are not very different from unity, falling well within the range discussed by Levine and Robinson (17, 18). This contrasts with the case of some oxianions where much higher values of g were observed (4, 16, 19). Finally, it must be noted that the values of g obtained here for azide anions are larger than those observed in single salt solutions (9), while according to the discussion above the opposite should be true. This was found to be due to the fact that the isotherm used in single salt solutions did not contain a term in q_s' which results in lower values of g. As an example, for $\mu = 0.25$, $q = 6\ \mu C\ cm^{-2}$, and in the region $|q'| > q$ the value obtained was $g = 1.14$. But if the therm in q_s' in the isotherm is disregarded it is found that $g = 0.75$. This value is indeed in good agreement with those obtained in single salt solutions (9).

This work presents a detailed evaluation of the effect of μ on the specific adsorbed charge for a system containing an active anion. The results were satisfactorily analyzed on the basis of the electrostatic model of the double layer. On the other hand, the double layer properties other than the amount adsorbed seem to be independent of μ. This observation cannot be generalized because there is some evidence that the situation may be different for other systems. The adsorption isotherm based on the electrostatic model is an adequate fit to the experimental results. In particular, the self-atmosphere parameter g and its dependence on μ are in accordance with this model but, again, this seems to be restricted to the present system.

Electrochemical gasification of lignite in phosphoric acid

KEITH E. JOHNSON AND LUC VERDET
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2
Received March 11, 1985[1]

KEITH E. JOHNSON and LUC VERDET. Can. J. Chem. **64**, 419 (1986).

A combination of simple voltammetry, cyclic voltammetry, chronopotentiometry, glc, proximate and ultimate analyses, and petrography were applied to the investigation of lignite electrogasification in phosphoric acid. Conversion of ~40% lignite to CO_2 occurs, in part by thermal reaction. Electrooxidation of the lignite occurs in part through electrocatalysis due to incorporated Fe(II). Lesser amounts of CO are produced thermally.

KEITH E. JOHNSON et LUC VERDET. Can. J. Chem. **64**, 419 (1986).

On a utilisé une combinaison de voltamétries simple et cyclique, de chronopotentiométrie, de cpg, d'analyses approximative et ultime et de pétrographie pour étudier l'électrogazéification de la lignite dans l'acide phosphorique. Environ 40% de la lignite se transforme en CO_2 et cette réaction est en partie thermique. L'électro-oxydation de la lignite se produit en partie par le biais d'une électrocatalyse due à du Fe(II) qui est incorporé. Il se produit thermiquement des quantités moins importantes de CO.

[Traduit par le journal]

Introduction

The notion of using an electrochemical method to convert coal into a gaseous fuel was revived recently by Coughlin and Farooque (1) who electrolyzed slurries of various coals in dilute sulfuric acid and obtained hydrogen and lesser amounts of carbon dioxide and carbon monoxide. It was noted that the required potential for electrolysis was ~0.9 V, much less than that required for water electrolysis. In other words, coal electrogasification might also be viewed as an interesting water electrolysis with depolarization of the anode reaction. Further studies of the coal – sulfuric acid electrolysis reactions were undertaken by Baldwin *et al.* (2), Bockris and co-workers (3), Park and co-workers (4 – 6), and Marooka *et al.* (7) among others. It was observed (*a*) that iron(II) species were extracted into solution from the coal and were oxidized to iron(III), thus contributing to the current flow (2); (*b*) that some chemical as well as electrochemical conversion of the coal to CO_2 occurred (3); (*c*) that iron(II) and added cerium(III) catalysed the coal oxidation (4).

Since the earlier work (1) indicated that increased temperatures produced greater currents and the coals apparently passivated by electrolysis at low temperatures could be reactivated by heating, we studied a variety of electrolytes for the process (8). While a molten carbonate system has theoretical appeal and such media have been investigated in the fuel cell context, we chose another fuel cell system, 85% phosphoric acid, for a first detailed study since it showed better current levels than sulfuric acid. We would note in passing that the highest currents were obtained using methane sulfonic acid as the electrolyte; these currents were roughly 10 times those from comparable phosphoric acid slurries.

Experimental

The samples used were Bienfait, Saskatchewan lignite, Boundary Dam (lignite) char, and carbon graphite. Saskatchewan lignites approximately comprise 1/3 carbon, 1/3 the elements of water, and 1/3 clay minerals. 85% Phosphoric acid (Fisher) was used as electrolyte.

The electrolysis cells consisted of stoppered glass beakers containing the coal slurries stirred by a magnetic stirring bar with a gold or platinum sheet anode. The catholyte was pure solvent in a tube terminating in a frittered glass disc; the cathode was a platinum sheet. The reference electrode consisted of a silver wire dipping into an electrogenerated silver(I) solution in phosphoric acid in another tube similarly terminated by a glass frit/salt bridge. Provision for adding a thermometer, Pt or Au microelectrode, and gas bubbler to the cell existed. Exit gases, usually in a stream of nitrogen carrier, could be vented to a hood or collected in a gas bag for analysis by a Carle Model III-H chromatograph. The cells were immersed in a thermostat.

Current–voltage curves were measured with a simple ammeter and voltmeter circuit.

Cyclic voltammograms and chronopotentiograms were obtained using a PAR 170 Electrochemistry System with a HP7035B *X–Y* Recorder.

Proximate and ultimate analyses

The moisture content was determined by the ASTM:D 3173–73 procedure. This method has been criticized, especially when used with low rank coals (9). However, tests showed that with the lignite used in the present work the procedure gave good reproducibility, and that oxidation because of the use of air was negligible.

Volatile matter was determined using the ASTM:D 3172–73 procedure, with the modification for sparking fuels.

The ash content was determined using the ASTM:D 3174–73 procedure.

Carboxylic acid functions were determined by exchange of the samples with calcium acetate and titration of the liberated acetic acid with base.

Petrographic analyses were performed by W. McDougall, V. Nambudiri, and J. Potter of the Energy Research Unit of the University of Regina by standard procedures (10).

Results

Figure 1 demonstrates the enhanced current produced by adding carbon graphite, lignite, or char to 85% phosphoric acid at 125°C and Fig. 2 shows the effect of temperature on the current–voltage profile. Measurements of the current at 2 V at 20 temperatures yielded an activation energy of 28.9 kJ/mol (6.9 kcal/mol), slightly high for a diffusion-controlled process but comparable to the Ce(IV) in H_2SO_4 oxidation rate for coal (6). The decay of current at fixed potential was slow for lignite and not quite so slow for char. If the lignite was previously extracted with H_3PO_4, the recorded current was lower, whereas the extract produced a higher initial current but one falling off more rapidly.

Extraction of the coal with H_3PO_4 gave gases with a CO_2:CO ratio of 3.2 after 30-h electrolysis at (30°C) compared with ratios of 4.9 for unextracted coal and 2.3 for coal extracted with a benzene–alcohol mixture.

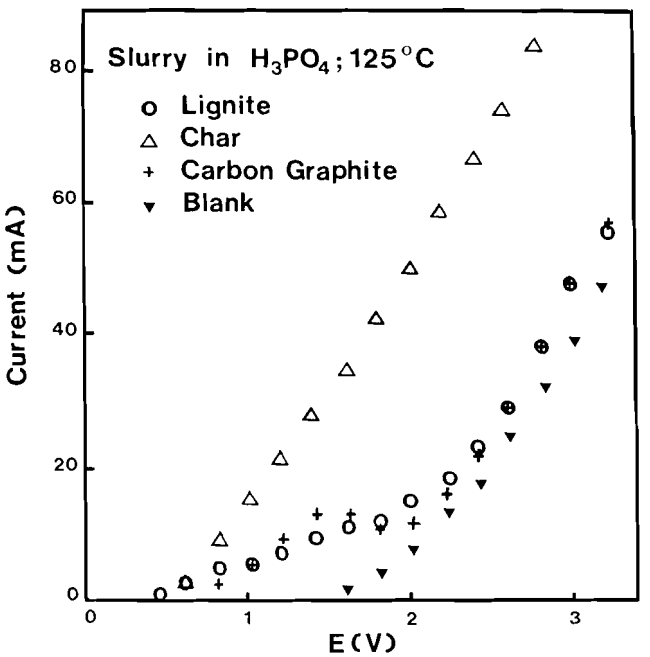

FIG. 1. Current–voltage profile for phosphoric acid at 125°C containing; o, lignite; Δ, char; and +, carbon graphite. Large platinum electrodes.

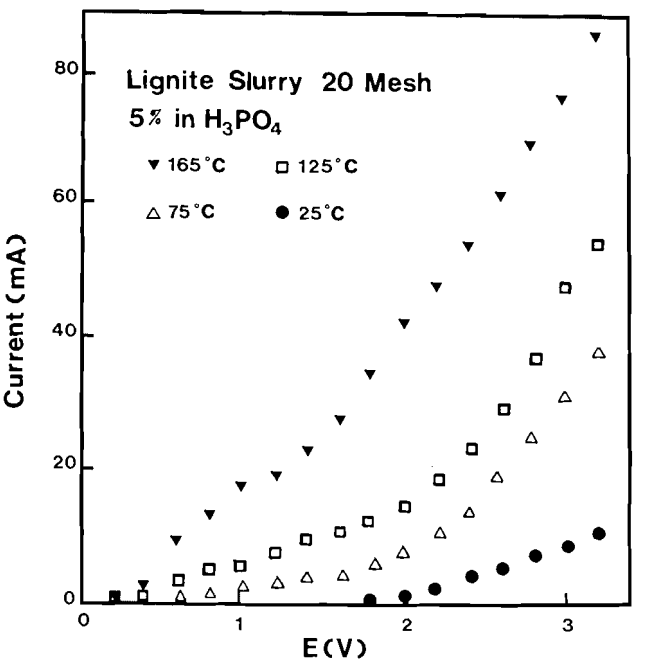

FIG. 2. The effect of temperature on the current–voltage profile of a 20-mesh lignite slurry in phosphoric acid. Large platinum electrodes.

Linear sweep voltammograms obtained with gold disc microelectrodes are shown for 30 and 150°C for H_3PO_4 alone and with added Fe(II) (Figs. 3 and 4) and for lignite in H_3PO_4 slurries (Figs. 5 and 6). The influence of formic acid on the voltammogram is noted in Fig. 5. The substitution of platinum for gold gave similar curves (Fig. 7) with lower current densities and no sharp anodic acid peak at ~0.8 V.

Chronopotentiograms obtained with currents of 75 and 130 μA merely highlighted the occurrence of electrode reactions at −0.4 and +0.8 V. Cyclic voltammograms showed the reversible Fe(III)/ Fe(II) peaks for Fe(II) solutions at ~−0.4 V, the

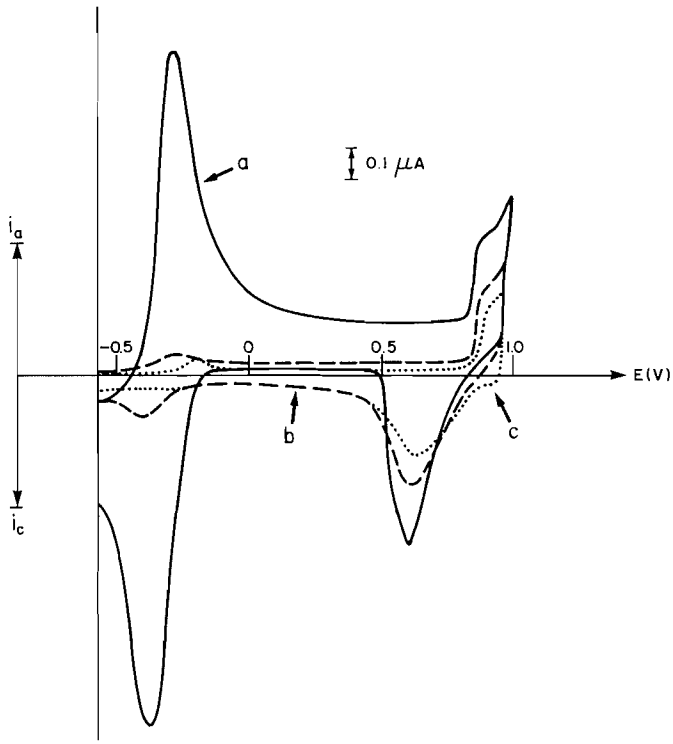

FIG. 8. Cyclic voltammograms in H_3PO_4 with 0.7-mm² gold microelectrode at 30°C: (*a*) 2×10^{-2} *m* Fe(II); (*b*) 3.3% lignite slurry; (*c*) base electrolyte.

same peaks for lignite slurries, gold oxide peaks in the 0.8 V region, and an additional anodic current rise around 0.5 V for slurries, the rise being more pronounced at 150°C. Figure 8 shows cyclic voltammograms for phosphoric acid, Fe(II) in phosphoric acid, and a slurry at 30°C, and Fig. 9 shows a similar set for 150°C. The cyclic voltammetry indicates the presence of iron ions, albeit trace amounts, in the H_3PO_4.

Several macroelectrolysis experiments were undertaken with platinum electrodes; the potential at constant current typically behaved as in Fig. 10, indicating several stages in electroactivity beyond the potential of Fe(II) oxidation. The evolved gases consisted of CO and CO_2 with traces of ethylene from thermal reaction of lignite and H_3PO_4 plus hydrogen when the slurry was electrolyzed. It was noted that the CO:CO_2 ratio was lowered once electrolysis commenced (Fig. 11).

3. Decrease in lignite ash	Inorganics dissolved by H_3PO_4
4. Increase in char ash	Char inorganics insoluble
5. Increase in calorific value	Decrease in moisture, H:C and ash
6. Increase in S content	S compounds involatile and insoluble

petrographic change; neither vesiculation nor any other evidence of devolatilization was noticed. The only recognizable difference between feedstock and residues was an increase in reflectance, R_0(av), from 0.39 to 0.43%. Detailed reflectograms of the chars showed a wide range of R_0(av) (0.40–4.79%) indicating nonuniform materials. This mitigated against any reliable measure of the effect of electrolysis but no vast changes were apparent.

Discussion

As in the case of sulfuric acid, lignite coal is chemically attacked by phosphoric acid with the production of gaseous CO and CO_2. This is due presumably to the dehydration of formyl and oxalyl groups. The rate of attack is slow but does increase with temperature. The formation of ethylene probably arises from the presence of some —OC_2H_5 groups on the coal. Electrolysis of coal slurries at 11 mA constant current produces a higher CO_2:CO ratio than does heating (12:1 vs. 4:1), suggesting Kolbe-type reactions of the —COOH groups on the coal (the —COOH groups were separately identified by infrared spectroscopy).

The linear voltammograms indicate the oxidation of Fe(II) to Fe(III) at −0.4 V, again as in sulfuric acid, but a further current flow occurs prior to the +0.8-V region. The current enhancement by formic acid addition suggests that isolated carbons in the coal macromolecules could be oxidized at this potential (+0.8 V). Comparison of Figs. 8 and 9 shows the distinct electroactivity of lignite at 150°C (+0.3→+0.8 V) as well as the iron redox peaks (−0.4 V) and the gold oxide peaks (+0.8 V oxidation, ~+0.7 V reduction).

The gold oxide formation peak is much more pronounced at 150°C and is decreased in the presence of added Fe^{2+} or lignite, presumably because the Fe^{2+}/Fe^{3+} exchange current is the higher one.

The current efficiency for H_2 production of only 88% could be due to slow leakage of Fe(III) into the catholyte or loss of gases from the apparatus, considering the length of the electrolysis time. The current efficiency for CO_2 production is surprisingly high at 39%. The rest of the charge presumably goes to humic acid and surface oxide production (cf. ref. 6 and references therein). The recent results of Dhooge and Park (6), in which 100% conversion to CO_2 by electro-oxidation of coal in H_2SO_4 was claimed, are not necessarily in conflict with our data. Their electrolyses were carried out at a *constant potential* of +1.0 V vs. NHE or ~+0.6 V vs. the Fe(III)/Fe(II) potential in 1 *M* H_3PO_4 (ref. 6, Table 1), which would correspond to ~+0.2 V vs. Ag^+/Ag in our system or close to the process following the Fe(II) oxidation. It is noteworthy that constant

current electrolysis produces substantially more (~10 times) CO_2 than CO. The experiments in which the CO_2 proportion in the gases is reduced by extraction confirm the availability of a soluble electroactive species (Fe(II)) and suggest that the CO is the product of a noncatalytic process. The coal moieties involved in the Fe(II)-catalysed reaction appear to dissolve in benzene–alcohol since the residue then produces even less CO_2.

In summary, the electrolysis of lignite slurries in phosphoric acid at 150°C gives rise to carbon dioxide and hydrogen with smaller amounts of carbon monoxide. While the carbon monoxide arises from a thermal reaction, the carbon dioxide has both thermal and electrochemical origins. Further, the electrooxidation of lignite is a mixed process of direct electrochemical oxidation and Fe(II) electrocatalysed oxidation. The ~40% conversion rate of lignite to CO_2 suggests that this electrogasification could be viable where low-cost or off-peak power is plentiful.

Received October 15, 1984

MIRKO DIKSIC, SIMIN FARROKHZAD, and LAWRENCE D. COLEBROOK. Can. J. Chem. **64**, 424 (1986).

Fluorination of uracil with acetylhypofluorite and fluorine in acetic acid is described. The influence of the acetate ion on the products of the fluorination reaction was examined. Two stereoisomers (*cis* (**3**) and *trans* (**4**)) were found in the reaction mixture following fluorination in the absence of the acetate ion, but only one isomer (**4**) and 5-fluorouracil were found when the acetate ion was present during the fluorination reaction. ^2H nuclear magnetic resonance revealed that acetate from the solution containing acetate ion rather than from the residue from acetylhypofluorite binds to position 6 of uracil to form intermediates. The synthesis yields 5-fluorouracil isolated as pure compound in a chemical yield, relative to the fluorine introduced, of about 45%. The influence of inorganic cations on the yield of acetylhypofluorite was also evaluated.

MIRKO DIKSIC, SIMIN FARROKHZAD et LAWRENCE D. COLEBROOK. Can. J. Chem. **64**, 424 (1986).

On décrit la fluoration de l'uracil à l'aide de l'hypofluorite d'acétyle et de fluor dans l'acide acétique. On a étudié l'influence de l'ion acétate sur la nature des produits de la réaction de fluoration. Lors des réactions effectuées en l'absence d'ions acétates, on a démontré que les mélanges réactionnels contiennent deux stéréoisomères, soit les produits *cis* (**3**) et *trans* (**4**); toutefois, les mélanges obtenus après des réactions effectuées en présence d'ions acétates ne contiennent que du fluoro-5 uracil et de l'isomère **4**. La rmn du ^2H permet de démontrer que ce sont les ions acétates de la solution plutôt que ceux de l'hypofluorite d'acétyle qui se lient à la position 6 de l'uracil pour former des intermédiares. La synthèse conduit au fluoro-5 uracil qui a été isolé à l'état pur, avec un rendement, basé sur la quantité de fluor utilisé, qui est d'environ 45%. On a ausi évalué l'influence des cations inorganiques sur le rendement de l'hypofluorite d'acétyle.

Introduction

^{18}F-labelled 5-fluorouracil (5-[^{18}F]FU) has been suggested as a tracer for in vivo investigation of the pharmacokinetics of uracil (1). Since its metabolic fragment continues to carry a positron-emitting radioisotope, the ^{18}F label, it can be used to investigate, in vivo, by means of positron emission tomography (PET), the metabolism of 5-[^{18}F]fluorouracil (2), possible incorporation of the [^{18}F]-labelled fluorouracil into RNA (3) in tumors, and, with this, the rate of RNA synthesis. The rate of RNA synthesis might, in turn, provide some indication of the activity of a tumor, which could be useful in assessing tumor therapy (4). Recently, the tissue distribution of 5-[^{18}F]fluorouracil was extensively evaluated in tumor-bearing animals (5, 6) and in humans with cancer (4). The results of these studies suggest that 5-fluorouracil indeed accumulates in different animal (5, 6) and human tumors (4).

Although attempts have been made to explain the reaction mechanism of the fluorination of uracil (7), it has never been completely understood. The intermediate, 5-fluoro-6-acetoxy-5, 6-dihydrouracil isomers **3** or **4** (Fig. 1), was isolated in 1979, but details of the reaction mechanism and stereochemical structure remained unexplained (7).

Uracil was first fluorinated with trifluoromethylhypofluorite (CF_3OF) (8). The synthesis of 5-[^{18}F]fluorouracil (**5**) (5-[^{18}F]FU) was first reported in 1973 (9) and the fluorination of uracil with [^{18}F]F_2 in acetic acid was reported in 1979 along with isolation of an intermediate. Recently we also reported a convenient high-yield synthesis of 5-[^{18}F]FU (10). In the present paper the isolation of intermediates produced in the fluorination of uracil, as well as their nmr spectra, is reported. Although positive stereochemistry of these intermediates could not be established by nmr spectra or chemical reactivity, we can now suggest a structure for these intermediates.

Results and discussion

Reactions of trifluoroacetylhypofluorite with stilbene (11), acetylhypofluorite with triacetylglucal (12–15), and trifluoromethylhypofluorite with uracil (16) have been reported. In all these cases, 100% regiospecificity was reported. Stereoselectivity in the syntheses of these fluoro compounds was also very good, but not always 100% (11, 20). This stereoselectivity is apparently influenced by the hardness of the base involved in the reaction (11). A mixture of *threo* and *erythro* forms was produced in the stilbene reaction with acetylhypofluorite in the presence of sodium acetate (11, 17). An addition of acetylhypofluorite across the double bond in triacetylglucal also resulted in two stereoisomers (18–20). Fluorination of uracil with molecular fluorine in acetic acid has also been reported, but the details of the reaction mechanism have never been established (7, 9, 22, 23).

Our results show that two major stereoisomeric adducts, *cis*- and *trans*-5-fluoro-6-acetoxy-5, 6-dihydrouracil, **3** and **4**, are produced by fluorination of uracil with molecular fluorine in acetic acid (reagent grade), or with acetylhypofluorite in acetic acid; however, 5-fluorouracil and one isomer, **4**, are found in the crude reaction mixture under both reaction conditions when an acetate ion is present during the fluorination reaction (Table 1). The ^1H nmr and ^{19}F nmr spectra were measured on the

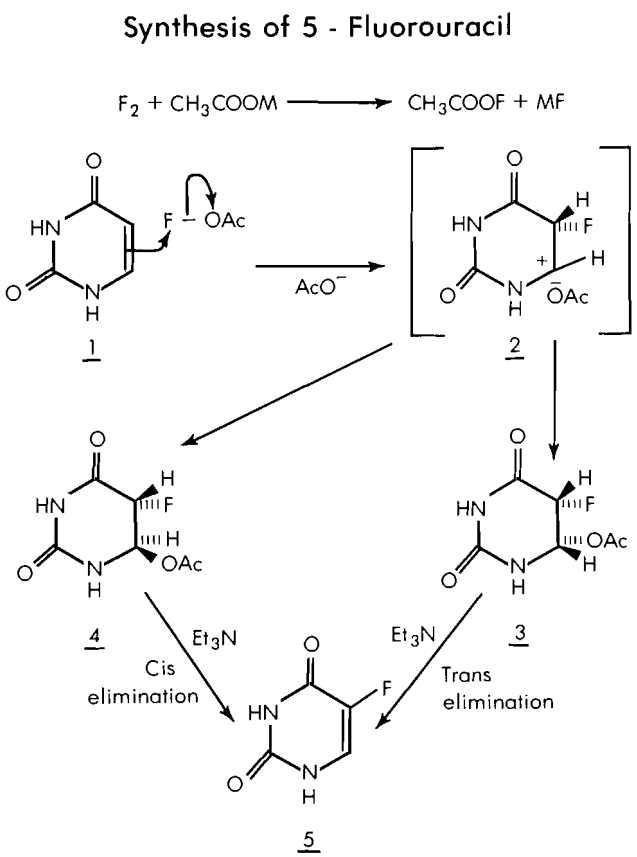

FIG. 1. Reaction scheme for the fluorination of uracil, **1**, with acethylhypofluorite.

relatively crude adducts prepared by fluorination of uracil (uracil present during bubbling) with F_2 in acetic acid (reagent grade). When acetate salt was not present during the reaction, the spectra revealed the presence of two geometric isomers (*trans* (**4**) and *cis* (**3**)) in a ratio of 1:2, but no 5-fluorouracil (Table 1). But when uracil was added (fluorination with CH_3COOF) after the end of bubbling, the ratio between *cis* (**3**) and *trans* (**4**) isomers was 4:1, and no 5-fluorouracil was found (Table 1). The presence of two geometric isomers indicates that the reaction does not have complete stereoselectivity. In contrast, in the presence of added acetate ion the spectra taken several hours after the end of bubbling showed the presence of a single isomer and 5-fluorouracil, suggesting that one of the isomers (Table 1) does not survive to the end of the reaction. We note that the reaction done in distilled acetic acid gave *trans* (**4**) and *cis* (**3**) isomers in a ratio of 2.5:1. This suggests that the removal of traces of impurities changes the mechanism of the reaction.

The ^1H and ^{19}F nmr spectra from positions 5 and 6 of the diastereomers were analyzed using iterative computer fitting, but positive identification of the stereochemistry at these positions could not be established on the basis of the coupling constants. Thus, $^3J_{H5-H6}$ is 3.9 and 4.3 Hz in **3** and **4**, respectively, while $^3J_{F5-H6}$ is 2.8 and 2.2 Hz in **3** and **4**, respectively. These values are too similar in magnitude to permit an unequivocal assignment of the configuration on the basis of the evidence of a coupling constant alone. Values of 4 and 2 Hz have also been reported for $^3J_{H5-H6}$ and $^3J_{F5-H6}$, respectively, for an isomer of 5-fluoro-6-acetyoxy-5,6-dihydrouracil prepared by fluorination of uracil in acetic anhydride – 5% acetic acid (23). Stereochemistry was not assigned (23).

TABLE 1. Ratios between *cis* (**3**) and *trans* (**4**) isomers formed under different fluorination conditions

Reaction medium	Ratio **3**:**4**	Acetate ion	Fluorinating reagent
AcOH (reagent)	Only **4***	Yes	F_2
AcOH (reagent)	2:1†	No	F_2
AcOH (distilled)	1:2.5†	No	F_2
AcOH (reagent)	4:1‡	No	CH_3COOF
AcOH (reagent)‡	8:1§	Yes	CH_3COOF

*Only one isomer (*trans* (**4**)) and 5-FUr found after evaporation of AcOH.
†Uracil present during bubbling.
‡Uracil added after the end of bubbling.
§Present in crude reaction mixture (before evaporation of AcOH), but after evaporation or about three hours after bubbling only *trans* (**4**) and 5-FUr were present.

Our results also suggest that the acetate ion is a strong enough base to facilitate acetic acid elimination in one of the isomers. This was confirmed in experiments where acetate ion was added to the crude reaction mixture containing the *cis*–*trans* mixture, ^{19}F nmr taken a few hours later showed that CH_3COOH was eliminated from the isomer assigned the *cis* configuration for that isomer (**3**), and the mixture contained only 5-fluorouracil and the *trans* isomer (**4**) in the same ratio in which the two isomers were present in the solution without acetate ion. The ease with which the *cis* isomer loses CH_3COOH supports our assignment, because the *cis* isomer (**3**) has H and CH_3COOH in the *trans* configuration favoured for the elimination of CH_3COOH.

Fluorination with fluorine

When fluorination with fluorine was carried out in the presence of an acetate ion, 60% of the fluorine was found in 5-fluorouracil (^{19}F nmr spectra), and the remainder (36–38%) in one stereoisomer (**4**), with a small admixture of 5,6-difluoro compound (2–4%). Fluorination of uracil with F_2 in CH_3COOH or CD_3COOD also yielded a minor product, which accounted for about 2–4% of the total F_2 approximately 1 h after introduction of F_2 was stopped. This compound was tentatively identified by its ^{19}F nmr spectrum as 5,6-difluoro-5,6-dihydrouracil. The $^{19}F\{^1H\}$ spectrum appeared as an AB quartet, $^3J_{F5-F6}=7.9$ Hz. When the fluorination reaction was carried out in CD_3COOD, the ^{19}F multiplet at δ −197.9 ppm showed loss of an H–F coupling (hydrogen on nitrogen-1). In consequence, this multiplet was assigned to F6, and the multiplet at −195.6 to F5. The geminal coupling constants, $^2J_{H5-F5}$ and $^2J_{H6-F6}$, were both 45.8 Hz.

Vine *et al.* (7), who investigated the fluorination of uracil with molecular fluorine in acetic acid with the addition of 25% (by volume) of acetic anhydride, reported the ^1H nmr spectrum of a single isomer with δ 2.13 (CH_3), 5.48 (J_{H5-F5} = 47 Hz, $J_{H5-H6}=4.5$ Hz, H5), and 6.27 ($J_{H5-H6}=45$ Hz, $J_{H6-F5}=2.22$ Hz, H6) ppm in acetic acid-d_4. They assigned the *cis* (H5—H6) configuration to this isomer on the basis of the magnitudes of the coupling constants. However, our experimental data on the two isomers show that the coupling constants are too similar to permit an unequivocal stereochemical assignment on the basis of coupling constants alone. In our work, the isomer produced in the fluorination of uracil in the presence of inorganic acetate has a ^1H nmr spectrum very similar to that reported by Vine *et al.* (7). The only difference is the value of J_{H-F} (geminal), for which 47 Hz was reported, compared with our value of 45.14 Hz. When we repeated the procedure of Vine *et al.* (7) we

TABLE 2. Yield of acetylhypofluorite as a function of acetate/fluorine ratio and cation

Cation X	CH_3COOX/F_2 (mmol/mmol)	Yield (%)	Number of determinations
Na^+	0.096	53 ± 3	2
	0.29	53 ± 4	2
	1.92	69 ± 3	3
	0.29	83 ± 4	3
	4	75 ± 3	3
	8	75 ± 3	2
	12	80 ± 2	3
	160	68 ± 3	3
K^+	0.9	71 ± 2	2
	1.9	78 ± 3	3
	2.9	90 ± 4	3
NH_4^+	0.096	55 ± 3	2
	0.29	60 ± 3	3
	1.9	70 ± 2	3
	2.9	90 ± 3	3
H^+	Glacial acetic acid	30 ± 3	3

obtained an isomer with J_{H-F} (geminal) = 45 Hz, which agrees well with the value obtained for the compound prepared by other procedures. On the basis of the nmr evidence, we conclude that the compound prepared by Vine *et al.* (7) is identical to the one we synthesized in the presence of an acetate ion. Our work indicates that the stereochemical assignments of Vine *et al.* (7), made on the basis of coupling constants, may not be correct. We consider that the opposite configuration is more likely.

The *trans* configuration of the intermediate 5-fluoro-6-acetoxy-5,6-dihydrouracil, **4**, obtained in the reaction of uracil and the fluorinating agent in the presence of inorganic acetate, was assigned on the basis of the observation that acetate from solution, rather than residue from CH_3COOF, adds in the 6 position and that this isomer is relatively more stable towards elimination of CH_3COOH. (See the experiments with deuterated acetate, analyzed by ^2H nmr, and discussion of possible reaction mechanisms.) The *trans* configuration of the intermediate is in accordance with other reactions involving ionic mechanisms, in which a halogen in the presence of a nucleophile is added to a double bond, yielding a compound with halogen and nucleophile in a *trans* configuration (24).

Indirect evidence for the stereochemistry of the *cis* isomer, **3**, is obtained from ^{19}F chemical shifts. This isomer has a chemical shift (δ −211.0 ppm) similar to *cis*-5-fluoro-6-methoxy-5,6-dihydrouracil (δ −208 ppm), for which the structure was positively assigned by X-ray crystallography (16). In this case, the fluorination reaction with CF_3OF proceeds with complete stereoselectivity (16), with only *syn* addition, and there is conclusive evidence that the nucleophile (methoxy) which adds to position 6 comes from the solvent rather than from the trifluoromethoxy residue of the CF_3OF (16). Values of $^3J_{H5-H6}(cis)$ = 4.0 and $^3J_{F5-H6}(trans)$ = 2.2 Hz were reported for *cis*-5-fluoro-6-methoxy-5, 6-dihydrouracil (16), comparable to the values noted above for the *cis*-acetoxy analogs (22). The ease with which stereoisomer **3** loses CH_3COOH also supports the assignment of the structure.

In the absence of added acetate ion, it is possible that fluorination (F_2 in CH_3COOH) of uracil proceeds through direct fluorination and *in situ* synthesis of acetylhypofluorite, which adds to the 5,6-double bond through a cation, **2**, (Fig. 1). The cation formed after the addition of fluorine (from F_2 or CH_3COOF) at C-5 will be more stable than fluorocarbon cations (16). This would allow the acetate ion to attack from either side and form two stereoisomers (equal probability would be expected only when the ion is planar and there is no hindrance of a nucleophilic attack).

The ratio between *trans* (**4**) and *cis* (**3**) isomers in the fluorination with F_2 in acetic acid differs from that observed in the fluorination with CH_3COOF (discussed later) (Table 1). This suggests that the reaction of molecular fluorine with uracil to form an intermediate occurs at a higher rate than that of fluorine with acetic acid to form acetylhypofluorite. The observation is not the same as that recently reported by Shiue *et al.* (21), who found no difference in the products in the fluorination of 2′,3′-di-O-acetyl-5′-deoxyuridine resulting from the two reactions.

Fluorination with acetylhypofluorite

The acetylhypofluorite yield is lower when it is synthesized in acetic acid without additional acetate ion (see Table 2 and ref. 13). As shown in Table 2, our results indicate that the yield of acetylhypofluorite is more a function of concentration than of the cation used. It is evident that the hypofluorite yield reaches a broad maximum when sodium acetate is used, while in other cases it increases with the concentration of acetate. A similar result was reported by Fowler *et al.* (13).

Fluorination of uracil with acetylhypofluorite (generated *in situ*) yielded intermediates **3** (*cis*) and **4** (*trans*) in different ratios (8:1) than fluorination with F_2, where it was 2:1 (Table 1). Fluorination done with acetylhypofluorite with acetate ion present during the reaction yielded mostly 5-fluorouracil (probably formed from *cis* isomer **3**) and a minor compound, *trans* isomer **4**. However, the fluorination of uracil with acetylhypofluorite when acetate ion was not present gave a ratio of 4:1 between the *cis* (**3**) and *trans* (**4**) isomers (Table 1).

That the incorporated acetate comes from the free acetate ion rather than from acetylhypofluorite was established by a labelling experiment (monitored by ^2H nmr) using deuterated acetate added to the reaction mixture after fluorine bubbling was stopped, but before uracil was added. No exchange between acetylhypofluorite and CD_3COO^- was observed. In this experiment, only one isomer was found, with deuterated acetate in position 6 of the intermediate. It was assigned the *anti*-configuration (*trans* (**4**)) as discussed above. The presence of deuterated, rather than regular, acetate in position 6, confirmed by ^2H nmr, supports the notion that the free acetate ion adds to position 6.

Fluorination of uracil with acetylhypofluorite also yields a small amount (2–4%) of the 5,5-difluoro adduct, 5,5-difluoro-6-acetoxy-5,6-dihydrouracil, identified by $^2J_{FF}$ = 284.2 Hz and the vicinal coupling constants $^3J_{FH}(cis)$ = 1.99 Hz and $^3J_{HF}(trans)$ = 6.73 Hz. The 6-methoxy analog of this compound has been reported by Robins *et al.* (16).

^{18}F-labelled 5-fluorouracil

The reaction scheme given in Fig. 1 for a non-radioactive synthesis was also applied when the ^{18}F-labelled compound was synthesized (10). ^{18}F-acetylhypofluorite was prepared first, and allowed to react *in situ* with uracil in the presence of acetate ion, yielding the intermediate, 5-[^{18}F]fluoro-6-acetoxy-5,6-dihydrouracil, **4**, which easily loses acetic acid, giving 5-[^{18}F]-fluorouracil (10).

Summary

On the basis of stability towards CH_3COOH, elimination of

one isomer, and the comparison of the ^{19}F chemical shifts with those of a related compound positively identified by X-ray crystallography (16), the stereochemistry of two intermediates formed in the fluorination reaction is suggested.

It was also observed that the ratio of *trans* (**4**) to *cis* (**3**) is greatly influenced by the purity of acetic acid, giving a ratio of 2.5:1 when the fluorination with F_2 was done in distilled acetic acid rather than in reagent grade, where it was 1:2. The fluorination in the presence of an acetate also yielded two isomers, but one (*cis* (**3**)) did not survive the work-up. Chemical and radiochemical yields were similar in both synthetic routes.

Experimental

General

Research grade chemicals obtained from regular suppliers were used in the syntheses. Thin-layer chromatography (tlc) was done on silica gel hard layer plates with a fluorescence indicator (254 nm). Two solvents were used for development of tlc plates: A, THF–hexane (65:35) and B, ethyl acetate – H_2O–HCOOH (13:1:1). ^{18}F compounds were investigated by visual identification under 254-nm uv light and by thin-layer radiochromatography, using a scanner with a windowless gas-flow proportional detector with a 1-mm opening. The final product was purified by simple filtration through a Sep-Pak column, using THF–hexane (40:6) as an elution solvent. In "cold" reactions, identification of reaction products was done by ^{19}F nmr, ^1H nmr, ^2H nmr, mass spectrometry, melting point, and tlc on silica gel. Reactions were followed by tlc.

The ^1H nmr spectra were obtained at 200 MHz on a Varian XL-200 spectrometer using DMSO-d_6 or acetic acid-d_4 solutions, with TMS as an internal reference. The ^{19}F nmr spectra were obtained at 75.39 MHz on a Bruker WP-80SY spectrometer, on a reaction mixture in acetic acid, acetic acid-d_4, or DMSO-d_6, using trichlorotrifluoroethane (^{19}F chemical shift, δ −82.20 ppm) as an external reference. Iterative analysis of nmr spectra was carried out using the PANIC program on a Bruker Aspect 2000 computer.

An authentic sample of 5-fluorouracil, used as a reference, was isolated from the drug, fluorouracil (Roche), by lowering the pH to about 6.5 (mp (uncorrected) 281°C (lit. (**25**) mp. 282–283°C).

In the first set of experiments, uracil (60–80 mg, 0.5–0.7 mmol) was fluorinated with acetylhypofluorite (prepared *in situ*) in acetic acid (10 mL) and acetic acid-d_4 (10 mL), with and without inorganic acetate.

In the second set of reactions, uracil (80 mg, 0.7 mmol) was suspended in glacial acetic acid, acetic acid-d_4, or in those acids (10 mL) in the presence of an acetate (deuterated or regular). Fluorine (0.1–0.6 mmol) in nitrogen was then introduced. The work-up was carried out as described later under B. In some experiments, the intermediates were analyzed directly in the acid solutions by ^1H nmr (deuterated acids) and ^{19}F nmr (regular and deuterated acids). When the intermediates were isolated, ^1H and ^{19}F nmr spectra were taken in DMSO-d_6 solution. In experiments done in acetic acid to which sodium deuteroacetate had been added, ^2H nmr spectra were taken on a crude reaction mixture.

A. *Reaction of acetylhypofluorite with uracil*

Acetylhypofluorite was prepared by reacting a 0.5–5% mixture of fluorine (0.1–0.6 mmol of F_2) in nitrogen with acetic acid in the presence of added acetate (generally 0.15 *M*) or with acetic acid without an acetate ion present, as described earlier (11–15). The presence of an OF group was established in the reaction mixture (from which all F_2 had been removed) by the appearance of a signal at 161.9 ppm in the ^{19}F nmr spectrum (acetic acid or acetic acid-d_4). At room temperature (about 22°C) the half-life of acetylhypofluorite is 20 min, as measured by ^{19}F nmr.

Acetylhypofluorite was allowed to react with uracil (80 mg, 0.7 mmol) by suspending it in a solution of hypofluorite in acetic acid, with (first set) and without (second set) added acetate ion. The reaction mixture from the first set was divided into two parts and a different work-up carried out on each. In the first part, acid was evaporated under reduced pressure (0.1 Torr; 1 Torr = 133.3 Pa) at a bath temperature of 60°C, the residue redissolved in DMSO-d_6 or acetic acid-d_4, and ^1H and ^{19}F nmr spectra taken. When the reaction was carried out in the presence of added acetate ion, *trans*-5-fluoro-6-acetoxy-5,6-dihydrouracil, **4**, was present, together with 5-fluorouracil. After evaporation of acetic acid, the residue proved to be over 80% final product, 5-fluorouracil, **5**, and only about 16–18% intermediate **4**. The second part was worked up by removing acid under reduced pressure and adding 0.7 mL of triethylamine to the residue. This was followed by a brief heating in a 60°C bath. The heating resulted in the complete elimination of CH_3COOH from the intermediate, giving pure 5-fluorouracil (**5**) in a quantitative yield.

In the second set (reaction done without addition of an acetate), the reaction mixture was divided and, on the first part, a similar work-up was done by evaporation under reduced pressure (0.1 Torr) in a 60°C bath. After evaporation, the residue consisted of about 88% of intermediate **3** and 12% of **4**, but no 5-fluorouracil in the first half. The second half of the reaction mixture was worked up with triethylamine as described above. Addition of 0.7 mL of triethylamine to the residue after evaporation, followed by brief heating in a 60°C bath, resulted in loss of CH_3COOH in both **3** and **4**, yielding 5-fluorouracil (**5**) or ^{18}F-labelled 5-fluorouracil. After evaporation of triethylamine, the residue was extracted with 1 mL of tetrahydrofuran–hexane (40:60) mixture, an the 5-fluorouracil or ^{18}F-labelled 5-FU was purified on a silica gel Sep-Pak column (10).

Purification of intermediate **3** was done only when working with non-radioactive materials. After fluorination in reagent grade acetic acid (no acetate added), isolation and purification were achieved using liquid chromatography (hplc) on silica gel with THF–hexane (35:75) as the solvent. It was not possible to determine the melting point because the intermediate was thermally unstable.

trans-*5-Fluoro-6-acetoxy-5,6-dihydrouracil (**4**)*

The ^1H nmr spectrum (acetic acid-d_4 δ : 2.07 (s, 3H, CH_3COO), 5.49 (d of d, 1H, $^2J_{H5-F5}$ = 45.1 Hz, $^3J_{H5-H6}$ = 4.27 Hz, H5), 6.31 (d, of d, 1H, $^3J_{H5-H6}$ = 4.38 Hz, $^3J_{H6-F5}$ = 2.26 Hz, H6); ^{19}F nmr spectrum (acetic acid-d_4) δ : −212.0 (d of d, 1F, $^2J_{F5-H5}$ = 45.24 Hz, $^3J_{F5-H6}$ = 2.19 Hz); (acetic acid/DMSO-d_6) δ : −212.0 (d of d, 1F, $^2J_{F5-H5}$ = 45.17 Hz, $^3J_{F5-H6}$ = 2.9 Hz). The ^{19}F nmr spectrum was best simulated by including a $^4J_{F5-H1}$ coupling of 2.2 Hz. The ^{19}F nmr spectra were analyzed by iterative computer fitting; TLC of the crude reaction mixture showed spots with R_f = 0.5 (5-FUr) and 0.81 in solvent A (*trans* (**4**) isomer). On heating, compound **4** was converted into 5-fluorouracil, mp 283°C, M^+ 130; tlc of the purified product showed R_f of 0.5 and 0.79, identical with an authentic sample of 5-fluorouracil, using, as developing solvent, solvent mixture A and solvent mixture B, respectively.

When the reaction was carried out in acetic acid in the presence of perdeuteroacetate, or in acetic acid-d_4 in the absence of acetate ion, the ^1H nmr spectrum of the reaction mixture showed no signal at 2.07 ppm, and it was unnecessary to use J_{F5-H1} in the simulation of the ^{19}F spectrum of the *trans* isomer.

Following fluorination with acetylhypofluorite in acetic acid (produced in acetic acid but no acetate), the solvent was evaporated and the resaidue dissolved in DMSO-d_6. The nmr analysis showed 10% of the residue to consist of 5-fluorouracil, the bulk of the remaining material being **3** and **4** in a 4:1 ratio. However, the ^{19}F nmr of the reaction mixture before evaporation had only two isomers present. A small amount (2–4%) of 5,5-difluoro-6-acetoxy-5,6-dihydrouracil, identified by its ^{19}F spectrum (acetic acid or acetic acid-d_4), was always present. On evaporation of the solvent, the 5,5-difluoro adduct was transformed into **3**.

5,5-Difluoro-6-acetoxy-5,6-dihydrouracil

The ^{19}F spectrum (acetic or acetic acid-d_4 δ: −114.3 ($^2J_{F5-F5'}$ = 284.20, $^3J_{F5-F6}$ (*cis*) = 1.99 Hz, F5), −132.0 ($^3J_{F5'-H6}$(*trans*) = 6.73 Hz, F5'). On broadband ^1H decoupling, the ^{19}F spectrum consisted of an AB quartet.

B. *Fluorination of uracil in acetic acid with molecular fluorine*

When uracil (0.7 mmol) suspended in acetic acid (10 mL) was

allowed to react with molecular fluorine (~0.5 mmol) in the absence of added inorganic acetate, a mixture of 1 part *trans*- (**4**) and 2 parts *cis*-5-fluoro-6-acetoxy-5,6-dihydrouracil (**3**) was obtained (the stereochemical assignments are given under Results and discussion). After evaporation of acetic acid and addition and subsequent evaporation of triethylamine, both isomers yielded 5-fluorouracil, with properties (mass spectrum, ^{1}H and ^{19}F nmr spectra, and melting point) identical to an authentic sample.

cis-5-Fluoro-6-acetoxy-5,6-dihydrouracil (3)

^{1}H nmr spectrum (acetic acid-d_4) δ : 2.10 (s, 3H, CH_3COO), 5.30 (d of d, 1H, $^2J_{F5-H5}$ = 46.69 Hz, $^3J_{H5-H6}$ = 3.96 Hz, H5), 5.34 (d of d, 1H, $^3J_{F5-H6}$ = 2.29 Hz, $^3J_{H5-H6}$ = 3.02 Hz, H6); ^{19}F nmr spectrum (acetic acid and acetic acid-d_4 δ : −211.0 (d of d, 1F, $^2J_{H5-F5}$ = 46.11 Hz, $^3J_{H6-F5}$ = 2.76 Hz). The ^{19}F spectra were analyzed by computer fitting. The ^{19}F spectrum of the acetic acid solution was best computer-simulated by allowing for a J_{F5-H1} coupling of 2.2 Hz. The *trans* isomer (**4**) had chemical shifts and coupling constants as described above.

5-Fluorouracil was identified by mp (281–283°C), ^{1}H and ^{19}F nmr spectra, and mass spectrometry (M^+ 130). The ^{1}H nmr spectrum in DMSO-d_6 was identical to that of an authentic sample of 5-fluorouracil.

In distilled acetic acid, 5-fluorouracil and the *trans* isomer **4** were found in the reaction crude when fluorination was done in the presence of an acetate ion, but a mixture of *trans* (**4**) and *cis* (**3**) isomers (in a ratio of 2:1) was formed when the reaction was carried out without addition of acetate ion. About 4% of 5,6-difluoro-5,6-dihydrouracil was identified in the reaction mixture by its ^{19}F nmr spectrum.

5,6-Difluoro-5,6-dihydrouracil

The ^{19}F nmr spectrum (acetic acid) δ : −195.6 (d of d, 1F, $^2J_{F5-H5}$ = 45.78 Hz, $^3J_{F5-F6}$ = 7.90 Hz, F5), −197.9 (d of d, 1F, $^2J_{F6-H6}$ = 45.78 Hz, $^3J_{F5-F6}$ = 7.90 Hz, F6).

Acknowledgments

This work was supported in part by a Medical Research Council of Canada Special Program Grant (SP-5), the Cone Memorial Fund, and a grant from the Killam Scholarship Fund of the Montreal Neurological Institute (to M. Diksic). The interest and encouragement of Drs. Y. L. Yamamoto and W. Feindel in this project are appreciated. We also express our thanks to Dr. Victoria Lees for editing and Ms. C. Elliot for typing this manuscript. A grant from the Faculty of Graduate Studies, McGill University, towards the purchase of a hplc unit is acknowledged. Funding towards the purchase of the nmr spectrometer (Concordia University) was provided by the Natural Sciences and Engineering Research Council of Canada. We wish to thank Dr. O. S. Tee for helpful discussions.

Structural, magnetic, and spectroscopic studies of tetrakis(pyridine) complexes of iron(II) sulfonates

JOHN S. HAYNES, STEVEN J. RETTIG, JOHN R. SAMS, ROBERT C. THOMPSON,[1] AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 7, 1985

JOHN S. HAYNES, STEVEN J. RETTIG, JOHN R. SAMS, ROBERT C. THOMPSON and JAMES TROTTER. Can. J. Chem. **64**, 429 (1986).

The iron(II) complexes $Fe(NC_5H_5)_4(RSO_3)_2$ where R = CF_3, CH_3, and p-$CH_3C_6H_4$ have been prepared and their crystal structures determined by single crystal X-ray diffraction. Crystals of *trans*-bis(methanesulfonato-*O*)tetrakis(pyridine)iron(II) are monoclinic, a = 16.524(2), b = 9.1127(6), c = 18.684(2) Å, β = 109.903(6)°, Z = 4, space group *Pn*. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.034 and R_w = 0.038 for 4243 reflections with $I \geq 3\sigma(I)$. Crystals of *trans*-bis(trifluoromethanesulfonato-*O*)tetrakis(pyridine)iron(II) are monoclinic, a = 10.456(1), b = 9.2981(8), c = 14.625(2) Å, β = 96.372(6)°, Z = 2, space group *Pn*. Structure solved and refined as above to R = 0.036, and R_w = 0.037 for 1483 reflections with $I \geq 3\sigma(I)$. Crystals of *trans*-bis(*p*-toluenesulfonato-*O*)tetrakis(pyridine)iron(II) are orthorhombic, a = 40.818(2), b = 9.8722(6), c = 17.3544(7) Å, Z = 8, space group *Fdd2*. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to R = 0.030 and R_w = 0.032 for 1851 reflections with $I \geq 3\sigma(I)$. All three structures show discrete octahedral molecules with monodentate *trans*-coordinated sulfonate groups. Two crystallographically independent molecules are observed in the R = CH_3 structure, the difference between them involving the orientation of the CH_3SO_3 groups with respect to the O—Fe—O vector. The FeN_4O_2 chromophore in each compound is a tetragonally compressed octahedron (approximate D_{4h} symmetry) with average Fe—N distances of 2.21, 2.23, and 2.24 Å and Fe—O distances of 2.11, 2.06, and 2.08 Å for the CF_3, CH_3, and p-$CH_3C_6H_4$ derivatives, respectively. The compounds were studied using vibrational, electronic, and Mössbauer spectroscopic methods, magnetic susceptibility measurements, and differential scanning calorimetry. Quadrupole splitting values from Mössbauer spectra indicate a $^5B_{2g}$ ground state for all three compounds and magnetic susceptibility data (310–4.2 K) have been analyzed assuming this ground state, using both a crystal field and a zero-field splitting model.

JOHN S. HAYNES, STEVEN J. RETTIG, JOHN R. SAMS, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **64**, 429 (1986).

On a préparé les complexes du fer(II) $Fe(NC_5H_5)_4(RSO_3)_2$ dans lesquels R = CF_3, CH_3 et p-$CH_3C_6H_4$ et on a déterminé leurs structures par diffraction des rayons-X sur des cristaux uniques. Les cristaux du bis(méthanesulfonato-*O*) tétrakis(pyridine)fer-(II) *trans* sont monocliniques avec a=16,524(2), b=9,1127(6), c=18,684(2) Å, β=109,903(6)°, Z=4 et groupe d'espace *Pn*. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R=0,034 et R_w=0,038 pour 4243 réflexions avec $I \geq 3\sigma(I)$. Les cristaux du bis(trifluorométhanesulfonato-*O*)tetrakis(pyridine)fer(II) *trans* sont monocliniques avec a=10,456(1), b=9,2981(8), c=14,625(2) Å, β=96,372(6)°, Z=2 et groupe d'espace *Pn*. On a résolu et affiinée la structure par les méthodes décrites plus haut jusqu'à des valeurs de R=0,036 et R_w=0,037 pour 1483 réflexions avec $I \geq 3\sigma(I)$. Les cristaux du bis(*p*-toluènesulfonato-*O*)tétrakis(pyridine) fer(II) *trans* sont orthorhombiques avec a=40,818(2), b=9,8722(6), c=17,3544(7) Å, Z=8 et groupe d'espace *Fdd2*. On a résolu la structure par des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R=0,030 et R_w=0,032 pour 1851 réflexions avec $I \geq 3\sigma(I)$. Dans le trois structures, on retrouve des molécules octaédriques individuelles avec des groupements sulfonates monodentates coordonnées en *trans*. Dans la structure où R=CH_3, on observe deux molécules qui sont cristallographiquement indépendantes; la différence entre les deux implique l'orientation des groupements CH_3SO_3 par rapport au vecteur O—Fe—O. Dans chacun des composés, le chromophore FeN_4O_2 est un octaèdre qui est comprimé d'une façon tétragonale (symétrie approximative D_{4h}) et dans lequel les distances Fe—N moyennes sont 2,21, 2,23 et 2,24 Å alors que les distances Fe—O sont 2,11, 2,06 et 2,08 Å respectivement pour les dérivés CF_3, CH_3 et p-$CH_3C_6H_4$. On a étudié les composés en faisant appel aux spectroscopies vibrationnelles, électroniques et de Mössbauer, à des mesures de susceptibilité magnétique et à la calorimétrie de balayage différentiel. Les valeurs des dédoublements quadrupolaires obtenus à partir des spectres de Mössbauer indiquent que les trois composés existent dans un état fondamental $^5B_{2g}$; on a analysé les données de susceptibilité magnétique (de 310 à 4,2 K) à l'aide des modèles tant de champ cristallin que de dédoublement à champ zéro en faisant l'hypothèse que l'état fondamental est bien celui-là.

[Traduit par le journal]

Introduction

The study of the coordinating properties of sulfonate anions, RSO_3^-, is of interest for a number of reasons. In view of the fact that they are the anions of relatively strong acids, they might be expected to coordinate only very weakly to transition metal ions. Indeed, there are numerous examples where the trifluoromethanesulfonate (triflate) ion has been utilized as a noncoordinating counter-anion (1–5). Nevertheless, examples where $CF_3SO_3^-$ and other sulfonates coordinate as monodentate (6–10) as well as bidentate and tridentate (11–14) ligands are known.

We had earlier utilized spectroscopic and magnetic techniques to investigate the coordination of sulfonate anions in anhydrous salts (15, 16) as well as in pyridine complexes (17). The basic structure proposed for the latter group of compounds, involving octahedral stereochemistry with *trans*-coordinated sulfonate groups, is confirmed in the present work by single crystal X-ray diffraction studies on the iron(II) methane-, trifluoromethane-, and *p*-toluenesulfonate derivatives. The bonding parameters for these three complexes are examined here with a view to assessing the relative coordinating strengths of the anions and the effects of coordination on anion geometries. This assessment is aided by comparisons with published structural data on other sulfonates and on pyridine complexes

[1]Author to whom correspondence should be addressed.

with other anions (18–22). Finally, the structural information provided by the X-ray diffraction studies on these three closely related compounds permits a detailed examination of the effects of small variations in the nature of the ligand field on the spectroscopic and magnetic properties of octahedral iron(II) complexes.

Experimental

Materials

Anhydrous iron sulfonates, $Fe(RSO_3)_2$, where R is CH_3, CF_3, and p-$CH_3C_6H_4$, were prepared as described previously (16). These compounds, as well as the pyridine complexes, are both moisture and oxygen sensitive and were handled in a nitrogen atmosphere glove box. Pyridine was dried before use by refluxing over barium oxide, then distilling. Methanol was allowed to stand over molecular sieves (4A) before distillation and diethyl ether was dried by refluxing with sodiumbenzophenone followed by distillation. All solvents were degassed prior to use via several freeze–pump–thaw cycles.

Syntheses

The three pyridine complexes were prepared by analogous routes involving addition of an excess of pyridine to a methanol solution of the appropriate iron(II) sulfonate. Over a period of a few hours, crystals of the pyridine complex started to form and, after leaving overnight, the product was isolated by filtration and washed with small quantities of diethyl ether. All manipulations were performed in the glove box. Yields of 60–70% were obtained. As an example, detailed conditions for the preparation of $Fe(NC_5H_5)_4(CF_3SO_3)_2$ are given. To a methanol (5 mL) solution of $Fe(CF_3SO_3)_2$ (1.37 mmol) was added 4 mL of pyridine. Yellow-green crystals of the product which appeared overnight were isolated by filtration and washed with a small amount (~3 mL) of diethyl ether (yield 64%). *Anal.* calcd. for $FeC_{22}F_6H_{20}N_4O_6S_2$: C 39.41, H 3.01, N 8.36; found: C 39.41, H 3.10, N 8.28. *Anal.* calcd. for $Fe(NC_5H_5)_4(CH_3SO_3)_2$: C 46.98, H 4.67, N 9.96, O 17.07; found: C 46.70, H 4.67, N 9.72, O 17.01. *Anal.* calcd. for $Fe(NC_5H_5)_4(CH_3C_6H_4SO_3)_2$: C 57.13, H 4.80, N 7.84, O 13.43; found: C 56.87, H 4.82, N 7.64, O 13.20.

X-ray crystallographic analyses

trans-*Bis(methanesulfonato-*O*)tetrakis(pyridine)iron(II)*

A crystal bounded by the 11 faces (followed by their distances in mm from a common origin) ±(0 0 1), 0.20, ±(0 1 1), 0.27, ±(0 1 −1), 0.27, ±(0 2 1), 0.28 ±(1 0 −1), 0.30, (1 0 0), 0.31 mm was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 35–42°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, ($\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{22}H_{26}FeN_4O_6S_2$ fw = 562.44

Monoclinic, a = 16.524(2), b = 9.1127(6), c = 18.684(2) Å, β = 109.903(6)°, V = 2645.3(5) Å^3, Z = 4, ρ_c = 1.412 Mg m^{-3}, F(000) = 1168, μ(Mo-$K\alpha$) = 7.61 cm^{-1}. Absent reflections: $h0l$, $h+l$ odd, space group Pn (nonstandard setting of Pc, C_s^2, No. 7, equivalent positions: x, y, z; $1/2+x$, $-y$, $1/2+z$) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 1.34–10.06° min^{-1} over a range of (0.85 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every hour throughout the data collection, showed only small random fluctuations. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (23, 24). Transmission factors ranged from 0.660 to 0.761 for 112 integration points. Of the 6042 independent reflections measured, 4243 (70.2%) had intensities greater than or equal to 3σ(I) above background, where $\sigma^2(I) = S + 2B + (0.04(S-B))^2$ with S = scan count and B = normalized background count.

The noncentrosymmetric space group Pn was indicated by the E-statistics. The structure was solved by conventional heavy atom methods. The coordinates of the Fe and S atoms from each of the two crystallographically independent molecules were determined from the Patterson function and those of the remaining non-hydrogen atoms from subsequent difference maps. Full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic temperature factors resulted in R = 0.050. In subsequent stages of refinement the hydrogen atoms were included as fixed contributors in idealized positions (methyl groups based on observed positions, C(sp^2)—H = 0.97 Å, C(sp^3)—H = 0.98 Å), recalculated after each cycle of refinement. The scattering factors of ref. 25 were used for non-hydrogen atoms and those of ref. 26 for hydrogen atoms. Anomalous scattering factors from ref. 27 were used for the Fe and S atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 629 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.034 and R_w = 0.038 for 4243 reflections with $I \geq 3\sigma(I)$. For all 6042 reflections R = 0.078. The polarity of the structure (for the particular crystal used) was determined by parallel refinement, the resulting R and R_w factor ratios of 1.023 and 1.028, respectively, representing a probability of >99.5% that the correct polarity has been chosen. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.16σ, respectively. The mean error in an observation of unit weight was 1.546. A final difference map showed maximum fluctuations of −0.85 to +0.36 e Å^{-3} near Fe atoms and was featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 5,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

trans-*Bis(trifluoromethanesulfonato-*O*-tetrakis(pyridine)iron(II)*

Experimental details are as above except where noted. The 8 bounding planes of the crystal used for data collection were: ±(−1 0 1), 0.09, ±(1 0 1), 0.31, ±(0 1 0), 0.06, ±(0 0 1), 0.33 mm. Reflections used in the refinement of the unit-cell constants had 2θ = 26–33°. Crystal data:

$C_{22}H_{20}F_6FeN_4O_6S_2$ fw = 670.38

Monoclinic, a = 10.456(1), b = 9.2981(8), c = 14.625(2) Å, β = 96.372(6)°, V = 1413.1(3) Å^3, Z = 2, ρ_c = 1.576 Mg m^{-3}, $F(000)$ = 680, μ(Mo-$K\alpha$) = 7.54 cm^{-1}. Absent reflections: $h0l$, $h+l$ odd, space group Pn from structure analysis.

An ω–2θ scan at 1.18–10.06° min^{-1} over a range of (0.65 + 0.35 tanθ)° in ω was employed. Of 2771 independent reflections measured (to 2θ = 52°), 1483 had intensities greater than 3σ(I) above background. An absorption correction was applied, transmission factors ranging from 0.895 to 0.909 for 88 sampling points.

The noncentrosymmetric space group Pn was suggested by both the E-statistics and by the Patterson function, from which the coordinates of the Fe and S atoms were determined. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.047. Hydrogen atoms were included as fixed contributors in idealized positions in the final stages of refinement. Convergence was reached at

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson; AGNOST, absorption corrections, by J. A. Ibers; TLS, thermal motion analysis, by V. Schomaker and K. N. Trueblood.

[3]The structure factor table, Table 5 (anisotropic thermal parameters), and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

$R = 0.036$ and $R_w = 0.037$ for 1483 reflections with $I \geq 3\sigma(I)$ (368 variables). For all 2771 reflections $R = 0.103$. The polarity was again determined by parallel refinement, the R and R_w ratios of 1.009 and 1.006 both corresponding to a >99.5% probability that the correct polarity has been chosen. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.02 and 0.09σ, respectively, and the mean error in an observation of unit weight was 1.363. A final difference map showed maximum fluctuations of −0.56 to +0.47 e Å^{-3} near Fe and was featureless elsewhere.

trans-*Bis*(p-*toluenesulfonato*-O)*tetrakis(pyridine)iron(II)*

The six bounding planes of the crystal used for data collection were: ±(1 0 0), 0.15, (−1 2 −2), 0.19, (−1 −2 −2), 0.20, (−1 −1 1), 0.18, (−1 1 1), 0.21 mm. Reflections used for the refinement of the lattice constants had 2θ = 30–40°. Crystal data:

$C_{34}H_{34}FeN_4O_6S_2$ fw = 714.63

Orthorhombic, $a = 40.818(2)$, $b = 9.8722(6)$, $c = 17.3544(7)$ Å, $V = 6993.0(6)$ Å^3, $Z = 8$, $\rho_c = 1.358$ Mg m^{-3}, $F(000) = 2976$, μ(Mo-$K\alpha$) = 5.91 cm^{-1}. Absent reflections: hkl, $h+k$ odd and $k+l$ odd, $0kl$, $k+l \neq 4n$, and $h0l$, $h+l \neq 4n$, uniquely indicate the space group $Fdd2$ (C_{2v}^{19}, No. 43).

An ω–2θ scan at 0.84–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ)° was employed. Of 2605 independent reflections measured (to 2θ = 60°), 1851 had $I \geq 3\sigma(I)$. Data were corrected for absorption, transmission factors ranging from 0.824 to 0.900 for 88 sampling points.

Space group symmetry requires the molecule to possess exact C_2 symmetry. The Fe and S coordinates were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.043$, a difference map gave the positions of all hydrogen atoms, which were refined with isotropic thermal parameters in subsequent least-squares cycles. Convergence was reached at $R = 0.030$ and $R_w = 0.032$ for 1851 reflections with $I \geq 3\sigma(I)$ (280 variables). For all 2605 reflections $R = 0.073$. The polarity was determined by parallel refinement, the R and R_w ratios of 1.055 and 1.069 clearly indicating the correct choice ($p > 99.9\%$). The mean and maximum parameter shifts on the final cycle of refinement were 0.015 and 0.23σ and the mean error in an observation of unit weight was 1.346. Maximum fluctuations on the final difference map were −0.25 to +0.17 e Å^{-3}.

Analysis of thermal motion

The thermal motion in the three compounds (Figs. 1 and 2) has been analyzed in terms of the rigid-body modes of translation, libration, and screw motion (TLS model) (28). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0031, 0.0053, and 0.0019 Å^2, respectively, for $Fe(NC_5H_5)_4(RSO_3)_2$, R = CH_3, CF_3, and p-$CH_3C_6H_4$. In each case, analyses of the entire molecule indicated significant independent motion of structural subunits, particularly the sulfonate groups. The subunits SO_3C, $O_2Fe(py)_4$, SCF_3, and tolyl were separately analyzed (rms $\Delta U_{ij} = 0.0012–0.0083$ Å^2). The appropriate distances have been corrected for libration (28, 29), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear along with the uncorrected values in Table 2. Bond angles are given in Table 3. Calculated hydrogen atom parameters for $Fe(NC_5H_5)_4(CH_3SO_3)_2$ and $Fe(NC_5H_5)_4(CF_3SO_3)_2$, anisotropic thermal parameters, bond lengths and angles involving hydrogen for $Fe(NC_5H_5)_4(p\text{-}CH_3C_6H_4SO_3)_2$, and complete listings of torsion angles (Tables 4–8) are included as supplementary material.

Spectroscopy

Infrared spectra in the region 4000–250 cm^{-1} were recorded on samples mulled in Nujol held between KRS-5 plates (Harshaw Chemical Co.) using a Perkin Elmer 598 spectrophotometer. Electronic spectra (3.8–30 kK) were recorded on samples mulled in Nujol using a Cary 14 spectrophotometer. ^{57}Fe Mössbauer spectra were obtained as reported previously (30). Samples were contained in Nylon holders sealed with epoxy resin. The Doppler velocity scale was calibrated with a metallic iron foil absorber and isomer shifts are quoted relative to the centroid of the iron foil spectrum.

Magnetic susceptibilities

Variable temperature magnetic susceptibility measurements were made between 130 and 4.2 K using a vibrating sample magnetometer (31) and between 300 and 80 K using Gouy equipment (32). Magnetic susceptibilities were measured at room temperature at three different values of $H\,dH/dx$ with a Faraday magnetic balance (33). No field dependence was observed for any of the complexes. Molar magnetic susceptibilities were corrected for the diamagnetic susceptibilities of all atoms; corrections used were Fe^{2+} −13, NC_5H_5 −49, $CF_3SO_3^-$ −46, $CH_3SO_3^-$ −35, $CH_3C_6H_4SO_3^-$ −89 (units 10^{-6} cm^3 mol^{-1}).

Differential scanning calorimetry (DSC)

The DSC runs were performed using a Mettler DSC 20 cell programmed with a Mettler TC 10A processor. Powdered samples (~5 mg) contained in aluminum crucibles were heated (35–450°C at a rate of 4° min^{-1}) in an atmosphere of dry nitrogen (flow rate 50 mL min^{-1}). The temperature calibration was achieved using the known fusion temperatures of indium, lead, and zinc and the heat flow was calibrated using an accurately known quantity of indium.

Results and discussion

Crystal structure analyses

The molecular structures of the three $Fe(NC_5H_5)_4(RSO_3)_2$ molecules are given in Figs. 1 and 2 along with the atom numbering schemes; intermolecular bond distances and angles are given in Tables 2 and 3. With the exception of possible weak C—H···O hydrogen bonds (Table 9, deposited supplementary materials), each of the three structures consists of discrete molecules separated by normal van der Waals distances. Structure analyses show all three compounds to be octahedral with monodentate *trans*-coordinated sulfonate groups. Two conformations are observed in the R = CH_3 compound, the difference between them involving the orientation of the CH_3SO_3 groups with respect to the O—Fe—O vector. The two independent R = CH_3 molecules and the R = CF_3 molecule have approximate C_2 symmetry and for R = p-tolyl the molecules possess exact C_2 symmetry. In each case the twofold axis lies in the FeN_4 plane and bisects opposite N—Fe—N angles.

The FeN_4 groups are nonplanar in all three compounds. For R = CH_3 and CF_3 the maximum deviations from the mean plane are less than 0.021 Å, while for R = p-tolyl the maximum deviation is 0.284(4) Å. In the R = CF_3 structure the four pyridine N atoms are coplanar; the Fe is displaced 0.015(1) Å from the N_4 plane. The pyridine rings are generally planar to within experimental error. While the pyridine rings containing N(1), N(4), and N(6) in the R = CH_3 structure and N(2) in the R = p-tolyl structure are nonplanar, no atom deviates by more than 0.015(4) Å. The bond distances and angles in the pyridine rings are similar to those found for free gaseous pyridine by electron diffraction and microwave spectroscopy (34, 35). An interesting structural feature present in all three compounds is that the four pyridine molecules are arranged in a staggered propeller fashion and the rings *trans* to one another are nearly orthogonal. The *trans*-pyridine bonds are very close to linear, whereas the O—Fe—O bond angles deviate significantly from 180°. Nevertheless, the overall distortion of the FeN_4O_2 chromophore is not great and the environment around the iron atom in all three compounds may be described as approximately D_{4h}.

The average Fe—N distances for the CF_3, CH_3, and p-$CH_3C_6H_4$ derivatives are 2.21, 2.23, and 2.24 Å, respectively. These are comparable to the distances 2.23 Å reported for

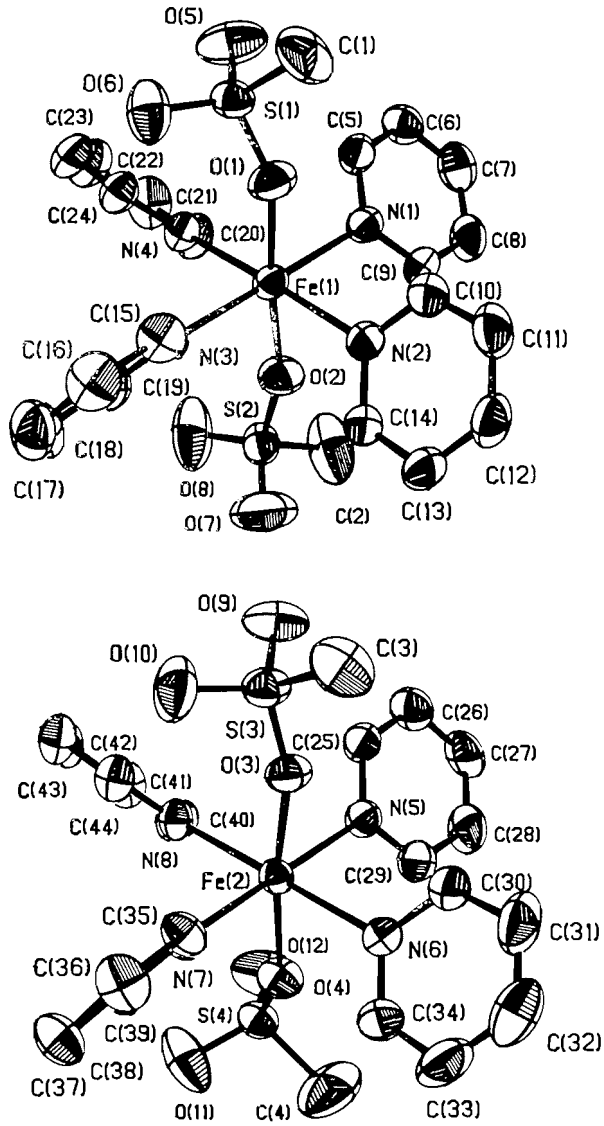

FIG. 1. Views of the two independent $Fe(NC_5H_5)_4(CH_3SO_3)_2$ molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

$Fe(py)_4Cl_2$ (18) and 2.26 Å for $Fe(py)_4(NCS)_2$ (19). The Fe—O distances range from 2.11 A in the trifluoromethanesulfonate complex to 2.06 Å in the methanesulfonate compound. Assuming that Fe—O bond distances in sulfonate complexes are good measures of the strength of the metal–anion coordination, it is interesting to note that in $[\eta^5\text{-}C_5(CH_3)_5](CO)_2FeOSO_2CF_3$ the Fe—O distance is only 2.007 Å (6). The presence of the strong π-acid ligands in this complex makes the iron centre strongly electrophilic and results in what is described in ref. 6 as a strong "electrostatic iron–triflate interaction."

Turning to a consideration of internal bonding parameters for individual anions, we note that the bond distances and angles observed here for $CF_3SO_3^-$ appear comparable to those seen in other unidentate coordinated trifluoromethanesulfonate groups (6–10). The anion assumes a staggered-ethane conformation about the S—C bond and, while the average C—F bond length is greater than those usually found in ionic $CF_3SO_3^-$ compounds (2–5), it is typical for the unidentate coordinated anion (6–10). The O—S—O angles are consistently greater than the C—S—O angles, a consequence of the fact that bond pair repulsions involving the multiply bonded S—O groups are greater than those involving the S—C group. The effect of coordination on the $CF_3SO_3^-$ group is most clearly seen in the S—O bond distances. The S—O bond involving the oxygen coordinated to iron is the longest such distance in this compound and the average bond length for the terminal S—O bonds (~1.44 Å) is close to the value found in ionic $CF_3SO_3^-$ compounds (2–5).

The methanesulfonate compound has the same staggered-ethane type structure for the anion with O—S—O angles greater and C—S—O angles smaller than the tetrahedral angle. The average S—C bond distance in this case (1.78 Å) is slightly shorter than in the $CF_3SO_3^-$ compound but longer than that seen in $Ca(CH_3SO_3)_2$ (ave. S—C = 1.75 A) (12). Again, the average S—O distance involving the iron-bound oxygens is longer (1.48 Å) than the average S—O distance involving terminal oxygens (1.45 Å). In the compounds $Ca(CH_3SO_3)_2$ (12) and $Cu(CO)(C_2H_5SO_3)$ (36) the sulfonate anion acts as a tridentate ligand and the range of S—O bond distances is much smaller, 1.429–1.456 Å and 1.445–1.462 Å, respectively. In these structures the effect of anion coordination only slightly affects the equality of S—O bond lengths. Two other methanesulfonates with known structures are relevant here, $Cu(CH_3SO_3)_2(H_2O)_4$ (10) and $Cd(CH_3SO_3)_2(H_2O)_2$ (14). In the copper complex the water molecules form the equatorial plane of a tetragonally distorted octahedron with two unidentate coordinated $CH_3SO_3^-$ groups in axial positions. Somewhat surprisingly, and in contrast to what is found here, the S—O bonds involving the terminal oxygens in the aquo complex are longer than those involving the oxygens bonded to the metal. This is likely a consequence of hydrogen bonding interactions

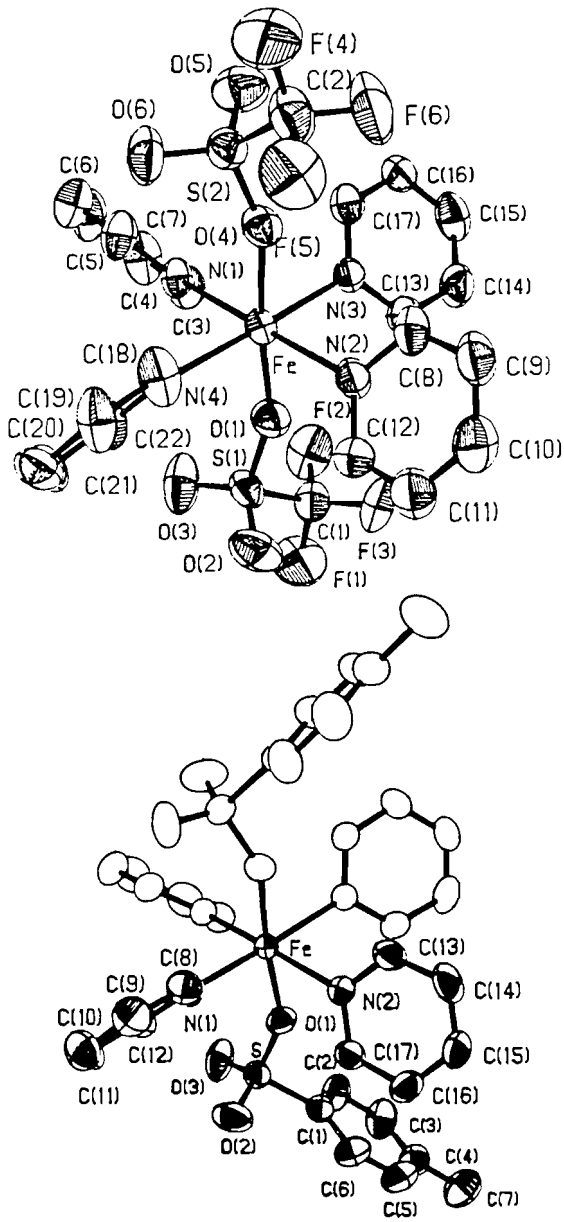

FIG. 2. Views of $Fe(NC_5H_5)_4(CF_3SO_3)_2$ (top) and $Fe(NC_5H_5)_4(p\text{-}CH_3C_6H_4SO_3)_2$ (bottom); 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

involving the terminal sulfonate oxygens that are present in the aquo complex but absent in the pyridine complexes studied here. The cadmium complex (14) contains metal atoms bridged by bidentate methanesulfonate groups to form an infinite chain structure. In this case the S—O terminal bond (1.436 Å) is shorter than the terminal S—O bonds in $Fe(py)_4(CH_3SO_3)_2$ (ave. 1.452 Å), as is expected due to the fact that in the cadmium complex the S—O π-bonding involves primarily only one terminal S—O bond while in the iron complex the π-bonding is shared between two such bonds.

In $Fe(py)_4(p\text{-}CH_3C_6H_4SO_3)_2$ the geometry around sulfur is, again, approximately tetrahedral with the largest distortion in the O(3)—S—O(2) angle (Fig. 2). The benzene ring is planar within experimental accuracy and the bond lengths and angles in the ring are as expected. Again, the terminal S—O distances are shorter (1.45 and 1.44 Å) than the S—O distance involving the oxygen coordinated to iron (1.49 Å). In organic *p*-toluenesulfonates (37–39), the S—O distances in the S—O—R groups are longer still (~1.57 Å). This is a clear illustration of the difference between bonding modes involving sulfonates and metals on the one hand and carbon on the other, the former being more ionic and one that does not distort the anion geometry as much. Consistent with this observation, we note that the S—O distances in the pyridine complex are closer to those observed in the parent acid hydrate (40), a compound that exists as an oxonium salt with all the S—O bonds approximately the same (ave. 1.454 Å).

Spectroscopy and magnetism

Partial infrared data with assignments are given in Table 10. Bands assigned to internal vibrations of the pyridine ligands are typical for complexes of this type and, in particular, the 8a, 6a, and 16b vibrations show the expected shift to higher frequencies on coordination (41–44). X-ray diffraction clearly showed that for all three complexes the CSO_3 moiety undergoes symmetry reduction from C_{3v} to approximate C_s on coordination. In C_{3v} symmetry six infrared active bands ($3E$ and $3A_1$) are expected for this group, while in C_s the E modes are split and nine bands are expected. In Table 10 infrared bands assigned to CSO_3 are listed according to the C_{3v} modes from which they are derived. Clearest evidence of symmetry reduction in all three complexes is the splitting by 80–90 cm^{-1} of the degenerate $\nu_4(E)$, SO_3 stretching mode in C_{3v} symmetry. Further evidence of symmetry reduction is seen in the SO_3 deformation regions of the spectra of the methyl and trifluoromethyl derivatives. In C_{3v} symmetry

	78[b]	1.16	3.63	0.28	0.28

[a]Estimated precision of parameters is ±0.01 mm s^{-1}.
[b]Source is at 291 K and absorber at 78 K. In all other cases source and absorber are at the same temperature.

only two bands, assignable to $\nu_3(A_1)$ and $\nu_5(E)$, are expected. For these complexes, three absorptions are clearly assignable to SO_3 deformation modes. In the past, anion spectra very similar to those observed here have been used to infer unidentate sulfonate coordination (17). The present results validate the earlier conclusions and support the use of infrared criteria for determining the nature of sulfonate ion coordination in complexes.

Mössbauer data are given in Table 11 and a representative spectrum is shown in Fig. 3. At all temperatures employed, the Mössbauer spectra consisted of simple quadrupole-split doublets, as expected for distorted octahedral high-spin iron(II) complexes. The room temperature isomer shifts are virtually identical for the three complexes, and approximately 0.3 mm s^{-1} lower than those of the anhydrous iron(II) sulfonates, $Fe(RSO_3)_2$ (16, 45). The lower isomer shifts of the present complexes are attributabe to the covalent nature of the Fe—N (pyridine) bonding, which increases the *s* electron density at the iron nucleus. It is evident that in these complexes with FeN_4O_2 chromophores, differences in anion basicity are not large enough to have an appreciable effect on the isomer shift. This is in contrast to the results (41) for $Fe(py)_4X_2$ (X = Cl, Br, I), where the room temperature isomer shift decreases from 1.06 mm s^{-1} for the chloride to 0.99 mm s^{-1} for the iodide.

The quadrupole splittings, ΔE_Q, exceed 3 mm s^{-1} in all cases. We, as well as Long and co-workers (41, 46), have cautioned about the dangers of using the magnitude of ΔE_Q to deduce the orbital degeneracy of the iron(II) ground state, particularly when ΔE_Q is small. This is because the major contribution to the electric field gradient (efg) tensor results from an unequal distribution of the sixth iron $3d$ electron among the d_{xy} and d_{xz}, d_{yz} orbitals (in tetragonal symmetry). As the low-symmetry distortion and hence the splitting of the t_{2g} orbitals approach zero, so also will the quadrupole interaction, regardless of the orbital degeneracy of the ground state. On the other hand, since an orbitally degenerate ^5E_g state can produce a quadrupole splitting of at most about 2 mm s^{-1} (30), values substantially higher than this are diagnostic of an orbitally nondegenerate ground state. Thus the present results are consistent only with a $^5B_{2g}$ ground state, corresponding to the d_{xy} orbital lying lowest. This is precisely as required by the molecular structures discussed above, which show in each case an axially compressed octahedron of approximate D_{4h} symmetry. Thus V_{zz}, the principal component of the efg tensor, is positive in these complexes and presumably lies close to the pseudo-tetragonal molecular axis.

Solid state electronic spectra recorded at room temperature for the three complexes are typical for high-spin iron(II) in a

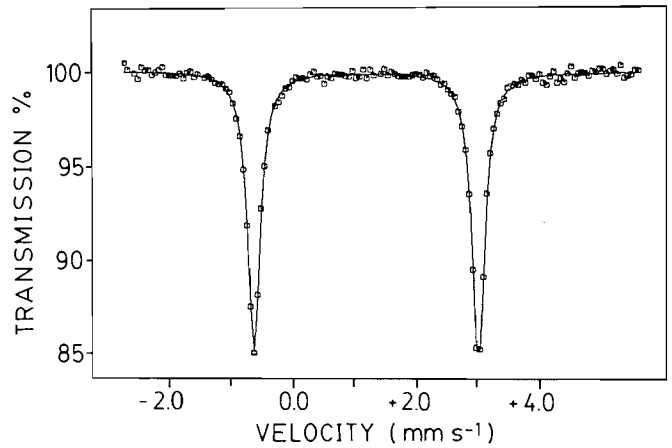

FIG. 3. Mössbauer spectrum of $Fe(NC_5H_5)_4(CH_3SO_3)_2$ at 78 K.

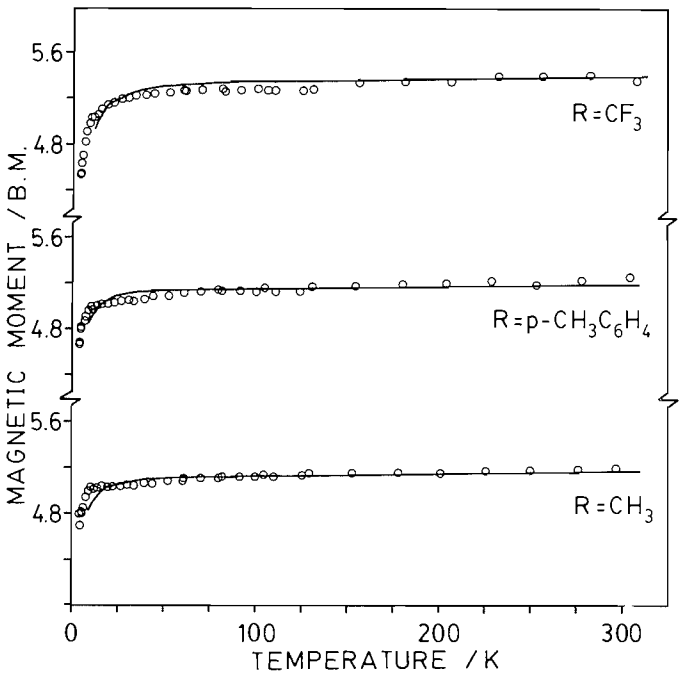

FIG. 4. Magnetic moment versus temperature plots for $Fe(NC_5H_5)_4(RSO_3)_2$. Solid lines are calculated (see text).

tetragonally distorted octahedral environment (47). Broad maxima are observed at 11.5, 11.4, and 11.0 kK for the R = CF_3, CH_3, and p-$CH_3C_6H_4$ derivatives, respectively. We tentatively assign these adsorptions to unresolved electronic transitions from the ground $^5B_{2g}$ state to the $^5A_{1g}$ and $^5B_{1g}$ levels derived from ^5E_g in cubic symmetry. The range of band energies observed is small, consistent with the relatively small differences in the FeN_4O_2 chromophores as shown by the X-ray structure determinations. We note, however, that on going from the CF_3 to the p-$CH_3C_6H_4$ derivative the energy decreases by about 500 cm^{-1}, a trend which parallels an increase in the average Fe—N distance from 2.21 to 2.24 Å. The triflate also exhibits a shoulder on its principal absorption band at about 9.2 kK. While this shoulder could result from some resolution of the $^5B_{2g} \rightarrow {}^5A_{1g}$, $^5B_{1g}$ transition, it is difficult to rationalize why the triflate should exhibit this feature and not the other two complexes, particularly in view of the fact that of the three pyridine complexes the triflate is the least tetragonally distorted. It is possible that the shoulder observed in the triflate arises from some other source, perhaps a weak spin-forbidden transition, and is a feature obscured in the spectra of the other two complexes by virtue of their relatively broader principal absorption bands.

Magnetic susceptibilities have been measured from 4.2 to 310 K for all three complexes and the data are given in Table 12 (deposited supplementary material). Magnetic moments as functions of temperature are displayed in Fig. 4. In both magnitude and temperature dependence the magnetic moments of these complexes are consistent with their formulation as pseudo-octahedral high-spin iron(II) compounds in which the orbital degeneracy of the $^5T_{2g}$ state is lifted by a low-symmetry crystal field. It is possible to analyze the temperature dependence of the magnetic moment as a function of distortion from O_h symmetry, spin-orbit coupling, and electron delocalization (48, 49). The distortion parameter Δ (or $3Ds$) is the separation of the $^5B_{2g}$ and ^5E_g states arising from the cubic field $^5T_{2g}$ ground term in the presence of a tetragonal ligand field. A positive value of Δ corresponds to the orbitally nondegenerate $^5B_{2g}$ state lying lowest. The spin-orbit coupling constant λ is expected to be reduced somewhat from its free-ion value of -100 cm^{-1} (50). The orbital reduction parameter k allows for electron delocalization in the t_{2g} orbital set. From powder magnetic susceptibility data it is difficult to determine the sign of Δ unambiguously. However, as discussed above, the Mössbauer data clearly show that the ground state in each of these complexes is an orbital singlet, as expected from the molecular geometries. Hence in analyzing the magnetic data only positive values of Δ have been considered.

The parameter values obtained by fitting the magnetic moment data (to ~10 K) are given in Table 13, and have been employed to construct the solid lines shown in Fig. 4. It will be seen that the fits are quite reasonable, especially at temperatures above about 20 K. In view of the approximate nature of this crystal field model (48, 49), the parameter values in Table 13 should be considered to be only semi-quantitative (i.e., ca. ±10%). With this in mind, it appears that the axial ligand fields are of about the same order of magnitude in all three cases. Values of λ are, as expected upon complex formation, substantially lower than the free ion value. For the methanesulfonate derivative, λ and k are reduced by corresponding amounts, although this correlation is not observed in the other two cases.

Disagreement at low temperatures between the observed moments and those calculated from the simple crystal field model (48, 49), is not unexpected. For example, the model ignores zero-field splitting of the spin quintet ground state of the iron(II) ion, which becomes particularly important at low temperatures. To show that zero-field splitting effects can account for the magnetic properties of these complexes, in particular in the low temperature region, we have analyzed the data in another way, utilizing the magnetic susceptibility equation for zero-field splitting of the $S = 2$ ground state multiplet (51). The axial zero-field splitting parameter D and the spectroscopic splitting parameter g were found for all three compounds by least-squares fitting of the molar susceptibilities as a function of temperature to the functions given in ref. 51. Information contained in the powder magnetic susceptibility data is insufficient to determine the sign of D and equally good fits are obtained using either positive or negative D values. For positive D, the best-fit parameters are given in Table 13 and the fitted magnetic susceptibility data for $Fe(py)_4(CH_3SO_3)_2$ are

TABLE 13. Parameters from fits of magnetic data

Compound	Crystal field parameters $\Delta(3Ds)$ (cm^{-1})	λ (cm^{-1})	k	Zero field splitting parameters D (cm^{-1})	g
$Fe(py)_4(CF_3SO_3)_2$	600	−80	1.00	6.1	2.15

displayed in Fig. 5. The agreement with experiment, particularly at low temperatures, is noticeably improved over that obtained with the crystal field model. The magnitude of the zero-field splitting is expected to be inversely proportional to the separation of the ^5E_g and $^5B_{2g}$ states (arising from the splitting of the $^5T_{2g}$ ground state) (52). Hence the relatively large D value obtained for the triflate derivative suggests a smaller $^5T_{2g}$ splitting, reflecting perhaps the lower degree of tetragonality for this complex as shown by the X-ray data.

Differential scanning calorimetry

In order to establish the range of thermal stabilities of these complexes and to evaluate the possibilities of obtaining complexes with lower pyridine-to-iron ratios through thermolysis, we studied the tetrakis(pyridine) complexes using differential scanning calorimetry. The results are summarized in Table 14. Thermograms of the triflate and *para*-toluenesulfonate derivatives show them to lose pyridine in two distinct steps. Approximate weight loss measurements indicate that the first step involves loss of two moles of pyridine per mole of complex to form bis(pyridine) derivatives. The remaining pyridine groups are lost in the second step at higher temperatures. The results for the methyl derivative are similar, in that two moles of pyridine are lost in a single first step. In this case, however, the higher temperature thermolysis is more complex, with the remaining two moles of pyridine dissociating in several endothermic steps. Similar results were obtained by Tominaga *et al.* (53) who observed that thermolysis of $Fe(py)_4Cl_2$ gave $Fe(py)_2Cl_2$, $Fe(py)Cl_2$, $Fe(py)_{2/3}Cl_2$, and, finally, $FeCl_2$ in distinct steps. In all three sulfonate complexes, infrared spectra and gravimetric analysis indicated that the residue remaining after removal of all pyridine was the corresponding anhydrous sulfonate compound.

Previous workers have used thermolysis as a preparative technique for obtaining bis(pyridine) complexes (41, 54). Our results suggest that it should be possible to obtain bis(pyridine)iron(II) sulfonates by heating bulk samples of the tetrakis(pyridine) complexes at appropriate temperatures. We have succeeded in obtaining $Fe(py)_2(CF_3SO_3)_2$ by this route and the preparation and characterization of such complexes is presently under study in this laboratory.

Received May 21 1985

E. BUNCEL, R. KUMAR, and A. R. NORRIS. Can. J. Chem. **64**, 442 (1986).

A number of methylmercurated complexes of 6-mercaptopurine riboside and 2-amino-6-mercaptopurine riboside (6-MNucH_2) containing S-bound CH_3Hg(II) in neutral and cationic complexes (as in [CH_3Hg(6-MNucH)] and [CH_3Hg(6-MNucH_2)]NO_3), S- and N-bound CH_3Hg(II) (as in [$(CH_3Hg)_2$(6-MNucH)]NO_3), and S-, N-, C-bound CH_3Hg(II) (as in [$(CH_3Hg)_3$(6-MNuc)]NO_3) have been prepared in aqueous solution at appropriate pH and mole ratios of the constituents. The complexes were characterized by means of ^1H and ^{13}C nmr and ir spectroscopy and elemental analysis. Formation of C-bound methylmercurated species extends our previous results obtained with xanthosine, inosine, and imidazole derivatives, and substantiates our proposal that activation through electrophilic coordination at N(7) is a requirement for C(8)—H abstraction. $^2J(^1H–^{199}Hg)$ coupling constants, measured in $(CD_3)_2SO$ for a number of CH_3Hg(II) complexes of N-, S-, and C-donor heterocyclic ligands, including the 6-mercaptopurine riboside of the present study, correlate well with the $^1J(^{13}C–^{199}Hg)$ coupling constants, according to $^1J = 8.460^2J - 155.6$. The significance of this correlation in terms of the strength of the Hg–ligand bond is considered. The results could provide insight into the apparent selectivity of binding of CH_3Hg(II) by bio-ligands, as well as in the design of chemotherapeutic agents for the treatment of methylmercury poisoning.

E. BUNCEL, R. KUMAR et A. R. NORRIS. Can. J. Chem. **64**, 442 (1986).

Opérant en solution aqueuse et utilisant des pH et des rapports molaires appropriés, on a synthétisé un certain nombre de complexes du méthylmercure avec les ribosides de la mercapto-6 purine et de l'amino-2 mercapto-6 purine (M-6NucH_2) qui contiennent du CH_3Hg(II) lié soit au S dans des complexes neutres ou cationiques (comme dans le [CH_3Hg(M-6NucH)] et dans le [CH_3Hg(M-6NucH_2)]NO_3), soit au S ainsi qu'au N (comme dans le [$(CH_3Hg)_2$(M-6NucH)]NO_3) soit au S, au N et au C (comme dans le [$(CH_3Hg)_3$(M-6Nuc)]NO_3). On a caractérisé les complexes en faisant appel aux analyses élémentaires, à la spectroscopie ir et à la rmn du ^1H et du ^{13}C. La formation d'espèces contenant du méthylmercure lié au C étend nos résultats antérieurs obtenus à l'aide de dérivés de la xantosine, de l'inosine et de l'imidazole et donne plus de poids à notre proposition selon laquelle l'activation par le biais d'une coordination électrophile en N(7) est nécessaire à l'enlèvement du C(8)—H. Dans le cas des constantes de couplage $^2J(^1H–^{199}Hg)$, mesurées dans le $(CD_3)_2SO$ pour un certain nombre de complexes du CH_3Hg(II) avec des ligands hétérocycliques donneurs de N, S ou C et incluant ceux des ribosides de la mercapto-6 purine et de l'amino-2 mercapto-6 purine rapportés dans cette étude, on a pu établir une bonne corrélation avec les constantes de couplages $^1J(^{13}C–^{199}Hg)$ et elle est définie par l'équation $^1J = 8{,}460^2J - 155{,}6$. On considère la signification de cette corrélation en fonction de la force de la liaison Hg–ligand. Ces résultats pourraient fournir des explications relativement à la sélectivité apparente de la liaison du CH_3Hg(II) avec des bio-ligands ainsi que dans la préparation de modèles pour des agents chémothérapeutiques pour le traitement des empoisonnements par le méthylmercure.

[Traduit par le journal]

Introduction

In connection with our studies (1) of the interactions of methylmercury(II) and mercury(II) derivatives with nucleic acid constituents as free bases, nucleosides, and nucleotides, the thio derivatives of nucleosides appeared to be of particular interest. A number of such compounds can be found in limited quantities in nucleic acids. Transfer RNAs have been found to contain 2-mercaptouridine, 2-mercaptocytidine, 4-mercaptouridine, and other mercapto-containing compounds (2,3). Each polynucleotide may contain one or more of these species. In addition, 6-mercaptopurines are drugs of choice in the treatment of acute lymphocytic and chronic mylelocytic leukemias (4). We therefore deemed it of interest to determine the likely coordinating sites of 6-mercaptonucleosides (6-MNucH_2) towards heavy metal ions. The methylmercury(II) cation, which binds analogously to other heavy metal ions at a variety of ligand sites, serves as a good probe because, with few exceptions, it is essentially unifunctional and its equilibria involving nucleosides are quickly attained (5,6).

It is noteworthy that in some cases the metal complexes of 6-mercaptonucleosides have been found to be more active chemotherapeutic agents than the free ligands. The palladium(II) and bismuth(III) complexes of 6-mercaptopurine have recently been found to exhibit moderate anticarcinogenic activities (7). At present little is known about the structures of these complexes. A crystallographic study has proven the existence of chelate rings involving S(6) and N(7) in bis(6-mercapto-9-benzylpurinato)palladium(II) dimethylacetamide and in the isostructural platinum(II) compound (8). In two additional metal complexes with 6-mercaptopurine, the metal ions, viz. Hg(II) and Cd(II), have been found to bind preferentially to S(6) (9). The results of nmr studies of the reactions of $[Rh(PPh_3)_2CO]^+$ with 6-mercaptopurine riboside have been interpreted in terms of the formation of complexes containing S-bonded ligands (10).

In the present paper, we report on the isolation and characterization by ^1H and ^{13}C nmr, as well as by ir spectroscopy, of the products from the reactions of methylmercury(II) with 6-mercaptopurine riboside and 2-amino-6-mercaptopurine riboside.

Experimental

The ^1H nmr spectra of the complexes dissolved in $(CD_3)_2SO$ were recorded on a Bruker HX-60 instrument operating at 60 MHz in the Fourier transform mode. The ^{13}C nmr spectra were recorded on a

Bruker CXP-200 instrument operating at 50.307 MHz. Chemical shifts are referenced relative to internal tetramethylsilane (TMS). All spectra were recorded at room temperature (25 ± 2°C). The ir spectra were recorded as 1% (w/w) KBr discs on a Perkin–Elmer 598 spectrophotometer. Microanalyses were performed by Guelph Chemical Laboratories Ltd (Table 1).

6-Mercaptopurine riboside (Sigma), 2-amino-6-mercaptopurine riboside (Sigma), [$(CH_3Hg)_3O$]OH (Alfa), and CH_3HgCl (Alfa) were used as received. CH_3HgNO_3 was prepared from CH_3HgCl and $AgNO_3$ as described previously (11).

*Complexes of 6-mercaptopurine riboside (6-MPRH$_2$, **1**a)*

*[CH_3Hg (6-MPRH)] (**2**a)*

To a stirred solution of **1***a* (0.100 g, 0.352 mmol) in 20 mL of distilled water was added a suspension of [$(CH_3Hg)_3O$]OH (0.080 g, 0.353 mmol) in 5 mL water. The solution was stirred for 10 min and the white precipitate that formed was filtered, washed with ethanol and a small quantity of water, and finally dried *in vacuo* (0.165 g, 94%).

*[CH_3Hg(6-MPRH$_2$)]NO_3 (**3**a)*

A solution of CH_3HgNO_3 (0.098 g, 0.353 mmol) in 5 mL of water was added to a suspension of **1***a* (0.100 g, 0.352 mmol) in 20 mL water. The clear solution which resulted was evaporated slowly to dryness and the solid residue was stirred with ethanol, filtered, and dried *in vacuo* (0.178 g, 90%).

*[$(CH_3Hg)_2$(6-MPRH)]NO_3 (**4**a)*

To a solution of **2***a* (0.088 g, 0.176 mmol) in 10 mL of water was added a solution of CH_3HgNO_3 (0.049 g, 0.177 mmol) in 5 mL water, followed by 5 mL of ethanol. Crystallization was allowed to occur at 5°C and the product was filtered and dried *in vacuo* (0.098 g, 65%).

*[$(CH_3Hg)_3$(6-MPR)]NO_3 (**5**a)*

To a solution of **2***a* (0.102 g, 0.204 mmol) in 15 mL of water was added a solution of CH_3HgNO_3 (0.114 g, 0.205 mmol) in 5 mL water. The pH of the solution was adjusted to ca. 8 with 2 *M* NaOH and the solution heated at 70°C for 1 h. On standing, a yellowish oil separated and was stirred in ethanol to yield a yellow powder. This was collected by filtration and dried *in vacuo*. Some decomposition occurred in the course of recrystallizations from ethanol, as evidenced by the appearance of a small amount of black material that was filtered off before taking the ^1H nmr spectrum. Hence, elemental analysis on this product was not performed (0.165 g, 82%).

*Complexes of 2-amino-6-mercaptopurine riboside (2-A-6-MPRH$_2$, **1**b)*

*[(CH_3Hg)(2-A-6-MPRH)] (**2**b)*

To a stirred and heated solution of **1***b* (0.100 g, 0.334 mmol) in 15 mL of water was added a suspension of [$(CH_3Hg)_3O$]OH (0.076 g, 0.335 mmol) in 5 mL water. This resulted in the formation of a thick white precipitate. Following heating and stirring for an additional 20 min, the white precipitate was collected by filtration, washed with hot water, and dried *in vacuo* (0.168 g, 98%).

*[(CH_3Hg)(2-A-6-MPRH$_2$)]NO_3 (**3**b)*

To a suspension of **1***b* (0.100 g, 0.334 mmol) in 10 mL of water was added a solution of CH_3HgNO_3 (0.093 g, 0.335 mmol) in 10 mL water. The suspension dissolved to give a clear solution. After stirring for 2 h the solution was set aside to evaporate slowly. This procedure yielded a white solid which was stirred with ethanol for 20 min, filtered, and dried *in vacuo* (0.181 g, 94%).

*[$(CH_3Hg)_2$(2-A-6-MPRH)]NO_3 (**4**b)*

A solution of CH_3HgNO_3 (0.057 g, 0.205 mmol) in 5 mL of water was added to a hot stirred suspension of **2***b* (0.105 g, 0.204 mmol) in 25 mL water. On cooling to room temperature, the solution transformed to a gel. It was heated again with stirring for 30 min following which a clear solution resulted. The hot solution was filtered and left to evaporate slowly. The resulting white solid was stirred with ethanol, filtered and dried *in vacuo* (0.148 g, 91%).

*[$(CH_3Hg)_3$(2-A-6-MPR)]NO_3 (**5**b)*

A solution of CH_3HgNO_3 (0.120 g, 0.216 mmol) in 5 mL of water was added to a stirred suspension of **2***b* (0.111 g, 0.216 mmol) in 10 mL water. The pH of the resultant solution was increased to ca. 8 with 2 *M* NaOH, and the solution was heated at 70°C for 1 h, during which time some decomposition occurred as evidenced by the formation of a greyish-black precipitate. After filtration, the solution was allowed to stand, whereupon a yellowish-white solid precipitated. This was collected by filtration and found by ^1H nmr to consist mainly of **2***b*. The filtrate was set aside to evaporate slowly to dryness and the resulting residue was stirred with ethanol before filtration and drying *in vacuo*. An elemental analysis was not performed on this product since it was found, by using ^1H nmr techniques, to be contaminated with a small amount of **4***b* (0.093 g).

Results and discussion

Binding sites and complex formation

The S-modified nucleosides 6-mercaptopurine riboside (**1***a*) and 2-amino-6-mercaptopurine riboside (**1***b*) offer a number of potential binding sites towards CH_3Hg(II). In relation to the parent substrates studied previously, in which N(1), N(7), and C(8) were found to be possible binding sites in methylmercuration, the mercapto analogs contain the sulfur atom as a likely additional binding site (1*c*). Thus, depending on the reactant stoichiometry, the pH of the medium, and the relative affinities of the N, S, and C centers towards CH_3Hg(II), a number of possible products should be obtained in these interactions. Although coordination to the oxygen atoms of the ribose moiety could also be possible, no evidence for such a process has been found in this or previous work (1).

Studies of the $(CD_3)_2SO$ solutions of the complexes by ^1H and ^{13}C nmr have been found to be most informative in establishing the binding sites, while more limited information has been derived from ir absorption data. The complexes obtained from the interaction of **1***a* and **1***b* with CH_3Hg(II) are shown in Scheme 1. In all cases, the compounds **1***a* and **1***b* form

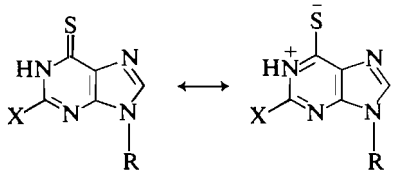
analogous complexes **2***a*/**2***b*, **3***a*/**3***b*, etc., which show very simple characteristics (*vide infra*).

In solution, 6-mercaptopurine riboside is generally considered to exist in the thione form —NH—C(S=S), **1**, although in one study evidence was given for the thiol form —N=C(—SH)—, **6**, as well (12). However, an X-ray crystal study of 6-mercaptopurine riboside reported, in addition to the thione form, a substantial contribution by the zwitterionic amidic form $—N^+H=C(—S^-)—$, **1′** (13).



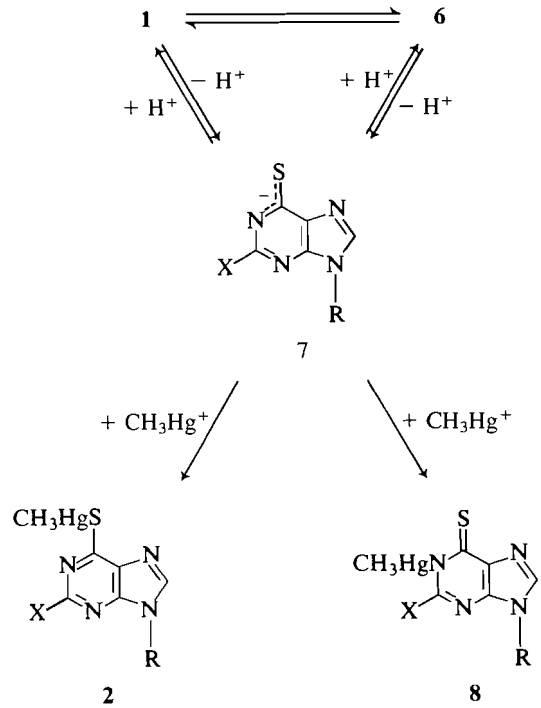
1 1′

Sites of metal ion binding in 6-mercaptonucleosides

(a) *S-methylmercuration (1:1 stoichiometry)*

Based on the above observations, we can view the deprotonation of **1** as giving rise to the delocalized anion **7** (14). This anion **7** has the potential to function as an ambidentate ligand with respect to both H^+ and metal ion coordination. According to HSAB theory, reaction of **7** with H^+ will occur at the "harder" site, that is, N rather than S, giving rise to **1**. On the other hand, reaction of **7** with CH_3Hg^+ can potentially lead to the formation of either **2** or **8** (Scheme 2). The tendency of heavy metal ions such as Hg(II) to favour the "soft" sulfur over the "hard" nitrogen donor atoms would point to the former as the most probable binding site for CH_3Hg^+. In accord with these considerations, reactions of thiolated nucleosides and thiolated polynucleotides with heavy metal ions have been shown to occur at sulfur rather than at nitrogen (17).

Thus the expected products in the reaction of **1***a* or **1***b* with CH_3Hg^+ at pH 7–8 will be **2***a* and **2***b*, respectively. The evidence we have obtained indicates that this is the case. The complex is found by microanalysis to correspond to [(CH_3Hg)-(6-MNucH)], where MNucH = purine riboside or 2-aminopurine riboside. Evidence in favour of the structure of **2** derives from the $^2J(^1H–^{199}Hg)$ value of ~185 Hz in $(CD_3)_2SO$, which is characteristic of S-bonded CH_3Hg(II) (15). Further evidence for the formation of **2** is the downfield shift of the C(8)—H



2 8

SCHEME 2

signal with respect to **1**. In the parent substrate, where N-bound CH_3Hg(II) has been documented in [CH_3Hg(NucH)], an upfield shift in the C(8)—H signal is observed with respect to the C(8)—H signal observed in the nucleoside itself (1*c*). Moreover, in the ^{13}C nmr spectrum, the C(6) resonance adjacent to the site of metal ion attack experiences a substantial upfield shift, together with a minor upfield shift in the C(5) resonance. The resonances due to C(2), C(4), and C(8) experience downfield shifts with respect to the corresponding resonances in **1**. A similar pronounced upfield shift in the C(6) resonance has been previously reported in 6-mercaptonucleosides on methylation (16). These results are in contrast to those obtained for the N-methylmercurated complexes [CH_3Hg(NucH)] (NucH = inosine or guanosine), where the C(2) and C(6) resonances adjacent to the site of coordination experience downfield shifts while the C(4), C(5), and C(8) resonances are relatively unaffected with respect to the parent (1*c*). Furthermore, the CH_3Hg(II) re-

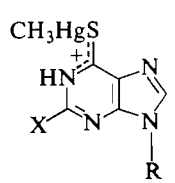
[a]Data for all **1***a* and **1***b* are taken from ref. 16.
[b]All resonances are singlets unless otherwise indicated: d = doublet.
[c]N(1)-H resonance is not observed due to exchange broadening caused by complexation at sulfur (27).
[d]N-, S-bound $CH_3Hg(II)$.
[e]C(8)-bound $CH_3Hg(II)$.

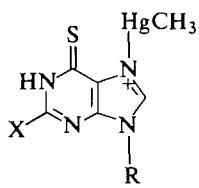
sonance at 9.0 ppm in **2**, when compared to the $CH_3Hg(II)$ resonance found at ca. 1.0 ppm in the N-methylmercurated species [CH_3Hg(NucH)], is good evidence in favour of structure **2** (1*c*). Further evidence in support of **2** is provided by our previous studies on the complex [CH_3Hg(MeImS)]. In this complex, methylmercuration at sulfur has been confirmed by X-ray crystal studies and the ^{13}C nmr spectrum exhibits a resonance associated with $CH_3Hg(II)$ at 8.7 ppm (1*d*).

When the reaction between **1** and CH_3HgNO_3 is carried out under acidic conditions (pH 2–3), a product **3** is obtained that corresponds to the formula [CH_3Hg(6-MNucH$_2$)]NO$_3$. The ^1H nmr spectrum of **3** (Table 2) exhibits a downfield shift in the C(8)—H resonance with respect to **1**, a feature characteristic of cationic complexes generated by addition of $CH_3Hg(II)$ at N(7). Also, the coupling constant, $^2J(^1H-^{199}Hg)$, of ca. 200 Hz is higher than the value of ca. 185 Hz found for the neutral complex with S-bonding in **2** (1*d*).

There are two possible structures for this cationic species, namely **3** and **9**. Evidence that coordination has not occurred at



3

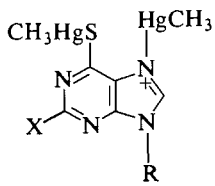


9

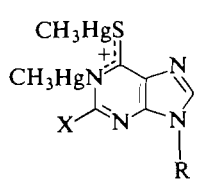
N(7) stems from the observation that N(7) coordination of $CH_3Hg(II)$ in inosine and guanosine leads to a $^2J(^1H-^{199}Hg)$ coupling constant of 229 Hz, significantly higher than that observed in the present case (1*c*). Also the $^2J(^1H-^{199}Hg)$ value in **3** is comparable to the $^2J(^1H-^{199}Hg)$ of 204.3 Hz for the complex [CH_3Hg(MeImSH)]NO$_3$, for which X-ray crystal studies have established sulfur to be the $CH_3Hg(II)$ binding site, with N protonated (1*d*, 1*f*). Further support for structure **3** is derived from the ^{13}C nmr spectrum. The resonances due to C(5) and C(6) experience upfield shifts while the C(2), C(4), and C(8) resonances experience downfield shifts with respect to **1** (Table 3). These observations are in contrast to the N(7)-methylmercurated complexes, e.g. [CH_3Hg(NucH$_2$)]NO$_3$, where upfield shifts in the C(2), C(4), C(5), C(6) resonances and a downfield shift in the C(8) resonance have been observed (1*c*). It is also pertinent that the N(7)-coordination of $CH_3Hg(II)$ in inosine and guanosine leads to a $CH_3Hg(II)$ carbon resonance of −0.7 ppm, which is significantly lower than the 8.0 ppm assignable to $CH_3Hg(II)$ coordinated at C(6)=S in **3** (1*c*). The ir spectrum shows the appearance of a characteristic band 1360 cm^{-1} due to free NO_3^- and is in accord with the proposed cationic nature of the complex (18).

(b) *N- and S-methylmercuration (2:1 stoichiometry)*

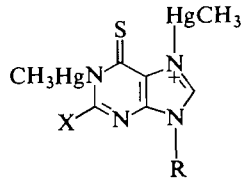
When the reaction of **2** with CH_3HgNO_3 is carried out at pH 3 under 2:1 stoichiometry of $CH_3Hg(II)$ / 6MNucH$_2$ one obtains a product that can be formulated as either **4**, **10**, or **11**.



4



10



11

The ^1H nmr spectrum of the product of this reaction exhibits an appreciable downfield shift in the C(8)—H resonance relative to **1** (Table 2). The coupling constant, $^2J(^1H-^{199}Hg)$, of 215 Hz is intermediate between the values obtained previously for N(7)-bound $CH_3Hg(II)$ in [CH_3Hg(NucH)]NO$_3$ (229 Hz) and the value (185 Hz) for **2**, which indicates rapid exchange of $CH_3Hg(II)$ between the two environments (1*c*). In the ^{13}C nmr spectrum, a pronounced upfield shift in the C(6) resonance relative to **1** (Table 3) is characteristic of S-bound $CH_3Hg(II)$, which is in accord with either **4** or **10** (16). The latter possibility is less likely, as indicated from the trends in the chemical shifts of the other resonances in the ^{13}C nmr spectrum. The carbon resonances C(4), C(6), and C(8) adjacent to the site of methylmercuration are the most affected (Table 3). The C(2) resonance is also affected to an extent comparable to **2**, for which exclusive sulfur methylmercuration has been established. The C(8) resonance in **2** is almost unchanged with respect to **1**. If structure **10**

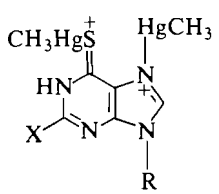
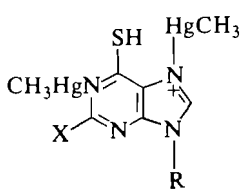
[e]Not observed under experimental conditions.

were to be favoured, the C(8) resonance should be affected little or not at all, while larger changes in the C(2) resonance should have been observed, which is not the case. Also, on steric grounds, a more favourable situation for **4** as compared to **10** is anticipated. Since the —SHgCH$_3$ function on C(6) is expected to be electron withdrawing overall, one would expect the donor ability of N(1) towards CH_3Hg^+ (or H^+) to be decreased, thereby rendering N(7) as the most reactive centre. Thus the weight of evidence is in favor of structure **4**. The carbon resonance of $CH_3Hg(II)$ at ca. 4.5 ppm is significantly higher than the value (−0.13 ppm) obtained in N(1),N(7)-bound methylmercury(II) in the inosine and guanosine complexes [$(CH_3Hg)_2$-(NucH)]NO$_3$, (1*c*), which further supports S- and N-involvement in $CH_3Hg(II)$ binding. The appearance of a strong band at 1360 cm^{-1} due to NO_3^- in the ir spectrum supports the cationic nature of the complexes (18).

A different product of stoichiometry, 2 $CH_3Hg(II)$: 1 6MNucH$_2$, could result in principle if the reaction was carried out using **1** as the reactant rather than **2** as above. The complexes that could form under these conditions at pH 2–3 can be formulated as **12** and **13**. However, the isolated product corresponds



12



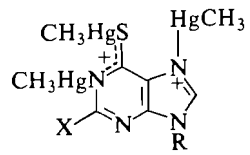
13

in fact to **4**, as shown by the analytical as well as the spectroscopic (^1H, ^{13}C nmr, and ir) data. This could be due to an increased acidity of N(1)—H on coordination of $CH_3Hg(II)$ at N(7) and S(6).

On the other hand, when **1** was titrated with two molar equivalents of CH_3HgNO_3 in $(CD_3)_2SO$, the ^1H nmr of the solution showed a downfield shift in the C(8)—H resonance, together with a higher value of the coupling constant $^2J(^1H-^{199}Hg)$ of 225 Hz. All ^{13}C nmr chemical shifts were very close to the values observed for **4** except for the $CH_3Hg(II)$ resonance, which occurred upfield by 0.5 ppm relative to **4** (Table 3). These results suggest that in $(CD_3)_2SO$ medium, the 2:1 complex has the structure given by **12**.

(c) *N-, and S-, and C-methylmercuration (3:1 stoichiometry)*

The complexes that could arise from a 3:1 interaction between $CH_3Hg(II)$ and the nucleosides under study are **14** and **5**.



14

An attempt to obtain complex **14** via the reaction of **2** with CH_3HgNO_3 (2 moles) at pH 3 led only to the formation of **4**. Also, when **4** was treated with CH_3HgNO_3 (1 mole) at pH 3, no reaction occurred and only unreacted **4** could be recovered. Presumably, the lack of formation of **14** can be ascribed to adverse steric and electronic factors, as was also noted in the case of complex **10**.

However, when the reaction of **4** with CH_3HgNO_3 (1:1 mole ratio) was carried out at pH 7–8, the product obtained was found to have the structure given by **5**. The same product was obtained when **1** was reacted with CH_3HgNO_3 (3:1 mole ratio) at pH = 8. Interestingly, the reaction of **1***a* with CH_3HgNO_3 (3:1 mole ratio) yields **5** almost quantitatively, while with **1***b* an appreciable amount of **4** was found in addition to **5**.

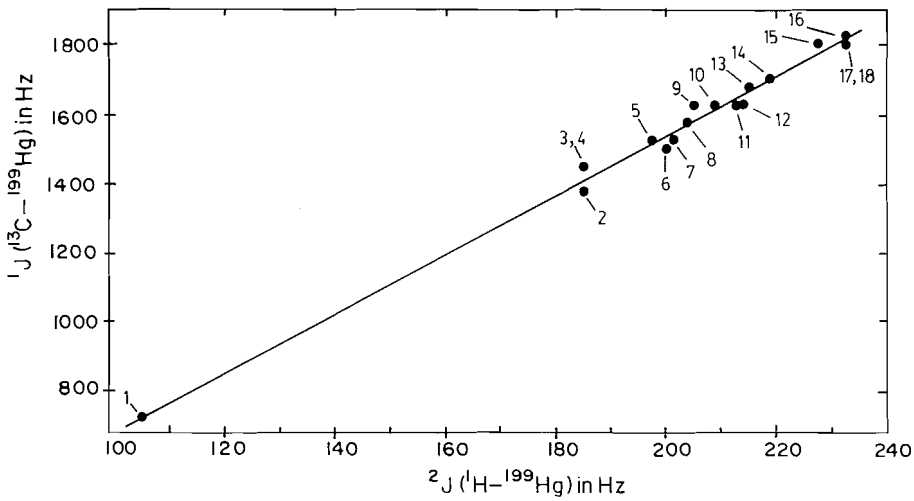


FIG. 1. The correlation between $^2J(^1H-^{199}Hg)$ and $^1J(^{13}C-^{199}Hg)$. Numbers 1 to 18 refer to compounds $(CH_3)_2Hg$; **1**; $[(CH_3Hg)(MeImS)]$, **2**; $[(CH_3Hg)(2\text{-A-6-MPRH})]$, **3**; $[(CH_3Hg)(6\text{-MPRH})]$, **4**; $[(CH_3Hg)_2(8\text{-ThioGuo})]$, **5**; $[(CH_3Hg)(6\text{-MPRH}_2)]NO_3$, **6**; $[(CH_3Hg)(uri)]$, **7**; $[(CH_3Hg)(MeImS)]NO_3$, **8**; $[(CH_3Hg)(2\text{-A-6-MPRH}_2)]NO_3$, **9**; $[(CH_3Hg)(Th)]$, **10**; $[(CH_3Hg)(8\text{-ThioGuoH}_2)]NO_3$, **11**; $[(CH_3Hg)_3(8\text{-ThioGuo})]NO_3$, **12**; $[(CH_3Hg)_2(2\text{-A-6-MPRH})]NO_3$, **13**; $[(CH_3Hg)_2(6\text{-MPRH})]NO_3$, **14**; $[(CH_3Hg)_2(Th)]NO_3$, **15**; $[(CH_3Hg)(Th)(NO_3)_2Hg]$, **16**; $[(CH_3Hg)(Th)]NO_3$, **17**; $[\{(CH_3Hg)(6\text{-MPRH})(NO_3)\}_2Hg]$, **18**; Data on coupling constants, $^2J(^1H-^{199}Hg)$ for complexes **1**, **2**, **5**, **7**, **8**, **10**, **11**, **12**, **15**, **16**, **17**, and **18** are taken from ref. 1.

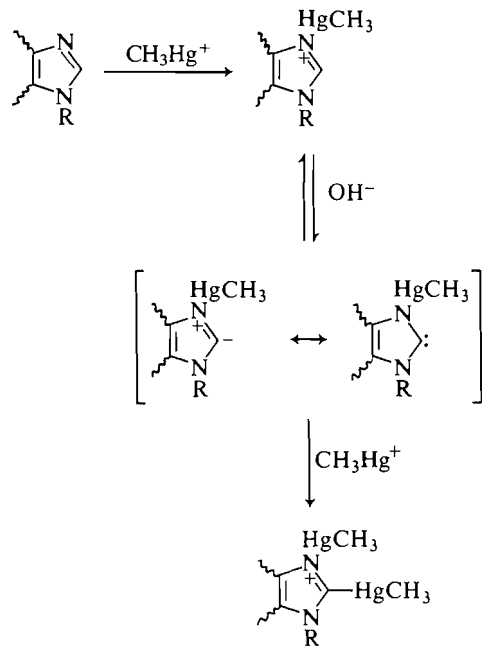
The occurrence of carbon methylmercuration is in accord with our previous findings on the activation of C(8)—H in inosine and xanthosine, and C(2)—H in imidazole derivatives, as a result of coordination of $CH_3Hg(II)$ to N(7)/N(1) in these systems (1*a*,*c*,*e*). Proton abstraction gives an ylid (carbenoid) form that then reacts with $CH_3Hg(II)$ to give the observed product, as shown in eq. [1].

[1]



The most significant proof for the structure of **5** is the appearance of two ^1H nmr signals due to $CH_3Hg(II)$ in an integral ratio of ca. 2:1, one signal occurring at 0.74 ppm and assignable to an averaged, rapidly exchanging, S- and N-bound $CH_3Hg(II)$, and the other signal at 0.62 ppm assignable to C-bound $CH_3Hg(II)$. The latter signal is in the same region as previously found for C-bound $CH_3Hg(II)$ in the inosine, xanthosine, and N-methylimidazole complexes. As well, different coupling constants, $^2J(^1H-^{199}Hg)$, are observed for the $CH_3Hg(II)$ groups in the different environments, which is characteristic of simultaneous binding at two different sites. The ^{13}C nmr confirms the presence of $CH_3Hg(II)$ in two different environments, one resonance at 4.50 ppm for both S- and N-bound $CH_3Hg(II)$ and one at 7.00 ppm for carbon-bound $CH_3Hg(II)$. It is also noted that the C(8) resonance in **5** has experienced a downfield shift of 61 ppm, which is closely similar to the shift observed in the methylmercurated C(8) atoms of inosine and xanthosine (1*c*,*e*).

^{13}C chemical shifts and correlation of $^2J(^1H-^{199}Hg)$ and $^1J(^{13}C-^{199}Hg)$ couplings

The ^{13}C chemical shifts of $CH_3Hg(II)$ that have been observed in this work for S-bound $CH_3Hg(II)$ (8–9 ppm in **2** and **3**) are considerably larger than previously observed for N-bound $CH_3Hg(II)$ (−1.00 to 2.00 ppm in inosine and guanosine) (1*c*). In compounds **4** and **5**, containing both S- and N-bound $CH_3Hg(II)$, the ^{13}C signal of $CH_3Hg(II)$ (4.00 to 5.00 ppm) occurs at an intermediate value compared to the respective N-bound/S-bound 1:1 complexes, showing that there is rapid exchange of $CH_3Hg(II)$ on the nmr time scale. Thus ^{13}C chemical shifts of $CH_3Hg(II)$ provide a useful indicator of the nature of the donor ligand (19, 20).

The donor ligands that give rise to substantial ^{13}C chemical shifts also give rise to substantial $^1J(^{13}C-^{199}Hg)$ couplings (Table 3). As well, almost parallel changes are apparent in $^1J(^1H-^{199}Hg)$, methyl proton – mercury couplings (Fig. 1). The two quantities are correlated by eq. [2] (correlation coefficient = 0.9949).

$$[2] \quad {}^1J = 8.460\,{}^2J - 155.6$$

The origin of this relationship is presumably that a strongly bound ligand weakens the Hg—C bond *trans* to it and thus decreases the "s" character in the Hg—C bond. Since the Fermi contact term dominates the two-bond mercury–proton coupling, a decrease in "s" character in the Hg—C bond results in a smaller *J* value (21). In the present systems, $^1J(^{13}C-^{199}Hg)$ for **2***a* is lower by 175 Hz than in the neutral N-bound $CH_3Hg(II)$ complex $[(CH_3Hg)Th]$, and approximately 753 Hz higher than in

the carbon-bound $CH_3Hg(II)$ group in $(CH_3)_2Hg$. Also, $^1J(^{13}C-^{199}Hg)$ for **3***a* is lower by 301 Hz than in the cationic N-bound complex $[(CH_3Hg)(ThH)]NO_3$. However, in the 2:1 complex **4***a*, the ^1J value is lower by 100 Hz than in the 2:1 complex $[(CH_3Hg)_2Th]NO_3$.

Concluding remarks

We have found in the present study that 6-mercaptopurine riboside (**1***a*) and 2-amino-6-mercaptopurine riboside (**1***b*), under basic and acidic conditions, respectively, form 1:1 $CH_3Hg(II)$ / 6-$MNucH_2$ complexes **2***a*/**2***b* and **3***a*/**3***b*, involving binding of $CH_3Hg(II)$ via the sulfur atom. Under 2:1 stoichiometry of $CH_3Hg(II)$ / 6-$MNucH_2$, complexes **4***a*/**4***b* are obtained in which both sulfur and N(7) are involved in binding. The observation of C(8)-, N(7)-, and S(6)-binding under 3:1 stoichiometry of $CH_3Hg(II)$ / 6-$MNucH_2$, **5***a*/**5***b*, reinforces our previously proposed mechanism for the ready formation of the C-bonded adducts by means of initial activation by a coordinated electrophilic species at N(7) (1*a*,*c*,*e*). Thus 6-thionucleosides show different coordination behaviour with respect to the parent guanosine and inosine, with N(1) no longer being the primary donor atom (1*c*). This is in accord with the preference of Hg(II) for soft (class b) donor atoms such as sulfur (22). $^2J(^1H-^{199}Hg)$ coupling constants correlated well with $J(^{13}C-^{199}Hg)$ coupling constants and their magnitudes reflect the increase in the strength of the mercury–ligand bond in the order Hg—C > Hg—S > Hg—N (23).

Extrapolating to biological systems, the interaction of $CH_3Hg(II)$ with thiols to form S-bonded adducts is believed to be important in both the toxicology of $CH_3Hg(II)$ and the use of antidotes containing thiol groups (24). Although the formation constants for S-bonded $CH_3Hg(II)$ thionucleosides must be very large (25), these compounds are found to undergo extremely rapid nucleophilic ligand displacement reactions (e.g. glutathione model). Clearly these rapid ligand exchange reactions are the key to the bioavailability of $CH_3Hg(II)$. A similarly essential role exists in the treatment of mercury poisoning with chemotherapeutic agents, which complex $CH_3Hg(II)$ and Hg(II) in a more rapidly eliminated form (26). Carbon-bound $CH_3Hg(II)$ species such as those obtained in the present work provide another pathway for $CH_3Hg(II)$ and Hg(II) uptake since their formation is essentially irreversible. The toxicity of $CH_3Hg(II)$ in living beings may be due as much to this factor as to the extensive binding of $CH_3Hg(II)$ to S-centers. Finally, it is possible that 6-thionucleosides could be effective in competing with sulfur containing bio-ligands following intoxication by mercury and its organic derivatives (4).

Two synthetic approaches for the synthesis of *N,N'*-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic acid (HBED) and derivatives are reported. The first involves conversion of *N,N'*-di(2-hydroxybenzyl)ethylenediamine to the diamide HBEDDA via reaction with formaldehyde and HCN followed by hydrolysis. Analysis of the species distribution curves of the Cu(II) chelates of *N,N'*-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic acid (HBED) and its diamide, HBEDDA, and of the nature of the coordination in each complex species formed, suggest the selection of the reaction conditions most favorable for the Cu(II)-catalyzed hydrolysis of HBEDDA to HBED. The rate of conversion was found to be low, and the reasons for these findings are described. Iron(III) catalysis of the conversion of HBEDDA to HBED was found to be rapid and complete with a pseudo-first-order rate constant of 3.1×10^{-3} s^{-1} at 25.0°C. The results provide the final step of a new method for the synthesis of HBED. The second synthetic approach involves reaction of *N,N'*-ethylenediamine-diacetic acid (EDDA) with substituted phenols and formaldehyde. These approaches appear to be general for the synthesis of HBED and derivatives.

ARTHUR E. MARTELL, RAMUNAS J. MOTEKAITIS, ERIC T. CLARKE et J. J. HARRISON. Can. J. Chem. **64**, 449 (1986).

On rapporte deux méthodes de synthèse de l'acide *N,N'*-di(hydroxy-2-benzyl)-éthylènediamine-*N,N'*-diacétique (HBED) et de ses dérivés. La première implique le transformation de la *N,N'*-di(hydroxy-2-benzyl)éthylènediamine en diamide HBEDDA par le biais d'une réaction avec le formaldéhyde et le HCN qui est suivie d'une hydrolyse. Une analyse des courbes de distribution des espèces qui se forment lors de la chélation du Cu(II) avec l'acide HBED et son diamide HBEDDA ainsi que celle de la nature de la coordination dans chaque espèce complexe qui se forme permet de déterminer les conditions de réaction qui sont les plus favorables pour l'hydrolyse, catalysée par le Cu(II), du HBEDDA en HBED. On a trouvé que la vitesse de conversion est faible et on décrit les causes de ce résultat. On a trouvé que la transformation, catalysée par le Fe(III), du HBEDDA en HBED est rapide et que la constante de vitesse de pseudo premier ordre est égale à $3{,}1 \times 10^{-3}$ s^{-1}, à 25°C. Ces résultats fournissent l'étape finale d'une nouvelle méthode de synthèse de l'acide HBED. La deuxième voie de synthèse implique la réaction de l'acide *N,N'*-éthylènediaminediacétique (EDDA) avec des phénols substitués et du formaldéhyde.Ces méthodes semblent générales pour la synthèse de l'acide HBED et de ses dérivés.

[Traduit par le journal]

Introduction

The synthesis of *N,N'*-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetic acid (HBED, **1**) is of considerable interest because of its usefulness as a chelating agent for Fe(III) (1, 2) and for other trivalent ions (3–5). The free ligand and its esters have been found to be effective in the removal of iron from test animals (4, 6. 7) and are therefore of interest for the treatment of Cooley's anemia. The corresponding Ga(III) and In(III) chelates may also be useful as radiopharmaceuticals for tumor imaging purposes (4–7).

Unfortunately, the development of HBED as a ligand for these purposes has been held back by lack of a good synthetic method. The procedure described previously (1) suffers from the formation of a resinous polymeric by-product, which seems to be promoted by treatment with acid or base, and to sometimes form spontaneously during recrystallization of the material (decomposition seems to be a reverse Mannich reaction involving the splitting out of formaldehyde).

A new method of HBED synthesis, suitable for moderate to large scale production, has been developed by Strem Chemicals, Inc.,[4] but a description of the procedure employed is currently subject to proprietary restrictions.

We report two approaches for the synthesis of HBED and derivatives. The first approach involves conversion of *N,N'*-di(2-hydroxybenzyl)ethylenediamine to the diamide (HBEDDA) via reaction with formaldehyde and HCN followed by hydrolysis. Because of the difficulty of hydrolyzing HBEDDA, **2**, to HBED, **1**, it was decided to investigate the promotion of

this reaction by Cu(II) and Fe(III) ions. To be successful, this must be done in such a manner as to utilize the formation of an HBED chelate of high stability as the driving force in reaction. This paper describes the selection of conditions most favourable for metal ion catalysis, and development of a procedure for the metal ion-catalyzed formation of HBED from its diamide.

A second approach for the synthesis of HBED derivatives, which involves reaction of *N,N'*ethylenediamine diacetic acid (EDDA) with substituted phenols and formaldehyde, is also reported.

Experimental

Materials

A pure sample of HBED was kindly donated by Mr. Mike Strem of Strem Chemicals, Inc., Newburyport, Massachusetts.

Potentiometry

Potentiometric measurements of hydrogen ion concentration were made in an apparatus of the type described previously (8). The potentiometric system was calibrated with dilute standard HCl and KOH solutions at 0.100 *M* ionic strength adjusted with KNO_3 so as to read p[H] directly, where p[H] = $-\log [H^+]$. The molar ligand to metal ion ratio was maintained at 1:1 for the determination of the formation constant of the Cu(II) chelates of HBEDDA and for the determination of the Fe(III) – potentiometric equilibrium curve.

Computations

Calculations of protonation constants of the ligand and its Cu(II) chelate, and of the formation constants of the chelate, were carried out with programs PKAS (9) and BEST (10), for the protonation constants and the Cu(II) chelate stability constants, respectively. The calculation of species distributions from equilibrium constants was carried out with program SPE, which employs the algorithm from BEST adapted to the Micromation computer system for graphic display on Houston Instruments DMP-29 HIPLOT X-Y plotter.

Kinetic measurements

The kinetics of conversion of the Cu(II) and Fe(III) chelates of HBEDDA to the corresponding HBED chelates was followed with a Perkin Elmer Model 553 fast scan uv/vis spectrophotometer. The absorptivities were such that $1.0 \times 1^{-4} M$ solutions (in 1.000-cm cells) provided sufficiently intense bands for quantitative measurements. The rates of conversion of the Cu(II) chelate were measured at p[H] 3.0 and 50.0°C, while those of the Fe(III) chelate were measured at p[H] values from 8 to 11 at 25.0°C.

Preparation of N,N'*-di(2-hydroxybenzyl)ethylenediamine*-N,N'*-di-acetonitrile, 4*

N,N'-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetonitrile, **4**, was synthesized, by a slight variation of published procedure (11), from the *N,N'*-di(2-hydroxybenzyl)ethylenediamine, **3** (12).

Preparation of HBEDdiamide.2HCl.2H$_2$O, 2

To a three-neck flask equipped with a magnetic stirrer cooling bath under argon were added 380 mL ethanol, 15.66 g HBEDacetonitrile (0.045 mol), and 34.8 g 30% H_2O_2 solution (0.307 mol). To this at 5°C was added 1.48 g (0.037 mol) sodium hydroxide dissolved in 16 mL water. This was stirred 3 h at 5–10°C, after which 31.1 g sodium bisulfite (0.30 mol) dissolved in 50 mL ice water was slowly added so that the temperature was held below 10°C. Then, after stirring at 10°C, the product was filtered to remove Na_2SO_4. The filtrate was mixed with 10 mL HCl and allowed to crystallize. A total of 4.75 g purified material was recovered, mp 200–205°C; 22% yield; ^{1}H nmr (CD_3OD/D_2O, NaOD)δ: 5.8–6.6 (m, 8H, ArH), 3.64 (s, 4H, H_2NOCCH_2N), 3.21 (s, 4H, $ArCH_2N$), 2.71 (s, 4H, NCH_2CH_2). *Anal.* calcd. for $C_{20}H_{26}N_4O_4.2HCl.H_2O$: C 50.32, H 6.33, N 11.75, Cl 14.85; found: C 50.29, H 6.20, N 11.56, Cl 15.22.

Fe(III)–HBED

The Fe(III)–HBED chelate was prepared in solution by mixing equivalent molar amounts of an Fe(III) salt and HBEDDA, adjusting the solution to neutral or alkaline pH, and stirring for 3–4 h at room temperature. The ammonia formed may be removed by refluxing briefly at pH 10.

Conversion of Fe(III)–HBED to HBED

To a 0.10 *M* solution of the Fe(III)–HBED reaction product obtained by Fe(III)-promoted hydrolysis of HBEDDA was added sufficient HCl solution to lower the p[H] to 5.0. To this solution an excess of 8-hydroxyquinoline in ethanol was added and the solution was warmed to about 50.0°C. The black precipitate of the Fe(III)–8-hydroxyquinoline chelate was filtered off, and the remaining deeply red-colored solution was repeatedly (5×) extracted at 50.0°C with chloroform containing 8-hydroxyquinoline. After three final extractions with pure chloroform, the remaining aqueous layer was shown spectrophotometrically to have been 96.6% converted to the metal-free ligand. The solution was acidified with HCl to p[H] 2 and the HBED was isolated by cooling the solution to 0°C. The first batch of nearly colorless crystals consisted of 55% of the theoretical amount. Additional material was obtained by reduction of the volume of the mother liquor and further crystallization at 0°.

Preparation of N,N'*-di(3,5-dimethyl-2-hydroxybenzyl)ethylenediamine*-N,N'*-diacetic acid 7a*

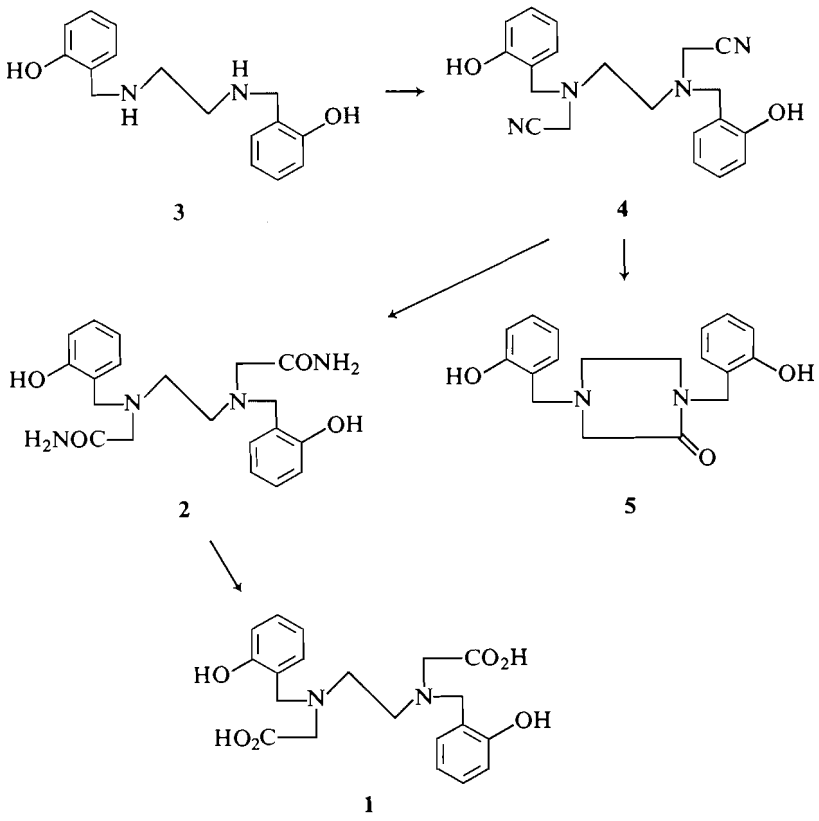
To a three-neck, 100-mL flask, equipped with a nitrogen source, thermometer, magnetic stirrer, heating mantle, SCM electrode and reference electrode, and dropping funnel was added 7 mL 30% NaOH solution and 15 mL methanol. To this was added 4.4 g (0.025 mol) ethylenediamine-*N,N*-diacetic acid and 12.2 g of 2,4-dimethylphenol (0.10 mol) dissolved in 12 mL methanol. The pH initially at 10.9 was adjusted by the addition of 10% HCl to pH 8.2. The reaction was heated to reflux and 8.1 g 37% formaldehyde solution (0.10 mol) in 24 mL methanol was added dropwise with stirring. The pH of the mixture was controlled at pH 8.0. This was heated at reflux for a total of 5 h, then the mixture was cooled to room temperature. The pH was adjusted with NaOH solution to 9.0 and a product precipitated. This was filtered and dried in a vacuum oven at 70°C overnight. A total of 8.08 g of product **7***a* as disodium salt was recovered, mp 181–183°C; 62% yield; ^{1}H nmr (CD_3OD) δ: 6.8 (br s, 2H, ArH), 6.5 (br s, 2H, ArH), 3.6 (s, 4H, HO_2CCH_2N), 3.1 (s, 4H, $ArCH_2N$), 2.6 (s, 4H, NCH_2CH_2), 2.20 (s, 6H, $ArCH_3$), 2.15 (s, 6H, $ArCH_3$). *Anal.* calcd. for $C_{24}H_{30}N_2O_6Na_2.2H_2O$: C 54.96, H 6.54, N 5.34, Na 8.77; found: C 54.54, H 6.26, N 5.35, Na 8.45.

Preparation of N,N'*-di(5-sodiumsulfonate-2-hydroxybenzyl)ethylenediamine*-N,N'*-diacetic acid, 7b*

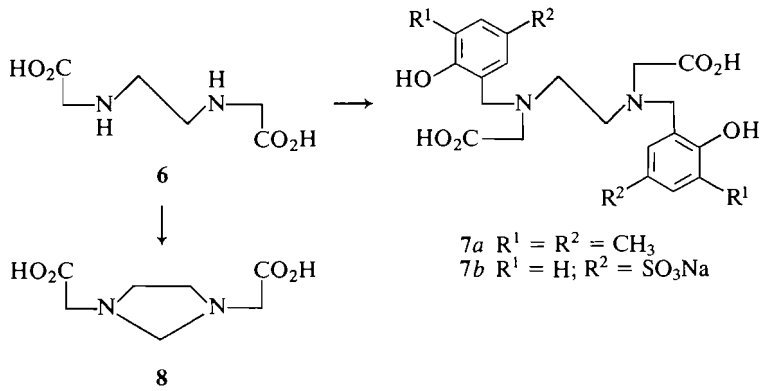
To a three-neck flask equipped with nitrogen source, thermometer, magnetic stirrer, heating mantle, SCM electrode and reference electrode, and dropping funnel was added 4.4 g ethylenediamine diacetic acid (0.025 mol), 23.22 g *p*-phenolsulfonic acid sodium salt (0.10 mol), and 60 mL methanol. This was heated to reflux and 1.8 g NaOH in 3 mL water was added. The pH was 8.7. To this slurry at reflux was added 8.2 g 37% formaldehyde solution (0.10 mol). Midway through the formaldehyde addition, the mixture became a solution. This was refluxed for 5.5 h, then cooled to room temperature overnight. The white solids which precipitated were filtered and dried *in vacuo* to give 5.0 g product; ^{1}H nmr (D_2O) δ: 6.6–7.8 (m, 6H, ArH), 3.8 (br s, 4H, HO_2CCH_2N), 3.3 (br s, 4H, $ArCH_2N$), 2.9 (br s, 4H, NCH_2CH_2). Attempted purification of **7***b* by recrystallization was unsuccessful.

Results and discussion

N,N'-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetamide **2**, was synthesized according to Scheme 1. The known (11, 12) *N,N'*-di(2-hydroxybenzyl)ethylenediamine, **3**, was treated with HCN and formaldehyde to give *N,N'*-di(2-hydroxybenzyl)ethylenediamine-*N,N'*-diacetontrile, **4**, in 97% yield. The order of addition of reagents was important in this reaction. When the formaldehyde was added before the sodium cyanide, only 19% yield of **4** was obtained. Compound **4** could



SCHEME 1



SCHEME 2

not be hydrolyzed to **1** by either acid or base catalysis (11). Instead, small amounts of *N*,*N*′-di(2-hydroxybenzyl)monoketopiperazine, **5**, were obtained. Compound **5** formed even after boiling **4** in water (11) at pH 7.

The diamide **2** was obtained by treating dinitrile **4** with excess H_2O_2 at 5–10°C using a catalytic amount of sodium hydroxide. The diamide could be precipitated as the di-HCl salt. Rather surprisingly, no evidence of an N-oxide was detected under these conditions where one might expect N-oxide to form.[5] This may be due to the unavailability of a reaction pathway for nitrogen atom substitution in these compounds **4** and **2**. Evidence supporting this was obtained by recovery after 8 h of unchanged **4** in the presence of excess H_2O_2 in methanol solution at room temperature. In contrast, when **4** was treated with H_2O_2 and a catalytic amount of sodium hyroxide at *room temperature* overnight, no amide could be recovered. Instead, a complex mixture that was not characterized was observed. Prolonged treatment of **4** with strong acid resulted in decomposition and loss of yield.

The diamide, **2**, could not be hydrolyzed in either acid or base solution or with sodium nitrite in acetic acid under a variety of conditions. Conversion to HBED, however, has been carried out by utilizing the catalytic effects of Cu(II) and Fe(III), as discussed below.

A second synthetic route suitable for the synthesis of derivatives of **1** substituted *para* to the phenolic hydroxyl group was accomplished by reacting ethylenediamine-*N*,*N*′-diacetic acid, **6**, with formaldehyde and a substituted phenol, as indicated in Scheme 2.

This reaction was examined using 2,4-dimethylphenol (14) under a variety of conditions and was found to be very sensitive

[5]See ref. 13 for conditions used in preparing nitrilotri(methylenephosphonic acid) N-oxide, for example.

TABLE 1. Effect of pH on synthesis of HBED derivatives[a]

Run	pH	Product yield (isolated) 7*a*	6
1	5	—	63%
2	7	Trace	53%
3[b]	8	62%	—
4[b]	9	27%	—
5[b]	11	21%	—
6[b]	13	Trace	—

[a]Reaction of 0.025 mmol EDDA, **6**, with 0.05 mmol 2,4-dimethylphenol and 0.05 mmol CH_2O solution in CH_3OH–H_2O at reflux for 5 h.
[b]Compound **8** was detected in the filtrate in large amounts.

to pH. At pH less than 7, only traces of desired product **7***a* were observed. Starting compound **6** was recovered unchanged and it appeared that only phenolformaldehyde reaction was occurring. Between pH 8 and 13, desired **7***a* could be isolated in moderate yield and all of **6** was consumed (Table 1). The best yield of desired product, **7***a*, 62% (see Experimental), could be obtained by reacting **6** and a twofold excess of 2,4-dimethylphenol at reflux temperature with a twofold excess of formaldehyde at pH 8.0. A by-product of this reaction, which became the predominant product under suitable conditions (deficiency of phenol or high pH), was identified by ^1H and ^{13}C nmr as **8** (Scheme 2). Compound **8** could be prepared in nearly quantitative yield in solution by reacting EDDA separately with 1 mol CH_2O and 1 mol base (Na_2CO_3 or NaOH).

The structural assignment of **8** follows by comparing its ^{13}C nmr spectrum (D_2O), δ: 176.0 (CO_2H), 75.9 (NCH_2N), 57.7 (NCH_2CH_2N), 51.6 (NCH_2CO_2H) with that of 1,3-dimethylimidazolidine (15) (CF_3CO_2H), δ: 74.48 (NCH_2N), 55.18 (NCH_2CH_2N), 42.70 (CH_3N), and from the ^1H nmr spectrum of **8** (D_2O), δ: 3.50 (2H, s, NCH_2N), 3.23 (4H, s, NCH_2CO_2H), 2.87 (4H, s, NCH_2CH_2N).

Presumably, by adding the formaldehyde last to a solution of **6** and 2,4-dimethylphenol at as low a pH as practical (pH 8), formation of **7***a* competes favorably with formation of **8**, which does not react further under these conditions to form **7***a*. The dimethyl derivative **7***a* prepared by this procedure precipitated as the disodium salt by adjusting the pH of the mixture at pH 9 and cooling.

A second HBED derivative **7***b* was also prepared by the reaction of **6** with formaldehyde and 4-phenolsulfonic acid sodium salt (14). Compound **7***b* was produced, as expected, and was characterized by nmr, but efforts to find a suitable crystalline derivative of **7***b* failed. As with compound **2**, the synthesis of **7***b* was sensitive to strong acid and at pH <4 yields starting compound phenol sulfonic acid and by-products. Compound **7***b* may hold promise as a very water-soluble iron chelating agent.

Hydrolysis of HBEDDA to HBED

Cu(II) complexes

The equilibrium data in the paper by L'Eplattenier *et al.* (1) were employed to determine the species formed from Cu(II) and HBED at a 1:1 molar ratio as a function of p[H]. The results for a 1.0×10^{-3} molar solution are presented in Fig. 1. It is seen that the three forms of the Cu(II) chelate, CuH_2L, $CuHL^-$, and CuL are related by chelate proton association constants (p*K*'s) of

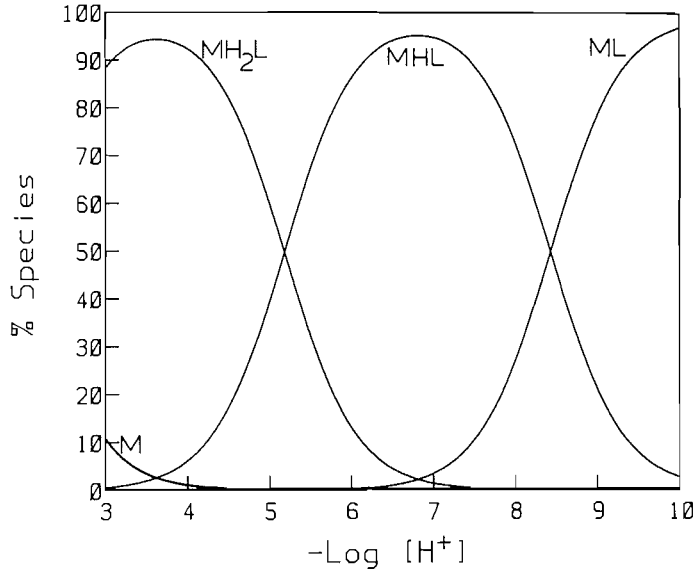


FIG 1. Species equilibrium distribution diagram for a 1:1 aqueous solution of Cu(II)–HBED as a function of −log [H] at 25.0°C; μ = 0.100 *M*; $T_L = T_M = 1 \times 10^{-3}$ *M*. Curve labelled M also represents the H_4L species.

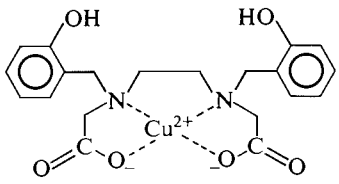
8.63 and 5.18. Thus the low p[H] form, **9**, the intermediate p[H] species, **10**, and the high p[H] form, **11**, have been shown to have the conformations indicated below (1).

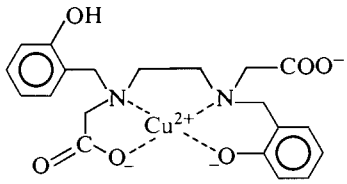
Because it was initially thought that the replacement of the carboxyl groups by amide groups would not have a major influence on the protonation constants of the Cu(II) chelates, it was reasoned that the corresponding amide groups of the Cu(II) chelates of HBED diamide would have conformations analogous to those of **9**, **10**, and **11**. Thus the low pH form would have the arrangement of coordinating donor groups indicated by **12**. At high pH values, by analogy with HBED itself, the diamide would be expected to involve phenolate coordination as indicated by **13**. In addition, an intermediate with a single coordinated phenolate group may also be formed in the mid-p[H] range.

Consideration of the factors involved in metal ion catalysis of amide hydrolysis (16) indicates that the most effective catalytic complex would be **12**, which should have its maximum concentration below pH 4. In **12**, coordination of the carbonyl oxygen should activate the carbonyl carbon toward nucleophilic attack by a base such as the water molecule or hydroxide ion. In **13**, the strong planar coordination by the Cu(II) ion is not directed toward the carbonyl oxygen. Because of the likelihood of weak axial coordination of the amide group, conformations such as that indicated by **14** should also be considered. It has been shown by Hopgood and Angelici (17) and others (18), however, that saturation of the coordination tendencies of Cu(II) by the planar donor groups leaves little additional coordination to be applied to the metal ion in the axial positions. In other words, the catalytic effect of Cu(II) directed toward the axial positions is relatively weak.

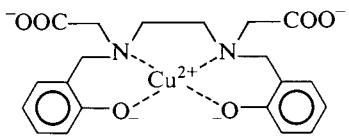
The amide nitrogen coordination, with proton dissociation of the type indicated by **15**, should be considered a definite possibility at intermediate and high pH. Such microspecies would be catalytically inactive, since coordinated amide groups are negatively charged and should have little or no tendency to react with nucleophiles. The inertness of such groups toward hydrolytic attack has previously been pointed out (19).



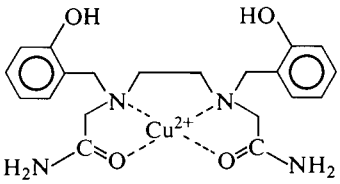
9 CuH_2L (below pH 5.18)



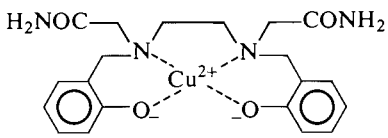
10 $CuHL^-$ (p[H] 5.18–8.63)



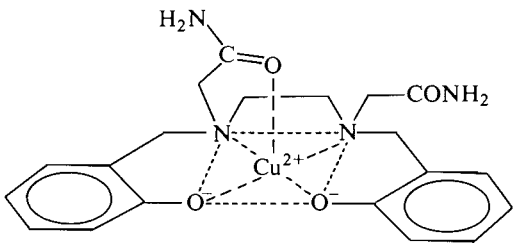
11 CuL^{2+} (above p[H] 8.63)



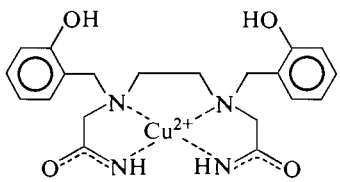
12 $CuH_2L'^{2+}$ (low p[H] form)



13 CuL′ (high p[H] form)



14 CuL′ (5-coordinate)



15 CuL′ (alternate high pH form)

It seems therefore, that the Cu(II) complexes below p[H] 5 would be the most catalytically active Cu(II) species in promoting amide hydrolysis, and p[H] 4.5 was therefore selected for carrying out the conversion of the HBED diamide to HBED. At this p[H], the hydrolysis of the aquo Cu(II) ion is minimal and may be neglected (19).

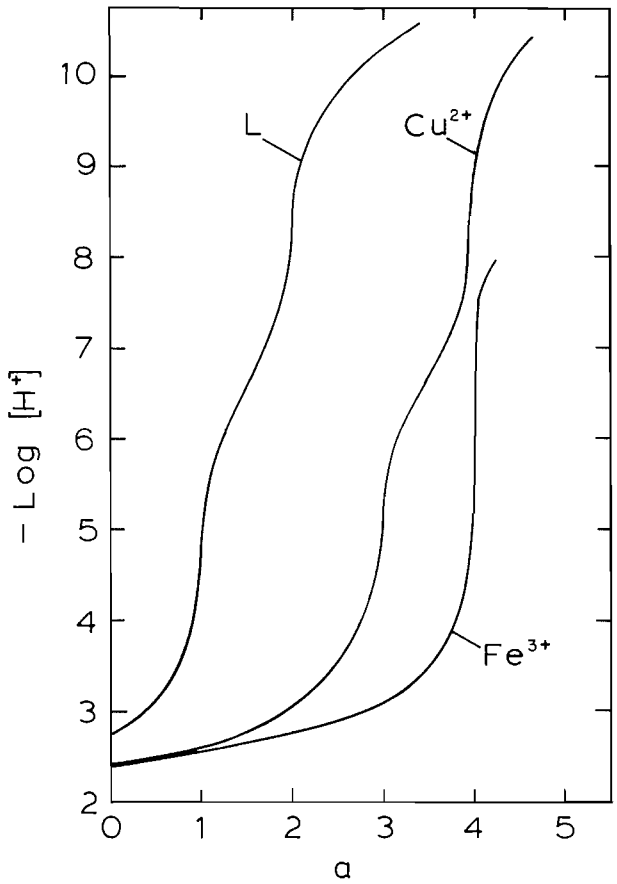


FIG 2. Potentiometric equilibrium curves for 2.000 millimolar solutions of HBEDDA (L), CuHBEDDA(Cu^{2+}) and FeHBEDDA(Fe^{3+}); μ = 0.100 *M* KCl; t = 25.0°C. The Fe^{3+} curve breaks after a = 4 (moles base/mole ligand) because of p[H] drift resulting from the initiation of Fe(III)-catalyzed hydrolysis of the amide groups of the ligand.

[c] This work.

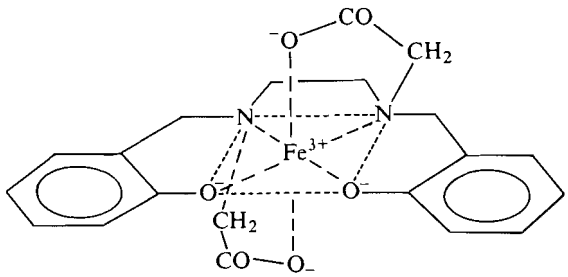
In order to quantify the reasoning described above, the protonation constants of HBED diamide and its Cu(II) complexes were measured potentiometrically by standard techniques, and the results are presented in the form of the potentiometric equilibrium curves illustrated by Fig. 2. From these data, the species distributions as a function of p[H] were calculated to give the distribution curves in Fig. 3. The protonation constants and metal chelate formation constants of HBEDDA, which were calculated from the data in Fig. 2, are given in Table 2, along with the corresponding value of HBED for comparison. It is apparent from the distribution curves in Figs. 1 and 3 that the partially deprotonated complex species $CuHL^+$ starts to form well below pH 3 and reaches its maximum value at pH 4.5, above which it is converted to the fully deprotonated complex, CuL, with a pK of 6.67. Thus even at low p[H] one of the phenolate donor groups is coordinated to Cu(II), and the catalytic effect of the metal on amide hydrolysis predicted above would be greatly diminished. At the low pH values at which Cu(II) coordinates the neutral ligand, H_2L, the catalytic activity of the metal ion would be expected to be quite low, because of the low concentrations of hydroxide ion under these conditions.

Cu(II) catalysis

This prediction has been verified by actually measuring the rate of conversion of HBEDDA to HBED at pH 3.0 and 50.0°C in the presence of an equivalent molar concentration of Cu(II). After 24 h only a small fraction of the diamide had been converted, with a pseudo-first-order rate constant of about $1.0 \times 10^{-7}\ s^{-1}$. This disappointing result is due to weak axial coordination in Cu(II) complexes, and to the formation of phenolate type Cu(II) complexes of HBEDDA at much lower p[H] than those of HBED. This striking difference in phenolate binding by these two ligands is now ascribed to the effective binding of Cu(II) by the EDDA moiety in HBED, which delays conversion to the phenolate type complexes to much higher p[H].

Fe(III) complexes

Because of the failure of Cu(II) as a catalyst for hydrolysis of the amide group of HBEDDA, it was decided to investigate catalysis by Fe(III). Although the completely deprotonated chelate, **16**, would be expected to form completely at low pH, it was felt that because of the additional charge on Fe(III), its strong octahedral coordination tendencies, and the high stability of the Fe(III)–HBED chelate, there would be considerable driving force favoring hydrolysis. This would be especially true at high pH, at which hydroxide ion concentration is high and the Fe(III) product chelate, **17**, would still be expected to be stable and soluble.



17 FeL^-

The potentiometric equilibrium curve of the Fe(III)–HBEDDA system at 25.0°C, 0.10 M ionic strength (Fig. 2), confirms that the phenolic protons are displaced initially at low p[H], leading to a strong acid titration curve. At and above p[H] 7.5 the system appeared to be unstable, presumably because of the onset of metal ion-catalyzed hydrolysis of the ligand.

Fe(III) catalysis

The reaction rate for conversion of Fe(III)–HBEDDA to Fe(III)–HBED was found to be so rapid in aqueous solution at p[H] 9.0 that the temperature was reduced to 25.0°C for convenience of measurement. The change of absorptivity with time, illustrated by Fig. 4, follows a pseudo-first-order rate law, and the value of k_{obs} was found to be $3.1 \times 10^{-3}\ s^{-1}$. The yield of Fe(III)–HBED was found to be essentially quantitative by comparison of the absorbance of the product of hydrolysis with that of an authentic sample of the HBED–Fe(III) chelate.

The absorbance curves for the Fe(III)-promoted conversion of HBEDDA to HBED at p[H] 9.0 are illustrated in Fig. 3. Although the reaction involving the hydrolysis of two coordinated amide groups (16) might be expected to occur in two steps, the isosbestic point in Fig. 4 clearly proves that the hydrolysis reactions are essentially concerted, and the Fe(III) chelate involving the coordination of one carboxylate group and one amide carbonyl oxygen is only an unstable intermediate present in negligible concentration.

The influence of p[H] on reaction rate was measured and the results are listed in Table 3. The expected increase in k_{obs} with increasing hydroxide ion concentration was observed, but was far below first-order dependence. The formation of hydroxo complexes at high pH could account for the low hydroxide ion dependence, because the formation of such complexes would reduce the concentration of the reactive intermediate **16**, as well as suppressing the catalytic activity of the iron(III) center by

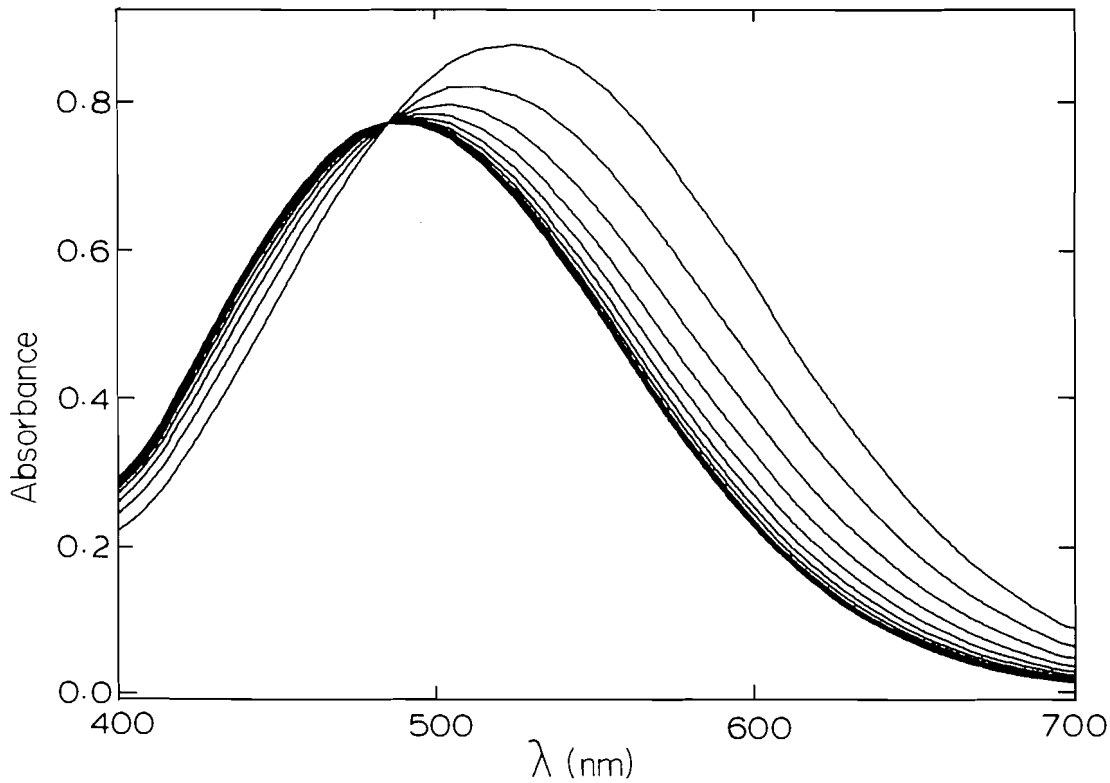


FIG 4. Spectral changes as a function of time (1-min intervals) for a solution of 2.30×10^{-4} *M* Fe HBEDDA at pH = 9.00 borax buffer; $\mu = 0.1000$ *M* at 25.0°C. The initial absorption band with a maximum at 517 nm for the Fe(III)–HBEDDA complex is rapidly converted to the 485-nm maximum band of the Fe(III)–HBED. the pseudo-first-order rate constant is computed as 3.1×10^{-3} s^{-1}.

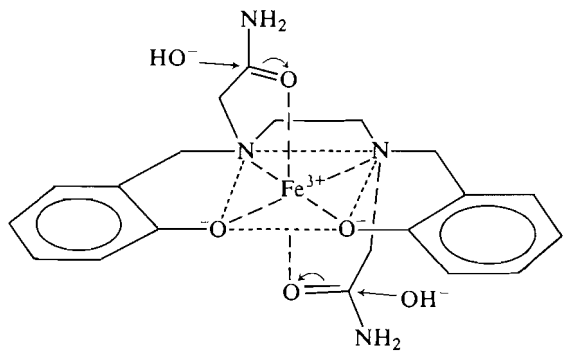
TABLE 3. Pseudo-first-order rate constants for the conversion of Fe(III)–HBEDDA to Fe(III)–HBED (25.0°C, μ = 1.00 *M*)

p[H]	k_{obs}, $s^{-1} \times 10^3$	Buffer
8.0	2.7	Tris
9.0	3.1	Borate
10.0	6.7	Ammonia
11.0	9.3	Ammonia + NaOH

strong hydroxo coordination of the metal ion. Another factor that could account for low hydroxide dependence is the possibility of general base catalysis, whereby the catalytic effects of the buffer anions at the lower hydroxide ion concentrations would make significant contributions to the observed reaction rate.



16

Fe(III)-promoted hydroxide-catalyzed hydrolysis of HBEDDA

Isolation of HBED

The conversion of the Fe(III) chelate of HBED to the free ligand involves special requirements. Because of its exceptionally high stability (20), treatment with strong excess mineral acid does not accomplish more than partial conversion. The sensitive methylene groups between the phenolic ring and the nitrogen atoms preclude the removal of Fe(III) by the use of excess alkali metal hydroxide, a method that works well for the related ligand, ethylenebis-*N*,*N*′-(*o*-hydroxyphenylglycine) (EHPG). The method that has been successful for the isolation of hydroxamate siderophores (21) from the corresponding iron(III) chelates resulted in only partial precipitation of the iron(III)–8-hydroxyquinoline chelate, apparently because the HBED–iron(III) chelate is much more stable than those of the hydroxamate siderophores. On the other hand, conversion to the oxine was sufficient to make it possible to remove nearly all of the remaining iron by successive extractions with chloroform. Conversion to the iron-free HBED was shown spectrophotometrically to be 96.6% complete.

Isomerization of alkyl branched alkynoic acids[1]

SUZANNE R. ABRAMS

Plant Biotechnology Institute, National Research Council of Canada, Saskatoon, Sask. Canada S7N 0W9

Received May 3, 1985

SUZANNE R. ABRAMS. Can. J. Chem. **64**, 457 (1986).

Acetylenic acids are isomerized by alkali metal amides of 1,3-diaminopropane to 3,5-dienoic acids. An acid with a methyl branch at C-3 separating the carboxyl from the triple bond is rearranged to a mixture of the terminal alkynoic acid and two isomeric 3,5-dienoic acids. The corresponding 4-methyl compound affords the terminal alkynoic acid, one 3,5-dienoic acid, and two cyclized products, *cis*- and *trans*-3-methyl-5-(octylidene)-1-cyclopentanecarboxylic acids. Propargylic acids branched at C-5 and C-6 are rearranged to the appropriately substituted 3,5-dienoic acids in moderate yield.

SUZANNE R. ABRAMS. Can. J. Chem. **64**, 457 (1986).

Sous l'influence des sels alcalins des amidures du diamino-1,3 propane, les acides acétyléniques s'isomérisent en acides diène-3,5 oïques. Un acide portant un groupement méthyle en position C-3, qui sépare le groupement carboxyle de la triple liaison, se transpose en un mélange d'acide alcynoïque terminal et de deux acides diène-3,5 oïques isomères. Le composé équivalent comportant un méthyle en position 4 conduit à un acide alcynoïque terminal, un acide diène-3,5 oïque et deux produits de cyclisation, les acides méthyl-3 octylidène-5 cyclopentanecarboxylique-1 *cis* et *trans*. Les acides propargyliques portant des substituants dans les positions C-5 et C-6 se transposent, avec des rendements modérés, en acides diène-3,5 oïques substitués appropriés.

[Traduit par le journal]

Introduction

Exceedingly strong bases that effect multipositional isomerization of triple bonds along methylene chains (1) cause acetylenic acids to be rearranged to *E,E*- and *E,Z*-3,5-dienoic acids (2). Based upon this observation, an efficient synthesis of *E,Z*-3,5-tetradecadienoic acid, the pheromone of the black carpet beetle (*Attagenus megatomia*), has been developed. The key step is the isomerization of 7-tetradecynoic acid with the sodium salt of 1,3-diaminopropane in 1,3-diaminopropane to afford a 1:1 mixture of *E,E*- and *E,Z*-3,5-tetradecadienoic acids in 65% yield (2).

This novel rearrangement is interesting from the point of view of possible applications in natural product syntheses. Specific 3,5-dienoic acids substituted on the carbons of the double bonds, useful as diene components in Diels–Alder reactions, might be readily accessible by isomerization of appropriately substituted alkynoic acids. Diels–Alder reactions with the sodium salts of 3,5-dienoic acids are found to have greatly accelerated rates when performed in water. The dienes are prepared by deconjugation of the corresponding 2,4-dienoic compounds (3).

Previous studies have shown that rearrangements of unsubstituted acetylenic acids with other less basic reagents afford allenic, acetylenic, or 2,4-dienoic acids (4). Julia and Descoins (5) reported that isomerizations with the potassium salt of ethylene glycol of a variety of 3-methyl acids containing a triple bond proceeded much more slowly than the unsubstituted analogs. In only one case did they isolate rearrangement products, a mixture of stereoisomers of 2,4-dienoic acids.

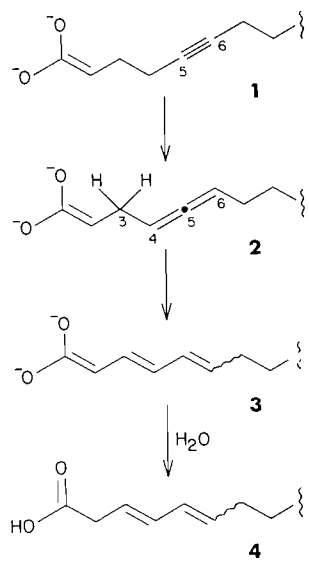
The rearrangement of alkynoic acids with strong base is interesting from a mechanistic point of view. The carboxyl group obviously has a great effect on the course of the triple bond migration. How it influences the sequence of proton abstractions involved in the formation of the diene system is unknown.

To explore both the synthetic and mechanistic aspects of the rearrangement, some alkyl branched alkynoic acids have been prepared and the isomerization of these compounds with strong base studied.

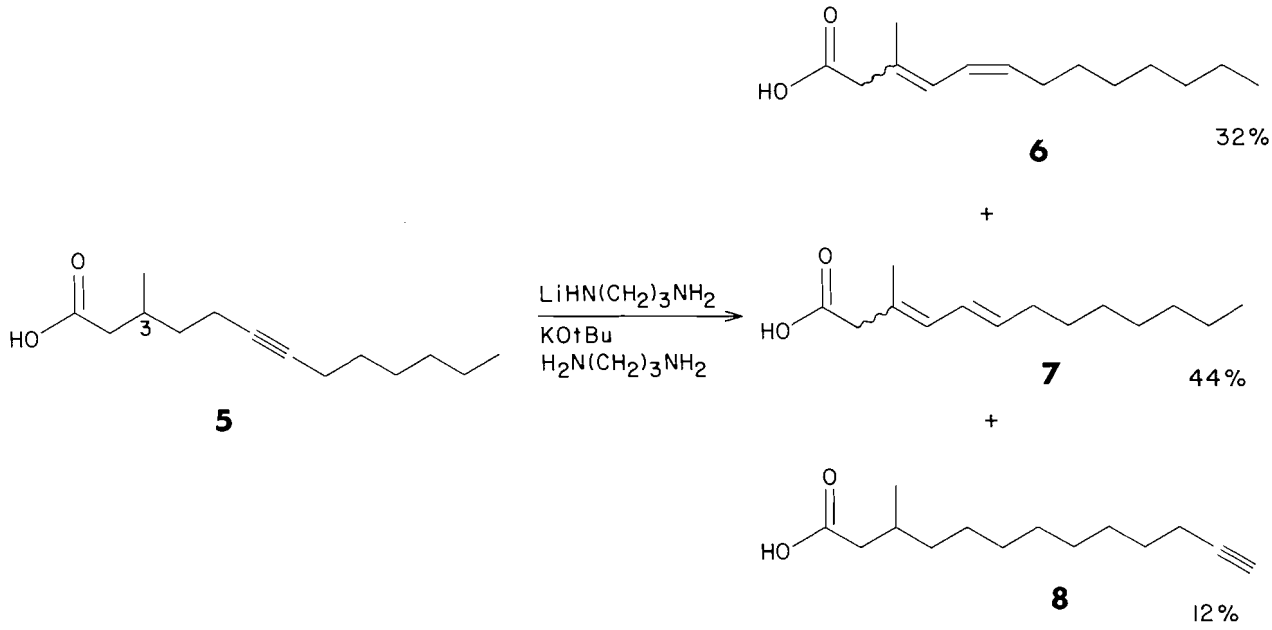
[1]NRCC No. 25196.

Results and discussion

It had previously been established (2) that the carboxyl group of the acetylenic acid is converted to the dianion (**1**) in the isomerization reaction. It is postulated (Scheme 1) that the triple bond, when remote from the dianion, undergoes normal acetylene–allene interconversions along the methylene chain, and that the 4,5-allenic isomer **2** is a key intermediate. It is thought that the proton abstraction pattern is altered at this stage and that the doubly allylic protons on C-3 are more acidic than the vinyl protons on C-4 and C-6. Thus, proton abstraction from C-3 by the reagent, followed by protonation at C-5, breaks the allene–acetylene interconversions and affords a particularly stable intermediate **3**, which has an extensively delocalized conjugated π system. Protonation at C-2 on work-up gives the observed 3,5-dienoic acid product mixture **4**. If the postulated mechanism is correct, and **1**, which has a triple bond at C-5,C-6, is an obligatory intermediate, then neither C-5 nor C-6 may be substituted. However, one of the protons on C-3, and one on



SCHEME 1



SCHEME 2

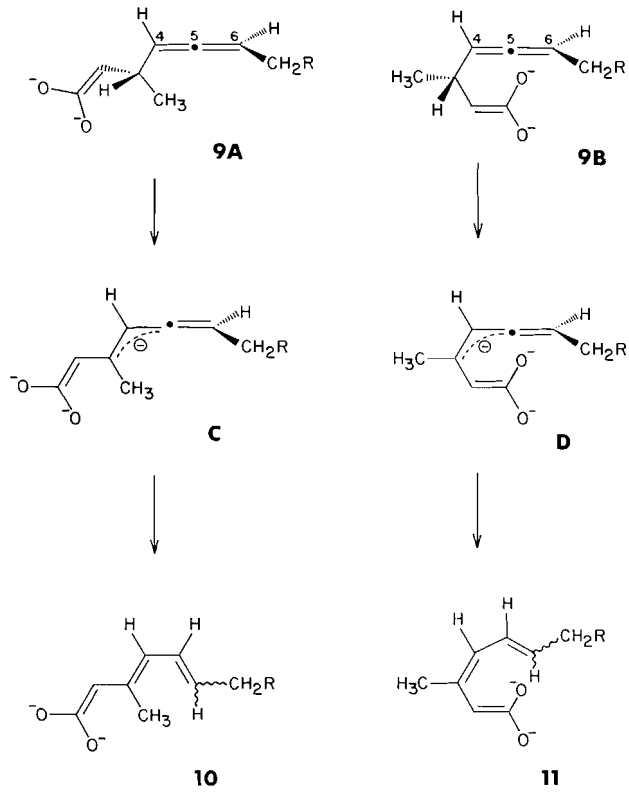
C-4, would not be required for the rearrangement to proceed. It ought to be possible to obtain dienoic acids with substitution at C-3 or C-4. To test this hypothesis, two alkynoic acids, one branched with a methyl group at C-3 and one at C-4, were synthesized by alkylation of the appropriately branched iodo-acid with octyne.

Rearrangement of 3-methyl-6-tridecynoic acid (**5**) with a mixed isomerization reagent (1) affords three products (Scheme 2), two dienoic acids **6** and **7**, and the terminal acetylenic acid **8**. In this case, and in all subsequent discussion, acids were methylated and structures of the isolated esters elucidated.

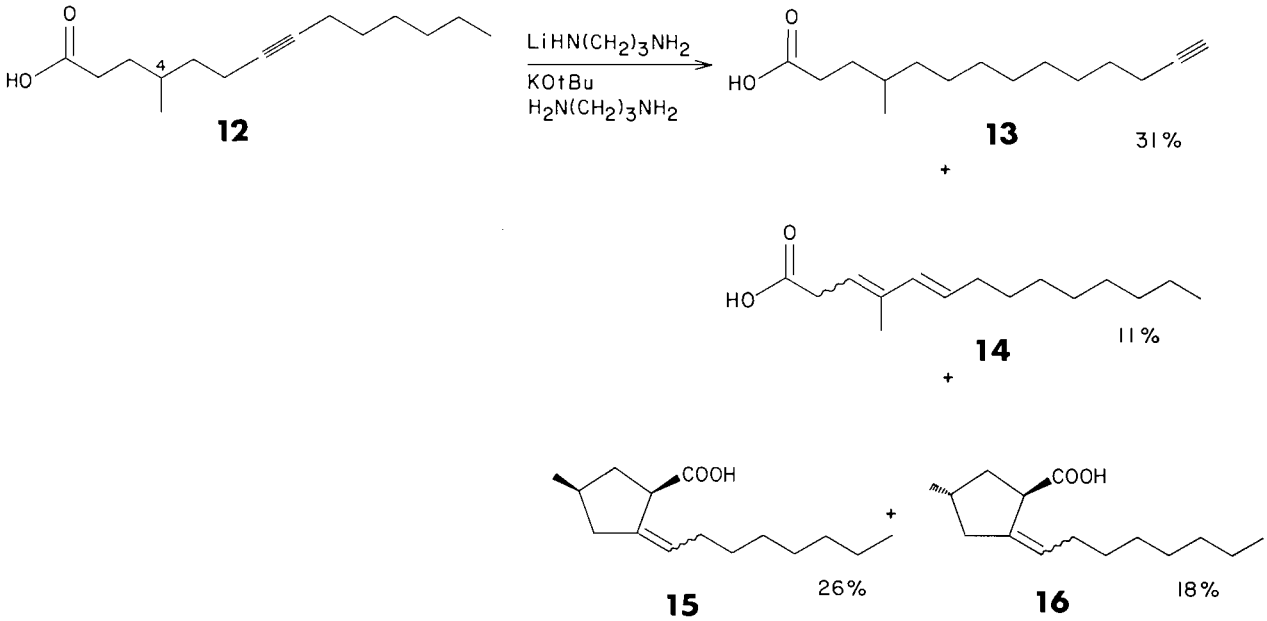
The formation of 3-methyl-12-tridecynoic acid (**8**) is evidence that the allene–acetylene interconversions are proceeding normally when the triple bond is remote from the carboxylate dianion.

The geometry of the C-5,C-6 double bonds of the diene systems of **6** (*Z*-) and **7** (*E*-) have been ascertained from the coupling constants for the protons on the double bond (**6**, $J_{5,6}$ = 8.4 Hz; **7**, $J_{5,6}$ = 15.2 Hz). The chemical shifts of the signal for the protons of the C-3 methyl group of **6** and **7** are nearly coincident (difference of 0.01 ppm), as are the chemical shifts of the methylene signals of C-2 (difference of 0.04 ppm). This suggests that the geometry about the C-3,C-4 bond is the same in both compounds. However, there is no direct evidence to allow an assignment of the geometry of the double bond. Indirect evidence supporting the assignment of the C-3,C-4 double bond as *trans* comes from two sources. First, in products of rearrangement reactions of the unsubstituted alkynoic acids and propargylic acids, in which the stereochemistry can be deduced from nmr using the coupling constants of H-3 and H-4, the *trans* geometry is found. As well, consideration of the geometry of intermediates postulated in the formation of the diene system supports the *trans* assignment (Scheme 3). The stereochemical assignment can be rationalized by considering abstraction of a proton from C-3 of **9** and the stability of the intermediate allylic allenic anion. Two conformations that **9** may adopt are **A**, in which a methyl group lies in the plane of the C-4,C-5 double bond, and **B**, in which the carboxylate dianion similarly is in the plane of the double bond. **A** would be expected to be of lower energy. If abstraction of a proton on C-3 is effected from **A**, then the allenic anion **C** should be formed preferentially (rather than **D** from **B**). The allenic anion **C** would be expected to be of much lower energy than the more hindered anion **D**. Protonation of **C** or **D** at C-5 could take place from either face of the allyl unit, affording **10** with both *Z* and *E* geometries at the C-5,C-6 double bond.

Attempts to synthesize isomeric 3-methyl-3,5-dienoic acids



SCHEME 3



SCHEME 4

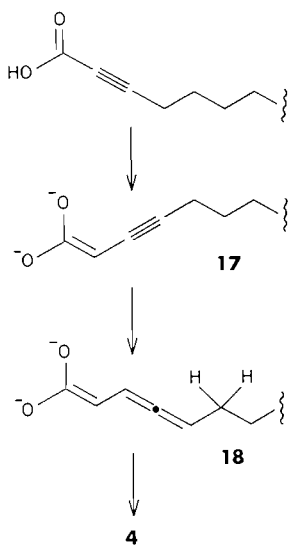
by equilibration of **6** and **7** with thiophenol (6) failed. Deconjugation of a mixture of ethyl (*E*,*E*)- and (*E*,*Z*)-3-methyl-2,4-decadienoate (7) with lithium diisopropylamide afforded only 3-methylene-4-decenoic acid. In this process a proton on the methyl group at C-3 was abstracted in preference to a proton on the chain at C-6.

From rearrangement of 4-methyl-7-tetradecynoic acid (**12**), under the same isomerization conditions, four products were isolated (Scheme 4). The most prominent component is 4-methyl-13-tetradecynoic acid (**13**). One 3,5-dienoic acid is observed. The stereochemistry of the C-3,C-4 double bond cannot be assigned. The C-5,C-6 double bond geometry is *trans* ($J_{5,6}$ = 15.5 Hz). The remaining two products, which account for 44% of the reaction mixture, are the result of the rearrangement taking a different course. It is proposed that the products are two cyclopentanecarboxylic acids **15** and **16**, differing only in the relative orientations of the methyl branch with respect to the carboxyl group. The assignment of relative stereochemistry is based on a chemical shift difference. The methyl signal for the isomer with the methyl and carboxyl groups on the same face of the ring is expected to be deshielded relative to the methyl signal for the isomer with the groups disposed *trans*. A difference of 0.09 ppm is observed. The geometry about the exocyclic double bond has not been established.

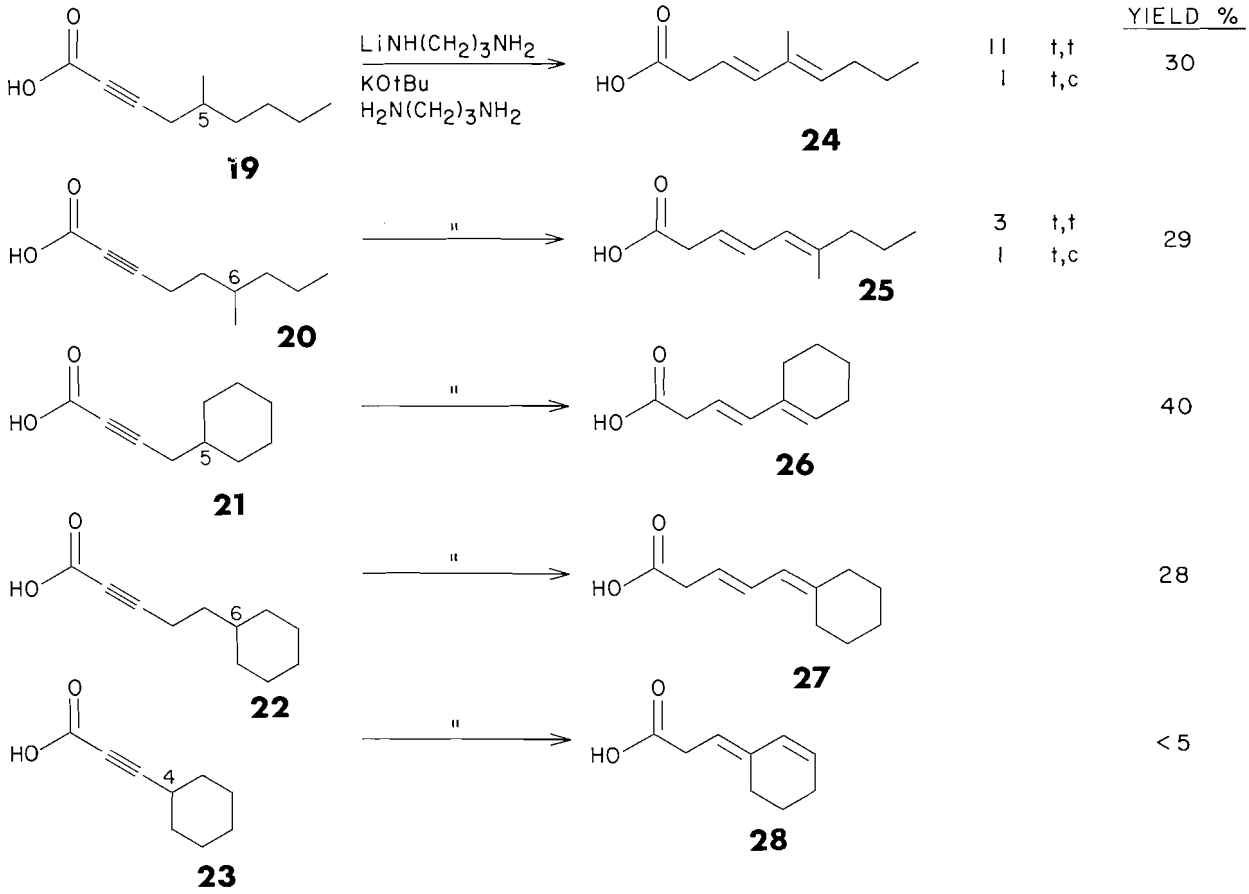
Others have observed analogous cyclizations of stabilized anions alkylating unactivated (8, 9) and activated triple bonds (10) to form five-membered cycles with exocylic double bonds. In the present case, the triple bond migrates from the C-7 to C-6 position before it is attacked by the stabilized dianion. This is an interesting example of a 5-*exo*-digonal taking precedence over a 6-*exo*-digonal ring closure. In theory both of these reactions should have the opportunity to take place. According to Baldwin's rules (11), both are favoured. In this example, only the five-membered ring is observed.

Acetylenic acids with the triple bond between the carboxyl and an alkyl branch were considered next. In the earlier study (2) it had been shown that the unbranched propargylic acid, 2-tetradecynoic acid, was also isomerized to 3,5-dienoic acids, and the homopropargylic acid was shown to be an intermediate. It is postulated that the rearrangement takes place as shown in Scheme 5. The dianion of the homopropargylic acid, **17**, is rearranged to the key intermediate **18**, at which point the allene–acetylene interconversions are terminated with the abstraction of a proton from C-6. The intermediate allenic anion is protonated at C-4, affording the dianion **4** with the extended delocalized π system. Substitution on either C-5 or C-6 should not hinder the rearrangement, but substitution at C-3 or C-4 should not be allowed if **17**, with its triple bond at C-3,C-4, is an obligatory intermediate. The formation of terminal acetylenic isomers is precluded by the positioning of the branch between the triple bond and the terminus of the chain, so the isomerization of propargylic acids should afford the 3,5-dienoic acids. A number of acetylenic acids branched at C-5 and C-6, and one at C-4 (Scheme 6), were prepared by alkylation of the tetrahydropyranyl ether of propargyl alcohol with the appropriate alkyl halide, followed by oxidation.

As for the unsubstituted case, isomerization of the 2-alkynoic



SCHEME 5



SCHEME 6

acids proceeded through the homopropargylic isomer. By carrying out the isomerization reaction at room temperature, 3-alkynoic acids could be isolated in good yield. One example is described in the experimental section.

It is interesting that, as predicted, 3-cyclohexylpropynoic acid (**23**) affords, on rearrangement, only traces of the 3,5-dienoic acids (**28**). The major products appeared to be dimeric and they were not investigated further.

Rearrangement of the substituted methyl- and cyclohexyl-alkynoic acids **19** to **22** using more vigorous reaction conditions (60°C) afforded the desired substituted 3,5-dienoic acids **24**–**27** in moderate yields. The C-3,C-4 double bond in each rearrangement product **24**–**27** is observed to be *trans*, from the coupling constants. Pairs of isomeric dienoic acids are formed in the case of the methyl branched series. The stereochemistry about the double bonds with the methyl group can be assigned by analysis of the chemical shifts of the protons adjacent to the double bond in question. Olefinic protons next to a *cis* double bond are shifted downfield relative to those adjacent to a *trans* double bond by 0.5 ppm, and methylene signals next to a *cis* double bond are similarly shifted by 0.2–0.3 ppm (2, 6, 12). In the 5-methyl case, the major product (78% of the mixture) is assigned the *trans,trans* configuration on analysis of the chemical shifts observed in comparison with those of the next most significant product (7% of the mixture). the signal for H-4 of the major component is observed at δ 6.12, while that of the minor component is found at δ 6.51. Similarly the methylene signal of C-7 is shifted downfield at 0.10 ppm in the case of the minor component. In the 6-methyl series, the (*E*,*E*)-compound is found to predominate by a ratio of 3:1. The signals in the olefinic region of the nmr spectrum are overlapped, but the methylene signals for C-7 are clearly separated, with the larger triplet at higher field (0.12 ppm).

There is no ambiguity in the geometry of the C-5,C-6 double bonds in the products **26** and **27**, and the C-3 and C-4 double bonds are found to be *trans*.

Conclusions

Alkyl branched acetylenic acids can be isomerized to substituted 3,5-dienoic acids. The position of the alkyl group, or the lack of one, on the chain affects the rate of the acetylene–allene interconversions and thus the distribution of products obtained. The 3-methyl branch (Scheme 2) does not appear to impede the formation of the 4,5-allenic dianon **2** relative to the unsubstituted case. From the synthetic point of view, 3-alkyl branched acetylenic acids offer good possibilities for construction of trisubstituted dienes. The 4-methyl branch does impede the rearrangement to 3,5-dienoic acids. The 4-alkyl branched isomers may, however, provide access to cyclopentanecarboxylic acid derivatives. Propargylic acids, which are readily accessible, should prove to be useful in the synthesis of 3,5-dienoic acids substituted at C-5 and C-6.

Experimental

All reactions requiring dry conditions were performed in vacuum flame-dried, or oven-dried (110°C for more than 2 h) glassware, under a positive pressure of argon. Solvents described as dry were obtained by distillation as follows: tetrahydrofuran (THF) from benzophenone ketyl; dichloromethane (CH_2Cl_2) and acetonitrile (CH_3CN) from CaH_2; hexamethylphosphorous triamide (HMPA) at reduced pressure

and subsequently stored over activated 4Å sieves; 1,3-diaminopropane from BaO, then stored over activated 4Å sieves.

Proton nmr spectra were recorded on a Varian EM 390 (90 MHz) or Bruker AM-360-WB (360 MHz) spectrometers, with $CDCl_3$ as solvent. Carbon spectra were recorded on the Bruker instrument in the Fourier transform mode at 90.6 MHz with proton noise decoupling, with $CDCl_3$ as solvent and lock. Infrared spectra were obtained with a Perkin Elmer 237B instrument. Gas chromatograms were obtained with a Varian 3700 instrument with FID, and 30-m SP 2100 capillary column. Retention times are given in minutes with the relative intensities in parentheses. Mass spectra were obtained on a Finnigan 4000E gc/ms instrument with an Incos 2300 data system and using an SP2100 column. Mass spectra are reported in mass to charge units (m/z) with the relative intensities given in parentheses as percentages of the base peak. Accurate mass measurements were provided by the Mass Spectrometry Laboratory, Psychiatric Research Unit, University of Saskatchewan, with an MS902S instrument with VG console update. Accurate masses were obtained at 1500 resolution and 3 s/decade using accurate-mass low-resolution software with PFTBA internal standard. Elemental analyses were performed by Spang Microanalytical Laboratory, Eagle Harbor, Michigan, U.S.A.

General isomerization procedure

Into a 25-mL pear-shaped flask fitted with magnetic stirring bar was charged lithium (42 mg, 7.0 mmol). 1,3-Diaminopropane (dry, 5.0 mL, **corrosive!**) was added by syringe and the mixture heated and stirred at 70°C until a white suspension of the lithium amide was formed. After cooling to room temperature, potassium *tert*-butoxide (500 mg, 5.0 mmol) was added, affording a lemon-yellow solution. A solution of the acetylenic acid (1.0 mmol) in a 1,3-diaminopropane (1.0 mL) was added by syringe, and the mixture stirred for 1.0 h, then poured into ice water. The mixture was acidified with HCl and extracted with $CHCl_3$ (3×). The combined organic phases were washed successively, once with 10% HCl, H_2O and NaCl solution, then dried over Na_2SO_4, filtered, and the solvent evaporated to afford a crude mixture of isomerized acids. Methyl esters were prepared either by reaction with methanolic HCl or with diazomethane, and then purified by chromatography.

The ratios of reagents in the different isomerization reactions were kept constant. The reaction temperature and time were varied with the particular substrate. Separations of the methylated products were effected either with silicic acid chromatography or hplc with reverse phase (Altex Ultrasphere ODS, 5 μm, 10 × 25 cm) or cation exchange (Whatman Partisil M9 10/50 SCX, Ag^+ form) columns.

3-Methyl-6-tridecynoic acid (5)

According to the method of Olah *et al.* (13), to a solution of 5-hydroxy-3-methylpentanoic acid (prepared by reduction of the half acid ester of 3-methylglutaric acid, followed by saponification, 3.7 g, 28 mmol) in CH_3CN (dry, 60 mL) was added first sodium iodide (18 g, 120 mmol), then chlorotrimethylsilane (15.3 mL, 120 mmol). The mixture was refluxed overnight, then cooled to room temperature, poured into ice water, and extracted with ether (3×). The combined ethereal extracts were washed first with H_2O (1×), then with 10% $Na_2S_2O_3$ solution (1×), and finally with $NaHCO_3$ (3×). The combined $NaHCO_3$ extracts were acidified with HCl and extracted with ether (3×). The combined ethereal extracts were washed with NaCl solution (1×), dried over Na_2SO_4, and the solvent evaporated to afford crude 5-iodo-3-methylpentanoic acid (4.8 g, 71%), which gave ^{1}H nmr δ: 3.2 (t, J = 7 Hz, CH_2I, 2H), 1.7–2.4 (m, 5H), and 1.0 (d, J = 6 Hz, CH_3, 3H). The crude acid was employed in the next step without further purification.

To a solution of 1-octyne (4.4 mL, 30.0 mmol) in THF (dry, 30 mL), at −70°C, was added first *n*-butyllithium (17.6 mL, 0.63 *M*, 28 mmol), then a solution of the lithium salt of 5-iodo-3-methylpentanoic acid (4.8 g, 20.0 mmol) in THF (100 mL) and HMPA (17 mL) (prepared by addition of *n*-butyllithium (11.3 mL, 0.63 M, 18 mmol) to the acid in THF–HMPA). The resultant mixture was stirred and allowed to warm to room temperature overnight, then poured into H_2O, acidified with HCl, and extracted with ether (3×). The combined ethereal extracts were washed with H_2O (1×), then with NaCl solution (1×), and dried over Na_2SO_4. Evaporation of the solvent afforded a brown oil (4.5 g) from which 3-methyl-6-tridecynoic acid (**5**) (860 mg, 20%) was isolated by chromatography of the methyl ester over a cation exchange column (Ag^+ form) eluting with methanol, followed by saponification. The acid **5** was distilled (bulb-to-bulb, over temp. 180°C, 0.1 Torr (1 Torr = 133.3 Pa)) and gave ν_{max} (film): 3500–2600, 1700 cm^{-1}; ^{1}H nmr (360 MHz) δ: 2.35 (dd, J = 14.5, 5.0 Hz, OOCCH, 1H), 2.0–2.2 (m, OOCCH, $H_2CC{\equiv}CCH_2$, 5H), 1.55 (m, $HCCH_3$, 1H), 1.20–1.48 (m, CH_2, 8H), 0.95 (d, J = 6.5 Hz, H_3CCH), and 0.85 (t, J = 7.1 Hz, H_2CCH_3); ^{13}C nmr; 179.1, 80.7, 79.3, 41.1, 35.8, 31.4, 29.4, 29.1, 28.6, 22.6, 19.2, 18.8, 16.5, and 14.0 ppm; gc/ms of methyl ester: 238 (0.05), 168 (13), 164 (10), 135 (8), 109 (12), 108 (20) and 95 (100). *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.95, H 10.78; found: C 74.95, H 10.71.

Rearrangement of 3-methyl-6-tridecynoic acid (5)

Isomerization of the acid **5** (224 mg, 1.0 mmol) as described above for 1.0 h at room temperature afforded a mixture of acids (176 mg, 75%), which was esterified with methanol HCl. Four major products, all isomeric, could be distinguished by glc (160°C, 16.3 (12), 17.7 (12), 18.1 (32), 20.8 (44)). Three of these were purified by hplc (reverse phase, eluting with 20% H_2O, 80% CH_3OH). Methyl 3-methyl-12-tridecynoate gave a single peak on glc (16.3 min); ir ν_{max} (film): 3300 and 1730 cm^{-1}; ^{1}H nmr (360 MHz) δ: 3.65 (s, OCH_3), 2.28 (dd, J = 14.6, 6.0 Hz, OOCCH, 1H), 2.16 (dt, J = 2.6, 7.0 Hz, $H_2CC{\equiv}C$, 2H), 2.09 (dd, J = 14.6, 8.1 Hz, OOCCH, 1H), 1.91 (t, J = 2.6 Hz, $C{\equiv}CH$, 1H), 1.2–1.6 (m, CH_2, CH, 15H), and 0.91 (d, J = 6.6 Hz, CH_3, 3H); gc/ms: 238 (missing), 207 (0.5), 195 (1.1), 164 (4.4), 101 (42), and 74 (100); accurate mass analysis of McLafferty rearrangement product calcd. for $C_{12}H_{20}$: 164.1565; found: 164.1453. Methyl 3-methyl-3,5-tridecadienoate (ester of **6**) gave a single peak on glc (18.1 min); ir ν_{max} (film): 1730 and 800 cm^{-1}; ^{1}H nmr (360 MHz) δ: 6.1–6.2 (m, H-4, H-5, 2H), 5.43 (dt, J = 7.2, 8.4 Hz, H-6, 1H), 3.67 (s, OCH_3, 3H), 3.06 (s, $OOCCH_2$, 2H), 2.13 (m, $C{=}CCH_2$, 2H), 1.80 (s, $H_3CC{=}C$, 3H), 1.2–1.4 (m, CH_2 10H), and 0.86 (t, J = 6.5 Hz, H_3C, 3H); irradiation of the signal δ 2.13 effects collapse of the signal δ 5.43 to a d, J = 8.4 Hz; gc/ms: 238 (51), 179 (8), 178 (7), 164 (32), 140 (40), 108 (45), 93 (100); accurate mass analysis for molecular ion calcd. for $C_{15}H_{26}O_2$: 238.1933; found: 238.1907. Methyl 3-methyl-3,5-tridecadienoate (ester of **7**) gave a single peak on glc (20.8 min); ir ν_{max} (film): 1730, 960, and 800 cm^{-1}; ^{1}H nmr (360 MHz) δ: 6.20 (dd, J = 10.3, 15.2 Hz, H-5, 1H), 5.87 (d, J = 10.3 Hz, H-4, 1H), 5.62 (dt, J = 15.2, 7.4 Hz, H-6, 1H), 3.66 (s, OCH_3, 3H), 3.02 (s, $OOCH_2$, 2H), 2.08 (dt, J = 7.6, 7.1 Hz, $C{=}CCH_2$, 2H), 1.79 (s, $H_3CC{=}C$, 3H), 1.2–1.6 (m, CH_2 10H), and 0.85 (t, J = 7.0 Hz, CH_3, 3H); gc/ms: 238 (61), 179 (11), 178 (8), 164 (31), 140 (40), 108 (42), and 93 (100); accurate mass analysis for molecular ion, calcd. for $C_{15}H_{26}O_2$: 238.1933; found: 238.1956.

4-Methyl-7-tetradecynoic acid (12)

According to the method of Whitesell *et al.* (14), to a stirred suspension of $NaHCO_3$ (8.4 g, 0.10 mmol) and *m*-chloroperbenzoic acid (85%, 9.6 g, approx. 0.05 mmol) in CH_2Cl_2 (dry, 50 mL) was added 4-methylcyclohexanone (5.6 g, 0.05 mmol). The temperature of the mixture was maintained between 18 and 30°C with an ice-water bath. After stirring for 5 h, H_2O was added and the CH_2Cl_2 layer was separated. The aqueous was extracted with CH_2Cl_2 (4×). The combined organic phases were washed with 10% Na_2CO_3 solution (2×), NaCl solution (1×), then were dried over Na_2SO_4, filtered, and the solvent evaporated to yield crude 4-methyl-7-oxacycloheptanone (15), 5.8 g, (90%), which gave ir ν_{max} (film): 1720 cm^{-1}; ^{1}H nmr (90 MHz) δ: 4.3 (m, OCH_2, 2H), 2.7 (m, $OCCH_2$ 2H), 1.3–2.2 (m, CH_2, CH, 5H), and 1.0 (d, J = 6 Hz, CH_3, 3H).

According to the method of Olah *et al.* (13), the lactone was converted to 6-iodo-4-methylhexanoic acid, 3.1 g (48%), which gave ir ν_{max} (film): 3400–2500, 1710 cm^{-1}; ^{1}H mnr (90 MHz) δ: 3.2 (m, CH_2I, 2H). 2.3 (t, J = 6 Hz, CH_2COO, 2H), 1.3–1.9 (m, CH_2CH, 5H), and 0.9 (t, J = 6 Hz, CH_3, 3H). The crude iodoacid was alkylated with the

lithium salt of octyne to afford 4-methyl-7-tetradecynoic acid (2.8 g). The acid **12** was converted to methyl ester with methanolic HCl and chromatographed over a cation exchange column (Ag^+ form), eluting with methanol, affording the methyl ester, 1.13 g (37%), which gave ms: 252 (0.6), 221 (3), 220 (2), 182 (21), 178 (12), 165 (11), 150 (24), 135 (17), 124 (26), 108 (55), 95 (92), and 81 (100). Saponification afforded the acid **12**, which was distilled (bulb-to-bulb, oven temp. 200°C, 0.1 Torr) and gave ^{1}H nmr (360 MHz) δ: 3.64 (s, OCH_3, 3H), 2.24–2.37 (m, $OOCCH_2$, 2H), 2.08–2.18 (m, $H_2CC{\equiv}C$, 4H), 1.2–1.7 (m, CH_2 CH, 13H), and 0.86 (m, CH_3, 6H); ^{13}C nmr: 180.5, 80.4, 79.8, 35.9, 31.8, 31.6, 31.4, 31.3, 29.1, 28.6, 22.6, 18.8, 16.5, and 14.0 ppm. *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.58, H 11.00; found: C 75.55, H 10.97.

Rearrangement of 4-methyl-7-tetradecynoic acid (12)

Isomerization of 4-methyl-7-tetradecynoic acid (230 g, 1.0 mmol) was carried out as described above for 1.0 h, at room temperature. The crude product (170 mg) was esterified with methanolic HCl, affording a mixture of methyl esters (200 mg) which gc/ms analysis indicated contained 4 major isomeric products that made up 86% of the mixture (170°C, 19.2 (18), 19.8 (26), 24.3 (31), and 27.5 (11)). Methyl 4-methyl-13-tetradecynoate was isolated by hplc (reverse phase, eluting with 10% H_2O, 90% CH_3OH) and gave a single peak on glc (24.1); ir ν_{max} (film): 3300 and 1730 cm^{-1}; ^{1}H nmr (360 MHz) δ: 3.65 (s, OCH_3, 3H), 2.25–2.35 (m, $OOCCH_2$, 2H), 2.16 (dt, J = 2.6, 7.0 Hz, $CH_2C{\equiv}C$, 2H),1.92 (t, J = 2.6 Hz, $C{\equiv}CH$, 1H), 1.2–1.7 (m, CH_2, 17H), and 0.85 (d, J = 6.3 Hz, 3H); ms: 252 (1–4), 237 (0.8), 109 (23), 95 (44), 87 (92), 81 (69), 74 (90), and 55 (100); accurate mass analysis for the molecular ion calcd. for $C_{18}H_{28}O_2$: 252.2088; found: 252.2058. Methyl *trans*-3-methyl-5-(1-octylidene)-1-cyclopentanecarboxylic acid was isolated by hplc (cation exchange column, eluting with 0.25% dimethoxyethane in hexane) and gave a single peak on glc (19.1); ir ν_{max} (film): 3320, 3310, and 1730 cm^{-1}; ^{1}H nmr (360 MHz) δ: 5.41 (m, HC=C, 1H), 3.65 (s, OCH_3, 3H), 3.37 (m, HCCOO, 1H), 2.49 (dd, J = 15, 7 Hz, H-4, 1H), 2.30 (m, H-3, 1H), 2.10 (m, H-2, 1H), 1.96 (q, J = 7 Hz, $H_2CC{=}C$, 2H), 1.80 (dd, J = 14, 7 Hz, H-4′, 1H), 1.43 (m, H-2′, 1H), 1.3–1.4 (m, CH_2 10H), 0.97 (d, J = 6.7 Hz, H_3CCH, 3H), and 0.86 (t, J = 7.0 Hz, H_3CCH_2, 3H); irradiation of the signal δ 2.30 causes the methyl doublet at δ 0.97 to collapse to a singlet, and the multiplets at δ 2.49 and 1.80 to collapse to doublets, J = 14 Hz; irradiation of the quartet at δ 1.96 causes collapse of vinyl signal at δ 5.41 to a singlet, and irradiation at δ 2.10 causes the signal at δ 3.31 to become a doublet, J = 8 Hz, and simplifies the multiplet at δ 1.43; ms: 252 (10), 237 (5), 193 (30), 192 (22), 164 (4), 150 (7), 139 (100), and 107 (84); accurate mass analysis for the molecular ion $C_{15}H_{26}O_2$ calcd.: 252.2088; found: 252.2081. The *cis* isomer **15** eluted after the *trans* compound and gave a single peak on glc (19.7); ir ν_{max} (film): 3320, 3300, 1720^{-1}; ^{1}H nmr (360 MHz) δ: 5.29 (m, HC=C, 1H), 3.68 (s, OCH_3, 3H), 3.31 (m, HCCOO, 1H), 2.49 (dd, J = 15.3, 6.3 Hz, H-4, 1H), 2.05 (m, H-2, 1H), 1.9–2.0 (m, $H_2CC{=}C$, H-3′, 3H), 1.79 (m, H-4′, 1H), 1.59 (q, J = 11 Hz, H-2′, 1H), 1.2–1.4 (m, CH_2, 10H), 1.06 (d, J = 6.2 Hz, H_3CCH, 3H), and 0.86 (t, J = 7.0 Hz, H_3CCH_2, 3H); irradiation of the signal δ 2.05 causes collapse of the signal at δ 3.31 to a doublet, J = 8 Hz, and simplifies the multiplet at δ 1.59; irradiation at δ 1.95 causes the multiplet at δ 2.49 to become a doublet, J = 6 Hz, and the methyl doublet at δ 1.06 and the vinyl proton δ 5.29 to become singlets; ms: 252 (12), 237 (5), 193 (38), 192 (33), 177 (11), 164 (13), 150 (21), 139 (96), and 107 (100); accurate mass analysis for the molecular ion $C_{15}H_{26}O_2$ calcd.: 252.2088; found: 252.2062. Methyl 4-methyl-3,5)tetradecadienoate was isolated using the same column, but with 1% dimethoxyethane in hexane, and gave a single peak on glc (27.5); ir ν_{max} (film): 1730, 960 cm^{-1}; ^{1}H nmr (360 MHz) δ: 6.30 (dd, J = 0.9, 15.5 Hz, H-5, 1H), 5.74 (dt, J = 7.2, 15.5 Hz, H-6, 1H), 5.38 (t further split, J = 0.6, 7.4 Hz, H-3, 1H), 3.67 (s, OCH_3, 3H), 3.18 (dd, J = 0.6, 7.4 Hz, $OOCCH_2$, 2H), 2.11 (dt, J = 6.9, 7.4 Hz, $H_2CC{=}C$, 2H), 1.82 (q, J = 1.1 Hz, $H_3CC{=}C$, 3H), 1.2–1.6 (m, CH_2, 12H), and 0.87 (t, J = 6.7 Hz, H_3CCH_2, 3H); ms: 252 (24), 221 (1.6), 178 (13), 165 (7), 154 (11), 140 (12), 135 (18), 105 (25), 95 (45), 94 (30), 93 (82), and 81 (100); accurate mass analysis for the molecular ion calcd.: 252.2088; found: 252.2091.

6-Methyl-2-nonynoic acid (20)

To a solution of the tetrahydropyranyl ether of propargyl alcohol (7.3 g, 47 mmol) in THF (dry, 50 mL) at 0°C was added a solution of *n*-butyllithium in hexane (33 mL, 52 mmol). After stirring for 0.5 h, a solution of 1-bromo-3-methylhexane (16) (8 g, 40 mmol) in HMPA (dry, 40 mL) was added dropwise. The stirred reaction was allowed to warm to room temperature over 3.5 h, then was poured into ice water, and was extracted with hexane (3×). The combined hexane extracts were dried over Na_2SO_4, filtered, and the solvent evaporated. The residue was taken up in CH_3OH (200 mL) and *p*-toluenesulfonic acid (approx. 100 mg) was added. The solution was refluxed overnight, then cooled, and the solvent evaporated. The residue was taken up in ether and washed with H_2O (1×), $NaHCO_3$ solution (1×), NaCl solution (1×), then dried over Na_2SO_4, filtered, and the solvent distilled. Chromatography over silicic acid afforded 6-methyl-2-nonyn-1-ol (2.65 g, 23% from 3-methyl-1-hexene), which gave ir ν_{max} (film): 3450, 2200, and 1010 cm^{-1}; ^{1}H nmr (90 MHz) δ: 4.2 (t, J = 2 Hz, OCH_2, 2H), 2.1–2.3 (m, $H_2CC{\equiv}C$, 2H), 1.0–1.7 (m, CH_2, CH, 7H), 0.8–1.0 (d and t superimposed, J = 7 Hz, $2CH_3$); ^{13}C nmr: 84.4, 78.4, 51.1, 38.9, 31.8, 20.0, 19.1, 16.5, and 14.3 ppm; ms of TMS ether: 226 (missing), 181 (20), 155 (8), 142 (8), 135 (9), 127 (17), 93 (19), 75 (100).

To a solution of the alcohol (2.25 g, 14.6 mmol) in acetone (60 mL) at 0°C was added dropwise a solution of CrO_3 (2.92 g, 29.2 mmol) in H_2O (11.2 mL) and H_2SO_4 (2.8 mL). After stirring for 0.5 h, isopropanol was added until the mixture was green, then the solvents were removed at reduced pressure. The residue was taken up in ether, then washed with H_2O (1×), and NaCl solution (1×), then dried over Na_2SO_4, filtered, the solvent evaporated, and the residue distilled (bulb-to-bulb, oven temp. 105°C, 0.075 Torr) to afford 6-methyl-2-nonynoic acid (**20**) (1.84 g, 75%). This compound gave ir ν_{max} (film): 3100 (br), 2220, and 1680 cm^{-1}; ^{1}H nmr (360 MHz) δ: 2.25–2.41 (m, $H_2CC{\equiv}C$, 2H), 1.04–1.66 (m, CH_2, CH, 7H), 0.87 (t, H_2CCH_3, J = 6.8 Hz, 3H), and 0.85 (d, $HCCH_3$, J = 6.6 Hz, 3H); ^{13}C nmr: 158.4, 92.9, 72.6, 38.8, 34.5, 31.9, 20.0, 19.1, 16.6, and 14.3 ppm; gc/ms of the methyl ester: 182 (missing), 151 (20), 139 (27), 125 (20), 121 (29), 111 (39), 107 (78), 93 (72), and 79 (100); accurate mass analysis for the TMS ester − CH_3 calcd.: 225.1310; found: 225.1297.

