These findings show that actual proton transfers from fluoroalcohols certainly are more complex than the model we utilize in our computations. However, our reasoning concerns the pure proton-transfer steps of the reactions, and the stable complexes could be considered as the starting species for these steps. All the systems gave such complexes with the O—H pointing more or less away from the C—C bond (see Fig. 1).

Our aim has been to investigate a relatively simple system where a perturbation some distance away from the reaction centre could be introduced stepwise. This was done in such a manner that the overall equilibrium of the reaction could be varied from balanced to more and more unbalanced.

Energy relationships

The computations refer to the gas phase since no solvent molecules are included. A simplified picture of the energy profiles for all the systems calculated in this investigation is given in Figs. 4 and 5.

The supply of experimental data pertinent to the present systems is not overwhelming. However, some gas phase measurements have been made on ethanol and β-fluoro-substituted ethanols (3). From these measurements the ΔH^0 values for the two last reactions in Fig. 4 can be calculated to be −9.1 kcal/mol and −11.7 kcal/mol, respectively. The corresponding ΔE values (−19.9 kcal/mol and −32.7 kcal/mol) obtained in the present investigation are thus too large in both cases. In order to see whether this is a result of computational difficulties connected with the anions, the experimental and the calculated heats of formation (Table 1) for the molecules treated in the present investigation have to be compared.

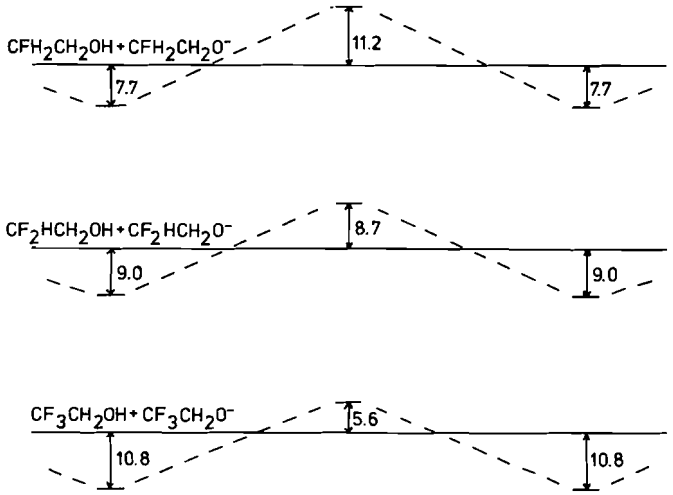

FIG. 5. Energy profiles for some thermoneutral proton transfers calculated by MNDO. Energy in kcal/mol.

[c]Estimated values, see ref. 3.

As can be seen in Table 1, the calculated value for ethoxide ion is in better agreement with the experimental value than is the value for ethanol. The reverse seems to be true for the alcohols substituted with fluorine atoms in the β-position. However, a general trend is not easily discernible.

The energies of the ion–molecule complexes could be compared with experimental data in one case. In a recent paper (9) dealing with anion–alcohol hydrogen bond strengths in the gas phase, the stability of EtO^-—HOEt compared to EtO^- + HOEt is determined to be −20.6 kcal/mol. The ion–molecule complex is thus far more stable than indicated by the present calculation. Comparable data for the β-fluoro-substituted reactions are not accessible.

From Fig. 4 it can be seen, in a qualitative way, that the activation barrier decreases as the reaction becomes more exoenergetic and, from the other direction of reaction, the barrier grows higher the more endoenergetic the calculated reaction becomes. To test if this qualitatively recognisable pattern could be tied to a quantitative relationship, we plotted the calculated barrier heights (calculated from ion–molecule complexes) against the energies of reaction (Fig. 6).

A number of equations of different mathematical form have been considered in the examination of a possible relationship between the activation energy $\Delta E^{\ddagger}$ and the energy of reaction ΔE (10). Among those, the Marcus equation is the one most used (see ref. 10 for references).

According to that:

$$\Delta E^{\ddagger} = \Delta E_0^{\ddagger} + \Delta E/2 + [\Delta E^2/16\Delta E_0^{\ddagger}]$$