Rearrangement of 6-methyl-2-nonynoic acid (20) at room temperature

Using the standard conditions the acid **20** (500 mg, 3.0 mmol) was rearranged for 1.0 h at room temperature. The crude product was esterified with methanolic HCl, affording a mixture of esters (220 mg, 40%) that appeared by glc to contain four products (120°C, 17.0 (78), 17.7 (3), 19.8 (5) and 22.6 (14)). The major product, the methyl ester of 6-methyl-3-nonynoic acid, was obtained after chromatography (hplc, reverse phase eluting 30% H_2O–70% CH_3OH) and gave ir ν_{max} (film): 1740 cm^{-1}; ^{1}H nmr (360 MHz) δ: 3.72 (s, OCH_3, 3H), 3.25 (t, J = 2.5–Hz, $OOCCH_2$, 2H), 2.16 (ddt, J = 16.4, 5.6, and 2.5 Hz, $HCC{\equiv}C$, 1H), 2.03 (ddt, J = 16.4, 6.9, and 2.5 Hz, $HCC{\equiv}C$, 1H), 1.62 (m, $HCCH_3$, 1H), 1.1–1.4 (m, CH_2, 4H), 0.94 (d, J = 6.7 Hz, $HCCH_3$, 3H), and 0.87 (t, J = 7.1 Hz, H_2CCH_3, 3H); ms: 192 (missing), 167 (0.2), 122 (4), 112 (11), 108 (11), 84 (23), and 43 (100).

Rearrangement of 6-methyl-2-nonynoic acid (20) at 60°C

The acid **17** (500 mg, 3.0 mmol) was rearranged with the standard reagent at 60°C for 2.0 h. Methylation afforded a mixture of methyl 6-methyl-*E*,*E*- and methyl 6-methyl-*E*,*Z*-3,5-nonadienoates (280 mg), which gave 2 peaks on glc (120°C, 20.0 (26), and 22.9 (74)) but which could not be separated by any of the chromatographic techniques employed. In the 360-MHz nmr spectrum of the mixture, the olefinic, H_2CCOO, OCH_3, and methylene signals overlapped, but the allylic H δ 2.09 (t, J = 7.2 Hz) and 1.98 (t, J = 7.4 Hz) and the C-6 methyl signals δ 1.72 (s) and 1.69 (s) in the ratio of 1:3 could be distinguished. Superimposable gc/ms spectra were obtained for the isomeric products: (*1*) 182 (43), 123 (27), 108 (70), 93 (100), 81 (96), 67 (42), and 55 (27); and (*2*) 182 (42), 123 (26), 108 (67), 93 (98), 81 (97), 67 (41), and 55 (27). Accurate mass analyses of the molecular ions calcd. for $C_{11}H_{18}O_2$: 182.1306; found: 182.1289 (major product) and 182.1242 (minor product).

*5-Methyl-2-nonynoic acid (**19**)*

By a series of reactions analogous to that employed for the synthesis of 6-methyl-2-nonynoic acid, 5-methyl-2-nonynoic acid was prepared in about 12% overall yield starting from 2-methyl-1-hexene. The intermediate 5-methyl-2-nonyn-1-ol (distilled bulb-to-bulb, oven temp. 90°C, 0.05 Torr, 31% from 2-methyl-1-hexene) gave ir ν_{max} (film): 3350, 2200, and 1010 cm^{-1}; ^1H nmr (360 MHz) δ: 4.21 (t, J = 2.2 Hz, OCH_2, 2H), 2.16 (ddt, J = 16.6, 5.7, and 2.2 Hz, C≡CCH, 1H), 2.03 (ddt, J = 16.6, 7.0, and 2.2 Hz, C≡CCH, 1H), 1.58 (m, $HCCH_3$, 1H) 1.1–1.4 (m, CH_2, 6H), 0.92 (d, J = 6.6 Hz, $HCCH_3$, 3H), and 0.86 (6, J = 6.8 Hz, H_3CCH_2, 3H); ^{13}C nmr: 85.2, 79.3, 51.3, 35.8, 32.6, 29.3, 26.2, 22.9, 19.5, and 14.1 ppm; gc/ms of TMS ester: 226 (missing), 211 (10), 181 (24), 169 (7), 142 (6), 135 (8), 127 (12), 75 (100), and 73 (65). Jones oxidation gave the acid **16** (77%), which was distilled (bulb-to-bulb, oven temp. 120°C, 0.1 Torr) and gave ir ν_{max} (film): 3100, 2220, and 1670 cm^{-1}; ^1H nmr (360 MHz) δ: 2.31 (dd, J = 17.2, 5.7 Hz, C≡CCH, 1H), 2.21 (dd, J = 17.2, 7.0 Hz, C≡CCH, 1H), 1.72 (m, $HCCH_3$, 1H), 1.2–1.5 (m, CH_2 6H), 0.98 (d, J = 6.7 Hz, $HCCH_3$, 3H), and 0.87 (t, J = 6.8 Hz, H_2CCH_3, 3H); ^{13}C nmr: 158.4, 91.7, 73.7, 35.8, 32.1, 29.2, 26.1, 22.8, 19.5, and 14.0 ppm; gc/ms of TMS ester: 240 (missing), 225 (61), 181 (82), 156 (29), 96 (26), 75 (83), 73 (94), and 43 (100); accurate mass analysis for TMS ester − CH_3 calcd. for $C_{12}H_{21}O_2Si$: 225.1310; found 225.1392.

*Rearrangement of 5-methyl-2-nonynoic acid (**19**)*

The rearrangement of 5-methyl-2-nonynoic acid (336 mg, 2.0 mmol) was carried out under standard conditions for 2.0 h at 60°C, affording, after methylation and chromatography, a mixture of isomeric compounds (102 mg, 28%), the principal component (78%) of which was methyl 5-methyl-*E*,*E*-3,5-nonadienoate. This compound gave gc/ms: 182 (24), 108 (47), 93 (100), and 81 (49). The mixture gave an ir ν_{max} (film): 1740, 1640, 960, and 760 cm^{-1}; ^1H nmr (360 MHz) δ: 6.12 (dd, J = 15.6, 0.3 Hz, H-4, 1H), 5.59 (dt, J = 15.6, 7.2 Hz, H-3, 1H), 5.42 (t, J = 7.3 Hz, H-6, 1H), 3.66 (s, OCH_3, 3H), 3.10 (d, J = 7.2 Hz, H-2, 2H), 2.07 (dt, J = 7.3, 7.4 Hz, C=CCH_2, 2H), 1.72 (d, J = 0.3 Hz, H_3CC=CH, 3H), 1.32–1.42 (m, CH_2, 2H), and 0.88 (t, J = 7.4 Hz, H_3CCH_2, 3H), and other signals of low intensity at δ: 6.51 (d, J = 15 Hz, H-4), 3.67 (s, OCH_3), 2.17 (m, C=CCH_2), and 1.86 (H_3CC=C) due to the *E*,*Z*-isomer. An accurate mass analysis was obtained for the molecular ion of the major component calcd. for $C_{11}H_{18}O_2$: 182.1306; found: 182.1228.

*4-Cyclohexyl-2-butynoic acid (**21**)*

To a solution of 4-cyclohexyl-2-butyn-1-ol (17) (2.0 g, 13.2 mmol) in acetone at 0°C was added a solution of CrO_3 (3.3 g, 33 mmol) in H_2O (13 mL) and H_2SO_4 (4.4 mL). After stirring for 0.5 h, isopropanol was added until the mixture was green, then the solvents were evaporated and ether was added. The aqueous phase was washed with ether (3×), and the combined organic phases were washed with $NaHCO_3$ solution (2×). The combined $NaHCO_3$ phases were acidified with HCl, then extracted with ether (3×). The combined organic phases were then washed with NaCl solution (1×), dried over Na_2SO_4, filtered, the solvent evaporated, and the residue distilled (bulb-to-bulb, oven temp. 120–150°C, 0.075 Torr) affording 4-cyclohexyl-2-butynoic acid (**21**) (1.0 g, 50%). This compound gave ir ν_{max} ($CHCl_3$ solution): 3600, 3100, 2200, and 1680 cm^{-1}; ^1H nmr (90 MHz) δ: 2.26 (d, J = 6 Hz, H_2CC≡C, 2H), and 0.8–2.0 (m, 11H); gc/ms of TMS ester: 238 (0.8), 223 (72), 179 (100) and 156 (44); accurate mass analysis for the molecular ion of the TMS ester − CH_3 calcd. for $C_{12}H_{19}O_2Si$: 223.1164; found 223.1159.

*Rearrangement of 4-cyclohexyl-2-butynoic acid (**21**)*

Rearrangement of the acid **21** (664 mg, 4.0 mmol) for 2.0 h at 60°C under the standard conditions afforded, after methylation with CH_2N_2 and chromatography over silica gel, the dienoic methyl ester of **26** (280 mg, 40%), which gave ir ν_{max} (film): 1730 and 960 cm^{-1}; ^1H nmr (360 MHz) δ: 6.08 (d, J = 15.8 Hz, H-4, 1H), 5.58 (br t, J = 7.4 Hz, HC=CCH_2, 1H), 5.56 (dt, J = 15.8, 7.2 Hz, H-3, 1H), 3.66 (s, OCH_3, 3H), 3.08 (d, J = 7.2 Hz, $OOCCH_2$, 2H), 2.02–2.12 (m, H_2CC=C, 4H), and 1.5–1.7 (m, CH_2, 4H); gc/ms of methyl ester: 180 (30), 165 (0.5), 130 (8), 121 (33), 106 (39), 91 (57), and 79 (100); accurate mass analysis for the molecular ion of the methol ester calcd. for $C_{11}H_{16}O_2$: 180.1151; found: 180.1121.

*5-cyclohexyl-2-pentynoic acid (**22**)*

Employing an analogous set of conditions to that for the synthesis of 4-cyclohexyl-2-butynoic acid, 5-cyclohexyl-2-pentynoic acid was prepared starting with 1-bromo-2-cyclohexylethane. The acid **22** (distilled bulb-to-bulb, oven temp. 130–145°C, 0.05 Torr) gave ir ν_{max} (film): 3100, 2220, and 1680 cm^{-1}; ^1H nmr (90 MHz) δ: 2.3 (t, J = 7 Hz, H_2CC≡C, 2H), and 0.8–1.9 (m, CH_2, CH, 13H); ^{13}C nmr: 158.6, 92.9, 72.5, 36.6, 34.7, 32.6, 26.4, 26.0, and 16.1 ppm; gc/ms of TMS ester: 252 (missing), 237 (27), 193 (38), 162 (21), 133 (22), and 73 (100); accurate mass analysis for TMS ester − CH_3 calcd. for $C_{13}H_{21}O_2Si$; 237.1295; found: 237.1302.

*Rearrangement of 5-cyclohexyl-2-pentynoic acid (**22**)*

Rearrangement of the acid **19** for 2.0 h at 60°C with the standard reagent afforded, after methylation with CH_2N_2 and chromatography over silica gel, eluting with 20% ether – 80% hexane, the methyl ester of **27**, (110 mg, 28%). This compound gave ir ν_{max} (film): 1730, 960 and 760 cm^{-1}; ^1H nmr (360 MHz) δ: 6.30 (ddt, J = 15.0, 10.9, and 1.4 Hz, H-4, 1H), 5.71 (d, J = 10.9 Hz, H-5, 1H), 5.57 (dt, J = 7.2, 7.0 Hz, H-3, 1H), 3.62 (s, OCH_3, 3H), 3.06 (dd, J = 7.2 Hz, 1.0 Hz, H-2, 1H), 2.18–2.24 and 2.05–2.08 (m, C=CCH_2, 4H), and 1.46–1.52 (m, CH_2, 4H); gc/ms: 194 (62), 162 (7), 144 (11), 135 (40), 120 (99), 91 (87), 79 (90), and 67 (100); accurate mass analysis for the molecular ion of the methyl ester calcd. for $C_{12}H_{18}O_2$: 194.1307; found: 194.1305.

Acknowledgments

Professor J. E. Baldwin is thanked for a preprint of a manuscript on stereochemical generalizations and prediction for 1,3-prototropic shifts under basic conditions. Professor J. W. ApSimon gave up several hours of sunshine and presented this material, in my place, at the PAC Chem meeting in Honolulu, December 1984. I would like to acknowledge the expert technical assistance of Angela C. Shaw. L. Hogge, D. Olson, and T. Mazurek performed the gc–ms and nmr experiments.

The structure of $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(Ph_2PCH_2PPh_2)_2][BF_4]$ and comparisons with its rhodium analogue and other related doubly bridged A-frames

BRUCE R. SUTHERLAND AND MARTIN COWIE[1]

Received August 7, 1985

BRUCE R. SUTHERLAND and MARTIN COWIE. Can. J. Chem. **64**, 464 (1986).

The structure of $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2][BF_4]$ (DPM=$Ph_2PCH_2PPh_2$) has been determined crystallographically. It crystallizes in the monoclinic space group $P2_1/n$ (a = 13.7740(6) Å, b = 15.277(2) Å, c = 23.581(2) Å, β = 97.015(5)°, V = 4924.9 Å^3, Z =4) and on the basis of 6628 unique observations and variation of 272 parameters, the structure converged to R = 0.031 and R_w = 0.043. This metal–metal bonded complex is similar to its rhodium analogue, having the two essentially identical Ir centres bridged by the carbonyl, hydride, and two diphosphine ligands. The major difference between this compound and the rhodium species (in the solid state) relates to the orientation of the phenyl groups of the diphosphine ligands; in the iridium complex four of these groups block the sites adjacent to the bridging hydride ligand, whereas these sites are relatively unobstructed in the rhodium analogue. This difference may result in different coordination sites for substrate molecules and therefore in different chemistry.

BRUCE R. SUTHERLAND et MARTIN COWIE. Can. J. Chem. **64**, 464 (1986).

Faisant appel à la cristallographie, on a déterminé la structure du complexe $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2][BF_4]$ (DPM=$Ph_2PCH_2PPh_2$). Il cristallise dans le groupe d'espace $P2_1/n$ (a = 13,7740(6) Å, b = 15,277(2) Å, c = 23,581(2) Å, β = 97,015(5)°, V = 4924,9 Å^3, Z = 4) et sur la base de 6628 observations uniques et de 272 paramètres, on a affiné la structure jusqu'à des valeurs respectives de R et R_w de 0,031 et 0,043. Ce complexe comportant une liaison métal–métal est semblable à son analogue contenant du rhodium et il possède deux centres Ir qui sont essentiellement identiques et qui sont liés par le carbonyle, l'hydrure et les deux ligands diphosphines. La principale différence entre ce composé et son analogue contenant du rhodium (à l'état solide) a trait à l'orientation des groupements phényles des ligands diphosphines; dans le complexe de l'iridium quatre de ces groupements bloquent les sites adjacents au ligand hydrure agissant comme pont alors que dans le complexe au rhodium ces sites ne sont pas bloqués. Il est possible que cette différence puisse provoquer des différences dans les sites de coordination pour les molécules de substrats et conduire ainsi à des chimies différentes.

Introduction

We have recently shown (1) that catalysis of the water–gas shift (WGS) reaction, by complexes containing two metal centres, can be effectively modelled by using DPM-bridged (DPM = $Ph_2PCH_2PPh_2$), hydrido, and hydroxy complexes of iridium. In particular, the observation of $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$ in our WGS cycle prompted us to suggest that this cycle could serve as a model for the one in which the rhodium analogue, $[Rh_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$, acted as catalyst or catalyst precursor (2). However, one notable difference in the chemistry of the above two hydrido-bridged complexes of Rh and Ir concerned their chemistry with acid; whereas the Rh species instantly evolved H_2 upon treatment with acid (2), the Ir complex yielded a stable dihydride from which H_2 could be evolved only under forcing conditions (1). Although this difference is in line with the well known greater stability of iridium-hydrides over those of rhodium (3), we were led to believe that an additional, equally important difference lay in the sites of protonation of the two complexes. We suggested (1) that protonation of the Rh complex occurred adjacent to the bridging hydride ligand such that reductive elimination of H_2 could be facile, whereas with the Ir complex initial protonation occurred opposite the bridging hydride ligand such that a ligand rearrangement would have to precede reductive elimination of H_2, thereby hampering the reductive elimination step.

In order to explain this postulated difference in protonation sites we undertook a structural determination of the above iridium hydride complex in order to compare it with the structure of the rhodium analogue (2). Furthermore, it was of interest to us to establish what differences might be present in the two compounds as an aid in determining how close an analogy could be drawn between complexes of rhodium and iridium. Such conclusions are important in studies in which rhodium-containing catalysts are modelled by their iridium analogues. Herein we report the results of this structure determination and a comparison between the two rhodium and iridium compounds.

Experimental

The complex $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2][BF_4]$ was prepared by the protonation of $[Ir_2(CO)_3(DPM)_2]$ using $HBF_4\cdot OEt_2$, as has previously been reported (1). Dark orange crystals of the title complex of suitable X-ray diffraction quality were obtained from the slow diffusion of diethyl ether into a saturated CH_2Cl_2 solution of the complex. These crystals proved to be air stable so they were handled in air and the one chosen for the crystallographic study was mounted on a glass fibre using epoxy adhesive. Unit cell parameters were obtained from a least-squares refinement of the setting angles of 25 reflections, in the range of $20.0° < 2\theta < 25.0°$, which were accurately centred on an Enraf–Nonius CAD4 diffractomer using MoKα radiation. The systematic absences ($h0l$: $h+l$ = odd, $0k0$: k = odd) were consistent with the space group $P2_1/n$; this nonstandard setting of $P2_1/c$ was retained because of the convenient β angle.

Intensity data were collected on a CAD4 diffractometer in the bisecting mode employing the ω–2θ scan technique up to 2θ = 50.00° with graphite monochromated MoKα radiation. Backgrounds were scanned for 25% of the peak width on either end of the peak scan. The intensities of three standard reflections were measured at 1 h intervals of exposure to assess possible crystal decomposition or movement. No significant variation in these standards was noted, so no correction was applied to the data. A total of 8677 unique reflections were measured and processed in the usual way using a value of 0.04 for p (4); of these, 6628 were considered to be observed and were used in subsequent

calculations. Absorption corrections were applied to the data by using Gaussian integration (5).[2] See Table 1 for pertinent crystal data and details of intensity collection.

Structure solution and refinement

The structure was solved in the space group $P2_1/n$ using standard Patterson and Fourier techniques. All atoms, including hydrogens, were ultimately located. Atomic scattering factors were taken from Cromer and Waber's tabulations (6) for all atoms except hydrogen, for which the values of Stewart *et al.* (7) were used. Anomalous dispersion terms (8) for Ir and P were included in F_c. The carbon atoms of the phenyl rings were refined as rigid groups having D_{6h} symmetry, C—C distances of 1.39 Å and independent isotropic thermal parameters. All hydrogen atoms of the diphosphine ligands were located and included as fixed contributions but were not refined. Their idealized positions were calculated from the geometries about their attached carbon atoms using C—H distances of 0.95 Å. Each hydrogen atom was assigned an isotropic thermal parameter of 1 Å^2 greater than the B (or equivalent isotropic B of anisotropic atoms) of its attached carbon. The bridging hydride ligand was successfully located and was refined isotropically. All other non-hydrogen atoms were refined anisotropically.

The final model in the space group $P2_1/n$ with 272 parameters refined converged to R = 0.031 and R_w = 0.043.[3] On the final difference Fourier map, the 20 highest residuals (0.7–1.2 e/Å^3) were in the vicinities of the Ir and P atoms and the BF_4^- counterion; these compare with intensities of ca. 6.0 e/Å^3 on earlier Fourier maps for carbon atoms. Listings of coordinates and isotropic thermal parameters for nongroup and group atoms are given in Tables 2 and 3, respectively. Anisotropic thermal parameters, hydrogen parameters, and structure amplitudes have been deposited as supplementary information and are available on request (Tables 6, 7, and 8, respectively).[4]

[a]Estimated standard deviations in this and other tables are given in parentheses and correspond to the least significant digits.

[b]For all atoms except H(1), the values given are the equivalent isotropic thermal parameters.

Description of structure and discussion

The complex, $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2][BF_4]$, crystallizes from CH_2Cl_2 in two crystal modifications, a red form and an orange form (the orange form has ir spectral parameters very similar to those of the solution spectrum (1)). The structure of the orange form has been determined crystallographically and is reported here. The unit cell contains four anions and four cations, all of which are separated by normal van der Waals distances between the constituent atoms. A perspective view of the complex cation is shown in Fig. 1, and tabulations of distances and angles are given in Tables 4 and 5. The BF_4^- anion has the expected tetrahedral geometry, and as is common with such pseudo-spherical groups, displays some degree of disorder as indicated by the large thermal parameters. Nevertheless, the metrical parameters of this group are normal.

[2]All initial computing, including structure solution, absorption correction and least-squares refinement, was carried out on a PDP-11 PLUS computer using the Enraf–Nonius structure solution package. The final few refinements using the rigid-group approximation for the phenyl rings, and other structure completion operations were carried out on the University Amdahl computer using programs that are described in ref. 5.

[3]$R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$.

*X_c, Y_c, and Z_c are the fractional coordinates of the centroid of the rigid group.

†The rigid group orientation angles, phi, theta, and rho (radians), are the angles by which the rigid body is rotated with respect to a set of axes *X*, *Y*, and *Z*. The origin is the centre of the ring, *X* is parallel to *a**, *Z* is parallel to *c*, and *Y* is parallel to the line defined by the intersection of the plane containing *a** and *b** with the plane containing *b* and *c*.

As shown in Fig. 1, the cation has the typical geometry for a bis DPM-bridged complex (9), with both diphosphine ligands in an essentially *trans* arrangement on each metal. The remaining ligands lie in the plane which is essentially perpendicular to the metal phosphine vectors, and are arranged symmetrically such that each metal shares the bridging hydride and carbonyl ligands and also has a terminal CO group. If the Ir–Ir interaction is ignored, the metal geometries can be described as square pyramidal with the bridging carbonyl at the common apex of the two pyramids. The angles between the pseudo-*trans* ligands in the two pyramids average 169.29(6) and 155(2)° for the P—Ir—P and OC—Ir—H(1) angles, respectively. The major distortion from the square pyramidal geometry for each metal results because the bridging carbonyl group is offset towards the adjacent metal yielding an average H(1)—Ir—C(3) angle (86(2)°) which is much less than average C(3)—Ir—CO(terminal) angle (119.0(3)°).

The compound is clearly metal–metal bonded, with the Ir(1)—Ir(2) distance of 2.7661(4) Å corresponding to a normal Ir—Ir single bond; a range of distances between 2.779(1) and 2.893(2) Å seems to be typical in related Ir—Ir bonded species (10–13). Support for a metal–metal bonded formulation comes from the intraligand P–P separations (av. 2.999(2) Å), which indicate a compression along the Ir—Ir axis due to mutual attraction of the metals. The geometry of the bridging carbonyl ligand is typical for such a group accompanied by a metal–metal bond (14), therefore the Ir(1)—C(3)—Ir(2) angle, of 81.9(3)° is acute. Both terminal carbonyl groups are normal, with Ir—C distances much shorter than those on the bridging group. All parameters within the bridging DPM ligands are normal.

Refinement of the bridging hydride ligand proceeded well and the resulting Ir—H distances (av. 1.75(7) Å) are in good agreement with each other and are in the range normally observed for hydrides which bridge second and third row group VIII metals (15, 16). The angle at the bridging hydride is 105(4)°. These parameters agree rather well with those in the closely related Rh analogue (2) where Rh—H distances of 1.97(11) and 1.75(11) Å and a Rh—H—Rh angle of 94(5)° were observed.

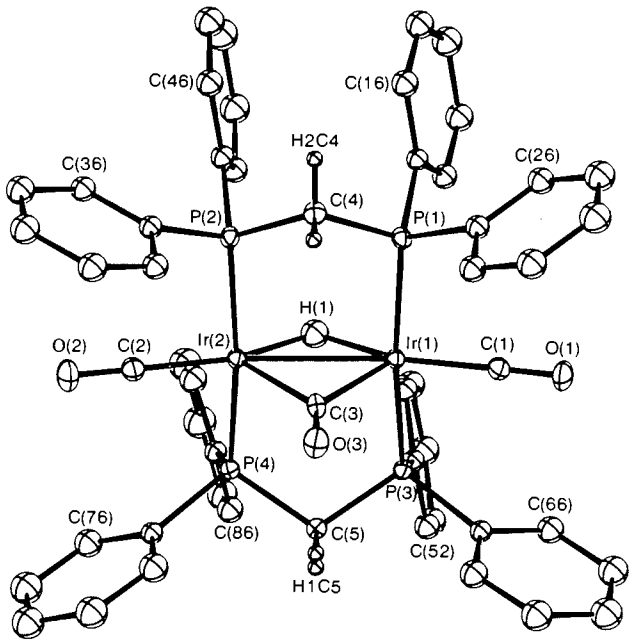

FIG. 1. A perspective drawing of the $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$ cation showing the numbering scheme. The numbering of the phenyl carbons starts at the one bound to phosphorus and proceeds sequentially around the rings. Thermal ellipsoids are shown at the 20% level except for the methylene hydrogen atoms, which are shown artificially small.

(*b*) Nonbonded distances

Atoms	Distance	Atoms	Distance
P(1)–P(2)	2.996(2)	Ir(1)–H(56)	3.20
P(3)–P(4)	3.001(2)	Ir(2)–H(42)	3.06
Ir(1)–H(12)	3.02	Ir(2)–H(82)	3.01

The differences in the metal–hydrogen bond lengths between the two compounds are not significant and the more acute angle at the hydride ligand in the Rh complex results from the somewhat shorter Rh—Rh separation and the one slightly longer Rh—H distance.

The present compound is most clearly related to three other so-called (17) doubly bridged A-frame complexes: namely, $[Rh_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$ (2), $[Rh_2(CO)_2(\mu\text{-}Cl)(\mu\text{-}CO)(DPM)_2]^+$ (18), and $[Ir_2(CO)_2(\mu\text{-}S)(\mu\text{-}CO)(DPM)_2]$ (13). All four compounds have pseudo-*trans* bridging DPM arrangements, one terminal CO on each metal, a bridging CO, a bridging formally anionic ligand, and a metal–metal bond. Superficially, the structures of all four complexes are essentially identical (apart from the obvious differences in the bridging anionic ligands). Although it is not surprising that Rh and Ir analogues are similar or that the two complexes containing bridging chloride and sulfide ligands are similar, it is surprising that the two bridging hydride complexes should so closely resemble the others since the hydride complexes have two fewer valence electrons. One might therefore expect differences in the metal–metal bond orders, although such is not observed. All four metal–metal separations correspond to normal single bonds (2.7661(4) (iridium hydride), 2.731(2) (rhodium hydride), 2.8415(7) (rhodium chloride), and 2.843(2) Å (iridium sulfide)). The longer distances in the chloride and sulfide complexes seem to result from the larger covalent radii of these bridging groups tending to force the metals apart. Consistent with these observations, extended Hückel calculations by Hoffman and Hoffmann (17) indicated that the molecular orbitals for $[Rh_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$ and $[Rh_2(CO)_2(\mu\text{-}Cl)(\mu\text{-}CO)(DPM)_2]^+$ were rather similar so that in spite of the two valence-electron difference no metal–metal bond-order difference was predicted.

In addition to the obvious comparisons noted above, the present compound can also be compared with other binuclear group VIII diphosphine compounds in which the metal–metal bonds are simultaneously bridged by hydrido and carbonyl groups. Two such species are $[Rh_2Cl_3(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]$ (19) and $[Pt_2(\mu\text{-}H)(\mu\text{-}CO)(DPE)_2]$ (DPE = $Ph_2PCH_2CH_2PPh_2$) (20). Not unexpectedly, the parameters involving the $M_2(\mu\text{-}H)(\mu\text{-}CO)$ cores in these molecules are quite similar and are normal for metal–metal bonded species.

The structure determination of $[Ir_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$ was undertaken to provide a basis for comparison between it and the analogous rhodium hydride. In particular, we sought to determine whether the structural information might suggest reasons for the apparent difference in protonation sites (1). The most obvious structural parameters which might explain these differences are the angles between the bridging hydrido and terminal carbonyl ligands and between the bridging and terminal carbonyl ligands; these would give a measure of the "openness" of the possible protonation sites. However, in our opinion, in the two hydride complexes these angles, averaging 153(4) and 113.5(9)°, respectively, for the Rh complex, and 155(2) and 119.0(3)° for Ir, do not differ enough to explain the different protonation sites, even though the Ir complex is somewhat more open adjacent to the bridging carbonyl ligand than the Rh analogue. There is one significant difference between the iridium hydride and the above three related A-frame complexes which may have a significant influence on the chemistry; this pertains to the orientations of the phenyl groups. In the three other complexes the diphosphine methylene groups are bent towards the bridging anionic ligands, thereby thrusting four phenyl groups (actually an *ortho* hydrogen from each) into the vacant sites between the bridging and terminal carbonyl ligands. This would effectively block these sites and would instead favour protonation at the sites adjacent to the bridging hydride ligand in $[Rh_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$. The present iridium hydride differs significantly in this regard; its DPM methylene groups bend towards the

bridging CO ligand, and four phenyl groups (1,4,5, and 8) block the sites adjacent to the bridging hydride ligand. Two of the *ortho* hydrogen – iridium contacts are less than 3.02 Å and are much less than those contacts on the other side of the dimer where all are greater than 3.7 Å. Although the short Ir—H contacts are not particularly unusual (rhodium – *ortho* hydrogen contacts of ca. 2.8 Å are observed in Wilkinson's compound (21)) they are shorter than those in the rhodium analogue of our compound (2), where the shortest such contact is 3.18 Å, but more importantly they are on the *opposite* face of the dimer. If the observed solid state structures were maintained in solution, the reason for the apparently different protonation sites would seem to be clear; in the rhodium compound the *ortho* hydrogens of four phenyl groups block the sites *opposite* the bridging hydride ligand whereas in the iridium analogue the sites *adjacent* to the hydride ligand are blocked. However, the structures in solution will *not* be static and might be expected to fluctuate between the two extremes observed for the Rh and Ir compounds. Nevertheless, a difference in energy of only a few kilojoules per mole between the two extremes will have a very significant effect on the equilibrium concentration of these species. We therefore propose that the solid state structure observed for the iridium complex is the more thermodynamically favoured in solution (for which we can offer no explanation). This would tend to favour subsequent protonation at the site *opposite* the bridging hydride ligand. It may also be that with the Rh complex the thermodynamically favoured protonation product has the two hydride ligands mutually *cis* (before reductive elimination of H_2) whereas for Ir the favoured product has the two hydride ligands mutually *trans*. Again, it is worth reemphasizing that the ir spectrum of the crystals studied is very similar to that in solution, suggesting that there are no major differences between the solid state structure and the structure in solution.

The observed structural differences between the compounds, $[M_2(CO)_2(\mu\text{-}H)(\mu\text{-}CO)(DPM)_2]^+$ (M = Rh, Ir), have other potentially relevant consequences regarding modelling of rhodium-catalyzed reactions by the iridium analogues. Although this approach can yield useful information, caution must be taken not to extend analogies too far. We can see this in the two hydrides being discussed and in their potential reactions with substrate molecules such as olefins; with the rhodium compound, a substrate molecule reacting adjacent to the bridging hydride group is in a position for hydride migration (yielding an alkyl species) to occur, whereas with the iridium analogue it is conceivable that the substrate molecule might coordinate *trans* to the hydride ligand and consequently *not* be in a position for a facile hydride migration. Clearly the chemistry would then differ. We are currently pursuing these ideas.

A bonded polyoxyethylene phase for gas and liquid chromatography[1]

PALITHA P. WICKRAMANAYAKE[2] AND WALTER A. AUE[3]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3
Received July 14, 1983[4]

PALITHA P. WICKRAMANAYAKE and WALTER A. AUE. Can. J. Chem. **64**, 470 (1986).

Bonded phases were produced by reacting 2,4,7,9-tetramethyl-5-decyne-4,7-bis(polyethyleneoxide 30 mol) ether (Surfynol® 485) with silicic supports of high and low surface area. There is circumstantial evidence (a) that the nonextractable layer is held by multiple hydrogen bonding and (b) that the synthesis of these packings involves a reaction at the crosslinking site of the surfactant. The bonded phases, with layer thicknesses between 10 and 30 Å, were tested with three chromatographic techniques. In gas–solid chromatography, the phase proved well deactivated and yielded a reduced plate height of 2.5 (using a silica gel support). In gel permeation chromatography, polyethyleneglycols eluted within the mobile-phase volume. In liquid–solid (normal-phase adsorption) chromatography, the elution pattern differed significantly from that of unmodified silica gel. In each case, high-efficiency separations were obtained. The chromatographic experiments thus demonstrated the potential usefulness of the new phase for both gas and liquid chromatography. However, it was not tested in direct comparison with conventional phases nor was its utility established by subjecting it to routine analytical use.

PALITHA P. WICKRAMANAYAKE et WALTER A. AUE. Can. J. Chem. **64**, 470 (1986).

On a préparé des phases liées en faisant réagir du Surfynol® 485 avec des supports siliciques possédant des surfaces élevées ou basses. Des preuves circonstancielles permettent de croire (a) que la phase qui ne peut pas être extraite est liée par des liaisons hydrogènes multiples et (b) que la synthèse des ces garnissages implique une réaction au site de réticulation de l'agent de surface. On a vérifié l'utilité des phases liées, dont l'épaisseur varie entre 10 et 30 Å, en faisant appel à trois techniques chromatographiques. Dans la chromatographie gaz–solide, la phase s'avère bien désactivée et conduit à une hauteur réduit de plateau de 2,5 (en utilisant un support de gel de silice). Dans la chromatographie par perméation de gel, les polyéthylèneglycols sont élués avec le volume de la phase mobile. Dans la chromatographie liquide–solide (adsorption de phase normale), les caractéristiques de l'élution diffèrent beaucoup de celles observées avec une gel de silice qui n'a pas été modifié. Dans tous les cas, on a obtenu des séparations avec une grande efficacité. Les expériences chromatographiques ont donc démontrées l'usage potentiel de la nouvelle phase tant en chromatographie liquide que gazeuse. Toutefois, on ne l'a pas évalué par comparaison directe avec des phases conventionnelles et on n'a pas établi non plus son utilité en la soumettant à des utilisations analytiques de routine.

[Traduit par le journal]

Introduction

Ever since we described the "unexpected behavior of a common gas chromatographic phase" (1) in forming thin, nonextractable layers on typical gc supports, we wondered if polymers other than Carbowax-20M (CW-20M) could be used to achieve an equally surprising performance. A variety of materials were tried, from other polyethers to polyesters, silicones, and even hydrocarbons (2–5). Some rivaled, but none excelled, CW-20M.

The "bonded" layers made from this modified polyethyleneglycol (as well as from other common liquid phases) have rather interesting uses and properties (6–34). As far as one can tell from the commercial literature, similar separation media have been produced under different trade names by a variety of chromatographic supply houses and, more recently, by HNU, Dow (35). The high-temperature bonding technique has also been used with great success for the deactivation of, and the formation of insoluble layers in, glass capillaries (36–40).

It is primarily this aspect of deactivation that has made the bonded layers valuable for gas chromatography. In liquid chromatography, deactivation is usually a matter of choosing a suitable solvent mixture. Hence, it is not surprising that, as far as we can tell, these particular CW-20M-based phases have not found significant use in hplc.

Typical hplc phases are, of course, produced by reacting the silica surface with silane *monomers* (41–45). Still, several reports can be found in the literature of *polymers* being bonded to microparticulate supports. Of particular interest in the present context are early syntheses using short-chain polyethyleneglycols (46, 47) in analogy to the esterification of silica with alcohols (48), and the more recent development of cross-linked polyethyleneimine layers (49, and references quoted therein).

Our heat-treated, CW-20-M-based layer was assumed to derive its nonextractability (i.e., its bonded character) primarily from the polymer stretching out on the surface. Nonextractability was postulated to arise from multi-point sorption coupled with conformational changes in the chain, which made it orient to, and fit the silicic surface at minimum potential energy (27, 32). The multi-point contacts were presumed to involve hydrogen bonds between surface silanols and polyether oxygens.

Such hydrogen bonding is, of course, well-known and has been exploited to a variety of ends (50). To cite a chromatographic example, polyethyleneglycols and similar materials are frequently used to prevent denaturation and irreversible adsorption of proteins in size exclusion chromatography (51–53, and references therein). The distinguishing feature of the heat-treated Carbowax phase is, however, that a thin (≈15 Å on Chromosorb W) layer remains affixed to the surface even through week-long continuous extractions with protic solvents such as methanol.

More recent support for the postulated conformational

[4]Revision received November 8, 1985.

changes induced by heat treatment (32) has come from interesting ir studies of Kaiser and Chase (54). The authors also claimed that the infrared spectra showed the terminal hydroxyls of the Carbowax entering ester bonds with the surface silanols.

Such a reaction is, of course, to be expected under aprotic conditions (48), provided the polymer did indeed contain terminal hydroxyls. If the heat-treated layers were extracted with, say, toluene, such terminal bonds should persist. If they were extracted with, say, methanol, the ester bonds should hydrolize (really, methanolize). As far as the bonded character of the layer is concerned, terminal ester linkages contribute, if at all, in a rather insignificant way; to wit, if nonextractability were primarily due to silicic ester bonds, the layer could not be stable to extended extraction by boiling methanol.

Whether in a synthetic, chromatographic, or analytical context, one can appreciate the potential magnitude of the two effects, terminal hydroxyl esterification versus hydrogen bonding of chain oxygens, by formally comparing the number of hydroxyls to the number of ether linkages in the polymer. Taking for demonstration a fictional, OH-terminated polyethyleneglycol of about 20 000 molecular weight, there are 227 —O— groups for a single —OH.

To characterize further the nature of the thin, bonded layers derived from CW-20M would clearly pose an interesting challenge. The present state of knowledge can perhaps be most aptly defined as reasonable conjecture. In a wider context, layers oriented within the range of surface forces are fascinating though complex objects of study. The interests involved range from basic investigations in physical chemistry (55, 56) and chromatography (57–65), over biological interfaces, adhesive joints, and the oceans' top layer, to dishwashing (66, 67). Some physicochemical aspects of thin layers, as seen by gas chromatography, have been reviewed (68). Not unexpectedly, the best performing of these systems exhibit a polarity lower than that of the polymer from which they originated. Furthermore, they are generally superior to conventional glc packings in resolving positional isomers; and their resistance to mass transfer in the stationary phase is very low.

Also of interest in this discussion is the excellent gas chromatography of alcohols on the CW-20M-based columns. A simple argument will show why. Alcohols often elute with poor peak shapes from conventional separation media, and this is commonly blamed on the interaction of their hydroxyl groups with the silanols of the silicic support. Now, one can exhaustively treat such a support with a small silanizing reagent. On the resulting thin, organic layer, atop mostly "capped" silanol groups, alcohols (of the same or larger size than the silanizing reagent) usually do migrate similarly with broad and (or) asymmetric concentration profiles. Compare this with the highly efficient alcohol chromatography on a Carbowax-modified surface, even though the latter kept its silanol groups intact (though partly hydrogen-bonded) under a comparably thin polyether layer. Clearly this situation is not adequately explained by the current conceptual framework.

The search for a new liquid phase to be used in the synthesis of improved bonded layers obviously raises the question of what constitutes improvement. In terms of one particular criterion, heat stability, this search has been successful. Verzele and coworkers developed a type of polyethyleneglycol free of polymerization catalyst and therefore of considerably higher stability (69). These low-bleed "Superox" phases have found extensive use as Carbowax substitutes. Similar to CW-20M, they can deactivate glass capillary columns (40). When used in our experiments like CW-20M on Chromosorb W, the material bonded well and the layer remaining after exhaustive extraction could be heated overnight at 300°C without loss of chromatographic performance.

With this exception, CW-20M has been by far the best of any polyethylene or polypropylene glycol tested. The only interesting fact to note from past attempts to find a superior material is that certain short polypropyleneglycol chains performed comparatively well with a wide-pore silica gel such as Davison grade 62. (The analogous reaction with CW-20M is troublesome since a high concentration of polymer is required and the support particles tend to stick together. There may also have been some difficulty for CW-20M molecules to migrate into some of the narrower pores, as discussed later.)

The unique structural characteristic of CW-20M among the polyethyleneglycols (including "linear CW-20M") is that it is "prepared by joining together two 7500 molecular weight alpha-*hydro*-omega-hydroxypoly(oxyethylene) molecules with a diepoxide" (70). That puts an aromatic "kink" in the structure and the obvious question arises whether this kink has anything to do with CW-20M's superior bonding ability.

The diepoxide employed for making CW-20M (as well as a series of other conventional cross-linking agents with two or more oxirane functional groups) did show some evidence of bonding when subjected to the same conditons as CW-20M in preliminary experiments. Without exception, however, the chromatographic performance was very poor. This suggested that the polyethyleneglycol chains were necessary for producing a chromatographically efficient layer. Furthermore, phases synthesized from CW-20M often had a phenol-like smell, a possible indication that (parts of) the cross-linking agent had indeed been liberated from its chains. Why this should lead to better bonding is not immediately clear. As far as the search for a competitor to CW-20M is concerned, however, it made empirical sense to look for a smaller molecule containing two polyethyleneglycol chains with a kink in the middle.

Fortunately, we became aware of an inexpensive commercial material that seemed to fit the bill. Figure 1 shows the structure of 2,4,7,9-tetramethyl-5-decyne-4,7-bis(polyethyleneoxide) 30 mol) ether. The material is known by its trademark as Surfȳnol® 485, a surfactant made by Air Products (71). Its acetylenic cross-linking agent, 2,4,7,9-tetramethyl-5-decyne-4,7-diol is also used as a surfactant, and is marketed as Surfȳnol® 104 (71). The performance of Surfȳnol 104 in bonding experiments was mediocre at best, not unlike that of its aromatic counterpart in CW-20M. Surfȳnol 485, on the other hand, did very well indeed.

Experimental

Chromosorb W, 45–60 mesh, and silica gel 62, 100–120 mesh, were exhaustively acid-washed. Lichrosorb and Lichrospher Si-100, 10 μm, were used as received.

The synthesis of the bonded phases was carried out in refluxing hexadecane under nitrogen as described earlier for CW-20M (4), followed by exhaustive extraction with methanol in a high-speed apparatus (72). Unless otherwise noted, Surfȳnol was added at 6 weight% load to Chromosorb and at 60% load to the other supports. Elemental analyses were carried out by Guelph Chemical Laboratories, Guelph, Ont.; surface area determinations were done by Micromeritics, Norcross, GA.

Gas chromatographic columns were 100 × 0.2 cm id, except as noted, and liquid chromatographic columns were 10 × 0.4 cm id. The latter were packed by the balanced-density method using tetrabromoethane and carbon tetrachloride.

FIG. 1. Structure of two Air Products Surfynol® surfactants.

Ancillary experiment

The Si—OH group of both Chromosorb W and silica gel 62 were converted to Si—NH_2 by a modification of Peri's method (73). Typically, the support was treated in a quartz tube at 800°C for 2 h with a stream of chlorine and nitrogen. After cooling in nitrogen, a stream of ammonia was turned on and the temperature raised to 700°C where it remained for 1 h with ammonia, and a further hour with pure nitrogen flowing. The support was then allowed to cool in nitrogen. Treatment of this support with water liberated ammonia. Bonding of Surfynol and other compounds to the dry material was carried out as described above.

Results and discussion

The ancillary experiment with aminated silicic surfaces provided additional, though circumstantial, support for the multipoint sorption (as opposed to the terminal ester linkage) model of polyethyleneglycol (PEG) bonding: If there are no more silanol groups to be found on the surface, the ester bonding mechanism cannot be used to account for any extraction-resistant PEG layer.

On the other hand, hydrogen bonds between the ether oxygens and the surface amino groups would still be expected to exist, although being obviously weaker than those formed with surface hydroxyls. Therefore, one expects to find that bonding is possible, but that the resulting phase is chromatographically inferior. In part this should be due to the easier extraction of polymer by, or possible reaction of silamine groups with, methanol, and to the reduced stability of the phase against atmospheric moisture.

These expectations are borne out by the gas chromatographic test shown in Fig. 2. There is clear evidence of an organic layer, but alcohols elute with peak shapes noticeably worse than those of alkanes. In other words, the phase is not sufficiently deactivated.

In contrast, Surfynol 485 on regular, i.e., hydroxylated, Chromosorb W elutes alcohols with much better peak shape. Figure 3 shows this chromatography, which is equivalent to that obtained from CW-20M derived layers (and significantly better than those from a variety of conventional polyethyleneglycols and polyethyleneoxides of lower and higher molecular weight than CW-20M).

Elemental analysis shows 0.14% C, which translates to a layer thickness of ~26 Å on a (nominal) 1 m^2/g support. Carbowax phases on this type of support are generally considered to hold 0.1–0.2% polymer load (25). Elemental analysis is stretched to the limit here, but from the evidence available it seems that the Surfynol-derived layer is roughly comparable to (or perhaps a bit thicker than) the Carbowax-based film.

The heat stability of the Surfynol 485 phase is also comparable: an overnight exposure to 280°C did not destroy the chromatographic properties of this column. (However, for practical purposes, 250–260°C is likely to prove a more reasonable upper temperature limit. Also, as with CW-20M columns, the carrier gas should be essentially free of oxygen.)

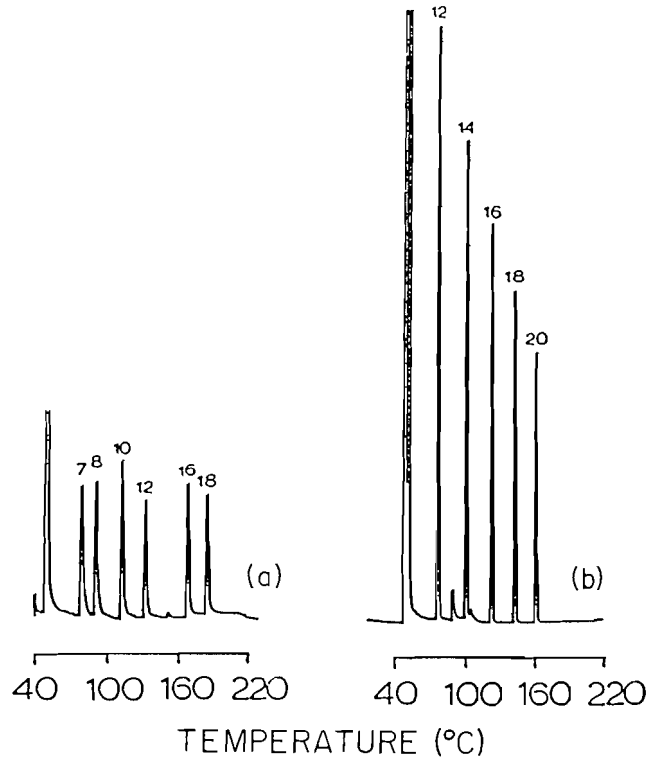

FIG. 2. Gas chromatography of (*a*) *n*-alkanols (carbon numbers 7, 8, 10, 12, 16, 18) and (*b*) alkanes (12, 14, 16, 18, 20) in an 8°C/min temperature program from 40 to 220°C on surface-aminated Chromosorb W, 45–60 mesh, modified with Surfynol 485.

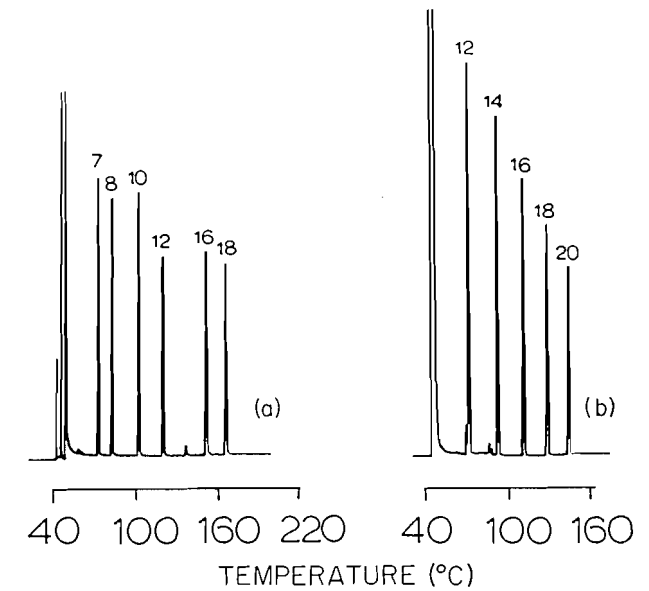

FIG. 3. Gas chromatography similar to that shown in Fig. 2 for (*a*) *n*-alcohols and (*b*) *n*-alkanes but on regular Chromosorb W modified with Surfynol 485.

Thus the gas chromatographic performance of Surfynol 485 and CW-20M does indeed turn out to be comparable on Chromosorb W. This lends credence to prior speculation that the presence of a cross-linking agent between two polyethylene-

glycol chains is conducive to obtaining a high-performance chromatographic phase by heat treatment. Aside from the reasons given earlier for believing in a rupture of link and chains, the following ancillary experiments support the viewpoint of a chemical change in the polymer during heat treatment.

Surfynol is typically bonded in boiling hexadecane (i.e., at 287°C). Similar runs with octadecane (316°C) or even eicosane (343°C) lead to a comparable product. Lower-boiling alkanes such as dodecane (216°C), however, do not. There the phase is yellow, bleeds heavily in the gas chromatograph, and changes with time in analyte retention. Only after conditioning at 250°C does it eventually settle down.

If Surfynol 485 is coated in heavy load, heat-treated in an inert atmosphere and then extracted (similar to the earlier procedure used on CW-20M, (1)), the gas chromatographic performance of the resulting material is poor and reminiscent of a thermosetting resin layer. For obvious reasons, no further experiments were conducted with that material.

In refluxing hexadecane, Surfynol 485 works as well as CW-20M on diatomaceous supports. But that would be of more academic than practical interest. However, Surfynol is decidedly superior to CW-20M on high-surface-area supports such as silica gels used for gas–solid or liquid chromatography.

For one, Surfynol can be used in the bonding reaction in almost any amount without fear of particle agglomeration. Subsequent extraction is easy and fast. This was demonstrated by adding Surfynol 485 to silica gel 62 at different weight ratios. The ratios were 0.3 (insufficient), 0.6, and 1.2. The latter 60 and 120% levels yielded essentially identical polymer loads.

The 60% material was subjected to prolonged extraction, monitored in this case for demonstration purposes. Right after the bonding reaction, and a few fast washes to remove the hexadecane, the phase's carbon content was about 16%. After about 10 h of continuous extraction with fast-flowing, hot methanol, it reached its final level of 15%, which it maintained for the duration of the experiment (40 h). Obviously, a long extraction is unnecessary for this material: a few washes will essentially do the job.

The carbon content corresponds to a layer of about 14 Å, which is significantly thicker than any achieved by using CW-20M. (This nominal layer thickness is less than the 26 Å mentioned above for the Chromosorb-based material. This is in agreement with the general trend of bonded layers to turn out thicker on low-surface-area supports (74). Assuming the elemental analyses to be reliable, 14 Å is, in fact, larger than would have been expected for analogous (74) extrapolation from 26 Å.)

Chromatographically that means a well-deactivated phase. And, indeed, as seen in Fig. 4, such solutes as 1-pentanol, hexanol, and heptanol separate with acceptable peak shapes, a behaviour rarely found with silica gel packings of (nominal) 300 m^2/g surface area.

This is still not a practical alcohol column, but it could serve very well for low-resolution work with highly volatile organics if one wants to avoid subambient programming. Figure 5 demonstrates this with a (composite) separation of *n*-alkanes from methane to tridecane starting at room temperature. A somewhat more applied example is shown in Fig. 6, the low-resolution chromatography of super unleaded gasoline.

Treatment with Surfynol 485 reduces the interaction of silica gel 62 even with alkanes: the bonded phase is somewhat less retentive; but it is more efficient, as shown in Fig. 7 by a comparison of Van Deemter plots. The solute nonane was run

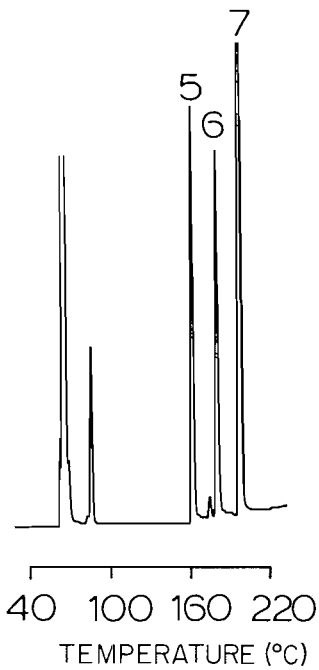

FIG. 4. Temperature-programmed gas chromatography of 1-pentanol, hexanol, and heptanol on modified silica gel 62.

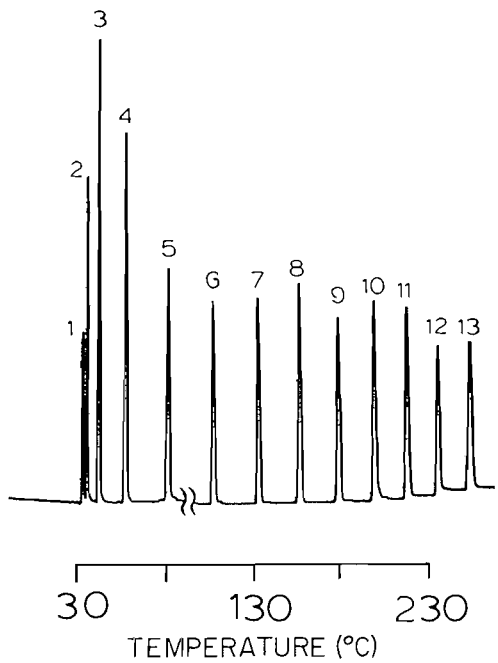

FIG. 5. Temperature-programmed gas chromatography of *n*-alkanes from methane to tridecane on modified silica gel 62, 100–120 mesh. Composite picture using a C-1–C-5 gas mixture and a C-6–C-13 solution. Column: 2 m × 2.1 mm id.

at 90°C on plain silica gel (upper curve) and at 80°C on the modified material (lower curve) in order to obtain roughly similar retention. The minimum plate height corresponds to about 2.5 particle diameters (i.e., a reduced plate height of 2.5), which is not all that far from the theoretically attainable limit.

The only disadvantage of the phase noted so far is its type of bleed. It made it unsuitable for high-sensitivity gc-ms analysis. Perhaps this bleed could be reduced by freeing the material of its polymerization catalysts, similar to the approach of Verzele *et*

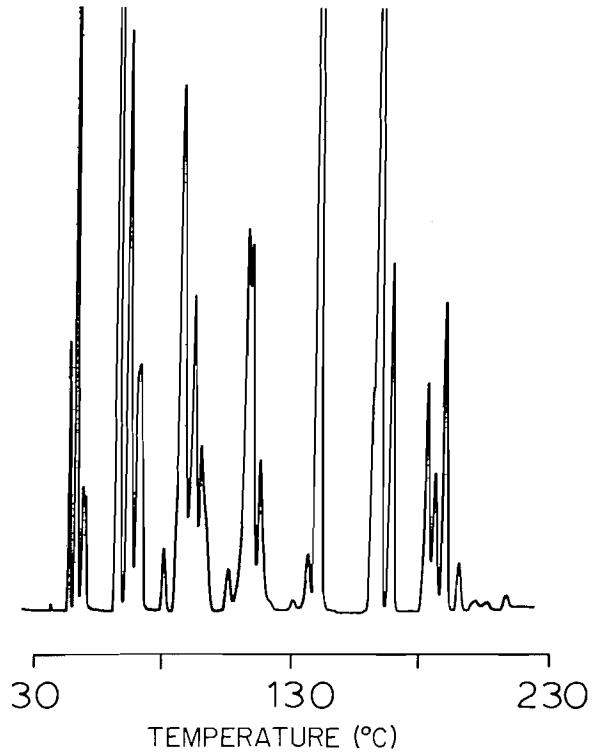

FIG. 6. Gas chromatography of super unleaded gasoline. Conditions as in Fig. 5.

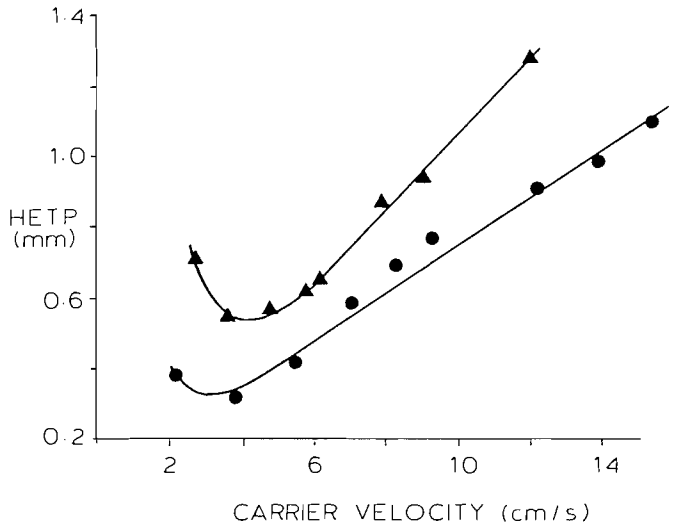

FIG. 7. Van Deemter plot for nonane at 90°C on plain (▲) and at 80°C on Surfynol 485 modified (●) silica gel 62, 100–120 mesh.

al. (69). The wetting ability of Surfynol 485 should make it an interesting candidate for the production of heat-immobilized layers of capillaries, similar to the earlier transfer of such technology from packed columns of CW-20M, SE-30, etc., but this possibility was not investigated.

Rather than investigating capillary gc, it was of greater interest at this stage to have a look at the performance of Surfynol-treated silica gel in liquid chromatography. It is obvious that the material would not serve well as a reversed phase (RP). It is easily wetted by water and, although RP-type behaviour can be observed under suitable conditions, the performance is poor. Besides, as Horvath has pointed out (75), it is possible to force even plain silica gel into RP behaviour.

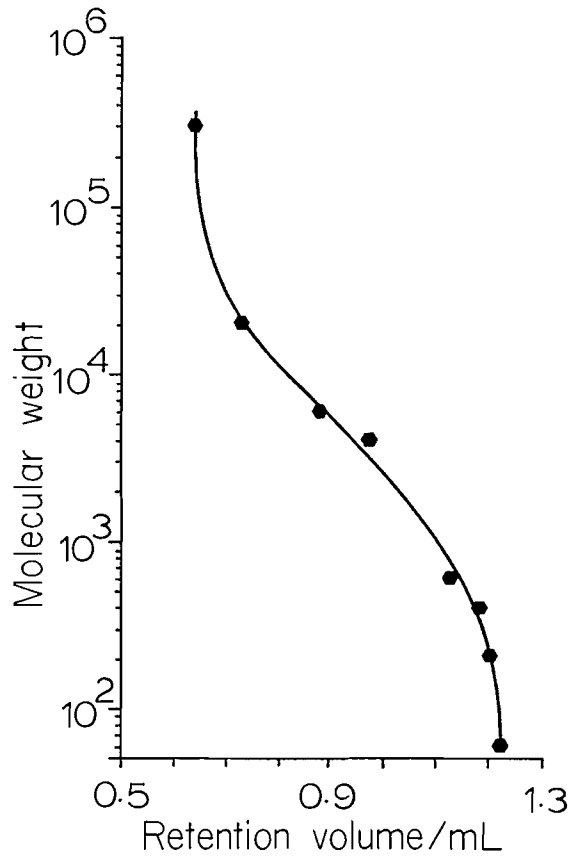

FIG. 8. Size exclusion chromatography of polyethyleneglycol molecular-weight standards, using methanol at 0.2 mL/min, a 0.4 × 10 cm column packed with 10 μm Lichrospher Si-100, and a refractive index detector. The Lichrospher particles were modified with Surfynol 485.

The more interesting aspect to pursue was the deactivated nature of the surface, even though, as mentioned before, deactivation in liquid chromatography is usually a question of choosing the right *mobile* phase.

A well-known problem in gel permeation chromatography is the undesirable sorption of hydrophilic molecules on silica-based surfaces (51–53). As a test, polyethyleneglycol molecular weight standards were chromatographed in methanol. The resulting calibration curve is shown in Fig. 8, corresponding to what one would expect from pure size-exclusion behaviour on a support of this porosity (76). It would have been interesting to follow this lead with more demanding analytes, enzymes for instance, to test for denaturation effects, etc. However, this was considered outside our primary area of interest.

Incidentally, Fig. 8 also provides an explanation, at least in part, why Surfynol 485 worked much better than CW-20M. This experiment used a Si-100 support and, for comparison, silica gel 62 has a mean pore diameter of 170 Å (77). It is obvious that the pores would have excluded intact CW-20M to a large extent while admitting the much smaller Surfynol 485. In this respect it may be worthwhile to mention that Surfynols of shorter polyethyleneglycol chains are available and these may be even better suited for treating narrow pores. (It bears repeating, however, that "regular" polyethyleneglycols of lower molecular weights, while showing evidence of bonding, gave inferior chromatographic performance.)

Another area of hplc where one would expect a modification of the surface to make a difference, is straightforward adsorp-

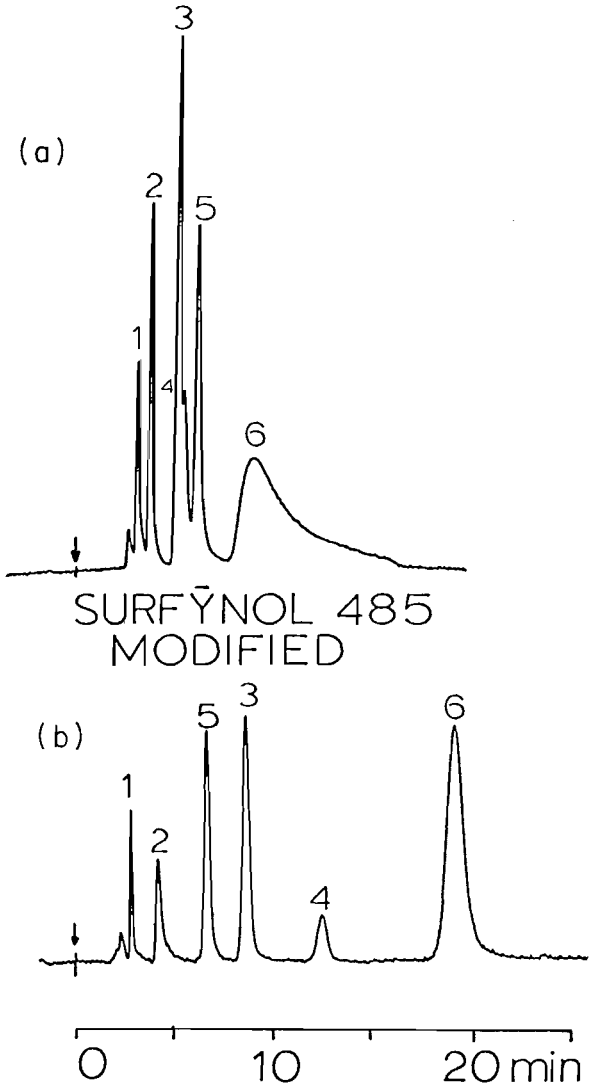

FIG. 9. Liquid–solid chromatography, using chloroform at 0.4 mL/min through a 0.4 × 10 cm column packed with 10 μm Lichrosorb Si-100 in (*a*) unmodified and (*b*) modified form. Peak designations are (1) *o*-chloroaniline, (2) *m*-chloroaniline, (3) phenol, (4), *p*-chlorophenol, (5) *p*-methoxyphenol, and (6) *p*-nitrophenol.

tion chromatography. That this is indeed so is shown in Fig. 9. Not only are the peak shapes different but the retention order itself shifts. It is not immediately obvious what effects did bring about these observed changes. One can think of a more homogeneous or a less acidic surface, one can envision different water retention by the particles, one can focus on the adsorbent properties of altered silanol groups on the surface or the additional ether oxygens in the layer, or one can speculate on the increased organic nature of the interface region. More experiments would have to be done to confirm or deny the applicability of such concepts to the case at hand and to capitalize on any that can be verified. Of more immediate importance, however, is to establish whether or not the new phase is sufficiently different from silica gel in selectivity across a wide range of solutes. Also important may be possible differences in response to water content of the mobile phase and in everyday ease of handling. In other words, the practical advantage of using such a phase in hplc still needs to be established.

Acknowledgments

This study was supported by the Natural Sciences and Engineering Research Council of Canada grant No. A-9604. We thank M. Verzele for a gift of Superox and M. Chinoy of Air Products for generous samples of Surfynol 104 and 485.

SP. CHIDAMBARAM, G. ARAVAMUDAN, G. C. ROUT, and M. SESHASAYEE. Can. J. Chem. **64**, 477 (1986).

The synthesis and crystal structure of the title complex are reported. Crystals are triclinic, space group $P\bar{1}$ with $a = 10.359(2)$, $b = 10.742(2)$, and $c = 13.604(2)$ Å, $\alpha = 87.25(1)$, $\beta = 88.89(1)$, $\gamma = 83.63(2)°$, and $Z = 2$. The structure was solved by the heavy atom method and refined by least squares to final R and R_w of 0.055 and 0.06 for 1707 unique reflections. The structure is comprised of planar $[Se_2(o\text{-phenylenethiourea})_6]^{4+}$ ions and bromide counterions with the water molecules providing extensive lattice stabilization through hydrogen bonding. The dinuclear complex arises by the fusion of two SeS_4 trapezoids with each Se bonded strongly to two terminal sulfur atoms Se—S(1) = 2.306(4), Se—S(3) = 2.286(5) Å and weakly to two other bridging sulfur atoms Se—S(2) = 2.840(5) and Se—S(2)′ = 2.852(5) Å.

SP. CHIDAMBARAM, G. ARAVAMUDAN, G. C. ROUT et M. SESHASAYEE. Can. J. Chem. **64**, 477 (1986).

On rapporte la synthèse et la structure cristalline du complexe mentionné dans le titre. Les cristaux sont tricliniques et cristallisent dans le groupe d'espace $P\bar{1}$ avec $a = 10,359(2)$, $b = 10,742(2)$, et $c = 13,604(2)$ Å, $\alpha = 87,25(1)$, $\beta = 88,89(1)$, $\gamma = 83,63(2)°$, et $Z = 2$. On a résolu la structure par la méthode des atomes lourds et on l'a affiinée par la méthode des moindres carrés jusqu'a des valeurs finales de R et R_w de 0,055 et 0,06 pour 1707 réflexions uniques. La structure comporte des ions plans de $[Se_2(o\text{-phénylènethiourée})_6]^{4+}$ et des contre-ions bromures avec des molécules d'eau qui fournissent une stabilisation importante de la maille par le biais de liaisons hydrogènes. Le complexe binucléaire provient de la fusion de deux SeS_4 sous forme de trapézoïdes dans lesquels chacun des Se est fortement lié aux deux atomes de soufre terminaux (Se—S(1) = 2,306(4) et Se—S(3) = 2,286(5) Å) et faiblement lié à deux autres atomes de soufre qui agissent comme ponts (Se—S(2) = 2,840(5) et Se—S(2)′ = 2,852(5) Å).

[Traduit par le journal]

Introduction

The interaction of selenium(IV) species with sulfur ligands has gained immense importance due to the formation of the Se(II)–sulfur ligated complexes which have been shown to be intermediates in the biochemical role of selenium (1, 2). Generally the interaction of selenium(IV) with sulfur containing ligands leads either to (*a*) reductive complexation, that is, reduction of selenium(IV) to selenium(II) and formation and stabilization of selenium(II) complexes with sulfur ligands (eg., thiosulphate (3), xanthates (4), dithiocarbamates (5), thiobenzoic acid (6), mercaptocarboxylic acids (7)) or to (*b*) reduction to elemental selenium (eg., hydrogen sulphide, thiourea). Very recently, with the use of concentrated hydrochloric acid medium, the highly unstable complex *cis*-dichlorobis(thiourea)-selenium(II) was isolated (8), and its structure determined. We have found (9) that, unlike thiourea, interaction of *o*-phenylenethiourea (ptu) with Se(IV) species leads to ready formation of Se(II) complexes, which are indefinitely stable at room temperature. In this paper we report the synthesis and structure of tris(*o*-phenylenethiourea)selenium(II) bromide pentahydrate. The structure consists of novel planar Se_2S_6 units (the first of its kind to be reported in Se(II) complexes with unidentate ligands) containing four moderately strong Se—S terminal bonds and four loose bridging Se—S bonds with each Se(II) displaying a trapezoidal sulfur coordination.

Experimental

Preparation of the complex

The reaction used for the preparation of the complex is

[1] 
SeO_2 (BDH, 0.5 mmol (0.055 g)) dissolved in 3 mL of methanol and of *o*-phenylenethiourea (Aldrich Co. 99% pure, 3 mmol (0.45 g)) dissolved in 15 mL of methanol were mixed in the presence of 12.5 mL of 2 *N* hydrobromic acid. The yellow solution obtained, gave needle shaped, yellow-orange crystals of the title complex on evaporation at room temperature (30°C). *Anal.* calcd.: Se 10.14, Br 20.54, S 12.32, N 10.78. C 32.24, H 3.59; found: Se 10.09, Br 20.48, S 12.34, N 10.70, C 32.21, H 3.96. To prevent contamination with excess ligand or oxidized product, the crystals formed were washed with ether. The crystals were extremely stable when preserved in paraffin. In dry atmosphere, the crystals turned opaque and brittle due to loss of water of crystallization.

It is interesting to report that the disulfide oxidation product in reaction [1] was found to undergo disproportionation rapidly under acidic conditions to *o*-phenylenethiourea and a  species, determination of whose composition and detailed characterization is in progress.

Crystal data (at 23°C)

$C_{21}H_{18}N_6S_3Br_2Se \cdot 5H_2O$ fw = 779.4

Triclinic, $a = 10.359(2)$, $b = 10.742(2)$, and $c = 13.604(2)$ Å, $\alpha =$

[1]To whom correspondence should be addressed.

[2]Revision received October 18, 1985.

87.25(1), β = 88.89(1), γ = 83.63(2)°, V = 1502.6 Å^3. Space group $P\bar{1}$, Z = 2, F(000) = 919.99, D_x = 1.72 Mg m^{-3}, μ(MoK$_\alpha$) = 4.11 mm^{-1}. Preliminary cell constants were obtained from Weissenberg photographs and a crystal of size 0.42 × 0.25 × 0.22 mm was mounted on a Enraf–Nonius CAD 4 diffractometer. Graphite monochromated MoK$_\alpha$(λ = 0.71069 Å) radiation was used. Lattice parameters were determined by least-squares refinement of θ values of 25 high angle reflections. The intensity data were collected by ω–2θ scan technique with scan interval Δω = (0.80 + 0.35 tan θ)°, extended by 25% on both sides for background measurements. Two check reflections ($42\bar{6}$ and $06\bar{1}$) recorded at the end of every hour of data collection time, showed no significant variation in intensity. A total of 5763 reflections were collected in the range of 2 < θ < 25° (h, 0–12; k, −12–12; l, −16–16). The 1707 reflections with $I > 3\sigma(I)$ formed a unique set. R_{int} equalled 0.01 after merging 123 reflections. No correction was made for absorption.

The SHELX-76 program (10) was used for all the computations done in solving the structure. Se and Br atoms were located from a Patterson map and the rest of the structure from Fourier maps. The function minimized in full matrix least-squares refinement was $\Sigma\omega(\Delta F)^2$. All but seven of the hydrogen atoms appeared in the final difference Fourier maps and were refined isotropically. Maximum peak height in the final difference Fourier map was 0.73 e Å^{-3}, maximum and average shift/esd in all non-hydrogen atom parameters were 1.615 and 0.022 in the final refinement cycle. Convergence was reached at R = 0.055 and R_w = 0.06 where w (the weighting scheme used) = $1/(\sigma^2(F_o) + 0.0599|F_o|^2)$.

Though the crystal used was of good quality as shown by the photographs and reflection profiles, only 30% of the possible reflections were observed, indicating that the diffractometer alignment should have been better, which would have yielded better quality data. This is also reflected in the large shift/esd in refinement, the data/parameter ratio being only 4.0.

Atomic scattering factors for non-hydrogen atoms, hydrogen atoms, and anomalous scattering factors are taken from refs. 11, 12, and 13, respectively.

The final positions are given in Table 1. Table 2 contains the bonding parameters in the structure. Fig. 1 was drawn using the ORTEP (14) program[3].

Results and discussion

Crystals of Se(ptu)$_3$Br$_2$·5H$_2$O are yellow-orange in colour, this being attributed to typical charge transfer bands. The compound is stable as such or when suspended in 2 N hydrobromic acid, but undergoes an immediate self-redox decomposition to Se and an oxidized product of the ligand when immersed in alkaline solution. The infrared spectrum of the complex does not have distinctive differences from that of the ligand which would enable positive conclusions regarding the coordination behaviour of the ptu ligand in the complex.

Figure 1 shows the ORTEP picture of the molecule. Only half of the centrosymmetrical [Se$_2$(ptu)$_6$]$^{4+}$ unit is featured in full. Additionally, the selenium and three sulfur atoms belonging to the other half are also shown for reasons of clarity. The structure is made up of an [Se$_2$(ptu)$_6$]$^{4+}$ cation, bromide counterions, and five water molecules of crystallization. In each cation, selenium, the soft acid site, is bonded to four phenylenethiourea ligands exclusively through sulfur atoms, the soft base site. The dinuclear complex arises by the fusion of two SeS$_4$ trapezoids with each selenium bonded strongly to two terminal sulfur atoms Se—S(1) = 2.306(4), Se—S(3) = 2.286(5) Å and weakly to two other bridging sulfur atoms Se—S(2) = 2.840, Se—S(2)′ = 2.852 Å. The SeS$_4$ group is planar to within 0.007 Å. The S—Se—S angles deviate substantially from 90°. The dihedral angle between the two SeS$_4$ trapezoids is nearly zero (0.03 (20)°). It is the first time in selenium(II) chemistry that a dimeric structure is reported with monodentate sulphur ligands. A [Te$_2$S$_6$]$^{4+}$ dimer with similar molecular geometry was reported (15) in the compound Te(tu)$_3$(HF$_2$)$_2$ (tu = thiourea).

It is interesting to comment on the coordination types of sulfur ligands reported till now around Se(II). The coordination number is observed to be two (bent) or four (square planar or trapezoidal). In two coordinated Se(II) complexes, the Se—S bond lengths are close to the sum of single covalent radii of selenium and sulfur (2.11 Å) as reported in refs. 3, 6, 7, 8, 16, and 17. This is because the ligands in these cases are mostly negatively charged and unidentate, and there are only two sulfur ligands bonded to selenium. In Se(S$_2$COCH$_3$)$_2$ (4) xanthate provides four sulfur atoms around the central metal atom selenium, two of these sulfurs (bridging ligands) are quite far from selenium so that their interaction with selenium is very weak, enabling the other thiolatosulfurs to bond strongly. Complexes such as Se(S$_2$CNC$_4$H$_8$O$_2$)$_2$ (5) and Se[N(Ph$_2$PS)$_2$]

(18) though arising from bidentate ligands, are structurally very close to the present case, which have two weaker and two stronger bonds in its four coordination leading to a planar trapezoidal structure. $[Se(ptu)_4]Cl_2 \cdot 2HCl$ (9) is the only complex so far reported in Se(II) chemistry which shows a near square planar coordination. In the present case, in which the same sulfur compound features as the ligand, the smaller number of ligands per Se(II) alters the molecular geometry of SeS_4 coordination from square planar to trapezoidal and also provides a dimeric Se_2S_6 unit. In all the SeS_4 species the average Se—S bond length is 2.53 Å, showing that the Se—S interactions in these complexes are weaker than in two-coordinated complexes. This can be attributed to the larger number of sulfur atoms around selenium in the tetra-coordinated complexes.

The ptu ligands are planar to within 0.04 to 0.07 Å. The C—S distances in the ligands are 1.75(2), 1.72(2), and 1.76(2) Å showing partial double bond character. The C(1)—N(1) and C(1)—N(2); C(2)—N(3) and C(2)—N(4); C(3)—N(5) and C(3)—N(6) pairs show no significant variation in bond lengths, clearly indicating that the ptu ligand in the Se(II) complex occurs exclusively in thione form with the molecular parameters close to those observed in the structure of the free ptu ligand (19), $Se(ptu)_4 \cdot Cl_2 \cdot 2HCl$ (9), and in tellurium(II) complexes of the ligand (20). The ligand in all these cases is present in the thione form. The other bond parameters in the ligands are normal. The average N—H, C—H, and O—H bond lengths are 0.88(7), 0.91(2), and 0.83(1) Å, respectively.

There are two bromide ions per formula unit. The bromines, water oxygens, and nitrogen atoms of ptu ligand form an extensive hydrogen bonding network. Bromine atoms are well outside the coordination sphere of Se and form hydrogen bonds with six water molecules and one nitrogen atom, with Br...O and Br...N distances in the range of 3.08(2)–3.33(2) and 3.35(1) Å, respectively. The angles Br...H—O are in between 157 and 175° and the Br...H—N angle is 128°. Also oxygen

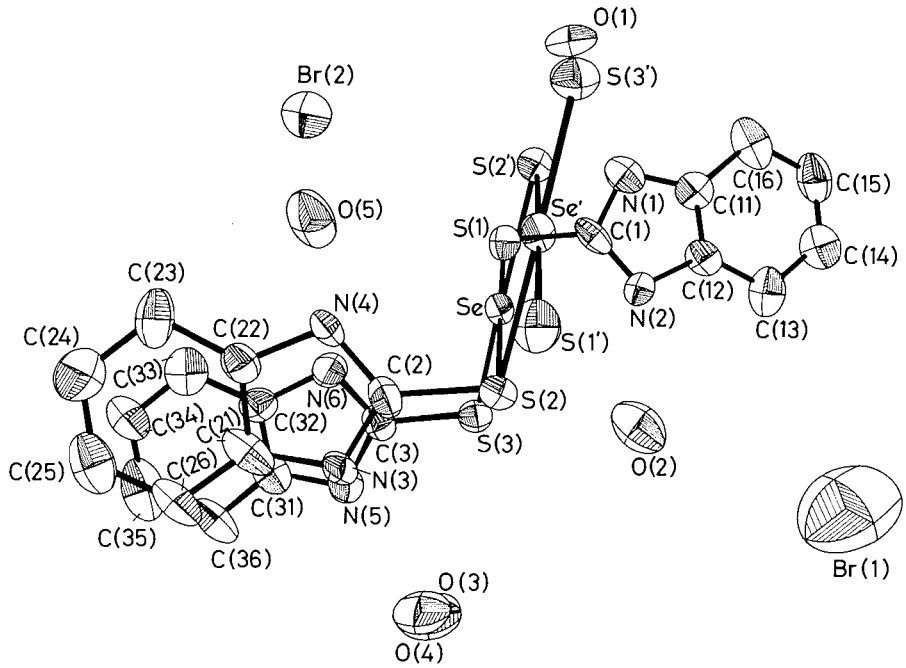

FIG. 1. Perspective view of the molecule showing atomic numbering, with 50% probability thermal ellipsoids.

atoms of water molecules form five hydrogen bonds with nitrogen atoms, as evidenced by the N...O distances of the order of 2.69(2) Å. N—H...O angles range between 163 and 176°. In addition, oxygen atoms among themselves form two hydrogen bonds with O...O distances 2.99(2) and 2.81(3) Å.

Some physical properties of long chain hydrocarbons

L. T. Chu, Carmen Sindilariu, Aaron Freilich, and Vojtech Fried

Department of Chemistry, The City University of New York, Brooklyn College, Brooklyn, NY 11210, U.S.A.

Received November 27, 1984[1]

L. T. Chu, Carmen Sindilariu, Aaron Freilich, and Vojtech Fried. Can. J. Chem. **64**, 481 (1986).

The densities, refractive indices, and viscosities of liquid *n*-nonadecane and *n*-nonadecyl benzene were investigated at temperatures not too far above their respective melting points. Except for the viscosities, no significant differences were observed in the behavior of the two hydrocarbons. The *n*-nonadecane + *n*-nonadecyl benzene system exhibits small positive excess volumes and small negative excess viscosities. The excess refractive index is zero in the entire concentration range.

L. T. Chu, Carmen Sindilariu, Aaron Freilich et Vojtech Fried. Can. J. Chem. **64**, 481 (1986).

Opérant à des températures juste au-dessus de leur point de fusion respectif, on a mesuré les densités, les indices de réfraction et les viscosités du *n*-nonadécane et du *n*-nonadécyl-benzène liquides. Excepté pour les viscosités, on n'a pas observé de différences significatives dans le comportement de ces deux hydrocarbures. Le système *n*-nonadécane + *n*-nonadécyl-benzène présente de faibles excès positifs des volumes et de faibles excès négatifs des viscosités. L'excès d'indice de réfraction est nul pour toute la gamme des concentrations.

Introduction

Long chain aliphatic compounds have been the subject of many investigations. Ralston and coworkers (1, 2) measured the solubilities of long chain organic compounds in solvents of various polarities. They observed that in nonpolar and slightly polar solvents the solubility curves of substituted (with polar groups) aliphatic compounds and of the normal aliphatic compounds of corresponding chain length are qualitatively similar. If this is really so then the shape of the solubility curve depends mainly on the length of the alkyl chain. Seyer (3) observed that the solubility of diacetyl in normal aliphatic solvents, ranging from C_6 to C_{12}, obeys the ideal solubility law. Cáceres and coworkers (4–6) noticed that the excess volumes of *o*-, *m*-, and *p*-xylene solutions with normal aliphatic hydrocarbons vary from negative values for *n*-hexane to relatively large positive values for *n*-hexadecane. Heric and Coursey (7, 8) found that the excess volumes and the excess viscosities of solutions of *n*-hexadecane in 1-*n*-chloroalkanes of different chain length obey the congruence principle (9) very well.

Some normal long chain aliphatic hydrocarbons exhibit unusual behavior in the solid state. Aliphatic hydrocarbons containing from 18 to 36 carbons are polymorphous and undergo a solid–solid phase transition at temperatures slightly above their respective freezing points (10–15). In the higher temperature solid phase, designated as the "rotator phase", the molecules rotate about their long axes. In the lower temperature solid phase, designated as the "rigid phase," the rotation is severely restricted. The rotator phase formed from the melt at the freezing point is metastable and converts after a sufficient time, depending on the chain length, into the more stable low temperature solid rigid phase. Piper *et al.* (11) measured the transition temperatures for a large number of compounds.

To get some insight into the behavior of long chain hydrocarbons, we decided to investigate the physical properties of long chain hydrocarbons in the pure state and in mixtures. For convenience we studied the properties of melts rather than of solids. In this work we deal with the dependence of density (volume), refractive index, and viscosity of *n*-nonadecane (ND) and *n*-nonadecyl benzene (NDB) melts for the pure hydrocarbons and their mixtures.

[1]Revision received October 16, 1985.

Table 1. Some physical properties of *n*-nonadecane at various temperatures

Temp. (°C)	Density (g/cm^3)	Refractive index (n_D)	Viscosity (cp)
35	0.7752	1.4356	3.91
40	0.7719	1.4335	3.49
45	0.7686	1.4314	3.11
50	0.7653	1.4293	2.79
55	0.7620	1.4273	2.51
60	0.7587	1.4252	2.26
65	0.7554	1.4231	2.05
70	0.7521	1.4210	1.86

Experimental

The ND and NDB were Aldrich commercial chemicals of the highest purity (99%+). No impurities were detected in glc measurements of either hydrocarbon. The melting points, measured with an NBS certified mercury in glass thermometer, were in close agreement with the literature values, though we encountered some difficulties in reproducing the melting point of NDB. ND: mp 31.2°C (lit. (12, 16, 17) mp 31-32°C); NDB: mp 25.01°C (lit. (12) mp 24.94 ± 0.03°C).

The densities of the two hydrocarbons and their mixtures were measured pycnometrically with a 25-cm^3 volumetric flask, calibrated with deionized, twice-distilled water. Dissolved air was expelled from the water prior to the calibration. Air buoyancy corrections were employed in all the weighings. Because of the low volatility of both hydrocarbons, evaporation losses were negligibly small and were ignored in the density evaluation. The volumetric flask was placed in a thermostated water bath for 1 h. The temperature of the water bath was monitored with an NBS certified thermometer. The accuracy of the temperature reading was better than ±0.01°C at the lower temperatures and about ±0.02°C at the higher temperatures. The reproducibility of the density measurement was within $\pm 1 \times 10^{-4}$ g cm^{-3} for the pure melts and $\pm 1.5 \times 10^{-4}$ g cm^{-3} for the mixture. To check the accuracy of the method, we took density measurements with cyclohexane at 25°C. All of the measurements were within $\pm 1 \times 10^{-4}$ g cm^{-3} of the literature values (16, 17). The density measurements reported in Tables 1–3 represent averages of five measurements.

The viscosities were measured with an Ostwald-Ubbelohde viscosimeter made from pyrex glass in our glassblowing shop. The flow time in the given temperature interval varied between 400 and 1200 s. The small kinetic energy contributions to the viscosity of the samples were neglected. The viscosity, η, was calculated from the formula $\eta = \nu d =$

Ctd where ν is the kinematic viscosity, d is the density, and t is the flow time. The viscosimeter constant, C, was determined from the flow time, density, and viscosity of highly purified glycerol ($d_4^{30} = 1.2552$ g cm^{-3}, $\eta = 5.87$ cp (16)). More than usual attention was paid in mounting the viscosimeter in the thermostated bath to ensure that the capillary was vertical. The thermostated bath was the same as that used for the density measurements. The reproducibility of the viscosity measurements was within $\pm 1 \times 10^{-2}$ cp at the lower temperatures and only $\pm 2 \times 10^{-2}$ cp at the higher temperatures. The values reported in Tables 1–3 are averages of at least five measurements.

The refractive indexes were measured with a Zeiss refractometer with a reproducibility of $\pm 1 \times 10^{-4}$ at the lower temperatures and $\pm 2 \times 10^{-4}$ at the higher temperatures. The values reported in Tables 1–3 are averages of five measurements.

Results and discussion

The experimental data are listed in Tables 1–3. The data for density and refractive index were fitted to

$$d = a + b(t/°C - 35°C)$$

$$n_D = a + b(t/°C - 35°C)$$

and for viscosity to

$$\ln \eta = \frac{a}{T} + b$$

The parameters of these expressions, obtained by a least-squares technique, are listed in Table 4.

According to the measured data, the molar volumes and refractive indices of the two hydrocarbons differ, but the rates of volume change and refractive index change with temperature are practically the same for the two hydrocarbons. Thus, with regard to volume and refractive index, the behavior of the two hydrocarbons is similar. If there is some rotational motion still present in the melt, it is not sufficient to cause deviations in the densities and refractive indices of the two hydrocarbons. This is not so when it comes to viscosity. At 35°C, the viscosity of NBD is about 2.4 times as large as that of ND. At 70°C, the viscosity of NDB is only 2.1 times as large as that of ND. Thus, the viscosity of NDB decreases more rapidly with temperature than that of ND. If this trend prevails, the viscosity vs. temperature curves of the two hydrocarbons will intersect. What is responsible for the different viscosity behavior of the two hydrocarbons? ND possesses dispersion forces only while NDB possesses dipole–dipole interaction forces in addition to the dispersion forces. It is our belief that it is the effect of temperature on the dipole–dipole forces (dispersion forces are practically temperature independent) and consequently on the rotational motion of the molecules that is responsible for the different viscosity–temperature behavior of the two hydrocarbons.

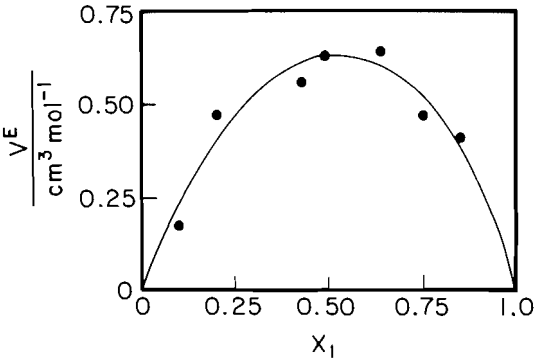

FIG. 1. The excess viscosity of the nonadecane + nonadecyl benzene system at 40°C.

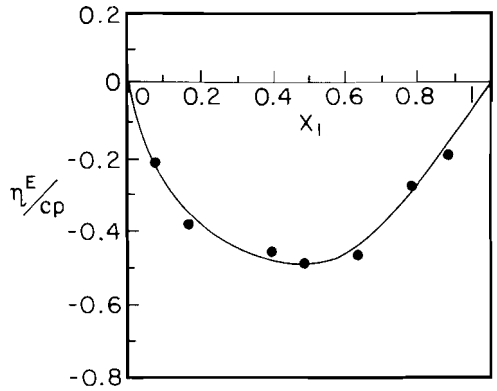

FIG. 2. The excess volume of the nonadecane + nonadecyl benzene system at 40°C.

The densities, refractive indices, and viscosities of the binary ND + NDB system, at 40°C, are given in Table 3. Analysis of the data reveals that the refractive index varies linearly with mole fraction: n_D^E is 0 in the entire concentration range. η^E and V^E are, however, different from zero (see Figs. 1 and 2). The V^E vs. mole fraction curve goes through a maximum and the η^E vs. mole fraction curve goes through a minimum. Because of the large molar masses of the two hydrocarbons, small errors in the densities and mole fractions affect substantially the V^E value ($V^E = (X_1M_1 + X_2M_2)/d - X_1M_1/d_1 - X_2M_2/d_2$). To a smaller extent this is also true for the η^E values.

TABLE 4. The parameters a and b obtained by the least-squares technique and the standard deviation, δ

	n-Nonadecane			*n*-Nonadecyl benzene

P. V. R. Rao, S. K. Gupta, and T. S. B. Narasaraju. Can. J. Chem. **64**, 484 (1986).

The solubility products of phosphate and vanadate apatites of lead and seven of their solid solutions, spread over the entire compositional range, were determined in 0.165 *M* sodium chloride solution at 37°C. These solubility products decreased with an increase in vanadium content. A theoretical interpretation was advanced based on changes in lattice and hydration energies resulting from isomorphous ionic substitutions. The aim of the studies was the understanding of the toxic effects of lead and vanadium on the human skeletal system.

P. V. R. Rao, S. K. Gupta et T. S. B. Narasaraju. Can. J. Chem. **64**, 484 (1986).

Opérant à 37°C et dans des solutions à 0,165 *M* de chlorure de sodium, on a déterminé les produits de solubilité du phosphate et du vanadate d'apatites de plomb et de sept de leurs solutions solides qui couvrent le spectre entier de compositions. Ces produits de solubilité diminuent avec une augmentation du contenu en vanadium. On propose une interprétation théorique qui est basée sur des changements dans le réseau et sur les énergies d'hydration qui résultent de substitutions ioniques isomorphes. Le but de ces études était de comprendre les effets toxiques du plomb et du vanadium sur le squelette humain.

[Traduit par le journal]

Introduction

Calcium phosphate apatite (CaPA), $Ca_{10}(PO_4)_6(OH)_2$, the principal inorganic constituent of human bones and teeth (1), undergoes several isomorphous cationic and anionic substitutions involving toxic ions. This constitutes the basis of the incorporation of toxic ions into the human skeletal system. It was established that the toxicity is controlled by the extent of incorporation of toxic ions during the principal bone processes calcification and resorption. Significant among such cationic substitutions has been the replacement of Ca^{2+} by Pb^{2+} forming lead phosphate apatite (PbPA), $Pb_{10}(PO_4)_6(OH)_2$, accounting for the incidence of plumbism, an occupational disease prevalent among workers of potteries and paints. While limited information on $Ca^{2+} \rightleftharpoons Pb^{2+}$ substitution in CaPA was available (2–4), substitution of PO_4^{3-} by VO_4^{3-} leading to the formation of lead vanadate apatite (PbVA), $Pb_{10}(VO_4)_6(OH)_2$, in the context of toxic effects of vanadium (5, 6) on human skeletal system, has not been studied. To investigate the combined effect of Pb^{2+} and VO_4^{3-} on calcification and resorption and to explore the possibility of their reversal, it was decided to study the solubility equilibria of PbPA, PbVA, and seven of their solid solutions spread over the entire compositional range, since these bone processes are controlled by the deposition and dissolution of CaPA at the interface of bone and body fluid. In addition, these studies were intended to clarify a few ambiguities associated with the available results on the solubilities of apatites.

Experimental

PbPA, PbVA, and a series of seven of their solid solutions were prepared through appropriate modifications of a wet method[3] and characterized to be of a high order of purity through X-ray, infrared, electromicroscopic, and thermal analyses, in addition to conventional chemical analyses.[3] The solubility product of each sample was determined at the biologically significant temperature of 37°C by analysis of its saturated solution, the pH of the dissolving medium being maintained constant using suitable buffer combinations. Each system was set up by adding 0.1 g of apatite to potassium hydrogen phthalate – hydrochloric acid buffer of required pH prepared in 100 mL of 0.165 *M* sodium chloride, the latter being needed to maintain the ionic strength of the medium effectively constant (7). Further, 0.165 *M* NaCl was considered as a standard reference solution (8), in which the activity coefficients of the dissolved ionic species could be taken as unity to avoid inaccuracies in their calculations, especially of polyvalent ions, and to enable products of ionic concentration in saturated solution of substances to be taken as their solubility products. Equilibration was carried out through shaking for about 12 h in air-tight polyethylene containers at a regulated speed using a mechanical shaker. The assembly was kept in a thermally insulated cabin maintained at 37 ± 0.5°C. The period of equilibration for attainment of saturation was found to be about 4 h based on a study of dissolution kinetics (9). To be doubly sure about the attainment of saturation, the equilibration period was extended to 12 h, at the end of which the pH of the system was measured. The colloidal component of the solute was separated from the solution by filtration through a 1G4 sintered glass crucible under suction at the temperature of equilibration, the suitability of the sintered glass crucibles for the purpose being verified by comparison with results obtained using colloidal filters (Millipore Filter Corporation, Bedford, U.S.A.) of pore size 10 mμm (10). From the saturated solutions thus obtained, lead was determined complexometrically (9) while phosphate and vanadate were estimated spectrophotometrically (11, 12), a separate aliquot being taken each time. Based on a series of such determinations the error limits were found to be ±1%.

Results and discussion

In Table 1 are included a few representative sets of results on the determination of the solubility products of PbPA, PbVA, and seven of their solid solutions. While the experimentally determined concentrations of lead, phosphorus, and vanadium are given in columns 2 to 4, the concentration of OH^- calculated from the final pH of each system is given in column 5, all the concentrations being taken as synonymous with activities as explained earlier. The gram atom ratios, Pb/P, Pb/V, and Pb/(P + V) calculated from the results of columns 2–4, are reported in column 8 of the table. It is evident that the ionic product K_{ip} of PbPA is equal to the product of the concentrations of the dissolved ions raised to appropriate powers, as given by $[Pb^{2+}]^{10}[PO_4^{3-}]^6[OH^-]^2$. While the concentrations of Pb^{2+} and

*Calculated from the measured final pH of the equilibrated system.
†Column numbers referred to text.

OH^- were available directly from the measurements, that of PO_4^{3-} was calculated as shown below from the overall analytical concentration of PO_4^{3-} represented as $C_{(PO_4)}$.

$$[1] \quad C_{(PO_4)} = [H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [PO_4^{3-}]$$

$$[2] \quad [PO_4^{3-}] = \frac{C_{(PO_4)} \times K_1K_2K_3}{[H^+]^3 + K_1[H^+]^2 + K_1K_2[H^+] + K_1K_2K_3}$$

where K_1, K_2, K_3 are dissociation constants for H_3PO_4 (13, 14) given respectively by 7.51×10^{-3}, 6.33×10^{-8}, and 4.73×10^{-13}. A similar set of calculations (15) was done for the K_{ip} of PbVA, while a combination of the two gave K_{ip} values of the solid solutions. In all such calculations the dissociation of H_3VO_4 to $H_2VO_4^-$, HVO_4^{2-}, and VO_4^{3-} was considered. The possibility of existence of polyphosphates and polyvanadates in presence of cations such as Pb^{2+} is remote under conditions prevalent in the present systems. All these subdivided values, excepting those of PO_4^{3-} and VO_4^{3-} given in columns 6 and 7, are not reported for the sake of brevity. For the apatite phase, the calculated values of the pK_{ip} and their averages are given in columns 9 and 10 respectively of the table; the corresponding values of the other possible phases such as $Pb(HPO_4)$, $Pb(H_2PO_4)_2$, and $Pb_2(HPO_4)(OH)_2$ (16) and their vanadate counter parts are not reported, again for the sake of brevity.

Since the powers to which the ionic concentrations are to be raised to get K_{ip} values of apatites are high, the errors in their determinations play a significant role in deciding the fluctuations of the K_{ip} values calculated. While establishing the constancy of K_{ip} values of each one of the samples at 37 ± 0.5°C, care was taken to see that there was an unambiguous constancy after making allowance for the fluctuations caused by errors in the determination of ionic concentrations required. For this purpose sets of positive and negative error limits of determination of Pb^{2+}, PO_4^{3-}, VO_4^{3-}, and pH/OH^- obtained from pilot experiments with known quantities were chosen to calculate the upper and lower limits of K_{ip}/pK_{ip} values of each sample. A similar scrutiny was made before concluding the effect of ionic replacement on pK_{ip} values of PbPA, PbVA, and their solid solutions.

The results could unambiguously confirm that the samples exhibited a stoichiometric dissolution since the gram-atom ratios given in column 8 are in close proximity with the theoretical value of 1.67 and the pK_{ip} values of the apatite phase are constant for each system. The earlier results (16–18) (which were based on the supposition that the solubility of apatites is non-stoichiometric, being controlled either by the secondary phosphates or surface coatings of extraneous phases) are not substantiated by the present findings which confirm the thermodynamically expected stoichiometric dissolution (19–23). An important finding of the present investigations was that the solubilities of the samples exhibited a marked decrease with an increase in vanadium content, the average pK_{ip} values of PbPA and PbVA being 168 and 187, respectively, with the solid solutions having intermediary values. A theoretical interpretation of dependence of solubility of an ionic crystal on cationic and anionic replacement is possible through thermodynamic considerations (24).

For an ionic compound, the free-energy change accompanying dissolution, ΔG_{soln}, is related to K_{sp} as shown below at a given temperature T,

$$[3] \quad \Delta G_{soln} = -RT \ln K_{sp}$$

and can be calculated from experimental values of K_{sp}. Alternatively, it can be evaluated by considering dissolution of an ionic compound to be consisting of, (*i*) breaking down of its crystal architecture and (*ii*) the hydration of the constituent ions so set free resulting in the expression

$$[4] \quad \Delta G_{soln} = \Sigma \Delta G_{hi} - \Delta G_{lattice}$$

where $\Sigma\Delta G_{hi}$ is the sum of the free-energy changes of hydration of the constituting ions of the solute, while $\Delta G_{lattice}$ is the free-energy change of formation of the lattice. It is evident from this expression that a high solubility results when the hydration energy is high and lattice energy low, the converse being the case for low solubility. The terms on the right-hand side of the above equation can be calculated (24) by the following expression for an ionic crystal of general formula M_mN_n.

$$[5] \quad \Delta G_{soln} = \frac{-164Z_+{}^2m}{r_+ + 0.85} - \frac{164Z_-{}^2n}{r_- + 0.1} + \frac{332Az_-{}^2}{R_0}\left(1 - \frac{1}{n_B}\right) - 8.03\,(m+n)\ \text{kcal/mol}$$

where Z_+ and Z_-, r_+ and r_- given the charges and ionic radii, respectively of the concerned ions; A, the Madelung constant; n_B, the Born exponent; R_0, the crystallographic radius; and 0.85 and 0.1 are the correction terms in the respective ionic radii. If the cation remains the same, the dependence of ΔG_{soln} on r_- is given by the equation

$$[6] \quad \left(\frac{\partial \Delta G_{soln}}{\partial r_-}\right)_{r_+} = \left(\frac{164Z_-{}^2n}{(r_- + 0.1)^2}\right) - \left(\frac{332Az_-{}^2}{R_0{}^2}\left(1 - \frac{1}{n_B}\right)\right) \times \left(\frac{\partial R_0}{\partial r_-}\right)_{r_+}$$

while the corresponding expression in the case of anion remaining the same is given by

$$[7] \quad \left(\frac{\partial \Delta G_{soln}}{\partial r_+}\right)_{r_-} = \left(\frac{164Z_+{}^2m}{(r_+ + 0.85)^2}\right) - \left(\frac{332Az_-{}^2}{R_0{}^2}\left(1 - \frac{1}{n_B}\right)\right) \times \left(\frac{\partial R_0}{\partial r_+}\right)_{r_-}$$

in either case the term $(1 - 1/n_B)$ being assumed to be constant.

It could be shown that the above equations are adequate to explain qualitatively the dependence of solubility of ionic crystals on ionic replacement. The first and second terms on the right-hand side of eqs. [5] and [6] represent, respectively, changes in hydration and lattice energies consequent upon anionic replacement. It is evident that on increasing the value of r_- a constant r_+, both these terms diminish, although the diminution in the second is less than that in the first, contributing to a decrease in solubility. The lower solubilities of PbVA and the solid solutions over that of PbPA could thus be explained. These conclusions are found to be in agreement with the corresponding results on the halides of Cs. Further, it can be shown from eq. [5] that for systems involving comparable values of r_+ and r_- as is the case with Pb^{2+} and VO_4^{3-} a solubility decrease is expected relative to its counterpart for which the disparity is more.

The application of fast atom bombardment (FAB) mass spectrometry to the determination of lead isotope ratios in nineteenth century pottery glazes from the Niagara Peninsula has been investigated with the aim of determining the source of the lead used in the glazes. Methods of sampling have been compared, including direct analysis of glass chips, analysis of powdered glaze scrapings, analysis of acid extracts of the former, and simple acid leaching of the surface of a piece of pottery. The latter method gave the best results. The FAB data, as obtained on an older mass spectrometer, can distinguish lead from igneous vs. sedimentary deposits, but is not adequate to determine specific mining locations. Although newer FAB instrumentation can narrow this range, the overlap of data from the Niagara Peninsula and England precludes a simple answer to the archeological question as to English vs. Canadian origin of the lead used in the Jordan pottery glazes. However, the data do suggest that the potter used a local source for the lead.

JACK M. MILLER, TIMOTHY R. B. JONES, TINA KENNEY, DAVID W. RUPP, BRIAN GREEN et ROBERT S. BARDOLI.Can. J. Chem. **64**, 488 (1986).

Faisant appel à la spectrométrie de masse par bombardement avec des atomes rapides et dans le but de déterminer la source du plomb utilisé pour fabriquer les émaux, on a déterminé les rapports des divers isotopes du plomb dans l'émail de poteries du dix-neuvième siècle provenant de la péninsule du Niagara. On a comparé les diverses méthodes d'échantillonnage, y compris l'analyse directe de morceaux de verre, l'analyse de poudres formées à partir de fragments d'émail, l'analyse d'extraits acides des premiers ou tout simplement en faisant un lavage acide de la surface des pièces de poterie. Cette dernière méthode donne les meilleurs résultats. Les données de la spectroscopie, telles qu'obtenues sur un spectromètre de masse plus vieux, permettent de distinguer du plomb provenant de sources ignées ou sédimentaires; toutefois, cette méthode n'est pas adéquate pour déterminer des sites spécifiques de mines. Même si les nouveaux appareils permettent de combler une partie de ces déficiences, le recouvrement des donnés provenant de la péninsule du Niagara et de l'Angleterre ne permet pas de donner une réponse simple aux questions archéologiques concernant l'origine anglaise ou canadienne du plomb utilisé dans les émaux de la poterie Jordan. Toutefois, les donnés suggèrent que le potier a fait appel à une source locale pour son plomb.

Introduction

The application of the tools of modern analytical chemistry to archeological problems, when combined with the tools of classical archeology, forms the relatively new field of archeological chemistry. The ability to study trace element occurrences, isotope ratios, etc. can, especially when combined with the other archeological information available, permit dating of objects, or the determination of place of manufacture, place of origin of raw materials, or both. Such information can be particularly useful in determining trade patterns and social interactions. The chemical makeup of objects such as coins, tools, and pottery, the commonest artifacts, usually contain ratios of elements or isotopes that reflect their region of origin. A technique is especially valuable to the archeologist if it is nondestructive, and whether destructive or not, if it is sensitive enough to use with very small samples. Several reviews of this field have been published (1, 2).

Lead is a particularly important element archeologically and is often found in its metallic form or alloyed with various metals, and in glasses and glazes. All these forms have high "survival" factors, i.e., they are found as identifiable objects subject to characterization by classical methods. Stable lead isotope ratios differ with the source of the lead around the world as a result of differing radioactive precursors. Certainly, lead from igneous deposits is readily distinguished from lead derived from sedimentary deposits (3, 4).[1] Thus a comparison of the lead isotope ratios of lead of archeological origin should help to pinpoint the source of the lead used in the manufacture of the object. However, in practice this is only possible if the errors associated with the measurement are smaller than the variations in isotope ratio with the source of the lead. An igneous and sedimentary source of lead could readily be distinguished even with crude instrumentation but, as we shall show, to distinguish between Niagara Peninsula lead and some English leads is not a trivial problem.

The advent of fast atom bombardment (FAB) source for conventional organic mass spectrometers (5) now makes the measurement of isotope ratios from solid inorganic samples a widely available technique and, if the systematic errors can be minimized, a powerful and easily accessible tool for the archeological chemist. Dolnikowski *et al.* (6) have recently demonstrated the application of FAB mass spectrometry to the determination of metals in archeological artifacts, including the determination of lead isotope ratios. In their case it proved easy

[1]R. Farquar. Private communication. 1985.

to demonstrate that the American copy of the British pottery under examination clearly had a glaze of American origin. However, some North American and English lead isotope ratios overlap in their plots of $^{207}Pb/^{206}Pb$ vs. $^{204}Pb/^{206}Pb$. This is just the region where the data we discuss below appear on such a plot.

Our problem was with the origin of the lead for the glazes used in the Benjamin Lent pottery on the Niagara Escarpment near Jordan, Ont., a site active in the pioneer period between 1835–1836 and 1841–1842, and recently excavated by one of us (7). Several hypotheses exist. Firstly, native Niagara lead may have been used, there being surface deposits of galena (naturally occurring PbS) found in the face of the Niagara escarpment and in the surrounding area. Also, there appears to be some evidence of lead having been smelted in the nearby area in pioneer times. Secondly, a large number of broken bottles have been excavated at the site and it has been hypothesized that glass bottles, either from England or North America, might have been the source of material for the glaze. An alternative hypothesis suggests that the lead which lined the tea chests in which tea was imported via England might have served as the potter's source of lead for his glazes. Such lead is likely to have been reused scrap lead from a number of locations and might not match the expected isotope ratios for any specific area. The bottle hypotheses was eliminated at an early stage, the bottle glass having a much lower lead content than the glazes. In the work described below we explore the other two possibilities.

Experimental

(a) Instrumentation

Fast atom bombardment mass spectra were obtained on two instruments, an early AEI MS 30 at Brock University and a large double focussing mass spectrometer, the prototype VG ZAB SE, located at the VG factory in Wythenshawe. In both cases the atom beam was provided by an Ion Tech atom gun, with xenon as the bombarding gas; atom energies were on the order of 8 kV.

The MS-30 had a Kratos FAB source retrofit, including fast pumping, with samples being inserted via a stainless steel probe and lock which penetrates the end flange. Data were collected with a Kratos DS 55 data system (Nova 4X and fast preprocessor) and via a set of data acquisition programs written in house, based in part on programs written by Lapp[2]. This was necessary since our Kratos DS-55 data system could not average and process raw data. Experiments were also done with data acquisition on chart paper and via an integrating voltmeter while the instrument was operated in a static mode, with the magnet being set to the top of each peak of interest in turn. The best results were obtained using 30 s/mass decade narrow scans (170–230 Daltons) with data averaged using the time averaging capabilities of our raw data acquisition routines. Samples were run at a nominal resolving power of 1000, averaged in groups of 16, with typically eight sets of such data being acquired.

The ZAB was run at a resolving power of approximately 800, with narrow scans between m/z 230–200 at either 30 or 100 s/mass decade. There were 100 scans collected for each sample using the 11/250 data system. The ZAB data from the data system were consistent with trial runs obtained from the oscillographic recorder. Ten minutes of instrument time was all that was required per sample. Higher resolution could have been used to eliminate the lead hydride peaks rather than correcting for them as discussed below. However, at the lower sensitivity which comes with higher resolution, longer data acquisition time would have been required. Work is now underway to determine the optimum in the resolution–sensitivity tradeoff.

All data were corrected for background detected in the lead isotope region (0.1–0.2%), i.e., 4–8% of the ^{204}Pb peak, and for the presence of (typically) 0.5–1.0% PbH species, corrected on the basis of the 209/208 intensity ratio. The hydride peaks are time dependent, which complicates their correction.

Data were not corrected for mass discrimination of the detectors which we believe to be much smaller than the other systematic instrument errors. For both instruments the 5 mass unit range in question is a tiny fraction of the normal scanning range for which they are designed. The manufacturers have not recommended a mass discrimination correction, and previous work in our lab involving deuterium substitution suggests that neglecting this correction is valid for data with the accuracy we are obtaining.

(b) Sampling

Four methods of obtaining samples for insertion into the FAB source were attempted.

(i) Direct glaze chip method

In this, perhaps the simplest of the methods as far as sample preparation is concerned, a chip of glaze is lifted from a sherd using a flat hardened knife or spatula. The glaze chip is then attached directly to the probe tip with double-sided masking tape. This method presented two problems, first the difficulty of getting a flat chip of glaze from the sherd, and secondly the relatively poor signal-to-noise ratio in the MS-30 with the hardened fired glaze surface exposed to the atom beam. This method may be suitable for use with the ZAB which was observed to have between one and two orders of magnitude sensitivity advantage over the MS-30 for FAB work in this mass range. We did not however pursue this approach as ZAB time was limited.

(ii) Direct powder method

Glaze was scraped from the surface of a sherd using a carbide tipped scriber, and 1–2 mg of the solid powder obtained was placed directly on the tip of the FAB probe, again using double-sided tape. Some tests were done with the powdered glaze pressed into a pellet, but this did not seem critical. The MS-30 data thus obtained were adequate to distinguish sedimentary from igneous lead, but the reproducibility of the data precluded their use for serious studies. Using the ZAB with its greater sensitivity, good data were obtained, equivalent or better in quality than that reported by Dolnikowski *et al.* (7). In an attempt to get better sensitivity with the MS-30 we attempted two acid extraction procedures, discussed below, with some degree of success.

(iii) Powder-acid extraction method

The powdered glaze scraped from the sherds as described above was subjected to a 24 h hot aqua-regia extraction. Several milligrams of glaze were extracted, the undissolved glaze centrifuged off, and the lead–acid solution was allowed to evaporate to dryness. This material was then redissolved in a minimum amount of water and a drop of the concentrated solution was applied to the probe tip followed by evaporation of the water in an oven. Several applications could be made to thicken the layer on the probe tip. The extract from 4 mg of sample digested with 2 mL of acid was sufficient to do 15 separate determinations. The total ion current obtained in this way using the extracted lead salts was an order of magnitude higher than working with the unextracted powdered glazes.

(iv) Sherd-acid extraction method

Since the extraction procedure seemed to be such an advance, we then tried to determine if acid extraction of the glazed surface of a sherd would also provide a sufficient lead concentration for the analysis without the tedious scraping of the glaze, and perhaps without noticeably defacing the sherd. In this technique the glazed surface of the sherd was dipped for 2–3 min in a boiling aqua-regia solution. No visible sign of degradation of the glazed surface was observed. The resulting solution gave the best results of the four methods used for sample preparation with the MS-30. In addition to achieving the best mass spectrometric data from his technique, it was also the easiest in terms of sample preparation, though taking slightly longer than affixing the glaze directly to the probe tip with double-sided tape. With spare FAB probe tips one person could easily prepare ten samples in an hour.

Ultrapure acids should normally be used for lead isotope determinations (8, 9) because traces of lead occur in normal reagent grade acids. However, no lead could be detected by the MS-30 in a blank extraction

[2]R. Lapp. University of Nebraska. Private communication. 1984.

TABLE 1. MS 30 data for the direct powder method

Average		2.132	0.8338

of lead-free glass, using high quality Baker Instra-analyzed reagent grade acids. Blank determinations on various grades of acids should be run with high sensitivity instruments before they are used in the extraction techniques described above.

Results and discussion

The sherds subjected to FAB-ms determination of their lead isotope ratios were obtained from the Jordan pottery site in Jordan, Ontario, in early nineteenth century pioneer pottery excavated by one of us (7).

In Table 1 we show the results of the isotope ratios measured using the direct powder method on the MS-30. The poor sensitivity made it difficult to measure the ^{204}Pb abundance with any accuracy. The data do, however, cluster in the region expected for English or Niagara Peninsula lead, and are distinct from data from most of the remainder of North America. The average value, however, falls outside the range of values expected. We did not have much confidence in these data although they were better than data obtained by directly examining a glaze chip. Detailed statistics were not collected on data points since it was obvious that improved methods would be needed. All the tabular ratio data are based on raw ion abundance that were first corrected for background and the presence of lead hydride species prior to calculation of the isotope ratios.

Dolnikowski *et al.* (6) in their FAB work used a plot of the $^{207}Pb/^{206}Pb$ ratio against that of $^{204}Pb/^{206}Pb$ as a visual indicator of the potential origins of lead samples. This plot has the disadvantage of using the ^{204}Pb abundance which is low and most subject to error. More commonly used is a plot of the 208/206 ratio vs. that of 207/206 (Fig. 1). The English data are taken from the literature (4),[1] while for the Niagara Peninsula and related areas in similar geological formations from northern New York State the data were kindly provided by Farquar.[1] It can be seen that the benchmark data for England and for the Niagara Peninsula overlap to a large extent so that we would expect to have difficulty in distinguishing between the two sources unless the standard deviations are very small. In the work of Dolnikowski *et al.* (6) it was suggested that there was a clear distinction between the lead isotope ratios from England and North America. However, their only points suggesting possible overlap come from the Niagara Peninsula. More detailed investigations[1] of the lead isotope ratios from the literature (3) point to further overlap of various lead sources from the original "Thirteen Colonies" with these of English lead, making life difficult for the archeologist.

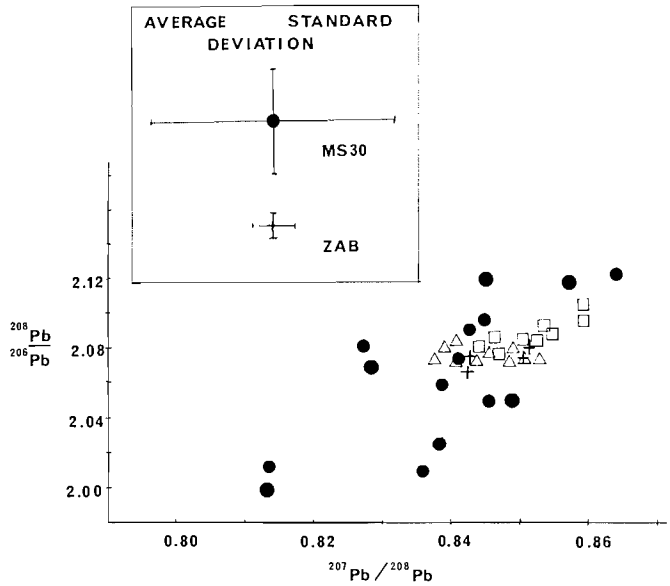

FIG. 1. Plot of $^{207}Pb/^{206}Pb$ vs. $^{208}Pb/^{206}Pb$ for (□) English (4)[1] and (△) Niagara Peninsula[1] lead, (and related escarpment samples from northern New York State), together with data from Jordan pottery sherds determined using (●) MS 30 and (+) ZAB SE mass spectrometers equipped with FAB sources. Standard deviations are shown for the two instruments.

It was clear that if the direct powder method was to be used successfully, higher sensitivity was needed. In Table 2 we show the data obtained on a VG ZAB SE prototype, a large high-mass, high-resolution, high-sensitivity reverse-geometry magnetic mass spectrometer. For the purposes of our experiments, only the stability of the instrument and its sensitivity were important to obtaining good results. The data obtained were of much higher quality, with standard deviations an order of magnitude smaller than for comparable runs on the MS 30. Figure 1 shows that the data from the ZAB fall directly on top of the Niagara Peninsula points. These also overlap with half of the values for English lead, so even with the greater precision, one cannot unequivocally state the origin of the lead in these glazes. However, the data appear to lie within the field of the Niagara Peninsula data points.

In an attempt to improve on the precision obtained with the MS 30 we experimented with the acid extraction techniques. Data are shown in Table 3 and plotted on Fig. 1. The standard

TABLE 4. Summary of data for sherd #846

Mass spec.	Sampling method	$^{208}Pb/^{206}Pb$	$^{207}Pb/^{206}Pb$
ZAB SE	Direct powder	2.077±0.005	0.8513±0.002
MS 30	Direct powder	2.094	0.8944
MS 30	Powder extn.	2.097±0.05	0.8449±0.013
MS 30	Sherd extn.	2.067±0.03	0.8504±0.014
MS 30	Sherd extn.	2.084±0.02	0.8413±0.015

deviations are reduced by a factor of two compared to the direct powder methods, but are still a factor of 5–10 worse than the ZAB powder data. This does suggest, however, that if the extraction techniques are used with the ZAB, data may be obtainable with sufficient precision to permit isolation of lead sources to particular mines. With the MS 30 data there is apparently some systematic error as the data seem shifted towards the lower left-hand side of the graph. However, the average value for all these lead extractions is very close to the Niagara Peninsula points, much closer to them than to the English data, again suggesting that the potter had a local source of lead.

One glaze sample from sherd #846, a green-glazed piece of pottery, was analyzed by both instruments, and the standard deviations calculated. These data are summarized in Table 4. Each MS 30 extraction method data point is within less than one standard deviation of the other MS 30 data points. The ZAB data fall close to the mean of the three MS 30 extraction samples.

Replicate determinations on separate samples of sherd #1166 were also done using the ZAB. Different scan speeds showed no significant differences (Table 2), although standard deviations were lower for the determination done using a 100 rather than 30 s/mass decade scan speed.

In conclusion, it would appear that if a modern mass spectrometer with a FAB source is used for lead isotope determinations for samples of archeological interest, it should be possible to develop the methodology to permit a rapid indication of probable origins of the lead in the artifact. Acid extraction techniques give the best results, and we predict that if these are used in conjunction with a modern high sensitivity instrument, high quality data can readily be obtained.

Acknowledgments

Complexes of hybrid ligands. Some Pd^{2+} and Pt^{2+} complexes of fluoro-alkoxy thioether ligands; the measurement of the *trans*-effect of phosphines on thioether inversion[1]

RENÉ T. BOERÉ AND CHRISTOPHER J. WILLIS

Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 15, 1985

RENÉ T. BOERÉ and CHRISTOPHER J. WILLIS. Can. J. Chem. **64**, 492 (1986).

The hybrid ligands R—S—CH_2—$C(CF_3)_2$—O^- (R = CH_3 or C_6H_5) have been used in conjunction with the other donors to prepare complexes of Pt^{2+} and Pd^{2+}. Five-membered chelate rings are formed by coordination through the hard alkoxy and the soft thioether donor sites. Products are of two types: neutral $MCl\{RSCH_2C(CF_3)_2O\}(PR_3)$ or cationic $[M\{RSCH_2C(CF_3)_2O\}(PR_3)_2]^+$, and their geometry is assigned. Variable temperature nmr measurements are used to follow the inversion of the thioether function in the hybrid chelate ring, and values of $\Delta G\ddagger$ are calculated. From a comparison of the barrier to inversion in various complexes, the dynamic *trans* effect of various ligands is assessed including, for the first time using this criterion, the trialkylphosphines.

RENÉ T. BOERÉ et CHRISTOPHER J. WILLIS. Can. J. Chem. **64**, 492 (1986).

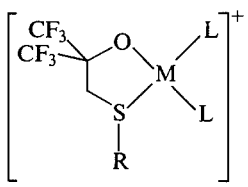
On a utilisé les ligands hybrides R—S—CH_2—$C(CF_3)_2$—O^- (R = CH_3 ou C_6H_5) en conjonction avec d'autres donneurs pour préparer des complexes du Pt^{2+} et du Pd^{2+}. Il se forme des chélates à cinq chaînons par coordination des sites donneurs dur de l'alcoolate et doux du thioéther. Les produits sont de deux types, soit neutres ($MCl\{RSCH_2C(CF_3)_2O\}(PR_3)$) ou cationiques ($[M\{RSCH_2C(CF_3)_2O\}(PR_3)_2]^+$) et on a attribué leur géométrie. On a utilisé des mesures de rmn à temperature variable pour examiner l'inversion de la fonction thioéther dans le cycle du chélate hybride et l'on a calculé les valeurs du $\Delta G\ddagger$. En se basant sur une comparaison de la barrière à l'inversion dans divers complexes, on a évalué l'effet dynamique *trans* de divers ligands dont les trialkylphosphines qui y ont été incluses pour la première fois en utilisant ce critère.

[Traduit par le journal]

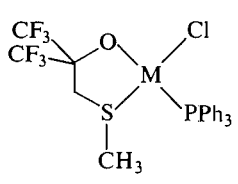
Introduction

In the first part of this series (2), we described the synthesis of molecules of general formula $RSCH_2C(CF_3)_2OH$, containing both a fluorinated alcohol and a thioether function. In the mono-ionized form, these may act as bidentate, chelating, ligands toward transition metal ions. The combination of the hard —$C(CF_3)_2O^-$ donor with the soft thioether function enables them to form stable complexes with the softer transition metal ions, and we have described studies on the neutral bis-complexes $M[RSCH_2C(CF_3)_2O]_2$, which show *cis* geometry for M = Pt and both *cis* and *trans* for M = Pd.

In the present paper, we describe the extension of this study to the preparation of two additional types of complexes of these hybrid ligands, cationic complexes of type **1** with alkyl- and arylphosphine as coligand, and neutral type **2** complexes with phosphine and chloride as coligands.



1



2

The cationic complexes are generally prepared with fluoroborate as counterion. Using phosphines as coligands, we have been able to make platinum(II) complexes with R = Me, L = PPh_3 (**3**), PPh_2Me (**4**), $PPhMe_2$ (**5**), or PMe_3 (**6**); R = Ph, L = PPh_3 (**7**), PPh_2Me (**8**), or $PPhMe_2$ (**9**). Palladium(II) phosphino complexes were more difficult to prepare, and were restricted to that with L = PPh_3, R = Me (**10**). Neutral type **2** complexes have been prepared for both Pt (**11**) and Pd (**12**).

In previous studies on related systems (2, 3) we have attempted to place the fluoroalkoxide function relative to other ligands in the dynamic *trans*-effect series by the measurement of the barrier to thioether inversion. Our object in synthesizing type **1** and **2** complexes was to extend this study and to include, for the first time, trialkylphosphines as coligands *trans* to the thioether group. The presence in these complexes of several nmr-active nuclei (^1H, ^{19}F, and ^{31}P), each of which may couple to ^{195}Pt, makes them particularly suitable for characterization by nmr.

Experimental section

General techniques and the preparation of the fluoroalcohol thioethers $CH_3SCH_2C(CF_3)_2OH$ and $C_6H_5SCH_2C(CF_3)_2OH$ have been described previously (2). As before, we will abbreviate the anionic forms of the ligands to Me—S—O^-, and Ph—S—O^-. Phosphine and thioether complexes of $PtCl_2$ and $PdCl_2$ were prepared by standard routes (3).

$[Pt(Me—S—O)(PPh_3)_2]BF_4$, 3

To *cis*-$PtCl_2(PPh_3)_2$ (1.0 g, 1.26 mmol) in CH_2Cl_2 (30 mL) was added $CH_3SCH_2C(CF_3)_2OH$ (0.29 g, 1.26 mmol) followed by the stoichiometric quantity of KOH in ethanol. (In this and following reactions, it was found convenient to measure out the required amount of KOH volumetrically using a standard solution, ~0.3 *M*, in ethanol). After stirring 3 h, the solution was centrifuged to remove KCl, then $AgBF_4$ (0.25 g, 1.26 mmol) was added, causing immediate precipitation of AgCl. The solution was centrifuged, stirred 16 h, filtered, and reduced in volume. Addition of pentane precipitated **3** as an off-white, air-stable solid (1.22 g, 94% yield) which was recrystallized from CH_2Cl_2–EtOH to give large colorless crystals, mp 294–296°C.

Complexes 4–9

Complexes **4**–**9** were prepared by the same general route, starting with the appropriate complex *cis*-$PtCl_2(PR_3)_2$ and the ligand alcohol $CH_3SCH_2C(CF_3)_2OH$ or $C_6H_5SCH_2C(CF_3)_2OH$. *$[Pt(Me—S—O)(PPh_2Me)_2]BF_4$*, **4**: colorless prisms from CH_2Cl_2–EtOH, mp 183–184°C. *$[Pt(Me—S—O)(PPhMe_2)_2]BF_4$*, **5**: Purification by dry-column chromatography on Florosil (CH_2Cl_2 eluant) yielded an oil which solidified to an amorphous cream solid when treated with ether, but could not be crystallized. *$[Pt(Me—S—O)(PMe_3)_2]BF_4$*, **6**: oil, giving light yellow powder, recrystallized from CH_2Cl_2–EtOH to give colorless crystals, mp 198–200°C. *$[Pt(Ph—S—O)(PPh_3)_2]BF_4$*, **7**:

pale yellow blocks from CH_2Cl_2 – 1-propanol, mp 225–230°C. *[Pt(Ph—S—O)(PPh$_2$Me)$_2$]BF$_4$*, **8**: oil, purified by dry-column chromatography (CH_2Cl_2 eluant), cream solid when treated with ether and vacuum-dried. *[Pt(Ph—S—O)(PPhMe$_2$)$_2$]BF$_4$*, **9**, similar to **8**.

[Pd(Me—S—O)(PPh$_3$)$_2$]BF$_4$, ***10***

To *trans*-$PdCl_2(PPh_3)_2$ (0.50 g, 0.72 mmol) suspended in benzene (40 mL) was added $CH_3SCH_2C(CF_3)_2OH$ (0.20 g, 0.72 mmol) followed by the stoichiometric amount of KOH in ethanol. As the base was added, the suspension passed through deep red to orange in color. KCl was removed, then $AgBF_4$ (0.14 g, 0.72 mmol) in EtOH was added and AgCl was immediately removed by centrifugation, giving a blood-red solution. Removal of solvent, followed by extraction with $CHCl_3$ and precipitation with ether gave a bright red powder, mp 200°C, which could not be recrystallized without decomposition; satisfactory analytical figures on the solid could not be obtained, but the compound was characterized by solution nmr data.

PtCl(Me—S—O)(PPh$_3$), ***11***

To *cis*-$PtCl_2(PPh_3)_2$ (0.50 g, 0.63 mmol) suspended in DMF (40 mL) was added $CH_3SCH_2C(CF_3)_2OH$ (0.14 g, 0.63 mmol) followed by KOH (0.63 mmol) in EtOH. After stirring 16 h, by which time the solids had dissolved, the solution was reduced in volume and the product precipitated in 44% yield by addition of hexane. Recrystallized from CH_2Cl_2–EtOH, beige flakes, mp 267–269°C.

PdCl(Me—S—O)(PPh$_3$), ***12***

To *trans*-$PdCl_2(PPh_3)_2$ (0.1 g, 1.43 mmol) suspended in benzene (150 mL) was added $CH_3SCH_2C(CF_3)_2OH$ (0.33 g, 1.43 mmol) and sulfur (0.046 g, 1.43 mmol) followed by KOH (1.43 mmol) in EtOH. The resulting deep-red solution was stirred 16 h, filtered, and solvent removed to give a yellow solid. After washing with ether, recrystallization from CH_2Cl_2–C_6H_{12} gave yellow platelets, mp 210°C.

Characterization

In all cases where a crystalline product was obtained, new complexes were characterized by elemental analysis. Data are given in Table 1; because of the variety of elements present, it was not possible to obtain reliable results for S and P analyses in every case.

Mass spectra of the cationic type **1** complexes gave peaks corresponding to the complete cation, $[M(PR_3)_2(Me—S—O)]^+$, only in the case of the Pt complexes with PR_3 = PPh_2Me and PMe_3. For all of the cationic Pt phosphine complexes, a strong peak appeared at a mass number corresponding to the loss of the substituent on sulfur, that is, the species $[Pt\{SCH_2C(CF_3)_2O\}(PR_3)_2]^+$, and for the species $[Pt(Pr_3)_2]^+$, where the complete fluoroalcohol thioether ligand has been lost. For the neutral type **2** complexes, the heaviest mass-number peak for both **11** and **12** corresponded to the loss of Cl^- from the molecule, together with typical fragmentation patterns corresponding to the loss of CF_3^-, etc. All species had infrared spectra consistent with their proposed structures. Nuclear magnetic resonance spectra, which provided the principal means for characterization, are discussed separately later in this paper.

Results and discussion

The synthesis of each of the complexes discussed in this work begins with the appropriate phosphine or thioether complex of the metal dichloride. Treatment with ligand and base (KOH) in the required molar ratio gives the type **2** chloro-complex, which may in some cases be isolated at that point. The addition of $AgBF_4$ then produces the cationic type **1** complex.

$$MCl_2(L)_2 + RSCH_2C(CF_3)_2OH + KOH \rightarrow MCl(L)\{RSCH_2C(CF_3)_2O\} + L + KCl$$

$$MCl(L)\{RSCH_2C(CF_3)_2O\} \xrightarrow{AgBF_4} [M(L)_2\{RSCH_2C(CF_3)_2O\}]BF_4 + AgCl$$

Careful choice of solvent and control of stoichiometry is needed in order to isolate these products, and yields at each stage were found to be very variable according to the nature of M, R, and L.

In the mass spectra of the cationic species, substantial peaks corresponding to the loss of the S-alkyl group in the ligand were observed in each case, and this suggested that it might be possible to prepare a neutral thiol complex by reductive dealkylation:

$$[M(L)_2\{RSCH_2C(CF_3)_2O\}]^+ + X^- \rightarrow M(L)_2\{SCH_2C(CF_3)_2O\} + RX$$

This is a well-recognized type of reaction carried out by nucleophilic attack on the thioether, although it has only been observed where the R—S group is attached to an aromatic ring (4, 5). Controlled dealkylation was not successful in our systems, however, since the stability of the complexes was not sufficient to prevent ligand displacement when treated with the strong nucleophiles needed (I^-, SCN^-).

Nuclear magnetic resonance studies

General features of the nmr spectra of the complexes are shown in Tables 2 and 3. Table 2 gives ^1H and ^{19}F data for the fluoroalcohol thioether ligand, while Table 3 gives ^1H and ^{31}P data for the phosphine ligands in the cationic complexes.

In a static situation, the pyramidal coordination of the thioether function induces inequivalence in the protons of the adjacent methylene group and in the geminal CF_3 groups attached to the ring. As we have previously demonstrated for the neutral bis-complexes of this ligand (2), this inequivalence may be removed by raising the temperature so that inversion of the chelate ring and inversion at sulfur becomes rapid (on the nmr time-scale), resulting in the chelate ring appearing dynamically planar. In each case, variable-temperature data are quoted under conditions designed to show, where possible, the limiting cases of such variations in the spectra.

(i) Neutral type 2 complexes

There are clearly two possible geometric isomers for these compounds; the *cis* form shown as **2** above, or the *trans* form in which positions of the Cl^- and PPh_3 ligands are reversed.

[g]Very broad singlet at 150°C.

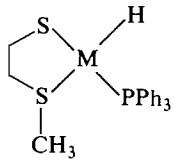
(Throughout, we use the term *cis* and *trans* with reference to the arrangement of the two soft ligands, phosphine and thioether, in the complexes.) It is immediately clear from the nmr spectra that the Pt complex **11** contains only one isomer, while the Pd analog **12**, is a mixture of two. In addition to the ^1H and ^{19}F data shown in Table 2, the Pt complex has a ^{31}P signal consisting of a singlet with ^{195}Pt satellites, δ = −1.87 ppm, ^1J(Pt,P) = 3455 Hz, while the Pd complex has two singlet ^{31}P signals, at 23.9 and 21.5 ppm.

Based on the known chemistry of the two metals, it would be expected that the antisymbiotic effect (6) would be stronger for the Pt complex, resulting in preferential formation of the isomer where the two soft ligands (PPh_3 and S—CH_3) are *cis* to each other. The nmr data are entirely consistent with this assignment. Firstly, there is no observed coupling from the CH_3—S group to phosphorus, whereas a value of 4–5 Hz for ^4J(P,H) is consistently observed for coupling to *one* phosphorus nucleus in the cationic type **1** complexes. It is well-established that *trans* coupling is considerably stronger than *cis*, so the absence of coupling is consistent with *cis* geometry in **11**. Secondly, ^3J(Pt,H) for the —SCH_3 group is 58–61 Hz, consistent with the presence of a *trans* chloride ligand, whereas in complex **3**, ^3J is only 40.8 Hz.

The CH_3 resonance in **11** is at 1.9–2.1 ppm, *more shielded* than the resonance in the free ligand (2.20 ppm), whereas the shift on coordination is in the opposite direction (to 2.8–2.9 ppm) in Pt(Me—S—O)$_2$ (2). This shielding is almost certainly due to the effect of the aromatic ring anisotropy of the phenyl groups in the *cis*-phosphine ligand in **11**, and similar effects occur for the cationic type **1** complexes. An upfield shift

on coordination has also been observed in a ruthenium complex, and attributed to nonbonding interactions between S—CH_3 and phenyl groups (5).

An analogous system in which chelated thioether and phosphine are coordinated to platinum has been reported (7).



In this compound, the CH_3—S resonance is at 1.6 ppm, ^4J(P,H) = 1 Hz, and ^3J(Pt,H) = 14 Hz. The small coupling of the methyl protons to phosphorus, and the very greatly reduced coupling to platinum, are consistent with hydride *trans* to SCH_3, rather than the phosphine as the authors suggest.

The methylene signal of **11** consists of an AB pattern (67%) with $J_{AB} \approx 14$ Hz, a typical value for geminal protons, which is superimposed on a well-defined ABX pattern (33%) due to coupling with ^{195}Pt. The latter is symmetrical, with $J_{AX} = J_{BX} = 31.0$ Hz. On raising the temperature, the difference between inequivalent methylene protons decreases as thioether inversion becomes more rapid. Coupling to ^{195}Pt persists throughout, demonstrating a nondissociative mechanism of inversion. At 180°C, the highest temperature attainable in DMSO solution, the former have collapsed to a sharp singlet with satellites; ^3J(Pt,H) = 31.0 Hz. The peaks from the inequivalent CF_3 groups consist of a doublet of quartets at 32°C; the latter collapse into two broad singlets at ~110°C and to one very broad singlet around 150°C. The higher coalescence temperature is due to the greater difference in chemical shift of the ^{19}F signals.

With the palladium complex **12** it is possible to observe isomerization in solution. Freshly prepared samples show a preponderance of one isomer (*cis*) which corresponds to the solid-state form. After ~10 min in solution, this has equilibrated into the *cis–trans* mixture, whose composition is solvent and temperature dependent. At 32°C, the *cis* isomer amounts to 54% in CD_2Cl_2 but only 18% in $CDCl_3$, the latter dropping to 13% at 60°C.

Discrimination of these isomers is made on the same arguments as for **11**. The two CH_3—S signals are at 1.78 ppm with ^4J(P,H) = 1.5 Hz and at 2.72 ppm with ^4J = 5 Hz; the combination of greater shielding and smaller coupling clearly indicates that the former has CH_3—S *cis* to phosphine.

Signals from the methylene protons in **12** show AB patterns for both *cis* and *trans* isomers. The former is resolved at ambient temperature, but the latter only gives sharp signals on cooling to −20°C. Coupling to ^{31}P (^4J = ~2.5 Hz) then appears for one of the CH_2 protons of the *trans* isomer. On heating to 60°C, the methylene signal of the *trans* isomer collapses to a sharp singlet; it is not possible to observe this accurately for the *cis* isomer because its population drops as the temperature is raised, but it may be estimated that its coalescence temperature is at least 30°C higher than *trans*. This is in accord with the geometrical assignments, as the *trans* effect on thioether inversion of PPh_3 is expected to be significantly greater than that of Cl^- (8, 9).

The ^{31}P signals of *cis* and *trans* **12** were assigned from a comparison of their relative intensities in different solvents where populations had been established using ^{1}H and ^{19}F nmr spectra, from which the peak at 23.9 ppm is assigned to the *cis* isomer and that at 21.5 ppm to the *trans*. The latter is therefore slightly more shielded by the presence of the *trans* thioether, consistent with previous observation that a ligand of greater *trans* influence shifts a ^{31}P resonance to higher field (10).

The ^{19}F nmr spectra of complex **12** show an interesting difference between isomers. The *cis* form shows the usual doublet of quartets associated with inequivalent geminal CF_3 groups, but the *trans* form gives a singlet signal even at −20°C. As noted above, the methylene protons in this isomer give an AB doublet showing inequivalence because of the adjacent pyramidal thioether. The unusual nmr equivalence of the CF_3 groups is also seen in the cationic complex **3**.

(ii) Cationic type 1 phosphine complexes

In the presence of chloride, complexes of type **11** and **12** form by displacement of phosphine. Removal of Cl^- with Ag^+ leads to the isolation of the cationic complexes, in which the ligand *trans* to the thioether is also a phosphine. The ^{31}P data for these complexes are summarized in Table 3. The two phosphines are, of course, required to adopt *cis* geometry by the presence of the chelating coligand, and spectra are consistent with the presence of two inequivalent ^{31}P nuclei. We denote the phosphine *trans* as P_B. The coupling between them, $^2J(P_A,P_B)$ lies within the narrow range of 24.0–26.1 Hz. This is typical of *cis* phosphine complexes, for example, in the dihalide complexes $PtX_2(PMe_3)_2$, ^2J(P,P) is 18.9, 16.2, and 14.0 for X = Cl^-, Br^-, and I^-, respectively, compared to values of ~500 Hz in the *trans* isomers (11).

Two arguments may be used in the assignment of the ^{13}P signals to P_A and P_B. Firstly, in complexes of Me—S—O^-, coupling of 4–5 Hz is observed from CH_3 protons to *one* phosphorus nucleus. Selective decoupling experiments then show that, in all cases, this coupling is to the ^{31}P with the downfield resonance. There is ample precedent to show that the *trans* phosphine couples more strongly than the *cis* in square-planar complexes (12), so the downfield resonance may be assigned to P_A. Secondly, the cationic PPh_3 complex **3** may be compared with the neutral complex **11**, which we have shown to have the phosphine and thioether functions *cis*. The ^{31}P peak in **11** is at −1.87 ppm, whereas those in **3** are at 14.75 and 0.44 ppm, so the latter is more likely to correspond to P_B, *cis* to the thioether group.

The differences in the value of ^1J(Pt,P) between P_A and P_B for the various complexes are given in Table 3, and show a consistent trend. In the two series, using either Me—S—O^- or Ph—S—O^- as coligand, the value of Δ^1J(P) increases as phenyl groups in PR_3 are successively replaced by methyl. Although ^1J is decreasing for both P_A and P_B in these sequences, it drops more rapidly for P_B. Thus, in going from PPh_3 (**3**) to PPh_2Me (**4**), ^1J decreases by 125 Hz for P_B but only 54 Hz for P_A. The value of ^1J(Pt,P) for P_A *trans* to the thioether function of the hybrid ligand is consistently smaller by ~60 Hz. for each Me—S—O^- complex than for its Ph—S—O^- analog, showing the expected greater *trans* influence of the methylthioether. The value of ^1J for P_B only changes by ~10 Hz between each pair of complexes, consistent with our assignment that this phosphine is *trans* to alkoxide in each case.

For the palladium complex **10**, assignment of the two ^{31}P signals was carried out by comparison with neutral complex **12**. The downfield resonance (δ = 30.0 ppm) is associated with P_B, and that to higher field (δ = 25.6 ppm) with P_A. The difference between these (6.4 ppm) is greater than that found between *cis*

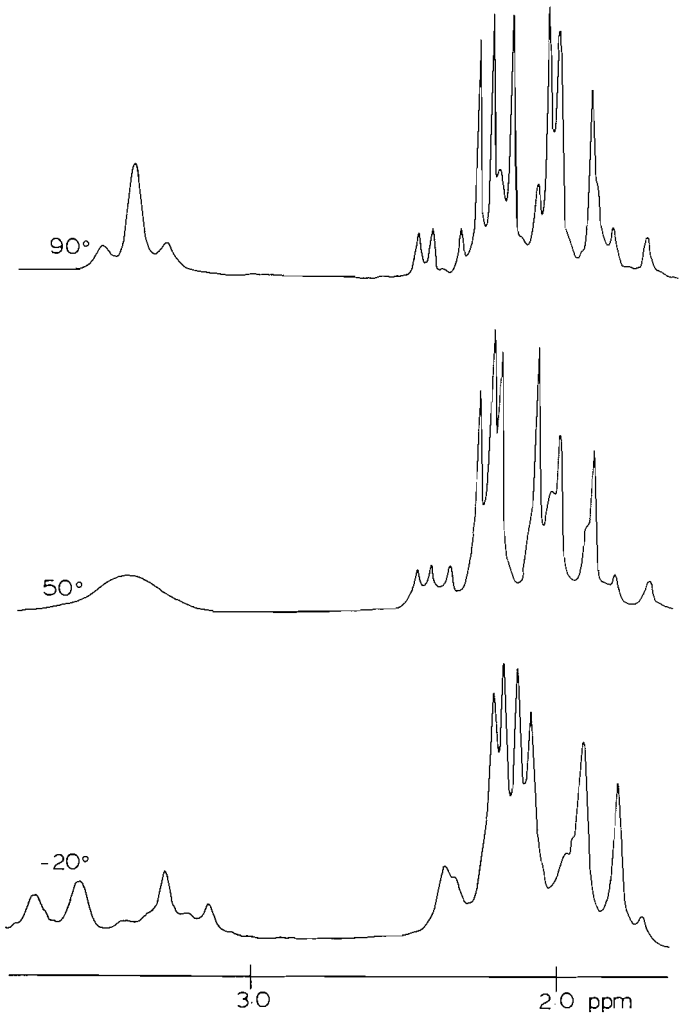

FIG. 1. The ^1H nmr spectrum of $[Pt(Me—S—O)(PPh_2Me)]^+$, **4**, showing coalescence of the CH_2 signal.

and *trans* forms of **12** (2.4 ppm), but less than the 14.3 ppm found in the Pt complex **3**. The value of $^2J(P_A,P_B)$ (23.7 Hz) is very similar to that in **3**. The relative positions of the ^{31}P resonances in the Pd complex are opposite to the assignments in the Pt series **3–9**, with P_B to low field of P_A, but such a reversal has been noted before in the *cis* and *trans* forms of the Pt and Pd complexes $MCl_2(PR_3)_2$ (13).

Variable temperature nmr studies were needed for a complete characterization of the ^1H and ^{19}F nmr spectra of the cationic complexes. Those of the Pt complexes with phosphines as coligand were generally similar, and the PPh_2Me complex **4**, shown in Fig. 1, will be discussed as an example.

At −20°C, the limiting[2] low temperature for this compound, the methyl region of the spectrum contains three doublets with doublet satellites, which are associated with CH_3S, CH_3P_A, and CH_3P_B. Each methyl group is coupled to both phosphorus and platinum, and ^4J for the CH_3S—P coupling is about half that of ^2J for CH_3—P coupling. The ^3J couplings for CH_3S—Pt and CH_3P_B—Pt are comparable, but that for CH_3P_A—Pt is smaller.

The ligand CH_2 resonance has a typical AB pattern (J_{AB} = 14 Hz, Δ_{AB} = 38.5 Hz) superimposed on a smaller ABX pattern due to coupling to ^{195}Pt. In contrast to the spectrum of the neutral complex **11**, this ABX pattern is unsymmetrical and buried under the major peaks, making analysis impossible. The ^{19}F spectrum[3] at −20°C consists of a doublet of quartets (J_{AB} = ~9.5 Hz, Δ_{AB} = 68.5 Hz), with slight second-order distortion, associated with the inequivalent geminal CF_3 groups.

The limiting high-temperature spectrum of complex **4** was run in $CDCl_3$ (sealed tube). All of the CH_3 resonances show some degree of temperature dependence in their chemical shifts, causing major changes in the appearance of the spectra (although the parameters are not greatly altered). The methylene signal is a fairly broad singlet, with ^3J coupling to ^{195}Pt of 20.5 Hz, less than ^3J for the CH_3S group (38 Hz). The ^{19}F signal has also collapsed to a singlet at 90°C; further sharpening would undoubtedly occur at higher temperatures, but no further information would be obtained.

In the spectrum of the $PPhMe_2$ complex **5**, most features are similar to those of **4** discussed above. However, there is a conspicuous difference in the low-temperature spectrum of the CH_3—P groups, which appear as *four* equal signals divided into two groups of two, all having essentially equal coupling to

[2]By limiting we imply that no significant change occurred in the spectrum when the temperature range was extended.

[3]No attempt was made to record the signal due to the BF_4^- counterion, which lies ~7000 Hz to high field of the CF_3 region.

^{31}P and ^{195}Pt. (The signals overlap, and selective decoupling was needed to resolve them.) They merge into the usual two peaks at high temperature. This low-temperature inequivalence can be explained by slow rotation (on the nmr time-scale) about the Pt–P bonds, associated with steric interaction, which could lead to conformational isomers having different environments for the methyl groups.

When the same phosphine is used as a coligand with the phenylthioether Ph—S—O^-, giving complex **9**, a similar effect is seen. In the low-temperature spectrum, two signals (each a doublet with ^{195}Pt satellites) are seen for CH_3—P_A, but only one signal for CH_3—P_B. This suggests that, in this complex, the steric restraints are such that there is restricted rotation about the Pt—P_A bond, but not the Pt—P_B bond. Alternatively, the preferred conformation may be such that the CH_3 groups attached to P_B are in similar environments.

For the PPh_3 complex **3**, the ^1H and ^{31}P nmr spectra are normal, but the ^{19}F signal is anomalous. It consists of a singlet, even at −20°C, indicating equivalent geminal CF_3 groups in the chelate ring. Under the same conditions, and up to 32°C, the adjacent methylene protons give the usual AB doublet because of the presence of the pyramidal thioether. A complete structural investigation of **3** (and, for comparative purposes, the PPh_2Me complex **4**) has been carried out to clarify this anomaly.[4]

The only cationic complex of palladium studied was $[Pd(PPh_3)_2(Me—S—O)]^+$, **10**. Its ^1H and ^{19}F spectra are similar to those of the Pt analog **3**, except that the coalescence temperature is considerably lowered; this difference is generally observed for thioether complexes of Pd and Pt (14). The CH_2 and CF_3 signals show the usual inequivalence at −40°C, but both have become equivalent at 32°C. The CH_3S signal is a doublet through coupling to the *trans* phosphine; $^4J(Pt,H)$ = 4.5 Hz, the same value as in **3**.

Thioether inversion studies

We have previously reported studies of inversion of coordinated thioethers in a number of systems where fluorinated alkoxide donors are also present, namely perfluoropinacol complexes $M(PFP)(SR_2)_2$, M = Pt or Pd (3), and neutral complexes of the hybrid ligands $M(R—S—O)_2$, M = Pt or Pd (2). In the present work, we have taken the same general approach; that is, we have obtained rate constants, and hence the inversion barrier $\Delta G^{\ddagger}$, from observations of band-widths at the coalescence point in variable-temperature nmr spectra. The treatment of data has been discussed in our previous papers and follows that given by Sandström (15).

In the complexes described in this paper, thioether inversion may be followed by observing the nmr signal of either the CH_2 protons or the CF_3 groups of the ligand, both of which will show inequivalence because of the presence of the pyramidal coordinated sulfur atom. In the former, this leads to AB type doublets at the lower limiting temperature, which coalesce to A_2 singlets. The spectral changes accompanying coalescence for complex **4** (Fig. 1) show the ^{195}Pt satellites in the limiting high-temperature spectrum, and the ABX pattern, at low intensity, visible under the dominant AB pattern at low temperatures. We have not attempted to account for Pt coupling in the inversion studies, and the contribution of the coupled nuclei to the linewidth at coalescence is assumed to be negligible.

A closed solution for the rate of exchange at the coalescence point for an AB spin system has been derived (15), and the rate constant, k, is given by

$$k = \pi \left[\frac{(w^*)^2 + 6J^2}{2} \right]^{1/2}$$

Here, w^* is the half-height linewidth at coalescence, and J is the coupling constant J_{AB}, which we have obtained from the low-temperature limiting spectra. The calculations are summarized, and the results presented in Table 4.

Inversion at sulfur exchanges ^{19}F signals from the CF_3 groups in A_3X_3 or A_3B_3 systems to yield eventually a singlet A_6 type spectrum. No closed analytical expression exists for this process, and previous Dnmr studies of CF_3 exchange have generally employed complete band-shape fitting. However, in cases where the value of Δ_{AB} is large, the effect on a doublet-of-quartets pattern of increasing the exchange rate is firstly to collapse the quartets internally into two broad singlets, then for this pattern to undergo further collapse into one broad singlet. We have, therefore, taken the simplified approach of applying the equation of Gutowsky and Holm (16) to the CF_3 spectra, taking the linewidth at half-height of this second coalescence point as Δ_{AB}. Calculations based on the ^{19}F spectra are summarized in Table 4; values of the activation energies

obtained in this way must be considered as approximations, especially as the value of Δ_{AB} decreases.

Mechanism of inversion of thioethers

The results of these studies further substantiate the application of the classical mechanism of inversion to coordinated thioethers, developed by Abel and coworkers (17). Key points of this approach, which we have developed in previous papers (2, 3), can now be applied to a further range of complexes.

(i) Metal dependence

Isostructural complexes of Pt and Pd can be compared in two cases in this series. For the neutral complexes **11** and **12**, $\Delta G^{\ddagger}$ is 10–11 kJ lower for Pd, while between the cationic pair with PPh_3 as coligand, **3** and **10**, the Pd complex is lower by ~8 kJ. We have previously noted a reduction of ~16 kJ in $\Delta G^{\ddagger}$ in the neutral bis-complexes M(R—S—O)$_2$ in going from Pt to Pd (2). The lower barriers in the case of Pd are consistent with its lower electronegativity (1.35 versus 1.44 (18)) and with the better π overlap between metal and sulfur, leading to stabilization of the transition state.

(ii) Substituent on sulfur

A comparison of the $\Delta G^{\ddagger}$ values for analogous complexes of Me—S—O$^-$ and Ph—S—O$^-$ shows little, if any, difference beyond experimental error. A reduction of the barrier has been observed when the backbone of a chelated thioether is replaced by an aromatic group, and this has been attributed to stabilization of the transition state by π conjugation with the ring (14, 19). However, in complexes with nonchelating aromatic substituents on sulfur, of the type M←S(R)Ph, a slight *increase* in $\Delta G^{\ddagger}$ compared to the Me—S analog (0.5–0.6 kJ mol^{-1}) has been noted (20), suggesting free rotation about the C—S bond and minimal conjugation effects. Such a change is below the experimental error in our data.

(iii) Trans *effect and the barrier to inversion*

The data available now, in conjunction with previous results (2), enable us to establish a *trans*-effect series for Pt and Pd thioether complexes that includes, for the first time, phosphines. Using the data in Table 4, where the thioether group is part of the hybrid ligand chelated to Pt in each case, the order of decreasing barrier height (that is, of *increasing trans* effect) as the *trans* ligand is varied is

	Compound		
	Pt(Me—S—O)$_2$	**11**	**3–6**
Trans-function	—C(CF$_3$)$_2$O$^-$	Cl	PR_3
Barrier, kJ/mol	89±1	82±1	65–67

Data from the Pd complexes show a parallel trend

	Compound			
	cis-Pd(Me—S—O)$_2$	*cis*-**12**	*trans*-Pd(Me—S—O)$_2$	**10**
Trans function	—C(CF$_3$)$_2$O$^-$	Cl$^-$	—S—CH$_3$	PR_3
Barrier, kJ/mol	73.5±1	71–72	68±1	56±1

Within the phosphine series, the differences are not significant, the barrier ranging from 67 ± 1 kJ with PMe_3 to 65 ± 1 kJ with PPh_3 as ligand. A recent study by Gosling and Tobe (21) of the kinetic *trans* effect on ligand substitution rates has given the order $SR_2 < OSR_2 < AsR_3 < PR_3 < P(OR)_3$. These workers also note that the effect of substitution of R groups in phosphines is small, and that the relative positions in the series of PMe_3 and PPh_3 depend on the nature of the reaction being studied. A study on various substituted thioethers led them to a similar conclusion (22).

Our results are, in general, complementary to those of Gosling and Tobe, and show that the use of thioether inversion barriers as a measure of the *trans* effect leads to the expected placing of the phosphines at the high end of the scale.

Structural parameters for the chair or twist-boat conformations of 1,3-dioxa-5,6-benzocycloheptene and its 2-methyl and 2,2-dimethyl derivatives

ROBERT ST-AMOUR, MARC J. OLIVIER, MAURICE ST-JACQUES,[1] AND FRANÇOIS BRISSE[1]
Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7
Received July 31, 1985

ROBERT ST-AMOUR, MARC J. OLIVIER, MAURICE ST-JACQUES, and FRANÇOIS BRISSE. Can. J. Chem. **64**, 500 (1986).

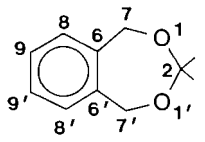
Low temperature X-ray studies of 1,3-dioxa-5,6-benzocycloheptene (**1**) and its 2-methyl (**2**) and 2,2-dimethyl derivatives (**3**) show that **1** and **2** exist in the crystal state exclusively in the chair (*C*) form while **3** exists exclusively in the twist-boat (*TB*) form. The final values of the agreement index, R_w, are 0.048, 0.059, and 0.046 for **1**, **2**, and **3**, respectively. Significant structural differences between the g^+g^+ arrangement of the acetal moiety with the *TB* form and the g^+g^- disposition in the *C* form are revealed. These differences can be interpreted as arising from a less efficient back-donation of an antiperiplanar lone pair on the oxygen atom in the g^+g^+ relative to the g^+g^- arrangement. Furthermore, the C—O bond lengths shed some light on the hybridization state of the lone pairs of electrons on oxygen. Finally the results are used to rationalize nmr observations in terms of molecular conformations in solution.

ROBERT ST-AMOUR, MARC J. OLIVIER, MAURICE ST-JACQUES et FRANÇOIS BRISSE. Can. J. Chem. **64**, 500 (1986).

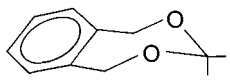
L'étude par diffraction des rayons X à basse température du dioxa-1,3 benzo-5,6 cycloheptène (**1**) et de ses dérivés méthyl-2 (**2**) et diméthyl-2,2 (**3**) montre que **1** et **2** existent à l'état solide seulement sous la forme chaise (*C*) alors que **3** n'existe que sous la forme bateau-croisé (*TB*). Les valeurs finales du facteur d'accord R_w sont 0,048, 0,059 et 0,046 pour **1**, **2**, et **3** respectivement. Des différences structurales significatives entre l'arrangement g^+g^+ du groupe acétal dans la forme *TB* et la disposition g^+g^- dans la forme *C* sont mises en évidence. On interprète ces différences par une rétrodonation moins efficace du doublet antipériplanaire de l'oxygène dans l'arrangement g^+g^+ relativement à l'arrangement g^+g^-. De plus, les longueurs des liaisons C—O clarifient le type d'hybridation des doublets de l'oxygène. Finalement, ces résultats permettent de rationaliser les observations de rmn sur les conformations des molécules en solution.

Introduction

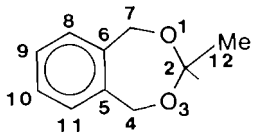
In recent years, we have studied the conformational properties of 1,3-dioxa-5,6-benzocycloheptene **1** and several derivatives in solution (1, 2) by means of ^1H and ^{13}C dnmr (dynamic nuclear magnetic resonance) methods. They reveal the existence of a mixture of the chair form **1***A* and the twist-boat form, **1***B*, in a ratio of 79:21 (in CHF_2Cl, at −130°C) (1).



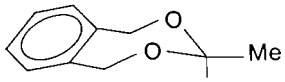
1



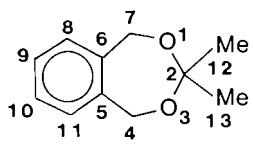
1A



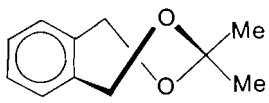
2



2A



3

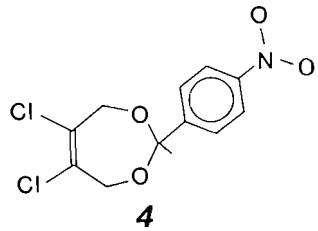


3B

Whereas the presence of a methyl group on the acetal carbon, C(2), slightly stabilizes the C_e form,[2] **2***A*, (96% at −115°C) (2), the addition of a second methyl on the same carbon destabilizes the *C* form completely in favor of the *TB* form, **3***B* (100%). This conformational behaviour was rationalized in terms of electronic and steric factors.

It is known that changes in electronic interactions can produce significant structural modifications in some organic compounds. For example, crystallographic studies (3) show that the bond distances in the C—O—C—O—C sequence in carbohydrates are dependent upon the orientation of the polar substituents on the anomeric carbon. The title compounds contain the same sequence of atoms, so that some structural differences between the chair and the twist-boat conformations might be expected.

To our knowledge, only the *TB* form of an analogue, 5,6-dichloro-2-*p*-nitrophenyl-1,3-dioxacyclohept-5-ene, **4**, has



4

been characterized and no structural information regarding the chair form has been found. This lack of information suggests a crystallographic investigation of compounds **1**, **2**, and **3**, yielding a precise characterization of the shape of the two most important conformations of the seven-membered ring containing the acetal function. Such data also permit a more complete assessment of the dependence of the structural parameters on electronic factors.

Experimental

The three compounds were prepared by known procedures (1, 2). Crystals of **1** were obtained by a bulb-to-bulb sublimation in a Kugelrohr apparatus. Those of **2** were grown at room temperature by sublimation onto a cold finger while crystals of **3** were recrystallized in an ethanol–water mixture. All X-ray measurements have been made at low temperature using the locally modified Nonius liquid nitrogen low temperature attachment.

The accurate cell parameters and the intensity data were obtained on an Enraf–Nonius CAD4 diffractometer, using 25 reflections randomly found in the diffraction sphere. The space groups were chosen according to the symmetry of axial films and systematic absences in the measured intensities. Crystal data of interest are given in Table 1. The intensity data were collected by the ω/2θ scan technique using graphite monochromatized Kα radiation (either Cu or Mo). The intensities of three reference reflections were monitored every hour to assess the stability of the crystals. The orientation of the crystals was verified after every 100 measurements. Structure factors were obtained after scaling of the intensity data and Lorentz and polarization corrections were applied.[3] No attempt was made to correct for absorption because the absorption coefficients were small. Furthermore, the FLAT option of the Nonius diffractometer was used for both **2** and **3**. This option allows for the intensity measurement to be made in an orientation which minimizes the absorption effects. The details of the data collections are summarized in Table 2. The structures were solved using the MULTAN set of programs. All non-hydrogen atoms were revealed in each case in the first computed E-map. The weighted least-squares refinement of the atomic coordinates, minimizing $\Sigma w(|F_o| - |F_c|)^2$, was conducted with anisotropic temperature factors for C and O atoms and isotropically for H atoms. The weights were derived from the counting statistics of the intensities. The refinements were concluded when the largest (displacement/σ) ratio was less than 0.30. The details of the least-squares refinements are given in Table 2 for all three compounds.

The scattering curves for non-hydrogen atoms were taken from ref. 5 and those for H atoms for ref. 6. The atomic coordinates for the compounds under investigation are listed in Table 3. The tables of observed and calculated structure factors are part of the supplementary material.[4]

[3]The programs used here are modified versions of NRC-2, data reduction; NRC-10, bond distances and angles; and NRC-22, mean planes; FORDAP, Fourier and Patterson maps (A. Zalkin); MULTAN, multisolution program; NUCLS, least-squares refinement; and ORTEP, stereodrawings (7–10).

[4]Structure factor tables, anisotropic temperature factor tables, details of the least-squares planes calculations, and the list of REFCODES of 1,3-dioxane containing compounds taken from the Cambridge Data File have been deposited. Copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

The atomic numbering is indicated on the structures **1**, **2**, and **3**. The packing diagrams for the three molecules are shown in Fig. 1. The bond distances and bond angles of the three compounds are listed in Table 4 and are compared to the corresponding quantities in **4**. The torsion angles of interest are listed in Table 5.

The conformations of the molecules fall into two categories. Compounds **1** and **2** have the *C* conformation with the acetal in the g^+g^- arrangement while compounds **3** and **4** have the *TB* conformation and a g^+g^+ acetal arrangement.

Previous theoretical studies of a model compound (3*d*), dimethoxymethane, have shown that an acetal sequence in the g^+g^- arrangement without constraint has an ideal torsion angle of 60°. Our observations in compound **1** (Table 5) are −75.0(2)° and 75.0(2)° for O(1)—C(2)—O(3)—C(4) and O(3)—C(2)—O(1)—C(1), respectively. The same torsion angles in compound **2** have values of −75.1(2)° and 74.4(2)°. The equatorial methyl group in **2***A* hardly perturbs the conformation of the seven-membered ring. The torsion angles are significantly lower than the experimental value of 82.7° reported for the g^+g^- disposition of dimethoxymethane (15).

In the twist-boat **3***B* with a g^+g^+ disposition, the torsion angles of interest have values of 47.1(2)° and 49.1(2)°. In **4** the same torsion angles are 51.6(4)° and 45.9(4)°. These quantities are significantly different from the calculated 62.4° and experimental 63.3° values for the g^+g^+ arrangement of dimethoxymethane (11).

From a study of a large number of 1,3-dioxane derivatives in the chair form, the average of 67 bond angles O(1)—C(2)—O(3) in the acetal sequence is 111.7°, a value slightly larger than the ideal for sp^3 hybridization. In compound **1**, this angle has a value of 113.6(2)° while in compound **2** it is 112.8(2)°. In contrast, in the twist-boat **3***B* this bond angle is only 109.6(2)°, rather close to the 110.5(3)° in **4**. A similar difference in bond angles is calculated by van Alsenoy *et al.* (11) in dimethoxymethane, for which the O—C—O angles in the g^+g^- and the g^+g^+ conformations are evaluated to be 115.7 and 112.4°,

TABLE 2. Summary of data collection and refinement

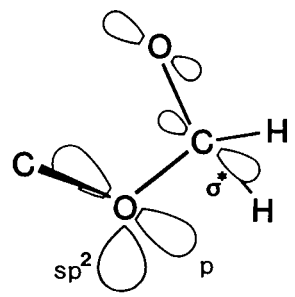
respectively. The larger angle values in g^+g^- may arise from *syn*-diaxial interaction between the two lone pairs on the oxygen. In our case, the *gem*-dimethyl effect (12) may also contribute to the 109° angle in **3***B*.

The structural parameters obtained for **1**, **2**, and **3** also allow us to assess the bond lengths to the anomeric carbon. A normal C—O bond length is 1.43–1.44 Å. For example, it is 1.425(5) Å in methanol and 1.435(5) Å in cyclopenteneoxide (16). These values are close to our results for the outer C—O bonds of the chair form **1***A*, 1.441(2) Å; **2***A*; 1.436(3) Å; and twist-boat **3***B*, 1.432(2) Å. On the other hand, the anomeric bond length of the acetal function is significantly shorter in the chair forms **1***A*, 1.409(2) Å; and **2***A*, 1.414(2), 1.408(2) Å; whereas in the twist-boat **3***B* the inner bond length is slightly longer, 1.425(2) Å. In the case of **4***B* one also notes that the anomeric C—O bonds are shorter than the outer C—O bonds.

The mean values of the inner and outer bond lengths in the acetal sequence reported for 67 1,3-dioxane rings in the Cambridge Data File are presented in Table 6. They are compared with their counterparts in dimethoxymethane and our own results.

It is of interest that, for the compounds studied here, it is also possible to rationalize the inner bond shortening in relationship to conformational changes in a manner similar to that used by Jeffrey (3*c*) for methylpyranosides.

According to many authors (3), the shortening of the inner C—O bond in a *gauche* conformation is due to the back-donation of one lone pair of an oxygen to the non-bonding orbital of the antiperiplanar C—O bond, as seen in **5**. The longer inner bond for the *TB* form **3***B*, which is in a g^+g^+ disposition compared to the *C* forms **1***A* and **2***A* possessing a g^+g^- conformation, may reflect a less efficient back-donation of the lone pair on the oxygen of the *TB* form because of a less favorable angular relationship.



5

The difference in the extent of back-donation, and consequently of the inner C—O bond lengths, between the *C* and the *TB* forms can be readily explained if the oxygen is considered to be sp^2 hybridized instead of sp^3. Both hybridization states have been considered previously (3*b*, 13) without firm evidence for one or the other. Molecular models and the torsion angles in

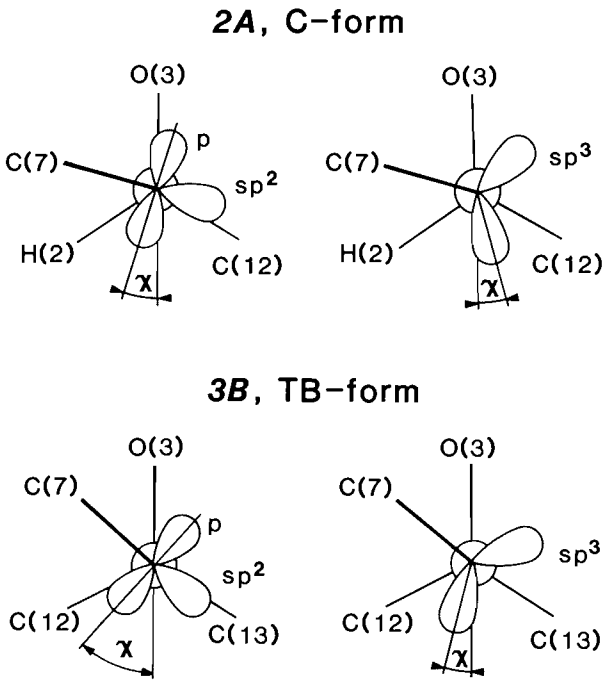

FIG. 2. Newman projections along O(1)→C(2) for **2***A* and **3***B*, where O(1) is either sp^2 or sp^3 hybridized. χ is the torsion angle between O(3) and the axis of the *p* or sp^3 orbital.

Table 5 for **2** (*C*) and **3** (*TB*) lead to the Newman projections along the O(1)—C(2) bond[5] shown in Fig. 2 for each of the possible hybridization states. When O(1) is sp^3, a similar torsion angle, χ, exists for **2***A* and **3***B* between a lone pair of O(1) and the σ* orbital of the C(2)—O(3) bond (χ ~ 15°). On the other hand, if O(1) is sp^2 hybridized, the torsion angle is more favorable for back-bonding in the *C* form **2***A* (χ ~ 15°) than the *TB* form **3***B* where χ is about 40°. The smaller χ value for *C* relative to *TB* in the latter case then explains the greater bond shortening observed for the *C* forms of **1** and **2**. This experimental observation in seven-membered rings constitutes the first evidence in favour of sp^2 hybridization for the acetal oxygen atoms.

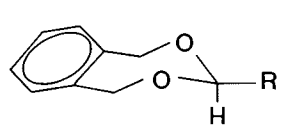
[5]The same result will be observed in a projection along O(3)—C(2).

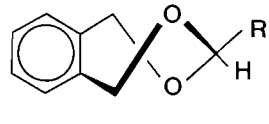
TABLE 7. Comparison of the dihedral angles (degrees) measuring the puckering in **1***A*, **2***A*, and 1,3-dioxane

	1*A*	**2***A*	1,3-Dioxane
[1]/[2]*	125.8	128.2	131.6
[2]/[3]	115.3	116.0	123.7

*Atoms included in the planes: [1] benzo group; [2] C(7), O(1), O(3), C(4); [3] O(1), O(3), C(2).

Although not included in the least-squares planes calculations (in each of the three compounds), atoms C(4) and C(7) are found to be coplanar with the benzo group, which forms plane [1]. Atoms C(7), O(1), O(3), and C(4) in the chairs **1** and **2** are also coplanar; they form plane [2]. Plane [3] is the acetal function made up of atoms O(1), O(3), and C(2). The puckering of the cycloheptene chair is measured by the angle between these planes. They are compared in Table 7 to those of 1,3-dioxane. It is clear that **1***A* and **2***A* have quite similar puckering. However, these two seven-membered rings are more puckered than 1,3-dioxane. The result of this puckering causes an increased interaction between an axial substituent on the anomeric carbon C(2) and the axial benzylic hydrogens H(41) and H(71) in **3**.





R = H	**1**	79%	21%
CH_3	**2**	96%	4%
C_6H_5	**6**	77%	23%

This also explains why only the *TB* form is observed for **3**.

Correlation between X-ray and nuclear magnetic resonance data

We now compare solid state information derived from the X-ray analyses with ^{13}C nmr information on the same compounds in solution (1, 2). As we will see next, the combination of these two techniques provides complementary information about the molecular geometry.

Whereas the two techniques reveal only the symmetrical *TB* form for **3** (dimethyl derivative) both in the crystalline state and

in solution at low temperature, slightly different results are obtained for the parent compound **1** and its monomethyl derivative **2**. The low temperature ^{13}C nmr spectra of **1** and **2** in solution show the presence of a major conformation (*C*) and a minor one (*TB*) in a ratio 79:21 for **1** (in CHF_2Cl at $-130°C$) and 96:4 for **2** (in CHF_2Cl at $-115°C$). The X-ray data identify only one conformation for each compound, the *C* form for **1** and the C_e form for **2**. Obviously, the absence of the *TB* form for **1** and **2** in the crystal state does not allow direct characterization of their *TB* geometries. Furthermore, the solution study of these compounds is complicated by the impossibility of slowing down, on the nmr time scale, the interconversion between the two identical *TB* forms, a fact which precludes observation of non-averaging *TB* signals by ^1H and ^{13}C nmr. In spite of this, the combined approach provides a better understanding of the features of the *TB* geometry of **2***B*.

In order to determine whether **2***B* is symmetrical or not, we use information from the two techniques. X-ray information (4) on the mono 4-nitrophenyl derivative, **4**, shows that it adopts a symmetrical *TB* ring **4***B*. But it is possible that the effect of the methyl group in **2** differs from that of the 4-nitrophenyl group in **4**. An answer to this question is provided by the analysis of the low temperature ^{13}C nmr results summarized under the structures below.

The reduced amount of the *TB* form for methyl substitution relative to phenyl substitution (**2** vs. **6**) was rationalized in terms of a larger non-bonding interaction for the methyl group. This stronger interaction could lead to a small deformation of the highly flexible *TB* form of **2**. Supporting evidence is provided by the value of the ^{13}C chemical shift γ-effect. As shown by Lambert and Vagenas (14) in carbocyclic rings, the γ-effect of a methyl substituent is linearly related to the dihedral angle θ between the methyl substituent and the γ-carbon. A similar linear relationship has already been proposed (2) to explain the γ-shift caused by a methyl group at C(2) on the benzylic carbons C(4) and C(7) in **2**. The average value of -2.83 ppm measured for **2***B* does not fit the linear relation, if we assume a symmetrical *TB* form with torsion angles taken as similar to the values of $-67.7°$ and $170.6°$ determined for **3***B* in the solid state (Table 5). But a slight twist, changing these angles by about 10° and leading to torsion angles of about $-80°$ and 180° for **2***B*, would increase the averaged γ-shift to about -3.1 ppm, a value that fits well with the linear relationship. The latter torsion angles, corresponding to an unsymmetrical geometry, then represent the extent of deformation brought about by steric interaction of the methyl group in the flexible *TB* conformation of **2**.

Received August 7, 1985

W. KLIEGEL, H.-W. MOTZKUS, D. NANNINGA, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **64**, 507 (1986).

Details of the synthesis, physical properties, and the crystal molecular structures of 2,2-diphenyl-1,3-dioxa-4a-azonia-2-borata-1,2,3,4-tetrahydronaphthalene, **5**, and 4,4-diphenyl-3-oxa-1-aza-4a-azonia-4-borata-1,2,3,4-tetrahydronaphthalene, **9**, are reported. Crystals of **5** are monoclinic, $a = 9.972(1)$, $b = 11.848(1)$, $c = 13.561(2)$ Å, $\beta = 106.231(5)°$, $Z = 4$, space group $P2_1/c$ and those of **9** are orthorhombic, $a = 20.676(1)$, $b = 15.4199(9)$, $c = 9.7533(4)$ Å, $Z = 8$, space group $Pbca$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to R values of 0.036 and 0.045 for 1060 and 1700 reflections with $I \geq 3\sigma(I)$ respectively. Compound **5** has the expected cyclic *B,N*-betaine structure, resulting from *N*-aklylation of 2(1*H*)-pyridone with formaldehyde followed by reaction with $(Ph_2B)_2O$. The aza analog, however, does not have the analogous structure. The alkylation of 2-aminopyridine with formaldehyde in the presence of $(Ph_2B)_2O$ yields **9**, derived from alkylation of the amine rather than the pyridine ring nitrogen atom.

W. KLIEGEL, H.-W. MOTZKUS, D. NANNINGA, STEVEN J.RETTIG et JAMES TROTTER. Can. J. Chem. **64**, 507 (1986).

On rapporte les détails relatifs à la synthèse, aux propriétés physiques et aux structures cristallines et moléculaires du diphényl-2,2 dioxa-1,3 azonia-4a borata-2 tétrahydro-1,2,3,4 naphtalène (**5**) et du diphényl-4,4 oxa-3 aza-1 azonia-4a borata-4 tétrahydro-1,2,3,4 naphtalène (**9**). Les cristaux du composé **5** sont monocliniques, avec $a = 9{,}972(1)$, $b = 11{,}848(1)$, $c = 13{,}561(2)$ Å, $\beta = 106{,}231(5)°$, $Z = 4$ et groupe d'espace $P2_1/c$ alors que ceux du composé **9** sont orthorhombiques avec $a = 20{,}676(1)$, $b = 15{,}4199(9)$, $c = 9{,}7533(4)$ Å, $Z = 8$ et groupe d'espace $Pbca$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs R de 0,036 et 0,045 respectivement pour 1060 et 1700 réflexions avec $I \geq 3\sigma(I)$. Les composé **5** possède la structure attendue d'une *B,N*-bétaïne cyclique qui provient d'une *N*-alcoylation de la 1*H*-pyridone-2 avec le formaldéhyde suivie d'une réaction avec le $(Ph_2B)_2O$. Toutefois, l'analogue azoté ne possède pas une structure analogue. L'alcoylation de l'amino-2 pyridine par le formaldéhyde en présence de $(Ph_2B)_2O$ conduit au composé **9**, qui provient d'une alcoylation de l'amine plutôt que de l'atome d'azote du noyau pyridinique.

Introduction

The tautomeric system 2(1*H*)-pyridone ↔ 2-hydroxypyridine **1** has been the subject of several experimental and theoretical studies (1–6). The alkylation of this bifunctional nucleophile still appears to be somewhat puzzling in spite of a number of detailed studies. For example, some thorough work is found in the literature (7–10) which demonstrates the possibility of both *N*- and *O*-alkylation to a variable extent depending on the alkylation reagent and the conditions of the reaction. The alkylation of 2(1*H*)-pyridones with formaldehyde has been shown to result in *N*-alkylation products (11,12). We have prepared 1-hydroxymethyl-2-pyridone **2** according to the literature (11) and allowed this compound to react with oxybis(diphenylborane) to yield the diphenylboron chelate **5**. The cyclic *B,N*-betaine **5** is a ring-enlarged analog (by formal methylene insertion) of the diphenylboron chelate **4** which has recently been synthesized (13) and characterized by X-ray structure analysis (14).

Since no unambiguous assignment of the structure of the chelate **5** could be made by chemical or spectroscopic means, an X-ray crystallographic study of **5** represented the best method for ruling out the alternate structure **6**, a possible result of hypothetical *O*-alkylation of **1** to **3**. A very similar analytical problem arose with the aza-analogous diphenylboron chelate which was obtained by the reaction of 2-aminopyridine (**7**), formaldehyde, and oxybis(diphenylborane) in a single step (without first forming the intermediate formaldehyde adduct). Since 2-aminopyridine also possesses two nucleophilic centers, both alternative structures, **8** and **9**, must be considered for the chelated alkylation product. Simple ir and nmr data were not sufficient for a definitive structural assignment, therefore an X-ray crystallographic analysis was undertaken.

Experimental

2,2-diphenyl-1,3-dioxa-4a-azonia-2-borata-1,2,3,4-tetrahydronaphthalene, 5

1-Hydroxymethyl-2-pyridone (0.50 g, 4 mmol), prepared according to the literature (11), and oxybis(diphenylborane) (0.70 g, 2 mmol) were dissolved in 20 mL ethanol. After reacting the solution under reflux conditions for 2–3 min and cooling down, colorless crystals were obtained. Intense cooling yielded 1.11 g (96%) of **5** mp 169–171°C (from benzene – petroleum ether); ir (KBr): 1650 cm^{-1} (C=N/C=O); ^1H nmr ($CDCl_3$–TMS) δ (ppm): 5.50 (s, N—CH_2—O), 6.30–6.73 (m, 14 H of Ph_2B and pyridone). *Anal.* calcd. for $C_{18}H_{16}BNO_2$: C 74.80, H 5.58, N 4.85; found: C 74.94, H 5.83, N 4.85. The substance gives a blue color reaction (15) with diphenylcarbazone in methanolic solution. Crystals suitable for X-ray

analysis were obtained by recrystallization from benzene–cyclohexane.

4,4-Diphenyl-3-oxa-1-aza-4a-azonia-4-borata-1,2,3,4-tetrahydronaphthalene, 9

2-Aminopyridine (0.47 g, 5 mmol), formaldehyde (5 mmol, 40% aqueous solution), and oxybis(diphenylborane) (0.87 g, 2.5 mmol) were dissolved in 10 mL ethanol at room temperature. Intense cooling produced 1.08 g (75%) of colorless crystals, mp 164–168°C (from ethanol); ir (KBr): 3260 (N—H), 1640 cm^{-1} (C=N); ^1H nmr (d_6-DSMO – TMS) δ (ppm): 4.72 (s, N—CH_2—O), 6.52, 6.78, and 7.59 (3 m, 3 H of pyridine), 7.18 (s, 10 H of Ph_2B), 8.46 (m, N—H). *Anal.* calcd. for $C_{18}H_{17}BN_2O$: C 75.03, H 5.95, N 9.72; found: C 75.15, H 5.99, N 9.72. The substance gives a blue color reaction (15) with diphenylcarbazone in methanolic solution. Crystals suitable for X-ray analysis were obtained by recrystallization from ethanol.

X-ray crystallographic analyses

2,2-diphenyl-1,3-dioxa-4a-azonia-2-borata-1,2,3,4-tetrahydronaphthalene, 5

A crystal bounded by the 12 faces (followed by their distances in mm from a common origin): ±(1 −1 0), 0.12, ±(1 0 0), 0.08, ±(1 1 0), 0.14, ±(0 1 1), 0.19 ±(0 −1 1), 0.19, ±(1 0 2), 0.18 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on the 2 sin θ/λ values for 25 reflections (2θ = 25–40°) measured on a diffractometer with Mo-Kα radiation (λ(Kα$_1$) = 0.70930, λ(Kα$_2$) = 0.71359 Å). Crystal data at 22°C are:

$C_{18}H_{16}BNO_2$ fw = 289.14

Monoclinic, a = 9.972(1), b = 11.848(1), c = 13.561(2) Å, β = 106.231(5)°, V = 1538.2(3) $Å^3$, Z = 4, ρ_c = 1.249 Mg m^{-3}, $F(000)$ = 608, μ(Mo-Kα) = 0.75 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromated Mo-Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.06–10.06° min^{-1} over a range of (1.00 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 52°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 4%. Of the 3018 independent reflections measured and processed,[2] 1060(35.1%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count. The majority of observed data had 2θ < 35°. Higher angle data were collected to maximize the number of observations. A 2σ cutoff would only increase the number of observed reflections by 32.

The structure was solved by direct methods. The positions of the non-hydrogen atoms being determined from an E-map. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were included as fixed contributors in idealized positions (C(sp^3)—H = 0.98, C(sp^2)—H = 0.97 Å), recalculated after each cycle of refinement. The scattering factors of ref. 16 were used for non-hydrogen atoms and those of ref. 17 for hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.036 and R_w = 0.040 for 1060 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.007 and 0.04σ, respectively. The mean error in an observation of unit weight was 1.690. The final difference map was essentially featureless, residual densities ranging from −0.15 to

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. J. Johnson.

+0.14 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6 respectively.[3] Calculated hydrogen atom parameters appear in Table 5.[3] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

4,4-diphenyl-3-oxa-1-aza-4a-azonia-4-borata-1,2,3,4-tetrahydronaphthalene, ***9***

Experimental details are as above except where noted. The 12 bounding planes of the crystal used for data collection were: {1 1 1}, 0.17, ±(0 1 0), 0.31, ±(1 0 0), 0.31 mm (from a common origin). Reflections employed in the refinement of the unit-cell parameters had 2θ = 30–41°. Crystal data:

$C_{18}H_{17}BN_2O$ fw = 288.16

Orthorhombic, a = 20.676(1), b = 15.4199(9), c = 9.7533(4) Å, V = 3110.1(3) Å^3, Z = 8, ρ_c = 1.231 Mg m^{-3}, $F(000)$ = 1216, μ(Mo-Kα) = 0.71 cm^{-1}. Absent reflections: 0kl, k odd, $h0l$, l odd, and $hk0$, h odd, uniquely indicate the space group $Pbca$ (D_{2h}^{15}, No. 61).

An ω–2θ scan at 1.01–10.06° min^{-1} over a range of (0.62 + 0.35 tan θ)° in ω was employed. Of 4517 independent reflections measured (to 2θ = 60°), 1700 had intensities greater than 3σ(I) above background. The intensities of the check reflections remained constant to within 3%.

The strucure was solved by direct methods, the non-hydrogen atoms being positioned from an E-map. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.082, the hydrogen atoms were positioned from a difference map and were subsequently refined with isotropic thermal parameters. Convergence was reached at R = 0.045 and R_w = 0.046 for 1700 reflections with $I \geq 3\sigma(I)$. The mean and maximum parameter shifts on the final cycle of refinement were 0.02 and 0.15σ and the mean error in an observation of unit weight was 1.813. The final difference map showed maximum fluctuations of −0.24 and +0.15 e Å^{-3}.

Analysis of thermal motion

The thermal motion in the two molecules (Fig. 1) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (TLS model) (18). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0021 and 0.0015 Å^2, respectively for **5** and **9**. Analyses of the entire molecules indicated independent motion of the phenyl groups. Subunits consisting of PhB groups and the ten atoms of the fused-ring systems were separately analysed for both structures (rms ΔU_{ij} = 0.0025–0.0034 Å^2 and 0.0024–0.0026 Å^2 for **5** and **9** respectively). The appropriate bond distances have been corrected for libration (18,19), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of chelate rings are listed in Table 4. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 7–9) are included in the supplementary material.[3]

Results and discussion

Compound **5** has the expected structure derived from the ligand **2**, the *N*-alkylation product of 2(1*H*)-pyridone with formaldehyde. The molecule **5** is related to the cyclic *B*,*N*-betaine **4**, which may be regarded as a diphenylboron chelate of an "*O*-adduct" of pyridone while **5** may be thought of as the corresponding chelate of an "OCH_2-adduct" of pyridone. Surprisingly, the aza analog does not have the analogous structure **8** which would be less sterically hindered about the Ph_2B moiety than in the observed structure **9**, in which an

[3]The structure factor table, Table 6 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

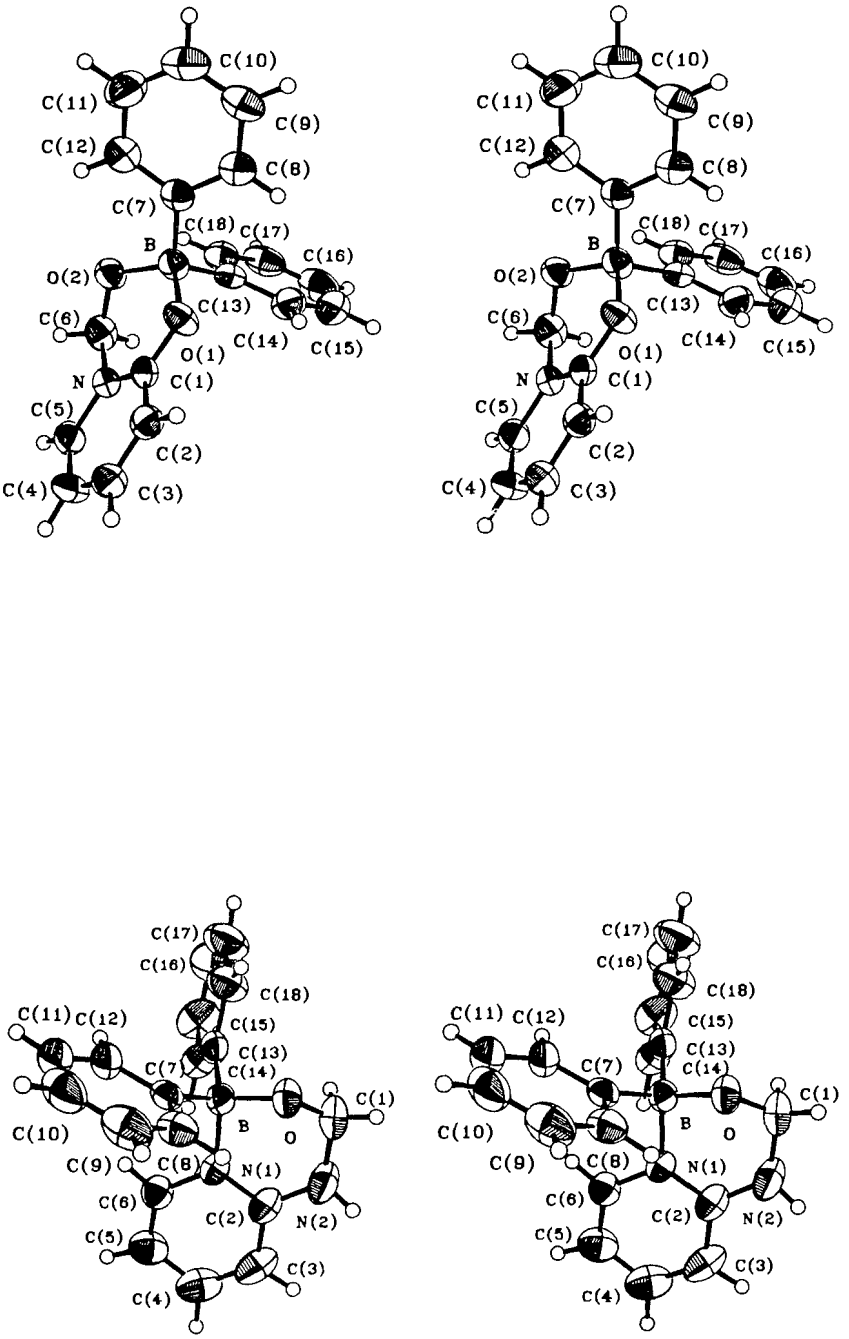

FIG. 1. Stereoscopic views of the 2,2-diphenyl-1,3-dioxa-4a-azonia-2-borata-1,2,3,4-tetrahydronaphthalene (top) and 4,4-diphenyl-3-oxa-1-aza-4a-azonia-4-borata-1,2,3,4-tetrahydronaphthalene (bottom) molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

intramolecular N→B interaction involving the pyridine ring nitrogen occurs. The structure **9** is consistent, however, with that postulated by Gragg *et al.* (20) on the basis of mass spectral data of the addition products of (2-pyridylamino)diphenylborane and various carbonyl compounds. Similar addition products with the basic ring structure of **9** were also formulated by Dorokhov *et al.* (21) on the basis of spectroscopic data and by analogy with the chemical behavior of comparable amidine adducts (22).

The pyridone C—O distance[4] of 1.308(3) Å in **5**, similar to the corresponding value of 1.316(3) Å observed for a compound of the type **4** (14), is indicative of considerable single bond character. The intracyclic C(1)—N bond of the pyridine ring in **5** is short at 1.348(4) Å, indicating double bond character. The corresponding C—O and C—N distances in 2-pyridones (both

[4]Libration-corrected bond lengths are employed throughout the discussion and are compared with similarly derived parameters.

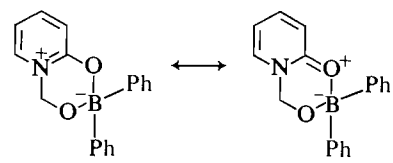
experimental and calculated) have been summarized in ref. 14 and range 1.221–1.264 and 1.373–1.410 Å, respectively. The observed geometry of **5** is thus consistent with a greater contribution of structure **5***a* to the overall mesomeric structure **5***a* ↔ **5***b*.

The C(2)–N(2) bond in **9** between the 2-amino group and the pyridine ring is relatively short at 1.335(3) Å. The corresponding distances[5] in 2-aminopyridine (23) and 3-aminopyridine (24) (which does not have an amidine grouping) are 1.355(2) and 1.390(4) Å, respectively. The endocyclic C—N bond within the amidine grouping of **9**, 1.354(3) Å, does not differ significantly from the corresponding distance of 1.359(2) Å in 2-aminopyridine. The related N(1)—C(2) distance in 3-aminopyridine is slightly shorter at 1.345(4) Å. The structural data for **9** are consistent with a more important contribution of the canonical form **9***b* to the overall structure **9***a* ↔ **9***b*. It is noteworthy that the main contributing canonical forms **5***a* and **9***b* of the overall mesomeric structures of **5** and **9** both represent 1,4-betaines with the greatest spatial separation of the formal positive and negative charges on nitrogen and boron, respectively.

The pyridine ring in **5** exhibits a distinct and significant alternation of double and single bond character, the average difference between the short and long bonds being 0.035(6) Å. A similar, but more pronounced, situation is noted in the case of **9** where the short and long bonds differ by an average of 0.046(5) Å. This type of bond length alternation was not observed for closely related molecules of the type **4** (14).



5*a* **5***b*

SCHEME C

The O—B distances in **5** are significantly different; the longer of the two (1.578(4) Å) involves the pyridone oxygen atom and is similar to the nearly equal O—B distances in compounds of the type **4** (1.557(3)–1.580(3) Å) and in other diphenylboron chelates with *N*-oxide[6] (25–27) or carbonyl (28, 29) oxygen coordinated to boron. The O(2)—C(6) distance of 1.369(4) Å in **5** is significantly shorter than the corresponding O—C(1) distance of 1.411(3) Å in **9**, indicating some double bond character in the former. Other bond lengths and angles in both structures (Tables 2 and 3) are normal.

[5]Corrected for libration from data in refs. 23 and 24 (rms ΔU_{ij} = 0.0012 and 0.0014 for the entire molecules).

[6]W. Kliegel, S. J. Rettig, and J. Trotter. 1.552(4) Å for 4,4-dimethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclohexane. In preparation.

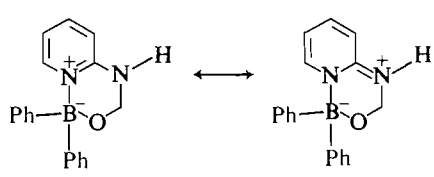
The chelate rings in **5** and **9** have slightly irregular O(2)- and O-envelope conformations (torsion angles in Table 4). The aromatic rings in **5** are all slightly but significantly nonplanar. (χ^2 = 10.1–21.5, maximum deviation from the mean plane 0.009(4) Å). In **9** the C(7)-phenyl ring is planar within experimental error while the C(13)-phenyl and pyridine rings are significantly nonplanar (χ^2 = 67.0 and 209.0, maximum deviations from the mean planes 0.015(3) and 0.019(2) Å). The pyridine ring in **9** is found to possess a flattened C(2),C(5)-boat conformation (see Table 4) with the B and N(2) atoms displaced from the mean plane by 0.170(2) and 0.078(2) Å in opposite directions, presumably a steric effect. The N(2) atom displays near planar geometry, being displaced 0.061(2) Å from the plane of its substituents, this plane being rotated 2.5(5)° with respect to the mean plane of the pyridine ring.



9a *9b*

SCHEME D

The crystal structure of **5** consists of discrete molecules separated by normal van der Waals distances and that of **9** consists of infinite chains of molecules linked by weak N(2)—H(N2)···O($1/2 - x, 1 - y, z - 1/2$) hydrogen bonds [H···O = 2.32(3), N···O = 3.127(3) Å, N—H···O = 161(2)°]. Both molecules show intramolecular interactions of possible significance [C(12)—H(12)···O(2) in **5**, C(8)—H(8)···O, and C(14)—H(14)···N(1) in **9** with H···(O/N) distances of 2.46, 2.53(2), and 2.54(2) Å; C···(O/N) distances of 2.844(4), 2.873(3), and 2.976(3) Å; and C—H···(O/N) angles of 103, 100(1), 102(1)° respectively], the C—H···N interaction in **9** involving the aromatic π-system of the pyridine ring.

A new truxillate and some flavonoid esters from the leaf gum of *Traversia baccharoides* Hook. f.

PALANIAPPAN KULANTHAIVEL AND M. H. BENN[1]

Chemistry Department, The University, Calgary, Alta., Canada T2N 1N4

Received August 19, 1985

PALANIAPPAN KULANTHAIVEL and M. H. BENN. Can. J. Chem. **64**, 514 (1986).

Investigation of the leaf washings of *Traversia baccharoides* Hook. f. (Asteraceae: Senecionae) revealed the presence, besides typical cuticular lipids, of labd-13-ene-5,18-diol, 13-*epi-ent.*-manoyl oxide, *n*-butyl caffeate and its mono-*O*-isobutyrate derivatives, an α-truxillate photodimer of *n*-butyl caffeate (di-*n*-butyl traversate), (2*S*)-5,3′,4′-trihydroxy-7-methoxyflavanone, and various derivatives of quercetin including the 3-, 3′-, and 4′-mono-*O*-isobutyrates.

PALANIAPPAN KULANTHAIVEL et M. H. BENN. Can. J. Chem. **64**, 514 (1986).

Un examen des eaux de lavage des feuilles du *Traversia baccharoides* Hook. f. (Asteraceae: Senecionae) révèle qu'elles contiennent, en plus des lipides cuticulaires typiques, du labdène-13 diol-5,6, de l'oxyde du manoyle-13-*epi-ent.*, du caféate de *n*-butyle ainsi que son dérivé mono-*O*-isobutyrate, un photodimère α-truxillate du caféate de *n*-butyle (le traversate de di-*n*-butyle), la trihydroxy-(2*S*)-5,3′,4′ méthoxy-7 flavanone, et divers dérivés de la quercétine, dont les mono-*O*-isobutyrates en positions 3, 3′ ou 4′.

[Traduit par le journal]

Traversia baccharoides Hook. f. (Asteraceae: Senecionae) is a low shrub of montane to sub-alpine shrub habitat, indigenous to the South Island of New Zealand. Among the characteristic features of the plant is a distinct stickiness to the touch, a yellow stain with a delicately resinous aroma remaining upon the skin. We report here the results of an investigation of this leaf-gum.

Freshly collected sprigs of *T. baccharoides* were briefly rinsed in chloroform to yield a yellow solution, removal of solvent from which gave a thick orange-yellow gum with the odour of the plant. The major components of the gum were separated and characterized, as detailed in the Experimental, with the following results.

A set of straight-chain even-numbered fatty acids, principally C_{22}–C_{30}, was representative of commonly encountered plant cuticular lipids (1).

The resinous odour of the gum appeared to be largely due to two diterpenes, 13-*epi-ent.*-manoyl oxide (**1**) and labd-13-ene-5,18-diol (**2***a*). After we had identified the skeletons of these compounds by ^1H and ^{13}C nmr we anticipated that they would belong to the same stereochemical series. The $[\alpha]_D$ value of **2***a*, unlike that of **1**, is unreliable for assignation of absolute stereochemistry (2). However, the ord (optical rotatory dispersion) curve of our material followed that of an authentic specimen of **2***a*. We thus found the diterpenes to be antipodal.

A major component of the leaf-gum proved to be a $C_{13}H_{16}O_4$ compound that was quickly recognized as *n*-butyl caffeate (**3***a*) (cf. data in the Experimental, and Tables 1 and 4). *n*-Butyl esters are relatively rare among known natural products and this is the first report of the occurrence of **3***a* in nature. (*n*-Butanol was not employed at any stage in the extraction and processing of the plant material, neither was it, or **3***a*, present as a contaminant in the solvents or absorbents; i.e. we have considered and excluded the possibility that **3***a* was an artefact.)

Besides **3***a* we isolated a mixture of its mono-*O*-isobutyrates (**4***a*, **4***b*), which were only able to separate after *O*-methylation with diazomethane, although the structures of the major (**4***a*) and minor (**4***b*) isomers could be deduced from the ^{13}C nmr spectrum of the mixture. The identifications were confirmed by synthesis of authentic reference specimens of the methyl ethers (**5***c*, **5***d*) from *n*-butyl ferulate (**5***a*) and isoferulate (**5***b*).

A further derivative of *n*-butyl caffeate was encountered in the form of a compound that we called di-*n*-butyl traversate (**6***a*). Our identification of this as an α-truxillate was based on the following evidence: (*i*) ms (mass spectra) measurements established the molecular composition as $C_{26}H_{32}O_8$, as required for a dimer of **3***a*; with (*ii*) the only fragment ions (**7***a*) corresponding to a truxillate rather than a truxinate (no ions seen for cleavage (b) in **7***b*) (3); (*iii*) in the 200-MHz ^1H nmr spectrum of **6***a* the cyclobutyl ring protons were observed as an AA′BB′ system (thus excluding isomers in which these nuclei form an A_2B_2 set) (3–5); and (*iv*) the chemical shift of the methyl function in dimethyl traversate (**6***c*), obtained by acid-catalysed methanolysis of **6***a*, corresponds to shielding by an adjacent *cis*-related aromatic ring (4).

It seemed reasonable to suspect that **6***a* was formed by the photochemical [2 + 2] dimerization of **3***a*, as the formation of other truxillates from cinnamates (3–6). Consistent with this idea, irradiation of **3***a* in aqueous suspension (6) with a medium-pressure Hanovia mercury vapour lamp produced **6***a*.

7b

The remaining seven compounds that we identified were flavonoids. Apart from the colourless (2*S*)-5,3′,4′-trihydroxy-7-methoxyflavanone (**8***a*), these were yellow and responsible for the colour of the leaf-gum. All these pigments proved to be derivatives of quercetin, three being the well-known methyl ethers rhamnazin (**9**), isorhamnetin (**10**), and rhamnetin (**11**), while the others were previously undescribed mono-*O*-isobutyrate ester derivates. Our identification of these latter substances as the 3-, 4′-, and 3′-esters (**12***a*, **13***a*, and **14***a*, respectively) can be summarized as follows. The ^{13}C nmr spectrum of **12***a* closely resembled that of quercetin (plus signals from the isobutyrate unit), except for the C-2 signal, which was shifted downfield by about 12 ppm, an observation consistent with acylation at C-3 (cf. the effect of glycosylation at this position) (7). Furthermore, the bathochromic shifts observed in the uv (ultraviolet) spectrum of **12***a* upon addition of $AlCl_3$, or $NaOAc–H_3BO_3$, were in accord with the ring-B diol system (8). The ms and ^1H nmr spectrum of the flavonoid and its tetra-*O*-acetate derivative were also in accord with structure **12***a*, and peresterification of **12***a* or quercetin with isobutyric anhydride yielded the same penta-*O*-isobutyrate (**12***c*).

Flavonoid acetate esters are well known as natural products (8) and a few other *O*-acyl derivatives have been described (9, 10) but, to our knowledge, **12***a* is the first example of an analogous isobutyrate.

Two more such compounds, **13***a* and **14***a*, were obtained as a mixture that we were unable to separate; they co-chromatographed in a variety of solvent systems, but both ^1H and ^{13}C nmr indicated their presence in ca. 1:3 ratio. We suspected that separation of these isomers (as also **4***a* from **4***b*) might be hampered by a facile O→O acyl migration moving the ester function between positions 3′ and 4′; however, after acetylating the mixture we were still unable to separate the isomers.

Phenolics have been demonstrated to contribute to plant defence both in the allelopathic inhibition of competitors (11), and as insect feeding-deterrents (12). *Traversia baccharoides* does not suffer from plant competition, and is markedly "under-utilized" by phytophageous insects (usually showing no sign of any such attack),[2] and it seems likely that *n*-butyl caffeate, the flavonoid esters, and possibly the truxillate contribute to the ecological defences of the plant.

Experimental

Instrumental and analytical methods were as described previously (14), supplemented by FT-IR using a Nicolet 5DX system. Analytical tlc was on 0.25-mm layers of Merck silica gel 60 F-254; and the radial centrifugal tlc was carried out on 2-mm-thick layers of Merck silica gel 60 PF 254 plus $CaSO_4 \cdot {}^1/_2H_2O$, using a Harrison Research Model 7924 Chromatotron.

Plant material, and the preparation of the leaf-gum extract

Traversia baccharoides (1.8 kg of fresh plant) was collected in early bloom in the N.W. Nelson region of New Zealand. A voucher specimen is deposited in the Herbarium of the University of Calgary. The twigs with flower heads and leaves were rinsed by swishing them for ca. 1–2 min in $CHCl_3$ (ca. 500 mL) contained in a beaker (1 L). When the wash liquid became bright yellow it was replaced by fresh solvent (a total of ca. 2.5 L of $CHCl_3$ were used). Evaporation of the combined washes at 40°C and under aspirator vacuum gave a yellow-orange gum (44.5 g).

Fractionation of the leaf-gum

The crude gum (44.5 g) was absorbed on silica gel (Woelm Pharma 70–230 mesh) by redissolving it in $CHCl_3$ (ca. 100 mL), stirring in the silica gel, and then removing the solvent under reduced pressure. This material was then loaded onto the top of a column (5 cm × 60 cm) of the

[a]At 200 MHz, of solutions in $CDCl_3$. Coupling constants (*J*) in Hz, are shown in parentheses below δ values (rel. TMS=0) and multiplicities of the signals (s = singlet, d = doublet, t = triplet, hpt = heptet). Where not specified, multiplicities and *J*-values are as for the first entry for such groups.

same absorbent (500 g) packed in hexane. The column was eluted, and fractions collected as follows: F1–3, hexane (3 × 500 mL); 4–13, hexane – ethyl acetate (19:1 v/v) (2 × 500 mL, 13 × 250 mL); 14–21, hexane – ethyl acetate (9:1 v/v) (8 × 250 mL); 22–23, hexane – ethyl acetate (4:1 v/v) (12 × 250 mL); 34–44, hexane – ethyl acetate (3:2 v/v) (12 × 250 mL); 45–48, hexane – ethyl acetate (2:3 v/v) (4 × 250 mL); 49–52, hexane – ethyl acetate (1:4 v/v) (4 × 250 mL); 53–56, ethyl acetate (4 × 250 mL); 57–58, ethyl acetate – methanol (19:1 v/v) (2 × 50 mL); and ethyl acetate – methanol (9:1 v/v) (2 × 500 mL).

Purification of F4–5 (200 mg) by ptlc (benzene–hexane 1:1 v/v) afforded *ent*.-13-*epi*-manoyl oxide (**1**), mp 97–98°C (MeOH); $[\alpha]_D$ −28° ($CHCl_3$) (lit. (2) mp 100–101°C (15) mp 98–99.5°C). The ^{13}C nmr of **1** was identical with that reported in the literature for this compound (16) with the exception of the shift observed for the C-10 resonance, which we observed at δ 36.8 ppm. The literature value for this signal (δ 39.6) seems to represent a typographic error, i.e. should be 36.9 ppm.

Concentration of F24 resulted in the separation of a solid (17 mg), recognized from its ms as a mixture of long-chain fatty acids. After treatment of this material with ethereal diazomethane, gc–ms analysis revealed a series of straight-chain fatty acid methyl esters, predominant being the hexacosanoate, octacosanoate, and triacontanoate, accompanied by lesser amounts of tetracosanoate, docosanoate, and eicosanoate, and traes of tricosanoate, pentacosanoate, heptacosanoate, and nonacosanoate.

Evaporation of F27–33 gave a gum (1.5 g), which was near homogeneous by tlc (benzene – ethyl acetate 4:1 v/v). Further purification by rechromatography on silica gel with diethyl ether – hexane (3:7 v/v) as eluant gave a gum, homogeneous by tlc, which was, however, ca 2:1 mixture of **4***a* and **4***b*; ir (film): 3350 (br), 1760, 1710, 1640, and 1610 cm^{-1}; ms (positive ion CI-NH_3) *m/z*: 307 (6), 251 (55), and 71 (2). The ^{1}H and ^{13}C nmr data are given in Tables 1 and 4.

Acetylation of a portion (60 mg) of the mixture with acetic anhydride (0.5 mL) in pyridine (1 mL) at room temperature overnight gave a mixture of the acetate derivatives (**4***c*, **4***d*) that we were also unable to separate (see Table 1 for ^{1}H nmr data).

Methylation of another portion of the mixture of **4***a* and **4***b* with excess ethereal diazomethane for 4 h at room temperature, followed by removal of excess reagent and solvent, gave a mixture of the methyl ethers, which were separated by centrifugal radial centrifugal tlc (diethyl ether – hexane 3:7 v/v), first eluted being **5***c*, as a noncrystalline gum;

[a]At 50.4 MHz in acetone-d_6 unless otherwise specified; format as in Table 4.
[b]In $CDCl_3$–DMSO-d_6.
[c]In CD_3OD.

ms: 320 (1), 250 (80), 194 (47), 177 (33), and 150 (20). Later fractions yielded **5***d*, also as a gum, with a ms nearly identical to that of **5***c*. The ^1H and ^{13}C nmr data for these derivatives are listed in Table 1 and 4, respectively. Their identity was confirmed by comparison of their ir spectra with those of authentic specimens (whose preparation is described later).

Trituration of F36–37 with hexane – ethyl acetate gave *n*-butyl caffeate (**3***a*) (2.53 g), mp 110°C (hexane – ethyl acetate) (lit. (17) mp 109–110°C). The ir spectrum (KBr) was superimposable upon that of synthetic **3***a*. The ^1H and ^{13}C data for this compound, as well as its diacetate derivative, are listed in Tables 1 and 4.

Fraction 38 (0.3 g) contained a mixture of **3***a* and **9**. The latter compound crystallized from F39 and was obtained as a yellow solid (0.18 g), mp 224–225°C (AcOH), identified as rhamnazin by direct comparison (ir, ^1H nmr, tlc and uv spectra) with an authentic specimen (lit. (18) mp 214–215°C).

Removal of solvent from F41 left a gum, which upon trituration with hexane – ethyl acetate gave (2*S*)-5,3′,4′-trihydroxy-7-methoxyflavanone (**8***a*) (refs. 19, 20), sternbin (ref. 21) (0.19 g), mp 222–223.5°C (lit. (19) mp 220°C). The cd (circular dichroism) (MeOH) revealed $[\theta]_{329}$ + 11 540°, $[\theta]_{312}$ 0°, and $[\theta]_{292}$ −32 980° (cf. ref. 22). The ^{13}C nmr data for **8***a*, not previously reported, are given in Table 5.

Concentration of F42–43 resulted in the crystallization of more **8***a* (0.64 g), then the separation of a mixture of **8***a*, **13***a*, and **14***a*, and finally a solid (0.43 g) that, although homogeneous by tlc in several solvent systems, was shown by ^1H and ^{13}C nmr to be a ca. 1:3 mixture of **13***a* and **14***a* (data in Tables 3 and 4). The ms of this material showed *m/z*: 372 (6.9), 302 (52), 153 (5), and 137 (5) as significant high-mass ions. The uv (MeOH) had λ_{max}: 372 (9 000), 304 sh (2 700), 272 (sh) (4 000), and 257 nm (6 600); upon addition of $AlCl_3$ (8), λ_{max}: 458 (13 300) (1 900), 271 (8 000), and 228 nm (6 100); with $AlCl_3$–HCl (8), λ_{max}: 428 (9 900), 360 (3 400), 304 (2 100), and 266 (7 400); with NaOAc, λ_{max}: 396 (5 900), 329 (5 100), and 275 nm (5 000); with NaOAc and H_3BO_3, λ_{max}: 386 (6 600), 296 (4 000), and 260 nm (5 900); and with NaOMe, λ_{max} 332 (10 000) and 246 nm (3 700), decomposition within minutes.

Acetylation (pyridine – acetic anhydride) gave a mixture of acetates (**13***b* and **14***b*) that co-chromatographed in several solvent systems. The ^1H nmr data for **14***b* are given in Table 3.

Evaporation of F45 and trituration of the residue with ethyl acetate gave a yellow solid (0.07 g) shown by tlc to be a mixture of two compounds. Separation of a portion (0.02 g) of this mixture by ptlc ($CHCl_3$–MeOH–EtOAc, 8:1:1 v/v) gave the less polar isorhamnetin (**10**) (7 mg), mp 296–300°C (MeOH) (lit. (13) mp 305–306°C). Comparison (uv, ir, ^1H nmr, and ms) with authentic isorhamnetin confirmed this identification. The more polar component (8 mg) formed a major part of F46 and was the sole constituent of F47, from which it was readily isolated (0.04 g). A yellow solid, the material had mp 292–294°C (MeOH), and it was identified as rhamnetin (**11**) by direct comparison (ir, ms, ^1H nmr, uv, and tlc) with an authentic reference sample (lit. (18) mp 290–295°C).

The mother liquors remaining after removal of **11** from F46 and 47 were combined and evaporated to yield a residual solid (3.1 g) that was rechromatographed on silica gel (160 g). Elution with chloroform–methanol (49:1 v/v) gave labd-13-ene-5,18-diol (**2***a*) (1.16 g), mp 127.5–128.5°C (hexane–benzene) (lit. (1) mp 130.5°C). Acetylation of **2***a* (acetic anhydride – pyridine) gave a monoacetate (**2***b*); ^1H nmr (200 MHz, $CDCl_3$) δ: 5.35 (qt, J = 1.2 and 7.5 Hz, H-14), 4.57 (brd, J = 7.5 Hz, H-15), 2.06 (Ac), 1.72 (brs, H-16), 1.13 (H-17), 0.87, 0.80, and 0.79 (H-18, -19, and -20). Oxidation of **2***a* (10 mg) with MnO_2 (50 mg) in chloroform (3 mL) overnight gave the unstable aldehyde (**2***c*); ^1H nmr (200 MHz, $CDCl_3$) δ: 9.99 (d, J = 8 Hz, H-15), 5.91 (brd, J = 8 Hz, H-14), 2.18 (d, J = 1 Hz, H-16), 1.16 (H-17), 0.88 (3H), and 0.79 (6H) (H-18, -19, and -20). Further elution of the column with chloroform–methanol (24:1 v/v) gave dibutyl traversate **6***a* (0.18 g) mp 182–183°C (EtOAc) ν_{max} (KBr): 3500, 3300, 2700, and 1610 cm^{-1}, $[\alpha]_D$ = 0 ($CHCl_3$); ms: 236 (44), 180 (85), and 163 (100). The ^1H and ^{13}C nmr data for **6***a* are given in Tables 2 and 4. Acetylation of **6***a* (25 mg) with acetic anhydride and pyridine gave the acetate derivative (**6***b*), mp 145–146.5°C (benzene); ν_{max} (KBr): 1771 and 1721 cm^{-1}; ms: 321 (8), 320 (7), 278 (48), 236 (90), 180 (39), and 163(33); the ^1H nmr data is in Table 2. Transesterification of **6***a* was achieved by boiling a solution of it (15 mg) in methanol saturated with HCl, under reflux for 4 h. Removal of solvent and recrystallization then gave dimethyl traversate (**6***c*), mp 268–271°C (MeOH); ν_{max} (KBr); 3390, 3322, 1709, and 1619 cm^{-1}; ms: 388 (4), 245 (11), 194 (65), 164 (51), and 136 (55); the ^1H nmr data are in Table 2.

From F50 a yellow solid (0.062 g) separated, and recrystallization gave pure quercetin 3-*O*-isobutyrate (**12***a*), mp 253–256°C ($CHCl_3$–MeOH); ν_{max} (KBr): 3417, 3293 (br), 1741, 1662, and 1613 cm^{-1}; uv (MeOH) λ_{max}: 347 (10 900, 262 (12 300), and 253 nm (12 600); after adding $AlCl_3$ (8), λ_{max}: 435 (17 400), 332 (3 700), 304 (4 900), and 275 nm (16 700); with $AlCl_3$–HCl (8), λ_{max}: 393 (10 900), 358 (10 900), 298 (7 200), and 268 (14 300); with NaOAc (8), λ_{max}: 366 (13 500), 260 sh (4 700), and 259 nm (17 000); with NaOMe (8), λ_{max}: 397 (15 600), 328 sh (6 500), and 269 (16 300); ms: 302 (14), 153 (5), 137 (17), and 109 (6); the ^1H and ^{13}C nmr data are in Tables 3 and 5. Acetylation of **12***a* with acetic anhydride and pyridine gave a tetra-*O*-acetate (**12***b*), mp 187–188°C (hexane–EtOAC); ν_{max}: 1775, 1648, and 1624 cm^{-1}; the ^1H nmr data are in Table 3.

*Photochemical synthesis of di-*n*-butyl traversate*

n-Butyl caffeate (**3***a*) (400 mg) was suspended in water (250 mL) and irradiated through a Pyrex filter with a 450-W Hanovia mercury vapour lamp, while a stream of nitrogen was bubbled through the solution. After 3 days tlc revealed the presence of the dimer **6***a*. Irradiation was continued for two more days and the mixture was then worked up to give a dark-brown gum, which was chromatographed on a column of silica gel (55 g). Elution with chloroform–methanol (49:1 v/v) gave first **3***a* and then (with 24:1 v/v eluant) crude dimer (110 mg), which was triturated with ethyl acetate to afford pure **6***a*, identical (ir, and ^1H nmr) with the natural product.

n-Butyl isoferulate 3-O-isobutyrate (5c)

Isoferulic acid (200 mg) was dissolved in *n*-butanol (25 mL) saturated with hydrogen chloride and the solution boiled under reflux for 4 h.

Removal of solvent and reagent under reduced pressure gave *n*-butyl ferulate (230 mg) as an oil; ν_{max} (film): 3400 (br), 1701, 1635, 1604, and 1592 cm^{-1}; ms: 250 (48), 194 (80), 177 (67), and 150 (37); the ^1H nmr data are given in Table 1. Acylation of this ester with isobutyric anhydride (2 mL) in pyridine (2 mL) overnight, at room temperature, followed by conventional work-up, gave **5***c* (245 mg).

n-*Butyl ferulate* 4-O-isobutrate (*5*d)

Ferulic acid (250 mg) was converted into **5***d* (250 mg) by the same procedure used to make **5***c* from isoferulic acid.

Quercetin penta-O-*isobutyrate (12*c)

Quercetin (0.2 g) was peracylated with isobutyric anhydride (3 mL) in pyridine (3 mL) at room temperature, overnight, and the reaction mixture worked up, in the usual way to give the penta-*O*-isobutyrate (**12***c*) (0.43 g), mp 169.5–171°C (acetone–hexane).

Acknowledgments

Financial support of this work was provided by way of a grant in aid of research to M. H. B. from the Natural Sciences and Engineering Research Council of Canada. We are grateful to Professor E. Wollenweber, Institute of Botany, Technische Hochschule Darmstadt, West Germany, and Professor P. R. Jefferies, Chemistry Department, University of Western Australia, for gifts of reference specimens of flavonoids, and labd-13-en-8,15-diol respectively. We also thank John Dugdale, Entomology Division, DSIR, Auckland, New Zealand, for his assessment of insect damage of *T. baccharoides*, and A. K. Walker and R. A. Galbreath, also of this address, for help in the collection of plant material.

Transformation of β-diketones to β-chloro-α,β-unsaturated ketones induced by lithium hydride and phenyl dichlorophosphate

HSING-JANG LIU, GUY V. LAMOUREUX, AND MONTSE LLINAS-BRUNET
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 19, 1985

HSING-JANG LIU, GUY V. LAMOUREUX, and MONTSE LLINAS-BRUNET. Can. J. Chem. **64**, 520 (1986).

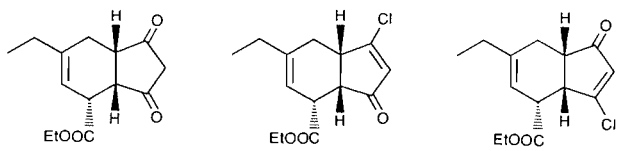
The conversion of β-diketones to the corresponding β-chloro-α,β-unsaturated ketones is facilitated by using lithium hydride as a base and phenyl dichlorophosphate as an activating agent.

HSING-JANG LIU, GUY V. LAMOUREUX et MONTSE LLINAS-BRUNET. Can. J. Chem. **64**, 520 (1986).

La transformation des β-dicétones en β-chloro cétones α,β non saturées est facilitée par l'utilisation de l'hydrure de lithium comme base et du dichlorophosphate de phényle comme agent d'activation.

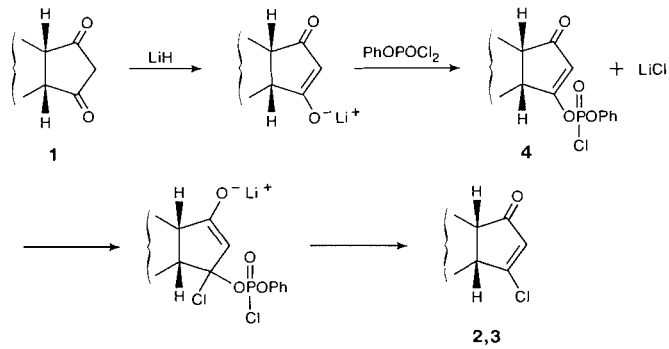
[Traduit par le journal]

During the course of our synthetic studies on cononafacic acid (1), it became necessary to convert diketone **1** to the corresponding β-chloro-α,β-unsaturated ketones **2** and (or) **3**. Several methods are known to effect this type of transformation using a variety of reagents, such as phosphorus trichloride (2), phosphorus oxychloride (2), acetyl chloride (3), thionyl chloride (4), phosgene (5), triphenylphosphine–carbon tetrachloride (6), oxalyl chloride (7), and triphenylphosphine dichloride (8), with or without the assistance of a base, usually a tertiary amine. Application of most of these methods to our system, however, met with little success. Invariably, the attempted reactions resulted in substantial loss of material without formation of the desired products in significant amount. As a consequence of these difficulties, alternative methods were investigated.



1 **2** **3**

Previously, phenyl dichlorophosphate was found in our laboratory to be an excellent activating agent for the condensation of carboxylic acids with alcohols (9) and thiols (10). Since 1,3-diones are normally completely enolized and possess characteristics similar to those of carboxylic acids, it is conceivable that phenyl dichlorophosphate can also serve as an activating agent to facilitate the desired transformation **1** → **2/3**. Contrary to this expectation, however, only a very small quantity of the desired products was formed when dione **1** was subjected to treatment with phenyl dichlorophosphate in tetrahydrofuran (THF) in the presence of triethylamine at room temperature. On the other hand, when the reaction was carried out subsequently, with lithium hydride substituting triethylamine and in the presence of hexamethylphosphoramide (HMPA), the results were rather promising and a substantial amount (~50% yield) of chloro enones **2** and **3** (3:2) was obtained for the first time. As the reaction is most likely to occur via the formation of a vinylogous mixed anhydride **4** followed by an overall replacement of the phosphate group with chloride (Scheme 1), a greater concentration of chloride ion is expected to facilitate the reaction, giving rise to an improved yield of the products. Indeed, when two equivalents of lithium chloride were added, the yield of **2** and **3** was increased considerably to 64% (1).



SCHEME 1

In search of a better activating agent, we have also examined phosphorus oxychloride and diphenyl chlorophosphate. Under comparable conditions, a 45% yield of **2** and **3**, again in 3:2 ratio, was obtained when the former reagent was applied, while an even lower yield of 25% resulted from the use of the latter reagent. Clearly, for the conversion of dione **1** to the corresponding chlorides **2** and **3**, phenyl dichlorophosphate is a more effective activating agent in the newly developed method, which in turn is superior to many existing methods attempted. The effectiveness of the new method could be attributed to the combination of a non-nucleophilic base and an adequately reactive and yet sufficiently stable activating agent.

The combination of LiH–$PhOPOCl_2$–LiCl proved to be generally useful for the transformation of β-diketones, cyclic ones in particular, to the corresponding β-chloro-α,β-unsaturated ketones. Table 1 summarizes the results obtained for a number of additional examples. During these studies, it was also recognized that the use of HMPA as a chelating agent was in fact unnecessary. The results were virtually unchanged in the absence of this reagent and a typical experiment could be simply carried out by sequential addition of lithium hydride (~1.3 equiv.), phenyl dichlorophosphate, and lithium chloride (~2 equiv. each[1]) to a solution of β-diketone in THF and allowing the reaction mixture to stir at room temperature for the required period of time.[2] The results obtained for cyclic β-diketones **5**–**8** (Entries 2–5) were uniformly good, with the

[1]With smaller quantities of the reagents, the reaction was considerably slower.

[2]The disappearance of the starting material and the intermediate mixed anhydride was monitored by thin-layer chromatographic analysis.

Table 1. Transformation of β-diones to β-chloro enones

Entry	Dione	Time (h)[a]	Product(s)	% Yield
1	**1**	16[b]	**2** + **3** (3 : 2)	64
2	 **5**	2	 **12**	76
3	 **6**	20	 **13**	77
4	 **7**	2	 **14**	83
5	 **8**	7	 **15**	85
6	 **9**	18	 **16**	72
7	 **10**	47	 **17** (one isomer)	35
8	 **11**	10	 **18**	53

[a]Unless otherwise stated, all reactions were carried out in THF at room temperature using 1.3 equiv. of LiH and 2 equiv. each of $PhOPOCl_2$ and LiCl.

[b]HMPA (1.3 equiv.) was added.

corresponding chloro enones **12–15** produced, typically, in ~80% yield. For acyclic diketones, however, the results were less consistent because of the apparent structural dependency. For example, β-keto aldehyde **9**, which does not contain any α′-hydrogen atom, was found to undergo the reaction normally, with complete regio- and stereoselectivity, to give β-chloro enone **16** (Entry 6) as the only product. On the other hand, the result (35% yield of **17**[3]) obtained for the corresponding methyl diketone **10** (Entry 7) was rather disappointing due to the competing reaction leading to cyclic enol phosphate formation. The latter process was found to occur exclusively in the case of

[3]This compound was also obtained as a single stereoisomer. Its stereochemistry remains to be ascertained.

2,4-nonanedione (**11**) (Entry 8) to give enol phosphate **18** as the only isolatable product.

In conclusion, the procedure described above was shown to be effective for the conversion of β-diketones (with the exception of the acyclic ones, which are also readily enolizable towards the α′-carbon(s)) to β-chloro-α,β-unsaturated ketones of considerable synthetic utility.[4]

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared (ir) spectra were recorded on a Nicolet 7-199 FT-IR spectrophotometer. Unless otherwise stated, ir samples were run as thin films. Proton nuclear magnetic resonance (^{1}Hmr) spectra were recorded on a Bruker WH-80, WH-200, or WH-400 spectrometer and, except where otherwise stated, were obtained on solutions in deuterochloroform with tetramethylsilane as internal reference. Carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker WH-400 spectrometer and were obtained on solutions in deuterochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using an A.E.I. model MS50 mass spectrometer.

*Transformation of β-diones **5**–**11** to β-chloro enones **12**–**17** and enol phosphate **18***

The reactions were carried out using the general procedure illustrated below with 2-methyl-1,3-cyclopentanedione (**7**). Times of reaction and yields of products are noted in Table 1. Products were purified by the following methods: **12**, **13**, **16**, and **17** by crystallization, **14** and **15** by distillation, and **18** by flash chromatography on silica gel (20% ether in petroleum ether).

At 0°C, to a solution of diketone **7** (508 mg, 4.5 mmol) in THF (20 mL) under an argon atmosphere, were sequentially added lithium hydride (45 mg, 5.6 mmol), phenyl dichlorophosphate (1.35 mL, 9 mmol), and lithium chloride (390 mg, 9.2 mmol). The reaction mixture was stirred at room temperature for 2 h. After cooling to 0°C, a solution of 10% aqueous sodium bicarbonate (20 mL) was added and the resulting solution extracted with dichloromethane (4 × 20 mL). The extracts were washed with water, dried over magnesium sulfate, filtered, and concentrated. Bulb-to-bulb distillation of the residue at 50°C (oven temperature)/1.5 Torr (1 Torr = 133.3 Pa) gave 492 mg (83% yield) of 3-chloro-2-methyl-2-cyclopentenone (**14**): ms M^+ 132.0153 and 130.0182 (calcd. for C_6H_7ClO: 132.0156 and 130.0186). The ir (1713 (C=O) and 1644 (C=C)cm^{-1}) and ^{1}Hmr (δ: 1.75 (t, 3H, J = 2 Hz, —CH_3), 2.58 (m, 2H, —CH_2CO—), and 2.83 (m, 2H, —CH_2CCl=)) spectra were found to be in agreement with those reported for **14** (8).

Compounds **12**, **13**, and **15**–**18** showed the following physical data:

*Chloro enone **12**:* mp 62–63°C (petroleum ether); ir: 1710 (C=O) and 1590 (C=C) cm^{-1}; ^{1}Hmr δ: 1.66 (br s, 6H, 2 × —CH_3), 2.30 (m, 4H, 2 × —CH_2—), 2.74 (ddd, 1H, J = J' = 6, J'' = 3.5 Hz, —CHCO—), 3.24 (dddd, 1H, J = 6, J' = 5, J'' = J''' = 1.5 Hz, —CHCCl=), and 6.21 (d, 1H, J = 1.5 Hz, —CH=); ms M^+: 196.0658 and 198.0630 (calcd. for $C_{11}H_{13}ClO$: 196.0655 and 198.0625). *Anal.* calcd. for $C_{11}H_{13}ClO$: C 67.18, H 6.66, Cl 18.02; found: C 67.11, H 6.58, Cl 17.87.

*Chloro enone **13**:* mp 67–68°C (petroleum ether); ir: 1699 (C=O) and 1580 (C=C) cm^{-1}; ^{1}Hmr δ: 1.62 (d, 1H, J = 8 Hz, —C*H*H—), 1.82 (ddd, 1H, J = 8, J' = J'' = 2 Hz, CH*H*—), 3.04 (dd, 1H, J = 5.5, J' = 4.5 Hz, —CHCO—), 3.16, 3.24 (both m, 1H each, 2 × =CCH—), 3.47 (ddd, 1H, J = 5.5, J' = 4.5, J'' = 1 Hz, —CHCCl=), 5.96 (d, 1H, J = 1 Hz, =CHCO—), 5.95 and 6.07 (both dd, 1H each, J = 5.5, J' = 3 Hz each, —CH=CH—); ms M^+: 180.0343 and 182.0317 (calcd. for $C_{10}H_9ClO$: 180.0341 and 182.0312). *Anal.* calcd. for $C_{10}H_9ClO$: C 66.49, H 5.02, Cl 19.63; found: C 66.53, H 5.06, Cl 19.61.

*Chloro enone **15*** obtained by bulb-to-bulb distillation of the crude product at 40°C (oven temperature)/0.5 Torr displayed ir (1679 (C=O) and 1627 (C=C) cm^{-1}) and ^{1}Hmr δ: 1.90 (t, 3H, J = 2 Hz, —CH_3), 2.02 (m, 2H, —CH_2—), 2.45 (t, 2H, J = 6 Hz, —CH_2CO—), and 2.73 (m, 2H, —CH_2CCl=) spectra in agreement with those reported (8). In the mass spectrum, molecular ions were observed at 144.0338 and 146.0312 (calcd. for C_7H_9ClO: 144.0342 and 146.0312).

*Chloro enone **16** (7):* mp 71–72°C (petroleum ether); ir: 1703 (C=O), 1636 (C=C), and 1610 (benzene) cm^{-1}; ^{1}Hmr δ: 3.76 (d, 2H, J = 2 Hz, —CH_2—), 7.38 (t, 1H, J = 2 Hz, =CHCl—), 7.40 (brdd, 1H, J = J' = 8 Hz, —CH=C*H*CH=), 7.48 (brd, 1H, J = 8 Hz, —C*H*=CCH$_2$—), 7.62 (ddd, 1H, J = J' = 8, J'' = 1.5 Hz, —CH=C*H*CH=), and 7.82 (br d, 1H, J = 8 Hz, CH=CCO—); ms M^+: 178.0180 and 180.0153 (calcd. for $C_{10}H_7ClO$: 178.0186 and 180.0156).

*Chloro enone **17**:* mp 102–103°C (petroleum ether): ir: 1696 (C=O), 1625 (C=C), 1605, and 1580 (benzene) cm^{-1}; ^{1}Hmr δ: 2.82 (t, 3H, J = 1 Hz, —CH_3), 3.80 (br s, 2H, —CH_2—), 7.39 (ddd, 1H, J = J' = 8, J'' = 1 Hz, —CH=C*H*CH=) 7.47 (ddd, 1H, J = 8, J' = J'' = 1 Hz, —C*H*=CCH$_2$—), 7.59 (ddd, 1H, J = J' = 8, J'' = 1 Hz, —CH=C*H*CH=), and 7.80 (dd, 1H, J = 8, J' = 1 Hz, —CH=CCO—); ^{13}Cmr; 190.9, 147.5, 146.6, 139.5, 134.4, 132.6, 127.5, 125.8, 124.2, 34.0, and 22.9; ms M^+: 192.0345 and 194.0317 (calcd. for $C_{11}H_9ClO$: 192.0342 and 194.0312). *Anal.* calcd. for $C_{11}H_9ClO$: C 68.58, H 4.71, Cl 18.40; found: C 68.45, H 4.68, Cl 18.24.

*Enol phosphate **18**:* ir: 1685, 1595 (C=C), 1305, and 950 (phosphate) cm^{-1}; ^{1}Hmr δ: 0.85 (t, 3H, J = 6 Hz, —$CH_2C\mathit{H}_3$), 1.28 (m, 4H, —$(C\mathit{H}_2)_2CH_3$), 1.93 (s, 3H, =CCH_3), 2.10 (m, 2H, =CH$C\mathit{H}_2$—), 4.79 (m, 1H, =C*H*CH_2—), 5.43 (br s, 1H, —C*H*=CCH_3), and 7.25 (m, 5H, —OC_6H_5); ms M^+: 294.1021 (calcd. for $C_{15}H_{19}PO_4$: 294.1021).

Evaluation of the diffusion coefficient of the zincate ion using a rotating disk electrode

ELISABETE JORGE PESSINE,[1] SILVIA M. L. AGOSTINHO, AND HÉLIO C. CHAGAS
Department of Fundamental Chemistry, University of São Paulo, CP 20780, Brazil
Received December 11, 1984[2]

ELISABETE JORGE PESSINE, SILVIA M. L. AGOSTINHO, and HÉLIO C. CHAGAS. Can. J. Chem. **64**, 523 (1986).

Using a rotating Hg-film disc electrode, the diffusion coefficient of the zincate ion in a 1–4 *M* aqueous solution of NaOH was measured. Experiments covered a temperature range from 25 to 40°C. The experimental results are in agreement with the predictions of the Stokes–Einstein theory for diffusivity. The obtained Stokes radii decrease with increasing alkali concentration, but the ratio $D\eta/T$ is reasonably constant within the whole range of temperature investigated.

ELISABETE JORGE PESSINE, SILVIA M. L. AGOSTINHO et HÉLIO C. CHAGAS. Can. J. Chem. **64**, 523 (1986).

Utilisant une électrode à disque tournant de mercure sous forme de film et opérant à des températures allant de 25 à 40°C, on a mesuré le coefficient de diffusion de l'ion zincate dans des solutions aqueuses de NaOH de 1 à 4 *M*. Les résultats expérimentaux sont en accord avec les prévisions qui peuvent être faites à l'aide de la théorie de diffusivité de Stokes et Einstein. Les rayons de Stokes qui sont obtenus diminuent avec une augmentation de la concentration en base; toutefois, le rapport $D\eta/T$ est raisonnablement constant sur tout l'intervalle des températures étudiées.

[Traduit par le journal]

Introduction

The electrochemical behaviour of zinc in alkaline aqueous media has been the subject of a relatively large number of investigations (1–6) due to the importance of this system for both industrial electrodeposition processes and high density electrical batteries. With regard to the latter, corrosion is one of the principal factors that restricts the application of the zinc–zincate system as an efficient energy source over very long periods of time. In the range of 1—10 *M* alkali, the predominant corrosion product is the complex ion tetrahydroxyzincate (7–9).

Many authors have observed that transport of the zincate ion from the electrode surface to the bulk of the solution is the rate limiting step in the process of zinc dissolution. Any kinetic study of the zinc–zincate system thus requires a knowledge of the diffusion coefficient (D) of the zincate ion. However, since the available literature data for the diffusion coefficient of zincate ion is both very scarce and discordant (10), many authors have employed only an order of magnitude estimate of the diffusion coefficient in the analysis of their kinetic studies (4, 11–13). Several factors account for the existence of discrepancies in the available diffusion coefficient data: (*a*) most of the published results are based on the polarographic method (10) in alkaline media, conditions under which the zincate ion presents maxima of the second kind created by kinetic factors owing to the movement of solution past the drop surface, and these maxima overestimate the limiting current; (*b*) the zincate ion is reduced at a very negative potential, restricting the utilization of certain types of solid electrodes. In this case the hydrogen evolution occurs at potentials near those of zincate reduction (due to the low hydrogen overvoltage) making the evaluation of the cathodic limiting current of the reduced ion difficult.

In the present work we report a determination of the diffusion coefficient of the zincate ion in alkaline medium using an amalgamated gold rotating disk electrode. The rotating disk electrode provides one of the most accurate electrochemical methods for evaluation of diffusion coefficients (14, 15) due in part to the fact that the method is based on an exact mathematical solution for the diffusive–convective problem, and that the electrode has a uniformly accesible surface. As pointed out by Opekar and Beran (16), this method offers additional advantages in relation to conventional polarography and other such methods. From the dependence of the limiting current on the angular velocity of the disk, it is possible to separate currents from two different processes when only one is diffusion controlled; this is the case for simultaneous reduction of the zincate ion and hydrogen evolution, the former being controlled by diffusion while the latter is chemically controlled at the same potential (13, 17). The use of an amalgamated gold rotating disk electrode further facilitates the determination of the limiting current for zincate ion reduction due to the high hydrogen overvoltage of mercury.

Experimental

All solutions were prepared using analytical grade reagents and triply distilled water. The zincate solutions (1–10 m*M*) were prepared by adding appropriate aliquots of an aqueous zinc sulfate stock solution ($ZnSO_4 \cdot 7H_2O$ in water) to NaOH solution (1–4 *M*). The solutions were deoxygenated with purified nitrogen prior to all measurements. Prior to amalgamation, the gold disk electrode (ϕ = 0.465 cm) was mechanically polished with emery paper and with chromic oxide (1–5 μ) and rinsed with water and ethyl alcohol. Simply placing mercury on the electrode surface and removing the excess by rotating the disk at 10 000 rpm (18) failed to give reproducible results. This problem was overcome by leaving the electrode immersed in mercury for several days. Prior to each experiment a new layer of mercury was added and the excess removed as before.

All experiments were performed at 25, 30, 35, and 40°C. Viscosities of the sodium hydroxide solutions were determined at the same temperatures. The electronic equipment and cell has been described previously (19). A saturated calomel – potassium chloride electrode was used as reference electrode and a platinum foil as the counter electrode.

Results

Voltammograms were determined for solutions containing 1, 2, 4, 6, 8, and 10 m*M* zincate ion in aqueous NaOH (1, 2, 3, and 4 *M*) at several temperatures (25, 30, 35, and 40°C) and at different angular velocities of the disk electrode ($f^{1/2}$ = 2, 3, 4, 5, 6, 7 $Hz^{1/2}$).

Figure 1 shows a typical I–V curve for the reduction of the zincate ion (A) and the hydrogen evolution (B) on the rotating

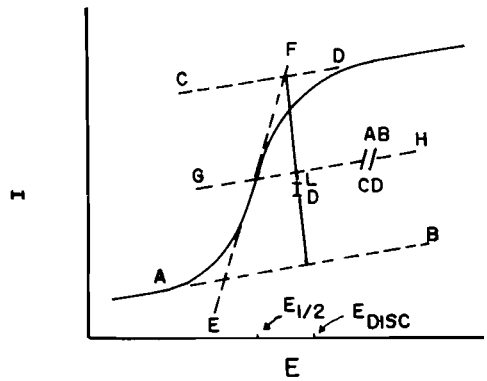

FIG. 4. Graphic evaluation of the limiting diffusion current without influence of H^+ ion discharge reaction and some residual current (22).

Hg-film disc electrode. Almost similar curves have been obtained in other situations studied here. This means that the wave of the zincate ion reduction begins at potentials less negative than the H^+ ion discharge waves. Thus, the influence of this last reaction on the measurements of the limiting diffusion current for the $Zn(OH)_4^{2-}$ reduction at the potential considered here is less pronounced.

Figure 2 demonstrates the linear dependence of the limiting diffusion current on the angular velocity at different concentrations of zincate ion in 1 *M* NaOH (25 ± 1°C). The same behaviour was observed for zincate solutions over the entire range of sodium hydroxide concentration and temperature studied. The diffusion coefficient of the zincate ion was calculated from these straight lines by linear regression using the Levich equation under diffusion control (20).

To compare the results obtained using both the Levich's diffusion and mixed controlled equations (20, 21), Fig. 3 has been constructed. Here are shown the variation of I^{-1} with $f^{-1/2}$ at $E = 1.625$ V vs. SCE (standard calomel electrode). This potential was taken after the determination of the limiting diffusion current of the $Zn(OH)_4^{2-}$ reduction using the scheme displayed in Fig. 4 (22). The calculated *D* values are listed in Tables 1 and 2.

TABLE 1. Average values of the zincate ion diffusion coefficient ($D \times 10^6$ cm^{2}s^{-1}) as a function of NaOH concentration and temperature*

NaOH concentration (M)	Temperature (°C)			
	25	30	35	40
1	4.90±0.20	5.40±0.30	7.10±0.10	6.70±0.10
2	4.60±0.20	4.70±0.20	4.90±0.20	6.30±0.10

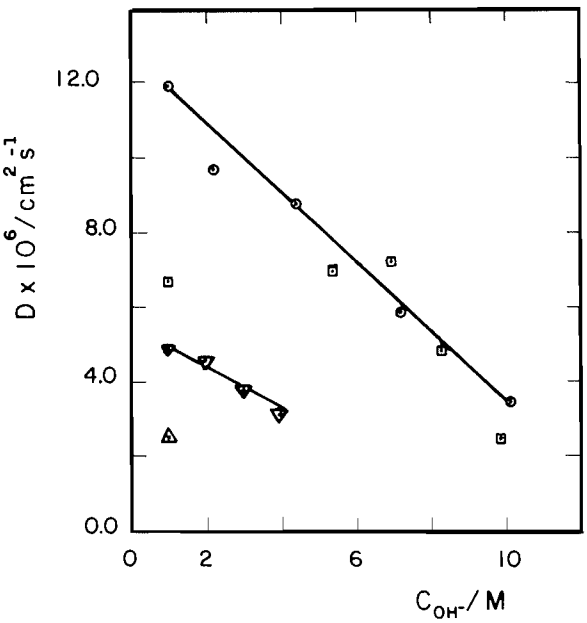

FIG. 6. Zincate ion diffusion coefficient at 25 C vs. OH^- concentrations. (⊙, ⊡) McBrien and Cairns (10); (△) Meites (24); and (▽) authors' data.

Figure 5 shows the temperature dependence of the diffusion coefficient at each sodium hydroxide concentration. From these data, we obtain the value of (10.00 ± 0.40) kcal/mol for the diffusion activation energy for zincate ion. The values of the solvodynamic radii (Table 3) were determined from the Stokes–Einstein equation (23).

Discussion and conclusion

Figure 6 compares the literature data for the zincate ion diffusion coefficient at 25°C in different alkaline media. The largest discrepancies in D values occur at alkali concentrations between 1 and 5 M. The polarographic values obtained by Dirkse (7) in KOH media are about five times larger than those of Meites (24) in NaOH media, a difference much too large to be ascribable to the change from potassium to sodium hydroxide. Indeed, McBreen's and Cairns' values (10) for the same alkali concentrations, are intermediate between these former values.

The value of 9×10^{-6} cm^2/s was used by Popova *et al.* (12) without reference to its origin and is listed in the Bard Encyclopedia (25). The results of Nanis (cf. 10) using the capillary method, indicate that the diffusion coefficient is independent of the zincate ion concentration over the range of 0.02–0.4 M. Finally, mention must be made of the values determined by Payne and Bard (26) using chronocoulometry (6.11×10^{-6} cm^2/s) and polarography (6.40×10^{-6} cm^2/s). These values were not included in Fig. 6 because it is not clear which alkali concentration was employed.

The results presented in this work (Tables 1 and 2), obtained through a great number of experiments and employing one of the most accurate electrochemical methods, show an accuracy of about 4% for the value of the diffusion coefficient of the zincate ion.

Quickenden and Jiang (27) have reported that the use of the diffusion control, instead of the mixed control, Levich equation in the evaluation of the diffusion coefficient introduces dispersion in the results obtained using the rotating disc method. The

zincate ion D values listed in Tables 1 and 2, evaluated with both Levich's equations varying over a narrow range, demonstrate that the nature of the surface reaction has more of an influence on the results than the way experimental data are treated.

The data in Table 3 indicate that the ratio $D\eta/T$ is temperature independent, within the experimental error, but increases with increasing sodium hydroxide concentration. The solvodynamic radius decreases about 20% in going from 1 to 4 M NaOH. Since both potentiometric and spectroscopic studies of the zincate ion system have shown that, in this hydroxide concentration range, the predominant species being tetrahydroxyzincate $Zn(OH)_4^{2-}$, the observed decrease in the solvodynamic radius can not be ascribed to a change in the complexation equilibria. We, therefore, attribute the decrease in the solvodynamic radius with increasing alkali concentration, to competition between solvation of $Zn(OH)_4^{2-}$, Na^+, and OH^-. This competition was especially important at sodium hydroxide concentrations above 2 M (Fig. 7). Indeed, at 4 M alkali there are only seven water molecules available for supporting electrolysis, or roughly the number of water molecules necessary to complete the first solvation shell of Na^+ and OH^-. In a study of the formate anion diffusion coefficient in different electrolytes (NaOH and KOH), Heitbaum and Gonzalez-Velasco (28) found that the solvodynamic radius of the formate anion is smaller in 5 M NaOH than in 5 M KOH. This can be explained in terms of the smaller ionic radius of the sodium ion (r = 0.95 Å) relative to the potassium ion (r = 1.33 Å) which results in a greater degree of solvation of the former. Consequently, in NaOH solution there will be less water available for hydration of the formate anion explaining the smaller solvodynamic radius as compared to the KOH medium.

The data (29) in Fig. 7 show that the viscosity is strongly dependent on the nature of the cation in the alkali concentration range above 2 M, being smaller for KOH solutions than for NaOH solutions. The source of this difference is probably the same as that outlined above. The data for the activation energy as a function of alkali concentration are not sufficiently precise to reveal a trend of the type expected on the basis of the significant change (20%) in the solvodynamic radius.

The assignment of the four outermost ionization energies obtained by uv-photoelectron spectroscopy (UPS) of *p*-*N*,*N*-dimethylaminobenzalmalonitrile is given. The X-ray photoelectron spectroscopy of the N 1*s* and C 1*s* core levels are also discussed. Two "shake-up" lines were observed at the high binding energy side of the N 1*s* spectral line. The energies of these spectral lines were found to correlate very well with the uv–visible spectrum. Also the energy difference of the two "shake-up" lines was found to be similar to the energy difference between the first and second ionization energies obtained by ups techniques. Only one "shake-up" line was observed in the case of C 1*s* photoionization. Theoretical studies by semiempirical methods including HAM/3, MINDO/3, and extended Hückel are also discussed.

A. KATRIB, B. D. EL-ISSA et A. W. POTTS. Can. J. Chem. **64**, 528 (1986).

On rapporte les attributions pour les quatre énergies d'ionisation les plus éloignées, obtenues par spectroscopie photoélectronique uv (spu), du *p*-*N*,*N*-diméthylaminobenzalmalonitrile. On discute aussi des spectroscopies photoélectroniques aux rayons X au niveau des noyaux N 1*s* et C 1*s*. On a observé deux raies "d'ébranlement" dans la partie de haute énergie de liaison de la raie spectrale du N 1*s*. On a trouvé qu'il existe une bonne corrélation entre les énergies de ces raies spectrales et les spectres uv–visible. On a aussi trouvé que la différence d'énergie entre les deux raies "d'ébranlement" est semblable à la différence d'énergie entre les première et seconde énergies d'ionisation qui ont été obtenues par les techniques de spu. On n'a observé qu'une seule des deux raies "d'ébranlement" dans le cas de la photoionisation du C 1*s*. On discute aussi d'études théoriques par des méthodes semi-empiriques incluant HAM/3, MINDO/3 et Hückel étendu.

[Traduit par le journal]

Introduction

In a study of some benzalmalonitrile derivatives, which are known to have the effect of sneeze and tear gases in addition to other physiological properties, some correlations in the uv, UP (uv-photoelectron) and XP (X-ray photoelectron) spectra have been found in the case of *p*-*N*,*N*-dimethylaminobenzalmalonitrile.

In order to assign the outermost molecular orbitals on the basis of ionization energies (IEs) obtained by UPS (uv-photoelectron spectroscopy) techniques, the photoelectron spectra of relevant molecules published previously have been used, as well as quantum mechanical calculations such as HAM/3, MINDO/3, and extended Hückel. In the case of aniline (1,2), the first IE was assigned to a ring π (b_1^{-1}) molecular orbital (MO). Also the second IE was assigned mainly to the nitrogen "lone pair" which has a similar binding energy to ammonia at 10.8 eV. The destabilization of the first orbital by 1.1 eV as compared to the $1e_g$ of benzene is explained in terms of conjugative and inductive effects. However, in the case of *p*-*N*,*N*-dimethylaniline (1), the first IE at 7.45 eV was assigned to a type of molecular orbital localized mainly on the nitrogen lone pair orbital, while the following two IEs are assigned to the benzene ring π orbitals. The molecule *p*-*N*,*N*-dimethylaminobenzalmalonitrile is expected to have similar behaviour concerning the outermost MOs especially since the nitrile group IEs are expected to be above 12 eV (3).

In the case of X-ray photoelectron spectroscopy (XPS), it has been found in certain types of compounds that the core level photoionization shows satellite structure which can be attributed to electronic transitions from the highest occupied (HOMO) to the lowest unoccupied molecular orbital (LUMO) {$\pi^* \leftarrow \pi$ transitions}; this is known as a "shake-up" process.

Shake-up lines are of relatively low intensity and are situated at the higher binding energy (lower kinetic energy) side of the main spectral line. Clark *et al.* (4–6) have used the shake-up lines to estimate the number of aromatic groups in polymers. A shake-up process was also observed in the case of —N=N— compounds (7) upon the removal of N 1*s* electrons. A correlation between the shake-up line and the uv–visible spectrum of the compound was also observed (7). It is expected that the shake-up process could provide valuable information concerning the nature of the outermost molecular orbital(s).

Theoretical methods

Three semiempirical theoretical methods were used to justify the assignment of the different IEs. Two of these methods, namely MINDO/3 (8, 9) and extended Hückel (EH) (10) employ the solution of the Schrödinger equation by using predefined overlap integrals between the different atomic orbitals. These methods are valuable in that they can be used to predict the order of the MOs and the composition of their respective eigenvectors. For practical purposes, the IEs can be taken as the negative of the orbital energies according to Koopmans' theorem (11), although this involves rather stringent approximations since the process of ionization is adiabatic and one would have to include relaxation effects. Nonetheless, if one were to assume that relaxation effects are approximately of the same order of magnitude for the outermost electrons, one can regard the difference in the orbital energies as a first approximation to the difference of ionization energies of the respective states. Invariably, the HAM/3 method (12–14) employs a suggestion first employed by Slater (15) in which the

[1]Revision received October 24, 1985.

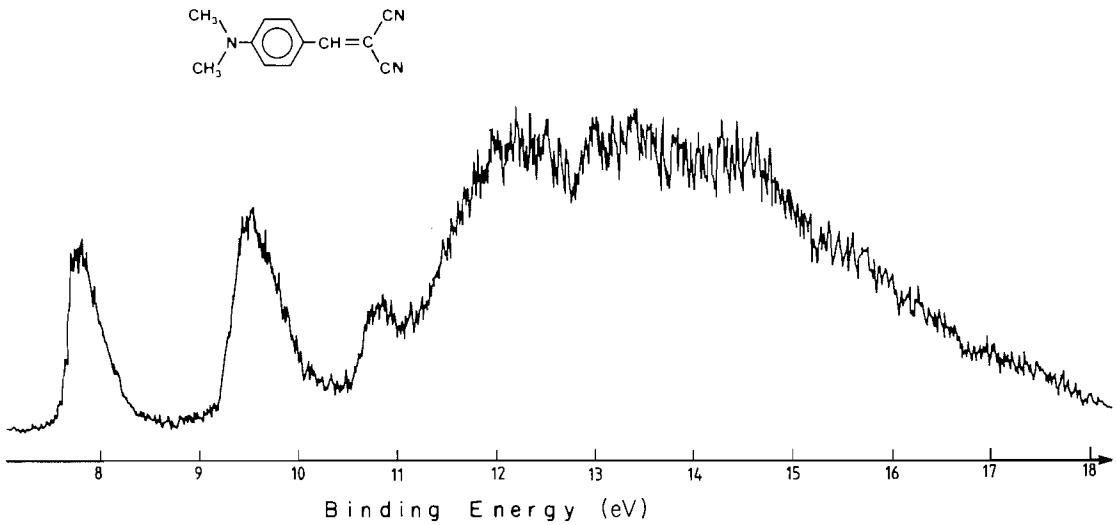

FIG. 1. The He(I) photoelectron spectrum of dimethylaminobenzalmalonitrile.

IE is calculated by removing half an electron from the respective orbitals. In HAM/3 the half electron is in effect equally removed from all the occupied MOs. The eigenvalues produced after such a condition is invoked, are then directly related to the ionization energies. Thus, unlike other semiempirical methods, but similar to the multiple scattering X-α method, HAM/3 makes a clear distinction between ionization and orbital energies. The difference between the two modes of energy is related to relaxation effects that accompany the process of ionization (16). Transition state excitation energies can be calculated by using configuration interaction of the molecule. Moreover, energies of core electrons can be calculated by taking the difference between the heat of formation of the molecule less the 1*s* electron from the heat of formation of the neutral molecule. In all three methods employed, the basis set used employed a minimal basis composed of one 1*s* Slater-type orbital (STO) of H, one 2*s*, and three 2*p* STOs for each of C and N. The bond lengths and bond angles used in the calculations are based on the equilibrium values of similar compounds (17).

Experimental

A McPherson ESCA-36 spectrometer with MgK_α source was used for measuring X-ray photoelectron spectra; a cryogenic pump in the sample chamber maintained a pressure of 10^{-8} Torr (1 Torr = 133.3 Pa). The sample was mounted on adhesive tape; its temperature was approximately ambient. The He(I) spectrum is obtained by using a Perkin Elmer P.S.16 spectrometer with a heated probe. To record the He(I) spectrum, the sample was heated to 125°C. The sample was prepared in the laboratory and its purity was tested spectroscopically.

Results and discussion

1.1 The He(I) spectrum

The uv photoelectron spectrum of *p-N,N*-dimethylaminobenzalmalonitrile shows the presence of three distinct peaks below 11 eV (Fig. 1). The first IE occurs at a vertical ionization potential of 7.8 eV and has no similar analogue in the photoelectron spectrum of benzal malonitrile.[2] However, in the case of *N,N*-dimethylaniline (1), the first IE occurs at 7.45 eV and is assigned to a π-type MO which is localized mainly on the nitrogen lone pair orbital, contrary to aniline, where the third IE at 10.8 eV is assigned to the nitrogen lone pair. The reason for this considerable change in the energy and position of the N lone pair orbital with respect to the two benzene π MOs can be explained in terms of resonance (conjugation) and inductive effects. In the case of aniline, the binding energy of the nitrogen lone pair moiety is expected to be close to that for ammonia at 10.8 eV, while the MO of the benzene ring occurs at 9.25 eV ($1e_g$). Therefore, the resonance interaction between the molecular orbitals would result in destabilization of the benzene ring π MOs and stabilization of the nitrogen lone pair orbital. On the other hand, the inductive effect of the nitrogen group will be of the opposite sign. In the case of *N,N*-dimethylaniline, the situation is reversed because the IE of the nitrogen lone pair is expected to be close to the dimethylamine at 8.93 eV, which is lower than was observed in the case of styrene (C=C π at 10.55 eV as compared to ethylene at 10.51 eV) (18).

The calculated orbital energies predicted by HAM/3, MINDO/3, and EH methods are given in Table 1. The type of each of the MOs is displayed next to the respective energies. The MINDO calculated value for the energy of the LUMO is positive and because this has no significant meaning, its value is not displayed. The measured and calculated IEs by HAM/3 taking into account relaxation effects are given in Table 2. Quantum mechanical calculations by using HAM/3, MINDO/3, and EH predict that the outermost molecular orbital (HOMO) is a π-type orbital localized mainly on the amino N (lone pair) orbital (Table 1). The IE predicted by HAM/3 by removing half an electron from the occupied orbitals at 7.5 eV is in good agreement with the experimental value at 7.8 eV (Table 2).

The second and third IEs predicted by HAM/3 at 8.78 and 9.36 eV (Table 2) are associated with π orbitals that are derived mainly from the conjugated C atoms of the benzene ring with some contribution of the nitrogen p_z orbital of the amino and nitrile groups. The EH and MINDO/3 calculations show that the second MO is a σ-type orbital involving interaction between the different atoms whereas the third MO is of a π-type character involving the benzene ring.

The HAM/3 method predicts a σ-type orbital close to the fourth π-derived orbital while the MINDO/3 and EH calculations predict that the fourth MO is a π type associated mainly

9.36	9.8	π(ring)
10.67	10.9	π(C=C)

with the benzene C atoms. It is important to note that the presence of a σ-type orbital at binding energies below 12 eV is excluded in these types of molecules (1, 2). The fifth IE at 10.67 eV is predicted by HAM/3 to be a C=C π MO of the ethylenic moiety which is in good agreement with the measured IE at 10.9 eV.

1.2 X-ray photoelectron spectrum

The N 1*s* spectrum shows the presence of a main spectral line at 399.3 eV, with two relatively low intensity lines at 402.0 and 403.8 eV (Fig. 2*a*). From this spectrum, it can be deduced that the N 1*s* binding energies of the amino and nitrile nitrogens are identical. The first shake-up line at 402.0 eV (ΔE = 2.7 eV) is assigned to a shake-up process involving the π* ← 1π transition (HOMO to LUMO) in *p-N,N*-dimethylaminobenzalmalonitrile. This energy seems to correlate with the first uv–visible absorption line (Table 4) at 430 nm (2.88 eV). The second shake-up line (ΔE = 4.5 eV) is assigned to the π* ← 2π transition from the second occupied MO to the lowest unoccupied MO. This elecronic transition correlates with the uv absorption line at 267 nm (4.64 eV) of the neutral molecule. It is interesting to note that the energy difference between the two shake-up lines (ΔE = 1.8 eV) is the same as the difference between the first and the second measured IEs as well as the difference between the first and second absorption lines (ΔE = 1.7 eV) measured by uv–visible radiation (see Table 3). These results imply that both molecular orbitals suffer the same contraction (relaxation) as a result of photoionization from the outermost or from the N 1*s* electrons. The XPS of the C 1*s* energy region shows a broad line at 284.6 eV and a low intensity shoulder at the high binding energy side (Fig. 2*b*). This line is assigned to a shake-up process which might involve the π* ← 2π transition from the second occupied MO in the molecule. The first shake-up, however, is not visible. Although it was not possible to differentiate between the amino and nitrile N 1*s* electrons, it is

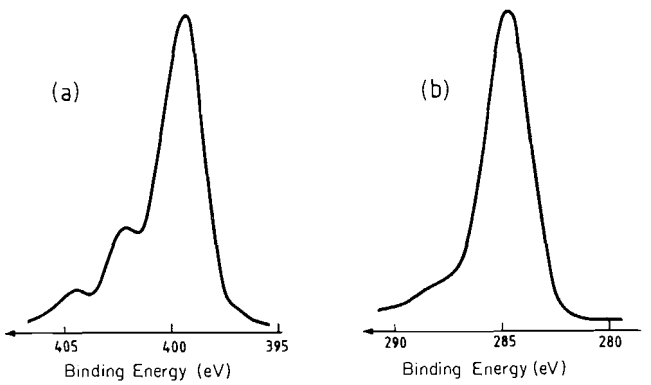

FIG. 2. The XPS of *p-N,N*-dimethylaminobenzalmalonitrile, (*a*) the N 1*s* energy region and (*b*) the C 1*s* energy region.

expected that the shake-up process should be associated with the photoionization of the amino N 1*s*, since the outermost molecular orbital is mainly localized on the amino group moiety. In Table 3, we display the difference in the IEs of the (1π) and (2π) MOs as obtained experimentally from the shake-up process and theoretically. The HAM/3 results are obtained from the difference of the IE of the (1π) and (2π) whereas this difference in the case of MINDO/3 and EH is derived from the difference in the energy of these orbitals. The HAM/3 difference of 1.22 eV seems to be underestimated relative to the experimental value which is reported as 1.8 eV. The MINDO/3 difference, however, is in agreement with the experimental value whereas the EH result is around 0.8 eV below the expected value. Table 4 displays the energies for the π* ← 1π and π* ← 2π transitions. The experimental transitions are obtained from the uv–visible spectrum whereas the theoretical results show the HAM/3 excitation energies with configuration interaction. The theoretical results are for singlet transitions which are obtained by adding to the energy difference of the orbitals involved in the transition the exchange integral that represents interaction between electrons having opposite spin, in comparison with triplet transitions that represent the same interaction between electrons having the same spin. The transition from 1π to the π* correlates very well with the experimental assignment whereas the second transition seems to be somewhat lower than the experimental value probably because the energy of the 2π MO is thought to be underestimated. The HAM/3 core level ESCA energies associated with the N 1*s* electrons were calculated by the method introduced earlier. The calculated energies for the three different types of N were found to be 402.77, 403.76, and 403.49 eV, the first being associated with the amino N while the other two are related to the nitrile nitrogen atoms. The experimental ESCA energy cannot differentiate between the N 1*s* electrons, a fact which may be due to the relative broadening of the N 1*s* spectral line (width at half maximum = 2.2 eV).

Conclusions

The He(I) photoelectron spectrum of *p-N,N*-dimethylaminobenzalmalonitrile shows that the outermost molecular orbital (HOMO) is a π-type MO predominantly of the amino nitrogen lone pair nature. Its stabilization by 0.3 eV as compared to the same MO in dimethyl aniline is attributed to the inductive effect of the nitrile groups in the molecule. The second and third π-type MOs are assigned to the benzene ring. The ethylenic group C=C π MO binding energy seems to be not affected as a result of conjugative and inductive effects with the benzene

$\pi^* \leftarrow 2\pi$	4.6	3.84

ring in a similar way to the situation in styrene. Quantum mechanical calculation on this molecule by using HAM/3, MINDO/3, and EH methods predicts that the outermost molecular orbital is mainly an amino nitrogen lone pair with a π-type character. The HAM/3 calculated IE of this MO is in good agreement with the experimental value. Similar results were obtained for the ethylenic —C=C— π MO. The presence of two shake-up lines of relatively low intensity associated with the photoionization of the N 1*s* electrons was assigned to $\pi^* \leftarrow \pi$ transitions of the HOMO (:N) and the second occupied orbital (π of the benzene ring) to the LUMO. The two shake-up line energies were found to correlate with the uv–visible absorption lines in the neutral molecule. It was also concluded that the highest two occupied MOs suffer the same contraction as a result of ionization by using He(I) or X-ray radiation of the valence or the N 1*s* electrons respectively. Such a conclusion was based on the energy difference between the two outermost orbitals, the two shake-up lines, and the two absorption lines observed by He(I), XP, and uv–visible spectra, respectively.

Stabilization effects for both saturated and unsaturated substituents were examined using MNDO calculations. (By "saturated substituents" we mean to imply that the substituent is attached to C^+ by sp^3 carbon, whether or not the substituent has a site of unsaturation at some point remote from the carbocationic center.) Relative gas phase stabilities of regioisomeric carbocations have been calculated. For simple groups, directly bound to $\overset{+}{C}$, π donation, σ donation, and polarization effects are found to be important. Saturated-substituent stabilization effects are examined by means of reaction enthalpies for isodesmic reactions between the appropriate neutral molecules and $\overset{+}{C}H_3$. Traditional analyses of substituent effects based solely on inductive effects for saturated groups have little or no significance. Inductive effects have no special importance in determining saturated substituent stabilization effects on carbocations.

AMIN MOHAMED AISSANI, JAMES CLAYTON BAUM, RICHARD FRANCIS LANGLER et JACK LEON GINSBURG. Can. J. Chem. **64**, 532 (1986).

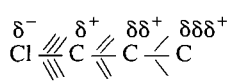
On utilise des calculs MNDO sur des carbocations choisis pour déterminer les effets de stabilisation de substituants tant saturés que non saturés. (Par "substituant saturé", on entend un substituant qui est attache au C^+ par un carbone sp^3 même si le substituant porte un site d'insaturation en un autre point éloigné du centre carbocationique.) On a calculé les stabilités relatives de carbocations régioisomères. Pour des groupements simples qui sont directement liés au $\overset{+}{C}$, on a trouve que les effets de donation π ou σ ainsi que de polarisation sont importants. On a étudié les effets de stabilisation des substituants saturés à l'aide des enthalpies de réactions isodesmiques entre les molécules neutres appropriées et le $\overset{+}{C}H_3$. Les analyses traditionnelles des effets de substituants qui sont uniquement basées sur les effets inductifs des groupements saturés n'ont que peu ou pas de signification. Les effets inductifs n'ont pas d'importance spéciale dans la détermination des effets de stabilisation des substituants saturés des carbocations.

[Traduit par le journal]

Introduction

As part of our work in organosulfur chemistry, we have recently initiated a program of theoretical studies. Our initial study (1) has raised two questions: (*i*) how does sulfur compare to saturated carbon as a carbocation stabilizer? and (*ii*) how useful is the concept of inductive stabilization in anticipating substituent-stabilization effects in carbocations? Recent studies authored by Topsom *et al.* (2, 3) have further stimulated our interest in problems associated with inductive effects.

Inductive effects accompany a shift of electron density in a σ bond toward the more electronegative atom involved in the bond. Predictions may be improved by utilizing group electronegativities (4, 5). The shift of electron density in one σ bond is supposed to trigger a parallel but smaller shift in adjacent bonds with the result that each donor atom will lose electrons in greater proportion than it receives them (6). This view may be illustrated pictorially as shown below:



A second approximation (6) consideration involves the well-known hyperconjugative effect associated with simple aklyl groups.

Our previous study of thionium ions (1) led us to the conclusion that, "The relative degree of stabilization is independent of whether the substituent is a good σ donor or indeed whether it is a σ donor or σ acceptor." That study was focused on cations which had strong π donors attached to the carbocationic center. We felt that the relevance of inductive effects to relative carbocation stabilities might be more clearly revealed if the present study examined substituents which are poor π donors.

Our subsequent study of *S*-substituted radicals[3] led to the conclusion that the CF_3 group is a polarization destabilizer when attached to positively charged carbon and a polarization stabilizer when attached to radical carbon. Thus, a third question has arisen; are polarization effects useful in analyzing substituent effects in carbocations?

Our approach to the investigation of these questions has been to carry out MNDO calculations on a series of isomeric carbocations (structures **1** and **2**), the corresponding saturated molecules, the methyl cation, and methane. For the sake of completeness, we have also carried out calculations on the simpler cations $\overset{+}{C}H_2X$, (structures **3**).

Methods

All computations were done using the MNDO (modified neglect of differential overlap) semiempirical method (1*a*). A program written by

Walter Thiel and modified by the National Resource for Computation in Chemistry was used (1*b*). Dewar and Thiel (7*a*) compared MNDO calculated heats of formation with experimental heats of formation for various cationic species, including carbocations. The mean accuracy was comparable to that for neutral species.

The method used to calculate MNDO enthalpies of formation was discussed by Dewar and Thiel in their initial paper (7*b*). They used the relationship

$$\Delta H_f^{mol} = E_{tot}^{mol} - \sum_A E_{el}^A + \Sigma \Delta H_f^A$$

where ΔH_f^{mol} is the enthalpy of formation of the molecule in question, E_{tot}^{mol} is the total electronic energy of the molecule, E_{el}^A is the total electronic energy of atom A, and ΔH^A is the experimental enthalpy of formation of atom A at 298° K.

Since experimental molecular enthalpies of formation (298° K) are included in the criteria used to determine MNDO parameters, Dewar (7*a*) maintains that vibrational corrections are accounted for in the MNDO parameterization. Dewar (7*b*) established and supported this position for MINDO/3 computed enthalpies of formation.

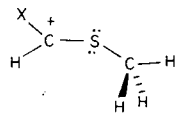
Since its inception, the MNDO method has been used successfully for studies of carbocations and heterocarbocations (e.g., 7*c*–7*i*).

Results and discussion

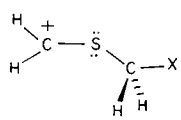
Substitution at sp^2 *carbon*

The first portion of the discussion will deal with the effects of substituents directly attached to sp^2 carbon (C_1 in structure **1**). Table 1 presents calculated relative gas phase stabilities, $\Delta\Delta H_f$, for isomeric pairs of carbocation **1** and **2**. $\Delta\Delta H_f$ is a measure of the stabilizing ability of X relative to H when attached to C_1.

Table 2 presents data for bond orders arising from the interactions of the C_1p_z and C_2p_z orbitals. We note that the difference in these "π bond" orders for the isomeric carbocations presented in Table 2 and the corresponding differences in CS π bond orders reported in our previous study (1) (for cations with structures **4** and **5**) are virtually identical. The correlation



4



5

between these two results suggests that the hyperconjugative effect of the ethyl groups in structures **1** is qualitatively similar to the π bonding effect of sulfur in structures **4**. The principal impact of sulfur substitution as opposed to alkyl sustitution is that the stabilizing–destabilizing effect of those substituents which have the largest influence on $\Delta\Delta H_f$ is substantially diminished by the presence of the superior π bonder S. For example, X = OH in structures **1** and **2** affords a value for $\Delta\Delta H_f$ of −36.9 kcal/mol whereas X = OH in structures **4** and **5** gives rise to a $\Delta\Delta H_f$ of −20.0 kcal/mol. The stabilizing ability of

groups common to the present and previous studies is in the same order.

Another indicator of the tendency of ethyl groups to act as weak π donors can be adduced from a comparison of the data for structures **1** and **3** presented in Table 3. Ethyl groups tend to enhance total π donation into C^+ while diminishing the π bonding interaction of other substituents also attached to C^+ in the same way that sulfenyl sulfur does.

Table 4 details the results of our analysis of electron donation into C_1 for structures **1**. Consistent with the results of our previous study (1), the results in Table 4 indicate that the stronger

π donors have a stabilizing effect which can be anticipated on the basis of their π donation into the "empty" C_1p_z orbital. The order so obtained is independent of σ-donation/withdrawal. The present study includes a larger selection of substituents which are poor π bonders than our previous study did. A brief examination of Table 4 shows that electron population in C_1p_z varies systematically with π donation from X when X is a strong π donor. For those groups which do not donate electron density from a π bond or lone pair, the electron population in C_1p_z is the only available indicator of π donation from X. There is no correlation between $\Delta\Delta H_f$ and electron population in the C_1p_z orbital for any of the poor π donors.

Table 5 presents more data for the poor π donors.[4] It is immediately obvious that $\Delta\Delta H_f$ values for the poor π bonders can *not* be correlated with (*i*) electron population in C_1p_z, (*ii*) transfer into C_1, or (*iii*) total electron transfer into C_1. In an attempt to rationalize the $\Delta\Delta H_f$ trends, we have examined the ionic bond orders for the cations of interest. Major polarization stabilization–destabilization in each case is associated with the bonds to C_1 so that the ionic bond orders listed in Table 5 are restricted to those involving C_1. There is some counterbalancing tendency for the poorer electron donors to enjoy polarization stabilization and for the better donors to suffer from polarization destabilization. The similarity of $\Delta\Delta H_f$ values for **1***b* and **1***c* suggests that a difference in ionic bond order of 0.0529 corresponds to a difference of ca. 0.12 e′ at C_1. From this relationship, it is possible to calculate effective electron donations into C_1 which account for π transfer, σ transfer, and polarization effects. Table 6 shows the results of our effective electron donation calculations. We conclude that polarization effects are comparable in importance to electron donation into the sp^2 carbon of carbocations substituted by poor π donors at sp^2 carbon.

Cyano-substituted carbonium ions have received a good deal of attention recently. In accord with both our present and past results (1), Gassman *et al.* (10–14) find that in comparison to H, the cyano group is a weak carbocation stabilizer when attached to C^+ but functions as a destabilizer at more remote centers in saturated substituents. Our calculations (on **1***c* and **2***c*) suggest a similar result for the acetyl group when that group is oriented perpendicular to the "empty" *p* orbital on C^+. Such an orientation avoids a direct interaction between the "empty" *p* orbital and the CO π bond. The possibility of α-keto stabilization of carbocations has been suggested previously (15) and is consistent with our own results on the carboethoxyl group (1).

Substitution at sp^3 *carbon*

Electron donations

In order to maximize the opportunity to focus on inductive effects, we have undertaken a series of calculations on systems which interpose an ethylene bridge between the carbocationic center and the groups examined in the first portion of this study. Substituent effects on carbocationic stability were evaluated by determining ΔH_r for the following isodesmic reaction

$$[1]\quad \underset{\mathbf{6}}{\overset{+}{C}H_3} + CH_3CH_2CH_2X \rightarrow \underset{\mathbf{2}}{\overset{+}{C}H_2CH_2CH_2X} + CH_4$$

The results of calculated gas phase heats of reaction, ΔH_r, are given in Table 7 along with the heats of formation for $\overset{+}{C}H_3$ and CH_4.

Typically, an analysis of carbocation stabilities, relying on inductive effects for saturated groups as outlined in the Introduction, proceeds in the following manner. Electron donation into sp^2 carbon is presumed to be the most important mechanism of carbocation stabilization. The substituent in question is expected to donate electron density in accord with its electronegativity. Group electronegativities are almost invariably ordered on the basis of the electronegativity of the most electronegative atom present in the substituent, e.g., CH_2F would be expected to be more electronegative than CH_2Cl because fluorine is more electronegative than chlorine. Since there are a variety of methods, currently available, for calculating group electronegativities, it is no longer necessary to use a single atomic electronegativity to estimate a group electronegativity.[5,6]

Table 8 presents a variety of group electronegativities for the groups included in our study along with MNDO electron donations from C_2H_2X into C_1 of structures **2**. While there is a tendency for the various approaches to substituent electronegativities to order the groups in the same way, our computational results cannot be anticipated from group electronegativities. For example, all approaches presented in Table 8 find that OH is more electronegative than Cl. As might be expected, both Huheey's original method (4, 5) and our modification of it (20) find that C_2H_4OH is more electronegative than C_2H_4Cl. How-

[4]Cl is excluded from consideration here because of the difficulty of comparing bonds involving only second shell orbitals with bonds involving both second and third shell orbitals.

[5]These methods have been developed in very different ways as an examination of refs. 4, 5, and 16 will show.

[6]Given the arbitrary nature of Mülliken population analyses, some caution is warranted in using substituent electronegativities derived from *ab initio* computations (16). An elaborate procedure has been developed to circumvent the problem of abstracting atomic electron densities from *ab initio* results (17*a*). The MNDO method avoids this ambiguity by using the density matrix system of population analysis which ignores the overlap integral (17*b*).

*These numbers correspond to the electron donation required to fully compensate for the removal of polarization effects. They were calculated using the following equation. 0.0529 au ≃ 0.12 e'.

ever, our MNDO calculations show that there is no significant difference in σ donation, π donation, or net electron donation from these two groups. We note that our modification (20) of Huheey's method for the calculation of group electronegativities tends to afford smaller differences in saturated substituent electronegativity values (4,5). As a result, our modification makes it somewhat easier to reach the unavoidable conclusion that *substituent electronegativities are not useful in attempting to assess either the electron donating ability of saturated substituents*[7] *or the relative impact of saturated substituents on the heats of reaction for carbocation formation.*

Table 9 displays results which permit an assessment of the more basic assumption that charge delocalization should correlate with substituent-stabilization effects. The differences in charge delocalization are very small. There is no systematic correlation of ΔH_r values with electron donation into C_1 or $C_1H_{11}H_{12}$. Furthermore, our introduction pictured a generalized scheme for the charge distributions accompanying inductive effects that is completely incompatible with our computational results. Typically, our calculations furnish partial charges of −0.10 on C_2 in structures **1** and −0.15 on C_2 in structures **2**. Systems which are denied strong π donation into C^+ invariably have a substantially *greater negative* charge built up on the carbon(s) adjacent to the carbocationic center. There is no correlation between the negative charge buildup on C_2 in structures **2** and the electronegativity of X or CH_2X. Some excess electron population on C_2 is accumulated in the C_2p_y orbitals.

A possible link between X and the buildup of electron population at C_2 in structure **2** is provided by the NH_2 group. Two configurations for the NH_2 group have been examined and

[7]By saturated substituents we mean to imply that the substituent is attached to $C^{\oplus}$ by sp^3 carbon, whether or not the substituent has a site of unsaturation at some point remote from the carbocationic center.

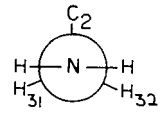
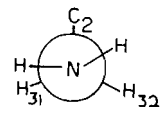
are presented as Newman projections (**2***l*-1 and **2***l*-2) along with their calculated heats of formation.

Both orientation of the —NH_2 group and the near planarity at nitrogen in **2***l*-1 suggest that there is an interaction between the nitrogen lone pair orbital and the C_2p_y orbital. Buildup of electron population in the C_2p_y orbital supports the hyperconjugative donation of electron density from H_{11} and H_{12} into the C_1p_z orbital. The overall surplus of electron population on C_2 establishes significant polarization stabilization for the C_1C_2 bond.



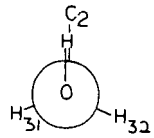
2*l*-1

ΔH_f = 217.7 kcal/mol



2*l*-2

ΔH_f = 223.2 kcal/mol



2*k*-1

We should also point out that a few groups (X) are oriented in structures **2**, in such a way as to indicate a preference for interaction with the C_2p_z orbital. A case in point is provided by the —OH group. A Newman projection of the energy minimized conformation of **2***k* is presented as **2***k*-1.

Differences in the net electron donations into C_1 or $C_1H_{11}H_{12}$ in the series of cations **2***a* → **2***l* are very small. Such differences never amount to more than a few hundredths of an electron. Allowance for polarization stabilization, using the relationship advanced in the discussion of sp^2 substituted systems, indicates that differences here are also equivalent to electron donations of the same magnitude. The consequent absence of any correlation between electron donations into C_1, even allowing for polarization effects, and ΔH_r values suggests that *conventional discussions of saturated-substituent*[7] *stabilization effects are simplified to the point of having little or no significance*.

There is some tendency for the cations **2**, which have poorer stabilizers (C_2H_4X groups), to suffer from greater polarization destabilization associated with the C_1H_{11} and C_1H_{12} bonds (due

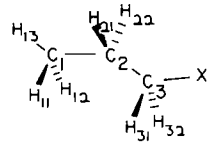
to the buildup of adjacent like charges). Table 10 presents the pertinent data for cations **2** (listed in order of increasing substituent stabilization). This tendency offers some basis for the common practice of overlooking inductive stabilization from hydrogen attached to C^+.

In each cation **2**, the H_{21}–H_{22} separation is diminished by ca. 0.015 Å when compared with the H_{21}–H_{22} distance in the corresponding structure **6**. This result indicates the operation of hyperconjugative stabilization in structures **2** and underscores the need for a buildup of electron density in the C_2p_y orbital. The similarity of the magnitudes of contractions for the H_{21}–H_{22} distances in structures **2** is consistent with the observed similarities of the electron densities in the C_1p_z orbitals of structures **2** (see Table 8).

In addition to the contraction of the $H_{21}C_2H_{22}$ angles, the C_1C_2 bond lengths are consistently shorter in structures **2** than they are in the corresponding structures **1** (except for the **1***a*, **2***a* pair). A typical value for such a contraction is 0.03 Å. The magnitude of this contraction in C_1C_2 bond lengths is identical, for each substituent common to the present study[8] and our previous study of thionium ions (1), to the corresponding contraction of the CS_π bond of structures **5** when compared to structures **4**. For example, when X = OH, the $C(sp^2)S$ bond length in



6

structure **5** is 0.06 Å shorter than the corresponding bond length in structure **4** and the C_1C_2 bond length is 0.06 Å shorter in structure **2** than the corresponding bond length in structure **1**. Along with our earlier discussion of C_1C_2 "π bond" orders in **1** and **2**, these bond length results make the analogy between a sulfur atom and a methylene group attractive.

As might be expected, the $C_1C_2C_3$ angle is wider in structures **2** where there is a relatively strong hyperconjugative effect, than it is in structures **1** where the hyperconjugative effect is considerably weaker. The same angle expansion can be observed by comparing the $C_1C_2C_3$ angles in structures **2** and **6**. The systematic contraction of the C_2C_3X bond angles in structures **2** (when compared with the corresponding angles in structures **6**) is a good deal more surprising. The sum of these skeletal angle differences for structures **2** and **6** correlates with C_1C_2 π bond order in structures **2**. Table 11 presents the bond angle information while Table 2 contains the C_1C_2 π bond orders for structures **2**. We note that those X groups which are the best π donors when attached to C_1, induce the greatest angle deformations when attached to C_3.

Conclusions

Good π donors attached to C^+ exhibit substituent-stabilization effects which correlate with electron donation into the "empty" *p* orbital on C^+.

Poor π donors attached to C^+ offer substituent-stabilization effects which can only be anticipated by a simultaneous accounting for π donation, σ donation, and polarization effects. These three factors are similar in importance for substituent-stabilization effects.

The usual view of inductive effects leads to expected charge distributions (for carbocations substituted at sp^2 carbon by saturated[7] substituents) which is intuitively unreasonable. This view requires the buildup of substantial *polarization destabilization* in order to achieve charge delocalization. The tra-

ditional view is entirely incompatible with our molecular orbital computations, which find that *sp^3 carbon attached to C^+ acquires substantial negative charge which results in significant polarization stabilization.*

There is no significant difference in electron donation into C^+ via inductive or hyperconjugative effects for the saturated substituents examined in this study. The heats of reaction reported here range over ca. 15 kcal/mol. Attempts to correlate differences in saturated substituent-stabilization effects in terms of electron donation appear to have no meaning whatsoever.

There is a useful analogy between the mode of stabilization of C^+ by sulfur and the mode of stabilization of C^+ by CH_2.

Received August 8, 1985

F. WILKINSON, C. J. WILLSHER, H. L. CASAL, LINDA J. JOHNSTON, and J. C. SCAIANO. Can. J. Chem. **64**, 539 (1986).

Transient absorption and luminescence from aromatic ketone triplets (xanthone, acetophenone, butyrophenone, valerophenone, *p*-methoxyacetophenone, β-phenyl-*p*-methoxypropiophenone and benzil) supported on the hydrophobic zeolite Silicalite have been obtained by time-resolved diffuse reflectance laser flash photolysis. These experiments were aimed at establishing the usefulness of this technique for studies of zeolite supported photoreactions. While the transient spectral properties can be used to examine the properties of the supporting media, the decays of the signals frequently follow complex kinetic behaviour. The decays for such heterogeneous systems cannot be easily fit to clean first or second order kinetics and are thought to be a mixture of several first order decays arising from triplets in different inclusion and adsorption sites. Evidence is presented for close-packing of the aromatic substrates and for triplet lifetime enhancement. Although the triplet spectrum of included benzil shows evidence for considerable axial freedom, the results for β-phenylpropiophenones indicate that other types of motion are restricted for included ketones. It is also found that the rate of the Norrish Type II reactions of valerophenone and butyrophenone supported on Silicalite are decreased with respect to the rates in solution.

F. WILKINSON, C. J. WILLSHER, H. L. CASAL, LINDA J. JOHNSTON et J. C. SCAIANO. Can. J. Chem. **64**, 539 (1986).

Faisant appel à la photolyse flash d'un laser à réflexion diffuse résolue, on a mesuré, l'absorption et la luminescence fugace d'états triplets de cétones aromatiques (xanthone, acétophénone, butyrophénone, valérophénone, *p*-méthoxyacétophénone, β-phényl *p*-méthoxypropiophénone et benzil) supportées sur le zéolite hydrophobe, Silicalite. On a réalisé ces expériences dans le but d'établir l'utilisé de cette technique pour des études de photoréactions supportées sur des zéolites. Alors que l'on peut utiliser les propriétés spectrales fugaces pour examiner les propriétés du support, les dégénérescences des signaux permettent souvent de suivre des comportements cinétiques complexes. Les dégénérescences de tels systèmes hétérogènes ne suivent pas exactement des cinétiques d'ordre un ou deux et on croit qu'elles sont des mélanges de plusieurs dégénérescences d'ordre un qui proviennent de triplets dans divers sites d'inclusion ou d'adsorption. On présente des données suggérant que les substrats aromatiques existent dans un arrangement compact et que les temps de vie des triplets sont augmentés. Même si le spectre triplet du benzil présente beaucoup de liberté axiale, les résultats obtenus avec les β-phénylpropiophénones indiquent que, pour ces cétones, d'autres types de mouvements sont restreints. On a aussi trouvé que les vitesses de réactions Norrish Type II de la valérophénone et de la butyrophénone supportées sur de la Silicalite sont plus faibles que les vitesses correspondantes en solution.

[Traduit par le journal]

Introduction

Organic photoreactions on zeolite supports have been the subject of attention during the last couple of years (1–4). Our own studies have concentrated on the hydrophobic zeolite Silicalite; this serves as a convenient substrate on which to probe both the effect of crystal lattices on organic photoreactions and the ways in which photochemical probes can be used to determine the nature of active sites in zeolites. Silicalite (5) is over 99% SiO_2, and its channel system consists of near-circular zigzag channels, cross-linked by elliptical straight channels. The diameter of the circular channels is 5.4 ± 0.2 Å and the free cross-section of the elliptical ones is 5.75 × 5.15 Å.

The recently developed technique of diffuse reflectance laser photolysis (6–9) has been successfully applied to the detection of excited states at interfaces and in various crystalline systems. We report here the results of an exploratory study of the photochemistry of various carbonyl compounds supported on Silicalite. Very recently Turro *et al.* have applied the same technique to study organic substrates on porous silicas (10).

Experimental section

Silicalite (from Union Carbide) had a particle size of ~1 μm and was calcined (500°C, 24 h) before use. All the ketones used were commercial materials and were purified by distillation or crystallization.

Samples were prepared using the techniques outlined in earlier reports in this series (1–3) and contained 1–3% ketone by weight. Based on a void volume of 0.19 mL/g for Silicalite (5) these inclusions would correspond to ≤20% occupancies. The samples (typically 0.5–1 g) were contained in a quartz spectrometer cell with an optical path of 3 mm, which in these experiments corresponds to the depth of the solid sample. The powder was shaken between laser shots to ensure that a fresh surface would be exposed each time.

Unless otherwise indicated, the samples had been purged with nitrogen. Earlier work (2) on similar samples has shown that a few minutes of purging with nitrogen are sufficient to remove oxygen.

The time-resolved diffuse reflectance measurements were carried out by exciting the samples with the frequency tripled (354 nm, 30–70 mJ) or frequency quadrupled (266 nm, ~10 mJ) pulses from a Nd-YAG laser. The monitoring source was a 200 W pulsed xenon lamp. The signals from the monochromator–photomultiplier system are captured by a Tektronix 7912-AD digitizer and processed using a PDP-11/03 computer. Special care was taken to minimize signals due to all specular reflections. Further details have been reported elsewhere (7).

All our kinetic analysis is based on the fraction of reflected light absorbed by the intermediate, i.e.,

$$\text{Signal} = \frac{J_0 - J}{J_0} = \frac{\Delta J}{J_0}$$

[1]Issued as NRCC No. 25018.

where J_0 and J refer to the photomultiplier signals before laser excitation and at time t after excitation, respectively. To a first aproximation this provides a suitable parameter for kinetic and spectroscopic analysis.

Results and discussion

In common with other zeolites, Silicalite offers more than one site for inclusion and (or) adsorption of organic compounds. Molecules with kinetic diameters comparable to that of benzene (~5.8 Å) are capable of being included in the channels of Silicalite. We have previously found that molecular geometry, size, and conformational flexibility play an important role in determining channel inclusion (2–3). Therefore, for the samples studied in this work there will be a combination of surface adsorption and channel inclusion. We use the term Silicalite-supported to describe these samples.

Xanthone

The molecular size and geometry of xanthone make it a borderline case for inclusion in the Silicalite channel framework. It seems likely that xanthone is located in a distribution of channel and surface sites.

The spectrum of the Silicalite-supported xanthone triplet, obtained using 354 nm excitation on a 4.88 μs per point time scale, is illustrated in Fig. 1 and shows its characteristic maximum at 605 nm, independent of how long after the laser pulse the signals were recorded. It is well known (11) that the position of λ_{max} for the xanthone triplet is a sensitive probe of the polarity of the environment, being ~610, 655, and 610 nm in 2-propanol, carbon tetrachloride, and sodium dodecyl sulfate (SDS) micelles, respectively (11). The value observed in Silicalite is in excellent agreement with the values of λ_{max} in polar media (2-propanol, SDS micelles) and suggests that xanthone is in a relatively polar environment in Silicalite. This result is rather surprising since other studies have shown that inclusion sites in Silicalite are nonpolar (12). However, we note that in the case of silica gel[2] the maximum is located at 580 nm, indicating that its surface sites may be substantially more polar in nature than those of Silicalite. This is a property that silica gel shares with other silicas (13).

The kinetics of triplet decay for xanthone on Silicalite are rather complex, extending over remarkably long periods of time. Figure 2 shows two traces obtained independently using the same sample with time scales differing by a factor of 1000. Note that the time per point in the longer time scale (trace B) is equivalent to 10 times the complete trace from the short time scale (trace A). The highest point in trace B corresponds to only a fraction of the initial signal in trace A since, on slower time scales, the fast information is not captured. The first point in trace B is actually an average or histogram of the earlier data. Not surprisingly, these data fail to fit either a first or second order decay. Bimolecular processes may play a role at very short time scales (*vide infra*), but at longer times these complex decays are probably best interpreted in terms of a distribution of first order decays arising from the multiple inclusion sites. While a more detailed understanding of the nature and number of decay modes would certainly be desirable, further elaboration is not warranted at the present time.

Luminescence lifetimes can be monitored using the same approach discussed above (but blocking the monitoring beam) and lead to traces in agreement with those recorded in the diffuse reflectance mode.

Attenuation of the laser dose, in either the diffuse reflectance or the luminescence mode, leads to signal reductions which are systematically less than the attenuation ratio itself. Figure 3 shows three normalized diffuse reflectance traces obtained with varying laser doses. The actual shape of the decay trace does not change significantly, suggesting that in the time scale monitored T–T annihilation does not play an important role. It should be

[2]Time-resolved diffuse reflectance studies of silica gel supported systems will be reported separately.

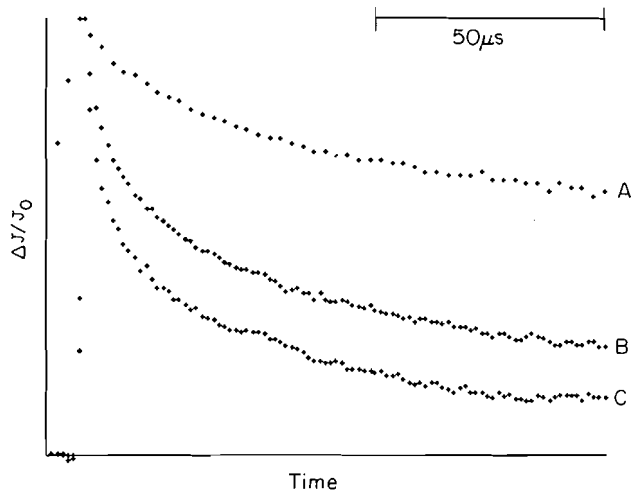

FIG. 4. Decay of triplet xanthone on Silicalite in the presence of nitrogen (A), air (B), and oxygen (C).

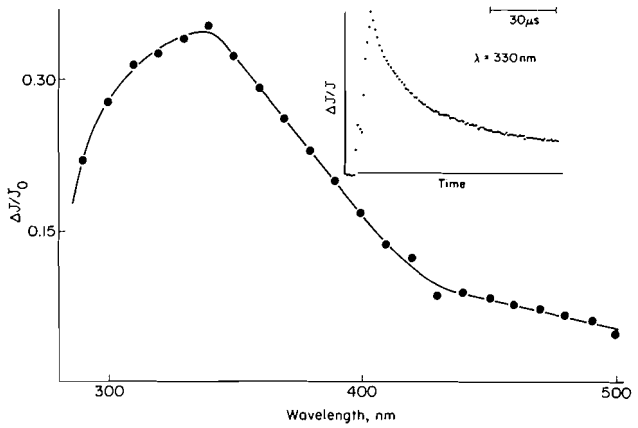

FIG. 5. Triplet diffuse reflectance spectrum of butyrophenone on Silicalite obtained by 266 nm excitation; the inset shows a decay trace at 330 nm.

noted that the small deviations in the latter parts of the decay traces are probably owing to the fact that the traces have been normalized, and the weaker signals obtained with the attenuated laser doses have large errors. The ratios of the initial signal intensities were 100:38:33 for laser doses of 100:20:10. Saturation effects of this type have also been observed for benzil triplets in crystals (8) and are to be expected based on current theory (14).

The effects of air and oxygen on the triplet decay were also examined. For a nitrogen purged sample the half-life of the decay was ~300 μs, whereas an air equilibrated sample had a half-life of 30 μs. The half-life was shorter still, ~5 μs, for an oxygen purged sample. Figure 4 illustrates this effect. We observe that while quenching does occur, the magnitude of the effect is substantially smaller than that which we have observed for oxygen quenching of xanthone on silica gel, where half-lives of 12 and 0.5 μs were measured for nitrogen and oxygen purged samples, respectively. This difference suggests that a large fraction of Silicalite-supported xanthone molecules are inside the channel structure and thus, not readily accessible to oxygen. To the extent that the exterior surface of Silicalite would resemble silica gel, the value of λ_{max} for T–T absorptions also supports extensive channel inclusion.

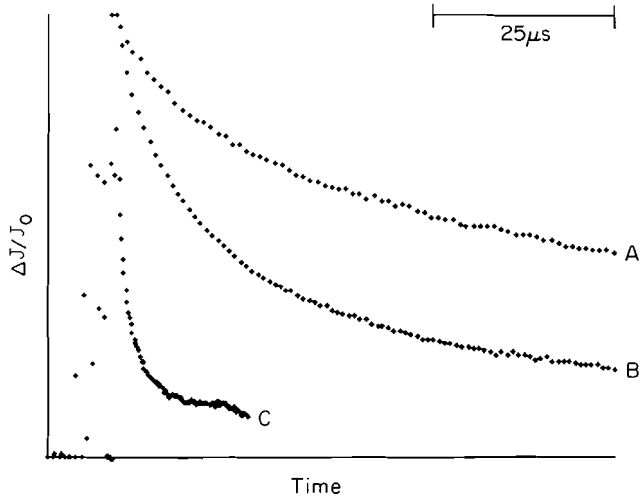

FIG. 6. Normalized decay traces for triplet acetophenone (A), butyrophenone (B), and valerophenone (C) on Silicalite (266 nm excitation).

Acetophenone, butyrophenone, and valerophenone

These ketones were selected because their kinetic diameters allow for easy channel inclusion. Furthermore, the Norrish Type II phototransformation of included valerophenone and butyrophenone could be compared with solution behaviour, thus, giving an idea of immobilization effects on this reaction.

Irradiation of Silicalite-supported butyrophenone samples yields the transient diffuse reflectance spectrum shown in Fig. 5. The spectrum is reasonable for a triplet benzoyl chromophore although somewhat broader than is normally observed in solution (15). Valerophenone and acetophenone in Silicalite give similar triplet spectra upon 266 nm excitation. The triplet decays for these three ketones all show complex kinetics. However, a comparison of the decays for each one on the same time scale (Fig. 6) showed that the lifetimes followed the order acetophenone > butyrophenone > valerophenone. For butyrophenone and valerophenone, which undergo the Norrish Type II reaction, the lifetimes are ~30 and ~2 μs, respectively; these represent a large increase in the triplet lifetime over those in solution (125 and ~5 ns) (16, 17).

Previous studies of valerophenone on Silicalite (2) have shown that the acetophenone produced in the Norrish Type II reaction plays a dominant role in determining the phosphorescence of the sample studied. This potential complication does not appear to be a problem here, since the two ketones which undergo the Type II reaction give transients which have different lifetimes and both of which are significantly shorter than that of the acetophenone triplet. Therefore, we conclude that the lifetime enhancement relative to the values in solution is real and attribute it to a decreased rate of the Norrish Type II reaction due to restrictions in molecular mobility. Similar results have recently been observed by Turro *et al.* for valerophenone and γ,γ-diphenylbutyrophenone adsorbed on porous silica (10). It is also interesting to note that the lifetimes for the two ketones still reflect the relative ease of abstraction of secondary vs. primary hydrogens. This suggests that the relative rates of decay are not determined by the rate at which the reactive conformation can be achieved. In other words, hydrogen abstraction remains the rate determining step for decay, with the favorable conformation for abstraction being less abundant in Silicalite than in solution.

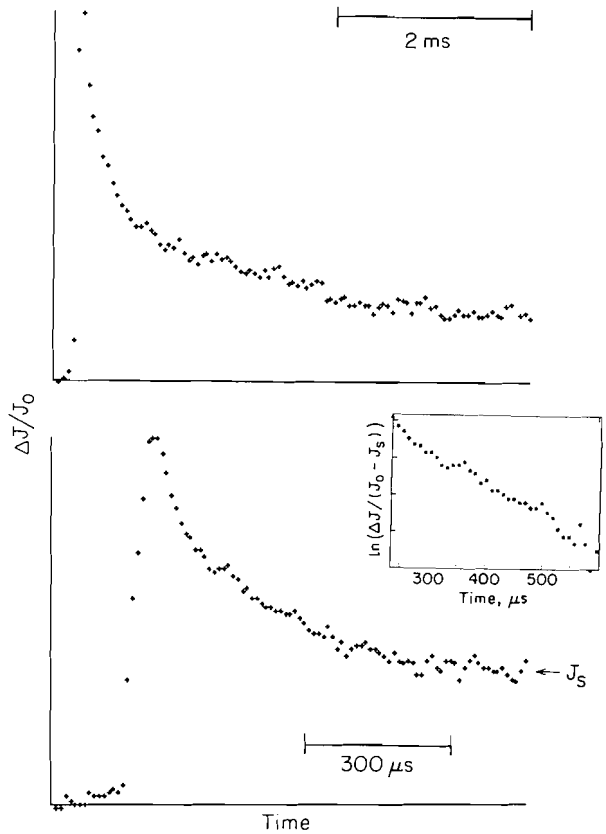

FIG. 7. Decay of triplet *p*-methoxyacetophenone on Silicalite (354 nm excitation), top. An expansion of the early part of this decay is shown at the bottom with an inset showing a first order analysis of the data (where $J_0 - J_s$ is the corrected baseline level).

p-*Methoxyacetophenone and* β-*phenyl*-p-*methoxypropiophenone*

The dimensions of these molecules are such that inclusion in Silicalite should be possible, although the methoxy substituent may restrict this process to some extent (3).

Figure 7 shows the decay of triplet *p*-methoxyacetophenone following 354 nm laser excitation. As in the case of xanthone the decay kinetics are complex and extend over a long period of time. However, in this case we observe a reasonably well defined "fast–slow" separation, as illustrated in Fig. 7 (top) for the time scale in which this differentiation is most evident. The fast part of the decay, shown in Fig. 7 (bottom) seems to approach first order kinetics (after an appropriate baseline shift) rather well (see insert in Fig. 7). The lifetime derived from this analysis was 230 μs; lifetimes of this magnitude had been determined previously using phosphorescence techniques for several aromatic ketones included in Silicalite (1, 2). The slow component's lifetime is too long to allow us to establish the dominance of first or second order decay modes (due to limitations of the digitizer); typical half-lives are of a few milliseconds. The luminescence from *p*-methoxyacetophenone also showed a fast and a slow component. The lifetime of the latter agreed well with the diffuse reflectance measurements; however, the fast component seems to incorporate luminescence from an additional (even shorter lived) species.

The diffuse reflectance spectrum of the triplet state of *p*-methoxyacetophenone is shown in Fig. 8. The intensity of the spectrum does, of course, change with time, but its spectral features do not. The value of λ_{max} = 410 nm is in excellent

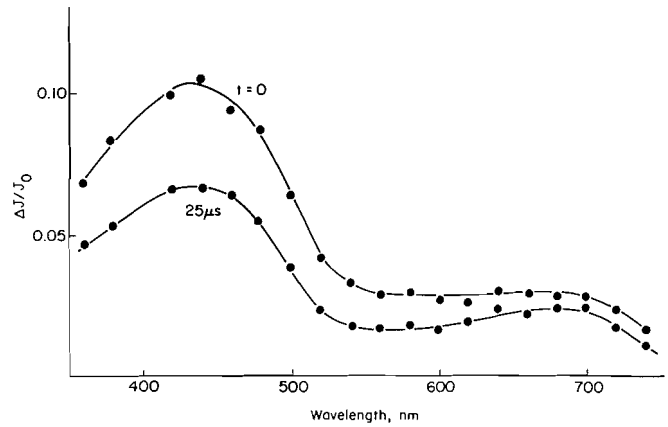

FIG. 8. Triplet spectrum of *p*-methoxyacetophenone on Silicalite (354 nm excitation).

agreement with that recorded in homogeneous solution for the same chromophore (18). The broad band in the 600 nm region is not present in the spectra of *p*-methoxybenzoyl monoketones in homogeneous solution; however, similar absorptions are observed in the case of poly(*p*-methoxyacrylophenone) (19), and to a lesser extent in its copolymers with other monomers (20). In the triplet spectra of polymers these broad bands around 600 nm have been suggested to reflect the close proximity of the chromophores (19, 20). Thus, correlation of this observation with the spectra of Silicalite-supported *p*-methoxyacetophenone suggests that the chromophores are also in close proximity on Silicalite.

β-Phenyl-*p*-methoxypropiophenone, like all β-arylpropiophenones, undergoes efficient deactivation in solution as a result of excited state interaction with the β-aryl moiety. Its triplet lifetime in isopentane at 300 K is 71 ns, compared with several microseconds for *p*-methoxyacetophenone (18).

Earlier work from our laboratory (3) has already shown that inclusion of ketones of this type in Silicalite essentially eliminates this decay mode as a result of restrictions of the molecular motions required to achieve an adequate conformation for quenching. Consistent with this, the behavior of β-phenyl-*p*-methoxypropiophenone triplet (354 nm excitation, monitoring diffuse reflectance transient absorption) was essentially the same as that of *p*-methoxyacetophenone; the only difference was some shortening of the fast decay.

Similar results were obtained upon 266 nm excitation of β-phenylpropiophenone. The triplet has a broad spectrum, λ_{max} ~320 nm, and decays within 500 μs with complex kinetics.

Benzil

Benzil (excited at 354 nm) gave a triplet spectrum (Fig. 9) with λ_{max} at 470 nm which is much closer to that of benzil triplet in solution (λ_{max} at 480 nm in cyclohexane or acetonitrile (21)) than to the spectrum for the crystalline material (λ_{max} at 520 nm (8)). The transient spectrum of the benzil–Silicalite sample showed an additional broad, weak band at long wavelengths, λ_{max} ~ 830 nm.

The emission spectrum has λ_{max} at 550 nm which is again shifted from those in glasses at 77 K and in the crystal which show λ_{max} at 510 (22) and 510 nm (8), respectively. These results confirm that we are not looking at microcrystalline benzil on the surface of the Silicalite but rather at adsorbed or included benzil molecules.

Benzil undergoes extensive conformational reorganization upon excitation into the triplet manifold; for example, the dipole

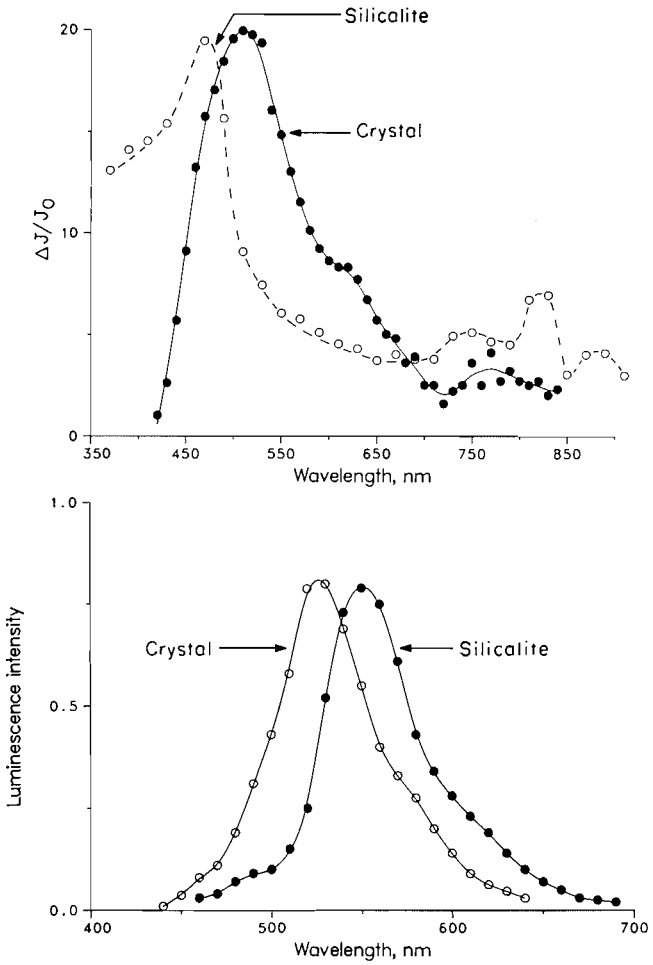

FIG. 9. Triplet diffuse reflectance (top) and emission (bottom) spectra of benzil crystals and benzil on Silicalite obtained by 354 nm excitation.

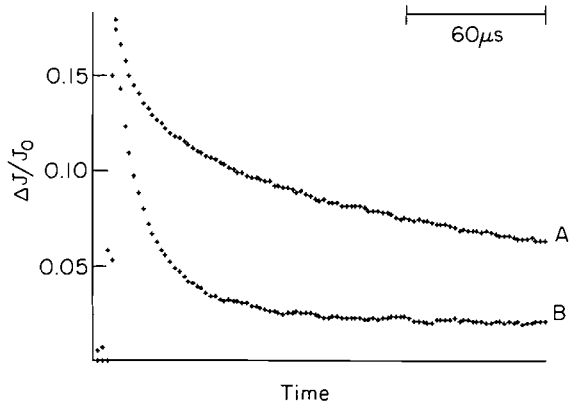

FIG. 10. Decay of triplet benzil on Silicalite in the presence of nitrogen (A) and air (B).

moment of the triplet is zero, as compared with 3.75 D for the ground state (23). The spectral characteristics mentioned above suggest that while the crystal structure of pure benzil severely limits this reorganization (8), the Silicalite framework allows it to occur rather freely. Since only axial motion is required this result is not entirely surprising; axial motions are not hindered on Silicalite (24).

Decay kinetics based on either the triplet absorption at 470 nm or emission at 550 nm gave similar results. The decays give reasonable fits to first order kinetics (except for a small amount of faster component at the beginning) and lead to lifetimes of ca. 360 μs. As with xanthone, the signal reductions upon laser attenuation do not match the laser attenuation ratio, following the order 100:36:31 for 100:20:10% of the laser dose. The presence of oxygen had a dramatic effect on the triplet lifetimes. Under air these lifetimes were reduced by a factor of approximately 20 from those measured under nitrogen. Thus, under air, over 80% of the decay took place with a lifetime of ca. 18 μs. Figure 10 shows a comparison of decay traces under air and under nitrogen. This dramatic oxygen effect on the triplet lifetime contrasts with the case of crystalline benzil where no effect was detected (8).

Conclusions

Time-resolved diffuse reflectance techniques can play an important role in developing an understanding of organic photoprocesses in zeolites. These studies can help us to understand the nature and properties of the active sites in these catalysts.

For aromatic ketones on Silicalite, complex triplet decay kinetics seem to be the rule, with decay processes extending over several orders of magnitude in time scale. Such complex kinetics would be expected for a heterogeneous system where ketone triplets in different channel or surface sites may decay with different rate constants. Similar behaviour has been observed in fluorescence decays of various aromatics adsorbed on solids (25).

Transient spectra can be quite useful in establishing some of the characteristics of the various adsorption sites on zeolites. Thus, the value of $\lambda_{max} = 605$ nm for triplet xanthone suggests a relatively polar environment, comparable with 2-propanol, but not as polar as in the case of silica gel where $\lambda_{max} = 580$ nm. The idea of closely packed guest molecules is supported by the spectral features of *p*-methoxyacetophenone triplet, and earlier evidence (2) for energy migration. The absorption and luminescence properties of benzil support the idea of considerable axial freedom for the included molecule. In the case of β-phenylpropiophenone, a similar degree of axial freedom cannot help the molecule undergo intramolecular quenching; in contrast, the folding motion required for deactivation is prevented by the Silicalite lattice. Butyrophenone and valerophenone show lifetime enhancements which reflect a decreased rate for the Norrish Type II reaction, owing to similar restrictions on molecular mobility.

Acknowledgments

The travel required to carry out the studies reported herein was generously supported by a NATO grant (372/84). This support is gratefully acknowledged. We are also grateful to Professor N. J. Turro for the communication of unpublished results.

Reçu le 15 juillet 1985

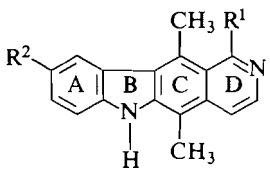
CHI HUNG NGUYEN, ÉMILE BISAGNI et JEAN-MARC LHOSTE. Can. J. Chem. **64**, 545 (1986).

Les dérivés lithiés en 2 des alkyl-1 chloro-4 pyrrolo[3,2-*c*]pyridines réagissent avec les acétophénones en donnant les alcools tertiaires correspondants. Après déshydration, les diaryl-1,1 éthylènes formés sont réduits en diaryl-1,1 éthanes et la transformation de ces derniers en chloro-1 alkyl-5 5*H*-pyrido[4,3-*b*]benzo[*f*] indoles est réalisée soit directement par le dichlorométhylméthyléther en présence de chlorure stannique, soit indirectement par formylation suivie de cyclodeshydratation par l'acide polyphosphorique. La substitution de l'atome de chlore par les dialkylaminoalkylamines fournit enfin les dialkylaminoalkylamino-1 alkyl-5 5*H*-pyrido[4,3-*b*]benzo[*f*]indoles, isomères des dialkylaminoalkylamino-1 ellipticines N-6 substituées.

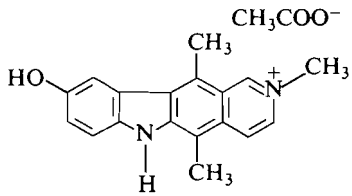
CHI HUNG NGUYEN, ÉMILE BISAGNI, and JEAN-MARC LHOSTE. Can. J. Chem. **64**, 545 (1986).

2-Lithio dérivatives of 1-alkyl-4-chloropyrrolo[3,2-*c*]pyridines react with acetophenones, giving the corresponding tertiary alcohols. After déhydration into 1,1-diarylethylenes and subsequent reduction to 1,1-diarylethanes, the synthesis of 1-chloro-5-alkyl-5*H*-pyrido[4,3-*b*]benzo[*f*]indoles was achieved either by direct cyclization with dichloromethylmethylether plus stannic chloride or by formylation and cyclodehydration with polyphosphoric acid. Finally, the substitution of the chlorine atom with dialkylaminoalkylamines leads to 1-amino substituted 5-alkyl-5*H*-pyrido[4,3-*b*]benzo[*f*]indoles, isomers of 1-dialkylamino-alkylamino 6-substituted ellipticines.

L'ellipticine **1***a*, dont les propriétés antitumorales sur la leucémie L1210 de la souris ont été reconnues vers la fin des années 60 (1) appartient à la famille des pyrido[4,3-*b*]carbazoles dont certains dérivés présentent des propriétés antitumorales plus importantes que l'alcaloïde **1***a*. C'est le cas,



1*a* $R^1 = R^2 = H$
1*b* $R^1 = NH(CH_2)_3N(CH_2CH_3)_2$; $R^2 = OCH_3$



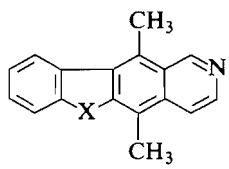
2

notamment, du composé **1***b* (2, 3) dont l'étude n'est pas achevée et du composé **2** qui est déjà utilisé chez l'homme (4, 5). Cette série hétérocyclique a donc largement retenu l'attention des chimistes et, depuis 15 ans, plus de 25 méthodes distinctes permettant d'y accéder en ont été décrites (6–9).

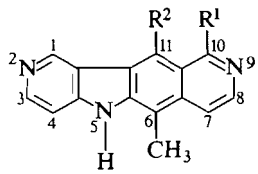
Par ailleurs, divers analogues structuraux du composé **1***a* ont également été préparés et, tandis que les dérivés oxygéné, soufré et hydrocarboné sur le sommet 6, respectivement **3** (10), **4** (11, 12) et **5** (13), sont dénués de toute activité, la série des aza-9 ellipticines ou pyrido[3′,4′:4,5]pyrrolo[2,3-*g*]isoquinoleines **6** (14, 15) a largement retenu l'attention des biologistes. Ainsi, le composé **7** s'est montré actif sur une grande variété de tumeurs expérimentales (16, 17) et il a même fait l'objet d'une étude clinique phase 1 dont les résultats semblent encourageants (18).

Cette série paraît donc intéressante et, puisque la présence de l'azote en 2 sur ce dernier système hétérocyclique se traduit en fait par une amélioration des propriétés antitumorales de ce type de substances, il nous a semblé utile de chercher à étudier les éventuelles propriétés biologiques des dérivés des 5*H*-pyrido-[4,3-*b*]benzo[*f*]indoles **8**.

En effet, en dehors de différentes quinones récemment synthéthisées par notre laboratoire (19), les dérivés de cet hétérocycle ne sont pas décrits et il s'agit de savoir si l'azote intracyclique en 2 peut en lui-même suffire au maintient de l'activité antitumorale, malgré le remplacement du système isoquinoléine des ellipticines par un noyau naphtalène. Cela devrait d'ailleurs permettre de préciser les caractéristiques



3 X = O
4 X = S
5 X = CH_2



6 R^1 = H ou $NH(CH_2)_nN(R_3)_2$; $R^2 = CH_3$ ou H
7 $R^1 = NH(CH_2)_3N(CH_2CH_3)_2$; $R^2 = H$

structurales, et peut-être les propriétés chimiques, nécessaires à l'apparition d'une telle activité dans la famille des intercalants du type ellipticine.

Dans ce mémoire, nous décrivons les résultats de nos recherches concernant une première voie d'accès à certains dérivés des méthyl-6 5*H*-pyrido[4,3-*b*]benzo[*f*]indoles **8**.

Chimie

Nous avons montré récemment que la lithiation de la méthyl-1 chloro-4 pyrrolo[3,2-*c*]pyridine **9***a* (20) par le *tert*-butyl lithium est régiospécifique de son sommet 2 (21).

De même qu'il réagissait avec l'acétaldéhyde pour donner 73,5% de la méthyl-1 (α-hydroxyéthyl)-2 chloro-4 pyrrolo-[3,2-*c*]pyridine (21), le dérivé lithié ainsi formé se condense avec l'acétophénone et la *p*-méthoxy-acétophénone pour engendrer, respectivement, 78% de la méthyl-1 (α-phényl α-hydroxy)-éthyl-2 chloro-4 pyrrolo[3,2-*c*]pyridine **10***a* et 71% de son analogue méthoxylé **10***b*. La deshydratation de ces deux composés, réalisée par l'anhydride acétique bouillant, conduit aux phényl-1 (et *p*-méthoxy phényl-1) (méthyl-1′ chloro-4′ pyrrolo-[3,2-*c*]pyridyl-2′)-1 éthylènes **11***a* et **11***b*. Cette réaction s'accompagne toutefois de l'hydrolyse partielle du chlore qui intervient probablement au cours du traitement du mélange réactionnel et, à côté de **11***a* (52,5%) et de **11***b* (44%), il se forme 23% de **12***a* et 26,5% de **12***b*. Ces derniers composés ont également été préparés à partir de la méthyl-1 méthoxy-4 pyrrolo[3,2-*c*]pyridine **13**. C'est ainsi que les alcools tertiaires **14***a* et **14***b* ont été préparés comme leurs analogues chlorés et que leur déshydratation en présence d'acide *p*-toluène sulfonique s'accompagne de leur déméthylation totale en **12***a* et **12***b*.

Par hydrogénation en présence de charbon palladié, ces derniers fournissent 90% des dérivés saturés correspondants **15***a* et **15***b*, normalement transformés par l'oxychlorure de phosphore bouillant en méthyl-1 (α-phényl)éthyl-2 (et α-(méthoxy-4′ phényl)éthyl-2 chloro-4 pyrrolo[3,2-*c*]pyridines **16***a* et **16***b*, également formés par hydrogénation de **11***a* et **11***b* en présence de rhodium sur alumine. Ce dernier catalyseur est toutefois le seul à avoir permis l'hydrogénation sélective de la double liaison. En effet, au cours des essais préliminaires réalisés à la température ambiante, le nickel de Raney commercial s'est avéré inefficace et le composé **11***a*, hydrogéné en présence de charbon palladié à 10%, a engendré, après absorption de la quantité théorique d'hydrogène, un mélange comprenant (en chromatographie en couche mince (ccm)) le composé de départ **11***a*, son dérivé d'hydrogénation **16***a* et un troisième produit correspondant très probablement au dérivé d'hydrogénolyse du chlore, que nous n'avons pas chercher à isoler.

Pour transformer les composés **16***a* et **16***b* en 5*H*-pyrido-[4,3-*b*]benzo[*f*]indoles **8**, deux voies distinctes ont été envisagées: d'une part, la formylation selon Vilsmeier–Haak, suivie de la cyclodéshydratation, et, d'autre part, la cyclisation directe. Bien que les rendements en aldéhydes **17***a* et **17***b* soient assez faibles, la formylation s'effectue dans les deux cas et la cyclodéshydratation en chloro-1 diméthyl-5,6 5*H*-pyrido-[4,3-*b*]benzo[*f*]indoles **18***a* et **18***b* est ensuite aisée. Au contraire, la cyclisation directe pour former **18** au départ de **16** au moyen du dichlorométhylméthyléther en présence de chlorure stannique est réalisable uniquement dans le cas de **16***a*. En effet, les essais réalisés dans les mêmes conditions experimentales au départ de **16***b* ont conduit à l'obtention d'un seul composé défini. Formé en très faible rendement, le spectre de rmn ^{1}H montre qu'il correspond à la formule **19**, indiquant ainsi que l'hétérocycle aza-5 indolique complexé par le chlorure stannique devient moins réactif que le cycle benzénique méthoxylé.

Disposant des dérivés chlorés **18***a* et **18***b*, il a été facile de les substituer par les dialkylaminoalkylamines pour former les dialkylaminoalkylamino-1 diméthyl-5,6 5*H*-pyrido[4,3-*b*]-benzo[*f*]indoles **20**–**23**. Cependant, pour compléter ce travail, nous avons cherché à accéder aux dérivés des 5*H*-pyrido-[4,3-*b*]benzo[*f*]indoles non substitués sur leur sommet 5. C'est pourquoi nous avons réalisé la même synthèse que précedemment au départ de la benzyl-1 chloro-4 pyrrolo[3,2-*c*]pyridine **9***c* (22, 23) lithiée et de la *p*-méthoxy-acétophénone.

En dehors de l'alcool tertiaire **10***c*, formé avec un rendement de 29% nettement inférieur à celui de **10***a* et **10***b* tous les autres intérmédiaires (**11***c*, **12***c*, **15***c*, **16***c*, **17***c* et **18***c*) ont été obtenus dans les mêmes conditions expérimentales et avec des rendements comparables à ceux de leurs analogues *N*-méthylés. De la même manière, la γ-diéthylaminopropylamine a bien transformé le composé **18***c* en dérivé aminé **24**. Malheureusement, les essais de débenzylation de ce dernier, tentés par hydrogénation catalytique sur charbon palladié dans diverses conditions expérimentales, ont conduit à un mélange comprenant principalement le composé de départ inchangé, à côté de traces d'un nouveau produit décelable en ccm mais que nous n'avons pas réuissi à isoler à l'état pur, même après plusieurs chromatographies sur alumine.

Conclusion

Nous avons montré que les 5*H*-pyrido[4,3-*b*]benzo[*f*]-indoles-5 substitués sont accessibles par une synthèse en 5–6 étapes au départ des chloro-4 pyrrolo[3,2-*c*]pyridines N-1 substituées. Celle-ci ne paraît toutefois pas applicable à la préparation des dérivés 5-NH correspondants, pourtant nécessaires pour pouvoir valablement comparer les propriétés biologiques des dérivés de cette série à celles des 6*H*-pyrido-[4,3-*b*]carbazoles (ellipticines) (24). Il sera donc utile d'en étudier une autre voie de synthèse car s'ils ne manifestent pas de propriétés antitumorales significatives sur la leucémie L1210,[2] les composés **20**–**23** N-5 méthylés sont néanmoins assez cytotoxiques in vitro pour justifier une étude plus complète de la série.

Partie expérimentale

Les points de fusion ont été pris au banc de Kofler. Les spectres de rmn ^{1}H ont été enregistrés sur un appareil Varian XL 100, dans les solvants indiqués, et les déplacements chimiques sont exprimés en ppm par rapport au Me_4Si.

Méthyl-1 (α-phényl α-hydroxy)éthyl-2 chloro-4 pyrrolo-[3,2-c]-pyridine ***10****a*

Le mélange formé par le composé **9***a* (21) (3,33 g, 20 mmol) en solution dans le THF anhydre (120 mL) est refroidi à −65°C et en maintenant l'ensemble sous agitation à la même température, le *tert*-butyl lithium (15,6 mL de la solution commerciale 1,6 *N*, soit 1,25 équivalent) est ajouté lentement. Après 10 min d'agitation à −65°C, l'acétophénone rectifiée (3,4 g, 30 mmol) dans le THF (10 mL) est ajoutée en 5 min. Le mélange est agité à −65°C pendant 45 min, puis 1 h à la température ambiante et versé dans 250 mL d'acide chlorhydrique 0,5 *N*. Après 1 nuit sous agitation, le mélange est extrait au chloroforme et l'évaporation du solvant fournit un résidu qui recristallise dans l'éthanol en donnant 3,92 g (68,4%) d'aiguilles incolores, *F* = 227–228°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,95 (s, 3H, CH_3—C—OH), 3,46 (s, 3H, N—CH_3), 6,26 (s, 1H, OH), 6,77 (s, 1H, H-3), 7,34 (s, 5H, C_6H_5), 7,45 (d, 1H, H-7, J_{7-6} = 5,5 Hz), 8,03 (d, 1H, H-6). *Anal.* calc. pour $C_{16}H_{15}ClN_2O$: C 67,02; H 4,24; N 9,77; Cl 12,39; trouvé: C 66,93; H 5,45; N 9,92; Cl 12,19.

[2]Testés sur les cellules en culture dans les conditions habituelles (16, 17), les composés **20**–**23** inhibent la croissance de 50% des cellules aux concentrations de $0,5 \times 10^{-6}$ *M* (**20** et **21**) et 5×10^{-6} *M* (**22** et **23**). Ils sont toutefois toxiques pour la souris à 35 mg/kg et totalement inactifs sur la leucemie L 1210 à la dose de 12,5 mg/kg.

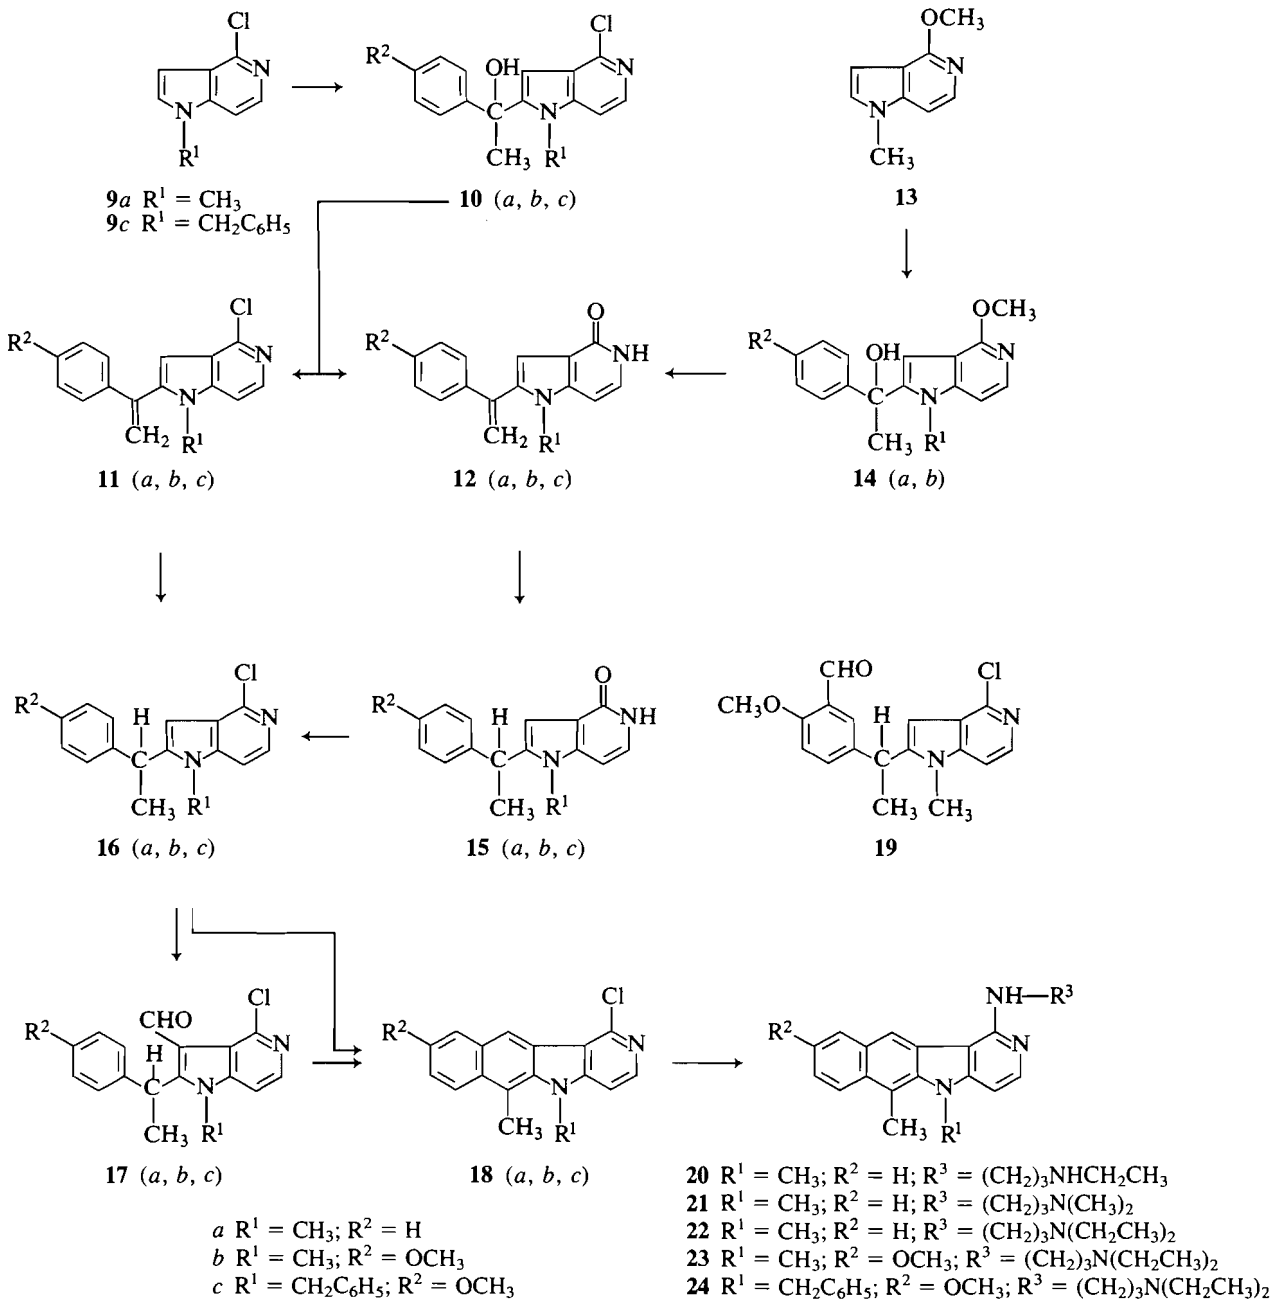

SCHÉMA 1

Méthyl-1 (α-méthoxy-4' phényl α-hydroxy)éthyl-2 chloro-4 pyrrolo-[3,2-c]pyridine ***10***b

Ce composé a été préparé comme le précédent à partir du dérivé chloré **9***a* (6,66 g, 40 mmol), lithié par 1,25 équivalent de *tert*-butyl lithium dans le THF (240 mL) et de la *p*-méthoxy-acetophénone (9 g, 60 mmol). Il recristallise dans l'éthanol en donnant 9 g (71%) d'aiguilles incolores, F = 210–212°C. *Anal.* calc. pour $C_{17}H_{17}ClN_2O_2$: C 64,46; H 5,41; N 8,84; Cl 11,19; trouvé: C 64,58; H 5,38; N 8,82; Cl 11,27.

Benzyl-1 (α-méthoxy-4' phenyl α-hydroxy)éthyl-2 chloro-4 pyrrolo-[3,2-c]pyridine ***10***c

La benzyl-1 chloro-4 pyrrolo[3,2-*c*]pyridine **9***c* (22, 23) 2,42 g, 10 mmol) en solution dans le diéthyléther sec (160 mL) est lithiée à −65°C par 11 mmol de *tert*-butyl lithium et traitée par la *p*-méthoxy acétophénone (1,8 g, 12 mmol) en solution dans l'éther (80 mL).[3] Après un traitement identique à celui mis en oeuvre dans les cas

[3]Dans le cas de la benzyl-1 chloro-4 pyrrolo[3,2-*c*]pyridine **9***c*, le rendement de la réaction est nettement abaissé si la lithiation est effectuée dans le THF. Ainsi, après réaction du lithien avec le DMF il se forme 58% de benzyl-1 formyl-2 chloro-4 pyrrolo[3,2-*c*]pyridine dans l'éther et seulement 29,6% dans le THF. Par ailleurs, en faisant réagir le lithien de **9***c* formé dans le THF avec l'acétaldéhyde, on isole environ 30% de benzyl-1 (α-hydroxyethyl)-2 chloro-4 pyrrolo[3,2-*c*]pyridine et 10% d'un mélange qui, après oxydation par le bioxyde de manganèse et chromatographie, fournit 2,5% de benzyl-1 chloro-4 acetyl-6 pyrrolo[3,2-*c*]pyridine, ce qui montre que la lithiation effectuée dans ces conditions n'est pas totalement spécifique du sommet 2 de **9***c*.

précédents, le mélange est extrait à l'éther et le résidu de l'évaporation du solvant est repris dans le minimum d'éthanol. Le solide insoluble est filtré pour donner 800 mg du composé **10***c* et l'évaporation des eaux mères fournit un résidu qui est chromatographié sur silice en éluant avec le dichlorométhane pur. La première fraction éluée correspond à la *p*-méthoxy-acétophénone, la seconde contient le composé chloré **9***c* inchangé et la troisième est constituée par une nouvelle quantité du composé attendu **10***c*. Les deux fractions de **10***c* réunies recristallisent dans l'éthanol pour donner des aiguilles incolores (1,15 g, 29%), F = 161–163°C. *Anal.* calc. pour $C_{23}H_{21}ClN_2O_2$: C 70,31; H 5,39; N 7,13; Cl 9,02; trouvé: C 70,34; H 5,62; N 7,17; Cl 8,85.

Méthyl-1 (α-phényl α-hydroxy)éthyl-2 méthoxy-4 pyrrolo-[3,2-c]-pyridine ***14***a

Le *tert*-butyl lithium (17 mL de la solution commerciale 1,6 *N*, soit 25 mmol) est ajouté à la solution de la méthyl-1 méthoxy-4 pyrrolo-[3,2-*c*]pyridine **13** (3,24 g, 20 mmol) dans le THF (100 mL) refroidie à −65°C. Après 5 min à cette température, le bain réfrigérant (acétone + Carboglace) est remplacé par un mélange glace + sel et le mélange réactionnel est agité pendant 15 min à −15°C.[4] La solution, devenue rose pâle, est de nouveau refroidie à −65°C et l'acétophénone (3,5 g, 30 mmol) en solution dans 10 mL de THF est ajoutée progressivement. Après 30 min d'agitation à −65°C et 1 h d'abandon à la température ambiante, le mélange est versé dans 250 mL d'acide chlorhydrique 0,5 *N*, agité pendant 15 min et extrait au dichlorométhane. Le résidu d'évaporation des phases organiques réunies est repris dans le minimum de toluène refroidi à −15°C et recristallisé dans le même solvant pour donner des cristaux incolores (4,5 g, 79,8%), F = 174–175°C. *Anal.* calc. pour $C_{17}H_{18}N_2O_2$: C 72,32; H 6,43; N 9,92; trouvé: C 72,34; H 6,43; N 9,90.

Méthyl-1 (α-méthoxy-4' phényl α-hydroxy)éthyl-2 méthoxy-4 pyrrolo-[3,2-c]pyridine ***14***b

Ce composé est obtenu suivant la même technique que le précédent à partir de **13** (6,5 g, 40 mmol), du *tert*-butyl lithium (50 mmol) et de la *p*-méthoxy-acétophénone (8 g, 60 mmol). Il recristallise dans le toluène pour donner des microcristaux incolores (7,6 g, 60,7%), F = 168–170°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,88 (s, 3H, *CH*$_3$—C—OH), 3,43 (s, 3H, N—CH_3), 3,75 (s, 3H, C_6H_4—O*CH*$_3$), 4,02 (s, 3H, O*CH*$_{3-4}$), 6,01 (s, 1H, *OH*), 6,64 (s, 1H, H-3), 6,89 (d, 2H, H-3' + H-5'-Ar, $J_{3'-2'}$ = 9 Hz), 7,02 (d, 1H, H-7, J_{7-6} = 6 Hz), 7,24 (d, 2H, H-2' + H-6'-Ar), 7,78 (d, 1H, H-6). *Anal.* calc. pour $C_{18}H_{20}N_2O_3$: C 69,21; H 6,45; N 8,97; trouvé: C 69,43; H 6,49; N 8,70.

Phényl-1 (méthyl-1' chloro-4' pyrrolo[3,2-c]pyridyl-2')-1 éthylène ***11***a *et phényl-1 (méthyl-1' dihydro-4',5' oxo-4' (pyrrolo-[3,2-c]-pyridyl-2')-1 éthylène* ***12***a

Le composé **10***a* (7,5 g, 26 mmol) est chauffé à reflux pendant 18 h dans 105 mL d'anhydride acétique et le mélange est évaporé sous pression réduite. Le résidu est repris dans l'eau, alcalinisé par addition de soude *N* et extrait au chloroforme.

Après évaporation du solvant, le résidu est repris dans 20 mL du mélange dichlorométhane–éthanol 9:1. La partie insoluble est filtrée. Elle correspond au composé **12***a*.

Le filtrat est chromatographié sour colonne de silice en éluant avec le mélange dichlorométhane–éthanol 9:1.

(a) La première fraction éluée contient le composé **11***a* qui recristallise dans le cyclohexane en donnant des paillettes incolores (3,7 g, 52,6%), F = 130°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 3,48 (s, 3H, N—CH_3), 5,68 (d, 1H, H-A CH_2═, J_{A-B} = 1 Hz), 6,07 (d, 1H, H-B CH_2═), 6,63 (d, 1H, H-3, J_{3-7} = 0,7 Hz), 7,41 (m, 5H, C_6H_5), 7,56 (q, 1H, H-7, J_{7-6} = 5,8 Hz), 8,08 (d, 1H, H-6). *Anal.* calc. pour $C_{16}H_{13}ClN_2$: C 71,51; H 4,84; N 10,43; Cl 13,22; trouvé: C 71,48; H 4,58; N 10,29; Cl 12.90.

(b) La seconde fraction éluée contient une nouvelle quantité du produit **12***a*. Après évaporation du solvant, celle-ci est jointe à la première partie filtrée précédemment et la recristallisation de l'ensemble dans le toluène fournit des microcristaux incolores (1,5 g, 22,9%), F = 235°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 3,35 (s, 3H, N—CH_3), 5,53 (d, 1H, H-A CH_2═, J_{A-B} = 1,2 Hz), 5,85 (d, 1H, H-B CH_2═), 6,51 (d, 1H, H-7, J_{7-6} = 7,1 Hz), 6,55 (s, 1H, H-3), 7,11 (d, 1H, H-6), 7,38 (s, 5H, C_6H_5), 10,89 (s large, 1H, NH-5). *Anal.* calc. pour $C_{16}H_{14}N_2O$: C 76,78; H 5,64; N 11,19; trouvé: C 76,92; H 5,79; N 10,86.

Préparation du composé ***12***a *à partir de l'alcool tertiaire* ***14***a

Le composé **14***a* (3 g) est chauffé à reflux pendant 70 h dans 150 mL de toluène en présence de 4,4 g d'acide *p*-toluène sulfonique et le solvant est évaporé. Le résidu est repris dans l'eau, extrait au dichlorométhane dans lequel il est peu soluble, lavé avec une solution d'hydrogénocarbonate de sodium et le solvant est évaporé. Le résidu recristallise dans le toluène en donnant 2,2 g (82,7%) de microcristaux incolores, F = 235°C, identiques au produit **12***a* déjà obtenu précédemment.

p-*Méthoxyphényl-1 (méthyl-1' chloro-4' pyrrolo[3,2-c]pyridyl-2')-1 éthylène* ***11***b *et* p-*méthoxyphényl-1 (méthyl-1' dihydro-4',5' oxo-4' pyrrolo[3,2-c]pyridyl-2')-1 éthylène* ***12***b

Le composé **10***b* (5 g) est chauffé à reflux dans l'anhydride acétique (75 mL) pendant 18 h et le mélange résultant est traité suivant la technique déjà utilisée pour préparer **11***a* et **11***b*. Après chromatographie sur colonne de silice, les deux fractions éluées par le mélange dichlorométhane–éthanol 9:1 sont évaporées.

(a) La première fournit un résidu qui recristallise dans le cyclohexane en donnant 2,5 g (44%) du composé **11***b*, F = 157–158°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 3,49 (s, 3H, NCH_3), 3,81 (s, 3H, OCH_3), 5,54 (d, 1H, H-A CH_2═, J_{A-B} = 1,1 Hz), 5,96 (d, 1H, H-B CH_2═), 6,61 (d, 1H, H-3, J_{3-7} = 0,8 Hz), 6,98 (d, 2H, H-3' + H-5' de C_6H_4, $J_{3'-2'}$ = 9 Hz), 7,29 (d, 2H, H-2' + H-6' de C_6H_4), 7,56 (q, 1H, H-7, J_{7-6} = 5,7 Hz), 8,08 (d, 1H, H-6). *Anal.* calc. pour $C_{17}H_{15}ClN_2O$: C 68,34; H 5,06; N 9,38; Cl 11,87; trouvé: C 68,18; H 4,97; N 9,34; Cl 12,14.

(b) La deuxième fraction contient le composé **12***b* qui recristallise dans l'éthanol en microcristaux incolores (1,4 g, 26,4%) qui se subliment et F = 260–270°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 3,36 (s, 3H, N—CH_3), 3,81 (s, 3H, OCH_3), 5,40 (d, 1H, H-A CH_2═, J_{A-B} = 1,2 Hz), 5,76 (d, 1H, H-B CH_2═), 6,51 (d, 1H, H-7, J_{7-6} = 6,6 Hz), 6,52 (s, 1H, H-3), 6,97 (d, 2H, H-3' + H-5' de C_6H_4, $J_{3'-2'}$ = 8,8 Hz), 7,21 (d, 1H, H-6), 7,27 (d, 2H, H-2' + H-6' de C_6H_4), 10,83 (s large, 1H, NH). *Anal.* calc. pour $C_{17}H_{16}N_2O_2$: C 72,84; H 5,75; N 9,99; trouvé: C 72,57; H 5,58; N 10,08. N.B. Le même composé **12***b* a également été obtenu avec un rendement de 89% en chauffant au reflux pendant 24 h 1 g de l'alcool tertiaire **14***b* dans 70 mL de xylène, en présence de 2,66 g d'acide *p*-toluène sulfonique, et en traitant ensuite comme déjà indiqué pour transformer **14***a* en **12***a*.

Dérivés benzylés ***11***c *et* ***12***c

L'alcool **10***c* (6,8 g) est déshydraté en le chauffant dans l'anhydride acétique (150 mL) à reflux pendant 20 h. Le mélange résultant est traité comme déjà décrit pour préparer **11***a* et **12***a* et la chromatographie sur silice, en éluant avec le mélange dichlorométhane–éthanol 95:5, fournit les deux composés attendus: (a) 5,8 g (68,2%) de **11***c*, F = 144–146°C (cyclohexane); rmn ^{1}H ($(CD_3)_2SO$) δ: 5,16 (s, 2H, *CH*$_2$-Ar), 5,47 (s, 1H, CH-A, C*H*$_2$═), 5,86 (s, 1H, CH-B C*H*$_2$═), 6,69 (s, 1H, H-3), 6,84–7,30 (m, 9H, 5H-Ar + 4H-Ar', $J_{3'-2'}$ = 10 Hz), 7,5 (d, 1H, H-7, J_{7-6} = 6 Hz), 8,08 (d, 1H, H-6). *Anal.* calc. pour $C_{23}H_{19}ClN_2O$: C 73,69; H 5,11; N 7,47; Cl 9,46; trouvé: C 73,39; H 5,19; N 7,41; Cl 9,20. (b) 1,4 g (19,8%) de **12***c*, F = 216–217°C (toluène); rmn ^{1}H ($(CD_3)_2SO$) δ: 3,8 (s, 3H, OCH_3), 5,02 (s, 2H, CH_2-Ar), 5,32 (s, 1H, CH-A C*H*$_2$═), 5,66 (s, 1H, CH-B C*H*$_2$═), 6,44 (q, 1H, H-7, J_{7-6} = 7,3 Hz, J_{7-3} = 0,5 Hz), 6,59 (d, 1H, H-3), 6,85—7,27 (m, 10H, 5H-Ar + 4H-Ar' + H-6, $J_{2'-3'}$ = 9,3 Hz). *Anal.* calc. pour $C_{23}H_{20}N_2O_2$: C 77,50; H 5,66; N 7,86. trouvé: C 77,25; H 5,77; N 7,88.

[4]Comme nous l'avons déjà signalé (21), si la lithiation du composé **13** est réalisée sans "réchauffer" le mélange réactionnel à −15°C pendant 15 min, le rendement de la réaction est seulement de 8–10%.

Alkyl-1 (α-aryl)éthyl-2 dihydro-4,5 oxo-4 pyrrolo[3,2-c]pyridines ***15***a, ***15***b *et* ***15***c

Le composé **12** voulu (*a*, *b* ou *c*) (10 mmol) en solution dans l'acide acétique (100 mL) est hydrogéné en l'agitant sous atmosphère d'hydrogène à la température ambiante et à la pression normale en présence de 150 mg de charbon palladié à 10%, jusqu'à cessation de l'absorption d'hydrogène (30–45 min). Le catalyseur est filtré, lavé avec l'acide acétique et ce dernier est évaporé. Le résidu est repris trois fois dans 30 mL de toluène, réévaporé à chaque reprise sous pression réduite pour bien éliminer l'acide acétique restant et le solide obtenu est recristallisé dans le minimum de toluène pour donner des microcristaux incolores.

15*a*: Rendement 91%; F = 253–254°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,60 (d, 3H, CH_3—CH, J_{CH_3-H} = 7,1 Hz), 3,36 (s, 3H, NCH_3), 4,32 (q, 1H, CH—CH_3), 6,44 (q, 1H, H-7, J_{7-6} = 7,1 Hz, J_{7-3} = 0,3 Hz), 6,53 (s, 1H, H-3), 7,01 (d, 1H, H-6), 7,14–7,46 (m, 5H, C_6H_5), 10,71 (s large, 1H, NH). *Anal.* calc. pour $C_{16}H_{16}N_2O$: C 76,16; H 6,39; N 11,10; trouvé: C 76,0; H 6,35; N 10,94.

15*b*: Rendement 85% F = 110–120°C, se resolidifie et F = 227°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,57 (d, 3H, CH_3—CH, J = 7 Hz), 3,40 (s, 3H, N—CH_3), 3,75 (s, 3H, OCH_3), 4,26 (q, 1H, CH—CH_3), 6,45 (d, 1H, H-7, J_{7-6} = 8,2 Hz), 6,49 (s, 1H, H-3), 6,88 (d, 2H, H-3′ + H-5′ Ar, $J_{3'-2'}$ = 8,8 Hz), 7,01 (d, 1H, H-6), 7,12 (d, 2H, H-2′ + H-6′ Ar), 10,8 (s large, 1H, NH-5). *Anal.* calc. pour $C_{17}H_{18}N_2O_2 \cdot H_2O$: C 67,98; H 6,71; N 9,33; trouvé: C 68,38; H 6,84; N 9,15.

15*c*: Rendement 90% en produit brut, qui a été directement transformé en son dérivé chloré **16***c*.

Alkyl-1 (α-aryl)éthyl-2 chloro-4 pyrrolo[3,2-c]pyridines ***16***a, ***16***b *et* ***16***c

Technique A

Le composé **15** voulu (10 mmol) est chauffé dans l'oxychlorure de phosphore bouillant (70 mL) pendant 2 h 30 (**15***a*), 3 h (**15***b*) et 5 h (**15***c*) et l'excès d'oxychlorure est évaporé sous pression réduite. Le résidu est décomposé dans l'eau glacée, alcalinisé par l'ammoniaque et extrait au dichlorométhane. Après évaporation du solvant, le résidu est chromatographié sur colonne de silice, en éluant avec le mélange dichlorométhane–éthanol 9:1. L'évaporation de la fraction d'élution contenant le composé attendu fournit un solide qui recristallise dans l'hexane ou le cyclohexane en donnant des microcristaux incolores.

Technique B

Le rhodium sur alumine (125 mg à 5%) est placé dans un tricol muni d'un agitateur magnétique et après avoir fait passer un courant d'hydrogène pour éliminer l'air, 25 mL d'éthanol sont ajoutés par une première ampoule à additionner. Le composé **11** (*a*, *b* ou *c*, 50 mmol) en solution dans 100 mL d'éthanol et primitivement placé dans une seconde ampoule est ensuite ajouté et l'ensemble est agité à la température ambiante, en atmosphère d'hydrogène à la pression normale, jusqu'à absorption de la quantité théorique d'hydrogène (environ 48 h). Après filtration et évaporation du solvant, le solide résiduel est chromatographié sur silice comme déjà décrit avec la Technique A.

16*a*: Rendement A 78%; Rendement B 75%; F = 109–110°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,67 (d, 3H, CH_3—CH, J_{CH_3-H} = 7 Hz), 3,54 (s, 3H, NCH_3), 4,48 (q, 1H, CH—CH_3), 6,60 (s, 1H, H-3), 7,24–7,34 (m, 5H, C_6H_5), 7,47 (d, 1H, H-7, J_{7-6} = 5,8 Hz), 8,0 (d, 1H, H-6). *Anal.* calc. pour $C_{16}H_{15}ClN_2$: C 70,98; H 5,54; N 10,35; Cl 13,12; trouvé: C 70,90; H 5,62; N 10,07; Cl 13,35.

16*b*: Rendement A 50%; Rendement B 85%; F = 114°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,65 (d, 3H, CH—CH_3), 3,54 (s, 3H, N—CH_3), 3,74 (s, 3H, OCH_3), 4,53 (q, 1H, CH—CH_3), 6,56 (d, 1H, H-3), 6,9 (d, 2H, H-3′ + H-5′, $J_{3'-2'}$ = 9 Hz), 7,17 (d, 2H, H-2′ + H-6′), 7,46 (q, 1H, H-7, J_{7-6} = 5,8 Hz, J_{7-3} = 0,8 Hz), 8,0 (d, 1H, H-6). *Anal.* calc. pour $C_{17}H_{17}ClN_2O$: C 67,88; H 5,70; N 9,31; Cl 11,79; trouvé: C 67,82; H 5,73; N 9,35; Cl 11,49.

16*c*: Rendement A 64%; Rendement B 69%; F = 126–128°C; rmn ^{1}H ($CDCl_3$) δ: 1,65 (d, 3H, CH_3—CH, J_{CH_3-H} = 7,2 Hz), 3,78 (s, 3H, OCH_3), 4,0 (q, 1H, CH—CH_3), 5,05 (q, 2H, CH_2-Ar, J_{H-H} = 17,1 Hz), 6,72–7,29 (m, 11H, 5H-Ar + 4H-Ar′ + H-3 + H-7, $J_{2'-3'}$ = 9 Hz), 8,0 (d, 1H, H-6, J_{6-7} = 5,7 Hz). *Anal.* calc. pour $C_{23}H_{21}ClN_2O$: C 73,30; H 5,62; N 7,43; Cl 9,41; trouvé: C 73,45; H 5,63; N 7,75; Cl 9,58.

Méthyl-1 (α-phényl)éthyl-2 formyl-3 chloro-4 pyrrolo[3,2-c]pyridine ***17***a

À la solution du dérivé chloré **16***a* (500 mg, 1,8 mmol) dans le DMF (1,26 mL) on ajoute, sans refroidir, 1,48 mL d'oxychlorure de phosphore et le mélange résultant est chauffé au bain d'huile à 120°C pendant 2 h. Après avoir ajouté successivement 1,26 mL de DMF puis 1,48 mL d'oxychlorure, l'ensemble est de nouveau chauffé à 110–120°C pendant 2 h, décomposé à froid en le versant dans l'eau glacée (100 mL) et alcalinisé par une solution d'hydroxyde de sodium 3 *N*. Le précipité formé est extrait au dichlorométhane, lavé avec une solution d'hydroxyde de sodium *N*, puis à l'eau, et l'évaporation de la phase organique séchée fournit un solide qui est repris dans le minimum d'éthanol et recristallisé dans le même solvant en cristaux jaune-pâle (90 mg, 16,3%), F = 163–164°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,8 (d, 3H, CH_3—CH, J_{CH_3-CH} = 7,4 Hz), 3,53 (s, 3H, NCH_3), 5,84 (q, 1H, CH—CH_3), 7,32 (m, 5H, C_6H_5), 7,67 (d, 1H, H-7, J_{7-6} = 5,8 Hz), 8,2 (d, 1H, H-6), 10,83 (s, 1H, CHO). *Anal.* calc. pour $C_{17}H_{15}ClN_2O$: C 68,34; H 5,02; N 9,38; Cl 11,89; trouvé: C 68,08; H 4,92; N 9,09; Cl 11,65.

Méthyl-1 (α-p-méthoxyphényl)éthyl-2 formyl-3 chloro-4 pyrrolo-[3,2-c]pyridine ***17***b

Le complexe formé à partir du diméthylformamide (9,2 mL, 0,12 mol) et de l'oxychlorure de phosphore (10,8 mL, 0,12 mol) est ajouté goutte à goutte à une solution du composé **16***b* (3 g, 10 mmol) dans du dichloro-1,2 éthane (10 mL) (rapport molaire 12:1). Le mélange résultant est chauffé au bain d'huile à 110°C pendant 24 h, versé dans l'eau, neutralisé par une solution d'hydrogénocarbonate de sodium et extrait au dichlorométhane. Le résidu de l'évaporation du solvant est repris dans le minimum d'éthanol pour donner 1,1 g d'un solide correspondant à l'aldéhyde attendu **17***b* pur. Les eaux mères sont évaporées et le nouveau résidu est chromatographié sur colonne d'alumine, en éluant avec le mélange éther de pétrole – acétate d'éthyle 4:1. La première fraction fournit 440 mg du composé **16***b* inchangé; la seconde contient une nouvelle quantité de **17***b* qui, réunie à la première, recristallise dans le méthanol en donnant au total 1,3 g, soit 38,6% d'aiguilles incolores, F = 184°C. Calculé par rapport au composé **16***b* réellement consommé, le rendement en **17***b* est de 46,4%; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,76 (d, 3H, CH—CH_3, J = 7,3 Hz), 3,53 (s, 3H, N—CH_3), 3,76 (s, 3H, OCH_3), 5,77 (q, 1H, CH—CH_3), 6,92 (d, 2H, H-3′ + H—5′, $J_{3'-2'}$ = 8,9 Hz), 7,18 (d, 2H, H-2′ + H-6′), 7,66 (d, 1H, H-7, J_{7-6} = 5,7 Hz), 8,20 (d, 1H, H-6), 10,83 (s, 1H, CHO). *Anal.* calc. pour $C_{18}H_{17}ClN_2O_2$: C 65,75; H 5,21; N 8,52; Cl 10,78; trouvé: C 65,48; H 5,25; N 8,35; Cl 11.06.

Benzyl-1 (α-p-méthoxyphényl)éthyl-2 formyl-3 chloro-4 pyrrolo-[3,2-c]-pyridine ***17***c

La formylation de **16***c* est réalisée avec les mêmes proportions de réactifs et en suivant la même technique que dans le cas précédent. Après la chromatographie sur alumine, l'aldéhyde **17***c* recristallise dans le méthanol en microcristaux incolores, F = 182–184°C (rendement: 31,6%); rmn ^{1}H ($CDCl_3$) δ: 1,64 (d, 3H, CH_3—CH, J_{CH_3-H} = 7,5 Hz), 3,77 (s, 3H, OCH_3), 5,10 (s, 2H, CH_2-Ar), 6,02 (q, 1H, CH—CH_3), 6,75–7,27 (m, 1OH, 5H-Ar + 4H-Ar′ + H-7), 8,06 (d, 1H, H-6, J_{6-7} = 5,7 Hz), 11,08 (s, 1H, CHO). *Anal.* calc. pour $C_{24}H_{21}ClN_2O_2$: C 71,19; H 5,23; N 6,92; Cl 8,76; trouvé: C 70,99; H 5,35; N 7,09; Cl 8,63.

*Chloro-1 diméthyl-5,6 5*H*-pyrido [4,3-b]benzo[f]indole* ***18***a

Méthode A

L'aldéhyde **17***a* (100 mg) est chauffé à 120°C sous agitation, pendant 2 h, dans 5 g d'acide polyphosphorique et le mélange est versé dans l'eau froide, puis alcalinisé par l'ammoniaque. Le précipité formé est

recristallisé dans le minimum d'éthanol pour donner 72 mg (76%) du composé **18***a* partiellement hydraté, F = 202°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 3,07 (s, 3H, CH_3-6), 4,14 (s, 3H, N—CH_3), 7,44–7,76 (m, 2H, H-8 + H-9), 7,60 (d, 1H, H-4, J_{4-3} = 5,9 Hz), 8,12–8,34 (m, 2H, H-7 + H-10), 8,35 (d, 1H, H-3), 8,84 (s, 1H, H-11). *Anal.* calc. pour $C_{17}H_{13}ClN_2 \cdot 1/2H_2O$: C 70,40; H 4,83; N 9,66; trouvé: C 70,63; H 4,59; N 10,04.

Méthode B

Le composé **16***a* (600 mg) est dissout dans le dichloroéthane (6 mL) et le chlorure stannique (1,02 mL, 4 équivalents) est ajouté à la température ambiante. À ce mélange, refroidi à 0°C, on ajoute le dichlorométhylméthyléther (0,35 mL, 1,7 équivalent). Après 1 h d'agitation à 0°C, l'ensemble est chauffé à reflux pendant 3 h, versé dans l'eau, alcanisé par l'ammoniaque et extrait au dichlorométhane. Le résidu de l'évaporation du solvant est chromatographié sur colonne d'alumine, en éluant avec le mélange éther de pétrole – acétate d'éthyle 4:1. La première fraction éluée contient le composé de départ inchangé (400 mg), la seconde fournit 110 mg (soit 53% par rapport au composé **16***a* consommé) du produit attendu **18***a*, F = 202°C, identique à celui préparé par la méthode A.

Chloro-1 méthoxy-9 diméthyl-5,6 5H-pyrido[4,3-b]benzo[f]indole ***18****b*

La solution de l'aldéhyde de **17***b* (200 mg) dans le mélange acide acétique (8 mL), plus anhydride acétique (5 mL) additionné de chlorure de zinc fondu sec (1,5 g), est chauffée à reflux pendant 2 h 30 et versée dans l'eau froide. Après avoir alcalinisé avec une solution d'hydroxyde de sodium *N* et extrait au dichlorométhane, le résidu de l'évaporation du solvant est chromatographié sur colonne d'alumine, en éluant avec le mélange éther de pétrole – acétate d'éthyle 1:1. L'évaporation de la principale fraction d'élution fournit un solide qui recristallise dans le toluène en donnant des microcristaux jaune-pâle (120 mg, 63,5%), F = 215–216°C, correspondant au composé **18***b* légèrement hydraté; rmn ^{1}H ($(CD_3)_2SO$) δ: 3,15 (s, 3H, CH_3-6), 4,01 (s, 3H, N—CH_3), 4,23 (s, 3H, OCH_3), 7,33 (q, 1H, H-8, J_{7-8} = 9,4 Hz, J_{8-10} = 2,8 Hz), 7,63 (d, 1H, H-10), 7,68 (d, 1H, H-4, J_{4-3} = 5,9 Hz), 8,24 (d, 1H, H-7), 8,38 (d, 1H, H-3), 8,88 (s, 1H, H-11). *Anal.* calc. pour $C_{18}H_{15}ClN_2O \cdot 0{,}25H_2O$: C 68,51; H 4,92; N 8,88; trouvé: C 68,54; H 4.97; N 8,61.

Méthyl-1 [α-(méthoxy-4′ formyl-3′ phényl)-1′ éthyl]-2 chloro-4 pyrrolo[3,2-c]pyridine ***19***

En cherchant transformer directement le composé **16***b* en dérivé tétracyclique **18***b* au moyen du dichlorométhylméthyléther en présence de chlorure stannique, dans les mêmes conditions expérimentales que celles utilisées précédemment pour former directement **18***a* à partir de **16***a*, 100 mg de **16***b* ont conduit, après chromatographie sur silice, à 8 mg d'un solide qui recristallise dans l'hexane en microcristaux jaunes, F = 186–188°C, dont le spectre de rmn ^{1}H présente les signaux suivants: ($(CD_3)_2SO$) δ: 1,66 (d, 3H, CH—CH_3), 3,56 (s, 3H, N—CH_3), 3,92 (s, 3H, OCH_3), 4,54 (q, 1H, CH—CH_3), 6,58 (s, 1H, H-3), 7,23 (d, 1H, H-5′, $J_{5'-6'}$ = 9 Hz), 7,56 (m, 3H, H-2′ + H-6′ + H-7), 7,99 (d, 1H, H-6, J_{6-7} = 5,8 Hz), 10,34 (s, 1H, CHO).

La faible quantité obtenue n'a pas permis de faire l'analyse centésimale de ce nouveau composé mais son spectre de rmn ^{1}H montre sans ambiguïté qu'il correspond à la structure **19** et son spectre de masse est en accord avec cette dernière. Ainsi, en desorption–ionisation (NH_3, 340 mA, 90 eV), il donne bien les pics moléculaires à 329 (M + 1, 100%) et à 331 (M + 1, pic isotopique Cl 37, 37%). De même, en impact électronique, (275°C, 0,25 Bar, 70 eV) les pics principaux sont à 328 ($M^{\cdot+}$, 100%) et à 313 (M − 15, —CH_3, 88,8%).

Chloro-1 benzyl-5 méthyl-6 méthoxy-9 5H-pyrido[4,3-b]benzo-[f]-indole ***18****c*

Le mélange constitué par l'acide acétique (20 mL), l'anhydride acétique (5 mL), l'acide *p*-toluène sulfonique anhydre (2,16 g) et l'aldéhyde **17***c* (270 mg) est chauffé sous agitation à 120°C pendant 4 h, versé dans l'eau (100 mL) alcalinisé à froid par l'ammoniaque et extrait au dichlorométhane. Le résidu de l'évaporation du solvant est chromatographié sur colonne d'alumine, en éluant avec le mélange éther de pétrole – acétate d'éthyle 3:2. Le composé **18***c*, qui se trouve dans la première fraction d'élution, recristallise dans l'hexane en microcristaux jaune pâle, F = 180–182°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 2,87 (s, 3H, CH_3-6), 3,96 (s, 3H, OCH_3), 5,97 (s, 2H, CH_2), 7,05–7,12 (m, 2H de C_6H_5), 7,22–7,37 (m, 4H, H-8 +3H de C_6H_5), 7,62 (d, 1H, H-4, J_{4-3} = 5,9 Hz), 7,63 (s, 1H, H-10), 8,15 (d, 1H, H-7, J_{7-8} = 9,4 Hz), 8,35 (d, 1H, H-3), 8,94 (s, 1H, H-11). *Anal.* calc. pour $C_{24}H_{19}ClN_2O$: C 74,51; H 4,95; N 7,24; Cl 9,16; trouvé: C 74,69; H 5,13; N 7,20; Cl 8,92.

Dialkylaminoalkylamino-1 alkyl-5 méthyl-6 5H-pyrido[4,3-b]-benzo[f]indoles ***20–24***

Le chloro-1 méthyl-6 5*H*-pyrido[4,3-*b*]benzo[*f*]indole voulu (**18***a*, **18***b* ou **18***c*, 300 mg) est chauffé dans l'amine choisie (10 mL) au bain d'huile à 160°C pendant 20 h et l'excès d'amine est évaporé sous pression réduite. Le résidu obtenu est repris dans l'eau, alcalinisé par addition d'une solution d'hydroxyde de sodium *N* et extrait au dichlorométhane. Après évaporation du solvant, les composés **20**, **21**, **22** et **23** sont directement cristallisés, puis recristallisés dans le cyclohexane, et le composé **24** est recristallisé dans le même solvant, mais après chromatographie sur colonne d'alumine en éluant avec le mélange dichlorométhane–éthanol 97:3.

20: Rendement 78,4%; F = 134–136°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,06 (t, 3H, CH_3—CH_2), 1,70–2,04 (m, 2H, CH_2-β), 2,6–2,81 (m, 4H, CH_2—CH_3 + CH_2-γ), 3,14 (s, 3H, CH_3-6), 3,62–3,82 (m, 2H, CH_2-α), 4,14 (s, 3H, N—CH_3), 6,88 (d, 1H, H-4, J_{3-4} = 6 Hz), 7,04 (s large, 1H, NH), 7,4–7,64 (m, 2H, H-8 + H-9), 8,10 (d, 1H, H-3), 8,16–8,33 (m, 2H, H-7 + H-10), 8,69 (s, 1H, H-11). *Anal.* calc. pour $C_{22}H_{26}N_4$: C 76,26; H 7,56; N 16,17; trouvé: C 76,12; H 7,49; N 15.97.

21: Rendement 74,3%; F = 183–185°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,74–2,04 (m, 2H, CH_2-β), 2,31 (s, 6H, $N(CH_3)_2$, 3,15 (s, 3H, CH_3-6), 3,60–3,84 (m, 2H, CH_2-α), 4,14 (s, 3H, N-CH_3), 6,89 (d, 1H, H—4, J_{4-3} = 6 Hz), 6,98 (s large, 1H, NH), 7,42–7,64 (m, 2H, H-8 + H-9), 8,0–8,31 (m, 3H, H-3 + H-7 + H-10), 8,57 (s, 1H, H-11). Le signal du CH_2-γ est partiellement masqué par celui du DMSO: 1 pic à 2,43. *Anal.* calc. pour $C_{22}H_{26}N_4$: C 76,26, H 7,56; N 16,17; trouvé: C 76,11; H 7,51; N 15,95.

22: Rendement 47%; F = 138–140°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,02 (t, 6H, CH_3—CH_2), 1,89 (m, 2H, CH_2-β), 2,52–2,70 (m, 6H, (CH_2—CH_3)$_2$ + CH_2-γ), 3,14 (s, 3H, CH_3-6), 3,72 (m, 2H, CH_2-α), 4,13 (s, 3H, N—CH_3), 6,8 (t, 1H, NH), 6,88 (d, 1H, H-4, J_{4-3} = 6 Hz), 7,52 (m, 2H, H-8 + H-9), 8,02–8,32 (m, 2H, H-7 + H-10), 8,11 (d, 1H, H-3), 8,60 (s, 1H, H-11). *Anal.* calc. pour $C_{24}H_{30}N_4$: C 76,96; H 8,07; N 14,96; trouvé: C 77,15; H 8,01; N 14,79.

23: Rendement 66%; F = 140–142°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,03 (t, 2 × 3H, CH_3—CH_2), 1,89 (m, 2H, CH_2-β), 2,39–2,69 (m, 3 × 2H, CH_2—CH_3 + CH_2-γ), 3,12 (s, 3H, CH_3-6), 3,69–3,75 (m, 2H, CH_2-α), 3,95 (s, 3H, N—CH_3-5), 4,11 (s, 3H, OCH_3), 6,71 (t, 1H, NH-1), 6,86 (d, 1H, H-4, J_{4-3} = 6 Hz), 7,23 (q, 1H, H-8, J_{8-7} = 5,7 Hz, J_{8-10} = 2,4 Hz), 7,40 (d, 1H, H-10), 8,09 (d, 1H, H-3), 8,17 (d, 1H, H-7), 8,52 (s, 1H, H-11). *Anal.* calc. pour $C_{25}H_{32}N_4O$: C 74,22; H 7,97; N 13,85; trouvé: C 73,95; H 7,94; N 13,60.

24: Rendement 72,5%; F = 122–125°C; rmn ^{1}H ($(CD_3)_2SO$) δ: 1,06 (t, 2 × 3H, CH_3—CH_2), 1,90 (m, 2H, CH_2-β), 2,37–2,73 (m, 3 × 2H, CH_2—CH_3 + CH_2-γ), 2,85 (s, 3H, CH_3-6), 3,75 (q, 2H, CH_2-α), 3,92 (s, 3H, OCH_3), 5,85 (s, 2H, CH_2), 6,81 (d, 2H, H-4 + NH), 7,03–7,35 (m, 6H, H-8 + C_6H_5), 7,42 (d, 1H, H-10, J_{10-8} = 2,5 Hz), 8,06 (d, 1H, H-3, J_{3-4} = 6 Hz), 8,11 (d, 1H, H-7, J_{7-8} = 9,5 Hz), 8,60 (s, 1H, H-11). *Anal.* calc. pour $C_{31}H_{36}N_4O$: C 77,46; H 7,55; N 11,66; trouvé: C 77,60; H 7,67; N 11,25.

Received September 30, 1985

MARIA I. COLOMBO, DANIEL A. BUSTOS, MANUEL GONZALEZ-SIERRA, ALEJANDRO C. OLIVIERI, and EDMUNDO A. RUVEDA. Can. J. Chem. **64**, 552 (1986).

An additional substituent parameter, the gauche–γ(X), was derived and a correction for the HC parameter of Beierbeck and Saunders is proposed; this new parameter would allow the semiempirical calculation of ^{13}C nuclear magnetic resonance shifts of six-membered ring epoxides and, consequently, their stereochemistry.

MARIA I. COLOMBO, DANIEL A. BUSTOS, MANUEL GONZALEZ-SIERRA, ALEJANDRO C. OLIVIERI et EDMUNDO A. RUVEDA. Can. J. Chem. **64**, 552 (1986).

On a développé un paramètre de substituant additionnel, le paramètre *gauche*–γ(X), et on propose une correction au paramètre HC de Beierbeck et Saunders. Le nouveau paramètre permettrait de calculer semi-empiriquement les déplacements chimiques, en rmn du ^{13}C, des époxydes à six chaînons et, par voie de conséquence, leur stéréochimie.

[Traduit par le journal]

The epoxy group on six-membered rings is a common functionality in natural products. However, the unambiguous configurational assignment of the oxirane ring was difficult to establish until the advent of ^{13}C nmr spectroscopy. In fact, the pioneering work of Lukacs and co-workers (1) on steroidal epoxides showed that the influence of this functional group on the chemical shifts of neighbouring carbons was useful for solving the problem satisfactorily. It was shown that the introduction of an epoxide into a six-membered unsaturated ring causes the homoallylic-positioned carbon atom, bearing an axial proton *cis* to the oxygenated function, to undergo an upfield shift of 4–6 ppm. The same effect was observed on terpenoids having a rigid framework (2–4), on six-membered ring monoterpenes (5), and, also, in aliphatic chains with preferred conformations (6).

It was suggested that the main effect of introducing a *gauche* γ-substituent is the elimination of an HC interaction, associated with 1,3-diaxial HH interactions (7). However, if the observed chemical shift variation is larger than that caused simply by removal of the HC interaction, as in the case of cyclohexane epoxides, an additional γ(X) parameter may be required for semiempirical calculation of ^{13}C nmr shifts. This new *gauche*–γ(X) (γ_g(X)) parameter could be used as a complement to those previously reported (7) and, consequently, for the determination of the stereochemistry of six-membered ring epoxides.

Applying the semiempirical parameters derived by Beierbeck *et al.* (7), we have computed the shifts for the sequence: saturated hydrocarbon → olefin → epoxide, considering the epoxide as a *cis*-1,2-dihydroxylated compound (Scheme 1). A shielding effect of 5.8 ppm is predicted for the labelled carbon in going from A to the epoxide C, whereas an upfield shift of 2.7 ppm is expected for the Δδ (B → C). On the other hand, in going from B to the epoxide D, a deshielding effect of 1.9 ppm is computed.

We have found, as the result of the analysis of the experimental data listed in Table 1, that a γ_g(X) of ca.

−3.8 ppm, leading to the shifts shown in Scheme 2, is necessary to obtain good agreement with the observed values. This parameter does not apply at quaternary carbons. Furthermore, upon assigning a 3-ppm value for the HC interaction, which we suggest naming $(HC)_e$ for this type of compound, a $\Delta\delta(B \rightarrow D)$ value of practically zero, also in accord with the experimental data, is found (Scheme 2). Such a small value for this HC parameter could be attributable to the less effective 1,3-diaxial HH interaction in the half-chair conformation of the epoxide.

In Table 1 is shown a comparison between calculated and observed ^{13}C nmr values for the compounds studied, using the parameters given in Scheme 3.

The conclusions at which we have arrived seem to be quite

19

general; however, the effect of a 5β,6β-epoxide on the homoallylic carbon shift of the withanolides deserves some comment. As was previously reported by Gottlieb and Kirson (8), C-8 of withaferin A diacetate (**17**) does not suffer the expected shielding effect induced by the oxirane ring. Also, the same carbon of withanolide G (**18**) is practically unaffected compared to that of withanolide E (**19**). These apparently abnormal results could be explained by assuming that, in **17**, ring B adopts a distorted half-chair conformation leading to a reduced γ-*gauche* interaction. This assumption is supported by the reported X-ray analysis of withaferin A acetate *p*-bromobenzoate (9), which indeed shows such a distortion. Other cases that do not exhibit the expected effect on the homoallylic carbon shifts may be due to conformational distortion.

Iminium ion-mediated cyclizations of 4-aryl-1,4-dihydropyridines. Alternate cyclization pathways

GEORGE D. HARTMAN,[1] WASYL HALCZENKO,[1] AND DAVID W. COCHRAN
Merck Sharp & Dohme Research Laboratories, West Point, PA 19486, U.S.A.

Received August 29, 1985

GEORGE D. HARTMAN, WASYL HALCZENKO, and DAVID W. COCHRAN. Can. J. Chem. **64**, 556 (1986).

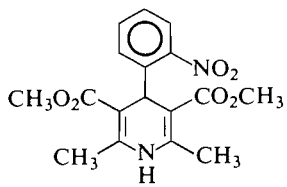
Acid-catalyzed cyclization of dimethyl 2,6-dimethyl-4-[(2-ethenyl-5-methoxy)phenyl]-1,4-dihydropyridine-3,5-dicarboxylate affords novel products via competing intramolecular processes. The present mechanistic pathways differ from previous iminium ion-mediated cycloadditions, to afford conformationally constrained dihydropyridine analogs for study as calcium antagonists. These results illustrate the ability of the dihydropyridine nucleus to function as either a nucleophile or an electrophile, depending upon substituents in the aryl ring.

GEORGE D. HARTMAN, WASYL HALCZENKO et DAVID W. COCHRAN. Can. J. Chem. **64**, 556 (1986).

La cyclisation acido-catalysée du diméthyl-2,6 [(éthènyl-2 méthoxy-5)phényl]-4 dihydro-1,4 pyridinedicarboxylate-3,5 de diméthyle conduit à de nouveaux produits via des processus intramoléculaires qui sont en compétition. Les voies réactionnelles impliquées ici diffèrent de celles présumées antérieurement lors de cycloadditions impliquant des ions iminium et elles conduisent à des analogues de dihydropyridines ayant des contraintes conformationnelles et pouvant servir dans des études comme antagonistes du calcium. Ces résultats illustrent la facilité du noyau dihydropyridine à agir soit comme un nucléophile soit comme un électrophile suivant la nature des substituants attachés au noyau aromatique.

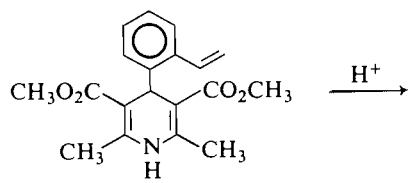
[Traduit par le journal]

Calcium antagonists encompass a heterogeneous group of compounds that inhibit calcium-dependent cellular processes (1). These agents are thought to decrease calcium influx through the slow calcium channel in the cell membrane, while having minimal effect on calcium extrusion or other ionic transport mechanisms (2). These attributes allow this class of compounds to inhibit calcium-mediated pathologic contractile events. Consequently, several calcium antagonists have gained clinical importance in the treatment of angina, hypertension, arrhythmias, and migraine (3). Among these, the 4-aryl-1,4-dihydropyridines, as characterized by nifedipine (**1**), have proven to be the most potent.

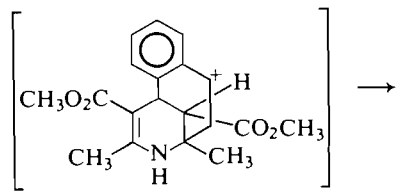


1

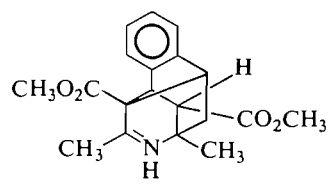
Development and further refinement of biologically active dihydropyridines have involved molecular classification according to drug receptor site and specific channel gating characteristics (4, 5). Pharmacologic progress in this area has hinged on the evolution of synthetic strategies that would provide molecules of appropriate topology. Inspired by suggestions that calcium entry blocker activity was correlated with the ring pucker in the dihydropyridine nucleus (6), a considerable amount of attention has lately been given to the preparation of conformationally constrained analogs (7, 8). As part of this effort we have described (9, 10) the synthesis of novel, rigid dihydropyridine derivatives arising from intramolecular biscyclization reactions between a 4-aryl substituent and the dihydropyridine/iminium species. Thus, treatment of dimethyl 2,6-dimethyl-4-(2-ethenyl)phenyl-1,4-dihydropyridine-3,5-dicarboxylate (**2**) with gaseous HCl gave cation **3**, which was



2



3



4

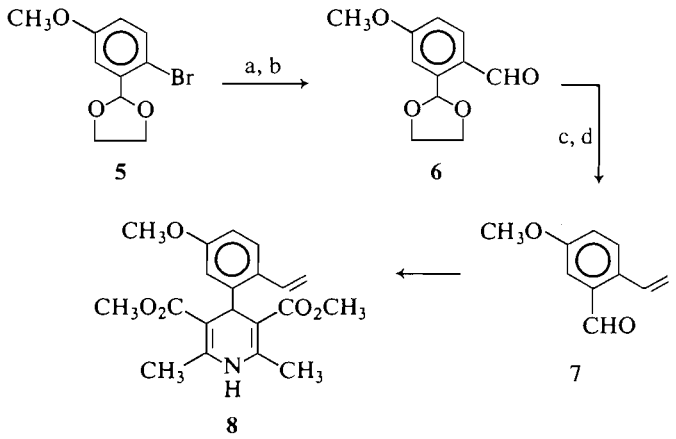
trapped internally by the aminocrotonate to provide **4**. In an effort to prepare more potent calcium entry blockers in this series, as well as with recognition that alternate reaction possibilities existed for intermediates such as **3**, we decided to explore the synthesis of aryl-substituted compounds. We now wish to report that acid-catalyzed cyclization of dimethyl 2,6-dimethyl-4-[(2-ethenyl-5-methoxy)phenyl]-1,4-dihydropyridine-3,5-dicarboxylate (**8**) affords products that are dramatically different from those observed for **2**, and which arise via competing intramolecular processes.

Results and discussion

The synthesis of dihydropyridine **8** is presented in Scheme 1. Treatment of the known 2-bromo-5-methoxybenzaldehyde acetal (**5**) (11) with *n*-BuLi followed by *N*-formylpiperidine gave

[1]Authors to whom correspondence may be addressed.

Printed in Canada / Imprimé au Canada



a: *n*-BuLi, THF, −70°C; b: *N*-formylpiperidine; c: $(C_6H_5)_3PCH_3Br$/*n*-BuLi, THF, 0°C to room temp. over 16 h; d: CH_3COCH_3,*p*-TSA, room temp. for 4 h; e: $CH_3COCH_2CO_2CH_3/H_2N(CH_3)C{=}CHCO_2CH_3$, CH_3OH, reflux for 72 h.

SCHEME 1

acetal aldehyde **6**. This compound was then methylidenated with the appropriate Wittig reagent and the aldehyde deprotected to give **7**, which was subjected to Hantzsch reaction with methyl acetoacetate and methyl 3-aminocrotonate to provide **8**.

When **8** in chloroform solution was treated with excess hydrogen chloride gas, starting material was consumed within 18 h and three new compounds were produced. The major products (Scheme 2) of reaction and basic work-up were dimethyl 1-methylidene-3,9-dimethyl-6-methoxy-2,4a-dihydro-9*H*-indeno[2,1-*c*]pyridine-4,9a-dicarboxylate (**14**) and its tautomer, **15**, which were obtained in 74% yield in a ratio of 1:1.25 as an inseparable mixture. The minor product of reaction was dimethyl 4,5-dihydro-10-methoxy-3,5-dimethyl-1,5-methano-1*H*-4-benzazonine-2,12α-dicarboxylate **11**, which was isolated in 12% yield. Surprisingly, none of the bis-cyclized adduct **12** was observed. The structure of **11** was proven by single-crystal X-ray analysis[2] and an ORTEP representation is presented in Fig. 1. The structures of **14** and **15** were assigned based upon 360-MHz ^{1}H nmr, elemental analysis, and mass spectral data. The assignment of the relative stereochemistry at the bridging carbon C-7 in **14** and **15** was made in the following manner. The mixture of **14** and **15** was reduced with sodium borohydride in acetic acid (12) to afford a single product whose 360-MHz ^{1}H nmr, elemental analysis, and mass spectral properties were correct for the gross structure of **16**. Nuclear Overhauser enhancement (nOe) experiments, wherein saturation of the C-6 methyl resonance at δ 0.62 gave an enhancement in the signals for N-H, N-6 and H-7, while saturation of the methyl resonance at C-7 produced an enhancement of the signals for H-4 and H-7, unequivocally indicated that the product had the relative stereochemistry shown in **16**.

The formation of cycloadducts **11**, **14**, and **15** from **8** suggests that reaction proceeds along two competing pathways. The major pathway (path a, Scheme 2) involves protonation of the styrenic double bond to give the methoxy-stabilized secondary benzylic cation **13**, which is attacked by C-3 of the dihydropyridine to provide **14** and **15**. Nucleophilic reactivity in this sense is directly analogous to that seen previously both in the

[2]Details of the structure will be published in full in the Journal of Medicinal Chemistry.

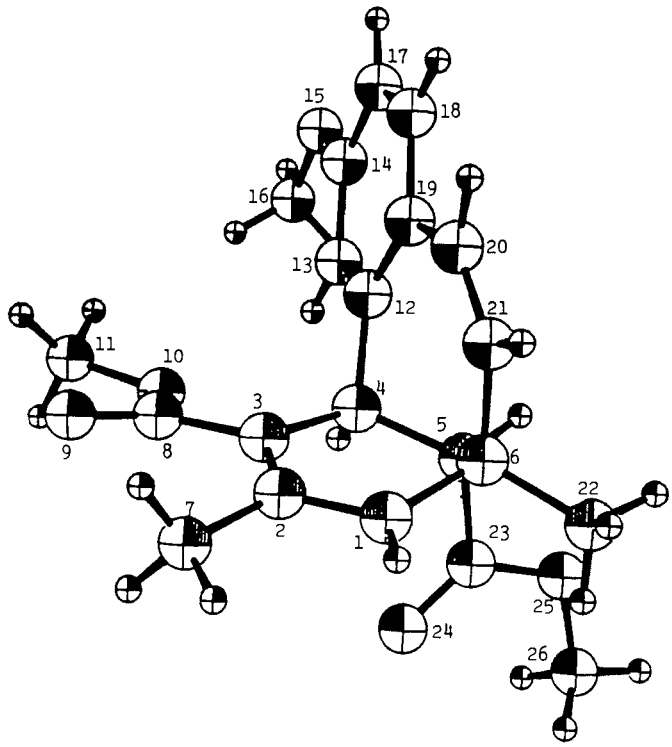


FIG. 1. ORTEP representation of **11**.

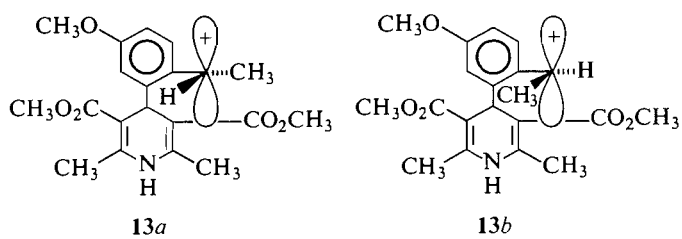
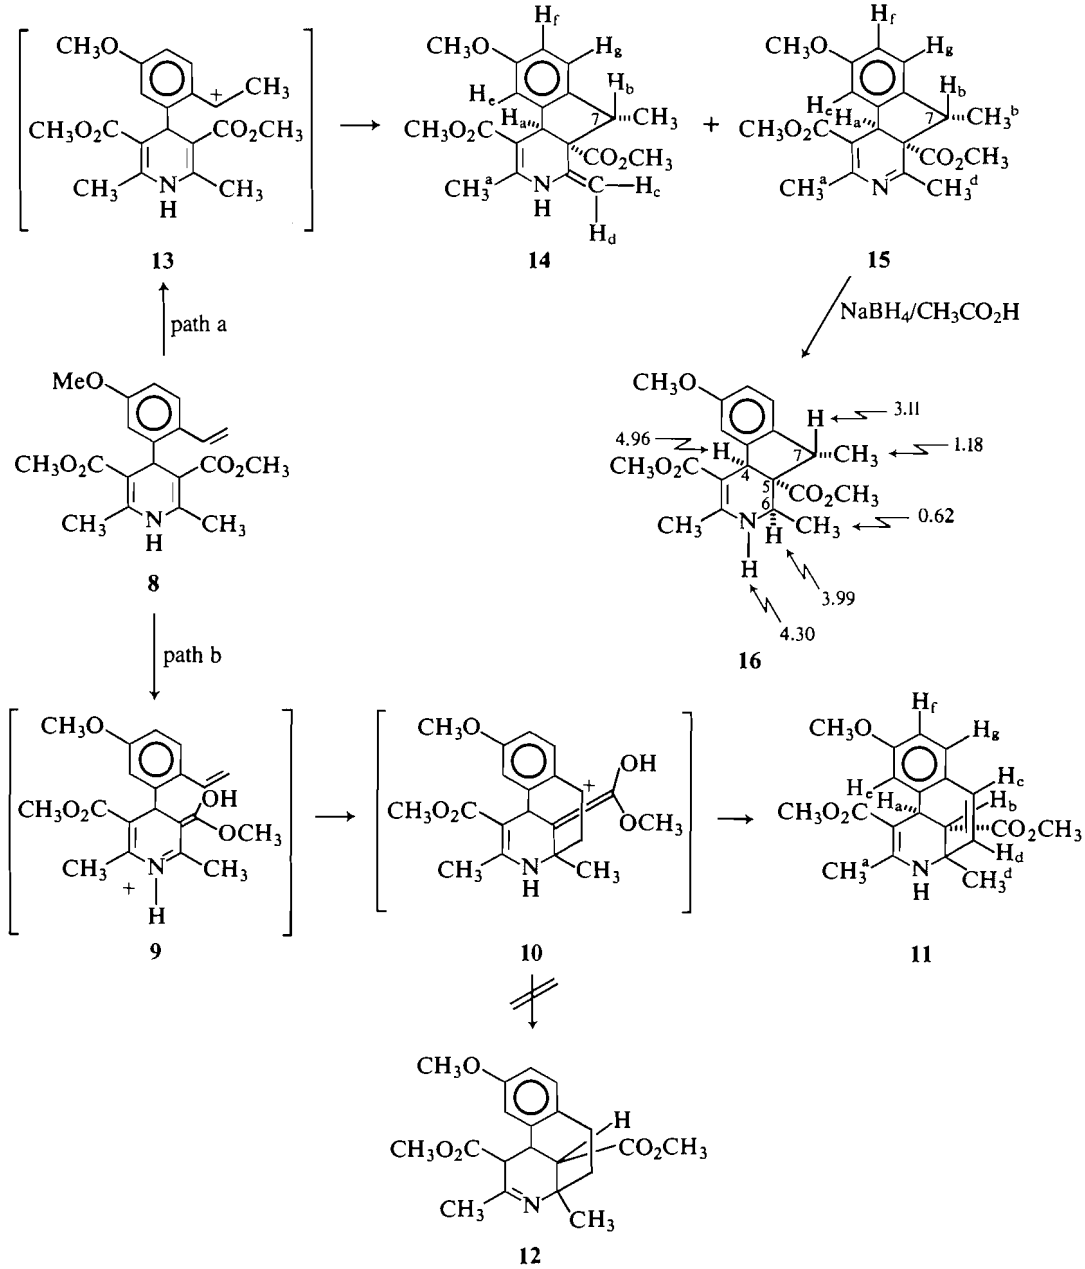
capture of cation **3** internally by the crotonate double bond (9), as well as in the acid-catalyzed opening of acetals (10). Similar reactivity has also been reported by Aritomi and Nishimura (13) in the internal capture of iminium salts by the dihydropyridine nucleus. It should also be noted that the formation of the indicated isomer at C-7 denotes, not unexpectedly, the capture of cation **15***b*. It is also apparent that the dramatic reversal in mechanism seen between **2** and **8** can be attributed to the rapid formation and trapping of the highly stabilized *p*-methoxybenzyl cation **13**.



13*a* **13***b*

The minor pathway (path b) features formation of iminium ion **9** followed by attack of the styrenic double bond on C-2 to give cation **10**. Elimination of a proton, rather than internal capture as seen for **3**, then occurs to yield **11**.

The present results support and extend several concepts that have recently been advanced with regard to dihydropyridine reactivity (9, 10). As demonstrated in path a, where the dihydropyridine nucleus functions as a nucleophile, and in path b, where it acts as an electrophile, the net reactivity can encompass both polarities. Moreover, in contrast to styrene **2** and acetals (9) that display a single behavior, olefin **8** illustrates the ability to utilize its dihydropyridine nucleus as either nucleophile or electrophile competitively. We thus conclude that reactivity of 4-aryl-1,4-dihydropyridines in the present acid-catalyzed cyclization processes is a function both of aryl



SCHEME 2

substituents that covalently interact with the nucleus, as well as those that only affect the stability of cyclization intermediates.

The compounds described in this paper represent novel, conformationally constrained dihydropyridine derivatives, which will be studied as calcium antagonists. Moreover, the pathways by which these cycloadducts arise represent a unique competitive reactivity previously unrecognized for 1,4-dihydropyridines. We feel that the application of these cyclization modes and preferences in analogous systems will be of synthetic utility.

Experimental

Melting points were taken on a Thomas–Hoover capillary apparatus and are uncorrected. The nmr spectra were recorded on an EM-390 or a Nicolet NT-360 spectrometer with Me_4Si as an internal standard. Mass spectra were obtained on a LKB-9000S mass spectrometer at 70 eV. *N*-formylpiperidine, methyl acetoacetate, and methyl 3-aminocrotonate were obtained from Aldrich and all were used without purification. *n*-Butyllithium (hexane) was purchased from Alfa.

2-[2-(1,3-Dioxalanyl)]-4-methoxybenzaldehyde (6)

To 38.87 g (0.15 mol) 2-bromo-5-methoxybenzaldehyde acetal (**5**) (11) in 500 mL tetrahydrofuran cooled to −75°C under nitrogen was added 0.15 mol *n*-butyllithium (in hexane) dropwise over 1.5 h. After stirring for 1 h at −70°C, a solution of 20.37 g (0.18 mol) *N*-formylpiperidine in 50 mL tetrahydrofuran was added dropwise while keeping the temperature < −70°C. The resulting yellow solution was allowed to come to room temperature with stirring overnight.

The reaction mixture was quenched with 75 mL of saturated ammonium chloride solution and extracted with 2 × 400 mL portions of ether. The combined organic extracts were washed successively with 4 × 100 mL portions of saturated ammonium chloride solution, then with brine, and dried. Solvent removal *in vacuo* gave an oil, which was fractionated through a 6-in. Vigreux column to give 22.8 g (73%) of **6** as an oil; ^1H nmr (90 MHz, $CDCl_3$): 3.55 (s, 3H, OCH_3), 3.80 (s, 4H, $-CH_2-CH_2-$), 6.15 (s, 1H, $HC(O)_2$), 6.72 (dd, 1H, aromatic, J = 2, 8 Hz), 6.95 (d, 1H, aromatic, J = 2 Hz), 7.65 (d, 1H, aromatic, J = 8 Hz), 10.05 (s, 1H, CHO).

2-Ethenyl-5-methoxybenzaldehyde (7)

To 95.0 g (0.226 mol) methyl triphenylphosphonium bromide suspended in 500 mL tetrahydrofuran and cooled to −75°C under nitrogen was added 0.252 mol *n*-butyllithium dropwise while keeping the temperature <−70°C. After addition was complete the temperature was allowed to gradually rise to 0°C over 3–4 h. Then, a solution of 21.5 g (0.103 mol) of **6** in 50 mL tetrahydrofuran was added dropwise while the temperature was kept <5°C. After addition was complete the reaction mixture was stirred in an ice bath overnight. The solvent was then removed *in vacuo* and the residue was taken up in 150 mL methylene chloride. This solution was passed through a pad of silica gel that was thoroughly rinsed with methylene chloride. The solvent was removed *in vacuo* to give a viscous oil that was purified by flash chromatography on silica gel, eluting with hexane – ethyl acetate, 85:15. The product acetal was isolated as a clear oil with R_f 0.5 in this solvent system. The yield was 14.9 g (70%).

Cleavage of the acetal was accomplished by treatment with *p*-toluenesulfonic acid monohydrate in acetone for 8 h at room temperature. The solvent was then removed *in vacuo* and the residue was taken up in either. This was washed with 2 × 50 mL portions of saturated sodium bicarbonate solution, then with brine, and dried. Solvent removal gave an oil, which was purified by flash chromatography on silica gel, eluting with hexane – ethyl acetate (9:1) to give pure **7**, R_f 0.5, as a slightly yellow oil, 8.02 g (48%); ^{1}H nmr (90 MHz, $CDCl_3$): 3.81 (s, 3H, OCH_3), 5.35 (dd, 1H, $=CH_2$), 5.54 (dd, 1H, $=CH_2$), 7.0–7.55 (m, 4H, aromatic + —CH=), 10.25 (s, 1H, CHO).

Dimethyl 2,6-dimethyl-4-[(2-ethenyl-5-methoxy)phenyl]-1,4-dihydropyridine-3,5-dicarboxylate (8)

To 8.0 g (0.049 mol) **7** dissolved in 50 mL methanol was added 5.68 g (0.049 mol) methyl 3-aminocrotonate and 5.72 g (0.049 mol) methyl acetoacetate and the resulting solution was heated at reflux for 3 days. The solvent was then removed *in vacuo* and the residue was triturated with ether. The pale yellow solid that separated was filtered off, washed with a small amount of cold ether, and air dried to give 6.55 g of **8**. The filtrate was purified by flash chromatography on silica gel, eluting with hexane–ether (1:2) to provide another 1.45 g of **8**, which had R_f 0.4 in this solvent system. The total yield of **8** was 8.0 g (46%), mp 141–143°C; ^{1}H nmr (360 MHz, $CDCl_3$): 2.32 (s, 6H, CH_3), 3.56 (s, 6H, CO_2CH_3), 3.74 (s, 3H, OCH_3), 5.19 (dd, 1H, $CH_2=$, J = 2, 12 Hz), 5.25 (s, 1H), 5.50 (dd, 1H, $CH_2=$, J = 2, 18 Hz), 5.60 (br, s, 1H, NH), 6.68 (dd, 1H, aromatic, J = 3, 9 Hz), 6.87 (d, 1H, aromatic, J = 3 Hz), 7.35–7.50 (m, 2H, aromatic), 7.45 (dd, 1H, —CH=, J = 12, 18 Hz); ms m/e: 357 (M^+). *Anal.* calcd. for $C_{20}H_{23}NO_5$: C 67.21, H 6.49, N 3.92; found: C 67.18, H 6.64, N 3.85.

Dimethyl 4,5-dihydro-10-methoxy-3,5-dimethyl-1,5-methano-1H-4-benzazonine-2,12α-dicarboxylate (11); dimethyl 1-methylidene-3,9-dimethyl-6-methoxy-2,4a-dihydro-9H-indeno[2,1-c]pyridine-4,9a-dicarboxylate (14); and dimethyl 1,3,9-trimethyl-6-methoxy-4a,9-dihydroindeno[2,1-c]pyridine-4,9a-dicarboxylate (15)

A stream of HCl gas was bubbled into a solution of 2.0 g (5.6 mmol) of **8** in 30 mL chloroform cooled to 0–5°C in an ice bath for 0.5 h. The reaction mixture was then stirred at room temperature overnight as the temperature gradually rose to ambient. The reaction mixture was diluted with 100 mL chloroform was 35 mL ice-cold water. This was neutralized with concentrated ammonium hydroxide solution and the phases were separated. The aqueous phase was extracted with 3 × 50 mL portions of chloroform and the combined organic extracts were washed with brine and dried. Solvent removal gave a yellow foam (2.1 g) which was a mixture of **11**, **14**, and **15**. This was purified by careful flash chromatography on silica gel (230–400 mesh), eluting with hexane–ether (1:2) to afford 1.48 g (74%) of a mixture of **14** and **15**, eluting first with an R_f 0.5, followed by 0.24 g (12% of **11**, R_f 0.4.

Compound **11**, mp 150–155°C; ^{1}H nmr (360 MHz, $CDCl_3$): 1.40 (s, 3H, CH_3^d), 2.23 (d, 3H, CH_3^a), 3.15 (s, 1H, H_b), 3.58 (s, 3H), 3.71 (s, 3H), 3.81 (s, 3H), 4.11 (br s, 1H, H_a), 4.21 (br, s, 1H, NH), 5.23 (d, 1H, H_d), 6.22 (d, 1H, H_c), 6.66 (d, 1H, H_f), 6.93 (d, 1H, H_g), 6.95 (d, 1H, H_e); ms m/e: 357 (M^+). *Anal.* calcd. for $C_{20}H_{23}NO_5$: C 67.21, H 6.49, N 3.92; found: C 66.90, H 6.64, N 3.92.

The tautomeric mixture **14/15** was determined, by integration of nmr peaks described below, to be a 1:1.25 ratio of these two compounds and had mp 170–172°C; ms m/e: 357 (M^+). *Anal.* calcd. for $C_{20}H_{23}NO_5$: C 67.21, H 6.49, N 3.92; found: C 67.50, H 6.65, N 3.99. **14** had ^{1}H nmr (360 MHz, $CDCl_3$): 1.21 (d, 3H, CH_3^b), 2.33 (s, 3H, CH_3^a), 4.45 (d, 1H, H_d), 4.69 (d, 1H H_c), 4.96 (s, 1H, H_a), 5.91 (br s, 1H, NH), 6.58 (br s, 1H, H_e), 6.68 (dd, 1H, H_f), 7.05, (d, 1H, H_c). **15** had ^{1}H nmr (360 MHz, $CDCl_3$): 1.18 (d, 3H, CH_3^b), 2.30 (s, 3H, CH_3^a), 2.42 (s, 3H, CH_3^d), 4.85 (s, 1H, H_a), 6.58 (br s, 1H, H_e), 6.72 (dd, 1H, H_f), 7.04 (d, 1H, H_g). In addition, the nmr spectrum of **14/15** contained absorptions that could not be specifically associated with either tautomer: 3.61 (q, 1H), 3.72 (s, 6H, CO_2CH_3), 3.79 (s, 3H, OCH_3), 3.74 (s, 3H, CO_2CH_3), 3.88 (s, 3H, CO_2CH_3).

Dimethyl 2,4a,9,9a-tetrahydro-6-methoxy-1,3,9-trimethyl-1H-indeno[2,1-c]pyridine-4-9a(α)-dicarboxylate (16)

To 5 mL glacial acetic acid was added 0.06 g (1.6 mmol) sodium borohydride at room temperature and, after the initial vigorous gas evolution, this suspension was stirred for 15 min. Then 0.10 g (0.28 mmol) of a mixture of **14/15** (1:1.25) was added in one portion and the resulting yellow solution was stirred at room temperature overnight.

The reaction mixture was then poured into 20 mL ice water, neutralized with saturated sodium bicarbonate solution, and filtered to give a tan solid. This was purified by flash chromatography on silica gel, eluting with hexane–ether (1:2) to give 0.32 g (31%) of **16**, R_f 0.4 in this solvent system, mp 134–140°C; ^{1}H nmr (360 MHz, $CDCl_3$): 0.62 (d, 3H, J = 7 Hz), 1.18 (d, 3H, J = 7 Hz), 2.25 (s, 3H, allylic CH_3), 3.11 (q, 1H, J = 7 Hz), 3.73 (s, 3H), 3.76 (s, 3H), 3.80 (s, 3H), 3.99 (m, 1H), 4.30 (br d, 1H, NH), 4.96 (s, 1H), 6.62–7.01 (3H, aromatic); ms m/e: 359 (M^+). *Anal.* calcd. for $C_{20}H_{25}NO_5$: C 66.83, H 7.01, N 3.90; found: C 66.93, H 7.30, N 3.67.

Acknowledgements

The authors wish to thank Mrs. Joan S. Murphy for the nmr spectra, Mr. John Moreau for elemental analyses, Dr. Harri Ramjit for mass spectral determinations, and Dr. James P. Springer for X-ray determinations. The authors also thank Dr. Steven M. Pitzenberger and Dr. Barry Trost for helpful discussions, and Mrs. M. Banker for preparation of the manuscript.

Received June 6, 1985

PHOTIS DAIS and GEORGE FAINOS. Can. J. Chem. **64**, 560 (1986).

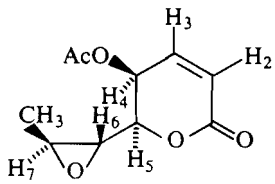
^{13}C nuclear magnetic resonance spin-lattice relaxation times (T_1) have been used to probe the motional behavior of 5-acetoxy-5,6-dihydro-6-(1,2-epoxypropyl)-2-pyrone ("asperlin") in dimethyl sulfoxide solution. This molecule offers structural features suited to a study of internal motions, i.e., epoxypropyl and methyl internal motions superimposed on an anisotropic overall reorientation. The rigidity of the pyrone ring and its semiplanar conformation result in an overall ellipsoidal shape, and hence the rotational dynamics of asperlin are adequately approximated by the diffusion of a prolate ellipsoid with the major axis passing through the C(2)—H(2) bond. The description of the internal motion of the epoxypropyl ring is strongly model dependent. Furthermore, the relaxation data for the oxirane ring carbons do not uniquely define a dynamic model. Due to similarities in the activation energies of the overall and internal motions, based on temperature-dependent measurements, it has not been feasible to interpret the relaxation data by a single type of motion. Internal rotation of the epoxymethyl substituent is rationalized by applying the stochastic diffusion model of multiple internal rotations.

PHOTIS DAIS et GEORGE FAINOS. Can. J. Chem. **64**, 560 (1986).

On a utilisé les temps de relaxation spin-réseau (T_1) de la rmn du ^{13}C pour étudier le comportement des mouvements de l'acétoxy-5 dihydro-5,6 (époxy-1,2 propyl)-6 pyrone-2 ("asperlin") en solution dans le diméthylsulfoxyde. Cette molécule présente des caractéristiques de structure qui sont adaptées à une étude des mouvements internes; il s'agit des mouvements internes de l'époxypropyle et du méthyle qui se superposent à une orientation globale anisotrope. La rigidité du cycle pyrone et sa conformation semi-planaire lui font adopter une forme globale ellipsoïdale et l'on peut décrire adéquatement la dynamique de la rotation de l'asperlin en faisant l'approximation qu'elle ressemble à la diffusion d'une ellipsoïde allongée avec un axe majeur qui passerait par la liaison C(2)—H(2). La description du mouvement interne du cycle époxypropyle dépend beaucoup du modèle. De plus, les données de relaxation des carbones du cycle oxirane ne permettent pas de définir un modèle dyamique. À cause de similarités dans les énergies d'activation des mouvements globaux et internes, que l'on a obtenues à partir de mesures qui dépendaient de la température, on n'a pas pu interpréter les données de relaxation par un seul type de mouvement. On a rationalisé la rotation interne du substituant époxyméthyle en appliquant le modèle de diffusion stochastique des rotations internes multiples.
[Traduit par le journal]

Introduction

A large number of natural products contain α,β-unsaturated lactone structures. These include compounds of the coumarin series, macrolides, the steroid withaferin, and 2-pyrones of fungal origin. Among the latter group is 5-acetoxy-5,6-dihydro-6-(1,2-epoxypropyl)-2-pyrone) (**1**), produced by *Aspergillus nidulans* (1) and termed "asperlin," which possess antibiotic and antitumor activity. The structure of **1** has been studied (2–4) by ^1H and ^{13}C nmr spectroscopy, as well as by chemical synthesis. It was concluded that the pyrone ring of **1** assumes a semi-planar conformation, in which five of the six carbons are held coplanar, that the C(4)—H(4) bond approaches coplanarity with the olefinic bonds, and also that the 4,5-substituents of the ring have the L-*threo* configuration. In addition, the data confirmed that the oxirane ring is *trans*, and indicated that **1** is the 6*R*,7*S* diastereomer. Finally, it was shown that the H-5 and H-6 protons are *anti*, in the most probable conformation of the side chain about the C(5)—C(6) bond.



1

To obtain a fuller understanding of the properties of **1**, we have measured the ^{13}C spin-lattice relaxation times (T_1) of **1** in DMSO-d_6 solution over the temperature range 20–100°C, and calculated the diffusion coefficients of the overall and internal motions from the relaxation data. The data are consistent, approximately, with an overall axially symmetric diffusion, upon which internal rotations are superimposed. The interpretation of the relaxation data for the oxirane ring is found to be strongly dependent on the models adopted, whereas the methyl internal rotation is described by using the stochastic diffusion model for multiple internal rotations.

Experimental

^{13}C nuclear magnetic resonance relaxation experiments were conducted on a Varian XL-200 spectrometer operating at 50.3 MHz under conditions of full ^1H noise decoupling. The temperature was controlled to within ±0.1°C by means of a precalibrated copper–constantan thermocouple in the probe insert. The relaxation times were measured by the FIRFT technique (5) and analysed by a three-parameter non-linear procedure (6). The pulse duration for a 180° flip angle, checked at various temperatures, was 29.6 μs. Other details on relaxation experiments and ^{13}C nOe (nuclear Overhauser enhancement) measurements are given elsewhere (7). The rms error in the three-parameter fit was ±5% or better, whereas the reproducibility was ±5–10%, the upper limit pertaining at high temperatures. Samples of a 0.8 *M* solution of **1** in DMSO-d_6 were degassed by saturation with dry nitrogen gas for 1–2 min before use. All of the calculations were performed with algorithms written in APL.

Results and discussion

Carbon-13 T_1 values obtained from 20 to 100°C for the protonated carbons of **1** are summarized in Table 1. The nOe values for all protonated carbons,[2] at all temperatures, ap-

[1]Author to whom all correspondence should be addressed.

[2]For consistency with previous publications (2–4), **1** is numbered as a lactone. Accordingly, its carbonyl carbon is position 1 rather than, as in the pyrone system, position 2.

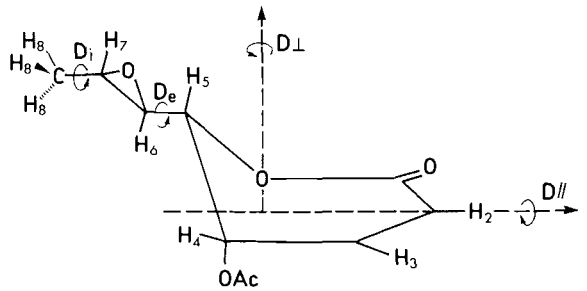

FIG. 1. Axes of rotation in "asperlin" and rotational diffusion coefficients.

proached the asymptotic value of 2.988 to within ±5%, indicating that these carbons relax predominantly via dipole–dipole interactions. The T_1 value of C-2 in the pyrone ring at all temperatures is smaller than the T_1's of the remaining ring carbons (Table 1). These differences, which are outside the experimental error, indicate that **1** reorients anisotropically about a preferential axis of rotation. Since C-3, C-4, and C-5 are characterized by similar T_1 values, their respective C—H vectors should form nearly equal angles with the preferential axis of rotation. Stereomodels indicate that this is the case, if the axis of rotation passes through, or forms small angles with, the C(2)—H(2) vector. The C(3)—H(3) vector forms an angle of 60° with this axis, whereas the C(4)—H(4) and C(5)—H(5) bonds form angles of 70.5° with the same axis. These qualitative relaxation characteristics reflect the molecular shape of **1**, which in turn determines the type of the overall molecular reorientation. The rotational dynamics of **1** can be adequately approximated by the diffusion of a prolate ellipsoid with a major axis passing through the C(2)—H(2) bond as in Fig. 1. The rotation about this axis is described by the rotational difusion coefficient, $D\|$, and the rotation of this axis is characterized by the rotational diffusion coefficient, $D\perp$.

Woessner has shown (8) that these two coefficients are related to the relaxation time by:

$$[1]\quad \frac{1}{T_1} = \frac{N\gamma_C^2\gamma_H^2\hbar^2}{r_{C-H}^6}(D\perp)^{-1}\left[\frac{A}{6} + \frac{B}{5+p} + \frac{C}{2+4p}\right], \qquad p = D\|/D\perp$$

where A, B, C are geometric functions (8) of the angle β formed by the pertinent C—H vector and the major axis of the ellipsoid. Because β = 0° for the C(2)—H(2) vector, its respective relaxation time is sufficient to determine $D\perp$ by means of the equation (8)

$$[2]\quad \frac{1}{T_1(\text{C-2})} = \frac{N\gamma_C^2\gamma_H^2\hbar}{r_{C-H}^6}(6D\perp)^{-1}$$

Using the relaxation data for C-4 (or C-5), a value of β = 70.5°, and of 1.09 Å for a C—H bond, the $D\perp$ and $D\|$ parameters displayed in Table 2 were calculated. By using the diffusion coefficients from Table 2 in eq. [1] with β = 60°, the angle formed by the C(3)—H(3) bond and the axis of rotation, the experimental T_1 values of C-3 are nicely reproduced (Table 3). This finding gives validity to the model used in the present treatment. Inspection of Table 2 reveals that over an 80°C temperature range the diffusion coefficients change by a factor of four, and that the pyrone ring rotates about the major axis ~1.5 times faster than about the perpendicular axis. The constancy of the $D\|/D\perp$ ratio is in accord with simple hydrodynamic theory (9), which requires that this ratio be determined by the molecular geometry. Plots of the diffusion coefficients $D\|$ and $D\perp$ on a semilogarithmic scale versus the reciprocal of the temperature (K^{-1}), in Fig. 2, give the following activation energies: 3.62 ± 0.46 kcal/mol for rotation about the major axis of the ellipsoid, and 4.07 ± 0.25 kcal/mol for rotation perpendicular to that axis.

The measured T_1 values of C-6 and C-7 are equal within the experimental error (Table 1), indicating that no puckering motion within the oxirane ring contributes to the relaxation of these carbons. The relaxation data may be interpreted in terms of motional anisotropy of a rigid molecule, since the major axis of the ellipsoid and the internal axis of rotation coincide, or, alternatively, by considering the superimposition of internal motion about the C(5)—C(6) bond upon the overall motion.

We first consider the effect of motional anisotropy, neglecting internal motion about the C(5)—C(6) bond. Anisotropic motion as described above will lead to differences in the T_1 values of the oxirane and pyrone ring carbons, if the angle formed by the C(6)—H(6) and (or) the C(7)—H(7) vectors and the axis of anisotropic motion is different from 109.5° or 120°, formed by the pertinent C—H vectors of C-4, C-5, and C-3, respectively. The HCH dihedral angle determined (10) for oxirane is 116.60°. A slightly larger value is probably expected for the disubstituted ring in **1**, due to increasing steric constraints caused by substitution.[3] However, such small angle differences, corresponding to a range ≤10°, must contribute very slightly to the T_1 calculated, assuming no internal motion. Therefore, the differences observed in the experimental T_1 values for the oxirane and pyrone carbons (Table 1), ranging

[3] A $HCC_{subst.}$ dihedral angle of 120° for the disubstituted oxirane ring was adopted in the following calculations.

[c]The values within parentheses are the angles θ that reproduce the experimental data.
[d]$\tau_A = 10^{-12}$ s, $\tau_B = 2 \times 10^{-12}$ s.
[e]$\tau_A = \tau_B = 10^{-11}$ s.
[f]By employing the model of multiple internal rotations as expressed by eqs. [9]–[11].

from 20 to 30%, are strong evidence against the possibility that overall anisotropic motion is responsible for the observed T_1 values of C-6 (or C-7).

A second approximate analysis is based on the assumption of an overall anisotropic reorientation, plus internal motion about the C(5)—C(6) bond. This analysis, however, is strongly model dependent. A model using unrestricted internal diffusion may be applied to this problem. Since the internal rotation axis is parallel to the major axis of the ellipsoid, the internal reorientation is independent of the reorientation of the remainder of the molecule about its symmetry axis (11). In this case, the relaxation of the oxirane ring can be described by eq. [1], in which $D\parallel$ is replaced by the internal rotational diffusion coefficient, D_e. The calculated diffusion coefficients for an angle $\beta = 120°$ are summarized in Table 2 and plotted vs. $(1/T)$ in Fig. 2. We find an activation energy of 4.06 ± 0.50 kcal/mol for the internal rotation of the epoxypropyl moiety. Moreover, inspection of Table 2 reveals that the epoxypropyl ring rotates about two times faster than the ellipsoid about its symmetry axis.

The temperature independence of the relaxation time ratio T_1(C-3,C-4,C-5)/T_1(C-6,C-7), observed in Table 1, can be explained by the constancy of the diffusion coefficient ratio $D_e/D\parallel$ throughout the temperature range of the measurements (Table 2). This result is a consequence of the similarity of activation energies for the internal and overall molecular diffusion processes. An analogous situation has been encountered in the study of the 3-chlorobiphenyl system (12). Activation energies for internal diffusion or jump models in a 25% solution of 3-chlorobiphenyl in DMSO-d_6 were found to be equal to that corresponding to the overall diffusion, within the experimental error.

A possible alternative to the approximate temperature independence of the relaxation time ratio could be that the internal motion is sufficiently rapid so that the relaxation rate falls within the geometric limit (13). In this case, the observed ratio becomes dependent on the diffusion coefficients of the overall motion only, with the rate reduced by the geometric factor $(3/2 \cos^2 \beta - 1/2)^2$ (13), i.e.,

$$[3] \quad \frac{T_1(\text{C-3,C-4,C-5})}{T_1(\text{C-6,C-7})} \rightarrow \frac{(3/2 \cos^2 120 - 1/2)^2}{\chi(p, \beta)}$$

where

$$[4] \quad \chi(p, \beta) = 1 + \frac{3(1-p)}{(5+p)} \sin^2 \beta + \frac{9(1-p)^2}{2(5+p)(1+2p)} \sin^4 \beta$$

Equation [4] is an alternative form (13*a*) of the expression in the brackets of eq. [1], with p and β defined previously. For $p = 1.5$ and $\beta = 109.5°$, expression [3] gives 0.0188. This geometric limit does not apply to the present data, since it predicts a relaxation time ratio that differs markedly from the observed value of ~0.75.

Next we consider restricted motion about the C(5)—C(6) bond. Some theoretical expressions (14–18) describe internal motion as a jump between several stable conformations.

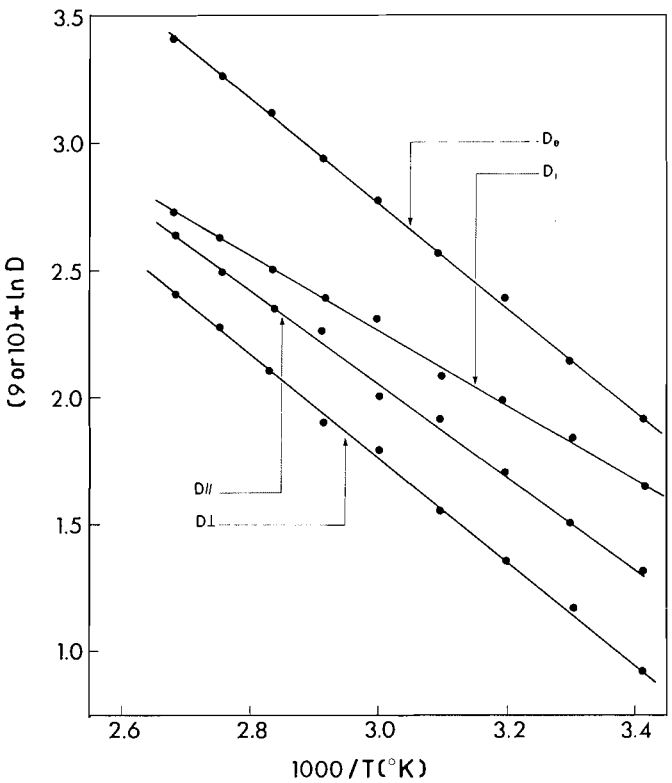

FIG. 2. Temperature dependence of the overall ($D\|$, $D\perp$), epoxypropyl (D_e), and methyl (D_i) rotational diffusion coefficients of "asperlin" in DMSO-d_6 solution.

According to these models, the rates of jumping or, equivalently, the lifetimes of the various conformations determine the relaxation rates. However, the fact that low amplitude diffusion is ineffective (15, 16) in causing relaxation suggests that a jump model involving relatively few conformations should be generally suitable for describing relaxation. Consequently, a model consisting of two alternate conformational states is taken to be an appropriate description of oscillation in the oxirane ring. The spectral density for such a model in the extreme narrowing region is given by (16, 17)

$$[5] \quad J(\omega) = \frac{(1 - C)}{6D\perp} + \frac{C}{6D\perp + 1/\tau_C}$$

where

$$[6] \quad \frac{1}{\tau_C} = \frac{1}{\tau_A} + \frac{1}{\tau_B}$$

and

$$[7] \quad C = \frac{3\tau_A\tau_B}{(\tau_A + \tau_B)^2}\{\sin^2\beta(1 - \cos 2\theta)\} \times \{2 - \sin^2\beta(1 - \cos 2\theta)\}$$

Expression [5] was derived by conceptualizing that the internal rotation axis is aligned with the symmetry axis of the ellipsoid. In eqs. [5]–[7], β is the angle formed by the C—H relaxation vector and the internal axis, τ_A and τ_B are the lifetimes of the two states, and θ is the half-range of the jump.

For very rapid internal jumping between the two states, this model would lead to a limiting relaxation time ratio of

$$[8] \quad \frac{T_1(\text{C-3,C-4,C-5})}{T_1(\text{C-6,C-7})} \rightarrow (1 - C)$$

Assuming $\tau_A = \tau_B$, the limiting value of the relaxation time ratio depends on the angle θ. Values of 0.72 and 0.70 were obtained for jumps between $\theta = \pm 20°$ and $\pm 90°$, respectively. These are in good agreement with the observed ratios in Table 1. In particular, an angle of $\theta = \pm 20°$ is commensurate with a very slight distortion of the *anti* orientation of the H-5 and H-6 protons deduced from the coupling data (4).

Although this model reproduces the experimental relaxation ratio, it does not give information about the actual rate of internal jumping nor a clear measure of the jumping amplitude. Of course, the internal motion does not have to be so fast that the observed relaxation ratio is described by a geometric factor only. The second term in eq. [5] could also contribute to the observed relaxation rate.

The problem of interpreting the relaxation data in terms of eqs. [5]–[7] is, clearly, unresolved. However, the temperature dependence of the relaxation data in Table 1 can be used to evaluate the validity of the approximations inherent in this model. T_1 values calculated for C-6,7 using different τ_A and τ_B lifetimes are summarized in Table 3 for comparison with experimental data. Good fits were obtained with $\tau_A = \tau_B = 10^{-12}$ s and $\tau_A = 10^{-12}$ s and $\tau_B = 2 \times 10^{-12}$ s, although these lifetimes gave small differences in the values of 2θ, i.e., 50–52° and 56–60° for the first and second case, respectively. It should be noted that plots of T_1 vs. θ corresponding to various values of $D\perp$ (Table 2) and $\tau_A = \tau_B$ are skewed, with the maximum T_1 value occurring at $\theta = 50°$. A maximal factor of 5 for τ_A/τ_B is possible in order to fit the data, although this value corresponds to a large range, $2\theta \simeq 120°$ for C-6,7. A factor of 6 is inconsistent with the data. Using $\tau_A = \tau_B = 10^{-11}$ s gives a range for $2\theta \simeq 60°$, which is similar to that when $\tau_A = 10^{-12}$ s and $\tau_B = 2 \times 10^{-12}$ s. Reducing τ_A and τ_B to 10^{-10} s renders even $\theta = 50°$ insufficient to fit the observed T_1 values of C-6,7. In summary, these calculations show that lifetimes in the range 10^{-11} to 10^{-12} s fit the data adequately, whereas longer lifetimes are inconsistent with the observed T_1 values.

The present findings demonstrate that the relaxation data for the protonated carbons of the oxirane ring of **1** do not uniquely define a dynamic model. The internal motion of the oxirane ring can be satisfactorily approximated either by free rotation about the C(5)—C(6) bond, or by a jumping process between two stable conformations. The problem of discriminating between these two models is due mainly to the fortuitous similarity in the activation energies of the internal and overall diffusional motions. However, inspection of molecular models indicates that geometrical constraints imposed on the rotation of the epoxypropyl moiety are not severe enough to justify restricted rotation about the C(5)—C(6) bond.

The relaxation of the carbon (CH_3-8) receives contributions from three types of molecular motion: (*1*) the internal rotation of the methyl group about its symmetry axis described by diffusion coefficient D_i; (*2*) the reorientation of the adjacent oxirane ring with diffusion coefficient D_e; and (*3*) the overall molecular motion characterized by diffusion coefficients $D\|$ and $D\perp$. Approximate separation of these relaxation contributions can be realized by applying the stochastic diffusion model of multiple internal rotations, developed initially by Wallach (19), and subsequently modified by Levine *et al.* (20, 21). In the present case, two motions about the C(5)—C(6) and C(7)—CH_3 bonds are considered to be free and independent of the overall molecular reorientation. Restricted rotation about the C(6)—C(7) bond ensures that the two internal motions are independent of one another. The spectral density used to

TABLE 4. Motional parameters and calculated relaxation times for **1**, including all C—H interactions[a]

373	1.26	11.4	14.4	3.14	3.34	3.43	3.45

[a]Using eq. [12].

calculate the required relaxation times is obtained by Fourier transformation of the appropriate autocorrelation function (19, 20):

$$[9] \quad J(\omega) = \sum_{\substack{m,a \\ b,c}} |d_{ma}(\beta_0)|^2 |d_{bc}(\beta_1)|^2 |d_{co}(\beta_2)|^2 \frac{\tau}{1 + \omega^2\tau^2}$$

where

$$[10] \quad \tau = (6D\perp + m^2(D\parallel - D\perp) + a^2D_e + c^2D_i)^{-1}$$

and $d_{ij}(\beta)$ are the second-rank Wigner rotation matrices (22). The angles β_0, β_1, β_2 correspond to angles between the first internal rotation axis and the major axis of the ellipsoid, the second and the third rotational axis, and the final rotation axis and the C—H relaxation vector, respectively. The subscripts, m, a, b, c are integers ranging from -2 to $+2$. It should be noted that the summation of the matrix elements $\sum_{a,b} |d_{ab}(\beta)|^2$ in eq. [9] is omitted, since it is equal to unity, as the second internal rotation about the C(6)—C(7) is frozen (19).

The relationship between spin-lattice relaxation times and spectral density is given by

$$[11] \quad \frac{1}{T_1} = \frac{N\gamma_C^2\gamma_H^2\hbar^2}{10r_{C-H}^6}\{J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H + \omega_C)\}$$

Using the spectral density eqs. [9]–[11], numerical results were obtained for values of $D\perp$, $D\parallel$, and D_e from Table 2. The parameter, D_i, fitting the experimental relaxation times, is depicted in the last column of Table 2 for each temperature, whereas Table 3 gives the T_1 values of the methyl carbons reproduced by the model of the multiple internal rotations. The agreement between the reproduced and experimental data is very good. The temperature dependence of the D_i diffusion coefficient, shown in Fig. 2, corresponds to an activation energy of 2.93 kcal/mol. This energy value implies that some resistance to free methyl internal rotation is likely to occur in **1**. This result is not unexpected due to the geminal disposition of the methyl group and H-7 in the oxirane ring of **1**.

The relaxation parameters of **1** shown in Table 1 are averages of at least two measurements. The effect of random noise and other sources of error (e.g., temperature fluctuations) contribute to the experimental uncertainty by 5–10%. The error introduced by nOe experiments was 5%. The overall effect of these sources of error results in a standard deviation of 7–11% for each individual T_1 measurements or a standard deviation of 5–8% for each mean value. This margin of experimental error appears to be quite substantial compared to the small anisotropy observed for **1**, which gives T_1 differences of the order of 10–16% (Table 1). Therefore, the legitimacy of the present quantitative analysis should be tested by considering those factors that may affect the anisotropy of the motion.

The first factor is related to the choice of the anisotropic axis of reorientation of the ellipsoid. A preferential axis of rotation that forms small angles with the C(2)—H(2) vector, it is not expected to modify the basic conclusions of this report. Larger deviations, however, may change the shape of the ellipsoid and consequently the interpretation of the relaxation data. Using Platzer's method (23), an anisotropic analysis for **1** was carried out by adjusting the anisotropic ratio, p, while varying the orientation of the anisotropic axis of rotation (i.e., the angles β relative to the various C—H vectors). The best agreement between the observed T_1 values of all the ring carbons and the bracketed quantity in eq. [1] was obtained when the axis formed angles of 10–20° with the C(2)—H(2) vector. For an angle of 20° between the C(2)—H(2) vector and the assumed symmetry axis of the ellipsoid for two sets of measurements, the motional parameters obtained by this approach were: $p = 1.37$, $D\perp = 2.4 \times 10^9\,s^{-1}$ at 293 K, and $p = 1.21$, $D\perp = 8.1 \times 10^9\,s^{-1}$ at 353 K. Consistent results were obtained for the remaining temperatures. Larger changes of the orientation of the anisotropic axis resulted in higher motional anisotropies than those reported in Table 2, but failed to reproduce the experimental data. Discrepancies of the order of 15, 25, and 40% were observed between the calculated and the experimental T_1 values for changes of the orientation of the anisotropic axis by 30, 40, and 50°, respectively.

The second factor we have investigated is the contribution of the intramolecular nonbonded C—H interactions to the relaxation of the ring carbons of **1**. T_1 values were calculated for each carbon, over a range of trial ratios p, with relaxation contributions summed over all protons in the molecule, i.e.,

$$[12] \quad \frac{1}{T_1^i} = \gamma_H^2\gamma_C^2\hbar^2\,(6D\perp)^{-1} \sum_j r_{ij}^{-6}\left(A_{ij} + \frac{6B_{ij}}{5+p} + \frac{6C_{ij}}{2+4p}\right)$$

where $A_{ij} = \frac{1}{4}(3\cos^2\beta_{ij} - 1)^2$, $B_{ij} = 3\sin^2\beta_{ij}\cos^2 B_{ij}$), $C_{ij} = \frac{3}{4}\sin^4\beta_{ij}$, and β_{ij} is the angle between the symmetry axis of the ellipsoid as in Fig. 1 and the vector joining the ith carbon with the jth proton. Internuclear separations, r_{ij}, were calculated using the ATCOOR computer program (24) assuming standard bond lengths and angles. Representative results at four temperatures are summarized in Table 4. Although no significant differences were found in the calculated diffusion coefficients from those obtained using bonded C—H interactions, it appears that contributions from nonbonded C—H interactions account for ~1.5% of the relaxation of the C-2 carbon and ~3% for each of the remaining ring carbons, which relax via two nonbonded protons at distances less than 2.5 Å. These contributions decrease the margin of the T_1 differences to 7–13%, which is comparable to the experimental uncertainty at high temperatures. This molecule, therefore, represents the borderline case, in which the overall motion may be described as isotropic at

high temperatures. The approximate assumption that **1** can be described by an overall isotropic motion plus internal rotation of the epoxypropyl ring leads to activation energies of 3.89 ± 0.16 kcal/mol and 4.28 ± 0.39 kcal/mol for the overall and internal motions, respectively. The latter value is considered as the upper limit for the internal rotation.

Synthesis, characterization, and X-ray structures of Rh(I) monocarbonyl complexes containing unsymmetric tridentate pyrazolylgallate ligands

DAVID A. COOPER, STEVEN J. RETTIG, AND ALAN STORR[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received June 25, 1985

DAVID A. COOPER, STEVEN J. RETTIG, and ALAN STORR. Can. J. Chem. **64**, 566 (1986).