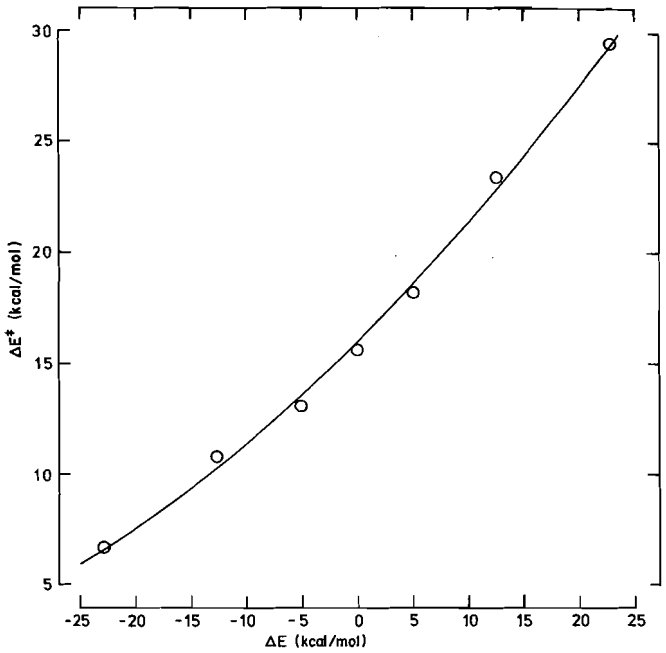

FIG. 6. Plot of $\Delta E^{\ddagger}$ versus ΔE for the MNDO calculated proton transfers in forward and reverse direction of reaction. The solid curve is a nonlinear least-squares fit of the points to the Marcus equation with $\Delta E_0^{\ddagger}$ = 15.96 kcal/mol.

where $\Delta E_0^{\ddagger}$ is the intrinsic barrier, i.e., the formal barrier when $\Delta E = 0$. The fulldrawn curve in Fig. 6 represents the Marcus expression with $\Delta E_0^{\ddagger}$ = 15.96 kcal/mol as determined from a nonlinear least-squares fit of ΔE and $\Delta E^{\ddagger}$ to the Marcus equation, treating $\Delta E_0^{\ddagger}$ as an adjustable parameter.

The Marcus relation could be used to find predictions for the barrier heights of the unsymmetrical reactions in an indirect way by using the additivity assumption:

$$\Delta E_0^{\ddagger} = (\Delta E_{AA}^{\ddagger} + \Delta E_{CC}^{\ddagger})/2$$

where $\Delta E_{AA}^{\ddagger}$ and $\Delta E_{CC}^{\ddagger}$ are the activation energies for the identity reactions (10, 11). The activation energies so calculated are included in Table 2 under the heading $\Delta E_{(Marcus)}^{\ddagger}$ and are seen to deviate only slightly from the directly computed values under the heading $\Delta E^{\ddagger}$. The significance of the found conformity with the Marcus equation should not be overestimated. However, it is gratifying to find that the MNDO method, as well as other SCF (self-consistent field) methods (11), give results which could be interpreted using this formalism.

The barriers for our symmetric reactions all fall in the region of 15–19 kcal/mol (Table 3). The term in the Marcus formula responsible for nonlinearity, i.e. $\Delta E^2/16\Delta E_0^{\ddagger}$, will thus be small compared to the terms corresponding to the kinetic ($\Delta E_0^{\ddagger}$) and thermodynamic ($\Delta E/2$) contributions to $\Delta E^{\ddagger}$. The very slight curvature in Fig. 6 is an indication of this.

Isotope effects

The calculated primary kinetic deuterium isotope effects are listed in Tables 3 and 4.

In Table 3 the symmetric reactions are given and the semi-classical isotopic rate constant ratios for these systems are all between 8.04 and 8.44, i.e., of rather normal magnitude.

The tunneling factors are calculated from the absolute values of the imaginary frequencies and the barrier heights above the most energetic complex. For the symmetric systems the hydrogen tunneling factors Q_{tH} are all very high, due to the high

imaginary frequencies (1409i–1447i cm^{-1}). The deuterium tunneling factors Q_{tD} are more reasonable (imaginary frequencies in the range 1035i–1060i cm^{-1}). However, the ratios of tunneling factors Q_{tH}/Q_{tH} give an unrealistically large contribution to the overall isotope effects for all of the symmetric systems. The reason for this will be discussed below.

Table 4 lists the unsymmetrical reactions. For these the tunnel correction factor for the direction of highest activation is taken from the direction of least activation, since no tunneling can occur from a lower level than the most energetic one of the reactants and products (*7c*).

Also here the semiclassical effects come out as expected and the tunnel effect ratios are of a more realistic magnitude, possibly with the exception of the two first entries due to high imaginary frequencies for the hydrogen cases.

As the reaction becomes more exoenergetic the barrier in the forward direction decreases and the decomposition frequency drops, signifying a broader barrier. The reason for this is not easily visualized in a complicated case like the present one. However, it could be illustrated in a qualitative way using a simple truncated parabola model for the activation barrier (12).

These facts should lead to a weaker semiclassical isotope effect as well as a smaller tunnel correction factor (*7c*). The trend in a series of progressively more perturbed reactions (0, 1, 2, 3 fluorine atoms) seems to come out as expected for increasingly unsymmetric reactions. The same trend was found in ref. 2 even though the proton transfers investigated there were more disparate than the present ones.