The reaction of the $[Rh(CO)_2Cl]_2$ dimer with the $Na^+[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]^-$ ligand has yielded the planar four-coordinate species $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$, (LRh(CO)), displaying the tridentate gallate ligand in a meridional coordination mode. In addition, a second product, of similar geometry but with one of the Me groups on the Ga replaced by a Cl atom, viz, $[(Cl)MeGa(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$, has also been isolated and characterized. The former complex undergoes a facile oxidative addition reaction with MeI, the transient six-coordinate Rh(III) species produced being rapidly converted, in a methyl migration step, to the five-coordinate Rh(III) acetyl complex, LRh(COMe)I. Crystals of $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ are monoclinic, a = 13.139(2), b = 13.324(2), c = 17.352(2) Å, β = 103.251(7)°, Z = 8, space group $I2/a$, and those of $[(Cl)MeGa(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ are triclinic, a = 8.846(2), b = 12.714(3), c = 7.631(2) Å, α = 93.82(1), β = 113.94(1), γ = 107.99(1)°, Z = 2, space group $P\bar{1}$. Both structures were solved by conventional heavy-atom methods and were refined by full-matrix least-squares procedures to final R values of 0.029 and 0.048 for 1890 and 1939 reflections with $I \geq 3\sigma(I)$, respectively. Both molecules display irregular square planar coordination geometry about Rh with Rh—O = 2.038(3) and 2.048(3), Rh—N(pyrazolyl) = 2.022(4) and 2.025(7), Rh—N(pyridyl) = 2.038(3) and 2.020(6), Rh—CO = 1.778(5) and 1.808(9) Å, respectively, for the two compounds. Molecules of $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ form weakly associated, centrosymmetric dimers via an intermolecular Rh···Rh interaction of 3.5445(7) Å.

DAVID A. COOPER, STEVEN J. RETTIG et ALAN STORR. Can. J. Chem. **64**, 566 (1986).

La réaction du dimère $[Rh(CO)_2Cl]_2$ avec le ligand $Na^+[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]^-$ conduit à la formation d'espèces tétracoordonnées planes $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$, (LRh(CO)), dans lesquelles le ligand tridentate gallate est dans un mode de coordination méridional. De plus, on a isolé et caractérisé un deuxième produit, de géométrie semblable, dans lequel un des groupements méthyles du Ga a été remplacé par un atome de Cl. Le premier complexe subit une réaction d'addition oxydative facile sous l'influence du MeI; l'espèce hexacoordonnée du Rh(III) qui se produit d'une façon transitoire se transforme rapidement, par une migration de méthyle, en un complexe pentacoordonné du Rh(III) acétylé, le LRh(COMe)I. Les cristaux du $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ sont monocliniques avec a = 13,139(2), b = 13,324(2), c = 17,352(2) Å, β = 103,251(7)°, Z = 8 et groupe d'espace $I2/a$ alors que ceux du $[(Cl)MeGa(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ sont tricliniques avec a = 8,846(2), b = 12,714(3), c = 7,631(2) Å, α = 93,82(1), β = 113,94(1), γ = 107,99(1)°, Z = 2 et groupe d'espace $P\bar{1}$. On a résolu les deux structures par les méthodes conventionnelles aux atomes lourds et on les affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs finales de R de 0,029 et 0.048 respectivement pour 1890 et 1939 réflexions avec $I \geq 3\sigma(I)$. Les deux molécules présentent des géométries de coordination autour du Rh qui sont du type plan carré irrégulier avec Rh—O = 2,038(3) et 2,048(3), Rh—N(pyrazolyle) = 2,022(4) et 2,025(7), Rh—N(pyridyle) = 2,038(3) et 2,020(6), Rh—(CO) = 1,778(5) et 1,808(9) Å respectivement pour les deux composés. Les molécules de $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ forment des dimères centrosymétriques, faiblement associés par le biais d'une interaction intermoléculaire Rh···Rh de 3,5445(7) Å

[Traduit par le journal]

Introduction

An earlier publication (1) reported the synthesis and complexation of the novel tridentate unsymmetric anionic organogallate ligand **1**. $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]^-$. The ligand, containing both pyrazolyl and pyridyl donor groups, was shown to coordinate in a *facial* mode in a number of octahedral transition metal carbonyl compounds. The present account details the reaction of this ligand with the $[Rh(CO)_2Cl]_2$ dimer. The major product isolated, LRh(CO), has been shown by ir, ^1H nmr, mass spectrometry, and, definitively, by X-ray crystallographic analysis to display the L ligand in a *meridional* coordination mode. The complex undergoes a facile oxidative addition reaction with MeI, followed by a migratory insertion reaction to yield Rh(III) acetyl compound. A second product from the reaction of NaL with $[Rh(CO)_2Cl]_2$, namely, the chloro substituted species $[(Cl)MeGa(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$, has been fully characterized and its X-ray crystal structure determined.

cals) and iodine (Aldrich) were used as supplied. MeI (Fisher) was distilled from P_2O_5 before use. The sodium salt, NaL, was prepared as a standard THF solution as described earlier (1).

Reaction of $[Rh(CO)_2Cl]_2$ with NaL

A two-molar equivalent of the NaL ligand solution was added dropwise to a stirred THF solution of $[Rh(CO)_2Cl]_2$ (0.276 g, 0.70 mmol) maintained at −78°C. The resulting reaction mixture was warmed slowly to room temperature and then refluxed for 18 h, during which time the original yellow solution turned dark reddish-brown. At this point the ir spectrum of the product mixture indicated complete disappearance of the starting rhodium carbonyl dimer and the presence of new carbonyl species giving ν_{CO} bands at 2018 and 1953 cm^{-1}. The solvent was then removed under vacuum and the resulting dark reddish-brown residue extracted with benzene. The benzene solvent was allowed to evaporate slowly from the filtered extracts to yield, first, orange cube-shaped crystals of LRh(CO) (~50% yield) and then, from more concentrated solutions, yellow platelet crystals of the chloro derivative [(Cl)MeGa($N_2C_3H_3$)($OCH_2(C_5H_4N)$)]Rh(CO) (~15%) yield). Analytical, ir, and ^{1}H nmr data for the two complexes are collected in Tables 1 and 2.

Reaction of LRh(CO) with MeI

A 1:1 molar ratio of LRh(CO) (0.056 g, 0.14 mmol) and MeI (0.020 g, 0.14 mmol) was stirred in CH_2Cl_2 at room temperature. The original solution gradually changed color from yellow to orange with the concomitant loss of the ν_{CO} band of LRh(CO) at 1962 cm^{-1} and the appearance of two new carbonyl bands at 1714 and 2042 cm^{-1} in the ir spectrum of the reaction mixture. After 2 h the solvent was allowed to evaporate slowly from the reaction mixture to yield small orange crystals of LRh(COMe)I in ~30% yield (see Tables 1 and 2).

Reaction of LRh(CO) with I_2

Iodine (0.030 g, 0.11 mmol) was stirred at room temperature with an equimolar amount of LRh(CO) (0.043 g, 0.11 mmol) in Ch_2Cl_2. The ν_{CO} band of the starting material (1962 cm^{-1}) gradually disappeared and was replaced by a new carbonyl band at higher frequency (2095 cm^{-1}) in the ir spectrum. A black solid was isolated from the solution at the end of the reaction but no analytically pure sample of the expected diiodide, $LRh(CO)I_2$, could be obtained.

X-ray crystallographic analyses

[Dimethyl(pyrazol-1-yl)(2-pyridylmethoxy)gallato-N^2,O,N^3]carbonylrhodium(I)

A crystal bounded by the 6 faces (followed by the distances in mm between parallel faces): {1 1 0}, 0.134, and {0 0 1}, 0.176, was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 30–35°) measured on a diffractometer with Mo-Kα radiation (λ(Kα$_1$) = 0.70930, (λ(Kα$_2$) = 0.71359 Å). Crystal data at 22°C are:

$C_{12}H_{15}GaN_3O_2Rh$ fw 405.90

Monoclinic, a = 13.139(2), b = 13.324(2), c = 17.352(2) Å, β = 103.251(7)°, V = 2956.6(8) Å^3, ρ_m = 1.82 (flotation in $CHBr_3$–$CHCl_3$), Z = 8, ρ_c = 1.824 Mg m^{-3}. $F(000)$ = 1600, μ(Mo-$K\alpha$) = 29.2 cm^{-1}. Absent reflections: hkl, $h+k+l$ odd, and $h0l$, h (and l) odd, space group $I2/a$ (non-standard setting of $C2/c$, C_{2h}^6, No. 15 with equivalent positions: (0 0 0), (1/2, 1/2, 1/2)±(x, y, z; 1/2-x, y, -z)) from structure analysis.

Intensities were measured with graphite-monochromated Mo-Kα radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 0.84–6.71° min^{-1} over a range of (0.70 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (2,3). Transmission factors ranged from 0.657 to 0.716 for 96 integration points. Of the 3388 independent reflections measured, 1890(55.8%) had intensities greater than or equal to 3σ(I) above background, where $\sigma^2(I) = S + 2B + (0.04(S-B))^2$ with S = scan count and B = normalized background count.

The centrosymmetric space group $I2/a$ was suggested by both the E-statistics and by the Patterson function, from which the coordinates of the Rh and Ga atoms were determined. The remaining non-hydrogen atoms were positioned from a subsequent difference map. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in calculated positions (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, U_H proportional to U_{eq} of the parent atom, methyl hydrogen positions based on observed positions). The scattering factors of ref. 4 were used for non-hydrogen atoms and those of ref. 5 for hydrogen atoms. Anomalous scattering factors from ref. 6 were used for the Rh and Ga atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 172 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.029 and R_w = 0.030 for 1890 reflections with $I \geq 3\sigma(I)$. For all 3388 reflections R = 0.093. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w|F_o| \propto -|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.007 and 0.038σ, respectively. The mean error in an observation of unit weight was 1.143. The final difference map showed no unusual features, the largest peak (0.45 e Å^{-3}) being near the Rh atom. The final positional and thermal parameters appear in Tables 3 and 9[3] respectively. Bond lengths, bond angles, and intra-annular torsion angles appear in Table 4–6, respectively. Calculated hydrogen parameters (Table 8) and complete listings of torsion angles (Table 10) have been deposited.[3] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[3]The structure factor table, Table 9 (anisotropic thermal parameters), and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

1939 had intensities greater than $3\sigma(I)$ above background. The variation in the standard reflections was less than 5%. Data were corrected for absorption, transmission factors ranging from 0.305 to 0.648 for 132 grid points.

The centrosymmetric space group was suggested by the Patterson function, from which the Rh, Ga, and Cl coordinates were determined. The remaining non-hydrogen atoms were positioned from a subsequent difference map and all non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions. Convergence was reached at $R = 0.048$ and $R_w = 0.055$ for 1939 reflection with $I \geq 3\sigma(I)$. For all 3336 reflections $R = 0.101$. Anomalous scattering corrections were also applied for Cl. On the final cycle of refinement the mean and maximum parameter shifts were 0.010 and 0.041 σ and the mean error in an observation of unit weight was 1.960. The final difference map showed maximum fluctuations of -2.8 and $+1.5$ e Å^{-3} near the Rh atom and was essentially featureless away from the heavier atoms.

Physical measurements

Infrared spectra were recorded on a Perkin–Elmer 598 spectrometer. The ^{1}H nmr spectra were obtained on Bruker WP80 and Bruker WH 400 MHz instruments using FT techniques. Mass spectra were recorded on a Kratos AES MS50 mass spectrometer at 120°C and 70 eV. Elemental analyses were performed by Mr. P. Borda of the U. B. C. microanalytical laboratory.

Results and discussion

The unsymmetric tridentate pyrazolylgallate ligand, **1**, has been incorporated in a *facial* coordination mode in numerous octahedral transition metal carbonyl complexes and in a tetrahedral "Ni(NO)" compound (1). The present study was initiated to demonstrate the capability of *meridional* coordination for this ligand system and this has been achieved in the formation of the four-coordinate square planar Rh(I) species, LRh(CO). Thus, the reaction of NaL with $[Rh(CO)_2Cl]_2$ in THF gave orange crystals of the target molecule in moderate yield. Infrared evidence indicates the formation of a transient dicarbonyl species, $LRh(CO)_2$, (ν_{CO} 2020, 2080 cm^{-1}) during the reaction but only the monocarbonyl complex (ν_{CO} 1962 cm^{-1}) could be isolated from solution. The incorporation of the related tridentate ligand systems $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NR_2)]^-$ (where R = H or Me) in similar square planar "Rh(I)CO" complexes has been reported recently (7). These complexes also formed via unstable dicarbonyl species, which again were not isolable from solution. The ν_{CO} stretching frequency of 1962 cm^{-1} for the present complex, LRh(CO), compares favorably with the values reported for the compounds $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NR_2)]Rh(CO)$ (ν_{CO} = 1955 cm^{-1} for R = H and 1957 cm^{-1} for R = Me). The slightly higher value in the present complex may well result from the π-acidity of the pyridyl ring in the L ligand.

The proton nmr of the LRh(CO) complex is shown in Fig. 1 and is clearly in agreement with a square planar complex in solution. Thus both the "$GaMe_2$" and —OCH_2— groupings give rise to singlets in the spectrum, as expected for the tridentate ligand in a *meridional* conformation about the Rh centre. The assignment of the other signals to the various pyrazolyl and pyridyl protons follows from previous studies (1, 7).

The mass spectrum of the LRh(CO) complex displayed a prominent signal due to the monomeric parent ion, P^+, with additional signals due to the $P-Me^+$, $P-CO^+$, and $P-Me-CO^+$ ions also being observed. The most intense signal in the spectrum was assigned to the $[OCH_2(C_5H_4N)]^+$ ion.

The molecular structure of LRh(CO) is shown in Fig. 2 and confirms the expected planarity about the Rh(I) centre with the fourth coordination site occupied by the terminal CO ligand (Rh—C—O = 176.2(5)°). Bond distances involving Rh are: Rh—O = 2.038(5), Rh—N(pyrazolyl) = 2.022(4), Rh—N(pyridyl) = 2.038(3), and Rh—CO = 1.778(5) Å. The coordination group (N_2OC) is significantly non-planar (χ^2 = 215), the atoms lying alternatively above and below the mean plane (O(1), 0.021(4); N(2), −0.027(4); C(1), 0.045(5); and N(3), −0.025(4) Å). The Rh atom is displaced from this mean plane by −0.0451(1) Å, a displacement greater than that of any of its substituents and, interestingly, in the direction of the symmetry-related Rh atom with which it interacts weakly (see below).

The pyrazolyl and pyridine rings are both planar within experimental error (χ^2 = 1.3 and 8.4, maximum deviations 0.005(6), and 0.009(6) Å, respectively). The chelate rings $RhOGaN_2$ and $RhONC_2$ are both significantly non-planar (χ^2 = 2095 and 99) but the deviations from planarity (max 0.069(4) and 0.042(6) Å) are relatively small (see torsion angles in Table 6). In fact, the entire non-hydrogen skeleton (excluding the Ga—Me carbon atoms) is planar to within ±0.325(1) Å.

Interestingly, the structure analysis also reveals the presence of weakly associated centrosymmetric dimer species in the solid state with a Rh···Rh interaction at 3.5445(7) Å (see Fig. 3). A weak metal–metal interaction is supported by the following facts: (a) the Rh—Rh distance is the shortest distance between non-hydrogen atoms of the two molecules forming the dimer; (b) the displacement of the Rh atom from its coordination plane is in the direction of the weak interaction (see above); and (c) the separation of 3.64 Å between the mean molecular planes (including all non-hydrogen atoms except C(2) and C(3)) is

longer than the 3.4–3.5 Å normally associated with a π–π interaction that could occur between overlapping ligands. These dimeric units are well separated from adjacent dimers in the crystal lattice. Similar Rh···Rh interactions have been observed in other square planar Rh(I) carbonyl complexes (8–11), as indicated in Table 7. In the present LRh(CO) system the Rh···Rh interaction is limited to dimer species rather than molecular stacking on a more extended scale as observed in the other Rh(I) complexes in Table 7 for reasons analogous to those presented for similar dimers in the structure of tetraethylammonium [4,4′,5,5′-tetracyano-2,2′-biimidazolato-(2−)]dicarbonyliridium(I) (12) (Ir···Ir = 3.183(1) Å).

The reaction between LRh(CO) and MeI in CH_2Cl_2 is thought to proceed via a six-coordinate Rh(III) oxidative addition product to give the five-coordinate Rh(III) acetyl complex LRh(COMe)I:

Thus the ν_{CO} band of the starting monocarbonyl species at 1962 cm^{-1} was replaced by two bands at 1714 and 2042 cm^{-1} in the metal carbonyl stretching region of the ir spectrum on addition of MeI, the 1714^{-1} band gaining in intensity with time. Attempts to isolate the species responsible for the 2042 cm^{-1} band were unsuccessful, only crystals of the Rh(III) acetyl complex LRh(COMe)I (ν_{CO} = 1714 cm^{-1}) being obtained from the product solution. It is postulated that the 2042 cm^{-1} band is due to the labile six-coordinate Rh(III) *trans*-addition product (this mode of addition being commonly found in oxidative addition reactions of alkyl halides on d^8 Rh(I) and Ir(I) complexes (ref. 13 and references therein)) and that this species readily undergoes a methyl migration to form a terminal acetyl group in the LRh(COMe)I complex. Interestingly, related rhodium complexes containing σ-bonded methyl groups have not been observed during the reaction of MeI with cyclopentadienyl rhodium carbonyls. For example, the reaction of MeI with $(\eta^5\text{-}C_5Me_5)Rh(CO)_2$ proceeds directly to the $(\eta^5\text{-}C_5Me_5)$-Rh(COMe)I complex at 50°C (14).

The ^{1}H nmr of the acetyl complex is shown in Fig. 4 and is consistent with the predicted formulation with a square pyramidal arrangement about the Rh atom. An X-ray structure determination has established this arrangement for the related compound $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Rh(COMe)I$ (7). The position of the —CO*Me* signal is similar to those reported earlier for related rhodium acetyl species (7, 15), and no signal was observed in the region near 9 τ where one might expect Rh—*Me* signals (7, 15–17). In addition, the non-planarity of the complex renders inequivalent the two methyl groups on Ga and the —OCH_2— protons. Thus two singlets are observed for

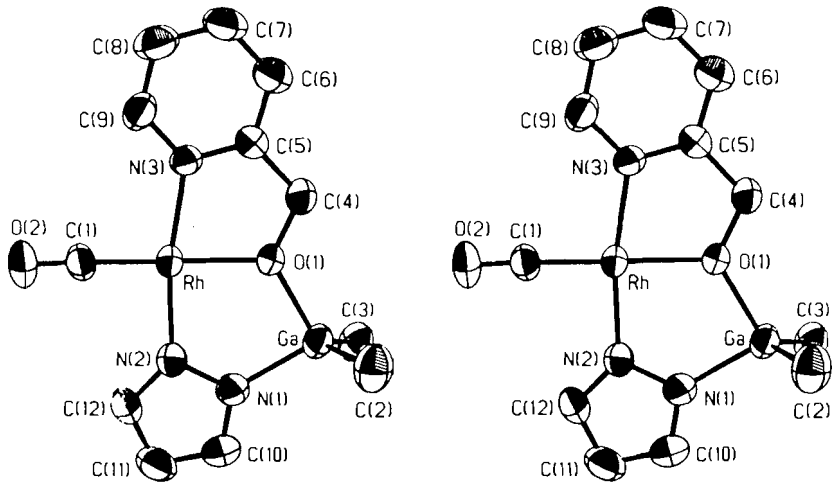

FIG. 2. Stereoscopic view of the [dimethyl(pyrazol-1-yl)(2-pyridylmethoxy)gallato-N^2,O,N^3]carbonylrhodium(I) molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted for the sake of clarity.

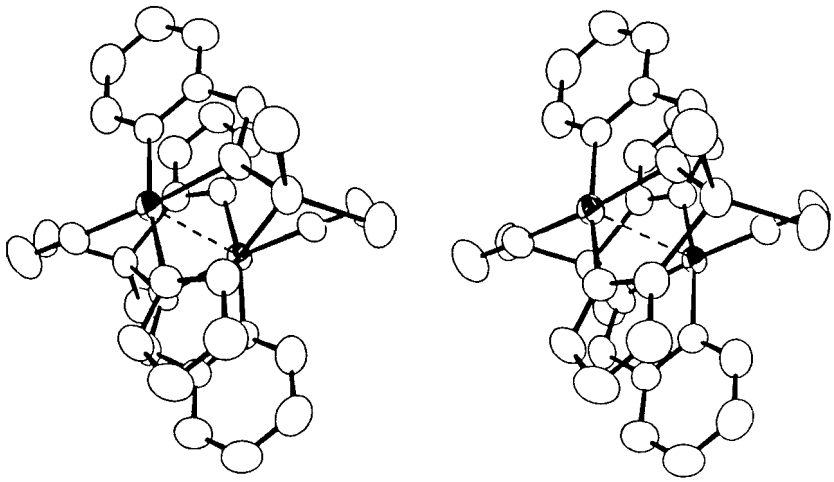

FIG. 3. Stereoscopic view of the [dimethyl(pyrazol-1-yl)(2-pyridylmethoxy)gallato-N^2,O,N^3]carbonylrhodium(I) dimer.

the "$GaMe_2$" moiety and an AB quartet for the methylene protons. A noteworthy feature of the spectrum is the significant downfield chemical shifts of the two signals due to the pyrazolyl and pyridyl protons that are adjacent to the iodine atom in the molecule, compared to their positions in the square planar LRh(CO) species, an effect possibly related to the deshielding influence of the electronegative halogen substituent.

The addition of iodine to a CH_2Cl_2 solution of LRh(CO) resulted in the immediate appearance of a new carbonyl band at 2095 cm^{-1} and the gradual disappearance of the ν_{CO} band attributable to the starting Rh(I) compound. This new band is probably due to the diiodide species $LRh(CO)(I)_2$, although analytically pure samples of this complex could not be obtained from the product solution. Difficulties in obtaining satisfactory elemental analyses for the complexes $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NR_2)]Rh(CO)(X)_2$ (X = I or Br, R = H or Me), with ν_{CO} ~2090 cm^{-1}, and for related pyrazolylborate dihalogen monocarbonyl species have been noted previously (7, 18, 19).

The second product isolated from the reaction of $[Rh(CO)_2Cl]_2$ with NaL, albeit in low yield, was in the form of yellow platelet crystals and analyzed as $[(Cl)MeGa(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$. The origin of the chlorine for methyl substitution on the gallium atom is puzzling since the only source of chlorine atoms is the $[Rh(CO)_2Cl]_2$ starting material, no chlorinated solvents being used in the reaction or work-up procedures. The ir spectrum of this chloro complex shows, in addition to a ν_{CO} band at 1968 cm^{-1} (CH_2Cl_2), a band at 360 cm^{-1} (C_6H_6), assigned to a ν_{GaCl} stretching vibration. This value is comparable to those found for other four-coordinate "GaCl" species (e.g. Me_3NGaH_2Cl, 345 cm^{-1} (C_6H_6) (20), Me_3NGaCl_3, 360 and 390 cm^{-1} (Nujol) (21), and Ph_3PGaCl_3, 352 and 391 cm^{-1} (CH_2Cl_2) (22)).

The predicted structure for the complex, with a square planar geometry about the Rh(I) center and a *meridional* coordination of the tridentate ligand, has been confirmed by X-ray structural analysis (see below) and is consistent with the ^1H nmr shown in Fig. 5. Thus, the —O*CH*$_2$— methylene protons are made inequivalent by the "(Cl)MeGa" moiety and give rise to an AB quartet in the spectrum. The remaining signals are readily assigned to the —Ga*Me*, pyrazolyl, and pyridyl protons, as indicated.

The mass spectrum of the $[(Cl)MeGa(N_2C_3H_3)(OCH_2(C_5H_4N))]Rh(CO)$ complex displayed a strong parent ion signal P^+, in addition to prominent signals due to the $P-CO^+$ and $P-Cl^+$ ions. The most intense signal in the spectrum corresponded to the $(Cl)Ga[OCH_2(C_5H_4N)]^+$ ion.

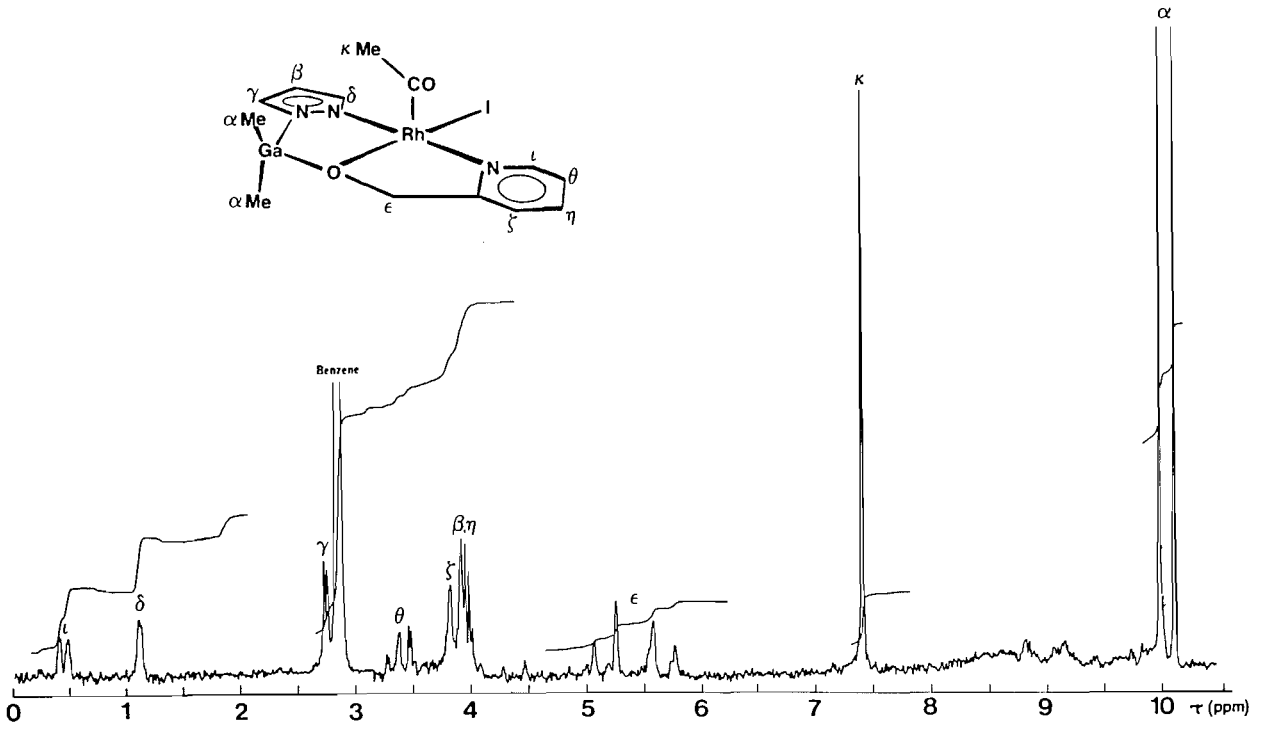

FIG. 4. Room temperature 80-MHz ^{1}H nmr spectrum of LRh(COMe)I in C_6D_6.

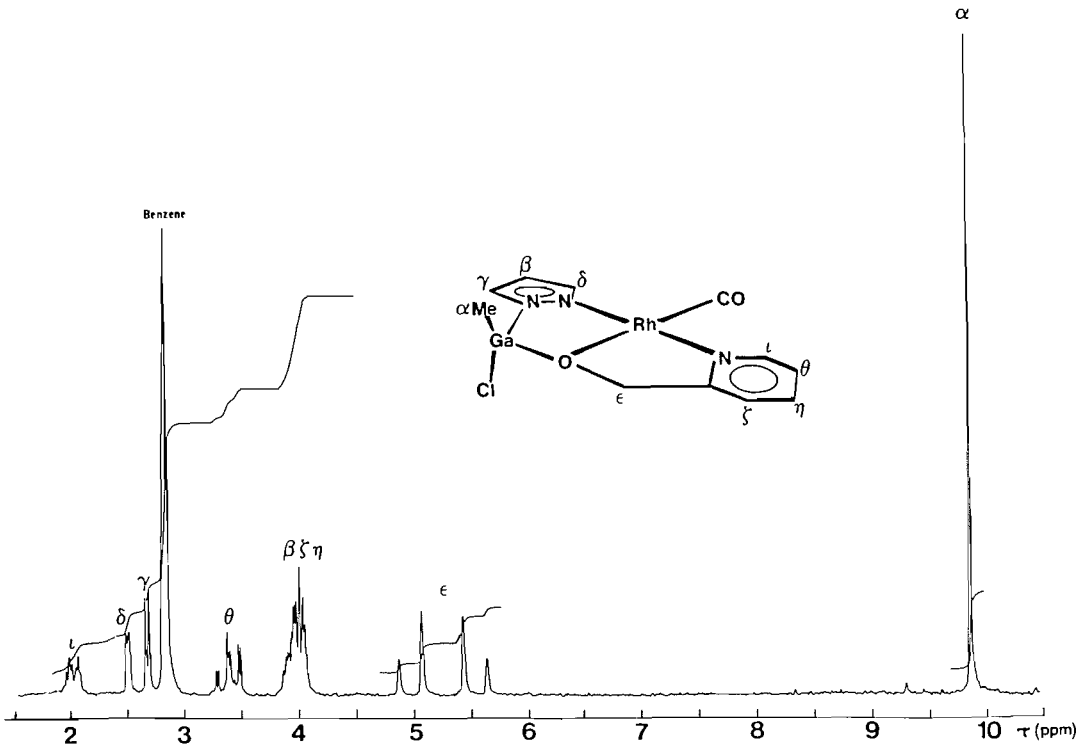

FIG. 5. Room temperature 80-MHz ^{1}H nmr spectrum of [(Cl)MeGa($N_2C_3H_3$)($OCH_2(C_5H_4N)$)]Rh(CO) in C_6D_6.

The molecular structure of the chloro complex, shown in Fig. 6, is very similar to that of the LRh(CO) compound described above. In [(Cl)MeGa($N_2C_3H_3$)($OCH_2(C_5H_4N)$)]Rh(CO) the coordination group (RhN_2OC) is planar within experimental error ($\chi^2 = 7.9$, maximum deviation 0.02(1) Å), in contrast to the situation observed for LRh(CO). The absence of the intermolecular Rh···Rh interaction in [(Cl)MeGa($N_2C_3H_3$)($OCH_2(C_5H_4N)$)]Rh(CO) (see below) is responsible for this difference. The Rh—C—O grouping is essentially linear with a bond angle of 177.1(8)° at carbon. Bond distances involving Rh are: Rh—O = 2.048(5), Rh—N(pyrazolyl) = 2.025(7), Rh—N(pyridyl) = 2.020(6), and Rh—CO = 1.808(9) Å. These values do not differ significantly from those in LRh(CO), but the Ga—O, Ga—N, and Ga—C bonds are all shorter than those in

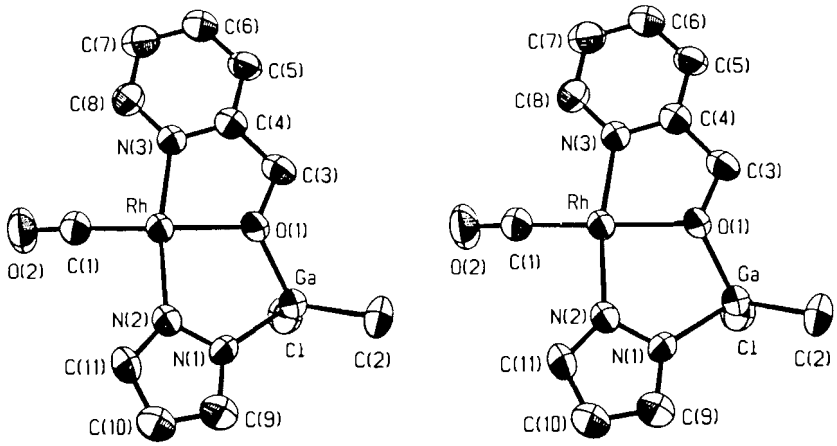

FIG. 6. Stereoscopic view of the [(chloro)methyl(pyrazol-1-yl)(2-pyridylmethoxy)gallato-N^2,O,N^3]carbonylrhodium(I) molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted for the sake of clarity.

LRh(CO) (see Table 4) as a result of orbital contraction at Ga induced by the electronegative Cl substituent. The Ga—Cl distance of 2.194(3) Å is normal.

The pyrazolyl and pyridyl rings are planar within experimental error (χ^2 = 2.4 and 2.0, maximum deviations 0.009(10) and 0.010(10) Å) and the two chelate rings $RhOGaN_2$ and $RhONC_2$ are both significantly non-planar (χ^2 = 3550 and 26), the maximum deviation for the latter (0.042(10) Å) being the same as that found for LRh(CO). The $RhOGaN_2$ ring in [(Cl)MeGa-($N_2C_3H_3$)($OCH_2(C_5H_4N)$)]Rh(CO) deviates more from planarity than does the same ring in LRh(CO) (maximum deviation 0.163(6) Å compared to 0.069(4) Å). This is reflected in the larger magnitude of the intra-annular torsion angles (see Table 6) and represents an out-of-plane movement of the Ga atom that results in the Cl occupying a distinctively pseudoaxial position with respect to the five-membered ring. The entire non-hydrogen skeleton except chlorine is planar to within 0.57(1) Å, the Ga atom being displaced more than the pseudoequatorial methyl carbon atom C(2).

Unlike the dimethyl analog, [(Cl)MeGa($N_2C_3H_3$)(OCH_2-(C_5H_4N))]Rh(CO) does not form Rh···Rh linked dimer species in the solid state. The bulky chloro ligand in its pseudoaxial position effectively blocks any close approach of neighboring molecules from one side of each molecule, making stacking unlikely. The closest approach of Rh atoms from the "open" side of the molecule is 4.220(1) Å. This distance is long as a result of slipping, which may be due to a pair of weak intermolecular C—H···Cl interactions that link molecules into ribbons extending along the body diagonal of the unit cell (C(8)—H(8)···Cl($1-x,1-y,1-z$) and C(9)—H(9)···Cl($-x$, $-y,-z$), H···Cl = 2.84 and 2.84, C···Cl = 3.680(9) and 3.783(11) Å, C—H···Cl = 145 and 164°).

A more rational approach to ligands of the type [(Cl)MeGa-($N_2C_3H_3$)($OCH_2(C_5H_4N)$)]$^-$ is being developed, with the obvious possibility of producing novel tetradentate ligand systems.

The condensation of trimethylsilylium with water and the proton affinity of trimethylsilanol

JOHN A. STONE,[1] ANASTASIA C. M. WOJTYNIAK, AND WILLUM WYTENBURG
Chemistry Department, Queen's University, Kingston, Ont. Canada K7L 3N6
Received August 21, 1985

JOHN A. STONE, ANASTASIA C. M. WOJTYNIAK, and WILLUM WYTENBURG. Can. J. Chem. **64**, 575 (1986).

The proton affinity (PA) of trimethylsilanol has been determined by high pressure mass spectrometry from the enthalpy change for the reaction $Me_3Si^+ + H_2O \rightleftharpoons Me_3SiOH_2^+$. $\Delta H^0 = -30.1 \pm 1.9$ kcal mol^{-1} giving PA (Me_3SiOH) = 183.7 kcal mol^{-1}. This latter value is 10 kcal mol^{-1} less than that of the carbon analogue, *tert*-butanol.

JOHN A. STONE, ANASTASIA C. M. WOJTYNIAK et WILLUM WYTENBURG. Can. J. Chem. **64**, 575 (1986).

Faisant appel à la spectrométrie de masse à haute pression, on a mesuré le changement d'enthalpie pour la réaction $Me_3Si^+ + H_2O \rightleftharpoons Me_3SiOH_2^+$ et l'on en a tiré l'affinité protonique (AP) du triméthylsilanol. Le $\Delta H^0 = -30{,}1 \pm 1{,}9$ kcal mol^{-1} conduit à une AP (Me_3SiOH) = 183,7 kcal mol^{-1}. Cette valeur est 10 kcal mol^{-1} plus faible que celle de l'analogue carboné, le *tert*-butanol.

[Traduit par le journal]

Although the proton affinities of alcohols have been soundly established, those of their silicon analogues are virtually unknown. The one exception to this generalization is a bracketed proton affinity for trimethylsilanol (1). Non-alkyl substituted silanols are chemically unstable, readily forming siloxanes by an intermolecular elimination of water. Substitution of alkyl for H in the silyl group does lead to greater stability of a silanol but such silanols are still somewhat unstable and are not readily available.

A further problem encountered when attempts were made, by the usual mass spectrometric gas phase equilibrium methods, to determine the proton affinities of silicon compounds with silicon attached directly to a heteroatom was the propensity to transfer a silicon-containing group rather than the proton (2). We have indeed found that, in a pulsed electron beam high-pressure ion-source mass spectrometer (HPMS), advantages may be taken of the preference for silyl group transfer to obtain a ladder of Me_3Si^+ affinities for a variety of compounds in the same manner as for proton affinities (3). One of the compounds examined was water and it was found that the following equilibrium could be observed at the high temperatures (up to 600 K) available in our HPMS.

[1] $Me_3Si^+ + H_2O \rightleftharpoons \underset{\mathbf{1}}{Me_3SiOH_2^+}$

The carbon analogue of **1** is prepared by the reaction of the *tert*-butyl cation with water.

[2] $Me_3C^+ + H_2O \rightleftharpoons \underset{\mathbf{2}}{Me_3COH_2^+}$

The standard enthalpy change for reaction [2] was determined from a van't Hoff plot to be -11.2 kcal mol^{-1} (-46.9 kJ mol^{-1}), which, together with the enthalpies of formation of Me_3C^+ and H_2O, yielded an enthalpy of formation of **2** that was essentially the same as that derived using the measured proton affinity of *tert*-butanol (4). It was therefore concluded that **2** is protonated *tert*-butanol. By analogy we propose that **1** be identified as protonated trimethylsilanol.

Me_3Si^+ is readily formed in a high-pressure ion source using either tetramethylsilane alone (5, 6), or by proton transfer from the reagent ions in methane (CH_5^+, $C_2H_5^+$) to tetramethylsilane

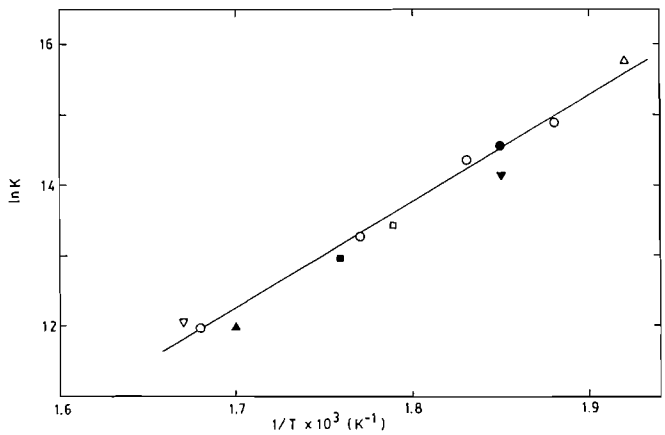

FIG 1. The van't Hoff plot for the reaction $Me_3Si^+ + H_2O \rightleftharpoons Me_3SiOH_2^+$. The ion source mixtures contained 99.5% CH_4, 0.5% Me_4Si, and 0.05 – 0.5% H_2O at total pressures between 400 and 600 Pa. Each different symbol represents a different sample. The standard state is 101 kPa and a least-squares analysis yields $\Delta H^0 = -30.1 \pm 1.9$ kcal mol^{-1} and $\Delta S^0 = -27.0 \pm 3.2$ cal K^{-1} mol^{-1} (the error limits represent one standard deviation).

(3, 7). The latter method yields only Me_3Si^+, while the former yields a more complicated spectrum due to the reactions of fragment ions with $SiMe_4$. In the presence of added water, equilibrium [1] is set up at 270–530 Pa and the equilibrium constant $i_{Me_3SiOH_2^+}/i_{Me_3Si^+}[H_2O]$ can be calculated, where i is a measured equilibrium ion current.

The standard enthalpy change obtained from the van't Hoff plot in Fig. 1 is -30.1 ± 1.9 kcal mol^{-1} while ΔS^0 is -27 ± 3.2 cal K^{-1} mol^{-1}. On the assumption that **1** is indeed protonated Me_3SiOH and taking $\Delta H_f^0(Me_3Si^+) = 150.5$ kcal mol^{-1}(8), $\Delta H_f^0(H_2O) = -57.8$ kcal mol^{-1}, and $\Delta H_f^0(Me_3SiOH) = -119.4$ kcal mol^{-1}(9), then the proton affinity of Me_3SiOH is 183.7 kcal mol^{-1}.

This value is far less than the range of 196 – 204 kcal mol^{-1} obtained by the bracketing technique with ion cyclotron resonance (icr) instrumentation (1).[2] The lower limit was

[1]Author to whom correspondence may be addressed.

[2]All values of proton affinities from the literature have been adjusted to be consistent with the value of 204 kcal mol^{-1} suggested for NH_3 in the compilation of ref. 10.

obtained using double resonance by observation of the reaction

[3] $Me_3SiOH_2^+ + Me_2C{=}CH_2 \rightleftharpoons Me_3SiOH + Me_2{}^+C{-}CH_3$

Irradiation of $Me_3SiOH_2^+$ led to a decrease in the product ion signal but there was no change in $Me_3SiOH_2^+$ when $Me_2C^+{-}CH_3$ was irradiated. We believe that this lower limit must be too high since the proton affinity of Me_3SiOH would then be higher than that of its carbon analogue Me_3COH, with a value of 193.7 kcal mol^{-1}(10). As discussed below, a compound with silicon bonded to the heteroatom being protonated appears to always have a proton affinity no greater than that of its carbon analogue. It is possible that the forward reaction, which could be perturbed, was a Me_3Si^+ transfer or the formation of a complex, although the latter is unlikely at the low pressures prevalent in icr studies. We do not have data on the Me_3Si^+ affinities of olefins.

The only equilibrium determination of the proton affinity of a compound in which silicon is bonded directly to the heteroatom that receives the proton involved (*t*-Bu)Me_2SiNMe_2 (2). This compound was found to have a proton affinity 5.2 kcal mol^{-1} less than its carbon analogue. Theoretical calculations carried out on silylamines lend credence to this difference. For example, the calculated proton affinities of MH_3NH_2, $(MH_3)_2NH$, and $(MH_3)_3N$ are higher for M = C than for M = Si by 8.9, 18.7, and 28.4 kcal mol^{-1}, respectively (11). The higher proton affinity of CH_3NH_2 relative to SiH_3NH_2 has been confirmed in another calculation, which yielded a difference of 6.9 kcal mol^{-1} (12). In addition, Me_2O is calculated also to have a proton affinity greater than that of its silicon analogue, $(SiH_3)_2O$, the difference being 11.8 kcal mol^{-1}(11). It is calculated that CH_3OH and SiH_3OH have identical proton affinities (12). The proton affinity of SiH_3OH has not been measured, but that of CH_3OH is 181.9 kcal mol^{-1} (10). While methyl substitution on silicon is calculated to stabilize silyl ions, it does so to a much smaller extent than does substitution on carbon in the analogous carbon compounds (13). If we accept equal proton affinities for SiH_3OH and CH_3OH, then substitution of Me for H on Si and C leads to a stabilization of the protonated species for silanol of only 2 kcal mol^{-1} compared with 12 kcal mol^{-1} for its carbon analogue.

It would be of value to confirm the validity of this proton affinity determination for Me_3SiOH by other equilibrium measurements, similar to that for reaction [1]. The next least strongly bound adduct containing the silicon oxygen bond is $Me_3SiOMeH^+$, obtained by the addition of MeOH to Me_3Si^+. Measurements of basicity differences by equilibrium measurements in our laboratory suggest that the binding energy for this complex is about 9 kcal mol^{-1} greater than that of the water complex. It is therefore too strongly bound for study at the temperatures available in our HPMS.

The very low enthalpy of dissociation of $Me_3COH_2^+$ to Me_3C^+ and H_2O (11.2 kcal mol^{-1}) reflects the great stability of Me_3C^+, solvation by a single H_2O molecule being unable to stabilize it further to any significant extent (4). Since an α-methyl group is far less effective in stabilizing a positive charge at silicon than at carbon (13), further substantial stabilization of Me_3Si^+ is therefore possible upon addition of H_2O to the positive Si centre, hence the much stronger bonding between Si and O in $Me_3SiOH_2^+$.

Experimental

The pulsed electron beam, high-pressure ion-source mass spectrometer and the method of determining gas phase equilibria have been described previously (14). Methane was Matheson Grade (99.99%) and tetamethylsilane, which was dried by standing over 13× molecular sieve, was from Merck Sharpe and Dohme, Canada Ltd.

Schmidt reaction of phthalic acid in 90–98% sulfuric acid gives anthranilic acid and anthranilazide (major products) by a process considered to involve 3,1-benzoxazin-2,4(1*H*)-dione as intermediate. Benzimidazol-2-one is produced in this reaction by a secondary process from anthranilazide; it is also produced by photolysis of anthranilazide. Under Schmidt reaction conditions, 1,2,3-benzotriazin-4(3*H*)-one gives *o*-azidobenzamide. Under similar conditions, the lactol of 4-formyl-5-phenanthroic acid gives 1-azapyren-2(1*H*)-one and phenanthrene-4,5-dicarboximide, while phenanthrene-4,5-dicarboxylic acid gives 1-azapyren-2(1*H*)-one. Diphenic acid yields phenanthridone and 2,2′-diaminobiphenyl in proportions dependent on the sulfuric acid concentration.

E. H. RUEDIGER, S. S. GANDHI, M. S. GIBSON, D. FĂRCAŞIU et C. UNCUŢA. Can. J. Chem. **64**, 577 (1986).

La réaction de Schmidt sur l'acide phtalique, dans l'acide sulfurique à 90–98%, conduit à l'acide anthranilique et à l'azoture de l'acide anthranilique (produits principaux) par un processus pour lequel on considère qu'il y a implication d'une 1*H*-benzoxazine-3,1 dione-2,4 comme intermédiaire. Au cours de cette réaction, l'azoture de l'acide anthranilique conduit à la formation de la benzimidazolone-2 par un processus secondaire; il s'en produit aussi par photolyse de l'azoture de l'acide anthranilique. Dans les conditions de la réaction de Schmidt, la 3*H*-benzotriazine-1,2,3 one-4 conduit au *o*-azidobenzamide. Dans des conditions semblables, le lactol de l'acide formyl-4 phénanthroïque-5 conduit à la 1*H*-aza-1 pyrènone-2 et au phénanthrènedicarboximide-4,5 alors que l'acide phénanthrènedicarboxylique-4,5 conduit à la 1*H*-aza-1 pyrènone-2. L'acide diphénique conduit à la phénanthridone et au diamino-2,2′ biphényle dans des proportions qui varient avec la concentration en acide sulfurique.

[Traduit par le journal]

The reactions of phthalic acid and of phthalic anhydride with sodium azide under acidic conditions have been variously reported as giving the following products: anthranilic acid and traces of *o*-phenylenediamine from phthalic acid in concentrated sulfuric acid (1); anthranilic acid, benzimidazol-2-one (**1**), and some 3,1-benzoxazin-2,4(1*H*)-dione (isatoic anhydride) (**2**) from phthalic anhydride in sulfuric acid (2); benzimidazol-2-one from phthalic anhydride in acetic acid (3); anthranilazide (**3**) and benzimidazol-2-one from phthalic acid and sodium azide in 90% sulfuric acid (1:6:15 molar ratio) (4). We now report details of our findings pertinent to these reactions together with details of experiments on several related topics.

In our experiments, phthalic acid in 1,2-dichloroethane (DCE) was treated with sodium azide in 90–98% sulfuric acid at 40–45°C. Under these conditions, the isolated products were anthranilic acid, anthranilazide, benzimidazol-2-one, and a small amount of *o*-phenylenediamine. The relative proportions of anthranilazide and benzimidazol-2-one were dependent both on reaction and isolation conditions, and separate experiments confirmed (5) that the former compound (by thermolysis) was the precursor of the later. In the cases previously noted (2, 3), benzimidazol-2-one presumably arose in the same way and we have since confirmed that anthranilazide is produced early in the reaction of phthalic anhydride with sodium azide in acetic acid (3).

This isolation of an acyl azide under Schmidt conditions is very unusual and the possibility that anthranilic acid, reported to be unreactive (1), might be the source of anthranilazide had to be considered. We found that anthranilic acid, when subjected to the same conditions, was consistently recoverable in 88–91% yields; anthranilazide was not detectable in the recovered samples. We conclude that anthranilic acid and its azide are formed from a common intermediate, most probably isatoic anhydride or its conjugate acid, by competing processes of hydrolysis and azidolysis in 90–98% sulfuric acid. Consistent with this view, we have observed that product compositions of anthranilic acid and anthranilazide from Schmidt reaction of isatoic anhydride and of phthalic acid are comparable under comparable conditions. Interestingly, the recently reported azidolysis of 2-amino-3,1-benzoxazin-4-one (**4**) follows a similar course, except that decarboxylation is blocked (6).

In a parallel experiment, we noted that 1,2,3-benzotriazin-4(3*H*)-one (**5**), unlike isatoic anhydride, did not function as an anthraniloylating agent under Schmidt conditions; instead, *o*-azidobenzamide was produced, an unusual example of formation of an azido compound from a triazinone under acidic conditions. We attribute this to acid-catalysed ring opening of the triazinone and reaction with hydrogen azide.[3]

Anthranilazide, now conveniently available by controlled Schmidt reaction of phthalic acid, was of interest in another connection, namely its photolysis. This might lead to a nitrene which could be trapped internally, by nitrene insertion into an

N—H bond, as indazol-3-one (**6**), or externally, using dimethyl sulfoxide, as *N*-(*o*-aminobenzoyl)-*S,S*-dimethylsulfoximine (7, 8); alternately, Curtius rearrangement could occur. Photolysis gave benzimidazol-2-one, showing that Curtius rearrangement was the dominant reaction.

Returning to our main concern, we gave consideration to the Schmidt reaction of 4-formyl-5-phenanthroic acid (lactol formulation (9)), previously reported by Medenwald (10) to give 1-azapyren-2(1*H*)-one (**7**). Formation of this product involves reaction at the latent aldehyde site, aryl migration (with electron pair), and deformylation. In this case, however, competitive hydrogen migration (with electron pair) is also possible. Reexamination of this Schmidt reaction confirmed the formation of **7**, but revealed that another major product was also produced. This was identified as phenanthrene-4,5-dicarboximide (**8**), the result (ultimately) of a competitive hydrogen migration.

Schmidt reaction of phenanthrene-4,5-dicarboxylic acid, prepared by oxidation of 4-formyl-5-phenanthroic acid (lactol), gave **7** as the major product. Unlike the case of phthalic acid, however, the Schmidt reactions of these phenanthrene derivatives were complex and it was not possible to characterize any minor products.

Finally, Schmidt reaction of biphenyl-2,2′-dicarboxylic acid (diphenic acid) has been reported to give mainly phenanthridone, with minor amounts of 2,2′-diaminobiphenyl (11), and we have confirmed this using 90% sulfuric acid. The formation of phenanthridone in this case parallels that of **7** from phenanthrene-4,5-dicarboxylic acid. However, the biphenyl system is less rigid than the phenanthrene system. Further examination of the diphenic acid case revealed that the product distribution was sensitive to the concentration of sulfuric acid employed; 2,2′-diaminobiphenyl was the major product, phenanthridone the minor, when 95–98% sulfuric acid was employed. Presumably both carboxyl groups in diphenic acid are significantly protonated in 95–98% sulfuric acid, repulsion then creating sufficient distancing between the charged groups for each to undergo Schmidt reaction independently. Product distributions in Schmidt reactions of other dicarboxylic acids are probably also susceptible to changes in sulfuric acid concentration in cases where molecular rotation or flexion are significant factors.

Experimental

Mass spectra were determined with an AEI MS-30 double beam spectrometer; *m/e* values are quoted for the lowest isotopic species. The ir spectra were recorded on Karl Zeiss Jena UR 10 and Perkin Elmer 237-B double beam spectrophotometers.

Thin-layer chromatography (tlc) was performed on silica gel 1B2-F plates (Baker); ligroin refers to the fraction bp 60–90′C.

Reference samples were prepared by previously published routes (4) or were purified commercial samples. After early experiments with phthalic acid in which products were separated by crystallization, product compositions were estimated by comparison with prepared mixtures of the possible products; the experiments described below were optimized for the isolation of anthranilazide and are representative of a number of runs.

Reaction of phthalic acid with sodium azide – sulfuric acid

During 40–50 min, NaN_3 (23 g, 0.35 mol) was added to a stirred mixture of phthalic acid (10 g, 0.06 mol), 1,2-dichloroethane (DCE) (50 mL), and 95–98% H_2SO_4(50 mL), the reaction temperature being maintained at 35–45°C. After being stirred at this temperature for a further 1.5 h, the mixture was chilled, diluted with water, and the pH was adjusted carefully (to avoid overheating) to 4–5 by addition of NaOH. The resulting mixture was extracted with ether (6 × 100 mL), and the extract was dried (Na_2SO_4) and evaporated carefully *in vacuo* (to avoid thermolysis of anthranilazide). This gave a brown solid (7.4 g), mp 68–70°C, shown by tlc (ligroin–ether) to contain anthranilic acid and anthranilazide (major products; ir and mass spectra), together with traces of other minor products; mass spectrum *m/e*: 137 (M^+, anthranilic acid) and 162 (M^+, anthranilazide).

Chromatography on Brockman alumina (activity class I) (ligroin–ether) gave, after careful evaporation of solvent, anthranilazide (3.5 g, 37%), mp 82°C (lit. (4) mp 83°C), identical (mixture mp, tlc, ir and mass spectra) with a reference sample. Later eluates (ether–acetone) gave trace amounts of *o*-phenylenediamine, identified by comparison (tlc; mass spectrum *m/e*; 108) with a reference sample. The column retained anthranilic acid.

A similar experiment using 90% H_2SO_4 gave 7.3 g of crude reaction products, mp 70–76°C, which yielded 3.4 g (35%) of anthranilazide after chromatography, followed by traces of *o*-phenylenediamine. Material insoluble in ether (prior to chromatography) was collected (730 mg, mp 250–255°C) and identified as impure benzimidazol-2-one (tlc; ir and mass spectra; mass spectrum, *m/e*; 134). From other experiments without temperature control or from those in which the crude products were allowed to remain for extended periods at room temperature prior to chromatography, benzimidazol-2-one, mp 305°C (lit. (4) mp 308°C) was isolated in larger quantities at the expense of anthranilazide.

Reaction of isatoic anhydride with sodium azide – sulfuric acid

Reaction of isatoic anhydride (4.9 g, 0.03 mol) with NaN_3 (7.6 g, 0.117 mol) in a mixture of 90% H_2SO_4 (27.1 mL), water (0.7 mL), and DCE (28 mL) was carried out as in the foregoing experiment (the amounts of NaN_3 and H_2O were adjusted to compensate for material used or produced in converting phthalic acid to isatoic anhydride in the former experiment). The crude product (4.2 g) possessed an ir spectrum virtually identical with that from the previous experiment; anthranilazide (1.35 g, 28%), recovered chromatographically, had mp 82°C.

Reaction of phthalic anhydride with sodium azide – acetic acid (ref. 3)

Phthalic anhydride (4.4 g, 0.03 mol) in glacial CH_3CO_2H (50 mL) was treated with NaN_3 (7.8 g, 0.12 mol) at 50°C as described previously, except that the reaction was quenched after 3 h. This gave a product consisting largely of phthalic anhydride, but clearly containing anthranilazide (ir spectrum). Chromatography, as above, gave 0.6 g (12%) of anthranilazide.

Reaction of 1,2,3-benzotriazin-4(3H)-one with sodium azide – sulfuric acid[4]

During 40 min, NaN_3 (6.8 g, 0.105 mol) was added to a stirred mixture of the triazinone (1.47 g, 0.01 mol), DCE (16.5 mL), and 90% H_2SO_4 (16.5 mL), the reaction temperature being kept at 40–50°C. After completion of the reaction as described above for phthalic acid, the pH was adjusted (NaOH) to 8–9 and the product (0.9 g) was isolated by extraction with ether. Crystallization from water gave *o*-azidobenzamide (0.8 g, 49%) as needles, mp 132–133°C (lit. 12) mp 135.5–136°C). *Anal.* calcd. for $C_7H_6N_4O$: C 51.85, H 3.70, N 34.57; found: C 52.33, H 3.73, N 34.66.

Photolysis of anthranilazide

A fused silica photolysis cell containing a solution of anthranilazide (0.2 g, 1.2 mmol) in acetone (5 mL) and cyclohexane (25 mL) was irradiated using a Hanovia Utility UV quartz lamp at 15-cm distance. The temperature of the reaction mixture remained below 30°C. The reaction was monitored by ir spectroscopy for the disappearance of starting material (azide band at ν_{max} 2135 cm^{-1}) and was complete within 60–90 min. Evaporation of the solvents gave a nearly quantitative yield of benzimidazol-2-one (0.11 g, 68% after purification), identical with a reference sample (tlc, ir and mass spectra).

A similar reaction in which dimethyl sulfoxide replaced cyclohexane gave, after purification, 0.09 g (56%) of benzimidazol-2-one. The mass spectrum of the crude product showed a minor peak at *m/e* 212, possibly due to traces of the sought sulfoximine, but this compound was not otherwise detectable.

Reaction of 4-formyl-5-phenanthroic acid (lactol) with sodium azide – sulfuric acid

A suspension of the lactol (13) (3.0 g, 12 mmol) in DCE (30 mL) and 95–98% H_2SO_4 (9 mL) was treated with NaN_3 (2.52 g, 39 mmol) in the manner described above for phthalic acid, but the reaction time was extended by 30 min. Ether extraction gave an ether-soluble yellow solid (780 mg) and an ether-insoluble brown solid (1.85 g). Thin-layer chromatography showed that the former fraction contained two major components, well resolved, together with several poorly resolved minor components; mass spectral evidence indicated that the predominant major component was probably **8**, the other **7**. Thin-layer chromatography of the ether-insoluble material revealed that it contained the same range of materials as the ether-soluble fraction, plus others (at least nine were discernible); there were two major components, **7** and, to a significantly lesser extent, **8** (mass spectrum).

Accordingly, a sample (500 mg) of the ether-soluble material was chromatographed on silica. Elution with benzene–ether (9:1) gave phenanthrene-4,5-dicarboximide **8** as a yellow solid (280 mg, pure by tlc), mp 237–238°C (from acetic acid) (lit. (10) mp 240°C) ir (KBr): 1672 and 1645 (C=O) cm^{-1}; mass spectrum, *m/e*; 247 (M^+, 100), 219 (54), 205 (29), 190 (11), and 176 (25).

Further elution with benzene–ether (3:1) gave 1-azapyren-2(1*H*)-one **7** as a yellow solid (45 mg, pure by tlc), mp 345°C after sublimation *in vacuo* (lit. (11) mp > 340°C); ir (KBr): 1664 (C=O) cm^{-1}; mass spectrum, *m/e*: 219 (M^+, 100), 190 (14), and 163 (6).

Further elution with ether, followed by acetone, gave a small amount of brown solid containing at least two compounds (tlc).

Medenwald's corresponding experiment (10) was repeated, but our procedure for work-up was followed. The ether-soluble and ether-insoluble fractions exhibited virtually the same tlc characteristics as those obtained in the foregoing experiment.

Reaction of phenanthrene-4,5-dicarboxylic acid with sodium azide – sulfuric acid

A suspension of the diacid (3.5 g, 13 mmol) in DCE (33 mL) and 95–98% H_2SO_4 (11 mL) was treated with NaN_3 (5.14 g, 78 mmol) in the manner described for the preceding lactol. An analogous procedure for isolation gave an ether-soluble material (0.94 g), mp 217–223°C, and an ether-insoluble residue (1.95 g), mp 267–272°C. Each solid was yellow-brown in colour, exhibited several spots on tlc, and contained the same major component, namely **7**. 1-Azapyren-2(1*H*)-one **7** was recovered from each fraction by sublimation *in vacuo*, 0.75 g from the former fraction and 1.17 g from the latter for a total recovery of 1.92 g (67%), mp 318–320°C. This sample was slightly impure (see preceding experiment), but its identity was satisfactorily established by ir and mass spectral correlations.

In the ether-soluble fraction there was evidence (tlc and mass spectrum) for the presence of **8** (mass spectrum, *m/e* 247), attributable to traces of lactol in the dicarboxylic acid, and other minor products.

Reaction of diphenic acid with sodium azide – sulfuric acid

Diphenic acid (5.0 g, 21 mmol) in DCE (23 mL) and 95–98% H_2SO_4 (17 mL) was treated with NaN_3 (8.0 g, 130 mmol) in the manner described above for phthalic acid, the reaction time being extended by 30 min. The extraction procedure gave a reddish-brown solid (2.8 g), together with some undissolved sediment. The reddish-brown solid was triturated with ether and the resulting ether-soluble material was chromatographed on alumina to yield 2,2′-diaminobiphenyl as beige crystals (1.65 g, 43%), mp 74–76°C (reference sample, mp 81°C); identity was confirmed by ir and mass spectral correlations.

The sediment from the original extraction was collected, washed, and dried to give a brown powder (0.3 g), mp 290–293°C. This was sublimed *in vacuo* to yield phenanthridone (0.24 g, 6%) as white needles, mp 293°C (reference sample, mp 293°C); identity was established by ir and mass spectral correlations. A further quantity of slightly impure phenanthridone (0.2 g), mp 287–290°C, was recovered as insoluble material from the intermediate ether trituration.

From a similar scale experiment conducted using 90% H_2SO_4, the quantities obtained of 2,2′-diaminobiphenyl and of phenanthridone were 0.18 g (5%) and 2.28 g (56%), respectively.

The structure of the title compound (**1**), isolated from *Hortia regia*, was established by nuclear magnetic resonance spectroscopy. The investigation demonstrates the value of indirect shift correlation experiments. The compound was further characterized by chemical and spectroscopic methods.

HELEN JACOBS, FRANK RAMDAYAL, WILLIAM F. REYNOLDS, JANUSZ POPLAWSKI et STEWART MCLEAN. Can. J. Chem. **64**, 580 (1986).

Faisant appel à la rmn, on a déterminé la structure du composé **1** qui est mentionné dans le titre. Cette étude a permis de démontrer la valeur des expériences de corrélations indirectes des déplacements. On a de plus caractérisé le composé en se basant sur des méthodes chimiques et spectroscopiques.

[Traduit par le journal]

As part of a collaborative investigation of the natural products of Guyana, samples of materials isolated in Guyana are sent to the Toronto laboratories for spectroscopic examination. It can be anticipated that many of these natural compounds will be of established structure and will simply require identification. Since we wished to test the potential of our nmr spectroscopic techniques to solve structural problems, the Toronto group has deliberately applied these techniques to some of the samples before any information regarding the type of compound expected, its formula, or any other spectroscopic data was made known to them.

The title compound was received as an oil, and ^1H, ^{13}C and DEPT-edited[2] (1) ^{13}C nmr spectra were used to arrive at a tentative assignment of its structure. The ^1H spectrum (Fig. 1) provided evidence for the presence of two equivalent C—Me groups (*gem*-dimethyl), two OMe groups, an apparent A_2B_2 spectrum in the aliphatic region, and two AX spectra, one (δ 5.66, 6.54) with J_{HH} = 9.9 Hz and the other (δ 6.50, 6.89) with J_{HH} = 8.4 Hz. The 9.9-Hz coupling suggested the presence of a *cis* disubstituted olefinic grouping and the 8.4-Hz coupling was attributed to *ortho*-related aromatic protons. Key features in the ^{13}C spectrum included a peak at δ 173.6 suggestive of an ester functionality, signals for two non-protonated aromatic carbons (δ 152.5, 154.3) with chemical shifts that indicated that they carried an OR substituent, and a relatively deshielded quaternary aliphatic carbon (δ 75.6). Complete data are summarized in Table 1.

Based on these data, **1** was deduced as the most probable

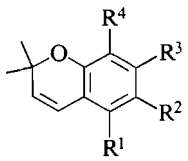
structure. However, we were reluctant to rely so heavily on ^1H (ref. 2) and ^{13}C (ref. 3) chemical shift arguments for structural assignments, particularly since there were obvious discrepancies between earlier ^{13}C assignments for 2,2-dimethyl-1-2*H*-benzopyran (4) and some of its ring-substituted derivatives (5). Consequently, we believed that further verification was necessary, particularly with respect to the ring substitution pattern.

Examination of the literature revealed that structure **1** had previously been assigned (6) to one constituent of an inseparable mixture isolated from *Hortia badinii*. The assignment was made on the basis of the ^1H spectrum of the mixture, from which the peaks associated with other components were subtracted. This procedure provided a set of data very similar to ours, although some small differences (up to 0.08 ppm) in chemical shift are apparent. The reservations we held concerning the rigor of our structural assignment apply also to the earlier assignment.

Confirmation of the structure by two-dimensional nuclear magnetic resonance spectroscopy

Other substitution patterns of the benzenoid ring that had to be considered are represented by structures **2 – 6**. (We note that



2 $R^1 = CH_2CH_2CO_2CH_3$, $R^2 = OCH_3$, $R^3 = R^4 = H$
3 $R^1 = R^2 = H$, $R^3 = CH_2CH_2CO_2CH_3$, $R^4 = OCH_3$
4 $R^1 = R^2 = H$, $R^3 = OCH_3$, $R^4 = CH_2CH_2CO_2CH_3$
5 $R^1 = CH_2CH_2CO_2CH_3$, $R^2 = R^3 = H$, $R^4 = OCH_3$
6 $R^1 = OCH_3$, $R^2 = R^3 = H$, $R^4 = CH_2CH_2CO_2CH_3$

some could, however, be considered improbable on the basis of chemical shifts observed.)

A standard direct ^1H–^{13}C shift-correlated experiment (7) was carried out first. This gives peaks for each directly bonded C—H pair at δ_H in F_1 and δ_C in F_2 (see Fig. 2), thus establishing direct ^1H–^{13}C connectivities. The experiment involves polarization transfer from ^1H to ^{13}C and requires a delay of $(2J_{CH})^{-1}$ to set up this polarization transfer. Consequently, it is possible to use the same experimental procedure to establish indirect ^1H–^{13}C connectivities by choosing delay times appropriate for geminal or vicinal ($^2J_{CH}$ or $^3J_{CH}$) couplings rather than one-bond ($^1J_{CH}$) couplings (8, 9). This experiment has already proved very useful for characterizing other natural products (10, 11). It does require some knowledge of $^2J_{CH}$ and $^3J_{CH}$ couplings, but extensive compilations of these are available (12, 13).

In the structures under consideration, values of $^3J_{CH} \sim 9$–10 Hz for *trans* couplings involving olefinic or aromatic protons and carbons are to be expected, while $^2J_{CH} \leq 2$ Hz. Both $^2J_{CH}$ and $^3J_{CH}$ are typically ca. 5 Hz for couplings involving aliphatic carbons. We chose the initial fixed delay prior to polarization transfer $\Delta_1 = 0.05$ s, with the second fixed delay $\Delta_2 = 0.033$ s, both optimized carbons (12). In fact, in addition to the cross peaks already noted for the *ipso* carbon, cross peaks are observed for the carbon peaks at δ 154.3 and δ 129.4 (not shown). This eliminates both **4** and **6** from consideration since both should show a cross peak with δ 152.5 (assigned to the carbon carrying the heterocyclic oxygen). Only structure **1** remains consistent in every respect with the spectroscopic data.

The structure of the compound is rigorously established on the basis of the data cited and the spectrum can be totally assigned with confidence (see Table 1). Although further confirmation appears unnecessary, we note that the experiment provides a number of additional cross peaks, all of which are in accord with the assignments already made. To cite just one example, a strong cross peak is observed between peaks assigned as C-6 and H-8 and confirms their *meta* relationship. All observed cross peaks are summarized in Table 2. In addition to the evidence cited above, the observation of a 0.6-Hz long-range coupling between H-4 and H-8 is also consistent with the proposed structure (14). The observation of this type of

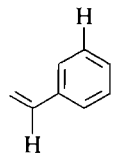
[a]Low intensity peak. The adjacent oxygen functionality apparently increases the magnitude of $^2J_{CH}$ sufficiently (12) that a weak cross peak is observed corresponding to this coupling.

[b]A cross peak is observed corresponding to polarization transfer from the protons of one of the equivalent methyl groups to a ^{13}C atom in the second methyl group ($^3J_{CH}$).

coupling has been claimed to be diagnostic for the presence of the part structure **7** (14);



7

However, it should be noted that styrene derivatives also show ca. 0.5-Hz couplings between α and *ortho* protons (15). Thus the reliability of this diagnostic test for **7** is questionable.

The results presented here illustrate the great utility of the indirect shift-correlated experiment.[3] The main structural features of the compound were deduced from the ^1H and ^{13}C spectra, but it was not possible to use these data to distinguish between a number of isomeric possibilities differing in substitution patterns. The direct shift-correlation experiment was required to identify unequivocally aromatic C—H pairs, but provided little further structural information; it is at this point that the recognition of 2-bond and 3-bond connectivities becomes crucial and the power of the indirect shift-correlation experiment in distinguishing between isomeric possibilities becomes apparent. In the present case the data were compatible with only one of the isomeric possibilities, and allowed structure **1** to be assigned unequivocally. In fact, the combination of direct and indirect shift-correlated spectra has some distinct advantages over the alternative $^{13}C-^{13}C$ connectivity (INADEQUATE) experiment (16). The most obvious is sensitivity (10), since the INADEQUATE experiment appears to be an order of magnitude less sensitive. The second advantage is that, while the INADEQUATE experiment establishes only direct $^{13}C-^{13}C$ connectivities, the indirect shift-correlated experiment can often establish connectivities to several adjacent protons (and carbons) from a single ^{13}C cross section. Consequently, the same connectivity may be established and confirmed in more than one way. Thirdly, as illustrated in Fig. 3, the indirect experiment can establish connectivities even through heteroatoms, e.g. oxygen, something which is not possible with INADEQUATE. In previous applications this experiment has been used to assign the spectra of compounds of established structure (10, 11, 17–19), but the present results clearly demonstrate its potential in the field of structure elucidation of new compounds. It was to test this potential that the present investigation was carried out by the spectroscopic group before any other structural information concerning the compound in hand was available to them.

Although, as it happens, a compound of structure **1** has been described in the literature (6), it had not previously been obtained in a homogeneous form. Consequently, we have treated **1** as a new natural compound, and completed its characterization. These data, all of which are in accord with the assigned structure, are reported in the experimental section.

As a further confirmation of the assignments made, **1** was reduced to a dihydro derivative by catalytic hydrogenation. The ^1H spectrum of dihydro-**1** showed an AA′XX′ spectrum (δ 1.74, 2.73) in place of the AX spectrum (δ 5.66, 6.54) of **1**, while the other signals showed little change. In the ^{13}C spectrum, the δ 117.2 and δ 130.4 signals of **1** were replaced by methylene signals at δ 17.44 and δ 32.20 while the rest of the spectrum showed only small and predictable changes (see Experimental). These results clearly confirm the assignments made to the vinylic and aromatic C—H groupings in **1**.

Experimental

Infrared spectra were recorded on a Nicolet 5DX FTIR spectrometer with samples as liquid films. Ultraviolet spectra were recorded on a Carey 14 spectrometer with samples dissolved in 95% ethanol.

Standard ^1H and ^{13}C spectra were obtained on a Varian XL-400 spectrometer operating at 399.93 MHz for ^1H and 100.57 MHz for ^{13}C, using a sample containing 8 mg of **1** in 0.5 mL of $CDCl_3$ in a 5-mm tube. The ^1H spectral width was 4000 Hz and 32 768 data points were collected and zero-filled to 65 536 points. No weighting was applied during Fourier transformation. The ^{13}C spectrum contained the same number of data points for a 20 000-Hz spectral width and 1-Hz exponential line broadening was applied prior to Fourier transformation.

The 2D spectra were obtained on a Varian XL200 spectrometer operating at 50 MHz for ^{13}C and using 30 mg of **1** in 2 mL of $CDCl_3$. For the direct shift-correlated experiment, the ^{13}C spectral width was 6000 Hz while the ^1H spectral width was 1400 Hz. 1024 data points were collected for each spectrum with 64 transients/spectrum, and 256 time increments were used with zero filling to 1024. Five-hertz line broadening was used for both frequency axes. For the indirect shift-correlated experiment the ^{13}C spectral width was 8000 Hz with 2048 data points. The ^1H spectral width was 1400 Hz and 96 increments were used with 256 transients/spectrum. Weighting parameters were identical to those used in the previous experiment. Delay times are discussed in the text.

Standard Varian software was used to obtain the 2D spectra.

[3]We use the terms direct and indirect to describe the two shift-correlated experiments in the context of the connectivities established, i.e. between directly or indirectly bonded pairs of nuclei. A referee has argued that it would be better to refer to one-bond or long-range shift correlations. However, in nmr spectroscopy, long-range usually refers to couplings over four or more bonds. An alternative acceptable terminology would be ^1J-based or ^nJ-based shift correlation.

Isolation and characterization of **1**

Dried roots of *Hortia regia* Vand.[4] were ground and exhaustively extracted by percolation with cold methanol. The material obtained after the methanol had been removed under reduced pressure was chromatographed on neutral alumina (activity III). The fraction eluted with 20% ethyl acetate in hexanes was rechromatographed on silica gel, and the fraction eluted with 5% ethyl acetate in hexanes was substantially pure **1** as a colorless oil (0.5% from dried plant). Bulb-to-bulb distillation at 7 Pa and a bath temperature of 170°C provided the sample of **1** used for this study. ir: 1738 cm^{-1}; uv: λ_{max} 267 (ε 6 500), 278 (ε 5 500), 313 (ε 1 850); ms: (*m*/*z*(rel. intensity)): 276(16), 262(18), 261(100), 203(10), 187(16). *Exact Mass* calcd. for $C_{16}H_{20}O_4$: 276.3161; found: 276.1360. *Anal.* calcd. for $C_{16}H_{20}O_4$: C 69.54, H 7.30; found: C 69.53, H 7.28.

Compound **1** in ethyl acetate was hydrogenated over 10% palladium on carbon at ambient temperature and pressure, and was obtained as a colorless oil: ir: 1738 cm^{-1}; ^{1}Hmr (400 MHz; $CDCl_3$) (δ (multiplicity, *J*, number of protons)): 6.88 (d, 8.4 Hz, 1H), 6.50 (d, 8.4 Hz, 1H), 3.73 (s, 3H), 3.65 (s, 3H), 2.86 (m, 2H), 2.73 (m, 2H), 2.59 (m, 2H), 1.74 (m, 2H), 1.29 (s, 6H); ^{13}Cmr (100 MHz; $CDCl_3$) (δ (number of connected hydrogens from edited spectrum)): 17.44 (2), 24.90 (2), 26.68 (2 × 3), 32.20 (2), 34.98 (2), 51.44 (3), 60.20 (3), 73.61 (0), 112.95 (1), 114.84 (0), 123.75 (0), 127.71 (1), 153.57 (0), 156.45 (0), 173.66 (0).

Synthesis of (±)-karahana ether and a (±)-labdadienoic acid by the electrophilic cyclization of epoxy allylsilanes

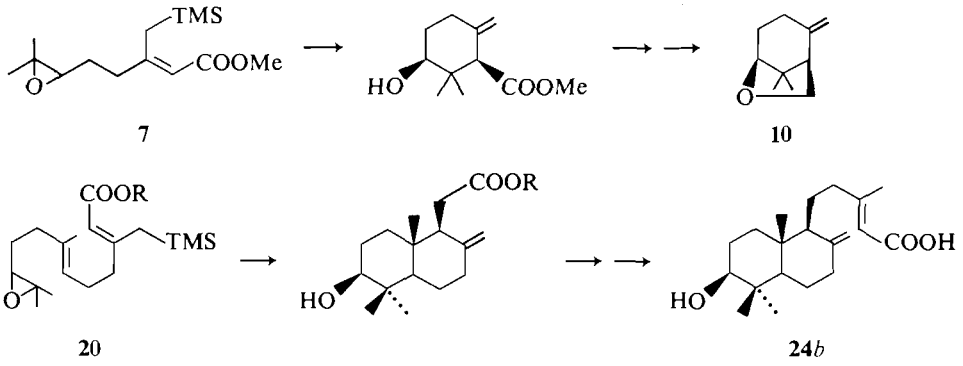
ROSEMARY J. ARMSTRONG AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 22, 1985

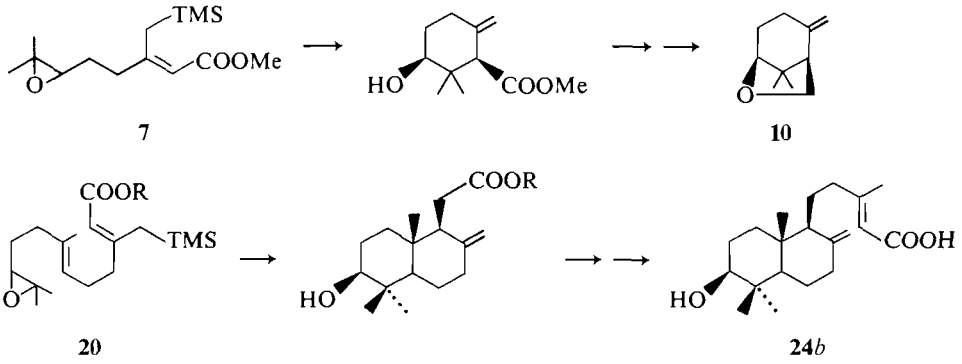
ROSEMARY J. ARMSTRONG and LARRY WEILER. Can. J. Chem. **64**, 584 (1986).

The epoxy allysilanes **7** and **16** were synthesized by stereoselective routes from β-keto esters and cyclized with Lewis acids in good yield. The monocyclic product from **7** was converted into (±)-karahana ether (**10**), and the bicyclic product from **20** was used in a synthesis of the 3-hydroxylabdadienoic acid **24***b*.



ROSEMARY J. ARMSTRONG et LARRY WEILER. Can. J. Chem. **64**, 584 (1986).

Utilisant des voies stéréosélectives appliquées à des β-céto esters, on a synthétisé les époxysilanes **7** et **16** et on les a cyclisés, avec de bons rendements, sous l'influence d'acides de Lewis. Le produit monocyclique obtenu à partir du produit **7** a été transformé en l'éther du (±)-karahana (**10**) alors que l'on a utilisé le produit bicyclique obtenu à partir du composé **20** pour effectuer la synthèse de l'acide hydroxy-3 labdadiènoïque (**24***b*).



[Traduit par le journal]

Introduction

For the past fifty years, organic chemists have often sought biomimetic type routes in their syntheses of natural products (1). These routes, based on the presumed biosynthetic pathway, frequently were very efficient and led to the development of new synthetic reactions. The concept of biomimetic polyolefin cyclizations is based upon the Stork–Eschenmoser hypothesis, which was proposed in 1955 (2). These authors suggested that many cyclic terpenoid natural products arise via a cyclization of the appropriate polyolefin initiated by an electrophile. The conformation of the polyolefin and an *anti*-periplanar addition to the olefin determine the structure and stereochemistry of the final product. There have been a variety of successful natural products syntheses based on this concept (1, 3). In most cases, the cyclization has been initiated by the attack of a Lewis acid or a Bronsted acid on an alkene (3, 4), allylic alcohol (5), or an acetal (6). In the first case the product is not functionalized at the electrophilic terminus, and in the last two cases the functionality at this terminus is either an alkene or an ether—two groups that frequently require substantial manipulation to convert into the desired natural products.

In an effort to introduce other functional groups at the electrophilic terminus of the polyolefin, several research groups have studied the initiation of these cyclizations using other electrophiles, such as mercury(II) (7), brominating agents (8), and sulfinating or selinating reagents (9). This approach to functionalized products from polyolefin cyclizations has not been generally successful. In all but a few examples, the yield of polycarbocyclic products is very low, the exceptions being some recent mercury(II) cyclizations (7*a*, *b*). Following these cyclizations, it is necessary to convert the heteroatom into another functional group, such as an alcohol. In general this cannot be carried out stereoselectively.

[1]Author to whom correspondence may be addressed.

In 1962, Goldsmith showed that a terminal epoxide of a polyolefin could function as the electrophilic initiator in these cyclizations (3*g*, 10). In addition, Goldsmith recognized that, if the cyclization that leads to a six-membered ring proceeded via a transition state with ring A in a chair conformation, the resulting alcohol should be equatorial (eq. [1]). In 1966, Corey *et al.* (11)

[1] 
and van Tamelen *et al.* (12) showed that squalene 2,3-epoxide was enzymatically converted into a tetracyclic product that had an alcohol at C-3 with the α stereochemistry. Following these *in vivo* experiments, van Tamelen's group played a leading role in studying the *in vitro* cyclization of polyolefin epoxides (13). Without exception, these cyclizations had serious limitations as synthetic tools. Frequently, the regioselective synthesis of the terminal polyolefin epoxide was difficult to achieve in high yield. The cyclizations often proceeded in low yield and usually gave a large number of products that were difficult to separate. However, these studies proved that the transition state in these *in vitro* cyclizations did, in fact, proceed through a ring A chair conformation as shown in eq. [1].

Most of the early work on polyolefin cyclizations involved the use of unsubstituted alkenes as terminators. These alkenes had the disadvantage that, once cyclization was complete, the resulting carbonium ion could lose a proton from a number of positions or be trapped by nucleophiles, resulting in a variety of products being formed. Johnson and co-workers found that the styryl terminating group did lead to preferential formation of products resulting from an intermediate benzylic carbonium ion (3*b*). However, one was then faced with the problem of efficiently removing the aromatic ring to obtain useful products.

Subsequently it was found that allenes (3*b*), acetylenes (3*b*, 14), or vinyl halides (15) could function as efficient and useful terminators in these polyolefin cyclizations. Several groups have shown that the enol or enol phosphate of β-keto esters was also a very versatile terminating group in olefin cyclizations (16).

One of the major problems in polyolefin cyclizations, which was briefly alluded to above, is the lack of regioselectivity in quenching the carbonium ion intermediate produced in the cyclization. In 1976, Fleming *et al.* found that an allylsilane had a dramatic effect in controlling the regioselectivity in an olefiin cyclization (17). For example, Johnson and co-workers had found that the acetal **1**, on treatment with acid, gave a mixture of five products (including the three isomeric alkenes) as shown in eq. [2] (18). On the other hand, the acetal **2** cleanly cyclized to

[2] 
(ref. 18)

(ref. 17*b*)

3

the exocyclic alkene **3** (17). Presumably the regioselectivity in the latter reaction is controlled by the remarkable ability of silicon to stabilize a developing carbonium ion β to itself (19). In a subsequent paper Fleming and Pearce noted that the silicon also appeared to activate the terminal alkene in this cyclization (eq. [2]), compared to the unsubstituted case (17*b*).

Chow and Fleming extended these results to show that this type of cyclization could be controlled to regioselectively yield the exocyclic alkene **3** above, or either of the endocyclic alkenes as shown in eq. [3] (17*c*). Following the initial report on

[3] 
(ref. 17*c*)

the utility of allyl- and vinylsilanes in olefin cyclizations, this concept has been applied to the synthesis of five-membered rings (20), six-membered rings (21), seven-membered rings (22), and polycyclic systems (23). The results of Wang and Chan are particularly noteworthy (22). Electrophilic cyclizations to seven-membered rings are rare; however, the allylsilane shown in eq. [4] cyclized cleanly and efficiently to the cycloheptane derivative.

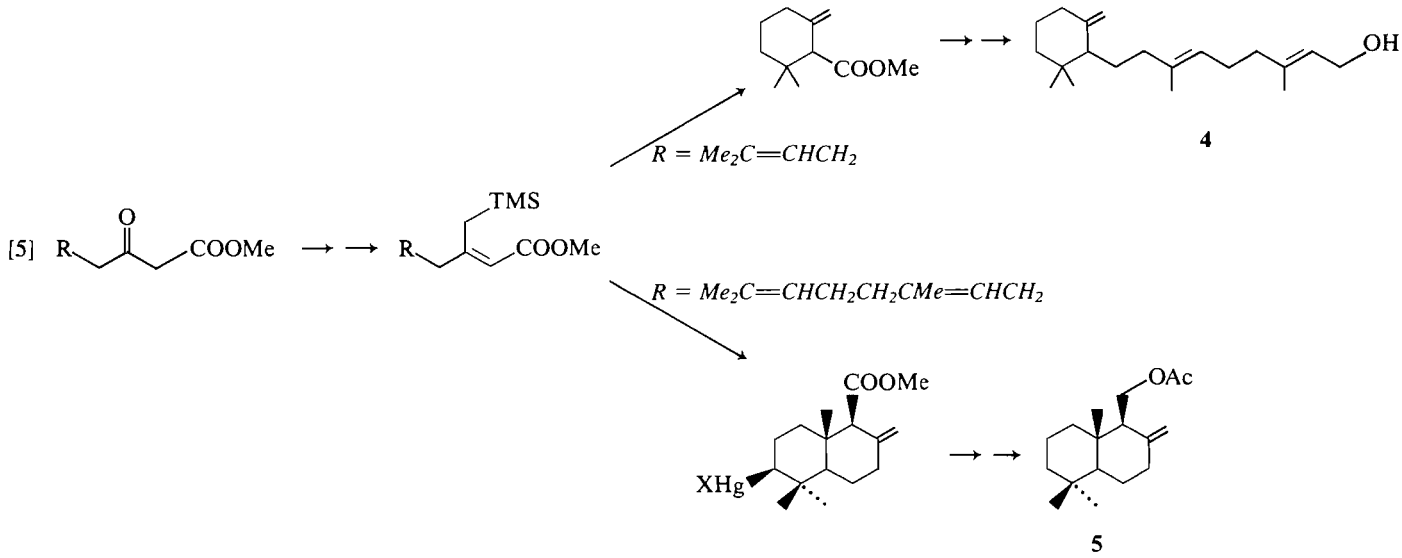
[4] 
(ref. 22)

We recently introduced a stereoselective synthesis of carboxylated allylsilanes using the Grignard coupling to the enol phosphate of a β-keto ester (24) as shown in eq. [5] (25, 26). These allylsilanes could be cyclized with Lewis acids or mercuric salts to give mono- or bicyclic products in good yield, and we demonstrated the utility of this cyclization in the synthesis of trixagol (**4**) (26) and albicanyl acetate (**5**) (25). It was clear from these results that the conjugated alkene, although deactivated in electrophilic reactions by the ester moiety, was sufficiently activated by the silicon to allow these cyclizations to proceed efficiently. An additional bonus in these cyclizations was the remarkable ability of the silane group to control the regioselective generation of the exocyclic alkene.

We then turned our attention to the cyclization of epoxy allylsilanes with the expectation that the epoxide would be opened stereoselectively and that the resulting alcohol could be used to introduce other functional groups. As noted above, *in vitro* cyclizations of epoxy olefins usually proceed in low to moderate yields (13). We would like to report our results on the cyclization of epoxy allylsilanes and the utility of this cyclization in the synthesis of two representative natural products.[2]

The diene **6** (26) was regioselectively epoxidized in 84% yield to the epoxy allylsilane **7** using *m*-chloroperoxybenzoic acid (MCPBA). This reagent is known to preferentially attack electron-rich alkenes, thus the electron-withdrawing effect of the carbomethoxy group must be greater than the electron-

[2]A preliminary report of some of these results has appeared (ref. 27).



donating effect of the trimethylsilyl group. Cyclization of the epoxy allylsilane **7** proved to be extremely facile. Treatment of a solution of **7** in dry methylene chloride with either stannic chloride or boron trifluoride etherate effected conversion to the cyclic hydroxy ester **8** in good yield. Boron trifluoride was the Lewis acid of choice. Gas chromatographic analysis showed that the crude product contained approximately 80% of **8**, 10% of starting **7**, and 10% of two other unidentified products. This is at least a three-fold improvement in yield over the optimum cyclization of an olefinic epoxide reported to this time. It was clear that the trimethylsilyl group endowed the nucleophilic terminus with just the right electronic properties to efficiently participate in the cyclization.

Some loss of material was experienced on the column chromatographic purification of **8**. However, when the crude cyclization mixture was treated with lithium aluminum hydride, the diol **9** was isolated in 68% yield from **7**. The spectral and chromatographic properties of **8** and **9** indicated that each was a single diastereomer. The spectral data of the diol **9** were identical to those reported by Coates and Melvin (28) for a sample of **9** prepared by another unambiguous route.[3] The structure and *cis* stereochemistry of the diol **9** was further confirmed by its conversion to (±)-karahana ether (**10**) following the procedure of Coates and Melvin (28). Karahana ether is a volatile monoterpene, with a pleasant camphor-like odor, which has been isolated from Japanese hops (29). Two other syntheses of karahana ether have been reported recently (30).

This sequence of reactions proves that the ester and the alcohol groups in the cyclized product **8** must have the *cis* stereochemistry shown. This stereochemistry can result from a cyclization of the epoxy olefin via a chair-like transition state (2, 10).

The extension of the monocyclic epoxy allylsilane cyclization to the bicyclic case was achieved after some effort. The first problem to be solved involved the regioselective synthesis of the terminal epoxide **11**. Oxidation of the triene **12** (25, 31) with MCPBA gave a mixture of regioisomers (1:1) involving epoxidation of the 6,7 and 10,11 double bonds, and the two epoxides were difficult to separate on preparative scale. The enol phosphate **13** could be regioselectively epoxidized with MCPBA at low temperature (−50°C) to give the 6,7- and 10,11-epoxides in a ratio of 1:4. Unfortunately we were unable to separate these isomeric epoxides and the coupling of the mixture of enol phosphates with trimethylsilylmethyl magnesium chloride was inefficient.

The most successful approach to the synthesis of the 10,11-epoxy allylsilane utilized the terminal epoxidation method of van Tamelen and co-workers (13*a*, 32). This involved conversion of the triene **12** to the terminal bromohydrin with *N*-bromosuccinimide (NBS), and closure to the desired epoxy allylsilane **11** with potassium carbonate. The NBS reaction could be carried out either in DME–H_2O (3:1) or in THF–H_2O (5:1). The resulting bromohydrin was unstable, hence the crude reaction mixture was usually treated immediately with base. It

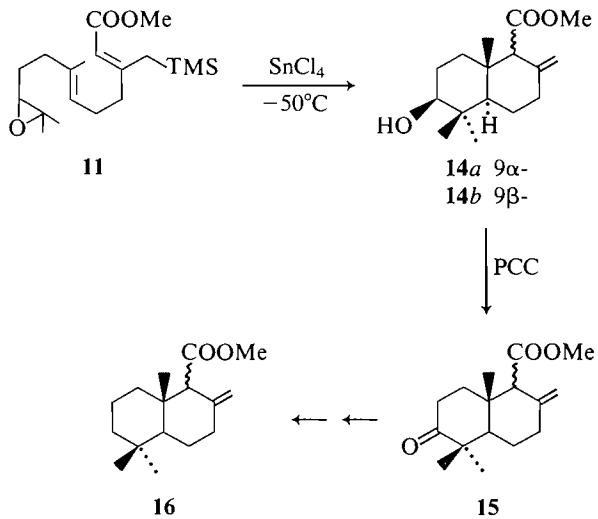
13

was necessary to carefully control the temperature of this cyclization and to monitor the progress of the reaction by tlc. The yield of terminal epoxide was generally from 45 to 55% after purification, and complete regioselectivity in epoxide formation was invariably obtained.

The epoxy allylsilane **11** was treated with a wide range of Lewis acids, and the ratio of products was determined by gas chromatography (gc) and ^{1}H nmr spectra (31). Boron trifluoride etherate in dry methylene chloride gave a good yield of the epimeric hydroxy esters **14**. Unfortunately the stereoselectivity in this reaction was poor, the two epimers, **14***a* and **14***b*, being formed in equal amounts. Cyclization at lower temperature (−50°C) gave improved stereoselectivity; however, a significant amount of a monocyclic product was obtained. Stannic chloride in dry methylene chloride gave the best yield and ratio of hydroxy esters **14***a* and **14***b*. On a small scale (<1 mmol), these esters were isolated in ca. 60% yield and the ratio of **14***a* to **14***b* was 1:2. Larger scale reactions (up to 5 mmol) gave ca. 55% yield of products, but the ratio of epimers fell to 2:3. On cooling the reaction, the stereoselectivity improved but again substantial amounts of monocyclic products were produced.

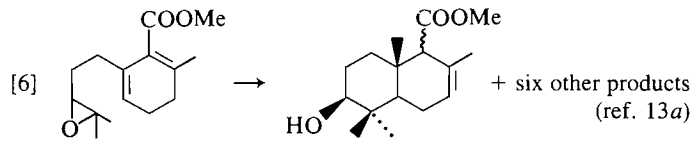


11 **14***a* 9α-
14*b* 9β-

16 **15**

The structures of the two cyclized products were confirmed by the following transformations. A mixture of cyclized esters, in a ratio of 2:3, was oxidized with pyridinium chlorochromate to give two ketones, **15**, also in a ratio of 2:3. This confirmed that the cyclized products were not epimeric at C-3. The ketone carbonyl of **15** was removed by formation of the tosylhydrazones and reduction with catecholborane (33) as shown above. Two products, **16**, were obtained in a ratio of 2:3 and they were shown to be the C-9 epimers by comparison with an authentic sample of these esters (25).

This clean cyclization of **11** can be contrasted with the cyclization of methyl 10,11-epoxyfarnesate (**17**), which on treatment with phosphoric acid or a Lewis acid gives a variety of products. The major bicyclic products in this latter example were the C-9 epimeric $\Delta^{7,8}$-alkenes which were isolated in 10–28% yield (eq. [6]) (13*a*). The ratio of the 9α/9β epimers varied with catalyst, but the 9α isomer was the major one. No exocyclic alkene **14** was found in the reaction mixture (13*a*).



17

Although the above conversions of **11** and its derivatives give no indication of the stereochemistry of the hydroxyl group at C-3, they do confirm the structure of the remaining carbon skeleton. The stereochemistry of the alcohol was determined to be equatorial from the 400-MHz ^{1}H nmr spectrum of the esters, which showed the C-3 proton to be a double doublet with $J = 5$ and 11 Hz. This stereochemistry is also in accord with the Stork–Eschenmoser hypothesis of a ring A chair-like transition state for this cyclization.

If one assumes that the cyclization of the epoxy allylsilane **11** occurs via a chair–chair transition state to give ester **14***b*, and via a chair–boat transition state to give ester **14***a*, then the energies of these two transition states must be very similar, to give the observed product distributions. The cyclization is irreversible and the esters **14** do not equilibrate under the reaction conditions. The α-ester is the more stable product presumably because of the $A^{(1,3)}$ strain in **14***b*. Thus we conclude that the ratio of the two products is kinetically controlled and depends on the activation energy of the transition states leading to **14***a* and **14***b*. It is not immediately apparent what the controlling factors are in these transition states. However, it is expected that steric interactions of the ester with other groups might play an important role in the cyclization. To test this hypothesis, we synthesized esters with different sizes and studied their cyclization.

The *tert*-butyl ester of **11** decomposed under the cyclization conditions. The isopropyl, neopentyl, and di-*tert*-butylmethyl esters were synthesized as above from the corresponding acetoacetate esters, which were prepared from diketene as shown in Scheme 2 (34).

Cyclization of the isopropyl ester **20***a* gave an epimeric mixture of bicyclic products **21** in 51% yield and a ratio of 9α/9β of 1:3. This modest improvement in stereoselectivity over the methyl cyclization encouraged us to study the neopentyl ester **20***b* and the di-*tert*-butylmethyl ester **20***c*. No noticeable improvement in the product ratios was observed in the cyclization of the neopentyl ester **20***b*. There was a small increase in the ratio of α/β isomers in the cyclization of the di-*tert*-butylmethyl ester **20***c* using stannic chloride as catalyst. Changing the Lewis acid catalyst did not lead to any increase in the stereoselectivity in either of these cyclizations. An unexpected improvement in the product distribution was obtained with the di-*tert*-butylmethyl ester by the addition of a small amount of acetic acid to the stannic chloride catalyzed reaction. The maximum stereoselectivity was obtained when 0.1 equiv.

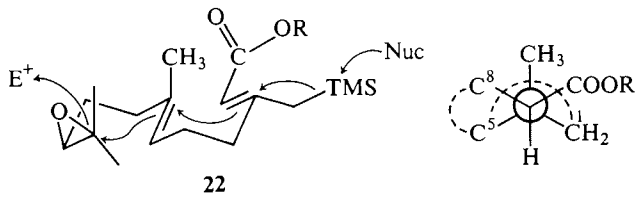
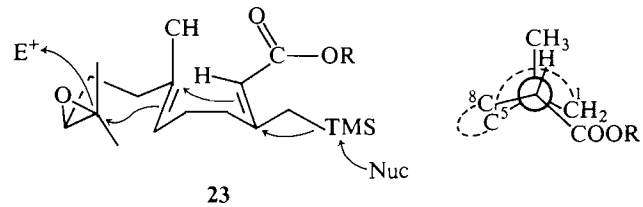
SCHEME 2. Cyclization of diene epoxides.

of acetic acid was added, giving a ratio of α/β = 1:5 on small scale. The stereoselectivity fell to 1:3 for larger scale reactions. However, this still represented a 100% improvement over the methyl ester cyclizations. A summary of these results is contained in Table 1.

These results show that increasing the size of the ester group in the diene epoxide leads to an increase in the amount of β isomer obtained, and hence a larger difference in the activation energy of the chair–chair transition state relative to the chair–boat transition state. This difference can be rationalized by comparing the interaction of the ester group with the angular methyl group at C-10 and with the C-1 methylene of the incipient A ring. In the chair–chair transition state there is a *gauche* interaction between the ester COOR and both the C-10 methyl and the C-1 methylene (see **22**). In the chair–boat transition state **23** the ester is eclipsed with the C-1 methylene. This eclipsing interaction will increase as the size of the ester increases. Hence the chair–chair transition state leading to the 9β epimer is preferred for larger esters.

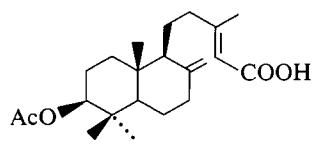


22

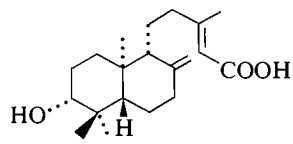


23

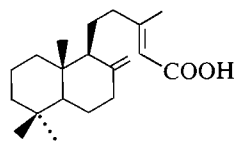
A large number of natural products possess the bicyclic carbon skeleton of **14** and **21**. However, those with a C-3 alcohol are less common. Two examples of these latter products are 3-acetoxylabda-8(20),13-dien-15-oic acid (**24***a*) and the corresponding alcohol **24***b*. The acetate **24***a* was isolated from the autumnal leaves of *Metasequoia glyptostroboides* (35), and its enantiomer was isolated from a Brazilian tree (popularly known as "Copaiba") as the alcohol **24***b* (36). The acid **25** is also a known natural product (37) and had been synthesized by Ohloff in 1958 (38). We outline below the first synthesis of the C-3 oxygenated labdadienes **24**.



24*a*



24*b*



25

Our first approach to the synthesis of the labdadienes was patterned after our trixagol synthesis (26). The C-3 alcohol of **21***c* was protected as its *tert*-butyldimethylsilyl (TBDMS) ether. In the first instance the alcohol was reacted with TBDMS-Cl under standard conditions (39) for up to 10 days to achieve complete reaction. However, treating the alcohol with TBDMS triflate (40) produced complete conversion to the silyl ether within 15 min. In the next step we hoped to selectively reduce the less hindered 9α ester and thus achieve a facile separation of the 9α and 9β isomers. Careful reduction of the esters **26** enriched with the β isomer (α/β = 3:7) gave a 60% mixture to the two C-9 hydroxymethyl compounds and 40% recovered ester, which was greater than 90% β. This ester was reduced with DIBAL (diisobutylaluminum hydride) to give the 9β-hydroxymethyl compound **27**.

The alcohol **27** was converted into the mesylate in quantitative yield, and the mesylate was transformed to the sulfide with potassium thiophenoxide in 94% yield (26). We were unsuccessful in oxidizing this sulfide with MCPBA or potassium hydrogen persulfate (41). However, the sulfide was oxidized to

the sulfone in 85% yield with diphenyl diselenide and hydrogen peroxide (42). Although the anion from this sulfone could be alkylated with methyl iodide (<50%), we were totally unable to alkylate it with any other alkylating agent. Thus we were forced to explore another route to introduce the side chain at C-9.

Treatment of the alcohol **27** with *N*-methyl-*N*,*N*′-dicyclohexylcarbodiimidium iodide (43) resulted in a 65% yield of the corresponding iodide. Here we were thwarted in our attempt to introduce the side chain by alkylation of this iodide with the dianion of methyl acetoacetate (44). This is one of the very few examples we have found of the failure of this dianion to undergo alkylation. Alkylation with the methyl acetoacetate dianion was eventually achieved, albeit in low yield, with the triflate **28**. This triflate was prepared by adding the alcohol **27** to a cold (−40 to −50°C) mixture of pyridine and triflic anhydride in the minimum amount of methylene chloride. Because the triflate decomposed above 0°C, the reaction had to be worked up at low temperature (see experimental) and the crude triflate was added to a solution of the methyl acetoacetate dianion to give a 28% purified yield of the γ-alkylated β-keto ester **29**. This is the first example of the dianion alkylation of a β-keto ester with a triflate, and the use of triflates should extend the scope of the β-keto ester dianion reaction (44).

The synthesis of the hydroxy labdadienoic acid **24** from the β-keto ester **29** involved, first, formation of the *Z*-enol phosphate, followed by a cuprate coupling (24) to give the *E*-alkene **30** in 75% yield. Somewhat surprisingly, treatment of the silyl ether **30** with tetra-*n*-butylammonium fluoride did not effect cleavage of the *tert*-butyldimethylsilyl ether. Instead, hydrolysis of the methyl ester occurred. The silyl protecting group in **30** was hydrolyzed with 5% hydrofluoric acid in acetonitrile (45), and the methyl ester was hydrolyzed with aqueous methanolic KOH. The spectral data of the synthetic (±)-**24***b* were in good agreement with those of an authentic sample (36).[4]

Experimental[5]

Methyl (Z)-6,7-epoxy-7-methyl-3-[(trimethylsilyl)methyl]-2-octenoate (7)

To 7.63 g (0.030 mol) of diene **6** in dry CH_2Cl_2 at 0°C was slowly added a solution of 5.70 g (0.033 mol) of MCPBA in CH_2Cl_2. The

[4]We are grateful to Professor Mahajan for this data.

[5]For outline of procedures see ref. 26.

reaction mixture was stirred for 2 h at 0°C, then warmed to room temperature and diluted with ether. The organic layer was washed three times with saturated $NaHCO_3$, once with saturated NaCl, dried, and concentrated to give 8.1 g of crude **7**. Purification by flash chromatography (46) using petroleum ether–ethyl acetate (12:1) as eluant gave 6.83 g (84%) of epoxide **7** as a colourless oil. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (7:1) gave **7** as a colourless liquid; bp (Kugelrohr distillation) 80°C/0.1 Torr (1 Torr = 133.3 Pa); ir ($CHCl_3$): 1700, 1615, 1250, 1160, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.10 (s, 9H), 1.30 (s, 3H), 1.35 (s, 3H), 1.60–1.90 (m, 2H), 2.15–2.50 (m, 4H), 2.75 (bt, J = 6 Hz, 1H), 3.68 (s, 3H), and 5.58 (s, 1H); mass spectrum, m/z: 271(3), 270(M^+, 11), 255(8), 123(12), 121(20), 96(17), 95(42), 91(11), 89(41), 85(16), 82(31), 80(10), 75(20), 74(12), 73(100), 71(10), 69(10), 67(14), and 59(38). *Exact mass* calcd. for $C_{14}H_{26}O_3Si$: 270.1650; found (ms): 270.1650.

Methyl cis*-3-hydroxy-2,2-dimethyl-6-methylenecyclohexanecarboxylate (**8**)*

To a solution of 4.05 g (0.015 mol) of the trimethylsilyl epoxide **7** in 130 mL of CH_2Cl_2 at −56°C was slowly added a solution of 3.69 mL (0.030 mol) of $BF_3{\cdot}Et_2O$ in 20 mL of CH_2Cl_2. The reaction mixture was stirred for 4 h at −56°C, then quenched with saturated NaCl at −56°C. The organic layer was diluted with ether, washed four times with saturated NaCl, dried, and concentrated to give 3.41 g of crude product, which was used without further purification in the preparation of diol **9**. Purification of a small amount of this material by flash chromatography using petroleum ether–ethyl acetate (8:1) gave **8** as a colourless liquid; bp (Kugelrohr distillation) 95°C/0.1 Torr; ir ($CHCl_3$): 3420, 1710, 1650, 1155, and 1075 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.93 (s, 3H), 1.04 (s, 3H), 1.70–2.80 (bm, 4H), 3.00 (s, 1H), 3.30–3.50 (m, 1H), 3.70 (s, 3H), 4.35 (bd, J = 10 Hz, 1H, exchangeable with D_2O), 4.85 (bs, 1H), and 4.95 (bs, 1H); mass spectrum, m/z: 198(M^+, 13), 180(20), 167(9), 139(12), 138(11), 123(14), 122(13), 121(100), 120(15), 109(10), 105(14), 97(14), 96(18), 95(80), 93(12), 83(16), 82(10), 81(13), 79(16), 69(13), 67(20), 59(14), and 55(25). *Anal.* calcd. for $C_{11}H_{18}O_3$: C 66.64, H 9.15; found: C 66.37, H 8.92.

cis*-3-Hydroxy-2,2-dimethyl-6-methylenecyclohexanemethanol (**9**)*

A slurry of 0.850 g (0.022 mol) of $LiAlH_4$ in dry ether was stirred at 0°C, and 3.41 g of the crude hydroxyl ester **8** in dry ether was slowly added to the slurry. The reaction mixture was heated at reflux for 2 h, then cooled to room temperature and quenched with 1 *M* HCl. The organic layer was washed once with 1 *M* HCl, twice with saturated NaCl, dried, and concentrated to give 1.95 g of crude **9**. Purification by flash chromatography using petroleum ether–ethyl acetate (1:1) as eluant gave 1.73 g (68% from trimethylsilyl epoxide **7**) of *cis*-diol **9** as a colourless oil. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (1:1.5) gave **9** as a colourless liquid; bp (Kugelrohr distillation) 105°C/0.1 Torr; ir ($CHCl_3$): 3600, 3400, 1640, 1080, and 1010 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.94 (s, 3H), 1.00 (s, 3H), 1.30–2.50 (m, 5H), 2.36 (bs, 2H, exchangeable with D_2O), 3.44 (dd, J = 4 Hz, 1H), 3.69 (A part of an ABX system, J_{AB} = 11 Hz, J_{AX} = 4 Hz, 1H), 3.91 (B part of an ABX system, J_{AB} = 11 Hz, J_{BX} = 7 Hz, 1H), 4.73 (bs, 1H), and 4.93 (bs, 1H); mass spectrum, m/z: 170(M^+, 0.5), 152(21), 138(8), 122(100), 121(55), 109(22), 108(20), 107(90), 96(26), 95(21), 93(30), 91(18), 81(37), 79(30), 71(21), 69(17), 67(31), 55(34), and 53(18). *Anal.* calcd. for $C_{10}H_{18}O_2$; C 70.55, H 10.66; found: C 70.40, H 10.70.

*8,8-Dimethyl-2-methylene-6-oxabicyclo[3.2.1]octane (karahana ether) (**10**)*

A solution of 0.850 g (5.0 mmol) of diol **9** in 7 mL of dry pyridine was stirred at 0°C, and 0.950 g (5.0 mmol) of *p*-toluenesulphonyl chloride was added to the solution. The reaction mixture was stirred for 5 h, while allowing it to warm to room temperature. The reaction mixture was diluted with ether, washed five times with 1 *M* HCl, once with saturated $NaHCO_3$, once with saturated NaCl, dried, and the solvent was removed to give 1.04 g of crude **10**. Purification by flash chromatography using petroleum ether–ether (9:1) as eluant gave 0.62 g (81%) of bicyclic ether **10** as a colourless liquid with a pleasant, camphor-like odour, whose spectral data (^1H nmr, ir, ms) are in good agreement with those of the literature (28–30).

General procedure A. Formation of epoxides from terminal bromohydrins (refs. 13a,32)

A solution of 1.0 equiv. of the olefin in THF–H_2O (5:1) (6 mL/mmol of olefin) was stirred at 10°C in the dark. To this solution was added NBS (1.1 equiv.) in small portions, and the reaction was stirred for 16 h while allowing it to warm to room temperature. The reaction was diluted with ether, washed three times with saturated NaCl, dried, and the solvent was removed. The crude bromohydrin was dissolved in anhydrous methanol and cooled to 0°C. Anhydrous potassium carbonate (K_2CO_3) (2.5 equiv.) was added to the reaction and the mixture was stirred for 15–30 min at 0°C, while monitoring the reaction by tlc. The reaction was diluted with ether, acidified with 1 *M* HCl, and the organic phase was washed once with 1 *M* HCl and three times with saturated NaCl. The aqueous washings were extracted three times with ether, the combined organic layers were dried, and the solvent was removed. Frequently the residue contained water, and was dissolved in ether, dried a second time, and the solvent was removed.

*Methyl (2Z,6E)-10,11-epoxy-7,11-dimethyl-3-[(trimethylsilyl)-methyl]-2,6-dodecadienoate (**11**)*

This compound was prepared according to the above general procedure A using 3.50 g (0.011 mol) of triene **12** and 2.13 g (0.012 mol) of NBS in 70 mL of a 5:1 solution of THF–H_2O. The crude bromohydrin obtained was moderately unstable, and was converted to epoxide **11** using 3.80 g (0.028 mol) of K_2CO_3 in anhydrous methanol. Work-up of the reaction mixture and purification of the crude product by flash chromatography using petroleum ether–ethyl acetate (15:1) as eluant gave 1.70 g (46%) of epoxide **11** as a colourless oil; bp (Kugelrohr distillation) 130°C/0.2 Torr; ir ($CHCl_3$): 1705, 1625, 1165, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.04 (s, 9H), 1.25 (s, 3H), 1.29 (s, 3H), 1.61 (s, 3H), 1.45–1.76 (m, 2H), 1.95–2.26 (m, 6H), 2.39 (s, 2H), 2.69 (t, J = 6 Hz, 1H), 3.65 (s, 3H), 5.00–5.28 (m, 1H), and 5.55 (s, 1H); mass spectrum, m/z: 338(M^+, 3), 323(14), 253(13), 211(14), 186(18), 149(41), 107(36), 89(23), 85(21), 82(40), 81(22), 73(100), and 59(37). *Anal.* calcd. for $C_{19}H_{34}O_3Si$: C 67.41, H 10.12; found: C 67.33, H 10.22.

General procedure B. Cyclization of epoxy allylsilanes

A solution of the epoxy allylsilane (1.0 equiv.) in dry CH_2Cl_2 (30 mL/mmol of allylsilane) was cooled to 0°C and to this solution was added the desired amount of acetic acid while stirring under nitrogen. The Lewis acid was slowly added as a solution in CH_2Cl_2 and the reaction was either stirred for 1–4 h at 0°C, or was allowed to warm to room temperature. The mixture was quenched with aqueous KF, diluted with ether, and the organic layer was washed three times with aqueous KF, once with saturated NaCl, dried, and the solvent was removed.

Methyl trans*-decahydro-6β-hydroxy-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate (**14**a, **14**b)*

These compounds were prepared according to general procedure B using 1.35 g (4.00 mmol) of compound **11** and 0.56 mL (4.8 mmol) of stannic chloride. The reaction was stirred for 3 h while allowing it to warm to room temperature. Work-up of the reaction mixture gave 1.14 g of crude product, which was purified by flash chromatography using petroleum ether–ethyl acetate (6:1) as eluant to yield 0.58 g (55%) of **14** (a/b = 1:1.5, as determined by ^1H nmr spectroscopy and gc (T = 180°C)). Preparative tlc of a small amount of this mixture using the same solvent system gave **14** as a viscous oil; bp (Kugelrohr distillation) 150°C/0.1 Torr; ir ($CHCl_3$): 3630, 3460, 1730, 1650, and 1160 cm^{-1}; ^1H nmr (400 MHz) ($CDCl_3$): δ: 0.77 (s, 1.2H), 0.80 (s, 1.8H), 0.92 (s, 1.2H), 1.00 (s, 1.8H), 1.04 (s, 1.2H), 1.06 (s, 1.8H), 1.25–1.76 (m, 7H), 1.95–2.16 (m, 1H), 2.28 (bd, J = 10 Hz, 1H, exchangeable with D_2O), 2.39–2.46 (m, 0.6H), 2.53–2.62 (m, 0.4H), 2.74 (s, 0.6H), 2.76 (s, 0.4H), 3.25 (dd, J = 11 Hz, 5 Hz, 1H), 3.62 (s, 1.2H), 3.64 (s, 1.8H), 4.66 (s, 0.6H), 4.73 (s, 0.4H), and 5.03 (s, 1H); mass spectrum, m/z: 266(M^+, 46), 248(27), 139(27), 135(100), 134(22), 121(28), 119(31), 114(28), 107(38), 105(24), 97(21), 95(29), 93(28), 91(24), 79(22), 69(26), 67(22), 55(34), 43(52), and

41(56). *Exact mass* calcd. for $C_{16}H_{26}O_3$: 266.1882; found (ms): 266.1881.

Methyl trans-*decahydro-5,5,8aβ-trimethyl-2-methylene-6-oxo-1ξ-naphthalenecarboxylate (**15**)*

A suspension of 0.310 g (1.5 mmol) of pyridinium chlorochromate, 0.040 g (0.48 mmol) of anhydrous sodium acetate, and 0.25 g (1% w/v of solvent) of 4 Å molecular sieves (dried and crushed) was stirred rapidly in 25 mL of CH_2Cl_2 at room temperature. To this solution was added 0.258 g (0.97 mmol) of alcohols **14** (a/b = 1:1.44) and the reaction was stirred for 2 h at room temperature. The reaction mixture was diluted with ether, stirred for 5 min, and the supernatant was passed through a 2.5 g Florisil column which had a layer of $MgSO_4$ on the top. The dark-brown residue was washed with ether, the ethereal extracts were passed through the column, eluted with ether, and the combined eluate was concentrated to give 0.250 g of **15** (a/b = 1:1.44, as determined by gc (T = 170°C)). Further purification by flash chromatography using petroleum ether–ethyl acetate (15:1) as eluant gave 0.228 g (89%) of **15** as an oil; bp (Kugelrohr distillation) 120°C/0.1 torr; ir ($CHCl_3$): 1735, 1705, 1650, and 1160 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.05 (s, 1.2H), 1.08 (s, 1.8H), 1.12 (s, 1.8H), 1.15 (s, 2.4H), 1.30 (s, 1.8H), 1.45–1.95 (m, 5H), 2.15–2.96 (m, 5H), 3.64 (s, 1.2H), 3.69 (s, 1.8H), 4.72 (bs, 0.6H), 4.81 (bs, 0.4H), and 4.92 (bs, 1H); mass spectrum, m/z: 264(M^+, 86), 249(55), 246(35), 232(68), 217(33), 199(42), 161(49), 148(39), 147(54), 135(32), 133(100), 125(37), 123(49), 121(41), 120(41), 119(52), 114(36), 109(51), 107(73), 105(53), 95(65), 93(45), 91(67), 81(57), 79(55), 77(39), 69(61), 68(56), 59(35), 55(82), and 53(38). *Exact mass* calcd. for $C_{16}H_{24}O_3$: 264.1725; found (ms): 264.1727.

Methyl trans-*decahydro-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate (**16**)*

To a solution of 0.053 g (0.20 mmol) of ketones **15** in 2 mL of dry ethanol was added 0.041 g (0.22 mmol) of *p*-toluenesulphonylhydrazine. The reaction mixture was heated at reflux for 4 h, cooled, and the solvent was removed to yield the *p*-toluenesulphonylhydrazones as a crystalline solid that was used without purification in the formation of compounds **16**; ir ($CHCl_3$): 1730, 1600, and 1160 cm^{-1}.

To a solution of these tosylhydrazones in chloroform (dried and distilled from $CaCl_2$) was added 0.026 g (0.22 mmol) of catecholborane at 0°C. The reaction was stirred for 1.5 h at 0°C; 0.082 g (0.60 mmol) of sodium acetate trihydrate was added, and the mixture was stirred at room temperature overnight. The reaction was diluted with ether, washed twice with saturated NaCl, dried, and the solvent was removed. Purification by flash chromatography using petroleum ether–ethyl acetate (10:1) gave 0.035 g (71%) of compounds **16** (a/b = 1.00:1.42, as determined by gc (T = 130°C)). The gc retention times were identical with those of an authentic sample of epimeric esters **16** (25).

General procedure C. Synthesis of alkyl acetoacetates from diketene (ref. 34)

A mixture of anhydrous sodium acetate (0.005 equiv.) and the alcohol (1.0 equiv.) was heated with stirring to 80–85°C, or to the boiling point of the alcohol. Diketene (1.05 equiv.) was added dropwise to the reaction mixture while maintaining the temperature below 115°C. The reaction was stirred for 2.5 h from the time of initial addition of diketene, and the product was distilled directly from the reaction mixture.

2-Propyl 3-oxobutanoate

This compound was prepared according to general procedure C using 8.2 mL (0.11 mol) of 2-propanol, 0.040 g (0.5 mmol) of anhydrous sodium acetate, and 8.8 mL (0.11 mol) of diketene. The product was distilled to give 13.3 g (86%) of β-keto ester as a colourless liquid; bp 90–100°C/45 Torr (lit. (47) bp 79–80°C/17 Torr); ir ($CHCl_3$): 1740, 1715, and 1105 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (d, J = 6 Hz, 6H), 2.26 (s, 3H), 3.42 (s, 2H), and 5.05 (septet, J = 6 Hz, 1H).

2,2-Dimethylpropyl 3-oxobutanoate

This compound was prepared according to general procedure C using 5.28 g (0.060 mol) of 2,2-dimethylpropyl alcohol, 0.025 g (0.30 mmol) of anhydrous sodium acetate, and 4.90 mL (0.063 mol) of diketene. The product was distilled to give 7.69 g (75%) of β-keto ester as a colourless liquid; bp 100–116°C/45 Torr (lit. (48) bp 60°C/3 Torr); ir ($CHCl_3$): 1740, 1705, and 1370 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.93 (s, 9H), 2.25 (s, 3H), 3.46 (s, 2H), and 3.80 (s, 2H)

2,2,4,4-Tetramethyl-3-pentyl 3-oxobutanoate

This compound was prepared according to general procedure C using 13.2 g (0.092 mol) of 2,2,4,4-tetramethyl-3-pentanol (49), 0.038 g (0.5 mmol) of anhydrous sodium acetate, and 7.84 mL (0.10 mol) of diketene. The product was distilled to give 18.2 g (87%) of β-keto ester as a colourless liquid; bp 120°C/5 Torr; ir ($CHCl_3$): 1730, 1715, and 1380 cm^{-1}: ^1H nmr ($CDCl_3$) δ: 1.01 (s, 18H) 2.32 (s, 3H), 3.51 (s, 2H), and 4.65 (s, 1H); mass spectrum m/z: 228(M^+, 0.1), 171(11), 103(17), 87(42), 85(100), 69(17), 58(20), 57(85), 43(83), and 41(40). *Anal.* calcd. for $C_{13}H_{24}O_3$: C 68.39, H 10.59; found: C 68.57, H 10.80.

*2-Propyl (E)-7,11-dimethyl-3-oxo-6,10-dodecadienoate (**18**a)*

This compound was prepared from the dianion (44) using 3.08 g (0.077 mol) of sodium hydride (60% dispersion in oil), 10.1 g (0.070 mol) of 2-propyl 3-oxobutanoate, 29.6 mL (0.077 mol) of a 2.6 *M* solution of *n*-butyllithium in hexane, and 16.3 g (0.070 mol) of geranyl bromide. Work-up of the reaction mixture gave 20.9 g of crude product, which was used without further purification in the preparation of enol phosphate. Preparative tlc of a small amount of this compound using petroleum ether–ethyl acetate (8:1) gave **18***a* as a colourless liquid; bp (Kugelrohr distillation) 150°C/0.25 Torr; ir ($CHCl_3$): 1735, 1705, and 1100 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.31 (d, J = 6 Hz, 6H), 1.63 (s, 6H), 1.73 (s, 3H), 1.9–2.25 (bs, 4H), 2.25–2.75 (m, 4H), 3.45 (s, 2H), 5.09 (septet, J = 6 Hz, 1H), and 5.0–5.3 (m, 2H); mass spectrum, m/z: 280(M^+, 5), 219(10), 169(17), 151(14), 136(33), 123(10), 109(81), 105(17), 93(15), 87(11), 81(26), 69(100), 68(14), 67(15), and 55(18). *Anal.* Calcd. for $C_{17}H_{28}O_3$: C 72.82, H 10.07; found: C 72.94, H 10.03.

*2,2-Dimethylpropyl (E)-7,11-dimethyl-3-oxo-6,10-dodecadienoate (**18**b)*

This compound was prepared from the dianion (44) using 1.63 g (0.041 mol) of sodium hydride (60% dispersion in oil), 6.35 g (0.037 mol) of 2,2-dimethylpropyl 3-oxobutanoate, 25.4 mL (0.041 mol) of a 1.6 *M* solution of *n*-butyllithium in hexane, and 9.04 g (0.039 mol) of geranyl bromide. Work-up of the reaction mixture gave 12.2 g of crude product, which was purified by distillation to yield 5.63 g (50%) of **18***b* as a yellow oil. Preparative tlc of a small amount of this compound using petroleum ether–ethyl acetate (5:1) gave **18***b* as a colourless liquid; bp 155°C/0.15 Torr; ir ($CHCl_3$): 1745 and 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.98 (s, 9H), 1.64 (s, 6H), 1.74 (s, 3H), 1.98–2.14 (m, 4H), 2.20–2.75 (m, 4H), 3.49 (s, 2H), 3.87 (s, 2H), and 4.95–5.25 (m, 2H); mass spectrum, m/z: 308(M^+, 12), 290(10), 247(12), 169(22), 136(36), 109(55), 93(20), 81(26), 71(68), 69(100), 57(24), 55(24), 43(87), and 41(74). *Anal.* calcd. for $C_{19}H_{32}O_3$: C 73.98, H 10.46; found C 74.05, H 10.40.

*2,2,4,4-Tetramethyl-3-pentyl (E)-7,11-dimethyl-3-oxo-6,10-dodecadienoate (**18**c)*

This compound was prepared via the dianion (44) using 3.30 g (0.083 mol) of sodium hydride (60% dispersion in oil), 17.1 g (0.075 mol) of 2,2,4,4-tetramethyl-3-pentyl 3-oxobutanoate, 53.2 mL (0.083 mol) of a 1.55 *M* solution of *n*-butyllithium in hexane, and 19.2 g (0.083 mol) of geranyl bromide. Work-up of the reaction mixture gave 30.5 g of crude product, which was used without further purification in the preparation of its enol phosphate. Preparative tlc of a small amount of this compound using petroleum ether–ethyl acetate (8:1) as eluant gave **18***c* as a colourless liquid; bp (Kugelrohr distillation) 120°C/0.1 Torr; ir ($CHCl_3$): 1735, 1710, and 1370 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.00 (s, 18H), 1.61 (s, 6H), 1.69 (s, 3H), 1.90–2.12 (m, 4H), 2.20–2.75 (m, 4H), 3.49 (s, 2H), 4.65 (s, 1H), and 4.96–5.23 (bt, 2H); mass spectrum, m/z: 364(M^+, 0.1), 238(11), 195(10), 136(10), 109(27), 81(16), 71(26), 69(62), 57(100), and 41(48). *Anal.* calcd. for $C_{23}H_{40}O_3$: C 75.78, H 11.06; found: C 75.73, H 10.96.

General procedure D. Formation of (Z)-allylsilanes from (Z)-enol phosphates

The Grignard reagent was prepared from magnesium turnings (1.5–2.0 equiv.) and trimethylsilylmethyl chloride (1.5–2.2 equiv.) in ether at room temperature under nitrogen, and to this stirred solution was added 0.025–0.05 equiv. of anhydrous nickel(II) acetylacetonate. The resulting dark-brown mixture was stirred for 5 min at room temperature and a solution of enol phosphate (1.0 equiv.) in ether was slowly added (exothermic reaction). The reaction mixture was stirred at room temperature or at reflux for the desired time, and various amounts of catalyst were added during this time. The reaction was cooled to room temperature, quenched by the careful addition of 1 *M* HCl (until the mixture was acidic to litmus paper), and diluted with ether. The organic layer was washed once with 1 *M* HCl, twice with saturated NaCl, dried, and the solvent was removed.

*2-Propyl (2Z,6E)-7,11-dimethyl-3-[(trimethylsilyl)methyl]-2,6,10-dodecatrienoate (**19**a)*

The enol phosphate of **18***a* was prepared (24) using 3.08 g (0.077 mol) of sodium hydride (60% dispersion in oil), 20.9 g of crude β-keto ester **18***a*, and 11.1 mL (0.077 mol) of diethyl chlorophosphate. Work-up of the reaction mixture gave a quantitative yield of an orange oil, which was used without further purification in the preparation of silyl ester **19***a*. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (2:1) gave pure enol phosphate as a viscous liquid; bp (Kugelrohr distillation) 190°C/0.2 Torr; ir ($CHCl_3$): 1720, 1670, 1270, 1105, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.28 (d, J = 6 Hz, 6H), 1.40 (dt, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 1 Hz, 6H), 1.63 (s, 6H), 1.71 (s, 3H), 1.95–2.15 (m, 4H), 2.23–2.53 (m, 4H), 4.28 (dq, $J_{CH_2CH_3}$ = 7 Hz, J_{POCH_2} = 7 Hz, 4H), 4.87–5.25 (m, 3H), and 5.35 (s, 1H); mass spectrum, m/z: 416(M^+, 5), 357(12), 287(32), 220(48), 192(19), 165(19), 155(100), 133(19), 127(37), 105(20), 99(38), and 69(31). *Anal.* calcd. for $C_{21}H_{37}O_6P$: C 60.56, H 8.95; found: C 60.36, H 8.90.

The crude enol phosphate (31 g) was reacted according to the general procedure D using 3.40 g (0.14 mol) of magnesium turnings, 21.4 mL (0.154 mol) of trimethylsilylmethyl chloride, and 0.45–0.90 (1.8–3.5 mmol) of anhydrous nickel(II) acetylacetonate. A further portion of 0.45–0.90 g (1.8–3.5 mmol) of catalyst was added immediately after addition of the enol phosphate, and the reaction was stirred at room temperature for 1 h. Work-up of the reaction mixture gave 27 g of crude product, which was purified by flash chromatography using petroleum ether–ethyl acetate (30:1) as eluant to yield 17.0 g (70% from isopropyl acetoacetate) of **19***a* as a yellow oil. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (20:1) gave **19***a* as a colourless oil; bp (Kugelrohr distillation)130°C/0.1 Torr; ir ($CHCl_3$): 1700, 1630, 1220, 1170, 1115, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.08 (s, 9H), 1.27 (d, J = 6 Hz, 6H), 1.64 (s, 6H), 1.71 (s, 3H), 1.97–2.30 (m, 8H), 2.45 (s, 2H), .4.85–5.25 (m, 3H), and 5.54 (s, 1H); mass spectrum, m/z: 350(M^+, 5), 281(7), 239(15), 223(10), 156(7), 149(29), 81(14), 75(26), 73(100), 69(50), 43(17), and 41(49). *Anal.* calcd. for $C_{21}H_{38}O_2Si$: C 71.94, H 10.92; found: c 72.20, H 10.99.

*2,2-Dimethylpropyl (2Z,6E)-7,11-dimethyl-3-[(trimethylsilyl)-methyl]-2,6,10-dodecatrienoate (**19**b)*

The enol phosphate of **18***b* was prepared (24) using 0.80 g (0.020 mol) of sodium hydride (60% dispersion in oil), 5.63 g (0.018 mol) of β-keto ester **18***b*, and 2.76 mL (0.019 mol) of diethyl chlorophosphate. Work-up of the reaction mixture gave 5.44 g (67%) of an orange oil, which was used without further purification in the preparation of silyl ester **19***b*. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (2:1) gave pure enol phosphate as a viscous oil; bp (Kugelrohr distillation) 180°C/0.1 Torr; ir ($CHCl_3$): 1720, 1670, and 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.96 (s, 9H), 1.37 (dt, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 1 Hz, 6H), 1.67 (bs, 6H), 1.74 (bs, 3H), 1.90–2.17 (m, 4H), 2.26–2.64 (m, 4H), 3.82 (s, 2H), 4.27 (dq, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 7 Hz, 4H), 5.0–5.26 (m, 2H), and 5.39 (s, 1H); mass spectrum, m/z: 444(M^+, 11), 308(17), 220(30), 155(100), 136(35), 127(39), 121(22), 109(49), 105(20), 99(45), 93(28), 85(27), 81(41), 71(60), 69(91), 67(24), 57(31), 55(34), 43(88), and 41(77). *Exact mass* calcd. for $C_{23}H_{41}O_6P$: 444.2651; found (ms): 444.2634.

This crude enol phosphate (3.44 g) was reacted according to general procedure D using 0.377 g (16 mmol) of magnesium turnings, 2.63 mL (17 mmol) of trimethylsilylmethyl chloride, and 0.050–0.10 g (0.19–0.33 mmol) of anhydrous nickel(II) acetylacetonate. A further portion of 0.050–0.10 g (0.19–0.33 mmol) of catalyst was added immediately after addition of the enol phosphate, and the reaction was stirred at room temperature for 1 h. Work-up of the reaction mixture gave 2.7 g of crude product, which was purified by flash chromatography using petroleum ether–ethyl acetate (40:1) as eluant to give 1.92 g (66% from β-keto ester **18***b*) of **19***b* as an orange oil. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (30:1) gave **19***b* as a viscous liquid; bp (Kugelrohr distillation) 120°C/0.1 Torr; ir ($CHCl_3$): 1690, 1620, 1240, 1150, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.10 (s, 9H), 0.98 (s, 9H), 1.64 (s, 6H), 1.73 (s, 3H), 1.92–2.30 (m, 8H), 2.47 (s, 2H), 3.80 (s, 2H), 4.98–5.25 (m, 2H), and 5.62 (s, 1H); mass specrum, m/z: 378(M^+, 22), 309(20), 239(35), 223(17), 149(38), 82(15), 81(19), 75(32), 73(100), 71(25), 69(51), 55(15), 43(45). and 41(27). *Anal.* calcd. for $C_{23}H_{42}O_2Si$: C 72.95, H 11.18; found: C 73.13, H 11.15.

*2,2,4,4-Tetramethyl-3-pentyl (2Z,6E)-7,11-dimethyl-3-[(trimethylsilyl)methyl]-2,6,10-dodecatrienoate (**19**c)*

The enol phosphate of **18***c* was prepared (24) using 3.80 g (0.083 mol) of sodium hydride (60% dispersion in oil), 30.5 g of crude β-keto ester **18***c*, and 11.5 mL (0.08 mol) of diethyl chlorophosphate. Work-up of the reaction mixture gave a quantitative yield of a yellow oil, which was used without further purification in the preparation of silyl ester **19***c*. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (1:1) gave pure enol phosphate as a colourless oil; bp (Kugelrohr distillation) 140°C/0.1 Torr; ir ($CHCl_3$): 1715, 1670, and 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.01 (s, 18H), 1.36 (dt, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 1 Hz, 6H), 1.62 (bs, 6H), 1.69 (bs, 3H), 1.90–2.16 (m, 4H), 2.25–2.55 (m, 4H), 4.26 (dq, $J_{CH_2CH_3}$ = 7 Hz, J_{POCH_2} = 7 Hz, 4H), 4.63 (s, 1H), 4.95–5.25 (bt, 2H), and 5.40 (s, 1H); mass spectrum, m/z: 500(M^+, 2), 357(22), 238(17), 220(38), 155(61), 136(16), 127(20), 109(30), 99(19), 81(22), 70(75), 69(25), 57(100), 55(18), 43(23), and 41(47). *Anal.* calcd. for $C_{27}H_{49}O_6P$: C 64.78, H 9.87; found: C 64.57, H 9.90.

This crude enol phosphate (20 g) was reacted according to general procedure D using 1.94 g (0.080 mol) of magnesium turnings, 12.2 mL (0.088 mol) of trimethylsilylmethyl chloride, and 0.25–0.50 g (1.0–2.0 mmol) of anhydrous nickel(II) acetylacetonate. The reaction mixture was stirred at room temperature for 2 h with no further addition of catalyst. Work-up of the reaction mixture, and purification by flash chromatography using petroleum ether–ethyl acetate (40:1) gave 12.20 g of **19***c* as a yellow liquid. Preparative tlc of a small amount of this material using the above solvent mixture gave **19***c* as a colourless oil; bp (Kugelrohr distillation) 120°C/0.1 Torr; ir ($CHCl_3$): 1690, 1620, 1155, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.08 (s, 9H), 1.03 (s, 18H), 1.64 (s, 6H), 1.72 (s, 3H), 1.97–2.28 (m, 8H), 2.51 (s, 2H), 4.59 (s, 1H), 4.98–5.26 (m, 2H), and 5.62 (s, 1H); mass spectrum, m/z: 434(M^+, 0.1), 308(26), 293(18), 292(14), 291(40), 239(18), 109(20), 73(85), 71(16), 69(45), 57(100), and 41(3). *Anal.* calcd. for $C_{27}H_{50}O_2Si$: C 74.59, H 11.59; found: C 74.28, H 11.75.

*2-Propyl (2Z,6E)-10,11-epoxy-7,11-dimethyl-3-[(trimethylsilyl)methyl]-2,6-dodecadienoate (**20**a)*

This compound was prepared according to general procedure A using 10.3 g (0.029 mol) of triene **19***a* and 5.76 g (0.032 mol) of NBS in 175 mL of a 5:1 solution of THF–H_2O. Work-up of the reaction gave 13.3 g of crude bromohydrin, which was used without further purification and was converted to epoxide **20***a* using 10.1 g (0.074 mol) of K_2CO_3 in anhydrous methanol. Work-up of the reaction mixture and purification of the crude product by flash chromatography using petroleum ether–ethyl acetate (15:1) as eluant gave 6.0 g (56%) of epoxide **20***a*. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (8:1) as eluant gave **20***a* as a colourless liquid; bp (Kugelrohr distillation) 160°C/0.15 Torr; ir ($CHCl_3$): 1700,

1625, 1255, 1210, 1170, 1110, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.08 (s, 9H), 1.29 (d, J = 6 Hz, 6H), 1.30 (s, 3H), 1.34 (s, 3H), 1.65 (s, 3H), 1.55–1.80 (m, 2H), 2.00–2.30 (m, 6H), 2.44 (s, 2H), 2.73 (t, J = 6 Hz, 1H), 5.00 (septet, J = 6 Hz, 1H), 5.00–5.27 (m, 1H), and 5.51 (s, 1H); mass spectrum, m/z: 366(M^+, 5), 239(11), 149(16), 107(18), 81(18), 75(26), 73(100), 71(18), 59(17), 43(39), and 41(16). *Anal.* calcd. for $C_{21}H_{38}O_{39}Si$: C 68.00, H 10.45; found: C 68.92, H 10.39.

*2,2-Dimethylpropyl (2Z,6E)-10,11-epoxy-7,11-dimethyl-3-[(trimethylsilyl)methyl]-2,6-dodecadienoate (**20**b)*

This compound was prepared according to general procedure A using 1.13 g (3.0 mmol) of triene **19***b* and 0.590 g (3.3 mmol) of NBS in 20 mL of a 5:1 solution of THF–H_2O. Work-up of the reaction gave a quantitative yield of crude bromohydrin, which was used without further purification. The crude bromohydrin was converted into epoxide **20***b* using 1.04 g (7.5 mmol) of K_2CO_3 in anhydrous methanol. Work-up of the reaction mixture and purification of the crude product by flash chromatography using petroleum ether–ethyl acetate (20:1) as eluant gave 0.64 g (54%) of epoxide **20***b*. Preparative tlc of a small amount of this material using the same solvent system gave **20***b* as a colourless liquid; bp (Kugelrohr distillation) 130°C/0.1 Torr; ir ($CHCl_3$): 1700, 1625, 1260, 1220, 1160 and 860 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.09 (s, 9H), 0.99 (s, 9H), 1.31 (s, 3H), 1.35 (s, 3H), 1.69 (bs, 3H), 1.59–1.81 (m, 2H), 2.04–2.31 (m, 6H), 2.47 (s, 2H), 2.74 (t, J = 6 Hz, 1H), 3.80 (s, 2H), 5.09–5.30 (m, 1H), and 5.59 (s, 1H); mass spectrum, m/z: 394 (M^+, 7), 379(10), 239(14), 149(20), 135(17), 121(16), 107(23), 85(17), 82(16), 81(24), 75(26), 73(100), 71(43), 69(17), 67(17), 55(17), 43(89), and 41(23). *Anal.* calcd. for $C_{23}H_{42}O_3Si$: C 70.00, H 10.73; found: C 69.83, H 10.80.

*2,2,4,4-Tetramethyl-3-pentyl (2Z,6E)-10,11-epoxy-7,11-dimethyl-3-[(trimethylsilyl)methyl]-2,6-dodecadienoate (**20**c)*

This compound was prepared via general procedure A using 13.5 g (0.031 mol) of triene **19***c* and 6.07 g (0.034 mol) of NBS in 180 mL of a 5:1 solution of THF–H_2O. Work-up of the reaction mixture gave a bromohydrin, which was used without purification. The crude bromohydrin was converted to epoxide **20***c* using 10.7 g (0.078 mol) of K_2CO_3 in anhydrous methanol. Work-up of the reaction mixture and purification by flash chromatography using petroleum ether–ethyl acetate (30:1) as eluant gave 7.9 g (57%) of epoxide **20***c*. Preparative tlc of a small amount of this material using the same solvent system gave **20***c* as a colourless liquid; bp (Kugelrohr distillation) 130°C/0.1 Torr; ir ($CHCl_3$): 1700, 1625, 1160, and 860 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.07 (s, 9H), 1.03 (s, 18H), 1.28 (s, 3H), 1.32 (s, 3H), 1.67 (bs, 3H), 1.55–1.80 (m, 2H), 2.05–2.22 (m, 6H), 2.51 (s, 1H), 2.73 (t, J = 6 Hz, 1H), 4.58 (s, 1H), 5.15–5.30 (bt, 1H), and 5.59 (s, 1H); mass spectrum, m/z: 450(M^+, 1), 307(9), 239(10), 197(14), 135(12), 125(13), 109(14), 107(13), 75(16), 73(89), 71(27), 57(100), 43(30), and 41(19). *Anal.* calcd. for $C_{27}H_{50}O_3Si$: C 71.94, H 11.18; found: C 71.66, H 11.33.

2,2,4,4-Tetramethyl-3-pentyl trans*-decahydro-6β-hydroxyl-5,5-8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate (**21**c)*

These compounds were prepared via general procedure B using 0.62 g (1.4 mmol) of compound **20***c*, 7.8 μL (0.14 mmol) of acetic acid, and 0.18 mL (1.5 mmol) of stannic chloride. The reaction was stirred at 0°C for 2 h. Work-up of the reaction mixture and purification by flash chromatography using petroleum ether–ethyl acetate (8:1) as eluant gave 0.287 g (55%) of alcohols **21***c* in a ratio of 1:3, as determined by ^1H nmr spectroscopy and gc (T = 250°C). Preparative tlc of a small sample of this mixture using petroleum ether–ethyl acetate (6:1) gave **21***c* as white foam; bp (Kugelrohr distillation) 145°C/0.1 Torr; ir ($CHCl_3$): 3630, 3460, 1720, 1660, 1375, and 1165 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.79 (s, 0.75H), 0.82 (s, 2.25H), 0.93 (s, 0.75H), 0.95 (s, 2.25H), 0.98 (s, 6.75H), 1.00 (s, 4.5H), 1.03 (s, 6.75H), 1.05 (s, 0.75H), 1.11 (s, 2.25H), 1.17–2.55 (m, 10H, 1H exchangeable with D_2O), 2.82 (bs, 1H), 3.07–3.44 (m, 1H), 4.54 (s, 0.25H), 4.59 (s, 0.75H), 4.75 (bs, 1H), and 4.86 (bs, 1H); mass spectrum, m/z: 378(M^+, 4), 252(38), 234(27), 233(22), 189(31), 135(21), 127(18), 119(8), 71(31), 57(100), and 41(21). *Anal.* calcd. for $C_{24}H_{42}O_3$: C 76.14, H 11.18; found: C 76.30, H 11.30.

2,2,4,4-Tetramethyl-3-pentyl trans*-decahydro-6β-[*tert*-butyldimethylsilyl)oxy]-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenecarboxylate (**26**)*

These compounds were prepared (40) using 0.08 g (2.1 mmol) of alcohols **21***c*, 0.60 mL (5.1 mmol) of 2,6-dimethylpyridine, and 0.73 mL (3.2 mmol) of TBDMS triflate in 3 mL of CH_2Cl_2. Work-up of the reaction mixture gave 1.0 g (99%) of compounds **26**, which were used without further purification in the preparation of alcohols **27**. Purification of a small amount of this material by preparative tlc using petroleum ether–ethyl acetate (60:1) as eluant gave the pure 9β epimer of **26** as a colourless glass; bp (Kugelrohr distillation) 140°C/0.1 Torr; mp 116–118°C; ir ($CHCl_3$): 1720, 1660, 1160, 1100, and 835 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.08 (s, 6H), 0.80 (s, 3H), 0.92 (s, 9H), 0.94 (s, 3H), 1.01 (s, 9H), 1.06 (s, 9H), 1.12 (s, 3H), 1.25–2.60 (m, 9H), 2.81 (bs, 1H), 3.27 (dd, J = 9 Hz, 6 Hz, 1H), 4.60 (s, 1H), 4.75 (bs, 1H), and 4.86 (bs, 1H); mass spectrum, m/z: 492 (M^+, 0.1), 309(6), 189(14), 91(17), 75(80), 73(41), 71(41), 69(21), 57(100), 55(44), 43(16), and 41(55). *Anal.* calcd. for $C_{30}H_{56}O_3Si$: C 73.11, H 11.45; found: C 73.07, H 11.40.

trans*-Decahydro-6β-[*tert*-butyldimethylsilyl)oxy]-5,5,8aβ-trimethyl-2-methylene-1ξ-naphthalenemethanol (**27**)*

To a solution of 0.984 g (2.0 mmol) of esters **26** in 50 mL of toluene was added 0.28 mL (3.5 mmol) of THF. The reaction was cooled to 0°C, 7.0 mL (7.0 mmol) of a 1 *M* solution of DIBAL in hexane was added, and the reaction was stirred at 0°C for 1 h. The reaction was quenched with 1 *M* HCl and diluted with ether. The organic phase was washed three times with 1 *M* HCl, once with saturated NaCl, dried, and the solvent was removed. Purification of the crude product by flash chromatography using petroleum ether–ethyl acetate (40:1) as eluant gave 0.400 g of esters **26** (9α/9β = 1:11, as determined by gc (T = 250°C)). The enriched β-ester **26** was dissolved in toluene and 3.52 mL (3.5 mmol) of a 1 *M* solution of DIBAL in hexane was added to the solution. The reaction was stirred at room temperature for 2 h, then diluted with ether, and quenched with 1*M* HCl. The organic layer was washed three times with 1 *M* HCl, once with saturated NaCl, dried, and the solvent was removed. Purification of the product by flash chromatography using petroleum ether–ethyl acetate (8:1) as eluant gave 0.271 g (95%) of alcohol **27**; bp (Kugelrohr distillation) 138°C/0.1 Torr; mp 65–67°C; ir ($CHCl_3$): 3620, 3450, 1650, 1100, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.07 (s, 6H), 0.76 (s, 3H), 0.77 (s, 3H), 0.91 (s, 9H), 0.94 (s, 3H), 1.12–2.62 (m, 10H), 1.37 (bs, 1H, exchangeable with D_2O), 3.15–3.37 (m, 1H), 3.65–3.90 (m, 2H), 4.66 (bs, 1H), and 4.95 (bs, 1H); mass spectrum, m/z: 352(M^+, 1), 295(21), 147(13), 107(18), 105(24), 95(20), 81(15), 75(100), 73(34), and 69(15). *Anal.* calcd. for $C_{21}H_{40}O_2Si$: C 71.53, H 11.43; found: C 71.28, H 11.52.

Mesylate from alcohol 27

To a solution of 0.67 mL (4.8 mmol) of triethylamine in ether at 0°C was added a solution of alcohols **27** (9α/9β = 1:2, as determined by ^1H nmr spectroscopy) in ether at 0°C with stirring. After 5 min, 0.27 mL (3.5 mmol) of methanesulphonyl chloride was added to the reaction, and the mixture was stirred at 0°C for 2 h, then at room temperature for 2 h. The reaction was quenched with 1 *M* HCl, and the organic phase was washed three times with 1 *M* HCl, three times with saturated $NaHCO_3$, once with saturated NaCl, and dried. The solvent was removed to give 1.39 g (quantitative yield) of a mesylate, which was used without further purification in the preparation of sulfide. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (6:1) gave pure mesylate (9α/9β = 1:2) as an oil which slowly crystallized; mp 72–77°C; ir ($CHCl_3$): 1360, 1175, 945, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.06 (s, 6H), 0.78 (s, 3H), 0.86 (s, 1.2H), 0.91 (s, 10.8H), 0.94 (s, 1.8H), 0.99 (s, 1.2H), 1.15–2.58 (m, 10H), 3.00 (s, 1.2H), 3.02 (s, 1.8H), 3.05–3.35 (m, 1H), 4.20–4.50 (m, 2H), 4.61 (bs, 0.6H), 4.72 (bs, 0.4H), 4.85 (bs, 0.4H), and 4.92 (bs, 0.6H); mass

spectrum, *m/z*: 430(M^+, 3), 203(100), 153(32), 147(28), 135(22), 133(23), 119(24), 109(25), 107(39), 95(31), 93(23), 81(21), 75(61), and 73(35). *Exact mass* calcd. for $C_{22}H_{42}O_4SSi$: 430.2573; found (ms): 430.2572.

trans-*Decahydro-6β-[*tert*-butyldimethylsilyl)oxy-5,5,8aβ-trimethyl-2-methylene-1ξ-(phenylthiomethyl)naphthalene*

A slurry of 1.02 g (6.4 mmol) of KH (25% in oil) in dry ethanol was stirred at room temperature and 0.66 mL (6.4 mmol) of thiophenol was added to the slurry. After 10 min a solution of 1.39 g of the above mesylate (1α/1β = 1:1.5) in ethanol was added to the mixture, and the reaction was heated at reflux for 16 h. The ethanol was removed under reduced pressure and the residue was partitioned between ether and saturated NaCl. The two phases were acidified with 1 *M* HCl, and the organic phase was washed twice with saturated NaCl, dried, and concentrated. The crude product was purified by flash chromatography using petroleum ether as eluant to remove the mineral oil and diphenyl disulfide. The column was then eluted with petroleum ether–ethyl acetate (40:1) to give 1.33 g (94% from alcohols **27**) of sulfide as a pale yellow solid. Preparative tlc of a small amount of this material using the above solvent system gave pure sulfide (1α/1β = 1:1.5) as a colourless crystalline solid; bp (Kugelrohr distillation) 180°C/0.1 Torr; mp 73–89°C; ir ($CHCl_3$): 1100 and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.07 (s, 6H), 0.79 (s, 3H), 0.93 (bs, 15H), 1.15–2.50 (m, 10H), 2.81–3.30 (m, 3H), 4.70 (bs, 1H), 4.84 (bs, 0.4H), 4.99 (bs, 0.6H), and 7.15–7.48 (bs, 5H); mass spectrum, *m/z*: 445(13), 444(M^+, 27), 387(26), 203(28), 133(15), 123(27), 119(15), 117(15), 109(16), 107(17), 95(17), 93(15), 81(16), 75(100), 73(56), 69(18), 57(19), and 55(51). *Exact mass* calcd. for $C_{27}H_{44}OSSi$: 444.2882; found (ms): 444.2876.

trans-*Decahydro-6β-[*tert*-butyldimethylsilyl)oxy]-5,5,8aβ-trimethyl-2-methylene-1ξ-(phenylsulfonylmethyl)naphthalene*

To a solution of 0.504 g (1.6 mmol) of diphenyl diselenide in a 5:1 mixture of ether–CH_2Cl_2 at 0°C was added 0.92 mL (8.1 mmol) of a 30% (w/v) solution of hydrogen peroxide in water. To this oxidizing mixture was added 0.717 g (1.6 mmol) of the above sulfide (1α/1β = 1:1.5) and the reaction was refrigerated at 5°C for 16 h, during which time colourless crystals were observed to form. The reaction mixture was diluted with ether and ethyl acetate, and filtered to remove the insoluble crystals. The filtrate was washed three times with saturated NaCl, dried, and the solvent was removed to give 0.90 g of sulfone as an oil that was insoluble in petroleum ether. The crude product was dissolved in ethyl acetate and adsorbed into silica gel. Purification by flash chromatography using petroleum ether–ethyl acetate (6:1) as eluant gave 0.65 g (85%) of sulfone (1α/1β = 1:1.5). Preparative tlc of a small amount of this material using the same solvent system gave pure sulfone as a colourless glass; bp (Kugelrohr distillation) 195°C/0.1 Torr; ir ($CHCl_3$): 1660, 1315, 1150, 1105, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.06 (s, 6H), 0.63 (s, 1.8H), 0.73 (s, 3H), 0.91 (s, 10.2H), 0.93 (s, 3H), 1.12–2.48 (m, 10H), 3.00–3.40 (m, 3H), 4.43 (bs, 1H), 4.60 (bs, 0.4H), 4.74 (bs, 0.6H), and 7.49–7.98 (m, 5H); mass spectrum, *m/z*: 476(M^+, 0.2), 420(29), 419(92), 217(61), 203(78), 201(34), 199(100), 147(23), 135(33), 109(20), 107(21), 95(24), 75(57), and 73(28). *Anal.* calcd. for $C_{27}H_{44}O_2SSi$: C 68.02, H 9.30; found: C 67.85, H 9.18.

A small portion of sulfone (1α/1β = 1:1.5), was crystallized from ether to give moderately pure β isomer; mp 156–159°C; ^1H nmr ($CDCl_3$) δ: 0.06 (s, 6H), 0.63 (s, 3H), 0.73 (s, 3H), 0.91 (s, 9H), 0.93 (s, 3H), 1.15–2.50 (m, 10H), 3.04–3.58 (m, 3H), 4.43 (bs, 1H), 4.74 (bs, 1H), 7.49–7.68 (m, 3H), and 7.80–7.98 (m, 5H).

*Methyl 5-[*trans-*decahydro-6'β-[(*tert*-butyldimethylsilyl)oxy]-5',5',8a'β-trimethyl-2'-methylene-1'β-naphthalenyl]-3-oxopentanoate (**29**)*

To a solution of 73 μL (0.91 mmol) of pyridine in 1 mL of CH_2Cl_2 at −40 to −50°C was added 139 μL (0.82 mmol) of freshly purified trifluoromethanesulphonic anhydride (triflic anhydride) with stirring. A white precipitate formed immediately and after 5 min a solution of 0.290 g (0.82 mmol) of alcohol **27** in 2 mL of CH_2Cl_2 was added to the mixture. The reaction was stirred at −40 to −50°C for 1 h, during which time the original precipitate disappeared and a new precipitate formed. The reaction was filtered through a glass sinter and the crystalline pyridinium triflate was washed with hexane that had been cooled to approximately −20°C. The filtrates were combined and the solvent was removed under high vacuum while maintaining the temperature below 0°C. The residue was dissolved in cold hexane (−20°C), and the insoluble matter was filtered through a glass sinter and washed with cold hexane. The filtrates were again combined and the solvent was removed under high vacuum while maintaining the temperature below 0°C. The resulting colourless to pink oil was dissolved in cold (−40°C) THF, and added to a preformed solution of the dianion of methyl acetoacetate in THF that was cooled to −40°C. (The dianion was prepared (44) from 0.056 g (1.4 mmol) of sodium hydride (60% dispersion in oil), 133 μL (1.2 mmol) of methyl acetoacetate, and 0.93 mL (1.4 mmol) of a 1.5 *M* solution of *n*-butyllithium in hexane.) The reaction mixture was allowed to warm to 0°C over a period of 1 h, then stirred at 0°C for a further 2 h. The mixture was quenched with 1 *M* HCl, ether, the organic phase was washed once with 1*M* HCl, once with saturated NaCl, and dried. The solvent was removed, while maintaining the temperature below 50°C, to yield an orange oil. Purification was performed, on the same day, by flash chromatography using petroleum ether as eluant to give 0.060 g (22%) of diene. The column was then eluted with petroleum ether–ethyl acetate (25:1) to remove any remaining nonpolar material. Elution with petroleum ether–ethyl acetate (10:1) gave the β-keto ester **29** (0.104 g, 28%) as a pale yellow oil. Preparative tlc of a small amount of this material using petroleum ether–ethyl acetate (6:1) gave **29** as a colourless oil; bp (Kugelrohr distillation) 170°C/0.1 Torr; ir ($CHCl_3$): 1750, 1720, 1255, 1100, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.06 (s, 6H), 0.71 (s, 3H), 0.76 (s, 3H), 0.91 (s, 12H), 1.08–2.73 (m, 14H), 3.24 (bt, J = 7 Hz, 1H), 3.42 (s, 2H), 3.74 (s, 3H), 4.43 (bs, 1H), and 4.84 (bs, 1H); mass spectrum, *m/z*: 450 (M^+, 5), 394(32), 393(90), 149(19), 135(20), 121(17), 119(16), 107(17), 95(15), 81(15), 75(100), 73(50), 69(22), 55(20), 43(19), and 41(20). *Exact mass* calcd. for $C_{26}H_{46}O_4Si$: 450.3165; found (ms): 450.3168.

*Methyl (*E*)-3-methyl-5-[*trans-*decahydro-6'β-[*tert*-butyldimethylsilyl)oxy]-5',5',8a'β-trimethyl-2'-methylene-1'β-naphthalenyl]-2-pentenoate (**30**)*

The enol phosphate from **29** was prepared (24) using 11 mg (0.27 mmol) of sodium hydride (60% dispersion in oil), 80 mg (0.18 mmol) of β-keto ester **29**, and 31 μL (0.21 mmol) of diethyl chlorophosphate. Work-up of the reaction mixture gave a yellow oil, which was purified by flash chromatography using petroleum ether–ethyl acetate (2:1) as eluant to give 94 mg (90%) of enol phosphate as a viscous liquid; ir ($CHCl_3$): 1730, 1670, and 1035 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.06 (s, 6H), 0.70 (s, 3H), 0.75 (s, 3H), 0.91 (s, 12H), 1.05–2.55 (m, 14H), 1.38 (dt, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 1 Hz, 6H), 3.23 (bt, J = 7 Hz, 1H), 3.71 (s, 3H), 4.27 (dq, $J_{CH_2CH_3}$ = 7 Hz, $J_{POCH_2CH_3}$ = 8 Hz, 4H), 4.49 (bs, 1H), 4.85 (bs, 1H), and 5.35 (s, 1H); mass spectrum, *m/z*: 586(M^+, 0.6), 530(29), 529(86), 432(16), 375(17), 300(14), 253(19), 252(82), 230(13), 229(100), 220(24), 211(26), 201(18), 183(20), 155(57), 135(16), 127(18), 119(16), 99(23), 81(15), 75(56), and 73(41). *Exact mass* calcd. for $C_{30}H_{55}O_7PSi$: 586.3455; found (ms): 586.3435.

A suspension of 67 mg (0.33 mmol) of cuprous bromide–dimethyl sulphide complex ($CuBr{\cdot}Me_2S$) in 2 mL of ether was stirred at 0°C, and 0.39 mL (0.66 mmol) of a 1.7 *M* solution of methyllithium–lithium bromide complex in ether was slowly added to the suspension. The resulting light tan solution was cooled to −78°C and a solution of 64 mg (0.11 mmol) of the above enol phosphate in 1.5 mL of ether was added to the reaction. The reaction mixture was warmed to −50°C and stirred for 1 h while maintaining the temperature between −40 and −50°C. During this time the colour of the reaction mixture changed from bright yellow to a reddish-purple colour. The reaction was quenched at −40°C by the addition of a mixture of 50% aqueous ammonium chloride and concentrated ammonium hydroxide (ca. 5:1), and diluted with ether. The organic phase was washed three times with this ammoniacal solution to remove all copper salts, once with saturated NaCl, dried, and the solvent was removed. The crude product was purified by flash

chromatography using petroleum ether–ethyl acetate (40:1) as eluant to give 40 mg (82%) of **30** as a pale yellow oil. Preparative tlc of this material using the same solvent system gave **30** as a colourless liquid; bp (Kugelrohr distillation) 130°C/0.1 Torr; ir ($CHCl_3$): 1720, 1650, 1155, 1105, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.08 (s, 6H), 0.72 (s, 3H), 0.77 (s, 3H), 0.92 (s, 12H), 1.06–2.55 (m, 14H), 2.18 (d, J = 1.5 Hz, 3H), 3.25 (bt, J = 7 Hz, 1H), 3.71 (s, 3H), 4.51 (bs, 1H), 4.88 (bs, 1H), and 5.65 (bs, 1H); mass spectrum, m/z: 448 (M^+, 2), 392(39), 391(100), 316(12), 285(11), 241(14), 171(12), 147(12), 135(23), 121(22), 119(16), 109(13), 107(17), 105(11), 95(29), 93(13), 81(13), 75(65), 73(34), and 69(12). *Anal.* calcd. for $C_{27}H_{48}O_3Si$: C 72.27, H 10.78; found: C 72.32, H 10.85.

*Methyl (*E*)-3-methyl-5-(*trans*-decahydro-5',5',8a'*β*-trimethyl-2'-methylene-6'*β*-hydroxy-1'*β*-naphthalenyl)-2-pentenoate*

The standard solution of 48% aqueous hydrofluoric acid and 10 volumes of acetonitrile was prepared (4.8% HF in CH_3CN), and 3 mL of this standard solution was added to 9.5 mg (0.02 mmol) of silyl ether **30**. This reaction was stirred at 0°C for 2 h while allowing it to warm to room temperature, then was diluted with ether. The organic phase was washed four times with water, dried, and the solvent was removed to give 7 mg (99%) of crude alcohol, which was used unpurified in the preparation of **24***b* (98% pure by gc (T = 250°C)). The spectral data (^1H nmr, ir, ms) are in good agreement with those found in the literature (35, 36); ir ($CHCl_3$): 3620, 3470, 1720, 1650, 1210, and 1155 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.72 (s, 3H), 0.80 (s, 3H), 1.01 (s, 3H), 1.1–2.55 (m, 15H, 1H exchangeable with D_2O), 2.18 (d, J = 1.5 Hz, 3H), 3.15–3.40 (m, 1H), 3.70 (s, 3H), 4.53 (bs, 1H), 4.88 (bs, 1H), and 5.65 (bs, 1H); mass spectrum, m/z: 334(M^+, 6), 319(19), 316(16), 301(25), 260(19), 203(23), 175(21), 135(100), 134(25), 123(26), 121(38), 119(29), 114(55), 109(29), 107(53), 95(38), 93(35), 83(26), 82(26), 81(38), and 55(27). *Exact mass* calcd. for $C_{21}H_{34}O_3$: 334.2508; found (ms): 334.2512.

*(*E*)-3-Methyl-5-(*trans*-decahydro-5',5',8a'*β*-trimethyl-2'-methylene-6'*β*-hydroxy-1'*β*-naphthalenyl)-2-pentenoic acid (3-hydroxylabda-8(20),13-dien-15-oic acid) (**24**b)*

To a solution of 10 mg (0.03 mmol) of the above methyl ester in 3 mL of methanol was added 1 mL of a 10% (w/v) solution of aqueous KOH at 0°C. The reaction was stirred at room temperature for 30 h, then diluted with ether, washed three times with 1 *M* HCl, and once with saturated NaCl. The aqueous washings were extracted three times with ether, the combined organic layers were dried, and the solvent was removed. The crude product was purified by flash chromatography using petroleum ether–ethyl acetate (1:1.5) as eluant to give 8 mg (83%, 2 steps) of **24***b* as a crystalline solid whose spectral data (^1H nmr, ir, ms) are in good agreement with those found in the literature (35, 36); mp 173–174.5°C; ir ($CHCl_3$): 3000, 1700, and 1640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.72 (s, 3H), 0.81 (s, 3H), 1.03 (s, 3H), 1.0–2.6 (m, 16H, 2H exchangeable with D_2O), 2.19 (d, J = 1.5 Hz, 3H), 3.10–3.37 (m, 1H), 4.52 (bs, 1H), 4.89 (bs, 1H), and 5.68 (bs, 1H); mass spectrum, m/z: 320 (M^+, 7), 302(22), 152(25), 149(52), 136(27), 135(100), 134(26), 133(24), 123(31), 122(36), 121(48), 119(31), 109(40), 107(61), 105(28), 97(33), 96(31), 95(27), 93(48), and 91(39). *Exact mass* calcd. for $C_{20}H_{32}O_3$: 320.2351; found (ms): 320.2354.

Acknowledgments

We are grateful to Professors Coates, Yamada, and Mahajan for spectral data and comparison samples, and to the Natural Sciences and Engineering Research Council of Canada for financial support. One of us (R.J.A.) is grateful to the Canadian Commonwealth Scholarship and Fellowship Plan for the award of a graduate scholarship.

Reçu le 26 février 1985[2]

J. P. PRADERE, J. C. ROZE, H. QUINOIU, R. DANION-BOUGOT, D. DANION et L. TOUPET. Can. J. Chem. **64**, 597 (1986).

La synthèse de nouvelles thiazines est décrite. Leur détermination structurale et leurs paramètres spectroscopiques sont examinés. La cyclocondensation [2+2] de ces thiazines sur les cétènes est étudiée ainsi que la réversibilité de la réaction en fonction de la nature des substituants en positions 4 et (ou) 5 des 6*H*-thiazines-1,3.

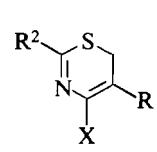
J. P. PRADERE, J. C. ROZE, H. QUINIOU, R. DANION-BOUGOT, D. DANION, and L. TOUPET. Can. J. Chem. **64**, 597 (1986).

The synthesis of new thiazines is described. Their structural determination and their spectroscopic parameters are examined. The [2+2] cyclocondensation of these thiazines with ketenes is studied along with the reversibility of the reaction as a function of the nature of the substituents on position 4 and (or) 5 of 6*H*-1,3-thiazines.

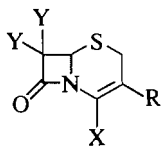
[Traduit par le journal]

Introduction

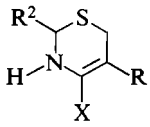
Des travaux mentionnent l'utilisation des dihydrothiazines **4** (R^2 = groupement générateur de cycle β-lactamique) comme précurseurs de céphalosporines (1) ou de céphèmes **3** (2). La synthèse de ces composés bicycliques a été également effectuée par réaction de cycloaddition [2+2] à partir de 6*H*-thiazines-1,3 **2** non substituées en position 2 et comportant en position 4 un groupement fonctionnel électroattracteur (3).



2



3



4

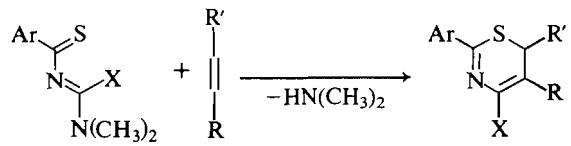
Les synthèses de composés β-lactamiques par action des cétènes sur la fonction imine de composés linéaires ou cycliques ont fait l'objet de nombreuses publications (4). Toutefois, peu de travaux concernent les 6*H*-thiazines-1,3 substituées en positions 2, 4 et 5. Dans certains cas, lorsque la position 2 des 6*H*-thiazines-1,3 **2** est substituée par un groupement aromatique, il n'a pas été possible d'obtenir le céphème correspondant (5).

Après avoir décrit l'accès à de nouvelles 6*H*-thiazines-1,3 polyfonctionnelles e leurs caractéristiques physico-chimiques (rayons X, rmn ^{13}C et ^{15}N), nous nous proposons de montrer l'influence de la température et de la nature des substituants en positions 4 et 5 sur la réactivité des phényl-2 6*H*-thiazines-1,3 vis-à-vis du diphénylcétène et du dichlorocétène.

1. Phényl-2 6*H*-thiazines-1,3 polysubstituées

1.1 Synthèse

Les 6*H*-thiazines-1,3 substituées **2** ont été obtenues selon une réaction de cyclocondensation [4+2].



1*a* X = H
1*b* X = CH_3
1*c* X = $CO_2C_2H_5$
Ar = C_6H_5

R = CHO, $COCH_3$
R′ = H, CH_3

2

Le thia-1 aza-3 butadiène **1***a* opposé à l'acroléine dans le dichlorométhane, ou à la méthylvinylcétone sans solvant, conduit thermiquement aux 6*H*-thiazines-1,3 **2***a* et **2***b*. Lorsque la fonction imine de l'hétérodiène **1** est substituée par un groupement carboxylate (X = $CO_2C_2H_5$), l'accès aux thiazines correspondantes **2***e* et **2***f* nécessite une catalyse acide (7). On peut utiliser les acides de Lewis : chlorure d'aluminium, acétate de zinc ou les acides sulfoniques : Nafion-H (8), Amberlyst 15 dans le dichlorométhane. L'efficacité de l'Amberlyst 15 s'est avérée générale pour cette réaction de cyclocondensation [4+2]. Cette méthode permet l'introduction en positions 4 et (ou) 5 sur le cycle thiazinique de groupements électroattracteurs. Le caractère électroattracteur du substituant en position 5 peut être modifié par blocage de la fonction aldéhyde (R = CHO), selon les méthodes décrites dans la littérature (9,10) : l'action du thiophénol en présence d'acide de Lewis conduit aux thiazines **2***g*, **2***i*, **2***j* tandis que l'éthylèneglycol en présence d'acide paratoluène sulfonique (APTS) permet d'isoler le composé **2***h*.

L'hétérodiène **1***a* opposé à l'aldéhyde crotonique fournit la 6*H*-thiazine-1,3 **2***k* méthylée en position 6 (voir tableau 1).

1.2. Spectrométrie de rmn ^{13}C et ^{15}N

Nous avons effectué les mesures spectroscopiques par résonance magnétique nucléaire ^{13}C et ^{15}N afin d'établir une corrélation entre la réactivité de la fonction imine et la nature des substituants portés par la thiazine.

La comparaison des déplacements chimiques δ C2 en rmn ^{13}C des composés **2***a* et **2***g* d'une part, **2***c* et **2***i* d'autre part,

[1]Auteur à qui adresser la correspondance.

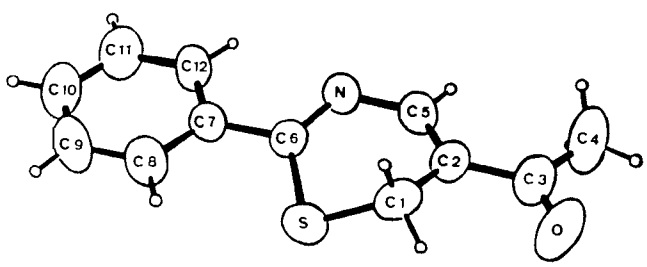
[a]Les atomes avec un astérique ont un coefficient d'agitation thermique isotrope fixe.

montre que l'introduction d'un groupement électroattracteur en position 5 provoque un déplacement vers les champs faibles d'environ 8 ppm pour ce carbone. Un groupement électroattracteur en position 4 a un effet très limité sur le déplacement chimique de C2. On peut toutefois remarquer que les effets des groupements électroattracteurs en positions 4 et 5 sont additifs (composés **2***a*, **2***e*, **2***g* et **2***j*) (voir tableau 1).

L'interprétation des déplacements chimiques $\delta^{15}N$, dans le cas des thiazines **2***c*, **2***d*, **2***i* est rendue difficile par l'existence de l'effet topologique β du groupement en position 4 qui pourrait entraîner une différence supérieure à 10 ppm entre la valeur observée et la valeur théorique (11).

Ainsi on observe pour ces composés, par rapport aux thiazines, **2***a*, **2***b*, **2***g*, un déplacement chimique vers les hautes fréquences du signal de l'atome d'azote comme il a été observé lorsque ce dernier est hybridé sp^3 (12).



Vue en perspective du composé **2***b*[3]

[3]Les coordonnées de tous les atomes avec les β_{eq}, les longueurs et angles de liaisons avec écart-type ainsi que la liste des facteurs de structure sont disponibles. On peut les acheter en s'adressant au Dépôt de données non publiées ICIST, Conseil National de Recherche du Canada, Ottawa, (Ont.), Canada K1A 0S2.

TABLEAU 3. Paramètres angulaires et longueurs de liaison pour la 6*H*-thiazine-1,3 **2***b*

A : Angles dièdres entre plans moyens en degrés

Plan	Angle dièdre, degrés
C7—C8—C9—C10—C11—C12 / C6—N—C5—C2	3,7(6)

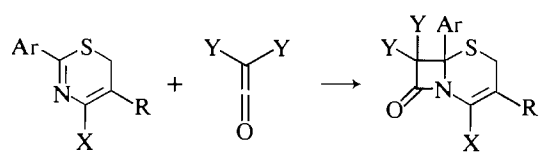
N—C6—S	124,3(3)

1.3. Diffractométrie X

Les résultats de la détermination structurale de **2***b* font apparaître le cycle benzénique, le groupe acétyle et l'enchaînement hétéroatomique C2—C5—N—C6 dans des plans très voisins, ce qui laisserait supposer l'existence d'un système conjugué. En fait, les longueurs de liaisons observées par rayons X sont très proches des valeurs mesurées pour ces mêmes liaisons dans des systèmes isolés (14). Les paramètres cristallographiques de la 6*H*-thiazines-1,3 **2***b* sont rassemblés dans les tableaux 2 et 3.

2. Céphèmes

L'accès aux composés β-lactamiques **3** par action du diphénylcétène en solution toluénique (90°C) ou du dichlorocétène généré *in situ* dans le benzène sur les 6*H*-thiazines-1,3 substituées dépend de la nature des substituants en positions 4 et 5 de la thiazine **2** (voir tableau 4).



2 **3**

Ar = C_6H_5 Y = C_6H_5, Cl

2.1. Cyclocondensation et cycloreversion

L'accès direct aux composés β-lactamiques **3** a été possible,

TABLEAU 4. Céphèmes **3** : paramètres rmn ^1H et ^{13}C, ppm (TMS), et infrarouge, cm^{-1}

Composés	R	X	Y	Rdt %	δH_A	δH_B	$J_{H_A-H_B}$,Hz	J_{H_A-X},Hz	$\delta_{C=O}$ lactame	$\nu_{C=O}$ lactame

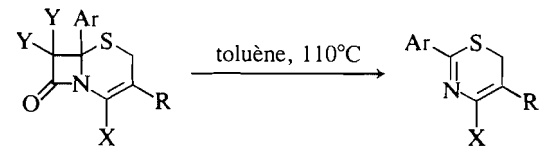
3′*a*	$CH{=}CCl_2$	H	Cl	15	2,95	3,63	17,0	2,2	157,2	1800
3*b*	$COCH_3$	H	C_6H_5	95	2,59	3,85	17,4	2	167,3	1780
3′*b*	$COCH_3$	H	Cl	27	2,59	3,98	17,6	2,1	158,3	1815
3*c*	CHO	CH_3	C_6H_5	33	2,52	3,66	16,7	—	168,3	1785
3*d*	$COCH_3$	CH_3	C_6H_5	79	2,75	3,37	16,3	—	167,8	1775
3*g*	$CH(SC_6H_5)_2$	H	C_6H_5	82	2,79	3,54	16,5	2,1	165,8	1760
3′*g*	$CH(SC_6H_5)_2$	H	Cl	60	2,77	3,67	17,0	2,1	156,9	1805
3*i*	$CH(SC_6H_5)_2$	CH_3	C_6H_5	55	2,84	3,59	16,4	—	167	1770
3*j*	$CH(SC_6H_5)_2$	CO_2Et	C_6H_5	75	3,12	3,61	17,3	—	166,1	1780
3*l*	$CH(OCH_2)_2$	CO_2Et	C_6H_5	50	2,75	3,37	18,3	—	166,3	1760

lorsque les 6*H*-thiazines-1,3 ne sont pas simultanément substituées en positions 4 et 5 par un groupement carbonylé (composés **2***g* et **2***i*) ou lorsque ces thiazines possèdent un seul groupement carbonylé en position 4 (composé **2***j*) ou 5 (composés **2***a*, **2***b*, **2***c*, **2***d*).

Les réactions de cyclocondensation entre les 6*H*-thiazines-1,3 **2** et le diphénylcétène ont conduit aux céphèmes correspondants **3** avec de bons rendements (toluène, 90°C). Toutefois une élévation de température peut entraîner la thermolyse du céphème obtenu. Ainsi les céphèmes **3***a*, **3***b*, **3***c*, **3***d* conduisent respectivement par cycloreversion (toluène, 110°C) aux 6*H*-thiazines-1,3 précurseurs **2***a*, **2***b*, **2***c*, **2***d*.

Ces réactions de cycloreversion sont à rapprocher de celles mentionnées dans la littérature pour des cycles β-lactamiques (15).

L'analyse par spectrométrie de masse des céphèmes indique la formation de l'ion $(M - (C_6H_5)_2C{=}C{=}O)^{+\cdot}$ pic de base des spectres en bon accord avec les fragmentations observées pour des structures β-lactamiques (16).



Y = Ar = C_6H_5
3*a*–**3***e* **2***a*–**2***e*

Dans les mêmes conditions nous n'avons pu accéder au céphème **3***e* par action du diphénylcétène sur **2***e*. La difficulté d'obtention de ce composé pourrait être liée à un écart relativement faible entre l'énergie nécessaire à la cyclocondensation et celle correspondant au seuil de reversibilité de la réaction. Nous avons pu vérifier que **3***e* obtenue par une synthèse indirecte se thermolysait effectivement.

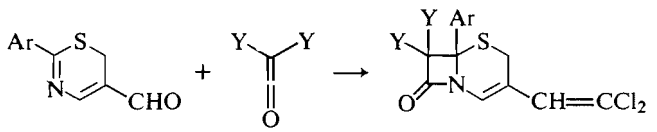
En effet, l'action de l'éthylène glycol en présence d'APTS suivie de l'addition du diphénylcétène sur la 6*H*-thiazine-1,3 **2***e* fournit le céphème **3***l*. La libération de la fonction aldéhyde à partir de **3***l* permet d'accéder à **3***e*. La thermolyse de **3***e* (toluène, 110°C) redonne la 6*H*-thiazine-1,3 **2***e*.

La mise en évidence de la cycloreversion indique que les réactions entre thiazines et cétènes sont sous contrôle thermodynamique. Les corrélations entre structure et réactivité ne peuvent être envisagées qu'avec une extrême prudence malgré la similitude des déplacements chimiques observés pour le carbone C2 entre **2***a*, **2***b* d'une part et **2***e*, **2***f* d'autre part (voir tableau 1).

2.2. *Réactions particulières*

Ces réactions sont observées avec les 6*H*-thiazines-1,3 substituées en position 5 par un groupement aldéhyde.

L'action du dichlorocétène sur la 6*H*-thiazine-1,3 **2***a* conduit au céphème **3**″*a*. Dans ce cas, le dichlorocétène réagit aussi sur la fonction aldéhyde (17).



2*a* **3**″*a*
Ar = C_6H_5 Y = Cl

D'autre part, il est possible d'accéder au céphème **3***g* après protection de la fonction aldéhyde du céphème **3***a* sans altérer le cycle β-lactamique (action du thiophénol en présence d'acide de Lewis).

Les données spectroscopiques enregistrées (ir, rmn ^{13}C) pour les céphèmes **3** sont en bon accord avec celles de la littérature (16,18).

En résumé, les résultats expérimentaux ci-dessus permettent de penser que les cyclocondensations de cétènes et précurseurs sont d'autant plus aisées que l'encombrement stérique en position 4 et l'attraction électronique sur les carbones C4 et C5 des 6*H*-thiazines-1,3 sont plus faibles.

Partie expérimentale

L'Amberlyst 15 commercial (Janssen Chimica) est séché à l'étuve à 120°C.

Les chromatographies sur colonnes sont effectuées sur gel de silice Merck (Kieselgel 60, 70–230 mesh ASTM). Les points de fusion sont déterminés à l'aide d'un microscope Reichert à platine chauffante Kofler. Les spectres ir sont enregistrés à l'aide d'un spectrophotomètre UNICAM SP 1100. Les mesures sont faites sur les substances dispersées dans le bromure de potassium. Les fréquences sont exprimées en cm^{-1}.

Les spectres de rmn ^1H et ^{13}C sont enregistrés respectivement à l'aide des appareils Perkin–Elmer R-24-B (60 MHz) ou JEOL MH 100 (100 MHz) et Brucker WH 90 (20, 115 MHz). Les produits sont examinés en solution dans le $CDCl_3$, les déplacements chimiques (δ par rapport au TMS) sont exprimés en ppm et les constantes de couplage en hertz (Hz). Les spectres de rmn ^{15}N sont enregistrés à l'aide d'un appareil Brucker WM 250 (25, 355 MHz). Les déplacements chimiques sont exprimés en ppm par rapport à CH_3NO_2 utilisé comme référence interne.

Les spectres de masse sont enregistrés à l'aide d'appareils Varian MAT 311 et Varian MAT 112 à double focalisation (énergie d'ionisation 70 eV).

Les analyses sont effectuées par le service de microanalyse du CNRS.

Caractéristiques cristallographiques de **2**b

$C_{12}H_{11}NOS$ Monoclinique, $P2_1/c$, a = 12,258(3), b = 9,313(2), c = 9,785(2) Å, β = 98,90(2)°, V = 1103,6(4) Å^3, Z = 4, d_{calc} = 1,31 Mg m^{-3}, μ = 0,25 mm^{-1}. Le cristal utilisé (plaquette 0,4 × 0,2 × 0,05 mm obtenue d'une solution dans l'éthanol) a fourni 3360 réflexions uniques dont 1048 avec $\mathbf{I} > \sigma(I)$. Les mesures ont été effectuées avec un diffractomètre automatique CAD-4 Enraf–Nonius du Centre de Diffractométrie de l'Université de Rennes. (λ(MoKα) = 0,71069 Å, balayage $\omega/2\theta$ = 1, θ_{max} = 25° ; h : 0,17; k = 0,13; l = −13,13; R_{int} = 0,018).

Après corrections de Lorentz polarisation, dispersion anomale du soufre comprise (la source des facteurs de diffusion étant les tables internationales de cristallographie, volume IV, 1974), la structure a été résolue en utilisant les méthodes directes à l'aide du jeu de programmes SDP Enraf–Nonius sur un calculateur PDP 11/60 Digital. La carte de densité obtenue avec le meilleur set a révélé la totalité des atomes non hydrogène. Après affinements isotropes, puis anisotropes, une seule différence de Fourier a suffi pour déterminer la totalité des atomes d'hydrogène (entre 0,40 et 0,21 e Å^{-3}). Le meilleur affinement par moindres carrés par matrice complète de tous les paramètres (sauf les coefficients thermiques des atomes d'hydrogène fixés à 4 Å^2) a donné R = 0,049, R_w = 0,043 et S = 1,21, le schéma de pondération utilisé étant : $1/w = \sigma^2/F_o = \frac{1}{4} \mid (\sigma^2/I) + (0{,}04)^2 I \mid$ et la fonction minimisée : $\Sigma w(\Delta F)^2$. Le résidu de densité électronique est alors inférieur à 0,15 e Å^{-3}.

*Formyl-5 phényl-2 6*H*-thiazine-1,3* **2**a

À une solution de 25 mmol de **1***a* dans 50 cm^3 de dichlorométhane on ajoute 100 mmol d'acroléine en présence d'hydroquinone. On maintient l'agitation magnétique 2 h à température ambiante. Après évaporation des solvants, la 6*H*-thiazine-1,3 est chromatographiée (éluant : dichlorométhane). Par cristallisation dans un mélange éthanol – éther de pétrole, on obtient, 3,8 g de **2***a*.

*Acétyl-5 phényl-2 6*H*-thiazine-1,3* **2**b

Une solution de 25 mmol de **1***a* dans 125 mmol de méthylvinylcétone en présence d'hydroquinone est portée à reflux pendant 2 h. Après concentration, **2***b* cristallise dans un mélange éthanol – éther de pétrole. On obtient 5,2 g de thiazine.

On peut obtenir également **2***b* en ajoutant 5 mmol de chlorure d'aluminium et 25 mmol de méthylvinylcétone à une solution de 5 mmol de **1***a* dans 20 cm^3 de dichlorométhane à −20°C.

*Méthyl-4 phényl-2 6*H*-thiazines-1,3* **2**c *et* **2**d

À une solution de 1 mmol de **1***b* dans 20 cm^3 de dichlorométhane, à température ambiante, on ajoute, 0,3 g d'Amberlyst 15 et 10 mmol d'acroléine ou de méthylvinylcétone en présence d'hydroquinone sous agitation magnétique. L'évolution de la réaction est suivie par chromatographie sur couche mince. Après filtration, la solution est chromatographiée sur colonne (éluant : éther de pétrole – acétate d'éthyle 80:20). **2***c* : cristaux jaunes fondant à 88°C; m/z = 217. **2***d* : cristaux jaunes fondant à 75–77°C. *Anal.* calc. pour $C_{13}H_{13}NOS$: C67,50, H 5,67, S 13,86; tr. : C 67,93, H 5,63, S 13,94.

*Éthoxycarbonyl-4 phényl-2 6*H*-thiazines-1,3* **2**e *et* **2**f

À une solution de 3 mmol de **1***c* dans 20 cm^3 de dichlorométhane, dans la glace, on ajoute 3 mmol de chlorure d'aluminium pulvérisé, puis 24 mmol d'acroléine ou de méthylvinylcétone en présence d'hydroquinone. Le mélange est maintenu sous agitation magnétique et l'évolution de la réaction suivie par chromatographie sur couche mince. En fin de réaction on ajoute 60 cm^3 de dichlorométhane et 40 cm^3 d'eau. Après décantation, séchage et évaporation des solvants, la thiazine est purifiée par chromatographie sur colonne (éluant : éther de pétrole – acétate d'éthyle 80:20). La cristallisation est effectuée dans un mélange éthanol – éther de pétrole. **2***e* : cristaux jaunes fondant à 88–90°C. *Anal.* calc. pour $C_{14}H_{13}NO_3S$: C 61,07, H 4,76, S 11,64; tr. : C 60,87, H 4,63, S 11,63. **2***f* : cristaux jaunes fondant à 66–67°C. *Anal.* calc. pour $C_{15}H_{15}NO_3S$: C 62,26, H 5,23, S 11,08; tr. : C 62,00, H 5,22, S 10,96.

*Phényl-2 bis(phénylthio) méthyl-5 6*H*-thiazines-1,3* **2**g, **2**i, **2**j

À 3 mmol de **2***a*, **2***c*, ou **2***e* dans 20 cm^3 de dichlorométhane, on oppose 9 mmol de thiophénol en présence de 9 mmol d'éthérate de trifluorure de bore. L'agitation magnétique à température ambiante est poursuivie pendant 3 h. La solution est ensuite lavée par l'hydrogénocarbonate de sodium et extraite à l'éther diéthylique, puis chromatographiée sur colonne (éluant : dichlorométhane – éther de pétrole 50:50). Les composés obtenus sont recristallisés dans un mélange éthanol – éther de pétrole. **2***g* : cristaux jaunes fondant à 104–105°C. *Anal.* calc. pour $C_{23}H_{19}NS_3$: C 68,11, H 4,72, S 23,72; tr. : C 68,34, H 4,71, S 23,51. **2***i* : cristaux jaunes fondant à 79–81°C; m/z = 419. **2***j* : cristaux jaunes fondant à 82–83°C. *Anal.* calc, pour $C_{26}H_{23}NO_2S_3$: C 65,37, H 4,85, S 20,14; tr. : C 65,84, H 4,87, S 19,59.

*(Dioxolanne-1,3 yl-2)-5 phényl-2 6*H*-thiazine-1,3* **2**h

À 5 mmol de **2***a* dans 50 cm^3 de benzène anhydre, on oppose 15 mmol d'éthylène glycol en présence d'une trace d'acide paratoluène sulfonique. Le mélange réactionnel est porté à reflux pendant 16 h. L'eau formée est éliminée à l'aide d'un séparateur de Dean et Stark. La solution est lavée à l'hydrogénocarbonate de sodium, puis extraite à l'acétate d'éthyle. Après élimination du solvant et recristallisation dans un mélange acétate d'éthyle – éther de pétrole, **2***h* est obtenu sous forme de cristaux jaunes fondant à 89°C. *Anal.* calc. pour $C_{13}H_{13}NO_2S$: C 63,13, H 5,30, S 12,97; tr. : C 62,87, H 5,30, S 13,01.

*Formyl-5 méthyl-6 6*H*-thiazine-1,3* **2**k

À une solution de 10 mmol de **1***a* dans 15 cm^3 de toluène, on ajoute 5 cm^3 de crotonaldéhyde (5 équiv.) à 15% d'eau. On porte à reflux sous agitation magnétique. La disparition de **1***a* est suivie par chromatographie sur couche mince. Après concentration et chromatographie sur colonne (éluant : éther de pétrole – acétate d'éthyle 90:10), on isole une huile jaune, m/z = 217.

Triphényl-6,7,7 céphèmes **3**a, **3**b, **3**c, **3**d, **3**g, **3**i, **3**j

Le diphénylcétène est préparé selon la méthode décrite dans la littérature (19).

À une solution de 5 mmol de thiazines **2***a*, **2***b*, **2***c*, **2***d*, **2***g*, **2***i* ou **2***j* dans 20 cm^3 de toluène sec, sous atmosphère d'azote, sont ajoutées

7 mmol de diphényl cétène en solution dans 10 cm^3 de toluène sec. Le mélange réactionnel est porté à 100°C sous agitation magnétique. L'évolution est suivie par rmn. Les produits obtenus sont recristallisés dans l'éthanol. **3***a* : cristaux blancs fondant à 162–164°C. *Anal.* calc. pour $C_{25}H_{19}NO_2S$: C 75,54, H 4,82, S 8.07, tr. : C 75,64, H 4,89, S 8,15. **3***b* : cristaux blancs fondant à 148–150°C. *Anal.* calc. pour $C_{26}H_{21}NO_2S$: C 75,88, H 5,14, S 7,79; tr. : C 76,38, H 5,40, S 7,52. **3***c* : cristaux blancs fondant à 168°C. *Anal.* calc. pour $C_{26}H_{21}NO_2S$: C 75,88, H 5,14, S 7,79 ; tr. : C 75,58, H 5,44, S 7,37. **3***d* : cristaux blancs fondant à 163–165°C. *Anal.* calc. pour $C_{27}H_{23}NO_2S$: C 76,20, H 5,45, S 7,54 ; tr. : C 76,24, H 5,38, S 7,63. **3***g* : cristaux blancs fondant à 132–134°C. *Anal.* calc. pour $C_{37}H_{29}NOS_3$: C 74,09, H 4,87, S 16,04 ; tr. : 74,16, H 4,87, S 15,83. **3***i* : cristaux blancs fondant à 130–132°C. *Anal.* calc. pour $C_{38}H_{31}NOS_3$: C 74,35, H 5,09, S 15,67 ; tr. : C 74,57, H 5,22, S 15,31. **3***j* : cristaux blancs fondant à : 147–149°C. *Anal.* calc. pour $C_{40}H_{33}NO_3S_3$: C 71,50, H 4,95, S 14,32 ; tr. : C 71,80, H 4,97, S 14,02.

Dichloro-7,7 phényl-6 céphèmes **3**″a, **3**′b, **3**′g

Une solution de 5 mmol de thiazines **2***a*, **2***b* ou **2***g* et de 10 mmol du chlorure de l'acide dichloroacétique dans 50 cm^3 de benzène anhydre est portée à reflux sous atmosphère d'azote, avant addition goutte à goutte et sous agitation, d'une solution de 10 mmol de triéthylamine dans 25 cm^3 de benzène sec. L'avancement de la réaction est suivi par rmn. Le milieu réactionnel est ensuite lavé par HCl, 4 *N*, puis à l'eau, avant séchage et distillation du solvant.

3″*a* : Le reflux est maintenu 24 h et le meilleur résultat est obtenu en doublant les proportions de dichlorocétène (20 mmol pour 5 mmol de thiazine). Une chromatographie sur couche mince (gel de silice selon Stahl à 13% de plâtre; éluant ; éther de pétrole – éther diéthylique 2/3:1/3) permet l'obtention après recristallisation dans l'éther diéthylique de cristaux blancs fondant à 150°C, $m/z = 379$.

3′*b* : Après 5 h de reflux, les polymères formés sont éliminés par chromatographie sur colonne (éluant : éther diéthylique). La recristallisation dans un mélange chloroforme – éther diéthylique donne des cristaux blancs fondant à 137°C. *Anal.* calc. pour $C_{14}H_{11}Cl_2NO_2S$: C 51,23, H 3,38, Cl 21,61, N 4,27, S 9,77 ; tr. : C 51,29, H 3,33, Cl 21,40, N 4,31, S 9,94.

3′*g* : Après 4 h de reflux, par dilution à l'alcool de l'huile obtenue, le céphème donne des cristaux blancs fondant à 148°C. *Anal.* calc. pour $C_{25}H_{19}Cl_2NOS_3$: C 58,13, H 3,71, Cl 13,73, N 2,71, S 18,62 ; tr. : C 57,88, H 3,79, Cl 13,59, N 2,62, S 18,42.

(Dioxolanne-1,3 yl-2)-3 éthoxycarbonyl-4 triphényl-6,7,7 céphème **3**l

Après blocage de la fonction aldéhyde de la thiazine **2***e* selon le même mode opératoire que celui utilisé pour transformer **2***a* en **2***h*, on ajoute 5 mmol de diphénylcétène à 3 mmol du composé obtenu dans 10 cm^3 de toluène sec, sous atmosphère d'azote. Le mélange réactionnel est porté à 90°C pendant 6 h sous agitation magnétique. Après concentration et recristallisation dans l'éthanol, on isole un solide blanc fondant à 161–162°C. *Anal.* calc. pour $C_{30}H_{27}NO_5S$: C 70,15, H 5,30, S 6,24 ; tr. : C 70,28, H 5,34, S 6,20.

Déprotection de la fonction aldéhyde du céphème **3**l *: éthoxycarbonyl-4 formyl-3 triphényl-6,7,7 céphème* **3**e

À une mmol de **3***l* dans 50 cm^3 d'éthanol on ajoute 0,5 cm^3 d'acide sulfurique concentré. L'agitation magnétique à température ambiante est poursuivie jusqu'à disparition totale du produit de départ (contrôle par chromatographie sur couche mince). Après lavage à l'eau, puis extraction par le dichlorométhane, une chromatographie est effectuée sur colonne de gel de silice (éluant : éther de pétrole – acétate d'éthyle 85:15). La recristallisation dans l'éther de pétrole fournit des cristaux blancs fondant à 155–156°C; Rdt 50%; ir(KBr) : 1790 (C=O β-lactame), 1735 (C=O ester), 1670 (C=O aldéhyde) cm^{-1}; rmn ($CDCl_3$) δ : 2,62, (d, 1H, H_A), 3,86 (d, 1H, H_B), J_{AB} = 18,4 Hz, 9,95 (s, 1H, CHO); sm m/z : 469 $(M)^+$, 194 $((C_6H_5)_2C{=}C{=}O)$. *Anal.* calc. pour $C_{28}H_{23}NO_4S$: C 71,62, H 4,94, S 6,83; tr. : C 71,23, H 4,94, S 6,82.

Thermolyse de **3**a–**3**e

Une solution toluénique (10 cm^3) de 0,25 mmol de céphèmes **3***a*–**3***e* est portée à reflux. L'apparition d'une coloration jaune intense de la solution ainsi que le contrôle par chromatographie sur couche mince révèlent la présence des thiazines **2***a*–**2***e* correspondantes. Après séparation des produits réactionnels par chromatographie sur colonne de gel de silice, les 6*H*-thiazines-1,3 **2***a*–**2***e* sont identifiées par résonance magnétique nucléaire.

JACQUES BERTHELOT et MICHEL FOURNIER. Can. J. Chem. **64**, 603 (1986).

L'action du tribromure de tétrabutylammonium ($TBABr_3$) sur différents alcynes (R—C≡C—R′, avec R et (ou) R′ = H, alcoyle, phényle, carboxyle, carbonyle) dans le chloroforme à 20°C conduit à la formation exclusive et stéréospécifique de l'isomère *E* de l'alcène 1-2 dibromé correspondant. Pour expliquer ce résultat nous proposons un mécanisme faisant intervenir comme intermédiaire un zwitterion bromé cyclique.

JACQUES BERTHELOT and MICHEL FOURNIER. Can. J. Chem. **64**, 603 (1986).

The reaction of tetrabutylammonium tribromide ($TBABr_3$) with alkynes (R—C≡C—R′, with R and (or) R′ = H, alkyl, phenyl, carboxyl, carbonyl) in chloroform at 20°C gives only the corresponding *E* 1,2-dibromo alkene in high yields. A mechanism involving a cyclic brominated zwitterion is suggested to account for the results, especially the stereospecificity of this *E*-addition.

De nombreux agents bromants, notamment les tribromures d'alkylammonium (triméthylphénylammonium (1), pyridinium, quinoleum (2)), ont été jadis utilisés pour éviter les inconvénients d'emploi du brome (très toxique et corrosif). En général, ils présentent l'inconvénient d'être peu stables, d'avoir un degré de brome actif diminuant rapidement au cours du temps ou d'être faiblement solubles.

Nous avons récemment décrit une méthode simple, pour additionner du brome sur les doubles liaisons éthyléniques (3) ou pour le substituer sélectivement en α d'acétals (3), qui utilise le tribromure de tétrabutylammonium ($TBABr_3$).[2] Ce réactif, solide orangé (F = 84°C), très stable, non toxique, à degré de brome constant, est facilement utilisable dans des conditions douces (20°C).

En outre, si l'addition électrophile du brome sur les oléfines a été très étudiée, les principaux détails étant bien connus (4), la réaction correspondante sur les alcynes l'est beaucoup moins et n'a suscité que peu d'attention (5).

L'halogénation des alcynes (chloration, iodation et surtout bromation) a été effectuée soit par l'halogène en solution (principalement dans l'acide acétique) (6*a, b*), soit à l'aide des halogénures métalliques (dérivés cuivriques essentiellement) en phase liquide et au reflux du solvant (7*a–e*). Dans tous les case, ces réactions conduisent à des mélanges d'alcènes 1–2 dibromés (*E* et *Z*), le plus souvent souillés de produits secondaires (alcènes monobromés, alcènes tribromés, composés d'addition du solvant) difficilement séparables. Dans les cas les plus favorables (absence de produits secondaires), il se forme toujours un mélange d'isomères *E* et *Z*, l'isomère *E* étant en général majoritaire (8). En outre, les rendements globaux en produits isolés purs sont souvent très moyens (45–65%) et l'halogène ou le sel cuivrique doivent être en large excès (de 5 à 20 fois la quantité d'alcyne). Dans la plupart des cas, il faut opérer au reflux du solvant. Par contre, nous signalons qu'en effectuant l'addition du brome, assistée d'ions bromures en

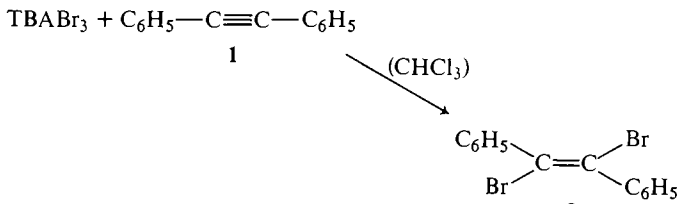

FIG. 1

milieu hydroacétique, sur l'ester éthylique de l'acide phénylpropionique, Berliner *et al.* n'obiennent que l'isomère *E* 1–2 dibromé (9, 10).

Pour ces raisons, il était tentant de comparer l'action de $TBABr_3$ sur les alcynes à celle des agents bromants habituellement utilisés en espérant un gain de rentabilité.

Résultats

Nous avons pris comme modèle d'étude la bromation du diphényl-1,2 acétylène (**1**) ou tolane (figure 1).

L'évolution de la réaction est suivie pour différents solvants, à diverses températures, en faisant varier les concentrations relatives des réactifs. Dans tous les cas, que ce soit à basse température avec des conditions stoechiométriques des réactifs ou en prolongeant la durée de réaction, à température plus élevée et avec une plus grande concentration en $TBABr_3$, seul l'isomère *E* est obtenu; nous n'avons jamais détecté (même en ccm (chromatographie sur couche mince)) la présence de l'isomère *Z* et aucun produit provenant de réactions secondaires ne vient perturber la réaction. Ces résultats sont résumés dans les tableaux 1 et 2.

Nous constatons que si la concentration relative de $TBABr_3$ augmente par rapport à celle du tolane, le rendement en alcène 1–2 dibromé diminue par suite de l'apparition d'une résinification, mais nous ne récupérons ni l'isomère *Z* de cet alcène, ni le produit de départ. Quels que soient la température et le rapport Br_3^-/alcyne, nous n'avons jamais obtenu le tétrabromo-1,1,2,2 diphényl-1,2 éthane. Comme nous l'avions déjà remarqué avec les alcènes (3) soumis à l'action bromante de $TBABr_3$, c'est le chloroforme, peu polaire, qui permet d'obtenir les

f	1	1	20	48	96	—
g	1	1	60	6	95	—
h	1	2	20	8	56	35
i	1	2	20	30	90	—
j	1	2	60	6	88	—
k	1	3	20	30	85	—
l	1	1	84	3	92	—
m	1	3	84	3	88	—

*Ces essais sont effectués sur 4 mmol de tolane, 4 mmol de $TBABr_3$ (1:1) dans 18 mL de $CHCl_3$. Les rendements indiqués sont ceux des produits isolés et purs après séparation par cp (éluant: éther de pétrole 95 – éther 5) s'il restait du produit initial. Les essais l et m ont été effectués en mélangeant $TBABr_3$ et le tolane solides et en portant à la fusion de $TBABr_3$ (84°C).

TABLEAU 2. Action de $TBABr_3$ sur le tolane dans différents solvants*

Solvant	Volume (mL)	**2** obtenu (%)	**1** restant (%)
$CHCl_3$	18	97	—
CCl_4	25	78	17
CH_3CN	20	80	15
THF	30	74	45
EtOH	45	25	70
MeOH	45	20	74

*Réactions toutes effectuées sur 4 mmol de tolane et 4 mmol de $TBABr_3$ à 20°C pendant 30 h. Les rendements sont indiqués en produits purs et isolés (cf. tableau 1). Les volumes de solvant utilisés sont fonction de la solubilité des réactifs.

meilleurs résultats; les alcools (plus polaires, mais solubilisant moins bien les réactifs) sont moins adaptés à ces réactions, ce qui avait déjà été remarqué par d'autres auteurs lors des différents essais d'halogénation (7*a*, 7*e*).

La différence de vitesse d'addition d'un même réactif conjointement sur un alcène et l'alcyne correspondant est bien connue (4, 10). Il en est de même lorsque nous faisons réagir $TBABr_3$ sur le *trans*-stilbène et le tolane dans la même solution chloroformique (à 20°) et en même concentration (tableau 3). En outre, si l'on soumet le dibromo-1,2 diphényl-1,2 éthylène *E* (**2**), lui-même, à l'action de $TBABr_3$ dans des conditions stoechiométriques et pendant dix jours à 20°C, seul (**2**) est récupéré quantitativement. Ces résultats obtenus avec le tolane comme modèle nous ont permis d'obtenir, dans les meilleures conditions et avec la même sélectivité, uniquement des alcènes 1–2 dibromés *E*, lorsque différents alcynes ont été soumis à l'action de $TBABr_3$ (tableau 4).

Dans tous ces essais, les rendements bruts sont pratiquement quantitatifs; les rendements en produits isolés sont plus faibles surtout dans le cas des liquides, s'ils sont purifiés par distillation, les alcènes 1–2 dibromés étant fragiles à la chaleur (polymérisation facile). Dans ce cas, la meilleure méthode de purification est la chromatographie préparative (cp) sur silice (cas de *d* notamment). La structure et la stéréochimie des produits **9–14** a été confirmée par comparaison avec des échantillons, connus, par leurs spectres de masse et de rmn ^1H (résonnance magnétique nucléaire) (cf. partie expérimentale). Il est à noter que, comme avec le tolane, nous n'avons jamais obtenu de composés tétrabromés.

Discussion

Dans les études antérieures (7*e*, 12) la bromation des alcynes, que ce soit par le brome ou par ses sels métalliques, semble toujours être de nature ionique. De même la bromation du tolane par $TBABr_3$ n'est par affectée par la présence de *méta*-dinitrobenzène ou d'oxygène (réputés capteurs de radicaux), et donne les mêmes résultats à la lumière ou à l'obscurité, sous gaz inerte (argon) ou à l'air. La réaction est toujours stéréospécifique, les rendements et les durées de réaction étant inchangés. Nous pensons donc que cette addition de $TBABr_3$ sur les alcynes est également de nature ionique. En utilisant le brome, ou $CuBr_2$, la formation du mélange en proportions variables des isomères *E* et *Z* pose des problèmes pour l'interprétation mécanistique du phénomène malgré des études approfondies (7*a*, 7*d*, 12). Il a déjà été montré que dans les tribromures d'ammonium, l'anion Br_3^- avait une structure linéaire (1), où les liaisons entre les atomes de brome étaient plus fragiles que celle de la structure moléculaire, et on a postulé qu'il pourrait réagir suivant:

$$Br_3^- \rightleftarrows Br^- + Br_2$$

Cette formation de brome moléculaire devrait donc conduire dans notre cas à la formation du mélange des isomères *E* et *Z* soit par addition analogue à celle du brome sur un alcyne soit par isomérisation ultérieure de l'alcène 1–2 dibromé *E* catalysée par le brome (7*e*). Or nous n'obtenons jamais d'isomère *Z*, même en laissant réagir d'une façon équimoléculaire du $TBABr_3$ et du diphényl-1,2 dibromo-1,2 éthylène pendant dix jours dans les conditions de la réaction. Par contre, si l'action du brome sur le méthylphénylacétylène conduit à un mélange d'isomères *E*, *Z*, seul l'isomère *E* est pratiquement (99%) obtenu quand il est soumis à l'addition du brome en présence de LiBr (16). De plus, comme nous l'avons déjà signalé, par addition de brome assistée d'ions bromures sur le phénylpropionate d'éthyle, seul l'isomère *E* est formé (9, 10). Ces résul-

TABLEAU 3. Différence d'action de $TBABr_3$ sur le tolane et le *trans*-stilbène*

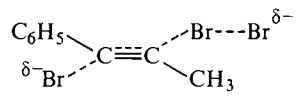

FIG. 2

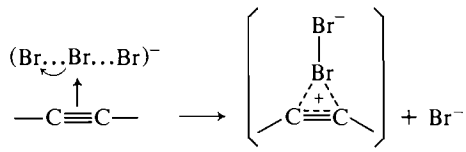

FIG. 3

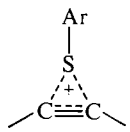

FIG. 4

tats avaient amené à postuler l'existence d'un ion Br_3^-, non dissocié, et son addition sur l'alcyne par un processus trimoléculaire de type Ad_E3, passant par un état de transition de nature comparable à celui de la fig. 2, après attaque du brome et de l'ion bromure sur les deux carbones de la triple liaison (10, 11). En ce qui concerne $TBABr_3$, nous pouvons rappeler que ce dernier, agissant sur un alcène *E*, tel que le *trans*-stilbène, conduit exclusivement à l'alcane 1–2 dibromé *méso* (3), donc à une addition en *anti* sur chaque carbone de la double liaison, compatible avec la formation intermédiaire, comme dans l'halogénation moléculaire (4), d'un ion bromonium cyclique.

De plus, nous opérons en solvant chloroformique alors que les essais d'addition du brome en présence d'ions bromures sont effectués dans l'acide acétique aqueux. C'est pourquoi, sans rejeter le mécanisme Ad_E3 cité précédemment, nous pouvons également supposer que l'action de $TBABr_3$ sur les alcynes se fait selon un mécanisme Ad_E2, impliquant le passage dans ce cas par un zwitterion cyclique bromé intermédiaire (fig. 3) suivi d'une addition *trans* d'ion Br^- (ou Br_3^-) sur ce zwitterion, conduisant à l'alcène 1–2 dibromé *E*. On peut noter que ce mécanisme avec un intermédiaire cyclique a déjà été établi dans le cas de l'addition d'halogénures de sulfényles sur le phényl-1 propyne (fig. 4), où aucune *cis* addition n'a été observée (17).

Conclusion

L'utilisation de $TBABr_3$, réactif non toxique, très facilement utilisable (stable et à degré de brome constant) dans des conditions expérimentales douces et dans les solvants usuels a donc permis de bromer, avec de bons rendements, des alcynes d'une façon très sélective (absence de produits secondaires) et très stéréospécifique puisque seul l'isomère 1–2 dibromé *E* est obtenu, ce qui est d'un intérêt synthétique évident. Bien que le mécanisme d'addition ne soit pas définitivement établi, nous apportons les indices sur sa nature très vraisemblablement ionique.

Partie expérimentale

Les points de fusion ont été déterminés au banc de Köfler, les spectres infrarouges (ir) ont été obtenus avec un spectromètre Pye–Unicam SP3-200, ceux de rmn ^1H (en solution dans $CDCl_3$, référence interne HMDS) avec un appareil Varian EM-360. Les spectres de masse (sm) ont été effectués sur un appareil AEI MS-30. Les chromatographie sur couche mince (ccm) et préparatives (cp) ont été réalisées sur gel de silice fluorescente "Merck PF 254." Les alcynes utilisés sont des produits commerciaux (Merck ou Alfa).

*Procédé général de bromation par $TBABr_3$ (cas du tolane **1**)*

À 4 mmol d'alcyne dans 18 mL de chloroforme on ajoute lentement, à température ambiante et sous agitation, 4 mmol de $TBABr_3$ (environ 20 min) ; la solution rouge intense vire lentement au rose puis au jaune. On laisse agiter pendant plusieurs heures en suivant l'évolution de la réaction par ccm (cf. tableau 1). La solution chloroformique est ensuite lavée deux fois par 20 mL d'une solution aqueuse contenant 5% de thiosulfate de sodium, puis trois fois par 20 mL d'eau, et enfin séchée sur sulfate de sodium. Le solvant est évaporé sous vide et le résidu est cristallisé (MeOH), puis recristallisé (MeOH). L'alcène 1–2 dibromé **2** est obtenu brut quantitativement, puis avec un rendement de l'ordre de 95% après purification (controlée par ccm) ; *F* net 214°C (litt. *F* (7*a*) 210°C). Quand le réaction est incomplète (cf. tableau 1) le tolane restant est séparé de **2** par cp. Comme nous l'avons déjà signalé (tableau 4), si les rendements bruts sont quantitatifs, avec les autres alcynes, ils sont plus faibles en produits purs quand ceux-ci sont liquides, après distillation (d'où l'emploi de la cp pour les obtenir, cas de **12** en particulier).

Principales caractéristiques spectrales des alcènes 1–2 dibromés E

La spectrographie de masse donne d'utiles indications, notamment par la présence déjà signalée (8) du pic moléculaire $M^{+\cdot}$ caractéristique d'un composé dibromé (formé de trois raies d'intensité relative 1, 2, 1). Ces alcènes dibromés présentent également tous les pics suivants : $(M - Br)^+$, formé de 2 raies d'égales intensités et $(M - 2Br)^+$ qui est souvent le pic de base (cas de **2**, **9**, **10**, **11** et **12** ; pour **11** il s'agit de $(M - (2Br + CO_2))^+$).

En ce qui concerne la rmn ^1H il a déjà été constaté, pour les alcènes dibromés vinyliques (8) ou contenant un groupement méthyle lié au carbone sp^2 (12), des déplacements différents pour les isomères *E* et *Z* en ce qui concerne cet hydrogène vinylique ou ce groupement méthyle. Avec les alcènes 1–2 dibromés de cette nature que nous obtenons, nous retrouvons bien uniquement ces pics caractéristiques d'isomères *E*: **9**: 6,7 ppm (s, 1H); **14**: 6,6 ppm (s, 1H); **10**: 2,6 ppm (s, 3H).

Propriétés de solvation des solutions concentrées en acide phosphorique

C. Louis et J. Bessière

Laboratoire de chimie et d'electrochimie analytique, Faculté des sciences, Université de Nancy 1, B.P. 239, 54506 Vandoeuvre Les Nancy CEDEX, France

Reçu le 10 avril 1985

C. Louis et J. Bessière. Can. J. Chem. **64**, 608 (1986).

Les variations de solvatation d'espèces en solution dans les milieux H_2O–H_3PO_4 (1–14 *M*) sont caractérisées par des coefficients d'activité de transfert de solvatation *f*. Ils sont calculés à partir des valeurs de potentiels normaux de systèmes redox ou de mesures de solubilité. Leur analyse met en évidence une augmentation de la solvatation des anions et une desolvatation des cations lorsque la concentration d'acide croît. L'amplitude de la variation dépend du nombre de charges portées par l'espèce considérée, de la présence d'atomes d'oxygène dans sa structure, de son caractère basique. Les conséquences des variations de solvatation sur les réactions d'oxydo-réduction et de précipitation sont analysées.

C. Louis and J. Bessière. Can. J. Chem. **64**, 608 (1986).

Solvation properties of ions in H_2O–H_3PO_4 media (1–14 *M*) are characterized with their solvation transfer activity coefficients *f*. These are calculated from normal potential or solubility values, and indicate an increasing solvation for anions and decreasing solvation for cations in concentrated acid solutions. For each species, the range depends on its number of charges, on the existence of oxygen atoms in its structure, and on its basic properties. The consequences of variation of solvation on oxidation–reduction reactions and solubility properties are studied.

Les variations avec la teneur en acide de la réactivité de solutés dans les milieux eau – acide phosphorique ont été étudiées dans le cas de réactions d'oxydo-réduction et de précipitation (1, 2). Elles peuvent être interprétées d'un point de vue thermodynamique à partir des variations de solvatation des espèces mises en jeu. Celles-ci sont caractérisées par des coefficients d'activité de transfert de solvatation *f*.

Rappel théorique

Les coefficients d'activité d'anions et de cations sont calculés à partir des potentiels normaux de systèmes redox les mettant en jeu d'après les relations:

[1] système M^{n+}/M_s $\quad \log f_{M^{n+}} = n(E_0^{H_2O-H_3PO_4} - E_0^{H_2O})/0{,}059$

[2] système $M^{n+}/M^{(n-m)+}$ $\quad \log f_{M^{(n-m)+}} = m(E_0^{H_2O-H_3PO_4} - E_0^{H_2O})/0{,}059$

[3] système $MO_p^{n+}/MO_q^{[n+2(p-q)-m]+}$ $\quad \log f_{MO_p^{n+}}/f_{MO_q^{[n+2(p-q)-m]+}} = m(E_0^{H_2O-H_3PO_4} - E_0^{H_2O})/0{,}059 + 2(p-q)R_0(H) + (p-q)\log a_{H_2O}$

[4] système AX_n/A_s $\quad \log f_{X^-} = (E_0^{H_2O} - E_0^{H_2O-H_3PO_4})/0{,}059$

où $E_0^{H_2O-H_3PO_4}$ représente le potentiel normal du système redox dans le milieu phosphorique exprimé par rapport au système de comparaison ferricinium/ferrocène (Fc^+/Fc) et $E_0^{H_2O}$ son potentiel normal dans l'eau; R_0 (H) est la fonction d'acidité du milieu phosphorique (1) et a_{H_2O} son activité en eau.

Ils sont dans certains cas calculés à partir de valeurs de produits de solubilité d'après la relation:

[5] $\quad pK_s^{H_2O-H_3PO_4} - pK_s^{H_2O} = \log f_{M^+} = \log f_{X^-}$

où $pK_s^{H_2O-H_3PO_4}$ représente le produit de solubilité du composé MX dans le milieu phosphorique et $pK_s^{H_2O}$ son produit de solubilité dans l'eau. La détermination de la solubilité de phosphate, par exemple $XHPO_4$, permet également le calcul des coefficients d'activité selon des relations analogues à:

[6] $\quad \log f_{X^{2+}} = R_0(HPO_4^{2-}) - pK_s^{H_2O} - \log [X^{2+}]$

où $R_0(HPO_4^{2-})$ caractérise le pouvoir donneur de HPO_4^{2-} du milieu et $pK_s^{H_2O}$ est le produit de solubilité dans l'eau.

Résultats et discussion

L'étude de l'évolution des propriétés d'oxydo-réduction et de solubilité dans les milieux H_2O–H_3PO_4 (2) conduit aux valeurs de $\log f$ ou de $\log f_{ox}/f_{red}$ rassemblées dans le tableau 1 et représentées par les figures 1 et 2.

1. Variation de solvatation de cations

Les cations Ag^+, Hg_2^{2+}, Cu^{2+}, Pb^{2+}, Sn^{2+}, Zn^{2+}, Cd^{2+} sont caractérisés par des valeurs positives et croissantes des logarithmes des coefficients d'activité avec la concentration d'acide. Ils sont donc de moins en moins solvatés lorsque la concentration d'acide augmente. Pour une concentration donnée en acide, les valeurs de $\log f_{M^{n+}}$ dépendent de la charge de l'ion. Ainsi, les variations de $\log f_{Ag^+}$ sont moins importantes que celles observées pour l'ensemble des cations divalents: l'écart est de 3 unités lorsque l'on passe du milieu 2 *M* au milieu 11,5 *M* alors qu'il est de 7 unités au minimum pour un cation divalent. Elles sont du même ordre de grandeur que celles de $\log f_{Fe^{3+}}/f_{Fe^{2+}}$ et $\log f_{V^{3+}}/f_{V^{2+}}$ qui correspondent à des systèmes mettant en jeu une seule charge et n'impliquant l'oxygène. Les valeurs $\log f_{Cu^{2+}}$ et $\log f_{Sn^{2+}}$ sont négatives dans les milieux peu concentrés en acide phosphorique, de même que

[1]Revision reçu le 13 novembre 1985.

$\log f_{I_3^-}$	−3,3	−4,0	−5,5		

les valeurs $\log f_{Fe^{3+}}/f_{Fe^{2+}}$ dans tout le domaine de concentration de H_3PO_4. Les espèces Cu^{2+}, Sn^{2+}, Fe^{3+} sont donc plus solvatées dans les milieux phosphoriques correspondants que dans l'eau. Dans la mesure où les systèmes considérés dans le solvant de référence ne font pas intervenir les phénomènes de complexation, on devait s'attendre, pour les solutions diluées en acide, à des valeurs négatives de $\log f_{Fe^{3+}}$ et dans un moindre mesure de $\log f_{Cu^{2+}}$, la complexation en solution diluée étant assimilable à un accroissement de solvatation. Une augmentation de la concentration de H_3PO_4 entraîne pour ces espèces une décomplexation (ou une diminution de solvatation), ce qui accroît leur réactivité. Ainsi, le pouvoir oxydant de Fe(III) est, en milieu 14 *M*, voisin de celui qu'il a dans l'eau en milieu non complexant ($\log f_{Fe^{3+}}/f_{Fe^{2+}} = -0,2$). Les ions Cd^{2+} et Zn^{2+}, qui ne donnent pas de complexe en solution aqueuse diluée en acide, sont caractérisés par des valeurs $\log f_{Cd^{2+}}$ et $\log f_{Zn^{2+}}$ positives dans le milieu de concentration 2 *M* en H_3PO_4. Ces ions sont déjà moins solvatés dans ce milieu que dans l'eau en milieu non complexant. Le terme $\log f_{M^{n+}}$ intègre donc les phénomènes de complexation qui peuvent avoir lieu en solution diluée, les notions de complexation et de solvatation dans de tels milieux étant confondues. Parmi les cations divalent, Cu^{2+}, Pb^{2+}, Hg_2^{2+} se desolvatent moins vite que Zn^{2+} et Cd^{2+}. Or, en milieu phosphorique, les espèces Pb^{2+} et Hg_2^{2+} donnent des composés insolubles avec les anions de l'acide, ce qui traduit une forte affinité. D'autre part, dans l'eau la stabilité des phosphates de cuivre et de plomb est supérieure à celle des phosphates de zinc et de cadmium: $Pb_3(PO_4)_2$, $pK_s = 43,5$; $Cu_3(PO_4)_2$, $pK_s = 36,9$; $Zn_3(PO_4)_2$, $pK_s = 32,0$; $Cd_3(PO_4)_2$, $pK_s = 32,6$ (3). La désolvatation des ions semble donc d'autant plus aisée qu'ils donnent des complexes moins stables avec les espèces phosphate. Les valeurs de pK_s de $Ba_3(PO_4)_2$ et $Ca_3(PO_4)_2$ sont respectivement de 29,3 et 26 (4) et les coefficients d'activité qui peuvent être calculés pour les cations Ba^{2+} et Ca^{2+} caractérisent une désolvatation comparable à celle de Zn^{2+}.

Lorsque l'on compare les systèmes UO_2^{2+}/U^{4+}, VO_2^+/VO^{2+}, VO^{2+}/V^{3+}, H_3AsO_4/AsO^+, l'effet de l'acidité est le même pour les trois premiers: deux protons mis en jeu pour un électron. Il est moins prononcé pour le dernier: trois protons pour deux électrons et c'est dans tous les cas la forme réduite qui est la plus chargée. C'est donc la désolvatation de cette espèce qui est prédominante. En effet, la quantité $\log f_{ox}/f_{red}$ est décroissante et sa variation est d'autant plus importante que l'écart entre le nombre des charges portées par la forme oxydée et la forme réduite est grand: elle est de 14 unités pour $\log f_{UO_2^{2+}}/f_{U^{4+}}$ et de 8 et 5 unités pour $\log f_{VO_2^+}/f_{VO^{2+}}$ et $\log f_{VO^{2+}}/f_{V^{3+}}$ lorsque l'on passe du milieu 2 *M* au milieu 14 *M* en H_3PO_4. Contrairement à ce qui a été observé pour les systèmes Fe^{3+}/Fe^{2+} et V^{3+}/V^{2+}, $\log f_{ox}/f_{red}$ est positif dans les milieux dilués en acide pour les trois systèmes UO_2^{2+}/U^{4+}, VO_2^+/VO^{2+}, VO^{2+}/V^{3+} ainsi que pour H_3AsO_4/AsO^+. Ceci signifie que ce sont les formes réduites qui sont initialement les plus fortement associées aux anions du solvant. Dans les milieux plus concentrés en acide où $\log f_{ox}/f_{red}$ est négatif, les termes de solvatation d'une part, d'acidité et d'activité de l'eau d'autre part, jouent un rôle antagoniste dans la variation du potentiel normal apparent des systèmes, mais la solvatation ne compense que partiellement l'influence de l'acidité et de l'activité de l'eau.

Le nombre des charges portées par les formes oxydées et réduites ne joue pas seul. La présence d'oxygène dans l'un ou l'autre des cations mis en jeu dans le système redox intervient également. Les deux systèmes UO_2^{2+}/U^{4+} et VO^{2+}/V^{3+} présentent une certaine analogie: les formes oxydées comportent des atomes d'oxygène, les formes réduites n'en comportent pas. Seul, les distingue le nombre des charges portées par les formes réduites et on observe que la variation de $\log f_{UO_2^{2+}}/f_{U^{4+}}$ est deux fois plus importante que celle de $\log f_{VO^{2+}}/f_{V^{3+}}$; les varia-

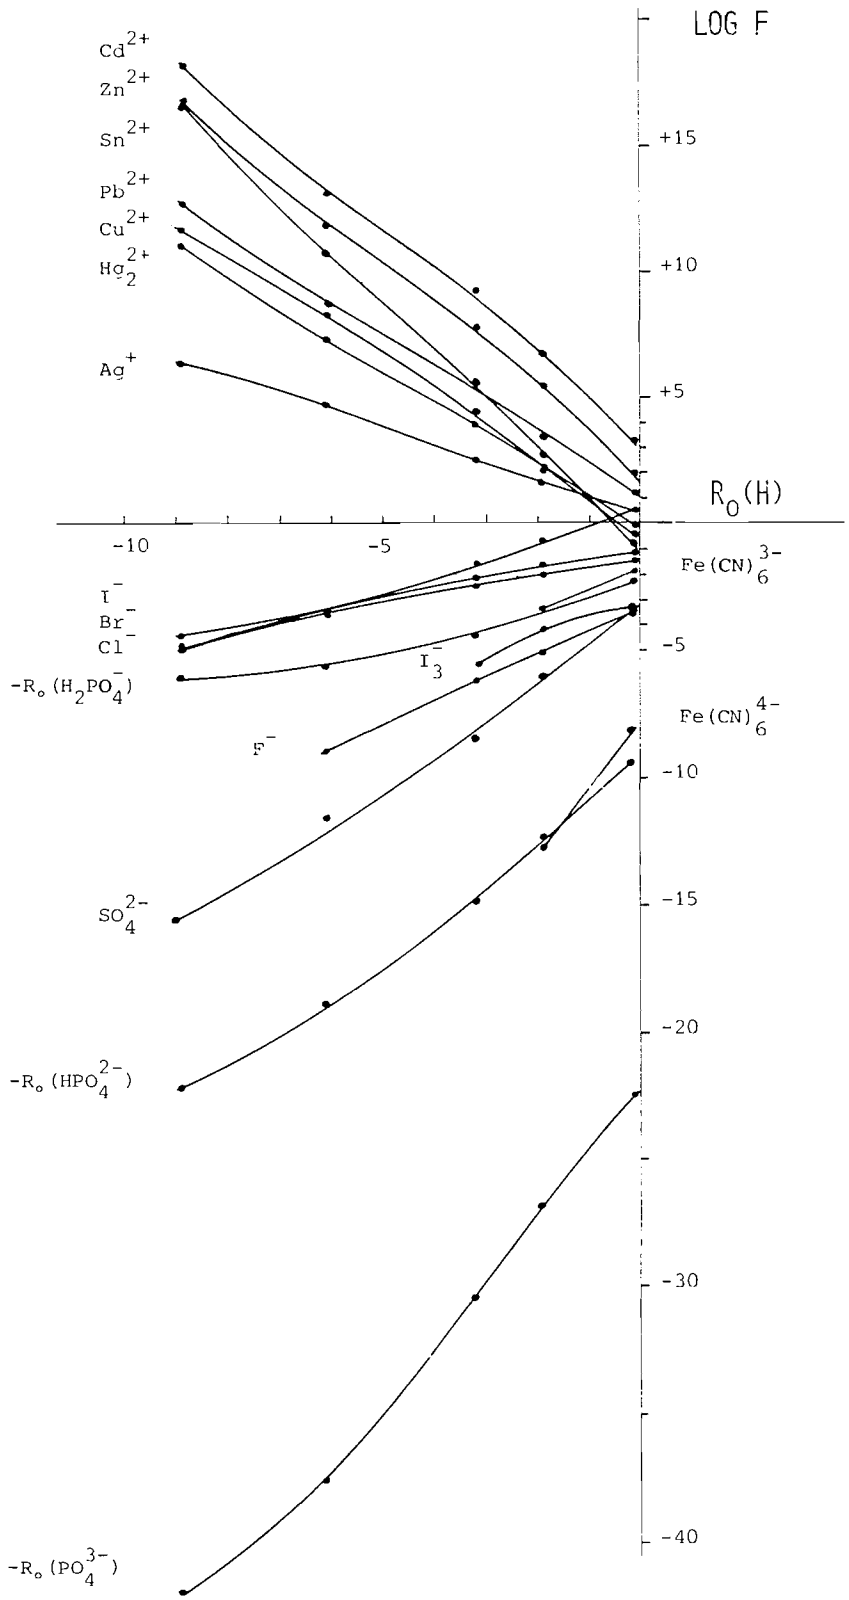

FIG. 1. Caractéristiques de solvatation des espèces en solution dans les milieux H_2O–H_3PO_4.

tions des potentiels normaux apparents de ces deux systèmes sont très voisines. La comparaison des systèmes VO_2^+/VO^{2+} et Fe^{3+}/Fe^{2+} ou V^{3+}/V^{2+}, pour lesquels le nombre de charges échangées est le même mais dont le premier seul met en jeu des espèces avec atome d'oxygène, montre que la variation de solvatation est deux fois plus grande dans le premier cas. L'effet de charge serait donc plus important pour les systèmes engageant deux espèces oxygénées.

2. Variation de solvatation des anions

La solvatation des anions croît avec la concentration de l'acide et sa variation est d'autant plus importante que les

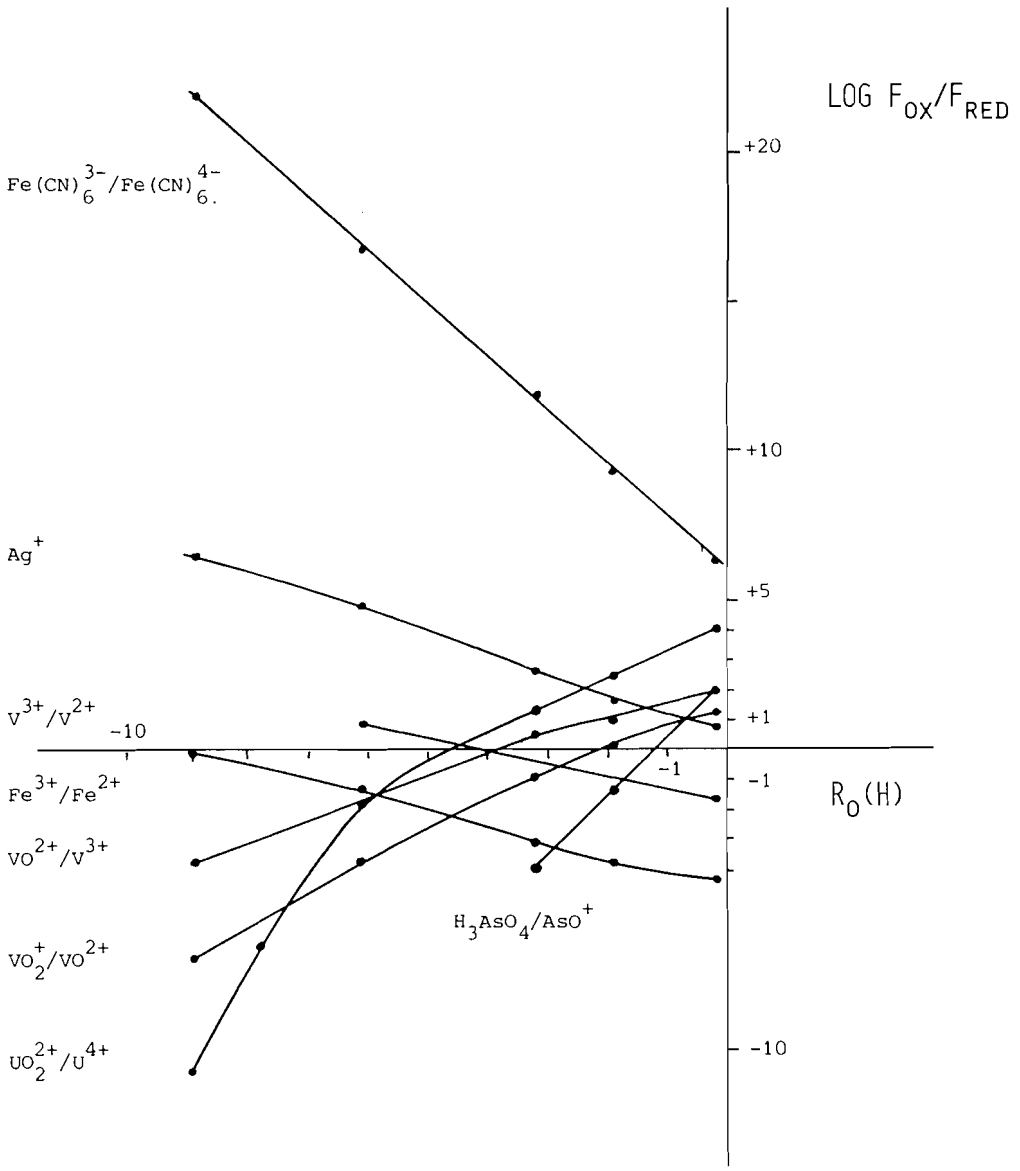

FIG. 2. Caractéristiques de solvatation dans les milieux H_2O–H_3PO_4 des espèces mises en jeu dans les systèmes de l'argent, du fer, de l'uranium, du vanadium, de l'arsenic et des hexacyanoferrate.

anions sont plus basiques. L'étude de la variation de la fonction H_0 par la détermination de la modification de la protonation de l'indicateur de Hammett: 4-chloro-2-nitroaniline (pK^{H_3O} = −0,9), lors de l'addition au milieu H_3PO_4 5,5 *M* de Cl^-, NO_3^-, SiF_6^{2-}, HSO_4^- à la concentration de 0,5 *M*, montre que ces anions sont dépourvus de propriétés basiques et que l'addition des acides conjugués se traduit par une augmentation du niveau d'acidité. Au contraire, les ions F^- et SO_4^{2-} basiques dans l'eau ($pK_{HF}^{H_2O}$ = 3,2, $pK_{HSO_4^-}^{H_2O}$ = 1,9) présentent des caractéristiques de basicité dans les milieux H_2O–H_3PO_4 et l'addition des acides conjugués ne modifie pas le niveau d'acidité de ces milieux.

Les anions Cl^-, Br^-, I^- ont un comportement voisin, l'effet de taille reste minime. Leur accroissement de solvatation est faible comparativement à celui de l'ion F^- dont les propriétés basiques expliquent que log *f* est trois fois plus élevé que celui des autres halogénures. Le coefficient d'activité des sulfates est supérieur au double de celui des chlorures dépourvus de basicité et à celui des fluorures. Ceci met en évidence l'intervention dans les caractéristiques de solvatation des anions de leur caractère basique et du nombre de charges qu'ils portent. De la même manière, les ions hexacyanoferrate(III), $Fe(CN)_6^{3-}$, dépourvus de propriétés basiques dans l'eau, ont des coefficients d'activité environ deux fois plus élevés que ceux des halogénures sans propriétés basiques dans l'eau. Au contraire, les hexacyanoferrate(II), $Fe(CN)_6^{4-}$, basiques dans l'eau $pK_{Fe(CN)_6H_2^{2-}}^{H_2O}$ = 3, $pK_{Fe(CN)_6H^{3-}}^{H_2O}$ = 4,2), ont des coefficients d'activité élevés et qui augmentent rapidement avec la concentration de l'acide.

La réactivité des anions du solvant est caractérisée par les fonctions $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$, $R_0(PO_4^{3-})$ (1). L'évolution des propriétés de solvatation d'une espèce en solution caractérisée par la variation de son coefficient d'activité se traduit par la modification de sa réactivité vis-à-vis des autres espèces présentes (ions du solvant ou solutés). Nous allons étudier les conséquences des phénomènes de solvatation dans le cas des réactions d'oxydo-réduction et de formation de composés insolubles.

3. Phénomènes de solvatation et réactions d'oxydo-réduction

Le diagramme potentiel – niveau d'acidité (2) est une traduction graphique des phénomènes de solvatation dans la mesure où la plupart des données concernant les coefficients d'activité ont été obtenues à partir de déterminations électrochimiques. Il rend compte de l'effet du niveau d'acidité, de l'activité de l'eau et de la solvatation relative des oxydants et des réducteurs conjugués sur la réactivité des espèces et permet de prévoir les réactions d'oxydo-réduction dans les milieux H_2O– H_3PO_4. Parmi les systèmes redox envisagés, trois groupes se dessinent: (*i*) les systèmes dont le potentiel varie fortement avec la teneur en acide. Ils engagent formellement deux protons pour un électron échangé (UO_2^{2+}/U^{4+}, VO_2^{+}/VO^{2+}, VO^{2+}/V^{3+}) et l'évolution est plus marquée pour les couples mettant en jeu une particule oxygénée. Les systèmes dont la forme réduite présente des propriétés basiques entrent également dans cette catégorie ($Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$). (*ii*) Les systèmes dont le potentiel redox varie peu avec la teneur en acide: Fc^{+}/Fc et à un moindre degré I_3^{-}/I^{-}. (*iii*) Les systèmes intermédiaires: d'une manière générale, leur pouvoir oxydant évolue dans le même sens. Cependant, les couples pour lesquels la réactivité du proton intervient seule présentent une variation de leurs propriétés d'oxydo-réduction plus importante. Ainsi, le pouvoir réducteur de l'hydrogène et de l'hydroquinone évolue plus vite que celui des métaux seuls ou en présence d'anions. Lorsque les systèmes font intervenir le proton et des espèces ioniques ou moléculaires (H_2SO_3/H_2SO_2, H_3AsO_4/AsO^{+}) l'effet dû à l'acidité peut être limité par les termes $\log f_{ox}/f_{red}$ et le pouvoir réducteur de ces composés varie alors moins vite que celui des métaux. Les termes $\log f_{ox}/f_{red}$ peuvent se compenser en partie lorsque deux systèmes appartenant au même type et faisant intervenir le même nombre d'électrons sont en présence, alors qu'ils peuvent s'ajouter lorsque les deux systèmes appartiennent à des types différents comme Fe^{3+}/Fe^{2+} et UO_2^{2+}/U^{4+}.

4. Phénomènes de solvatation et réactions de précipitation

4.1 *Formation de composés insolubles n'engageant pas les phosphates*

La comparaison des valeurs $\log f_{M^{n+}}$ et $\log f_{X^{n-}}$ permet de prévoir l'évolution de la solubilité des sels MX avec la teneur en acide. Cependant, la solubilité réelle diffère de la quantité calculée si il se forme des espèces solubles MX ou $MX_m^{(n-m)-}$.

D'une manière générale, il y a compensation partielle des effets de changement de milieu sur l'anion et sur le cation. Les pK_s de quelques composés calculés d'après la relation [5] sont présentés dans le tableau 2. Lorsque l'anion est, comme Cl^{-}, dépourvu de propriétés basiques, l'effet de cation peut l'emporter sur l'effet d'anion. Ainsi, AgCl est plus stable en milieu H_3PO_4 14 *M* que dans l'eau. Il en est de même pour $PbCl_2$ et Hg_2Cl_2. Des résultats analogues seraient obtenus pour les bromures et les iodures puisque $\log f_{Br^-}$ et $\log f_{I^-}$ sont très peu différents de $\log f_{Cl^-}$. Dans le cas de $PbSO_4$, l'effet d'anion l'emporte sur l'effet de cation mais l'écart reste pratiquement constant dans tout le domaine de concentration; la solubilité de $PbSO_4$ varie donc peu avec la teneur en acide.

La présence d'acide peut modifier nettement la stabilité de sels engageant des cations dont la variation de solvatation se fait différemment. Ainsi, les hexacyanoferrates(II) de cuivre, de zinc et de cadmium, dont la stabilité est voisine dans l'eau, ont des caractéristiques de dissolution différentes en milieu H_3PO_4 2 et 5,5 *M*. Cu^{2+} et Pb^{2+} se desolvatent moins vite que Cd^{2+} et Zn^{2+}; l'effet d'anion est donc plus marqué dans le cas des sels de cuivre et de plomb que dans celui des sels de zinc et de cadmium. En milieu H_3PO_4 5,5 *M*, la stabilité du sel de cadmium est plus grande que dans l'eau bien que l'espèce $Fe(CN)_6^{4-}$ soit fortement solvatée en raison de sa basicité. Une inversion entre la stabilité dans l'eau et dans les milieux phosphoriques peut intervenir pour les sels engageant le même anion et les cations M^{n+} et N^{n+} lorsque la différence de leur pK_s dans l'eau est inférieure à $\log f_{M^{n+}}/f_{N^{n+}}$. Ainsi, l'iodate de cuivre ($pK_s^{H_2O} = 7,1$), qui est plus stable dans l'eau que l'iodate de zinc ($pK_s^{H_2O} = 5,4$) est moins stable que ce dernier en milieu acide.

TABLEAU 2. Effet de la concentration de H_3PO_4 sur la solubilité de quelques composés

		H_3PO_4 (*M*)				
pK_s	H_2O	2,0	5,5	8,0	11,5	14,0
AgCl	9,7	9,4	9,7	10,2	10,9	11,2
$PbCl_2$	4,8	4,1	5,0	6,5	6,5	7,7
Hg_2Cl_2	17,9	15,9	17,9	17,9	17,9	19,1
$PbSO_4$	7,7	5,7	5,1	5,0	4,9	4,8
$Pb_2[Fe(CN)_6]$	16,9	11,4	11,0			
$Cd_2[Fe(CN)_6]$	15,0	13,7	16,1			
$Cu_2[Fe(CN)_6]$	15,7	8,2	7,0			
$Zn_2[Fe(CN)_6]$	15,4	11,3	13,7			
$\log f_{Cd^{2+}}/f_{Cu^{2+}}$		3,7	4,9	4,8	4,8	
$\log f_{Zn^{2+}}/f_{Cu^{2+}}$		2,3	3,5	3,4	3,5	

Les réactions de précipitation engageant des anions peu basiques comme les halogénures ou les iodates sont favorisées dans les milieux concentrés en acide. Lorsque les anions sont basiques, l'effet de cation peut compenser dans certains cas l'accroissement de solvatation de l'anion. Mais de nombreuses espèces minérales qui précipitent dans l'eau sont solubles en milieu acide phosphorique. L'élimination d'une espèce par précipitation ou son dosage par formation d'un composé peu soluble seront donc plus difficiles.

4.2 *Précipitation des phosphates*

Phosphates de plomb

Lors de l'étude des systèmes mettant en jeu le plomb, nous avons déterminé la solubilité des phosphates de plomb $PbHPO_4$ dans les milieux de concentration inférieure à 8 *M* et du $Pb(H_2PO_4)_2$ dans les milieux plus concentrés. Puisque les fonctions basiques ont été évaluées indépendamment à partir des systèmes redox Hg_2HPO_4/Hg et $BiPO_4/Bi$, nous avons comparé (tableau 3) les valeurs expérimentales de solubilité du plomb à celles calculées à partir de relations analogues à [6] avec $pK_{s(PbHPO_4)}^{H_2O} = 9,9$ et $pK_{s(Pb_3(PO_4)_2)}^{H_2O} = 42,1$.

Il y a donc une concordance satisfaisante en ce qui concerne les limites des domaines de précipitation des différents phosphates. $Pb_3(PO_4)_2$ est soluble même pour de faibles concentrations de H_3PO_4. $PbHPO_4$ précipite jusqu'à une concentration d'acide de 8 *M*. Dans les milieux plus concentrés, c'est $Pb(H_2PO_4)$ qui est insoluble.

Phosphates d'argent

L'étude de la solubilité des phosphates d'argent dans les milieux H_2O–H_3PO_4 (5) montre que Ag_3PO_4 précipite pour des concentrations d'acide inférieures à 4 *M*, Ag_2HPO_4 pour des concentrations d'acide allant jusqu'à 9,5 *M* et que AgH_2PO_4 est insoluble dans les milieux plus concentrés. La solubilité de l'argent peut être calculée à partir du coefficient d'activité du

TABLEAU 3. Solubilité des phosphates de plomb dans les milieux H_2O–H_3PO_4

H_3PO_4 (M)	R_0 (HPO_4^{2-})	$\log f_{Pb^{2+}}$	$[Pb^{2+}]^a$	$[Pb^{2+}]^b$
2,0	9,4	1,3	1.6×10^{-2}	4×10^{-3}
5,5	12,2	3,4	8×10^{-2}	6×10^{-3}
8,0	14,8	5,8	0,1	7×10^{-3}
11,5	18,9	8,7	2	$Pb(H_2PO_4)_2$ insoluble $PbHPO_4$ soluble
H_3PO_4 (M)	R_0 (PO_4^{3-})	$\log f_{Pb^{2+}}$	$[Pb^{2+}]$	$[Pb^{2+}]$
2,0	22,4	1,3	0,4	$PbHPO_4$ insoluble
5,5	26,8	3,4	2,7	$Pb_3(PO_4)_2$ soluble

[a]Valeurs calculées.
[b]Valeurs expérimentales.

cation Ag^+ et de la fonction $R_0(PO_4^{3-})$ pour les faibles concentrations de H_3PO_4, où Ag_3PO_4 seul se forme, d'après la relation [6] où $pK_s^{H_2O} = 20,83$ (6). Les valeurs calculées et les résultats expérimentaux sont présentés dans le tableau 4.

Dans le domaine de concentration où la forme insoluble est Ag_3PO_4, les valeurs de solubilité expérimentales et calculées sont concordantes. La valeur élevée de 1,9 calculée en milieu 5,5 M est cohérente avec le fait qu'à cette concentration d'acide, il a été montré que la forme insoluble est Ag_2HPO_4.

Phosphates de baryum et de calcium

Les résultats des études de solubilité des phosphates de baryum (6–9) et de calcium (10, 11) dans les milieux phosphoriques nous ont permis de calculer les coefficients d'activité de Ba^{2+} et Ca^{2+} qui n'avaient pu être déterminés autrement. Les coefficients d'activité du cation Ba^{2+} sont calculés d'après la relation [6] où $pK_s^{H_2O} = 7,6$ (4) pour des concentrations d'acide de 3 M. Au delà de cette concentration c'est la forme $Ba(H_2PO_4)_2$ qui précipite; $\log f_{Ba^{2+}}$ est alors calculé d'après la relation

$$[7] \quad \log f_{Ba^{2+}} = 2\,R_0(H_2PO_4^-) - pK_s^{H_2O} - \log [Ba^{2+}]$$

Comme $pK_s^{H_2O}$ n'est pas connu, c'est la variation de $\log f_{Ba^{2+}}$ que nous avons calculée à partir de la limite de la zone de concentration d'acide où la forme insoluble est $BaHPO_4$ (3 M) jusqu'à une concentration d'acide de 13 M.

Pour les concentrations de H_3PO_4 inférieures à 3,8 M, $CaHPO_4$ est insoluble. La relation utilisée est analogue à [6] avec $pK_s^{H_2O} = 7,0$ (4). Pour des concentrations plus élevées d'acide, $Ca(H_2PO_4)_2 \cdot H_2O$ précipite. La relation:

$$[8] \quad \log f_{Ca^{2+}} = 2\,R_0(H_2PO_4^-) - pK_s^{H_2O} - \log [Ca^{2+}] - \log a_{H_2O}$$

conduit au calcul de la variation de $\log f_{Ca^{2+}}$.

Les valeurs de $\log f_{Ba^{2+}}$ et $\log f_{Ca^{2+}}$ sont rassemblées dans le tableau 5. Les cations Ba^{2+} et Ca^{2+} ont des caractéristiques de solvatation analogues à celles déterminées pour les autres cations divalents; ils sont voisins de Zn^{2+}, Sn^{2+}, Cd^{2+}, c'est-à-dire de ceux qui se désolvatent le plus. Ceci est en accord avec la stabilité dans l'eau plus faible de $Ba_3(PO_4)_2$ et de $Ca_3(PO_4)_2$ et avec le fait que le sulfate de baryum est stable même dans les milieux concentrés en acide: le renforcement de solvatation de l'anion est compensé par la désolvatation importante du cation.

TABLEAU 4. Solubilité des phosphates d'argent dans les milieux H_2O–H_3PO_4

H_3PO_4 (M)	R_0 (PO_4^{3-})	$\log f_{Ag^+}$	$[Ag^+]^a$	$[Ag^+]^b$

[a]Valeurs calculées.
[b]Valeurs expérimentales (5).

Phosphates d'uranium

L'étude de la solubilité des phosphates d'uranium(IV) en milieu phosphorique (12, 13) montre que, pour les concentrations d'acide inférieures à 9 M, la forme insoluble est $U(HPO_4)_2 \cdot 6H_2O$, et pour les concentrations plus élevées, c'est $U(HPO_4)_2H_3PO_4 \cdot H_2O$ qui précipite. En admettant que les solubilités des phosphates d'uranium(IV) ont été déterminées à l'équilibre et que les "gels" qui se forment peuvent être considérés comme des solides de structure définie et constante, les coefficients d'activité de l'espèce U^{4+} peuvent être calculés d'après la relation:

$$[9] \quad \log f_{U^{4+}} = -pK_s^{H_2O} + 2\,R_0(HPO_4^{2-}) - 6 \log a_{H_2O} - \log [U^{4+}]$$

avec $pK_s^{H_2O} = 27,5$ (12) en se limitant au domaine de concentration 2–8,8 M en H_3PO_4 où le solide est toujours $U(HPO_4)_2 \cdot 6H_2O$ et la solubilité de U^{4+} est inférieure à 0,5 M.

Des valeurs de $\log f_{UO_2^{2+}}$ peuvent en être déduites puisque $\log f_{UO_2^{2+}}/f_{U^{4+}}$ a été déterminé par une autre voie (tableau 1). Les résultats sont rassemblés dans le tableau 6. Pour les milieux de concentration d'acide inférieure à 4 M, la structure du phosphate d'uranium(VI) insoluble est $UO_2(HPO_4) \cdot 4H_2O$; dans les milieux plus concentrés, elle est $UO_2(H_2PO_4)_2 \cdot 3H_2O$ (14). La solubilité des phosphates d'uranium(VI) est beaucoup plus élevée que celle des phosphates d'uranium(IV): elle n'est inférieure à 0,5 ion g/L que pour des concentrations d'acide allant jusqu'à 2,5 M. Le domaine de concentration d'acide où il est possible de calculer à la fois $\log f_{UO_2^{2+}}$ et $\log f_{U^{4+}}$ à partir des solubilités des phosphates de U(VI) et U(IV) est donc très

TABLEAU 7. Coefficients d'activité de l'espèce UO_2^{2+} calculés à partir de la solubilité de $UO_2(HPO_4) \cdot 4H_2O$

H_3PO_4 (M)	$[UO_2^{2+}]^a$	R_0 (HPO_4^{2-})^b	$\log a_{H_2O}$	$\log f_{UO_2^{2+}}$
0,9	0,1	+8,1	0	−1,6
1,3	0,2	+8,7	−0,01	−1,2
1,7	0,3	+9,1	−0,015	−1,0
2,4	0,6	+9,8	−0,025	−0,5

[a]D'après réf. 14.
[b]D'après réf. 1.

restreint. Nous donnons dans le tableau 7 les valeurs du coefficient d'activité de UO_2^{2+} calculées d'après la relation:

$$[10] \quad \log f_{UO_2^{2+}} = -pK_s^{H_2O} + R_0(HPO_4^{2-}) - 4 \log a_{H_2O} - \log [UO_2^{2+}]$$

avec $pK_s^{H_2O} = 10{,}7$.

Il semble donc que U^{4+} soit plus fortement solvaté dans les milieux phosphoriques dilués que dans l'eau, puis se désolvate très rapidement lorsque la concentration d'acide augmente, ce qui est conforme, en raison du nombre de charges portées par cette espèce, à l'analyse qui a été faite. UO_2^{2+} a, dans le même domaine de concentration d'acide, des caractéristiques de solvatation voisines de celles des cations divalents qui, comme Sn^{2+} ou Zn^{2+}, se désolvatent le plus lorsque la concentration d'acide augmente.

Conclusion

Les variations de solvatation des espèces ioniques en solution dans les milieux phosphoriques concentrés sont caractérisées par leurs coefficients d'activité de transfert de solvatation. Les cations sont moins solvatés lorsque la concentration d'acide augmente tandis que la solvatation des anions est renforcée. Pour une espèce donnée, l'amplitude de la variation de solvatation dépend du nombre de charges, de la présence d'oxygène dans sa structure, de son caractère basique. Les coefficients d'activité permettent d'interpréter ou de prévoir les réactions d'oxydo-réduction (diagramme potentiel – niveau d'acidité), l'évolution des propriétés de solubilité y compris celles des phosphates. Ils devraient également intervenir dans la prévision des réactions mises en jeu dans les processus de séparation comme l'extraction liquide–liquide et la flottation ionique.

Laboratoire de chimie des organominéraux, Unité associé N° 477 du Centre national de la recherche scientifique, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse CEDEX, France

Reçu le 19 avril 1985[2]

J. BARRAU, M. EL AMINE, G. RIMA et J. SATGÉ. Can. J. Chem. **64**, 615 (1986).

Les hétérocycles germaniés et phosphorés anisyl-2 diméthyl-4,4 thio-2 dithiaphosphagermetanne-1,3,2,4, $Me_2GeSP(An)S$ (**1**), et anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3, $Me_2GeGe(Me_2)SP(An)S$ (**2**), sont obtenus par action de l'anisyltrithiophosphonate d'ammonium sur les dichlorures germaniés correspondants. Le composé **1** est instable à température ambiante et se décompose pour conduire à (Me_2GeS) et $(AnPS_2)_n$. Le composé **2** subit une fragmentation thermique à 200°C avec formation de $(Me_2GeS)_3$ et $(AnPS)_n$. Ces résultats sont expliqués par deux mécanismes de décomposition faisant intervenir les espèces doublement liées transitoires $(Me_2Ge{=}S)$ et $(AnPS_2)$ ou (AnPS) respectivement. Les réactions d'échange entre **2** et divers chlorures métallés (M_{IVB}) sont décrites. La réaction avec Me_2SiCl_2 conduit à la diméthylsilathione $[Me_2Si{=}S]$ via un dithiaphosphasiletanne intermédiaire.

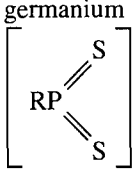
J. BARRAU, M. EL AMINE, G. RIMA, and J. SATGÉ. Can. J. Chem. **64**, 615 (1986).

The synthesis of the new germylated and phosphorylated heterocycles 2-anisyl-4,4-dimethyl-2-thio-1,3,2,4-dithiaphosphagermetane, $Me_2GeSP(An)S$ (**1**), and 5-anisyl-2,2,3,3-tetramethyl-5-thio-1,4,5,2,3-dithiaphosphadigermolane, $Me_2GeGe(Me_2)SP(An)S$ (**2**), are described. The decomposition of **1** with formation of $(Me_2GeS)_3$ and $(AnPS_2)_n$ is observed at room temperature. At 200°C **2** undergoes thermal fragmentation leading to $(Me_2GeS)_3$ and $(AnPS)_n$. These results are explained by two mechanisms of decomposition involving formation of transient species $[Me_2Ge{=}S]$ and $[AnPS_2]$ or [AnPS], respectively. Exchange reactions between **2** and various metal (M_{IVB}) chlorides are described. With Me_2SiCl_2 the reaction leads to silathione $[Me_2Si{=}S]$, probably via transient dithiaphosphasiletane.

Introduction

Dans ce mémoire, nous présentons l'étude de nouveaux hétérocycles germaniés, l'anisyl-2 diméthyl-4,4 thio-2 dithiaphosphagermetanne-1,3,2,4, $Me_2GeSP(An)S$ (**1**), et l'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3, $Me_2GeGe(Me_2)SP(An)S$ (**2**).

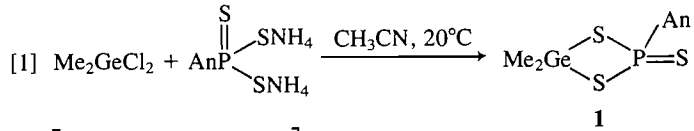
Ces hétérocycles sont les premiers représentants de thiophosphonates germaniés cycliques. Ils sont par décomposition intramoléculaire, comme diverses autres stuctures hétérocycliques germaniées (1–11), sources d'espèces à double liaison du germanium $[Me_2Ge{=}S]$ (12) et également du phosphore



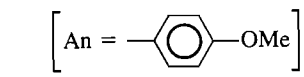
et [RP=S]. Ces éthers cycliques germaniés d'acides trithiophosphoniques peuvent également être utilisés comme agents de synthèse en chimie organogermaniée ou organophosphorée.

Résultats et discussion

Le dithiaphosphagermetanne **1** est obtenu à 20°C au sein de l'acétonitrile par action de l'anisyltrithiophosphonate d'ammonium (13) sur le dichlorodiméthylgermanium.



[1] $Me_2GeCl_2 + AnP(S)(SNH_4)_2 \xrightarrow{CH_3CN,\ 20°C} Me_2Ge(S)_2P(An)=S$ (**1**)

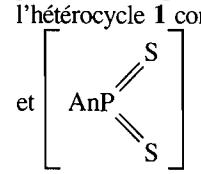


[An = —C₆H₄—OMe]

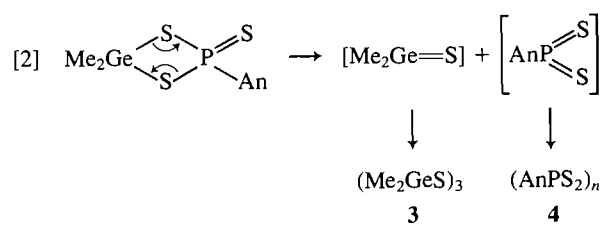
rmn ^1H δ_{Me} = 1,0 ppm (s) et 1,1 ppm (s)

^{31}P δ_P = 79,9 ppm (s)

Toute tentative de concentration sous vide ou distillation conduit à $(Me_2GeS)_3$ et $(AnPS_2)_n$ (14). La formation de ces entités peut être interprétée par un mécanisme de β-décomposition de l'hétérocycle **1** conduisant aux espèces monomères $[Me_2Ge{=}S]$



et



[2] $Me_2Ge(S)_2P(S)An \longrightarrow [Me_2Ge{=}S] + [AnP(S)_2]$

$(Me_2GeS)_3$ (**3**) $\quad (AnPS_2)_n$ (**4**)

L'addition de thiiranne au milieu réactionnel permet d'isoler le diméthylgermadithiolanne $Me_2GeSCH_2CH_2S$ (**5**) et le dithiaphospholanne-1,3,2, $AnP(S)SCH_2CH_2S$ (**6**). Ces hétérocycles représentent respectivement les adduits des deux espèces π liées

[1]Auteurs à qui adresser toute correspondance.

[2]Révision reçue le 8 novembre 1985.

$[Me_2Ge{=}S]$ et $\left[\text{AnP}(=S)(=S)\right]$ et du thiiranne.

[3] $Me_2GeCl_2 + AnP(=S)(SNH_4)_2 \xrightarrow[(2)\ -NH_4Cl]{(1)\ CH_3CN,\ 20°C} (3) + \text{thiiranne}$

Me_2Ge(dithiolane) + AnP(=S)(dithiolane)

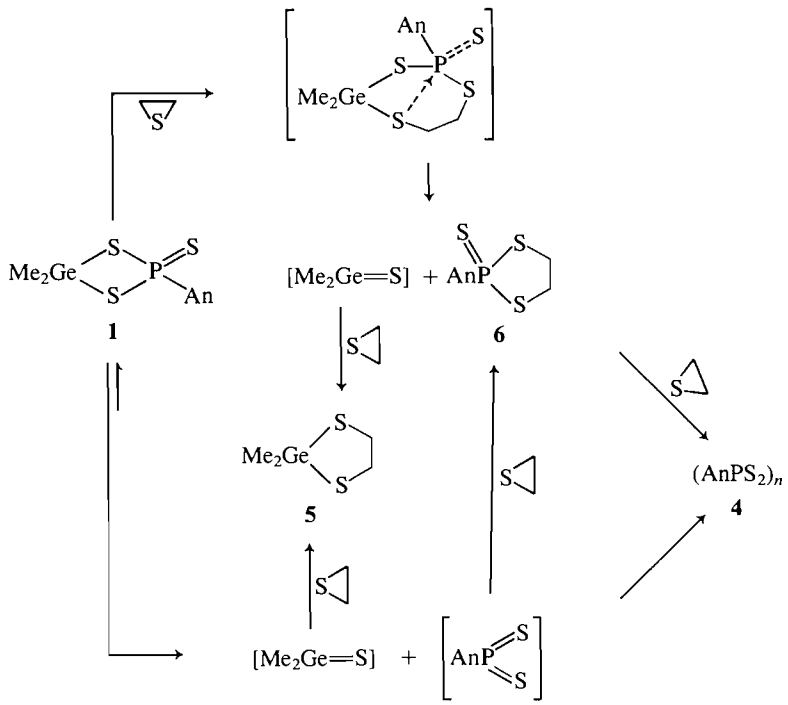
5 **6**

Soulignons cependant que l'obtention du dithiaphospholanne-1,3,2 (**6**) n'est pas une preuve irréfutable de la condensation de l'intermédiaire monomère $\left[\text{AnP}(=S)(=S)\right]$ sur le thiiranne puisque ce même hétérocycle (**6**) peut être obtenu à partir du télomère $(AnPS_2)_n$.

[4] $(AnPS_2)_n$ + thiiranne $\xrightarrow{20°C}$ AnP(=S)(dithiolane) (Rdt ≥ 65%)

6

D'autre part, une insertion directe du thiiranne sur le dithiaphosphagermetanne **1** avec formation d'un hétérocycle à 7 chaînons instable (cf. réactivité de **2**) peut également expliquer la formation du dithiaphospholane **6** et du diméthylgermadithiolane **5** via $[Me_2Ge{=}S]$.



L'action directe de l'anisyltrithiophosphonate d'ammonium sur le tétraméthyl-1,1,2,2 dichloro-1,2 digermane (10) permet également d'accéder à l'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3 (**2**) avec un rendement de l'ordre de 95%.

[5] $AnP(=S)(SNH_4)_2 + Me_2Ge(Cl)—Ge(Cl)Me_2 \xrightarrow[-2NH_4Cl]{CH_3CN,\ 20°C}$ Me_2Ge—$GeMe_2$(dithiolane)P(=S)An

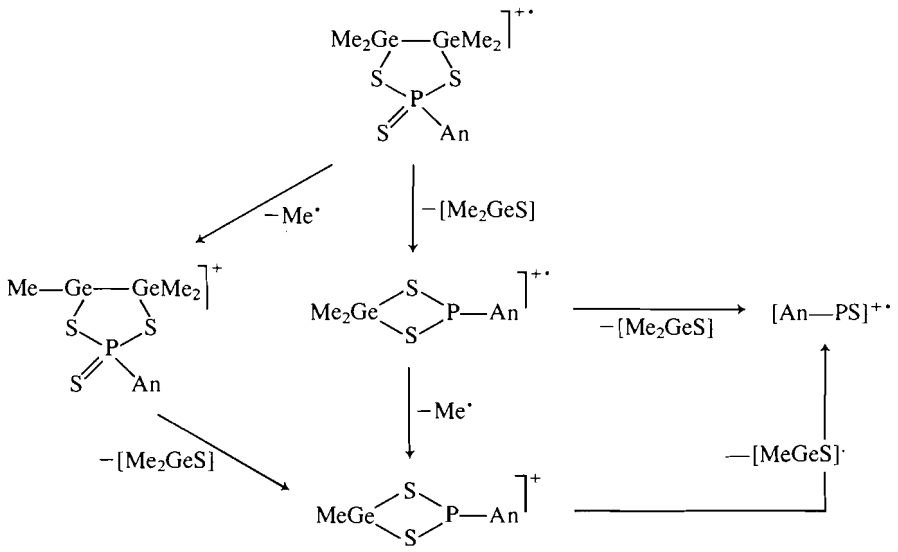
2

Le dithiaphosphadigermolanne à phosphore tétracoordonné ainsi synthétisé a été caractérisé par analyse de rmn (^1H: δ_{Me} = 0,56 ppm (s) et 1,10 ppm (s); δ_{OMe} = 3,16 ppm (s); ^{31}P: δ_P = 86,0 ppm) et spectrométrie de masse.

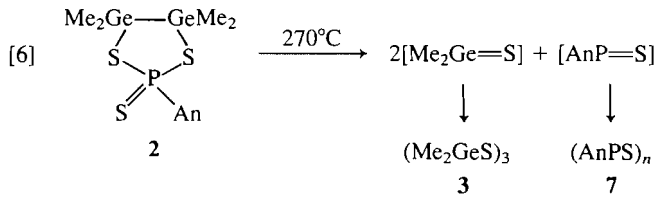
La spectrographie de masse par désorption par champ permet d'observer uniquement le massif de l'ion moléculaire $M^{+\bullet}$ pour un courant de filament variant de 5 mA à 20 mA.

L'analyse du spectrogramme effectuée sous impact électronique (70 eV) révèle notamment la présence de quatre massifs correspondant à l'ion moléculaire $M^{+\bullet}$ et aux ions $[Me_2GeS]^{+\bullet}$, $[M - Me_2GeS]^{+\bullet}$ et $[AnPS]^{+\bullet}$. Faibles à 20°C, les intensités relatives de ces trois derniers pics augmentent très fortement lorsque la température de la source dépasse 100°C.

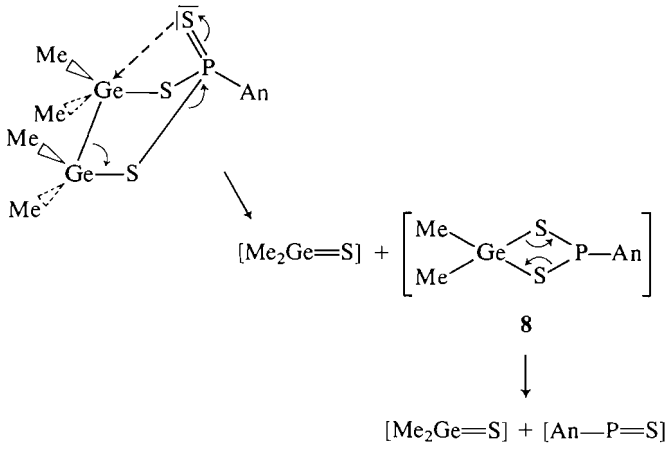
Une étude de filiation par identification des ions métastables permet de proposer le diagramme de fragmentation suivant:



Le composé **2** est stable à température ordinaire mais instable à température plus élevée. Opérant à 270°C en tube scellé sa thermolyse et sa pyrolyse en phase vapeur conduisent à la formation exclusive de $(AnPS)_n$ (**7**) (15) et de $(Me_2GeS)_3$ (**3**) via les espèces monomères [AnP=S] et $[Me_2Ge{=}S]$.

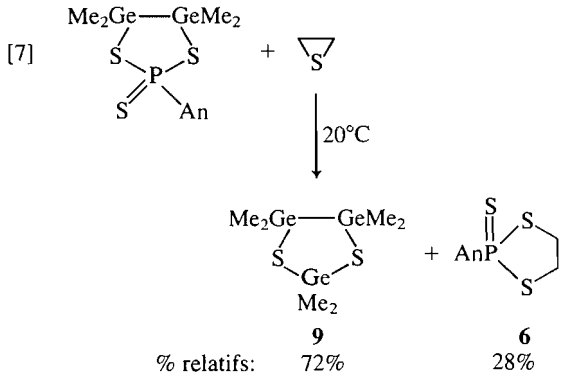


L'existence de corrélation entre les processus de fragmentation sous impact électronique et les comportements sous effet thermique de petits hétérocycles siliciés précurseurs d'espèces π liées du silicium (16) nous amène à proposer, pour rendre compte de cette thermolyse, un mécanisme de décomposition thermique de **2** en accord avec son comportement sous impact électronique. Ce mécanisme initié par attaque nucléophile d'un germanium par le soufre (P=S) conduit, à côté de $[Me_2Ge{=}S]$, à un dithiétanne intermédiaire (**8**) instable subissant lui-même une β-décomposition.

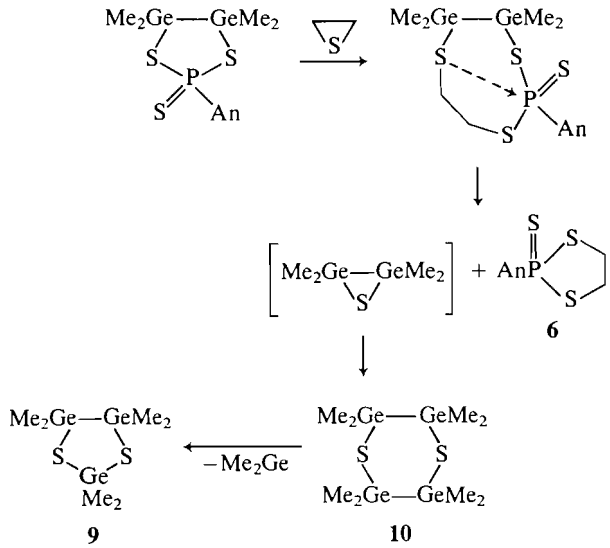


À l'appui de cette hypothèse, signalons que nous n'observons aucune décomposition de **2** à 270°C au sein de la triéthylamine. Celle-ci doit vraisemblablement former avec **2** un complexe instable non isolable, empêchant ainsi toute attaque nucléophile du soufre sur le germanium.

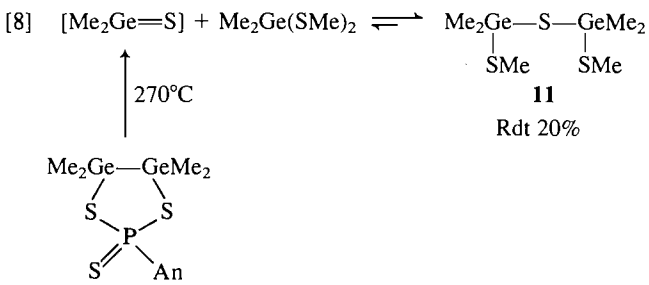
La réaction classique (4) de condensation de la diméthylgermathione monomère sur le thiiranne ne peut cependant pas être réalisée à partir de **2**. Le thiiranne réagit en effet à 20°C sur **2** avec formation de dithiaphospholanne, **6**, et d'hexaméthyl-2,2,3,3,5,5 trigerma-2,3,5 dithiolanne-1,4, **9** (10).



Ce bilan réactionnel peut s'interpréter par une insertion du thiiranne dans une liaison Ge—S de **2** suivie d'une décomposition (procédant par attaque nucléophile intramoléculaire d'un atome de S en α du germanium sur l'atome de phosphore) de l'hétérocycle ainsi obtenu. Le passage par un digermathiiranne intermédiaire qui se dimérise pour conduire à l'octaméthyltétragermadithiacyclohexane (**10**) instable (10) permet d'expliquer la formation de **9**.



La diméthylgermathione peut cependant être caractérisée par addition sur la liaison germanium–soufre de $Me_2Ge(SMe)_2$ en réalisant la thermolyse de **2** en présence de ce dérivé. Le sulfure de bis(diméthylméthylthiogermanium) attendu (**11**) (4) est obtenu avec un rendement de 20%.

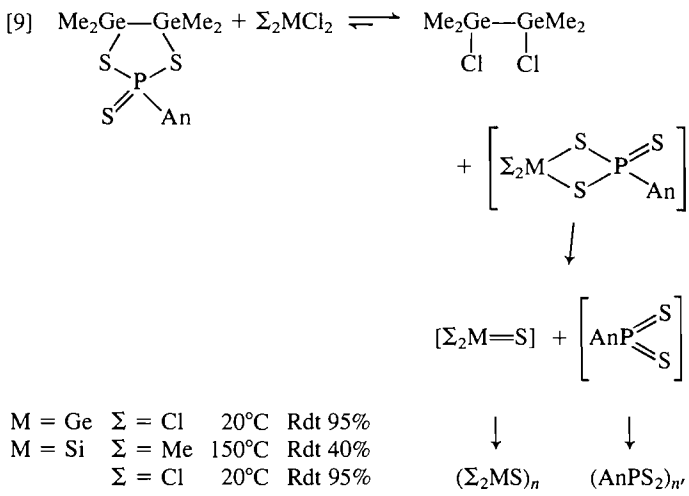


Bien que la spectroscopie photoélectronique ait déjà permis la mise en évidence de la diméthylgermathione $[Me_2Ge{=}S]$ (P. I exp:[3] n_S 8,6; π Ge—S 9,55; σ Ge—S 10,75; σ Ge—C 11,47 eV) lors de dépolymérisations thermiques de cyclogermathianes (17)

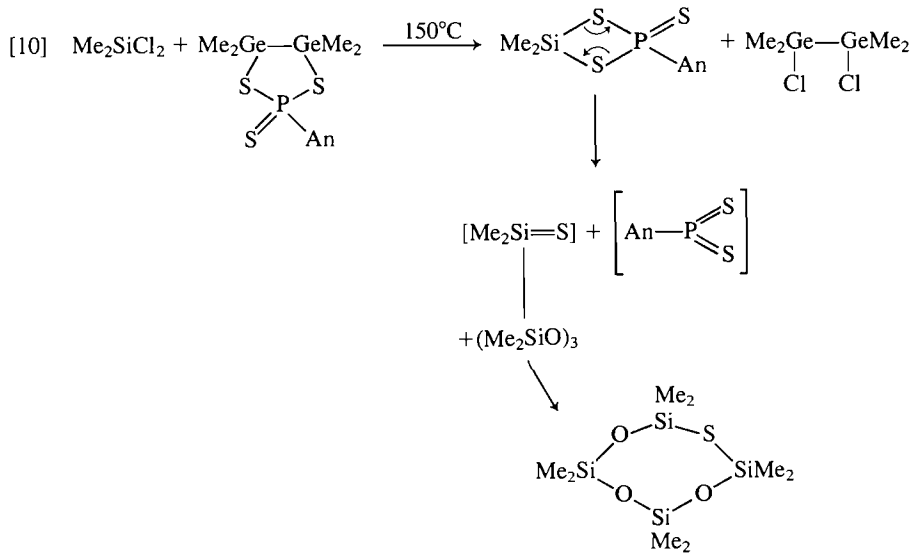
$$(R_2GeS)_3 \overset{\Delta}{\rightleftharpoons} [R_2Ge{=}S] + (R_2GeS)_2 \ (R = \text{alkyl})$$

nous ne pouvons pas utiliser cette technique pour suivre la décomposition de **2** puisque le phosphore porte un groupe anisyl —C_6H_4—OCH_3 dont les divers potentiels d'ionisation masquent ceux de $[Me_2Ge{=}S]$.

La sensibilité des liaisons Ge—S vis-à-vis des réactifs dipolaires a pu être mise à profit pour accéder à partir de **2** et divers chlorures métallés à d'autres espèces π liées $\left[\begin{smallmatrix}\diagdown\\ \diagup\end{smallmatrix} M_{IVB} = X\right]$



Avec M = Si et Σ = Me, la diméthylsilathione intermédiaire peut être caractérisée par condensation sur l'hexaméthyltrisiloxanne (16).



Avec le tétrachlorure de germanium (1/2 mole pour 1 mole de **2**) et le dichlorogermylène, les réactions d'échange ont lieu à 20°C et conduisent aux polymères $(GeS_2)_n$ et $(GeS)_n$ vraisemblablement via les intermédiaires disulfure de germanium monomère $[S{=}Ge{=}S]$ d'une part, et monosulfure de germanium ($:Ge{=}S$] d'autre part.

Partie expérimentale

Toutes les réactions ont été réalisées en atmosphère inerte d'argon. Les spectres de rmn ^1H ont été enregistrés sur spectromètre Varian EM 360A à 60 mégacycles; toutes les valeurs des déplacements chimiques sont données par rapport au TMS pris comme référence interne. Les spectres de rmn ^{31}P ont été réalisés sur spectromètre Bruker WP 90 à 36,4 mégacycles; les déplacements chimiques sont donnés par rapport à H_3PO_4 pris comme référence externe.

Les spectres de masse ont été effectués sur spectromètre de masse Ribermag R1010.

Anisyl-2 diméthyl-4,4 thio-2 dithiaphosphagermetanne-1,3,2,4, $Me_2GeSP(An)S$ (1)

Diméthyldichlorogermanium (1 g, 0,0057 mol) en solution dans 150 cm^3 de CH_3CN est traité par 1,55 g de $AnP(SNH_4)_2$ (13) (0,0057 mol). Après filtration, les analyses de rmn (^1H et ^{31}P) et de spectrométrie de masse du filtrat mettent en évidence la formation d'anisyl-2 diméthyl-4,4 thio-2 dithiaphosphagermetanne-1,3,2,4; rmn (CH_3CN) ^1H δ_{Me}:

[3] P.I exp = potentiel d'ionisation experimental.

1,0 ppm (s) et 1,1 ppm (s); ^{31}P δ_P: 79,0 ppm; spectre de masse, *m/e*: 338 $[Me_2GeSP(An)S]^{+\bullet}$.

Après concentration de ce filtrat sous 10 Torr (1 Torr = 133,3 Pa), les analyses cpv (chromatographie en phase vapeur), rmn et spectrométrie de masse dénotent la présence de $(Me_2GeS)_3$ (rmn (C_6H_6) ^1H δ_{Me}: 0,82 ppm) et de $(AnPS_2)_n$ ($n = 2$ essentiellement, rmn ($O—C_6H_4Cl_2$) ^{31}P δ_P: 14,5 ppm).

Anisyl-5 tétraméthyl-2,2,3,3 dithiaphosphadigermolanne-1,4,5,2,3, $Me_2GeGe(Me_2)SP(An)S$ (2)

Le mélange de 3,32 g de dichloro-1,2 tétraméthyldigermane (10) (0,0120 mol) et de 3,24 g de $AnP(SNH_4)_2$ (0,0120 mol) dans 500 cm^3 de CH_3CN est maintenu 24 h à température ambiante sous agitation. Après filtration, le filtrat est concentré sous 10 Torr. Les cristaux obtenus sont recristallisés dans le benzène. On obtient ainsi, 3,68 g d'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3 (Rdt 70%); P_F = 150–151°C; rmn (C_6D_6) ^1H δ_{Me}: 0,56 ppm (s) et 1,10 ppm (s); δ_{OMe}: 3,16 ppm (s); $\delta_{C_6H_4}$: 8,50 ppm (dd, J_{PH} = 19 Hz) et 6,70 (dd, J_{PH} = 3 Hz); ^{31}P δ_P: 86,0 ppm. Spectre de masse *m/e*: 440 $[Me_2GeGe(Me_2)SP(An)S]^{+\bullet}$; 425 $[MeGeGe(Me_2)SP(An)S]^+$; 304 $[Me_2GeSP(An)S]^{+\bullet}$; 289 $[MeGeSP(An)S]^+$; 170 $[AnPS]^{+\bullet}$; 136 $[MeGeS]^{+\bullet}$; 121 $[MeGeS]^+$. *Anal.* calcd. pour $C_{11}H_{19}OS_3PGe_2$: C 30,05; H 4,32; S 21,85; tr.: C 30,10; H 4,35; S 21,78%.

Thermolyse de l'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3

Un échantillon de $Me_2GeGe(Me_2)SP(An)S$ est maintenu en tube scellé à 200°C pendant 14 h. Les analyses de cpv, rmn et spectrométrie de masse dénotent la formation de $(Me_2GeS)_3$ (27%) et $(AnPS)_n$ ($n \geq 3$, *m/e* 510 $[AnPS]_3^{+\bullet}$) (15) à côté de 43% de dérivé de départ.

Pyrolyse de l'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3

Une solution de 0,20 g de **2** dans 5 cm^3 de C_6H_6 anhydre est introduite goutte à goutte dans un pyrolyseur muni à sa sortie d'un piège refroidi à la neige carbonique et maintenu à 270°C sous courant faible d'argon (durée d'introduction 15 min). Après rétablissement de la température ordinaire le pyrolyseur est rincé avec quelques cm^3 de C_6H_6. Une analyse cpv du mélange permet de caractériser la formation de $(Me_2GeS)_3$ (76%) et l'absence totale de dérivé de départ.

Caractérisation de la diméthylgermathione

Le mélange de 0,39 g de diméthyldithiométhylgermanium (0,002 mol) et 1 g d'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3 (0,0022 mol) est maintenu en tube scellé à 270°C pendant 4 h. Les analyses de cpv et de rmn ((C_6H_6) δ_{Me_2Ge}: 0,71 ppm (s); δ_{SMe}: 1,96 ppm (s)) permettent de mettre en évidence la formation de $[Me_2Ge(SMe)]_2S$ (20%) par comparaison avec un échantillon authentique synthétisé par ailleurs.

Synthèse du sulfure de bis(diméthylméthylthiogermanium)

Une quantité (0,69 g, 0,0017 mol) de $(Me_2GeS)_3$ est chauffé 14 h à 150°C en tube scellé en présence de 1 g de $Me_2Ge(SMe)_2$ (0,0051 mol). Les analyses de cpv, rmn et spectrométrie de masse permettent alors d'identifier $[Me_2Ge(SMe)]_2S$ (Rdt 26%) à côté de $(Me_2GeS)_3$ et $Me_2Ge(SMe)_2$ n'ayant pas réagi. $[Me_2Ge(SMe)]_2S$: rmn (C_6H_6) δ_{Me_2Ge}: 0,71 ppm (s); δ_{SMe}: 1,96 ppm (s). Spectre de masse, *m/e* 332 $[[Me_2Ge(SMe)_2]S]^{+\bullet}$.

Action du thiiranne sur l'anisyl-5, tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3

Une quantité de thiiranne (0,28 g, 0,0046 mol) est ajouté goutte à goutte à 1 g d'anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3 (0,0022 mol) en solution dans 5 cm^3 de C_6H_6. Les analyses de cpv (comparaison avec un échantillon pur) et de rmn permettent de mettre en évidence la formation d'hexaméthyl-2,2,3,3,5,5 trigerma-2,3,5 dithiolanne-1,4 déjà décrit (10) (rmn (C_6D_6) $\delta_{Me_2GeGeMe_2}$: 0,56 ppm; δ_{SGeMe_2S}: 0,76 ppm) et de sulfure d'anisyl-2 dithiaphospholanne-1,3,2 (**6**) (synthétisé par ailleurs) (% relatifs 72 (28%)).

Anisyl-2 thio-2 dithiaphospholanne-1,3,2, $AnPSCH_2CH_2S$ (6)

À 5 g de dianisyl-2,4 dithio-2,4 dithiadiphospholanne-1,3,2,4 (0,0123 mol) en suspension dans 20 cm^3 de benzène anhydre, on ajoute 20 g de thiiranne (0,3333 mol). Le mélange est maintenu sous agitation pendant 4 h, puis concentré et distillé. On obtient ainsi 2 g d'anisyl-2 thio-2 dithiaphospholanne-1,3,2 (Rdt 31%); Eb = 112°C/0,1 Torr; rmn (C_6D_6) ^1H δ_{OMe}: 3,20 ppm (s); $\delta_{C_6H_4}$: 6,70 ppm (dd, J_{PH} = 3,5 Hz) et 8,18 ppm (dd, J_{PH} = 9,5 Hz); δ_{CH_2S}: 2,90 ppm (m); ^{31}P δ_P: 92 ppm. *Anal.* calc. pour $C_9H_{11}OS_2P$: C 41,22; H 4,19; S 36,64; tr.: C 41,35; H 4,21; S 36,72%.

Anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,-5,2,3 et divers chlorures métallés

Le mélange de quantités stoechiométriques de dithiaphosphadigermolanne-1,4,5,2,3 et de chlorure métallé Σ_2MCl_2 est soit maintenu à 20°C, soit porté à 160°C pendant 4 h en tube scellé (cf. tableau de la réaction [9]).

Les analyses cpv et rmn révèlent alors la disparition quasi complète du dithiaphosphadigermolanne et la formation de dichloro-1,2 tétraméthyldigermane (10) et de $(AnPS_2)_n$ à côté des sulfures métallés correspondants $(\Sigma_2MS)_n$ ($(Me_2GeS)_3$ déjà décrit (18); $(Me_2SiS)_{2,3}$ déjà décrit (19), $(Me_2SiS)_2/Me_2SiS)_3 \simeq 1:2$; $(Cl_2GeS)_n$ caractérisé par analyse %tr. (calc.): Cl 40,12 (40,39); S 18,35 (18,23)).

Caractérisation de la diméthylsilathione

L'addition goutte à goute de 0,14 g de diméthyldichlorosilane (0,0011 mol) à un mélange anisyl-5 tétraméthyl-2,2,3,3 thio-5 dithiaphosphadigermolanne-1,4,5,2,3 (0,5 g = 0,0011 mol) et oxyde trimère $(Me_2SiO)_3$ (0,72 g = 0,0033 mol) donne un mélange réactionnel maintenu 1 h 30 à 150°C en tube scellé. Une analyse cpv du mélange permet de constater la formation de

$Me_2SiO(Me_2SiO)_2—SiMe_2S$ (25%)

déjà décrit (20).

Le lithio-2 naphtalène carbonitrile-1 et ses produits de substitutions

R. R. FRASER ET S. SAVARD[1]
Ottawa–Carleton Chemistry Institute, Université d'Ottawa, Ottawa, Ont., Canada K1N 9B4
Reçu le 23 juillet 1985

R. R. FRASER et S. SAVARD. Can. J. Chem. **64**, 621 (1986).

La lithiation du naphtalène carbonitrile-1 conduit à la formation du dérivé lithio-2 exclusivement. La réaction de cet intermédiaire avec dix différents électrophiles permet d'obtenir les dérivés substitués en position 2 avec des rendements de modérés à bons. Les alkyl-2 naphtalène carbonitriles-1 sont facilement lithiés et subséquemment alkylés pour donner un substituant alkyle modifié sur la position α. Les valeurs des pK_a pour les hydrogènes de la position 2 du naphtalène carbonitrile-1 et du méthyl-2 naphtalène carbonitrile-1 ont été déterminées et sont respectivement de 36,3 et 28,5.

R. R. FRASER and S. SAVARD. Can. J. Chem. **64**, 621 (1986).

Lithiation of 1-naphthonitrile provides the 2-lithio derivative exclusively. Reaction of this intermediate with ten different electrophiles produces 2-substituted derivatives in moderate to good yields. 2-Alkyl-1-naphthonitriles are readily lithiated and further alkylated to provide alkyl substituents modified at the α position. The pK_a values for the hydrogen at the 2-position of 1-cyanonaphthalene and 2-methyl-1-cyanonaphthalene have been determined to be 36.3 and 28.5, respectively.

L'*ortho*-lithiation directe de composés aromatiques est une méthode efficace pour la préparation d'intermédiaires aryllithiums utilisables ensuite dans les différentes synthèses. Plusieurs substituants sont bien connus pour diriger et stabiliser l'*ortho*-métalation, par exemple le $CH(OR)_2$, OCH_2OCH_3, $N(R)_2$ et $CH_2N(CH_3)_2$ (1). De même, certains électrophiles se sont avérés très efficaces comme agent activateur d'une telle lithiation dont le $CON\bar{R}$, le $CS\bar{N}R$, le $CONR_2$, l'oxazoline et le $OCONR_2$ (1). Dans ce dernier cas, trois méthodes ont été utilisées pour éviter la condensation du carbanion avec le produit de départ afin de permettre une concentration acceptable d'aryllithium avant l'addition d'un électrophile externe (2): (*i*) l'utilisation d'une basse température de réaction (−78°C ou moins); (*ii*) l'utilisation d'un électrophile stériquement (oxazoline (3)) ou électroniquement (carbamate, amide (1*c*)) déactivé qui réagit suffisamment lentement avec la base nucléophile (alkyllithium) ou avec l'anion formé, pour permettre l'attaque subséquente d'un agent électrophilique; (*iii*) l'addition *in situ* de l'électrophile pour piéger l'intermédiaire aryllithium immédiatement après sa formation par une base très stériquement encombrée, le tétraméthylpipéridine amidure de lithium (LTMP) (2, 4). Cette dernière méthode appliquée par Krizan et Martin permet d'obtenir des dérivés benzonitrile-2 et (dicyano-1,3 benzene)-2 dans d'excellents rendements, comme dans le cas des résultats obtenus précédemment avec un échange halogène–métal (5), contrairement à ceux obtenus par une lithiation directe (1*b*, 6).

Le groupement nitrile a été aussi utilisé comme agent activateur dans la métalation directe d'autres composés aromatiques, dont le thiophène (7, 8) et le sélénophène (8).

Nous voulons présenter ici la formation du lithio-2 naphtalène carbonitrile-1, **1** provenant d'une *ortho*-lithiation directe (LTMP, THF, −78°C). L'anion formé dans ces conditions est suffisamment stable pour réagir par la suite avec une grande variété d'électrophiles sans que de condensation nitrile–anion ne soit décelée. Cette réaction permet d'obtenir un naphtalène substitué-1,2 possédant le groupement nitrile-1 transformable par la suite de diverses façons.

La tableau 1 présente les divers électrophiles utilisés: les halogénures d'alkyles, les disulfures, l'iode ainsi que le chlorure de triméthylsilyle conduisent à de bons résultats. La constatation générale est, toutefis, que l'utilisation d'un équivalent de base ne permet pas un rendement supérieur à 85%.

L'utilisation de composés carbonylés comme agent électrophilique conduit à l'obtention de deux types de produits suivant la nature du produit de départ. Ces composés se forment probablement lors de l'isolement lorsque le mélange réactionnel est traité avec l'acide chlorhydrique dilué. Le benzaldéhyde avec le lithio-2 naphtalène carbonitrile-1, **2** donne la lactone cyclique **12**, identique à celle obtenue par Watanabe et Snieckus lors de la réaction du lithio-2 naphtalène carboxamide-1 *N*,*N*-diéthyle avec le benzaldéhyde (9). Lorsque la cycloheptanone est utilisée, la formation d'une lactame **11** (ir ($CHCl_3$): 1668 cm^{-1}; sm: 265 (M^+)) est constatée.

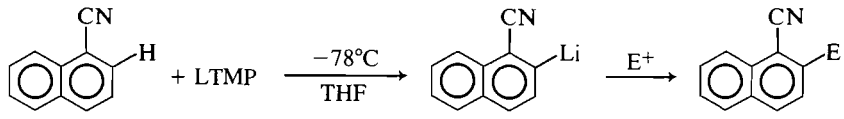
Le diéthylchlorocarbamate, le chlorure d'acétyle, le bromure de benzyle et la benzophénone ne permettent pas l'obention de résultats utilisables dans les conditions telles que décrites. Avec cette dernière, toutefois, la présence d'un composé de masse 335 correspondant au produit de substitution (alcool tertiaire, lactame ou imine) peut être détectée par gc–ms parmi les produits multiples de la réaction.

Le tableau 2 présente les pourcentages de deutération obtenus lors de la réaction du naphtalène carbonitrile-1, **1** avec le diisopropyl amidure de lithium (LDA) et le LTMP, suivi d'un piégeage avec D_2O. Avec le LTMP, 83% de deutération sur la position 2 est constaté alors qu'avec la LDA on n'en retrouve que 23%. Aucune deutération sur un autre site n'est observée. Ces résultats indiquent une acidité intermédiaire entre les deux bases qui correspond à un pK_a approximatif de 36,3 ± 0,6 (10). Cette mesure n'étaient valable que si la quantité de produit deutéré correspond à la valeur à l'équilibre de l'espèce lithiée en présence de base.[2] La métalation complète du nitrile aromatique est donc impossible avec le LTMP (pK_a = 37,3) (10*b*, *c*) si un équivalent de base est utilisé, expliquant le fait que le rendement maximum obtenu dans le tableau 1 soit de 85%. Le LDA n'est pas assez basique pour déprotonner de façon efficace le naphtalène carbonitrile-1, **1**. Il est intéressant de constater que le

[1]Présente adresse: CRIQ (Centre de Recherche Industrielle du Québec), 333, rue Franquet, C.P. 9038, Sainte-Foy (Qué.), Canada G1V 4C7.

[2]Une expérience démontrant que la quantité de produit lithié, mesurée par deutération après 15 et 45 min de réaction, est identique, permet de supposer une réaction à l'équilibre.

TABLEAU 1. Substitutions du naphtalène carbonitrile-1 par lithiation directe avec LTMP



1 **2** **3–10**

Electrophile	Produit	Point de fusion (°C)[a]	Rendement[b]
$ClSi(CH_3)_3$	**3**, E = $Si(CH_3)_3$	70–71	85
CH_3I	**4**, E = CH_3	85–86 (Litt. (19) 87–88)	80[d]
CH_3CH_2I	**5**, E = CH_2CH_3	66–67 (Litt. (20) 66,5–67,5)	54[d,f]
$CH_3CH_2CH_2I$	**6**, E = $CH_2CH_2CH_3$	[c]	63[g,i]
CH_3SSCH_3	**7**, E = SCH_3	93,5–94,5	70[e]
PhSSPh	**8**, E = SPh	100–101	80[d]
I_2	**9**, E = I	97–99	72[d]
CH_2=$CHCH_2Br$	**10**, E = 	[c]	43[h,i]
Cycloheptanone	**11**, 	106,5–107,5	56[d,j]
Benzaldéhyde	**12**, 	169–170 (Litt. (21*a*) 171–173) (Litt. (21*b*) 164–166)	20[e]

[a]Le composé isolé indique habituellement une pureté 98% par gc–ms.
[b]Matériel isolé après purification (recristallisation ou chromatographie). On utilise 10 équivalent de LTMP et 1.1 équivalent d'électrophile.
[c]Liquide incolore.
[d]Recristallisation dans l'hexane.
[e]Recristallisation dans l'éther.
[f]2 équivalents d'électrophile utilisés.
[g]4 équivalents d'électrophile utilisés.
[h]Rendement maximum avec l'équivalent de base et d'électrophile, 50%.
[i]Isolé par chromatographie.
[j]Une autre structure, l'iminolactone correspondante proposée par un examinateur, est aussi possible. L'évidence de l'infrarouge et de la rmn de ^{15}N n'est pas claire à cause du manque de modèles appropriés.

pK_a du produit **1** est environ de 2 unités (100 fois) plus acide que celui du benzonitrile (6).

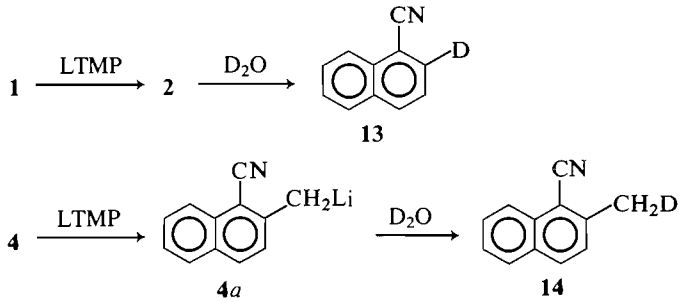
Lors de l'addition des halogénures d'alkyles sur le lithionitrile **2**, un produit secondaire (de 3 à 8%) est détecté. Une analyse par gc–ms indique que pour l'iodure de méthyle, ce produit correspond au dérivé éthyl-2 naphtalène carbonitrile-1, **5**.[3] La séquence de formation de ce composé est présenté dans le schéma 1. Ainsi, après l'addition du groupement alkyle en position 2 (A, B) une faible quantité du produit formé réagit avec le lithio-2 nitrile **2** provenant de la métalation de **1** (C) pour donner le composé lithié en position benzylique qui réagit ensuite (D) avec l'halogénure d'alkyle. Un phénomène semblable a déjà été observé par Krizan et Martin (2) lors de l'addition *in situ* d'iodure de méthyle au lithio-2 dicyano-1,3 benzène, l'utilisation d'un équivalent de l'halogénure conduit à la formation presqu'exclusive du dérivé éthyl-2. Dans notre expérience, la quantité faible présente de ce dérivé **5** indique que l'attaque de l'électrophile (B) semble plus rapide que l'échange entre l'aryllithium et le dérivé alkyl-2 (C). Des résultats identiques sont obtenus avec l'utilisation de l'iodure d'éthyle (gc–ms, 5% d'un composé, 209 (M^+)) et de l'iodure de *n*-propyle (gc–ms, 3% d'un composé, 237 (M^+)). Avec l'utilisation du bromure d'allyle le seul produit d'alkylation isolé correspond au produit de diaddition **10**. Dans ce cas, l'acidité des protons allyliques est accrue par la présence du lien double.

Ces résultats suggèrent une acidité plus importante pour les protons benzyliques que pour le proton aromatique de la position 2. Dans l'article de revue de Ronald et Winkle (11), la réaction d'un alkyllithium sur différents toluènes *ortho*-substitués dont, par exemple, le 2-CH_2NMe_2, le 2-COOH (12) et le 2-CONHMe, conduit à une métalation exclusive de la position benzylique.

Le pK_a de cette position a donc été vérifié et le tableau 2 présente les pourcentages de deutération obtenus lors de la lithiation de **4**. Le produit est presque entièrement déprotonné par le *n*-propyltriméthylsilyl amidure de lithium (94% D, après addition de D_2O) alors qu'aucune réaction n'a lieu avec le bis-triméthylsilyl amidure de lithium (LHMDS) (13), indiquant

[3]Des fragmentation par spectroscopie de masse et rmn ^1H sont identiques au produit **5**.

TABLEAU 2. Lithiation et deutération du naphtalène carbonitrile-1 et de son dérivé méthyl-2



Lithio-nitrile	Base	% D^a	pK_a ^{b}
2	DIPA	23[d]	36,7 ± 0,6[e]
2	LTMP	83[c]	35,9 ± 0,6[e]
4*a*		94[d]	28,5 ± 0,6
4*a*	HMDS	~0	>28,3

[a]Mesuré à partir des valeurs obtenues par rmn ^{1}H et sm.

[b]pK_a approximatif en tenant compte d'un équilibre atteinte entre la base et le nitrile et basé sur les valeurs suivantes d'acidité pour les bases, DIPA: 35,7; LTMP: 37,3; HMDS: 25,8;  : 30,9 (10*c*).

[c]Valeur moyenne de 2 expériences avec des temps de lithiation de 15 et 45 min.

[d]Valeur moyenne de 2 expériences avec des temps de lithiation de 25 et 240 min.

[e]La valeur de 36,3 ± 0,6 dans le texte provient de la moyenne de ces deux valeurs.

un pK_a approximatif de 28,5 ± 0,6, les protons benzyliques étant environ 10^8 fois plus acides que celui de la position 2.

Cette grande acidité des protons benzyliques permet le prolongement ou la modification de la chaîne latérale de façon efficace (tableau 3). Ainsi la métalation, suivi de l'addition d'iodure de méthyle, sur le dérivé éthyl-2, **5** conduit à la formation du dérivé isopropyl-2, **15**.

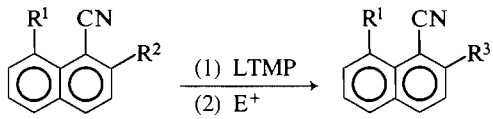
L'influence du substituant nitrile-1 sur l'acidité du groupement méthyl-8 a été aussi étudiée. La lithiation du méthyl-8 naphtalène carbonitrile-1, suivie de l'addition de chlorure de triméthylsilyle conduit uniquement au dérivé triméthylsilyl-2, **17** (tableau 3). Si ce dérivé est traité à nouveau dans les mêmes conditions, aucun dérivé silylé sur les protons benzyliques de la position 8 n'est observé. L'utilisation d'une base plus forte (10*c*), le (cyclohexyl-1 néopentyl) *tertio*-butyl amidure de lithium conduit au même résultat. Ainsi l'acidité du méthyl-8 (pK_a 42) est beaucoup plus faible que celle retrouvée avec le méthyl-2.

Certains substituants en position 1 sur le naphtalène pouvant activer l'hydrogène de la position 8 (1*a*, 1*b*) (OCH_3 (14), NHR (15), $CH_2N(CH_3)_2$ (16), $SO_2NHC_4H_9$-*t* (17)), l'effet du nitrile a été analysé. En bloquant préalablement la position 2, la plus acide, par un groupement triméthylsilyle **3**, une tentative de lithiation avec le LTMP et ensuite le (cyclohexyl-1 néopentyl) *tertio*-butyl amidure de lithium, suivie d'une addition de chlorure de triméthylsilyle, n'a donné aucun résultat observable. Avec le *n*-butyllithium et le tétraméthylènediamine (TMEDA) dans le THF, suivi de l'addition de l'iodure de méthyle, le seul produit isolé correspond au produit d'addition de l'alkyllithium sur le nitrile et à la *N*-méthylation de l'imine formé.

Dans le cas du naphtalène carbonitrile-1, **1**, le groupement nitrile n'induit une forte influence qu'en position 2, l'acidité de la position 8 semblant très peu affectée par la présence de ce substituant.

La métalation directe du naphthalène carbonitrile-1, **1**, est une méthode efficace pour obtenir un dérivé substitué en position 2. L'aryllithium formé à partir d'une base non-nucléophile comme le LTMP est suffisamment stable à basse température (−78°C) pour effectuer ensuite l'addition d'un électrophile. De plus, les protons benzyliques obtenus lors de l'alkylation de la position 2 étant beaucoup plus acides que ceux sur le cycle aromatique, il est d'autant plus facile de modifier la chaîne latérale introduite antérieurement. Un autre avantage observé est que le groupement nitrile, activant très peu le proton

TABLEAU 3. Métalation et réacton des dérivés alkyl-2 et -8 du naphtalène carbonitrile-1



R^1	R^2	Électrophile	Produit (R^1, R^3)	Rendement[b] (%)	Point de fusion (°C)[a]
H	CH_3	CH_3I	**5**, R^1 = H, R^3 = CH_2CH_3	85[e]	66–67[d]

[d]Composé identique à celui obtenu précédemment (Tableau 1).

[e]Recristallisation dans l'hexane.

[f]Isolé par chromatographie.

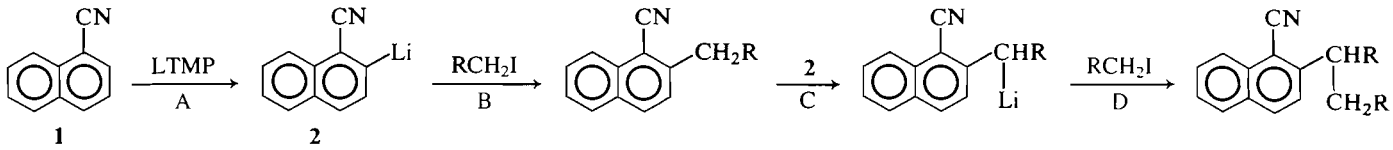

SCHÉMA 1

de la position 8, ou les protons benzyliques attachés à cette position, leur acidité demeure donc trop faible pour obtenir une déprotonation par les amines lithiés.

Partie expérimentale

Tous les nouveau composés ont été charactérisés par gc–ms ainsi que par rmn du ^1H (300 MHz) et du ^{13}C (20 MHz).

Les spectres du carbone 13 étaient enregistrés sur un spectromètre rmn Varian FT-80, opérant a une fréquence de 20 MHz. Les déplacements chimiques étaient obtenu dans des solutions de $CDCl_3$ utilisant comme référence interne la bande à 77,00 ppm du $CDCl_3$. L'attribution des résonances était faite à partir d'expériences de découplage hors-résonance et des effets de substituants connus (18). Les spectres des protons étaient enregistrés sur un spectromètre rmn Varian XL-300, opérant à une fréquence de 300 MHz. Les échantillons étaient en solution dans le $CDCl_3$ et la référence interne était la résonance à 7,24 ppm du chloroform. Les déplacements chimiques sont donnés en ppm, avec entre parenthèse la multiplicité et la constante de couplage en Hz (s = singulet, d = doublet, t = triplet, q = quadruplet, m = multiplet). Les spectres infrarouges étaient enregistrés sur un spectromètre ir Perkin Elmer 783 la valeur des absorptions est donnée en cm^{-1} et les échantillons étaient préparés en solution dans le chloroforme. Les spectres de masse étaient enregistrés sur un spectromètre VG 7070-E.

*Préparation du méthyl-2 naphtalènecarbonitrile-1, **4** (Procédure habituelle de lithiation et de substitution du naphtalène carbonitrile-1 et de ses dérivés alkyl-2)*

Une solution de 1,02 mL (0,006 mol) de TMP dans 25 mL de THF (anhydre) est refroidie à 0°C et agitée pendant 30 min sous atmosphère inerte (argon) après l'addition de 4,85 mL (0,006 mol) d'une solution de méthyl lithium dans l'éther diéthylique (1,25 *M*). On refroidit à −78°C et une solution du nitrile **1** (0,926 g, 0,006 mol dans 3 mL de THF) est additionnée lentement. La solution brune est agitée pendant 35 min avant l'ajout de l'iodure de méthyle (0,42 mL, 0,0066 mol). Après 2 h à −78°C, le mélange réactionnel est réchauffé à la température de la pièce et agité pendant 1 h. Pour isoler, 20 mL d'eau glacée sont ajoutés, la phase organique est lavée avec HCl 10% (2 × 50 mL), avec une solution de NaCl (saturé) (4 × 50 mL) et séchée sur $MgSO_4$ avant d'évaporer le solvant. Le solide obtenu est purifié par chromatographie sur gel de silice (hexane) et recristallisé dans l'hexane; 809 g (80%) d'un solide blanc (pf: 84–85°C) est ainsi recueilli, le méthyl-2 naphtalène carbonitrile-1, **4**.

Application des conditions de réaction par transfert de phase à la synthèse d'amino-éthers dérivés du *trans* phénoxy-2 cyclohexanol

P. DEPREUX ET A. MARCINCAL-LEFEBVRE

Laboratoire de chimie organique, Faculté de pharmacie de Lille, 3, rue du Professeur-Laguesse, 59045 Lille CEDEX, France

Reçu le 4 janvier 1985[1]

P. DEPREUX et A. MARCINCAL-LEFEBVRE. Can. J. Chem. **64**, 626 (1986).

On a préparé des amino-éthers du *trans* phénoxy-2 cyclohexanol en faisant appel à des méthodes impliquant des conditions anhydres (alcoolates de sodium dans le xylène) ou des conditions de catalyse par transfert de phase (CTP) (systèmes à deux phases liquide – liquide ou solide–liquide). On a optimisé divers facteurs. Dans le cas du système à deux phases liquide – liquide dans lequel on n'ajoute pas de catalyseur, la réaction se produit avec des rendements, qui sont comparables ou supérieurs à ceux obtenus avec adjonction de catalyseurs de transfert de phase, un ammonium quaternaire se formant *in situ*. En se basant sur le fait qu'il ne se produit pas d'extraction de OH^- dans la phase organique et que les rendements dépendent de la vitesse de l'agitation, on a pu démontrer que la déprotonation du ROH se produit à l'interface. En présence d'Aliquat, le rendement ne change pas avec la concentration organique du catalyseur. Les corrélations statistiques obtenues entre les variations de rendements et plusieurs paramètres étaient bonnes.

P. DEPREUX and A. MARCINCAL-LEFEBVRE. Can. J. Chem. **64**, 626 (1986).

Amino-ethers of *trans*-2-phenoxycyclohexanol were prepared by methods involving anhydrous conditions (sodium alkoxides in xylene) or phase transfer catalysis conditions (liquid–liquid or solid–liquid two-phase systems). Various factors were optimized. In the liquid–liquid two-phase system, when no catalyst was added, reaction proceeds with comparable or even better yields than with some PTC catalysts, a quaternary salt being formed *in situ*. It was shown that the deprotonation of ROH takes place at the interface, since there was no OH^- extraction in organic medium and the yield depends on the stirring speed. In the presence of Aliquat, the yield does not change with the organic concentration of the catalyst. Statistical correlations obtained between the variations in yield and several other parameters were good.

Dans le cadre de travaux sur les dérivés du *trans* phénoxy-2 cyclohexanol, nous avons étudié plus particulièrement la synthèse d'amino-éthers de type **1** (schéma 1), afin d'optimiser leurs conditions d'obtention par un procédé commode et peu coûteux, telle la catalyse par transfert de phase.

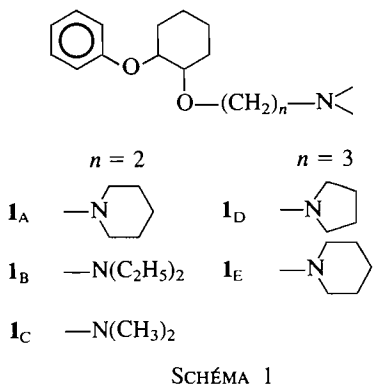

SCHÉMA 1

L'importance pharmacologique du chaînon—O—$(CH_2)_2$—N est reconnue; on le rencontre dans de nombreuses molécules à activités biologiques diverses. Ainsi le test de Winter appliqué au composé $\mathbf{1}_A$, en vue de déterminer son activité anti-inflammatoire potentielle, révèle une activité du même ordre de grandeur que celle de l'Indométhacine utilisée comme substance de référence.[2]

Nous avons réalisé la synthèse de type Williamson des éthers **1**, d'une part par réaction dans le xylène à reflux entre l'alcoolate de sodium du *trans* phénoxy-2 cyclohexanol et l'amine tertiaire halogénée aliphatique (schéma 2), et d'autre

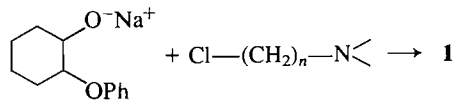

SCHÉMA 2

part par réaction de l'alcool lui-même dans des conditions de réaction par transfert de phase (schéma 3), catalysée par des ammoniums quaternaires (1) ou des éthers-couronnes (2), ou par addition d'amines tertiaires (3) ou de polyamines (4), susceptibles de former des ammoniums quaternaires (24), soit en présence de solution aqueuse de soude à 40% (système liquide – liquide (5)), soit en présence de soude en pastille (système solide – liquide (5)) et en employant différents solvants organiques.

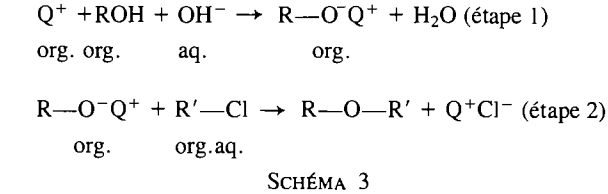

SCHÉMA 3

Les réactions de substitution nucléophile par transfert de phase ont été beaucoup étudiées (6–10) et il est particulièrement intéressant de pouvoir appliquer ce type de réactions par transfert de phase à la synthèse médicamenteuse qui se heurte souvent à la fragilité des molécules polyfonctionnelles préparées, dans les conditions de formation des alcoolates.

En ce qui concerne la réactivité et la stabilité des amines tertiaires halogénées, la présence de deux groupements fonctionnels dans ces composés laisse prévoir une réactivité complexe pour laquelle trois directions ont été mises en évidence (11) (schéma 4). Selon le milieu et sa constante diélectrique, la dimérisation en (b) se produit en proportions variables (11) et, lorsque $n = 2$, on a observé, dans l'eau, 70% de dimérisation

1. Révision reçue le 16 octobre 1985.

SCHÉMA 4

(voie d'inactivation des amines tertiaires halogénées), alors que dans le benzène aucune réaction ne se produit.

Le dimère ainsi formé («diquat») possède deux groupements ammoniums et pourrait jouer le rôle de catalyseur par formation d'un alcoolate d'ammonium P^+ R—O^- dans des réactions de type transfert de phase. Cette hypothèse fut avancée par J. Jarousse (12) pour expliquer la réaction du cyclohexanol avec le chloro-2 *N,N*-diméthylaminoéthane en présence d'une solution aqueuse de soude à 50%. Néanmoins peu de précisions étaient données quant aux conditions opératoires et au rendement. De même, J. Dockx (13) a étudié la réaction d'alcools de type benzhydrol avec des dérivés halogénés en présence d'ammoniums quaternaires, mais n'a pas publié les résultats obtenus.

Les composés préparés ont été isolés sous forme d'oxalates recristallisés de l'acétate d'éthyle. Les rendements ont été calculés par rapport au *trans* phénoxy-2 cyclohexanol mis en réaction. Dans chaque essai, nous avons récupéré en fin de synthèse un pourcentage variable de cet alcool. Les corrélations entre différents paramètres et le rendement ont été établies.

Système biphasique liquide – liquide

Pour les réactions effectuées en *milieu biphasique liquide – liquide*, les conditions standards utilisées sont les suivantes: cinq équivalents de NaOH (solution aqueuse à 40%) par rapport au phénoxy-2 cyclohexanol (en solution benzénique) et un équivalent de chlorhydrate d'amine tertiaire halogénée. Le mélange est maintenu à reflux, sous agitation à 450 tours/min, pendant 4 h, en présence éventuellement de 0,1 équiv. de catalyseur. Les variations de conditions opératoires ont porté sur la quantité de soude, le solvant organique, le temps et la température de réaction ainsi que la nature du catalyseur.

(A) *Les résultats obtenus pour le composé* $\mathbf{1}_A$ sont rassemblés dans le tableau 1.

(a) Dans les conditions standards, en présence de *chlorure de benzyltriéthylammonium* (CBTEA) (réaction 1), d'Aliquat[3] ou de sulfate acide de tétrabutylammonium (TEBA) (réactions 4 et 6), les rendements sont respectivement de 14, 37 et 34%. Si l'on augmente la quantité de catalyseur et de soude (réaction 2), le rendement est comparable. Une température de réaction inférieure est défavorable (réactions 3 et 5).

(b) *Sans adjonction de catalyseur*, le rendement dans les conditions standards (réaction 7) est de 33%. Les variations des conditions (réactions 8–14) montrent l'influence favorable de l'augmentation de température (réaction 12, 43%, xylène à reflux) ou de l'augmentation de la quantité de soude, mais seulement si on opère à température ambiante (réaction 14).

(c) Une *amine tertiaire*, telle la triéthylamine, bien que pouvant avoir un rôle catalytique dans les réactions des dérivés halogénés par formation d'un ammonium quaternaire, provoque une chute du rendement de 27 (réaction 14) à 9% (réaction 17).

3. Aliquat: mélange de $(nC_8–C_{12})_3N^+CH_3Cl^-$.

Si l'on étudie la corrélation entre les variations de rendement observées et le rapport molaire NaOH – alcool, la température de réaction, le temps de réaction, la constante diélectrique de la phase organique et le nombre de carbone de l'ammonium (Q^+ ou P^+), on observe que 74% des variations de rendement peuvent être expliqués par la corrélation avec les paramètres cités précédemment. Si l'on compare, au moyen du test statistique F de Fischer – Snedecor, les variations de rendement expliquées par ces paramètres et celles dues au « hasard expérimental », il existe une différence significative entre ces deux types de variations au seuil de 3%. La *température de réaction* apparaît comme un facteur prépondérant dans les variations de rendement (coefficient de corrélation $r = 0{,}64$). De même, le *temps de réaction* n'est pas à négliger ($r = 0{,}46$); il est directement lié au facteur température ($r = 0{,}88$) et, si l'on ne tient pas compte du facteur temps dans les corrélations avec les variations de rendement, alors seulement 58% de celles-ci peuvent être expliquées et le seuil du test F est alors de 7%.

Herriot et Picker (14) ont étudié l'activité catalytique des ammoniums quaternaires et ont montré que deux facteurs intervenaient: d'une part, un grand nombre d'atomes de carbone (haute lipophilie) pour P^+ ou Q^+ et, d'autre part, une disposition symétrique autour de l'hétéroatome, ce deuxième facteur étant cependant moins important (24). Ainsi, le CBTEA (13 carbones) contient le nombre minimum d'atomes de carbone et son manque de symétrie est considéré comme peu favorable.

Sur la base de cette notion, nous avons, dans la corrélation, fait intervenir l'ammonium quaternaire par son *nombre d'atomes de carbone*. Ce facteur possède une corrélation positive ($r = 0{,}44$) avec les variations de rendement. Dans le cas du tétrabutylammonium (symétrique, 16 C), du trioctylméthylammonium (25 C) ou du dimère cyclique provenant du chloro-2 pipéridinoéthane (P^+ symétrique, 14 C), les cations sont volumineux; de ce fait, l'anion alcoolate semble moins associé, donc beaucoup plus réactif, comparativement aux cations hydrophiles et moins volumineux tels que le benzyltriéthylammonium et celui résultant de l'utilisation de triéthylamine, qui permet la formation de $(CH_2)_5N—CH_2—CH_2—N^+(C_2H_5)_3$.

Les baisses de rendement lors de l'addition de CBTEA ou de triéthylamine par rapport au rendement obtenu sans addition de catalyseur pourraient donc être expliquées par compétition entre paires d'ions et par une augmentation de l'hydrophilie dans le cas des ions triéthylammoniums, qui possèdent des propriétés tensio-actives défavorables (24).

Étant donné la lipophilie de l'alcool de départ (log *P* (calculé) = 3),[4] on peut penser que la formation de l'alcoolate s'effectue à l'interface de deux phases liquides, selon le mécanisme décrit pour les composés à CH acide qui sont eux-mêmes lipophiles (24, 25). Pour vérifier cette hypothèse, nous avons étudié les variations de rendement en fonction de la vitesse d'agitation et de la concentration en catalyseur, et montré[5] que, dans les conditions où nous opérons, l'Aliquat extrait les ions OH^- en phase organique ($3{,}6 \times 10^{-2}$ équiv. OH^- : 1 équiv. d'Aliquat dans le benzène), ce qui n'est pas le cas avec le pipéridinochloréthane, après 2 h d'agitation à 80°C uniquement en présence d'une solution de soude à 40% et de benzène; l'extraction de

4. log *P*: logarithme du coefficient de partage calculé par la méthode des constantes fragmentales de Rekker (voir réf. 15).

5. Titrage, par HCl 0,11 *N* en présence de fuchsine acide 1‰ et de 10 mL de H_2O, de 4 mL de la phase organique prélevés après 2 h d'agitation à 80°C d'une solution aqueuse de soude à 40% (5 mL) et de benzène (10 mL) en présence d'Aliquat (0.38 g).

0,1	450	37
0,15	700	46
0,20	700	43

l'anion OH^- est reconnue comme difficile et négligeable dans de nombreuses réactions (5, 16, 25).

En présence des seuls réactifs (soude, R—O—H et chloro-2 pipéridinoéthane dans le benzène), le catalyseur formé *in situ* (P^+) est moyennement hydrophile, relativement symétrique et volumineux; comme il n'extrait pas les ions OH^- en phase organique et que les rendements sont améliorés par augmentation de l'agitation (tableau 2) et donc de l'interface, on peut envisager un mécanisme interfacial pour l'arrachement de H^+ à ROH (étape 1) et que les étapes se produisant à l'interface limitent la vitesse de réaction[6] (schéma 2 où $P^+ = Q^+$). La paire d'ions $R—O^- P^+$ est formée d'un anion stabilisé par P^+ suffisamment volumineux pour ne pas lui être trop associé. La substitution (étape 2) peut se produire à la fois à l'interface, puisque le dérivé halogéné est soluble dans les deux phases, et simultanément dans la phase organique, puisque les rendements sont diminués en présence de catalyseurs plus hydrophiles, tels le CBTEA ou la triéthylamine. Par contre, l'addition aux réactifs d'un catalyseur plus lipophile, tel que l'aliquat, ou plus symétrique tel que le TEBA (réactions 4 et 6), augmente légèrement les rendements, par rapport à ceux obtenus dans les conditions standards (réaction 7) ; à la différence des catalyseurs précédents, y compris de P^+, ces catalyseurs extraient les ions OH^- en phase organique, ce que nous avons vérifié ; néanmoins la formation de RO^- reste prépondérante à l'interface, car les rendements ne sont pas augmentés par l'augmentation de la concentration en catalyseur, mais le sont par l'élévation de la vitesse d'agitation (tableau 3).

Cette légère augmentation des rendements peut signifier une amélioration de l'étape 2 par échange de cation: en faveur de $RO^- Q^+$ avec $:Q^+$: $(Bu)_4N^+$ ou $(octyl)_3N^+CH_3.Q^+$ étant plus lipophile, et donc plus efficace pour détacher RO^- de l'interface que P^+.

(B) Nous avons ensuite appliqué les différentes conditions de synthèse envisagées précédemment, en phase liquide – liquide, à l'obtention des amino-éthers $\mathbf{1}_{B,C,D}$ (schéma 1) ; et d'autre part, nous avons voulu comparer la réactivité d'un alcool moins lipophile, tel que le cyclohexanol (log P = 1,8) et l'avons fait réagir avec les chloro-2 pipéridino- (17) et diméthylamino-éthanes (18) (schéma 5) sans adjonction de catalyseur dans le benzène, 4 h à reflux en présence de 5 équiv. de soude (conditions standards). Les résultats obtenus lors de la *synthèse des éthers* $\mathbf{1}_{B,C,D}$ sont rassemblés dans la fig. 1.

Quelques soient les conditions opératoires, les dérivés $\mathbf{1}_{B,C,D}$ sont obtenus avec des rendements inférieurs à ceux du dérivé $\mathbf{1}_A$. Cette différence pourrait être expliquée par trois facteurs: la basicité de l'amine, l'encombrement stérique au niveau de son

6. Lors des réactions se produisant selon un mécanisme par extraction des ions OH^-, la vitesse de réaction augmente avec la lipophilie du catalyseur et sa concentration, mais est indépendante de la vitesse d'agitation au-dessus d'une certaine valeur (environ 300 tours/min (16)).

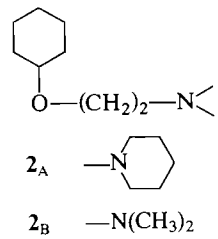

SCHÉMA 5

atome d'azote et la lipophilie ; ces facteurs interviennent essentiellement au niveau de l'activité du catalyseur et de sa formation *in situ* par dimérisation de l'amine chlorée. Il semble vraisemblable que les effets stériques interviennent de façon prépondérante, d'une part dans l'association du dimère avec l'anion alcoolate, et d'autre part dans la stabilité de ce dimère vis-à-vis des ions OH^- et, par exemple, de la température (19). Ainsi, le chloro-2 pipéridino-éthane donne de meilleurs rendements que le chloro-2 pyrrolidino-éthane, dont l'azote est moins encombré.

Si l'on compare les résultants obtenus dans le dichlorométhane (réactions 2′), on observe que les éthers **1** n'ont pu être obtenus qu'avec les chloro-2 pipéridino- et diéthylamino-éthanes qui sont plus lipophiles et plus encombrés que les dérivés pyrrolidiniques et diméthylaminés,[7] le meilleur rendement étant obtenu avec le dérivé le plus lipophile. Dans ces conditions opératoires le volume de soude est élevé et favorise la transformation irréversible en phase aqueuse des amines chlorées en dimère et particulièrement des plus hydrophiles, ce qui peut rendre compte du rendement quasi nul en $\mathbf{1}_C$ et $\mathbf{1}_D$ par consommation de ces dernières.

La *réactivité du cyclohexanol* n'est pas supérieure à celle du phénoxy-2 cyclohexanol. Avec le cyclohexanol, nous avons obtenu les dérivés $\mathbf{2}_A$ et $\mathbf{2}_B$ avec des rendements respectifs comparables à ceux obtenus pour $\mathbf{1}_A$ et $\mathbf{1}_C$, ce qui semble exclure pour le phénoxy-2 cyclohexanol l'intervention d'effets stériques (du groupement phénoxy en 2) ou de stabilisation de la paire d'ions Q^+ R—O^- par les doublets des deux atomes d'oxygène.

(C) Nous avons étudié pour l'obtention des dérivés de type **1** et **2** (25 essais) la *corrélation globale* entre les variations de rendement et les paramètres suivants: (*1*) rapport molaire NaOH–alcool ; (*2*) temps de réaction ; (*3*) température de réaction ; (*4*) constante diélectrique du solvant organique ; (*5*) nombre de carbone de Q^+ ; (*6*) log *P* de l'alcool ; (*7*) rapport molaire eau – amine chlorée ; (*8*) log *P* de l'amine chlorée. Les résultats amènent les commentaires suivants:

Dans les conditions d'étude (25 essais, 8 paramètres explicatifs), 65% des variations de rendement peuvent être expliqués par la corrélation. Il existe une différence significative au seuil de 1,22% entre les variations de rendement expliquées par le modèle et celles dues au hasard.

La lipophilie de l'alcool est peu corrélée ($r = -0,07$) mais ce résultat est peu indicatif, étant donné la faible gamme de lipophilie employée. Il existe naturellement une très bonne corrélation ($r = 0,97$) entre les paramètres 1 et 7 du fait de l'emploi dans tous les cas d'une solution aqueuse de soude à 40%. Une corrélation similaire ($r = -0,89$) existe entre temps et température de réaction.

Parmi les paramètres, nous pouvons noter une corrélation

7. log *P* des amines chlorées, calculé selon réf. 15: pipéridinique, 2,2; diéthylaminée, 2; pyrrolidinique, 1,6; diméthylaminée, 0,99.

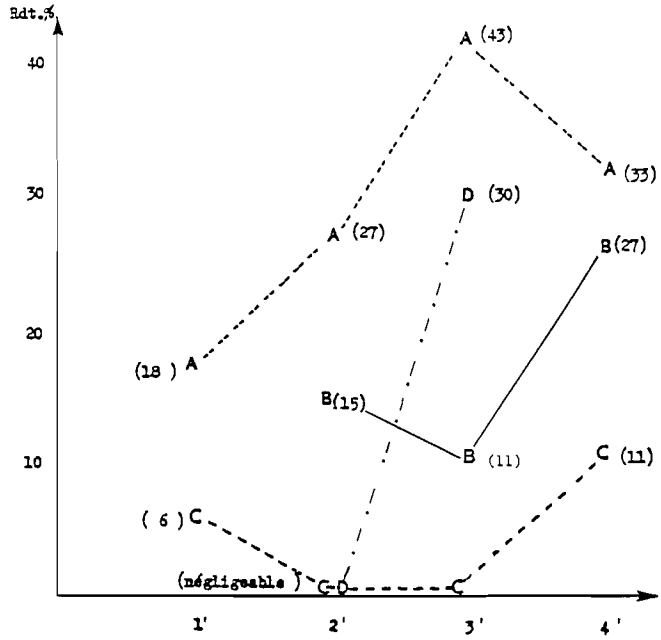

FIG. 1. Variations de rendement pour les amino-éthers **1**. 1′: CBTEA (0,25 équiv.) – C_6H_6 – 40 équiv. de NaOH, 4 h à 80°C; 2′: pas de catalyseur – CH_2Cl_2 – 40 équiv. de NaOH, 24 h à 20°C; 3′: pas de catalyseur – xylène – 5 équiv. de NaOH, 4 h à 110°C; 4′: pas de catalyseur – C_6H_6 – 5 équiv. de NaOH, 4 h à 80°C. A: pipéridino-amino-éther $\mathbf{1}_A$; B: diéthylamino-éther $\mathbf{1}_B$; C: diméthylamino-éther $\mathbf{1}_C$; D: pyrrolidinoamino-éther $\mathbf{1}_D$.

négative des variations de rendement avec le rapport molaire NaOH–alcool ($r = -0,44$), le temps de réaction ($r = -0,40$), la lipophile de l'alcool ($r = -0,07$), le rapport molaire eau – amine chlorée ($r = -0,41$) et la constante diélectrique ($r = -0,29$). Il existe une corrélation positive avec la température ($r = 0,38$), le nombre de carbone de Q^+ ($r = 0,57$) et le log *P* de l'amine chlorée ($r = 0,55$). Les paramètres 1–3, 5, 7, 8 apparaissent donc comme prépondérants dans les variations de rendement.

Étant donné les baisses de rendement observées dans le cas des composés $\mathbf{1}_B$ et $\mathbf{1}_C$, en présence de 5 équivalents de soude, sans adjonction de catalyseur, lors du passage du benzène à 80°C (réactions 4′ et 3′, fig. 1), baisse qui peut être expliquée par une décomposition à cette température (110°C) du dimère de l'amine chlorée, nous avons étudié la corrélation entre les variations de rendement et les paramètres 1–5 et 8 pour les essais effectués à une température inférieure à 110°C (21 essais). Dans ces conditions, 76% des variations de rendement sont expliquées et le test F indique une différence significative entre les variations expliquées par les facteurs envisagés et celles dues au hasard au seuil de 0,10%. La quantité de soude et d'eau ($r = -0,50$), le nombre de carbone de P^+ ou de Q^+ ($r = 0,60$) et le log *P* de l'amine chlorée ($r = 0,55$) sont les facteurs prépondérants. Si l'on fait intervenir la basicité de l'amine tertiaire, la corrélation n'est pas améliorée ($r^2 = 0,76$) et de plus ce paramètre intervient peu dans les variations de rendement ($r = 0,17$).

(D) Dans les conditions de réaction en milieu liquide–liquide, en présence de 40 équivalents de soude dans le benzène et de 0,05 équivalent d'un éther couronne, le "benzo-15-crown-5", les rendements en éther $\mathbf{1}_A$ sont semblables à ceux obtenus dans les mêmes conditions avec le CBTEA (18% après 4 h à 80°C) ; le complexe de l'éther couronne avec l'ion Na^+ étant

TABLEAU 4. Réactions dans un système solide–liquide. Variations de rendement en oxalate de $\mathbf{1}_A$ (agitation: 450 tpm)

	Paramètres						
Catalyseur	Phase organique	Quantité de soude (équiv.)	Na_2CO_3	Quantité de catalyseur (équiv.)	Temps de réaction (h)	Température de réaction (°C)	Rendement en $\mathbf{1}_A$ (%)

TEBA	Benzène	3,5	+	0,1	4	70	17
Tétraméthyléthylène diamine	Benzène	3,5	+	0,1	4	80	28

comme la CBTEA, un catalyseur de transfert de phase trop hydrophiles (24).

Système biphasique solide–liquide

Afin d'étudier *l'influence de l'eau*, nous avons réalisé la synthèse du composé $\mathbf{1}_A$ dans un système biphasique solide–liquide en employant comme phase solide un mélange soude (3,5 équiv.) – Na_2CO_3 dans du benzène (70 ou 80°C). Dans ce type de catalyse, la déprotonation de l'alcool se produit à la surface du mélange solide. Les résultats obtenus avec un tel système sont réunis dans le tableau 4.

En absence de catalyseur, les résultats sont similaires à ceux obtenus en phase liquide–liquide. Comparativement à la réaction en phase liquide–liquide, la quantité d'eau étant faible (et provenant essentiellement de la déprotonation de l'alcool), la dimérisation serait plus lente, mais suffisante pour catalyser la réaction de l'anion alcoolate avec l'amine chlorée.

Les couronnes sont de bons catalyseurs dans les transferts de phase solide–liquide et l'utilisation du "benzo-15-crown-5" s'avère bénéfique. Dans le benzène, après 4 h à 80°C le rendement est de 55%. Avec un composé de type cryptand, le Kryptofix 5, les résultats sont similaires. Ces réactions sont classiquement réalisées en présence de NaOH + Na_2CO_3, mais la présence de carbonate, utilisé classiquement dans ce type de catalyse (20), n'est pas indispensable. A l'inverse, l'utilisation de Na_2CO_3 seul, décrite par certains auteurs (21), ne permet pas, dans le cas du composé $\mathbf{1}_A$, la condensation.

Dans ce procédé en phase solide–liquide, l'utilisation de CBTEA (0,1 équiv.), 4 h dans le benzène à 80°C, a donné un rendement de 21% (il était de 14% en phase liquide–liquide). De même le TEBA donne un rendement de 17% après 4 h à 70°C, équivalent à celui obtenu dans les mêmes conditions sans adjonction de catalyseur. Enfin en présence de tétraméthyléthylènediamine, le rendement est de 28%, après 4 h à 80°C dans le benzène.

Pour l'étude des *corrélations en phase solide–liquide*, nous avons utilisé comme paramètre dans le cas des essais à 70, 80, 110°C (12 essais), le temps et la température de réaction, le rapport molaire NaOH–alcool, le rapport molaire entre l'eau et l'amine chlorée, la constante diélectrique de la phase organique (2,3 pour le benzène et 2,11 pour le xylène) et pour différencier les ammoniums des éthers couronnes le nombre de carbone du contrion positif et le nombre de sites électroniques.

Nous pouvons constater que 95% des variations de rendement observés dans la catalyse solide–liquide peuvent être expliqués par la corrélation avec les paramètres envisagés. Dans des conditions de réaction identiques, c'est-à-dire 4 h à 70 ou 80°C dans le benzène en présence du mélange NaOH–Na_2CO_3 avec utilisation d'un éther couronne, d'une polyamine ou d'ammoniums quaternaires, nous avons envisagé la corrélation entre les rendements et la température de réaction, le nombre d'atomes de carbone du contrion positif et le nombre de sites électroniques, 76% des variations de rendement sont expliqués par ce paramètres. La température de réaction est un facteur prépondérant (r = 0,69).

Réactions en milieu anhydre

Lors de l'étude du procédé en milieu biphasique liquide–liquide, nous avons remarqué l'importance de la formation du dimère. Pour confirmer ce fait, nous avons effectué *la synthèse des éthers 1 en milieu anhydre*, en solution dans le xylène (D = 2) à reflux avec formation préalable du phénoxy-2 cyclohexanolate de sodium sous l'action du sodium fondu (1 équiv.). Après 3 h de réaction, les rendements de la condensation entre l'alcoolate de sodium et les amines chlorées sont les suivants: chloro-2 pipéridinoéthane, rendement 25%; chloro-2 diéthylaminoéthane, rendement 27%; chloro-2 pyrrolidinoéthane, rendement 20%. Dans ces conditions si l'on admet qu'il ne se forme pas de dimère, le contrion de l'anion est l'ion Na^+ et les trois amines donnent des rendements comparables. Nous avons étudié l'effet de l'addition de CBTEA ou de TEBA qui peuvent donner comme phase liquide–liquide la pair d'ions (b)

$$\underset{(a)}{RO^-Na^+} + R'_4N^+X^- \rightarrow \underset{(b)}{RO^-R'_4N^+} + Na^+X^-$$

dont la réactivité se rapprocherait de celle de l'anion dissocié et dans laquelle les interactions anion–cation seraient diminuées par rapport à (a) (22). Effectivement par ce procédé, les rendements sont améliorés: par exemple dans le cas du dérive $\mathbf{1}_A$, le rendement est de 40% en présence de CBTEA et de 46%

en présence de TEBA (0,1 équiv.); ayant dû ajouter de l'acétonitrile pour dissoudre le catalyseur, nous avons vérifié que l'amélioration de rendement résultait bien de l'utilisation d'un ammonium quaternaire et non de celle d'acétonitrile, solvant polaire qui peut également augmenter la vitesse de substitutions nucléophiles par solvation spécifique du cation (dans un mélange xylène–acétonitrile le rendement en $\mathbf{1}_A$ est de 19%). Nous avons confirmé l'effet favorable sur le rendement de l'addition de CBTEA avec le chloro-2 pyrrolidino-éthane (Rdt: 31%), le chloro-2 diméthylamino-éthane (27%) et avec la chloro-2 diéthylamino-éthane (30%). Si l'on utilise le chloro-3 pipéridinopropane en milieu anhydre, le rendement passe de 19% avec RO^-Na^+ seul comme nucléophile à 29% en présence de CBTEA.

Conclusion

La réaction entre le *trans* phénoxy-2 cyclohexanol et diverses amines tertiaires halogénées aliphatiques s'effectue avec des rendements moyens en général. Dans des conditions de transfert de phase en *milieu liquide–liquide*, les rendements dépendent principalement de la dimérisation d'une certaine quantité d'amine chlorée en ammonium quaternaire ; cette dimérisation, voie d'inactivation irréversible des amines chlorées, est fonction de la constante diélectrique du milieu et de la lipophilie de l'amine chlorée. Dans le cas du composé $\mathbf{1}_A$, l'amine chlorée est faiblement soluble dans l'eau ($\log P = 2{,}2$) ; de ce fait, si à 80°C on augmente le volume d'eau par utilisation de 8 fois plus de lessive de soude (40 équiv.) on favorise cette condensation irréversible en ammonium quaternaire, d'où la diminution de rendement par consommation d'amine chlorée. À température ambiante, la dimérisation est plus lente, de ce fait l'utilisation d'un volume d'eau plus important est favorable à la formation d'une quantité suffisante de catalyseur. Parallèlement à la lipophilie, l'encombrement de l'ammonium quaternaire (nombre de carbone de P^+ ou Q^+) apparaît déterminant dans le rendement.

Étant donné le lipophilie de l'alcool mis en réaction, les ammoniums jouent davantage le rôle de contrion vis-à-vis de l'anion alcoolate que de catalyseur de transfert de phase, la déprotonation se produisant vraisemblablement à l'interface.

L'étude en phase *solide–liquide* a confirmé l'intérêt des éthers couronnes dans ces conditions.

En milieu anhydre, dans le xylène, il n'y a vraisemblablement pas de dimérisation et l'utilisation de CBTEA ou de TEBA augmente le rendement en apportant un contrion moins associé à RO^-, l'amine chlorée réagissant sous la forme activée d'ion éthylène immonium (23).

Malgré des rendements moyens pour un cycle de réactions le procédé par transfert de phase s'avère donc intéressant dans la réaction d'éthérification de cyclohexanols par sa facilité de mise en œuvre et le recyclage possible de l'alcool n'ayant pas réagi.

Partie expérimentale

Lors du traitement du milieu réactionnel, les phases organiques, séchées sur sulfate de sodium anhydre, ont été évaporées sous pression réduite au moyen d'un évaporateur rotatif Büchi à la pression de la trompe à eau. Les résidus d'évaporation sont dissous dans de l'éther anhydre et transformés en oxalate par addition progressive d'une solution éthérée d'acide oxalique.

Les points de fusion non corrigés ont été déterminés par la méthode en tube capillaire.

Les spectres infrarouges (ir) ont été enregistrés avec un spectromètre Beckman IR20 à double faisceau ou un appareil Perkin Elmer 297. Les bases huileuses sont étalées en film entre deux pastilles de bromure de potassium. Les résultats sont donnés en cm^{-1}.

Les spectres de résonance magnétique nucléaire (^1H rmn) ont été réalisés à la fréquence de 60 MHz sur un appareil JEOL C.60HL. Les déplacements chimiques sont en ppm par rapport au tétraméthylsilane. Les signaux sont désignés par les abréviations suivantes: s (singulet), d (doublet), t (triplet), q (quadruplet), m (massif ou multiplet). Les constantes de couplage (J) sont données en Hz. La structure *trans* est vérifiée à cette fréquence par la largeur de signal à demi-hauteur.

Les différentes corrélations concernant les variations de rendement ont été déterminées par un programme informatique de régression multiple sans répétitions sur un ordinateur PDP 11.

Méthodes générales de synthèse

(A) *Procédé en milieu biphasique liquide–liquide*

À un mélange de 0,0156 mol de chlorhydrate d'amine tertiaire halogénée et 10 mL d'une solution aqueuse de soude à 40%, on ajoute ou non selon le cas 0,1 équiv. d'ammonium quaternaire, puis 0,0156 mol de *trans* phénoxy-2 cyclohexanol en solution dans 10 à 20 mL de benzène. On chauffe à reflux (80°C) 3 h sous agitation à une vitesse de rotation comprise entre 450 et 500 tours/min.

Après refroidissement, on sépare la phase organique, la lave à l'eau, puis l'évapore sous pression réduite après séchage. Le résidu d'évaporation est transformé en oxalate qui recristallise de l'acétate d'éthyle après filtration et concentration du filtrat.

(B) *Procédé en milieu biphasique solide–liquide*

Un mélange de *trans* phénoxy-2 cyclohexanol (0,026 mol) dans 20 mL de benzène, d'hydroxyde de sodium en pastilles (2,1 g), de carbonate de sodium (1,25 g) et de 10 mol% de catalyseur est agité vigoureusement vers 60°C pendant 30 min. À cette température, on ajoute ensuite goutte à goutte une solution de chloro-2 pipéridinoéthane (0.026 mol) dans 10 mL de benzène. L'agitation est alors poursuivie pendant 4 h à reflux (80°C). Après refroidissement on ajoute de l'eau et l'éther $\mathbf{1}_A$ est isolé, puis transformé en oxalate comme précédemment.

(C) *Procédé en milieu anhydre*

À une solution de phénoxy-2 cyclohexanolate de sodium (0,0156 mol) dans 20 mL de xylène anhydre, on ajoute à froid une solution de 10 mol% de CBTEA ou de TEBA dans 5 mL d'acétonitrile, puis 0,0156 mol d'amine tertiaire halogénée dans du xylène anhydre. On chauffe à reflux 3 h sous agitation. Après refroidissement on reprend par l'eau. Les amino-éthers sont extraits, puis isolés sous forme d'oxalate comme précédemment.

COMMUNICATION

The anesthetic potency of *n*-alcohols. A model spectroscopic study in inverted micelles

PIERRE MÉNASSA, THÉRÈSE LUSSIER, AND CAMILLE SANDORFY
Département de chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3J7
Received December 12, 1985

PIERRE MÉNASSA, THÉRÈSE LUSSIER, and CAMILLE SANDORFY. Can. J. Chem. **64**, 633 (1986).

A relation has been found between the anesthetic potency of *n*-alcohols ($n = 1, 3, 6, 7, 9, 11, 14$, and 16) and their association constants with polar groups in inverted micelles. From this point of view, cholesterol and 7-dehydrocholesterol behave like short-chain *n*-alcohols while cholestanol behaves like a long-chain *n*-alcohol.

PIERRE MÉNASSA, THÉRÈSE LUSSIER et CAMILLE SANDORFY. Can. J. Chem. **64**, 633 (1986).

On a pu démontrer qu'il existe une relation entre le pouvoir anesthésique des *n*-alcools et leur constante d'association avec des groupements polaires dans des micelles inverses, qui a été determinée pour $n = 1, 3, 6, 7, 9, 11, 14$ et 16. De ce point de vue, le cholestérol et le dehydro-7 cholestérol se comportent comme des *n*-alcools à chaîne courte alors que le cholestanol s'apparente aux *n*-alcools à chaîne longue.

Alcohols are known to have anesthetic potency (1). Pringle *et al.* (2) have shown that this potency increases with the length of the hydrocarbon chain in *n*-alcohols. There is, however, a "cutoff" at C_{13}. While the latter still possesses a weak anesthetic potency, C_{14} has no anesthetic potency at all (3).

In an attempt to find a correlation between this behavior and the physico-chemical properties of alcohols, Wilson *et al.* (4) compared the hydrogen bond (H-bond) forming tendencies in the series of alcohols from C_1 to C_{18} by infrared spectroscopic means. They found that in neutral solvents, the free/H-bonded ratio for self-association is independent of the chain length. The same applies to ester carbonyl/*n*-alcohol association. Subsequently, Ménassa and Sandorfy (5) undertook similar studies in a membrane mimetic environment. Their system consisted of sodium di(2-ethylhexyl) sulfosuccinate (AOT) with traces of water in carbon tetrachloride to which an alcohol was added. The detergent AOT containing traces of water forms inverted micelles in carbon tetrachloride (6). The infrared spectra were recorded on a Nicolet model 5DXB Fourier-transform ir spectrometer with a resolution of $2\,cm^{-1}$. The method for computing association constants has been given previously (5, 7). The association constants of *n*-alcohols with AOT exhibit a pronounced dependence on chain length. The alcohol/AOT association constant decreases with increasing chain length as shown in Fig. 1. The spectra give evidence that association occurs between the alcohols and the SO_3^- group of AOT. The carbonyl bands were not observably affected with the dilute solutions that were used in those studies. However, with higher water content and alcohol concentrations, alcohol/carbonyl (AOT) association could also be detected.

More importantly, the H-bond association constants stopped decreasing at C_{10} (5) and remained constant at about $5\,L\,mol^{-1}$. Thus there appears to be a parallelism between the effect of the chain length on the H-bond equilibria of alcohols in these systems and their anesthetic potency. While AOT can only be a remote model for actual cell membranes, an analogy exists: the alcohol (anesthetic) must cross a hydrophobic region before reaching the polar groups. So the inverted micelles used in this work, which consist of a hydrophobic belt containing polar groups inside, mimic to some extent a lipid membrane surrounding a protein that contains an ion channel (8). It is perhaps

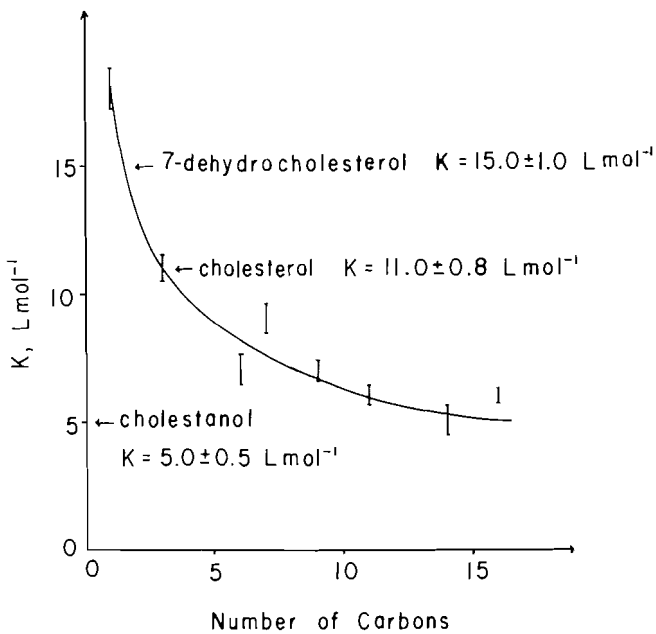

FIG. 1. The dependence of the AOT/alcohol association constants on the number of carbon atoms in *n*-alcohols (5). The association constants for the sterols depicted in Fig. 2 are also shown.

interesting in this respect that the breadth of the hydrophobic part of AOT (13 Å) is about the same as the length of C_{10}. In actual cell membranes, the breadth of the hydrophobic portion of the lipid is typically about 18 Å, about the same as the length of C_{14}.

A second observation made in our earlier work (5) concerns cholesterol. That cholesterol readily self associates by forming O—H...:O—H...:O—H... type H-bonds has been known for some time (9, 10). Now we have shown, by determination of H-bond association constants in the cholesterol/AOT/carbon tetrachloride system, that from this point of view cholesterol behaves like a short-chain alcohol (C_3), despite its bulky hydrocarbon moiety.

It then seemed interesting to us to ascertain whether this is a general property of sterols or if cholesterol represents a special

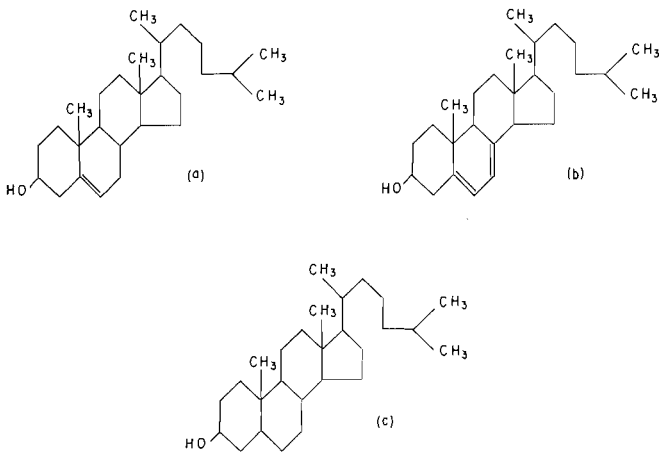

FIG. 2. The formulas of (a) cholesterol, (b) 7-dehydrocholesterol, and (c) cholestanol.

case. Cholestanol, a saturated sterol, and 7-dehydrocholesterol, which contains two conjugated double bonds, were studied (Fig. 2). The sterol/AOT association constants were found to be the following:

Cholesterol	$11.0 \pm 0.8\,L\,mol^{-1}$
Cholestanol	$5.0 \pm 0.5\,L\,mol^{-1}$
7-Dehydrocholesterol	$15.0 \pm 1.0\,L\,mol^{-1}$

Previously we found that cyclohexanol or *trans*-decahydro-2-naphthol have low alcohol/AOT association constants, like the long-chain *n*-alcohols (5). It appears then that the rings do not make it easier for the molecule to cross the hydrophobic belt of the AOT inverted micelles but that the double bonds, which make the molecules approach coplanarity, do.

Whether or not the above mentioned sterols possess an anesthetic potency is not known to us. However, certain steroids do possess anesthetic potency (11, 12) and the more potent ones contain the 3-OH group. All these observations seem to indicate that both hydrogen-bonding and hydrophobic interactions play a role in the anesthetic activity of alcohols. Their properties are likely to depend on a delicate balance between the two.

Estimation of heats of vaporization for non associating organic liquids from the boiling points at various pressures

J. PETER GUTHRIE

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 30, 1985

J. PETER GUTHRIE. Can. J. Chem. **64**, 635 (1986).

At any pressure the heat of vaporization can be expressed as a quadratic function of the boiling point at that pressure. A seven parameter equation expressing the simultaneous dependence on boiling point and pressure can be fitted to the data; six pressures from 1 to 760 Torr (1 Torr = 133.3 Pa) were used. $\Delta H_{vap} = b_{11} + b_{12} \ln (p) + b_{13}p + (b_{21} + b_{22} \ln (p))t_{bp} + (b_{31} + b_{32} \ln (p))t_{bp}^2$. This relationship served as a guide for developing a relationship between vapour pressure at 25°C and the calorimetric heat of vaporization, and also a relationship between vapor pressure at 25°C and the boiling point at some other pressure. Parameters for both these relationships could be derived from the parameters obtained for ΔH_{vap} as a function of temperature and pressure. A third method was developed starting from an equation for vapor pressure and fitting to the heat of vaporization, the heat capacity of vaporization, and at least one t,p point. These methods allow the estimation of the vapor pressure at room temperature from very meager data. The problems of errors in estimated values are discussed.

J. PETER GUTHRIE. Can. J. Chem. **64**, 635 (1986).

À toutes les pressions, la chaleur de vaporisation peut être exprimée comme une fonction quadratique de son point d'ébullition à cette température. Toutes les données peuvent être accomodées par une équation à sept paramètres exprimant la dépendance simultanée sur le point d'ébullition et sur la pression; on a utilisé six pressions de 1 à 760 Torr. $\Delta H_{vap} = b_{11} + b_{12} \ln (p) + b_{13}p + (b_{21} + b_{22} \ln (p))t_{bp} + (b_{31} + b_{32} \ln (p))t_{bp}$. Cette relation a servi de guide pour développer une relation entre la pression de vapeur à 25°C et la chaleur de vaporisation calorimétrique ainsi que le point d'ébullition à d'autres pressions. On a pu obtenir les paramètres pour ces deux relations à partir des paramètres obtenus pour le ΔH_{vap} en fonction de la température et la pression. On a développé une troisième méthode à partir d'une équation pour la tension de vapeur et en y insérant la chaleur de vaporisation, la capacité calorifique de vaporisatin et au moins un point de t,p. Ces méthodes permettent d'évaluer la tension de vapeur à la température ambiante à partir de très peu de données. On discute des problèmes des erreurs dans les valeurs prédites.

[Traduit par la revue]

Introduction

In calculating the standard heat of formation of a gaseous compound, starting from a heat of formation determined by calorimetry on the liquid, it is necessary to have a value for the heat of vaporization at 25°C. Although there are standard methods for measuring heats of vaporization calorimetrically (1), the technique remains somewhat specialized and recourse is frequently had to estimation procedures (1). Of these, one of the simplest is that reported by Wadso (2), which needs only the normal boiling point.[1] The method is limited to non-hydrogen bonding liquids, with normal boiling points below 200°C. We have had occasion to determine heats of formation (3–8) which were used to calculate free energies of formation in aqueous solution. In the course of these calculations it was necessary to estimate the heat of vaporization. We have encountered difficulties when the normal boiling point could not be determined because of the thermal instability of the compound, or when the normal boiling point was higher than 200°C. Accordingly, we have sought for ways to extend the range of the Wadso equation, and took advantage of a report by Hildebrand and Scott (9) that ΔH_{vap} was a quadratic function of the normal boiling point. This approach could be applied at any vapour pressure. We have also had a need for estimates of the vapor pressures of organic liquids at 25°C, as part of the calculation of free energies of transfer from the gas to aqueous solution. In the present paper we wish to report the results of our attempts to generalize the Wadso equation. We have found empirical relations between the heat of vaporization at 25°C and the boiling point at various pressures, using a quadratic relation which allows a wider range of temperatures. The parameters of the quadratic can themselves be expressed as a function of pressure, allowing boiling points at any pressure to be used as the starting points for heat of vaporization estimates. Furthermore, the process can be inverted to allow the vapor pressure at any temperature to be estimated given only the heat of vaporization. We found that even better estimates of the vapor pressure can be obtained from any boiling point – pressure datum, using a relationship based on the empirical relationship found for ΔH_{vap}. Finally we have found that by fitting an equation, derived by Prausnitz *et al.* (10) from the theory of fluids, to ΔH_{vap}, ΔC_{vap}, and one p,t point we can obtain quite good vapor pressure estimates.

[1]Normal boiling point means boiling point at 1 atm = 101.325 kPa.

Results and discussion

The starting point for this work was the compilation of vapor pressure data by Stull *et al.* (11, 12), which gives boiling points at a series of pressures for a wide range of compounds. From this body of data, were selected those compounds which could not form hydrogen bonds, and for which there were calorimetric heats of vaporization available from the literature. For a number of ketones we used data from work by Ambrose *et al.* (13), and for the heavier hydrocarbons we replaced the values from ref. 12 by values from ref. 14 where these were significantly different; in both cases boiling points at the desired pressures were calculated from the empirical equations given by refs. 13 or 14. The set of data which we used is found in Table S1.[2] There are vapor pressure data for a number of large *n*-alkanes for which there are no heats of vaporization; since these compounds are solids with very low vapor pressures at room temperature, it is

unlikely that experimental values for the heats of vaporization of the supercooled liquids at 25°C will become available in the near future. For the *n*-alkanes the heat of vaporization is a very good linear function of number of carbon atoms for *n*-butane to *n*-heptadecane (15) or *n*-pentane to *n*-heptadecane (16) so that it seemed legitimate to include estimated values of the heat of vaporization for these compounds. This was done in order to have some data for high temperatures at the lowest vapor pressures. We used the equation $\Delta H_{vap} = 0.46 + 1.18 n_C$ (r = 0.99999), which is essentially identical to that reported by Mansson *et al.* (16). Similarly, values of ΔH_{vap} were estimated for 2-undecanone and 2-tridecanone by linear interpolation based on values for a series of 2-alkanones (17), for which we found $\Delta H_{vap} = (3.12 \pm 0.10) + (1.17 \pm 0.01 n_C)$ by least squares. The estimated values were given larger error limits to ensure that they were lightly weighted in the least squares calculations. For each pressure the data were fitted to the following quadratic expression in t_{bp} the boiling point (°C) at that pressure:

$$[1] \quad \Delta H_{vap} = a_1 + a_2 t_{bp} + a_3 t_{bp}^2$$

The fitting was done using a general least squares program which is based on the Marquardt algorithm[3] (18). The parameters evaluated in this way are found in Table 1. This table includes parameters fitting all the data in Table S1 and also a final restricted data set where all boiling points less than 0°C or greater than 300°C were excluded. This final set used only the range of practical interest and allowed a fit giving fewer serious deviations without needing additional parameters.

The parameters so determined are clearly all functions of pressure; Fig. 1 shows that they are all smooth functions of pressure, and in fact that a_2 and a_3 are linear in ln (p). For a_1 it is necessary to use a more elaborate function; in fact a constant term, a term linear in ln (p), and a term linear in p were required to account for the variation in a_1 with pressure.

$$[2] \quad a_i = b_{i1} + b_{i2} \ln (p) + b_{i3} p$$

Again, the best fit values of the parameters were determined by least squares, using eq. [2] with two or three parameters as needed. For eqs. [2] and [3] p is in atm (1 atm = 101.325 kPa).

[3]For polynomials it would actually be more efficient to use linear least squares, but the computational times are trivial and we have a convenient general program able to fit equations linear or nonlinear in the parameters.

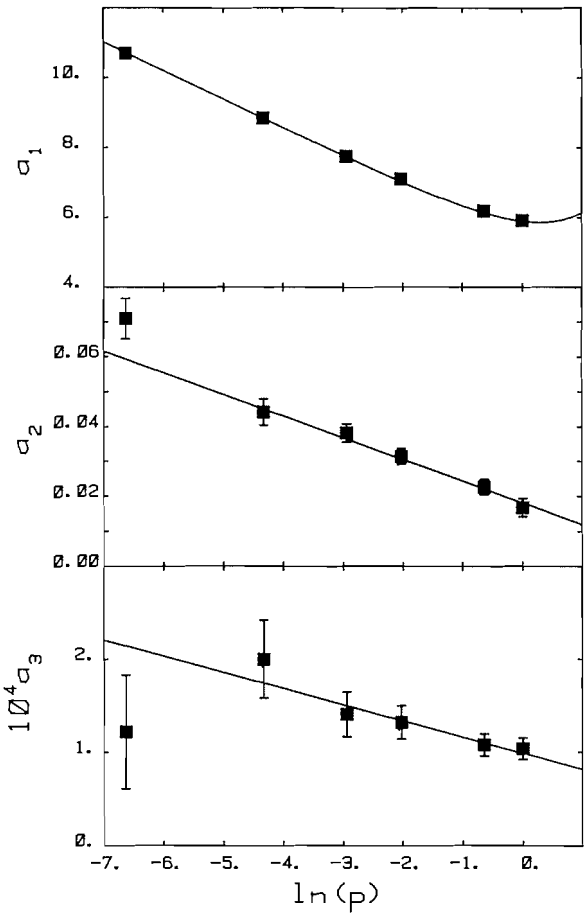

FIG. 1. Parameters for the quadratic relationship between heat of vaporization and boiling point, as a function of pressure. Parameter values from Table 1 for the full data set are plotted vs. ln (p) in atm, and the lines are drawn using the corresponding parameters from Table 2.

These parameters were used as initial estimates for the next stage of the calculations in which all the data in the full or the restricted set from Table S1 were fitted to the combined eq. [3], determining all the parameters at once to ensure that a set of parameters suited to fitting data at any pressure was obtained.

$$[3] \quad \Delta H_{vap} = b_{11} + b_{12} \ln (p) + b_{13} p + (b_{21} + b_{23} \ln (p)) t_{bp} + (b_{31} + b_{32} \ln (p)) t_{bp}^2$$

The parameters so determined are found in Table 2. The quality of the final fit is shown in Fig. 2.

With these parameters defined, it is clearly possible to calculate a version of eq. [1] for any pressure for which boiling point data at that pressure are available. It will, of course, be essential to exercise proper caution in evaluating the reliability of vapor pressure – temperature data from the literature, particularly when the data are simply physical properties of a compound and not measurements intended for high accuracy.

The fit to eq. [1] is actually very good at each pressure; for approximately 150 compounds, the weighted rms error is about 0.28 kcal/mol, and the worst deviations are only about 1.0 kcal/mol. The deviations may be summarized as: pressure (Torr), number of points, number of deviations greater than 1 kcal/mol, number of deviations greater than 2 kcal/mol; (full data set) 1, 142, 12, 4; 10, 150, 8, 0; 40, 154, 7, 1; 100, 154, 8, 0; 400, 154, 8, 0; 760, 154, 7, 0; (truncated data set) 1, 39, 5, 0; 10, 92, 10, 3; 40, 120, 3, 0; 100, 129, 3, 0; 400, 143, 4, 0; 760,

TABLE 2. Parameters for the dependence of the heat of vaporization parameters on the vapor pressure

Parameter	b_{i1}	b_{i2}	b_{i3}
	(a) Full data set		
a_1	5.14(0.04)	−0.841(0.010)	0.589(0.077)
a_2	0.0212(0.0010)	−0.00662(0.00023)	
a_3	$8.74(0.51)\times10^{-5}$	$-8.55(1.52)\times10^{-6}$	
	(a) Truncated data set		
a_1	5.28(0.07)	−0.822(0.017)	0.616(0.082)
a_2	0.0182(0.0014)	−0.00620(0.00060)	
a_3	$9.88(0.70)\times10^{-5}$	$-1.74(0.46)\times10^{-5}$	

140, 3, 0. The fit to eq. [3] is similarly good; the weighted rms deviation was 0.28 kcal/mol for either data set. For the full data set of 908 points there were only 50 deviations of more than 1.0 kcal/mol, and only 13 greater than 2.0 kcal/mol, while for the truncated data set of 526 points there were only 19 deviations of more than 1.0 kcal/mol, and none greater than 2.0 kcal/mol.

Although there was no improvement in the rms error using the restricted data set it seems better to use parameters based on this data set, because they give better description for high boiling compounds, even though there are severe deviations for boiling points less than 0°C. Leaving out points with boiling points less than 0°C has allowed a better description of the range of interest, at the price of a much poorer description of very low boiling compounds. The calculated curves begin to deviate seriously from the observed points at high temperatures (where the heats of vaporization are estimates and were accordingly given less weight in the fittng procedure). Clearly, the parameters reported allow a good calculation of ΔH_{vap} up to a boiling point of 300°C, but are not useful beyond this point. In a practical sense, however, it is rare to find compounds which are sufficiently thermally stable that meaningful boiling points above 300°C can be recorded, so the treatment reported here covers the normally accessible range of boiling points.

It is now possible to invert the procedure and develop an equation for estimating the vapor pressure given the heat of vaporization. For each parameter a_i in eq. [1] we substitute the appropriate form from eq. [2]; then by rearranging terms we get a transcendental equation, eq. [4], relating p and ΔH_{vap}

$$[4]\quad b_{13}p + [b_{12} + b_{22}\theta + b_{32}\theta^2]\,[\ln(p)] + [b_{11} + b_{21}\theta + b_{31}\theta^2 - \Delta H_{vap}] = 0$$

where θ is the temperature (°C) at which the vapor pressure (atm) is to be estimated. The term in p is insignificant at low pressures where the equation is of interest, so that in fact we have a linear equation in ln (p)

$$[5]\quad \ln(p) = [\Delta H_{vap} - b_{11} + b_{21}\theta + b_{31}\theta^2]/[b_{12} + b_{22}\theta + b_{32}\theta^2]$$

Substituting numerical values, and setting $\theta = 25$°C, we obtain eq. [6] giving the vapor pressure at room temperature, which is a quantity which we frequently need for free energy of transfer calculations.

$$[6]\quad \ln(p) = 5.66 - 0.988\Delta H_{vap}\ \text{(full data set)}$$
$$\ln(p) = 5.86 - 1.01\Delta H_{vap}\ \text{(truncated data set)}$$

The quality of the estimation was tested by using the data base in Table S1; for each compound the data were fitted to the simple Clausius Clapeyron equation, eq. [7], and the vapor pressure

$$[7]\quad \ln(p) = A + B/T$$

at 25°C was estimated. This value was compared to the value obtained by solving eq. [6] using the experimental heat of vaporization. The agreement is reasonable for pressures greater than 0.1 Torr, but becomes increasingly poor for lower pressures. Thus, eq. [6] is useful for interpolation. It should be borne in mind that the Clausius Clapeyron equation itself should not be used for long extrapolations because the heat of vaporization is not temperature independent, and consequently ln(p) is not a truly linear function of $1/T$. The curvature is slight, and a straight line is a remarkably good approximation (19). Nevertheless, any long extrapolation will be very sensitive to curvature or slight errors in the slope and will be unreliable.

Another approach is possible when there is no calorimetric heat of vaporization: since as we have shown ΔH_{vap} is a function of temperature and vapor pressure, $\Delta H_{vap} = f(t,p)$, it necessarily follows that $f(t_{bp},p_{obs}) = f(\theta,p)$ where t_{bp} is the boiling point (°C) at pressure p_{obs} (atm) and p is the vapor pressure at a reference temperature θ, normally 25°C. As before, since we are interested in the low pressure region, the term in eq. [3] linear in p can be neglected and we get

$$[8]\quad \ln(p) = \{b_{21}(t_{bp} - \theta) + b_{31}(t_{bp}^2 - \theta^2) + \ln(p_{obs})(b_{12} + b_{22}t_{bp} + b_{32}t_{bp}^2)\}/\{b_{12} + b_{22}\theta + b_{32}\theta^2\}$$

By collecting terms which are constant for a given value of θ taken as 25°C, we can simplify this to:

$$[9]\quad \ln(p) = c_1 + c_2\ln(p_{obs}) + (c_3 + c_4\ln(p_{obs}))t_{bp} + (c_5 + c_6\ln(p_{obs}))t_{bp}^2$$

The values of c_i were calculated from the values of b_{jk} given in Table 2; the values so calculated are given in Table 3.

This approach was tested using the data base from Table S1; the boiling point at 100 Torr was used as the reference point for calculating the vapor pressure at 25°C. Once again the agreement with the value obtained by a Clausius Clapeyron extrapolation was quite good for pressures greater than 0.1 Torr.

The most common situation where one needs to estimate a vapor pressure is one where the desired vapor pressure is quite low so that it is not practical to measure it without specialized apparatus. In order to estimate such vapor pressures one must take account of the nonlinear nature of the plot of ln (p) vs. $1/T$. Various methods have been suggested in the literature for the situation where good p–T data are available for a range of temperatures. King (20) and Ambrose (21) have proposed very similar equations involving four or five parameters which allow

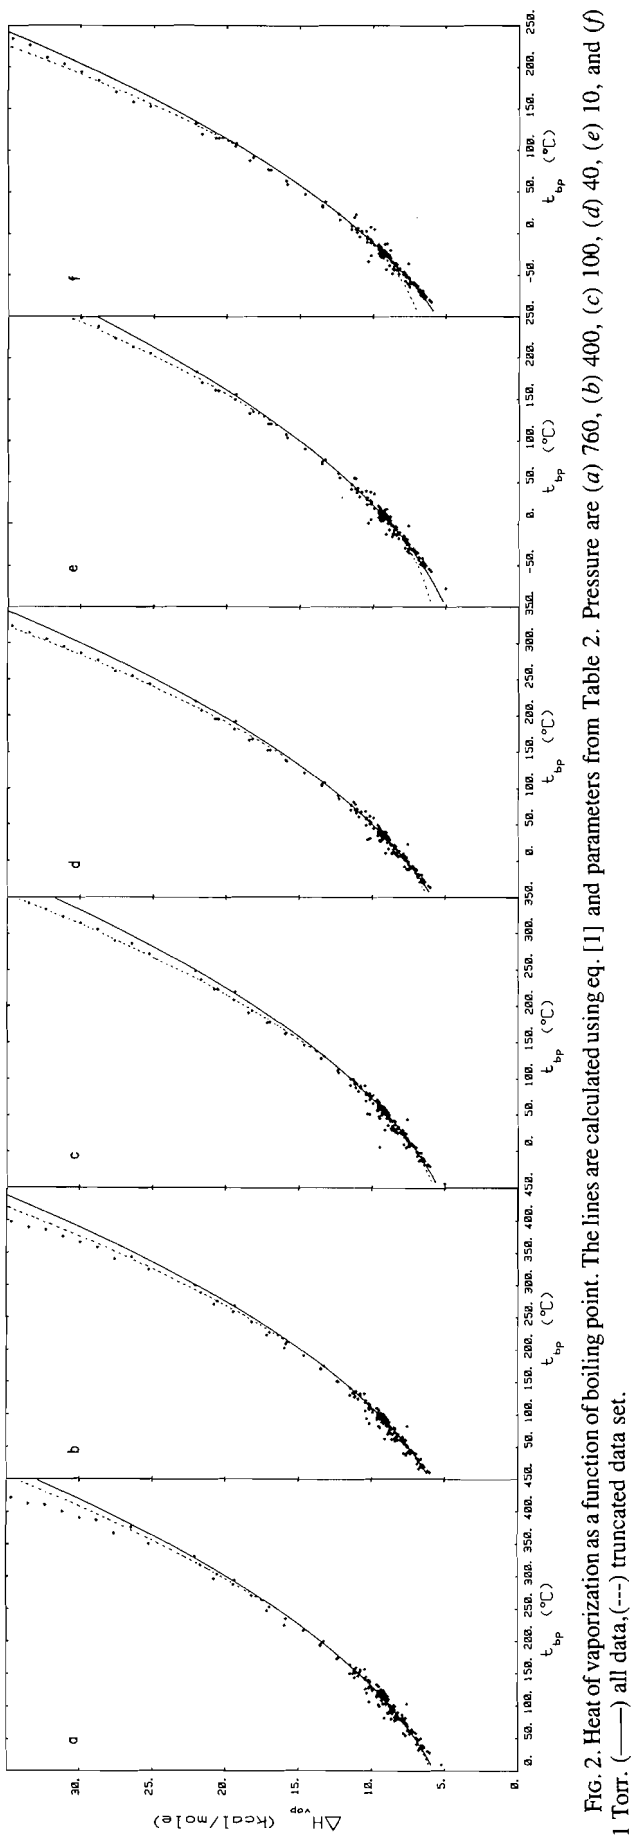

FIG. 2. Heat of vaporization as a function of boiling point. The lines are calculated using eq. [1] and parameters from Table 2. Pressure are (*a*) 760, (*b*) 400, (*c*) 100, (*d*) 40, (*e*) 10, and (*f*) 1 TORR. (——) all data, (---) truncated data set.

extrapolations down to very low pressures. Prausnitz (10) has proposed a five parameter equation which involves only two adjustable parameters from which the five parameters are calculated using relations based on the theory of fluids. For the situation where the data are not good enough for direct evaluation of the parameters, these (20, 21) and other (22, 23) authors have proposed making use of the approximate parallelism of $p-T$ curves by relations such as

$$[10] \quad \ln (p_A) = m \ln (p_B) + b$$

to estimate the pressure of substance A at a given temperature from the pressure of a reference substance B at the same temperature. Unfortunately this approach requires data over a significant range of temperatures and pressures in order to allow accurate determination of the slope and intercept required for extrapolation. If the range of data available is small then the extrapolation will be uncertain. This is precisely the situation in which we often find ourselves.

A solution to the dilemma is offered by the Prausnitz equation which requires only two adjustable parameters. Furthermore it differs from the equation favored by Ambrose and King in that the coefficients of the terms in T and T^2 are much smaller even though the overall curve is very similar. This suggests that the exact values of the parameters are not well determined by the data, but are subject to severe correlation. A similar conclusion is suggested by the fact that despite the empirical success of [10], which suggests that the coefficients for corresponding functions of T should be related by the slope parameter, m, we find that these coefficients frequently change sign as well as magnitude from one compound to another without impairing the fit. When the curvature is small the correction terms are not well defined and numerous sets of parameters may work equally well.

Our suggestion is that when the data are very sparse, one could obtain an estimate of the vapor pressure from the heat of vaporization, the heat capacity of vaporization, and a few $p-T$ points, even when these latter data would not themselves allow good extrapolation to lower temperatures. Since we have in this and previous papers (24, 25) reported methods for obtaining useful estimates of the heat and heat capacity of vaporization at 25°C, this seems an attractive way to make use of all of the limited information available. The procedure is to calculate Prausnitz' parameters, E_0/R and s, from the expressions for ΔH_{vap} and ΔC_{vap} derived from this equation. The equation is

$$[11] \quad \ln p = A + B/T + C \ln (T) + DT + ET^2 \; (p \text{ in atm}, T \text{ in K})$$

The first step was to express ΔH_{vap} and ΔC_{vap} in terms of the parameters as:

$$\Delta \mathrm{H}_{vap}/R = -B + CT + DT^2 + 2ET^3$$

$$\Delta \mathrm{C}_{vap}/R = C + 2DT + 6ET^2$$

where,

$$B = -E_0/R$$

$$C = 3/2 - s$$

$$D = (s - 1)/(E_0/R)$$

$$E = (s - 1)(s - 3)/2(E_0/R)^2$$

Then by an iterative solution E_0/R and s can be calculated. Although A could then be calculated (10), it seemed better to determine it empirically by fitting the equation to one or several

TABLE 3. Parameter values for eq. [9]

Parameter	Parameter value based on Full data set	Truncated data set
c_1	0.578	0.523
c_2	0.831	0.832
c_3	−0.0210	−0.184
c_4	0.00654	0.00628
c_5	-8.64×10^{-5}	-1.00×10^{-4}
c_6	8.45×10^{-6}	1.76×10^{-5}

p–T points to guarantee correctness at the lowest temperature for which the vapor pressure is known.

As a test of the procedure, we can use toluene, and from the following data:

$$\Delta H_{vap} = 9080 \text{ cal/mol } (1, 24)$$

$$\Delta C_{vap} = -12.5 \text{ cal/deg mol } (25, 26)$$

$$t = 1.5°\text{C at } p = 7.5 \text{ Torr } (21)$$

the parameters were determined to be: $A = 56.7632$, $B = -6594.12$, $C = -7.2539$, $D = 1.176\times10^{-3}$, $E = 5.130\times10^{-7}$, $E_0/R = 66594.12$, and $s = 8.7539$. The calculated pressure for 159 K was 0.00117 Pa; Ambrose (21) gives 0.001 Pa. This is a 17% error for a 115° extrapolation. Although this is not very good when compared to the performance of either the Ambrose or Prausnitz equations when they are fitted to good data, it is adequate for our purposes, which are to get vapor pressures accurate enough that the contribution from errors in vapor pressure is less than or comparable to the other errors in the thermochemical calculations, i.e., not more than a few tenths of a kcal/mol.

We may attempt to estimate the sensitivity to errors in ΔH_{vap} and ΔC_{vap} by using the Kirchhoff equation, eq. [12], in which ΔH_{vap} is taken as linear in temperature

$$[12] \quad \ln (p) = A + B/T + C \ln (T)$$

At temperature $\theta = 298$ K, $-\Delta H_\theta/R = -B + CT$, and $\Delta C_{vap} = \Delta C_\theta = -RC$; then $B = \Delta H_\theta/R - \Delta C_\theta/R$, and $C = -\Delta C_{vap}/R$. This leads to

$$\ln (p_\theta) = \ln (p_T) - \Delta H_\theta(1/\theta - 1/T)/R + \Delta C_\theta\theta(1/\theta - 1/T) + [\Delta C_\theta/R] \ln (T/\theta)$$

$$\sigma \ln p = [[-(1/R)(1/\theta - 1/T)]^2\sigma_{\Delta H}{}^2 + [(\theta/R)(1/\theta - 1/T) + (1/R) \ln (T/\theta)]^2\sigma_{\Delta C}{}^2]^{1/2}$$

The significance of the contributions can be seen by calculating the coefficients of $\sigma_{\Delta H}$ and $\sigma_{\Delta C}$ for various temperatures T, as shown in Table 4.

For errors of 1000 cal/mol in ΔH_θ and 1 cal/deg mol in ΔC_o and $T = 298$ K we expect an error of 1.27 in $\ln (p_\theta)$.

There are very few values of vapor pressures for high boiling liquids for use in testing these proposed extrapolation methods. Landolt-Bornstein (27) gives data for diethyl phthalate, for which $\ln (p_\theta) = -13.98$. The Clausius Clapeyron equation leads to $\ln (p_\theta) = -12.29$, with an error of 1.69, confirming that it is often a poor procedure for extrapolation . Equation [6] leads to $\ln (p_\theta) = -13.92$, in excellent agreement; eq. [9] leads to −14.77, in poorer agreement, and eq. [11] leads to −13.45 in useful agreement. Experimental values are available for hexadecane (20, 28, 29), $\ln (p_\theta) = -13.14$. The Clausius Clapeyron equation leads to $\ln (p_\theta) = -12.06$, again in poor agreement, eq. [6] leads to $\ln (p_\theta) = -14.00$, in poor agreement, eq. [9] leads to $\ln (p_\theta) = -13.76$, in only slightly better agreement; eq. [11], using the boiling point at 1 Torr to define A, leads to $\ln (p_\theta) = -13.22$, in excellent agreement.

TABLE 4. Sensitivity $\sigma \ln p$ to errors in ΔH and ΔC.

T (K)	Sensitivity to $\sigma_{\Delta H}$	$\sigma_{\Delta C}$
398	0.00042	0.27
498	0.00068	0.45
598	0.00085	0.60
698	0.00097	0.72

We found that $\ln (p_\theta)$ at 25°C is an excellent linear function of the number of carbon atoms for a series of n-alkanes from hexane to hexadecane (data from refs. 20, 28, 29), $\ln (p_\theta) = 5.206 - 1.1477n$ ($r = 0.99994$). Using this equation we could estimate values for the higher n-alkanes; these values were in reasonable agreement with those estimated using [6], [9], and [11], with errors of about 1 in $\ln (p_\theta)$ at $n = 29$.

The methods reported above extend and generalize the Wadso equation and make it possible to get useful thermochemical information from very meager physical data. We have encountered the need for such methods from our thermochemical investigations and hope that these methods will prove useful to other workers.

Reactions of hydrocarbon and carbon/nitrogen ions with diacetylene and of the diacetylene radical cation with various molecules have been examined with a view to molecular growth by ion–molecule reaction. Measurements were performed with a Selected-Ion Flow Tube (SIFT) apparatus at 296 ± 2 K of the rate constants and product distributions for the reactions of C^+, CH_3^+, $C_2H_2^+$, C_3H^+, CN^+, C_2N^+, and $C_2N_2^+$ with C_4H_2 and of $C_4H_2^+$ with H_2, CO, C_2H_2, C_2N_2, and C_4H_2. Condensation and association reactions which build up the carbon content of the ion were observed to compete with charge transfer. For the reactions of CN^+ and $C_2N_2^+$ with C_4H_2 this growth involved the addition of cyanide to the carbon chain. The kinetics of protonation of diacetylene were also investigated. It was possible to bracket the proton affinity of diacetylene between the known proton affinities of HCN and CH_3OH with a value for $PA(C_4H_2)$ = 177 ± 5 kcal mol^{-1}, which results in a heat of formation for $C_4H_3^+$ of 305 ± 5 kcal mol^{-1}. Numerous secondary association reactions were observed to form adduct ions in helium buffer gas at total pressures of a few tenths of a Torr with rates near the collision rate. This was the case for $C_6H_4^+$ ($C_4H_2^+.C_2H_2$), $C_7H_5^+$ ($C_3H_3^+.C_4H_2$), $C_8H_4^+$ ($C_4H_2^+.C_4H_2$), $C_8H_5^+$ ($C_4H_3^+.C_4H_2$), $C_9H_3^+$ ($C_5H^+.C_4H_2$), $C_9H_4^+$ ($C_5H_2^+.C_4H_2$), $C_9H_5^+$ ($C_5H_3^+.C_4H_2$), $C_{10}H_4^+$ ($C_6H_2^+.C_4H_2$), $C_{10}H_5^+$ ($C_6H_3^+.C_4H_2$), $C_{11}H_7^+$ ($C_3H_3^+.(C_4H_2)_2$), $C_{12}H_6^+$ ($C_4H_2^+.(C_4H_2)_2$), $C_9H_3N^+$ ($HC_5N^+.C_4H_2$), and $C_{10}H_4N^+$ ($C_2N^+.(C_4H_2)_2$) where the reactants are indicated in parentheses. The observed high rates of association imply the formation of chemical bonds in the adduct ions but the structures of these ions were not resolved experimentally. In most instances there seems little basis for preferring acyclic over cyclic adduct ions.

SEKSAN DHEANDHANOO, LEONARD FORTE, ARNOLD FOX et DIETHARD K. BOME. Can. J. Chem. **64**, 641 (1986).

Dans le but d'évaluer la croissance des molécules par des réactions ion–molécule, on a étudié les réactions d'ions hydrocarbonés et d'ions carbone/azote avec le diacétylène ainsi que les réactions du radical cation du diacétylène avec diverses molécules. On a effectué les réactions à 296 ± 2 K et on les a étudiées à l'aide d'un appareil à tube à écoulement à ion choisi; on a mesuré les constantes de vitesse et les distributions de produits pour les réactions du C_4H_2 avec C^+, CH_3^+, $C_2H_2^+$, C_3H^+, CN^+, C_2N^+ et $C_2N_2^+$ et pour les réactions du $C_4H_2^+$ avec H_2, CO, C_2H_2, C_2N_2 et C_4H_2. On a observé que les réactions de condensation et d'association qui provoquent une croissance dans le contenu en carbone de l'ion sont en compétition avec le transfert de charge. Pour les réactions du CN^+ et du $C_2N_2^+$ avec le C_4H_2, cette croissance implique l'addition de cyanure sur la chaîne carbonée. On a aussi étudié la cinétique de la protonation du diacétylène. Il est possible de situer l'affinité protonique du diacétylène entre les affinités protoniques connues du HCN et du CH_3OH et ceci conduit à une valeur de $PA(C_4H_2)$ = 177 ± 5 kcal/mol et à une valeur de la chaleur de formation du $C_4H_3^+$ qui est égale à 305 ± 5 kcal/mol. On a observé que plusieurs réactions secondaires d'association forment des ions adduits dans un tampon d'hélium à des pressions totales de quelques dixièmes de Torr et avec des vitesses qui sont proches des vitesses de collision. Tel est le cas avec les ions suivants, où l'on a indiqué les réactifs entre parenthèses: $C_6H_4^+$ ($C_4H_2^+.C_2H_2$), $C_7H_5^+$ ($C_3H_3^+.C_4H_2$), $C_8H_4^+$ ($C_4H_2^+.C_4H_2$), $C_8H_5^+$ ($C_4H_3^+.C_4H_2$), $C_9H_3^+$ ($C_5H^+.C_4H_2$), $C_9H_4^+$ ($C_5H_2^+.C_4H_2$), $C_9H_5^+$ ($C_5H_3^+.C_4H_2$), $C_{10}H_4^+$ ($C_6H_2^+.C_4H_2$), $C_{10}H_5^+$ ($C_6H_3^+.C_4H_2$), $C_{11}H_7^+$ ($C_3H_3^+.(C_4H_2)_2$), $C_{12}H_6^+$ ($C_4H_2^+.(C_4H_2)_2$), $C_9H_3N^+$ ($HC_5N^+.C_4H_2$) et $C_{10}H_4N^+$ ($C_2N^+.(C_4H_2)_2$). Les taux élevés d'association observés impliquent qu'il y a formation de liaisons chimiques dans les ions adduits; toutefois, les structures de ces ions ne sont pas résolues expérimentalement. Dans la plupart des cas, il ne semble pas y avoir de préférence pour des ions adduits linéaires ou cycliques.

[Traduit par la revue]

Introduction

Extended "chain-like" molecules of bonded carbon atoms are formed naturally under a wide range of physical conditions. For example, cyanopolyynes with up to 11 carbon atoms have been identified at the low temperatures and low densities of the interstellar medium (1), while polyacetylenes with at least 12 carbon atoms have been found present at the high temperatures and the high densities of hydrocarbon flames (2). In the presence of ionization the formation and destruction of these chain molecules may involve ions (1, 2) and so it is of interest to establish the rates and products of ion–molecule reactions involving carbon chains. Here we report laboratory studies directed towards the identification and characterization of reactions of ions with diacetylene and reactions of the diacetylene radical cation with various molecules. Neutral and ionized diacetylene can be expected to be early intermediates in the growth of long carbon chain molecules from single carbon units.

Special emphasis is given in this investigation to reactions of diacetylene with the carbonaceous cations C^+, CH_3^+, $C_2H_2^+$, and C_3H^+, which are primal ions in the growth of molecules in the chemistry of interstellar gas clouds (3). Also, several reactions of carbon/nitrogen cations of the type $C_nN_m^+$ with diacetylene and of the diacetylene ion with C_2N_2 have been chosen for study because of their possible role in the chemistry of the ionosphere of Titan (4). Finally, a number of selected proton-transfer reactions have been investigated to estimate the proton affinity of diacetylene, which is useful in the elucidation of the neutralization of protonated diacetylene by proton transfer or electron–ion recombination.

Experimental

All measurements were taken with the Selected-Ion Flow Tube (SIFT) – flowing afterglow apparatus in the Ion Chemistry Laboratory at York University (5, 6). The reagent ions were derived from appropriate parent gases by electron impact at low pressures. An axial electron impact ionizer (Extranuclear, Model 041-3) was used as the ion source. Typical ion ejection energies were in the range 10–20 V. The initial spectrum for the experiments in which $C_4H_2^+$ was the selected ion is

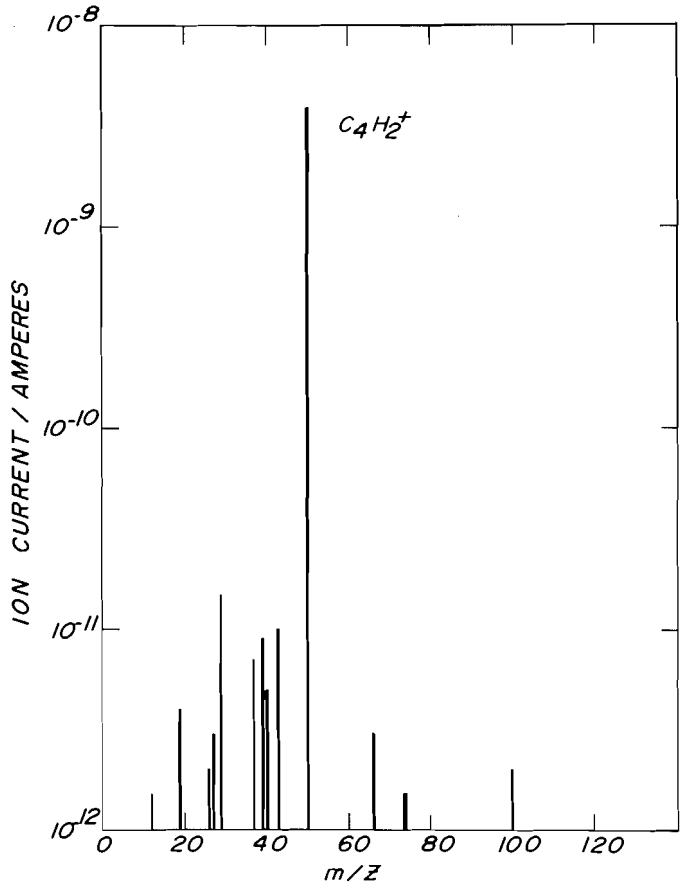

FIG. 1. SIFT spectrum for $C_4H_2^+$ derived from diacetylene (20% in helium) by electron impact at 53 eV. The $C_4H_2^+$ ions are injected at 16 V; the buffer gas is helium at 0.35 Torr. The background spectrum arises in part from collisional dissociation of $C_4H_2^+$ and in part from ion–molecule reactions with water vapour and other impurities in the helium, and with diacetylene leaking through the selection quadrupole.

shown in Fig. 1. Unless otherwise indicated, the individual reagent ions (and impurity ions) were generated in the manner described in a recent study of reactions with cyanoacetylene (7). The carrier gas was either helium or hydrogen. To remove traces of water vapour, the carrier gas was passed through zeolite traps (a 50:50 mixture of Union Carbide molecule sieves 4A and 13X) cooled to liquid nitrogen temperature. The diacetylene was prepared by the alkaline hydrolysis of 1,4-dichlorobut-2-yne (8) and was stored at Dry Ice temperature to avoid polymerization. Experiments with H_3^+ as the "chemical ionization" reagent indicated a purity of greater than 99%. All measurements were taken at an ambient temperature of 296 ± 2 K.

Results

Tables 1 and 2 present summaries of the reaction rate constants and product distributions obtained in this study for reactions of ions with diacetylene. Table 1 gives the results for reactions of carbonaceous ions and nitrogen-containing carbonaceous ions with cyanoacetylene, while Table 2 is restricted to results obtained for the proton-transfer reactions. Table 3 provides a summary for the reactions investigated with the diacetylene cation. Rate constants and product distributions were determined in the usual manner (5, 9). The tables include all of the primary product ions that were observed to contribute more than 5% to the total primary products. The branching ratios have been rounded off to the nearest 5% and are accurate to ±30%. The reaction rate constants are compared with collision rate constants derived with the Langevin theory (10)

TABLE 1. Summary of rate constants (in units of 10^{-9} cm^3 molecule^{-1} s^{-1}) and product distributions measured at 296 ± 2 K for ion–molecule reactions with diacetylene

Reactant ion	Products	Branching ratio	k_{exp}[a]	k_c[b]
C^+	$C_5H^+ + H$	0.50	2.9	1.84
	$C_4H_2^+ + C$	0.45		
	$C_3H^+ + C_2H$	0.05

$C_2N^+.C_4H_2$	$C_2N^+.(C_4H_2)_2$	1.0	~1	1.02

[a]The accuracy of the rate constants is estimated to be better than ±30% unless the rate constant is indicated to be approximate. Only the apparent bimolecular rate constant is given. The measurements were taken at helium pressures in range from 0.27 to 0.37 Torr and helium densities in the range from 9.0×10^{15} to 1.2×10^{16} atoms cm^{-3}.

[b]Collision rate constants derived from the Langevin theory (10).

with an estimated polarizability for diacetylene of 6.0 Å^3 (11). Thermochemical data were taken from the usual sources (12, 13).

He^+/He_2^+

He^+ was derived from helium at 35 eV and injected into helium carrier gas at 0.32 Torr (1 Torr = 133.3 Pa). Approximately 30% conversion of He^+ to He_2^+ was observed downstream. Both ions reacted rapidly with diacetylene to yield a variety of product ions corresponding to charge transfer and dissociative charge transfer. No attempt was made to discern branching ratios for the reactions of the two helium ions. The rate constant for the reaction of He^+ was determined to be 2.7×10^{-9} cm^3 molecule^{-1} s^{-1}.

C^+

More than 95% of the C^+ was in the ^2P ground state (7). The C^+ was observed to react rapidly with diacetylene to produce three product ions, as can be seen from Fig. 2. The $C_4H_2^+$ arises from the charge transfer reaction, which is 25 kcal mol^{-1} exothermic. The other major product ion was C_5H^+, which is

TABLE 2. Summary of rate constants (in units of 10^{-9} cm^3 molecule^{-1} s^{-1}) measured at 296 ± 2 K for proton-transfer reactions with diacetylene

Reactant ion	Product	k_{exp}[a]	k_c[b]
H_3^+	$C_4H_3^+$	2.6	3.4
N_2H^+	$C_4H_3^+$	1.1	1.3
H_3O^+	$C_4H_3^+$	1.1	1.5
H_2CN^+	$C_4H_3^+$	1.4	1.3
$CH_3OH_2^+$	$CH_3OH_2^+.C_4H_2$	0.37[c]	1.3

[a]The accuracy of the rate constants is estimated to be better than ±30%.
[b]Collision rate constants derived from the Langevin theory (10).
[c]In hydrogen buffer gas at a total pressure of 0.36 Torr and concentration of 1.2×10^{16} molecules cm^{-3}.

TABLE 3. Summary of rate constants and product distributions measured at 296 ± 2 K for reactions with $C_4H_2^+$ derived from diacetylene

Neutral reactant	Products	Product distribution[a]	Rate constant[b]
H_2			≤5 (−13)
CO	$C_4H_2^+.CO$	0.5	1.9 (−11)
	$HC_5O^+ + H$	0.5	
C_2H_2	$C_4H_2^+.C_2H_2$	1.0	8.4 (−10)
C_4H_2	$C_4H_2^+.C_4H_2$	0.9	1.3 (−9)
	$C_6H_2^+ + C_2H_2$	0.1	
C_2N_2	$C_4H_2^+.C_2N_2$	0.98	4.3 (−11)
	$HC_5N^+ + HCN$	0.02	

[a]The branching ratio may be in error by as much as ±20%.
[b]Rate constants are expressed as a $(-b)$ to represent $a \times 10^{-b}$. The units are cm^3 molecule^{-1} s^{-1}. The accuracy is estimated to be better than ±30%. All rate constants are effective bimolecular rate constants for the disappearance of $C_4H_2^+$ in helium buffer gas at total pressures in the range from 0.26 to 0.36 Torr and helium concentrations from 8.4×10^{15} to 1.2×10^{16} atoms cm^{-3}.

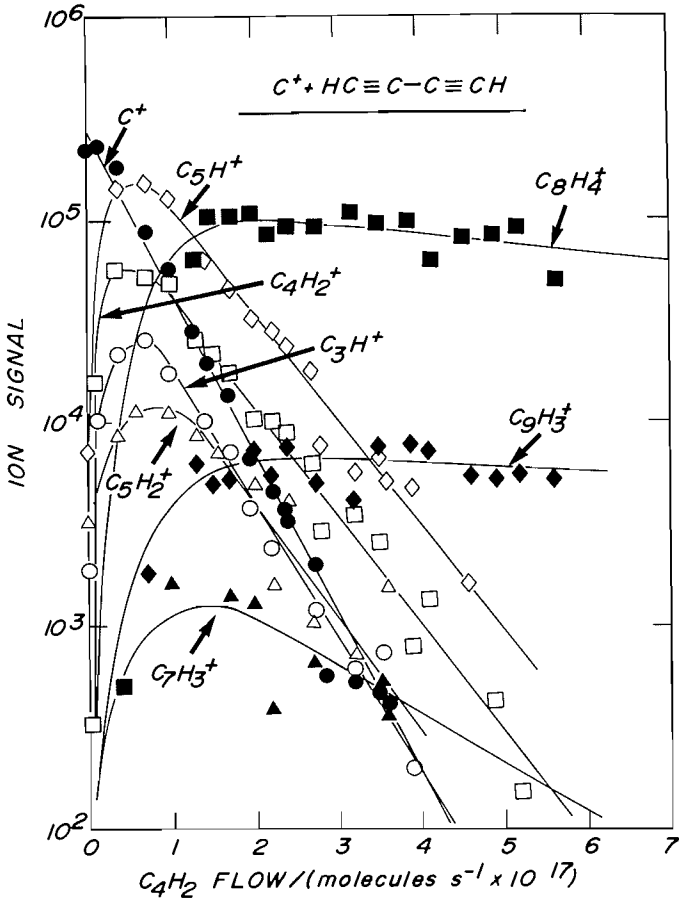

FIG. 2. The varieties in ion signals observed for the addition of diacetylene into the reaction region of the SIFT apparatus in which C^+ is initially established in helium buffer gas. $P = 0.275$ Torr, $\bar{v} = 5.6 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 295$ K. The C^+ is derived from cyanogen (10% in helium) at an electron energy of 60 eV.

probably the carbene cation HC≡C-C≡C-C:$^+$ that may be formed by C—H bond insertion with elimination of a hydrogen atom. Cyclic isomers of C_5H^+ are likely to be less stable. A minor channel of the reaction of C^+ with diacetylene leads to C_3H^+, which is probably the carbene cation HC≡C-C:$^+$ that may arise by C—C bond insertion with elimination of C_2H. The branching ratios observed for the production of C_3H^+ and C_5H^+ suggest that C—C bond insertion occurs 10 times less frequently than C—H bond insertion. C—H bond insertion can be expected to be more likely since it leads to a secondary carbocation intermediate in which the positive charge can be delocalized, while C—C bond insertion involves a primary carbocation intermediate in which the positive charge is localized.

Figure 2 also shows that secondary reactions were observed for all three primary product ions. The C_5H^+ was observed to rapidly add a molecule of diacetylene according to reaction [1].

[1] $C_5H^+ + C_4H_2 \rightarrow C_9H_3^+$

The structure of the $C_9H_3^+$ product ion is uncertain. However, if the C_5H^+ has carbene character, it can be expected to react with diacetylene by C—H bond insertion to form the acyclic cation $^+CH(C_4H)_2$. The high specific rate of association is consistent with such chemical bond formation in the adduct, as is the failure to observe rapid addition of a second molecule of diacetylene. The secondary reactions of $C_4H_2^+$ and C_3H^+ were similar to those observed in separate experiments, described later in the text, in which these ions were prepared directly in the electron impact source.

CH_3^+

Charge transfer is slightly (7 kcal mol^{-1}) endothermic in this case and was not observed. Figure 3 shows that the major product ion was $C_3H_3^+$ and that $C_5H_3^+$ was a minor product. The secondary reactions [2] to [4]

[2] $C_3H_3^+ + C_4H_2 \rightarrow C_7H_5^+$

[3] $C_7H_5^+ + C_4H_2 \rightarrow C_{11}H_7^+$

[4] $C_5H_3^+ + C_4H_2 \rightarrow C_9H_5^+$

were also observed to occur. They all involve the addition of diacetylene. The fast secondary reaction of $C_3H_3^+$ with diacetylene provides insight into the structure of this ion. Available thermochemical data indicate that the reaction of CH_3^+ with diacetylene may produce either the linear (propargyl) or the cyclic (cyclopropenium) isomer of $C_3H_3^+$. The ICR (ion cyclotron resonance) measurements of Smyth *et al.* (14) at low pressure have shown that only the linear isomer reacts with diacetylene. Our observation of the secondary reaction of $C_3H_3^+$ therefore implies that the reaction of CH_3^+ with diacetylene predominantly forms the linear isomer of $C_3H_3^+$. In the case of the formation of the minor $C_5H_3^+$ product ion, there is no basis for preferring an acyclic isomer (e.g.

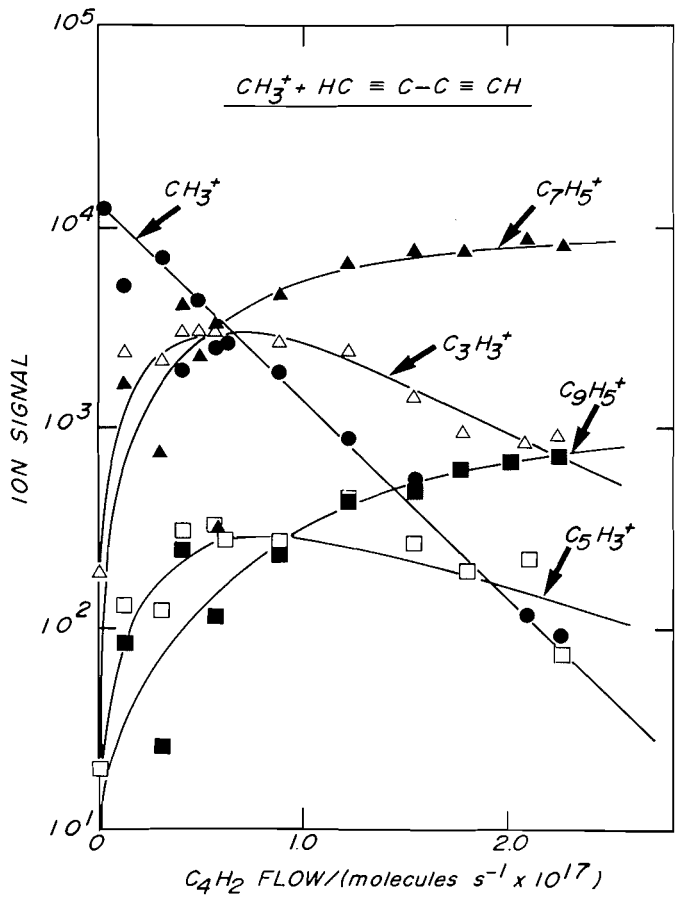

FIG. 3. The variations in ion signals observed for the addition of diacetylene into the reaction region of the SIFT apparatus in which CH_3^+ is initially established in helium buffer gas. $P = 0.335$ Torr, $\bar{v} = 5.3 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 293$ K. The CH_3^+ is derived from pure methane at an electron energy of 23 eV.

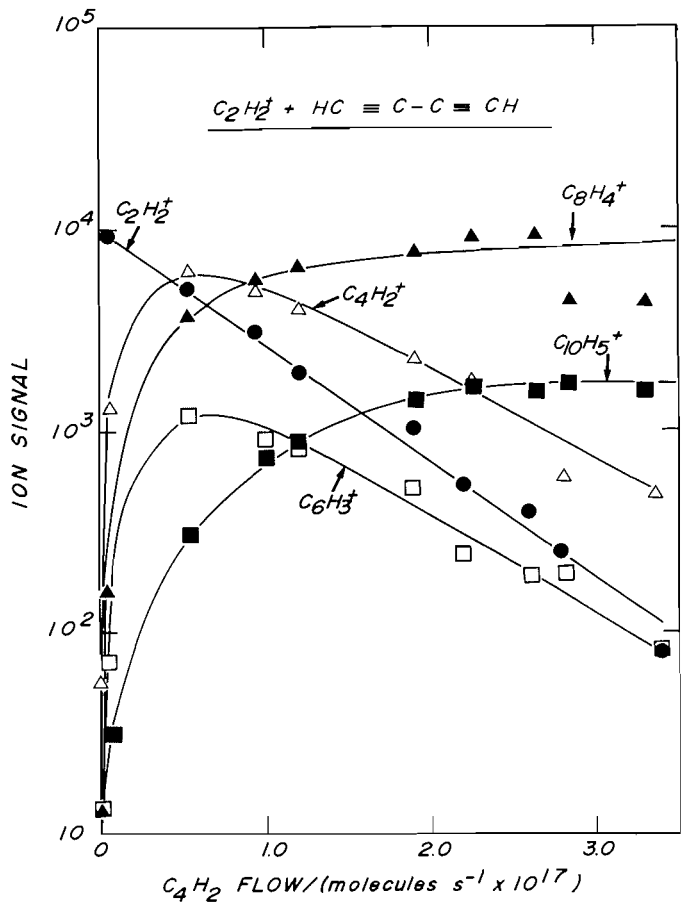

FIG. 4. The variations in ion signals observed for the addition of diacetylene into the reaction region of the SIFT apparatus in which $C_2H_2^+$ is initially established in helium buffer gas. $P = 0.372$ Torr, $\bar{v} = 6.7 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 295$ K. The $C_2H_2^+$ is derived from pure acetylene at an electron energy of 35 eV.

$^+CH_2$-C≡C-C≡CH) over a cyclic isomer (e.g. a C_2H substituted cyclopropenium ion), except perhaps by analogy with the preferred production of the linear propargyl isomer of $C_3H_3^+$.

The structures of the diacetylene adduct ions produced by reactions [2]–[4] are also not known. However, the high specific rates for their formation again imply formation of strong chemical bonds. A possible and interesting cyclic isomer of the $C_7H_5^+$ ion formed in reaction [2] is the phenyl carbene cation, $C_6H_5C:^+$. This carbene cation may add a second molecule of diacetylene, as in reaction [3], by C—H bond insertion to yield $^+CHC_4H(C_6H_5)$, a possible cyclic isomer of $C_{11}H_7^+$. Finally, the $C_9H_5^+$ ion formed in reaction [4] may also have a cyclic structure. One possibility is the formation of c-$C_5H_4(C_4H)^+$.

$C_2H_2^+$

Charge transfer was observed to be the main product channel for this reaction but there was a significant (10%) channel leading to carbon-chain lengthening with elimination of H in the formation of $C_6H_3^+$, which presumably is protonated triacetylene. This is evident in Fig. 4. Also, both product ions were seen to rapidly react further with diacetylene. The $C_6H_3^+$ responded to diacetylene with the addition reaction [5]. The

[5] $C_6H_3^+ + C_4H_2 \rightarrow C_{10}H_5^+$

resulting $C_{10}H_5^+$ is likely to be a proton-bound adduct of diacetylene and triacetylene but cyclic isomers again cannot be ruled out. The $C_4H_2^+$ responded to diacetylene in the manner indicated later in the text for the separate study of this reaction.

C_3H^+

The C_3H^+ carbene cation was observed to react with diacetylene primarily by condensation with elimination of C_2H or C_2H_2 leading to carbon-chain lengthening in the ion. Charge transfer appeared as only a minor channel. The predominant $C_5H_2^+$ product ion may result from C—H bond insertion with loss of C_2H and formation of HC≡C—CH=C=C$^{\bullet +}$ or from C—C bond insertion with loss of C_2H and formation of the radical cation $^\bullet C^+(C{\equiv}CH)_2$. The C_5H^+ formed by elimination of C_2H_2 is likely to be the carbene cation HC≡C—C≡C—C:$^+$. All three product ions were observed to react further. The C_5H^+ responded according to reaction [1] and the $C_4H_2^+$ reacted in the manner described later in the text. The $C_5H_2^+$ radical cation appeared to react further by addition and by condensation with elimination of C_2H in the following manner:

[6*a*] $C_5H_2^+ + C_4H_2 \rightarrow C_9H_4^+$

[6*b*] $\rightarrow C_7H_3^+ + C_2H$

In this case C—H insertion could lead to the acyclic radical cation HC≡C—CH=C=CH—C$^\bullet$=C$^+$—C≡CH, which may lose C_2H to form the carbon-chain cation HC≡C—CH=C=CH—C≡C$^+$.

$C_4H_2^+$

Ionized acetylene was reacted with carbon monoxide, acetylene, diacetylene, and cyanogen. No reaction was observed with hydrogen. Charge transfer and hydrogen atom transfer are endothermic with this molecule. Available heats of formation indicate that formation of the adduct ion $C_4H_4^+$ may be exothermic and that several isomers of $C_4H_4^+$ are possible, but it is not clear which one might be preferred. In any case, the very low upper limit to the rate constant for this reaction suggests that formation of the adduct involves a positive activation energy.

A slow reaction was observed with carbon monoxide. Approximately equal amounts were produced of the adduct ion $C_4H_2^+$.CO and the condensation product HC_5O^+, which involves elimination of H. No further reaction with CO was noticed with either product.

Acetylene was observed to add to $C_4H_2^+$ with a rate constant close to the collision limit but addition of a second molecule of acetylene was not rapid. It is not known whether the failure to add a second molecule of acetylene is indicative of the formation in the initial addition reaction of a cyclic product ion such as ionized benzyne, or an acylic product ion such as ionized 3-hexene-1,5-diyne, but both types of product are possible.

Addition was also the major channel with diacetylene, although in this case about 10% of the reaction led to the elimination of acetylene with formation of what may be ionized triacetylene. Again the measured rate constant for the loss of $C_4H_2^+$ is close to the collision limit. Results are shown in Fig. 5. The $C_6H_2^+$ is seen also to add a molecule of diacetylene but addition of a second molecule of diacetylene appears to be relatively unfavourable for both adduct ions in the product spectrum.

The primary product distribution observed for the reaction of $C_4H_2^+$ with C_4H_2 differs from that measured at lower pressures with an ICR (15), which indicates loss of C_2H_2 (83%), H_2 (17%), and H (1%) without any adduct formation. One cause of this difference may be the collisional stabilization of reactant and adduct ions, which proceeds at the moderate pressures of the SIFT experiments and which will be essentially absent in the ICR experiments. Observations that are consistent with such an interpretation have been made very recently in an ICR – high pressure mass spectrometer study (16). Loss from the adduct ion of both acetylene and hydrogen was noted in ICR experiments at $\sim 5 \times 10^{-6}$ Torr, but the loss of H_2 was observed to be entirely quenched in mass spectrometer experiments at pressures above ~0.01 Torr. Furthermore, the $C_6H_2^+$ produced by the reaction of $C_5H_2^+$ with C_4H_2 was seen to react further with C_4H_2, under ICR conditions, to produce $C_8H_2^+$ and $C_{10}H_2^+$ by elimination from the adduct ion of C_2H_2 and H_2, respectively. In contrast, all the adduct ions were observed to be stabilized in the high pressure mass spectrometer.

There is good agreement between the SIFT and ICR results on the rate constants for the loss of $C_4H_2^+$ and $C_6H_2^+$ in their reactions with C_4H_2. In the case of $C_4H_2^+$ the SIFT rate constant of $(1.3 \pm 0.4) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} is the same, within experimental error, as the ICR rate constants of 1.4×10^{-9} cm^3 molecule^{-1} s^{-1} (15) and $(1.39 \pm 0.5) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (16). Also, for the reaction of $C_6H_2^+$ with C_4H_2, the ICR rate constant of $(1.06 \pm 0.4) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} is the same as the value of 1×10^{-9} cm^3 molecule^{-1} s^{-1} estimated from the SIFT results.

It is of interest to consider briefly the possible structures of the highly unsaturated hydrocarbon ions $C_8H_4^+$ and $C_{10}H_4^+$

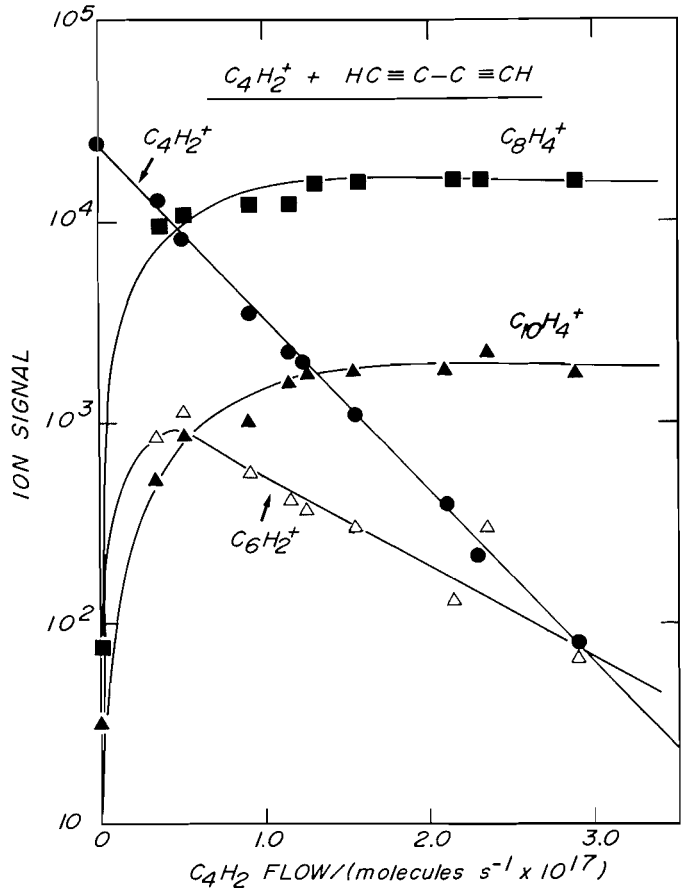

FIG. 5. The variations in ion signals observed for the addition of diacetylene into the reaction region of the SIFT apparatus in which the diacetylene radical cation is initially established in helium buffer gas. P = 0.259 Torr, $\bar{v} = 5.3 \times 10^3$ cm s^{-1}, L = 45 cm, and T = 297 K. The $C_2H_2^+$ is derived from diacetylene (10% in helium) at an electron energy of 35 eV.

produced in the addition reactions of $C_4H_2^+$ and $C_6H_2^+$ with C_4H_2. Carbon-chain isomers may be achieved by the addition of the C—H bond of one reagent across the triple bond of the other. The $C_8H_4^+$ isomer produced in this way would be HC≡C—C≡C—CH=CH—C≡CH$^+$, while HC≡C—C≡C—CH=CH—C≡C—C≡CH$^+$ would be a possible $C_{10}H_{4+}$ chain isomer. Formation of carbon-ring isomers can also be imagined. For example, $C_8H_4^+$ may have a cyclic structure with two alternating triple and double bonds while the analogous cyclic $C_{10}H_4^+$ structure would have an additional triple bond. Possible structures of $C_{2n}H_n^+$ and $C_{2n+2}H_n^+$ ions in general have been considered in more detail by Buckley *et al.* (16), who have observed sequential addition of diacetylene up to the formation of $C_{20}H_{10}^+$ and $C_{18}H_8^+$, respectively. Furthermore, these authors have identified reactivity patterns that suggest that the sequence initiated by $C_4H_2^+$ involves production of both cyclic and acyclic ions, with the latter being unreactive and increasingly preferred as the ion grows.

Adduct formation was also predominant in the SIFT experiments for the reaction of $C_4H_2^+$ with cyanogen, but there was also an indication of a minor channel (2%) leading to elimination of HCN and production of what is likely to be ionized cyano- or isocyanodiacetylene. Both product ions did not appear to rapidly react further with cyanogen. The specific rate for the addition of cyanogen to $C_4H_2^+$ is relatively low, so that the

adduct ion may not involve chemical bond formation in this case. The ion HC(CN)=C(CN)—C≡CH$^+$ would be one possible chemically bound adduct.

CN^+

The CN^+ ion was observed to react with diacetylene predominantly by charge transfer and by H atom elimination to form what is likely to be ionized cyanodiacetylene. The nature of these reaction channels and the measured branching ratios is very similar to those we have determined previously for the reaction of CN^+ with acetylene (17). Both product ions were observed to rapidly react further with diacetylene in the manner described earlier in the text in the case of $C_4H_2^+$, and by addition in the case of HC_5N^+ to form $HC_5N^+.C_4H_2$. The possible structures of the latter adduct are likely to be analogous to those discussed earlier for the $C_4H_2^+.C_4H_2$ adduct ion.

C_2N^+

The C_2N^+ was derived by electron impact at 60–80 eV from a 10% mixture of cyanogen in helium and exhibited only a single reactivity towards diacetylene (7). Product channels were observed corresponding to charge transfer, formation of C_5H^+, and adduct formation. Formation of C_5H^+ with elimination of HCN was the preferred channel. Since C_2N^+ may have carbene character, it seems likely that the formation of the adduct involves C—H bond insertion. Thus N≡C—CH$^+$—C≡C—C≡CH is a plausible intermediate, most of which eliminates HCN to form C_5H^+ and some of which is stabilized by collision to produce the $C_6H_2N^+$ product. Figure 6 shows that all three primary product ions add a molecule of diacetylene in rapid secondary reactions. The addition reactions with $C_4H_2^+$ and C_5H^+ have already been discussed, while the addition reaction with $C_6H_2N^+$ may proceed in analogy with the addition reaction of $C_5H_3^+$ noted earlier in the text.

$C_2N_2^+$

The $C_2N_2^+$ derived from cyanogen by electron impact was observed to react primarily by charge transfer. A minor channel was observed to lead to what is presumably ionized cyanodiacetylene. The observed secondary reactions of $C_4H_2^+$ and HC_5N^+ with diacetylene were as those described earlier in the text.

H_3^+, N_2H^+, H_3O^+, H_2CN^+, $CH_3OH_2^+$

Except for $CH_3OH_2^+$, these ions all reacted rapidly with diacetylene by proton transfer with rate constants close to the collision limit. The results are summarized in Table 2. The $CH_3OH_2^+$ was observed to react only by addition but with a high effective bimolecular rate constant. The high efficiency implies that the adduct is strongly bound, presumably by the proton. The secondary ion chemistry in helium buffer gas indicated a further rapid reaction of the $C_4H_3^+$ proton transfer product with diacetylene. The main channel of this secondary reaction was observed to correspond to addition to form $C_8H_5^+$ but a significant competing channel, about 10%, led to the formation of $C_6H_3^+$ as indicated in reaction [7].

[7*a*] $C_4H_3^+ + C_4H_2 \rightarrow C_8H_5^+$

[7*b*] $\rightarrow C_6H_3^+ + C_2H_2$

The $C_8H_5^+$ adduct may be the proton-bound diacetylene dimer but cyclic isomers are also possible, such as, for example, $C_6H_5C_2^+$. Complications arose in the secondary ion chemistry from the presence of hydrogen, which was added in the helium buffer gas experiments to generate the primary ions. Reactions with hydrogen became dominant in hydrogen buffer gas. They led to ions with $m/z = 103$ and 79 and the reactions are believed to be as indicated in [8] and [9].

[8] $C_8H_5^+ + H_2 \rightarrow C_8H_7^+$

[9] $C_8H_7^+ + H_2 \rightarrow C_6H_7^+ + C_2H_2$

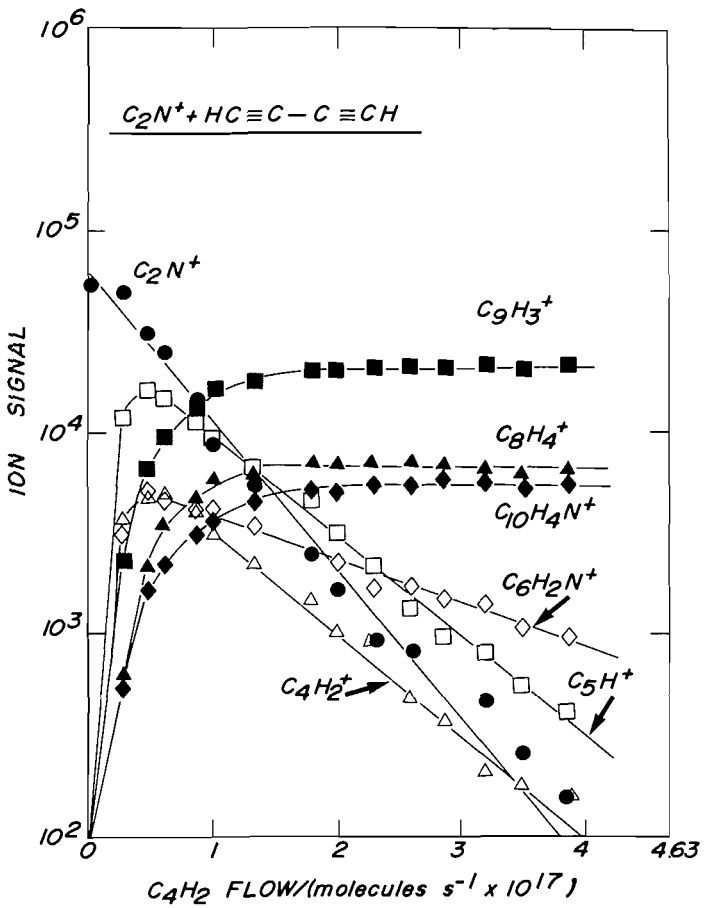

FIG. 6. The variations in ion signals observed for the addition of diacetylene into the reaction region of the SIFT apparatus in which C_2N^+ is initially established in helium buffer gas. $P = 0.296$ Torr, $\bar{v} = 5.8 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 296$ K. The C_2N^+ is derived from pure cyanogen at an electron energy of 80 eV.

Discussion

Diacetylene was found to be reactive towards all of the carbonaceous and carbon/nitrogen cations chosen for study. Aside from charge transfer, the predominant reaction channels observed correspond to condensation and association, both of which are suited for molecular growth by ion–molecule reactions. Condensation results when the adduct of the reacting ion and molecule dissociates into products before it is stabilized, while association refers to the process in which the adduct is stabilized by collision with a third molecule or by loss of radiation before separation into reactants or products.

Charge transfer was often an exothermic option because the ionization energy of diacetylene, 10.180 ± 0.003 eV, is relatively low in the range of the recombination energies of the selected reagent ions. Indeed, charge transfer was an observed product channel for all the primary ions with a recombination energy known to be larger than the ionization energy of diacetylene, including He^+ (24.6), CN^+ (14.5), $C_2N_2^+$ (13.374),

C_2N^+ (~13), $C_2H_2^+$ (11.41), C^+ (11.260), and C_3H^+ (10.35 ± 0.15) where the recombination energy is given in parentheses in eV (13, 6). The recombination energy of C_2N^+ is not well established. We can improve on the available approximate value by coupling the observation of charge transfer with diacetylene (ionization energy, IE = 10.180 eV) with the failure to observe charge transfer with cyanoacetylene (IE = 11.60 eV). These results imply a recombination energy of 10.9 ± 0.7 eV for the C_2N^+ generated in our experiments from cyanogen by electron impact. CH_3^+ was observed not to charge transfer. It is the only one of the selected ions with a recombination energy (9.842 eV) known to be smaller than ionization energy of diacetylene.

A number of the reaction channels observed to compete with charge transfer are of the condensation type leading to the lengthening of, or the addition of cyanide to the diacetylene carbon chain. Thus C_5H^+, $C_5H_2^+$, and $C_5H_3^+$ were produced from the reactions of C^+, C_3H^+, and CH_3^+ with diacetylene, respectively, and $C_6H_2^+$ and $C_6H_3^+$ were produced from $C_4H_2^+$ and $C_4H_3^+$, respectively. Both CN^+ and $C_2N_2^+$ were observed to produce HC_5N^+, which is presumably ionized cyano- or isocyanodiacetylene. In contrast, C_2N^+ reacted to produce C_5H^+ and thus to effect carbon-chain lengthening without cyanide addition. The most effective chain builders were C_3H^+, C_2N^+, and C^+.

The synthesis of molecules in an ionized environment by means of ion–molecule reactions requires the neutralization of the product ion as a final step. The neutralization may proceed in a number of different ways including electron–ion recombination (EIR), proton transfer (PT), or charge transfer (CT). Thus the carbonaceous neutrals C_5, C_5H, C_5H_2, and C_5H_3 may be derived from C_5H^+, $C_5H_2^+$, and $C_5H_3^+$ as, for example, in reactions [10] and [11]. However, these neutralization steps

[10] $C^+ \xrightarrow{C_4H_2} C_5H^+ \xrightarrow[EIR]{PT} :C{=}C{=}C{=}C{=}C:$

[11] $CH_3^+ \xrightarrow{C_4H_2} C_5H_3^+ \xrightarrow{CT} H_2C{=}C{=}C{=}C{=}\dot{C}H$

generally have not been studied in the laboratory and little is known about the relevant recombination energies or proton affinities. The $C_6H_2^+$ and $C_6H_3^+$ ions derived from the reactions of ionized and protonated diacetylene with diacetylene are likely to be ionized and protonated triacetylene, respectively, which may form neutral triacetylene by charge transfer and proton transfer, respectively. The reactions of CN^+ and $C_2N_2^+$ with diacetylene both produce some HC_5N^+ and so are potential sources of cyano- and isocyanodiacetylene, but other isomers are possible. It is interesting to note that under the SIFT conditions the HC_5N^+ was observed to react with diacetylene primarily to form the adduct, even though charge transfer is also exothermic if HC_5N^+ is ionized cyanodiacetylene.

Addition reactions were observed to be quite common, especially as secondary reactions, and several were observed to compete effectively with exothermic dissociation channels. Thus $C_3H_3^+$, C_5H^+, $C_5H_3^+$, $C_6H_2^+$, $C_6H_3^+$, and HC_5N^+ appeared to react with diacetylene to form stabilized adduct ions exclusively. In contrast, the addition of diacetylene to $C_4H_2^+$, $C_4H_3^+$, $C_5H_2^+$, and C_2N^+ was observed to occur in competition with dissociation channels. Also, the adduct ions $C_3H_3^+.C_4H_2$, $C_4H_2^+.C_4H_2$, and $C_2N^+.C_4H_2$ were observed to add a second molecule of diacetylene. The nature of the mechanism of stabilization of these adduct ions was not discerned and none of these reactions were studied systematically as a function of pressure. Also, no attempts were made to obtain structural information on the adduct ions, most of which may be cyclic or acyclic. In principle such information is available from comparative studies of ion reactivities. However, an elaborate experimental campaign would be required in practice to provide unequivocal results in this fashion.

In a few instances some insight into pressure dependence and stabilization mechanism is available from comparisons with results of photoionization mass spectrometer and ICR measurements performed at much lower pressures. The observation of dissociation products instead of adduct formation for the fast reaction of $C_4H_2^+$ with C_4H_2 in the ICR spectrometer (15, 16) implies collisional stabilization of the adduct at the moderate pressures of the SIFT apparatus. A similar situation appears to apply for the fast reaction of $C_6H_2^+$ with C_4H_2, which has been shown to lead to dissociation in ICR experiments (16) and to adduct formation in photoionization mass spectrometer experiments at ca. 0.01 Torr (16). Adduct formation is the reaction also observed in the SIFT experiments. The situation for the fast reaction of $C_3H_3^+$ with C_4H_2, which proceeds by adduct formation in the SIFT apparatus, is less clear. A similarly fast reaction has been observed with an ICR spectrometer for the linear isomer of $C_3H_3^+$, but products were not elucidated (14).

The diacetylene radical cation was observed to react primarily by addition to the molecules chosen for study, with the exception of hydrogen. The latter molecule failed to react with a measurable rate and this has implications for the lifetime of $C_4H_2^+$ in environments rich in H_2, such as dense interstellar clouds. With CO and C_2N_2, dissociative channels were observed, which lead to ions that, upon neutralization, allow for the growth of the carbon chain and the incorporation of a heteroatom. This is illustrated in the reaction sequences [12] and [13].

[12] $C_4H_2^+ \xrightarrow{CO} HC_5O^+ \xrightarrow[EIR]{PT} :C{=}C{=}C{=}C{=}C{=}O$

[13] $C_4H_2^+ \xrightarrow{C_2N_2} HC_5N^+ \xrightarrow[EIR]{PT} {}^{\cdot}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}N$

The reaction of $C_4H_2^+$ with C_4H_2, only slightly dissociative at the moderate pressures of the SIFT apparatus, becomes completely dissociative at low pressures (15) without changing its overall reaction efficiency and allows for growth of molecules with up to eight carbon atoms. The reaction with C_2H_2 appears to have quite a different behaviour. Only adduct formation is observed, even at low pressures (18, 19). Also, there is some disparity of an unknown origin in the rate constants measured at moderate and low pressures. The SIFT rate constant is 2 to 3 times as large as those determined from measurements at low pressures. Recent ICR experiments have found the disappearance rate constant to be (3.3 × 0.8) × 10^{-10} cm^3 $molecule^{-1}$ s^{-1} and independent of pressure in the range from 2 × 10^{-6} to 3 × 10^{-5} Torr (18). Earlier trapped-ion measurements led to a rate constant of (2.3 ± 0.3) × 10^{-10} cm^3 $molecule^{-1}$ s^{-1} at ca. 10^{-4} Torr, which was also reported to be pressure independent (19). The pressure independence of the rate constant at low pressures has been rationalized both in terms of bimolecular radiative association (19) and in terms of saturated termolecular collisional association (18). The latter interpretation requires a lifetime for the $C_6H_4^+$ collision complex in the millisecond regime. The actual mechanism of stabilization remains unresolved.

There appears to be no previous information on the kinetics

of protonation of diacetylene. We have found that protonation occurs with considerable ease under our experimental conditions. The proton-transfer reactions that were observed all proceed essentially at the collision rate at room temperature. The occurrence of proton transfer with H_2CN^+ and the failure of proton transfer with $CH_3OH_2^+$ allow the proton affinity of diacetylene to be bracketed between the known proton affinities of HCN and CH_3OH. The proton affinities available for these two molecules (20) yield a proton affinity for diacetylene of 177 $\pm$ 5 kcal mol^{-1}. This value corresponds to a heat of formation for $C_4H_3^+$ of 305 $\pm$ 5 kcal mol^{-1}, which agrees well with the value of 307 kcal mol^{-1} that may be derived from the appearance potential for $C_4H_3^+$ from vinylacetylene (12). The bracketed value for the proton affinity agrees with the results of bracketing measurements performed recently with the techniques of ICR and high pressure mass spectrometry (20).

Cyanothiolacetate as a masked β-hydroxyproprionitrile carbanion in Michael reactions[1]

HSING-JANG LIU AND HLA WYNN
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 21, 1985

HSING-JANG LIU and HLA WYNN. Can. J. Chem. **64**, 649 (1986).

A facile method for the introduction of a highly functionalized isopropyl unit, in the form of β-hydroxyproprionitrile or acrylonitrile, to the β carbon of an α,β-unsaturated ketone has been developed using *S-tert*-butyl cyanothiolacetate as a β-hydroxyproprionitrile equivalent in Michael reactions.

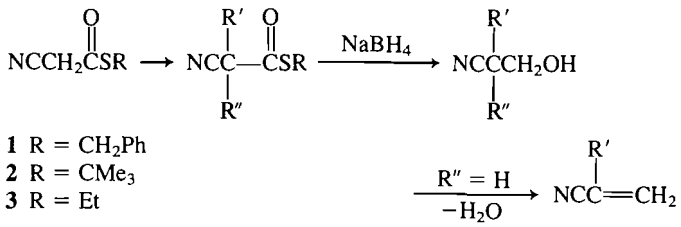
HSING-JANG LIU et HLA WYNN. Can. J. Chem. **64**, 649 (1986).

On a développé une méthode facile d'introduction d'une unité isopropyle hautement fonctionalisée, sous la forme d'un β-hydroxyproprionitrile ou d'acrylonitrile, au carbone β d'une cétone α,β-non saturée; la méthode est basée sur l'utilisation d'un cyanothiolacétate de *S-tert*-butyle comme carbanion équivalent à un β-hydroxypropionitrile dans des réactions de Michael.
[Traduit par la revue]

Introduction

One of the synthetically useful features of the thiolester group is its susceptibility to reduction with sodium borohydride to the alcohol level. This was first observed by Fujita and co-workers on the highly activated thiolesters derived from 2-mercaptothiazoline (3). Later it was found that ordinary thiolesters could also be reduced in the same way (4). It was further shown that the thiolester group could be selectively reduced in the presence of other commonly encountered acid derivatives such as amide, ester, and nitrile (4).

The ease of reduction of the thiolester group with sodium borohydride suggests a number of interesting possibilities for its use as a latent hydroxymethyl unit in synthesis, especially when such a unit, with or without protection, cannot be directly involved in a desired transformation. In a recent report (1), we described a convenient approach to β-hydroxypropionitrile and acrylonitrile derivatives involving alkylation or Knoevenagel-type reactions of cyanothiolacetate as the initiating step. As illustrated in Scheme 1, the synthetic approach is greatly



SCHEME 1

facilitated because of the ability of the thiolester group present in the starting material to serve both as an activating group for the carbon–carbon bond formation and as a convenient source of hydroxymethyl moiety. The overall transformation can be considered as the replacement of one to two α-protons of β-hydroxypropionitrile (or acrylonitrile) by electrophiles using cyanothiolacetate as a β-hydroxypropionitrile carbanion equivalent.

The use of cyanothiolacetate as a convenient source of a masked β-hydroxypropionitrile carbanion has a considerable potential in organic synthesis. One interesting application is in its use as a Michael donor to facilitate the introduction of a highly functionalized isopropyl unit to the β-carbon of an α,β-unsaturated ketone. This process, which is described herein, is expected to have broad utility in the synthesis of natural products, especially those of isoprene origin.

Results and discussion

A. *Michael reactions of cyanothiolacetates*

Three cyanothiolesters (benzyl (**1**), *tert*-butyl (**2**), and ethyl (**3**)) were examined. These compounds were readily prepared from the corresponding thiols and cyanoacetic acid according to the reported procedure (5). *S*-Benzyl cyanothiolacetate (**1**) was initially used but exploration on this compound was very brief due to its instability. On the other hand, cyanothiolester **2**, which was used extensively throughout this work, was shown to be stable and could be stored at room temperature for a prolonged period of time. In the large-scale preparation, this thiolester was purified first by distillation at 100°C/2 Torr (1 Torr = 133.3 Pa). The distillate was then chromatographed on silica gel as described (5). *S*-Ethyl cyanothiolacetate (**3**), bp 100°C/4 Torr, was purified in a similar manner.

1,4-Diazabicyclo[2.2.2]octane (DABCO), which was found to be a highly effective base to induce Michael reactions of β-keto thiolesters (6) and *S,S'*-diethyl dithiomalonate (7), was used initially for the present studies. The experimental results obtained for the addition of thiolester **2** to five α,β-unsaturated ketones are summarized in Table 1. These results showed that DABCO was only effective in a limited number of cases (Entries 1, 6, and 7). In most cases, however, the yields of adducts were rather disappointing (Entries 8–12) and occasionally bis-addition was observed (Entry 12).

In search of adequate conditions for the Michael reaction, we have examined a series of tertiary amine bases including 4-dimethylaminopyridine (DMAP), ethyldiisopropylamine (Hunig's base), *N,N*-dimethylaniline, pyridine, and imidazole. Apart from *S-tert*-butyl cyanothiolacetate (**2**), the corresponding ethyl derivative **3** was also used as a Michael donor. As shown by the experimental results compiled in Table 2, none of the amines applied was particularly effective. Consequently, alternative methods were sought. In the subsequent studies thiol ester **2** was used exclusively, since thiol ester **3** was shown, in spite of its smaller size, to be inferior as a Michael donor (cf. Table 1, Entry 1 and Table 2, Entry 2).

Generally, in Michael reactions in which the donor can also serve as a good leaving group, the rate-limiting step in which the new carbon–carbon bond is formed is reversible. The position of the equilibrium depends, to a large extent, on the stability of

[a]Unless otherwise stated, these reactions were performed in DME at room temperature.
[b]All these products were obtained as diastereomeric mixtures.
[c]Yields were calculated on the basis of the yield-limiting reactant.
[d]This reaction was carried out in refluxing ether.
[e]These reactions were carried out in THF.

the intermediate enolate ion (8). In principle, the equilibrium could be shifted to the side of product formation by trapping the intermediate enolate ion with an adequate electrophile. As shown in Scheme 2, one such electrophile could be chlorotrimethylsilane, which is expected to react with the enolate ion rapidly to give a stable silyl enol ether that could then be converted to the desired ketone. Based on this principle, a general method for the Michael reaction was developed. Initially, the Michael reaction of thiolester **2** and 2-cyclohexen-1-one was examined in DME at room temperature in the presence of imidazole and chlorotrimethylsilane. The results were promising but not highly satisfactory. After a number of trials and modifications, it was found that the best results were obtained by the use of sodium hydride as a base, chlorotrimethylsilane as a trapping agent, and benzene as a solvent. By the use of this combination, a number of reactions were successfully explored. Results are compiled in Table 3.

In a typical experiment, thiolester **2** (1 equiv.) was treated with 1.2 equiv. of 2-cyclohexen-1-one, 0.9 equiv. of chlorotrimethylsilane, and 1.5 equiv. of sodium hydride in benzene at room temperature for 17 h. An 86% yield of adduct **4** was isolated after standard aqueous work-up and purification. In this case and two other cases (Entries 7 and 10) the normal work-up was found to be sufficient to generate the ketone carbonyl from the corresponding enol ether. In other cases (Entries 2–6, 8, and 9), however, the silyl enol ether moiety was shown to be rather

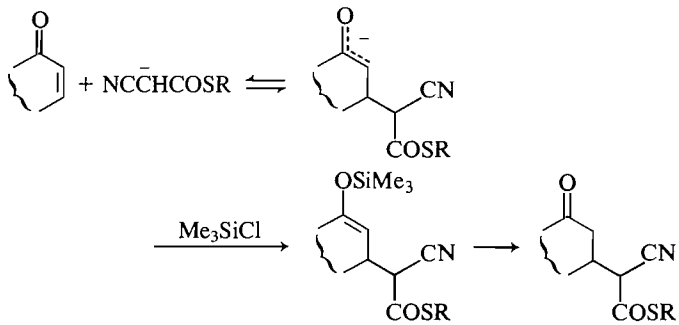
stable and a brief treatment (10 min) of the crude product with potassium fluoride in methanol was necessary to secure the desired product.

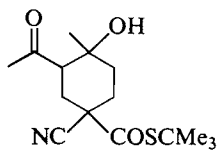
During the studies, it was also noted that it was important to keep the amount of the trapping agent slightly less than that of the thiolester. In a number of experiments, when an excess of



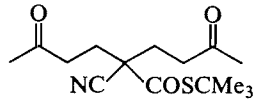
SCHEME 2

chlorotrimethylsilane was used, the desired product was not formed.[2]

Of the results shown in Table 3, three cases are particularly noteworthy. Whereas all the products possessing two or more chiral centers were obtained as mixtures of diastereomers, adducts **13** and **14** were produced, surprisingly, each as a single stereoisomer. Each compound displayed a single set of signals in the ^{1}Hmr spectrum as well as in the ^{13}Cmr spectrum. Another noteworthy case is the addition of thiolester **2** to methyl vinyl ketone (Entry 10), a highly reactive Michael acceptor. The best yield obtained for the adduct **15** was 48%, when the reaction was carried out in benzene at 10°C for 3 h. The low yield was partly due to the formation of a by-product, which was characterized as a diastereomeric mixture of compound **16**. This compound was apparently formed via bis-addition product **17**, involving an intramolecular aldol process. In order to suppress the formation of this bis-product, as well as to improve the yield of adduct **15**, the reaction was performed in toluene at low temperatures (−40°C and −60°C). Contrary to our expectation, the yields obtained for the desired product were lower and an increasing amount of compound **16** to the extent of 34% yield was obtained.



16



17

[2]To account for this observation, it is very likely that chlorotrimethylsilane reacts first with the thiolester and the resulting silyl enol ether is the effective trapping agent.

[a]The amount of sodium hydride used was 1.5 equiv. based on thiolester **2**.
[b]The amount of chlorotrimethylsilane used was 0.9 equiv. based on thiolester **2**.
[c]Room temperature.
[d]Toluene was used as a solvent.
[e]No reaction.

The reactions of thiolester **2** with β,β-disubstituted enones such as 3-methyl-2-cyclohexen-1-one (Entry 11) and α,β-disubstituted enones such as 3-methyl-3-penten-2-one and 2-methyl-2-cyclohexen-1-one (Entries 12 and 13) were also examined using the described conditions. In all of these cases, no detectable amount of adduct was produced. These two types of enones are known to be poor Michael acceptors, which do not usually undergo addition reaction with Michael donors of low nucleophilicity, such as malonic acid derivatives (9). Our case was no exception.

TABLE 4. Ketalization[a] and reduction[b] of Michael adducts

		Ketalization		Reduction

[a]These reactions were performed using ethylene glycol (10 equiv.) and *p*-toluenesulfonic acid (0.1 equiv.) in refluxing benzene.

[b]All the reactions were run at room temperature.

Table 3 also summarizes the results of several Michael reactions carried out under similar conditions in the absence of chlorotrimethylsilane. These experiments were performed in order to determine whether chlorotrimethylsilane indeed played a role in assisting the Michael reaction. An examination of the results reveals that, although in several cases (Entries 1, 4, 5, and 7) the yields of adducts were comparable, in other cases (Entries 2, 8 and 9) the adducts were obtained in substantially better yields when chlorotrimethylsilane was present.

Standard conditions for Michael reaction of analogous donors such as dialkyl malonate often involve the combination of a base, such as hydroxide and alkoxide, and a protic solvent, such as water and alcohol (10, 11). These conditions are apparently inadequate for the cyanothiolester under investigation, since the thiolester group is labile toward these strongly nucleophilic reagents. Experimentally, this was proven to be true. When the addition of cyanothiolester **2** to 4,4-dimethyl-2-cyclohexen-1-one was attempted in ethanol with potassium hydroxide at room temperature, adduct **14** was obtained in a poor yield of 19%.

B. *Conversion of Michael adducts to β-hydroxypropionitrile and acrylonitrile derivatives*

Since the ketone carbonyl is more reactive towards sodium borohydride than the thiolester carbonyl, its protection was necessary prior to the selective reduction of the latter functional group. In all the cases examined, the protection was readily achieved in the form of a ketal using standard ketalization conditions. Thus, treatment of adduct **4** with ethylene glycol in refluxing benzene in the presence of *p*-toluenesulfonic acid with continuous removal of water gave ketal **18** in virtually quantitative yield. Subsequent reduction of ketal **18** with sodium borohydride in ethanol at room temperature gave rise to the desired alcohol **19** in 90% yield over two steps (Table 4, Entry 1). Under similar conditions, four additional Michael adducts were ketalized and reduced to give the desired ketal alcohols in good overall yields. Particulars of these experiments are summarized in Table 4, Entries 2–5.

The conversion of ketal alcohols to the corresponding acrylonitriles was equally straightforward. Two methods were found to be readily applicable. Direct dehydration of ketal alcohol **19** with 1,3-dicyclohexylcarbodiimide (DCC) in refluxing ether in the presence of a trace amount of cuprous chloride (1, 12) proceeded smoothly to give a 79% yield of acrylonitrile derivative **28** (Table 5, Entry 1).

Ketal alcohol **21** was converted by two different methods into acrylonitrile derivative **29**. Direct dehydration with DCC gave a 60% yield of the latter compound (Entry 2). Indirectly, mesylation of **21** with methanesulfonyl chloride and triethylamine in dichloromethane at room temperature, followed by treatment of the resulting mesylate with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in refluxing benzene, gave the same compound in

TABLE 5. Dehydration of ketal alcohols

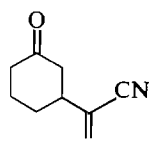
Entry	Ketal alcohol	Method[a]	Time (h)	Product	% Yield
1.	**19**	A	16	 **28**	79
2.	**21**	A	48	 **29**	60
3.	**21**	B	*b*	**29**	58
4.	**23**	A	24	 **30**	77
5.	**25**	A	31	 **31**	65
6.	**27**	A	21	 **32**	87

[a]Method A: A direct dehydration using DCC (1.5 equiv.) and a trace amount of copper(I) chloride in refluxing ether. Method B: A two-step procedure involving mesylation using methanesulfonyl chloride and triethylamine, followed by elimination with DBU in refluxing benzene.

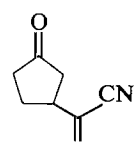
[b]The time for mesylation was 24 h and the time required for elimination was 50 min.

comparable yield (Entry 3). Table 5 also summarizes the results obtained for the conversions of **23** → **30**, **25** → **31**, and **27** → **32** (Entries 4–6).

Having successfully completed the investigation on the conversion of Michael adducts to β-hydroxypropionitrile derivatives and, further, to acrylonitriles, the removal of the ketal protecting group was examined. Experimental results showed that the deprotection could be readily achieved without destruction of the rather labile acrylonitrile moiety. When exposed to *p*-toluenesulfonic acid in acetone at room temperature, both compounds **28** and **31** were found to undergo transketalization smoothly to give ketones **33** (81% yield) and **34** (97% yield) respectively.



33



34

In conclusion, cyanothiolacetate **2** was shown to undergo Michael reaction with conjugated enones. The thiolester group of the products could be selectively reduced, after proper protection of the ketone carbonyl, with sodium borohydride to the alcohol level. Hence, a highly functionalized isopropyl unit in the form of β-hydroxypropionitrile could be easily introduced to the β-carbon of a conjugated enone, utilizing cyanothiolacetate as a masked β-hydroxypropionitrile carbanion equivalent. Furthermore, the β-hydroxypropionitrile group was readily dehydrated either directly with DCC or indirectly via a two-step sequence involving mesylation and elimination. Hence, cyanothiolacetate can also be conveniently used as a masked acrylonitrile unit in Michael reactions.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared (ir) spectra were recorded on a Perkin–Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer. Unless otherwise stated, ir samples were run as thin films. Proton nuclear magnetic resonance (^{1}Hmr) spectra were recorded on a Varian HA-100, HA-100/Digilab, Bruker WH-80, WH-200, or WH-400 spectrometer and, except where otherwise stated, were obtained on solutions in deuterochloroform with tetramethylsilane as internal reference. Carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker HF-90/Nicolet 1085 system or a Bruker WH-200 or WH-400 spectrometer and were obtained on solutions in deuterochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS9, MS12, or MS50 mass spectrometers. Silica gel, 0.040–0.063 mm particle size, 230–400 mesh ASTM, was used as adsorbent for flash chromatography, and silica gel, 60–120 mesh, was used as adsorbent for column chromatography. Unless otherwise stated, anhydrous magnesium sulfate was used for drying organic solutions.

*Michael reactions of cyanothiolacetates **2** and **3** with α,β-unsaturated ketones*

The reactions were carried out using the general procedures illustrated below with 2-cyclohexen-1-one. Details of each reaction, such as temperature, time, yield, and relative quantities of reagents and reactants, are noted in Tables 1–3.

A. *Using tertiary amine as a base*

At 0°C, to a solution of *S-tert*-butyl cyanothiolacetate (**2**) (500 mg, 3.18 mmol) in DME (10 mL), were added DABCO (357 mg, 3.18 mmol) and 2-cyclohexen-1-one (0.26 mL, 2.65 mmol). After stirring at room temperature under an argon atmosphere for 36 h, the reaction mixture was poured into ice-cold 1 *N* aqueous hydrochloric acid (20 mL) and extracted with chloroform (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. Chromatography of the residue on silica gel, eluting with 10% ethyl acetate in petroleum ether, gave adduct **4** (410 mg; 61% yield) as a mixture of two diastereomers (ca. 1:1); ir ($CHCl_3$): 1677 (thiolester C=O), 1715 (ketone C=O), and 2240 (C≡N) cm^{-1}; ^{1}Hmr δ: 1.50 (s, 9H, —C(CH$_3$)$_3$), 3.45 (d, ~0.5H, J = 6 Hz, —CHCN of one isomer), and 3.60 (d, ~0.5H, J = 4 Hz, —CHCN of another isomer); ms M$^+$: 253.1137 (calcd. for $C_{13}H_{19}NO_2S$: 253.1136). *Anal.* calcd. for $C_{13}H_{19}NO_2S$: C 61.63, H 7.56, N 5.53, S 12.65; found: C 61.38, H 7.75, N 5.28, S 12.46.

B. *Using sodium hydride as a base in the presence of chlorotrimethylsilane*

Cyanothiolester **2** (348 mg, 2.21 mmol) was dissolved in benzene (8 mL) and stirred at ~5°C under an argon atmosphere. Chlorotrimethylsilane (0.22 mL, 1.73 mmol), 2-cyclohexen-1-one (0.25 mL, 2.56 mmol), and sodium hydride (50% dispersion in oil; 154 mg, 3.2 mmol) were sequentially added and the reaction mixture stirred for 17 h at room temperature. The reaction was worked up as in method A

and the crude product[3] purified by flash chromatography on silica gel (20% ethyl acetate – petroleum ether) to give adduct **4** (478 mg; 86% yield).

C. *Using sodium hydride as a base in the absence of chlorotrimethylsilane*

Cyanothiolester **2** (92 mg, 0.58 mmol) was dissolved in benzene (8 mL) and stirred at ~5°C under an argon atmosphere. Sodium hydride (50% dispersion in oil; 28 mg, 0.58 mmol) was introduced, followed by addition of 2-cyclohexen-1-one (0.07 mL, 0.7 mmol). After stirring for 22 h at room temperature, the mixture was worked up as in method A. Purification of the crude product by column chromatography on silica gel (20% ethyl acetate – petroleum ether) gave adduct **4** (132 mg; 90% yield).

The adducts **7–16** showed the following data:

Adduct **7**: mp 81–85°C (benzene – petroleum ether); ir ($CHCl_3$): 1675 (thiolester C=O), 1730 (ketone C=O), and 2240 (C≡N) cm^{-1}; ^{1}Hmr δ: 1.52 and 1.54 (both s, ~1:1, total 9H, —$C(Ch_3)_3$), 3.54, 3.64 (both d, ~1:1, 1H total, J = 10 Hz each, —CHCN), and 6.20 (br s, 2H, —CH=CH—); ms M^+: 303.1292 (calcd. for $C_{17}H_{21}NO_2S$: 303.1293). *Anal.* calcd. for $C_{17}H_{21}NO_2S$: C 67.30, H 6.98, N 4.62, S 10.57; found: C 67.48, H 7.15, N 4.48, S 10.31.

Adduct **8**: mp 42–43°C (benzene – petroleum ether); ir: 1685 (thiolester C=O), 1725 (ketone C=O), and 2260 (C≡N) cm^{-1}; ms M^+: 241.1138 (calcd. for $C_{12}H_{19}NO_2S$: 241.1136). *Anal.* calcd. for $C_{12}H_{19}NO_2S$: C 59.72, H 7.94, N 5.81, S 13.26; found: C 59.64, H 7.95, N 5.71, S 13.09. The ^{1}Hmr spectrum displayed two sets of signals in a ratio of 2:1, indicating the presence of two diastereomers. The following signals were attributed to the major isomer: δ 1.07 (d, 3H, J = 6 Hz, CH_3CH—), 1.54 (s, 9H, —$C(CH_3)_3$), 2.28 (s, 3H, CH_3CO—), and 3.90 (d, 1H, J = 4 Hz, —CHCN). The following signals were attributed to the minor isomer: δ 1.13 (d, 3H, J = 6 Hz, CH_3CH—), 1.49 (s, 9H, —$C(CH_3)_3$), 2.12 (s, 3H, CH_3CO—), and 3.52 (d, J = 6 Hz, —CHCN).

The ^{1}Hmr spectrum displayed two sets of signals in a ratio of 4:1. The following signals were attributed to the major diastereomer: δ 1.18 (s, 3H, —CH_3), 1.50 (s, 9H, —$C(CH_3)_3$), and 2.19 (s, 3H, —$COCH_3$). The following signals were attributed to the minor isomer: δ 1.25 (s, 3H, —CH_3), 1.52 (s, 9H, —$C(CH_3)_3$), and 2.16 (s, 3H, —$COCH_3$).

*Ketalization and selective reduction of Michael adducts **4** and **7–10***

The reactions were carried out using the general procedures illustrated below with adduct **4**. Reaction time and yield of individual reactions are noted in Table 4.

Ketone **4** (501 mg, 1.98 mmol) was dissolved in benzene (40 mL). Ethylene glycol (1.23 g, 19.8 mmol) and *p*-toluenesulfonic acid monohydrate (36 mg, 0.2 mmol) were added. The reaction flask was fitted with a Dean–Stark water separator charged with type 3A molecular sieves in the take-off arm. The reaction mixture was heated at reflux for 7 h under an argon atmosphere and then cooled to room temperature. Saturated aqueous sodium bicarbonate solution (10 mL) was added and the resulting solution extracted with dichloromethane (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated to afford ketal **18** (596 mg); ir ($CHCl_3$): 1050–1100 (C—O), 1678 (C=O), and 2240 (C≡N) cm^{-1}; ^{1}Hmr δ: 1.50 (s, 9H, —$C(CH_3)_3$), 3.45, 3.49 (both d, 1H total, J = 7 Hz each, —CHCN), and 3.95 (br s, 4H, —OCH_2CH_2O—); ms M^+: 297.1409 (calcd. for $C_{15}H_{23}NO_3S$: 297.1399). *Anal.* calcd. for $C_{15}H_{23}NO_3S$: C 60.58, H 7.80, N 4.71, S 10.76; found: C 60.52, H 7.76, N 4.65, S 10.88.

Ketal **18** (248 mg, ~0.84 mmol) was dissolved in absolute ethanol (5 mL) and sodium borohydride (124 mg, 3.26 mmol) was added. The reaction mixture was stirred under an argon atmosphere at room temperature for 1 h. It was then poured into ice-cold saturated aqueous ammonium chloride solution (20 mL) and extracted with dichloromethane (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride solution, dried, filtered, and concentrated. The crude material was purified by column chromatography on silica gel (50% ethyl acetate – petroleum ether) to give a mixture of

[3]For compounds **7**, **8**, **9**, **13**, and **14**, the crude product was further treated with an equal amount (by weight) of potassium fluoride in water–methanol (1:2; 100 mL per each gram of the crude product) at room temperature for 10 min. This was followed by acidification with 1 *N* aqueous hydrochloric acid, extraction with chloroform, and work-up of the extracts in the usual manner.

diastereomeric alcohols **19** (163 mg; 90% yield from **4**); ir 2240 (C≡N) and 3400–3500 (—OH) cm^{-1}; ^{1}Hmr δ: 2.80 (m, 1H, —CHCN), 3.82, 3.86 (both d, 1H each, J = 6 Hz each; —CH_2OH), and 3.95 (m, 4H, —OCH_2CH_2O—); ms M^+: 211.1209 (calcd. for $C_{11}H_{17}NO_3$: 211.1208).

Compounds **20–27** displayed the following physical data:

Ketal **20**: ir: 1680 (C=O) and 2260 (C≡N) cm^{-1}; ^{1}Hmr δ: 1.49, 1.54 (both s, 9H total, —C(CH_3)$_3$), 3.60, 3.65 (both d, 1H total, J = 10 Hz each, —CHCN), 3.90 (br s, 4H, —OCH_2CH_2O—), and 6.20 (m, 2H, —CH=CH—); ms M^+: 347.1557 (calcd. for $C_{19}H_{25}NO_3S$: 347.1555).

Alcohol **21**: ir: 2260 (C≡N) and 3400–3500 (—OH) cm^{-1}; ^{1}Hmr δ: 3.80 (m, 2H, —CH_2OH), 3.90 (m, 4H, —OCH_2CH_2O—), and 6.20 (m, 2H, —CH=CH—); ms M^+: 261.1366 (calcd. for $C_{15}H_{19}NO_3$: 261.1365).

Ketal **22**: ir: 1680 (C=O) and 2250 (C≡N) cm^{-1}. *Anal.* calcd. for $C_{14}H_{23}NO_3S$: C 58.92, H 8.13, N 4.91, S 11.21; found: C 59.00, H 8.16, N 4.83, S 11.04. The following ^{1}Hmr data were attributed to the major isomer: δ 1.10 (d, 3H, J = 7 Hz, CH_3CH—), 1.36 (s, 3H, CH_3CO—), 1.52 (s, 9H, —C(CH_3)$_3$), 3.98 (s, 4H, —OCH_2CH_2O—), and 4.26 (d, 1H, J = 4 Hz, —CHCN). The following ^{1}Hmr data were attributed to the minor isomer: δ 1.22 (d, 3H, J = 7 Hz, CH_3CH—), 1.36 (s, 3H, CH_3CO—), 1.52 (s, 9H, —C(CH_3)$_3$), 3.60 (d, 1H, J = 4 Hz, —CHCN), and 3.90 (br s, 4H, —OCH_2CH_2O—).

Alcohol **23**: ir: 2260 (C≡N) and 3400–3500 (—OH) cm^{-1}; ms m/e: 184.0973 (M^+ −15; calcd. for $C_9H_{14}NO_3$: 184.0974). Alcohol **27**: ir: 2250 (C≡N) and 3400–3500 (—OH) cm^{-1}; ^{1}Hmr δ: 2.50 (br s, 1H, —OH), 2.70 (m, 1H, —CHCN), 3.76 (dd, 2H, J = 6, J' = 2 Hz, —CH_2OH), and 3.86 (m, 4H, —OCH_2CH_2O—); ms M^+: 237.1359 (calcd. for $C_{13}H_{19}NO_3$: 237.1365).

*Dehydration of alcohols **19**, **21**, **23**, **25**, and **27***

The dehydration reactions were carried out using the general procedures illustrated below with alcohol **21**. Time of reactions and yields of products are noted in Table 5.

A. *Direct dehydration*

Alcohol **21** (291 mg, 1.11 mmol) was dissolved in ether (5 mL). DCC (342 mg, 1.67 mmol) was introduced, followed by addition of a small amount of copper(I) chloride (15 mg). The mixture was heated at reflux for 48 h under an argon atmosphere, cooled to room temperature, and filtered. Concentration of the filtrate gave a residue which was dissolved in *n*-pentane, filtered, and concentrated. The crude product was purified by flash chromatography on silica gel (20% ethyl acetate – petroleum ether) to afford ketal olefin **29** (165 mg; 60% yield); ir: 1080 (C—O), 1630 (C=C), and 2220 (C≡N) cm^{-1}; ^{1}Hmr δ: 3.92 (m, 4H, —OCH_2CH_2O—), 5.76 (d, 1H, J = 2 Hz, =CHH), 5.86 (br s, 1H, =CHH), 6.10 (dd, 1H, J = 6, J' = 4 Hz, —CH=), and 6.34 (dd, 1H, J = 6, J' = 3 Hz, —CH=); ^{13}Cmr δ: 138.4, 132.3, 132.1, 128.8, 126.5, 115.4, 92.1, 64.5, 64.0, 55.1, 53.2, 50.8, 44.8, 44.7, 43.6; ms M^+: 243.1256 (calcd. for $C_{15}H_{17}NO_2$: 243.1259). *Anal.* calcd. for $C_{15}H_{17}NO_2$: C 74.04, H 7.05, N 5.76; found: C 74.06, H 7.20, N 5.59.

B. *Indirect dehydration*

Alcohol **21** (249 mg, 0.95 mmol) was dissolved in dichloromethane (10 mL). Methanesulfonyl chloride (0.22 mL, 2.85 mmol) and triethylamine (0.66 mL, 4.75 mmol) were added and the mixture stirred for 24 h at room temperature under an argon atmosphere. The resulting solution was evaporated to dryness *in vacuo* and the residue dissolved in benzene (5 mL). DBU (0.5 mL) was introduced and the solution refluxed for 50 min under an atmosphhere of argon. It was then cooled to room temperature, poured into 1 *N* aqueous hydrochloric acid (30 mL), and extracted with dichloromethane (4 × 20 mL). The extracts were washed sequentially with water, saturated aqueous sodium carbonate, and saturated aqueous sodium chloride, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel (20% ethyl acetate – petroleum ether) afforded ketal olefin **29** (135 mg; 58% yield from alcohol **21**).

Ketal olefins **28** and **30–32** showed the following physical data:

Ketal olefin **28**: ir: 1080 (C—O) and 2220 (C≡N) cm^{-1}; ^{1}Hmr δ: 3.95 (s, 4H, —OCH_2CH_2O—), 5.70 (d, 1H, J = 2 Hz, =CHH), and 5.82 (br s, 1H, =CHH); ms M^+: 193.1102 (calcd. for $C_{11}H_{15}NO_2$: 193.1103).

Ketal olefin **30**: ir: 1050–1100 (C—O), 1630 (C=C), and 2220 (C≡N) cm^{-1}; ^{1}Hmr δ: 1.20 (d, 3H, J = 7 Hz, CH_3CH—), 1.36 (s, 3H, CH_3CO—), 3.96 (s, 4H, —OCH_2CH_2O—), 5.70, and 5.78 (both d, 1H each, J = 2 Hz each, =CH_2); ms m/e: 166.0868 (M^+ −15; calcd. for $C_9H_{12}NO_2$: 166.0868).

Ketal olefin **31**: ir: 1110 (C—O) and 2220 (C≡N) cm^{-1}; ^{1}Hmr δ: 3.94 (s, 4H, —OCH_2CH_2O—), 5.75 (d, 1H, J = 2 Hz, =CHH), 5.83 (br s, 1H, =CHH); ms m/e: 127.0759 (M^+ −52; calcd. for $C_7H_{11}O_2$: 127.0759).

Ketal olefin **32**: ir: 1120 (C—O), 1620 (C=O), and 2238 (C≡N) cm^{-1}; ^{1}Hmr δ: 3.80 (m, 4H, —OCH_2CH_2O—), 5.78, and 5.86 (both br s, 1H each, =CH_2); ms M^+: 219.1262 (calcd. for $C_{13}H_{17}NO_2$: C 71.19, H 7.82, N 6.39; found: C 71.06, H 7.93, N 6.23.

*Deketalization of ketal olefins **28** and **31***

A solution of ketal olefin **28** (62 mg, 0.32 mmol) and *p*-toluenesulfonic acid monohydrate (30 mg, 0.16 mmol) in acetone (5 mL) was stirred at room temperature under an argon atmosphere for 24 h. It was made basic with saturated aqueous sodium bicarbonate and extracted

with dichloromethane (4 × 10 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. The crude product was purified by flash chromatography on silica gel (20% ethyl acetate in petroleum ether) to afford ketone **33** (39 mg; 81% yield); ir: 1710 (C=O) and 2220 (C≡N) cm^{-1}; ^{1}Hmr δ: 5.80 (d, 1H, J = 2 Hz, =C*H*H) and 5.94 (br s, 1H, =CH*H*); ms M^+: 149.0839 (calcd. for $C_9H_{11}NO$: 149.0841).

Treatment of ketal olefin **31** (67 mg, 0.37 mmol) with *p*-toluenesulfonic acid monohydrate (70 mg, 0.37 mmol) and acetone (5 mL) under similar conditions for 36 h gave ketone **34** (49 mg; 97% yield); ir: 1620 (C=C), 1740 (C=O), and 2230 (C≡N) cm^{-1}; ^{1}Hmr δ: 3.10 (m, 1H, —CH—), 5.84, and 5.95 (both br s, 1H each, $=CH_2$); ms M^+: 135.0683 (calcd. for C_8H_9NO: 135.0684).

Thiol esters in organic synthesis. XIV.[1] The total synthesis of racemic α-costal

HSING-JANG LIU AND HLA WYNN
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 29, 1985

HSING-JANG LIU and HLA WYNN. Can. J. Chem. **64**, 658 (1986).

The first total synthesis of α-costal (**1**) in racemic form has been achieved in an unequivocal manner whereby the structure previously assigned to the natural aldehyde is confirmed. A salient feature of the synthesis is the use of *S-tert*-butyl cyanothiolacetate to facilitate the introduction of the labile acrolein unit.

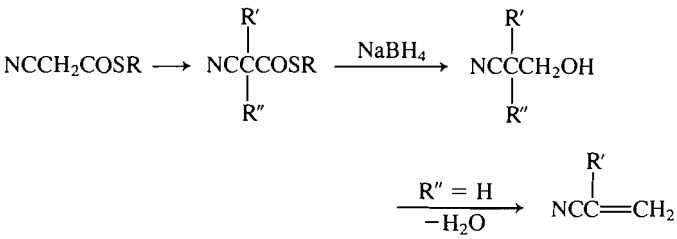
HSING-JANG LIU et HLA WYNN. Can. J. Chem. **64**, 658 (1986).

On a réalisé la première synthèse totale et non-ambigüe de l'α-costal (**1**) à l'état racémique et l'on a ainsi confirmé la structure qui a été antérieurement attribuée à cet aldéhyde naturel. La caractéristique principale de cette synthèse est l'utilisation du cyanothiolacétate de *S-tert*-butyle pour faciliter l'introduction de l'unité acroléine labile.

[Traduit par la revue]

Introduction

During the course of our studies on cyanothiolesters, we have established a methodology to facilitate the synthesis of β-hydroxypropionitrile and acrylonitrile derivatives through the use of cyanothiolacetate as a masked β-hydroxypropionitrile carbanion equivalent (Scheme 1) (1, 2). In essence, this method provides a convenient means for the incorporation of a highly functionalized isopropyl unit.[2] In order to test the applicability of this method in the area of natural product synthesis, α-costal (**1**) was chosen as a target molecule.



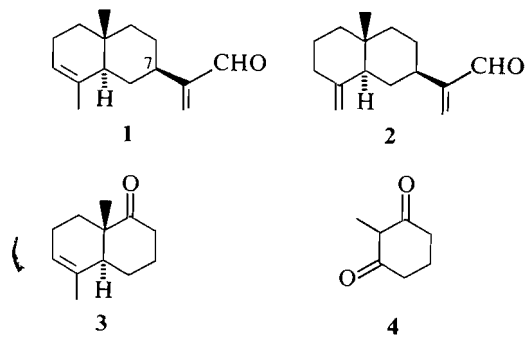
SCHEME 1

α-Costal (**1**) is one of the constituents of the leaf oil of *Thujopsis dolabrata* Sieb. et Zucc. It was first isolated in 1965 by Ito *et al.* (5), along with several other sesquiterpenes. This compound was found to be inseparable from its double-bond isomer, β-costal (**2**).[3] It was based solely on the information gathered on this mixture that the structure of α-costal was tentatively assigned (5).

In the approach to the synthesis of α-costal, the most suitable starting compound appeared to be ketone **3**, which was readily available from 2-methyl-1,3-cyclohexanedione (**4**) (6, 7). This compound already possesses some of the required features of the target molecule, such as a *trans*-decalin system, the angular and vinylic methyl groups, and a trisubstituted double bond. The transformation of ketone **3** to α-costal (**1**) requires the incorporation of an acrolein unit onto the carbon β to the ketone carbonyl. Involving the developed methods (1, 2) outlined in Scheme 1, this requirement could be achieved, in principle, by the three possible routes illustrated in Scheme 2.

Route A requires a 1,3-oxygen transposition of the ketone carbonyl. The resulting ketone is expected to undergo Knoevenagel-type condensation with cyanothiolacetate to facilitate the installation of the acrolein unit found in the target molecule. In route B, a leaving group will be introduced to the β carbon of the ketone carbonyl. This is to be followed by an alkylation reaction with cyanothiolacetate. In route C, the Michael addition of cyanothiolacetate is considered as a convenient means for the introduction of a highly functionalized isopropyl unit.

All of the outlined approaches were examined and, by the use of route A, the first total synthesis of α-costal (**1**) in racemic



form has been achieved, confirming the structure and stereochemistry tentatively assigned to the natural aldehyde.[4]

Results and discussion

The starting 2-methyl-1,3-cyclohexanedione (**4**) was prepared in 90% yield by hydrogenation of the monosodium salt of 2-methylresorcinol at room temperature under 50 psi (1 psi = 6.89 kPa) pressure of hydrogen using 5% rhodium on alumina as a catalyst (9). This procedure compares favorably with the traditional one by Mekler (10), which requires substantially higher pressure using Raney nickel as a catalyst. Enedione **5** was prepared by modification of a reported procedure (11). Treatment of diketone **4** with ethyl vinyl ketone in 1,2-dimethoxyethane (DME) at room temperature in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) (12) gave trione **6** in 90% yield. Intramolecular aldol condensation of **6** with benzoic acid and triethylamine in refluxing xylene (13) resulted in the formation of crystalline enedione **5**, mp 40–42°C (lit. (11) mp 39–40°C), in 89% yield. Ketalization of enedione **5** with an

SCHEME 2

excess of ethylene glycol in the presence of a catalytic amount of either *d*-10-camphorsulfonic acid or *p*-toluenesulfonic acid in refluxing benzene gave ketal **7** (82–88% yield). In the case of camphorsulfonic acid, a small amount (~6% yield) of diketal **8** was also formed.

Ketal enone **7** was subjected to Birch reduction (14) in liquid ammonia at −78°C with an excess of lithium metal in the presence of *tert*-butyl alcohol. The resulting lithium enolate was trapped with diethyl phosphorochloridate in tetrahydrofuran (THF) at 0°C with (6) or without (7) the presence of *N,N,N′,N′*-tetramethylethylenediamine. The yield of the desired enol phosphate **9** ranged from 50 to 69%, comparable to that obtained by Ireland and Pfister (6). In addition to enol phosphate **9**, a variable amount (10–20%) of ketone **10**, apparently formed by the protonation of the intermediate enolate ion, was also obtained. In spite of the extreme care undertaken in carrying out the reaction, the formation of this ketone could not be suppressed.

Ketal enol phosphate **9** underwent reductive elimination of the phosphate group smoothly when treated with lithium in ethylamine in the presence of *tert*-butyl alcohol (6). Transketalization of the resulting ketal olefin **11** (84% yield) with acetone in the presence of *p*-toluenesulfonic acid gave rise to the known ketone **3** (6, 7) in quantitative yield. According to the synthetic plan shown in Scheme 2, three routes are conceivable to incorporate an acrolein unit onto the β-carbon of the ketone carbonyl. In order to activate the center to which the acrolein unit is to be attached, ketone **3** was converted to the α,β-unsaturated ketone **12** as follows.

Ketone **3** was treated sequentially with lithium diisopropylamide and phenylselenenyl chloride in THF at −78°C (15). After 3 h, the reaction was complete and selenide **13** was isolated in 88% yield as a single stereoisomer. The stereochemistry of the newly incorporated chiral center was deduced on the basis of the ^{1}Hmr spectrum, which showed a signal at δ 4.54 for the proton attached to this chiral center. The signal appeared as a doublet of doublets with coupling constants of 12 and 6 Hz, indicating that the proton was axial and thus the phenylselenenyl substituent equatorial. When selenide **13** was exposed to 30% hydrogen peroxide in THF at 0–15°C for 5 h, the α,β-unsaturated ketone **12** was isolated in 78% yield, resulting from concomitant oxidation of the phenylselenenyl group and elimination of the resulting selenoxide.

With enone **12** in hand, the three synthetic routes leading to α-costal (**1**) were individually explored as planned (Scheme 2). The first route to be examined was route A, in which a Knoevenagel-type condensation was conceived as a means for the introduction of a highly functionalized isopropyl unit required for the synthetic target.

Towards this end, enone **12** was converted to alcohol **14** by the use of Wharton's reaction (16). Epoxidation of enone **12** with 30% hydrogen peroxide in ethanol in the presence of sodium hydroxide afforded an 89% yield of epoxy ketone **15** as a single stereoisomer in crystalline form, mp 54–55°C. The stereochemistry of this compound could not be assigned unambiguously at this stage. However, the subsequent transformation requires its stereochemistry as shown, resulting from the epoxidation of enone **12** from the less hindered side. Initial attempts to induce the Wharton reaction on epoxy ketone **15** were carried out as follows, using standard conditions. Hydrazine hydrate (2 equiv.) and acetic acid (0.2 equiv.) were added sequentially to a methanolic solution of epoxide **15** and the resulting solution was stirred for 3 h at room temperature. The results were found to be rather unsatisfactory; the desired product **14** was isolated only in 38% yield, along with a substantial quantity of an unidentified material which appeared to be dimeric in nature (bishydrazone?), as suggested by its mass spectrum. When the reaction was carried out in neat hydrazine hydrate in the absence of glacial acetic acid at elevated temperature (17), a poor yield (18%) of the desired rearrangement product **14** was obtained. To avoid formation of the dimeric material, the reaction was performed with the following modifications. A dilute methanolic solution of epoxy ketone **15** was added slowly to a solution of hydrazine hydrate (5 equiv.) and glacial acetic acid (0.2 equiv.) in methanol. This experiment, involving the reverse addition and the use of a large excess of hydrazine hydrate, proved to be superior and the desired product **14** was obtained in a much improved yield of 74%. In the ^{1}Hmr spectrum, the C-7 proton appeared as a broad triplet at δ 4.22. Decoupling experiments showed that this proton was coupled with the axial proton on C-8 at δ 2.72 with a rather small coupling constant of 2.5 Hz. On the basis of this observed small coupling constant, the stereochemistry of compound **14** was deduced.

Oxidation of allylic alcohol **14** with pyridinium dichromate (18) gave an 89% yield of dienone **16**. The conversion of this compound to the corresponding saturated ketone **18** requires the selective reduction of the double bond conjugated with the ketone carbonyl. In the presence of Wilkinson's catalyst (tris(triphenylphosphine)rhodium chloride), hydrosilanes have been shown (19) to add to α,β-unsaturated ketones exclusively by 1,4-addition, to give silyl enol ethers which readily undergo hydrolysis to give saturated ketones. When enone **16** was subjected to hydrosilation with triethylsilane in the presence of Wilkinson's catalyst for 6 h at room temperature, silyl enol ether **17** was isolated in quantitative yield. On exposure to tetra-*n*-butylammonium fluoride in THF, this compound was converted to ketone **18** in 73% yield. An improved yield of 89% was obtained when the hydrosilation product was directly subjected to the fluoride treatment without purification.

Having successfully prepared the saturated ketone **18** from **3** via an overall 1,3-oxygen transposition, its condensation with *S-tert*-butyl cyanothiolacetate was investigated. Initially,

ketone **18** was treated with the latter reagent in THF in the presence of DABCO at room temperature. This set of conditions has been successfully used previously to effect the Knoevenagel-type condensation of *S-tert*-butyl cyanothiolacetate with various ketones (2). In the present case, however, the reaction was not highly effective. Although the reaction occurred readily at the outset, as indicated by thin-layer chromatographic (tlc) analysis, it could not be brought to completion even after 15 h at refluxing temperature, and only 21% yield of the desired product was formed. These results suggested that the reaction was probably reversible. In order to facilitate product formation, water, which was produced during the condensation, needed to be removed. Towards this end, magnesium sulfate was added to the reaction mixture. Surprisingly, this resulted in the rapid consumption of the thiolester reagent without substantial formation of the desired product, for reasons which have yet to be determined. In further attempts, sodium sulfate was used as a dehydrating agent. This experiment proved to be successful, giving an isomeric mixture of **19** along with compound **20** in ca. 4:1 ratio in a total of 73% yield.

To complete the synthesis of α-costal (**1**), it remained to modify the newly incorporated cyanothiolester unit to the required acrolein moiety, preferably with control of stereochemistry. Previously, it was shown (2) that the carbon–carbon double bond of α,β-unsaturated cyanothiolester systems present in the Knoevenagel-type condensation product could be selectively reduced with sodium borohydride under controlled conditions. In the presence of an excess of the reducing agent at higher temperature, further reduction of the thiolester to the alcohol level could also be simultaneously effected. The selective reduction of the carbon–carbon double bond of compound **19** was first examined in an attempt to determine the selectivity of the reduction. It was gratifying to find that when a mixture of **19** and **20** was subjected to sodium borohydride (1 mol equiv.) reduction at 0°C in ethanol, not only was the reduction of the former compound effected, but the carbon–carbon double bond of the latter compound was also smoothly reduced. Apparently, the conditions were sufficient to effect the isomerization of the double bond into conjugation with cyano and thiolester groups. The reduction product **21** obtained in 74% yield was found to be homogeneous by tlc. However, the ^{1}Hmr spectrum indicated the presence of all four diastereomers, showing four doublets in a ratio of 2:2:1:1 for the methine proton of the cyanothiolester group. Further reduction of cyanothiolacetate **21** with sodium borohydride in ethanol at room temperature gave an 88% yield of the corresponding alcohol **22** as a mixture of diastereomers. The same diastereomeric mixture could also be prepared directly from **19** and **20** using an excess of sodium borohydride (4 mol equiv.) in ethanol at −40°C[5] for 4 h and at room temperature for 12 h. The yield (91%) thus obtained was far superior to the two-step sequence.

Alcohol **22** was subjected to dehydration with dicyclohexylcarbodiimide in refluxing ether in the presence of a catalytic amount of copper(I) chloride (1, 2, 20) to give a mixture of cyano olefins **23** and **24** in 2:1 ratio and 94% total yield. These isomeric compounds were separated by Chromatotron. Both compounds showed in the ir spectrum, olefin absorption band at 1620 cm^{-1} and nitrile absorption band at 2210 cm^{-1}. The epimeric nature of these compounds was further confirmed by the mass spectra, each of which showed a molecular ion peak (215.1676 for the major and 215.1663 for the minor) in accordance with the molecular formula of $C_{15}H_{21}N$. The stereochemistry of these two compounds was assigned after careful examination of their respective ^{1}Hmr spectra. The major isomer showed a multiplet at δ 2.28 for the C-7 hydrogen atom. By decoupling experiments, this proton was found to be coupled to the vinylic protons of the acrylonitrile moiety at δ 5.74 (a doublet of doublets) and 5.82 (a broad singlet). Similarly, the C-7 proton of the minor isomer, which appeared at δ 2.72 as a multiplet, was also shown to couple with the terminal vinylic protons observed at δ 5.85 and 6.07, each as a doublet. It has been shown by sufficient examples that the axial and equatorial protons of cyclohexane derivatives (especially when rigid) are not equally shielded (21). The axial proton normally absorbs at a much higher field than the equatorial counterpart, with the relative chemical shift difference of ca. 0.2–0.8 ppm. The fact that the C-7 proton of the major isomer appeared at a much higher field (δ 2.28) than that of the minor isomer (δ 2.72) by 0.44 ppm indicated the axial orientation of this proton. Accordingly, the stereochemistry of **23** and **24** was deduced as shown.

The predominant formation of epimer **23** possessing the desired stereochemistry was apparently a result of preferential reduction of the conjugated carbon–carbon double bond of compound **19** with sodium borohydride, involving the addition of the hydride ion from the less hindered side of the molecule. In an attempt to improve the stereoselectivity, the mixture of compounds **19** and **20** was subjected to reduction with a bulky reducing agent. Unexpectedly, sequential reduction of the mixture of **19** and **20** with lithium tri-*tert*-butoxyaluminum hydride and then with sodium borohydride, followed by dehydration of the resulting alcohol, afforded mainly the undesired epimer **24** (~3 parts) and a smaller quantity of **23** (1 part).

Cyano olefins **23** and **24** were individually reduced with diisobutylaluminum hydride at −78°C in toluene for 3 h. From the former epimer an aldehyde was obtained in 59% yield. This compound was shown to be identical with natural α-costal (**1**) by comparison of its ^{1}Hmr spectrum with published values (5). Reduction of **24** gave a 60% yield of compound **25**, an epimer of α-costal (**1**). In agreement with the stereochemical assignments, the C-7 proton of this compound appeared, in the ^{1}Hmr spectrum, again at a much lower field (δ 3.04 in $CDCl_3$) than the corresponding one (δ 2.56) of α-costal (**1**).

After completing the first total synthesis of α-costal (**1**) in a stereoselective manner, the other two possible routes outlined in Scheme 2 were also examined in order to determine (*i*) the feasibility of these approaches leading to the natural product and (*ii*) the possible improvement of the total synthesis. For route B, alcohol **14**, which was produced as a single stereoisomer with a well-defined stereochemistry, provided an interesting opportunity to carry out the total synthesis with complete stereochemical control. It is conceivable that the replacement of the hydroxyl group with *S-tert*-butyl cyanothiolacetate with inversion of stereochemistry could lead eventually to the target molecule. The required replacement reaction could be directly effected using a Mitsunobu reaction (22). The best result was obtained when alcohol **14** and *S-tert*-butyl cyanothiolacetate (2 equiv.) were sequentially added to a THF solution of 1.5 equiv. each of diethyl azodicarboxylate and triphenylphosphine. After 3.5 h at −35°C, an inseparable mixture of the desired compound **26** and its isomer **27** (ca. 2:1) was isolated in

[5]When the reduction was carried out first at −78°C and then at room temperature, the same diastereomeric mixture was produced but in somewhat poorer yield.

54% yield. Treatment of this mixture with sodium borohydride resulted in the exclusive reduction of compound **26** to give two epimeric alcohols **28** (1:1; 78% yield), with compound **27** recovered intact. The transformation of **28** to α-costal (**1**) requires the selective saturation of its disubstituted double bond. Unfortunately, this requirement could not be satisfactorily fulfilled in spite of numerous trials using different methods

(catalytic hydrogenation, diimide reduction, and homogeneous hydrogenation with Wilkinson's catalyst) under various conditions.

The synthesis of α-costal (**1**) by route C requires the Michael addition of *S-tert*-butyl cyanothiolacetate to enone **12**. This was readily effected by treatment of the latter compound with the cyanothiolacetate and sodium hydride in the presence of chlorotrimethylsilane (1) in refluxing benzene for 16 h. A 76% yield of the desired adduct **29** was obtained. This material was shown to be a mixture of four diastereomers by the ^{1}Hmr spectrum, which displayed four doublets for the methine proton of the cyanothiolacetate group at δ 3.44, 3.53, 3.46, and 3.64,

integrating to a 2:2:1:1 ratio. In order to remove its ketone carbonyl,[6] compound **29** was converted to the corresponding alcohol **30** by brief treatment with sodium borohydride at 0°C. Deoxygenation of **30** was examined but without any success; the reduction of the corresponding mesylate **31** with sodium iodide and zinc dust (23) in refluxing *N,N*-dimethylformamide (24) gave hydroxy nitrile **32** as the only isolatable product, while attempted preparation of halide and xanthate derivatives failed to yield any desired products. The poor stereoselectivity of the Michael addition (**12** → **29**) and the lack of simple solutions to effect the removal of the ketone carbonyl of the adduct made further exploration of route C to α-costal (**1**) unattractive.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared (ir) spectra were recorded on a Perkin–Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer. Unless otherwise stated, ir samples were run as thin films. Proton nuclear magnetic resonance (^{1}Hmr) spectra were recorded on a Varian HA-100/Digilab, Bruker WH-80, WH-200, or WH-400 spectrometer and, except where otherwise stated, were obtained on solutions in deuterochloroform with tetramethylsilane as internal reference. Carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker HFX-90/Nicolet 1085 system or a Bruker WH-200 or WH-400 spectrometer and were obtained on solutions in deuterochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS9, MS12, or MS50 mass spectrometers. Unless otherwise stated, anhydrous magnesium sulfate was used for drying organic solutions.

Materials

DME and THF were freshly distilled over sodium metal. Benzene and ether were freshly distilled over lithium aluminum hydride. Dichloromethane was washed with an equal volume of 10% aqueous sodium carbonate and distilled over powdered calcium chloride. Gaseous ammonia was passed through potassium hydroxide pellets and distilled over sodium metal. *N,N,N′,N′*-Tetramethylethylenediamine was freshly distilled over sodium metal. Diethyl phosphorochloridate was distilled over powdered lead carbonate (25). Ethylamine, xylene, and diisopropylamine were freshly distilled over calcium hydride. Ethanol was distilled over magnesium turnings. *S-tert*-Butyl cyanothiolacetate was prepared according to the reported procedure (26).

2-Methyl-2-(3-oxopentyl)cyclohexane-1,3-dione (6)

2-Methylresorcinol (10 g, 0.08 mol) was dissolved in distilled water (70 mL). Sodium hydroxide (3.75 g, 0.09 mol) and 5% rhodium on alumina (1 g) were added and the hydrogenation bottle fitted in a Parr hydrogenation apparatus. The mixture was shaken under 50 psi pressure of hydrogen at room temperature for 9.5 h. The reaction mixture was then filtered through a sintered glass funnel and the filtrate acidified by dropwise addition of concentrated hydrochloric acid (~25 mL) to a pH of ~4. The resulting solution was extracted with ethyl acetate (4 × 200 mL). The extracts were dried, filtered, and concentrated to give dione **4** (9.1 g; ~90% yield), which was subjected to further reaction without purification.

Dione **4** (19 g, 0.15 mol) was dissolved in DME (300 mL). DABCO (19.38 g, 0.17 mol) was added. The solution was chilled to 0°C and stirred for 15 min under an argon atmosphere. Ethyl vinyl ketone (17.3 mL, 0.17 mol) was added dropwise and the reaction mixture stirred for 12 h at room temperature. The mixture was poured into ice-cold 1 *N* aqueous hydrochloric acid solution (~200 mL) and extracted with dichloromethane (4 × 300 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. The product **6** (28.37 g; ~90% yield) thus obtained was used directly for the next reaction. An analytical sample obtained by flash chromatography (20% ethyl acetate in petroleum ether) on silica gel showed the following spectral data: ir: 1715 (C=O) and 3500 (enol —OH) cm^{-1}; ^{1}Hmr δ: 1.02 (t, 3H, J = 7 Hz, CH_3CH_2—), 1.26 (s, 3H, CH_3—), and 1.8–2.9 (complex, 12H, 6 × —CH_2—); ms M$^+$: 210.1258 (calcd. for $C_{12}H_{18}O_3$: 210.1256).

5,8a-Dimethyl-3,4,8,8a-tetrahydro-1,6[2H, 7H]-naphthalenedione (5)

The crude trione **6** (3.95 g, ~19 mmol), obtained from the above experiment, and benzoic acid (2.47 g, 20 mmol) were dissolved in xylene (20 mL). Triethylamine (2.0 mL, 14 mmol) was added and the solution was heated at reflux with a Dean–Stark water separator. After 22 h, the solution was cooled and extracted with ether. The extracts were washed with water, 5% aqueous sodium bicarbonate, 2 *N* aqueous sulfuric acid, and water. Drying, filtration, and concentration gave the crude product, which was purified by flash chromatography on silica gel. Elution with 50% ether in petroleum ether gave enedione **5** (3.23 g; 89% yield based on crude **6**); mp 40–42°C (ether); ir 1610 (C=C), 1660 (conjugated C=O), and 1710 (saturated C=O) cm^{-1}; ^{1}Hmr δ: 1.38 (s, 3H, CH_3—) and 1.79 (s, 3H, CH_3C=); ^{13}Cmr δ: 212.1, 197.7, 158.2, 130.8, 50.7, 37.4, 33.3, 29.7, 29.5, 27.3, 23.4, and 21.6; ms M$^+$: 192.1149 (calcd. for $C_{12}H_{16}O_2$: 192.1150). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.96, H 8.39; found: C 74.89, H 8.54.

5,5-Ethylenedioxy-1,4a-dimethyl-4,4a,5,6,7,8-hexahydro-2[3H]-naphthalenone (7)[7] and 1,1,6,6-diethylenedioxy-5,8a-dimethyl-1,2,3,5,6,7,8,8a-octahydronaphthalene (8)

A solution of *d*-10-camphorsulfonic acid (50 mg, 0.2 mmol) and ethylene glycol (2 mL, 38.61 mmol) in benzene (20 mL) was heated at reflux for 13 h with a Dean–Stark water separator. A portion of benzene (~10 mL) was distilled off and the solution cooled to room temperature. Enedione **5** (414 mg, 2.15 mmol) in benzene (10 mL) was added. The mixture was heated at reflux for 3 h under an argon atmosphere. After cooling to room temperature, the mixture was made basic with saturated aqueous sodium bicarbonate. The organic layer was separated and the aqueous solution extracted with ether (4 × 20 mL). The organic solutions were combined, dried, filtered, and concentrated. The crude product was purified by flash chromatography on silica gel (30% ethyl acetate in petroleum ether) to give ketal **7** (418 mg; 82% yield); ir: 1040–1200 (C—O), 1618 (C=C), and 1670 (C=O) cm^{-1}; ^{1}Hmr δ: 1.31 (s, 3H, CH_3—), 1.80 (s, 3H, CH_3C=), and 3.94 (br s, 4H, —OCH_2CH_2O—); ms M$^+$: 236.1410 (calcd. for $C_{14}H_{20}O_3$: 236.1412). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.14, H 8.54; found: C 71.06, H 8.63.

Further elution with the same solvent system afforded diketal **8** (36 mg; 6% yield): ir: 1040–1180 (C—O) cm^{-1}; ^{1}Hmr δ: 1.04 (d, 3H, J = 7 Hz, CH_3CH—), 1.28 (s, 3H, CH_3—), 3.95 (m, 8H, 2 × —OCH_2CH_2O—), and 5.44 (br s, 1H, —CH=); ms M$^+$: 280.1671 (calcd. for $C_{16}H_{24}O_4$: 280.1675).

1,1-Ethylenedioxy-6-diethylphosphoryloxy-5,8aβ-dimethyl-1,2,3,4,4aα,7,8,8a-octahydronaphthalene (9)[8] and 5,5-ethylenedioxy-1α,4aβ-dimethyl-1,4,4a,5,6,7,8,8aα-octahydro-2[3H]-naphthalenone (10)

To a solution of lithium (169 mg, 0.02 g-atom) in ammonia (35 mL), was added dropwise a solution of ketal **7** (1.52 g, 6.35 mmol) in ether (25 mL) containing *tert*-butyl alcohol (0.5 mL, 5.31 mmol). The resulting solution was stirred under an argon atmosphere for 1.5 h at −78°C. Excess lithium was destroyed by dropwise addition of freshly distilled isoprene until the blue color discharged. The mixture was

[6]Standard methods for reducing a ketone to the hydrocarbon level are incompatible with other existing functionalities.

[7]Ketal **7** was obtained as the only product in 88% yield when the reaction was carried out using *p*-toluenesulfonic acid as a catalyst.

[8]The stereochemical designations used in this and all other chemical names in this section denote relative stereochemistry. All compounds used and obtained were racemic.

warmed to room temperature and concentrated under reduced pressure. The residue was cooled to 0°C and a solution of *N,N,N',N'*-tetramethylethylenediamine (13 mL) in ether (22 mL) was added slowly. After stirring for 5 min under an argon atmosphere, a solution of diethyl phosphorochloridate (3 mL, 20.76 mmol) in ether (10 mL) was slowly added. After stirring for 5 h, the mixture was poured into ice-cold water and extracted with ether (4 × 50 mL). The extracts were washed with water, dried, filtered, and concentrated. The crude product was chromatographed on silica gel. Elution with 40% petroleum ether in ether gave ketone **10** (151 mg; 10% yield); ir: 1050–1200 (C—O) and 1710 (C=O) cm^{-1}; ^{1}Hmr δ: 1.02 (d, 3H, J = 8 Hz, CH_3CH—), 1.25 (s, 3H, CH_3—), and 3.9–4.0 (m, 4H, —OCH_2CH_2O—); ms M^+: 238.1565 (calcd. for $C_{14}H_{22}O_3$: 238.1569).

Further elution with 30% petroleum ether in ether gave enol phosphate **9** (1.65 g, 69% yield); ir: 1690 (C=C) cm^{-1}; ^{1}Hmr δ: 0.98 (s, 3H, CH_3—), 1.38 (t, 6H, J = 7 Hz, 2 × CH_3CH_2O—), 1.63 (br s, 3H, CH_3C=), 3.95 (s, 4H, —OCH_2CH_2O—), 4.16 (qd, 4H, J = J' = 7 Hz, CH_3CH_2O—); ms M^+: 374.1851 (calcd. for $C_{18}H_{31}O_6P$: 374.1858).

*1,1-Ethylenedioxy-5,8aβ-dimethyl-1,2,3,4,4aα,7,8,8a-octahydronaphthalene (**11**)*

At 0°C, small pieces of lithium wire (2.0 g, 0.29 g-atom) were added to ethylamine (200 mL) under an argon atmosphere and the mixture was stirred for 1 h. A solution of ketal phosphate **9** (10.59 g, 28 mmol) and *tert*-butyl alcohol (4.5 mL, 48 mmol) in THF (194 mL) was added dropwise over 1 h. After stirring for 2 h at 0°C, ethylamine was removed under reduced pressure and water was added dropwise to discharge the blue color. The resulting mixture was extracted with ether (4 × 200 mL) and the extracts were washed with ice-cold water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel (30% ether in petroleum ether) afforded ketal olefin **11** (5.22 g; 84% yield); ir: 1080–1200 (C—O) cm^{-1}; ^{1}Hmr δ: 0.92 (s, 3H, CH_3—), 1.63 (br s, 3H, CH_3C=), 3.90 (s, 4H, —OCH_2CH_2O—), and 5.29 (m, 1H, —CH=); ^{13}Cmr δ: 134.9, 120.8, 113.0, 65.2, 65.1, 43.9, 41.4, 30.5, 26.9, 23.2, 23.0, 22.6, 21.5, and 14.1; ms M^+: 222.1617 (calcd. for $C_{14}H_{22}O_2$: 222.1620). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.62, H 9.98; found: C 75.99, H 9.99.

*5,8aβ-Dimethyl-3,4,4aα,7,8,8a-hexahydro-1[2H]-naphthaleneone (**3**)*

Ketal olefin **11** (620 mg, 2.79 mmol) was dissolved in acetone (15 mL) and *p*-toluenesulfonic acid (530 mg, 2.79 mmol) was added. After stirring at room temperature under an argon atmosphere for 16 h, the reaction mixture was poured into ice-cold saturated aqueous sodium bircarbonate and extracted with dichloromethane (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel (10% ethyl acetate – petroleum ether) gave ketone **3** (500 mg; 100% yield); ir: 1710 (C=O) cm^{-1}; ^{1}Hmr δ: 1.06 (s, 3H, CH_3—), 1.66 (s, 3H, CH_3C=), and 5.35 (m, 1H, —CH=); ms M^+: 178.1360 (calcd. for $C_{12}H_{18}O$: 178.1358).

*5,8aβ-Dimethyl-2α-phenylselenenyl-3,4,4aα,7,8,8a-hexahydro-1[2H]-naphthalenone (**13**)*

Diisopropylamine (0.3 mL, 2.14 mmol) was dissolved in THF (9 mL) at −78°C under an argon atmosphere. Methyllithium (1.29 mL, 1.3 *M* solution in *n*-hexane) was added dropwise and the mixture stirred for 10 min. A solution of ketone **3** (250 mg, 1.4 mmol) in THF (0.5 mL) was added. After 10 min, a solution of phenylselenenyl chloride (320 mg, 1.67 mmol) in THF (0.5 mL) was added and the reaction mixture stirred for 3 h at −78°C. Ice-cold 1 *N* aqueous hydrochloric acid (10 mL) was added and the resulting solution extracted with ether (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. The residue was purified by flash chromatography on silica gel, eluting with 10% ethyl acetate in petroleum ether, to give selenide **13** (410 mg; 88% yield); ir: 1590 (aromatic) and 1710 (C=O) cm^{-1}; ^{1}Hmr δ: 1.15 (s, 3H, CH_3—), 1.65 (s, 3H, CH_3C=), 4.54 (dd, 1H, J = 12, J' = 6 Hz, —CHSe—), 5.34 (m, 1H, —CH=), and 7.45 (m, 5H, aromatic protons).

*5,8aβ-Dimethyl-4aα,7,8,8a-tetrahydro-1[4H]-naphthalenone (**12**)*

At 0°C, to a solution of selenide **13** (300 mg, 0.9 mmol) in THF (10 mL), were added 30% hydrogen peroxide (0.26 mL) and water (0.73 mL). The mixture was stirred for 5 h at 15°C, poured into saturated aqueous sodium bicarbonate (20 mL), and extracted with ether (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. Purification of the residue by flash chromatography (10% ethyl acetate – petroleum ether) afforded dienone **12** (130 mg; 78% yield); ir: 1690 (C=O) cm^{-1}; ^{1}Hmr δ: 1.02 (s, 3H, CH_3—), 1.68 (s, 3H, CH_3C=), 5.42 (m, 1H, —CH=C—), 5.94 (ddd, 1H, J = 11, J' = 3, J'' = 1.5 Hz, =CHCO—), 6.90 (ddd, 1H, J = 11, J' = 6, J'' = 2 Hz, —C*H*=CHCO—); ms M^+: 176.1198 (calcd. for $C_{12}H_{16}O$: 176.1201).

*2α,3α-Epoxy-5,8aβ-dimethyl-2,3,4aα,7,8,8a-hexahydro-1[4H]-naphthalenone (**15**)*

At 10°C, to a solution of dienone **12** (351 mg, 2 mmol) in ethanol (3 mL), were added with stirring a solution of sodium hydroxide (30 mg) in water (0.1 mL) and 30% hydrogen peroxide (0.34 mL, 3 mmol). After 1 h at room temperature, the mixture was diluted with water and extracted with dichloromethane (4 × 10 mL). The extracts were washed with saturated aqueous sodium chloride solution, dried, filtered, and concentrated. Purification of the crude product by flash chromatography on silica gel (5% ethyl acetate – petroleum ether) gave epoxide **15** (339 mg; 89% yield). Single recrystallization from petroleum ether gave pure white crystals (mp 54–55°C); ir: 1720 (C=O) cm^{-1}; ^{1}Hmr δ: 0.96 (s, 3H, CH_3—), 1.66 (s, 3H, CH_3C=), 3.20 (d, 1H, J = 4 Hz, —CHCO—), 3.56 (br s, 1H, —CH_2CHO—), and 5.40 (m, 1H, —CH=); ms M^+: 192.1153 (calcd. for $C_{12}H_{16}O_2$: 192.1150).

*7α-Hydroxy-1,4aβ-dimethyl-3,4,4a,7,8,8aα-hexahydronaphthalene (**14**)*

A solution of epoxide **15** (380 mg, 1.96 mmol) in methanol (5 mL) was added dropwise over a period of 1 h to a solution of hydrazine hydrate (0.48 mL, 9.77 mmol) and glacial acetic acid (0.02 mL, 0.38 mmol) under an argon atmosphere. The reaction mixture was stirred for 2.5 h at room temperature and then ice-cold water was added. The solution was extracted with dichloromethane (4 × 20 mL) and the extracts were washed with saturated aqueous sodium bicarbonate, dried, filtered, and concentrated. The residue was subjected to flash chromatography on silica gel. Elution with 20% ethyl acetate in petroleum ether gave allylic alcohol **14** (258 mg; 74% yield); ir: 1650 (C=C) and 3300–3400 (—OH) cm^{-1}; ^{1}Hmr δ: 0.86 (s, 3H, CH_3—), 1.68 (s, 3H, CH_3C=), 4.22 (br t, 1H, J = 4 Hz, —C*H*OH), 5.36 (m, 1H, —C*H*=CCH_3), 5.65 (ddd, 1H, J = 10, J' = 4, J'' = 1.5 Hz, —CH=C*H*CH—), and 5.78 (dd, J = 10 Hz, J' = 1 Hz, —C*H*=CHCH—); ms M^+: 178.1355 (calcd. for $C_{12}H_{18}O$: 178.1358).

*4aβ,8-Dimethyl-4a,5,6,8aα-tetrahydro-2[1H]-naphthalenone (**16**)*

Allylic alcohol **14** (64 mg, 0.36 mmol) was dissolved in dichloromethane (4 mL). Pyridinium dichromate (188 mg, 0.54 mmol) was added. The mixture was stirred at room temperature under an argon atmosphere for 4 h and filtered. The residue was washed thoroughly with dichloromethane. Concentration of the filtrate gave the crude product, which was subjected to flash chromatography on silica gel.

Elution with 10% ethyl acetate in petroleum ether gave dienone **16** (56 mg; 89% yield); ir: 1675 (C=O) cm^{-1}; ^{1}Hmr δ: 1.06 (s, 3H, CH_3—), 1.65 (br s, 3H, CH_3C=), 5.38 (m, 1H, —CH=C—), 5.86 (dd, 1H, J = 10, J' = 1.5 Hz, =CHCO—), and 6.83 (d, 1H, J = 10 Hz, —C*H*=CHCO—); ms M^+: 176.1198 (calcd. for $C_{12}H_{16}O$: 176.1201). *Anal.* calcd. for $C_{12}H_{16}O$: C 81.76, H 9.16; found: C 81.38, H 9.09.

7-Triethylsilyloxy-1,4aβ-dimethyl-3,4,4a,5,8,8aα-hexahydronaphthalene (17)

Dienone **16** (287 mg, 1.62 mmol) was dissolved in triethylsilane (10 mL). A catalytic amount (15 mg) of *tris*(triphenylphosphine)rhodium chloride was added. The mixture was stirred at room temperature under an argon atmosphere for 6 h and concentrated. The residue was then subjected to column chromatography, using 20% ethyl acetate in petroleum ether as an eluent, to give enol ether **17** (508 mg; 100% yield); ir: 1186–1208 (Si—OCH_2CH_3) and 1665 (C=C) cm^{-1}; ^{1}Hmr δ: 0.5–1 (complex, 15H, 3 × CH_3CH_2—), 1.00 (s, 3H, CH_3—), 1.63 (s, 3H, CH_3C=), 4.80 (br s, 1H, —CH=CO—), and 5.36 (br s, 1H, —CH=); ms M^+: 292.2224 (calcd. for $C_{18}H_{32}OSi$: 292.2222).

4aβ,8-Dimethyl-3,4,4a,5,6,8aα-hexahydro-2[1H]-naphthalenone (18)

Enol ether **17** (500 mg, 1.71 mmol) was dissolved in THF (10 mL) and tetra-*n*-butylammonium fluoride (1 *M* solution in THF; 1.7 mL, 1.71 mmol) was added at 0°C. The mixture was stirred for 1 h at room temperature under an argon atmosphere. Concentration of the solution gave a residue, which was purified by flash chromatography using 10% ethyl acetate in petroleum ether as an eluent to afford the saturated ketone **18** (226 mg; 73% yield); ir: 1710 (C=O) cm^{-1}; ^{1}Hmr δ: 1.00 (s, 3H, CH_3—), 1.58 (s, 3H, CH_3C=), and 5.40 (br s, 1H, —CH=); ms M^+: 178.1356 (calcd. for $C_{12}H_{18}O$: 178.1358). Under similar conditions, ketone **18** was obtained in 89% yield from enone **16** without purification of the intermediate enol ether **17**.

7[8H]-(tert-Butylthiocarbonylcyanomethylene)-1,4aβ-dimethyl-3,4,4a,5,6,8aα-hexahydronaphthalene (19) and 7-(tert-butylthiocarbonylcyanomethyl)-1,4aβ-dimethyl-3,4,4a,5,8,8aα-hexahydronaphthalene (20)

S-tert-Butyl cyanothiolacetate (458 mg, 2.92 mmol) and DABCO (330 mg, 2.95 mmol) were dissolved in THF (10 mL). Anhydrous sodium sulfate (622 mg, 4.38 mmol) was introduced, followed by the addition of a solution of ketone **18** (261 mg, 1.46 mmol) in THF (1 mL). The mixture was stirred at room temperature for 48 h, poured into ice-cold 1 *N* aqueous hydrochloric acid, and extracted with dichloromethane (4 × 20 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel (40% benzene in petroleum ether) afforded compound **19** (269 mg; 58% yield) as a mixture of two isomers (ca. 1:1); ir: 1670 (C=O), and 2240 (C≡N) cm^{-1}; ^{1}Hmr δ: 0.90, 0.94 (both s, total 3H, CH_3—), 1.52, 1.54 (both s, 9H total, —$C(CH_3)_3$), and 5.38 (br s, 1H, —CH=); ms M^+: 317.1814 (calcd. for $C_{19}H_{27}NOS$: 317.1813).

Further elution with the same solvent gave compound **20** (70 mg; 15% yield) as a mixture of two diastereomers (ca. 3:2); ir: 1670 (C=O) cm^{-1}; ^{1}Hmr δ: 0.78 (s, 3H, CH_3—), 1.50 (s, ~5.5H, —$C(CH_3)_3$, for major isomer), 1.52 (s, ~3.5H, —$C(CH_3)_3$, for minor isomer), 4.05 (br s, ~0.4H, —CHCN, for minor isomer), 4.75 (br s, ~0.6H, —CHCN, for major isomer), 5.38 (m, 1H, —C*H*=CCH_3), and 5.90 (m, 1H, —CH=); ms M^+: 317.1813 (calcd. for $C_{19}H_{27}NOS$: 317.1813).

7-(tert-Butylthiocarbonylcyanomethyl)-1,4aβ-dimethyl-3,4,4a,5,6,7,8,8aα-octahydronaphthalene (21)

A mixture of compounds **19** and **20** (113 mg, 0.35 mmol) was dissolved in absolute ethanol (7 mL) at 0°C. Sodium borohydride (3.3 mg, 0.09 mmol) was added and the mixture stirred for 2 h at 0°C under an argon atmosphere. Ice-cold saturated aqueous ammonium chloride was added and the resulting solution extracted with dichloromethane (3 × 10 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. Flash chromatography of the crude product on silica gel (50% benzene in petroleum ether) afforded saturated cyanothiolester **21** (83 mg; 74% yield) as a mixture of four diastereomers (2:2:1:1); ir: 1678 (C=O) and 2240 (C≡N) cm^{-1}; ^{1}Hmr δ: 0.80 (s, 3H, CH_3—), 1.52 (s, 9H, —$C(CH_3)_3$), 3.37, 3.39 (both d, ~0.33H each, J = 8 Hz each, —CHCN), 3.69, 3.70 (both d, 0.17H each, J = 12 Hz each, —CHCN), 5.33 (br s, ~0.33H, —CH=, for two minor isomers), and 5.34 (m, ~0.66H, —CH=, for two major isomers); ms M^+: 319.1971 (calcd. for $C_{19}H_{29}NOS$: 319.1970).

7-(1-Cyano-2-hydroxyethyl)-1,4aβ-dimethyl-3,4,4a,5,6,7,8,8aα-octahydronaphthalene (22)

A. *From reduction of compound 21*

Compound **21** (185 mg, 0.58 mmol) was dissolved in absolute ethanol (7 mL) at 0°C. Sodium borohydride (90 mg, 2.43 mmol) was added. The mixture was stirred at room temperature for 10 h under an argon atmosphere, poured into ice-cold saturated aqueous ammonium chloride solution, and extracted with dichloromethane (3 × 20 mL). The extracts were washed with aqueous sodium chloride solution, dried, filtered, and concentrated. The residue was chromatographed on silica gel (50% ethyl acetate in petroleum ether) to give alcohol **22** (119 mg; 88% yield) as a mixture of diastereomers; ir: 1060 (C—O), 2260 (C≡N), and 3400–3500 (—OH) cm^{-1}; ms M^+: 233.1778 (calcd. for $C_{15}H_{23}NO$: 233.1780). The ^{1}Hmr spectrum showed two sets of signals in ca. 2:1 ratio, with major signals at δ 0.80 (s, 3H, CH_3—), 1.60 (s, 3H, CH_3C=), 2.72 (dt, 1H, J = 7, J' = 6 Hz, —CHCN), 3.90 (m, 2H, —C*H*$_2$OH), and 5.36 (m, 1H, —CH=). The minor set of signals appeared at δ 0.87 (s, 3H, CH_3—), 1.66 (s, 3H, CH_3C=), 3.02 (m, 1H, —CHCN), 3.90 (m, 2H, —C*H*$_2$OH), and 5.36 (m, 1H, —CH=).

B. *From direct reduction of compounds 19 and 20*

The mixture of compounds **19** and **20** (124 mg, 0.39 mmol) was dissolved in ethanol (7 mL) and cooled to −40°C. Sodium borohydride (69 mg, 1.82 mmol) was added and the reaction mixture stirred for 4 h at −40°C under an argon atmosphere. Temperature was increased to room temperature and stirring continued for 24 h. Isolation and purification processes were performed in the same manner as mentioned above to give alcohol **22** (83 mg; 91% yield), identical in all respects with that obtained above.

7β-(1-Cyanoethenyl)-1,4aβ-dimethyl-3,4,4a,5,6,7,8,8aα-octahydronaphthalene (23) and 7α-(1-cyanoethenyl)-1,4aβ-dimethyl-3,4,4a,5,6,7,8,8aα-octahydronaphthalene (24)

The diastereomeric mixture of alcohols **22** (42 mg, 0.18 mmol) was dissolved in ether (5 mL). Dicyclohexylcarbodiimide (74 mg, 0.36 mmol) and a catalytic amount (2 mg) of copper(I) chloride were added. The mixture was heated at reflux under an argon atmosphere for 8.5 h, cooled to room temperature, diluted with ether, and filtered. Concentration of the filtrate, followed by purification of the crude product by flash chromatography on silica gel (40% petroleum ether in benzene), gave a mixture of two epimeric nitriles **23** and **24** (38 mg; 94% yield) in ca. 2:1 ratio, according to ^{1}Hmr integration. This mixture was subjected to separation by Chromatotron using 5% ether in petroleum ether as an eluent to give pure β-isomer **23** (11 mg) and pure α-isomer **24** (7 mg). The rest of the material was recovered as a mixture. The following spectral data were obtained for the β-isomer **23**: ir ($CHCl_3$): 1620 (C=C) and 2210 (C≡N) cm^{-1}; ^{1}Hmr δ: 0.82 (s, 3H, CH_3—), 1.62 (br s, 3H, CH_3C=), 2.28 (m, 1H, —C*H*C=CH_2), 5.36 (m, 1H, —CH=), 5.74 (dd, 1H, J = 2, J' = 1 Hz, =C*H*H), and

5.82 (br s, 1H, =CH*H*); ms M^+: 215.1676 (calcd. for $C_{15}H_{21}N$: 215.1674). The α-isomer **24** showed the following spectral data: ir ($CHCl_3$): 1620 (C=C) and 2210 (C≡N) cm^{-1}; ^{1}Hmr δ: 0.87 (s, 3H, CH_3—), 1.66 (br s, 3H, CH_3C=), 2.72 (m, 1H, —C*H*C=CH_2), 5.34 (m, 1H, —CH=), 5.85 (d, 1H, J = 2 Hz, =C*H*H), and 6.07 (d, 1H, J = 2 Hz, =CH*H*); ms M^+: 215.1663 (calcd. for $C_{15}H_{21}N$: 215.1674).

Nitriles **23** and **24** were also obtained in 1:2.8 ratio by reduction of compounds **19** and **20** with lithium tri-*tert*-butoxyaluminum hydride as follows. To a solution of the mixture of compounds **19** and **20** (99 mg, 0.31 mmol) in THF (5 mL) at 0°C, was added lithium tri-*tert*-butoxyaluminum hydride (119 mg, 0.47 mmol). The mixture was stirred under an argon atmosphere for 3.5 h at 0°C, acidified with ice-cold 1 *N* aqueous hydrochloric acid, and extracted with dichloromethane (3 × 10 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated to give cyanothiolester **21**, which, without purification, was subjected to further reduction (**21** → **22**) with sodium borohydride and dehydration (**22** → **23** and **24**) with dicyclohexyl carbodiimide using described conditions (*vide supra*). Nitriles **23** and **24** (34 mg; 50% overall yield) thus formed were shown to be in a ratio of 1:2.8 by ^{1}Hmr analysis.

*(±)-α-Costal (**1**)*

Cyano olefin **23** (10 mg, 0.047 mmol) was dissolved in toluene (0.5 mL) and cooled to −78°C with stirring under an argon atmosphere. After 5 min, diisobutylaluminum hydride (25% by wt. in toluene; 0.05 mL, 0.07 mmol) was added. After stirring for 3 h at −78°C, the mixture poured into dilute aqueous oxalic acid and extracted with ether (2 × 2 mL). The extracts were dried, filtered, and concentrated. The resulting crude product was subjected to column chromatography on silica gel (40% petroleum ether in benzene) to give racemic α-costal (**1**) (6 mg; 59% yield); ir ($CHCl_3$): 1620 (C=C), 1694 (CHO), and 2700 (aldehyde C—H) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.84 (s, 3H, CH_3—), 1.60 (s, 3H, CH_3C=), 2.56 (m, 1H, —CH—C=), 5.32 (m, 1H, —CH=), 5.90 (br s, 1H, =C*H*H), 6.30 (br s, 1H, =CH*H*), and 9.54 (s, 1H, —CHO); ^{1}Hmr (CCl_4) δ: 0.83 (s, 3H, —CH_3), 1.58 (s, 3H, CH_3C=), 2.53 (m, 1H, —CH—C=), 5.28 (m, 1H, =CH—), 5.90 (br s, 1H, =C*H*H), 6.21 (br s, 1H, =CH*H*), and 9.52 (s, 1H, —CHO); ^{13}Cmr δ: 194.6, 155.4, 134.7, 132.8, 121.2, 46.9, 40.2, 37.9, 37.2, 32.4, 29.7, 29.0, 27.0, 23.0, and 21.1; ms M^+: 218.1671 (calcd. for $C_{15}H_{22}O$: 218.1671).

*(±)-Epi-α-costal (**25**)*

Cyano olefin **24** (5 mg, 0.023 mmol) was dissolved in toluene (0.5 mL) and cooled to −78°C with stirring under an argon atmosphere. Diisobutylaluminum hydride (5% by wt. in toluene; 0.15 mL, 0.05 mmol) was added. The mixture was stirred for 3 h at −78°C, poured into dilute aqueous oxalic acid, and extracted with ether (2 × 2 mL). Drying, filtration, and concentration gave the crude product, which was subjected to column chromatography on silica gel. Elution with 40% petroleum ether in benzene gave racemic epi-α-costal **25** (3 mg; 60% yield); ir ($CHCl_3$): 1697 (CHO) and 2852 (aldehyde C—H) cm^{-1}; ^{1}Hmr δ: 0.85 (s, 3H, —CH_3), 1.54 (br s, 3H, CH_3C=), 3.04 (m, 1H, —CH—C=), 5.34 (m, 1H, —CH=), 6.11 (s, 1H, =C*H*H), 6.48 (d, 1H, J = 1.5 Hz, =CH*H*), and 9.48 (s, 1H, —CHO); ms M^+: 218.1672 (calcd. for $C_{15}H_{22}O$: 218.1671).

*7β-(tert-Butylthiocarbonylcyanomethyl)-1,4aβ-dimethyl-3,4,4a,7,8,8aα-hexahydronaphthalene (**26**) and 7β-(2-tert-butylthio-3-cyano-1-oxapropenyl)-1,4aβ-dimethyl-3,4,4a,7,8,8aα-hexahydronaphthalene (**27**)*

Triphenylphosphine (110 mg, 0.42 mmol) was dissolved in THF (3 mL) under an argon atmosphere at −15°C. Diethyl azodicarboxylate (0.07 mL, 0.42 mmol) was added and the solution cooled to −30°C with stirring. A solution of allylic alcohol **14** (50 mg, 0.28 mmol) in THF (0.5 mL) was introduced, followed by the addition of a solution of *S-tert*-butyl cyanothiolacetate (88 mg, 0.56 mmol) in THF (0.5 mL). After stirring for 3.5 h at −35°C, ice-cold water and then 1 *N* aqueous hydrochloric acid were added and the resulting solution was extracted with dichloromethane (4 × 15 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. The crude product was subjected to flash chromatography on silica gel (40% benzene in petroleum ether) to give a mixture of compounds **26** and **27** (50 mg; 54% yield) in ca. 2:1 ratio. The ^{1}Hmr spectrum of the mixture displayed two sets of signals in ca. 2:1 ratio. The major set of signals was attributed to compound **26** (a 1:1 diastereomeric mixture); δ: 0.95, 0.98 (both s, 1.5H each, —CH_3), 1.52 (s, 9H, —$C(CH_3)_3$), 1.66 (br s, 3H, CH_3C=), 3.50, 3.58 (both d, 0.5H each J = 6 Hz each, —CHCN), and 5.34 (m, 1H, —CH=). The minor signals were found to be identical with those observed for pure **27** (see the following experiment). The mixture also showed the following spectral data: ir: 1680 (C=O), 2210 (C≡N), and 2240 (C≡N) cm^{-1}; ms M^+: 317.1819 (calcd. for $C_{19}H_{27}NOS$: 317.1813).

*7β-(1-Cyano-2-hydroxyethyl)-1,4aβ-dimethyl-3,4,4a,7,8,8α-hexahydronaphthalene (**28**)*

The 2:1 mixture of compounds **26** and **27** (46 mg, 0.14 mmol) was dissolved in absolute ethanol (5 mL) and cooled to 0°C with stirring. Sodium borohydride (21 mg, 0.55 mmol) was added and stirring continued for 30 h at room temperature. The mixture was then poured into saturated aqueous ammonium chloride and extracted with dichloromethane (3 × 5 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. The residue was chromatographed on silica gel (20% ethyl acetate in petroleum ether) to give 15 mg of compound **27**; ir: 2210 (C≡N) cm^{-1}; ^{1}Hmr δ: 1.01 (s, 3H, CH_3—), 1.43 (s, 9H, —$C(CH_3)_3$), 1.66 (br s, 3H, CH_3C=), 5.00 (s, 1H, =CHCN), and 5.4–5.8 (complex, 4H, —CH= and —CH=CHCHO—); ms M^+: 317.1806 (calcd. for $C_{19}H_{27}NOS$: 317.1813).

Further elution with the same solvent system gave alcohol **28** (17 mg; ~78% yield based on **26**) as a mixture of two diastereomers (ca. 1:1); ir: 2260 (C≡N) and 3400–3500 (—OH) cm^{-1}; ^{1}Hmr δ: 0.93, 0.96 (both s, 1.5H each, CH_3—), 1.66 (br s, 3H, CH_3C=), 3.90 (br s, 2H, —CH_2O—), and 5.3–5.8 (complex, 3H, —CH= and —CH=CH—); ms M^+: 231.1617 (calcd. for $C_{15}H_{21}NO$: 231.1623).

*3-(tert-Butylthiocarbonylcyanomethyl)-5,8aβ-dimethyl-3,4,4aα,7,8,8a-hexahydro-1[2H]-naphthalenone (**29**)*

At 5°C, to a solution of *S-tert*-butyl cyanothiolacetate (160 mg, 1.01 mmol) in benzene (7 mL), were added chlorotrimethylsilane (0.11 mL, 0.92 mmol) and sodium hydride (50% dispersion in oil; 72 mg, 1.52 mmol). After stirring for 5 min under an argon atmosphere, a solution of dienone **12** (121 mg, 0.68 mmol) in benzene (0.5 mL) was introduced. The mixture was heated at reflux for 16 h. It was then cooled to room temperature, poured into 1 *N* aqueous hydrochloric acid, extracted with dichloromethane (3 × 10 mL), and the extracts concentrated. The residue was dissolved in methanol (20 mL) and treated with 5 mL of aqueous potassium fluoride solution (0.5 g/10 mL) for 10 min. The resulting solution was poured into 1 *N* aqueous hydrochloric acid (20 mL) and extracted with dichloromethane (4 × 20 mL). The extracts were dried, filtered, and concentrated. The crude product was purified by flash chromatography on silica gel (10% ethyl acetate – petroleum ether) to give 27 mg of starting dienone **12**. Further elution with the same solvent system gave 1,4 adduct **29** (136 mg; 76% yield based on consumed starting material) as a mixture of four diastereomers in ca. 2:2:1:1 ratio by ^{1}Hmr integration. The following ^{1}Hmr data were attributable to the two major isomers: δ 1.08, 1.12 (both s, 3H total, CH_3—), 1.52, 1.54 (both s, total 9H, —$C(CH_3)_3$), 1.68 (br s, 3H, CH_3C=), 3.44, 3.53 (both d, 1H total, J = 5 Hz each, —CHCN), and 5.42 (m, 1H, —CH=). The

following ^{1}Hmr data were attributable to the two minor isomers: δ 1.20, 1.28 (both s, total 3H, CH_3—), 1.56 (s, 9H, —$C(CH_3)_3$), 1.68 (br s, 3H, CH_3C=), 3.46, 3.64 (both d, 1H total, J = 5 Hz each, —CHCN), and 5.42 (m, 1H, —CH=). The following spectral data were also recorded on the mixture: ir ($CHCl_3$): 1679 (thiolester C=O), 1710 (ketone C=O), and 2220 (C≡N) cm^{-1}; ms M^+: 333.1765 (calcd. for $C_{19}H_{27}NO_2S$: 333.1762).

*3-(*tert*-Butylthiocarbonylcyanomethyl)-1-hydroxy-5,8aβ-dimethyl-1,2,3,4,4aα,7,8,8a-octahydronaphthalene (**30**)*

Ketone **29** (41 mg, 0.12 mmol) was dissolved in absolute ethanol (4 mL) and cooled to 0°C with stirring. Sodium borohydride (10 mg, 0.26 mmol) was added and the mixture stirred for 1.5 h at 0°C. Saturated aqueous ammonium chloride solution was added and the resulting solution extracted with dichloromethane (3 × 5 mL). Drying, filtration, and concentration gave the crude product, which was purified by flash chromatography on silica gel (40% ethyl acetate – petroleum ether) to give alcohol **30** (30 mg; 75% yield) as a mixture of diastereomers. The following spectral data were recorded on the mixture: ir: 1680 (C=O), 2250 (C≡N), and 3500–3600 (—OH) cm^{-1}; ^{1}Hmr δ: 0.84 (br s, 3H, CH_3—), 1.51 (br s, 9H, —$C(CH_3)_3$), 1.62 (br s, 3H, CH_3C=), 3.4–3.6 (m, 2H, —CHCN and —C*H*OH), and 5.40 (m, 1H, —CH=); ms M^+: 335.1919 (calcd. for $C_{19}H_{29}NO_2S$: 335.1919).

*3-Cyanomethyl-1-hydroxy-5,8aβ-dimethyl-1,2,3,4,4aα,7,8,8a-octahydronaphthalene (**32**)*

Alcohol **30** (74 mg, 0.22 mmol) was dissolved in chloroform (4 mL) and cooled to 0°C under an argon atmosphere. Methanesulfonyl chloride (0.05 mL, 0.66 mmol) and triethylamine (0.15 mL, 1.1 mmol) were added and the mixture stirred for 6 h at room temperature. The mixture was acidified with ice-cold 1 *N* aqueous hydrochloric acid and extracted with dichloromethane (4 × 8 mL). The extracts were washed with saturated aqueous sodium bicarbonate, dried, filtered, and concentrated. This crude mesylate **31** (134 mg) showed satisfactory ir and ^{1}Hmr spectra as follows: ir: 1185, 1360 (O=S=O), 1680 (C=O), and 2260 (C≡N) cm^{-1}; ^{1}Hmr δ: 0.81 (br s, 3H, CH_3—), 1.49 (s, 9H, —$C(CH_3)_3$), 1.58 (br s, 3H, CH_3C=), 3.00 (s, CH_3SO_3—), 3.4–3.6 (complex, 2H, —CHCN and —CHO—), and 5.33 (m, 1H, —CH=).

The crude mesylate was dissolved in *N*,*N*-dimethylformamide (7 mL). Sodium iodide (480 mg, 3.2 mmol) and zinc dust (420 mg, 6.4 mmol) were added. The mixture was heated at reflux for 7 h under an argon atmosphere. It was then cooled to room temperature and filtered and the residue washed thoroughly with dichloromethane. The filtrate was subsequently washed with water and the aqueous solution extracted with dichloromethane (4 × 5 mL). The extracts were washed with saturated aqueous sodium chloride, dried, filtered, and concentrated. The crude product was purified by flash chromatography (30% ethyl acetate in petroleum ether) to afford alcohol **32** (6 mg; 14% yield from **30**) as a mixture of diastereomers; ir: 2260 (C≡N) and 3400–3500 (OH) cm^{-1}; ^{1}Hmr δ: 0.80, 0.82 (both s, ~1.5 H each, CH_3—), 1.64 (br s, 3H, CH_3C=), 2.38 (d, 2H, J = 6 Hz, —CH_2CN), 3.39 (dd, 1H, J = 11, J' = 4 Hz, —C*H*OH), and 5.38 (m, 1H, —CH=); ms M^+: 219.1621 (calcd. for $C_{14}H_{21}NO$: 219.1623).

α-*N*,*N*-Dimethylaminoethylferrocene. A nuclear magnetic resonance study relating to stereoselective metalation

IAN R. BUTLER, WILLIAM R. CULLEN,[1] F. GEOFFREY HERRING, AND N. R. JAGANNATHAN

Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received November 5, 1985

IAN R. BUTLER, WILLIAM R. CULLEN, F. GEOFFREY HERRING, and N. R. JAGANNATHAN. CAN. J. CHEM. **64**, 667 (1986).

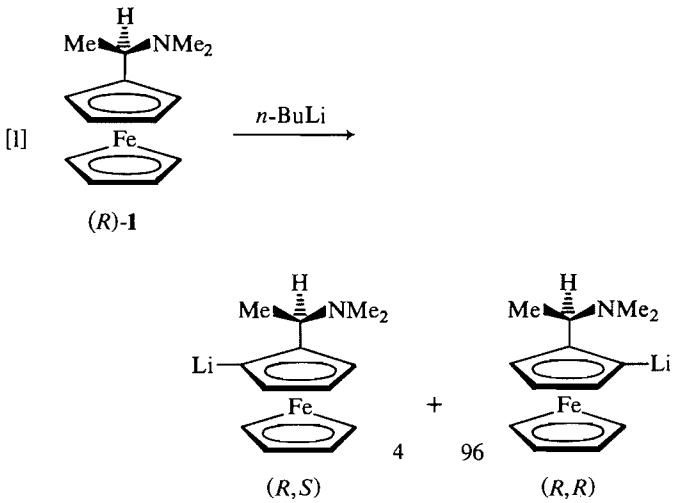
A ^{1}H nmr study of Fe($C_5H_4CHMeNMe_2$-η)($C_5H_4PPh_2$-η), **2**, using the nOe difference experiment, shows a spatial correlation between the —NMe_2 group and the site of stereoselective lithiation.

IAN R. BUTLER, WILLIAM R. CULLEN, F. GEOFFREY HERRING et N. R. JAGANNATHAN. CAN. J. CHEM. **64**, 667 (1986).

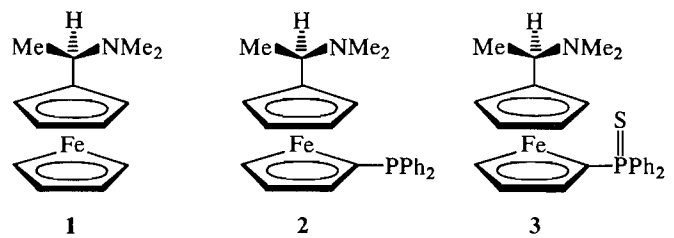
Sur la base d'une étude à l'aide de la rmn du ^{1}H et faisant appel à une expérience de différence d'eOn effectuée sur le Fe($C_5H_4CHMeNMe_2$-η)($C_5H_4PPh_2$-η) (**2**), on peut démontrer l'existence d'une corrélation spatiale entre le groupement —NMe_2 et le site de la lithiation stéréosélective.

[Traduit par le journal]

One of the most frequently used starting materials for the synthesis of chiral ferrocene compounds is α-*N*,*N*-dimethylaminoethylferrocene, **1** (1). This compound is easily resolved into its enantiomers via its tartrate salts (2). The metalation of **1** with lithiumalkyls is stereoselective, the nitrogen atom directing the reaction as shown in eq. [1]. Thus



the use of chiral **1** allows the isolation of essentially optically pure products following substitution of the lithium with a variety of electrophiles. Ugi and co-workers have attributed this remarkable stereoselectivity to steric effects involving primarily the C-methyl group, which is presumed to prefer to stay above the plane of the upper ring (3).



1 **2** **3**

X-ray crystallographic studies of products derived from the lithiation reaction indicate that there is no one preferred orientation for the $CHMeNMe_2$ group; there are examples showing that any one of the groups attached to the asymmetric carbon atom can be situated between the cyclopentadienyl rings (3–6).[2] In the absence of a structure for lithiated **1**, that of the dilithio derivative of **1** (7),

$$[Fe(\eta^5\text{-}C_5H_4Li)(\eta^5\text{-}C_5H_3(Li)(CHMeNMe_2)\text{-}1,2)]_4\text{-}[LiOEt]_2[TMED]_2$$

where TMED = tetramethylethylenediamine, should come closest to that of the transition state involved in the lithiation of **1**. Here one of the two different—NMe_2 groups in the molecule is situated well outside the interplane region, such that the methyl group—$CHMeNMe_2$ lies between the rings. This lithium atom, which is bonded to the —NMe_2 group and the deprotonated carbon atom, is also situated outside the interplane region. Nevertheless, this carbon atom is the one that would more likely be lithiated, according to eq. [1]. The other —NMe_2 is part of a —$CHMeNMe_2$ group of opposite chirality to the first. This amino function and its —$CHMeNMe_2$ group lie in the interplane region and the nitrogen is coordinated to a lithium atom that lies almost in the same plane as the cyclopentadienyl ring. However, this lithium atom is bonded to the carbon atom that would be less likely to be lithiated, according to eq. [1]. Thus, in the cluster of the dilithio derivatives the 4:96 ratio "expected" from eq. [1] is found to be 50:50. This observation has not been made previously (7) and probably accounts for the isolation of the unexpected (*S*,*S*) diastereomer of [Fe(η^5-C_5H_3($P(CMe_3)_2$-1,3][η^5-C_5H_3($CHMeNMe_2$)$P(CMe_3)_2$-1,2)] (6). This compound should have had the (*S*,*R*) configuration because the first step in its synthesis was the lithiation of (*S*)-**1** according to eq. [1].

Clearly the stereoselectivity observed in reactions involving **1** must be due to effects other than, or in addition to, those previously envisioned. This paper describes the probing of these effects using ^{1}H nmr spectroscopy.

The cyclopentadienyl proton resonances of **1** are overlapped even at 400 MHz and therefore a derivative is required in which the resonances are more dispersed and which retains the integrity of the $C_5H_4CHMeNMe_2$ group. The recently synthesized compound **2** has most of the required properties (8). The proton resonances overlap only slightly, as is seen in Figs. 1 and 2, the number of resonances being greater than might be expected at first sight because of the combination of the asymmetric center with the planar chirality of both rings. This makes all the protons inequivalent.

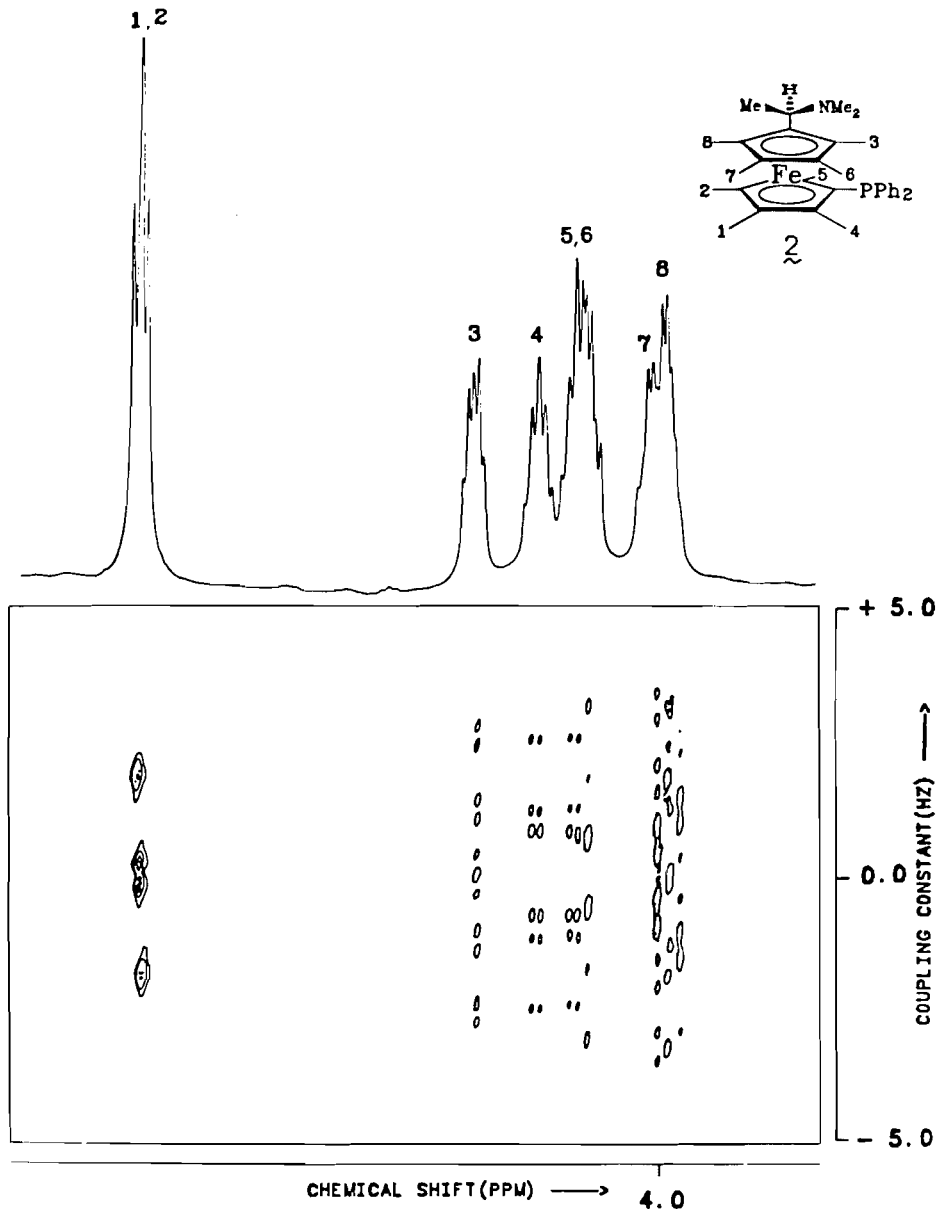

FIG. 1. 2D-*J* resolved contour plot of ferrocenyl proton region of **2**; 128 experiments in the t_1 axis with 1024 data points on the t_2 axis with a relaxation delay of 5 s and 32 scans for each t_1 experiment. Sinebell apodization was employed in both dimensions before Fourier transform.

Protons 1 and 2 have almost identical chemical shifts and give rise to the pseudo triplet. Protons 4 and 5 can be readily identified by their residual ^{31}P couplings observed in the 2D-*J* spectrum (Fig. 1). Each appears as a set of overlapping doublet of doublets of doublets in the one-dimensional spectrum. The ^{31}P couplings to 4 and 5 are ~3.5 Hz. Proton 3 is readily assigned from its splitting pattern (it shows the typical 1,2,2,2,1 pattern of a ferrocenyl proton adjacent to a single substituent) and homonuclear decoupling experiments. Similarly, resonances 6, 7, and 8 can be assigned, using the 2D-*J* spectrum to identify the resonance multiplicity and decoupling experiments to determine their relative positions.

To check the assignment, **2** was lithiated with *n*-butyllithium and the resulting product solution treated with D_2O. The ^1H nmr spectrum of the deuterated product indicates that site 3 has been deuterated almost exclusively.

Reaction of **2** with sulfur results in oxidation of the phosphorus, affording **3**. The enhanced electronegativity of the $PPh_2(S)$ side chain results in increased deshielding of the cyclopentadienyl resonances to which the phosphorus is attached. The nmr spectrum of **3** shows only 5 resonances because of overlap; however, these can be readily assigned as described for **2**. The two low-field resonances δ 4.45, 4.40 are due to the phosphorus-substituted cyclopentadienyl ring protons. The remaining three resonances δ 4.29, 4.11, 4.03 are assigned to protons in the 3, 6/7, and 8 positions, respectively. Oxidation of the phosphorus shifts all cyclopentadienyl resonances downfield. In both compounds **2** and **3** the resonances of protons 3 and 8 are separated by approximately 0.3 ppm, which is probably reflected in the stereoselectivity of the lithiation reaction.

Having assigned the resonances in **2**, a series of nOe (nuclear Overhauser effect) difference experiments were undertaken to garner further information about the preferred site of methalation. The first of these experiments was carried out by irradiating the NMe_2 singlet. As is seen in Fig. 2C, only two

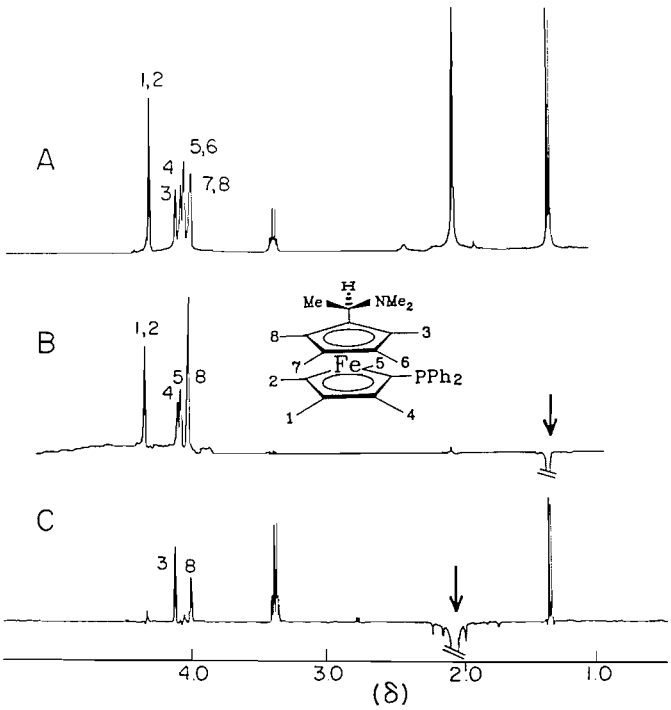

FIG. 2. 400-MHz ^{1}H spectra of **2** in $CDCl_3$ excluding phenyl region. A: normal spectrum, B: nOe difference spectrum with irradiation of CCH_3 (↓). C: nOe difference spectrum with irradiation at $N(CH_3)_2$ (↓).

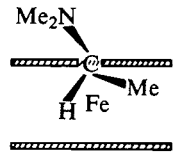
proton sites are significantly enhanced, namely 3 and 8, with the greater effect on 3. If there is free rotation about the bond between the $CHMeNMe_2$ group and the ring, enhancement would be expected at 3 and 8 and, in addition, some effect on the bottom ring protons would be expected. Thus the $—NMe_2$ group seems to have a preference for a position above the rings and in proximity to the site of metalation at proton 3.

The second nOe difference spectrum shown in Fig. 2B was obtained by irradiation of the $C—CH_3$ resonance. In this case positive nOe enhancements are observed into proton sites 1, 2, 4, 5, and 8. By far the largest enhancement is observed at site 8, which is expected from the result of the first nOe experiment. However, since positive nOe effects are observed in all four proton sites on the lower cyclopentadienyl ring, the methyl group must lie preferentially between the rings as shown in **4**. Certainly this geometry is found in some known structures. A third nOe different experiment was conducted by irradiation of the *ortho* protons of the phenyl rings. Weak positive nOe enhancements were observed only into the ring proton sites 4



4

and 5, adjacent to the phosphorus. Thus there is little interaction of the PPh_2 group with the protons of any other rings and extrapolation of the results from **2** to **1** seems justified.

Indeed, nOe difference spectra of **1**, although more difficult to assign, do show these effects.

Thus it appears that in solution the NMe_2 group lies predominantly outside the rings, as indicated in **4**. Making the assumption that prior to metalation the incoming RLi coordinates to the amine function, it seems that the site of metalation is governed by the movement of the C-methyl group away from the area between the rings. This would result in stereoselectivity.

In this model the conformation of the transition state would look somewhat like that seen in **4** and in the appropriate part of the structure of the dilithio derivative described above. However, the result that the opposite diastereomer can be isolated suggests that the initial diastereoselectivity is a kinetic phenomenon associated with favored conformations such as **4** in solution. Apparently, there is little energy difference between the two possible diastereomers.

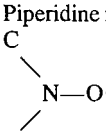
M. CYGLER, J. GRABOWSKI, W. STRZYŻEWSKI, L. TURAŁA, and R. SKOWROŃSKI. Can. J. Chem. **64**, 670 (1986).

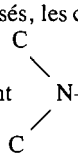
The synthesis of 5,5,7,7-tetramethyl-1-oxa-6-azaspiro[2.5]octane and modified synthesis of 5,5,7,7-tetramethyl-1-oxa-6-azaspiro[2.5]oct-6-yloxy are described. Reaction of these spiro-oxiranes with phenols gave corresponding 4-aryloxymethyl 4-piperidinols and their 1-piperidinyloxy derivatives. The same products have also been obtained by reaction with ethanol. The crystal structures of two derivatives: 4-phenoxymethyl-2,2,6,6-tetramethyl-4-piperidinol (**3***a*, 2880 reflections, $R = 0.054$) and 4-phenoxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy (**6***a*, 4395 reflections, $R = 0.084$) have been determined. Piperidine rings are in a chair conformation in both compounds with the phenoxymethyl substituent in an equatorial position. The



group is not planar, with the N—O bond inclined by 18.4° to the CNC plane. Although the space groups are different for these two compounds the molecules are packed in the crystal lattice in a topologically equivalent way.

M. CYGLER, J. GRABOWSKI, W. STRZYŻEWSKI, L. TURAŁA et R. SKOWROŃSKI. Can. J. Chem. **64**, 670 (1986).

On décrit la synthèse du tétraméthyl-5,5,7,7 oxa-1-aza-6 spiro[2.5]octane et une synthèse modifiée du tétraméthyl-5,5,7,7 oxa-1-aza-6 spiro[2.5]octyloxy-6. La réaction de ces spiro-oxiranes avec des phénols conduit aux aryloxyméthyl-4 pipéridinols-4 correspondants ainsi qu'à leurs dérivés pipéridinyloxy-1. On a aussi obtenu les mêmes produits par réaction avec de l'éthanol. On a déterminé les structures cristallines de deux dérivés: le phénoxyméthyl-4 tétraméthyl-2,2,6,6 pipéridinol-4 (**3***a*, 2880 réflexions et $R = 0{,}054$) et le phénoxyméthyl-4 hydroxy-4 tétraméthyl-2,2,6,6 pipéridinyloxy-1 (**6***a*, 4395 réflexions et $R = 0{,}084$). Dans chacun de ces composés, les cycles des pipéridines existent dans le conformation chaise et le substituant occupe la position équatoriale. Le groupement



n'est pas polaire et la liaison N—O est inclinée de 18,4° par rapport au plan CNC. Même si les groupes d'espace de ces deux composés sont différents, les molécules sont entassées dans le réseau cristallin de façons qui sont topologiquement équivalentes.

Introduction

Stable nitroxyl radicals incorporated in 2,2,6,6-tetramethylpiperidine have attracted the attention of chemists for over 10 years (1). These compounds have found many industrial applications. Together with their precursors, the free amines, they are recommended as light and heat stabilizers in the production of plastics (there are over 200 patents on that application of nitroxyl radicals cited in Chem. Abstr., e.g. ref. 2). Their utilization as spin labels in the investigation of biological systems (3) is one of the most important research applications. The synthesis of the title compounds was undertaken with a view to their potential further applications. We have chosen a method of synthesis based on spiro-oxirane chemistry to gain more insight into such reactions. The structural investigations described in this paper are a continuation of our interest in the conformation of substituted piperidine rings and the conformational differences between the nitroxy radicals and their parent amines.

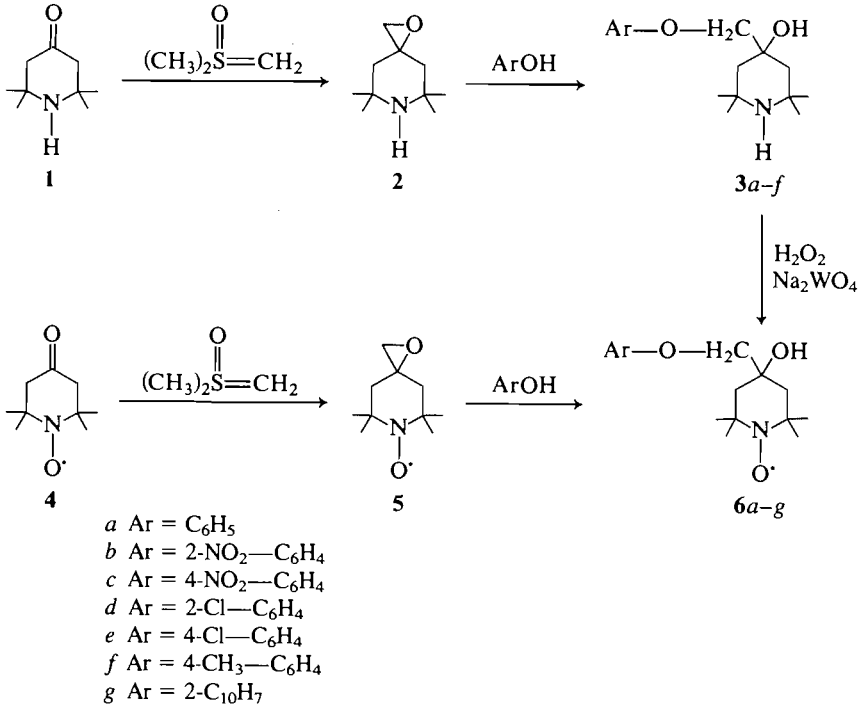
Results and discussion

Synthesis

The steps in the synthesis of 4-aryloxymethyl-2,2,6,6-tetramethyl-4-piperidinol **3** and 4-aryloxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy **6** are shown in Scheme 1. 5,5,7,7-Tetramethyl-1-oxa-6-azaspiro[2.5]oct-6-yloxy **5** has previously been obtained by two methods: through the reaction of the ketone **4** with diazomethane (yield = 34%) (4) and by the method of Corey and Chaykovsky in the reaction of the ketone **4** with dimethylsulfonium methylide (yield = 71%) (5). We have applied a variant of the Corey reaction using dimethyloxosulfonium methylide (6), which is safer in use and more easily available. In addition to compound **5** we have obtained the epoxide **2**, which has not previously been described in the literature. The reaction yields were 54.0% and 51.8% for **5** and **2**, respectively. The structures of these intermediate compounds were confirmed by ir, ^{1}H nmr, and mass spectroscopy.

These epoxides (**2** and **5**) were then subjected to reaction with phenols under basic conditions. In each case only one product was obtained, which, as expected (7), turned out to be a tertiary alcohol. This was confirmed by the reaction of compounds **3**



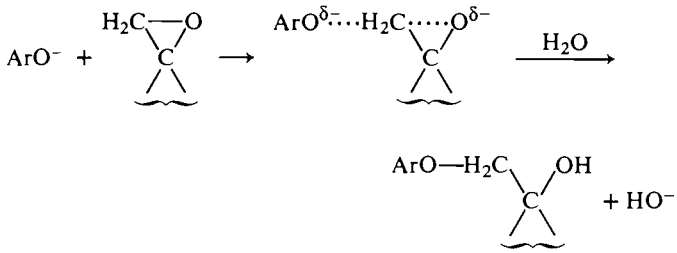
1 2 3*a–f* 4 5 6*a–g*

a Ar = C_6H_5
b Ar = 2-NO_2—C_6H_4
c Ar = 4-NO_2—C_6H_4
d Ar = 2-Cl—C_6H_4
e Ar = 4-Cl—C_6H_4
f Ar = 4-CH_3—C_6H_4
g Ar = 2-$C_{10}H_7$

SCHEME 1

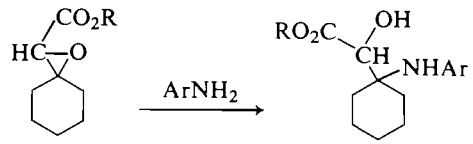
with CrO_3 (this excludes primary and secondary alcohols). The oxidation of **3** with hydrogen peroxide in the presence of Na_2WO_4 and verseniane gave a product identical to **6**, which confirmed its deduced structure. X-ray analyses of **3***a* and **6***a* proved these assignments to be correct.

It is clear that the reaction of epoxides **2** and **5** with phenols proceeds typically, according to the S_N2 mechanism, with the expected reaction product (8). The approaching group attacks the least substituted carbon atom of the oxirane ring. The physical properties, results of analysis, and spectral data for the compounds obtained are presented in Tables 1 and 2.



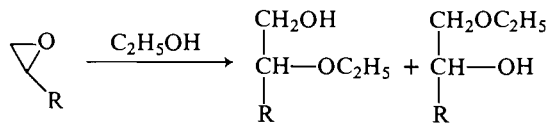
SCHEME 2

A different reaction mechanism was invoked for the reaction of aromatic amines with glycide esters (oxiranes substituted with polar groups), including the spiro-oxiranes (9). In this reaction only secondary alcohols were obtained, as is shown in Scheme 3:



SCHEME 3

Reactions of alkyl derivatives of ethylene oxide with alcohols in acidic medium gave, on the other hand, a mixture of two isomers (7).



SCHEME 4

For these reactions an S_N1 mechanism has been proposed (8).

We have also followed the reaction of epoxides **2** and **5** with ethanol in a variety of conditions. In all cases (acidic or basic conditions), just as in the reactions with phenols, only one isomer of 4-ethoxymethyl-2,2,6,6-tetramethyl-4-piperidinol or 4-ethoxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy was obtained.

Crystal structure determination

Compounds **3***a* and **6***a* are representative of the two groups of end products and have been chosen for further crystallographic studies.

*Structure of 3*a

The final atomic coordinates are given in Table 3. A view of the molecule is shown in Fig. 1 and bond lengths, valence angles, and some torsion angles are given in Table 5. The piperidine ring exists in a chair conformation with an axial hydroxyl group. The phenyloxymethyl group is in a fully extended conformation with torsion angles around C(41)—O(42) and O(42)—C(7) bonds being 179.1(5)° and 179.7(5)°, respectively. The phenyl ring is nearly perpendicular to the mean plane of the piperidine ring. The hydroxyl group is not equally disposed toward the piperidine ring but is more inclined to one of the methylene groups (the exocyclic OCC angles differ by 5.2°). The distances between the axial substituents to the piperidine ring are listed in Table 5. The interactions of these substituents decrease the ring puckering significantly and lead to an increase of the valence angles at the ring methylene groups to 116.5(3)°. The average endocyclic torsion angle is 45.9°, as compared to 57° in an unsubstituted piperidine ring (10) and 53.5° in 2,2,6,6-

tetramethylpiperidinium ion (TMP^+, ref. 11), where there are only two axial substituents. The flattening of the ring in **3***a* is nearly uniform, with the lowest puckering around C(4) where the mean CCCC torsion angle is 45.5(5)°. The degree of puckering of the ring at C(4) in 2,2,6,6-tetramethylpiperidine derivatives correlates well with the size of the axial substituent at this position. In TMP^+ (11) and *N*,*N*′-bis(2,2,6,6-tetramethyl-4-piperidyl)succinamide dihydrate (DTMP, ref. 12), where a H atom is axial to the ring at C(4), the CCCC torsion angle is similar to that in an unsubstituted piperidine ring (59.2(9)° in TMP^+, 55.8° and 57.9° in two independent molecules of DTMP). A related compound, 4-ethynyl-2,2,6,6-tetramethyl-4-piperidinol (TMPE, ref. 13) has an axial ethynyl group at C(4) and the CCCC torsion angle in this molecule is 49.7(8)°. Finally, in **3***a* with the axial hydroxyl group this torsion angle is even smaller. Hydrogen bonds also play a role in the ring distortion, as was shown in the case of DTMP (12) where two independent molecules with different geometry of H bonds display different degrees of puckering, which correlates with stretching or bending effects of the hydrogen bond interactions. The main effect is, however, observed at the end of the molecule around the N atom (hydrogen bond acceptor) with relatively small changes at the opposite side of the ring. The observed order of puckering around C(4) in **3***a* and TMPE can not be attributed to H bond interactions. The hydrogen bonds in TMPE are stronger (N...O = 2.790(9) Å *versus* 2.971(3) Å in **3***a*) and they are equatorial to the ring (stretching), while the effect of the hydrogen bond formed by the axial hydroxyl group of **3***a* must be less pronounced. Yet **3***a* displays smaller puckering at the C(4) part of the ring.

The size of an equatorial substituent has an opposite effect on the puckering of the ring, as was shown for *N*-methyl-2,2,6,6-tetramethyl-4-piperidinols (14). The magnitude of changes at the C(4) position is, however, smaller, with more pronounced changes occurring around the N atom. The degree of puckering of the ring is determined primarily by the bulkiness of the axial group. The size of an equatorial substituent plays a secondary role in defining the ring shape. This is exemplified by the structures of **3***a* and TMPE, where both axial and equatorial substituents are different and the degree of puckering at C(4) is determined by the size of the axial group.

The hydrogen atom at N(1) takes an axial position. As we have pointed out earlier (13), owing to a low energy difference between the axial and equatorial configuration, a hydrogen atom adopts a position which allows the free electron pair of the nitrogen atom to maximize the hydrogen bond interactions with a neighbouring molecule. Here a strong hydrogen bond is formed when the free electron pair is oriented equatorially with respect to the ring.

An increase of endocyclic angles at unsubstituted ring atoms (N(1), C(3), C(5)) observed here was also found in other derivatives with 2,4,6 axial substituents (13–15) and reveals the positions in the ring least resistant to deformation. The angles at the fully substituted C(2) and C(6) atoms are characteristic for an axial orientation of a substituent at N(1) (Table 4 in ref. 15).

Structure of **6***a*

The final atomic coordinates are given in Table 4. There are two independent molecules in the unit cell. Both have very similar conformations. The bond lengths, valence angles, and some torsion angles are given in Table 5. A view of one of the molecules (**I**) is shown in Fig. 2.

The overall conformation of **6***a* is similar to that of its free amine (compound **3***a*). The piperidine ring of the molecule assumes a chair conformation with an axially oriented hydroxyl group. The phenoxymethyl group exists in an extended conformation, with the phenyl ring nearly perpendicular to the mean plane of the piperidine ring (see Fig. 2). There are small but statistically significant differences in the torsion angles along the C(41)—O(42) and O(42)—C(7) bonds in both molecules. In molecule **II** these angles are −179.4(6) and 179.0(6)° respectively, while they are −174.6(6) and 175.2(6)°, respectively, in molecule **I**. A coupled change in both of these angles seems to be necessary to avoid clashes between hydrogens on the C(41) atom and on the phenyl ring. A rotation around the C(41)—O(42) bond alone would move the H(81) atom of the phenyl ring towards one of the hydrogens of the C(41) methylene group. A simultaneous rotation in the opposite direction along the O(42)—C(7) bond moves that hydrogen atom back towards its starting position. Such a concerted movement along these two bonds is obviously not changing significantly the energy of the molecule and shows that there is some rotational freedom along them.

The conformation of the piperidine ring is similar to that found in other six-membered nitroxyl derivatives (16,17). The ring is most flattened in the N part, with the CNCC torsion angles (36.4(4)° in mol **I** and 32.2(4)° in mol **II**) being in the range found in other compounds (16). As we have shown previously (16), the puckering of the C(4) part of the ring

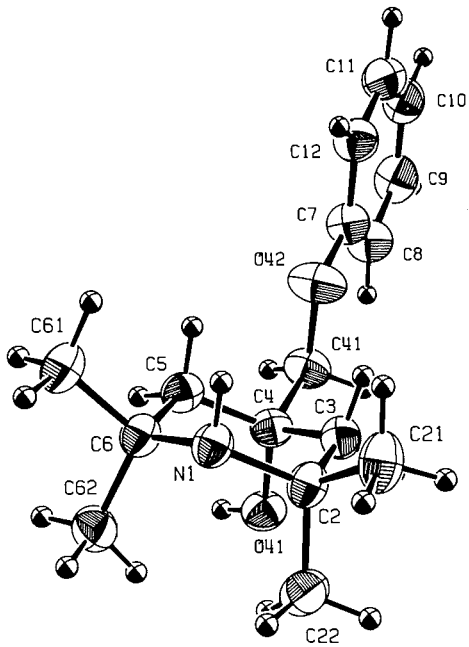

FIG. 1. A view of the molecule of 4-phenoxymethyl-2,2,6,6-tetramethyl-4-piperidinol, **3***a*.

depends on the degree of substitution of the C(4) atom. When an axial substituent to the ring is present at C(4) there is a significant decrease in the CCCC torsion angles. The average value of that torsion angle in both molecules of **6***a* is 53.0(1.0)° and agrees well with the value found for bisubstituted rings (53.7°). The flattening of that part of the ring is also reflected in an opening of the endocyclic angles at the methylene groups (C(3) and C(5) atoms). The distances between axial substituents are given in Table 5.

The average length of the N—O bond in both molecules is 1.280(4) Å. The  group is not planar. The N—O bond makes an angle of 18.6(2) and 18.3(2)° with the CNC plane in molecules **I** and **II**, respectively. The length of this bond, its inclination to the CNC plane, and the CNC angle are within the limits observed in other compounds (16). Similarly, as in **3***a*, the C(4)—C(41) bond is evenly disposed toward the piperidine ring while the C(4)—O(41) bond is somewhat inclined toward one side (the exocyclic OCC angles differ by 6°), probably as a result of hydrogen bond formation between H(O41) and O(1) from the neighbouring molecule (see Fig. 4).

The average C—C bond length in the phenyl ring is 1.376(14) Å. Some bonds in the ring are rather short but their calculated lengths are probably affected by a relatively large thermal motion of the phenyl ring.

Crystal packing

Diagrams representing packing of molecules are shown in Figs. 3 and 4. Molecules of both compounds form intermolecular hydrogen bonds. In **3***a* the H bond is formed between the hydroxyl group and the N atom of a neighbouring molecule. It is oriented equatorially to the ring. The geometry of that bond is: O—H = 0.89(3), O...N = 2.971(3), H...N = 2.11(3) Å, O—H...N = 163(2)°.

In **6***a* the H bond is formed between the hydroxyl group of one molecule and the nitroxyl oxygen of the other independent molecule. The geometry is as follows: $O^{I}(1)\ldots O^{II}(4)$ = 2.776(3), $O^{II}-H^{II}(O4)$ = 0.85(2), $O^{I}(1)\ldots H^{II}(O4)$ = 1.94(2) Å, $O^{I}(1)\ldots H^{II}(O4)—O^{II}(4)$ = 168(2)°, $O^{II}(1)\ldots O^{I}(4)$ = 2.708(4), $O^{I}(4)—H^{I}(O4)$ = 0.93(2), $O^{II}(1)\ldots H^{I}(O4)$ = 1.78(2) Å, $O^{II}(1)\ldots H^{I}(O4)—O^{I}(4)$ = 174(2)°.

Chion and Lajzérowicz-Bonneteau (18) have analyzed the directionality of hydrogen bonds involving nitroxyl groups incorporated in five- and some six-membered rings. They found that in the majority of cases this bond is inclined by 10 to 30° (a_2) to the plane containing the N—O· group and parallel to the

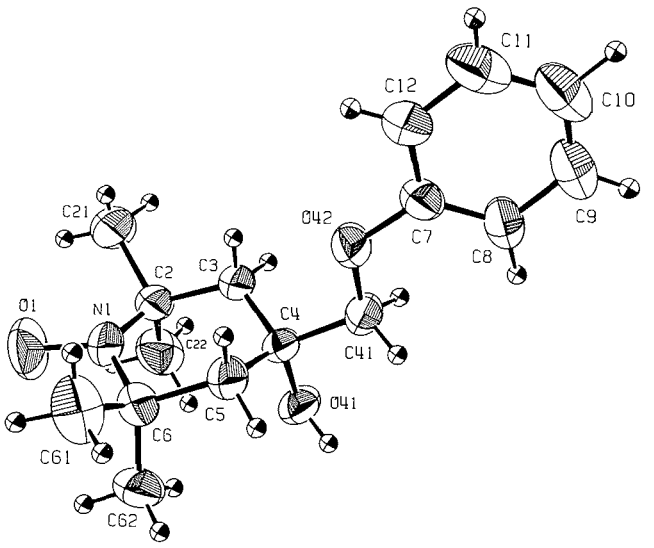

FIG. 2. A view of molecule **I** of 4-phenoxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy, **6***a*.

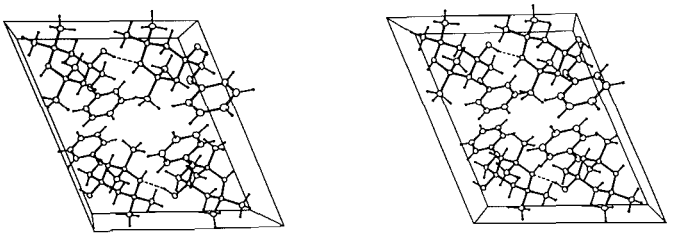

FIG. 3. A stereoscopic view of the unit cell of **3***a* with hydrogen bonds marked by dotted lines. The origin is in the lower left corner, the *Z*-axis is horizontal, the *X*-axis is vertical, and the *Y*-axis points toward the reader.

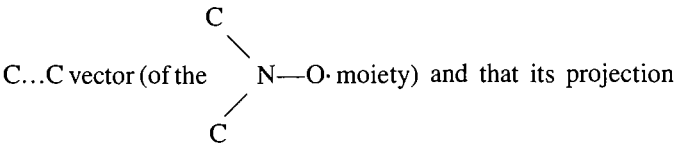

makes an angle of 20–50° (a_3) with the N—O vector. In all but one case the donor atom has also been found on the same side of this plane as the C...C atoms. In the present compound the corresponding angles are: a_2 = 10.3(3), a_3 = 32.5(3)° for the O atom involved in the hydrogen bond to the O(1) atom of molecule **I** and a_2 = 8.9(3), a_2 = 41.6(3)° for molecule **II**. The disposition of the donor group with respect to the above described plane containing the N—O group is, however, different in both molecules. In molecule **I** it is on the same side as the C...C atoms, while it is on the opposite side in molecule **II**.

Figures 3 and 4 show that the organization of the molecules of both compounds in the crystalline state is very similar although not identical. The same, topologically equivalent, system of H bonds is retained and nonbonded contacts of neighbouring molecules are similar. To accommodate the additional O(1) atom, by which the molecules of **6***a* differ from **3***a*, within the crystal structure of **3***a* and maintain favourable van der Waals interactions, the molecules have to move apart and slightly rotate. This results in changes in cell dimensions and lowering the crystal symmetry to triclinic. Such a similar packing arrangement can be rationalized on the basis that only a small

TABLE 4. Final atomic parameters and equivalent temperature factors ($\times 10^4$, $\times 10^3$ for H atoms) for 4-phenoxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy **6***a*

[a]R-factors for 4395 reflections with $I > 0.5\sigma(I)$ are given in parentheses (see text).
[b]Weights: $w^{-1} = \sigma^2(F) + k|F|^2$ were used during refinement.

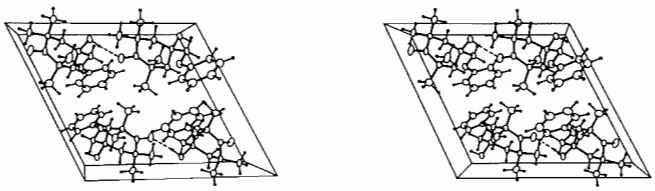

FIG. 4. A stereoscopic view of the unit cell of **6a** with hydrogen bonds marked by dotted lines. The origin is in the lower left corner, the X-axis is horizontal, the Z-axis is vertical, and the Y-axis points away from the reader.

part of the molecule has been modified, leaving its large hydrophobic surface unchanged. TMPE and 4-ethynyl-4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl (TMPEOx, ref. 19) form a pair of compounds that differ in a similar manner to **3a** and **6a**. With the smaller size of a substituent at C(4), however, an exchange of a hydrogen to an oxygen atom constitutes a much larger change of the molecular surface than in the above case. Consequently TMPE and TMPEOx display different modes of packing in the crystalline state.

Experimental

Melting points were determined with a Boetius apparatus and were not corrected. The ir spectra were recorded on a Perkin–Elmer PE-325 spectrometer with the KBr or liquid film technique. The ^{1}H nmr spectra were recorded on Tesla BS 487B (80 MHz) or Tesla 467 (60 MHz) spectrometers using TMS as an internal standard (δ = 0). Electron paramagnetic resonance (epr) spectra were measured on a JEOL JES-Me3X apparatus. Mass spectra were obtained on a LKB 2091 spectrometer at an ionization energy of 15 and 70 eV. Products from preparative scale reactions were isolated by column chromatography using Merck silica gel 60 (230–400 mesh) or Merck aluminium oxide 90 (70–230 mesh) packed in glass columns (1.5 cm in diameter, 40 cm length). The purity of separated compounds was controlled by thin-layer chromatography (tlc) using Merck silica gel 60 F 254 or aluminium oxide 60 F 254 analytical sheets.

2,2,6,6-Tetramethyl-4-piperidinone ***1***

This compound was obtained from acetone, NH_4Cl, and CaO as described earlier (20) and was converted to 2,2,6,6-tetramethyl-4-oxo-1-piperidinyloxy **4** (21).

5,5,7,7-tetramethyl-1-oxa-6-azaspiro[2.5]octane ***2***

Sodium hydride (3.1 g, 0.02 mol) and trimethyloxosulfonium iodide (5.28 g, 0.024 mol) were placed in a four-neck flask filled with dry nitrogen. DMSO (40 cm^3) was added dropwise, followed by 2,2,6,6-tetramethyl-4-piperidinone **1** (3.1 g, 0.02 mol) dissolved in 10 cm^3 DMSO. The contents of the flask were stirred at room temperature for 6 h under the N_2 atmosphere, then heated to 50°C, stirred for another 1.5 h, and slowly cooled to room temperature. Water (60 cm^3) was added to the mixture, followed by extraction with ether. The extract was washed 3 times with water and dried with anhydrous $MgSO_4$. After ether evaporation the sample was distilled under low pressure and fractions collected at 101–102°C/37 hPa. Yield 1.75 g (51.8%); ir (film) ν cm^{-1}: 1260 (C—O—C), 860 (oxirane), 3350 (NH); ^{1}H nmr (CCl_4), δ (ppm): 1.55 (s, 6H, 2,6-CH_3 eq.), 1.67 (s, 6H, 2,6-CH_3 ax.), 2.00 (s, 4H, —C—CH_2—C), 3.6 (s, 2H, —C—CH_2—O); ms (15 eV) m/e (%): 169$^+$ (2.6), 154 (100), 58 (53.3), 98 (39.5), 99 (15.3). *Anal.* calcd. for $C_{10}H_{19}NO$: C 70.96, H 11.31, N 8.28; found: C 71.29, H 11.37, N 8.21.

5,5,7,7-Tetramethyl-1-oxa-6-azaspiro[2.5]oct-6-yloxy ***5***

Synthesis was achieved as for compound **2**. The crude product was purified on a chromatography column filled with aluminium oxide (eluted with ethyl octane – hexane 1:4 mixture). A total of 1.98 g (yield 54.0%) of red crystals (mp 64–65°C) was obtained from 3.4 g (0.02 mol) of 2,2,6,6-tetramethyl-4-oxo-1-piperidinyloxy **4**; ir (KBr) ν

cm^{-1}: 1230 (C—O—C), 870 (oxirane), 1370 (N—O); ^1H nmr (CCl_4) (*in situ* reduction with the excess of *N,N*-diphenylhydrazine), δ (ppm): 1.14 (s, 6H, 2,6-CH_3 eq.), 1.19 (s, 6H, 2,6-CH_3 ax.), 1.59 (s, 4H, —C—CH_2—C), 2.51 (s, 2H, —C—CH_2—O); ms (15 eV) *m/e* (%): 184^+ (30.1), 56 (100), 98 (68.8), 83 (40.8), 70 (33.9), 81 (33.4).

4-Aryloxymethyl-2,2,6,6-tetramethyl-4-piperidinol **3** *or 4-aryloxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy* **6**

General procedure

The flask containing the mixture of phenol (0.03 mol), NaOH (0.44 g, 0.011 mol), and water (1.5 cm^3) was immersed in a boiling water bath. 5,5,7,7-Tetramethyl-1-oxa-6-azaspirol[2.5]octane **2** or 5,5,7,7-tetramethyl-1-oxa-6-azaspirol[2.5]oct-6-yloxy **5** (0.01 mol) was then added all at once. The heating was continued for 5 h. The reaction mixture was then transferred to 100 cm^3 of 4% NaOH solution having a temperature of 10–15°C. The product was extracted with ether. The ether extract was dried with anhydrous K_2CO_3 and the ether was distilled away under low pressure. The crude product was purified by crystallization. Compounds **3***a–d* were crystallized from *n*-hexane and **3***e–f* from a mixture of hexane – ethyl acetate, while compounds **6***a–g* were crystallized from water–methanol (1:1) mixtures. Physical properties, and spectral and analytical results are shown in Tables 1 and 2.

Oxidation of 4-aryloxymethyl-2,2,6,6-tetramethyl-4-piperidinols **3** *to 4-aryloxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxys* **6** (shown below for the oxidation of **3***a* to **6***a*)

4-Phenoxymethyl-2,2,6,6-tetramethyl-4-piperidinol **3** (2.63 g, 0.01 mol) was dissolved in 15 cm^3 of methanol and mixed in a flask with Na_2WO_4 (0.4 g) and disodium versenate (0.4 g). Next, 10 cm^3 of water and 10 cm^3 fo H_2O_2 (30%) were added. The flask containing the solution was heated for 1 h in a water bath and then slowly cooled to room temperature. The crystalline product was filtered out. There was 2.7 g of 4-phenoxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy **6***a*, mp 133–134°C, yield 97.1%.

Compounds **3***b–f* were oxidized in a similar way to **6***b–f* with yields in the range of 90–98%.

Reaction of 5,5,7,7-tetramethyl-1-oxa-6-azaspiro[2.5]octane **2** *with ethanol*

Reaction condition 1

Sodium (0.23 g) was added to 5 cm^3 of absolute ethanol. After the reaction was completed compound **2** (1.69 g, 0.01 mol) was added (at boiling temperature). The temperature was maintained for 3 h. The alcohol was then distilled away under low pressure and 50 cm^3 of water was added, followed by extraction with ether. The extract was first dried with anhydrous $MgSO_4$ and then the ether was distilled away. The remaining material was recrystallized from *n*-hexane. 4-Ethoxymethyl-2,2,6,6-tetramethyl-4-piperidinol (1.2 g) was obtained (mp 70–71°C, yield 55.8%); ir (KBr) ν cm^{-1}: 3500–3100 (OH, NH), 1240 (C—O—C), 1115 (C—O); ^1H nmr (CCl_4), δ (ppm): 1.45 (d, 12H, 2,2,6,6-CH_3), 1.22 (3H, CH_3), 1.77 (s, 4H, —C—CH_2—C), 3.00 (q, 2H, —C—CH_2—O), 3.33 (m, 2H, —CH_2 ethoxy group); ms (15 eV) *m/e* (%): 200 (100), 58 (36.2), 182 (23.2), 98 (15.3).

Reaction condition 2

Ethanol (6.4 cm^3) was mixed in the flask with concentrated H_2SO_4 (0.55 cm^3) and compound **2** (1.69 g, 0.01 mol) was added at a temperature not exceeding 45°C. The mixture was left at room temperature for 24 h and a 20% NaOH solution was added. Ethanol was distilled away under low pressure, 50 cm^3 of water was added, and the product was extracted with ether. The extract was dried with anhydrous $MgSO_4$ and the ether distilled away. The remaining material (0.69 g, yield 32%) was recrystallized from *n*-hexane, giving a compound identical to the one obtained under reaction condition 1.

Reaction of 5,5,7,7-tetramethyl-1-oxa-6-azaspiro[2.5]oct-6-yloxy **5** *with ethanol*

The reaction was carried out using reaction condition 1 as in the synthesis of epoxide **2**. The crude product was crystallized from ethyl acetate – hexane (1:4) solution. Red crystals of 4-ethoxymethyl-4-hydroxy-2,2,6,6-tetramethyl-1-piperidinyloxy were obtained starting with compound **5** with the yield 69.8%; ir (KBr) ν cm^{-1}: 3400–3100 (OH), 1260 (C—O—C), 1130 (C—O), 1360 (N—O); ^1H nmr (CCl_2) δ (ppm): 1.03 (3H, CH_3), 1.14 (s, 6H, 2,6-CH_3 eq.), 1.32 (s, 6H, 2,6-CH_3 ax.), 1.58 (d, 4H, —C—CH_2—C), 3.10 (s, 2H, —C—CH_2—O), 3.42 (m, 2H, —CH_2 ethoxy group); ms (15 eV) *m/e* (%): 87 (100), 230^+ (87.5), 59 (63.6), 83 (58.0), 55 (34.5), 56 (32.1).

X-ray analysis

Suitable crystals of **3***a* were obtained from *n*-hexane and those of **6***a* from methanol–water (1:1) mixture. Diffraction data were collected on a CAD-4 diffractometer using monochromated CuKα radiation. The unit cell dimensions were obtained from a least-squares refinement of the angular settings for 25 reflections with θ in the range 18 –53° for **3***a* and 10 – 42° for **6***a*. The space group $P2_1/c$ for **3***a* was determined from systematic absences on Weissenberg photographs. Crystal data and pertinent details of refinement are given in Table 6.

An $\omega/n\theta$ scan technique was used for data collection with the scan width $\Delta\omega = (A + 0.2 \tan\theta)°$, extended by 25% on either side for background measurements (*A* equals 0.7 for **3***a* and 0.6 for **6***a*). One reflection was frequently monitored during the data collection and used for scaling purposes. The structures were solved with direct methods (SHELX 76, ref. 22). Compound **3***a* was refined using full-matrix least-squares while a block-diagonal least-squares method with one molecule per block was used for **6***a* (SHELX 76, ref. 22). Scattering amplitudes were taken from ref. 23. For **6***a* only 46% of measured reflections were above 3σ level. The percentage of "observed" reflections decreased rapidly with the θ angle. For $\theta > 57°$ only about 20% of the measured reflections were above the 3σ threshold. In the preliminary stages of refinement, reflections above the 3σ threshold were used. Since there are 553 parameters to refine, the reflections/parameter ratio was only 5.3. In the last few cycles of refinement, 4395 reflections with $I > 0.5\sigma(I)$ were used. Two reflections in the case of **3***a* and six for **6***a* were affected by extinction and were given zero weight in the refinement. Non-hydrogen atoms were refined with anisotropic temperature factors. The highest peaks in the difference map are 0.2 e/Å^3 and they appear near oxygen atoms. Final atomic coordinates for both compounds are given in Table 4.[2]

Excess thermodynamic properties of tetraalkyltin compounds with *Trans*-decalin and highly branched alkanes. Effect of steric hindrance

HONG PHUONG-NGUYEN AND GENEVIÈVE DELMAS

Chemistry department, Université du Québec à Montréal, P.O. Box 8888, Station A, Montréal, Que., Canada H3C 3P8

Received July 19, 1985

HONG PHUONG-NGUYEN and GENEVIÈVE DELMAS. Can. J. Chem. **64**, 681 (1986).

Molar excess thermodynamic quantities h^E, c_p^E, and v^E have been measured at 25°C over the whole composition range for mixtures of four globular $Sn(C_nH_{2n+1})_4$ (SnR_4) ($n = 1-4$) with *t*-decalin, and 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}) as well as h^E for the same SnR_4 compounds with 2,2,4-trimethylpentane (br-C_8). The excess viscosities are measured at −20, 25, and 40°C for the *t*-decalin + SnR_4 systems. By introducing g^E in the solution activation energy, the free energy of mixing can be related to and calculated from the excess viscosities. The steric hindrance contribution, corresponding to an increase of order or diminution of mobility in solution, known to occur either with compounds having highly substituted atoms or with flat-shaped molecules, was investigated. The free volume contribution to the different thermodynamic properties is calculated from the Prigogine–Patterson–Flory theory. The difference between the experimental and calculated excess data is associated with the steric hindrance contribution. Values of h^E, c_p^E, v^E, and s^E confirm the existence of a large steric hindrance contribution ($h^E < -200$ J mol^{-1} and $Ts^E < -400$ J mol^{-1} for two systems). Another contribution, found to occur for the two smaller globular SnR_4, may originate in the liberation of movement induced in solution by the second component.

HONG PHUONG-NGUYEN et GENEVIÈVE DELMAS. Can. J. Chem. **64**, 681 (1986).

Nous avons mesuré, à 25°C, sur tout le domaine de concentration les propriétés thermodynamiques d'excès suivantes: h^E, c_p^E et v^E pour des mélanges de *t*-décaline et de heptamethyl-2,2,4,4,6,8,8 nonane (ram-C_{16}) avec les quatre premiers composés de la serie SnR_4 ($R = C_nH_{2n+1}$, $n = 1-4$). Les h^E ont aussi été mesurées avec le triméthyl-2,2,4 pentane (ram-C_8). Des mesures de viscosités d'excès ont été faites à −20, 25 et 40°C sur les mélanges de *t*-décaline + SnR_4. En introduisant g^E dans l'énergie d'activation de la solution, on peut relier l'énergie libre de mélange (non-combinatoire) aux viscosités d'excès. La contribution d'empêchement stérique, qui se traduit par une diminution de mobilité ou une augmentation d'ordre en solution, était l'objet de ce travail. Elle se manifeste soit avec des molécules qui possèdent un atome très substitué soit avec d'autres qui ont une forme moléculaire assez plate. La théorie de Prigogine–Patterson–Flory est utilisée pour calculer les contributions de volume libre. La différence entre les valeurs expérimentales et calculées des viscosités d'excès est identifiée à la contribution à Ts^E venant de l'empêchement stérique. Les résultats de h^E, c_p^E, v^E et s^E confirment l'existence d'une contribution importante aux propriétés thermodynamiques venant de l'empêchement stérique ($h^E < -200$ J mol^{-1} et $Ts^E < -400$ J mol^{-1} pour deux systèmes). Pour les deux plus petits SnR_4, une autre contribution apparaît qui pourrait être reliée à la libération, par le deuxième composé, d'un mouvement dans ces molécules très symétriques.

Introduction

Previous work (1–3) on the tetraalkyltin compounds has shown that the long-chain molecules $Sn(C_nH_{2n+1})_4$ (or SnR_4) have orientational order which is destroyed in solution with globular molecules. The short-chain or globular SnR_4 seemed very interesting since the h^E (2, 3) and c_p^E (1) of their mixtures with long-chain compounds, either linear alkanes or SnR_4, show important irregularities instead of varying smoothly with the size or free volume of SnR_4.

Steric hindrance effect

Analysis of the h^E of the SnR_4 mixtures and of others leads to the definition of a new contribution to the thermodynamic properties of mixing arising from an increase of order or diminution of mobility of the molecules in solution in comparison to the pure liquids. This contribution, named steric hindrance contribution (2), condensation contribution (4), or coupling of torsional oscillations (5), occurs either when a molecule in the mixture has a crowded central atom, such as the highly branched alkanes, the SnR_4 compounds, and some disubstituted cyclohexanes (6*a*), or when it has a special flat shape such as cyclopentane or *trans*-decalin (6*b*). The steric hindrance character of many branched alkanes (with the carbon atom number $n \leq 8$) has been related (5) to the number of *trans* configurations of the molecule in the liquid state. The interaction of this type of molecule with the second component gives an exothermic contribution to h^E which makes the total h^E either negative or less endothermic than expected from comparison with similar systems. Since the steric hindrance contribution is less important at higher temperature, the c_p^E values associated with steric hindrance are positive. As can be expected from an increase of cohesion or from a contraction, steric hindrance gives a negative contribution to the excess volume v^E.

The aim of the present work was to study the steric hindrance effect in mixtures where the two components have either characteristic which is known to induce the steric hindrance effect. The compounds chosen were, on one hand, the four lower members of the SnR_4 series and, on the other hand, two highly branched alkanes namely, 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}) and 2,2,4-trimethylpentane (br-C_8) and the flat shaped molecule, *t*-decalin.

Values of the excess free energy are valuable to obtain the excess entropy and eventually the steric hindrance contribution to s^E. Since the g^E could not be measured by vapor pressure for the systems composed of nonvolatile compounds, they were calculated by an indirect method from excess viscosity data (7, 8).

For eight systems, namely the four lower members of the SnR_4 series, mixed with *t*-decalin and br-C_{16}, h^E, c_p^E, and v^E have been measured at 25°C as a function of concentration. For br-C_8, h^E values with the SnR_4 compounds with *t*-decalin have been obtained at −20, 25, and 40°C. The names of the tetraalkyltin compounds have been abbreviated in the following way: $SnMe_4$, $SnEt_4$, etc., for $Sn(methyl)_4$, $Sn(ethyl)_4$, etc.

Experimental

Materials

The SnR_4 compounds were purchased from the Organisch Chemisch

Instituut (Utrecht), *t*-decalin from Chemical Samples Co. (Columbus, OH), and the branched alkanes from the K and K Co. (White Plains, NY). The purity, as measured by gc was 99.8% for *t*-decalin and br-C_8 and 97.4% for br-C_{16}. The physicochemical constants of the SnR_4 compounds, measured together with those of other series (9) are given in ref. 1.

Apparatus

The density measurements were made with an Anton Paar densitometer, the characteristics of which have been described earlier (10).

The calorimeters are respectively a Picker flow apparatus for the c_p^E and a tilting Tian-Calvet calorimeter for the h^E. Details on the cells, accuracy, and calibration can be found in refs. 2 and 11 for h^E, and refs. 1 and 12 for c_p^E.

The viscosities are measured in an Ubbelohde viscosimeter installed in a constant-temperature water or water–methanol bath. The dynamic viscosities expressed in centipoises are obtained from the flow time, t, by the relation $\eta = (d_l - d_v)(Ct - B/t)$ where d_l and d_v are the liquid (pure or solution) and vapor densities, and C and B are calibration constants obtained as described in ref. 13.

Theory

Equation of state theory

The parameters required to characterize a liquid are V^*, the core volume or volume at 0 K, P^*, the pressure reduction parameter associated with the cohesive character of the liquid, and T^* the reduction temperature. Large, cohesive compounds have larger values of these parameters than volatile ones. The V^*, P^*, and T^* parameters and the reduced volume $\tilde{v}$ are calculated, with a model, from the density, the expansion coefficient α, and the thermal pressure coefficient γ of the pure liquid (14). The free volume contributions, h^E(fv), v^E(fv), g^E(fv), and c_p^E(fv) which depend on the difference in state of expansion of the liquids mixed can be calculated as described in the appendix of ref. 12*a* or in the original papers. They are negative for h^E, v^E, and c_p^E since the difference of expansion of the pure liquids leads to a kind of condensation of the more expanded component in the less expanded one, and since this difference of expansion becomes larger at higher temperature. In the present systems, the free volume contributions are of some size only in systems involving $SnMe_4$ and br-C_8 as seen in the corresponding columns in the tables. The term $X_{12}s_1^{-1}$ is the non equation-of-state part of h^E. It cannot be calculated *ab initio* but is obtained by subtracting from the experimental heats of mixing h^E(fv). s_1 and s_2 are the molecular surface-to-volume ratios of the molecules of liquids 1 and 2 obtained from molecular models.

Sign of X_{12}

In nonpolar systems, the h^E values are rarely negative because the free volume contribution is usually not large enough to overcome the positive h^E coming from the difference in force field between the two molecules and so the X_{12} values are also usually positive. The steric hindrance effect has been discovered both in systems with a negative h^E, more negative than the calculated h^E(fv), and in systems whose h^E value was less endothermic than could be expected by comparison with similar compounds. If the steric hindrance contribution is dominant, the X_{12} parameter will be found negative.

Separation of the different contributions to the thermodynamic functions

Excess heats and heat capacities. Measuring thermodynamic functions in a series helps to detect the different contributions and the variation of their relative importance from one system to another. The comparison of the sign of h^E and c_p^E is also a useful indication of the dominant contribution. The disordering and steric hindrance contributions are both diminishing when T increases. Accordingly, the corresponding contributions to c_p^E are negative and positive respectively (since the contributions to h^E are of contrary signs). Further, the presence of different contributions of comparable size can be inferred from the concentration dependence of the excess functions which can be either skewed or even can change sign over the composition range.

Excess volumes. The calculated v^E can be broken down into three terms (10) namely $v^E(h^E)$ which has the sign of h^E(exp.), v^E(fv) which is negative and $v^E(P^*)$ which can have either sign since it is proportional to $(\tilde{v}_1 - \tilde{v}_2)(P_1^* - P_2^*)$. This last term, which can give large contributions to v^E has been investigated in systems composed of liquids of different state of expansion and cohesive energy (11, 12, 15).[1]

Excess viscosity and free energy of mixing. Several definitions have been used for the excess viscosity but the more appropriate one for establishing the relation between the solution viscosity and g^E is

$$[1] \quad \Delta \ln \eta = \ln \eta - (x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

where η_1, η_2, and η are the dynamic viscosities of the pure components and the solution respectively; the term in parentheses is considered as the logarithm of the viscosity of the ideal solution.

In order to be displaced and flow, a molecule has to overcome the attractive forces of its neighbours and find an empty site nearby. An expression which takes account of these requirements has been developed by Macedo and Litovitz (7) and has been applied by Bloomfield and Dewan (8).

$$[2] \quad \eta = A \exp(\Delta G^*/RT + (\tilde{v} - 1)^{-1})$$

where A is a parameter, ΔG^* the activation energy, and $\tilde{v}$ the reduced volume. A bridge can be made between the flow and thermodynamic properties of mixing if one assumes the simple relation between the pure liquids and solution activation energies ΔG_1^*, ΔG_2^*, ΔG^*, and the excess (noncombinatorial) free energy of mixing, g^E

$$[3] \quad \Delta G^* = x_1 \Delta G_1^* + x_2 \Delta G_2^* - g^E$$

If eq. [2] is applied to liquids 1 and 2 and to the solution and substituted in eq. [1] after using eq. [3] one finds

$$[4] \quad \Delta \ln \eta(\text{calcd.}) = -g^E/RT + (\tilde{v} - 1)^{-1} - (x_1(\tilde{v}_1 - 1)^{-1} + x_2(\tilde{v} - 1)^{-1})$$
$$= -h^E/RT + s^E/R + \ln \eta(v^E)$$
$$= \ln \eta(h^E) + \ln \eta(s^E) + \ln \eta(v^E)$$

where $\ln \eta(h^E) = -h^E/RT$

$$[5] \quad \ln \eta(s^E) = s^E/R$$
$$\ln \eta(v^E) = (\tilde{v} - 1)^{-1} - [x_1(\tilde{v}_1 - 1)^{-1} + x_2(\tilde{v}_2 - 1)^{-1}]$$

The physical meaning of eqs. [4] and [5] is as follows: a positive value of h^E which entails a loss of cohesive energy upon mixing the pure liquids will give a negative contribution to $\Delta \ln \eta$, corresponding to a solution less viscous than the ideal solution. The inverse will hold for a more cohesive solution displaying a negative h^E. The third term, $\ln \eta(v^E)$ will give a positive contribution to $\Delta \ln \eta$ or increase the viscosity of the solution if there is a contraction on mixing as is the case in systems with a difference in free volume between the components.

[a]The positive X_{12} is very likely due to the overestimation of h^E(fv).
[b]Reference 8.
[c]Number of experimental points in parentheses.

The second term, $\ln \eta(s^E)$ corresponds to the effect of the excess entropy of the system. Only the free volume part of s^E can be calculated by the theory used for the other free volume contributions. As with $\ln \eta(v^E)$, it is a function of the difference in reduced volumes of the components but the pressure parameter P^* and the core volume V^* come in the final expression

$$[6]\quad s^E/R = (3x_1P_1^*V_1^*/RT)(\ln(\tilde{v}_1^{1/3} - 1)/(\tilde{v}^{1/3} - 1)) + (3x_2P_2^*V_2^*/RT)(\ln(\tilde{v}_2^{1/3} - 1)/(\tilde{v}^{1/3} - 1))$$

The noncalculable excess entropy will be reflected in $\Delta \ln \eta$(exp) but not in $\Delta \ln \eta$(calcd.) so that the difference between the two will be a measure of Ts^E

$$[7]\quad Ts^E(\text{visc.}) = RT\delta = RT(\Delta \ln (\eta(\text{exp.}) - \Delta \ln \eta(\text{calcd.}))$$

Results and discussion

Tables 1 and 2 give the maximum of h^E, v^E, and c_p^E and the concentrations at which these functions are maximum for the mixtures with *t*-decalin and br-C_{16} respectively. Table 3 shows the h^E data with br-C_8 and Table 4 the excess viscosities of the SnR_4 compounds with *t*-decalin. Measurements have been done at 25°C but excess viscosities have been also measured at 40 and −20°C. The coefficients of the Redlich–Kister equations of the measured property y^E

$$[8]\quad y^E = x_1x_2 \sum_{i=0}^{i=2} Y_i(x_1 - x_2)^i$$

are also listed for most of the systems. The values $(h^E)_v$ and $(c_p^E)_v$ added in the tables are obtained by dividing the data at the maximum by the average core volume $x_1V_1^* + x_2V_2^*$. The equation of state contributions h^E(fv), c_p^E(fv), the different contributions to v^E, and the $X_{12}s_1^{-1}$ values have been tabulated also.

To compare the different systems, the maxima of h^E, c_p^E, and v^E have been plotted in Fig. 1 vs. V^* the core volume of the SnR_4 compounds for *t*-decalin (○), br-C_{16} (●), and br-C_8 (□).

In the following discussion, the steric hindrance contribution will be analysed in the series as it is reflected in turn from h^E, c_p^E, v^E, and $\Delta \ln \eta$.

Heats and excess heat capacities

Observation of Figs. 1*a* and 1*b* suggests that, as a simplifying assumption, the systems studied can be divided into two groups.

The first group consists of the six mixtures containing $SnPr_4$ and $SnBut_4$. The h^E values of these compounds with *t*-decalin, br-C_{16}, and br-C_8 are large and exothermic. This holds also for $X_{12}s_1^{-1}$ (see Tables 1–3) so that one can conclude that the steric hindrance contribution is dominant. The positive c_p^E values are also consistent with the above assumption.

The second group consists of the mixtures of $SnEt_4$ and $SnMe_4$ with *t*-decalin, br-C_{16}, and br-C_8 which, with the exception of the $SnMe_4$ + *t*-decalin system have a positive h^E. The h^E, larger for the $SnEt_4$ mixtures by 200–300 J mol^{-1} than for the next in the series, $SnPr_4$, are particularly striking and indicate that another contribution is active and dominant here. A difference in force-field between the two components of the mixture, a difference larger with $SnEt_4$ and $SnMe_4$ than with the other SnR_4 compounds, seems the obvious explanation for the endothermic heats. However, this effect cannot be the only one because it was not apparent in mixtures with other nonpolar molecules such as the linear alkanes or long-chain SnR_4 compounds. The positive h^E must be associated with a special contribution due to the shape of the present molecules, i.e., an effect of the disorder-type found with other systems (11) but not well understood presently.

Judged by the magnitude of h^E and $X_{12}s_1^{-1}$, the $SnMe_4$ + *t*-decalin system seems to be right at the temperature at which the two effects make comparable contributions to the thermodynamic functions. The concentration dependence of X_{12} shown in Fig. 2 (▽) supports this analysis. In decalin-rich solutions, the negative X_{12} suggests that steric hindrance is dominant while in $SnMe_4$-rich mixtures X_{12} is positive and has the same magnitude as in the $SnEt_4$ solutions. On the other hand, the moderate variation of X_{12} for the other systems reflects the rather symmetrical shape of their h^E (■, □, ○).

Figure 3 shows the concentration dependance of c_p^E in the *t*-decalin systems. The larger c_p^E for the $SnMe_4$ is indicative of a larger temperature dependence of h^E for this volatile liquid. The skewed or S-shaped curves of c_p^E for $SnBut_4$ and $SnPr_4$ seem in contradiction with the above description of a dominant contribution in h^E. However, the magnitude of the c_p^E is such that the predicted variation in h^E, even over a large temperature interval, is moderate. Results of excess viscosities at different temperatures (Fig. 4), confirm the small variation of the thermodynamic properties with temperature in the SnR_4 + *t*-decalin mixtures except for the $SnMe_4$ solutions. Consequently, the c_p^E data do not invalidate the above distinction between the two groups of systems.

Excess volumes

The values of v^E(exp.) − v^E (calcd.) listed in Tables 1 and 2 are large and negative indicating that the steric hindrance effect induces a contraction in the systems larger than that taken into account by the negative contribution coming from $v^E(h^E)$ or v^E(fv). In the present series, the values for the four more sterically hindered systems, $SnPr_4$ and $SnBut_4$ with *t*-decalin and br-C_{16} varies between −0.18 and −0.31 cm^3 mol^{-1}, the numbers for $SnMe_4$ being, as expected from the h^E value, intermediary (−0.14, −0.03) between those and the $SnEt_4$

TABLE 4. Excess viscosities $\Delta \ln \eta$ for the SnR_4 + *trans*-decalin systems at the concentration x_1 of the maximum. The A_i parameters are the coefficients of the Redlich–Kister equations. values (−0.01, 0.02). It is worthwhile to compare the present $SnBut_4$ +br-C_{16} system with the $SnBut_4$ + *n*-C_{16} mixture. Due to the lack of the steric hindrance contribution, v^E(exp.) − v^E(calcd.) is small and positive (0.037) for the linear alkane while it is −0.19 cm^3 mol^{-1} with br-C_{16}.

Effect of P* *on* v^E

The two systems $SnMe_4$ (1) + *t*-decalin (2) and $SnMe_4$ (1) +br-C_{16} (2) are well suited to see the effect on v^E of the term $(\tilde{v}_1 - \tilde{v}_2)(P_1^* - P_2^*)$. The first factor $(\tilde{v}_1 - \tilde{v}_2)$ has the same value for the two systems. On the other hand, $(P_1^* - P_2^*)$ is negative and small for $SnMe_4$ +br-C_{16} and positive and larger for $SnMe_4$ + *t*-decalin (respectively 396 − 409 = −13 and 504 − 409 = 95 J cm^{-3}). Consequently, the v^E are predicted more negative for the first system than for the second and this is what is found experimentally namely −0.96 and −0.20 cm^{-3} mol^{-1} respectively.

Excess viscosities and excess entropies

In Table 4, the excess viscosity results are presented for the *t*-decalin mixtures, the experimental values on the left part and the calculated contributions, as defined in eq. [5], on the right. The coefficients of the Redlich–Kister equation are listed as well as the maxima of $\Delta \ln \eta$ and the concentration of the maxima. In the lower part of the table, experimental $\Delta \ln \eta$ values at 40 and −20°C are reported. In Fig. 4, the maxima of $\Delta \ln \eta$(exp.) are plotted against the temperature for the four systems. The trends of the temperature dependence are similar for the three higher SnR_4 compounds, a larger variation being reasonably found for $SnEt_4$. The rapid change of $\Delta \ln \eta$ for the $SnMe_4$ mixture between 25 and 40°C and between 25 and −20°C supports the analysis made from the h^E results of terms of opposite sign being in balance at 25°C. The positive value of $\Delta \ln \eta$ at 40°C can be accounted for by the increased difference between the free volume of *t*-decalin and $SnMe_4$ but the increase of $\Delta \ln \eta$ between 25 and −20°C is difficult to explain, considering the trend in the other systems. However, the positive (although small) values of $\Delta \ln \eta$ found at −20°C for the *t*-decalin +$SnBut_4$ system in $SnBut_4$-rich solutions ($x > 0.7$) shows that the trend for a positive $\Delta \ln \eta$ value at low temperature is not unique to the $SnMe_4$ system.

In Table 4, the difference δ between the experimental and calculated $\Delta \ln \eta$ values are reported as well as Ts^E(visc.) obtained from eq. [7] (7th and last column of the table).

In the present analysis, the question to be asked is whether the Ts^E values confirm the above analysis, namely the dominance of steric hindrance in the higher SnR_4 and the sharp change in the balance of the contributions for the two lower ones. From the negative values in Table 4, one sees that indeed the expected negative contribution for the steric hindrance effect is present and unexpectedly large (between −100 and −500 J mol^{-1}). It is interesting to note that although the difference in Ts^E between the propyl and ethyl derivatives is about as large as that between their h^E values, s^E is negative throughout the series. The positive Ts^E which could have been expected from the sign of h^E for the lighter SnR_4 compounds, does not occur because the contributions to Ts^E due to steric hindrance (as obtained from the excess viscosities) are about twice as large as the contributions to h^E due to steric hindrance. The negative values of v^E(exp.) − v^E(calcd.) are quite consistent with the Ts^E results.

In a previous study (13*a*) of long alkanes disordered by mixing with a globular molecule, the Ts^E(visc.) values in the series of the linear alkanes were found to correlate with

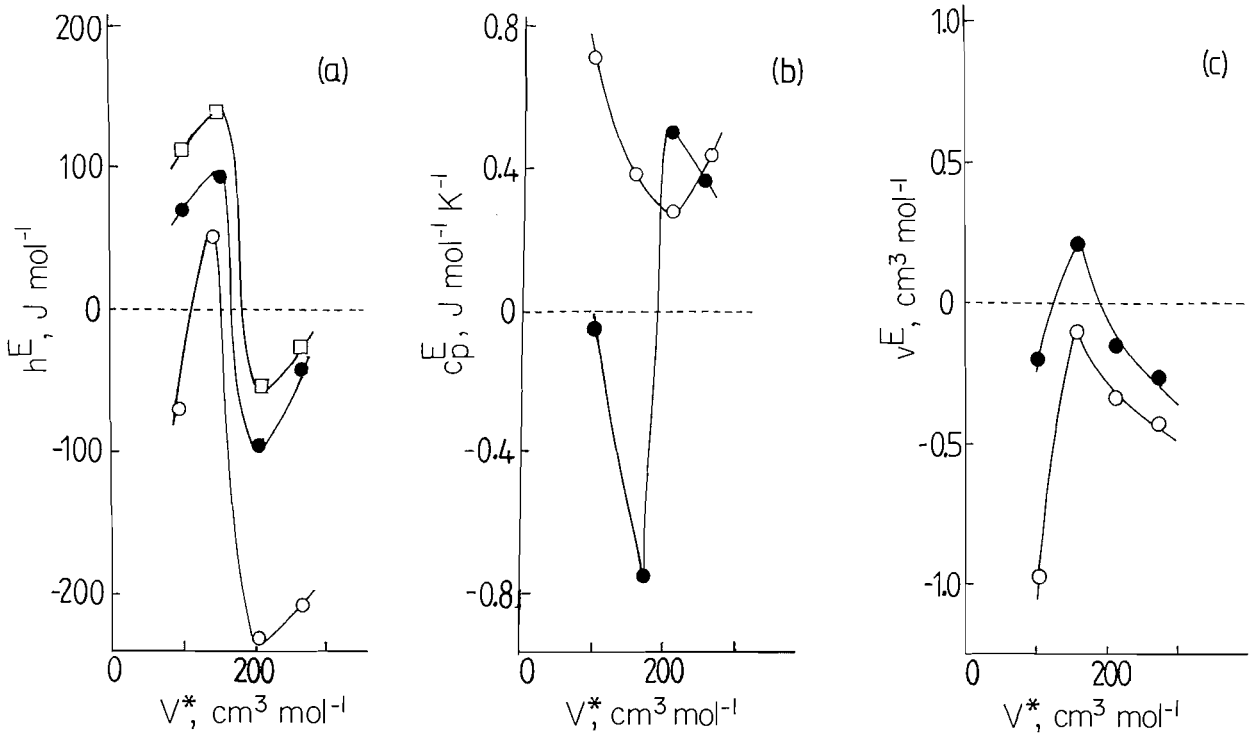

FIG. 1. Excess molar thermodynamic properties at 25°C, at the concentration of the maximum, plotted against the molar volume at 0 K, V^*, of the SnR_4 compound (methyl to butyl). The second component is *t*-decalin (○), br-C_{16}(●), or br-C_8 (□). Curves *a* for h^E, curves *b* for c_p^E, and curves *c* for v^E.

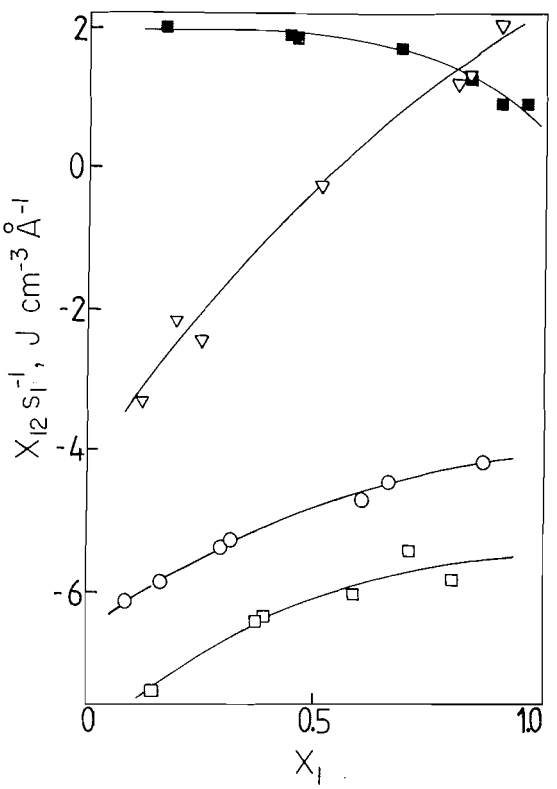

FIG. 2. The concentration dependence of the non-free-volume part of h^E, $X_{12}s_1^{-1}$, is shown for the mixtures of *t*-decalin with $SnMe_4$ (▽), $SnEt_4$ (■), $SnPr_4$ (□), and $SnBut_4$ (○).

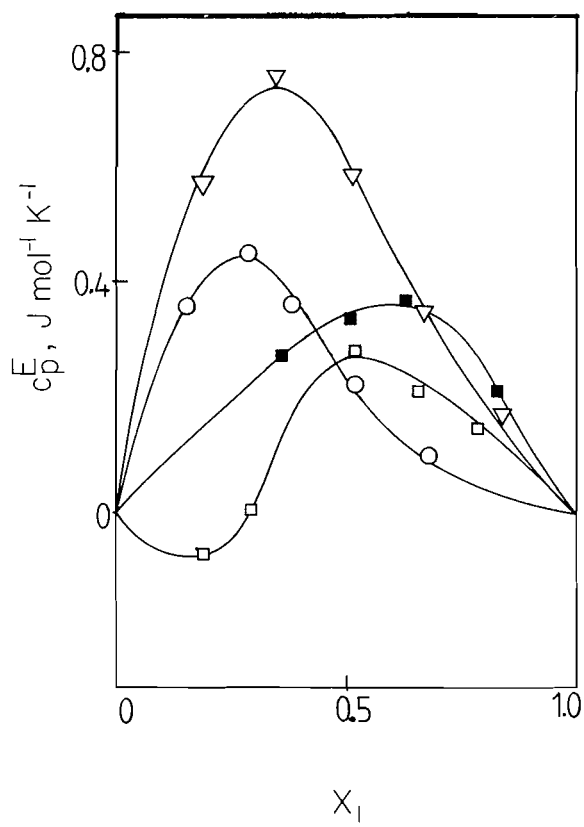

FIG. 3. The concentration dependance of c_p^E is given for the *t*-decalin + SnR_4 systems. Same symbols as in Fig. 2.

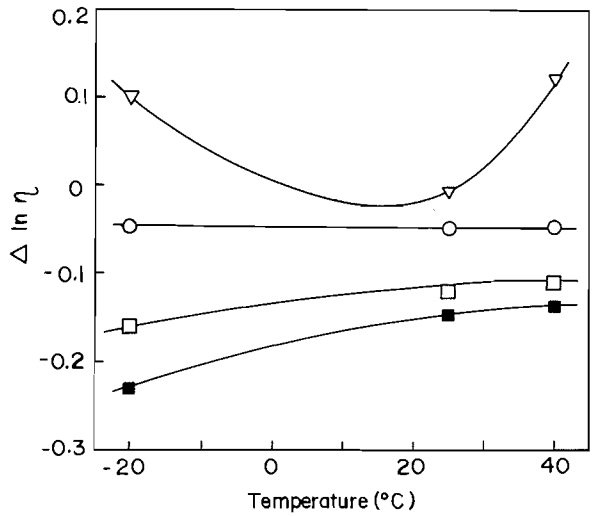

FIG. 4. The excess viscosities, $\Delta \ln \eta$, at the concentration of the maximum, are plotted for the *t*-decalin $+SnR_4$ systems versus the temperature. Same symbols as in Fig. 2.

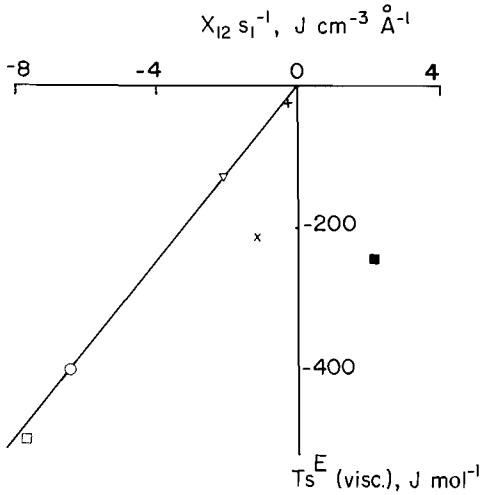

FIG. 5. The steric hindrance contributions to the excess viscosities, Ts^E(visc.) (Table 4, last column), are plotted for the *t*-decalin $+SnR_4$ systems at 25°C versus the corresponding contributions to h^E, $X_{12}s_1^{-1}$ (Tables 1 and 2). Same symbols as in Fig. 2. Data are given for two others mixtures (13*a*) showing the steric hindrance effect: $SnBut_4$ + br-C_{16} (×) and + br-C_{12} (+) (2,2,4,6,6-pentamethylheptane). The position of the $SnEt_4$ + *t*-decalin mixture on the graph (■) points to another effect.

h^E(disorder). Furthermore, in one system studied between 25 and 80°C, the decrease of Ts^E(visc.) was matching that of h^E(disorder) becoming zero at the temperature known for the disappearance of correlations of molecular orientations between the chains. The same type of correlation between the enthalpic and entropic contributions due to steric hindrance has been tested in Fig. 5 in which Ts^E(visc.) (at the maximum of $\Delta \ln \eta$) has been plotted against the X_{12} parameters (at the maximum of h^E). It is probably a coincidence that the point for $SnMe_4$ is in line with the others since X_{12} varies rapidly with concentration for this system. From previously obtained results (13*a*), data on $SnBut_4$ + br-C_{16} (×) and br-C_{12} (+) have been added in Fig. 5. They show that the steric hindrance effect exerted on the SnR_4 by *t*-decalin is stronger than that due to these branched alkanes. This had been found already by comparing the thermodynamic properties of *c*-C_5 and *t*-decalin (6*b*, 16) with that of *c*-C_5 and br-C_{16} (15). The other contribution is apparent in the $SnEt_4$ system whose positive X_{12} puts the point (■) quite distant from the correlating line.

In conclusion, the rapid change in h^E between $SnEt_4$ and $SnPr_4$ may be due to two effects: on one hand, to the diminution for the lower SnR_4 of the steric hindrance contribution as indicated by Fig. 4 and, on the other hand, to the existence for the $SnEt_4$ and $SnMe_4$ of the right conditions (free volume, molecular shape) for the liberation of movement in these compounds apparently quite cohesive (they have higher P^* than the longer homologues or than an alkane of the same molecular weight) in the liquid state.

Measurements of the ^{119}Sn relaxation times by nmr in the pure SnR_4 compounds and in their solutions in *t*-decalin are being made with the aim of obtaining a finer picture of the molecular changes associated with some of the unexpected values of the thermodynamic functions measured in the present work.

A premixed, fuel-rich, methane–oxygen flame at atmospheric pressure was doped separately with 0.2 mol% of H_2S, OCS, and SO_2 to probe the behaviour of fuel sulphur during combustion. These three additives represent compounds occurring early, intermediate, and late in the oxidation sequence of fuel sulphur. They are chemically ionized in the reaction zone of a hydrocarbon flame to give large signals of sulphurous negative ions. Those detected include S^-, SH^-, SO^- (uncertain), SO_2^- (S_2^-), SO_3^-, HSO_3^-, $CH_3O^- \cdot SO_2$, SO_4^- ($S_2O_2^-$, S_3^-), and HSO_4^-. Ion concentration profiles of these ions were measured along the conical flame axis by sampling the flame into a mass spectrometer. The shapes of the profiles are insensitive to the nature of the additive, but their relative magnitudes are indicative of the additive's position in the sulphur oxidation sequence. For each additive, the very large HSO_4^- signal has analytical implications as an indicator for total fuel sulphur. The sulphurous anion chemistry is discussed for each additive in terms of roughly twenty ion (electron)-molecule reactions of six basic types, whose rate constants were known previously, or were measured at room temperature using the York flowing afterglow apparatus.

Dans le but d'examiner le comportement de combustibles/soufre au cours de combustions, on a ajouté séparément 0,2 mol% de H_2S, de OCS et de SO_2 à des flammes prémélangées de méthane–oxygène, riches en combustibles et qui opéraient à la pression atmosphérique. Ces trois additifs représentent les composés qui se retrouvent respectivement dans les stades préliminaires, intermédiaires et finaux de la séquence d'oxydation de mélanges combustibles/soufre. Ils sont ionisés chimiquement dans la zone de la réaction de la flamme d'hydrocarbure pour donner des signaux importants des ions négatifs des entités sulfurées. Les entités détectées comportent: S^-, SH^-, SO^- (incertain), SO_2^- (S_2^-), SO_3^-, HSO_3^-, $CH_3O^- \cdot SO_2$, SO_4^- ($S_2O_2^-$, S_3^-) et HSO_4^-. On a mesuré les profils des concentrations ioniques de ces ions en fonction de l'axe conique de la flamme en faisant appel à un échantillonage de la flamme dans un spectromètre de masse. Les formes de ces profils ne varient pas avec la nature des additifs; toutefois, leurs amplitudes relatives sont reliées à la position de l'additif dans la séquence de l'oxydation du soufre. Pour chaque additif, le signal très important du HSO_4^- a des implications analytiques comme indicateur de la quantité totale du soufre/combustible. Pour chacun des additifs, on discute de la chimie des anions sulfureux en fonction d'environ vingt réactions ion (électron)/molécule de six types de base dont les constantes de vitesse étaient antérieurement connues ou qui ont été mesurées à la température ambiante en faisant appel à un appareil de phosphorescence continue de York.

Introduction

The control of SO_x emissions from the combustion of fossil fuels has become important for reasons of public health and because of the impact on the environment by acid rain. Industry reports (1) indicate that the sulphur content of coal and heavy fuel oil can amount to 1–5% by weight; an average figure for gasoline is 0.03%. Increasing energy costs and problems of supply may necessitate the burning of high-sulphur fuels in the future, a trend which is at odds with an increasingly stringent body of environmental and health regulations.

Other combustion pollutants such as NO_x and soot are, to some extent, amenable to chemical modification during the combustion process. Undesirable products can be converted into less harmful forms by altering the combustion conditions or by means of additives (2). On the other hand, sulphur does not appear to offer the same possibilities for its chemical manipulation into harmless forms. The seemingly inevitable conversion of fuel sulphur into SO_2 has focussed effort in two other directions; namely, sulphur removal from the fuel before combustion, and stack-gas scrubbing of SO_2 from the burnt gas afterwards. However, continued study of the sulphur chemistry occurring in a flame may provide insight into more esoteric approaches to sulphur removal at source during the combustion process. It is also valid because of the analytical implications for the evaluation of sulphur-containing fuels.

An important insight was gained in a previous study (3) in which flame ionization was employed as a probe for sulphurous intermediates leading to SO_x formation in the reaction zone and burnt gas of a premixed, CH_4–O_2 flame doped with 0.2% of OCS. It was found that sulphur species readily form negative ions in the flame, and that these negative ions reveal features of the stepwise oxidation of OCS. These results encouraged us to extend the investigation further to include the addition of 0.2% of H_2S and of SO_2 for comparison with OCS. The three additives represent a progression in the sulphur oxidation chain with H_2S occurring early, OCS being intermediate and SO_2 being late as the final oxidation product.

For each additive, sulphurous negative ions are formed by chemical ionization (CI) processes of the neutral sulphur intermediates with the natural ions which are present in any hydrocarbon flame. The ion chemistry of the source and sink reactions is discussed, and comparisons are drawn amongst the three additives. The advantage of this method is that the sulphurous ions serve as a probe of the neutral sulphur chemistry in the flame reaction zone where it originates.

Experimental

All of the ion concentration measurements were performed on the same CH_4–O_2 flame of fuel-rich composition (equivalence ratio ϕ = 2.15) whose ion chemistry we have studied extensively in the past (4, 5). It was of the laminar premixed type with a conical luminous reaction zone (height $\simeq$ 5 mm, base diameter $\simeq$ 3 mm, thickness $\simeq$ 0.3 mm) to facilitate ionic sampling along the flame axis into a mass spectrometer. The flame has an adiabatic flame temperature of 2460 K and burnt gas velocity of approximately 1 m s^{-1}. It was stabilized at atmospheric pressure on a simple, tubular, quartz burner (2.3 mm id) surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. Provision was made to add 0.2 mol% of H_2S or of SO_2 to the premixed gas in exactly the same way as was done previously for OCS (3). The additives could be introduced or removed without altering the flame. All gases were used straight from the cylinders

without further purification ($CH_4 > 99.0\%$, $O_2 > 99.6\%$, Ar > 99.9%, $H_2S > 97.5\%$, OCS > 97.5%, $SO_2 > 99.90\%$). The burner was mounted on a motor-driven carriage with accurate alignment of the flame axis with the sampling orifice of the mass spectrometer. The calibrated burner drive provided spatial resolution of ±0.02 mm along the flame axis (designated z) for measurements of ion concentration profiles.

The flame–ion mass spectrometer has been described previously in detail (4). The flame burned against a 60°, conical, chromium, sampling nozzle of orifice diameter *ca.* 0.1 mm mounted in a water-cooled flange of the type described by Hayhurst and Telford (6). The sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday cage connected to a vibrating reed electrometer having a grid-leak resistance of 10^{11} ohms. The ion signal magnitudes in the figures are quoted in volts based on the detected ion current passing through 10^{11} ohms. Modifications to the quadrupole power supply have improved the resolution of the mass filter, particularly at high mass numbers. We have adopted the same normalization technique described in the paper with OCS additive (3). The profiles shown in the figures include a correction for mass discrimination in the filter against ions of high m/e measured at high resolving power. The dynamic range of sensitivity of the apparatus is five orders of magnitude. A method has been described (4) for locating a reproducible origin ($z = 0$) in the *flame* (not referred to the burner) corresponding to the downstream edge of the luminous reaction zone on the flame axis. In this way, a family of ion profiles at different mass numbers m/e can be accurately overlaid on the distance scale z.

The shapes of the profiles obtained for the three additives at the same mass number are very similar. However, some of the profiles presented in this work are somewhat different from those reported earlier (3) in that they are not as noticeably double-peaked. This is due to the use of a new chromium sampling nozzle having a larger orifice diameter such that the effect of boundary layer cooling, as discussed in the previous study (3), is less. In the present case, negative ion equilibria shift less in the exothermic direction, and electron attachment to form negative ions is reduced, particularly downstream where the temperature is high. That is, the free electron concentration is enhanced at the expense of the negative ion concentration, and distortion of the profiles due to sampling is reduced.

Results and discussion

Anion profiles

Figure 1 displays the dramatic enhancement observed in the total negative ion profiles with the separate additions of equimolar amounts of H_2S, OCS, and SO_2 into the premixed flame gas. In contrast, the total positive ion profiles showed no change in peak magnitude for these three cases. It is clear from Fig. 1 that SO_2 has the largest effect on the upstream concentration of negative ions and that H_2S and OCS also enhance negative ion formation and do so about equally. The bulk of the observed increases could be accounted for by the anions listed in Table 1. Individual profiles for the ions with m/e equal to 33, 64, 80, and 97 are shown in Figs. 2–5. While differences in the peak magnitudes of these profiles are again noticeable with the three different additives, the shapes of the individual profiles appear to be quite insensitive to the nature of the additive.

The ion assignments of the individual masses are given in Table 1. In making these assignments account has been taken of isotopic contributions as indicated previously (3). Increases in signal are apparent for all the ions in Table 1 with the following exceptions: $m/e = 32$ decreases for all three additives and $m/e = 33$ decreases for the addition of SO_2 only. The former ion is O_2^- in the undoped flame and reacts when the sulphur compounds are added. The $m/e = 33$ ion is HO_2^- in the undoped flame and it reacts when SO_2 is added to the premixed

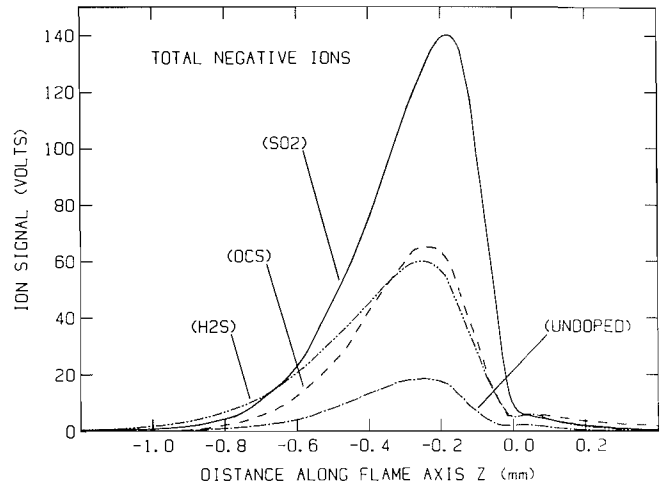

FIG. 1. Total negative ion profiles of the undoped flame and of the flame doped with 0.2 mol% of H_2S, OCS, and SO_2. The flame reaction zone is located upstream of $z = 0$.

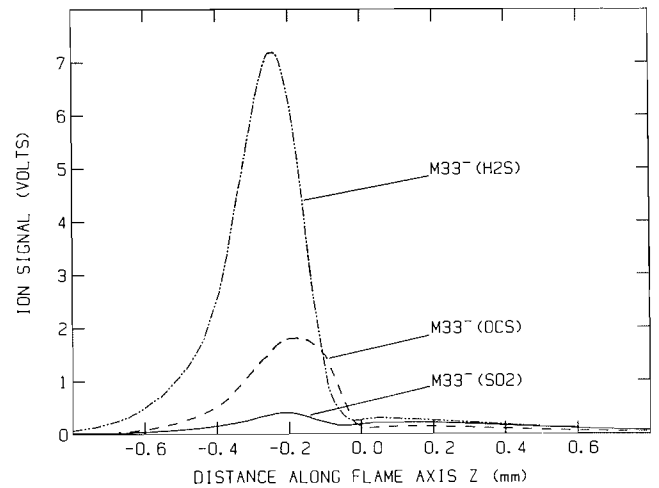

FIG. 2. Profiles of $m/e = 33$ representing SH^- and (or) HO_2^- when the flame is doped with 0.2 mol% of H_2S, OCS, and SO_2. The flame reaction zone is located upstream of $z = 0$.

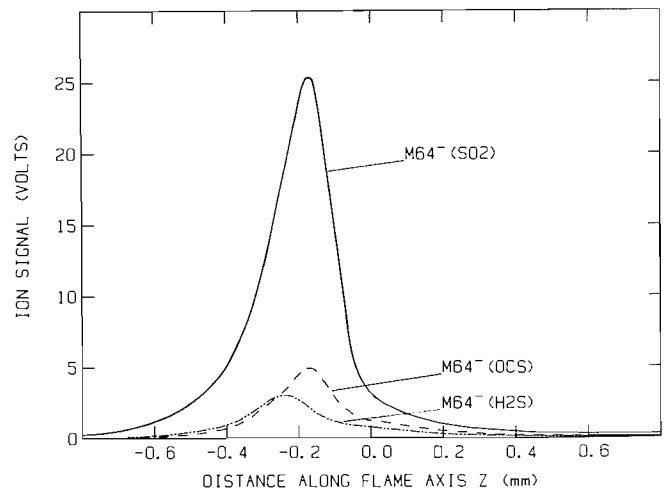

FIG. 3. Profiles at $m/e = 64$ representing SO_2^- (and possibly S_2^-) when the flame is doped with 0.2 mol% of H_2S, OCS, and SO_2. The flame reaction zone is located upstream of $z = 0$.

TABLE 1. Peak intensities of anion signals (in volts) in the reaction zone of the undoped flame, and with the flame doped with 0.2 mol% of H_2S, OCS, and SO_2

Parent ion	Mass number	No additive	H_2S	OCS	SO_2
Total positive		320	320	320	320
Total negative		18.5	60	65	140
S^-	$M32^-$	6.5 (O_2^-)	1.1	0.56	0.57
SH^-	$M33^-$	0.82 (HO_2^-)	7.2	1.8	0.40
SO_2^- (S_2^-)	$M64^-$	0.50	3.0	4.9	25.3
SO_3^-	$M80^-$	0.05	11.7	12.7	20.6
HSO_3^-	$M81^-$	0.01	2.3	3.0	3.1
$CH_3O^-SO_2$	$M95^-$	—	2.9	3.9	10.3
SO_4^- ($S_2O_2^-$, S_3^-)	$M96^-$	—	3.1	4.0	10.0
HSO_4^-	$M97^-$	—	29.5	38.0	88.3
Σ (sulphur anions)		—	60.8	68.9	158.6

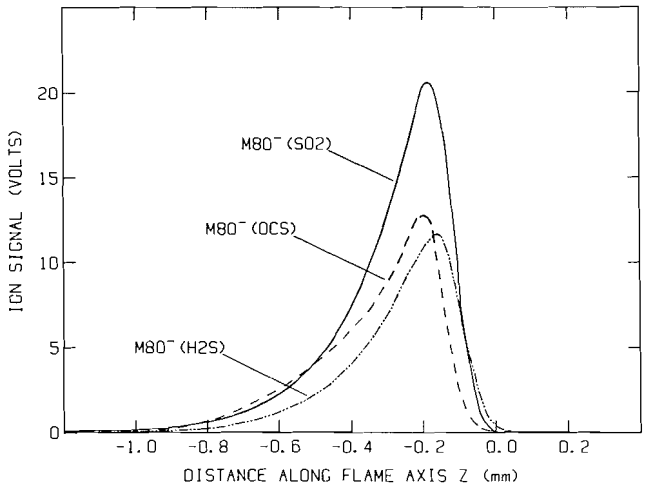

FIG. 4. Profiles at $m/e = 80$ representing SO_3^- when the flame is doped with 0.2 mol% of H_2S, OCS, and SO_2. The flame reaction zone is located upstream of $z = 0$.

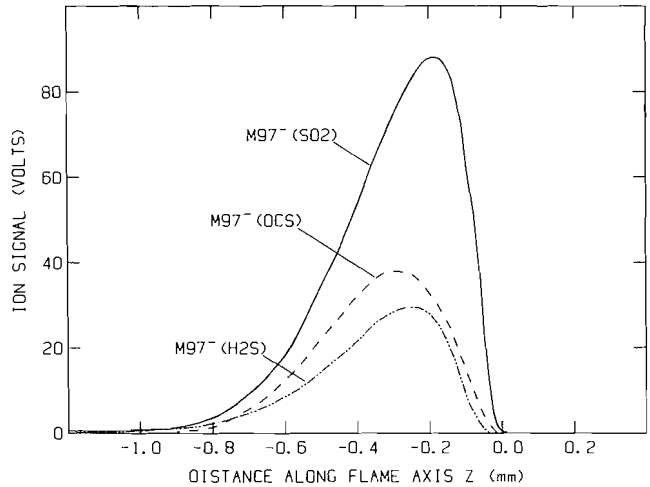

FIG. 5. Profiles at $m/e = 97$ showing the large signals of HSO_4^- obtained when the flame is doped with 0.2 mol% of H_2S, OCS, and SO_2. The flame reaction zone is located upstream of $z = 0$.

flame gas. The sulphur content of the residual peaks at $m/e = 32$ and $m/e = 33$ could not be determined with confidence due to the complications discussed previously (3). All the ions which were observed to increase contained at least one sulphur atom. Several of the sulphurous ions observed contained hydrogen and (or) oxygen and one at $m/e = 95$ must contain carbon.

Inspection of the ion peak intensities in Table 1 reveals that the appearance of sulphurous anions is dominated by HSO_4^- and, to a lesser extent, by SO_3^- in all three doped flames, approximately in proportion to the total negative ion peaks. Distinguishable features for the different additives are manifested with several of the relatively minor ions. The SO_2 flame is characterized by a considerably enhanced abundance of SO_2^- and a shortage of SH^-. The flame doped with H_2S clearly shows an enhanced SH^- peak. In general, the OCS peaks are intermediate between those of the other two additives.

Sulphurous anion chemistry

It is clear from the observed increases in the total negative ion profiles that the additives provide the flame with additional anions. These new anions may arise by attachment or dissociative attachment of electrons with the additive or with molecules derived from the additive by neutral chemistry. The ion assignments indicate that all of the new negative ions are sulphurous so that the sulphur in the additive becomes entrained in the ion directly in the initial formation by attachment or dissociative attachment, or indirectly through secondary ion–molecule reactions. The secondary ion chemistry will be complex but should be dominated by reactions of sulphurous anions with the dominant (non-sulphurous) neutrals in the flame. Secondary reactions with the additive itself or some of its neutral derivatives will have less impact but may still be noticeable.

Dissociative attachment in OCS should proceed in the manner indicated by reaction [1]

[1] $e^- + OCS \rightarrow S^- + CO$

since it is by far the least endothermic option of five possible channels (7). The endothermicity of reaction [1] is about 25 kcal mol^{-1}. The two channels given by reaction [2] appear likely with H_2S

[2*a*] $e^- + H_2S \rightarrow S^- + H_2$

[2*b*] $e^- + H_2S \rightarrow SH^- + H$

They are approximately 23 and 38 kcal mol^{-1} endothermic, respectively. Formation of H^- and SH is endothermic by more than 70 kcal mol^{-1} and is thus not expected to be significant. With SO_2, direct exothermic attachment to form SO_2^- is

expected (8) according to

[3] $e^- + SO_2 + M \rightarrow SO_2^- + M$

The channels leading to SO^-, S^-, O_2^-, or O^- in this case are all endothermic by more than 80 kcal mol^{-1}. We may therefore conclude that all the new primary ions formed from the three additives by electron attachment are sulphurous: S^- from OCS, S^- and SH^- from H_2S, and SO_2^- from SO_2.

Some of the secondary ion chemistry in OCS has been discussed previously in considerable detail (3). Briefly, with S^- as the primary ion we can expect the following secondary reactions to predominate

[4*a*] $S^- + O_2 \rightarrow SO_2 + e^-$

[4*b*] $S^- + O_2 \rightarrow SO^- + O$

[4*c*] $S^- + O_2 + M \rightarrow SO_2^- + M$

[5] $SO^- + O_2 + M \rightarrow SO_3^- + M$

[6] $SO_2^- + OH \rightleftharpoons SO_3^- + H$

[7] $SO_3^- + XH \rightleftharpoons HSO_3^- + X$

[8] $SO_2^- + O_2 + M \rightarrow SO_4^- + M$

[9] $SO_4^- + XH \rightleftharpoons HSO_4^- + X$

where M is a third body and XH is likely to be OH. Other reactions are possible if secondary sulphurous neutrals are present in sufficient concentration

[10] $S^- + SO_2 + M \rightarrow S_2O_2^- + M$

[11] $CH_3O^- + SO_2 + M \rightarrow CH_3O^- \cdot SO_2 + M$

Reaction [10] could account for the formation of some $S_2O_2^-$ at $m/e = 96$ although SO_4^- predominates from analysis of the ^{34}S isotope contribution at $m/e = 98$. Improved resolving power of the mass filter has led to the unequivocal identification of a sulphurous anion at $m/e = 95$, presumably formed by association of SO_2 with CH_3O^- via reaction [11]. It is noteworthy that the magnitude of this ion peak is approximately equal to that of SO_4^- at $m/e = 96$ for all three additives. This is the first sulphurous anion which must contain carbon that we have been able to detect. It is significant because it indicates the presence of appreciable SO_2 in the reaction zone of the OCS flame. It was also possible to detect the parent CH_3O^- ion at $m/e = 31$ in the undoped flame, which was not resolved previously because it occurs in the asymmetric foot of the very large O_2^- signal at $m/e = 32$. With OCS additive we can expect the following additional reactions to contribute

[12] $O_2^- + OCS \rightarrow SO_2^- + CO$

[13] $OH^- + OCS \rightarrow SH^- + CO_2$

[14] $S^- + OCS \rightarrow S_2^- + CO$

Isotope contributions of ^{34}S at $m/e = 66$ indicate that SO_2^- predominates over S_2^- at $m/e = 64$.

Reactions [10] and [12]–[14] have been examined separately at room temperature with the flowing afterglow technique in the Ion Chemistry Laboratory at York University. Reaction [10] has an effective second-order rate constant of 8.4×10^{-12} cm^3 $molecule^{-1}$ s^{-1} at 294 ± 2 K and a pressure of 1.5 Torr (1 Torr = 133.3 Pa).[1] This is a relatively high value for addition reactions of this type and suggests a stability for $S_2O_2^-$ brought about by covalent bonding. However, the ion has not often been observed in the gas phase although it has been identified previously in sulphur-doped crystals at low temperatures. Reactions [12]–[14] have all been found to occur rapidly with rate constants of (4.1 ± 1.2), (9.5 ± 2.9), and (9.1 ± 2.7) × 10^{-10} cm^{-3} $molecule^{-1}$ s^{-1}, respectively.[1] Also, no further reactions were observed for SO_2^-, SH^-, and S_2^- with OCS; i.e., $k \leq 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1} in each case. Thus, reactions [1] and [4]–[14] together can account qualitatively for all the predominant sulphurous ions observed with the OCS additive; the importance of [10] and [14] is doubtful.

The enhanced abundance of SO_2^- in the flame seeded with SO_2 clearly is to be attributed to the direct attachment of electrons to SO_2. The lack of production of SH^- in this case is not unexpected. OH^- is known to add to SO_2 to produce HSO_3^- (9, 10) according to

[15] $OH^- + SO_2 + M \rightarrow HSO_3^- + M$

Production of SH^- from these reagents is about 20 kcal mol^{-1} endothermic and requires considerable bond redisposition. The ion signal at $m/e = 33$ actually decreases with SO_2 addition, presumably because of the charge transfer reaction

[16] $HO_2^- + SO_2 \rightarrow SO_2^- + HO_2$

The charge transfer is almost thermoneutral according to the known electron affinities of 1.16 eV for HO_2 (11) and 1.1 ± 0.1 eV for SO_2 (12).

The identifying features of the flame doped with H_2S can also be understood in terms of the ion chemistry with the additive. More SH^- can clearly be expected with H_2S than with OCS because of proton transfer reactions of the type

[17] $X^- + H_2S \rightarrow SH^- + XH$

which can be expected to occur between H_2S and a number of the anions present in the undoped flame. Also, some production of SH^- is expected from the dissociative attachment reaction [2*b*]. Starting with reaction [2*a*], the S_2^- and S_3^- ions might be expected to arise from the following two reactions with H_2S and (or) SH

[18] $S^- + H_2S\ (SH) \rightarrow S_2^- + H_2\ (H)$

[19] $S_2^- + H_2S\ (SH) \rightarrow S_3^- + H_2\ (H)$

Sulphur bond formation reactions of this type may be generalized by the reaction

[20] $S_n^- + XS \rightarrow S_{n+1}^- + X$

Their energies may be expressed with equation [21]

[21] $\Delta H^0 = D(X—S) - D(S_n—S) + EA(S_n) - EA(S_{n+1})$

where D and EA are the bond dissociation energy and electron affinity, respectively. $D(S_n—S)$ is approximately 70 kcal mol^{-1} for n = 2–7 and 103 kcal mol^{-1} for $n = 1$. $D(X—S)$ for H_2S is 72 kcal mol^{-1} and for SH is 85 kcal mol^{-1}. Values of 2.077, 1.663, and 2.0 eV are available for $EA(S)$, $EA(S_2)$, and $EA(S_3)$, respectively (11, 13). They indicate that reaction [18] is exothermic for both H_2S and SH; reaction [19] is exothermic for H_2S and slightly endothermic for SH. We have investigated the reactions of S^-, S_2^-, and S_3^- with H_2S separately with the flowing afterglow technique near room temperature. S_2^- and S_3^- were found not to react at 473 K while S^- reacted at 317 K primarily according to reaction [22], which may be either proton transfer or hydrogen atom transfer, with a rate constant of (5.2 ± 1.6) × 10^{-10} cm^3 $molecule^{-1}$ s^{-1};[1]

[22] $S^- + H_2S \rightarrow SH^- + SH$

[1] D. K. Bohme and co-workers. Unpublished results. York University, Downsview, Ont., Canada M3J 1P3.

Reaction channel [22] is only thermoneutral. The observation that it is preferred over the more exothermic reaction channel [18] near room temperature may reflect the kinetic barrier which is likely to be associated with the considerable bond redisposition required to bring about reaction channel [18]. Apparently the same chemistry is operative at flame temperatures; reaction channel [22] is the preferred route rather than the reaction sequence [18] + [19]. This behaviour is borne out by the ^{34}S isotope analysis which indicates the presence of SO_2^-, not S_2^-, at $m/e = 64$, 66 and SO_4^-, not S_3^-, at $m/e = 96$, 98.

Influence of the sulphurous neutral chemistry

It is possible that the discussion to this point underestimates the amounts of secondary sulphurous neutrals formed from the parent additives within the short time scale of the flame reaction zone. Certainly the observation of $CH_3O^- \cdot SO_2$ with all three additives gives pause for thought since neutral SO_2 must be involved in its formation. In this fuel-rich flame where H_2 is the major combustion product, relatively large concentrations of free H atoms will be present in the reaction zone and also upstream of it because of their very large diffusivities (4, 14). Thus, the following sequence of reactions may be near to being balanced

[23] $SO_2 + H \rightleftharpoons SO + OH$

[24] $SO + H \rightleftharpoons S + OH$

[25] $S + H_2 \rightleftharpoons SH + H$

[26] $SH + H_2 \rightleftharpoons H_2S + H$

Overall, the net reaction is

[27] $SO_2 + 2H_2 \rightleftharpoons H_2S + 2OH$

Since the OH concentration exceeds its equilibrium value in the reaction zone (4, 14), then the production of H_2S, and to a lesser extent SH, is suppressed with SO_2 additive. In contrast, the production of SO_2 with H_2S additive is enhanced. The entry and participation of OCS into the above scheme will occur via the reaction

[28] $OCS + H \rightleftharpoons SH + CO$

which has the same H-atom dependence as the reverse of reaction [26]. On the other hand, radical reactions of H and OH with sulphur species may be minimized if SO_2 catalyzes radical recombination according to

[29] $SO_2 + OH(H) + M \rightarrow HSO_3(HSO_2) + M$

[30] $HSO_3(HSO_2) + H \rightarrow SO_2 + H_2O(H_2)$

Other channels akin to reaction [30] might produce neutral SO_3

[31] $HSO_3 + H(OH) \rightarrow SO_3 + H_2(H_2O)$

or even sulphuric acid

[32] $HSO_3 + OH + M \rightarrow H_2SO_4 + M$

Thus, radical attack on the additives in the flame reaction zone may give rise to a variety of species (S, SH, SO, SO_2, HSO_2, SO_3, HSO_3, H_2SO_4) which can attach electrons to form sulphurous negative ions. The degree to which the neutral sulphur chemistry affects the observations of sulphurous anions is difficult to assess quantitatively, but its influence cannot be disregarded.

Conclusions

The present range of additives including H_2S, OCS, and SO_2 is representative of fuel sulphur compounds occurring early, intermediate, and late in the sulphur oxidation sequence. Thus, more general conclusions can be advanced than were possible with OCS in isolation (3).

(*1*) All three additives produce a dramatically increased concentration of sulphur anions in the flame reaction zone, and it is reasonable to assume that any fuel sulphur will do the same. This means that fuel sulphur gives rise to species (e.g., S, SH, SO_2, etc.) having higher stabilities than those of the C—H—O molecules normally present in a hydrocarbon flame.

(*2*) The ambient concentration of negative ions represents a balance between the rates of electron attachment and detachment. Three-body and dissociative attachment have a negative temperature dependence. Associative detachment by radicals and thermal detachment (near $z = 0$ in the profiles) have a positive temperature dependence. Thus, possible attempts to remove sulphur from combustion products as sulphurous anions will benefit from a lower temperature.

(*3*) The profile shape of a given sulphurous anion is remarkably insensitive to the nature of the additive. This will be the case if the rates of production and loss of the sulphurous anion are fast such that its profile essentially replicates that of the reagent C—H—O anion (or free electrons in the case of attachment).

(*4*) The profile magnitudes are not sufficiently distinct to predict the nature of the fuel sulphur from the anion signals. However, some useful qualitative trends are discernible at each end of the oxidation sequence; H_2S enhances SH^- at one end, while at the other end, SO_2 enhances SO_2^- and SH^- is absent.

(*5*) The anions are dominated by HSO_4^- which accounts for roughly half of the total ion signal present for each of the three additives. This has analytical implications for the detection of total sulphur. It does *not* necessarily imply the presence of sulphuric acid in the flame, however.

(*6*) The full range of sulphurous anions detected (in order of increasing m/e) includes S^-, SH^-, SO^- (uncertain), SO_2^- (S_2^-), SO_3^-, HSO_3^-, $CH_3O^- \cdot SO_2$, SO_4^- ($S_2O_2^- \cdot$, S_3^-), and HSO_4^-. Thus, S—H and S—O bonds may form, but evidently C—S and S—S bond formations are not favoured.

(*7*) The $CH_3O^- \cdot SO_2$ ion is revealing since its formation via reaction [11] requires the presence of SO_2 as a reagent. For the H_2S and OCS additives, appreciable secondary SO_2 must be present as a combustion product in the flame reaction zone. Evidently the oxidation of sulphurous neutrals (e.g., $H_2S \rightarrow SH \rightarrow SO \rightarrow SO_2$ or $OCS \rightarrow S \rightarrow SO \rightarrow SO_2$) proceeds very rapidly under flame conditions.

(*8*) The sulphurous anion chemistry is explicable in terms of roughly twenty ion (electron) – molecule reactions. The types of reactions are diverse and include attachment and dissociative attachment, association, atom transfer, proton transfer, and charge (electron) transfer.

(*9*) Sufficient time is available in the flame reaction zone for the occurrence of at least four consecutive ion–molecule reactions. This is evident from sequences such as $S^- \rightarrow SO_2^- \rightarrow SO_3^- \rightarrow HSO_3^-$ or $S^- \rightarrow SO_2^- \rightarrow SO_4^- \rightarrow HSO_4^-$ with the H_2S or OCS additives. The sequences might be longer except that we have not been successful in detecting sulphurous anions unambiguously having $m/e > 100$. Fast reaction rates are aided by the high (atmospheric) pressure of the flame (many of the reactions are termolecular) but not necessarily by the high flame temperature (many of the reactions have a negative or zero temperature dependence).

(*10*) These results bear out a general contention of flame-ion chemistry; namely, that the elevated flame temperature is

sufficient to overcome reaction endothermicities of at least 25 kcal mol^{-1}. Reactions [1] and [2*a*] are cases in point. This behaviour is in contrast to room-temperature studies, for example, using the flowing afterglow apparatus, in which endothermic reactions generally do not proceed at measurable rates.

Acknowledgements

Support of both the flame ionization work and the flowing afterglow studies by the Natural Sciences and Engineering Research Council of Canada is acknowledged. We wish to thank Dr. A. N. Hayhurst for his helpful comments with regard to the influence of the sulphurous neutral chemistry.

A photoconductivity study was made on γ-irradiated low and high density polyethylene using 3-methylpentane, methylene chloride, and hexafluorobenzene as dopants. Electron spin resonance (esr) and optical absorption measurements were made together with photoconductivity. A study was also made for poly(4-methylpentene-1). The process of photocurrent generation is not ascribed totally to photodetrapping of trapped electrons in polyethylene; the process by photodetrapping of trapped electrons dominantly contributes to photocurrent generation in the ir region and may partly contribute in the visible region but not in the uv region. Another process for photocurrent generation other than photodetrapping of trapped electrons exists in the uv and perhaps partly in the visible region. We have tentatively ascribed this process to photodetachent of electrons from carbanions whch are formed by the reaction between radicals and electrons.

TOYOAKI KIMURA, YUTAKA UEDA et YOHICHI HIRAI. Can. J. Chem. **64**, 695 (1986).

On a effectué une étude de photoconductivité sur des polyéthylènes de basse et de haute densité, irradiés aux rayons γ et contenant les substances suivantes comme dopants: méthyl-3 pentane, chlorure de méthylène et hexafluorobenzène. En plus de la photoconductivité, on a aussi effectué des mesures de rpe et d'absorption. On a aussi étudié le poly(méthyl-4-pentène-1). On n'attribue pas tout le processus de la génération du photocurant au photodépiégeage des électrons piégés dans le polyéthylène; ce processus de photodépiégeage des électrons piégés contribue d'une façon dominante à la génération du photocourant dans le région de l'ir et peut aussi contribuer en partie dans la région du visible, mais pas dans la région de l'uv. En plus du photodépiégeage des électrons piégés, un autre processus de génération de photocourant existe dans l'uv et peut-être aussi dans le visible. Sur une base préliminaire, on a attribué ce processus au photodétachement des électrons des carbanions qui se forment par la réaction des radicaux et des électrons.

[Traduit par la revue]

Introduction

Trapped electrons generated by ionizing radiation have been widely investigated in organic solids especially in frozen organic glasses at the liquid nitrogen temperature (1). Concerning trapped electrons in nonpolar hydrocarbon glasses at 77 K, it is well known that the electron spin resonance (esr) spectra for those electrons show a singlet line with a line width of ~4 G(1), that absorption maxima of optical absorption spectra are ~1700 nm(1), and that photoconductivity maxima of photoconductivity spectra are ~1000 nm(2). It is also known that electrons are efficiently trapped in glassy matrices but not in crystalline matrices.

Hydrocarbon polymers such as polyethylene (PE), polypropylene (PP), or poly(4-methylpentene-1) (P4MP) have chemical unit structure similar to low molecular weight hydrocarbons such as 3-methylpentane (3MP) or 2-methylpentane (2MP). Thus it is interesting to compare the nature of electrons trapped in low molecular hydrocarbon glasses and the nature of those trapped in hydrocarbon polymers. Electron spin resonance spectra of trapped electrons in γ-irradiated polymers show singlet signals which are similar to those in low molecular hydrocarbon glasses although the line widths are slightly narrow: 3.4 G for PE and 2.6 G for P4MP (3). Concerning the optical absorption spectrum in a hydrocarbon polymer, Keyser and Williams have reported that the position of the absorption maximum (λ^{ab}_{max}) of trapped electrons in γ-irradiated P4MP at 77 K lies beyond 2000 nm (4). This result seems to be similar to that for low molecular weight hydrocarbon glasses, although the λ^{ab}_{max} in P4MP is longer than those in the glasses. On the other hand Partridge has shown a photoabsorption spectrum λ^{ab}_{max} which is ~280 nm in γ-irradiated low density polyethylene (LDPE) at 98 K and ascribed this to trapped electrons.

Polyethylene is widely used as electrical insulators. Thus, the nature of PE is widely studied in the field of electrical engineering by means of thermoluminescence (TL) (6–13), thermally stimulated current (TSC) (14–21), and photostimulated detrapping current (PSDC) (22,23). Trapped electrons, which are defined as electrons trapped physically in a matrix, are proposed to be the origin of TL (7–10), TSC (17,19), and PSDC (22,23). The reported PSDC spectra of trapped electrons in high density polyethylene (HDPE) X-irradiated at 90 K have shown only a small peak at ~1 eV and almost monotonous increase with considerable extent up to 5 eV (23).

The optical absorption and photoconductivity spectrum in γ- and X-irradiated PE in refs. 5 and 23, respectively, are dominant in the uv region and these have been ascribed to trapped electrons, as is described above. However, this is unacceptable from a viewpoint of trapped electrons in low molecular hydrocarbon glasses. It is conclusive that optical absorption and photoconductivity maxima lie in the ir region in low molecular hydrocarbon glasses. Freeman has demonstrated that even in highly polar media the upper limit of the absorption maximum of trapped electrons would be about 2.5 eV (24). Electron trapping in PE is an important and interesting phenomenon not only in the field of radiation chemistry but also in that of electrical engineering. Nevertheless, no further paper has been published since then.

Another point which we should note is the relationship between trapped electron yields in polymers and their crystallinities. It is reported that the higher the crystallinity of a polymer, the higher the trapped electron yield (4), which conflicts with the results from low molecular organic glasses as is described already.

In order to clarify these points described above we have measured optical, photoconductivity, and esr spectra for LDPE and HDPE γ-irradiated at 77 K. We have also studied the effect of doping using 3MP, methylene chloride, and hexafluoroben-

[1]To whom correspondence should be addressed.

[2]Present address is Tokai Kohgyo Co. Ltd., Ohbu, Aichi, Japan.

zene as dopants. In addition to LDPE and HDPE an investigation was also made for P4MP.

Experimental

Low density polyethylene and high density polyethylene were BE-R3000 (Ube Industries Ltd., the density was 0.919) and Sholex 6006M (Showa Denko K.K., the density was 0.958), respectively. LDPE and HDPB films made by hot press (1 mm thickness) were immersed in hot methylene chloride for a few days under argon atmosphere in a separable flask with three necks and a condenser. Following this, LDPE and HDPE were purified by hot hexane by the same procedure as above. On the other hand, another purification was made by dissolving PE pellets in hot xylene and then precipitating in methanol. However, no detectable difference in measured results can be observed between the samples purified by the former and latter method. Therefore, the former purification was mainly used through this work. Polyscience P4MP pellets were purified by the same procedure as that for PE. Purified PE and P4MP were dried *in vacuo*. Purified P4MP was pressed into a 1 mm thickness film by hot melt.

3-Methylpentane was Tokyo Kasei extra pure reagent and purified by molecular sieve 13X, which was evacuated at 300°C for 10 h. Nakarai Chemicals methylene chloride (spectro grade) and hexafluorobenzene (guaranteed reagent) were used as received.

Samples for photoconductivity measurements were made using films (1 × 9 × 50 mm) of LDPE, HDPE, and P4MP. Electrodes were made on the surfaces of both sides of a film by the following two methods. One is aluminum vapor deposition, where the front electrode was made to have a few slits through which incident photons were injected. The other is pressing brass meshes on both sides of a film by a flatiron. We have confirmed that the samples with aluminum deposited electrodes gave essentially the same results as those with mesh electrodes. However, since the adhesion between deposited aluminum and a film was poor which resulted in the poor reproducibility in the results and also the detachment of aluminum from the film when a dopant was used, the latter method was mainly used. Copper flat rings with a lead wire were contacted to the electrodes by a Teflon screw and nut which were set through a hole at the top of the film with electrodes. A sample in the photoconductivity cell, the main part of which was made of Supracil quartz, was evacuated on a vacuum line and sealed off immediately before the measurement. The scheme of the experiment was the same as that in ref. 25. A dc voltage of 500 V was applied for a sample of 1 mm thickness (5 kV/cm).

The samples for optical absorption measurement and for esr were a film (9 × 50 mm) and ~6–8 pieces of cut film (~1 × 50 mm), respectively. Samples in esr cells (Supracil quartz tube) and those in optical absorption cells (rectangular Supracil quartz) were evacuated on a vacuum line and sealed off. The esr measurements were made on a JEOL JES-3BX spectrometer with a ES-SCXA microwave unit. Optical absorption measurements were made on a Hitachi 323 spectrophotometer.

Doping for LDPE or HDPE was made by transferring a degassed dopant into the photoconductivity cell in which LDPE or HDPE was kept *in vacuo*. Then LDPE or HDPE was kept immersed in the dopant liquid overnight. After that the dopant was removed by vacuum distillation. The content of a dopant was measured by the difference in the weight before and after doping.

γ-Irradiation was made by γ-rays from a ^{60}Co source. The irradiation dose was 3.9×10^5 rad (1 rad = 10 mGy). γ-Irradiation and measurement were carried out at 77 K through this work.

Results and discussion

It is more difficult to purify polymers than low molecular hydrocarbons. In the latter case impurities such as olefines, aldehydes, ketones, etc. are satisfactorily removed from hydrocarbons by the use of a molecular sieve and purified hydrocarbons are separated from the molecular sieve by vacuum distillation. However, this technique cannot be used for polymers because the separation by vacuum distillation is practically inapplicable. Then, impurities may remain in polymers to some extent, which may lead to the difference in the results between low molecular hydrocarbons and PE as described before. There remains the following possibility: impurities in PE suppress the formation of trapped electrons and thus, the optical absorption spectrum ($\lambda_{max} \approx 280$ nm) in ref. 5 cannot be ascribed to trapped electrons. To check this possibility the effect of doping with a small amount of 3MP was investigated because it is expected that a small amount of 3MP does not compete with impurities for electrons. On the other hand, if trapped electrons do exist in γ-irradiated PE, doping of PE with electron scavengers such as methylene chloride or hexafluorobenzene will reveal the structure of trapped electrons in esr, optical absorption, and photoconductivity spectra. Thus, the effect of doping with electron scavengers was also investigated.

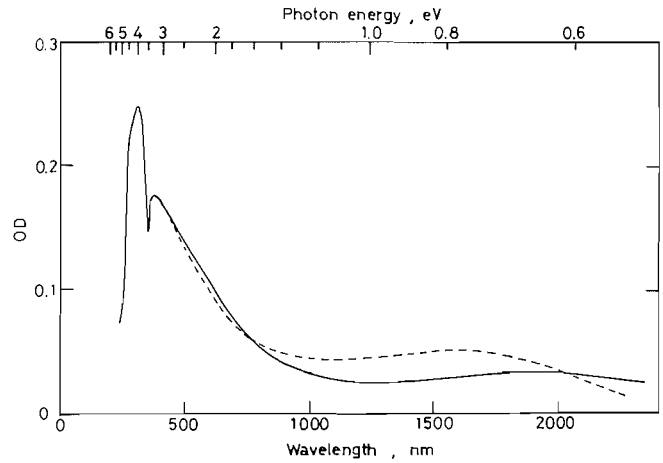

FIG. 1. Optical absorption spectra of photobleachable species in γ-irradiated nondoped LDPE (——) and LDPE doped with 3MP (---) system.

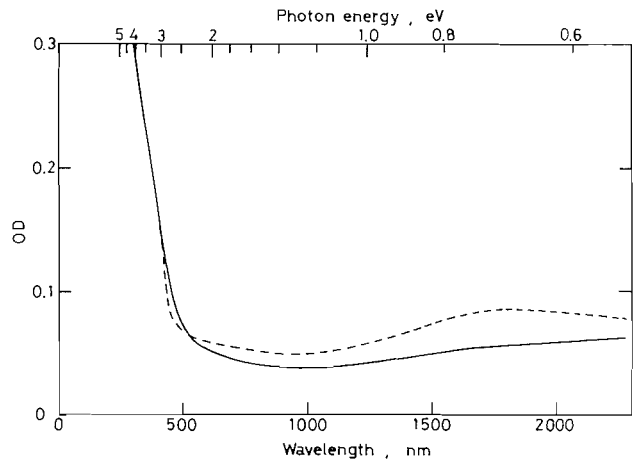

FIG. 2. Optical absorption spectra of photobleachable species in γ-irradiated nondoped HDPE (——) and HDPE doped with 3MP (---) system.

(1) Effect of 3MP doping on esr, optical absorption, and photoconductivity spectrum.

Some intermediate species produced in γ-irradiated LDPE and HDPE are photobleachable with visible light. We call these, "photobleachable species" through this work. Optical absorption spectra of photobleachable species in the γ-irradiated LDPE and HDPE sample were obtained by subtracting the

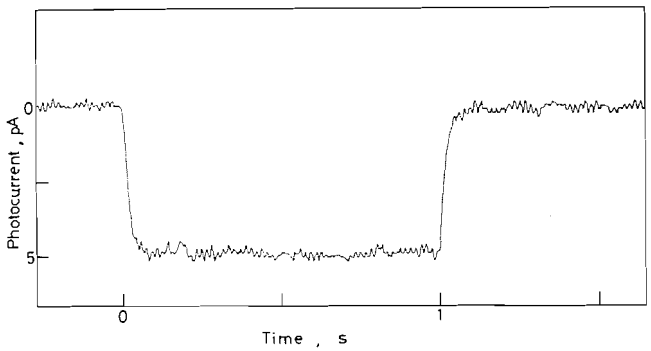

FIG. 3. Time profile of photocurrent in nondoped HDPE system. Wavelength of incident light was 1200 nm.

spectra of photobleached samples from those before the photobleach. Optical absorption spectra of photobleachable species in γ-irradiated nondoped LDPE and HDPE are shown as the solid line in Figs. 1 and 2, respectively. The optical absorption spectrum of bleachable species in LDPE in Fig. 1 is similar to that in ref. 5. In the case of HDPE, the spectrum was not measured at wavelengths shorter than ~300 nm because of the lack in transparency of HDPE films.

An example of photocurrent from γ-irradiated HDPE is shown in Fig. 3. The rise time of the amplifier was 100 or 300 ms through this work. In Fig. 3 it is shown that the photocurrent rises instantaneously when the shutter, through which the incident light comes, is opened and falls instantaneously to zero when the shutter is closed. Similar time profiles were obtained through this work. Photoconductivity spectra, meaning the photocurrent per incident photon versus the wavelength of incident light, for nondoped LDPE and HDPE system are plotted as circles in Figs. 4 and 5, respectively. The photoconductivity maxima at which the photocurrent per incident photon shows a maximum are ~280–300 nm for both nondoped LDPE and HDPE. This is similar to the result in ref. 26. It is interesting that for the nondoped LDPE system the photoconductivity spectrum is similar to the optical absorption spectrum (Figs. 1 and 4).

The amounts of 3MP dopant were 4 and 3 wt% for 3MP-LDPE and 3MP-HDPE systems, respectively. Doping of LDPE and HDPE with 3MP resulted in an increase in signal intensities of esr singlets. Since the amounts of samples for esr were not enough to neglect the quartz signal, we did not determine the increment of signal intensities as a result of 3MP doping. However, it can be obviously concluded from esr measurement that 3MP doping leads to an increase in esr singlet, which can be ascribed to trapped electrons. The nature of the singlets in 3MP-LDPE and 3MP-HDPE is different from those in nondoped LDPE and HDPE as will be described later.

The effect of 3MP doping on the optical absorption spectra of photobleachable species in LDPE and HDPE is clearly shown in Figs. 1 and 2, respectively. It is interesting to see that doping of LDPE and HDPE with 3MP causes the optical absorption spectra of photobleachable species to increase in the ir region and that the effect of 3MP doping is negligible in the visible and uv regions as is shown in Figs. 1 and 2.

Photoconductivity spectra for 3MP doped LDPE and HDPE are shown in Figs. 4 and 5, respectively together with those for nondoped LDPE and HDPE. The results from the photoconductivity spectra are similar to those from the optical absorption spectra in Figs. 1 and 2. In both cases of LDPE and HDPE in Figs. 4 and 5, doping with 3MP causes an enhancement in the spectrum in the ir region, but gives only a small and almost negligible effect in the visible and uv region, respectively.

From the results by esr it can be concluded that no impurity, which suppresses completely the formation of trapped electrons described above, exists in LDPE and HDPE systems and that 3MP doping causes the trapped electron yield to increase in LDPE and HDPE systems. Then both results by the optical absorption and photoconductivity measurements indicate that trapped electrons in 3MP doped systems are dominant in the ir region, which agrees well with the results on trapped electrons in low molecular hydrocarbon glasses.

The increase in the intensities in the optical and photoconductivity spectra as a result of 3MP doping in Figs. 1, 2, 4, and 5, indicates that new trapping sites for electrons are created by 3MP dopant molecules. The structure of the new trapping sites is not known at present. However, as is shown later, the nature of the new trapping sites is quite different from that in nondoped PE systems. It is generally expected that polymers swell when they absorb a low molecular substance. In the present case of LDPE and HDPE the increments in the volume after 3MP doping were 3.9 and 3.1% at room temperature, respectively. Although we did not measure the increase in the volume at 77 K, it can be said that the swelling of LDPE and HDPE is small at 77 K. If the swelling leads to a lower total density and if we ignore the role of doped 3MP molecules in new trapping sites, then the yield of trapped electrons in the swollen system would be lower than that in the nonswollen system. This is because the trapped electron yield is higher in HDPE than in LDPE (4). Therefore, doped 3MP molecules probably play an important role in the new trapping sites.

It is expected that 3MP molecules migrate into an amorphous region but not inside the crystalline region. The HDPE has less amorphous region than HDPE. Therefore the content of 3MP dopant in HDPE is actually less than that in LDPE. Nevertheless, the increment of trapped electrons as a result of 3MP doping in the HDPE system is even more than that in LDPE system as is seen in Figs. 1 and 2. This can be explained if we assume that electron traps are dominant in the interfacial region between the crystalline and amorphous part, which has been suggested by Kobayashi and Yahagi (17). Because of the existence of the esr singlet and optical absorption in the ir region and also from the reason which will be described later, we consider the existence of trapped electrons in γ-irradiated nondoped LDPE and HDPE. The role of doped 3MP molecules is not clear except that they contribute to form new trapping sites. New trapping sites are probably dominant in the interfacial region between the crystalline and amorphous parts as is described above. According to the cavity model for trapped electrons, potential wells with suitable depths and sizes are necessary (27). Therefore, some of doped 3MP molecules are arranged in PE to form suitable potential wells for new trapping sites.

In Fig. 6, power saturation curves, namely relative intensities of esr singlet signals versus square root of microwave power, for nondoped and 3MP doped HDPE system are shown. Since the power unit was not calibrated, only relative power values were available. The curves were adjusted to give the same intensity at the square root power of 2.236 au. It is seen from Fig. 6 that the signals for nondoped HDPE system saturate at a lower power than those for 3MP doped HDPE system. Namely, the new trapping sites which are formed as a result of 3MP doping show a different power saturation characteristic from that for trapping sites in nondoped PE system.

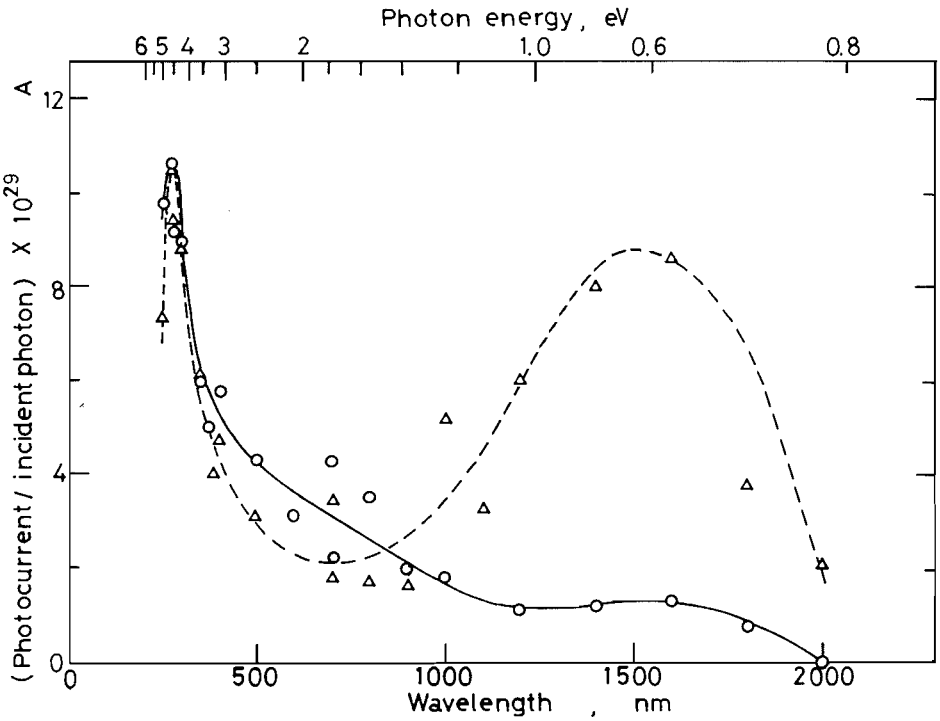

FIG. 4. Photoconductivity spectra for γ-irradiated nondoped LDPE (—○—) and LDPE doped with 3MP (--△--) system.

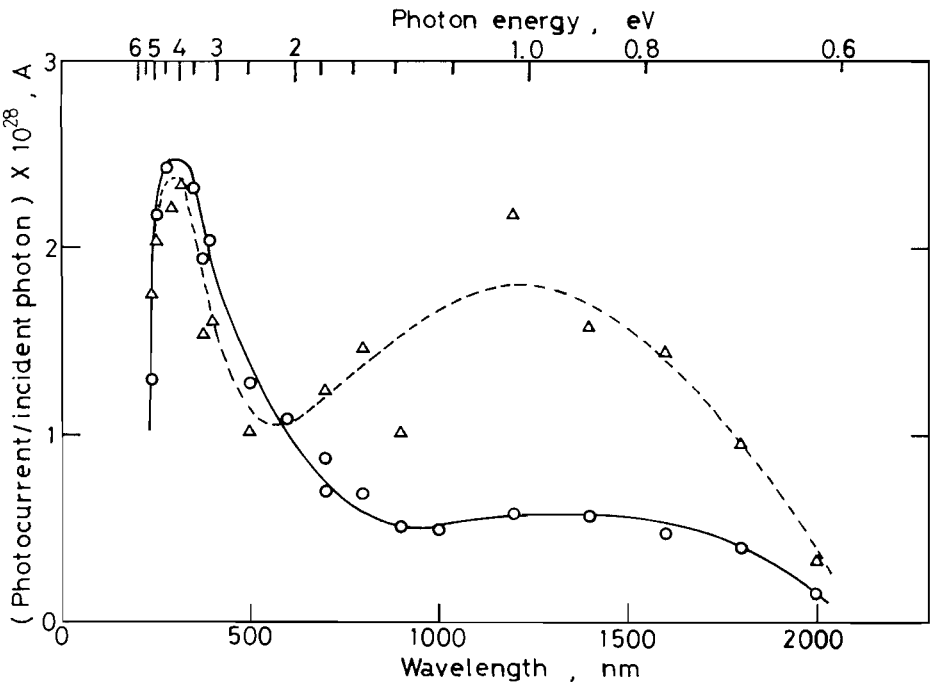

FIG. 5. Photoconductivity spectra for γ-irradiated nondoped HDPE (—○—) and HDPE doped with 3MP (--△--) system.

We do not intend to deny the existence of the cavity traps that include 3MP molecules in amorphous region. However, taking the fact that the increment of trapped electron yield as a result of 3MP doping in HDPE system is even more than that in 3MP doped LDPE system, it is better to say at present, that cavity traps that include 3MP are dominant in the interfacial region as is described above.

(2) Effect of doping with electron scavengers

It is well known that methylene chloride reacts with an electron to form Cl^- and the corresponding radical. It is also known that hexafluorobenzene reacts with an electron to form an anion (28). These dopants were used as electron scavengers. Contents of methylene chloride in LDPE and HDPE were 5 and 3 wt%, respectively and those of hexafluorobenzene in LDPE

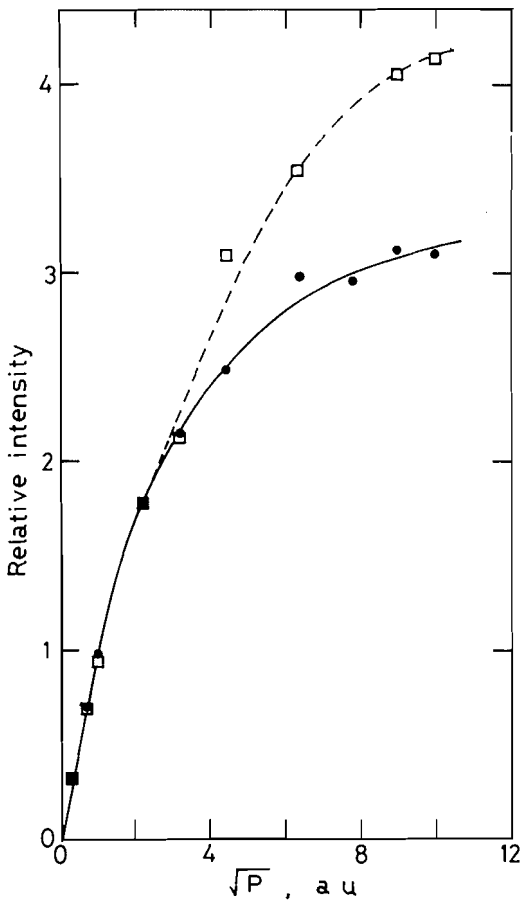

FIG. 6. Power saturation curves for singlet signals in esr spectra for nondoped HDPE (—●—) and HDPE doped with 3MP (--□--) system.

and HDPE were 4 and 2 wt%, respectively. Electron spin resonance measurements were made for LDPE and HDPE doped with methylene chloride and hexafluorobenzene γ-irradiated at 77 K. In each of these four systems (CH_2Cl_2-LDPE, C_6F_6-LDPE, CH_2Cl_2-HDPE, and C_6F_6-HDPE) it is hard to discern the singlet which is ascribed to trapped electrons. So, even if trapped electrons exist in these systems, the amount should be low.

Optical absorption measurements have also revealed that doping with methylene chloride or hexafluorobenzene reduces drastically the specrum in the ir region. This is shown in Fig. 7 for HDPE systems. In the case of C_6F_6 doping the spectrum in the visible region is higher than that in the nondoped HDPE because of the tail of $C_6F_6^-$ absorption. In the case of LDPE systems, similar results as those in Fig. 7 were obtained. However, the spectra in the ir region for the CH_2Cl_2 and C_6F_6 doped LDPE systems were almost negligible, indicating that electron scavenging by these scavengers in this system is more effective. In conclusion, dopants reduce drastically the spectrum in the ir region whereas the spectrum in the visible and uv regions is almost the same or increases because of the absorption of $C_6F_6^-$. Then it can be said that the optical absorption by trapped electrons in LDPE and HDPE is dominant in the ir region. This is also supported by the results from esr and agrees well with the results from low molecular hydrocarbon glasses.

Photoconductivity spectra for nondoped, CH_2Cl_2 doped, and C_6F_6 doped systems are shown in Figs. 8 and 9 in the case of

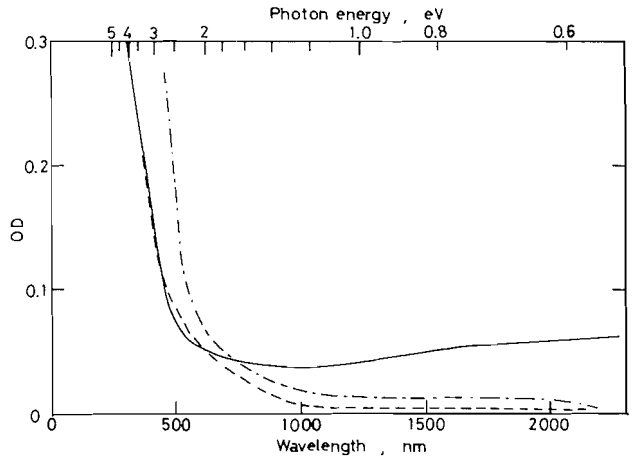

FIG. 7. Optical absorption spectra of photobleachable species in γ-irradiated nondoped HDPE (——), CH_2Cl_2 doped HDPE (– – –), and C_6F_6 doped HDPE (–·–·–) system.

LDPE and HDPE, respectively. It should be noted from Fig. 8 that doping with methylene chloride and hexafluorobenzene in LDPE systems suppresses considerably the photoconductivity spectra in the ir region but that the effect of doping is negligible in the uv region. In the case of HDPE, the photoconductivity spectra are suppressed by the doping as is seen in Fig. 9. In the uv region around the photoconductivity peak in Fig. 9, it can be said that the effect of the doping is small, although the curve for CH_2Cl_2-HDPE system and that for C_6F_6-HDPE system are somewhat higher and lower than that for the nondoped HDPE system, respectively. In both cases of LDPE and HDPE, the photoconductivity spectra in the visible region are suppressed by the doping with these electron scavengers. The reason for this may be as follows. Photoconductivity spectra of trapped electrons in LDPE and HDPE may have relatively high intensities compared with the photoconductivity maxima. This is observed in 3-methylheptane glass where the photoconductivity maximum lies at ~1000 nm but the intensity at 500 nm is 73% of the peak intensity at ~1000 nm (2). An alternative explanation for the suppression of photoconductivity spectra in the visible region by the doping may be that these dopants might suppress a precursor (other than trapped electrons) which gives the photocurrent. The photocurrent in γ-irradiated hydrocarbons is generally explained by the detrapping of electrons from their traps. However, we will suggest below a process of photocurrent generation which does not involve trapped electrons. This process is responsible for the photocurrent for the LDPE and HDPE systems doped with those electron scavengers in Figs. 8 and 9.

(3) Electron spin resonance, optical absorption, and photoconductivity spectrum for P4MP systems

No singlet which is ascribed to trapped electrons was observed in the esr spectrum for the γ-irradiated P4MP system. Optical absorption measurements for γ-irradiated P4MP showed that photobleachable species are produced also in this system. The optical absorption spectrum exists in the uv and the visible region, but only the absorption tail in the ir region up to 1400 nm. This indicates that trapped electrons are not produced in P4MP used in the present study. Nevertheless, we observed a photocurrent for the γ-irradiated P4MP system. In Fig. 10 the photoconductivity spectrum for the P4MP system is shown

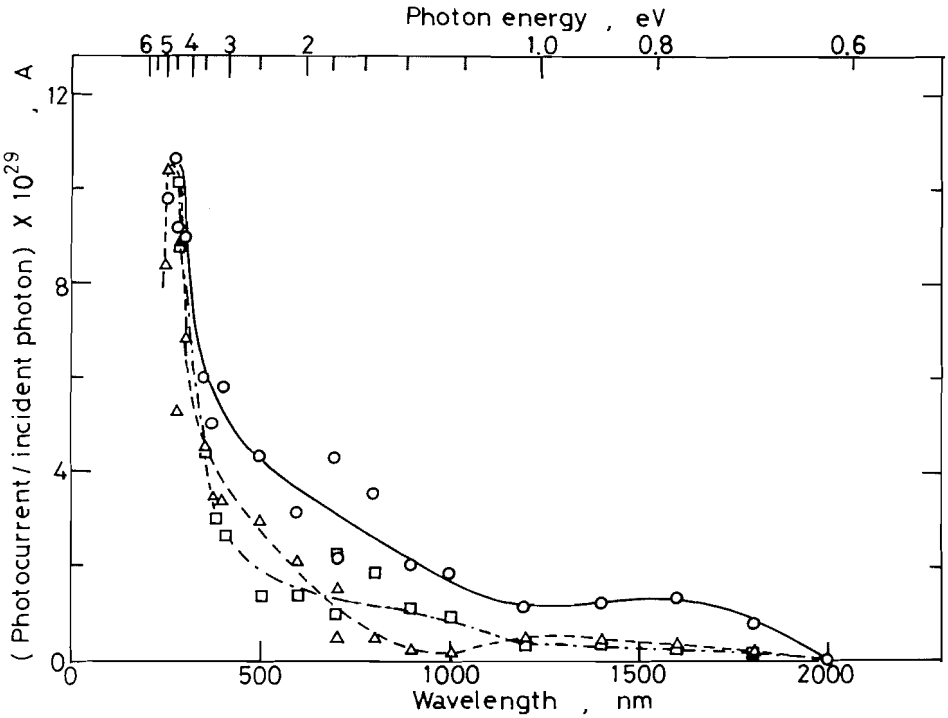

FIG. 8. Photoconductivity spectra for γ-irradiated nondoped LDPE (—○—), CH_2Cl_2 doped LDPE (--△--), and C_6F_6 doped LDPE (-·-□-·-) system.

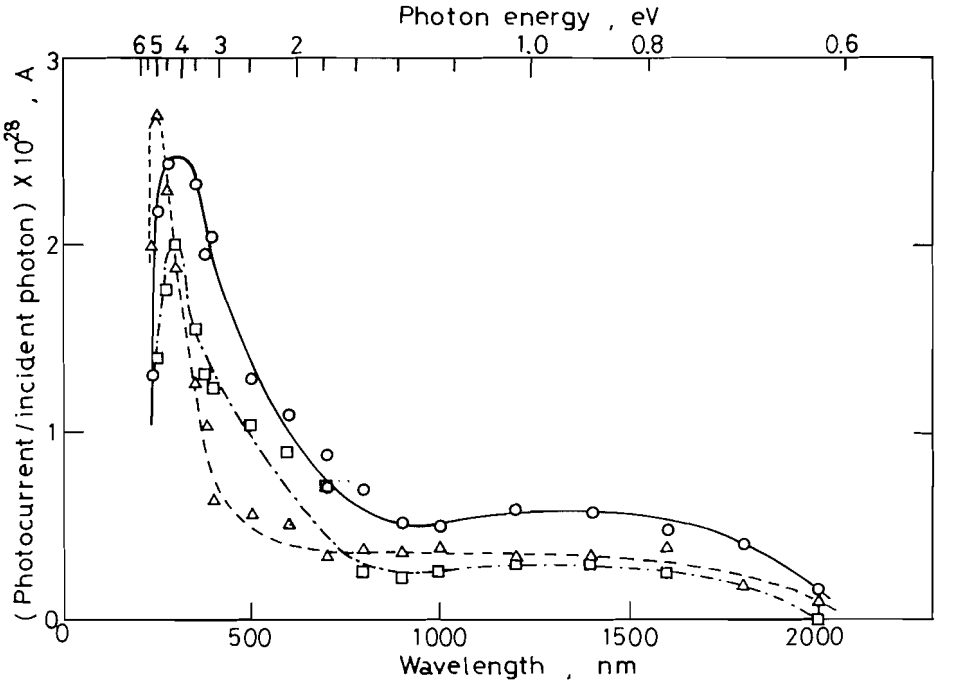

FIG. 9. Photoconductivity spectra for γ-irradiated nondoped HDPE (—○—), CH_2Cl_2 doped HDPE (--△--), and C_6F_6 doped HDPE (-·-□-·-) system.

together with the optical absorption spectrum of photobleachable species. It is interesting to note that the two curves in Fig. 10 fit well with each other except for the long wavelength side. It should be noted that the photoconductivity spectrum for the P4MP system in Fig. 10 is similar to those for the CH_2Cl_2 doped and C_6F_6 doped LDPE systems in Fig. 8 and, also, to those CH_2Cl_2 doped and C_6F_6 doped HDPE systems in Fig. 9. These five conductivity spectra described above indicate that photocurrent generation from the process of photodetrapping of trapped electrons is negligible because singlets in esr signals for these five systems are negligible. It is also interesting to note that the five photoconductivity spectra for the P4MP, CH_2Cl_2-LDPE, C_6F_6-LDPE, CH_2Cl_2-HDPE, and C_6F_6-HDPE systems have maxima at nearly the same position, 300 nm.

We did not observe photobleachable optical absorption in the ir region. This does not agree with the results in ref. 4. This

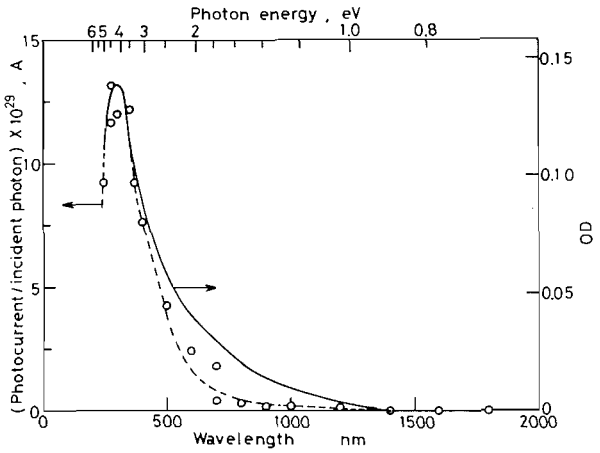

FIG. 10. Optical absorption spectrum of photobleachable species (——) and photoconductivity spectrum (––O––) for γ-irradiated P4MP system.

discrepancy may arise from the difference in P4MP itself. Unfortunately we could not obtain P4MP from the same company as that in ref. 4.

(4) Mechanism of photocurrent generation other than photodetrapping of trapped electrons

In TL studies heat detrapping of electrons from their traps and subsequent recombination are proposed as a mechanism of TL (7, 8, 10, 13). It has been found that similar glow peaks as those in TL are obtainable in TSC work. Then, photodetrapping of electrons from their traps has been proposed as a mechanism of photocurrent generation (17, 19). In the present study it is true that photocurrent by photodetrapping of trapped electrons is dominant in the ir region in the case of the LDPE and HDPE systems, as is described already. However, another mechanism other than photodetrapping of trapped electrons is necessary for photocurrent generation in the uv and perhaps in the visible region.

The mechanism of photocurrent generation other than photodetrapping of trapped electrons is not clear at present. One of the provable mechanisms is photodetachment of electrons from carbanions which are formed by the reaction between radicals and electrons:

$$RH \rightsquigarrow R^+ + e^-$$
$$R^+ + e^- \longrightarrow R\cdot + H$$
$$R\cdot + e^- \longrightarrow R^-$$
$$R^- \xrightarrow{h\nu} R\cdot + e^-$$

Willard *et al.* have shown that the absorption onset of 3-methylhexane carbanion is longer than 800 nm (29). It is not clear, however, whether electrons are photodetachable by the visible light. In the case of polyethylene it may be possible for electrons to be photodetached from carbanion by visible light because the electron affinities for $CH_3\cdot$, $C_2H_5\cdot$, n-$C_3H_7\cdot$, and iso-$C_3H_7\cdot$ are ~1.08–1.8, 1.4, 1.0, and ~1.0 eV, respectively (30). Optical absorption spectra of bleachable species in the uv region for the LDPE, HDPE, and P4MP systems, shown in Figs. 1, 2, and 10, respectively, could be ascribed to carbanions. The spectrum of 3MP carbanion in the uv region proposed by Willard *et al.* (31) is similar to ours but the absorption maximum is slightly shorter than ours.

Voltammetric studies of the electrochemical behaviour of salicylidene-2-aminopyridine at a hanging-mercury-drop-electrode

REFAT ABDEL-HAMID
Department of Chemistry, Faculty of Science, Sohag, Egypt

Received August 9, 1985

REFAT ABDEL-HAMID. Can. J. Chem. **64**, 702 (1986).

Electrochemical behaviour of salicylidene-2-aminopyridine has been investigated in 0.1 *M* tetraethylammonium perchlorate – dimethylformamide solutions by cyclic voltammetric and convolution potential sweep voltammetric methods. It was found that the depolarizer exhibits two well-defined diffusion-controlled irreversible one-electron waves. The cyclic voltammetric characteristics and the convolution, deconvolution, and logarithmic convolution analyses reveal that salicylidene-2-aminopyridine in such conditions follows a set of two one-electron transfer reactions each followed by an irreversible chemical reaction. The values of the first-order rate constant of the irreversible chemical reaction and $E_{1/2}$ were computed.

REFAT ABDEL-HAMID. Can. J. Chem. **64**, 702 (1986).

Faisant appel à des méthodes de voltamétrie cyclique et de voltamétrie à balayage de potentiel avec convolution et opérant dans des solutions à 0,1 *M* de perchlorate de tétraéthylammonium dans le diméthylformamide, on a étudié le comportement électrochimique de la base de Schiff formée par l'aldéhyde salicylique et l'amino-2 pyridine. On a trouvé que le dépolarisant présente deux vagues monoélectroniques, bien définies, irréversibles et contrôlées par la diffusion. Les caractéristiques de la voltamétrie cyclique, de la convolution, de la déconvolution et des analyses logarithmiques de la convolution suggèrent que, dans les conditions utilisées, la base de Schiff suit un mécanisme électronique–chimique–électronique–chimique. On a calculé les valeurs des constantes de vitesse du premier ordre de la réaction chimique irréversible ainsi que de $E_{1/2}$.

[Traduit par la revue]

Introduction

The electrochemical reduction mechanism of numerous aromatic imines or Schiff bases at a mercury electrode has been investigated in aprotic media (1–6). Relatively few studies, on the other hand, have concerned the electrochemical behaviour of heteroaromatic Schiff bases (7). In view of the considerable success achieved by others in clarifying the mechanism of reduction of aromatic hydrocarbons and carbonyl compounds through investigations in aprotic solvents, a study of the electrochemical reduction behaviour of heteroaromatic Schiff bases in *N,N*-dimethylformamide was undertaken.

This communication is concerned with electrochemical reduction of salicylidene-2-aminopyridine as investigated by cyclic voltammetry and convolution and deconvolution potential sweep voltammetry. The reduction mechanism at the hanging-mercury-drop-electrode (HMDE) is elucidated and discussed.

Experimental

Salicylidene-2-aminopyridine was synthesized by the condensation of salicylaldehyde with 2-aminopyridine in a 1:1 ratio in an ethanolic solution as reported earlier (8). The solid product obtained was recrystallized from ethanol. Tetraethylammonium perchlorate (Fluka) was recrystallized from methanol and dried in a vacuum oven at 60°C. *N,N*-Dimethylformamide (A.R. grade BDH) was purified by passing it through active neutral alumina as described elsewhere (9).

Fresh stock solution of tetraethylammonium perchlorate (TEAP) (0.1 mol dm^{-3}) in dimethylformamide (DMF) was prepared. Fresh stock solution of the Schiff base (10 m*M*) was prepared from a fresh electrolyte solution on the same day that measurements were carried out.

The experiments were performed using 0.1 *M* TEAP/DMF as supporting electrolyte. The measurements were done using a three electrode cell. It consists of a hanging mercury electrode with surface area of 1.05×10^{-2} cm^2 as working electrode, $Ag/AgNO_3$ (0.01 *M*) in 0.1 *M* TEAP/DMF as reference electrode and 1-cm^2 platinum sheet as auxiliary electrode.

Cyclic voltammetry was performed using an E.G. & G. PAR model 363 scanning potentiostat–galvanostat. The current response and potentials were stored on magnetic disk via a fast data-capture system based upon twin chanel 12-bit analogue-to-digital converter (50 μs conversion time) and a Gemini Galaxy 2 microcomputer. Data capture was written in Macro 80 assembler language which allowed a minimum acquisition time of 100 μs per point. In all experiments 500 data points were routinely captured, equally spaced in time, with a time interval appropriate to the time-scale of the particular experiment. Background data were also stored, and were subtracted from the experimental data set, minimizing effects such as double-layer charging currents.

Solutions were purged with nitrogen before each experiment and an atmosphere of nitrogen was maintained above the working solution. Internal resistance ohmic drop distortions were minimized by applying positive feedback compensation.

Convolution and deconvolution procedures were carried out according to the method described earlier (10). The convolution logarithmic analysis was carried out on the basis of the following general equations[1]

$$[1] \quad -\xi = \ln\left[\frac{(I_{lim} - I_1)}{I_2\left(\frac{D_A}{D_B}\right)^{1/2} + \frac{I_{lim} i \exp(1-\alpha)\xi)}{i_o}}\right]$$

and

$$[2] \quad -\alpha\xi = \ln\left[\frac{I_{lim} - I_1 - I_2(D_A/D_B)^{1/2}\exp(-\xi)}{I_{lim}\frac{i}{i_o}}\right]$$

where $\xi = (E - E^\theta)nF/RT$, α is the symmetry factor, I_1 and I_2 are the convolution currents given in eqs. [3] and [4], respectively, I_{lim} is the limit of I_1 and E approaches infinity and i_o is the exchange current for the electron-transfer process at $E = E^\theta$.

$$[3] \quad I_1'' = I_1(t) = \pi^{-1/2}\int_0^t \frac{i(u)}{(t-u)^{\frac{1}{2}}}du$$

$$[4] \quad I_2' = I_2(k',t) = \pi^{-1/2}\int_0^t \frac{i(u)\exp(-k_c'(t-u))}{(t-u)^{\frac{1}{2}}}du$$

Results and discussion

It has been found that salicylidene-2-aminopyridine was readily hydrolysed in aqueous and aqueous–organic solvent media into their parent constituents (8, 12). Thus, *N,N*-dimethylformamide is a convenient medium for this electrochemical investigation. Furthermore, studies in DMF give a more direct insight into the electrochemical properties of the azomethine group since, under the usual conditions, a preprotonation step can be excluded in this solvent.

Cyclic voltammograms of salicylidene-2-aminopyridine in anhydrous *N,N*-dimethylformamide containing 0.1 mol dm^{-3} tetraethylammonium perchlorate as supporting electrolyte show two well-defined irreversible waves. The reversal peaks of the two waves are almost nonexistent, indicating that the two waves correspond to two slow one-electron transfers or a fast one-electron transfer coupled with a rapid chemical reaction. The cathodic peak currents, i_p, of the two waves correlated with the square root of the sweep rate, $\nu^{1/2}$, with correlation coefficients of 0.9997 and 0.9987 for the first and second waves, respectively. They are also proportional to the concentration of the Schiff base in the range 0.49–1.19 × 10^{-3} *M* (r = 0.9967 and 0.9970, respectively). These are consistent with diffusion as the rate-limiting step (13). A number of electrochemical criteria are applied to establish the nature of the two waves.

The widths of the first cyclic voltammetric wave ($E_p - E_{p/2}$) at different sweep rates are observed to be insignificantly greater than the theoretical value expected for a reversible charge-transfer step (Table 1) (13). The peak potential, E_p, does shift in a negative direction with increasing scan rate. The plot of E_p against log ν yields a straight line with a slope less than 28.8 mV per decade (−6.9 ± 1 mV). Both observations are indicative of reversible electron transfer coupled with a follow-up chemical reaction (13, 14). This reaction could be regarded as a protonation of the Schiff base radical anion (2).

The variation of current function, $i_p/\nu^{1/2}$, with scan rate ν is an important diagnostic criterion for establishing the type of mechanism by cyclic voltammetry. For a reversible electronic process followed by an irreversible chemical process ($E_{rev}C_{irr}$) the current function should slightly increase with scan rate (15). The ratio slowly increases with scan rate (Table 1) revealing that the observed behaviour is consistent with a reversible electron-transfer process followed by a first-order irreversible chemical reaction.

Convolution of the cyclic voltammetric data of salicylidene-2-aminopyridine is carried out according to eqs. [3] and [4]. Figure 1 illustrates convoluted currents I_1 and I_2 cyclic voltammograms for the first wave of 1.19 × 10^{-3} *M* solution. It is clear that the convoluted current I_1 does not reach the same plateau value, regardless of the scan rate, and does not return

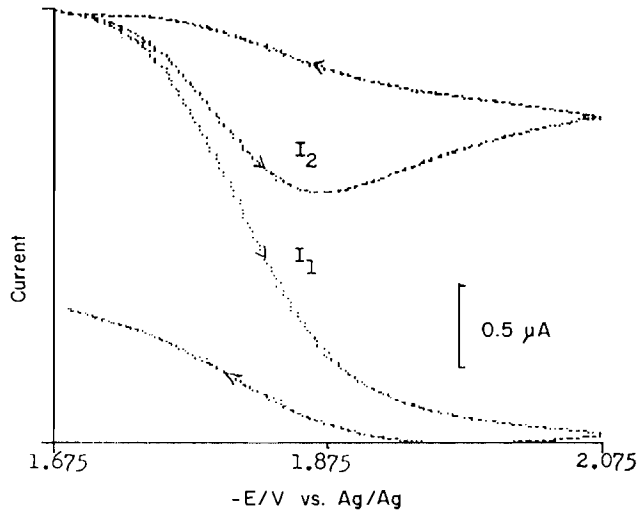

FIG. 1. Cyclic convoluted currents I_1 and I_2 voltammograms for the first wave of 1.19 × 10^{-3} *M* salicylidene-2-aminopyridine in 0.1 *M* TEAP/DMF solution at ν = 500 mV s^{-1}.

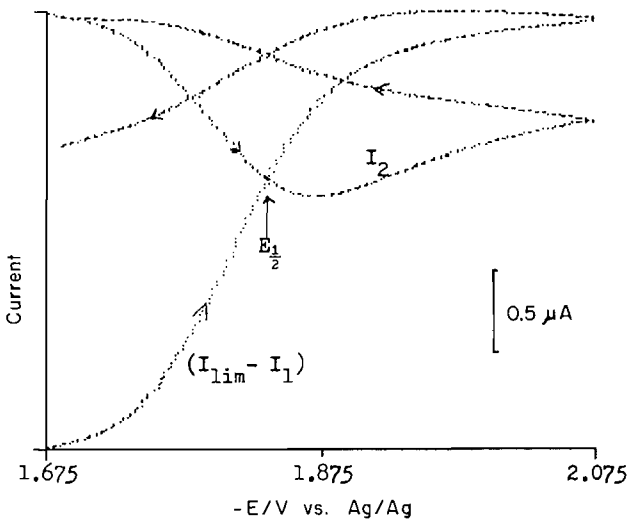

FIG. 2. Curves of ($I_{lim} - I_1$) for the correct treatment of k_c, I_2, and $E_{1/2}$ for the first wave of salicylidene-2-aminopyridine in 0.1 *M* TEAP/DMF solution at ν = 500 mV s^{-1}.

during the reverse half of the sweep to its initial (zero) value. This shows that the starting material is not conserved within the course of the cycle. This behaviour can be ascribed to irreversible electron-transfer or reversible electron-transfer coupled with a rapid chemical reaction.

Deconvolution cyclic voltammetric results reveal that the

[a]Deconvoluted peak current potential.
[b]$k_c \pm 4\%$.

anodic to cathodic deconvoluted peak-current ratio, dI_{1pa}/dI_{1pc}, is almost less than unity (0.28) through the scan rate range used. This is consistent with the reversible electron-transfer process followed by an irreversible first-order chemical reaction ($E_{rev}C_{irr}$ mechanism), because the anion radical formed is removed from the vicinity of the electrode surface by reaction as well as by diffusion.

The first-order rate constant of the following chemical reaction, k'_c, the convoluted current I_2, and $E_{1/2}$ of the first wave are computed using the digital simulation and experimental data according to the method described earlier[1] (Table 1). The method relies on the equality of $(I_{lim} - I_1)$ and I_2 on both the forward and reverse halves of the sweep at $E = E_{1/2}$, where $E_{1/2} = E^\theta + (RT/nF) \ln (D_A/D_B)^{1/2}$. This is done by iterating different values of k'_c. If the k'_c value used to compute I_2 is large the crossing point of the $(I_{lim} - I_1)$ and $I_2 - E$ curves on the reverse sweep lies negative of the crossing on the forward sweep and I_2 rapidly changes sign after this point. For the low value of k'_c used, the crossing point on the return lies positive of the crossing on the forward scan and I_2 fails to return to zero at the end of the sweep. The correct treatment of data, the correct convoluted I_2 data, and the k'_c and $E_{1/2}$ values show zero displacement of the crossings which both lie at correct $E^{1/2}$. Also I_2 reaches zero at the end of the sweep. The crossing points of $(I_{lim} - I_1)$ and I_2 as a function of potential are demonstrated in Fig. 2 for the correct treatment of data as a representative example.

The convolution logarithmic analysis is tested for various reaction schemes (E_{rev}, EC, CE, E_{irr}, ECE, ...) according to eqs. [1] and [2]. In the sweep-rate range used, it is found that the data of the first wave fit satisfactorily the following equation

$$[5] \quad -\frac{(E - E^\theta)}{RT} nF = \ln[(I_{lim} - I_1)/I_2]$$

It gives rise to straight lines (correlation coefficients nearly one) with slopes close to 39.88 V^{-1} (at 18°C) expected for an $E_{rev}C_{irr}$ mechanism. This gives further support to the above conclusion that the first wave is ascribed to a reversible one-electron transfer followed by irreversible first-order chemical reaction.

The cyclic voltammetric results in the study of the second wave are recorded in Table 2. It can be seen that $(E_p - E_{p/2})$ is slightly greater than the value expected for a reversible process and E_p does shift towards more negative potentials, to the extent of −24.5 mV per log ν unit. Furthermore, the ratio $i_p/\nu^{1/2}$ decreases on increasing the scan rate. All the above evidence suggests that the irreversibility of the second wave is due to a moderately fast first-order reaction involving the product of the second electron-transfer.

Examination of the convoluted cyclic voltammetric data (I_1) for the second wave shows that I_1 during the reverse of the sweep, whatever the scan rate, does not coincide with I_1 on the forward scan and also it does not reach its initial (zero) value at the end of the sweep. Moreover, the anodic-to-cathodic deconvoluted peak-current ratio is always less than unity (0.37) through the scan rate range used. These facts indicate very good consistency of the data and provide a further verification of the $E_{rev}C_{irr}$ mechanism. The first-order rate constants of the follow-up reaction are computed as mentioned above and the values obtained are collected in Table 2.

Logarithmic analysis of the convoluted results is tested for various mechanisms and it is found that the data follow satisfactorily the $E_{rev}C_{irr}$ mechanism.

Taking into account the acid–base properties of the salicylidene-2-aminopyridine (HSAP) ($pK_a = 8.25$ in aqueous solutions (16)), the radical anions should be rapidly protonated by the starting compound through the "father–son" reaction (17) (reactions *ii* and *iv*).

Thus, the whole electrochemical reduction of HSAP in anhydrous *N*,*N*-dimethylformamide can be represented as follows:

$$[i] \quad HSAP + e \rightleftharpoons HSAP^{\cdot-}$$

$$[ii] \quad HSAP^{\cdot-} + HSAP \xrightarrow{k'_c} HSAPH^{\cdot} + SAP^- \quad \Big\} \text{1st wave}$$

$$[iii] \quad HSAPH^{\cdot} + e \rightleftharpoons HSAPH^-$$

$$[iv] \quad HSAPH^- + HSAP \xrightarrow{k'_c} HSAPH_2 + SAP^- \quad \Big\} \text{2nd wave}$$

SHAWN E. RAMER, RICHARD N. MOORE, and JOHN C. VEDERAS. Can. J. Chem. **64**, 706 (1986).

The ring closure of *N*-benzyloxycarbonyl-L-serine (**1**) under Mitsunobu conditions (Ph_3P, dimethyl azodicarboxylate, −78°C) to give the corresponding β-lactone (**2**) is shown by deuterium and oxygen-18 labelling studies to proceed by hydroxy group activation, in contrast to analogous cyclizations of more hindered β-hydroxy acids, which usually occur by carboxy group activation. Samples of **1** stereospecifically labelled with deuterium at C-3 were prepared by hydrogenation of (*Z*)-2-acetamido-3-methoxyacrylic acid (**9**) with deuterium, followed by selective Acylase I deacetylation of the 2*S* isomer, removal of the protecting groups, and *N*-acylation of the resulting L-serine with benzyl chloroformate. Mitsunobu cyclizations of this 3*R* deuterated *N*-acyl serine, of the [hydroxy-^{18}O] analog **1***g*, and of the [carboxy-^{18}O] derivative **1***f* show that lactonization occurs with inversion of configuration at C-3, loss of the hydroxy oxygen, and retention of the carboxy oxygens. Similar labelling experiments demonstrate that aqueous sodium hydroxide opens the β-lactone ring by exclusive attack at the carbonyl to regenerate **1**, whereas acidic hydrolysis proceeds primarily by attack of water at the C-3 methylene group of **2**. This information allows interconversion of L-serines that are stereospecifically labelled at C-3 with hydrogen isotopes and affords access to other labelled β-substituted alanines.

SHAWN E. RAMER, RICHARD N. MOORE et JOHN C. VEDERAS. Can. J. Chem. **64**, 706 (1986).

Faisant appel à des études par marquage au deutérium et à l'oxygène-18, on a démontré que la cyclisation de la *N*-benzyloxycarbonyl L-sérine (**1**), dans des conditions de Mitsunobu (Ph_3P, azodicarboxylate de diméthyle, −78°C), qui conduit à la formation de la β-lactone corespondante se produit par le biais d'une activation du groupement hydroxyle; ceci est en opposition avec ce qui se produit lors de cyclisations analogues d'acides β-hydroxylés plus empêchés qui se produisent habituellement par le biais d'une activation du groupement carboxyle. On a préparé des échantillons de **1** marqués stéréospécifiquement par du deutérium en C-3 en procédant à une hydrogénation de l'acide acétamido-2 méthyoxy-3 acryliques-(*Z*) (**9**) avec du deutérium suivie d'une déacetylation sélective de l'isomère 2-(*S*) par l'Acylase I, de l'enlèvement des groupes protecteurs et finalement d'une *N*-acylation de la L-sérine qui en résulte par du chloroformate de benzyle. Les cyclisations, selon Mitsunobu, de cette *N*-acyl sérine deutérée en 3(*R*), de son analogue **1***g* portant un hydroxyle ^{18}O et du dérivé **1***f* portant un carboxyle ^{18}O démontrent que la lactonisation se produit avec une inversion de configuration en C-3, avec une perte d'oxygène de l'hydroxyle et avec rétention des oxygènes des groupements carboxyles. Des expériences semblables de marquage ont permis de démontrer que, sous l'influence de l'hydroxyde de sodium aqueux, le cycle de la β-lactone s'ouvre par une attaque qui se produit exclusivement au niveau du groupement carbonyle pour regénérer le composé **1** alors que l'hydrolyse acide se produit principalement par une attaque de l'eau au niveau de groupement méthylène en C-3 du composé **2**. Cette information permet une interconversion de L-sérine qui sont stéréospécifiquement marquées en C-3 avec des isotopes de l'hydrogène et permet un accès facile à d'autres alanines β-substituées qui seraient marquées.

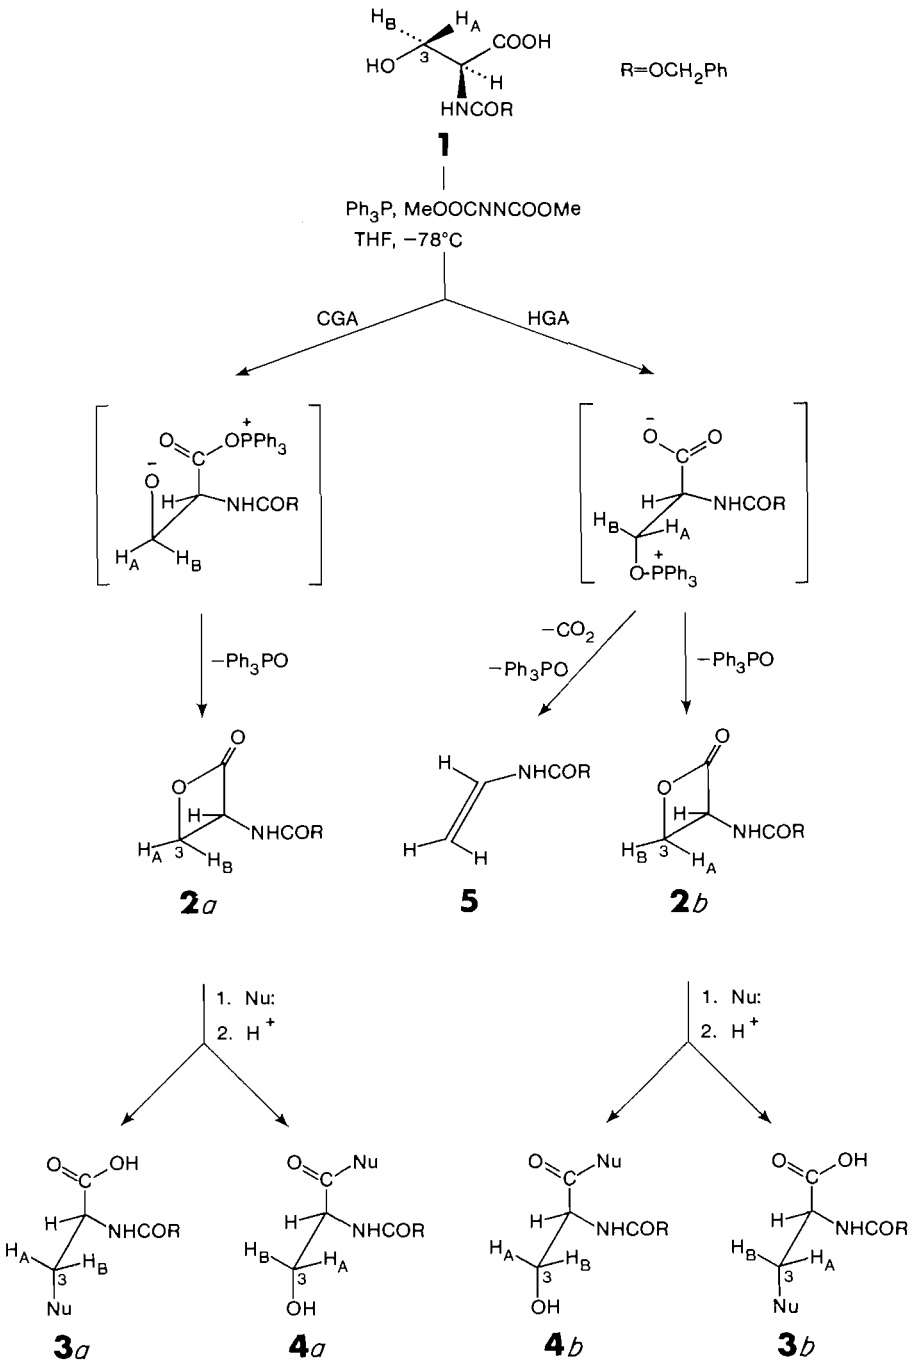
[Traduit par la revue]

Introduction

The Mitsunobu reaction (1) of β-hydroxy carboxylic acids can produce alkenes and (or) β-lactones depending on substrate structure and solvent polarity (2–5). Although a number of earlier attempts to cyclize serine derivatives to β-lactones with various reagents proceeded in low to modest yields (≤1% to 45%) (6–11), we recently reported that reaction of optically pure *N*-acyl serines (e.g., **1**) under slightly modified Mitsunobu conditions (triphenylphosphine and dimethyl azodicarboxylate, −78°C) gives β-lactones (e.g., **2**), without racemization, in good yield (60–72%) (Scheme 1) (12). Previous investigations on the mechanism of the Mitsunobu reaction have shown that an initially-formed triphenylphosphine–azodicarboxylate adduct (13,14) can react with β-hydroxy acids to give either hydroxy group activation (HGA) or carboxy group activation (CGA) (2, 4). Although *intermolecular* Mitsunobu coupling of alcohols with carboxylic acids to form esters generally proceeds by the HGA pathway (1,13), this type of activation of β-hydroxy acids has been reported to result primarily in decarboxylative elimination to olefinic products (2–5). In the cases previously studied, β-lactone products arose principally by the CGA pathway (2,4). Since serine β-lactones are versatile intermediates for synthesis of important β-substituted alanines **3** (Scheme 1) (12), and the availability of the latter compouds stereospecifically labelled with hydrogen isotopes at C-3 would be useful for studies of enzyme mechanisms (15,16), we decided to examine the mode of formation of serine β-lactone **2** using *N*-benzyloxycarbonyl serine (**1**) labelled with oxygen-18 and deuterium at C-3. The site of nucleophilic attack on **1** by water and hydroxide to form **3** and **4** (Scheme 1, Nu = OH) was also investigated.

It is well established that ester or lactone formation by the HGA process in the Mitsunobu reaction proceeds with inversion of configuration at the carbon bearing the hydroxyl, whereas the CGA mechanism results in retention at that position (1, 2, 4). Therefore the position of activation during formation of serine β-lactones can be determined by cyclization of an *N*-protected serine that is stereospecifically labelled with deuterium at C-3. For example, a sample of protected L-serine **1** bearing deuterium in the H_B (pro *R*) position would cyclize to β-lactone **2***a* (^{2}H and nitrogen *cis*) or **2***b* (^{2}H and nitrogen *trans*) depending on whether the reaction follows the CGA or HGA pathway (Scheme 1). Similarly, nucleophilic opening at C-3 of **2***a* or **2***b* would result in inversion of configuration at that carbon to give

[1]Author to whom correspondence should be addressed.



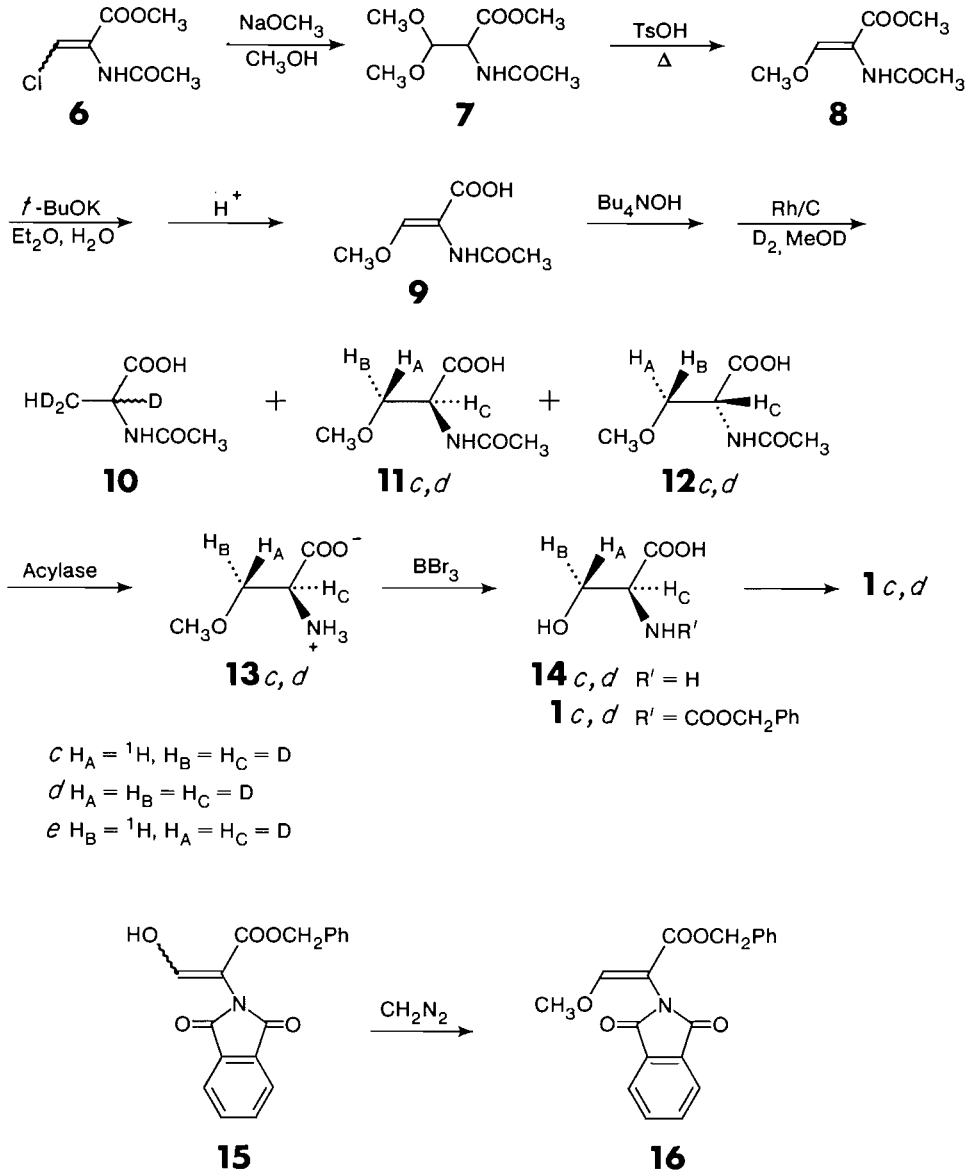
SCHEME 1

3*a* or 3*b*, respectively, whereas carbonyl attack would give 4*a* or 4*b*. If the nucleophile (Nu) is water or hydroxide, isotopic labelling is essential to distinguish between the two types of ring cleavage. Early studies on reaction of β-butyrolactone with [^{18}O]water (17) and on hydrolysis kinetics of β-propiolactone (18) report alkyl-oxygen cleavage at neutral pH and acyl-oxygen fission under strongly acidic or basic conditions.

A number of syntheses of serine labelled stereospecifically with deuterium or tritium at C-3 have been reported (19–26), but many either lack stereochemical purity or are able to produce only very small quantities of material after considerable effort. However, a recent synthesis published while our work was in progress utilizes an approach similar to the one described here (26).

Results

One of the required intermediates, *N*-benzyloxycarbonyl (2*S*, 3*R*)-[2,3-^{2}H$_2$]serine (**1***c*), was synthesized as shown in Scheme 2. Treatment of the known (27) protected chlorodehydroalanine **6** with sodium methoxide in methanol gives the acetal **7** in 96% yield. Elimination of methanol affords exclusively the *Z* isomer of the dehydroserine derivative **8**. The geometry of the double bond was confirmed by nmr spectral comparison to a large number of analogous compounds, including **16** and its *E*



SCHEME 2

isomer, which were prepared by *O*-methylation of 3-oxoalanine derivatives (e.g., **15**) with diazomethane. The structure of the *Z* isomer **16** was determined by X-ray crystallographic analysis.[2] An ORTEP drawing is shown in Fig. 1.

Attempts to hydrogenate the ester **8** with deuterium gas using a variety of conditions gave a mixture of serine and alanine derivatives. Moreover, the ^1H nmr spectra of the resulting serine showed some hydrogen at C-2 and a significant scrambling of deuterium stereochemistry at the C-3 position. Therefore the methyl ester was hydrolysed to the acid **9** using conditions (28) that avoided Michael addition of hydroxide, and the correspoding tetrabutylammonium salt was prepared to decrease the amount of *N*-acetylalanine (**10**) formed during hydrogenation with deuterium. Under optimal conditions (5% Rh/C, methanol-d_1) the deuteration yields the desired 2*S*,3*R* and 2*R*,3*S* compounds **11***c* and **12***c*, respectively, as well as the corresponding trideuterio racemate, **11***d* and **12***d*, and the racemic over-reduction product, *N*-acetylalanine (**10**). However, nmr analysis clearly shows that no 2*R*,3*R* or 2*S*,3*S* serine derivatives are produced.

In general, the deuteration mixture was treated directly with Acylase I from hog kidney (29) to hydrolyse the *N*-acetyl group of the 2*S* amino acids, which are then easily separated from the *N*-acylated 2*R* isomers. The methyl ether of **13***c*,*d* is cleaved without epimerization using boron tribromide (30). Analysis of the product by ^1H and ^2H nmr spectroscopy showed that the dideuterated 2*S*,3*R*-[2,3-$^2H_2$] serine (**14***c*) and the trideuterated 2*S*-[2,3,3-$^2H_3$] serine (**14***d*) are formed in a 2:3 ratio by the hydrogenation procedure. The ^1H nmr spectrum (10% NaOD/D_2O) exhibits a single peak at 3.58 ppm for the H_S proton but has no signal at 3.72 ppm for the H_R proton of the unwanted isomer. The ^2H nmr (10% NaOH/H_2O, $CDCl_3$ internal standard) shows peaks at 3.72 ppm (1D), 3.59 ppm (0.6D), and

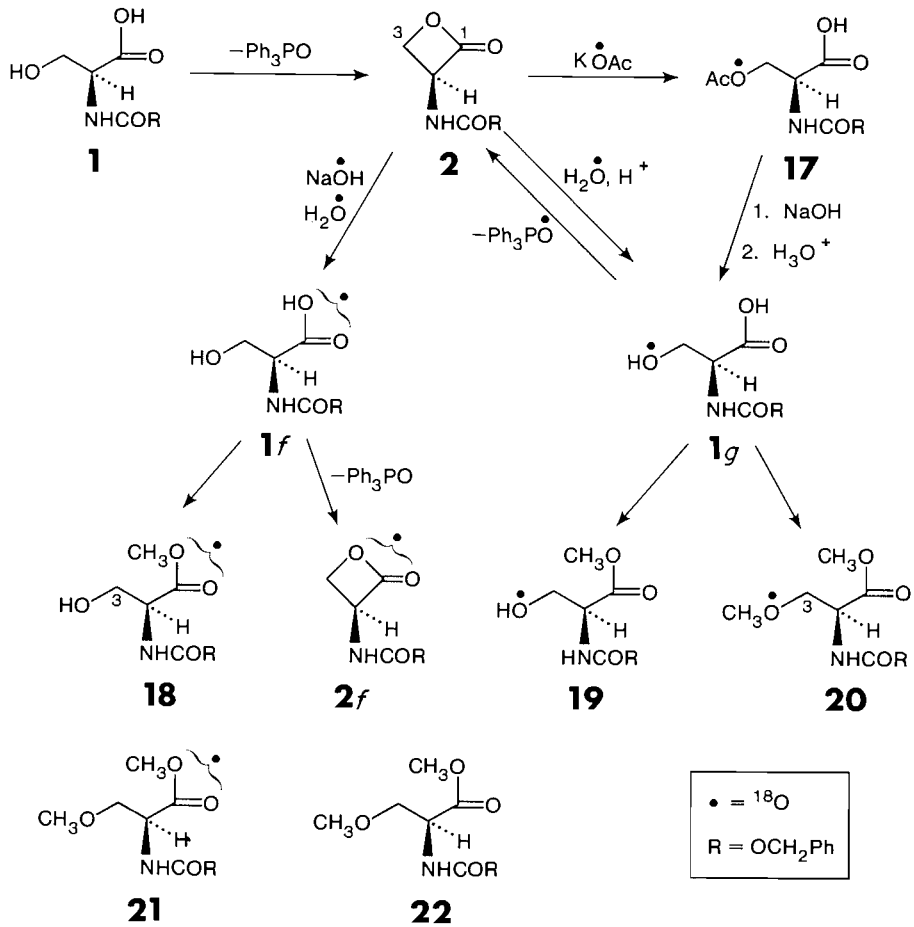

SCHEME 3

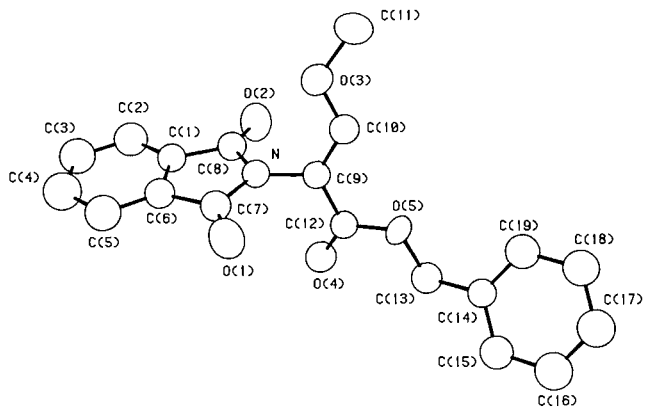

FIG. 1. An ORTEP drawing of (*Z*)-2-(*N*-phthalimido)-3-methoxypropenoic acid phenylmethyl ester **16**. The numbering of the atoms corresponds to that used in the Supplementary X-ray Material.

3.31 ppm (1D at C-2) for this mixture of trideuterated and stereospecifically dideuterated serines **14***d* and **14***c*. The spectra are in agreement with those reported previously for these labelled compounds (25). Treatment of **14***c*,*d* with benzyl chloroformate gave the required *N*-benzyloxycarbonyl serines **1***c*,*d* (31).

Cyclization of **1***c*,*d* afforded the corresponding mixture of trideuterated and dideuterated β-lactones **2**, which were isolated and subsequently opened with aqueous sodium hydroxide to regenerate the *N*-benzyloxycarbonyl-L-serines **1**. The benzyl group was removed by hydrogenolysis and the L-serine was analyzed by nmr spectroscopy as above. The results clearly showed that the process of Mitsunobu cyclization and basic ring opening proceeded with net *inversion* of configuration at C-3 to give **1***d*,*e*. This is consistent either with CGA cyclization and nucleophilic attack at C-3 to form **3***a* (Nu = OH) or with HGA cyclization and nucleophilic attack at the carbonyl to give **4***b* (Nu = OH) (Scheme 1).

The oxygen-18 labelling experiments depicted in Scheme 3 permit discrimination between these two possibilities. Treatment of unlabelled β-lactone **2** with sodium [^{18}O]hydroxide in [^{18}O]water (50% isotopic purity) and tetrahydrofuran (THF) rapidly cleaves the ring to generate the sodium salt of *N*-benzyloxycarbonyl-L-serine (**1***f*). This was acidified under nonaqueous conditions and trapped by diazomethane esterification as its methyl ester **18** to avoid possible exchange of oxygen at the carboxyl. Examination of the ^{13}C nmr spectra of **18** shows ^{18}O isotope shifts of the expected magnitude (32, 33) at the carbonyl carbon ($\Delta\delta$ = 0.015 and 0.038 ppm) and at the methyl carbon ($\Delta\delta$ = 0.026 ppm) but no detectable shift at the hydroxyl carbon, C-3. The complete lack of oxygen-18 at the hydroxyl was confirmed by comparison of the mass spectra of **18** and the isotopic isomer **19**. The latter compound was prepared by opening of the unlabelled β-lactone **2** with potassium [$^{18}O_2$]acetate (34) at C-3 (12) to form [$^{18}O_2$]acetyl-*N*-benzyloxycarbonyl-L-serine (**17**), followed by hydrolysis to hydroxy-labelled **1***g* and esterification (diazomethane) to give **19**. The high resolution electron impact mass spectra of **18** and **19** both display molecular ions and fission of a $COOCH_3$ fragment. With

compound **18** this results in complete loss of all ^{18}O label ($C_{10}H_{12}NO_3$ = 194.0810), but the hydroxy-labelled isomer **19** shows complete retention of ^{18}O ($C_{10}H_{12}NO_2{}^{18}O$ = 196.0684). The results demonstrate that hydroxide attacks the β-lactone **2** exclusively at the carbonyl carbon. Taken together with the deuterium labelling experiment above, it is clear that Mitsunobu cyclization of *N*-benzyloxycarbonyl serine (**1**) follows a hydroxy group activation (HGA) pathway to give β-lactone **2***b* with inversion at C-3; this is then cleaved by hydroxide at the carbonyl to produce **4***b* (Nu = OH) (Scheme 1).

To confirm these observations, the *N*-benzyloxycarbonyl serines **1***f* and **1***g* bearing oxygen-18 in the carboxyl and hydroxy group, respectively, were cyclized to β-lactones (Scheme 3). Mass spectral analysis of these prodcuts demonstrated that ring closure of **1***f* results in retention of all ^{18}O label to form **2***f*, whereas cyclization of **1***g* proceeds with complete loss of ^{18}O to give unlabelled lactone **2**.

Interestingly, reaction of unlabelled β-lactone **2** with [^{18}O]-water and HBF_4 at 20°C causes slow (ca. 11 days) ring opening to hydroxy-labelled *N*-benzyloxycarbonyl serine (**1***g*), which was isolated as its dimethyl derivative **20** by direct treatment with diazomethane. Since carboxylic acids exchange oxygen relatively rapidly under these conditions (35), ^{18}O label also appears in the carboxylate group. The location of label was determined by mass spectral comparison with reference samples of **20**, **21**, and **22**. These were obtained by diazomethane–HBF_4 methylation of the ^{18}O-hydroxy compound **1***g* (derived from acetate **17**), of the ^{18}O-carboxy analog **1***f*, and of unlabelled **1**, respectively. The high resolution electron impact mass spectra of **20**, **21**, and **22** display expected molecular ions as well as loss of a $COOCH_3$ fragment. This fission gives mass peaks $C_{11}H_{14}NO_3$ (208.0980) for compounds **21** and **22**, but produces peaks $C_{11}H_{14}NO_2{}^{18}O$ (210.1020) for the samples of **20** obtained after opening of β-lactone **2** either by [^{18}O]water/HBF_4 or by [^{18}O]acetate. Although the possibility of a certain amount of carbonyl attack on **2** by aqueous acid cannot be excluded under the experimental conditions, it is clear that at least a major portion of the nucleophilic opening occurs by attack at C-3.

Discussion

Our experiments show that Mitsunobu ring closure of *N*-benzyloxycarbonyl serine (**1**) proceeds by hydroxy group activation (HGA) with subsequent loss of the oxygen at C-3 and inversion of configuration at that site to give β-lactone **2***b* (Scheme 1). Opening of this lactone with aqueous hydroxide involves exclusive attack at the carbonyl to form **4***b* (Nu = OH). In contrast, under acidic conditions with water as the nucleophile, displacement at C-3 to give **3***b* (Nu = OH) is the major (if not exclusive) pathway of ring cleavage.

The vast majority of reported β-lactone formations by Mitsunobu coupling of β-hydroxy carboxylic acids occur by carboxyl group activation (CGA), (2,4). In a few cases where the α-carbon (C-2) has much greater steric bulk than the β-carbon (C-3), a minor amount (12–44%) of β-lactone formation by the HGA mechanism has been detected (4). Generally the HGA pathway with β-hydroxy acids has been described to give primarily decarboxylative elimination (2–5), presumably because of antiperiplanar alignment of the breaking bonds. However, these transformations were usually done at about 20°C, and we find that at such temperatures the primary product of Mitsunobu reaction of *N*-benzyloxycarbonyl serine (**1**) is the known (36) olefin **5**.[3] If the rate of addition of **1** to the triphenylphosphine–azodicarboxylate adduct is carefully controlled and the temperature is kept at −78°C, the olefin **5** becomes a minor product and 60% isolated yields of β-lactone **2** can be consistently achieved (12). Since thermal elimination of carbon dioxide from β-lactones once they are formed requires high temperatures (≥100°C) (5), it is the partitioning of the initial HGA adduct which accounts for formation of **5** and **2***b*. The precise factors that control this partitioning remain unknown. Possible explanations for the temperature effect may include the degree of ionization of the C-3 to oxygen bond, the participation of pentacoordinate phosphorus intermediates (13), and the conformational interconversion (2) of *syn* and *anti* coplanar alignments of the carboxy and activated hydroxy groups. Although increase of solvent polarity should promote charge separation and has been shown to affect the ratio of olefin to CGA β-lactone formation in other systems (2), preliminary indications are that a change from THF to acetonitrile has little effect on cyclization of *N*-acyl serines.[3] Apparently, steric interactions favor the HGA intermediate regardless of solvent polarity, and its partitioning to olefin **5** or β-lactone **2***b* is influenced primarily by temperature.

In the cleavage reactions, attack by hydroxide at the carbonyl to give **4***b* (Nu = OH) is in accord with earlier studies (17,18) and with behaviour of β-lactones with other "hard" nucleophiles like methoxide (12, 37). However, hydroxide, unlike methoxide (12), does not cause epimerization at the α-carbon (C-2). Most soft nucleophiles generally displace at C-3 to give **3***b* (12), in agreement with the observed mode of ring opening by [^{18}O]water under acidic conditions. Use of an acid with a non-nucleophilic counter ion (e.g., HBF_4) is essential to obtain attack by water; use of dilute aqueous HCl results in rapid formation of β-chloroalanine (Nu = Cl) (12, 38). Cleavage by nucleophiles other than water is probably a complicating factor in the early studies of acidic β-lactone hydrolysis (17, 18). However, the general observation of alkyl-oxygen fission at neutral to moderately low pH agrees with our results. The previously reported acyl-oxygen cleavage in very strong acid (8 *N* H_2SO_4) was not examined with serine β-lactones **2** because of product decomposition.

Knowledge of the stereochemical outcome of formation of serine β-lactones **2** and their cleavage mechanism permits synthesis of a large variety of β-substituted alanines **3** (12) that are stereospecifically labelled at C-3. Such compounds find continuing use in work on enzyme mechanisms (15, 16, 39, 40). In addition, Mitsunobu cyclization and hydroxide opening of *N*-acyl serines stereospecifically labelled with hydrogen isotopes at C-3 permits facile interconversion of the 3*R* and 3*S* isomers. These compounds are widely employed in biochemical studies, but generally each isomer has required an independent multistep synthesis.

Experimental

Melting points are uncorrected. Infrared (ir) spectra were recorded on a Nicolet 7199 FT system. Proton nuclear magnetic resonance spectra (^1H nmr) were measured using Bruker spectrometers, models WP80, WH200, and (or) WH400. Deuterium (^2H nmr) and carbon-13 (^{13}C nmr) nuclear magnetic resonance spectra were measured on the Bruker WH400. The internal standards were tetramethylsilane for organic solvents and sodium 3-trimethylsilyl-[2,2,3,3-D_4]-propionate for deuterium oxide. High resolution mass spectrometric (ms) measurements were obtained on a Kratos A.E.I. MS50 mass spectrometer using electron impact (EI) and chemical (NH_3) ionization (CI). Microanalyses were obtained using a Perkin Elmer 240 CHN analyser.

Cyclization of N*-benzyloxycarbonyl-*L*-serines* ***1***, ***1***c, ***1***g, *and* ***1***f *to* β*-lactones* ***2***, ***2***b, *and* ***2***f

Unlabelled β-lactone (**2**) was prepared on large scale in 60% yield

[3]Unpublished results, Lee D. Arnold and J. C. Vederas.

from *N*-benzyloxycarbonyl-L-serine (**1**) (Sigma) as previously described (12). In a typical smaller scale experiment, a solution of triphenylphosphine (157.9 mg, 0.601 mmol) in 2 mL of dry tetrahydrofuran was cooled to −78°C and dimethylazodicarboxylate (87.6 mg, 0.600 mmol) was added dropwise. After 10 min a white precipitate formed, to which was added over 10 min *N*-benzyloxycarbonyl-L-serine (**1**) (121.5 mg, 0.508 mmol) in 2 mL of dry tetrahydrofuran. This was stirred at −78°C for 25 min, then allowed to warm to room temperature and stirred for an additional 2.5 h. The solvent was removed and the residue was purified using flash silica chromatography (60:40 Skelly B–ethyl acetate). This gave 48.7 mg (43%) of the β-lactone **2** as a white solid; ir (film): 3363, 1845, 1685 cm^{-1}; ^1H nmr (CD_2Cl_2) δ: 4.48 (2H, d, CH_2-CH), 5.08 (1H, dd, C*H*), 5.15 (2H, s, CH_2-C_6H_5), 5.50 (1H, br s, N*H*), 7.37 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{11}H_{11}NO_4$: 221.0688; found: 221.0685.

Similarly, when the ^2H labelled *N*-benzyloxycarbonyl-L-serine (**1***c*,*d*) (see below) was used, the labelled β-lactone **2***b* was formed and showed the expected chromatographic and spectral properties; ^1H nmr (CD_2Cl_2) δ: 4.44 (0.46H, s, C*H*D), 5.14 (1H, s, CH_2), 5.50 (1H, br s, N*H*), 7.38 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{11}H_9{}^2H_2NO_4$: 223.0813; found: 223.0810.

From *N*-benzyloxycarbonyl-L-serine with ^{18}O in the carboxyl oxygen (**1***f*) (isotopic content: 71 ± 1% ^{18}O), the β-lactone **2***f* was formed with ^{18}O in the carbonyl and lactone oxygens. This had the expected chromatographic and spectral properties when compared to the unlabelled material (**2**). Isotopic content: 73 ± 1% ^{18}O by chemical ionization (NH_3) mass spectrometry.

From *N*-benzyloxycarbonyl-L-serine with ^{18}O in the hydroxyl oxygen (**1***g*) (isotopic purity: 76% ^{18}O, see below), β-lactone was formed, which showed identical properties to **2** and no indication of ^{18}O in the chemical ionization mass spectrum.

*2-Acetamido-3,3-dimethoxypropanoic acid methyl ester (**7**)*

A solution of sodium metal (1.85 g, 80 mmol) in 150 mL dry methanol was added to 2-acetamido-3-chloroacrylic acid methyl ester **6** (27) (14.3 g, 80 mmol) and the resulting solution was refluxed for 13 h. The methanol was removed *in vacuo* and saturated potassium bicarbonate solution was added. This was extracted with chloroform, and the extracts were dried over sodium sulfate and concentrated *in vacuo* to give 15.7 g (96%) of the dimethoxy compound **7** as an oil; ir (film): 3290, 1750, 1665 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.05 (3H, s, $COCH_3$), 3.45 (6H, s, CH_3O-CH), 3.78 (3H, s, CO_2CH_3), 4.61 (1H, d, J = 3.5 Hz, $(CH_3O)_2$-C*H*), 4.88 (1H, dd, J = 3.5, 8.0 Hz, C*H*-NH) 6.33 (1H, br d, J = 8.0 Hz, N*H*); ms m/e: 174 ($M^+ - OCH_3$). *Anal.* calcd.: C 46.82, H 7.37, N 6.83; found: C 46.59, H 7.51, N 6.55.

*(Z)-2-Acetamido-3-methoxyacrylic acid methyl ester (**8**)*

To a solution of 2-acetamido-3,3-dimethoxypropanoic acid methyl ester (**7**) (20.1 g, 99 mmol) in 300 mL of dry toluene was added 500 mg of *p*-toluenesulfonic acid and 130 mg of hydroquinone, and the solution was refluxed for 3.5 h with azeotropic distillation of methanol/toluene. Additional dry toluene was added as necessary. The toluene was removed *in vacuo*, and the residue taken up in 225 mL of saturated sodium chloride solution and extracted with chloroform. The chloroform extracts were dried over sodium sulfate and concentrated *in vacuo* to yield a dark brown oil. This was repeatedly recrystallized from ethyl acetate to give 7.33 g (43%) of colourless vinyl methoxy compound **8**, mp 91–92°C (lit. (41) mp 93°C); ir (film): 3160, 3020, 1720 1660 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.03 (3H, s, $COCH_3$), 3.68 (3H, s, CO_2CH_3), 3.83 (3H, s, vinyl-OCH_3), 7.23 (1H, s, vinyl *H*), 7.38 (1H, br s, N*H*). *Exact Mass* calcd. for $C_7H_{11}NO_4$: 173.0688; found: 173.0690. *Anal.* calcd.: C 48.55, H 6.40, N 8.09; found: C 48.57, H 6.34, N 7.90.

*(Z)-2-Acetamido-3-methoxyacrylic acid (**9**)*

To a suspension of potassium *tert*-butoxide (7.50 g, 66.8 mmol) in 150 mL anhydrous ether at 0°C was added 0.195 mL (10.8 mmol) of water. This was stirred for 5 min, methyl ester (**8**) (1.50 g, 8.66 mmol) was added, and stirring was continued at 20°C for 3 h. Ice was added and the separated aqueous phase was run down a 20 mm × 150 mm AG 50 acid-washed ion exchange column. The product was eluted with 100 mL of water and concentrated *in vacuo* to yield 1.32 g (96%) of the free acid **9** as a fluffy white powder; mp 172–174°C; ir (film): 3230, 3030, 1692, 1650 cm^{-1}; ^1H nmr (D_2O) δ: 2.05 (3H, s, $COCH_3$), 3.88 (3H, s, vinyl-OCH_3), 7.38 (1H, s, vinyl *H*). *Exact Mass* calcd. for $C_6H_9NO_4$: 159.0531; found: 159.0532. *Anal.* calcd.: C 45.28, H 5.70, N 8.80; found: C 45.14, H 5.60, N 8.54.

Deuterated L-*serine (**14**c,d)*

In a typical experiment the tetrabutylammonium salt of **9** was prepared by dissolving 0.51 g (3.2 mmol) in one eqivalent of tetrabutylammonium hydroxide and lyophilizing the resulting solution. This was lyophilized 3 times from D_2O if preparing deuterated serine. The oil was taken up in 40 mL of methanol (or CH_3OD) and added to 5% Rh(C) (0.20 g) prehydrogenated for at least 3 h in 100 mL of ethyl acetate. The resulting solution was stirred under 1 atm (101.3 kPa) of hydrogen (deuterium) for 3 h, filtered through Celite, and the solvent removed *in vacuo*. The free acid was obtained by stirring with acid-washed AG50 × 8 ion exchange resin, filtering, and lyophilizing to give a white solid (0.51 g, 96%). This is a mixture of *N*-acetyl-*O*-methylserine (**11** and **12**) and *N*-acetylalanine (**10**) in a 2:3 ratio. When the serine derivative was purified it was spectrally and chromatographically identical to authentic samples (42).

The 2*S* *N*-acetyl compounds (1.20 g of the above mixture) were selectively deacetylated by Acylase 1 using literature methods (29) and the resulting 2*S* amino acids were isolated by AG50 (H^+) ion exchange chromatography (372 mg, 42%). The (2*S*)-*O*-methylserine (**13**) obtained showed the expected spectral and chromatographic properties, compared to authentic *O*-methylserine (Sigma).

The above mixture (0.35 mg, 2.9 mmol) was treated with boron tribromide (12 mmol) in dichloromethane for 2.5 days at room temperature and the L-serine (**14**) (173 mg, 17% from **9**) was isolated from the L-alanine by careful ion exchange chromatography. This had identical spectral properties to authentic L-serine. The deuterated serine obtained in this manner was a 3:2 mixture of **14***d*/**14***c*, ir (film): 1755, cm^{-1}; ^1H nmr (10% NaOD/D_2O) δ: 3.58 (s, C*H*); ^2H nmr (10% NaOH/H_2O, $CDCl_3$ int. standard) δ: 3.31 (1D, s), 3.59 (0.6D, s), 3.72 (1D, s).

Deuterated N-*benzyloxycarbonyl*-L-*serine (**1**c,d)*

This material was prepared from the mixture of (2*S*, 3*R*)-[2,3-$^2H_2$]serine (**14***c*) and (2*S*)-[2,3,3-$^2H_3$]serine (**14***d*) by literature procedure (31); ir (film): 3340, 1715 cm^{-1}; ^1H nmr (D_2O) δ: 3.86 (0.4H, s, C*H*OH), 5.16 (2H, s, CH_2), 7.46 (5H, s, aryl-H). *Exact Mass* calcd. for $C_{11}H_{11}{}^2H_2NO_5$: 241.0919; found: 241.0919.

Hydrolysis of ^2H-labelled β-*lactone **2**b with sodium hydroxide: **2**b → **1**e*

To a cooled (0°C) solution of 0.5 mL tetrahydrofuran, 0.5 mL of water, and 0.194 mL of 0.587 *M* NaOH (0.114 mmol, 1.05 equiv.) was added dropwise a solution of the labelled β-lactone **2***b* (24.2 mg, 0.108 mmol) in 1 mL of tetrahydrofuran. This was stirred 10 min, the tetrahydrofuran removed *in vacuo*, and the water lyophilized. The residue was taken up in 1 mL of 1 *N* HCl and extracted with ethyl acetate. The solvent was removed to give 24.5 mg (95%) of the labelled *N*-benzyloxycarbonyl-serine **1***e* as a white solid; ir (film): 3340, 1715 cm^{-1}; ^1H nmr (D_2O) δ: 3.84 (0.4H, s, C*H*), 5.15 (2H, s, CH_2), 7.45 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{11}H_{11}{}^2H_2NO_5$; 241.0919; found: 241.0921.

N-*Phthalimido-3-oxoalanine phenylmethyl ester (**15**)*

The literature preparation was adapted (43). A solution containing 30.0 g (0.101 mol) of *N*-(phthalimido)glycine phenylmethyl ester (44) in 250 mL of benzyl formate (dried over phosphorus pentoxide) was cooled to 5°C and 220 mL of a THF solution of potassium *tert*-butoxide (1 *M*) was added over 1 h. The mixture was kept at 5°C for 36 h and quenched at 0°C by the addition of 10 mL of glacial acetic acid (178 mmol) in 250 mL of dry benzene. After 30 min, the reaction mixture was added to 250 mL of 0.5 *M* aqueous hydrochloric acid and extracted with 4 L of benzene. The combined benzene extracts were concentrated *in vacuo* to yield 26.1 g of **15** (yield 80%); mp. 136.5–138°C; ir (film): 1790, 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.20 (s, 1H, N*H*), 5.38 (s, 2H, CH_2), 7.2–7.4 (m, 7H, Ar*H*), 7.85–7.95 (m, 2H, Ar*H*). *Exact Mass* calcd. for $C_{18}H_{13}NO_5$: 323.0794; found: 323.0794. *Anal.* calcd.: C 66.87, H 4.05, N 4.33; found: C 67.09, H 4.22, N 4.27.

Z-2-(N-Phthalimido)-3-methoxypropenoic acid phenylmethyl ester (16)

A solution containing 1.02 g (3.15 mmol) of *N*-phthalimido-3-oxoalanine phenylmethyl ester **15**, 0.5 mL of 1% aqueous HBF_4, and 300 mL of ether was cooled to 0°C. A solution of diazomethane in ether was added until a yellow colour persisted. The mixture was then warmed to 20°C, stirred for 15 h, filtered, and concentrated to a yellow solid. Column chromatography on silica gel (5 × 45 cm), using 32% ethyl acetate in chloroform followed by gradient elution to 100% ethyl acetate, gave 0.93 g of **16** (yield 87%); mp 116–117°C; ir (film): 1790, 1760, 1720, 1650 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.89 (s, 3H, CH_3O), 5.21 (s, 2H, CH_2), 7.32 (m, 5H, Ar*H*), 7.71 (m, 3H, Ar*H*, vinyl-*H*), 7.87 (m, 2H, ArH). *Exact Mass* calcd. for $C_{19}H_{15}NO_5$: 337.0950; found: 337.0953. *Anal.* calcd.: C 67.65, H 4.48, N 4.15; found: C 67.58, H 4.50, N 4.11.

Potassium [$^{18}O_2$]acetate

This material was prepared by literature procedure (34) from unlabelled acetonitrile and [^{18}O]water. In order to determine the isotopic content, a portion was treated with α-bromo-*p*-phenylacetophenone using the method reported for preparation of *p*-bromophenacylformate (33). Mass spectrometric (CI) examination of the resulting purified *p*-phenylphenacylacetate (74% yield) gave an isotope ratio of 21.6% $^{18}O_1$ and 76.9% $^{18}O_2$; mp 105–106°C; ir (film): 1724, 1717, 1700, 1600 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.23 (3H, s, CH_3), 5.34 (2H, s, CH_2), 7.35–8.08 (9H, m, aryl-*H*). *Exact Mass* calcd. for $C_{16}H_{14}O^{18}O_2$: 258.1029; found: 258.1031.

[^{18}O-Acetyl]-O-acetyl-N-benzyloxycarbonyl-L-serine (17)

The β-lactone **2** (59.6 mg, 0.27 mmol) was added to a solution of potassium [$^{18}O_2$]acetate (142 mg, 1.39 mmol) in dimethylformamide (6 mL) and water (0.5 mL). The mixture was stirred 1.5 h, water (6 mL) was added, and the solution was acidified to pH 2 with 1 *N* HCl. The solution was extracted with chloroform and the extracts were concentrated *in vacuo* to give 77 mg (99%) of pure ^{18}O-labelled *O*-acetyl-*N*-benzyloxycarbonyl-L-serine (**17**); ir (film): 3140, 1710, 1530 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.93 (3H, s, $COCH_3$), 4.40 (3H, br, C*H* and CH_2OAc), 5.05 (2H, s, CH_2-C_6H_5), 5.95 (1H, br s, N*H*), 7.23 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{13}H_{15}NO_4{}^{18}O_2$: 285.0984; found: 285.0987. Isotopic ratio: 21.4% ^{18}O, 77.1% $^{18}O_2$.

[Hydroxy-^{18}O]-N-benzyloxycarbonyl-L-serine (1g)

A solution of [^{18}O-acetyl]-*O*-acetyl-*N*-benzyloxycarbonyl-L-serine (**17**) (77 mg, 0.27 mmol), 2 mL THF, 2 mL water, and 0.59 *M* sodium hydroxide (1 mL) was stirred at 4°C for 2.5 h. This was acidified with 1 *N* HCl and extracted with ethyl acetate. The solvent was removed *in vacuo* to give 53 mg (82%) of pure ^{18}O-labelled *N*-benzyloxycarbonyl-L-serine (**1g**); ir (film): 3320, 1720 cm^{-1}; ^1H nmr (CD_3OD) δ: 3.85 (2H, d, J = 4.4 Hz, CH_2OH), 4.28 (1H, t, J = 4.2 Hz, C*H*), 5.09 (2H, s, CH_2-C_6H_5), 7.31 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{11}H_{13}NO_4{}^{18}O$: 241.0836; found: 241.0830. Isotopic purity: 76.2% ^{18}O.

Hydrolysis of β-lactone 2 with sodium [^{18}O]hydroxide: 2 → 1f → 18

Sodium metal (10.9 mg, 0.473 mmol) was added cautiously to cold (0°C) [^{18}O]water (50% isotopic purity) under an argon stream. To this was added 0.5 ml of THF, followed by the dropwise addition of a solution of *N*-benzyloxycarbonyl-L-serine-β-lactone (**2**) (99.6 mg, 0.450 mmol) in 3 mL of THF. This was stirred for 0.5 h at 20°C, the THF was removed *in vacuo*, and the water was lyophilized to give the crude sodium salt of **1***f*. In preparative experiments the free acid of **1***f* was obtained by dissolving the sodium salt in water, acidifying with 1 *N* HCl, and extracting with ethyl acetate. The ethyl acetate extracts were dried (Na_2SO_4) and concentrated *in vacuo* to give the pure free acid **1***f* (89% yield) with the expected spectral and chromatographic properties. This had an isotopic ratio CI-ms of 71% ^{18}O (prepared from 90 at.% ^{18}O water). *Exact Mass* calcd. for $C_{11}H_{13}NO_4{}^{18}O$: 241.0836; found: 241.0833.

In studies of the mechanism of β-lactone opening, anhydrous ether (10 mL) and *p*-toluenesulfonic acid monohydrate (85.4 mg, 0.449 mmol) were added to the sodium salt of **1***f* and the mixture was treated with an ether solution of diazomethane until a slight yellow color persisted. This was stirred for 0.5 h, filtered, and the solvent was removed *in vacuo* to yield an oil (117.6 mg). This was purified on a silica gel column using Skelly B – ethyl acetate as the eluant to give 56.5 mg (50%) of the methyl ester **18** whose spectral and chromatographic properties were compared to unlabelled material and the corresponding [^{18}O-hydroxy] compound **19**. The ir and ^1H nmr were identical; for compound **18**, ^{13}C nmr ($CDCl_3$) δ; 52.69 (isotope shift 0.026 ppm upfield), 56.17, 63.18, 67.25, 128.16, 128.29, 128.60, 136.20, 156.39, 171.17 (isotope shifts 0.015 and 0.038 upfield). *Exact Mass* calcd. for $C_{12}H_{15}NO_4{}^{18}O$: 255.0992; found: 255.0995.

Acidic hydrolysis of β-lactone 2 with [^{18}O]water: 2 → 1g → 20

A solution of *N*-benzyloxycarbonyl-L-serine-β-lactone (**2**) (72.9 mg, 0.330 mmol) in 1.5 mL THF was added dropwise to a solution of [^{18}O]water (0.70 g, 50% isotopic purity), 0.5 mL THF, and HBF_4 (0.060 mL, 0.329 mmol). This was stirred at room temperature for 11 days, lyophilized, and the residue was taken up in ether. Excess diazomethane was added to the stirred ether solution and the solvent was removed *in vacuo*. The resultant oil **20** was compared spectrally (ir, ^1H nmr, ms) to the unlabelled analog **22** and the [carboxy-^{18}O] analog **21**; for compound **20**. *Exact Mass* calcd. for $C_{13}H_{17}NO_4{}^{18}O$: 269.1149; found: 269.1142.

Esterification of N-benzyloxycarbonyl-L-serine (1) and its [^{18}O-hydroxyl] analog: 1g → 19

A solution of diazomethane in ether was added to *N*-benzyloxycarbonyl-L-serine (**1**) (263 mg, 1.10 mmol) in ether (10 mL) until a yellow color persisted. This was stirred an additional 0.5 h and the solvent removed *in vacuo* to give the unlabelled methyl ester (279 mg, 99%); ir (film): 3350, 1708 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.96 (1H, br, s, O*H*), 3.73 (3H, s, CH_3), 3.90 (2H, br, CH_2OH), 4.39 (1H, m, C*H*), 5.09 (2H, s, CH_2-C_6H_5), 5.88 (1H, br d, N*H*), 7.30 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{12}H_{15}NO_5$: 253.0950; found: 253.0953.

Similarly, **19** was prepared from **1***g*; the product showed the expected spectral and chromatographic properties. *Exact Mass* calcd. for $C_{12}H_{15}NO_4{}^{18}O$: 255.0992; found: 255.0995.

N-benzyloxycarbonyl-O-methylserine methyl ester (22)

Unlabelled *N*-benzyloxycarbonyl-*O*-methylserine methyl ester was prepared by literature methods (45) from *O*-methylserine to give **22** as an oil; ir (film): 3345, 2947, 1723 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.38 (3H, s, OCH_3), 3.78 (3H, s, CO_2CH_3), 3.7 (2H, br m, CH_2OCH_3), 4.5 (1H, m, C*H*), 5.15 (2H, s, CH_2-C_6H_5), 5.6 (1H, br d, N*H*), 7.33 (5H, s, aryl-*H*). *Exact Mass* calcd. for $C_{13}H_{17}NO_5$: 267.1106; found: 267.1104.

Nuclear magnetic resonance spectra of oriented bicyclic systems containing heteroatom(s): the spectrum of 2-thiocoumarin

S. ARUMUGAM AND C. L. KHETRAPAL[1]

Indian Institute of Science, Bangalore 560 012, India

Received September 27, 1985

S. ARUMUGAM and C. L. KHETRAPAL. Can. J. Chem. **64**, 714 (1986).

From the proton nmr studies of 2-thiocoumarin and coumarin, it is concluded that the relative interproton distances in the two oxygen heteroatom bicyclic systems are similar. The values for the phenyl ring protons do not deviate significantly from the regular hexagonal geometry, unlike bicyclic systems with nitrogens as the heteroatoms, such as diazanaphthalenes. Larger values of the indirect spin–spin couplings within the protons of the ring containing the oxygen heteroatom, compared to the values between the *ortho* protons in the phenyl rings in coumarin and 2-thiocoumarin, correspond to the olefinic nature of these protons. This is in contrast to results for the nitrogen heterocycles where both the rings are aromatic.

S. ARUMUGAM et C. L. KHETRAPAL. Can. J. Chem. **64**, 714 (1986).

Sur la base d'études rmn de la thio-2 coumarine et de la coumarine, on peut conclure que les distances relatives interprotons, dans ces deux systèmes hétérocycliques oxygénés, sont similaires. Les valeurs pour les protons des cycles aromatiques ne dévient pas beaucoup par rapport à la géométrie hexagonale régulière; cette observation est en opposition avec celle qui a été faite avec des systèmes hétérocycliques bicycliques contenant de l'azote, comme les diazanaphtalènes. Par rapport aux valeurs comparables pour les protons *ortho* des noyaux aromatiques de la coumarine et de la thio-2 coumarine, les valeurs observées pour les couplages indirects spin–spin entre le protons du cycle contenant l'oxygène comme hétéroatome sont plus élevées; ce résultat correspondrait à la nature oléfinique de ces protons et cette observation est en opposition avec les résultats obtenus avec les hétérocycles azotés dans lesquels les deux cycles sont aromatiques.

[Traduit par la revue]

Introduction

The proton nmr spectra of oriented bicyclic ring systems containing nitrogen, oxygen, and sulphur as heteroatom(s) have been investigated earlier (1–5). The systems examined are 1,3-, 2,3-, and 1,4-diazanaphthalenes (1–3), coumarin (4), and thialene (5). Except for the system with the oxygen heteroatom, in all the systems the arrangement of protons in the phenyl rings has been found to be distorted from the regular hexagonal geometry. In the oxygen compound (coumarin), no significant deviations from the regular hexagonal geometry have been observed for the relative arrangement of the phenyl protons. The bicyclic system 2-thiocoumarin, which is similar to coumarin, was studied and the results are reported in the present paper. It may be noted that the rings containing the heteroatoms attached to the phenyl ring are aromatic in all cases, except for coumarin and 2-thiocoumarin.

Experimental

A 5 mol% solution of 2-thiocoumarin was prepared in *N*-(*p*-ethoxybenzylidene-)*p'*-*n*-butylaniline (EBBA). The spectrum of the solution was recorded on a Bruker WH-270 FT nmr spectrometer equipped with a BNC-12 computer and 20 K data memory. At 303 K, 240 free induction decays were accumulated and Fourier transformed in order to obtain the frequency domain spectrum. A typical spectrum is shown in Fig. 1. An average line width of 10 Hz was obtained.

Spectral analysis

The iterative analysis of the spectrum was carried out as an ABCDEF system using the LAOCOONOR (6) programme on a DEC-1090 computer. All the 15 direct dipolar HH couplings between the interacting nuclei i and j (D_{ij}'s) were iterated upon, along with the 5 chemical shifts ($\nu_i - \nu_j$). The indirect spin–spin couplings used were taken from the analysis of the spectrum of coumarin in isotropic medium (4). A root-mean-square (rms) error of 0.8 Hz was obtained between the observed and the calculated line positions, with no line deviating by more than 2.0 Hz when 239 spectral lines were assigned for the analysis. The derived parameters are reproduced in Table 1.

[1]Author to whom correspondence should be addressed.

In another analysis, iterations on all the indirect spin–spin coupling constants were also carried out, in addition to those on the direct dipolar couplings and the chemical shifts. Within experimental error, values of the indirect couplings thus determined were similar to those for coumarin. A value for J_{12} of 9.56 Hz was thus obtained, compared to values for the *ortho* protons in the phenyl ring of 7.35 and 7.72 Hz.

Results and discussion

*The order parameters with respect to the right-handed Cartesian coodinate system with x, y axes being in the ring plane, such that the positive y-axis is the line joining proton 5 to 4, are: $S_{xx} = 0.2958 \pm 0.0009$, $S_{yy} = -0.0718 \pm 0.0001$, $S_{xy} = -0.1185 \pm 0.0005$. The value $r_{45} = 2.481$ Å was used for the calculation of the S-values.

eters (*S*-values) have to be obtained from 15 direct dipolar couplings. The least-squares-fit programme SHAPE (7) was used to determine the "best-fit" values of the relative interproton distances and the order parameters from the experimental dipolar couplings. A root-mean-square error of 0.2 Hz with a maximum deviation of 0.6 Hz between the observed and the "best-fit" computed dipolar couplings was obtained. The values of the calculated dipolar couplings are given in Table 1, within parentheses, and the derived geometrical and order parameters are reproduced in Table 2. The geometrical parameters for coumarin and some heteroaromatic bicyclic ring systems derived essentially from studies in aromatic liquid crystal solvents are included in Table 2 for comparison.

An agreement between the observed and the best-fit calculated dipolar couplings (Table 1) justifies the assumption of the planar structure of 2-thiocoumarin. A comparison of the geometrical data for coumarin and 2-thiocoumarin (Table 2) shows that the structures of the two are very similar and substitution of the sulphur atom for oxygen does not significantly alter the relative proton positions.

Furthermore, the relative interproton distances in the phenyl rings of coumarin and 2-thiocoumarin do not deviate significantly from the regular hexagonal geometry. On the other hand, there are significant distortions in the arrangement of the phenyl protons in the diazanaphthalenes (Table 2).

The larger value of J_{12} in coumarin and 2-thiocoumarin compared to the value for the *ortho* protons of the phenyl ring indicates that the 1 and 2 protons are olefinic in nature and the α-pyrone rings of coumarin and 2-thiocoumarin are both nonaromatic. On the other hand, in the diazanaphthalenes both the rings are aromatic.

Values of the order parameters with respect to the Cartesian coordinate system defined in Table 2 incidate that the principal axis of the order matrix is titled with respect to the selected Cartesian coordinate system by 16.4°.

Harmonic force fields for 2-thiocoumarin could not be located in the literature and hence vibrational corrections have not been applied. Furthermore, for a comparison of the structural data with other heteroaromatic systems where the vibrational corrections have not been applied, it is more reasonable to use the data without applying such corrections.

Conclusions

The structures of 2-thiocoumarin and coumarin are similar. No distortions in the phenyl ring protons are observed in these molecules. In contrast, the fused rings containing nitrogen heteroatoms produce significant distortions in the relative arrangements of the phenyl protons in diazanaphthalenes.

The thermal diffusion of aqueous solutions of glucose, sucrose, ethylacetate, and 1,4-dioxan (0.1 *m*) contained in the pores of a sintered glass disc (or porosity G4), which is subjected to a temperature gradient, has been studied. The resulting heat of transport data have been interpreted, in terms of local changes in entropy in the solvent brought forth by the presence of the solutes, and correlated to the hydrophobic hydration effects.

A. K. MUKHERJEE et S. K. SANYAL. Can. J. Chem. **64**, 717 (1986).

On a étudié la diffusion thermique de solutions aqueuses de glucose, de sucrose, d'acétate d'éthyle et de dioxanne-1,4 (0,1 *m*) contenues dans les pores d'un disque de verre fritté (de porosité G4) soumis à un gradient de température. On a interprété les données relatives au transport de chaleur qui en résulte en fonction de changements locaux d'entropie dans le solvant, qui sont causés par la présence de solutés et qui sont reliés à des effets d'hydration hydrophobe.

[Traduit par la revue]

Introduction

Experiments on thermal diffusion through coarsely porous diaphragm have been reported in the past (1–4), but little attention has been paid to the thermal diffusion of nonelectrolytes under these conditions. In the present communication, the thermodiffusive phenomenon of aqueous glucose, sucrose, ethylacetate, and 1,4-dioxan has been studied at a mean temperature of 25°C and a mean concentration ($\bar{m}$) of 0.1 *m* by using a diffusion call designed and fabricated for the present experiment.

Theoretical

A solution-filled pore in a highly porous nonisothermal diaphragm (e.g., a sintered G4 glass disc) may be considered to be equivalent to a microscopic Soret cell in which thermal diffusion proceeds at a moderately fast rate. Thus, the relations used for thermal diffusion in a binary system (5) (and for a solvent-fixed reference frame) can be adopted in the persent case, subject to a supposition (6, 7) that the chemical potential of the component *i* (μ_i) just within the diaphragm at each of its surfaces is the same as that in the adjacent layer of free solution outside the diaphragm. The latter holds true for the assumed equilibrium across each surface of the disc. The heat of transport of the solute ($\hat{Q}$) is thus given by eq. [1] (8)

$$[1] \quad \hat{Q} = RT^2\sigma\left(1 + \frac{\mathrm{d}\ln\gamma}{\mathrm{d}\ln m}\right)_T$$

where σ is the Soret coefficient, and is obtained as,

$$[2] \quad \sigma = -\left(\frac{\mathrm{d}\ln m}{\mathrm{d}T}\right)_{st} = -\frac{1}{\bar{m}}\left(\frac{\Delta m}{\Delta T}\right)_{st}$$

$\bar{m}$ the mean molal concentration, γ the mean activity coefficient on molality scale, and T the mean (absolute) temperature. Δm refers to the concentration difference between the two sides of the diaphragm at the steady state (denoted by subscript "st" in eq. [2], the solution in each half-cell of the glass being kept thoroughly mixed by means of magnetic stirrers (see below).

Experimental

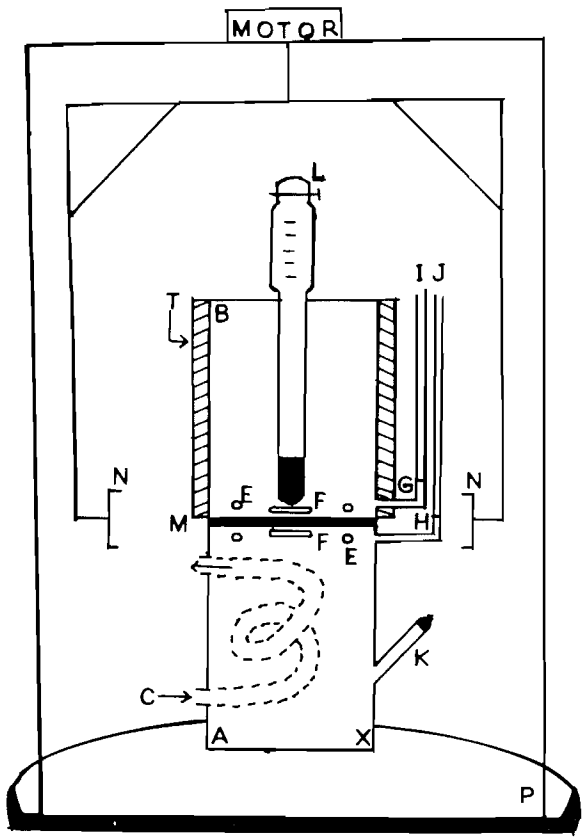
(a) Thermodiffusive cell

The cell (Fig. 1) used is in two parts, containing glass tubes inverted onto each other. The one at the bottom has the G4 glass disc (of thickness 2 mm) fused onto its inner walls, and slips into the tube at the top through a ground glass joint, forming two compartments of nearly equal volumes (245.5 and 246.3 mL, respectively) above and below the diaphragm. A heating element of nichrome wire, covered by glass wool tape is wound around the top glass tube (Fig. 1) and forms a component of a thermoregulating system, also consisting of an electrical contact thermometer, inserted into the top compartment, and a relay unit. The contents of the lower compartment are cooled by passing cold thermostated water through glass cooling coils located inside the compartment. There are side filling tubes, one in each compartment just above and below the glass disc, which are connected through standard joints to graduated vertical glass capillary tubes. The lower compartment is provided with an additional inlet to facilitate the filling procedure. The temperature difference across the diaphragm is measured (to within ±0.02°C) by two pairs of face-to-face copper–constantan thermocouples, held fixed in the two compartments close to the diaphragm. Small magnetic stirrers are provided in two half-cells and are moved by means of a rotating magnet. The whole set-up is enclosed in a large air thermostat maintained at the mean temperature of the experiment.

(b) Materials and method

The nonelectrolytes used, i.e., glucose, sucrose, ethylacetate, and 1,4-dioxan were of high purity grade, and their solutions were prepared in double distilled (deaerated) water of conductivity less than 0.5 μmho cm^{-1}. The initial concentration of each solution studied was 0.1 *m*.

The cell was assembled and filled, from the bottom half-cell through the disc to the top half-cell, with solution, taking care to eliminate the entrapped air bubbles from the whole system. On applying a thermal gradient across the diaphragm, the temperatures were monitored by the thermocouples, and any solvent flow was ascertained by noting the rate of development of pressure difference between the glass capillary tubes emerging from the top and the bottom half-cells. Such solvent flow,



GLASS CELL

Legend: A, lower compartment (246.3 mL); B, upper compartment (245.5 mL); C, glass cooling coil (diameter 1 cm, total length in the lower half-cell is 11.5 cm); E, thermocouple points; F, stirrer; G, H, outlets with standard joints; I, J, graduated tubes; K, inlet for solution; L, contact thermometer (the length of the immersed portion of the thermometer in the upper-half is 12.5 cm and the diameter of that portion is 1 cm); T, heating tape; N, rotating bar magnet; P, iron base; M, glass disc (2 mm thick). Total length of the cell, *AB* is 26.2 cm, diameter of the cell, *AX* is 5.0 cm.

however, turned out to be negligible after making proper correction for unequal thermal expansions in the two compartments.[1]

At the steady state, the aliquots were withdrawn from each compartment, and the concentration difference was determined by a Brice–Phoenix differential refractometer. The latter was previously calibrated with a number of standard pairs of solutions of each solute having known concentration differences.

A number of tests as follows have been applied to the present equipment to insure its satisfactory operation.

(*1*) Initial experiments were run with aqueous solutions of 0.1 *m* $CdSO_4$ and 0.417 *m* urea at 25.0°C to check the reliability of the results obtained with the present cell. The Soret coefficients (σ) thus obtained were within ± 1% of the corresponding values for 0.1 *m* $CdSO_4$ (9) and 0.417 *m* urea (10), determined by independent techniques.

(*2*) For a given solution at the mean temperature of 25°C, the apparatus has been operated at ΔTs from 4 to about 9°C and the same value of σ, within the limits of experimental error, were obtained. The temperatures were monitored throughout a run on a Leeds–Northrup potentiometer capable of recording electromotive force within ±0.5μV.

(*3*) In general, about 1 mL of solution was withdrawn from each compartment to determine the steady state concentrations and the separations obtained were found to be independent of these amounts provided that the volume removed were within 1–3 mL. Similar results were obtained for 0.1 *m* $CdSO_4$ and 0.417 *m* urea solutions of known Soret coefficients.

(*4*) The separation obtained was also found to be independent of the stirrer speed within the range of 140–160 rpm of the rotating magnet. A higher speed tended to lead to lower separations due presumably to some convective remixing which resulted from stirring into the diaphragm (1*b*).

(*5*) The relaxation time (τ) for the present solutions in the given cell was in the range of 800–1000 (taking the effective path length of diffusion to be equal to the thickness (0.2 cm) of the disc, i.e., by neglecting any probable internal structure of the porous disc, and assuming the diffusion coefficient of the given solutes to be of the order of 5×10^{-6} cm^2s^{-1}. Thus, for the composition of the solutions to reach within 1% of the final value at the steady state, a time of 5τ or about 70–90 min must be allowed. The given runs lasted for about 100 min. (Some runs were continued even longer up to 150 min without recording significantly different σ values.)

In addition, trial runs were performed for each solution to find out the time for attainment of the steady state concentrations in each half-cell, and the former turned out to be well within 100 min, in agreement with the requirement of relaxation times as above.

(*6*) The sintered diaphragm is known to be effective in preventing disturbance of the Soret equilibrium by convection (8), even though, for dilute electrolyte solutions (at concentrations less than 0.05 *m*) the results may be influenced by ionic adsorption or other surface effects (8). For the given nonelectrolyte solutions at 0.1 *m* concentrations, such surface effects are considered unimportant. Furthermore, essentially the same σ for a solution obtained for different ΔTs applied at a given mean temperature indicates that the convective remixing is not appreciable (the latter should have been more prominent at a higher ΔT leading to a larger separation). The absence of convective remixing was also ensured by virtue of obtaining a good agreement of σ values of 0.1 *m* $CdSO_4$ and 0.417 *m* urea with the corresponding literature data. It is also known that the amount of convection is inversely related to the sum of the two Rayleigh numbers, R_c and R_T (11) (for a given design of thermal diffusion cell). This sum ($R_c + R_T$), is of the same order of magnitude for 0.1 *m* glucose and 0.1 *m* $CdSO_4$ solutions. The latter is known to be relatively stable to convective remixing.

It may be noted here that the present design of the cell using a G4 sintered diaphragm for separating the hot and the cold compartments has some similarity to the design originally developed by Saxton *et al.* (1954) (1*b*) for the study of thermal diffusion in binary mixtures of organic liquids. Thus, the heating arrangement used for the top half-cell, the temperature measuring devices, and the sample withdrawing outlets, as well as the mode of analysis of the concentration differences have been similar in both cases. However, in the present case, one half-cell simply slips into the other through a ground glass joint with the sintered disc fused onto the walls of the former (Fig. 1), while in the design of Saxton *et al.*, the two half-cells were screwed together externally. Further, the cooling coil in the given case is located inside the lower half-cell unlike the external cooling arrangement used in the cell of Saxton *et al.* Instead of a single external magnet activating the magnetic stirrers in both compartments, as employed in the latter method, the present design uses a rotating framework with a pair of small bar magnets so fixed as to face each other across the diaphragm of the glass cell, and this ensures effective stirring of the solutions in the two compartments.

Results and discussion

The results are incorporated in Table 1. The errors in the determinations of σ and the heat of transport ($\hat{Q}$) are calculated as the standard deviations and shown in parenthesis below each value.

[1]By using the known volume of each half-cell, as well as thermal expansion coefficients of water and glass (the latter being about two order of magnitude less than the former), an allowance was made to account for the unequal thermal expansion of water while recording Δh values between the two glass capillary tubes at each mean temperature of study.

TABLE 1. Experimental parameters for the solutions studied

Solution (0.1 *m*)	T/A	B^a	$10^3\sigma_{mean}{}^b$ (deg^{-1})	$\hat{Q} = RT^2\sigma B$ ($J\,mol^{-1}$)
Glucose	298	1.0	1.69 (±0.03)	1248 (±22.1)
Sucrose	298	1.0	0.58 (±0.02)	428 (±14.8)
Ethylacetate	298	1.0	6.51 (±0.06)	4806 (±44.3)
1,4-Dioxan	298	1.0	6.12 (±0.02)	4518 (±14.8)

[a]The thermodynamic factor defined as $(1 + (d \ln \gamma)/(d \ln m))_T$.
[b]From eq. [2].

The value of the thermodynamic factor, $(1 + (d \ln \gamma)/(d \ln m))_T$, is assumed to be unity in the absence of relevant literature data on activity (or, osmotic) coefficients and is a reasonable approximation for such dilute solutions of nonelectrolytes. The steady state hydrostatic pressure differences (Δh), corrected for unequal thermal expansions, was found to be negligible in all the cases studied.

Positive $\hat{Q}$ corresponds to the promotion of "local" structure (8) of water, i.e., it finds an interpretation in terms of the local ordering (i.e., loss of entropy) of water adjacent to the solute molecules in dilute solutions. The much larger $\hat{Q}$ values of ethylacetate and dioxan than those of the sugars, evidently arise from a more hydrophobic character of the former, which further reinforces such ordering influences. Again, between the two sugars studied sucrose, having a greater number of structure breaking (free) hydroxyl groups than glucose, has a lower $\hat{Q}$. This also agrees with the above picture.

A somewhat higher $\hat{Q}$ for ethylacetate than that of dioxan may possibly be attributed to a ring structure of dioxan so that the (hydrophobic) surface area in contact with neighbouring water is reduced. This finds qualitative support from the reported larger "entropy loss" for the transfer of open chain amines and ethers from the gas phase (at 1 atm pressure) to dilute aqueous solution, as compared to their cyclic analogues (12).

Diastereoselectivity and asymmetric induction in the Diels–Alder reaction of *o*-quinodimethanes

JAMES L. CHARLTON

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 5, 1985[1]

JAMES L. CHARLTON. Can. J. Chem. **64**, 720 (1986).

The extent of asymmetric induction in the bimolecular Diels–Alder reactions of chiral *o*-quinodimethanes with dimethyl fumarate, methyl acrylate, and maleic anhydride has been studied. *o*-Quinodimethanes with chiral α-alkoxy groups were prepared from 1-alkoxy-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxides **4***a–f* or 1-alkoxy-3-phenyl-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxides **4***g–h* by thermolysis. These alkoxybenzosulfones were prepared from the corresponding hydroxybenzosulfones **8** and 1-phenylethanol, 2-phenyl-1-propanol, 4-phenyl-2-butanol, 1-phenyl-2-propanol, 3,3-dimethyl-2-butanol, or 1-cyclohexylethanol. The 1-phenylethoxy substituent yielded the largest asymmetric induction. The absolute configurations of the major cycloadducts of methyl acrylate with the *o*-quinodimethanes generated from 1-(*R*-1-phenylethoxy)- and 1-(*S*-1-phenylethoxy)-1,3-dihydrobenzo[*c*]thiophene-2,2-dioxides **4***i* and **4***j* have been determined to be 1*S*,2*S*-1-(*R*-1-phenylethoxy)- and 1*R*,2*R*-1-(*S*-1-phenylethoxy)-2-carbomethoxy-1,2,3,4-tetrahydronaphthalene **11***i* and **11***j*, respectively. The proposition that a chiral alkoxy substituent can block one face of the *o*-quinodimethane towards addition of a dienophile is discussed.

JAMES L. CHARLTON. Can. J. Chem. **64**, 720 (1986).

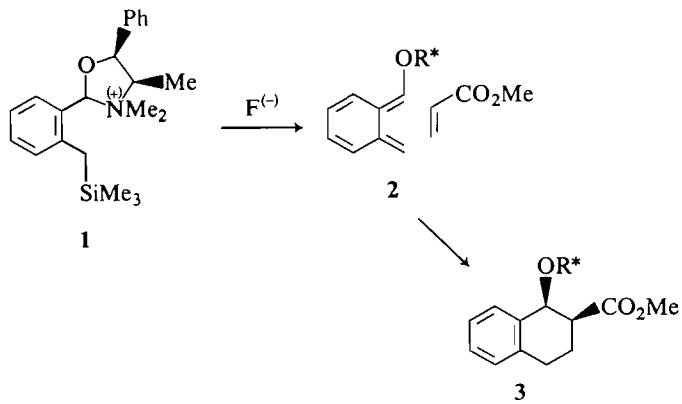
On a étudié le degré d'induction asymétrique qui se produit lors de réactions de Diels–Alder bimoléculaires d'*o*-quinodiméthanes chiraux avec le fumarate de diméthyle, l'acrylate de méthyle et l'anhydride maléique. On a préparé les *o*-quinodiméthanes portant les groupements α-alkoxy chiraux en procédant à la thermolyse d'alkoxy-1 dihydro-1,3 benzo[*c*]thiophène dioxydes-2,2 (**4***a–f*) ou d'alkoxy-1 phényl-3 dihydro-1,3 benzo[*c*]thiophène dioxydes-2,2 (**4***g–h*). On a préparé ces alkoxybenzosulfones à partir des hydroxybenzosulfones (**8**) et du phényl-1 éthanol, du phényl-2 propanol-1, du phényl-4 butanol-2, du phényl-1 propanol-2, du diméthyl-3,3 butanol-2 et du cyclohexyl-1 éthanol. Le substituant phényl-1 éthoxy a conduit aux inductions asymétriques les plus élevées. On a déterminé que les configurations absolues des principaux cycloadduits de l'acrylate de méthyle avec les *o*-quinodiméthanes générés à partir du (phényl-1*R* éthoxy)-1 et du (phényl-1*S* éthoxy)-1 dihydro-1,3 benzo[*c*]thiophène dioxydes-2,2 (**4***i* et **4***j*) sont respectivement les (phényl-1*R* éthoxy)-1*S*,2*S* et (phényl-1*S* éthoxy)-1*R*,2*R* carbométhoxy-2 tétrahydro-1,2,3,4 naphtalène (**11***i* et **11***j*). On discute de l'hypothèse selon laquelle un substituant alkoxy chiral peut bloquer une face d'un *o*-quinodiméthane lors de l'addition d'un dièNophile.

[Traduit par la revue]

Introduction

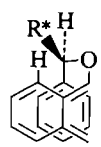
Due to their readiness to undergo Diels–Alder reactions, *o*-quinodimethanes (*o*-QDMs) have been used as intermediates in the synthesis of lignans, alkaloids, steroids, and anthracyclines (1–9). In contrast to the extensive work on asymmetric induction in Diels–Alder reactions of butadienes (10–12), relatively fewer studies have been made of asymmetric induction in Diels–Alder reactions of *o*-QDMs (5, 7, 9). Quinkert and Stark, Oppolzer *et al.*, and Kametani and Fukumoto exploited the stereoselectivity of the intramolecular Diels–Alder reaction of *o*-QDMs to prepare optically active steroids (9). Franck *et al.* have studied the reaction of an achiral *o*-QDM with a chiral dienophile to determine the relative roles of steric and secondary orbital interactions on the asymmetric induction (7). More recently Ito *et al.* (4) have reacted the oxazolidinium system **1** with fluoride ion to give the *o*-QDM **2** bearing a chiral auxiliary that partially controls the stereochemistry of the subsequent addition of dienophiles.[2]

In each of the cases cited above the asymmetric induction was attributed to the ability of the chiral auxiliary to block one face of the *o*-QDM, or to specifically direct the dienophile to one face of the *o*-QDM. In the case of the work of Ito *et al.* it was suggested that π-stacking of the substituent phenyl group blocked one face of the *o*-QDM, as shown by conformations **2A** and **2B**. This suggestion follows from a similar analysis of the addition of dienophiles to chiral butadienes made by Trost *et al.* (11) and Dauben and Bunce (12). By determining the absolute configuration of the cycloadduct **3**, it was concluded that reaction had occurred from conformation **2A**, despite the fact that nonbonded interactions would appear to favour conformation **2B**.

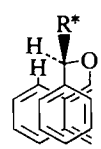


1 2 3

We have recently developed a simple synthesis of 1-alkoxy-



2A

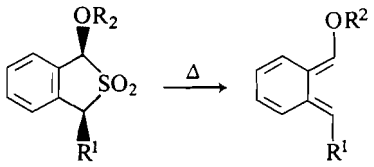


2B

[1]Revision received October 28, 1985.

[2]The absolute configuration of the molecules in the figure is inverted from Ito's work to facilitate comparison to later figures.

1,3-dihydrobenzo[*c*]thiophene-2,2-dioxides **4** (R^1=H, R^2=alkyl) and their 3-phenyl derivatives **4** (R^1=Ph), both of which can be thermalized to the α-alkoxy *o*-QDM **5** (13, 14).

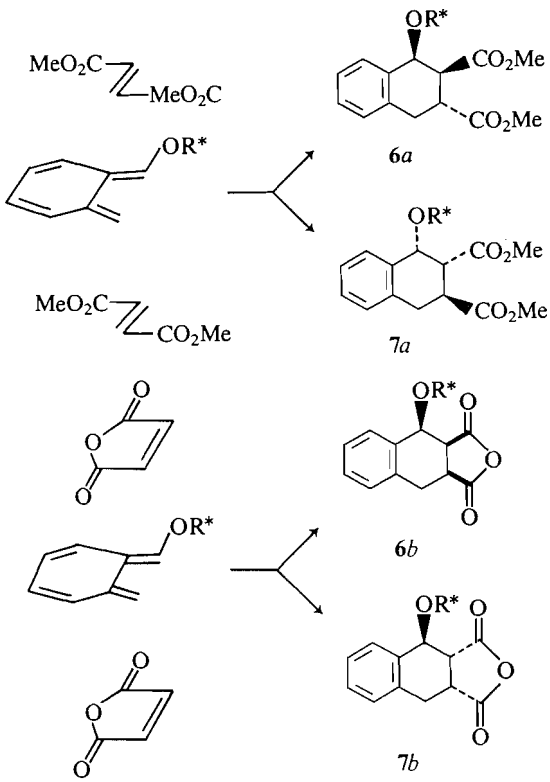


4 **5**

Using these precursors we have undertaken a study of the addition of dimethyl fumarate, methyl acrylate, and maleic anhydride to *o*-QDMs bearing a variety of chiral alkoxy groups, to determine the effect of structure of the chiral auxiliary on the extent of asymmetric induction (15). This study has also yielded information on the mechanism of the induction.

Results and discussion

The addition of α-alkoxy *o*-QDMs to fumarate has been shown previously to give exclusively the *cis*-1,2-*trans*-2,3 adduct (5, 13, 14). Similarly, addition to maleic anhydride has been shown to yield only the all-*cis endo* adducts (5, 16). Asymmetric induction results if a chiral and optically pure group R is able to favour formation of one of the diastereomers **6** or **7**. Separation of **6** and **7** followed by removal of the chiral auxiliary R would yield the optically pure adducts. Typically a large asymmetric induction is desirable as it enables selective synthesis of one of the desired stereoisomers **6** or **7**.



6a

7a

6b

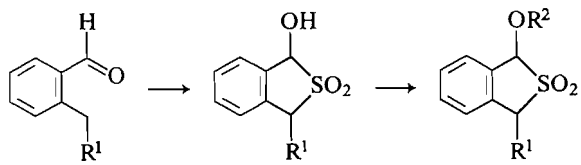
7b

In order to test whether a particular auxiliary can induce asymmetry in the cycloadducts, it is not necessary to use an optically pure group R since the ratio of the diastereomeric cycloadducts can be determined by ^{1}H nmr of the racemic adducts. In this way we have tested several chiral auxiliaries for their ability to give diastereoselectivity in the addition reaction.

In two cases, **4***i* and **4***j*, we have used an optically pure auxiliary to prepare optically pure acrylate cycloadducts, which could be related to a compound of known configuration thereby establishing the absolute configuration of the major cycloadduct.

The chiral auxiliaries were specifically chosen to test the effect of varying the position of the phenyl group and the position of the chiral center, within the auxiliary, on its ability to control the addition sterically. Two auxiliaries having no phenyl group were chosen to investigate asymmetric induction by groups incapable of any π-stacking interactions.

Thus the alkoxysulfones **4***e–j* were synthesized using the approach described previously (13, 14) and illustrated below.



8*a* R^1 = H
8*b* R^1 = Ph

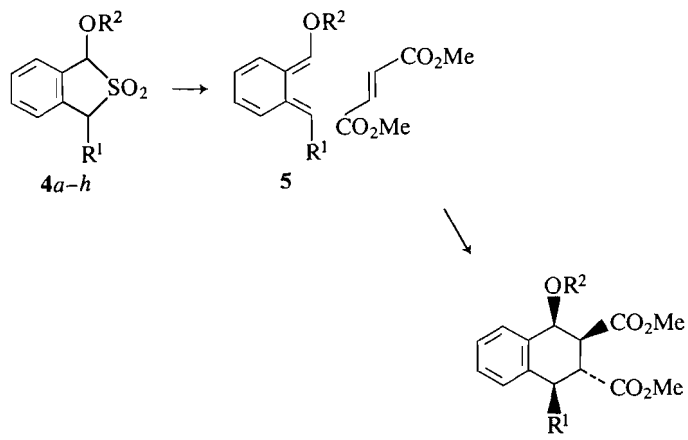
4*a* R^1 = H; R^2 = (+/−)-$CHCH_3Ph$
4*b* R^1 = H; R^2 = (+/−)-$CHCH_3CH_2Ph$
4*c* R^1 = H; R^2 = (+/−)-$CHCH_3CH_2CH_2Ph$
4*d* R^1 = H; R^2 = (+/−)-CH_2CHCH_3Ph
4*e* R^1 = H; R^2 = (+/−)-$CHCH_3$cyclohexyl
4*f* R^1 = H; R^2 = (+/−)-$CHCH_3$-tert-butyl
4*g* R^1 = Ph; R^2 = (+/−)-$CHCH_3$-tert-butyl
4*h* R^1 = Ph; R^2 = (+/−)-$CHCH_3Ph$
4*i* R^1 = H; R^2 = (*R*)-$CHCH_3Ph$
4*j* R^1 = H; R^2 = (*S*)-$CHCH_3Ph$

Sulfones **4***a–j* existed as a mixture of diastereomers and these mixtures could only be partially separated by chromatography on silica gel. The ratio of the diastereomers was determined in each case from the ratio of the methyl doublets in the nmr of the crude product and can be found in Table 1. In the case of **4***h* the two diastereomers were separated by chromatography on silica gel to give the individual diastereomers **4***h*-I and **4***h*-II. The yields of **4** (see Table 1) are based on the alcohol. The cycloadducts **9***a–h* were prepared by refluxing in toluene, benzene, or cyclohexane (see Experimental) (5 h) a mixture of **4** (100–200 mg) with four equivalents of dimethyl fumarate and 30 mg of anhydrous zinc oxide powder.



4*a–h* **5** **9***a–h* (+/−)

TABLE 1. Yields and diastereomer ratios

Sulfone	Sulfone yields[a]	Cycloadduct yields[b]	Elimination yields	Diastereomer ratios 4	Diastereomer ratios 9 or 10
4*a,i,j*	85	**9***a,i,j* 85(100)	81	4.3:1	2.8:1
		10*a* (100)			1.6:1
4*b*	83	**9***b* 77(87)	90	1.7:1	1.9:1
4*c*	93	**9***c* 79(91)	87	1.1:1	1:1
4*d*	84	**9***d* (63)	76	1.1:1	1:1

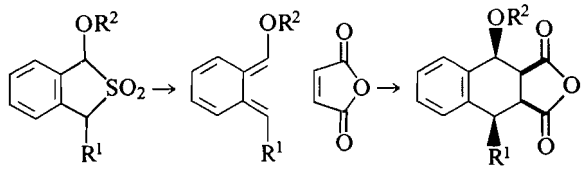
4*f*	78	**9***f* (83)	70	1.2:1	1.4:1
4*g*	90	**9***g* (92)	82	1.1:1	1.1:1
4*h*	68	**9***h* (91)	82	1.7:1	2.6:1
		10*h* (100)			1.8:1

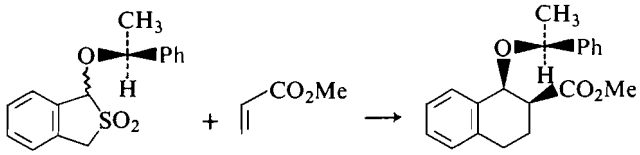
[a]Yields are after chromatography.
[b]Includes 5–20% of the *trans*-1,2-adduct. Crude yields in brackets.

4*a* and **4***h* were likewise reacted with maleic anhydride in benzene to give **10***a* and **10***h*.

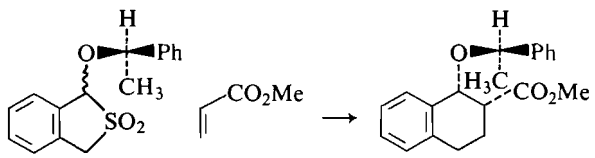


4*a*, **4***h* **5** **10***a*, **10***h* (+/−)

The zinc oxide markedly improves the yield of cycloadducts, presumably by preventing acid-catalysed hydrolysis of **5** due to adventitious water. The two optically active sulfones **4***i* and **4***j* were reacted with methyl acrylate by heating in toluene with an excess of methyl acrylate, in the presence of zinc oxide, at 150°C in a large sealed pressure flask. The adducts were isolated by filtering, evaporation, and recrystallization from hexane.



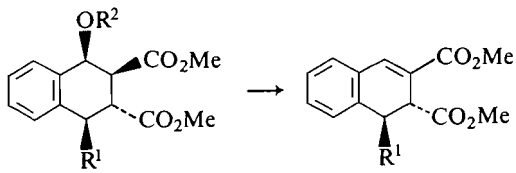
4*i* **11***i* (1′*R*, 1*S*,2*S*)



4*i* **11***j* (1′*S*, 1*R*, 2*R*)

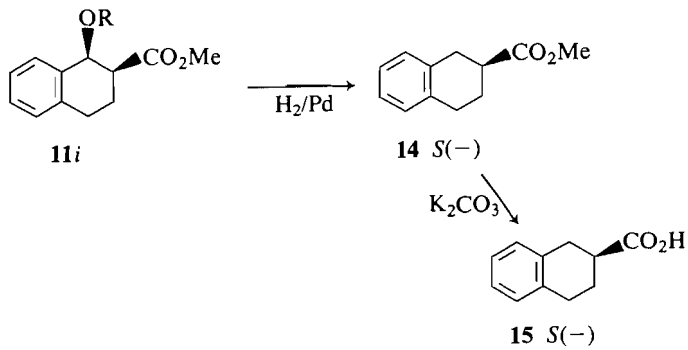
Nuclear magnetic resonance spectra of the crude and recrystallized adducts **11***i* and **11***j* indicated that the crystalline material was the major 1,2-*cis* adduct, making up ca. 40% of the crude mixture (nmr). The enantiomeric relationship between **11***i* and **11***j* was confirmed by their opposite rotations (**11***i*, $[\alpha]_D^{20}$ −50.0°; **11***i*, $[\alpha]_D^{20}$ +48.0°; *c* 0.50, $CHCl_3$), and their mirror image cd (circular dichroism) spectra.

The structures of the cycloadducts **9***a–h* were confirmed by elimination (refluxing toluene, toluenesulfonic acid) to form the known dihydrophthalenes **12** and **13** (13).



9 *a–f*(+/−) **12** (+/−) R^1 = H **13** (+/−) R^1 = Ph

The optically pure adduct **11***i* was reduced and hydrolysed to the acid **15**.



11*i* **14** *S*(−) **15** *S*(−)

The observed rotation of the acid **15** produced from **11***i* was −49.0°, which, when compared to the known configuration and rotation (*R*(+), $[\alpha]_D^{22}$ 55.5°) (17), establishes the configuration of **11***i* as 1′*R*,1*S*,2*S* and that of **11***j* as 1′*S*,2*R*,3*R* as shown.

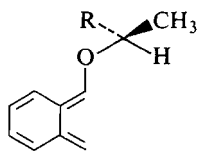
The crude cycloaddition products **9***a–h* although primarily diastereomeric mixtures of the *cis*-1,2 adducts as determined by nmr (13), also contained 5–30% of the *trans*-1,2 adducts. Despite the complexity of the nmr spectra, it was possible to assign chemical shifts and coupling constants for some of the individual *cis*-1,2 diastereomers (see Experimental). In particular, the diastereomers of the phenyl substituted adduct **9***h* were both analyzable and the spectra confirmed the *cis*-1,2-*trans*-3,4 stereochemistry. This in turn confirmed the *cis* relationship of the phenyl and alkoxy groups in **4***h* since only the *cis*-sulfone could open via a pericyclic reaction to the *E,E o*-QDM **5** and give the observed adduct stereochemistry (13). The yields of the alkoxy sulfones, the cycloadducts, and the diastereomer ratios of each are given in Table 1. The greatest diastereoselectivity was found for the auxiliary 1-phenylethyl, both in the formation of the alkoxysulfones and in the formation of the cycloadducts.

Since the cycloadducts were prepared from the mixture of alkoxysulfone diastereomers, it is tempting to conclude that the diastereoselectivity in adduct formation is actually a chiral memory from the corresponding sulfone. This cannot be the case, however, since the chirality at the benzylic carbon of the sulfone is lost when it thermalizes to the *o*-QDM **5**. To confirm this, the diastereomeric sulfones **4***h*-I and **4***h*-II were each thermalized with fumarate and it was found that the two diastereomeric sulfones gave the identical mixture of cycloadducts.

Mechanism of asymmetric induction

The simplest mechanism that would explain the diastereoselectivity – asymmetric induction in the formation of cycloadducts from the chiral *o*-QDMs, **5**, is one in which the chiral group preferentially blocks one face of the *o*-QDM. In work on the Diels–Alder reactions of dienes, Trost has suggested that chiral auxiliaries containing a phenyl group might block one face of the diene (11). By the use of models we determined that π-stacking in the *o*-QDM should be sterically difficult for a 1-phenylethyl group although this group gave the largest diastereoselectivity. In addition, if one considers the two π-stacked conformations **2**A and **2**B (having an *R*-1-phenylethyl substituent), it can be seen that **2**B should be preferred due to fewer nonbonded interactions relative to **2**A. However, *endo* addition of acrylate to **2**B would have ultimately yielded the *R*(+) acid 15, which was the opposite to that observed. For these reasons we do not think that π-stacking is the mechanism by which the 1-phenylethyl auxiliary directs addition of dienophiles to *o*-QDMs. It should be noted that Ito *et al.* inexplicably came to the opposite conclusion in considering a similar example (4).

In alkyl phenyl esters it has been shown that the most stable conformation is one in which the alkyl group lies in the plane of the aromatic ring allowing *p*–π overlap (18). Rotational barriers of up to 6 kcal/mol have been observed. Based on this analogy we suggest that the preferred conformation of the α-(*R*-1-phenylethyl) *o*-QDM is given by **16**. The relative steric



16 *a,b,c* R = Ph, cyclohexyl, *tert*-butyl

bulk of the phenyl and methyl groups serves to block the lower face of the *o*-QDM and cycloaddition of methyl acrylate to the upper face would give the 1′*R*,1*S*,2*S* cycloadduct, as was observed experimentally. This hypothesis is supported by the observation that the *o*-QDM **16***c*, which has a *tert*-butyl substituent in place of the phenyl of **16***a*, also induces asymmetry in the cycloadducts. The effect was smaller and may be because the phenyl group actually has a larger effective size due to specific and stronger solvation. The chiral auxilaries *c*, *d*, and *e* are less conformationally rigid and as such are not as effective in specifically blocking one face of the orthoquinodimethane.

Although we have not determined the absolute configuration of the fumarate and maleic anhydride adducts, we anticipate that this reaction will exhibit the same face selectivity as was observed with methyl acrylate.

Experimental

The nmr spectra were recorded on a Bruker AM-300 spectrometer using tetramethylsilane as an internal standard. The ir spectra were recorded on a Unicam 1000 spectrometer. Merck Kieselgel 60 was used for all column chromatography. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada. The structures of substituted sulfones **4***a–j* and the cycloadducts **9***a–h* and **11***i,j* are based on the conversion of the cycloadducts to known compounds (**9***a–h* to **12** or **13** and **11***i* to **14** and **15**). Elemental analyses are not included for these compounds.

1-Hydroxy-1,3-dihydrobenzo[c]thiophene-2,2-dioxide, **8**a

This compound was prepared from *o*-methylbenzaldehyde (9.4 g) using the method previously described (13, 14) to yield 6.4 g (34%). Traces of *o*-toluic acid were removed by trituration with a small volume of carbon tetrachloride at 30°C.

1-Hydroxy-4 phenyl-1,3-dihydrobenzo[c]thiophene-2,2-dioxide, **8**b

The sulfone was prepared as described previously (13, 14) from *o*-benzylbenzaldehyde (9.3 g) to yield 8.0 g (65%).

1-Alkoxy-1,3-dihydrobenzo[c]thiophene-2,2-dioxides and 1-alkoxy-3-phenyl-1,3-dihydrobenzo[c]thiophene-2,2-dioxide, **4**

The alkoxysulfones **4***a–j* were prepared by refluxing, for 5 h, a methylene chloride solution of 1.1–1.5 mmol of the corresponding hydroxy sulfone **8***a* or **8***b*, 5 mg of toluenesulfonic acid, and 1.0 mmol of the alcohols *rac*-1-phenylethanol, *rac*-2-phenylethanol, *rac*-3-phenylbutanol, *rac*-1-phenyl-2-propanol, *rac*-3,3-dimethyl-2-butanol, or *rac*-1-cyclohexylethanol. Compounds **4***i* and **4***j* were prepared from the pure enantiomers *R*-(+)-phenylethanol and *S*-(−)-phenylethanol. The alkoxy sulfones were isolated by washing the methylene chloride solution with 5% aqueous bicarbonate, drying, and evaporating, or more simply by filtering the mixture through a short silica gel column (5 cm × 1.5 cm) with methylene chloride, and evaporating. Crude yields were typically 90–100%. In most cases the mixture of diastereomeric sulfones was further purified by chromatography on silica gel using 20% ethyl acetate – hexane as eluant. In one case (**4***h*), the two constituent diastereomers were separated using the same solvent system. The following spectral data were obtained from the mixed diastereomers **4***a–h* and the separated diastereomers **4***h*-I and **4***h*-II.

4*a*: Major isomer I: ^{1}H nmr ($CDCl_3$) δ: 1.612 (d, J = 6.46, CH_3), 4.192 (d, J = 15.74, H-3A), 4.449 (d, J = 15.74, H-3B), 5.120 (s, H-1), 5.232 (q, J = 6.46, H-1′), 7.2–7.5 (m, aromatics).

4*a*: Minor isomer II: ^{1}H nmr ($CDCl_3$) δ: 1.691 (d, J = 6.44, CH_3), 4.187 (d, J = 15.6, H-3A), 4.371 (d, J = 15.6, H-3B), 5.176 (q, J = 6.44, H-1′), 5.531 (s, H-1), 7.2–7.5 (m, aromatics).

4*b*: Major isomer I: ^{1}H nmr ($CDCl_3$) δ: 1.461 (d, J = 6.22, CH_3), 2.905 (dd, J = 5.39, 13.75, H-1A′), 2.992 (dd, J = 7.76, 13.75, H-1B′), 4.145 (d, J = 15.59, H-3A), 4.312 (d, J = 15.59, H-3B), 4.4 (m, H-2′), 5.191 (s, H-1), 7.2–7.5 (m, aromatics).

4*b*: Minor isomer II: ^{1}H nmr ($CDCl_3$) δ: 1.289 (d, J = 6.08, CH_3), 2.771 (dd, J = 8.69, 13.23, H-1A′), 3.280 (dd, J = 4.67, 13.23, H-1B′), 4.221 (d, j = 15.60, H-3A), 4.394 (d, J = 15.60, H-3B), 4.4 (m, H-2′), 5.498 (s, H-1), 7.2–7.5 (m, aromatics).

4*c*: Mixture of two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 1.398 (d, J = 6.08) and 1.458 (d, J = 6.25) H-1′, 1.90(m(and 2.06(m) H-3′, 2.7–2.9(m(H-4′, 4.151(m) and 4.25(m) H-2′, 5.492(s) and 5.470(s) H-1, 4.383 (d, J = 15.7), 4.383 (d, J = 15.6), and 4.373 (d, J = 15.7) H-3, 7.1–7.5 (m, aromatics).

4*d*: Mixture of two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 1.323 (d, J = 6.85 and 1.366 (d, J = 6.98) H-3′, 3.164 (octet, J = 7.17) H-2′, 3.882 (dd, J = 7.45, 9.39) H-1A′, 3.918 (dd, J = 7.72, 9.50) and 4.33(m) H-1′, 4.171 (d, J = 15.8), 4.185 (d, J = 15.8), 4.329 (d, J = 15.8), and 4.334 (d, J = 15.8) H-3, 5.192(s) and 5.332(s) H-1, 7.026 (d, J = 5.35) H-4, 7.2–7.45 (m, aromatics).

4*e*: Mixture of two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 1.15(m) and 1.75(m) cyclohexyl, 1.337(d, J = 6.17) and 1.354(d, J = 6.42) H-1′, 3.919(d of quart, J = 6.39, 5.42) and 3.988(quintet, J = 6.11) H-2′,

4.21(br d, J = 15.9) and 4.37(br d, J = 15.9) H-3, 5.506(s) H-1, 7.726(m) H-4, 7.743 (m, aromatics).

4*f*: Major isomer I: ^{1}H nmr ($CDCl_3$) δ: 0.984 (s, *tert*-butyl), 1.309 (d, J = 6.22, CH_3), 3.945 (q, J = 6.22, H-1′), 4.207 (d, J = 15.6, H-3A), 4.347 (d, J = 15.6, H-3B), 5.546 (s, H-1), 7.2–7.6 (aromatics).

4*f*: Minor isomer II: ^{1}H nmr ($CDCl_3$) δ: 1.024 (s, *tert*-butyl), 1.410 (d, J = 6.41, CH_3), 3.733 (q, J = 6.41, H-1′), 4.217 (d, J = 15.6, H-3A), 4.355 (d, J = 15.6, H-3B), 5.546 (s, H-1), 7.2–7.6 (aromatics).

4*g*: Isomer I: ^{1}H nmr ($CDCl_3$) δ: 0.926 (s, *tert*-butyl), 1.328 (d, J = 6.22, CH_3), 3.901 (q, J = 6.22, H-1′), 5.278 (s, H-1), 5.676 (s, H-3), 7.0–7.7 (aromatics).

4*h*-I: ^{1}H nmr ($CDCl_3$) δ: 1.733 (d, J = 6.44, H-2′), 5.213 (q, J = 6.44, H-1′), 5.270 (s, H-1), 5.708 (s, H-3), 7.07 (m, H-4), 7.2–7.6 (m, aromatics).

4*h*-II: ^{1}H nmr ($CDCl_3$) δ: 1.563 (d, J = 6.45, H-2′), 5.190 (q, J = 6.44, H-1′), 5.270 (s, H-1), 5.708 (s, H-3), 7.07 (m, H-4), 7.2–7.6 (m, aromatics).

trans-*1,2*-trans-*2,3-1-Alkoxy-2,3-dicarbomethoxy-1,2,3,4-tetrahydronaphthalene,* **9**a–f, *and* trans-*1,2*-trans-*2,3*-trans-*3,4-1-alkoxy-2,3-dicarbomethoxy-4-phenyl-1,2,3,4-tetrahydronaphthalene,* **9**g *and* **9**h

The cycloadducts were prepared by refluxing a solution (10 mL) of each of **4***a–g*, **4***h*-I, or **4***h*-II (100–200 mg), four equivalents of dimethyl fumarate, and 30 mg of anhydorus zinc oxide powder for 5 h. The following solvents were used: **4***a–f* toluene, **4***g* benzene, **4***h* cyclohexane. The solution was filtered through a 5 cm × 1.5 cm silica gel column with methylene chloride, evaporated to dryness, and then heated at 100°C at high vacuum to remove excess fumarate. The mixture of diastereomerers was then analysed by nmr. The structures of the cycloadducts were confirmed by elimination of the alcohol as described below.

9*a*: Major isomer I: ^{1}H nmr ($CDCl_3$) δ: 1.400 (d, 6.40, H-1′), 2.800 (dd, J = 10.85, 16.8, H-4a), 3.137 (dd, J = 3.19, 11.35, H-2), 3.259 (dd, J = 6.6, 17.0, H-4e), 3.622 (dt, J = 6.75, 11.15, H-3), 3.747 (s, OCH_3), 4.501 (q, J = 6.40, H-2′), 6.686 (d, J = 7.2, H-5), 6.95–7.40 (m, aromatics).

9*a*: Minor isomer II: ^{1}H nmr ($CDCl_3$) δ: 1.197 (d, 6.45, H-1′), 2.881 (dd, J = 9.45, 16.85, H-4a), 3.002 (dd, J = 2.285, 11.07, H-2), 3.392 (dd, J = 7.63, 16.8, H-4e), 3.74 (ddd, J = 7.6, 7.5, 11.1, H-3), 3.661 (s, OCH_3), 3.736 (s, OCH_3), 4.363 (q, J = 6.39, H-2′), 6.95–7.4 (m, aromatics).

9*b*: Mixture of two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 0.845 (d, J = 6.11, CH_3), 1.106 (d, J = 6.04, CH_3), 2.4–3.8 (series of mult), 3.717 (s, OCH_3). 3.74 (s, OCH_3), 4.847 (d, J = 3.06, H-1), 4.931 (d, J = 2.98, H-1), 6.87 (m, H-5), 7.0–7.3 (m, aromatics).

9*c*: Mixture of (mainly) two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 0.885 (d, J = 6.14, CH_3), 1.114 (d, J = 6.02, CH_3), 1.45–1.95 (m, H-3′), 2.1–3.65 (series of mult), 3.694 (s, OCH_3), 3.723 (s, OCH_3), 3.737 (s, OCH_3), 3.739 (s, OCH_3), 4.45 (d, J = 3.10, H-1), 4.876 (d, J = 2.98, H-1), 6.76 (d, H-5), 7.0–7.4 (m, aromatics).

9*d*: Mixture of two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 1.136 (d, J = 7.01, CH_3), 1.193 (d, J = 6.88, CH_3), 2.75–3.8 (series of mult, H-2, H-3, H-4), 3.534 (s, OCH_3), 3.709 (s, OCH_3), 3.728 (s, OCH_3), 3.740 (s, OCH_3), 4.706 (d, J = 3.30, H-1), 4.724 (d, J = 3.28, H-1), 7.1–7.3 (m, aromatics).

9*e*: Mixture of two diastereomers: ^{1}H nmr ($CDCl_3$) δ: 0.694 (d, J = 6.33, CH_3), 1.053 (d, J = 6.19, CH_3), 1.1(br m, cyclohexyl), 1.6 (br m, cyclohexyl), 2.8–3.5 (series of mult, H-2–H-4), 3.743 (s, OCH_3), 3.738 (s, OCH_3), 3.728 (s, OCH_3), 4.111 (d, J = 3.11, H-1), 4.849 (d, J = 2.91, H-1), 7.1–7.3 (m, aromatics).

9*f*: Major isomer: ^{1}H nmr ($CDCl_3$) δ: 0.590 (s, *tert*-butyl), 1.031 (d, J = 6.18, CH_3), 2.8–3.4 (series of mult, 4H), 3.295 (q, J = 6.18, H-1′), 3.73 (s, OCH_3), 4.805 (d, J = 2.97, H-1).

9*f*: Minor isomer: ^{1}H nmr ($CDCl_3$) δ: 0.806 (s, *tert*-butyl), 0.490 (d, J = 6.3, CH_3), 2.8–3.4 (series of mult, 4H), 3.200 (d, J = 6.3, H-1′), 3.73 (s, OCH_3), 4.839 (d, J = 2.79, H-1).

9*g*: Major isomer: ^{1}H nmr ($CDCl_3$) δ: 0.723 (s, *tert*-butyl), 1.10 (d, J = 6.15, CH_3), 3.2–3.8 (series of mult, 5H), 3.455 (s, OCH_3), 3.707 (s, OCH_3), 4.088 (d, J = 11.3, H-4), 4.904 (d, J = 2.97, H-1), 6.81 (m, 1H), 7.1–7.4 (aromatics).

9*g*: Minor isomer: ^{1}H nmr ($CDCl_3$) δ: 0.855 (s, *tert*-butyl), 0.703 (d, J = 6.24, CH_3), 3.2–3.8 (series of mult, 5H), 3.505 (s, OCH_3), 3.707 (s, OCH_3), 4.088 (d, J = 11.3, H-4), 4.923 (d, J = 2.47, H-1), 6.81 (m, 1H), 7.1–7.4 (aromatics).

9*h*: Major isomer I: ^{1}H nmr ($CDCl_3$) δ: 1.447 (d, J = 6.38, CH_3), 3.300 (dd, J = 11.97, 2.77, H-2), 3.498 (s, OCH_3), 3.792 (s, OCH_3), 3.733 (br t, J = 11.44), 4.054 (d, J = 10.99, H-1), 4.645 (q, J = 6.35, H-1′), 5.022 (d, J = 2.72, H-1), 6.78 (m, H-5), 6.95–7.40 (m, aromatics).

9*h*: Minor isomer II: ^{1}H nmr ($CDCl_3$) δ: 1.310 (d, J = 6.44, CH_3), 3.179 (dd, 2.50, 12.12, H-2), 3.542 (s, OCH_3), 3.628 (s, OCH_3), 3.878 (dd, 10.58, 12.10, H-3), 4.119 (d, J = 10.59, H-4), 4.575 (q, J = 6.44, H-1′), 4.669 (d, J = 2.62, H-1), 6.78 (m, H-5), 6.95–7.40 (m, aromatics).

Maleic anhydride adducts **10**a *and* **10**h

The cycloadducts **10***a* and **10***h* were prepared by refluxing a benzene solution (10 mL) of **4***a* or **4***h*, (200–400 mg), four equivalents of maleic anhydride, and 30 mg of powdered zinc oxide for 20 h. The solution was filtered to remove zinc oxide, evaporated, and then heated to 100°C under high vacuum to remove maleic anhydride. The mixture of diastereomers was then analysed by nmr. Compound **10***a* recrystallized from benzene–hexane to give the major diastereomer as colourless crystals, mp 152–154°C; ir(CH_2Cl_2): 1790(s) and 1875(w) cm^{-1}; nmr ($CDCl_3$) δ: 1.192 (d, J = 6.47, C_3), 3.088 (dd, J = 8.9, 15.0, H-4), 3.232 (dd, J = 8.6, 15.0, H-4A), 3.317 (dd, J = 3.7, 10.5, H-4A), 3.463 (dt, J = 8.6, 10.5, H-3), 4.056 (q, J = 6.47, H-1′), 4.969 (d, J = 3.7, H-1), 6.9–7.4 (aromatics). Minor diastereomer, nmr ($CDCl_3$) δ: 1.403 (d, J = 6.39, 3.0–3.5 (m, 4H), 4.410 (q, J = 6.39, H-1′), 4.990 (d, J = 3.82, H-1), 6.9–7.4 (aromatics). *Anal.* calcd. for $C_{20}H_{18}O_4$: C 74.52, H 5.63; found: C 74.96, H 5.96.

Compound **10***h* recrystallized from benzene–hexane gave a mixture of diastereomers as colourless crystals; ir(CH_2Cl_2): 1790(s) and 1865(s) cm^{-1}; major isomer, nmr ($CDCl_3$) δ: 1.597 (d, J = 6.35, CH_3), 3.83 (m, H-2 and H-3), 4.243 (d, J = 5.5, H-4), 4.772 (d, J = 5.8, H-1), 4.915 (q, J = 6.35, H-1′), 6.9–7.5 (aromatics). Minor isomer, nmr ($CDCL_3$) δ: 1.366 (d, J = 6.41, CH_3), 3.83 (m, H-2), 3.364 (dd, J = 10.1, 4.9, H-3), 4.480 (q, J = 6.41, H-1′), 4.64 (d, J = 10.1, H-4), 4.656 (d, J = 4.9, H-1), 6.9–7.5 (aromatics). *Anal.* calcd. for $C_{26}H_{22}O_4$: C 78.37, H 5.57; found: C 78.49, H 5.82.

*(1S,2S)-1-(*R*-1-Phenylethoxy)-2-carbomethoxy-1,2,3,4-tetrahydronaphthalene,* **11**i

The alkoxysulfone **4**g (479 mg) was heated with methyl acrylate (1 mL), toluene (10 mL), and anhydrous powdered zinc oxide (30 mg) at 150°C under nitrogen in a sealed pressure flask (200 mL) for 2 hours with stirring. The solution was filtered through a 5 × 1.5 cm silica gel column with methylene chloride, evaporated, and recrystallized from hexane to give 96.1 mg (19%), mp 89–91°C, nmr of the crude reaction mixture indicted that the isolated adduct was the major adduct and made up ca. 40% of the crude reaction mixture.

11*i* ir(CH_2Cl_2): 1738 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.419 (d, 6.44, CH_3), 2.064 (m, H-3e), 2.423 (m, H-3a), 2.724 (m, H-4a), 2.794 (m, H-2), 2.987 (m, H-4e), 3.820 (s, OCH_3), 4.590 (q, J = 6.40, H-1′), 4.857 (d, H-1), 6.71 (br d, J = 8.1, H-5), 6.9–7.45 (m, aromatics). The following coupling constants were determined by spectrum simulation and iterative fitting: $J_{1,2}$ = 3.26, $J_{2,3e}$ = 3.36, $J_{2,3a}$ = 12.01, $J_{3e,4e}$ = 2.991, $J_{3e,4a}$ = 6.68, $J_{3a,4e}$ = 6.30, $J_{3a,4a}$ = 11.12, $J_{3e,3a}$ = −13.66, $J_{4e,4a}$ = −17.32; $[\alpha]_D^{20}$ −50.0° (*c* 0.5, $CHCl_3$).

*(1*R*,2*R*)-(*S*-1-Phenylethoxy)-2-carbomethoxy-1,2,3,4-tetrahydronaphthalene,* **11**j

Compound **11***j* was prepared from 493 mg of **4***h* in a manner identical to that described for **11***i* to yield 125 mg of crystals (24%); ir and nmr spectra were identical to those of **11***i*; $[\alpha]_D^{20}$ +48.0° (*c* 0.5, $CHCl_3$).

Racemic ***11*** *(****11****i+****11****j)*

The racemic acrylate adduct was prepared from **4***a* in a manner identical to that described above for **11***i* and **11***j* and was recrystallized from hexane, mp 65–67°C; ir and nmr identical to **11***i*. *Anal.* calcd. for $C_{20}H_{22}O_3$: C 77.39, H 7.14; found: C 77.66, H 7.23.

2,3-Dicarbomethoxy-3,4-dihydronaphthalene, ***12****, and* trans*-1-phenyl-2,3-dicarbomethoxy-1,2-dihydronaphthalene,* ***13***

Elimination of the alcohol from the adducts **9***a–h* was accomplished by refluxing a toluene solution of each adduct (mixture of diastereomers) (50–150 mg) and toluene sulfonic acid (5 mg) in toluene (5–10 mL) for 5 h, filtering through a 5 cm × 1.5 cm silica gel column with methylene chloride and evaporating. The residue was chromatographed on silica gel (20% ethyl acetate – hexane) to give **12** (or **13**) in the yields given in Table 1. Compounds **12** and **13** were identified by comparison of their properties to those previously reported (13).

S*-(−)-2-Carboxyethyl-1,2,3,4-tetrahydronaphthalene,* ***14***

The adduct **11***i* (113 mg) was hydrogenated at 1 atm (1 atm = 101.3 kPa) and 20°C over 5% Pd/C (50 mg) in 10% acetic acid – methanol (10 mL). After 15 h the solution was filtered and evaporated to leave 75 mg of an oil, identified as the ester **14** by comparison to the literature (19); [α] −45° (*c* 1.34, $CHCl_3$).

S*-(−)-2-Carboxy-1,2,3,4-tetrahydronaphthalene,* ***15***

The ester **14** (75 mg) was refluxed with K_2CO_3 (200 mg) in 17% water–ethanol (20 mL) for 4 h. The solution was partially evaporated, diluted with water, acidified, and extracted with methylene chloride to yield 57.8 mg of **15** (83%); $[\alpha]_D^{20}$ −49.0° (*c* 0.5, $CHCl_3$), cf. $[\alpha]_D^{20}$ +55.5° (*c* 1.4, $CHCl_3$), for the *R*(+) isomer (17).

Acknowledgments

I would like to acknowledge the very capable technical assistance of Kirk Marat, who recorded and analysed the nmr spectra.

Alkylation of camphor imines of glycinates. Diastereoselectivity as a function of electronic factors in the alkylating agent[1]

JOHN M. MCINTOSH AND PRATIBHA MISHRA[2]
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 24, 1985

JOHN M. MCINTOSH and PRATIBHA MISHRA. Can. J. Chem. **64**, 726 (1986).

Alkylation of the (*R*)-camphor imine of *tert*-butyl glycinate with a variety of alkylating agents gave diastereoselectivities ranging from 0–100%. Simple alkyl halides larger than methyl give de's (diastereomeric excesses) of ca. 50% whereas those derived from allylic type systems afford de's of 75–100%. The results are best explained by invoking a transition state interaction between the π system of the alkylating agent and the imine which, for steric reasons, requires alkylation to occur from the pro-*R* face.

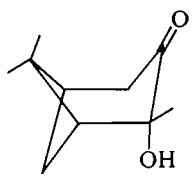
JOHN M. MCINTOSH et PRATIBHA MISHRA. Can. J. Chem. **64**, 726 (1986).

Les diastéréosélectivités des réactions d'alkylation de l'imine formée par la (*R*)-camphre et le glycinate de *tert*-butyle par divers agents alkylants varient de 0 à 100%. Les sélectivités des réactions affectuées avec des halogénures simples plus volumineux que le méthyle sont de l'ordre de 50% alors que celles effectuées avec des systèmes de types allyliques vont de 75 à 100%. La meilleure explication de ces résultats implique une interaction dans l'état de transition entre le système π de l'agent alkylant et l'imine qui, pour des raisons stériques, nécessite que l'alkylation se fasse par le face pro-*R*.

[Traduit par la revue]

Introduction

Some time ago, several reports on the alkylation of chiral imines of glycinates appeared. In particular, the use of menthone (1) and hydroxynopinone (**1**) (2) gave modest to fair stereoselectivities with the latter being the better *c*hiral *d*erivatizing *a*gent (CDA). The enhanced selectivity using **1** as CDA was attributed to the presence of the extra chelating center, which forced the enolate system into an arrangement in which the steric influence of the *syn*-methyl group could impede the attack of the electrophile from the top face of the molecule. While more recent developments (3) have displaced this methodology, the rationale given implied that camphor (**2***a*) might be more effective due to the closer proximity of the C-8 methyl group to the carbanionic center. In addition, the rigid



1

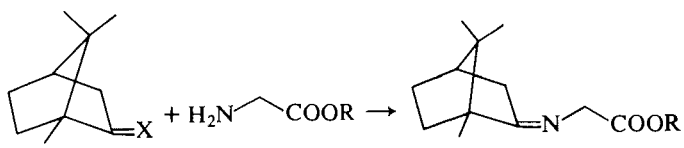
structure of **2** which would facilitate stereochemical reasoning, its ready availability in both enantiomeric forms, and the ease with which substituents can be introduced at many positions in stereospecific ways suggested that an investigation of its use as a CDA in glycinate alkylations would prove instructive.[3]

Because of the hindered nature of the carbonyl in **2***a*, its condensation with amines is known (5) to be a difficult reaction requiring vigorous reaction conditions. However, prior conversion into the thione **2***b* (6) markedly increases the facility of "carbonyl" additions (7). For derivatization with glycine esters, the use of **2***b* appears to be mandatory, as we have been unable to effect such condensations with **2***a* under a number of conditions.

Condensation of **2***b* with the hydrochlorides of methyl or ethyl glycinates in the presence of DABCO (1,4-diazabicyclo[2.2.2]octane) as a base required a large excess of amino ester and gave **3***a* or **3***b* severely contaminated with polyglycine. However, the corresponding *t*-Bu glycinate (free base) smoothly condensed with **2***b* to give **3***c* in high yield.

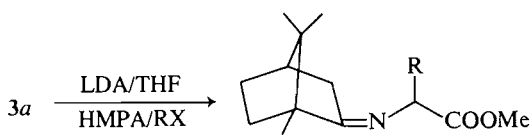
Two diastereomers of **3** are possible. However, both the 75-MHz ^{13}C nmr and the 300-MHz ^{1}H nmr were consistent only with the presence of one diastereomer. Models show that the *Z* isomer is severely destabilized by a steric interaction with the C-10 methyl group and, for this reason, **3***a*, *b*, *c* are assigned the *E* configuration as shown in Scheme 1 (5*b*).

Preliminary experiments on the alkylation of **3***a* gave the following results. Alkylation with MeI (**6***a*) or BzBr (**7**) gave

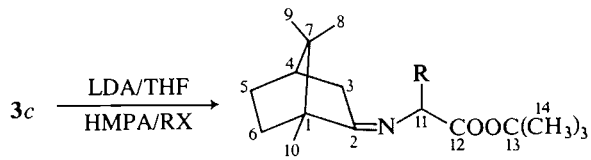


2*a* X = O
b X = S

3*a* R = Me
b R = Et
c R = *t*-Bu



4*a* R = Me
b R = Bz



5 *a–m* (see Table 1).

SCHEME 1

[1]Presented in part at the annual conference of the Chemical Institute of Canada, Kingston, Ontario; June 1985.

[2]Holder NSERC predoctoral fellowship, 1981–present.

[3]Camphor has been used as a CDA in many other reactions. For some recent examples, see ref. 4.

TABLE 1. Products, yields, and stereochemical compositions of alkylation products **5**

[a]Isolated yields. Yields in parentheses are those based on unrecovered starting material.
[b]Based on the integration of the methine hydrogens at 300 MHz, unless otherwise noted.
[c]Based on the peak heights of the camphor methyl groups in the ^1H nmr spectrum.

diastereomeric mixtures of products **4***a* and **4***b* in ratios of 3:2 and 3:1, respectively. In hindsight, this former result was most useful, as the ^1H nmr of **4***b* showed a large difference ($\Delta\delta$ = 0.5) in the chemical shift of the C-8 methyl groups for the two diastereomers. Smaller differences were observed for the same signals in **4***a*. In addition, two doublets of doublets were evident for the methine proton in **4***b*. No dialkylated products were obtained. The presence of one equivalent of HMPA (hexamethylphosphoramide) in the reaction mixture was essential for good chemical yields. In its absence the yield of **4***b* fell to 40%, while the use of two equivalents gave a 2:1 mixture of diastereomers. When **4***b* was treated with LDA (lithium diisopropylamide) under the same conditions used for the alkylation of **3***c*, and the reaction was quenched with a 100-fold excess of either D_2O or CF_3COOD, ca. 50% of the recovered **4***b* was monodeuterated. (Previous workers (2*a*) have assumed that the absence of dialkylated material ensured that the product was a result of a kinetic process. Our deuteration result calls this into question.) As a result of steric factors, the imine bond in **5** is remarkably inert to many conditions. While this is advantageous in terms of the alkylation reactions, it causes some problems in the generation of the free amino ester. To date, the best method we have found for achieving this transformation is transamination using hydroxylamine (2*a*, *b*). Hydrolysis with citric acid (2*a*, *b*) was ineffective.

When the alkylation and deuteration experiments were repeated on imine **3***c* a high chemical yield of **5***a* was obtained, which consisted of a ca. 1:1 mixture of diastereomers. However, the **5***b* obtained was shown to be stereochemically homogeneous by hydrolysis to (*R*)-phenylalanine *tert*-butyl ester and by 300-MHz nmr. An AMX set of signals (J_{AM} = 13 Hz, J_{AX} = 10 Hz, J_{MX} = 4 Hz) was exhibited by the benzyl and methine protons. No sign of a second set of signals for the other possible diastereomer was evident. In addition, the methyl region was clean, whereas multiple signals were observed in all cases where two diastereomers were formed. Attempted deuteration of **5***a* and **5***b* failed completely. No deuterium incorporation could be detected by mass spectrometry. Thus it appears that the presence of the bulky ester group effectively ensures that the observed stereochemistry is a result of a kinetically controlled process. These results also clearly preclude attempts at further alkylation.

These results are most easily attributed to the differing steric requirements of the alkylating agent. The working model of the reacting system[4] involved an internally chelated enolate anion that is coplanar with the camphor moiety. Although models indicate that the C-8 methyl is somewhat removed from the path required for *exo*-attack (on the pro-*S* face), increasing the steric bulk of the alkylating agent might be expected to enhance the selectivity. To explore the stereoselectivity further, the alkylation of **3***c* with a range of alkylating agents that differ in reactivity (10) and steric requirements was examined. The results are shown in Table 1. The stereochemical composition of the product from each reaction was determined by integration of the nmr absorptions of the methine proton of the imine in the 300-MHz ^1H nmr spectrum (each diastereomer gave a doublet of doublets) and by comparison of the relative intensities of the two signals for C-8. It was also usually possible to estimate the diastereomeric ratio from the intensities of the camphor C-8 absorptions in the 60-MHz spectra. In the case of **5***b*, hydrolysis to the amino ester was performed and the optical purity determined by comparison of the specific rotation with the reported value. In all other cases, the absolute stereochemistry of the product present in the larger diastereomeric excess (de) was assumed to be *R*. Supporting this assumption is the fact that in all cases in which diastereomeric mixtures were obtained, the methine proton of the *R*,*R* isomer appeared at lower field than that of the *R*,*S* isomer. The same order was observed for the stereoisomeric mixtures of **4***a* and **4***b*.

While the tabulated chemical yields of products appear to correlate well with established concepts of reactivity, the stereochemical results do not. The more reactive halides

[4]It is well documented that *simple* lithio enolates are not monomeric (8) and also that coordinating solvents (HMPA, etc.) at least partially deaggregate the clusters (9). Thus, although the models proposed herein are undoubtedly a simplified version of the actual structure, they are useful in a *predictive* sense.

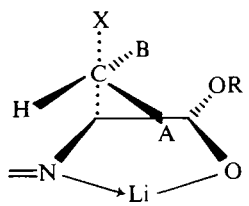
[a] At 75 MHz in $CDCl_3$.
[b] Values in brackets [ ] for the minor diastereomer.

(allylic, benzylic) should involve more reactant-like transition states and this should lead to lower stereoselectivities. A recent comprehensive review (11) is replete with such examples in which methyl iodide affords higher de's than benzyl bromide. Alkylation of glycine derivatized with **1** also shows this behaviour. Examination of Table 1 shows that our results with the camphor-derivatized glycinates are in complete conflict with this concept, that the reaction temperature has only a minor effect (compare runs 7 and 8, 9 and 10), and that the steric bulk of the alkylating agent does not correlate with the observed de's (compare runs 8 and 10).

The common feature of the alkylating agents which give de's of 75% or greater is the presence of a carbon π system immediately adjacent to the reacting center. Using the model previously mentioned, the *sterically* preferred transition state geometry for alkylation is undoubtedly that in which the R-group of RCH_2X is oriented away from the congested lithiated amine (A = H, B = R, Scheme 2). However, models

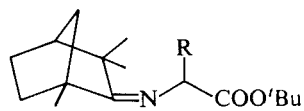


SCHEME 2

suggest that a much larger preference for attack on the pro-*R* face would result from a conformation in which the R group of the alkylating agent lies in an "eclipsed" arrangement with the lithiated imine (A = R, B = H, Scheme 2). The positive charge induced in the π system by the partial breaking of the carbon–halogen bond could favor A. This would account for the apparent abnormality of the α-haloesters, since such an interaction would be unfavorable. This thesis is also supported by comparison of the results obtained using **17** with **15** and **13** with **16**. In each case, when a favorable resonance interaction of the π system with a developing charge on the carbon undergoing substitution would cause an electron deficiency in the π system, increased diastereoselectivity is observed.

Catalytic hydrogenation of **5***i* gave **5***g*, the same product obtained using **12** as the alkylating agent but with a significant increase in selectivity. Catalytic reduction of **5***g* gave the propyl compound without loss of stereochemical integrity. Also it should be noted that the use of α-haloalkyl phenyl sulfides (e.g., **15**) as synthons for simple alkyl halides to achieve higher stereoselectivities may be generally useful in this system.

It is noteworthy that the imine (**18***a*) of fenchone and *t*-Bu



18*a* R = H
b R = Bz

glycinate can be prepared in an analogous manner, albeit with much more difficulty. In this case the stereochemistry of the imine is homogeneous and must be *syn* to the bridgehead methyl group (*E* stereochemistry). Alkylation of **18***a* with **7** affords the alkylated imine **18***b* as a 3:1 mixture of diastereomers. This is unexpected, as models indicate that little steric difference exists between the two diastereofaces of the lithiated imine.

The previously noted stability of the imine bond is illustrated by the observation that attempted deprotonation of **5***b* with BuLi led to the formation of two new products, which have been tentatively identified (mass spectroscopy) as **19** and **20**, the

products of addition to the *t*-Bu ester. No addition to the imine bond was detectable. Further, LAH (lithium aluminum hydride) reduction of **5***g* did not occur until refluxing ether was employed. Under these conditions, **21***a* was obtained from **5***g* and **21***b* from **5***b* with little loss of stereochemical integrity observed (de = 48% and >98% respectively).

From the foregoing results, it seems clear that the use of camphor in place of menthone or **1** subtly alters the transitions states for alkylation. Further investigations into the use of modified camphor derivatives and other alkylating agents is required before more definitive conclusions regarding the transition state structure can be reached. Such work is currently in progress.

Experimental

Unless otherwise noted, infrared spectra were run as neat liquids on either a Perkin–Elmer Model 180 instrument or on a Nicolet 5-DX instrument in the FT mode. The five strongest peaks are reported. The nmr spectra were run on a Nicolet QE-300 instrument (^{1}H nmr at 300 MHz and ^{13}C nmr at 75 MHz) or at 60 MHz (^{1}H nmr) or 22.64 MHz (^{13}C nmr) in $CDCl_3$ solution, and are referenced to internal TMS. The data are presented in the format: (multiplicity, number of hydrogens, coupling constant) and are at 300 (proton) or 75 (carbon) MHz unless otherwise specified. Values in brackets ([ ]) are for the minor diastereomer. Optical rotations were measured on a Perkin–Elmer model 241 polarimeter in 95% ethanol solution with c = 10 unless noted to the contrary. Gas chromatographic analyses were performed using a 1.5 ft × 1/8 in. column packed with 5% OV-101 on Chromosorb W. Mass spectra were run on a Varian MAT CH-5 DF instrument in the field ionization (fi) mode. Solvents were removed at reduced pressure and the drying agent was anhydrous $MgSO_4$. Column chromatography utilized silica gel 60 (Merck) and 20% ether in petroleum ether as eluant unless otherwise specified. Satisfactory analyses (C, H, N) were obtained for all compounds (see Table 3). Microanalyses were performed by Canadian Microanalytical Services, Vancouver or Guelph Chemical Laboratories, Guelph, Ontario.

Imine **3**a

Camphorthione (**1***b*) (6) (13.7 g, 81 mmol), $[\alpha]_D^{25}$ −30.4°, 1.4-diazabicyclo[2.2.2]octane (DABCO) (10.1 g, 90 mmol), and methyl glycinate hydrochloride (40.2 g, 320 mmol) were dissolved in 500 mL of methanol and stirred at 45–50°C for 20 h. The solution was concentrated, diluted with ether, filtered, and the creamy solid washed with ether. The ether solution was concentrated and chromatographed to give 13.75 g (76%) of imine **3***a*, bp 93–95°C (0.8 Torr; 1 Torr = 133.3 Pa); ir: 2970, 1745, 1675, 1195, 1175 cm^{-1}; ^{1}H nmr (60 MHz): 4.03 (s, 2H), 3.67 (s, 3H), 2.60–0.90 (m, 7H), 0.98 (s, 3H), 0.92 (s, 3H), 0.77 (s, 3H); ^{13}C nmr (22.64 MHz): 187.1, 170.7, 54.1, 53.7, 51.6, 47.2, 43.8, 35.5, 31.9, 27.2, 19.3, 18.9, 11.1.

Imine **3**b

A mixture of ethyl glycinate hydrochloride (4 mmol), **1***b* (3 mmol), and DABCO (3 mmol) in 80 mL of xylene was stirred and heated at 145°C. Additional portions of ester and DABCO were added several times during the reaction. A tarry material (assumed to be polyglycine) formed during the reaction. The solution was cooled, decanted from the residue, concentrated, and chromatographed (3:2 hexane–ether) to give 0.38 g (54%) of imine **3***b*; ir: 2970, 1740, 1675, 1370, 1180 cm^{-1}; ^{1}H nmr (60 MHz): 4.14 (q, 2H, J = 7 Hz), 4.05 (s, 2H), 2.63–0.90 (m, 7H), 1.23 (t, 3H, J = 7 Hz), 0.98 (s, 3H), 0.92 (s, 3H), 0.78 (s, 3H); ^{13}C nmr (22.64 MHz): 187.2, 170.1, 60.5, 54.2, 53.8, 47.2, 43.9, 35.6, 31.9, 27.4, 19.4, 18.8, 14.0, 11.1.

Imine **3**c

tert-Butyl glycinate (12) (5.7 g, 44 mmol) and **1***b* (7 g, 42 mmol) were combined in 70 mL of toluene and refluxed for 24 h. The solution was cooled, concentrated, and the crude product chromatographed to give 9.7 g, (88%) of imine **3***c*; $[\alpha]_D^{26}$ −12.5°; ir: 2990, 1740, 1680, 1365, 1145 cm^{-1}; ^{1}H nmr: 3.97 (ABq, 2H, J = 16 Hz), 2.34–2.22 (m, 1H), 1.95–1.34 (m, 5H), 1.46 (s, 9H), 1.25–1.16 (m, 1H), 0.99 (s, 3H), 0.91 (s, 3H), 0.79 (s, 3H); ^{13}C nmr: (see Table 2).

Imine **18**a

tert-Butyl glycinate (1.3 g, 10 mmol) and fenchone thione (13) (1.7 g, 10 mmol) were combined in 70 mL of toluene and refluxed for 4 days. The solution was cooled, concentrated, and the crude product chromatographed to give 1.9 g (70%) of imine **18***a*; ^{1}H nmr: 4.26 (ABq, 2H, J = 18 Hz), 1.85–1.35 (m, 7H), 1.47 (s, 9H), 1.23 (s, 3H), 1.22 (s, 3H), 1.18 (s, 3H); ^{13}C nmr: 188.0, 170.2, 80.8, 53.6, 53.1, 50.1, 44.5, 42.3, 33.8, 28.2, 25.3, 24.6, 23.9, 17.6.

General alkylation procedure

LDA (8.3 mmol) was prepared at 0°C in 15 mL of dry THF and then

cooled to −78°C. Imine **3***c* (2.0 g, 7.5 mmol) in 10 mL of THF was added. An orange solution resulted. HMPA (8.3 mmol) was added and the solution was stirred at −78°C for 10–15 min and then the alkylating agent (8 mmol) was added. The solution was stirred at −78° to −40°C (see Table 1) for 1–4 h, by which time the color of the solution usually became yellow. The reaction was quenched with 10 mL of water and allowed to warm to ambient temperature. Water (10 mL) was added, the layers were separated, and the aqueous phase was extracted with ether (2 × 50 mL). The organic layers were combined, washed with water (3 × 20 mL), dried, concentrated, and chromatographed to give the products listed in Table 1. No attempt was made to separate the diastereomers. When the de ratio of the products was greater than ca. 75%, the material frequently solidified. The ^{13}C nmr data for **5** are given in Table 2 and the ^1H nmr, infrared, and polarimetric data are given below.

5*a*: $[\alpha]_D^{26}$ −27.8°; ir: 2970, 1735, 1680, 1365, 1150 cm^{-1}; ^1H nmr: 3.90 (q, 1H, J = 7 Hz) [3.89 (q, 1H, J = 7 Hz)], 2.43–2.22 (m, 1H), 1.95–1.60 (m, 5H), 1.40 (s, 9H) [1.43 (s, 9H)], 1.34 (d, 3H, J = 7 Hz) [1.33 (d, 3H, J = 7 Hz)], 0.97 (s, 3H), 0.91 (s, 3H), 0.78 (s, 3H) [0.70 (s, 3H)].

tert-*Butyl phenylalaninate*

To a cold solution of NaOH (0.19 g, 4.6 mmol) in 50 mL of methanol was added hydroxylamine hydrochloride (0.32 g, 4.6 mmol) and acetic acid (0.28 g, 4.6 mmol). A solution of imine **5***b* in 20 mL of methanol was added and the mixture was stirred at ambient temperature for 20 h. The solution was concentrated, diluted with 10% hydrochloric acid, extracted with ether (3 × 50 mL), and the extracts were dried and concentrated to give 0.70 g (100%) of camphor oxime. The aqueous layer was basified and extracted with ether, the extracts dried and concentrated to give 0.416 g (45%) of *tert*-butyl phenylalaninate $[\alpha]_D^{24}$ − 22.4° (c = 10, EtOH) (lit. (14) $[\alpha]_D$ − 24.8° (neat).

When **5***a*, **5***b*, or **5***g* was treated with LDA in the same manner used for the alkylation, and the reaction was quenched at −78°C with a large excess of either CF_3COOD or D_2O, the isolated product showed no incorporation of deuterium (mass spectrum).

Alkylation of imine ***18****a*

In the same manner as described above, the alkylation of imine **18***a* was effected using 415 mg (1.6 mmol) of **18***a* and 0.3 g (1.7 mmol) of benzyl bromide. Chromatography afforded 0.49 g (84%) of imine **18***b*; ^1H nmr: 7.25 (m, 5H), 4.41 (dd, 1H, J = 4, 9 Hz) [4.43 (dd, 1H, J = 4, 9 Hz)], 3.27 (dd, 1H, J = 4, 13 Hz) [3.24 (dd, 1H, J = 4, 13 Hz)], 3.04 (dd, 1H, J = 9, 13 Hz) [3.03 (dd, 1H, J = 9, 13 Hz)], 1.67 (m, 2H), 1.55–1.20 (m, 5H), 1.48 (s, 9H) [1.51 (s, 9H)], 1.24 (s, 3H), 1.12 (s, 3H) [1.09 (s, 3H)], 0.58 (s, 3H) [0.61 (s, 3H)]; ^{13}C nmr: 171.4, 139.0 [138.9], 130.1 [130.0], 127.9 [128.0], 126.3 [126.4], 80.7 [80.7], 65.1 [65.0], 53.0, 50.3 [49.9], 46.3 [46.2], 44.5 [44.3], 42.3, 40.5 [40.3], 33.7, 33.4, 28.1, 25.3 [25.3], 24.6 [24.3], 17.9.

Hydride reduction of **5***b and* **5***f*

To a solution of **5***b* (750 mg, 2.1 mmol) in 15 mL of dry THF was added 80 mg (100% excess) of $LiAlH_4$. The suspension was stirred at reflux for 18 h, cooled and 25 mL of water was added cautiously. The aqueous layer was extracted with ether and the combined organic phases were dried and concentrated to give 582 mg (97%) of a gummy solid (**21***b*) that crystallized on standing. In the same way, but using ether as solvent, **5***f* was converted into **21***a*.

21*a*: mp 74–96°C; ir ($CHCl_3$): 3340, 2975, 1675, 1385, 1365, 1020 cm^{-1}; ^1H nmr: 3.61–3.52 (m, 2H), 3.49–3.38 (m, 1H), 2.52–

2.18 (m, 2H), 2.07–1.11 (m, 9H), 1.00 (s, 3H), 0.97 (s, 3H), 0.91 (d, 6H, J = 7 Hz) [0.89 (d, 6H, J = 7 Hz)], 0.79 (s, 3H) [0.80 (s, 3H)]; ^{13}C nmr: 183.6, 66.4, 60.5 [60.2], 53.9, 46.7 [46.5], 43.9, 41.3 [41.2], 36.0 [36.2], 32.9 [32.3], 27.4 [27.5], 24.8 [24.7], 23.3 [23.2], 22.5 [22.7], 19.5 [19.6], 18.9 [18.9], 11.6. The de ratio was the same as the starting ester, indicating no racemization had taken place during the reduction.

21*b*: ir ($CHCl_3$): 3450, 2970, 1675, 1450, 1090, 1015 cm^{-1}; ^{1}H nmr: 7.42–7.16 (m, 5H), 3.71 (dd, 1H, J = 11, 21 Hz), 3.69 (dd, 1H, J = 11, 18 Hz), 3.61–3.49 (m, 1H), 2.88 (dd, 1H, J = 4, 13 Hz), 2.72 (dd, 1H, J = 9, 13 Hz), 2.43–2.00 (m, 2H), 1.82–1.40 (m, 4H), 1.34–0.80 (m, 4H), 0.97 (s, 3H), 0.82 (s, 3H), 0.72 (s, 3H); ^{13}C nmr: 139.6, 129.9, 128.2, 126.1, 66.6, 64.3, 54.0, 46.6, 43.6, 38.7, 36.0, 32.2, 27.1, 19.6, 18.9, 11.7. The de ratio was 100%, which corresponds to complete retention of optical purity.

Catalytic reduction of **5**i

Hydrogenation of **5***i* over 10% Pd/C in ethanol solution led to the absorption of 1.0 equiv. of hydrogen. Filtration through Celite and evaporation afforded a quantitative yield of **5***g* (mp 52–58°C), whose ir and nmr spectra were identical in form to those obtained from the alkylation of **3***c*. The diastereomeric excess was determined to be 76% from the ^{1}H nmr, which corresponds to complete retention of optical purity, and the optical rotation was $[\alpha]_D^{25}$ +82.0°.

Acknowledgements

The financial assistance of the Natural Sciences and Engineering Research Council of Canada in the form of operating grants and a fellowship (to P.M.) made this work possible. The cooperation of the Chemistry Department of Wayne State University in running the high-field nmr spectra and Dr. R. D. Bach (W.S.U.) in donating time on the polarimeter is gratefully acknowledged.

B. Mario Pinto, Jesus Sandoval-Ramirez, R. Dev Sharma, Anthony C. Willis, and Frederick W. B. Einstein. Can. J. Chem. **64**, 732 (1986).

The synthesis of 2-(4-methoxyphenylseleno)-1,3-dithiane **3** and 2-(4-trifluoromethylphenylseleno)-1,3-dithiane **5** from 2-chloro-1,3-dithiane **1** and the corresponding sodium arylselenolates is described. Nuclear magnetic resonance spectroscopic investigation of the products indicates that the compounds exist predominantly in a conformation in which the arylseleno moiety adopts an axial orientation. X-ray crystallographic investigation indicates that the 1,3-dithiane ring exists in the chair conformation with the arylseleno moiety in the axial orientation. Compound **3** is orthorhombic, space group $P2_12_12_1$ with $a = 5.449(2)$ Å, $b = 9.217(2)$ Å, $c = 24.860(3)$ Å, $V = 1248.5$ Å^3, $Z = 4$. The structure was refined to $R = 0.038$ for 689 reflections with $I > 2.3\sigma(I)$. Compound **5** is monoclinic, space group $C2/c$, with $a = 28.628(7)$ Å, $b = 5.246(2)$ Å, $c = 21.342(5)$ Å, $\beta = 121.12(1)°$, $V = 2743.8$ Å^3, $Z = 8$. Its structure refined to $R = 0.064$ for 966 reflections with $I > 2.3\sigma(I)$.

On décrit la synthèse du (méthoxy-4 phénylséléno)-2 dithiane-1,3 (**3**) et du (trifluorométhyl-4 phénylséléno)-2 dithiane-1,3 (**5**) à partir du chloro-2 dithiane-1,3 (**1**) et des arylsélénolates de sodium correspondants. Une étude des produits par spectroscopie rmn indique que les composés existent principalement dans une conformation dans laquelle la portion arylséléno se trouve dans une orientation axiale. Des études par diffraction des rayons-X indiquent que le cycle dithiane-1,3 existe dans une conformation chaise et que les groupements arylséléno se trouvent dans une conformation axiale. Le composé **3** est orthorhombique, groupe d'espace $P2_12_12_1$, avec $a = 5{,}449(2)$, $b = 9{,}217(2)$ et $c = 24{,}860(3)$ Å, $V = 1248{,}5$ Å^3 et $Z = 4$. On a affiné la structure jusqu'à une valeur de $R = 0{,}038$ pour 689 réflexions avec $I > 2{,}3\sigma(I)$. Le composé **5** est monoclinique, groupe d'espace $C2/c$, avec $a = 28{,}628(7)$ Å, $b = 5{,}246(2)$ Å et $c = 21{,}342(5)$ Å, $\beta = 121{,}12(1)°$, $V = 2743{,}8$ Å^3 et $Z = 8$. On a affiné la structure jusqu'à une valeur de $R = 0{,}064$ pour 966 réflexions avec $I > 2{,}3\sigma(I)$.

[Traduit par la revue]

Introduction

As part of a program designed to investigate the nature and origin of conformational effects, we have been studying the interaction of X and Y atoms in X—C—Y fragments. Our approach is experimental in nature and focusses on the systematic evaluation of substituent effects on conformational equilibria. Although there have been many experimental (1) and theoretical (2) investigations of such X—C—Y anomeric interactions (3), these studies have generally dealt with interactions involving first- and second-row elements. For instance, the most recent reports by Juaristi *et al.* (4) and Mikolajczyk *et al.* (5) describe the nature of the interaction between the two second-row elements, sulfur and phosphorus. A noteworthy exception is the investigation by Drew and Kitching (6) of the interaction in S—C—Y fragments, in which Y is one of the Group IVa elements, Si, Ge, Sn, or Pb. Our principal interest was in the conformational behaviour of compounds containing the more electropositive elements in Group VIa, namely, the third- and fourth-row elements, selenium and tellurium. To the best of our knowledge, there have been only two reports of relevance to the work undertaken here: a brief mention of the conformational preference in 2-methylseleno-1,3-oxathiane (7), and a detailed study of the conformational analysis of 2-phenylseleno cyclohexanone (8). We now report the synthesis of two 2-arylseleno-1,3-dithianes, and their conformational properties in solution and in the solid state.

Experimental

Melting points were determined with a Fisher–Johns melting-point apparatus and are uncorrected. The ^{1}Hmr (400.13 MHz) and ^{13}Cmr (100.6 MHz) spectra were recorded on a Bruker WM400 spectrometer. Spectra were measured in chloroform-*d*. Chemical shifts are given in ppm downfield from TMS. Chemical shifts and coupling constants were obtained from first-order analyses of the nmr spectra. Assignments were confirmed by means of double irradiation experiments.

Analytical thin-layer chromatography (tlc) was performed on precoated glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 0.25 mm). The developed plates were air-dried and exposed to uv light. Column chromatography was performed on silica gel (Kieselgel 60, 230–400 mesh) at a pressure of 300–500 kPa according to a published procedure (9).

Solvents were distilled before use and were dried, as necessary, by literature procedures. Solvents were evaporated under reduced pressure without heating. Reactions were performed under oxygen-free nitrogen in deoxygenated solvents. Transfers under nitrogen were effected by means of standard Schlenck tube techniques.

2-(4-Methoxyphenylseleno)-1,3-dithiane (3)

Sodium borohydride (0.155 g, 4.1 mmol) was added to a solution of 4,4′-dimethoxydiphenyl diselenide (10) (0.763 g, 2.05 mmol) in a mixture of ether (10 mL) and ethanol (10 mL) at ambient temperature. The orange solution became colourless. When evolution of gas had ceased (≈0.5 h), the solvent was removed under high vacuum to give a white solid. Anhydrous THF (15 mL) was added and the mixture was cooled to 0°C.

A solution of 1,3-dithiane (0.56 g, 4.16 mmol) in dry benzene (10 mL) at 0°C was treated with *N*-chlorosuccinimide (0.61 g, 4.58 mmol). The mixture was stirred at 0°C for 0.5 h, then at ambient temperature for 15 min. The solution of 2-chloro-1,3-dithiane (**1**) thus obtained was filtered under nitrogen directly into the solution of sodium 4-methoxyphenylselenolate, prepared as described above. The reaction mixture was stirred vigorously at 0°C for 0.5 h, then at ambient temperature for 0.5 h. Saturated ammonium chloride solution was added and the mixture was extracted with dichloromethane. The organic phase was washed successively with saturated sodium chloride

[1]Authors to whom correspondence may be addressed.

solution and water, was dried over anhydrous sodium sulfate, and the solvent removed under reduced pressure without heating. The crude product (1.26 g) contained only a trace of the starting diaryl diselenide, as indicated by tlc. Rapid chromatography (9) on silica gel using hexane – ethyl acetate (95:5) as eluant afforded the title compound **3** as a white solid (0.875 g, 70%). Recrystallization from ether yielded **3** as white prisms; mp 74°C. *Anal.* calcd. for $C_{11}H_{14}OS_2Se$: C 43.27, H 4.62; found: C 43.23, H 4.62.

2-(4-Trifluoromethylphenylseleno)-1,3-dithiane (5)

The title compound was prepared from 2-chloro-1,3-dithiane **1** and 4,4′-bistrifluoromethyldiphenyl diselenide (11), as described for the preparation of **3**. Compound **5** was obtained as white prisms from hexane; yield: 79%, mp 66°C. *Anal.* calcd. for $C_{11}H_{11}F_3S_2Se$: C 38.49, H 3.23; found: C 38.55, H 3.19.

r-*2-(4-Methoxyphenylseleno)*-trans-*4*-trans-*6-dimethyl-1,3-dithiane* **6** *and* r-*2-(4-methoxyphenylseleno*-cis-*4*-cis-*6-dimethyl-1,3-dithiane* **7**

Sodium 4-methoxyphenylselenolate (0.95 mmol) was treated with 2-chloro-*cis*-4,6-dimethyl-1,3-dithiane **9** (0.95 mmol) (prepared from *cis*-4,6-dimethyl-1,3-dithiane **8** (12) in analogous fashion to that described for the synthesis of **1**), as described for the preparation of **3**. The crude product (0.31 g) was chromatographed on silica gel using hexane – ethyl acetate (98:2) as eluant. Compound **6** was obtained as white prisms from hexane (0.178 g); mp 80°C. Compound **7** was obtained as a syrup (0.058 g); overall yield: 74%. *Anal.* calcd. for $C_{13}H_{18}OS_2Se$: C 46.84, H 5.44; found: C 47.01, H 5.60.

X-ray crystallographic analysis

Crystals of **3** and **5** were selected [0.22 × 0.05 × 0.16 mm for **3**; 0.18 × 0.26 × 0.24 mm for **5**][2] sealed in thin-walled glass capillaries and mounted on an Enraf–Nonius CAD4F diffractometer employing graphite-crystal monochromated MoKα radiation ($\lambda(\alpha_1) = 0.70930$ Å; $\lambda(\alpha_2) = 0.71359$ Å). Accurate cell dimensions and the orientation matrix were obtained by least-squares analysis of the setting angles of [25;23] reflections [20° < 2θ < 27°; 20° < 2θ < 32°], widely separated in reciprocal space, which were accurately centered on the detector.

Crystal data of 3

$C_{11}H_{14}OS_2Se$ fw = 305.32

Orthorhombic, $P2_12_12_1$, $a = 5.449(2)$, $b = 9.217(2)$, $c = 24.860(3)$ Å, $V = 1248.5$ Å^3, $Z = 4$, $D_c = 1.624$ g cm^3, μ(MoKα) = 32.69 cm^{-1}.

Crystal data of 5

$C_{11}H_{11}F_3S_2Se$ fw = 343.30

Monoclinic, $C2/c$, $a = 28.628(7)$, $b = 5.246(2)$, $c = 21.342(5)$ Å, $\beta = 121.12(1)°$, $V = 2743.8$ Å^3, $Z = 8$, $D_c = 1.662$ g cm^{-3}, μ(MoKα) = 30.10 cm^{-1}.

The intensities of unique data sets [*hkl*; *hkl* and *ħkl*] were collected for 2θ < 45° using ω–2θ scans with scan widths of ([0.71; 1.00] + 0.35 tan θ)° in ω and scan rates [3.29–0.66; 5.48–0.82]° min^{-1} in ω. Background counts were determined by extending the scans by 25% on each side. A total of [987;1798] reflections were measured of which [689;966] with $I > 2.3\sigma(I)$ were regarded as observed and used in structure solution and refinement. Two standards were measured at intervals of [90;60] min of X-ray exposure time. For **3** the standards varied from their mean < ∓2% and showed no systematic trends, so no scaling was applied, but in **5** the standards showed a systematic decrease in intensity of about 18% over the duration of the data collection, so a five-point smoothed curve was fitted to the standards and all reflection intensities were scaled by this curve. An analytic absorption correction (13) was applied to the data of **3** ($T = 0.64$–0.84) and an empirical absorption correction (14) based on Ψ-scans was applied to **5** (range 1.00–0.92).

Both structures were solved by conventional heavy-atom methods. Successive refinement and difference electron density maps led to the location of all non-H atoms, which were refined initially with individual isotropic temperature factors and then anisotropically. Non-methyl H atoms were positioned geometrically and assigned isotropic temperature factors derived from those of the C atoms to which they were attached; they were included in structure factor calculations but their parameters were not refined.

As its space group is polar, refinement of **3** was also performed with its atomic coordinates transformed by $(1 - x, 1 - y, 1 - z)$. The R value decreased from 0.058 to 0.049, establishing the latter as the correct hand of the molecule in this particular crystal, and so the transformed coordinates were used for all subsequent refinement. A difference map revealed two of the methyl H atoms and the other was calculated geometrically. These atoms were added to the model with fixed parameters. The least-squares refinement was continued until all shift/error ratios were <0.01. All features in a final difference map were of magnitude <0.41(3) e Å^{-3}. Final $R = 0.038$, $R_w = 0.034$ for 136 variables.

The structure of **5** was less well behaved. A difference map showed large peaks between the F atoms, suggesting that the CF_3 group was rotationally disordered about the C(8)—C(11) bond. A model was set up with three F atoms of occupancy g at the original positions and three of occupancy $(1 - g)$ between them; g was initially set at 0.55. In view of the instability of the refinement of these atoms, the "soft" constraints C(8)—F = 1.33(1) Å and F ... F = 2.17(1) Å within each group of three F atoms were applied within the least-squares refinement (15) and only one isotropic thermal parameter was assigned to all F atoms. Occupancy g refined to ca. 0.80, so F(1)—F(3) were next refined with individual isotropic temperature factors and, finally, individual anisotropic temperature factors. In addition, the H atom coordinates were recalculated and linked to ride on their respective C atoms. Refinement was continued until shift/error ratios were <0.4 for F atoms, <0.03 for non-F. A difference map showed no outstanding features (all peaks <0.51 e Å^{-3}). Final $R = 0.064$, $R_w = 0.058$ for 165 parameters.

Refinement of both structures was by full-matrix least squares minimizing the function $\sum w(|F_o| - |F_c|)^2$. The weights were initially unity but in the later cycles $w = [(\sigma(F_o))^2 + p(F_o)^2]^{-1}$ where $\sigma(F_o)$ was derived from the counting statistics and $p = 0.0003$ for **3** and 0.0004 for **5**. Neutral-atom scattering factors with anomalous dispersion corrections were used (16). Computer programs (17–19) were run on a VAX 11-750 computer.

Final atomic coordinates for non-H atoms are listed in Table 1 and selected bond lengths and angles in Table 2. Figures 1 and 2 show the molecular structure of **3** and **5**, respectively, with the atom labelling scheme. H atoms coordinates, anisotropic temperature factors, additional interatomic distances and angles, selected least-squares planes, torsion angles, and structure factor listings are deposited.[3]

Results and discussion

Synthesis

Initially, we envisaged the synthesis of the desired 2-arylseleno-1,3-dithianes by reaction of the anion of 1,3-dithiane (generated from 1,3-dithiane and butyl lithium, in THF) with the diselenides or their corresponding selenenyl halides. However, under these conditions the desired compounds were formed in low yield, large amounts of the diselenides being recovered after processing. This was in spite of the fact that initial discoloration of the solution of the selenium reagent was observed, indicating consumption of the reagent. This behaviour likely results from attack of the generated selenolate or halide ion at selenium in the 2-arylseleno-1,3-dithianes to regenerate the dithiane anion and the selenium reagent. We turned, therefore, to the reaction of the selenolate anions with 2-chloro-1,3-dithiane (**1**). Thus, reaction of 2-chloro-1,3-dithiane **1** (generated by *N*-chlorosuccinimide oxidation of 1,3-dithiane (20)) with sodium 4-methoxyphenyl selenolate **2** (obtained by sodium borohydride reduction of 4,4′-dimethoxy-

[2]Within this section, the values within square brackets are for **3** and **5**, respectively.

diphenyl diselenide (10)) in a mixture of benzene and tetrahydrofuran at 0°C proceeded smoothly to give 2-(4-methoxyphenylseleno)-1,3-dithiane **3** in 70% yield (see Scheme 1). It was imperative that **3** be obtained in a pure state fairly rapidly to avoid significant decomposition. This was effected by means of rapid column chromatography on silica gel (9) followed by crystallization of the homogeneous product. Similar treatment of sodium 4-trifluoromethylphenyl selenolate **4** (obtained by sodium borohydride reduction of 4,4′-bistrifluoromethyldiphenyl diselenide (11)) with 2-chloro-1,3-dithiane **1** afforded, after processing as described above, 2-(4-trifluoromethylphenylseleno)-1,3-dithiane **5** in 79% yield (see Scheme 1).

Conformational analysis

The conformational equilibrium of interest is shown in Fig. 3. The conformational analysis of these systems was effected by means of nmr spectroscopy. Thus, the ^{1}Hmr spectra (400 MHz) of the conformationally-averaged systems in deuteriochloroform at ambient temperature were carefully analyzed. The H-2,

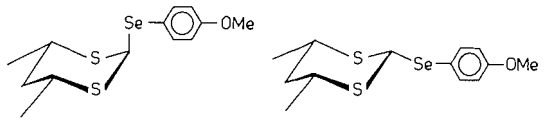
FIG. 3. Conformational equilibrium in 2-arylseleno-1,3-dithianes.

H-4,6 axial, and H-4,6 equatorial signals appeared as distinct multiplets in the spectra of **3** and **5**, whereas partially overlapped multiplets were observed for the H-5 axial and H-5 equatorial signals (see, for example, Fig. 4); these were readily assigned on the basis of their vicinal coupling constants and the assignments were confirmed by means of spin-decoupling experiments. Analysis of the spectra yielded the chemical shifts and coupling constants listed in Table 3. The salient features of the spectra are (1) the chemical-shift differences observed for H-4,6 axial and equatorial proton signals, $\Delta\delta$(ax/eq) (0.54 ppm and 0.56 ppm in the spectra of **3** and **5**, respectively); (2) the appearance of the H-2 signals as broad singlets; and (3) the presence of significant long-range $^4J_{2,4e}$ and $^5J_{2,5e}$ couplings (see Table 3). The deshielding effect of an axial substituent at C-2 of 1,3-dithianes and 1,3,5-trithianes on H-4,6ax relative to H-4,6eq is well documented (4, 5, 21). Larger values of $\Delta\delta$(ax/eq) (H-4,6) have been noted for 2-diphenylphosphoryl-1,3-dithiane (1.2 ppm) (4)), 2-dimethoxyphosphoryl-1,3,5-trithiane (1.63 ppm (5)), and 2-phenylthio-1,3,5-trithiane (1.07 ppm (21)), which have been shown to exist predominantly in the conformation in which the 2-substituent adopts the axial orientation. Nonetheless, it would appear that the axial conformer is present to a significant extent in the equilibrium mixture of both **3** and **5**, since $\Delta\delta$(ax/eq) (H-4,6) in 2-*tert*-butyl-1,3-dithiane is reported to be only 0.09 ppm (4).

The appearance of the H-2 signals in the spectra of **3** and **5** as broad singlets ($W_{1/2}$ = 2.8 Hz) can be attributed principally to long-range four- and five-bond couplings to H-4e and H-5e, respectively. Thus, irradiation of the H-2 resonances resulted in loss of $^4J_{2,4e}$ (0.8 Hz in **3** and 1.0 Hz in **5**) and $^5J_{2,5e}$ (0.8 Hz in **3** and 1.0 Hz in **5**) in the signals corresponding to H-4e and H-5e, respectively. These results auger well for the predominantly axial orientation of the arylseleno moiety in the preferred conformations of **3** and **5**, since this orientation would permit significant long-range coupling between H-2e and H-4e and between H-2e and H-5e. The corresponding couplings to H-2a are known to be much smaller (6, 12, 22, 23).

The conformational preference was confirmed, for the *p*-methoxy derivative **3**, by synthesis of the corresponding anancomeric derivatives **6** and **7** (prepared from *cis*-4,6-dimethyl-1,3-dithiane **8** (12) in analogous fashion to that described for the synthesis of **3** and **5**) and by comparison of their spectroscopic properties with those of **3**. Thus, for example, the H-4a,6a resonance in the ^{1}Hmr spectrum of the axial isomer **6** resonates at lower field than that in the corresponding spectrum of the equatorial isomer **7**, in accord with the aforementioned deshielding effect of axial C-2 substituents. The chemical shift difference for H-4a,6a in **6** and **7** (0.53 ppm) compares



6 **7**

favourably with that observed for $\Delta\delta$(ax/eq) (H-4,6) in **3** and **5**. That H-2a resonates at higher field than H-2e ($\Delta\delta$ = 0.41 ppm) is also in accord with previous results (21) in 2-phenylthio thianes and 1,3,5-trithianes but not with the data on the unsubstituted compounds (12, 24). Interestingly, the H-2e resonance in the spectrum of **6** appears as a broad singlet ($W_{1/2}$ = 2.5 Hz), whereas H-2a in the spectrum of **7** appears as a sharp singlet ($W_{1/2}$ = 0.9 Hz) showing selenium satellites ($^1J_{^{77}Se,H\text{-}2a}$ = 12.3 Hz). Furthermore, the H-5e signal in the former spectrum displays long-range coupling to H-2e (confirmed by decoupling), whereas the corresponding signal in the latter spectrum shows little or no such coupling (see Fig. 5). The assignment of axial and equatorial orientations of the arylseleno substituent was further corroborated by the ^{13}Cmr data for **6** and **7** (see Table 4). Thus, C-4 and C-6 in the axial isomer **6** exhibit a shielding of 7.2 ppm relative to those in the equatorial isomer, owing to the γ-*gauche* effect (25).

It is clear, then, that the 2-arylseleno-1,3-dithianes **3** and **5** in solution exist predominantly in the conformation in which the arylseleno moiety adopts an axial orientation.

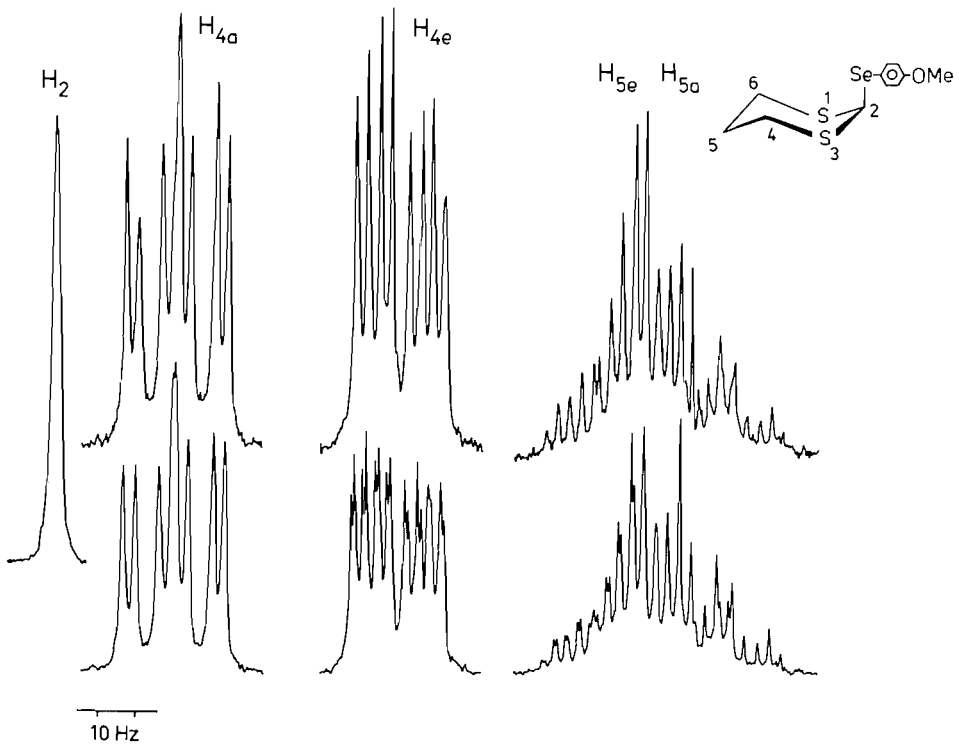


FIG. 4. Partial ^{1}Hmr spectrum of 2-(4-methoxyphenylseleno)-1,3-dithiane **3** recorded in deuteriochloroform at 400 MHz; top trace: with irradiation at ν(H-2).

[b]Coupling constants represent measured spacings and are not calculated values.

X-ray crystallographic studies

In both structures, the 1,3-dithiane ring is in a chair conformation with the arylseleno moiety in the axial orientation. Atoms S(1), C(2), C(4), and S(2) form a plane at an angle of 58° to the plane C(1), S(1), S(2) and 55° to the plane C(2), C(3), C(4) in **3**; in **5** these values are both 56°. The aryl group is oriented to produce a staggered conformation of atoms about the Se—C(1) bond with S(1)—C(1)—Se—C(5) torsion angles of −176° for **3** and −175° for **5**. Steric effects derived from this orientation lead to the angles Se—C(1)—S(2) being greater than Se—C(1)—S(1) in both compounds (116.0(5)° cf. 107.9(4)° for **3**; 116.0(6)° cf. 107.5(6)° for **5**).

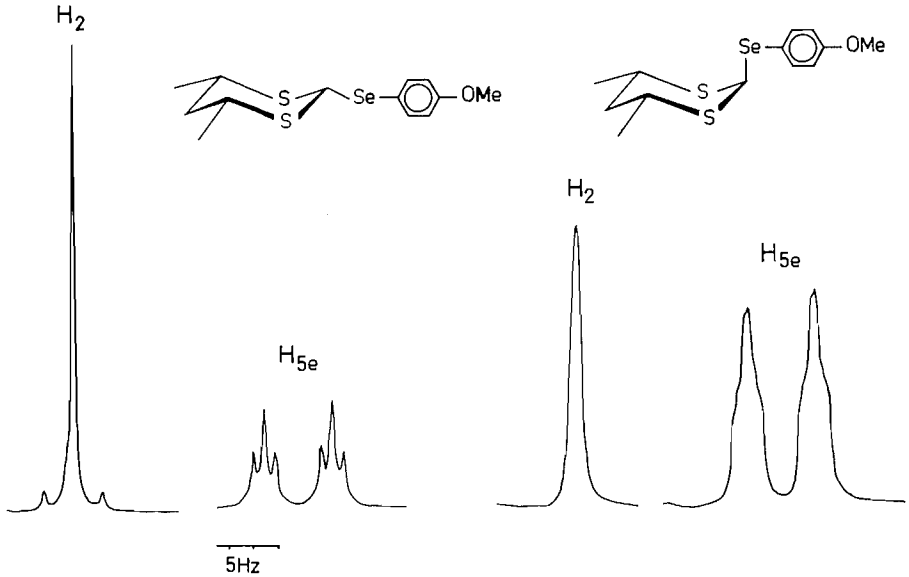

FIG. 5. Partial ^{1}Hmr spectra of *r*-2-(4-methoxyphenylseleno)-*trans*-4-*trans*-6-dimethyl-1,3-dithiane **6** and *r*-2-(4-methoxyphenylseleno)-*cis*-4-*cis*-6-dimethyl-1,3-dithiane **7** recorded in deuteriochloroform at 400 HMz.

[a]In ppm downfield from TMS in chloroform-*d*.

The axial disposition of the arylseleno group is consistent with expectations based on the anomeric effect (1–3). The expression of this effect would also be expected to influence structural features within the molecules. Within the framework of Perturbational Molecular Orbital (PMO) theory, increasing electronegativity of a substituent atom leads to a lowering of the energies of molecular orbitals associated with that atom (see for example ref. 26). Thus, the σ^*_{C-Se} orbital will be of lower energy in the *p*-trifluoromethyl derivative **5** than in the *p*-methoxy derivative **3** and it follows (27) that the n_S–σ^*_{C-Se} orbital interaction would be more important in the former compound. These arguments predict a smaller value for the angle C(1)—Se—C(5), a shorter Se—C(1) bond, and longer C(1)—S(1) and C(1)—S(2) bonds in **3** than in **5**. Unfortunately, these structure determinations are not sufficiently precise to confirm these predictions.

Conclusions

The axial conformational preference of the arylseleno moiety in the 2-arylseleno-1,3-dithianes **3** and **5** both in solution and in the solid state constitute support for the anomeric effect operating in S—C—Se fragments. The quantitation of this conformational effect in these and related compounds by means of low temperature nmr spectroscopy is in progress and the results will be reported elsewhere (for a preliminary account, see ref. 28).

Received December 5, 1985

F. BRISSE, D. THORAVAL, and T. H. CHAN. Can. J. Chem. **64**, 739 (1986).

The crystal structure of the enol silyl ether compound, $C_{28}H_{33}NO_3Si$, **1**, has been established by direct methods and refined to a final *R* value of 0.053 for 1825 observed reflections. The crystals belong to the monoclinic system, $a = 8.683(5)$, $b = 12.689(5)$, $c = 24.585(11)$ Å, $\beta = 105.33(4)°$, and the space group is $P2_1/c$. The C(sp^2)—C(sp^2) bond distance is normal but the Si(1)—O(1)—C(1) angle with a value of 132.5(4)° is larger than usual. This is attributed to an interaction between Si(1) and O(2) of the *N*-acetate group, d(Si ... O) = 3.320(4) Å. There is a distortion of the tetrahedral coordination around the silicon atom since the bond angles involving Si vary from 102.8(4) to 112.6(5)°. All three phenyl rings and the *N*-acetate group are planar. The two phenyls at C(3) are inclined by $\phi_1 = 66.5$, $\phi_2 = 58.7°$ with respect to the ethylenic group constituted of the two C(sp^2) atoms and their four substituents. The molecules are held in the crystal by van der Waals forces only.

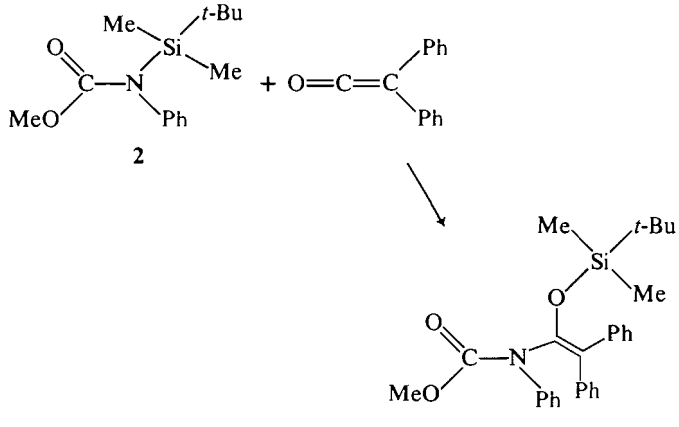
F. BRISSE, D. THORAVAL et T. H. CHAN. Can. J. Chem. **64**, 739 (1986).

La structure cristalline de l'éther enolique silylé, $C_{28}H_{33}NO_3Si$, **1**, a été déterminée par des méthodes directes et affinée jusqu'à la valeur *R* finale de 0,053 pour 1825 réflexions observées. La maille monoclinique a pour dimension, $a = 8,683(5)$, $b = 12,689(5)$, $c = 24,585(11)$ Å, $\beta = 105,33(4)°$ et le groupe spatial est $P2_1/c$. La longueur de la liaison C(sp^2)—C(sp^2) est normale, par contre l'angle Si(1)—O(1)—C(1) avec une valeur de 132,5(4)° est plus ouvert que d'habitude. Ceci est attribué à une interaction entre Si(1) et O(2) du groupe *N*-acétate, d(Si ... O) = 3,320(4) Å. Les angles de valence autour de l'atome Si varient de 102,8(4) à 112,6(5)° reflétant ainsi la distortion de la coordination tétraédrique de cet atome. Les atomes de chacun des trois groupes phényles ainsi que du groupe *N*-acétate sont coplanaires. Les deux phényles fixés en C(3) sont inclinés de $\phi_1 = 66,5$ et $\phi_2 = 58,7°$ par rapport au plan éthylénique constitué des deux atomes C(sp^2) et de leurs quatre substituants. La cohésion moléculaire n'est assurée que par des forces de van der Waals.

Introduction

The chemistry of enol silyl ethers has undergone dramatic development since their first introduction into organic synthesis (1–4). Enol silyl ethers now rival enolate anions in importance. Reactions equivalent to aldol (5), Michael (6), Claisen (7), and Stobbe (8) can all be performed with enol silyl ethers. Compared to enolate anions, enol silyl ethers have several characteristic features which render them particularly useful. Whereas enolates are ionic compounds, enol silyl ethers are covalent molecules. For this reason, enol silyl ethers are in general less "reactive" than the corresponding enolates. In terms of experimental convenience, enolates are usually generated and used *in situ*, whereas enol silyl ethers can often be purified and stored for a finite period. Another important difference is that, whereas enolate anions are basic in character, enol silyl ethers are neutral molecules. Reactions of enol silyl ethers can be conducted under either neutral or acidic conditions, thus complementing the basic nature of enolate anion chemistry (8). Finally, it is possible to prepare *bis*- (10) or *tris*-enol silyl ethers[1] whereas generation of the corresponding enolate di- or trianions would be difficult. By using enol silyl ethers, one can extend the polyanion chemistry without many of the inherent difficulties.

In spite of the many reactions unravelled for enol silyl ethers and their growing popularity in organic synthesis, there is essentially no structural information regarding enol silyl ethers and few mechanistic studies on their reactions (11). As part of our overall interest in enol silyl ether chemistry, we have undertaken the first X-ray crystal structure study of an enol silyl ether. The compound under investigation is the *t*-butyldimethylsilyl ether (**1**) of the enol derived from a carbamate. Compound **1** was prepared according to the following reaction:



Methyl *N*-*t*-butyldimethylsilyl-*N*-phenylcarbamate (**2**) was first prepared from the silylation of the anion derived from methyl *N*-phenylcarbamate. Reaction of **2** with diphenylketene gave the enol silyl ether **1**. The reaction of *N*-silylamides with ketenes is the subject of a general study by us and will be reported separately.[2]

Experimental

Methyl N-*phenyl*-N-t-*butyldimethylsilylcarbamate (2)*

To a suspension of sodium hydride (50% in mineral oil, washed with dry hexane) in tetrahydrofuran at 0°C, methyl *N*-phenylcarbamate (10 mmol) was added. After hydrogen evolution had ceased, the

TABLE 1. Crystal data and summary of data collection and structure refinement

Crystal

$C_{28}H_{33}NO_3Si$ mw = 459.666
Crystal system: monoclinic Space group: $P2_1/c$
a = 8.683(5), b = 12.689(5), c = 24.585(11) Å, β = 105.33(4)°,
V = 2612.5 Å^3, d_c = 1.168 g cm^{-3}, Z = 4, $F(000)$ = 984,
λ(MoKᾱ) = 0.71069 Å, μ(MoKα) = 1.12 cm^{-1}, T = 22°C
Crystal size: 0.12 × 0.20 × 0.36 mm

Data collection

ω–2θ scan, scan width Δω = (1.0 + 0.35 tan θ)°
Collection limits: 2θ ≤ 45°, $0 \leq h \leq 9$, $0 \leq k \leq 13$, $-26 \leq l \leq 26$
Fluctuations of the three standard reflections: 2.2, 2.3, 1.5%
Number of reflections measured = 3410
Number of reflections accepted = 1825
Acceptance threshold, $I \geq 1.96\,\sigma(I)$

Structure refinement

$R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.053$, $wR = [\Sigma w\Delta F^2/\Sigma wF_o^2]^{1/2} = 0.051$
$S = [\Sigma w\Delta F^2/(m-n)]^{1/2} = 0.73$
Average $\Delta/\sigma = 0.20$, maximum $\Delta/\sigma = 0.72$
Residual electron density −0.25, 0.17 e Å^{-3}

mixture was cooled to −78°C and treated with a THF solution of *t*-butyldimethylchlorosilane. The mixture was then warmed slowly to room temperature and stirred overnight. The solvent was then evaporated *in vacuo* and the residue treated with hexane. The mixture was filtered under N_2 and the filtrate was evaporated to dryness. The residual oil was purified by distillation to give **2** in 86% yield, bp 94–96°C (1.0 mm Hg (1 mm Hg = 133.3 Pa)); ir(neat)ν: 1700, 1590, 1485, 1435, 1310, 1250, 1085, 960, 930, 885 cm^{-1}; ^{1}H nmr ($CDCl_3$)δ: 0.05 (s, 6H), 1.01 (s, 9H), 3.6 (s, 3H), 6.9–7.3 (m, 5H); ^{29}Si nmr ($CDCl_3$)δ: 5.53 ppm.

Methyl N-*phenyl*-N-*(2,2-diphenyl-1-*t*-butyldimethylsiloxy)-vinyl-carbamate (**1**)*

To a stirred solution of **2** (200 mg) in ether (10 mL) at 0°C was added diphenylketene (1 equiv.) dropwise. The reaction can be followed by the disappearance of the orange colour of diphenylketene. At the end of the reaction (~20 h), the solvent was evaporated *in vacuo* and the residue was purified by flash chromatography (5% ether in hexane) to give **1** as a colorless oil in 85% yield. The pure **1** could be crystallized from hexane slowly to give crystals for X-ray analysis; ir(neat)ν: 1725, 1640, 1600, 1495, 1440, 1320, 1245, 1095, 835 cm^{-1}; ^{1}H nmr ($CDCl_3$)δ: 0.1 (s, 6H), 0.86 (s, 9H), 3.8 (s, 3H), 7.1–7.4 (m, 15H); ms *m/e*: 459 (M^+).

X-ray analysis of **1**

The unit-cell dimensions were obtained, from a single crystal mounted on a Nonius CAD4 diffractometer, by least-squares fit to the angular settings of 25 centered reflections in the range $13 \leq 2\theta \leq 28°$. The systematic absences of the type $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ uniquely determine the $P2_1/c$ space group. The crystal data of interest are presented in Table 1. Intensity data for both *hkl* and *hkl* octants were collected up to $2\theta_{max} = 45°$ using MoKᾱ radiation and a graphite monochromator. The data were corrected for Lorentz and polarization factors and reduced to structure factors in the usual manner.[3] The absorption coefficient for the MoKα radiation being small, no absorption correction was applied to the intensity data. The structure was solved by direct methods using the MULTAN set of programs. Most non-hydrogen atoms were revealed on the first E-map except for the *tert*-butyl group which was only found after a few refinement cycles followed by a difference Fourier synthesis. In the block-diagonal least-squares refinement, all non-hydrogen atoms were treated anisotropically. Then, another difference Fourier synthesis revealed all hydrogen atoms except those on the methyl groups. They appeared following a few more refinement cycles. The H atoms were refined with isotropic temperature factors. The function minimized was $\Sigma w||F_o| - |F_c||^2$. The scattering factors were taken from Cromer and Mann (16) for Si, O, N, and C and from Stewart *et al.* (17) for H atoms. The real and imaginary parts of the anomalous dispersion of Si were taken from Cromer and Liberman (18).

Results and discussion

The final atomic coordinates[4] for **1** ($C_{28}H_{33}NO_3Si$) are given in Table 2. A schematic of the atomic numbering adopted here is shown in Fig. 1. A stereopair showing the molecular conformation is shown in Fig. 2 while the bond distances, the bond angles, and the torsion angles are listed in Tables 3 and 4, respectively.

The enol silyl ether double bond

The C(1)—C(3) double bond, 1.346(8) Å long, is not significantly longer than that reported for unsubstituted ethylene. Values of 1.337(3), 1.339(2), and 1.333(2) Å were obtained by infrared spectroscopy (19), Raman spectroscopy (20), and electron diffraction in the gas phase (21), respectively. A more recent study (22) of the structure of C_2H_4 by X-ray diffraction at 85 K gives a C=C distance of 1.314(6) Å. The value measured here is, however, very close to that reported for a symmetrically substituted ethylene. In 1,1-bis(*p*-ethoxyphenyl)ethylene (23) the C=C bond is 1.342(3) Å long. The sum of the angles around C(1) and C(3) are 359.7 and 360.0° respectively, as expected for the sp^2 hybridization of these atoms. Both the C(21)—C(3)—C(31) and O(1)—C(1)—N(1) angles have values significantly lower than 120°. This is also observed in ethylene (19–22) where the H—C—H angle is found between 115.5(6) and 117.6(5)°.

[3]The programs used here are modified versions of NRC-2, data reduction, NRC-10, bond distances and angles, and NRC-22, mean planes (12), FORDAP, Fourier and Patterson maps (A. Zalkin), MULTAN, multisolution program (13), NUCLS, least-squares refinement (14), and ORTEP, stereodrawings (15).

[4]Tables of mean planes, anisotropic temperature factors, hydrogen atom coordinates, and lists of observed and calculated structure factors have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

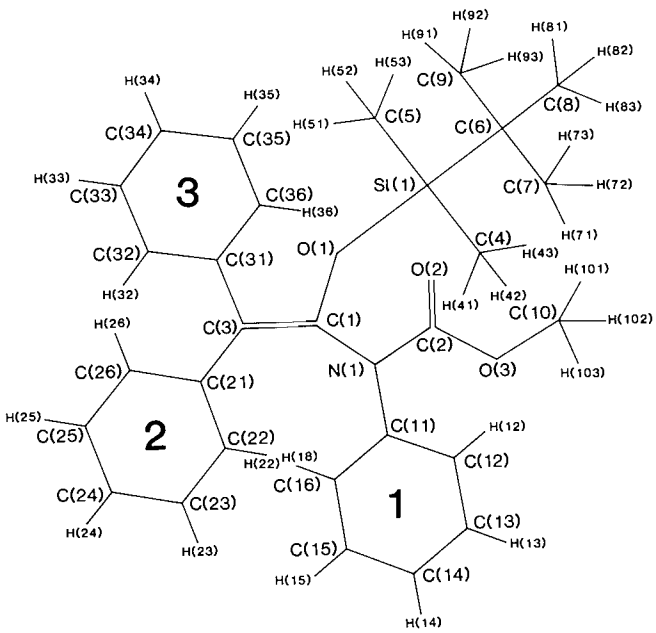

FIG. 1. Atomic numbering.

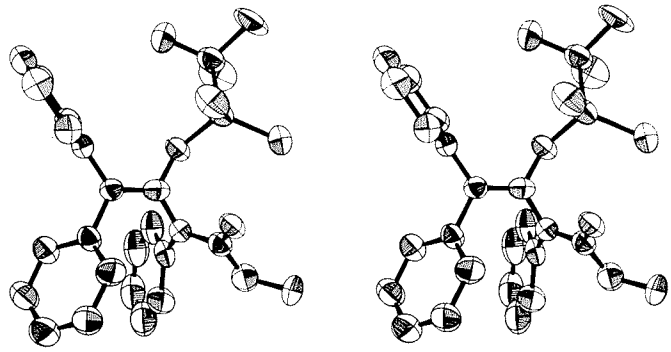

FIG. 2. Stereopair showing the molecular conformation of $C_{28}H_{33}NO_3Si$.

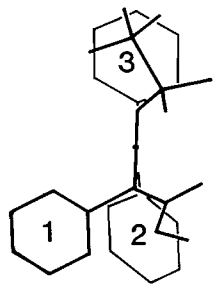

FIG. 3. Projection of the molecule along C(1)—C(3).

In the spectroscopic and electron diffraction studies, the C_2H_4 molecule was assumed to be planar and highly symmetrical. One finds here that there is a slight twist around the ethylenic bond. It is measured by the angle between the planes C(1), C(3), N(1), O(1) and C(1), C(3), C(21), C(31) and has a value of 4.2°. This distortion is also confirmed by a mean plane calculation. The atoms of the ethylenic bond and its four substituents are displaced by 5–20σ from their least-squares plane. This is not unusual for substituted ethylenes. It also suggests that the siloxy substituent does not confer unusual structural features on the double bond.

The phenyl groups

The atoms of each of the three phenyl groups are coplanar. However, the atoms C(3) and N(1) to which they are bonded significantly deviate from their corresponding phenyl planes. A view of the molecule, projected along the C(1)=C(3) bond (Fig. 3) reveals clearly the relative orientations of the three phenyl rings. The phenyl rings 1 and 2 are twisted around the C(11)—N(1) and the C(21)—C(3) bonds respectively in such a way that they are almost parallel to one another. At the same time, they are displayed laterally so that there is no overlap. The atoms constituting the phenyl rings 2 and 3, both attached at C(3), are in planes nearly perpendicular to one another. The relative orientation of the phenyl ring is described in a more quantitative manner using the conformational angles defined by Shields *et al.* (24). The dihedral angle between a phenyl plane and the group of atoms formed by C(1), C(3), C(21), C(31) is ϕ, while the dihedral angle between the two phenyls on C(3) is δ. Here ϕ_1 is 66.5° and ϕ_2 is 58.7° for the two phenyl groups at C(3) and δ_1 = 80.8°. These values compare well with ϕ_1 = 51.4, ϕ_2 = 54.5, and δ = 81.6° or ϕ_1 = 78.7, ϕ_2 = 45.4, and δ = 80.2° for the two molecules of 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (24). These conformational angles take the values of $\phi_1 = \phi_2$ = 47.8 and δ = 82.9° for 1,1-dichloro-2,2-bis(*p*-methoxyphenyl)ethylene (23).

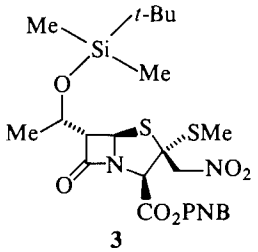
C(1)—O(1)—Si(1)—C(4)	81.6	C(1)—C(3)—C(31)—C(36)	−116.3
C(1)—O(1)—Si(1)—C(5)	−42.9		
C(1)—O(1)—Si(1)—C(6)	−162.6		

The *N*-acetate group of atoms (N(1), O(2), O(3), C(2), C(10)) is nearly coplanar. Its orientation and that of the phenyl group at N(1) are described by the dihedral angles ϕ_3 and ϕ_4 they make with the plane constituted of O(2), N(1), C(1), C(2), C(11). In this case one finds $\phi_3 = 11.4$, $\phi_4 = 43.4°$ while δ_2, the angle between the *N*-acetate and the phenyl plane is 54.0°.

The t*-butyl silyl group*

The bond distances and angles in this group of atoms compare well with their homologs in a penam (4-thia-1-azabicyclo[3.2.0]haptan-7-one) derivative,[5] **3**. In particular the bond angles show the same deformation of the tetrahedral coordination around Si. The smallest bond angle, O(1)—Si(1)—C(6) = 102.8(4)° and the largest, C(4)—Si(1)—C(5) = 112.6(5)° are found to be also the extreme values for the corresponding angles, 103.6(5)° and 112.6(6)°, respectively, in **3**. One has to note the particularly wide angle at O(1), C(1)—O(1)—Si(1) =

[5]A. Bedeschi, F. Bélanger-Gariépy, S. Hanessian, and F. Brisse. Acta Cryst. Submitted.



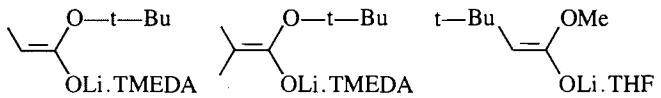
3

PNB = *para*-nitrobenzoate

132.4(4)°. The corresponding value in **3** is only 127.6(6)°. This is attributed to repulsions between O(2) and Si and its two methyl groups. The distances O(2) ... Si, O(2) ... C(4), and O(2) ... C(5) are among the shortest[6] in the molecule with values of 3.320(4), 3.197(8), and 3.381(8) Å, respectively. There are no short contacts between either C(4) or C(5) and any atom of the phenyl group 3.

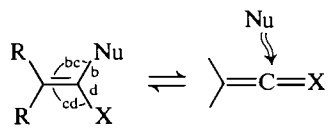
Another interesting observation is the torsion angle for C(3)—C(1)—O(1)—Si(1) of 101.4(8)°. This places the O(1)—Si(1) bond in an orientation nearly parallel to the *p* orbitals of the C(1)—C(3) π bond suggesting the possibility of σ → π overlap.

ADDENDUM: Since the submission of our manuscript, a paper by Seebach *et al.* describing the structure of a number of lithium ester enolates (**4–6**) by X-ray diffraction has appeared (26).



4 **5** **6**

Because of the complementary nature of the reactivities of enolates and enol silyl ethers, it is of interest to contrast the structures of these compounds. The first obvious difference is that in all lithium enolates, the crystalline compounds are either dimeric or tetrameric even with solvent of coordination. In the case of enol silyl ether **1**, the compound is monomeric. In spite of this difference, the C=C double bond length in **4–6** falls in between 1.350 and 1.341 Å, a value remarkably close to the double bond length in **1** (1.346 Å). The C—O bond length of the siloxy oxygen in **1** (1.372 Å) is in between the C—O bond length of the enol ether oxygen (1.379–1.419 Å) and of the enolate (1.304–1.314 Å). The siloxy C—O bond is, thus, more similar to the enol ether C—O bond. In their paper, Seebach *et al.* further argued that there is a correlation between bond length differences b − d and bond angle difference cd − bc (scheme 1)



SCHEME 1

and this can be used to map the breakdown of the ester enolate into ketene and an alcoholate: Whether such an approach is valid and can be applied to map the breakdown of **1** to the precursor ketene and the silylated carbamate is of obvious mechanistic significance. Its answer will require X-ray structure determinations of several more enol silyl ethers of compounds analogous to **1**.

[6]When compared to the sum of van der Waals radii (25).

JOHN S. HAYNES, JOHN R. SAMS, and ROBERT C. THOMPSON. Can. J. Chem. **64**, 744 (1986).

Magnetic susceptibilities from 130 to 4.2 K are reported for a series of $Fe(RSO_3)_2$ compounds, where R is F, CF_3, CH_3, and p-$CH_3C_6H_4$. The β form of $Fe(CH_3SO_3)_2$ exhibits a maximum in susceptibility at approximately 22.5 K and a sharp drop in susceptibility below the maximum indicating a transition to a magnetically ordered state. None of the other compounds exhibit magnetic ordering although abnormally low magnetic moments down to 2.0 K are observed for α-$Fe(CH_3SO_3)_2$. Variable-temperature Mössbauer studies on $Fe(CF_3SO_3)_2$ and β- and α-$Fe(CH_3SO_3)_2$ are reported and the magnitude of axial field splitting is estimated for these compounds. The first two have trigonally elongated FeO_6 chromophores, whereas the third is trigonally compressed. The nature of the distortion in α-$Fe(CH_3SO_3)_2$ is confirmed by magnetic perturbation Mössbauer studies. Spectra in applied fields of 4.50 and 5.63 T show a doublet–triplet pattern, with the triplet at higher energy, indicating a negative V_{zz} and an orbital singlet ground state.

JOHN S. HAYNES, JOHN R. SAMS et ROBERT C. THOMPSON. Can. J. Chem. **64**, 744 (1986).

On a mesuré, de 130 à 4,2 K, les susceptibilités magnétiques d'une série de composés $Fe(RSO_3)_2$ dans lesquels R = F, CF_3, CH_3 et p-$CH_3C_6H_4$. Dans les cas de la forme β du $Fe(CH_3SO_3)_2$, on observe un maximum de susceptibilité à environ 22,5 K et une diminution marquée lorsqu'on diminue ensuite la température; ce résultat indique la présence d'une transition vers un état qui est magnétiquement ordonné. Aucun autre composé ne présente ce phénomène, même si des moments magnétiques anormalement faibles sont observés à 2,0 K avec l'α-$Fe(CH_3SO_3)_2$. On rapporte les résultats d'études de l'effet Mössbauer à diverses température sur le $Fe(CF_3SO_3)_2$ et sur les formes β et α du $Fe(CH_3SO_3)_2$ et l'on a évalué l'amplitude du dédoublement du champ axial dans ces composés. Les deux premiers possèdent des chromophores FeO_6 qui sont allongés trigonalement; par ailleurs, le troisième est trigonalement comprimé. La nature de la distorsion dans l'α-$Fe(CH_3SO_3)_2$ est confirmée par des études de perturbations magnétiques de Mössbauer. Les spectres obtenus lorsque des champs de 4,50 et 5,63 T sont appliqués mettent en évidence la présence d'un arrangement de doublet-triplet avec le triplet au niveau d'énergie le plus élevé. Ce résultat indique que le V_{zz} est négatif et qu'il existe une orbitale singulet dans l'état fondamental.

[Traduit par la revue]

Introduction

Previously we reported the preparation and study of a series of iron(II) sulfonate compounds, $Fe(RSO_3)_2$, where R is F, CF_3, CH_3, and p-$CH_3C_6H_4$ (1, 2). It was proposed that these compounds adopt a polymeric layered structure like that of $Ca(CH_3SO_3)_2$ (3), in which each RSO_3^- group acts as a tridentate bridging ligand to three different metal centres. This results in each metal being in an approximately octahedral environment of oxygen atoms, each oxygen atom being from a different sulfonate group (see Fig. 1, ref. 4). The methanesulfonate, unlike the others, was found in the earlier work to be obtainable in two isomeric forms (5) and the β form of this material was shown by Mössbauer spectroscopy to undergo a magnetic phase transition to an antiferromagnetically ordered state at approximately 23 K. None of the other sulfonates gave Mössbauer evidence for magnetic ordering, although magnetic susceptibility measurements from 80 to 300 K suggested the presence of weak antiferromagnetic exchange in α-$Fe(CH_3SO_3)_2$ (2). Our earlier studies on magnetic exchange effects in these materials were limited by the lack of suitable equipment for obtaining magnetic susceptibility data at cryogenic temperatures; this laboratory now has facilities which permit such studies down to 2.0 K and these are reported here.

Attempts to correlate magnetic properties with structure in these systems are hampered somewhat by the difficulty in obtaining precise structural information; unfortunately, the iron(II) sulfonates have not been obtainable in crystalline form suitable for single-crystal X-ray diffraction work. Nevertheless, considerable structural information was obtained previously for two of the sulfonates being considered here, namely $Fe(FSO_3)_2$ (6) and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ (4), from Mössbauer spectroscopy, particularly from the temperature dependence of the quadrupole splitting and from magnetic perturbation Mössbauer. Variable-temperature Mössbauer studies have now been completed on $Fe(CF_3SO_3)_2$ and on α- and β-$Fe(CH_3SO_3)_2$. In addition, magnetic perturbation Mössbauer spectra of α-$Fe(CH_3SO_3)_2$ are reported here and fits of the data to the phenomenological model of Varret (7) are discussed.

[1]Authors to whom correspondence may be addressed.

Experimental

The iron(II) sulfonates[2] were prepared as described previously (1, 2). Their purity was checked by microanalysis and by infrared and Mössbauer spectroscopy.

Magnetic susceptibility measurements (4.2–130 K) were made using a vibrating sample magnetometer as previously described (9). For α-$Fe(CH_3SO_3)_2$, additional data were collected to 2 K, temperatures below 4.2 K being achieved by reducing the vapor pressure of the helium in the sample zone of the magnetometer. The data reported here are in good agreement in the region of temperature overlap with the results reported earlier using the Gouy equipment (2, 6). The molar magnetic susceptibilities were corrected for the diamagnetism of all atoms: Fe^{2+} = 13, FSO_3^- = 40, $CF_3SO_3^-$ = 46, $CH_3SO_3^-$ = 35, and p-$CH_3C_6H_4SO_3^-$ = 89 (all 10^6 cm^3 mol^{-1}).

Samples for Mössbauer studies were contained in Nylon holders and sealed with epoxy resin to avoid hydrolysis and decomposition problems. The sample holder was attached to a copper ring before being mounted in the cryostat, to ensure good thermal contact.

[2]Recently, Sharma *et al.* (8) reported the preparation of $Fe(CH_3SO_3)_2$ by direct reaction of anhydrous iron(II) chloride with methanesulfonic acid, followed by washing with diethylether. Earlier (2) we had shown that this same reaction yields an acid solvate of composition $Fe(CH)_3SO_3)_2.CH_3SO_3H$ when the product is washed with CH_3SO_3H followed by drying in vacuum at 150°C. The data reported by the other workers (8) for their sample of $Fe(CH_3SO_3)_2$ do not correspond well with those reported by us for either the α or β forms.

[a]Temperatures (T) are in K; molar susceptibilities (χ_m) are in 10^3 cm^{-3} mol^{-1}; magnetic moments μ_{eff} are in BM.

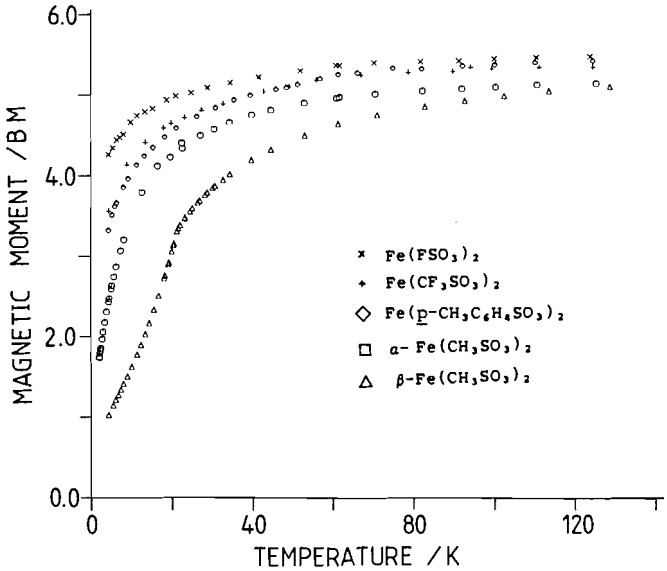

FIG. 1. Magnetic moment versus temperature for $Fe(RSO_3)_2$ compounds.

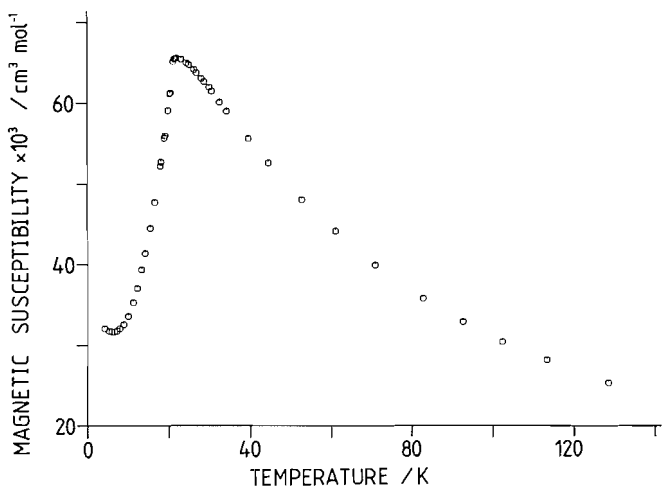

FIG. 2. Magnetic susceptibility versus temperature for β-$Fe(CH_3SO_3)_2$.

Zero-field Mössbauer spectra were recorded with the absorber in a Janis model DT-6 variable-temperature cryostat. Mössbauer spectra, at 4.3 K and below, and all applied field measurements were made with both source and absorber at the same temperature in a Janis model 11-MDT cryostat containing a Westinghouse superconducting solenoid. All spectra were recorded in transmission geometry and the Doppler velocity scale was calibrated with an enriched ^{57}Fe foil absorber; all isomer shifts are quoted relative to the centre of the iron foil spectrum. The Mössbauer spectrometers have been described previously (10, 11).

Results and discussion

Magnetic susceptibility data from 130 to 4.2 K for all $Fe(RSO_3)_2$ compounds (additional data to 1.97 K for α-$Fe(CH_3SO_3)_2$) are given in Table 1 and magnetic moments are plotted as a function of temperature in Fig. 1. For all compounds the moment is in excess of 5.0 BM (Bohr magneton) above 120 K and decreases with decreasing temperature, as expected for high-spin iron(II) in an octahedral ligand environment. With the exception of β-$Fe(CH_3SO_3)_2$, the moments decrease monotonically to a value in the range 2.4–4.3 BM at 4.2 K. The moment decreases more rapidly for β-$Fe(CH_3SO_3)_2$, reaching 1.04 BM at 4.2 K; moreover, the μ_{eff} versus T plot for this material shows an abrupt change in slope around 23 K. This phenomenon is more dramatically illustrated by the magnetic susceptibility versus temperature plot (Fig. 2), which shows a maximum in susceptibility at approximately 22.5 K, indicative of an antiferromagnetically coupled system, and a sharp drop in susceptibility at temperatures below the maximum, indicative of a phase transition to a magnetically ordered state. These findings coincide very well with the observations made earlier on variable-temperature Mössbauer studies, in which spectra were seen to change from a simple quadrupole doublet to a complex hyperfine pattern over a small temperature range around 23 K (5), a phenomenon ascribed then, and now confirmed, as due to magnetic ordering. The small increase in magnetic susceptibility below approximately 5.5 K may be due to a small amount of paramagnetic impurity, possibly a trace of the α form. This is quite plausible since the β form is prepared by conversion from α-$Fe(CH_3SO_3)_2$.

The magnetic exchange exhibited by β-$Fe(CH_3SO_3)_2$ is likely propagated by a superexchange mechanism involving the O—S—O bridging system. This is not the first example of exchange via such a system; in fact, the first definite observation of a susceptibility maximum corresponding to an antiferromagnetic transition was made on $FeSO_4$ (12, 13), where bridging sulfate anions form an extended three-dimensional lattice (14). Linear chain systems with either single or double O—S—O bridges arising from sulfate anions have also been found to have magnetic properties characteristic of low-dimensional magnetic exchange (15), and in some cases Mössbauer spectroscopy has revealed long-range magnetic ordering (16–18). For these linear chain systems, the magnetic properties have been analyzed using either the Ising or Heisenberg linear chain models. For two-dimensional layer systems, Lines (19) has proposed a quadratic layer Heisenberg antiferromagnetic model and this has been applied successfully in a number of cases (20–22). We find we can fit our experimental data for β-$Fe(CH_3SO_3)_2$ above the ordering temperature to the Lines model; however, we feel this is of questionable significance since the lattice which we propose for the sulfonate and that assumed in the Lines model are not compatible. The latter has each metal site interacting with four nearest-neighbour metal ions in a square or rectangular array, while the former has each iron interacting with six nearest neighbours.

The low-temperature magnetic moment data for the R = F, CF_3, and p-$CH_3C_6H_4$ compounds show a similar temperature dependence (Fig. 1) and the magnetic susceptibilities follow Curie–Weiss behaviour, no maximum being observed. The higher temperature (80–300 K) magnetic data for these compounds were previously fitted to a crystal field model (23) in which magnetic moments are determined by the values of λ, the spin-orbit coupling constant; ν, the axial field splitting parameter; and k, the orbital reduction parameter (2, 6). We have extended the theoretical curves, calculated employing the parameters determined by fits to the high temperature data, into the low temperature region and find generally that the agreement with experiment is poor. This is illustrated for $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ in Fig. 3. In particular, at temperatures below approximately 50 K the observed magnetic moments are significantly less than the values predicted by the model. As noted earlier (2, 4, 6), several criticisms have been laid against this model and it appears that, for these compounds, either the model is not valid over the entire temperature region of 4.2–300 K or weak antiferromagnetic exchange interactions

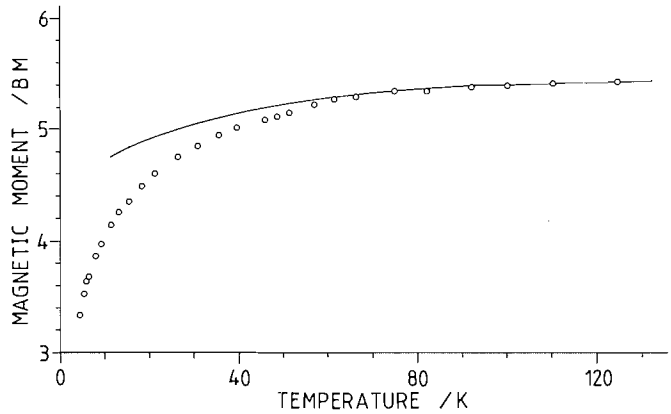

FIG. 3. Magnetic moment versus temperature for Fe(p-$CH_3C_6H_4SO_3$)$_2$. Line calculated from crystal field model with $\lambda = -90\ cm^{-1}$, $\nu = 3$, and $k = 0.75$.

[a]Units of δ, ΔE_Q, and Γ are all given in mm s^{-1}.

may be present. In general, however, it must be concluded that the low temperature magnetic susceptibility measurements show that any magnetic concentration present in these compounds must be very weak, a result consistent with the earlier Mössbauer studies on Fe(FSO_3)$_2$ (6) and Fe(p-$CH_3C_6H_4SO_3$)$_2$ (4), which show symmetric quadrupole doublets at 4.2 K with no evidence for magnetic hyperfine interactions. The spectrum of Fe(CF_3SO_3)$_2$ at 4.2 K is a quadrupole doublet that shows some assymmetry due to a slow spin-relaxation rate (see below).

In our earlier work on α-Fe(CH_3SO_3)$_2$ (5) the Mössbauer spectrum at 4.2 K was reported as a symmetric quadrupole doublet and the compound was described as acting as a fast-relaxing paramagnetic. Nevertheless, it was noted that the compound exhibits magnetic moment values significantly below those of other sulfonates (except for the β isomer) over the 80–300 K region, suggesting that this may be caused by weak antiferromagnetic coupling effects (2). In order to confirm this we were particularly interested in the low temperature magnetic behaviour and for this compound we extended the measurements below 4.2 K. As the data in Fig. 1 and Table 1 show, although the abnormally low moments continue to the lowest temperature studied, no maximum in magnetic susceptibility is observed even down to 1.97 K; hence there is no proof for magnetic exchange in this compound. It now seems more likely that the abnormally low moments observed for α-Fe(CH_3SO_3)$_2$ are a consequence of the fact that the compound has a well-isolated spin-orbit singlet ground state arising because, unlike the other sulfonates studied, it has a trigonally compressed FeO_6 chromophore (see below).

The present study has shown that the presence of significant magnetic exchange in a Fe(RSO_3)$_2$ compound is not simply related to electronic or steric effects associated with the substituent R. While magnetic ordering is seen in β-Fe(CH_3SO_3)$_2$, no ordering is seen in other systems whether R is more electronegative (F or CF_3) or the same or similar in electronegativity (α-CH_3 or p-$CH_3C_6H_4$). It seems likely that the different magnetic properties observed for these compounds arise more from differences in their detailed molecular geometries. The need for more structural information, particularly on the R = CF_3 compound and both forms of the R = CH_3 compound, prompted variable-temperature Mössbauer studies on these materials.

The Mössbauer spectra of Fe(CF_3SO_3)$_2$ and both α- and β-Fe(CH_3SO_3)$_2$ have been recorded at various temperatures from 4.2 to 300 K and the relevant parameters are given in Table 2. Agreement with values reported previously at 293 and 80 K (2) is good. As discussed in the earlier work, the isomer shift values, δ, are all relatively high, consistent with significant ionic character in the metal–ligand bonds. All three compounds exhibit a symmetric quadrupole doublet at room temperature and, for α-Fe(CH_3SO_3)$_2$, a symmetric doublet is retained down to 4.2 K. As described previously (4), β-Fe(CH_3SO_3)$_2$ shows the onset of complex hyperfine splitting below approximately 23 K. Fe(CF_3SO_3)$_2$ remains a symmetric quadrupole split doublet down to 8 K, below which it shows some assymmetry that may be caused by a slow spin-relaxation rate as observed in hexakis(pyridine-N-oxide) iron(II) perchlorate (24).

Values of the quadrupole splitting parameter, ΔE_Q, are plotted as a function of temperature in Fig. 4, where, for comparison, the data previously reported for Fe(FSO_3)$_2$ (6) and Fe(p-$CH_3C_6H_4SO_3$)$_2$ (4) are included. The magnitude and temperature dependence of ΔE_Q for Fe(CF_3SO_3)$_2$ follow very

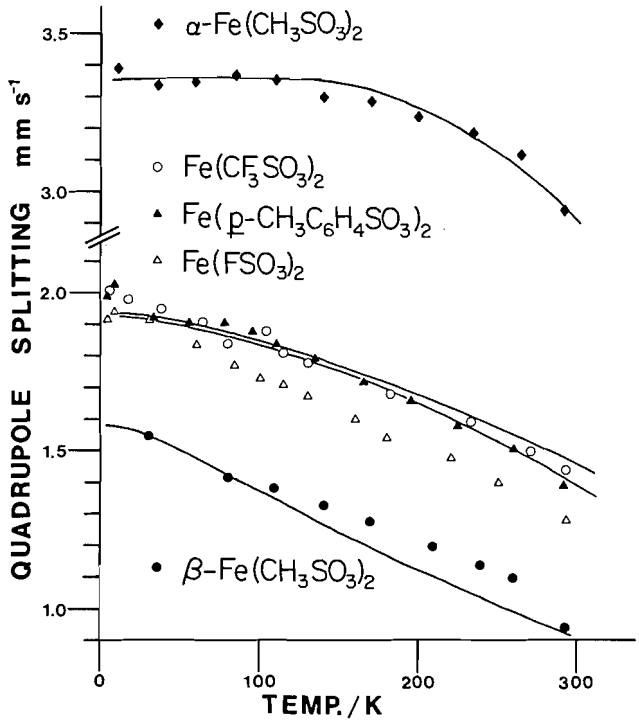

FIG. 4. Quadrupole splitting versus temperature for $Fe(RSO_3)_2$ compounds. Lines generated using parameters listed in Table 3.

TABLE 3. Crystal field splitting parameters derived from quadrupole splitting data

Compound	3Ds (cm^{-1})	λ (cm^{-1})	$D\sigma$ (cm^{-1})
$Fe(FSO_3)_2$[a]	−288	−90	−22
$Fe(CF_3SO_3)_2$	−320	−80	−20

closely what was observed previously for $Fe(FSO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ and support the conclusion reached earlier (2) that the CF_3 compound, like the other two, has an FeO_6 chromophore that is distorted by a trigonal elongation along the C_3 axis. The ΔE_Q values observed for β-$Fe(CH_3SO_3)_2$ are significantly lower than those observed for the other compounds, suggesting that while this material in all probability also has a trigonally elongated FeO_6 chromophore, the magnitude of distortion from regular stereochemistry is significantly less. The very large ΔE_Q values observed for α-$Fe(CH_3SO_3)_2$ are consistent only with an orbital singlet ground state and, as earlier magnetic perturbation Mössbauer studies showed (5), this arises from a trigonal compression of the FeO_6 chromophore along the C_3 axis.

As described previously (4, 6), the quadrupole splitting data may be analyzed in terms of a crystal field model to provide estimates of the magnitude of axial distortions. The solid lines in Fig. 4 are calculated using the crystal field parameter values given in Table 3 where, for comparison, the values previously reported for the R = F and $p\text{-}CH_3C_6H_4$ compounds are also listed. The values of the spin-orbit coupling constant are, as expected, of the order of, or less than, the free ion value

H_{APP} (T)	Γ ($mm\ s^{-1}$)	ΔE_Q ($mm\ s^{-1}$)	η	HIX (T)	HIY (T)	HIZ (T)
4.50	0.40	−3.31	0.30	−1.00	−0.60	−2.00
5.63	0.40	−3.31	0.35	−1.00	−0.60	−2.50

[a]Temperature 4.2 K.

(−103 cm^{-1}) and the values of the fine-structure term, $D\sigma$, are of the same magnitude as those reported previously (4, 6). The magnitude of the axial field, as measured by 3Ds (magnitude of splitting of $^5T_{2g}$ state), is highest at 510 cm^{-1} for the one compound, α-$Fe(CH_3SO_3)_2$, that has a trigonally compressed FeO_6 chromophore. The values of 3Ds for the others are all approximately −300 cm^{-1} with the exception of that for β-$Fe(CH_3SO_3)_2$, which is only half that value. This represents the only clear correlation we have been able to find between the magnitude of magnetic exchange and structure in these iron(II) sulfonates. The compound which clearly exhibits magnetic ordering, β-$Fe(CH_3SO_3)_2$, is the one having the least distorted FeO_6 chromophore. Greater distortion, whether involving trigonal compression or elongation, seems to result in a damping of the magnetic exchange. Similar correlations between magnetic exchange effects and the geometry of the metal–ligand chromophore have been found for some copper(II) and manganese(II) phosphinate polymers (9, 25).

The presence of trigonally elongated FeO_6 chromophores and orbital doublet ground states in $Fe(FSO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ was confirmed earlier by magnetic perturbation Mössbauer studies (4, 6). In a preliminary report (5) we indicated that similar studies on α-$Fe(CH_3SO_3)_2$ confirm the presence of a unique (for iron(II) sulfonates) trigonally compressed FeO_6 chromophore and an orbital singlet ground state; however, few details were given. Moreover, at that time we reported that attempts to fit the applied field spectrum of α-$Fe(CH_3SO_3)_2$ assuming isotropic magnetic interaction were unsuccessful but that a treatment using a phenomenological model such as that suggested by Varret (7), which enables the anisotropy of the hyperfine field to be parameterized in the case of weak magnetization, should be more successful. We report here the details of our magnetic perturbation studies on α-$Fe(CH_3SO_3)_2$, including analysis using the Varret model.

Mössbauer spectra of α-$Fe(CH_3SO_3)_2$ have been recorded in longitudinal applied magnetic fields of up to 5.6 T at a temperature of 4.2 K. A field of 1.1 T serves only to broaden the spectral lines. However, in applied fields of 4.50 and 5.63 T a doublet–triplet pattern is produced (Fig. 5). The triplet is at higher energy relative to the doublet, indicating that V_{zz}, the principal component of the electric field gradient tensor, is negative (5, 10). This sign for V_{zz} is, as discussed previously (5), consistent with an orbital singlet ground state and a distortion from octahedral symmetry corresponding to a compression along the trigonal axis. Spectra computed employing the Varret model and the parameters given in Table 4 are shown as solid lines in Fig. 5. Reasonable fits of experimental and computed spectra may be obtained by assuming a zero value for the asymmetry parameter, η, and identical values of HIX and HIY, the internal magnetic fields in the X and Y directions. However, better agreement is obtained using the finite value of $\eta \approx 0.3$ and HIX ≠ HIY. This suggests a small rhombic

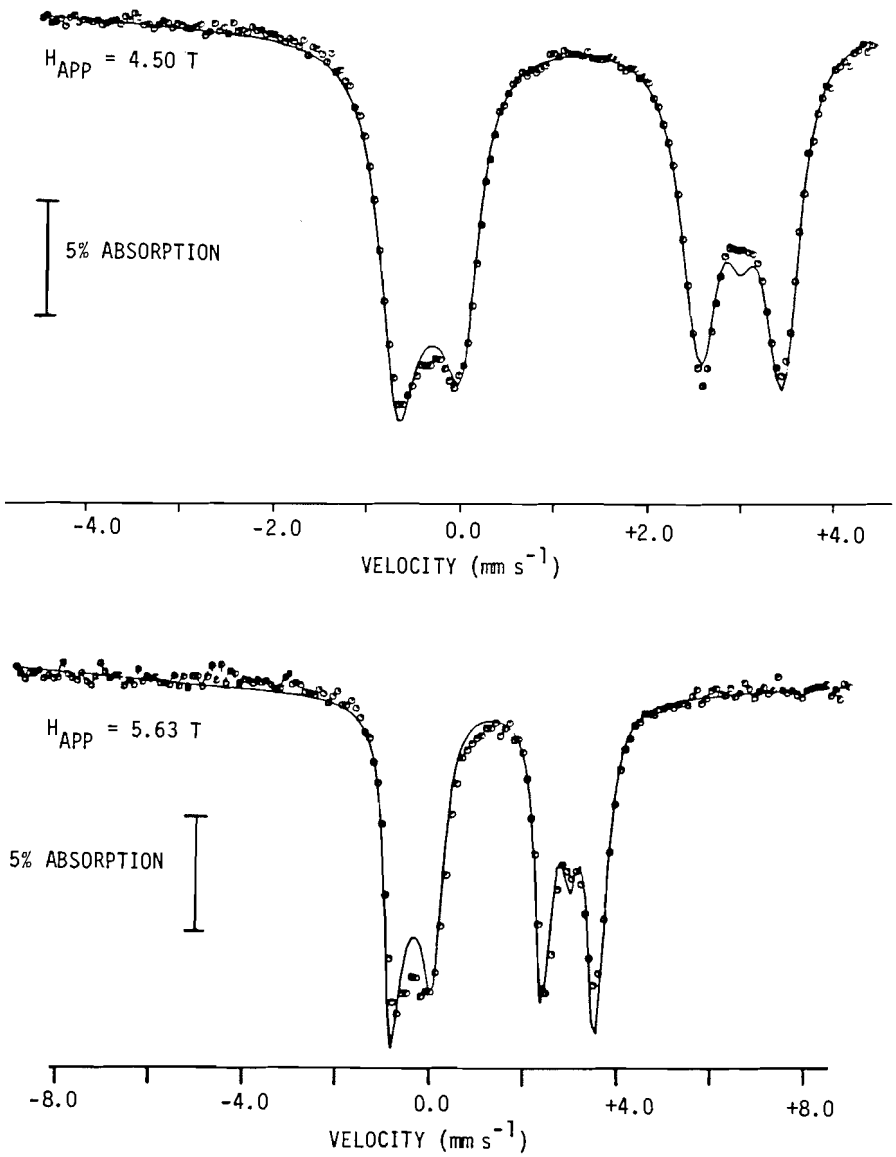

FIG. 5. Mössbauer spectra of α-$Fe(CH_3SO_3)_2$ at 4.2 K in applied magnetic fields of 4.50 and 5.63 T. Computed spectra generated by the parameters given in Table 4.

distortion in this compound, a fact which is consistent with infrared spectral data that show the anion to have C_s (rather than C_{3v}) symmetry (2).

Received July 2, 1985

DANIEL COZAK, ABDELHAKIM MARDHY, and ANDRÉ MORNEAU. Can. J. Chem. **64**, 751 (1986).

The reaction of $CpTi(CO)_2$ (**1**), Cp_2TiCl (**2**), and Cp_2TiCl_2 (**3**) (Cp = η^5-C_5H_5) with purine (PuH) and adenine (AdH) in organic solvents is described. The compound **1** reacts with both molecules in an oxidative fashion giving $Cp_2Ti(C_5H_3N_4)(C_5H_4N_4)$ (**4**) and $(Cp_2Ti)_2(C_5H_3N_5)$ (**5**) with concomitant liberation of molecular carbon monoxide and hydrogen (4:1) following a first order rate law in metal complex. The compound **2** forms an adduct compound $Cp_2TiCl(C_5H_4N_4)$ (**6**) with PuH. Monosubstituted derivatives $Cp_2TiCl(C_5H_3N_4)$ (**7**) and $Cp_2TiCl(C_5H_4N_5)$ (**8**) are formed from the reaction of the deprotonated bases with **3**. In addition to the usual elemental analysis, the characteristic ir, ^1H nmr, epr, and ms results are given for the new compounds.

DANIEL COZAK, ABDELHAKIM MARDHY et ANDRÉ MORNEAU. Can. J. Chem. **64**, 751 (1986).

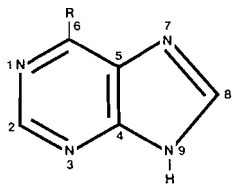
On décrit les réactions, en milieux organiques, des complexes $CpTi(CO)_2$ (**1**), Cp_2TiCl (**2**) et Cp_2TiCl_2 (**3**) (Cp = η^5-C_5H_5) avec la purine (PuH) et l'adénine (AdH). On a isolé et caractérisé les dérivés métallocéniques obtenus de ces réactions. Le composé **1** réagit avec ces ligands, par le biais d'une réaction oxydative, pour donner naissance aux produits $Cp_2Ti(C_5H_3N_4)(C_5H_4N_4)$ (**4**) et $(Cp_2Ti)_2(C_5H_3N_5)$ (**5**) avec un dégagement concomitant de monoxyde de carbone et d'hydrogène moléculaire (4:1) et en suivant une équation de vitesse du premier ordre par rapport au complexe métallique. La réaction de **2** avec la PuH donne le composé $Cp_2TiCl(C_5H_4N_4)$ (**6**). La réaction de **3** avec les bases déprotonées conduit aux produits monosubstitués $Cp_2TiCl(C_5H_3N_4)$ (**7**) et $Cp_2TiCl(C_5H_4N_5)$ (**8**). En plus des analyses élémentaires usuelles, on présente aussi les caractéristiques spectroscopiques ir, rmn ^1H, rpe et sm des nouveaux produits.

[Traduit par la revue]

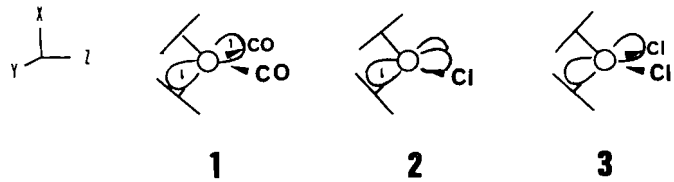
Introduction

The titanocene dichloride complex, **3**, belongs to a group of metallocene compounds which have recently been found to be efficient antitumor agents (1–3). Biological tests and spectroscopic data indicate that the titanium complex has a similar biological and chemical action on tumor cells as the well known *Z*-dichlorodiaminoplatinum(II) class of antitumor complexes (4–6). However, **3** is an organometallic compound of the so called early groups of the transition metal series, by opposition to the platinum complex which belongs to the late groups. Hence, the physicochemical properties of these organometallic compounds are quite different. In the present case, this is particularly evident for the molecular and electronic structures of these complexes. Nevertheless, both are Lewis acids with 16 electrons in their metal valence shell (7).

In view of these facts we decided to examine the reactivity of **1**, **2**, and **3** with the free bases purine (PuH) and adenine (AdH), two molecular building blocks of DNA. The metallocene complexes chosen for study are tetragonal molecules with three oxidatively different titanium metals for which are known several cases of simple and oxidative substitution or addition reactions with nitrogen containing ligands or heterocyclic molecules related to the bases studied.



R=H (PuH), NH_2 (AdH)



The molecular structures for the studied metallocenes are depicted above with the molecular orbital expected to contain the metal nonbonding electrons. These structures have been successfully interpreted from spectroscopic data by Petersen and Dahl (8) and by molecular calculations by Lauher and Hoffmann (9).

The low valent oxidation state of the titanium metal in **1** and the d^2 lone pair, which is exposed to the sides of the tilted rings, are largely responsible for the observed physicochemical properties of this complex. For example, the metal—carbonyl bond is unusually labile, as evidenced by the strong ir solvent dependent shifts observed for the CO stretching vibration and the facile CO substitution reaction known (10, 11). The carbonyl ligands are easily displaced by phosphine and phosphite derivatives (PR_3) to give the analogues $Cp_2Ti(PR_3)_2$ titanium(II) subsitution complex (12, 13). Carbonyl substitution by alkene, alkyne, ketone, aldehyde, acyl halide, carboxylic acid, and haloalkyl molecules has been amply studied and show that the nucleophilic attack by **1** follows an SN_2 mechanism (14–18). Noteworthy is a recent report by Stucky *et al.* for the reaction of **1** with thymine resulting in the metal oxidation to titanium(III) and liberation of molecular carbon monoxide and hydrogen (19). These authors also report the same type of oxidative substitution for titanium with several other analogous nitrogen containing aromatic heterocyclic molecules.

Monomeric **2** has only 15 electrons in its valence shell and will readily increase this number by addition of a lone pair of electrons from donating ligands such as amines or phosphines (20). In certain adduct complexes the neutral bidentate nitrogen containing ligand (L) is capable of displacing the chloride ion

[1]Taken in part from the M.Sc. thesis of A.M., Université Laval, 1984; presented in part at the XXIII International Conference on Coordination Chemistry, Boulder, CL, June 1984.

[2]To whom all correspondence should be addressed.

from the metal coordination sphere to form cationic $[Cp_2TiL]^+$ complexes. Oxidative addition to the metal or substitution involving the chloride ligands are the other two reaction paths commonly encountered for **2** (21). Closer to our interests, anionic uracil and different deprotonated imidazole, pyrimidine, benzimidazole, and pyrazole ring analogues are reported to give the substituted titanium(III) metallocenes when reacted with **2** (22, 23).

The reaction of **3** with the monoanions of chelating heterocyclic rings (XL), such as salicylaldimine and mercaptoquinazole, are reported to give mono or disubstitution compounds of the type $Cp_2Ti^{IV}Cl_x(XL)_{2-x}$, where ir spectroscopic data seem to indicate that an additional dative bond from the bidentate ligand is also involved in the metal bonding in these complexes (24, 25). Exchange of a chloride by an amino group occurs in liquid ammonia in the presence of excess amine (NH_2R) to give the $Cp_2TiCl(NHR)\cdot NH_2R$ metallocene and the corresponding hydrochloric ammonium salt (26). Deprotonation of naphthole by an alkyl amine has also been used to obtain the naphtholate complexes of mono and dichloride substituted **3** (27). Also, several substitution products can be obtained by metal exchange with the alkali salts of aromatic heterocyclic ligands (28, 29). In an earlier communication, we have reported the crystal structure of $Cp_2TiCl(Pu)$ synthesized from **3** and PuH in the presence of an amine base (30).

The complexes described hereafter all contain Cp_2Ti moiety and were obtained by reacting the ligand, or its deprotonated anion, with **1**, **2**, or **3** in aprotic organic solvents.

Experimental

Reactions and manipulation of the compounds were done under a blanket of purified nitrogen using Schlenk type vessels. Oxygen and water impurities from nitrogen were controlled by passing the gas first over supported copper catalyst (BASF-R3-11) heated at 200°C, purchased from Badische Anilin and Soda-Fabrik AG, W. Germany, and followed by 4A molecular sieve beds. The solvents used were refluxed for 1 h in a nitrogen atmosphere and over a drying agent before being distilled and stored. Sodium metal was used for drying aromatic solvents 1,2-dimethoxyethane (DME) and diglyme; sodium–benzophenone mixture for tetrahydrofuran (THF); 4A molecular sieve for pentane; and a magnesium – magnesium alkoxide mixture for drying methanol.

Melting and decomposition points were measured in nitrogen atmosphere sealed glass capillaries on a Thomas Hoover oil immersion type apparatus and are reported uncorrected. Mass spectra (ms) of the studied complexes were recorded on a Hewlett Packard 5995A mass spectrometer. The spectra were obtained by raising the temperature of the solid samples at a rate of 64°C/min to 200°C with 10^{-6} Torr (1 Torr = 133.3 Pa) pressure in the apparatus. Background subtracted spectra were regularly recorded for 15 min. Infrared (ir) spectra of air sensitive products were recorded on a Beckman IR-4250 spectrometer from KBr pellets of the samples prepared in a controlled atmosphere dry box (O_2 and H_2O < 5 ppm) equipped with a Teledyne Analytical Instrument oxygen analyzer model 317X. The spectra were calibrated (± 3 cm^{-1}) using the 2850.7, 1583.1, 1181.4, and 906.7 cm^{-1} bands of polystyrene film. A Varian EM 360A and a Bruker HX90 CW instrument were used to record the protonic nuclear magnetic resonance (nmr) spectra. Chemical shifts were measured relative to internal TMS or DSS in deuterated chloroform or dimethylsulfoxide (DMSO-d_6) and are reported in δ units from TMS. Electron paramagnetic resonance (epr) spectra were recorded on a JEOL JES-ME (9.3 GHz) spectrometer from polycrystalline solids or dilute (10^{-3} *M*) benzene solutions at ambient temperature. Diphenylpicrylhydrazyl (DPPH, g = 2.0036) was used as reference in epr spectra. Air sensitive samples were introduced in 3 mm od quartz tubing (5 mm od thin wall Pyrex glass tubing for nmr spectroscopy) mounted with a glass ground joint and stopper (5/20ST) to prevent their oxidation. Elemental C, H, and N analyses were performed in duplicate in our laboratory on a Hewlett Packard model 185 CHN analyzer using the appropriate anaerobic methods. X-ray intensity and cell parameter data for the structure determination were obtained with an Enraf-Nonius CAD4 diffractometer. Detailed structure data and methodology are described elsewhere (30).

Titanium trichloride, $TiCl_3$ 98%, was purchased from Ventron-Thiokol-Alfa; di(cyclopentadienyl)dichlorotitanium(IV), Cp_2TiCl_2 (**3**), and the thallium sulfate, $Tl_2(SO_4)$, from Aldrich Chemical Co.; purine, $C_5H_4N_4$, and adenine, $C_5H_5N_5$, from Sigma Chemicals Co. Di(cyclopentadienyl)monochlorotitanium(III), Cp_2TiCl (**2**), was prepared either by reduction of the dichloride **3** over aluminium metal (yield 85%) or by substitution from $TiCl_3$ and $Tl(C_5H_5)$ (yield 90%) as described in the literature (31, 32). Di(cyclopentadienyl)dicarbonyltitanium(II), $Cp_2Ti(CO)_2$ (**1**), was prepared by reduction of the dichloride complex **3** over aluminium in the presence of a CO atmosphere (33): yield 78%; ir (KBr) ν(CO): 1966 and 1871 cm^{-1}; ^{13}C nmr (C_6D_6) δ: 260.8 (s, CO) and 92.3 (s, Cp) ppm; ^{1}H nmr δ: 3.88(s) ppm; ms, m/z 234 (M^+, 5). We noticed while preparing this complex that special care must be taken to insure that the product is free of Cp_2TiCl and $Cp_2TiCl_2AlCl_2$ impurities. These partial reduction products are reaction intermediates resulting from the disproportion equilibrium between the unreacted starting complex **3** and the dicarbonyl product **1**, or the addition of $AlCl_3$ formed during the reduction reaction (34). The other reactants and the new titanocene derivatives described in this paper were prepared as described hereafter.

*Kinetic measurements. Reaction of **1** with PuH and AdH*

The experimental conditions described are those used for the kinetic curves given in the discussion (Fig. 1). Purine 0.302 g (2.52 mmol), or 0.590 g (4.37 mmol) AdH, was introduced in a nitrogen filled reaction cell thermostated at 85°C together with 10 mL diglyme. When the system reached thermal equilibrium the reaction was started by adding 10 mL of **1**, 80.0 m*M* (80.4 m*M* for the AdH experiment) in diglyme, from a dropping funnel. The reaction was followed by measuring the gas evolution with a mercury filled gas burette. Details of the experimental set-up and methodology are described elsewhere (35).

The gaseous reaction products were analyzed by gc on a Hewlett-Packard 7620A instrument equipped with a 13 m long column filled with molecular 13X sieves heated at 50°C and with a 21-620A mass spectrometer manufactured by Electro Dynamics Co. Kinetic experiments were carried out in a 1.3 L apparatus. Temperature of the reaction all-glass jacket-cell (300 mL) was regulated between 70 and 85°C (±0.05°C) using a Haake model F3-Q circulator bath.

Preparation of PuK

In a 100 mL flask, 1.93 g (16.1 mmol) purine was magnetically stirred together with 0.74 g (13.2 mmol) potassium hydroxide in 40 mL freshly distilled methanol for 1 h. The reaction mixture was then filtered to remove the excess purine and the filtrate was evaporated to dryness under reduced pressure on a rotary evaporator. The white solid was quantitatively recovered and used without any further purification; ir, see Table 1; ^{1}H nmr (DMSO-d_6) δ: 8.66 (s), 8.50 (s), 7.96 (s) ppm (lit. (H_2O) 9.2 (s, H6), 9.1 (s, H2), 8.9 (s, H8) ppm (36)).

Preparation of AdNa

In a 100 mL flask, 2.44 g (18.1 mmol) adenine was mixed together with 0.72 g (18.0 mmol) sodium hyroxide and 40 mL methanol. The reaction mixture was magnetically stirred for 1 h at room temperature and then filtered to remove the excess insoluble adenine. The methanol solvent was then vacuum evaporated on a rotary evaporator. Analytically pure adeninate was quantitatively recovered; ir, see Table 1; ^{1}H nmr (DMSO-d_6) δ: 7.90 (s), 7.66 (s), 6.30 (s) ppm (lit. 8.06 (s, H2), 7.96 (s, H8), and 6.85 (s, NH_2) ppm in 3 *N* aqueous NaOH; (DMSO-d_6) 7.83 (s, H2), 7.52 (s, H8) for AdK (37, 38)).

*Reaction of **1** with purine. Synthesis of $Cp_2Ti(C_5H_3N_4)(C_5H_4N_4)$ (**4**)*

In a 100 mL Schlenk flask, 1.69 g (7.22 mmol) dicarbonyl complex **1** was dissolved with 50 mL distilled THF. To this solution 1.74 g

(14.5 mmol) purine was added and the mixture heated on a paraffin bath at 55°C. The red solution turned violet within 15 min. Infrared spectroscopy showed that the reaction was over after 5 h (ν(C≡O): 1967 and 1889 cm^{-1} in THF). The cooled reaction mixture was then filtered over a fritted glass disk to remove a gray precipitate and the filtrate was evaporated to dryness under reduced pressure. The violet colored solid residue was then taken-up with a minimum quantity of THF and filtered. The filtrate was then reduced to half its volume and pentane was added to the solution till precipitation of the complex occurred. The compound was recovered by filtration and dried for 2 h at ambient temperature and 10^{-3} Torr. This yielded 1.83 g (61%) of a violet colored solid compound having the following analytical and spectroscopic properties. Mp 175°C; ir, see Table 1; epr (benzene) g = 1.981; ms, m/z (relative intensity >7%): 178 (7), 177 (9), 167 (11), 120 (10), 93 (16), 66 (29), 65 (12), 52 (12). *Anal.* calcd. for $C_{20}H_{17}N_8Ti$: C 57.56, H 4.11, N 26.85, Ti 11.48%; found: C 56.80, H 4.30, N 27.33, Ti 11.37%.

Reaction of ***1*** *with adenine. Synthesis of* $(Cp_2Ti)_2(C_5H_3N_5)$ ***(5)***

Following the same procedure given above for the purine reaction, 2.28 g (9.74 mmol) of **1** was reacted with 2.65 g (19.6 mmol) adenine in 50 mL THF at 55°C. The solution turned from red to blue in 15 min and the ir solution spectrum indicated that the reaction was over in 1 h. A greyish reaction precipitate was removed from the solution and the complex recrystallized from THF following the same work-up procedure given above for the reaction with PuH. After drying, a blue solid was recovered from the reaction in quantitative yield. The isolated compound has the following analytical and spectroscopic properties. Dec. point 230°C; ir, see Table 1; epr (benzene) g_1 = 1.981, g_2 = 1.975; ms, m/e (relative intensities >5%): 379 (15), 312 (7), 247 (5), 178 (100), 135 (7), 113 (30), 66 (19), 65 (25). *Anal.* calcd. for $C_{25}H_{23}N_5Ti_2$: C 61.37, H 4.74, N 14.31, Ti 19.57%; found: C 61.30, H 5.37, N 14.22, Ti 18.73%.

Reaction of ***2*** *with purine. Synthesis of* $Cp_2TiCl(C_5H_4N_4)$ ***(6)***

In a 100 mL Schlenk flask, 0.700 g (3.29 mmol) complex **2** was dissolved in 50 mL toluene. Then, 0.400 g (3.33 mmol) purine was added under a positive nitrogen pressure to the magnetically stirred solution. The purine slowly dissolved in a few minutes while the solution gradually changed color from green to violet and subsequently back to green. The reaction mixture was stirred for 48 h at ambient temperature. The product precipitated during this time and was recovered by filtration on a glass frit. After washing the solid with two 50 mL portions of cooled pentane, the compound was transferred to a Schlenk flask and thoroughly dried for 2 h at ambient temperature and 10^{-3} Torr. The analytically pure product was obtained by recrystallization from THF/pentane. This yielded 0.900 g (90%) of an air sensitive green complex. The compound gave the following analytical and spectroscopic data. Mp 120–130°C; ir, see Table 1; epr (solid) g_1 = 1.991, g_2 = 1.980, g_3 = 1.966; ms, m/e (relative intensities >8%): 213 (16), 178 (8), 148 (30), 120 (100), 93 (14), 83 (12), 66 (30), 65 (24). *Anal.* calcd. for $C_{15}H_{14}N_4ClTi$: C 54.00, H 4.23, N 16.79%; found: C 52.37, H 4.85, N 16.26%.

Similarly, the same reaction product was obtained using THF or DME instead of toluene as solvent. The total reaction time was 24 h. In these solvents **6** is soluble and was recovered by evaporating the solvent under reduced pressure after filtration to remove any unreacted solid purine.

Reaction of ***3*** *with purine and potassium purinate. Synthesis of* $Cp_2TiCl(C_5H_3N_4)$ ***(7)***

With PuH.

Complex **3**, 1.50 g (6.05 mmol) and purine 1.45 g (12.1 mmol) were placed together with 40 mL THF in a 100 mL Schlenk flask. To this solution, 1.68 mL (12 mmol) distilled triethylamine, $N(C_2H_5)_3$, was added and the mixture heated under positive nitrogen pressure. During the first few hours of reflux the solution darkened. The reaction was followed by nmr in deuterochloroform prepared from aliquots syringed regularly from the reaction mixture. After 18 h, no trace of the starting compound was found in the spectrum (^{1}H nmr ($CDCl_3$) δ: 6.60 (s) ppm for **3** and 6.70 (s) ppm for **7**) and the reaction mixture was then cooled to room temperature before being filtered to remove a white precipitate. The resulting filtrate was evaporated to dryness under reduced pressure and the red-brown residue taken up with a minimum amount of warm THF. The reaction product started to precipitate as the solution was left standing at ambient temperature. The resulting red crystals were recovered by filtration, washed with two 50 mL portions of cooled pentane and dried for 2 h at ambient temperature and 10^{-3} Torr. This yielded 1.65 g (82%) red crystalline product having the following analytical and spectroscopic data. Mp 155°C; ir, see Table 1; ^{1}H nmr (DMSO-d_6) δ: 9.00 (s, purine) and 9.23 (s, purine), 8.70 (s, purine), 6.73 (s, Cp); ms, m/e (relative intensities >5%) 332 (M^+, 5), 269 (19), 267 (46), 213 (19), 185 (33), 183 (43), 150 (31), 149 (17), 148 (81), 147 (12), 122 (18), 121 (15), 120 (100), 93 (18), 85 (17), 83 (29), 66 (36), 65 (34), 52 (16). *Anal.* calcd. for $C_{15}H_{13}N_4ClTi$: C 54.16, H 3.94, N 16.84%; found: C 54.68, H 3.53, N 16.93%.

With PuK.

A mixture of 1.20 g (4.84 mmol) **3** and 0.76 g (4.8 mmol) potassium purinate in 40 mL THF was refluxed for 18 h. The work-up procedure followed was identical to that given above for the reaction with PuH. This reaction yielded 1.09 g (68%) of product. The analytical and spectroscopic properties for this complex are identical with those given above for the PuH reaction.

Reaction of ***3*** *with sodium adeninate. Synthesis of* $Cp_2TiCl(C_5H_4N_5)$ ***(8)***

In a 100 mL Schlenk flask, 1.50 g (6.05 mmol) complex **3** and 2.84 g (18.1 mmol) sodium adeninate were reacted in 25 mL THF at ambient temperature and constant magnetic stirring. After 30 min, the original red color of the solution turned to pale orange. Progress of the reaction was followed by nmr. Aliquots were periodically taken from the reaction mixture and the THF replaced by deuterochloroform before checking for the presence of **3** (^{1}H nmr ($CDCl_3$) δ: 6.60 (s) ppm for **3** and 6.33 (s) for **8**). After 3.5 h, **3** had all reacted and the reaction mixture was filtered on a glass frit to remove a white precipitate. This solid product was washed, while on the frit, with 25 mL THF and the resulting filtrate was evaporated under reduced pressure. This gave 0.40 g (19%) of orange solid product which has the following analytical and spectroscopic properties. Dec. point 208°C; ir, see Table 1; ^{1}H nmr (DMSO-d_6) δ: 8.23 (s, adenine cycle), 8.20 (s, adenine cycle), 7.15 (s, NH_2), 6.46 (s, Cp); ms, m/z (relative intensities >5%): 381 (5), 380 (5), 379 (15), 377 (17), 376 (5), 374 (15), 312 (6), 215 (12), 214 (6), 213 (31), 211 (6), 185 (5), 183 (6), 180 (6), 179 (20), 178 (100), 177 (14), 176 (13), 152 (6), 150 (18), 148 (42), 129 (6), 122 (6), 113 (30), 83 (8), 66 (10), 65 (25). *Anal.* calcd. for $C_{15}H_{14}N_5ClTi$: C 51.82, H 4.02, N 20.14, Ti 13.78%; found: C 51.21, H 3.59, N 20.85, Ti 14.03%.

Results and discussion

The newly synthesized complexes **4**, **5**, and **6** are extremely air sensitive in solution and gave the expected epr spectra for titanium +3 complexes. Moreover, **7** and **8** gave normal diamagnetic proton nmr signals and did not show any signs of decomposition when exposed to air for short periods of time. Nevertheless, all compounds were prepared and kept under a purified nitrogen atmosphere as described in the experimental part.

The compounds isolated in this work were characterized by elemental analysis, ir, epr, ms, and ^{1}H nmr spectroscopy. The crystal structure of **7** has been determined by single crystal X-ray diffraction analysis and is reported in detail elsewhere (30).

Though both bases studied here are structurally quite similar, marked differences for their reactivity with the diferent titanocene complexes were observed. For instance, the oxidation product for the dicarbonyl complex **1** with PuH is monometallic (**4**) whereas, under similar conditions, the AdH derivative is

[b]Legend: s = strong, m = medium, w = weak, v = very, sh = shoulder, br = broad; Py = pyrimidine ring modes, Im = imidazole ring modes.

[c]The assignments are those of the neutral and anion ligands taken from refs. 41–47 and the metallocene moiety from refs. 48 and 49.

bimetallic (**5**). Repeated attempts to react the neutral AdH ligand or its alkali (Li, Na, K) salts with the monochloride complex **2** resulted in the displacement of the cyclopentadienyl rings to give insoluble titanium containing products. This result is not completely unexpected since cyclopentadienyl has been reported to be displaced in **1** by strong bases such as *o*-phenantroline, and adducts of **2** are not isolable for bulky secondary or tertiary amines, or alkyls and aryl substituted phosphites (20, 32). Conversely, with PuH this reaction readily gives, in good yields, the adduct product **6** described hereafter. Finally, with **3** the chloride substitution product **8** was isolated only for the reaction with the adeninate salt AdNa, whereas PuH in the presence of NEt_3 or PuK gave in good yield the monosubstituted purine derivative **7**.

Carbon monoxide and hydrogen gas evolution was observed for the reaction of **1** with PuH and AdH. A 3.8–3.9:1 CO/H_2 molar ratio in the gas mixture over the reaction solution was determined by ms. This is very close to the expected 4:1 ratio for the overall oxidative addition reaction of **1** to these bases, as given in eqs. [1] and [2] below, corresponding to the formation of **4** and **5**. Moreover, reaction yields of 80–82% were found based on the evolved experimental–theoretical volume ratio and the unreacted base recovered after the reaction. Both reactions follow first order kinetics in the metal complex as evidenced by the linear $\ln(V_\infty - V_t)$ *vs.* time curves shown in Fig. 1. Using these plots, rate constants were calculated for a few ligand/complex ratios between 70 and 85°C to verify this first order dependence. The following results and observations were made.

The reaction rate constants measured at 85°C for PuH in xylene and diglyme solvents using a 3:1 ligand/complex molecular ratio are $0.97(\pm0.06) \times 10^{-4}\,s^{-1}$ and $2.0(\pm0.1) \times 10^{-4}\,s^{-1}$ (shaded circles in Fig. 1), respectively. The rate constants discussed here are for the reactions in diglyme at different temperatures. For the molecular ratios AdH/**1** = 1.5:2 and 11:2, the observed rate was the same, $0.49(\pm0.01) \times 10^{-4}\,s^{-1}$ (85°C, shaded squares in Fig. 1) and decreased to $0.325(\pm0.003) \times 10^{-4}$ when the reactant ratio was increased to 20:2. When the PuH/**1** ratio was increased from 3:1 to 40:1, an increased of the observed reaction rate constant from $1.39(\pm0.03) \times 10^{-4}$ to $2.9(\pm0.1) \times 10^{-4}\,s^{-1}$ resulted (80°C). In all cases, the activation enthalpies calculated from the Arrhenius plots give $\Delta H^* = 98$ and 108 (±8) kJ mol^{-1} ($\Delta S^* = -50$ and -34 J mol^{-1} K^{-1}), respectively for reactions [1] and [2]. More experimental results for different ligand concentrations are needed to verify the exact nature of these pseudo first-order laws. The decrease in reaction rates, above a given reactant ratio, observed for AdH/**1** indicates a more complicated rate law for this reaction. Moreover, the crude activation energy and entropy values (negative) calculated from the Arrhenius plots for these reactions agree well with the complex-ligand associative mechanism usually proposed as a limiting step in several oxidative SN_2 reactions of **1** and for other transition metal compounds in general (15, 16, 39, 40).

[1] $\underset{\mathbf{1}}{Cp_2Ti(CO)_2} + 2PuH \rightarrow \underset{\mathbf{4}}{CpTi(Pu)(PuH)} + 2CO + 0.5H_2$

[2] $2\underset{\mathbf{1}}{Cp_2Ti(CO)_2} + AdH \rightarrow \underset{\mathbf{5}}{(Cp_2Ti)_2(C_5H_3N_5)} + 4CO + H_2$

Formation of an insoluble amine salt, $[HNEt_3]^+$, during the reaction of **3** with PuH in the presence of NEt_3 was confirmed by ^1H nmr spectroscopy, $\delta(CD_2Cl_2)$: 3.08 (q, CH_2) and 1.36 (t, CH_3) ppm. Hence, our results point to the formation of the substitution product **7** given by eq. [3]. Attempts to prepare the disubstituted derivative by using an excess of ligand (PuH/complex ratio, 7:1) were to no avail. However, the ^1H nmr spectra of the crude reaction product with PuK showed the presence of a secondary titanocene product at $\delta(CDCl_3)$ 6.35 (s, Cp) ppm believe to be disubstituted. We were unable to properly isolate this product because of poor yields.

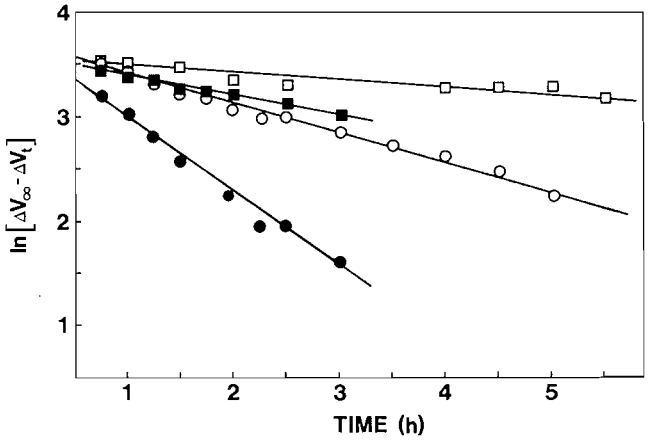

FIG. 1. Curves of $\ln[V_\infty - V_t]$ for the reaction of PuH (circles) and AdH (squares) with **1** in diglyme. The unshaded circles are for T = 75°C and shaded circles for 85°C using a PuH/**1** = 3:1 reactant ratio. The unshaded squares are for T = 75°C (AdH/**1** = 1.5:2) and the shaded squares for T = 85°C (AdH/**1** = 11:2). At 75°C, $k = 0.76(\pm0.01) \times 10^{-4}\,s^{-1}$ for PuH and $k = 0.172(\pm0.003) \times 10^{-4}\,s^{-1}$ for AdH. See text for details.

[3] $\underset{\mathbf{3}}{Cp_2TiCl_2} + PuH + NEt_3 \rightarrow \underset{\mathbf{7}}{Cp_2Ti(Pu)Cl} + [HNEt_3]Cl$

Infrared spectra

The observed infrared spectrum in the 4000–250 cm^{-1} range for the studied compounds are given in Table 1. The band assignment for the free ligands are those given in the literature (41–47). The frequencies for complexes **4–8** were tentatively correlated as much as possible with those of the ligands.

Hence, all the titanium complexes exhibit strong π-bonded cyclopentadienyl ligand around 1440, 1015, and 800 cm^{-1} expected for the titanocene unit (48, 49). The presence of the purine and adenine ligands in **4–8** is confirmed by the characteristic Py and Im ring skeleton vibrations which are given in the table. These skeleton modes can be divided into two groups. Those located around 1600, 1570, 1470, and 1400 cm^{-1} are due to the Py ring vibrations and those near 1460, 1415, and 1330 cm^{-1} to the Im ring. Also, the absorptions at 1440 cm^{-1} present for all the complexes is attributed to the Cp ring. However, several bands in the 800 cm^{-1} region renders difficult the unambiguous attribution of the characteristic frequencies in this region for the Cp or the purine ring modes.

A comparative look at the ir spectra of **4**, **6**, and **7** does not reveal major discrepancies for the observed frequencies. However, like PuH, the spectra of **4** and **6** have vibrations in the 2800–2400 cm^{-1} region superimposed to a broad base line deformation (not mentioned in Table 1) owing to the Im N—H stretching vibrations, whereas **7** has none. The only absorption seen at 2800 cm^{-1} for **7** is believed to be owing to a combination band. These observations are in agreement with spectroscopic and analytical results which indicate that **6** and **7** are, respective-

ly, titanium(III) addition and titanium(IV) substitution products with similar chemical compositions (i.e., $Cp_2TiCl(PuH_x)$, x = 1 and 0).

Another interesting feature is the presence of a medium intensity band at 395 cm^{-1} for **6** and **7** assigned to the Ti—Cl stretching. The weak band observed at 385 cm^{-1} for **4** must, in this case, be assigned to the other possibility, that is, the symmetric or asymmetric Ti–Cp metal–ring stretching of the metallocenic moiety (49). This vibration mode is also present in the spectrum of the nonchloride-containing complex **1** at 395 cm^{-1} (see footnote in Table 1). The bands near 570 cm^{-1} were assigned in each case to the Ti–N stretching frequencies. There was no evidence in the ir data whether N1, N3, N9, or N7 coordination to titanium is preferred in **4** or **6**, by way of comparison with **7**, or if the labile N7–H proton migrates to other nitrogen atoms in these complexes. This type of ligand rearrangement has been reported for several transition metal complexes of neutral or protonated purine, e.g., $[Cu(H_2O)_4(PuH)]SO_4$ (50), $ZnCl_3(PuH_2)$ (51), and $Cu_2Cl_6(PuH_3)$ (52). In general this type of structural nuance is difficult to detect by routine ir alone.

For the adenine derivatives **5** and **8**, the spectra are very similar to those of free AdNa and AdH, respectively. The vibrations for which these similitudes are most evident are in the 3400–2400 cm^{-1} and 1700–1600 cm^{-1} regions. More precisely, the AdNa and **5** spectra have both a very broad band near 1640 cm^{-1} attributed to the NH_2 deformation vibration which is slightly at higher frequencies and much sharper for AdH and **8**. Hence, in the latter spectra the NH_2 deformation band is well resolved from the sharp Py ring vibration near 1600 cm^{-1}, contrary to the former. Overlapping and very broad absorptions in the 3400–2800 cm^{-1} region have been assigned to the NH_2 stretching mode and a broad band in the 2800–2400 region to the Im N—H stretching, by Lautié and Novak (42). The two main absorption bands present at 3320 and 3100 cm^{-1} in the spectra of **5** can be assigned to a secondary rather than a primary amine if the low field band is assumed to be cause by a C—H stretching mode. Also, the 2800–2400 cm^{-1} region is void of the Im N—H stretching absorption for this complex. Furthermore, the important NH_2 wagging present at 650 cm^{-1} in the spectrum of AdH was not observed for **8** although a stretching mode is present as indicated by the absorptions at 3300 and 3130 cm^{-1}. The amino wagging mode should be manifest for the titanium derivative based on the spectra of the sodium metal salt, which contains a huge deformation of the base line ranging from 800 to 400 cm^{-1} owing to this mode (not mentioned in Table 1). Hence, based on its ir data, there is no evidence for the ring deprotonation in **8**, and the amino group should be involved in some type of bonding interaction. Data for **5** suggest that the amino group environment is significantly changed in this complex and clearly shows that the Im ring is deprotonated.

Several molecular and polymeric structures of purine base complexes with transition metals have been precisely determined by X-ray diffraction (53–55). In view of the great flexibility of the chelate–metal interactions in these solids, definitive structures based on ir data alone are difficult.

Electron paramagnetic resonance spectra

Solid and benzene solution spectra were recorded at room temperature for the paramagnetic **2**, **4**, **5**, and **6** compounds. The observed g values are typical of titanium +3 oxidation state.

The characteristic features of the solid state epr are as follows. The spectrum for polycrystalline **4**, see Fig. 2, has the general shape of an axially symmetric resonance with anisotropic tensors $g_{\|}$ = 1.994 and $g_{\perp}$ = 1.975. The powder spectrum of **6** is typical of a rhombic g tensor, giving rise to three g values: g_1 = 1.991, g_2 = 1.980, and g_3 = 1.966. The spectrum is also shown in Fig. 2. This type of spectrum has been observed for similar $Cp_2Ti^{III}XL$ addition complexes (56, 57). Contrasting with these special features, the powder spectrum for **5** gives an extremely broad single derivative shape resonance

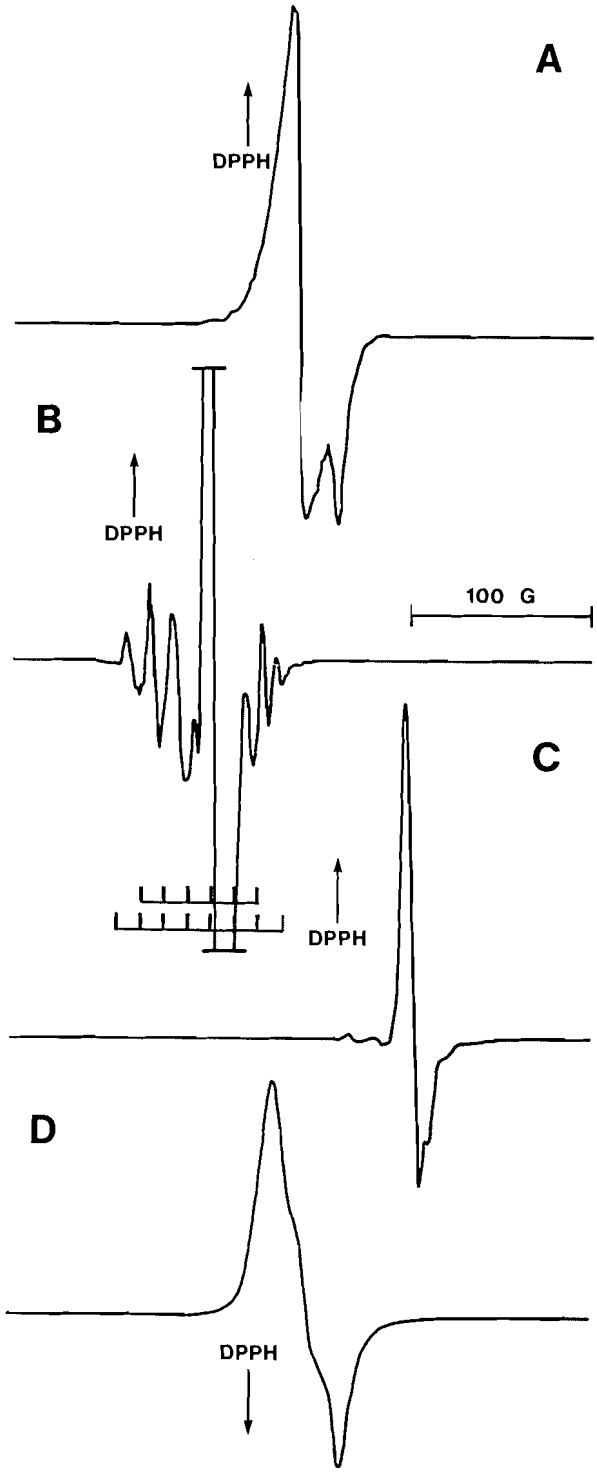

FIG. 2. Room temperature epr spectra of polycrystalline **4** (A) and in solution 10^{-3} M in benzene (B); of **5** in solution 10^{-3} M in benzene (C); and of polycrystalline **6** (D).

centered at $g = 2.001$ having approximately 82 G peak-to-peak, double the width observed in the spectra of the monochloride complex **2** which has a g value of 1.980.

Dilute solution spectra in benzene for the paramagnetic complexes show a narrow single resonance derivative signal. In addition to this, **5** has an unresolved resonance at high field of the main epr derivative resonance giving rise to two g values for this complex: $g_1 = 1.981$ and $g_2 = 1.975$. All the solution spectra showed hyperfine metal–spin coupling with ^{47}Ti ($I = 5/2$, natural abundance 7.5%) and ^{49}Ti ($I = 7/2$, natural abundance 5.5%) as shown in Fig. 2 for **4** ($g = 1.981$). The interline spacings measured are; for **2**, 15 G; for **5**, 10 G; for **4** and **6**, 13 G. The scale drawn for spectrum B of Fig. 2 depicts a sextet superimposed to an octet splitting centered around the more intense singlet resonance due to ^{46}Ti, ^{48}Ti, and ^{50}Ti (natural abundance 87.0%) metal atoms, $I = 0$ nuclei. The observed hyperfine resonance intensities coincide with those calculated from the natural isotopic abundance of titanium, 1:2.6:2.6:2.6:115:2.6:2.6:2.6:1 (58). Furthermore, the averaged interline splitting observed here is somewhat stronger than the 8–11 G range reported for bipyridine, imidazole, biimidazole, benzimidazole, and carboxylic acid complexes (59, 60).

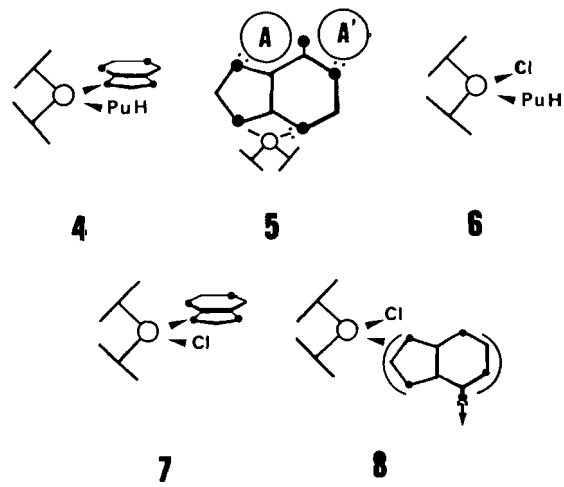
Closer examination of the hyperfine structure in the solution spectra of **5** indicated the presence of a second less intense unresolved hyperfine splitting, with *ca.* 4 G interline spacing with the former. Similar splitting has been reported for dinuclear titanocene complexes of dicarboxylic acids (59, 61). Intramolecular magnetic exchange between neighboring titanium atoms [i.e., $J \gg A(\mathrm{Ti})$] has been shown to be the cause of this splitting. Hence, this feature is consistent with the dinuclear composition found by elemental microanalysis for **5**.

Mass spectra

The pertinent electron impact mass spectral data are given in the experimental part. The spectra of the studied compounds did not show any molecular ion fragments except **7** where a fragment at m/z 332 (5) corresponding to the molecular ion $[C_{15}H_{13}N_4ClTi]^+$ was present. For all the complexes, the $[C_{10}H_{10}Ti]^+$ and $[C_5H_5Ti]^+$ fragments typical for titanocene derivatives were more or less abundant at m/z 178 and 113 (percent relative intensity, 2–31%). For **6**, **7**, and **8** the mass peak at m/z 213 corresponding to the $[C_{10}H_{10}ClTi]^+$ ion can be explained by the loss of the neutral base ligand from the parent molecular ion. The base peak for the purine complexes were present at m/z 120 (100) due to the ionized pure ligand. The ms of the adenine complexes, on the other hand, gave a base peak corresponding to the titanocene unit at m/z 178 (100). Also, in the spectra of **8** several metal–adenine containing fragments were detected. The more intense fragments are at m/z 381 (5), 379 (15), 314 (4), and 312 (6), and coincide with the formulation of ions with two adenine rings $[(C_5H_5)(C_5H_xN_5)_2Ti]^+$ with $x = 4$ and 3, or one adenine ring $[(C_5H_5)_2(C_5H_yN_5)Ti]^+$ with $y = 6$ and 5 species, respectively. Primary elimination of neutral cyclopentadienyl fragments from the parent ion has been reported for several titanocene complexes with strong O, N, or S bonded chelating ligands (19, 23).

Structures

Crystallographic measurements for **7** show that the molecule contains a bent-cycle metallocene unit to which the deprotonated purine ligand is bonded through the N9 nitrogen (30). The ligands are tetragonally disposed around the metal with the purine ring pointing away as shown in the structure given below. This feature contrasts with the preferred N7 protonation



site of the free ligand and is probably due to the different Lewis acid properties of H^+ and the Cp_2Ti^+ cations. The titanium—ligand bond lengths and angles fall within previously reported values for titanium(IV) metallocenes.

The expected structures for complexes **4**–**6** and **8** are shown below. Analytical and spectroscopic results indicate the presence of π-cyclopentadienyl ligands in all four complexes. Moreover, titanium metallocenes generally adopt a tetragonally arranged *clino*-structure for its ligands. Also, the proposed structures are consistent with the 17 or 16 valence electron configuration usually encountered for titanium +3 and +4 oxidation state, respectively.

Kinetic, analytic, and spectroscopic results indicate that one of the two purine ligands in **4** is deprotonated and **5** must be a bimetallic complex with one doubly protonated adenine ligand. In **4** the deprotonated purine ligand is possibly coordinated through its N9 nitrogen as in **7**. Moreover, in these compounds and in **6** the titanium has a +3 oxidation state. Hence, structures **4** and **6** can reasonably be proposed and represent PuH addition compounds. The structure for **5** is more difficult to predict. If the assumption that the N9 and N6 nitrogens are the more probable deprotonation sites for adenine, then one $(\eta^5\text{-}C_5H_5)_2Ti$ unit can be expected to bond to the N9 nitrogen of the adenine ring, plus a dative bond from N3 is possible. The second titanium unit can then bond to the amino N6 nitrogen with an additional dative bond from either the N7 or the N1 atom of the ring. These two distinct structures are depicted in structure **5** by circles A and A′ respectively. For these two structures, it can be argued that formation of a five-member metallocycle (A) is expected to be favored over the smaller four-membered ring (A′). However, the greater basicity of N1 over N7 is an equally important property of the free adenine molecule in favor of the latter structure (A′).

Finally, for titanium compounds no information was available, as of yet, on the coordination properties of adenine. There are strong indications here, from ir and ms results for **8**, that the amino group is involved in inter- or intra-molecular chelation in the solid state, possibly with titanium. Seemingly, saturated penta-coordinated titanium(IV) complexes are rare but have been previously reported (24, 25).

NICK HENRY WERSTIUK, DOUGLAS NEVE BUTLER, and SUSHIL DATTA. Can. J. Chem. **64**, 760 (1986).

The ultraviolet photoelectron spectra of 2,7-diazatetracyclo[3.3.3.0.^{4,9}0.^{8,11}]undecane (**1**) and its *N,N*-dimethyl- and methylene-bridged analogues **2** and **3** are documented. The spectrum of **2**, which exhibits a nitrogen lone-pair splitting of 0.95 ± 0.1 eV, is interpreted on the basis of an interaction of "inside" lone pairs of the 1,2-diamine. Apparently this is the first report of a study of such an interaction. The spectrum of **1** is consistent with our view that **1** is an intramolecularly hydrogen bonded species in which the lone pairs are "inside–outside".

NICK HENRY WERSTIUK, DOUGLAS NEVE BUTLER et SUSHIL DATTA. Can. J. Chem. **64**, 760 (1986).

On a mesuré les spectres photoélectroniques ultraviolets du diaza-2,7 tétracyclo[3.3.0.^{4,9}0.^{8,11}]undécane (**1**) et de ses analogues *N,N*-diméthylé (**2**) ou portant un pont méthylénique (**3**). Le spectre du composé **2** présente un couplage de la paire d'électrons libres de l'azote de 0,95 ± 0,1 eV que l'on interprète sur la base d'une interaction des paires d'électrons "internes" de la diamine-1,2. Le spectre du composé **1** est en accord avec notre hypothèse selon laquelle ce composé est une espèce qui possède des liaisons hydrogènes intramoléculaires dans lesquelles les paires libres sont du type "intérieur–extérieur".

[Traduit par la revue]

Introduction

Over the past fifteen years, studies of nitrogen, oxygen, and sulfur compounds by ultraviolet photoelectron spectroscopy have yielded a wealth of information on the factors that determine the magnitudes of through-space and through-bond interactions of lone pairs. Studies of diamines have been especially fruitful (1). In a significant paper in 1970, Heilbronner and Muszkat (2) confirmed early EH and MINDO/2 calculations that predicted significant interaction between the nitrogen lone pairs of 1,4-diazabicyclo[2.2.2]octane. They established that the lone-pair splitting was 2.13 eV, that n^+ was higher in energy than n^-, and thereby that interaction of the lone pairs occurred predominately through the ethano bridges. Subsequently, Nelsen and Buschek (3) studied 1,5-diazabicyclo[3.2.2]nonane, 1,5-diazabicyclo[3.2.1]octane (**7**), 1,5-diazabicyclo[3.3.1]nonane (**8**), and several piperazines and hexahydropyrimidines to evaluate through-space and through-bond interactions. They conclude that the magnitudes of the splittings of 1,1- and 1,2-diamines depend on the spatial orientation of the lone pairs, as shown in Fig. 1. More recently, Alder *et al.* (4), in a significant paper, described the effects of ring strain and three-electron σ-bonding on the ionization energies of bicyclic diamines.

In this paper we document and discuss the photoelectron spectra of 2,7-diazatetracyclo[3.3.3.0.^{4,9}0.^{8,11}]undecane (**1**) and its *N,N*-dimethyl- and methylene-bridged analogues **2** and **3**, the syntheses of which will be reported in a following publication. Diamine **2** provides an unique opportunity to investigate previously unknown (1) through-space interactions between the "inside" lone pairs of an alicyclic 1,2-diamine and **3** (essentially the "outside" analog of **2**). Diamine **1**, which is a stronger proton sponge[2] than 1,8-diaminonaphthalenes (1), provides an opportunity to study a rigid intramolecularly hydrogen-bonded 1,2-diamine.

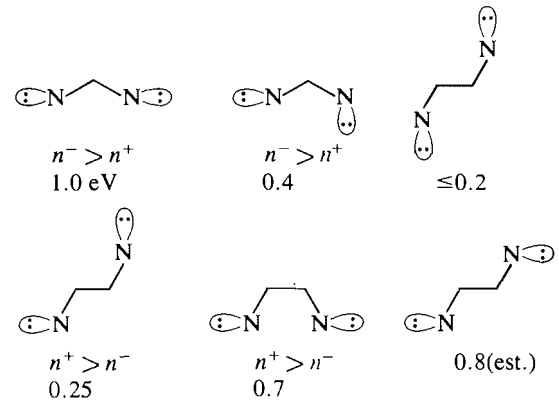

FIG. 1. Magnitudes of lone-pair splittings of 1,1- and 1,2-diamines as a function of spatial orientation.

Results

The photoelectron spectra of **1**, **2**, and **3** are given in Figs. 2(A), (B), and (C), respectively. The maxima of the lone pair IPs (ionization potentials) are taken as the vertical IPs, and splittings are listed in Table 1. Substantial splittings are observed for the diamines, and the lone-pair IPs of **2** are unusually low.

Aspects of the structures of diamines 1 and 2

Although the lone pairs of **3** are fixed, three limiting configurations are possible for **1** and **2**: **1**-i,i and **2**-i,i (i = in, o = out); **1**-i,o and **2**-i,o: **1**-o,o and **2**-o,o.

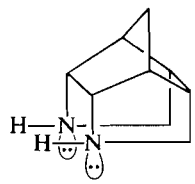
TABLE 1. Ionization potentials and splittings of diamines

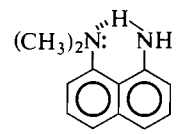
Diamine	IP^1_{max} (eV)	IP^2_{max} (eV)	ΔIP (eV)
1	8.20 ± 0.05 (n^-)	8.80 ± 0.05 (n^+)	0.6 ± 0.1[a]
2	7.29 ± 0.05 (n^-)	8.24 ± 0.05 (n^+)	0.95 ± 0.1
3	8.05 ± 0.05 (n^-)	9.00 ± 0.05 (n^+)	0.95 ± 0.1

[a]Estimated from the sum of two Gaussian peaks.

Although amine-to-amine hydrogen bonding is weak, it is expected that **1** is intramolecularly hydrogen bonded and the **1**-i,o is the most stable configuration. That partially alkylated 1,8-diaminonaphthalene **4** adopts a conformation with a N—H:N

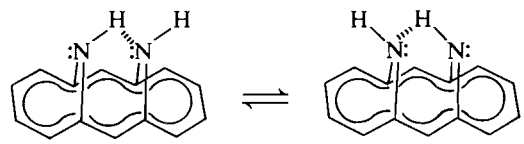


1-i,o



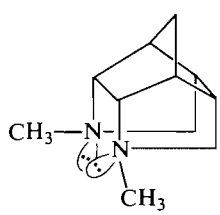
4

hydrogen bond (1), but 1,8-bis(dimethylamino)naphthalene is forced to adopt a structure with some lone-pair interaction, supports this expectation (6). While hydrogen bonding would provide a stabilization of approximately 10–15 kJ mol^{-1}, a further stabilization would result from a decrease of the lone-pair repulsion because the lone pairs would be directed away from each other. Our view that **1** is intramolecularly hydrogen bonded is further supported by the work of Vogel and Günther *et al.* (7). They established conclusively that *syn*-1,6:8,13-13-diimino[14]annulene (**5**) is intramolecularly hydrogen bonded and the $\Delta H\ddagger$ and $\Delta S\ddagger$ for inversion at nitrogen (**5***a* ⇄ **5***b*) are 26.1 kJ mol^{-1} and −76.5 J mol^{-1} K^{-1}, respectively. This was corroborated recently by a determination of the crystal and molecular structures of **5** (8).

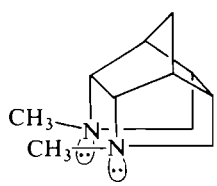


5*a* **5***b*

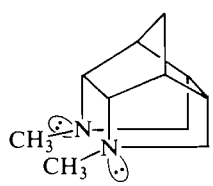
From models it is clear that **2**-o,o, with the nitrogens pyramidal, would be impossibly strained due to the steric interaction of the methyl groups. Similarly, in the case of **2**-i,o, if both nitrogens are sp^3-like, models show that there is severe crowding of the inside lone pair and the hydrogens of the methyl group. Furthermore, the stereoisomer in which the nitrogens are constrained to the triangular planar (sp^2 hybridized) would also be a high energy species due to angle strain and repulsion of the lone pairs that would be directed towards each other. Consequently, we expect that **2**-i,i with the nitrogens pyramidal is the most stable stereoisomer of the *N*,*N*-dimethyldiamine. In keeping with this expectation, the ^{13}Cmr of **2** exhibits only six



2-i,i



2-i,o

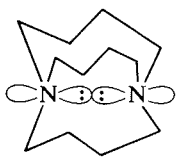


2-o,o

resonances: 67.9 ppm (C-1,C-8), 55.3 (C-3,C-6), 45.4 (CH_3), 42.9 (C-9,C-11), 41.3 (C-4,C-5), and 28.1 (C-10). Furthermore, the ^{13}Cmr spectrum obtained at −70°C showed no significant change relative to that obtained at ambient temperature. One aspect of the spectrum of **2** deserves comment. Unlike C-2- and C-3-*endo*-substituted bicyclo[2.2.1]heptanes that exhibit C-7 resonances at 35–40 ppm (5), C-10 of **2** appears at 28.1. In this connection, it is interesting to note that C-7 of quadricyclene appears at 32 ppm (5). Apparently the upfield shift is associated with bridging between C-2,C-6 and C-3,C-5. Although ^{13}Cmr results are consistent with our proposal that **2**-i,i is the stable isomer, **2**-i,o presumably would also exhibit six signals if inversion involving a "windshield-wiper" motion was rapid on the nmr time scale. Our expectation that **2**-i,i is the stable configuration of the *N,N*-dimethyl analogue of **1** is also supported by the work of Simonetta and co-workers (8). They established by X-ray diffraction that the *N,N*-dimethyl analogue of **5** has both *N*-methyl groups pointing outward.

Discussion and conclusions

The low values of the IPs for the lone pairs of **2** (7.29 and 8.24 eV; $\Delta IP = 0.95$ eV) are in keeping with our proposal that **2**-i,i is the most stable configuration of the *N,N*-dimethyldiamine. In fact, the onset of the low IP band is at 6.9 eV. By comparison, the IP of the "lone-pair" band in the PE spectrum of *N*-methylpyrrolidine is 8.41 eV (9). In the case of **2**-i,i, n^- should be higher in energy than n^+ and the IPs should be low because of the proximity of the lone pairs. The shift to lower binding energies in the case of **2** is similar to, but not as dramatic as, the shift observed for the "inside" lone pairs of 1,6-diazabicyclo[4.4.4]tetradecane (**6**) studied by Alder *et al.* (4). The authors (4) estimated the N...N distance in **6**-i,i (IPs 6.64 and



6-i,i

7.77 eV; $\Delta IP = 1.13$ eV), the most stable isomer of the diamine, to be 2.61 Å by a force field calculation.

In the case of **2**-i,i, models show that the N...N distance is slightly greater than the N...N distance of **6**-i,i but, more importantly, that the lone pair orbitals are not directed towards each other. Assuming that the N atoms are sp^3 hybridized, the angle between the lone pairs is approximately 70° (Fig. 3). These factors would account for the fact that the shift to lower binding energies is not as large as it is in the case of **6**-i,i and also that the splitting referred to is smaller as well.

In the case of **3**, the binding energies (8.05 and 9.00 eV) are essentially normal for a tertiary amine (*vide supra*). This fact provides additional support for our view that **2** has the i,i configuration. For **3** we propose that $n^- > n^+$, in keeping with Nelsen and Buschek's assignment for **7** (3). It is interesting to note that the splitting of 0.95 eV is somewhat larger than the splitting (0.75 eV) observed for **7** by Nelsen and Buschek. It may be that the back-lobes of the lone pair orbitals of **3** are slightly better aligned than they are in **7**. In the case of **8**, where the orbitals are exactly directed towards each other, the splitting is 1.03 eV.

For the parent diamine, if **1**-i,i is the most stable configuration, the ordering should be $n^- > n^+$ and the splitting, based on

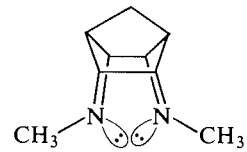


FIG. 3. Proposed structure of diamine **2**-i,i.

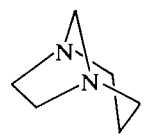
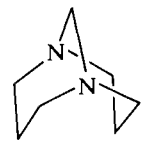
2-i,i, should be in the range of 0.95 eV. If, as expected, the diamine is intramolecularly hydrogen bonded, then n^- should be stabilized and n^+ destabilized or remain unaffected because the lone-pair interaction is decreased (Fig. 4). Since hydrogen bonding to nitrogen increases the lone-pair ionization energy, as established by Brown (10, 11), it is conceivable that hydrogen bonding to n^- also leads to a stabilization of n^-. Consequently,



7



8

the splitting for **1**-i,o should be smaller than the splitting for **2**-i,i. In fact, this is observed experimentally—we estimate that the splitting for **1** is approximately 0.6 eV.

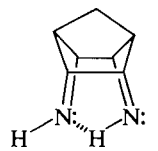


FIG. 4. Proposed structure of diamine **1**-i,o.

Experimental

The He(I) photoelectron spectra were obtained with a noncommercial instrument constructed from the design of Frost *et al.* (12) and based on a 10-cm diameter aluminum hemispherical electrostatic energy analyser. The photoelectrons are retarded and focussed onto a rectangular entrance slit (0.5 × 2 mm) by a suitable lens. He(I) photons were generated by an air-cooled DC discharge lamp operated at 1.3 kV. With this lamp the typical count rate on Ar $^2P_{3/2}$ is 100 000 Hz with a 40-meV fwhm. The spectra represent averages of 15–20 scans collected using an APPLE II+/ISAAC system that controls the spectrometer operations and data collection.

Diamines **1**, **2**, and **3**, whose syntheses will be reported in a following publication, exhibited ^{1}Hmr, ^{13}Cmr, and mass spectrometric spectral data consistent with the proposed structures, including, of course, the photoelectron spectra.

Received September 16, 1985

MICHAEL B. STRINGER, DENNIS J. UNDERWOOD, JOHN H. BOWIE, JOHN L. HOLMES, ALEXANDER A. MOMMERS, and JAN E. SZULEJKO. Can. J. Chem. **64**, 764 (1986).

The $(M - H^+)^-$ ion of butyrophenone undergoes the following reactions on collisional activation: losses of $CH_3^{\bullet}$, CH_4, $(C,H_5^{\bullet})$, C_2H_4, $C_3H_7^{\bullet}$, $(CO + CH_4)$, together with formation of $C_6H_5^-$ and $C_4H_5O^-$. Labelling studies (^{13}C and ^2H) show that the losses of $CH_3^{\bullet}$, $C_3H_7^{\bullet}$ and the formation of $C_6H_5^-$ and $C_4H_5O^-$ are specific and occur without hydrogen scrambling. All other reactions involve prior or accompanying hydrogen rearrangement. In particular, the loss of C_2H_4 is very complex: it involves loss of ethyl carbon atoms, but *all* hydrogen atoms are involved via specific rearrangement reactions. The phenyl–alkyl H rearrangements which are noted for this process occur *after* collisional activation of the $(M - H^+)^-$ ion.

MICHAEL B. STRINGER, DENNIS J. UNDERWOOD, JOHN H. BOWIE, JOHN L. HOLMES, ALEXANDER A. MOMMERS et JAN E. SZULEJKO. Can. J. Chem. **64**, 764 (1986).

Sous l'influence d'une activation par collision, l'ion $(M - H^+)^-$ de la butyrophénone subit les réactions suivantes: pertes de $CH_3^{\bullet}$, de CH_4, de $(C,H_5^{\bullet})$, de C_2H_4, $C_3H_7^{\bullet}$, de $(CO + CH_4)$ avec formation de $C_6H_5^-$ et de $C_4H_5O^-$. Des études de marquage (^{13}C et ^2H) ont démontré que les pertes de $CH_3^{\bullet}$ et de $C_3H_7^{\bullet}$ ainsi que les formations de $C_6H_5^-$ et de $C_4H_5O^-$ sont spécifiques et qu'elles se produisent sans redistribution des hydrogènes. Toutes les autres réactions impliquent des transpositions d'hydrogènes qui se produisent avant ou d'une façon concomitante avec les réactions. En particulier, la perte de C_2H_4 est très complexe: elle implique la perte des atomes de carbone de l'éthyle, mais *tous* les atomes d'hydrogène sont impliqués par le biais de réactions de transpositions spécifiques. Les transpositions des H des phényle–alkyle qui sont notées pour ce processus se produisent *après* l'activation par collision de l'ion $(M - H^+)^-$.

[Traduit par la revue]

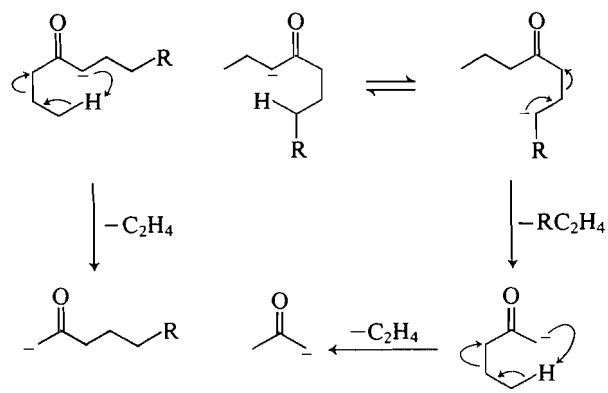
Introduction

In the past decade there have been significant advances in the analytical applications of negative ion mass spectrometry, for example in the areas of electron capture, negative ion chemical ionization, secondary ion mass spectrometry, and fast atom bombardment (1). These "soft ionization" techniques often give molecular weight information, but in many cases fragment negative ions that in principle could yield structural information are absent in the spectra. Collision induced dissociations of negative ions can give structural information (1, 2); in addition, fundamental information concerning ion behaviour may be obtained by such studies (1, 3).

Hunt *et al.* have studied the collisional activation mass spectra of a variety of $(M - H^+)^-$ ions derived from ketones (4, 5). They have suggested (4) that the rearrangement peaks observed for dialkyl ketones may be explained by the γ-hydrogen rearrangements and olefin eliminations shown in Scheme 1. Deprotonation may occur at two positions in such systems and it is thus difficult to be certain which is the decomposing carbanion. In this paper we report the decompositions of the collisionally activated $(M - H^+)^-$ ion of butyrophenone. We chose this system for three reasons: (*i*) it should only deprotonate from one position to yield one initial carbanion; (*ii*) butyrophenone is relatively easy to label with ^2H and ^{13}C; and (*iii*) it is unable to undergo the type of γ-hydrogen rearrangement proposed by Hunt *et al.* (4) (see Scheme 1).

Results and discussion

All collisional activation (CA) mass spectra (6) were measured with a VG ZAB 2F mass spectrometer (7) operating at 70 eV in the negative chemical ionization mode. Water was used to produce HO^- reactant ions (8), and helium was used as the collision gas.



SCHEME 1

Details are provided in the experimental section.

The CA mass spectrum of the $(M - H^+)^-$ ion of butyrophenone is shown in Fig. 1. In order to determine the atoms involved in the fragmentations shown in Fig. 1, the corresponding spectra of the labelled compounds **2**–**9** were studied. Certain of the fragmentations are straightforward, others occur with or after extensive hydrogen scrambling. Let us deal first with some of the simpler fragmentations. The phenyl negative ion (m/z 77) is formed by simple cleavage, and this may be rationalized as shown in sequence [1]. The second *specific* reaction is that which produces $C_4H_5O^-$ (m/z 69). This ion is formed by loss of C_6H_6 (reaction [2]). The peak at m/z 69

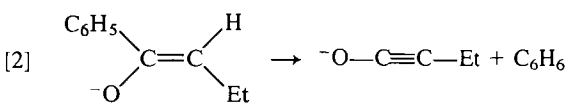
(Fig. 1) has a width at half height of 40 V, a value that corresponds to a small kinetic energy release, 0.050 V.

The losses of $CH_3^\bullet$, CH_4, and $C,H_5^\bullet$ (see Fig. 1) are complex and the appropriate relative peak abundances for ions derived from compounds **2**–**9** are listed in Table 1. From these figures



we may make the following observations. The loss of $CH_3^\bullet$ occurs exclusively from the terminal methyl group; neither carbon nor hydrogen scrambling precedes or accompanies this reaction (sequence [3]). Elimination of CH_4 involves the terminal methyl group together with a hydrogen atom from the phenyl ring. The CA mass spectrum of the $(M-H^+)^-$ ion of the ring d_3 derivative (**5**) shows that partial ring hydrogen scrambling precedes or accompanies the loss of the fourth hydrogen; further H/D mixing must be responsible for loss of 16 amu from **6**. This reaction is best rationalized by the first step of sequence [4]. The loss of the fifth hydrogen occurs primarily from the

position shown in the second stage of sequence [4]. The structures shown in sequence [4] are speculative: they are used solely to illustrate the two processes.

The peaks at m/z 103 and 104 in Fig. 1 are produced by the respective losses (CH_4+CO) and $C_3H_7^\bullet$. The relative peak abundances in this region are summarized in Table 2 for ions derived from compounds **1**–**9**. The loss of (CH_4+CO) follows precisely the first step of sequence [4], with additional loss of

the original carbonyl group (of butyrophenone). The elimination of $C_3H_7^{\bullet}$ involves C_3H_6 from the side chain together with one phenyl hydrogen. The CA mass spectrum of the ring d_3 derivative (**5**) shows almost exclusive loss of $C_3H_6D^{\bullet}$; only a 3% peak corresponding to loss of $C_3H_7^{\bullet}$ is observed. We proposed an almost specific elimination of an *ortho*-hydrogen as shown in sequence [5].

[5] 
Our major interest in the CA mass spectrum shown in Fig. 1 concerns the loss of C_2H_4. Is this elimination a four-centre process [6], a six-centre reaction [7], or some more complex rearrangement?

[6] 
a

[7] 
b

The first task was to determine whether the product ion of the reaction corresponds to *a* (sequence [6]) or *b* (sequence [7]). Thus we compared both the CA mass spectra and the charge inversion spectra (9) of *m/z* 119 and the $(M-H^+)^-$ ion of acetophenone (see Table 3). *Each pair of spectra are identical.* In particular, the charge inversion mass spectrum contains an ion corresponding to the process *m/z* 119 − CH_2, indicating the presence of a methylene group in the precursor negative ion. Thus we believe the product ion *m/z* 119 in Fig. 1 corresponds to the keto negative ion *a*. Whether it is formed directly (sequence [6]) or indirectly through *b* (sequence [7]) is not clear at this stage.

The collision-induced elimination of C_2H_4 from the butyrophenone $(M-H^+)^-$ ion produces a peak that shows no fine structure, is steep sided with a rounded top, and is unusually wide. The width of the peak of half height is 94 V (cf. the Gaussian type peak 40 V wide for reaction [2]), corresponding to a kinetic energy release of 0.44 eV. This is in keeping with a reaction having a reverse energy barrier.

The relative abundances of peaks arising from losses of ethene and deuteriated ethene from the $(M-H^+)^-$ (or $(M-D^+)^-$ where appropriate) negative ions from compounds **5**–**9** are summarized in Table 4. The corresponding spectra of the ^{13}C labelled compounds **3** and **4** show that the carbon atoms

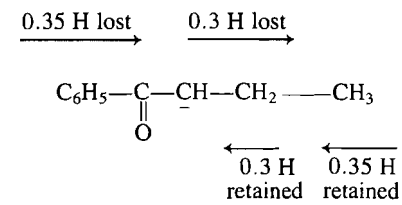
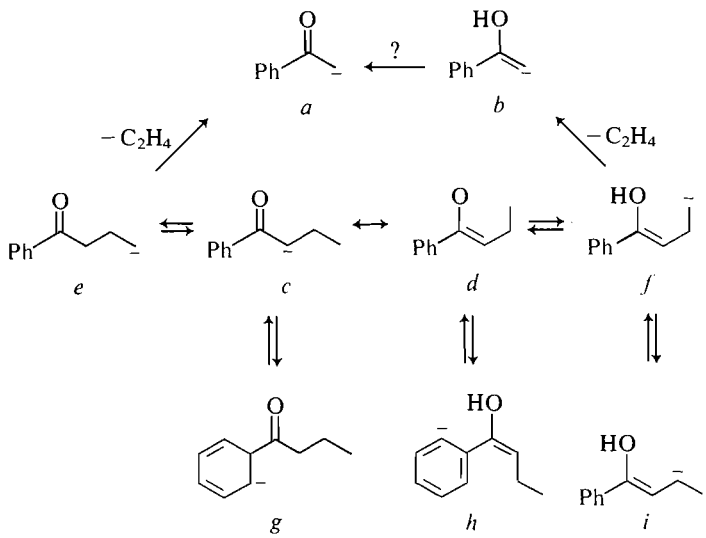
eliminated are exclusively those of the terminal ethyl group. *No carbon scrambling accompanies the elimination of C_2H_4.* In marked contrast, *a number of specific hydrogen rearrangements precede or accompany the loss of C_2H_4.*



10

The data in Table 4 can be simplified as shown above in representation (**10**). Within experimental error, 0.65 of a hydrogen atom is transferred out of the ethyl substituent and is retained in the product ion while 0.65 of a hydrogen atom is transferred into the ethyl group and lost when ethene is eliminated. We propose the mechanisms in Scheme 2 in order to rationalize the experimental observations. The observation that the ion from **7** eliminates 27% of C_2H_3D (see Table 4) demands that there be a transfer of the remaining deuterium into the terminal ethyl substituent. We propose equilibrium *c* ⇄ *e* to account for this transfer. A comparison of the decomposition of the ions from **5** and **6** (Table 4) shows that ring hydrogens are involved in part *and that statistical ring hydrogen scrambling is co-occurring with aryl H transfer*. Either of the equilibria *c* ⇄ *g* or *d* ⇄ *h* together with *h* ⇄ *i* could account for the involvement of aryl hydrogen. Finally, a comparison of the losses of variously labelled ethenes from the $(M-H^+)^-$ ions from **8** and **9** shows that partial scrambling of the ethyl hydrogens also occurs. This could occur through either *e* or *f*: we prefer the equilibrium *f* ⇄ *i* because it involves the allylic species *i*. The mechanisms shown in Scheme 2 are speculative but they fit the experimental observations in a qualitative sense.

We believe that of the two possible decomposing intermediates, *e* and *f*, *e* is the more likely and that it decomposes



SCHEME 2

to *a* directly. It was explained above that the product ion corresponds to *a*; however, the possibility that some of *b* is formed from *f* and that *b* then tautomerizes to the more thermodynamically stable species *a* cannot be excluded.

There are few examples of hydrogen rearrangements in the *unimolecular* reactions of negative ions (1); e.g., aryl H scrambling is the exception (10) rather than the rule (1). The complex aryl–alkyl H rearrangements that occur in the CA mass spectrum of the butyrophenone $(M-H^+)^-$ ion have no prior analogy. Therefore it is of interest to determine whether these rearrangements occur in the negative ion *before or after* the collisional activation process. We cannot determine this for the aryl H scrambling, but the following experiment answers the question for aryl–alkyl H rearrangements. The charge inversion spectrum of the $(M-H^+)^-$ ion of 2,4,6-$^2H_3$-butyrophenone (**5**) shows two major peaks. These correspond to $C_6H_2D_3$—$C{\equiv}O^+$ (*m/z* 108) and $C_6H_2D_3^+$ (*m/z* 80). There is no evidence in the spectrum for the formation of ions $C_6H_3D_2$—$C{\equiv}O^+$ (*m/z* 107) or $C_6H_3D_2^+$ (*m/z* 79). Thus, even though the two experiments may not sample identical populations of ions, the results show that the aryl–alkyl H rearrangements observed for the CA mass spectrum are processes that occur *after* collisional activation of the $(M-H^+)^-$ ion.

Conclusions

The collision-induced fragmentations of the $(M-H^+)^-$ ion of butyrophenone provide interesting examples of differing decomposition time scales. Simple cleavages are fast (e.g., reactions [1] and [3]) and occur without any rearrangement of the side chain. Some rearrangement reactions are also fast: for example the loss of C_6H_6 (reaction [6]) occurs without hydrogen rearrangement in the side chain; elimination of $C_3H_7^\bullet$ (reaction [5]) is also fast since virtually no phenyl H scrambling is observed. All reactions involving loss of CH_4 co-occur with partial phenyl hydrogen scrambling. The loss of C_2H_4 is the slowest rearrangement; complete phenyl hydrogen randomization precedes or accompanies this reaction.

Experimental

Collisional activation mass spectra (7) and charge inversion spectra of negative ions (11) were recorded with a MM VG ZAB 2F spectrometer operating under the following conditions: negative ion chemical ionization mode, reactant ion HO^- formed from water (for full details see ref. 11), electron energy 70 eV, measured pressure of collision gas (He) in second field-free region collision cell 1.5 × 10^{-7} Torr (1 Torr = 133.3 Pa). The ion acceleration voltage was 8000 V.

The ^{13}C labelled 1-phenyl-1-butanones 2–4

1-(^{13}C)-1-phenyl-1-butanone (**2**), 3-(^{13}C)-1-phenyl-1-butanone (**3**), and 4-(^{13}C)-1-phenyl-1-butanone (**4**) were prepared in 60, 63, and 65% yield respectively by the following method. The labelled precursors 1-(^{13}C)-1-phenyl-1-ethanone (91.8% ^{13}C), 1-(^{13}C)-iodoethane (91.1% ^{13}C), and 2-(^{13}C)-iodoethane (90.6% ^{13}C) were commercial products.

Acetophenone was converted (in quantitative yield) to acetophenone dimethylhydrazone by a standard method (12). The hydrazone was allowed to react with lithium diisopropylamide (from butyllithium and diisopropylamine in tetrahydrofuran) by the method of Corey and Enders (13) to produce α-lithiated acetophenone dimethylhydrazone, which in turn was treated with iodoethane to produce 1-phenyl-1-butanone dimethylhydrazone (14). Treatment with copper^{II} acetate (14) gave 1-phenyl-1-butanone, which was purified by preparative hplc (Spectra Physics Chromatronix 3500 instrument using a Lichrosorb S 160 column of 10-μ particle size and dimensions 250 mm × 10 mm). Overall yield from acetophenone was in the range 60–65%.

The ^2H labelled 1-phenyl-1-butanones 5–9

1-(2,4,6-$^2H_3$-phenyl)-1-butanone (**5**) and 1-($^2H_5$-phenyl)-1-butanone (**6**) were prepared in 40 and 49% yield respectively by the following method. The labelled precursors used were 2,4,6-$^2H_3$-bromobenzene (from 2,4,6-$^2H_3$-aniline (15) ($^2H_3$ > 98%) by a standard method (16)), and $^2H_5$-bromobenzene ($^2H_5$ > 99%), which was a commercial product.

Bromobenzene was allowed to react with lithium (in diethyl ether) to form a solution of phenyllithium. Butyllithium was added to butanoic acid (in diethylether) to give the lithium salt as a suspension. The two lithium derivatives were allowed to react by the method of Levine *et al.* (17) to produce 1-phenyl-1-butanone, which was purified by thick-layer chromatography on silica gel, followed by distillation. The overall yield (from bromobenzene) was in the range 40–50%.

3-($^2H_2$)-1-phenyl-1-butanone (**8**) and 4-($^2H_3$)-1-phenyl-1-butanone (**9**) were prepared (both in 74% yield) by the general method described above for the ^{13}C labelled compounds **2–4**, expect that 1-phenyl-1-butanone dimethylhydrazone was hydrolysed using a mixture of diethyl ether and 2 *M* hydrochloric acid for 3½ h at 25°C. The 1-phenyl-1-butanone was purified by thick-layer chromatography on silica gel, followed by distillation. The labelled precursors, 1-($^2H_2$)-iodoethane (>99% $2H_2$) and 2-($^2H_3$)-iodoethane (>99% $^2H_2$) were commercial products.

2-($^2H_2$)-1-phenyl-1-butanone (**7**, $^2H_3$ > 98%) was prepared by exchanging 1-phenyl-1-butanone twice in refluxing 2 *M* sodium hydroxide for 16 h.

A comparison of electron spin resonance α- and β-hyperfine coupling constants in *para*-substituted α-phenethyl radicals[1]

DONALD R. ARNOLD,[2] A. MARTIN DE P. NICHOLAS, AND KENT M. YOUNG
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada, B3H 4J3

Received August 14, 1985

DONALD R. ARNOLD, A. MARTIN DE P. NICHOLAS, and KENT M. YOUNG. Can. J. Chem. **64**, 769 (1986).

The linear relationship between the electron spin resonance hyperfine coupling constants (hfc) of the α- and β-hydrogens of *para*-substituted α-phenethyl radicals provides experimental evidence that the magnitude of both the α- and β-hfc is determined largely by the extent of spin delocalization in these benzylic systems. The $\sigma_\alpha^\bullet$ scale, developed using substituted benzyl radicals, is shown to apply to phenethyl radicals as well.

DONALD R. ARNOLD, A. MARTIN DE P. NICHOLAS et KENT M. YOUNG. Can. J. Chem. **64**, 769 (1986).

La relation linéaire qui existe entre les constantes de couplages hyperfins (chf) de la rpe des hydrogènes α et β radicaux α-phénéthyles substitués en *para* fournit une preuve expérimentale du fait que, dans ces systèmes benzyliques, l'amplitude des couplages hyperfins α ainsi que β est principalement déterminée par le degré de délocalisation du spin. On démontre que l'échelle $\sigma_\alpha^\bullet$, qui a été développée pour les radicaux benzyles substitués, s'applique aussi aux radicaux phénéthyles.

[Traduit par la revue]

Introduction

Theory predicts that both the α- and β-hydrogen hyperfine coupling constants (hfc) in the electron spin resonance (esr) spectra of a radical are proportional to the spin density (2). This applies in spite of the fact that the mechanism of coupling is different for the two positions, the main cause of coupling being due to spin polarization for hydrogens in the α position and hyperconjugation in the case of β-hydrogens. Experimental proof of this conclusion is scarce because other factors, such as deviation from planarity at the radical center, differences in conformation of the hydrogens at the β-carbon relative to the half-filled orbital, and direct interaction (i.e. bridging) of groups in this β position with the radical center, can also influence the hfc. It is difficult to vary the spin density at the radical center and yet keep these other factors constant.

A series of *para*-substituted α-phenethyl radicals is ideally suited to test this theory. In this case the nature of the radical center should remain constant, all these radicals should be essentially planar, there should be free rotation of the adjacent methyl group that bears the β-hydrogens, and there can be no direct interaction of the substituent with the radical center other than that which is transmitted through the phenyl ring. Therefore, if spin density is the dominant factor influencing both α- and β-hfc, the two values should correlate throughout the series.

We have proposed that the magnitude of the α-hfc of substituted benzyl radicals is a measure of spin delocalization in benzylic radicals (3). We believe the substituent effect on spin density, expressed as $\sigma_\alpha^\bullet$ values (eq. [1]) will be generally

$$[1] \quad \sigma_\alpha^\bullet = 1 - [(\alpha - \mathrm{hfc_X})/(\alpha - \mathrm{hfc_H})]$$

useful in Hammett-type linear free energy relationships for radical reactions. If the α- and β-hfc of substituted α-phenethyl radicals correlate, indicating that both are affected primarily by spin density, and if they both correlate with the effect of substituents on the α-hfc of the benzylic radicals, the conclusion that $\sigma_\alpha^\bullet$ reflects the variation in spin density caused by the substituent will be confirmed.

[1]This is Part 6 of the series, "Substituent effects on benzyl radical hydrogen hyperfine coupling constants" (Part 5, see ref. 1).

Results

The α-phenethyl radicals were generated photochemically in the microwave cavity of the esr spectrometer by hydrogen abstraction from the appropriately substituted ethylbenzene. The hydrogen was abstracted by *tert*-butoxy radicals formed from di-*tert*-butylperoxide. The procedure has been described previously (1, 3). Hyperfine coupling constants were measured directly from the spectra and then refined by iterative computer simulation (4). These results are summarized in Table 1.

The observed spectrum of the *para*-methoxyphenethyl radical was complicated by the competitive hydrogen abstraction from the methoxy methyl group. The experimental spectrum was simulated by a one-to-one mixture of the α-phenethyl

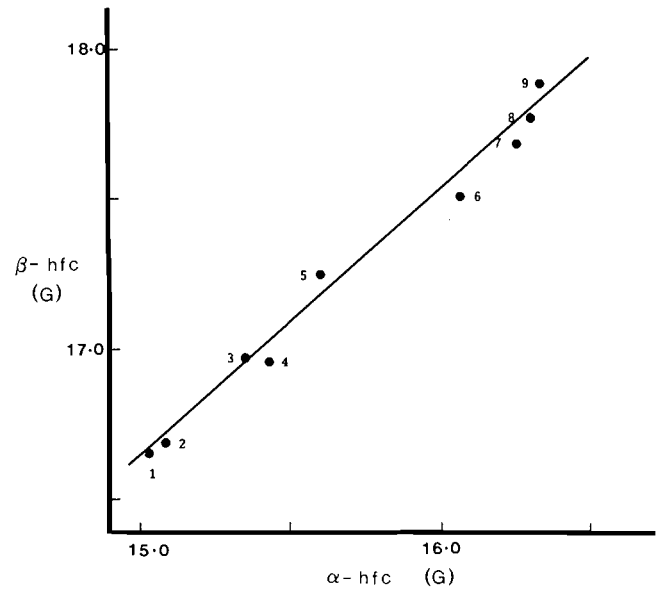

FIG. 1. A plot of the β-hfc versus the α-hfc of the α-phenethyl radicals. Points are numbered according to Table 1.

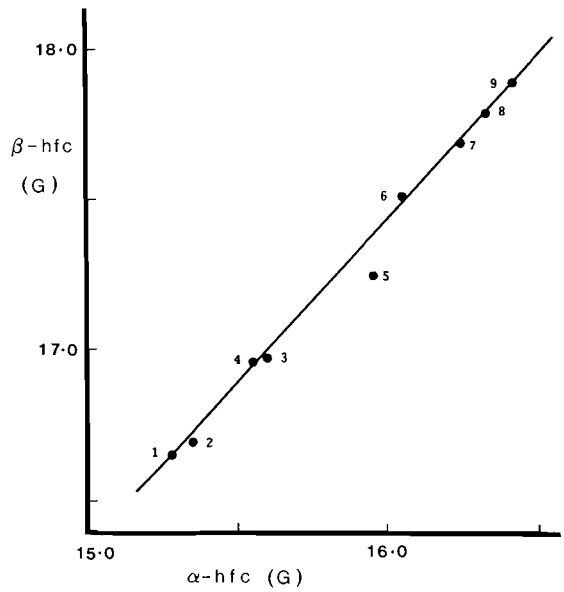

FIG. 2. A plot of the β-hfc of the α-phenethyl radicals versus the α-hfc of benzyl radicals. Points are numbered according to Table 1.

radical and aryloxymethyl radical with $a(CH_2)$ = 17.65 ± 0.1 G.

Discussion

The relationship between α- and β-hfc of *para*-substituted α-phenethyl radicals is illustrated in Fig. 1. A good (r = 0.993) linear correlation (β-hfc = (0.89 ± 0.09)α-hfc + (3.3 + 1.4)) is observed. This result indicates that both α-hfc and β-hfc are linearly related to the spin density at the benzylic position.

The relationship between the β-hfc of the α-phenethyl radicals and the α-hfc of the benzyl radicals is illustrated in Fig. 2. A good (r = 0.995) linear correlation (β-hfc(phen.) = (1.09 ± 0.09)α-hfc(benzyl) − (0.0 ± 1.5)) is observed. Of course, a similar correlation is observed between the α-hfc of these systems (Table 2). These results show that the $\sigma^{\bullet}_{\alpha}$ scale

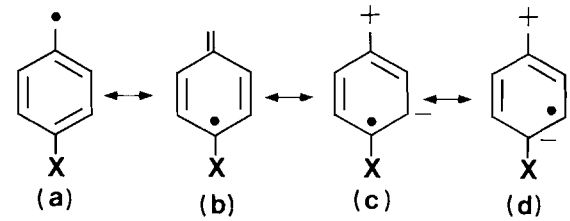

FIG. 3. Charge effects on spin delocalization in benzylic radicals.

should be directly applicable to reactions involving radicals of the α-phenethyl type.

A study comparing the effects of substituents on cumyl and benzyl radicals revealed charge effects acting on the β-hfc (3*c*). These effects were explained by proposing that dipolar valence bond structures, such as (c) and (d) in Fig. 3, contribute to provide additional spin delocalization in the cumyl radical series when the *para*-substituent is electron withdrawing. The correlation of β-hfc of the cumyl radicals and the α-hfc of the benzyl radicals was significantly improved by inclusion of the polar substituent parameter (σ_P) to account for the additional delocalization due to these charge-separated structures.

Notice that the correlation of α-hfc of the phenethyl radicals and the α-hfc of the benzyl radicals is not significantly improved by including the polar substituent parameter. Charge effects, if present, must be similar in these series. This, of course, is expected since the cumyl cation is significantly more stable than the benzyl cation, the α-phenethyl cation being intermediate in stability.

Conclusions

The correlation of α- and β-hfc in the α-phenethyl radical series indicates that both coupling mechanisms are proportional to spin density.

The differences that are observed between the α-hfc of substituted benzyl radicals and the β-hfc of the analogous cumyl radical are attributed to variation in the contribution of charge-separated valence bond structures, which influence spin density. The benzyl and α-phenethyl radicals are similar enough so that differences resulting from charge separation can be ignored.

Radical reactivity that depends upon variation in spin density should correlate directly with $\sigma^{\bullet}_{\alpha}$ so long as the radicals are as similar as benzyl and α-phenethyl. When the radicals are as different as benzyl and cumyl, polar factors that take into account the variation in spin delocalization due to the contribution of charge-separated valence bond structures must be included.

Experimental

General information

The esr spectra were recorded on a Varian Associates E-109 B electron paramagnetic resonance spectrometer, equipped with a liquid nitrogen variable temperature accessory, at 0.5 mW microwave power and 0.5–0.8 G modulation amplitude. All spectra were recorded with the aid of a Nicolet 1170 signal averager. Typically, 12, 100-G wide, scans were accumulated (0.5 min/scan). Coupling constants were measured directly from the oscilloscope and refined by computer simulation using an IBM-PC. Details of the procedure have been reported previously (1, 3).

The ^{1}H nmr spectra were recorded on a Varian CFT-20 spectrometer and are reported in parts per million downfield from TMS. Infrared spectra were recorded on either a Pye Unicam SP1000, or a Perkin–Elmer 283B or 1320 infrared spectrometer and are reported in wave numbers (relative to the 1601.8 cm^{-1} absorption of polystyrene). Mass

spectra were obtained on a modified Du Pont CEC Model 21-104 mass spectrometer. Statistical calculations were done using the MINITAB statistical package, release 81.1, from Penn State University (University Park, Penn.).

The ethylbenzenes were purified by gas chromatography. A 5 ft. × 5/8 in. column packed with 5% SE-30 on Chromosorb-W (60/80) incorporating helium as the carrier gas was used.

Materials

Di-*tert*-butyl peroxide (DTBP) was obtained from Pfaltz and Bauer Inc. and was used without further purification. Ethylbenzene and *para*-diethylbenzene were obtained from Aldrich Chemical Co. and were purified by gas chromatography as described above. All solvents were distilled prior to use.

Synthesis

4-Ethylacetophenone

4-Ethylacetophenone (7) was prepared by the reaction of ethylbenzene and acetyl chloride in the presence of aluminum chloride, using carbon disulphide as the solvent (8). The reaction mixture was purified by vacuum distillation; 4-ethylacetophenone (bp 128–129°C/25 Torr; 1 Torr = 133.3 Pa) was obtained as a colourless oil in 54% yield; ir PE 1320 (neat): 1680, 1610, 1270, 835 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 7.85 (d, 2H), 7.23 (d, 2H), 2.66 (q, 2H), 2.53 (s, 3H), 1.22 (t, 3H).

4-Ethylbenzophenone

4-Ethylbenzophenone (9) was prepared by a procedure similar to that used for the acetophenone except using benzoyl chloride. Vacuum distillation afforded 4-ethylbenzophenone as a colourless oil in 43% yield; ir PE 1320 (neat): 1660, 1610, 850, 705 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 7.20–7.82 (m, 9H), 2.68 (q, 2HO), 1.23 (t, 3H).

Methyl 4-ethylbenzoate (ref. 10)

In a 250-mL 3-necked flask equipped with a magnetic stirrer, reflux condenser, and a constant pressure dropping funnel, was placed 12.2 g (91 mmol) of aluminum chloride. To the aluminum chloride was added 8.0 g (83 mmol) of ethylbenzene dissolved in 175 mL of carbon disulphide. The flask was cooled in an ice bath; to the cooled mixture was added a solution of 11.6 g (91 mmol) of oxalyl chloride in 25 mL of carbon disulphide. After the evolution of gases (**caution**: carbon monoxide) had ceased, the mixture was allowed to warm to room temperature. The mixture was then refluxed for 2.0 h and the cooled mixture was poured into 200 mL of methanol. The carbon disulphide was removed by distillation and the residue was poured into water and extracted with ether. The combined organic layers were washed with 5% sodium hydroxide, saturated salt solution, dried with magnesium sulphate, and evaporated. The yield of a pale yellow liquid was 8.2 g (60%). The product was distilled under vacuum to yield a colourless oil (bp 55–58°C/0.01 Torr); ir PE 1320 (neat): 1725, 1610, 1280, 1110 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 7.94 (d, 2H), 7.20 (d, 2H), 3.85 (s, 3H), 2.65 (q, 2H), 1.21 (t, 3H).

4-Ethylphenyl acetate

4-Ethylphenyl acetate (8, 11) was prepared by the reaction between 4-ethylphenol and acetic anhydride in 3 *M* aqueous sodium hydroxide. The product was purified by vacuum distillation to give 2.7 g (82% yield) of a colourless oil (bp 82–85°C/1 Torr); ir PE 1320 (neat): 1770, 1515, 1375, 1220, 1025, 920, 855 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 6.88–7.19 (m, 4H), 2.58 (q, 2H), 2.16 (s, 3H), 1.17 (t, 3H).

4-Cyanoethylbenzene

4-Cyanoethylbenzene (8, 12) was prepared by a Sandmeyer reaction using the diazonium salt formed from 4-ethylaniline and cuprous cyanide. The product was purified by chromatography over silica gel eluting with a hexane – methylene chloride gradient; the product was obtained in 62% yield as a colourless oil; ir SP 1000: 2240, 1610, 840 cm^{-1}.

4-Methoxyethylbenzene

4-Methoxyethylbenzene (13) was prepared by the reaction of 4-ethylphenol with dimethyl sulphate in 5% aqueous potassium hydroxide. The product was purified by vacuum distillation to give a 45% yield; ir PE 1320 (neat): 1615, 1590, 1515, 1250, 1180, 1040, 915, 830, 735 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 7.10 (d, 2H), 6.79 (d, 2H), 3.74 (s, 3H), 2.57 (q, 2H), 1.19 (t, 3H).

4-Fluoroethylbenzene

4-Fluoroethylbenzene (8) was prepared by the thermal decomposition of the diazonium fluoroborate salt formed from 4-ethylaniline with fluoroboric acid. The product was purified by distillation to give a 35% yield of colourless oil, bp 140–144°C/760 Torr; ir PE 283B (neat): 1505, 1155, 830 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 7.03 (m, 4H), 2.60 (q, 2H), 1.20 (t, 3H).

A multinuclear nuclear magnetic resonance study of methylammonium nitrate

RODERICK E. WASYLISHEN
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 19, 1985

RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 773 (1986).

Deuterium nmr line shapes in the solid II phase of methylammonium nitrate (MAN) indicate that motion of the cation is restricted to internal rotations of the ND_3 group about the C—N axis. In the high temperature plastic phase, solid I, of MAN, ^2H, ^{14}N, and ^{17}O nmr results demonstrate that both the cation and anion undergo rapid overall rotations that result in complete averaging of all nuclear quadrupolar interactions. Spin-lattice relaxation results imply that rotations of the cation and anion are anisotropic and that the overall rotations are strongly coupled in both the solid I and liquid phases. At the melting point, overall rotations of the cation are only slightly faster in the liquid phase than in the solid I phase. In the solid I phase, in-plane rotations of the nitrate ion are about twice as rapid as end-over-end rotations of the C_3 axis. In the neat liquid, rotations of the NO_3^- ion are more isotropic, with overall rotations being slightly faster than rotations about the symmetry axis.

RODERICK E. WASYLISHEN. Can. J. Chem. **64**, 773 (1986).

Sur la base des formes des raies en rmn du ^2H de la phase solide II du nitrate de méthylammonium (NMA), on peut déduire que les mouvements du cation sont restreints aux rotations internes du groupement ND_3 autour de l'axe C—N. Dans la phase plastique qui existe à des températures plus élevées pour le solide I du NMA, les résultats de la rmn du ^2H, du ^{14}N et du ^{17}O démontrent que le cation ainsi que l'anion subissent des rotations globales rapides qui font que l'on n'observe qu'une moyenne de toutes les interactions quadrupolaires nucléaires. Les résultats de la relaxation spin-réseau impliquent que les rotations du cation ainsi que celles de l'anion sont anisotropes et que les rotations globales sont fortement couplées tant dans la phase solide I que dans le liquide. Au point de fusion, les rotations globales ne sont que légèrement plus rapides dans la phase liquide que dans la phase solide I. Dans la phase solide I, les rotations dans le plan de l'ion nitrate sont environ deux fois plus rapides que les rotations d'un bout à l'autre de l'axe C_3. Dans le liquide pur, les rotations de l'ion NO_3^- sont plus isotropes et les rotations globales sont légèrement plus rapides que les rotations autour de l'axe de symétrie.

[Traduit par la revue]

Introduction

Molecular motion involving the methylammonium ion has been the subject of numerous ^1H nmr studies (1–9). At atmospheric pressure many methylammonium salts are capable of existing in two or more solid phases depending upon temperature (1–10). For example, both methylammonium chloride (1) and methylammonium bromide (6, 7) exist in at least three different solid phases. Nuclear magnetic resonance studies indicate that although the CH_3 and NH_3 groups undergo rapid reorientation(s) about the C—N axis in many of these phases, the C—N axis itself does not reorientate (1–9).

Recent ^1H nmr studies of methylammonium nitrate, MAN, indicate an unusual phase transition at 352 K, approximately 32 degrees below the reported melting point (8). Although it was possible to conclude that the frequency of rotation of the cation exceeded 10^{10} Hz in this solid phase, no information on the rotations of the anion is available from the ^1H nmr study (8). Here we report the results of ^{14}N nmr relaxation measurements on both the methylammonium cation and the nitrate anion. These measurements permit us to calculate rotational correlation times for both the $CH_3NH_3^+$ and NO_3^- ions in the high temperature solid phase (solid I) and the liquid phase. Also, natural abundance ^{17}O nmr relaxation measurements yield information on the anisotropy of nitrate ion rotations. Finally, deuterium nmr results are reported for both the solid II phase ($T < 352$ K) and solid I phase (352 K $< T <$ 391 K) of $CH_3ND_3^+NO_3^-$.

Experimental

Methylammonium nitrate was prepared by neutralizing an aqueous solution of methylamine with nitric acid and subsequent drying under vacuum. Deuteration of the amino group was achieved by dissolving $CH_3NH_3NO_3$ in excess deuterium oxide. The resulting sample was dried on a vacuum rack at 343 K for several days before sealing in an nmr tube. All nmr measurements were performed on the deuterated sample, $CH_3ND_3NO_3$.

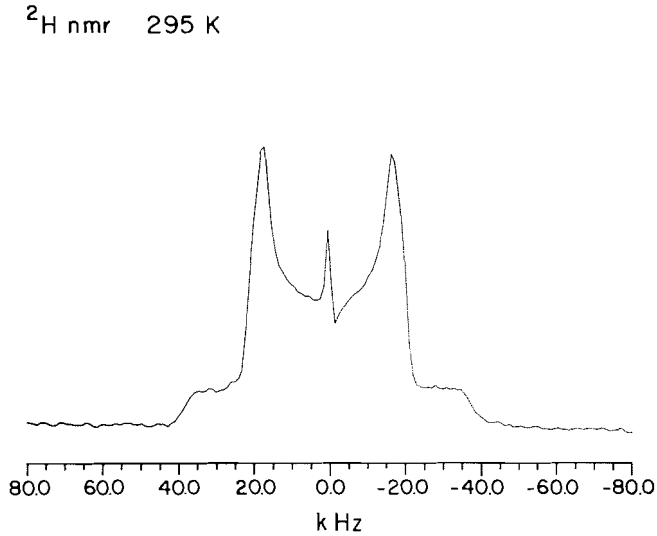

FIG. 1. The ^2H nmr powder pattern for $CH_3ND_3^+NO_3^-$ at 295 K (solid II) obtained at 30.72 MHz.

Spin-lattice relaxation measurements were performed on a Nicolet 360 NB (B_0 = 8.48 T) using the inversion recovery pulse sequence, which uses compensating pulses (11). The $\pi/2$ pulse widths were 40–55 μs. T_1 values were calculated from peak heights obtained at 12 or more different τ values using a nonlinear, three-parameter least-squares fitting procedure available on the Nicolet software (12).

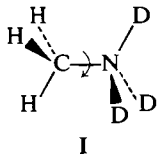
Deuterium nmr spectra of MAN in the solid II phase were recorded on a Bruker MSL-200 (B_0 = 4.7 T).

Results and discussion

(b) *Solid II phase*

The deuterium nmr spectrum of $CH_3ND_3^+NO_3^-$ at 295 K is shown in Fig. 1. The observed quadrupolar splitting of 37 ± 2 kHz is approximately one-third the anticipated static value and

is indicative of rapid reorientation of the N—D bond about the CN axis, **I**.



I

In general, the quadrupolar splittings between the spectral discontinuities of a ^2H nmr powder pattern are given by eq. [1] (13, 14),

$$[1]\quad \Delta\nu_1 = 3\chi(1-\eta)R/4$$
$$\Delta\nu_2 = 3\chi(1+\eta)R/4$$
$$\Delta\nu_3 = 3\chi R/2$$

where $\chi = e^2qQ/h$ is the ^2H quadrupolar coupling constant, 175 ± 10 kHz (15), η is the asymmetry parameter, less than 0.1 in the case of $CH_3ND_3^+$, and R is a reduction factor, $|(3\cos^2\beta - 1)/2|$, which results because of rapid rotation (or jumps) about some axis. β is defined as the angle between the largest principal component of the electric field gradient (the N—D bond) and the axis of rotation. For rotations of the ND_3 group about the C—N axis, **1**, $\beta = 109.5°$ and eq. [1] predicts $\Delta\nu_1 = \Delta\nu_2 = 43.7 \pm 2.5$ kHz. The smaller observed splitting may result from β values slightly larger than the tetrahedral angle and (or) averaging resulting from librations of the C—N axis.

We were unable to observe the nitrogen-14 nmr spectrum for the solid II phase of MAN. This was not unexpected since ^{14}N nmr studies indicate $\chi = 745$ kHz for the nitrate ion in sodium nitrate (16) and ^{14}N nqr studies show $\chi = 913 \pm 2$ kHz ($\eta = 0.109$) for the methylammonium cation in methylammonium chloride (17). A somewhat larger value for χ, 1106.7 ± 1.5 kHz, has been reported from a liquid crystal study of the methylammonium ion (18).

(b) *Solid I and liquid phases*

At temperatures above the solid II ↔ solid I phase transition, 352 K (8), the ^2H nmr powder pattern (Fig. 1) collapsed into a sharp single peak ($\nu_{1/2} < 40$ Hz); the ^{14}H nmr spectrum consisted of two chemically shifted peaks (Fig. 2). Also, above 352 K, a relatively sharp natural abundance ^{17}O nmr spectrum was observed for MAN. These results indicate that both the methylammonium cation and the nitrate anion are undergoing rapid overall rotations and (or) jumps that completely average all quadrupolar splittings (^2H, ^{14}H, and ^{17}O) to zero.

In order to gain further information about the time scale of these rotations, we have measured the temperature dependence of ^2H, ^{14}N, and ^{17}O spin-lattice relaxation time (Tables 1 and 2, Fig. 3). Our sample of MAN was solid at 388 K and melting occurred at 391 ± 2 K, approximately 7 K above the previously reported value (8); this is probably a deuterium isotope effect on the melting point. We summarize below the results obtained from each nmr active isotope investigated in this study.

(i) ^{14}N nuclear magnetic resonance

The ^{14}N resonances of the NO_3^- and $CH_3ND_3^+$ ions in the solid I phase of MAN are at 357.4 and −0.1 ppm, respectively, with respect to the ^{14}N resonance of the ammonium ion in a 5 *M* aqueous solution of $NH_4^+NO_3^-$. These nitrogen chemical shifts are in excellent agreement with those observed for the same ions in solution (19).

The temperature dependence of the experimental nitrogen

relaxation times for the nitrate and methylammonium ions in Fig. 3 can be described by

$$[2]\quad \ln T_1(NO_3^-) = 0.100 - 1.264\left(\frac{10^3}{T}\right)$$

and

$$[3]\quad \ln T_1(CH_3ND_3^+) = -1.716 - 0.969\left(\frac{10^3}{T}\right)$$

The slopes of these two linear equations correspond to activation energies of 10.5 ± 1.6 kJ mol^{-1} and 8.1 ± 1.2 kJ mol^{-1} for

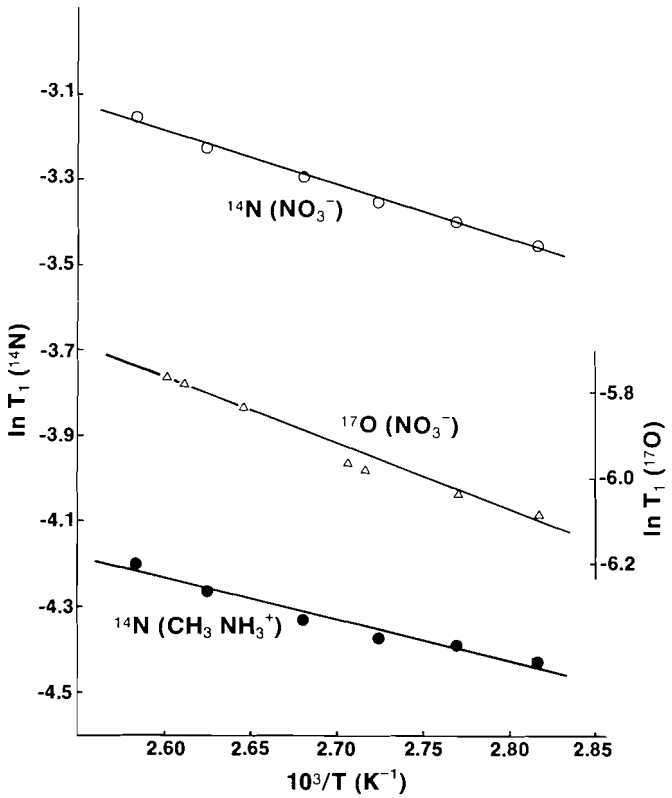

FIG. 3. Plots of ln $T_1(^{14}N)$ and ln $T_1(^{17}O)$ vs. $10^3/T$ for MAN (solid I).

the nitrate and methylammonium ions, respectively. The slopes are the same within the estimated experimental error (±15%). Nitrogen relaxation of both these ions is governed by the quadrupolar mechanism, eq. 4 (20), with $I = 1$.

$$[4]\quad \frac{1}{T_1} = \frac{3\pi^2}{10}\frac{2I+3}{I^2(2I-1)}\chi^2\tau_{eff}$$

Since the largest principal component of the electric field gradient for the nitrate ion is the C_3 symmetry axis, $\tau_{eff}(^{14}NO_3)$ is the correlation time describing rotations of the symmetry axis (i.e. end-over-end rotations). Similarly, the effective correlation time from ^{14}N measurements of the $CH_3ND_3{}^+$ resonance describes rotations of the C—N axis.

Substitution of experimental ^{14}N relaxation times at 355 K, $\chi(^{14}NO_3{}^-) = 745$ kHz (16) and $\chi(CH_3ND_3{}^+) = 1106.7$ kHz (18), into eq. [4] leads to overall rotational correlation times of 4.7 ps for the methylammonium ion and 3.9 ps for the nitrate ion. Calculated correlation times at 385 K and 393 K (liquid) are given in Table 3. Similar values of τ_{eff} for overall rotation of the nitrate and methylammonium ion suggest that the rotations of these ions are highly correlated or coupled. Because of the nonspherical shapes of these ions one might expect their rotational correlation times to be identical. Also, overall rotations of these two ions in the melt (liquid) are only slightly faster than those observed in the solid I phase. The consistently longer correlation times for the methylammonium ion (approximately 25%) compared to those of the nitrate ion may result from the substitution of inappropriate χ values into eq. [4]. (Note, any uncertainty in χ is squared in the calculation of τ_{eff}). Also, it is important to point out that there may be mechanisms for anion and cation rotations that permit different correlation times for the two ions.

The time scale for nitrate anion rotations in the solid I and liquid phases of MAN is slightly longer than what we have measured in dilute aqueous solutions of sodium nitrate (τ_{eff} = 1.1 ps) at 295 K (20*b*) but is significantly shorter than that observed in the solid I phase of ammonium nitrate at 413 K (τ_{eff} = 8.3 ps) (21).

(ii) ^{17}O nuclear magnetic resonance

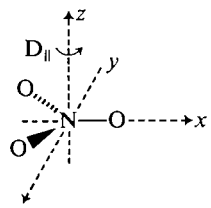
At 373 K the ^{17}O nmr chemical shift of the nitrate ion of MAN is 419.2 ppm to high frequency of H_2O. The ^{17}O line width at half height was 120 ± 15 Hz at this temperature. Because of the low natural abundance of ^{17}O (0.037%), the error in the ^{17}O T_1 values is estimated to be ±10%. The best straight line describing the ^{17}O relaxation data is given by eq. [5], with a slope corresponding to 12.7 ± 2.5 kJ mol^{-1},

$$[5]\quad \ln T_1 = -1.79 - 1.53\left(\frac{10^3}{T}\right)$$

Oxygen-17 has a spin $I = 5/2$ and nuclear relaxation is governed by the quadrupolar mechanism, eq. [4]. For the nitrate ion, nqr studies (22) and *ab initio* molecular orbital calculations (20*b*, 22) indicate that the largest principal component of the ^{17}O electric field gradient (EFG) tensor lies along the N—O bond (x-axis), while the smallest component is along the C_3 symmetry axis (z-axis). The other principal component of the EFG tensor lies in the molecular plane of the ion, and is only slightly smaller than the x-component. Effective relaxation data will reflect rotations both parallel and perpendicular to the C_3 symmetry axis. Oxygen-17 τ_{eff} values calculated using χ = 12.57 MHz (22) and eq. [4] ($I = 5/2$) are summarized in Table 3. The shorter τ_{eff} values derived for the nitrate ion from the ^{17}O data compared to those derived from the ^{14}N data in the solid I phase imply that in-plane rotations are faster than overall rotations of the nitrate ion. In the liquid phase, in-plane rotations are slower than they are in the solid I phase.

By assuming that rotations of the nitrate ion can be described by a rotational diffusion model, one can relate $\tau_{eff}(^{17}O)$ for the

nitrate ion to the rotational diffusion constants $D_\perp$ and $D_\parallel$ (II),



II

using eq. [6] (20).

[6] $\tau_{eff}(^{17}O) = \{[4 + (n_q - 1)^2]D_\perp + (n_q + 1)^2 D_\parallel\}/4D_r$

where

$$D_\perp = D_{xx} = D_{yy} = \frac{1}{6\tau_\perp(^{14}N)}$$

$$D_\parallel = D_{zz}$$

$$D_r = 3D_\perp(D_\perp + 2D_\parallel)$$

and $n_q = (q_{yy} - q_{zz})/q_{xx} = -0.747$ for the ^{17}O of the nitrate ion (20*b*, 22). The calculations indicate that the ratio, $D_\parallel/D_\perp \simeq 2$ in the solid I phase and approximately 0.8 in the neat liquid. Although it is important to recognize the possible limitations of a diffusion model, we feel that the qualitative results regarding the anisotropy of the nitrate ion rotations are significant; i.e., in-plane rotations or jumps of the nitrate ion are faster in the solid I phase than rotations of the C_3 symmetry axis. In the liquid phase rotations are more isotropic.

Similar calculations utilizing ^2H and ^{14}N relaxation data for the methylammonium ion yield, $D_\parallel/D_\perp$ ratios of 7.6 ± 2 and 4.3 ± 1, respectively, in the solid I and liquid phases. In this calculation we have assumed the CNH angle is tetrahedral. The qualitative result is that rotations of the $CH_3NH_3^+$ ion about the symmetry axis are faster than rotations of the symmetry axis. Again, rotations in the liquid phase are found to be more isotropic, as expected.

Conclusion

In this study we have demonstrated how one can combine ^2H, ^{14}N, and ^{17}O nmr relaxation data to characterize the temperature dependent rotations of the methylammonium cation and nitrate anion in $CH_3ND_3^+NO_3^-$ in both the solid and liquid state. In the solid I phase both ions are undergoing very rapid anisotropic rotations, which are strongly coupled. On melting, the rotations of each ion are more isotropic and the rate of overall rotations increases slightly. The high temperature orientationally disordered "plastic" phase is almost certainly cubic and similar to that of ammonium nitrate. Diffraction and calorimetry studies of this intriguing solid will lead to a better understanding of the structure and nature of the phase transition in methylammonium nitrate.[1]

[1] While this paper was in press the crystal structure of MAN appeared (23).

Received November 4, 1985

TOSHINORI WADA, NORMAN GEE, and GORDON R. FREEMAN. Can. J. Chem. **64**, 777 (1986).

The density-normalized mobility of $n\mu$ of cations in nitrogen gas at densities up to $n_c = 6.7 \times 10^{27}$ molecules/m^3 increases with temperature. At $n \leq 5.7 \times 10^{25}$ molecules/m^3 and $T > 250$ K, the dominating ion is N_4^+. At lower temperatures and higher densities, relatively loosely bound clusters $N_4^+(N_2)$, $N_4^+(N_2)_2$, ... form. Momentum transfer cross sections for $N_4^+-N_2$ are governed at low energies by the polarization potential, and at high energies by the hard body potential. The cross section for $N_2^+-N_2$ at high energies is larger than that for $N_4^+-N_2$.

TOSHINORI WADA, NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **64**, 777 (1986).

La mobilité normalisée pour la densité, $n\mu$, de cations dans l'azote gazeux, à des densités allant jusqu'à $n_c = 6{,}7 \times 10^{27}$ molécules/m^3, augmente avec la température. Pour $n \leq 5{,}7 \times 10^{25}$ molécules/m^3 et $T > 250$ K, l'ion dominant est N_4^+. A des températures plus basses et à des densités plus élevées, il se forme des agrégats relativement faiblement liés de $N_4^+(N_2)$, $N_4^+(N_2)_2$, ... A basse énergie, les sections droites les transferts de moments, pour $N_4^+-N_2$, sont influencées par le potentiel de polarisation; par ailleurs, à des énergies plus élevées, elles sont gouvernées par les potentiels des corps durs. A des énergies élevées, la section droite pour $N_2^+-N_2$ est plus grande que celle pour $N_4^+-N_2$.

[Traduit par la revue]

Introduction

The mechanism of cation transport in simple molecular fluids undergoes a gradual transition from normal gas-phase-type to liquid-phase-type over a wide density range, $0.5 \lesssim n/n_c \lesssim 1.9$, where n_c is the number density of the vapor–liquid critical fluid (1). The transport mechanism does not change abruptly at the critical point. The mobility μ of ions in the low density gas is limited by binary collisions. In the normal liquid ($n/n_c \gtrsim 2.0$) it is limited by multibody, viscous interactions.

In the dense gas, at $n/n_c \gtrsim 0.5$, the density-normalized mobility $n\mu$ increases (1). This implies that the attractive ion–molecule scattering interactions interfere destructively when the ion interacts with several molecules at a time. The high density at which the increase of $n\mu$ takes place indicates that the scattering interaction has a relatively short range.

The present paper examines, in more detail, the temperature and density effects on cation transport in nitrogen gas.

Experimental

Ultra high purity nitrogen (99.9995%), obtained from Matheson, was further purified in a grease free vacuum line by: 1) passage through two cold traps at 113 K, 2) passage at 773 K through a 60-cm column of copper grains previously treated with hydrogen to remove oxide, 3) bubbling through a sodium–potassium alloy at 294 ± 1 K, and 4) contact as a gas with a series of potassium mirrors (2).

The conductance cell could contain ~6 MPa (3). The drift distance was 3.20 mm, measured with a small-hole caliper and micrometer. Prior to filling with sample, the cell was degassed by heating to 523 K while evacuating to 10^{-5} Pa.

The cations were generated with 100 ns pulses of 1.7 MeV X-rays (dose $\approx 9 \times 10^{-9}$ J/g). The mobility was measured by time of flight (4). Ion drift signals were averaged for eight pulses at each voltage to obtain the drift time. The mobility was independent of field strength, E/n, over the range 0.01–1 Td (Td = 10^{-21} V m^2/molecule). Each mobility reported herein is the average of about 15 values measured over the 100-fold range. The precision is ±2%.

The temperature was measured at the top, electrode level, and bottom of the cell with copper-constantan (Thermoelectric Canada Ltd. type t special) thermocouples connected to a Fluke 2100A digital thermometer. The temperature difference between the top and bottom of the cell was <1 K, except near T_c where it was 0.2 K (2). Constant temperature was maintained within ±0.2 K.

The amount of material put into the 15.0-cm^3 cell was measured by the gas pressure in the cell at 77 K for the smaller amounts, and by the volume of liquid transferred from a burette at 77 K to the cell at solid nitrogen temperature (63 K) for larger amounts.

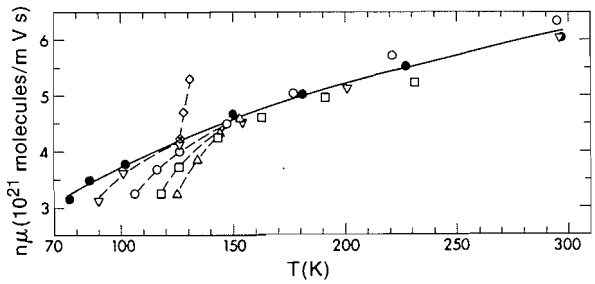

FIG. 1. Density-normalized mobility $n\mu$ of cations as a function of temperature at several densities. $n(10^{26}$ molecules/m^3): ●, 0.57; ▽, 2.30; ○, 7.8; □, 17.4; △, 32.0; ◇, 67.1 = n_c. The lines are guides for the eye.

The critical temperature, pressure, and density of nitrogen are T_c = 126.2 K, P_c = 3.3 MPa, and $n_c = 6.7 \times 10^{27}$ molecules/m^3 (5).

Results and discussion

A. Effect of temperature at different densities

The mobility increases with increasing temperature over the range 77–297 K (Fig. 1). To compare the results at different densities, the density-normalized mobility $n\mu$ is plotted against T. At $T > 150$ K the values of $n\mu$ are independent of n, within the experimental uncertainty of ±2%. At $T < 150$ K the $n\mu$ curves fan out, the value of $n\mu$ decreasing as n is increased from 0.57×10^{26} to 32×10^{26} molecules/m^3 (Fig. 1). However, at the density of the vapor–liquid critical fluid $n_c = 67 \times 10^{26}$ molecules/m^3, the values of $n\mu$ are higher, indicating a change of behavior.

The change of behavior is illustrated by plotting $n\mu$ against n at fixed T (Fig. 2). The value of $n\mu$ decreases gently with increasing n up to ~32×10^{26} molecules/m^3, then increases at higher densities. The increase of $n\mu$ with n signals destructive interference of the attractive ion–molecule scattering interactions as the ion interacts with several molecules at a time. This is the beginning of the transition region of densities, through which transport mechanism changes from gas-type to liquid-type (1).

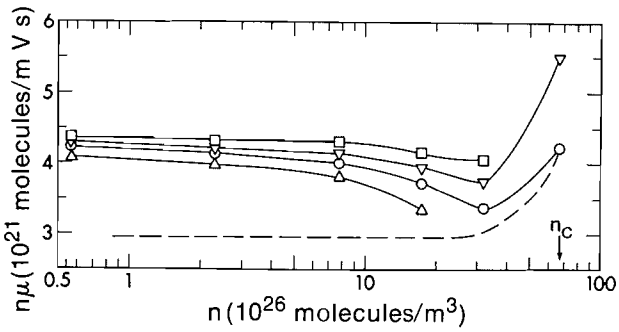

FIG. 2. Density-normalized mobility $n\mu$ of cations as a function of density at several temperatures. △, $0.95T_c$ = 119.9 K; ○, T_c = 126.2 K; ▽, $1.05T_c$ = 132.5 K; □, $1.10T_c$ = 138.8 K. ---, saturated vapor (1).

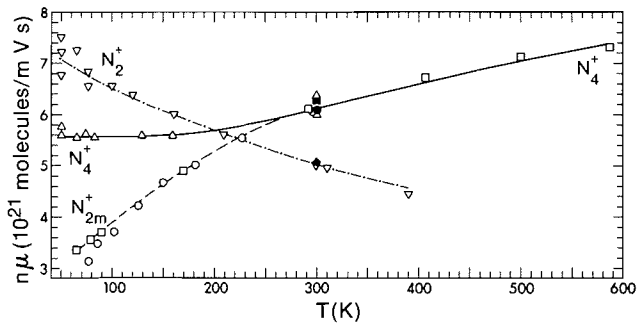

FIG. 3. Temperature dependence of the density-normalized mobility $n\mu$ in low density nitrogen gas. The gas density (10^{24} molecules/m^3) is the number following the point symbol. Unidentified N_{2m}^+: ○, 57, present work; □, ~0.3–0.8 (8). N_4^+: △, ≤0.5 (7); ■, 0.01–0.03 (6). N_3^+: ●, 0.001–0.03 (6). N_2^+: ▽, ≤0.5 (7); ◆, 0.001–0.03 (6). —— and –·–·–, calculated from eq. [6] using the corresponding (σ_m, ϵ) values from Fig. 4. --- is empirical. The different sets of N_4^+ and N_{2m}^+ data were normalized at 300 K to provide a more accurate shape of the temperature dependence: ○ and ■, 1.00 $n\mu$; □, $n\mu$/1.10; △, 1.07 $n\mu$. The stated uncertainties of $n\mu$ were ±4% in ref. 6 and ±10% in ref. 7.

The main question in the present work is why the curves in Fig. 1 fan out at T < 150 K and not at higher temperatures. The answer probably lies in the thermodynamics of the ion–molecule clustering reactions. At higher temperatures the ions are probably mainly N_4^+, and at low temperatures they are probably larger clusters.

The mobilities of mass-identified N_2^+, N_3^+, and N_4^+ have been measured at densities 10^2–10^3 times smaller than the lowest used in the present work (6, 7). The $n\mu$ of N_2^+ decreases with increasing temperature (Fig. 3); that of N_4^+ is independent of temperature between 50 and ~200 K, then increases gently at higher temperatures (Fig. 3). There is a crossover of $n\mu$ for N_2^+ and N_4^+ at 220 ± 20 K (7). The mobility of N_3^+ has only been measured at 300 K, where it is essentially the same as that of N_4^+ (6).

At 300 K the value of $n\mu$ of our mass-unidentified ions, designated N_{2m}^+, is essentially the same as that of N_4^+ (6, 7). At low temperatures $n\mu$ of N_{2m}^+ is smaller than that of N_4^+ (Fig. 3).

Early results of Tyndall and Pearce (8) in highly purified nitrogen, showed nearly the same temperature dependence as ours, even though we used a 100-fold larger density (Fig. 3). The $n\mu$ values calculated from the data of Tyndall and Pearce were approximately 10% greater than ours. Their value at 292 K is 10% higher than that of N_4^+ at 300 K at the same and lower densities; we attributed the difference to a 10% systematic error and divided their values by 1.10, to plot in Fig. 3.

The reaction

[1] $N_2^+ + 2N_2 \rightleftharpoons N_4^+ + N_2$

has $\Delta H^0_{2,4} = -95$ kJ/mol and $\Delta S^0_{2,4} = -84$ J/mol K, with standard state 1 atm (1 atm = 101 kPa) (9, 10). The equilibrium constant

[2] $K_{2,4} = \exp(-\Delta G^0_{2,4}/RT)$

therefore has the value 3×10^{12} atm^{-1} at 298 K, which is equivalent to 1×10^{-13} m^3/molecule. Thus equilibrium [1] is essentially completely on the side of N_4^+ when $n > 10^{14}$ molecules/m^3. Our system had $n \geq 57 \times 10^{24}$ molecules/m^3, so the concentration of N_2^+ was negligible.

The values of $n\mu$ indicate that at $T > 250$ K the main ions in our system were N_4^+ (Fig. 3). The lower values of $n\mu$ at $T <$ 250 K are attributed to the formation of larger clusters.

[3] $N_4^+ + 2N_2 \rightleftharpoons N_4^+(N_2) + N_2$

The results indicate that the equilibrium constant $K_{4,6}$ becomes > 1 at $T <$ 250 K, or $\Delta G^0_{4,5} \approx 0$ at 250 K. The value of $\Delta S^0_{4,6}$ is probably similar to that of $\Delta S^0_{2,4} = -84$ J/mol K. Hence, $\Delta H^0_{4,6} \approx -84 \times 250 = -21\,000$ J/mol = −21 kJ/mol.

The value $\Delta H^0_{2,4} = -95$ kJ/mol indicates that N_2^+–N_2 is held together by a one-electron bond, whereas $\Delta H^0_{4,6} = -21$ kJ/mol indicates that N_4^+–N_2 is a relatively loosely bound cluster.

The fanning out of $n\mu$ values with increasing density at $T <$ 150 K (Fig. 1) is attributed to an increase of the cluster size as in the following reactions:

[4] $N_4^+(N_2) + 2N_2 \rightleftharpoons N_4^+(N_2)_2 + N_2$

[5] $N_4^+(N_2)_2 + 2N_2 \rightleftharpoons N_4^+(N_2)_3 + N_2$

and so on. Assuming $\Delta S^0 \approx -80$ J/mol K and $\Delta G^0 = 0$ at ~140 K for each of reactions [4] and [5], one obtains $\Delta H^0 \approx -80 \times 140 = -11$ kJ/mol for each step.

The increase of reduced mass of the colliding pair is not enough to explain all the decrease of $n\mu$ in this region. The increasing hard core radius of the ion must also make a contribution.

B. Momentum transfer cross sections

The ions in Tyndall and Pearce's system (8) at $T > 250$ K would have been unclustered N_4^+ with a trace of N_3^+. The ratio of concentration $[N_3^+]/[N_4^+]$ would equal the ratio $[N^+]/[N_2^+]$ initially formed, which would be smaller in Tyndall's system than the 0.04 in a 70 V mass spectrum (11). The N_3^+ was therefore negligible in ref. 8 and in the present work.

To obtain a self-consistent view of the temperature coefficient of $n\mu(N_4^+)$ over the range $50 \leq T/K \leq 587$, the $n\mu$ values in refs. 7 and 8 were normalized at 290–300 K to those in ref. 6 and the present work. Thus, $n\mu$ values from ref. 8 were divided by 1.10, and those for N_4^+ from ref. 7 were multiplied by 1.07 (Fig. 3). The N_4^+–N_2 momentum transfer cross section as a function of collision energy ϵ was extracted from the ($n\mu$, T) values by numerically fitting them to eq. [6] (12).

$$[6] \quad n\mu = \frac{3}{8} e (k_B T)^{5/2} \left(\frac{2\pi}{M_r}\right)^{1/2} \Big/ \int_0^\infty \epsilon^2 \sigma_m \exp(-\epsilon/k_B T) d\epsilon$$

where e is the charge on the ion, k_B is Boltzmann's constant, and M_r is the reduced mass of the collision pair. The ions are in thermal equilibrium with the gas.

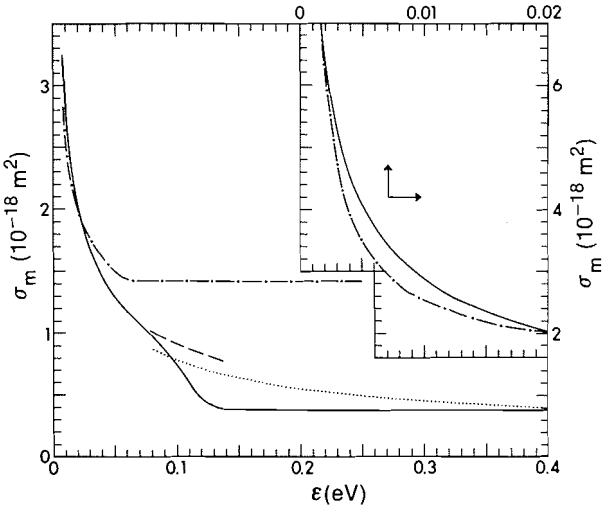

FIG. 4. Momentum transfer cross sections of N_2 for the cations N_4^+ (——) and N_2^+ (–·–·–), obtained by fitting the data in Fig. 3 to eq. [6]. – – –, σ_{pol} using α_m; ···, σ_{pol} using $\bar{\alpha}$ (see text).

The cross sections are shown in Fig. 4. At $\epsilon < 0.08$ eV the value of σ_m for N_4^+–N_2 collisions is equal to that expected from the polarization potential (13)

$$[7] \quad \sigma_{pol} = \left(\frac{2.21\pi e}{4\pi\epsilon_0 v}\right)\left(\frac{\alpha}{M_r}\right)^{1/2}$$

where ϵ_0 is the permittivity of vacuum and α is the polarizability of N_2. The value of α in eq. [7] is in SI units, C m^2/V (dipole moment (C m)/field strength (V m^{-1}); the non SI unit m^3 corresponds to $\alpha/4\pi\epsilon_0 = 8.99 \times 10^9\alpha$). If the values of the constants are inserted in eq. [7], and α is expressed in 10^{-40} C m^2/V and ϵ in eV, one obtains

$$[8] \quad \sigma_{pol}(m^2) = 1.76 \times 10^{-19}(\alpha/\epsilon)^{1/2}$$

At low energies the slowly moving molecule and ion interact for a sufficiently long time (>1 ps) during a collision that the nitrogen molecule tends to become oriented, such that its axis of maximum polarizability is directed towards the ion (1). Under these circumstances the maximum component $\alpha_m = 2.65 \times 10^{-40}$ C m^2/V (14) of the nitrogen polarizability matrix is used in eq. [8]. This gives the experimental values of σ_m for N_4^+–N_2 at $\epsilon < 0.08$ eV and the dashed line at $\epsilon > 0.08$ eV (Fig. 4).

At the higher energies the ion–molecule interaction time during a collision is too brief (≤1 ps) to allow the long polarization axis of the molecule to become oriented in the field of the ion. Under these circumstances the average value $\bar{\alpha} = 1.96 \times 10^{-40}$ C m^2/V (14) is used in eq. [8]. This gives the dotted line in Fig. 4.

The N_4^+–N_2 momentum transfer cross sections are therefore similar to those expected from the polarization interaction. The apparently low values in a broad region around $\epsilon \approx 0.15$ eV might be an artifact due to an imprecise normalization of the different sets of $n\mu$ values (ref. 7 values still too low). However, the constant σ_m at $\epsilon > 0.14$ eV is a hard body value similar to that for two nitrogen molecules, 4×10^{-19} m^2 (15).

Cross sections extracted from the $n\mu$ values of N_2^+ in Fig. 3 are also displayed in Fig. 4. The negative $d(n\mu)/dT$ indicates a relatively small dependence of σ_m on energy. The scattering potential for N_2^+–N_2 has a shorter range than that for N_4^+–N_2. The power p in the distance dependence of the interaction potential

$$[9] \quad V(r) \propto r^{-p}$$

is ~6–10 for N_2^+–N_2, and ~3–4 for N_4^+–N_2 at $\epsilon \approx 0.01$–0.13 eV (ref. 13, pp. 78–79).

The value of σ_m for N_2^+–N_2 at $\epsilon < 3$ meV in Fig. 4 has been arbitrarily drawn to join σ_{pol} at ~2 meV, although the $n\mu$ data at $T < 80$ K do not actually require such a large value of σ_m. At $\epsilon > 0.06$ eV, σ_m is constant with a value four times larger than the hard-body cross section for N_4^+–N_2 (Fig. 4) or the neutral N_2–N_2 (15). The larger cross section for N_2^+–N_2 can be attributed to resonant charge transfer (16).

Electrostatic and nonelectrostatic, conventional and unitary thermodynamic quantities of reaction. I. Metal–ligand reactions in aqueous solvent

ROBERTO ARUGA

Department of Analytical Chemistry, University of Turin, via Giuria 5, 10125 Turin, Italy

Received July 25, 1985

ROBERTO ARUGA. Can. J. Chem. **64**, 780 (1986).

A calculation method of the electrostatic and nonelectrostatic parts of thermodynamic quantities of reaction, previously proposed and applied to complex-formation reactions of aminic and carboxylic ligands, is applied, in the present work, to association reactions of several other ligands. In particular, to check its reliability, this method is applied to ΔG^0, ΔH^0, and ΔS^0 data of literature for the formation of metal–anion pairs and for associations of metals with ligands containing pyridine nitrogen, ethereal oxygen, or thioethereal sulfur. Experimental data referring only to aqueous solutions are considered. The results obtained by this method are in agreement, in most cases, with those expected for the reactions examined. Therefore, it seems reliable and useful for a more significant interpretation of conventional thermodynamic parameters.

ROBERTO ARUGA. Can. J. Chem. **64**, 780 (1986).

Dans le présent travail, on applique à des réactions d'association de plusieurs autres ligands la méthode de calcul des composantes électrostatiques et non-électrostatiques de quantités thermodynamiques de réactions, qui avait été proposée et appliquée antérieurement à des réactions de formation de complexes de ligands amines et acides carboxyliques. Dans le but d'évaluer la fiabilité de cette méthode, on l'a appliquée en particulier à des données de ΔG^0, ΔH^0 et ΔS^0 relatives à la formation de paires de métal–anion et à des associations de métaux avec des ligands contenant l'azote d'une pyridine, l'oxygène d'un éther et le soufre d'un thioéther. On a considéré des données expérimentales se référant uniquement à des solutions aqueuses. Dans la plupart des cas, les résultats obtenus avec cette méthode sont en accord avec ceux que l'on pourrait espérer pour les réactions examinées. La méthode semble donc fiable et utile pour une interprétation significative des paramètres thermodynamiques conventionnels.

Introduction

Two successive phases seem to have, in general, been characterized in the study of stabilities of metal–ligand complexes in solution. The former phase was characterized by the determination of stability constant data, the latter by the determination of Gibbs function together with its enthalpy and entropy contributions.

The determination of enthalpy and entropy data leads to a better comprehension of the causes which determine different complex stabilities in solution. Interpretation of entropy data is, in general, fairly simple, as this quantity is often determined by the so-called environmental factors, which consist of interactions of the solute with the surrounding solvent particles (1). The enthalpy value appears more complex, as it is affected by both environmental and internal factors, the latter being determined by the strength and nature of solute–solute and solute–solvent direct bonds. As a consequence of this fact, the need has been felt to divide the thermodynamic quantities, especially enthalpy, into two contributions which allow an evaluation of the relative importance of external and internal factors in the association process.

A method of calculation of electrostatic (or external) and nonelectrostatic (or internal) contributions of thermodynamic parameters was first proposed by Gurney (2) for the investigation of acid–base equilibria. Only later (3–6) the possibility was suggested to extend its application to metal–ligand reactions. Actual application of the Gurney method to experimental thermodynamic data for metal–ligand complexes is the subject of a limited number of papers (7–9). Moreover, the method was only used in the case of aminic and carboxylic ligands.

Taking into account these observations it was thought of interest, in the present study, to extend the experimental verification of Gurney's method to the case of ligands not yet investigated in previous works. This treatment, in particular, is applied here to several calorimetric data of literature for the formation, in aqueous solution, of the less stable ion pairs, and for ligands containing less investigated coordinating sites, such as pyridine nitrogen, ethereal oxygen, or thioethereal sulfur. Verifications of the above theory may also be useful in view of an extension of this treatment to association reactions in different solvents, which will be the subject of the next paper of this series (this issue, Can. J. Chem.).

Treatment of the experimental data

Referring to previous papers for fuller details (2, 9–12), it may be observed that the equilibrium constant for a general complex formation reaction

$$[1] \quad M + nL \rightleftarrows ML_n$$

can be expressed in terms of the mole fraction of the species (K^x) instead of the moles per liter. This is the same as assuming pure substance (i.e., unitary mole fraction) as the standard state for both the solute and the solvent. It can be demonstrated that K^x for equilibrium [1] is related to the conventional constant K in the following manner:

$$[2] \quad K = K^x M_s^{-n}$$

where M_s is the concentration of the solvent and n is the number of moles of the reagents minus the moles of the products. Therefore the conventional constant, as well as Gibbs function, consist of two parts: K^x, the unitary part, and M_s^{-n}, the cratic part.

The following observations can be made on the cratic term. (*a*) The existence of this term is due to different standard states for the solute and the solvent, as it disappears when K^x is used instead of K. (*b*) The cratic term is constant only for reactions of the same stoichiometric type and in the same solvent. On this basis several authors consider only the unitary part as a characteristic and specific quantity for every single reaction (2, 10). In general, the use of K^x is recommended when

Printed in Canada / Imprimé au Canada

TABLE 1. Electrostatic (el), nonelectrostatic (non), unitary (x), and cratic (c) contributions of the conventional thermodynamic parameters ΔX^0 ($X = G, H, S$)

ΔX^0	ΔX_{non}	ΔX_{el}
ΔG^0	$nRT \ln M_s + RCa$	$RCe^{T/\theta}$
ΔH^0	RCa	$RC(1 - T/\theta)e^{T/\theta}$
ΔS^0	$-nR \ln M_s$	$-e^{T/\theta}(RC/\theta)$
	ΔX^c	ΔX^x

quantities for reactions in different solvents or with different stoichiometry are compared, as different cratic parts are present in these cases. To eliminate any extraneous influence by the term M_s^{-n}, in the present study, it was also thought necessary to take the unitary term into consideration when the electrostatic and the covalent contribution of a certain thermodynamic quantity are compared with each other.

Unitary ΔG^0 may be divided into the electrostatic part (ΔG^x_{el}) and the nonelectrostatic part (ΔG^x_{non}) (2, 4, 8, 9). ΔG^x_{el} represents long-range electrostatic interactions, which are affected by the dielectric nature of the solvent and by the temperature. Therefore, it is determined by solute–solute electrostatic bonds and by long-range solute–solvent interactions. ΔG^x_{non} is determined by all short-range factors, independent of the dielectric constant and of the temperature. They consist mainly of solute–solute covalent bonds and of solute–solvent contact interactions (i.e., solvation interactions) (8). An evaluation of the above contributions can be made taking into account the following considerations. First of all, it may be shown that for an association reaction $\Delta G^x_{el} = \alpha/D$, where α is constant and D is the dielectric constant of the medium (2, 7, 9). The variation of D with temperature is expressed empirically by: $D = D_0 e^{-T/\theta}$, where D_0 is a constant and θ is a temperature characteristic of the solvent. From the values of D at various T, a value for θ of about 212 is obtained for water (13). From the above expressions, taking also into account that $\Delta G^x = \Delta G^x_{el} + \Delta G^x_{non}$, the following relation is obtained:

$$[3] \quad -\ln K^x = C(a + e^{T/\theta})/T$$

where $C = \alpha/RD_0$ and $a = \Delta G^x_{non} D_0/\alpha$. From eq. [3], using parameters C and a, the following expressions may be derived for the conventional thermodynamic quantities (9):

$$[4] \quad \Delta G^0 = nRT \ln M_s + RC(a + e^{T/\theta})$$

$$[5] \quad \Delta H^0 = RC[a + (1 - T/\theta)e^{T/\theta}]$$

$$[6] \quad \Delta S^0 = -nR \ln M_s - (RC/\theta)e^{T/\theta}$$

The electrostatic and nonelectrostatic contributions of conventional and unitary thermodynamic functions may be obtained from the preceding discussion. The corresponding expressions are summarized in Table 1. C and a are determined knowing the experimental values of ΔG^0 and ΔH^0 (or ΔG^0 and ΔS^0) and using eqs. [4] and [5] (or eqs. [5] and [6]).

It follows from the data in Table 1 that the cratic part of ΔH^0 is zero, i.e., $\Delta H^0 = \Delta H^x$. Therefore, comparisons between conventional quantities are valid, in the case of enthalpy, also for equilibria in different solvents. Moreover, it follows from Table 1 that $\Delta X_{el} = \Delta X^x_{el}$ and $\Delta H_{non} = \Delta G^x_{non}$.

Results and discussion

Thermodynamic quantities of the literature for associations in aqueous media at 25°C are collected in Table 2. According to the above statements, electrostatic and nonelectrostatic quantities are also listed in Table 2. Only the enthalpy values obtained by direct calorimetry are reported. Furthermore, values referred to the same ionic strength were compared when possible.

Evaluation of the reciprocal importance of electrostatic and nonelectrostatic factors for various types of equilibria (i.e., ΔG^x_{el} vs. ΔG^x_{non}, ΔH_{el} vs. ΔH_{non}) is an important point in the discussion of the present results. For metal–thiosulfate associations (14) negative values of ΔG^x_{el} are obtained, while values of ΔG^x_{non} are not distant from zero. This indicates prevailing electrostatic phenomena in the formation of the pairs, in accord with what is generally admitted for this kind of associations (1, 14). The only ΔG^x_{non} value considerably different from the others is that of cadmium ($\Delta G^x_{non} = -7.4$ kJ mol^{-1}). This value is in accord with a covalent character of the Cd—thiosulfate bond (14). It must be noted, in particular, that thiosulfate contains the —S^- group as bonding site and also that cadmium shows the greatest "soft" character among the metals listed in Table 2 for this anion.

The mean value of ΔG^x_{el} for the metal–thiosulfate associations (about -13 kJ mol^{-1}) is approximately determined by 5 kJ mol^{-1} of ΔH_{el} and by -18 kJ mol^{-1} of $-T\Delta S_{el}$. Taking into account that (*a*) ΔS_{el} is not affected by the association process (i.e., by the decrease from two to one solute particle) as the latter concerns the cratic part of ΔS^0 (see Table 1); (*b*) the endothermic values of ΔH_{el} show that they are not greatly affected by the formation of solute–solute bonds, the conclusion can be drawn that the above values of ΔH_{el} and $T\Delta S_{el}$ are mainly determined by external (i.e., solvent-destructuring) processes. It is also clear that the pair formation is a consequence of these processes, and that they favour the association through the entropy factors more than they oppose it through enthalpy. Similar considerations are also valid for the metal–sulfate associations (ref. 15, see Table 2). The only difference (which appears easily explainable) with respect to thiosulfate regards cadmium. In fact ΔG^x_{el} and ΔG^x_{non} of this metal with sulfate are similar to those of the other metals. Finally, a direct comparison of the thermodynamic quantities for sulfate and thiosulfate shows that the electrostatic parts of ΔH^0 and ΔS^0 for the former are more positive than for the latter, as though greater solvent-destructuring processes were present in the association of sulfate. This fact is in accord with a higher ionic strength ($I = 0.5$ mol L^{-1}) used for thiosulfate (and, consequently, with a more ordered structure of water in this case), while the results for sulfate refer to $I = 0$. It is also interesting to observe that differences in ionic strength do not remarkably affect the covalent part of the thermodynamic functions.

Comparisons of the electrostatic and nonelectrostatic part of Gibbs function may be interesting also for associations without charge neutralization. The results previously obtained in this laboratory for metal associations of 1-methylimidazole may be taken as an example (16). The second step of formation of certain mixed complexes where two electrically neutral particles take part in the association (17) is an even more typical example (see Table 2). Opposite results than for sulfate and thiosulfate are obtained in these cases. ΔG^x_{non} and ΔH_{non} are now clearly negative, while ΔG^x_{el} and ΔH_{el} are not distant from zero.

Previous experimental data for associations of pyridine-2-carboxylate with two groups of metals (the group from magnesium to barium and the nickel–zinc–copper group) are reported in Table 2 (18, 19). Different bonds may be formed by

*Gibbs function and enthalpy are expressed in kJ mol^{-1}; entropy in J K^{-1} mol^{-1}. For the meaning of indexes and corresponding quantities see "Treatment of the experimental data" and Table 1.

†ΔS_{non} for the reactions listed in the table is constant: $\Delta S_{non} = -R \ln 55.35 = -33.4$ J K^{-1} mol^{-1}.

‡L′: (a) cyclopropane-1,1-dicarboxylate, (b) cyclobutane-1,1-dicarboxylate, (c) cyclopentane-1,1-dicarboxylate, (d) cyclohexane-1,1-dicarboxylate, (e) malonate, (f) succinate, (g) maleate, (h) phthalate.

this ligand: prevailingly, an electrostatic bond through the carboxylate group (8), and a covalent one through the pyridine nitrogen. The latter, in particular, is able to form π-bonds with the *d* electrons of the metal ion (20). The values of ΔH_{el} and ΔH_{non} seem in accord with these possibilities. In fact, similar ΔH_{el} values are obtained for all the above mentioned metals, in agreement with similar electrostatic phenomena (i.e., same charge-neutralization processes). On the other hand, very different values of ΔH_{non} are obtained: weakly exothermic values for group IIA metals (between −5 and −9 kJ mol^{-1}) and markedly exothermic values for Ni, Cu, Zn (between −23 and −35 kJ mol^{-1}). These results agree with a lower ability of the former metals to give covalent bonds. It must be noted, in particular, that they have no *d* electron. Similar observations can be made for the association of the above metals with pyridine-2,6-dicarboxylate (see Table 2).

Inversion of the stability order between magnesium and calcium with these two ligands is a fairly interesting point. In the case of pyridine-2-carboxylate the magnesium complex is more stable than that of calcium; for pyridine-2,6-dicarboxylate the order is reversed. This fact was previously justified considering the small dimensions of magnesium (1), which might have difficulty in forming stable bonds with the tridentate ligand. Such an explanation is related to short-range, steric factors, which should affect the nonelectrostatic part of enthalpy (8). The enthalpy data of Table 2 are in accord with this hypothesis. In fact, for both magnesium and calcium, the positive value of ΔH_{el} increases from the bidentate to the tridentate ligand, as a consequence of increasing charge-neutralization processes. ΔH_{non}, on the contrary, becomes more exothermic in the case of calcium, while it passes from −5.3 to +5.0 kJ mol^{-1} for magnesium. Therefore, ΔH_{non} seems to be the determining factor of the inversion of stabilities.

The presence of differently membered chelate rings is another example of a typical internal factor (8), which, in general, should affect the nonelectrostatic part of enthalpy. The above examined data for Ni, Cu, and Zn with pyridine-2-carboxylate (five-membered chelate ring), compared with the data of the same metals with pyridine-2-acetate (six-membered ring) (21) support this hypothesis. In fact (see Table 2), the higher stability of the pyridine-2-carboxylate complexes in comparison with those of pyridine-2-acetate is determined by ΔH_{non}, while ΔH_{el} values, for the three metal ions, show an opposite trend.

As regards the metal complexes of ethereal–oxygen or thioethereal–sulfur containing ligands (see Introduction), accurate calorimetric values are available in literature for "crown" ligands (22) and for polyaminopolycarboxylic ligands (23). Five oxygen atoms are present in the molecule of the first cyclic ether listed in Table 2, while one oxygen atom is replaced by one sulfur atom in the molecule of the second one. The following observations can be made on the thermodynamic quantities of reaction of these ligands with Ag, Tl(I), Pb. (*a*) The oxygen → sulfur replacement in the ligand molecule makes the covalent part of ΔG^x more negative. The decrease of ΔG^x_{non} is fairly limited for Pb and Tl(I), while it is greater for Ag. More precisely, the values of $\Delta\Delta G^x_{non}$ are −5.3 kJ mol^{-1} for Pb, −10.3 kJ mol^{-1} for Tl(I), and −24.9 kJ mol^{-1} for Ag. (*b*) The same sequence indicated at point (*a*) for $\Delta\Delta G^x_{non}$ is obtained when these metals are ordered following the increasing "soft" character: Pb < Tl(I) < Ag (24). (*c*) $\Delta\Delta G^x_{el}$ for the oxygen → sulfur replacement does not follow the above indicated sequence. The observations at points (*a*), (*b*), and (*c*) appear in accord

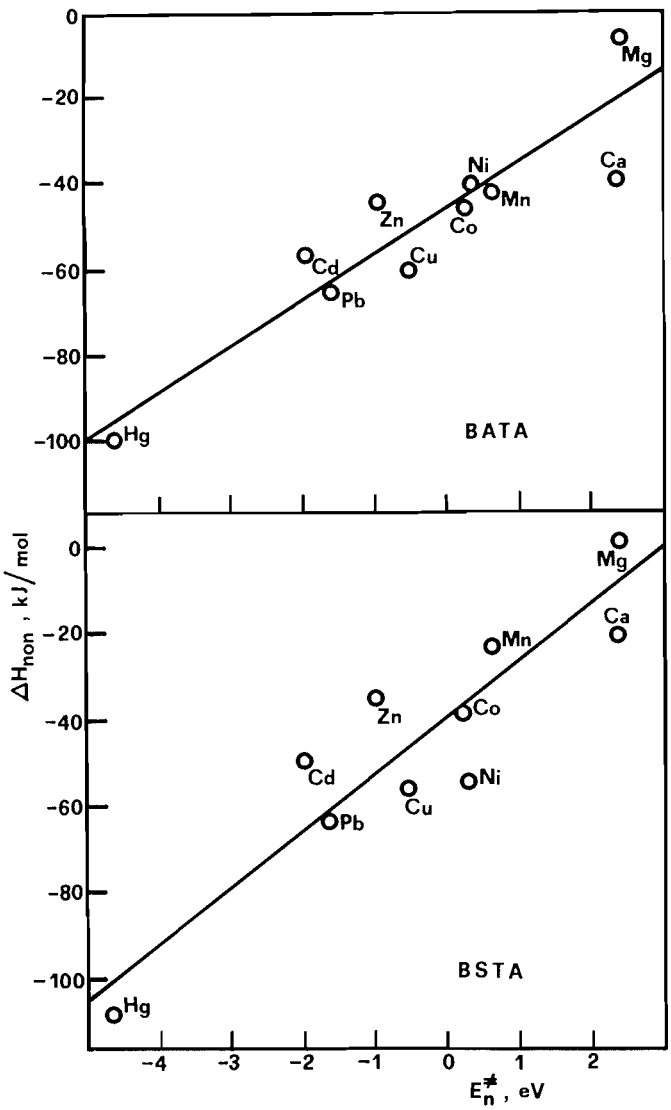

FIG. 1. Relationship between the nonelectrostatic contribution of enthalpy, ΔH_{non}, and the softness and hardness of metal ions, $E_n^{\neq}$ (24), for the complex formation reaction with BATA (above) and with BSTA (below) in aqueous solution.

with the nature and strength of the bonds which are probably formed between these metals and the sulfur atom. Similar considerations can be made also for ΔH_{el} and ΔH_{non}.

The ΔH_{el} and ΔH_{non} values for the bivalent metals listed in Table 2 with 2,2′-oxybis(ethyliminodiacetate) (BATA) and 2,2′-thiobis(ethyliminodiacetate) (BSTA) (23) suggest the following remarks. ΔH_{el} is almost constant; small endothermic deviations are only observed for smaller cations (Mg, Ni) and exothermic deviations for those with greater dimensions (Ca, Pb, Hg), in accord with different solvent-destructuring processes during the association. ΔH_{non}, on the other hand, becomes more negative with increasing softness of the metal ion, both in the case of BATA and of BSTA. An inversion is observed between ΔH_{non} for BATA (less negative) and for BSTA (more negative) in the case of Hg(II), which has the greatest soft character among the metal ions listed in Table 2. For a more significant examination of the ΔH_{non} dependence on softness of metal ions, the quantity $E_n^{\neq}$ should be considered. It was first introduced by Klopman (24) as a measure of hardness and softness of a metal ion in aqueous solution. A soft metal is characterized by a large negative value in $E_n^{\neq}$ and vice versa. Plots of ΔH_{non} vs. $E_n^{\neq}$ are reported in Fig. 1 for the association of BATA and BSTA with the bivalent metals of Table 2. Two straight lines are obtained by the least square method, with a slope of 10 and 13 for BATA and BSTA, respectively. A straight line with a slope of 10 (the same as for BATA) had been obtained previously for bivalent metals with EDTA (9). Taking into account that in metal complexes of BATA and BSTA both ethereal oxygen and thioethereal sulfur seem to form bonds with the cation (25), the conclusion can be drawn that the presence of an ethereal oxygen bound to the metal (as in the case of BATA) does not change (in comparison with EDTA) the trend of the ΔH_{non} values, while a considerable variation is caused by the sulfur atom of BSTA. If the electrostatic nature of an oxygen–metal bond and the covalent nature of a sulfur – soft metal bond are taken into account, the above conclusion is in agreement with the definition given for ΔH_{non}.

In conclusion, the present discussion shows that the calculation method of electrostatic and nonelectrostatic parts of thermodynamic quantities gives results which seem in satisfactory agreement with the nature and the course of the reactions examined. In particular, this method seems useful in clarifying phenomena which are implicit in conventional thermodynamic quantities but not immediately deducible from them.

Electrostatic and nonelectrostatic, conventional and unitary thermodynamic quantities of reaction. II. Proton–ligand and metal–ligand reactions in mixed solvents

ROBERTO ARUGA
Department of Analytical Chemistry, University of Turin, via Giuria 5, 10125 Turin, Italy

Received July 25, 1985

ROBERTO ARUGA. Can. J. Chem. **64**, 785 (1986).

A calculation method of the electrostatic and the nonelectrostatic parts of thermodynamic quantities of reaction, previously proposed and applied to association reactions in aqueous medium, is applied, in the present work, to reactions in mixed solvents. The aim of the present treatment is to clarify the importance of the various factors (dependent and independent of the dielectric constant) through which the solvent affects complex stability. The method is applied to ΔG^0, ΔH^0, and ΔS^0 data of literature for proton–ligand and metal–ligand reactions in several water–methanol, water–ethanol, and water–dioxane mixtures. The conclusions of the present study seem to confirm a leading role of solvation equilibria in determining different stabilities of complex in different solvents, while a minor role is assigned to the dielectric properties of the solvent.

ROBERTO ARUGA. Can. J. Chem. **64**, 785 (1986).

Dans ce travail, on applique à des réactions dans des solvants mixtes, une méthode de calcul des portions électrostatiques et non-électrostatiques des quantités thermodynamiques de réactions, qui avait été proposée antérieurement et qui avait été appliquée à des réactions d'association dans des milieux aqueux. Le but du présent travail est de clarifier l'importance de divers facteurs (qui dépendent et qui sont indépendants de la constante diélectrique) par le biais desquels les effets de solvants affectent la stabilité des complexes. On applique la méthode aux données de ΔG^0, ΔH^0 et ΔS^0 trouvées dans la littérature pour des réactions proton–ligand et métal–ligand dans plusieurs mélanges de méthanol–eau, éthanol–eau et eau–dioxanne. Les conclusions de nos études semblent confirmer le rôle prépondérant de l'équilibre de solvatation dans la détermination des différents stabilitées des complexes dans divers solvants alors que les propriétés diélectriques du solvant ne joueraient qu'un rôle mineur.

[Traduit par la revue]

Introduction

The study of proton–ligand and metal–ligand equilibria, similarly to what took place in the study of aqueous media, passed through two successive phases also in the case of mixed and nonaqueous solvents (1). The former phase was, in general, characterized by the determination of stability data, while the latter saw the evaluation of the enthalpy and entropy contributions of ΔG^0.

Two principal facts take place passing from water to mixed or nonaqueous solvents. Firstly, a decrease is observed in the dielectric constant, at least for the most common organic solvents. Secondly, a general increase is observed in the stability of the reaction products, mainly in the case of associations between electrically charged particles (i.e., heteroelectric associations). From the above observations the conclusion was drawn that, for a metal–ligand or a proton–ligand system in different solvents (being equal the other experimental conditions), the dielectric constant of the medium has a determining influence on complex stability.

Afterwards, when sufficient amounts of enthalpy and entropy data were available for reactions in solvents other than water, this conclusion was remarkably modified. It was observed, for example, that the apparently simple and regular trend of ΔG^0 for various values of the dielectric constant was a consequence of more complex and not easily explainable variations in ΔH^0 and ΔS^0 (2). Other papers (3, 4) pointed out that not only the dielectric constant but solute–solvent direct interactions too, may have an important role in determining complex stability. In other words, the solvent may exert its influence in two ways, both through electrostatic (or environmental) factors and through short-range factors, the importance of which varies and is not always well understood.

To clarify this problem it may be of interest to extend, to equilibria in solvents other than water, the Gurney method of calculation of the electrostatic (or external) and nonelectrostatic (or internal) contributions of thermodynamic quantities of reaction. This method was previously used for reactions in aqueous medium (see ref. 1 and the relative bibliography).

Although enthalpy and entropy data of literature for complex-formation reactions in solvents other than water are not yet numerous (5), some accurate works are available at present on the subject. They treat proton–ligand as well as metal–ligand equilibria in aqueous–organic mixed solvents with variable water–cosolvent ratios (see Table 1).

Treatment of the experimental data

The concept of the electrostatic and nonelectrostatic parts of thermodynamic quantities of reaction, as well as the concept of the cratic and unitary contributions, were first introduced by Gurney (6). The electrostatic part represents long-range interactions, which are affected by the nature of the solvent and by the temperature. Therefore, it is determined by solute–solute electrostatic bonds and by long-range solute–solvent interactions (i.e., solvent-structuring and destructuring processes). The nonelectrostatic part is determined by all short-range factors, independent of the dielectric constant and temperature. They consist mainly of solute–solute covalent bonds and of solute–solvent contact interactions (i.e., solvation interactions) (7). Some notes about the use of this method in solvents other than water are reported below. Fuller details, together with general expressions for the calculation of the above partial quantities, are reported in the preceding paper of this series (1).

As concerns the present calculation method for equilibria in mixed solvents, the following observations must be taken into account. (*a*) For a correct comparison of thermodynamic parameters in different solvents the use of the unitary part of these quantities is recommended by some authors. The same applies when the electrostatic part of a quantity is compared with the corresponding nonelectrostatic part (1). Comparisons between conventional quantities are valid in the case of

[a]For α-alaninate with Cu and Ni the second step of association is also considered. Therefore, A^{n+} indicates the 1:1 complex species too in these cases (see the table, first column).

[b]Gibbs function and enthalpy are expressed in kJ mol^{-1}; entropy in J K^{-1} mol^{-1}. For the meaning of indexes and corresponding quantities see ref. 1.

enthalpy, as its cratic part is zero ($\Delta H^0 = \Delta H^x$). (*b*) θ (see Table 1 of ref. 1) is a temperature characteristic of each solvent or solvent mixture. It is calculated by means of the empirical expression $D = D_0 e^{-T/\theta}$ (where D is the dielectric constant of the solvent and D_0 is a constant), knowing the values of D over a sufficiently wide range of temperatures. For the water–methanol, water–ethanol, and water–dioxane mixtures investigated in the present work the values of θ have been obtained from dielectric constant data published in previous papers (8, 9).

Results and discussion

The data of the literature for proton–ligand and metal–ligand equilibria in mixed solvents examined in the present work are listed in Table 1.

Besides the conventional thermodynamic parameters, the corresponding electrostatic, nonelectrostatic, and unitary parts have also been collected in the table. It must be pointed out that enthalpy values determined only by direct calorimetry were considered. Moreover, data for reactions in mixed solvents have been preferred to those in pure nonaqueous solvents and only the papers which report results for numerous water–cosolvent ratios have been considered. In fact the trend of thermodynamic quantities as a function of solvent composition is often complex, so that a sufficiently high number of mixtures is necessary for an accurate investigation.

The experimental data of Table 1 for proton, copper, and nickel associations with α-alaninate in water–dioxane and in water–methanol mixtures are those of the extensive work of Gergely and Kiss (10). The data in Table 1 suggest the following

observations on the protonation reaction of α-alaninate. In the first place, ΔG^x for the protonation of the amino group is about constant for increasing quantities of dioxane in the mixture, while it becomes a little less negative for increasing quantities of methanol. For the protonation of the carboxylate group, on the other hand, ΔG^x becomes much more favourable with increasing quantities of both the organic cosolvents. The different trends of Gibbs function for $—COO^-$ and $—NH_2$ were justified in the usual way (10), taking into account the decrease in the dielectric constant for increasing quantities of the organic cosolvent, and concluding that the protonation of $—NH_2$ should be less affected by this fact compared to the protonation of $—COO^-$, the former (at least partially) being isoelectric, the latter hetereoelectric. In reality, the values of ΔG^x_{el} for carboxylate indicate that factors depending on the dielectric constant have no determinant influence on the trend of ΔG^x of protonation. ΔG^x_{el} in fact shows an opposite trend with respect to ΔG^x over a wide range of solvent compositions, while the determinant sequence is that of ΔG^x_{non}.

In the second place, ΔG^x_{non} of protonation of the carboxylate group is very different than for the amino group (i.e., it is more favourable for $—NH_2$ than for $—COO^-$), while ΔG^x_{el} is about equal for these two groups. The conclusion should be drawn from these data that it is incorrect to consider protonation of $—NH_2$ as isoelectric, since in this case ΔG^x_{el} for $—NH_2$ should be of much smaller magnitude than for $—COO^-$. This conclusion is in complete agreement with a previous hypothesis (10) according to which an intramolecular hydrogen bond may develop in α-alaninate, via a water molecule between the carboxylate and amino groups. Because of the resulting electron shift, the protonation of the amino group should not be isoelectric.

As already mentioned above, an opposite trend of ΔG^x_{el} with respect to ΔG^x is observed for water-prevailing solvent compositions, while in the range of organic cosolvent prevalence (although data are less numerous in this case) ΔG^x_{el} shows the same trend as ΔG^x. More precisely, a minimum in stability is observed for ΔG^x_{el} at approximately 40–60 wt% of water. This fact is observed in several cases, as results from successive data of Table 1.

Other data of the table concern proton–acetate (11) and proton–phenate (12) associations, over a wide range of water–methanol mixtures. The results for these equilibria confirm the preceding observations for the protonation of the $—COO^-$ group of α-alanine. In this case, too, ΔG^x_{el} shows minimum stability at 40–60 wt% of water. It must also be noted that ΔH^0 and ΔS^0 for the protonation of phenate show maxima (i.e., minimal exothermicity for ΔH^0) at about 10% water. This does not appear from ΔG^0 because of the compensation of the enthalpy and entropy maxima. The present results show that the cause of such behavior of ΔH^0 and ΔS^0 is in the corresponding electrostatic part.

The data of copper and nickel with α-alaninate (Table 1) show the usual increase in complex stability with increasing amounts of organic cosolvent, both in the case of dioxane and of methanol. In this case too, calculation of the electrostatic and the nonelectrostatic contributions of ΔG^x indicates the latter as the determining factor of different stabilities in different solvents, for both the first and second step of association.

To investigate ion-pairing equilibria the data of a previous paper may be examined (13), concerning copper–chloride associations in several water–methanol and water–ethanol mixtures. ΔG^0 (and ΔG^x), as usual, becomes more negative with increasing concentrations of the organic cosolvent, for both methanol and ethanol mixtures (Table 1). Nevertheless, two new facts seem present in this case. Firstly, ΔG^x_{non} does not seem to be determinant on the ΔG^x sequence in different solvents, both in the case of methanol and of ethanol. Secondly, the magnitude of each ΔG^x value is determined by ΔG^x_{el}, while ΔG^x_{non} is in general not distant from zero and endothermic.

Within the limits of validity of the present theory, the following general conclusions can be drawn.

(*a*) The present results demonstrate that, in most cases, the trend of ΔG^x in different solvents is determined by nonelectrostatic, short-range factors (ΔG^x_{non}), while factors depending on the dielectric constant of the solvent (ΔG^x_{el}) show different trends, and do not appear to be determinant on stabilities. This conclusion is in accord with the results of recent works (3, 4).

(*b*) Taking the two main short-range factors into consideration (see "Treatment of the experimental data" and ref. 7), it may be observed that with a change of solvent, solute–solute covalent interactions are the same, while solute–solvent direct interactions (i.e., solvation interactions) are different. Consequently, the influence of the solvent on complex stability should be determined by the latter factor. This confirms the concept that a complex-formation equilibrium in a solvent, must be considered as a competition (with a consequent exchange reaction) between the ligand in a strict sense and the solvent–ligand (3, 4, 14).

(*c*) As concerns the role of the solvent in metal–ligand equilibria, outer-sphere associations should be considered as a particular case. It is interesting to consider again, in this connection, the data of copper with chloride, which appeared unusual with respect to the other data of Table 1. A prevailing outer-sphere character was suggested for these pairs (13). This fact should limit covalent solute–solute interactions and desolvation processes, i.e., internal processes taken as a whole. The small magnitude of ΔG^x_{non} may be justified in this way, as well as the fact that ΔG^x_{non} in this case is not determinant on the order of ΔG^x for different solvents.