The calculated isotopic rate constant ratios may also be subjected to an analysis according to an expression derived from the Marcus relation (13). A nonlinear least-squares fit of

$$\ln (k_H/k_D) = \ln (k_H/k_D)_{max}[1 - (\Delta E/4\Delta E^{\ddagger}_0)^2]$$

to the semiclassical isotopic rate constant ratios and reaction energies for all the unsymmetric reactions in forward and reverse direction of reaction was carried out. With $(k_H/k_D)_{max}$ and $\Delta E^{\ddagger}_0$ treated as adjustable parameters, an acceptable fit was reached when $(k_H/k_D)_{max} = 8.8$ and $\Delta E^{\ddagger}_0 = 10.7$. The same procedure without the two points for the trifluorinated species yielded $(k_H/k_D)_{max} = 8.3$ and $\Delta E^{\ddagger}_0 = 15.9$. As can be seen from Fig. 7 this latter procedure gives a better fit to the remaining four points. The values are also in better agreement with the ones in Table 3. The reaction involving the trifluorinated species represents a relatively larger perturbation than the other reactions and this may cause the relation to break down.

The reason for the unrealistic outcome of the ratio of tunneling factors probably stems from MNDO's known weakness to overestimate frequencies (14, 2) (a weakness shared with simple *ab initio* calculations also, ref. 15). Another contribution to the large tunneling factors may be too high $\Delta E^{\ddagger}$ values calculated by the MNDO method (16). The tunnel factors for the hydrogen species of the symmetric reactions are especially

TABLE 5. Tunnel correction factors calculated for downscaled imaginary frequencies

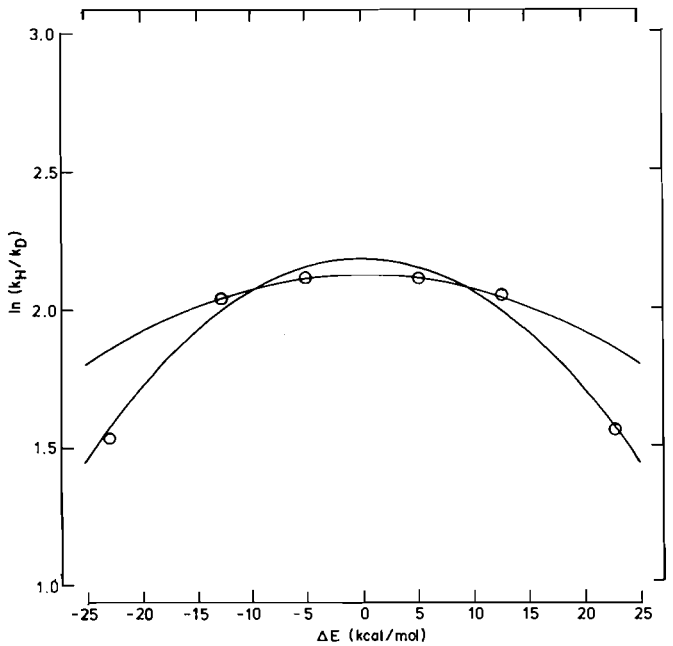

FIG. 7. Plot of ln (k_H/k_D) versus ΔE for the calculated semiclassical isotopic rate constant ratios. Included are two curves representing nonlinear least-squares fits of all six points and of the four points excluding the trifluorinated species.

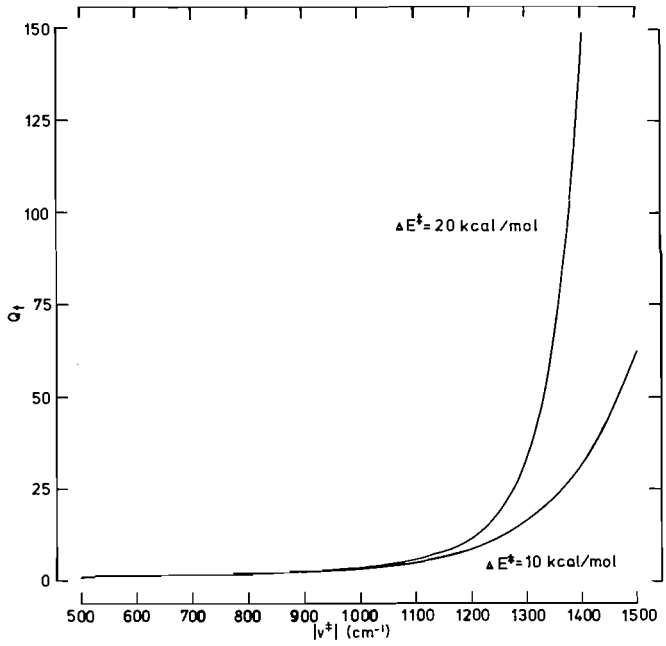

FIG. 8. The shape of the tunnel correction factor function for two barrier heights.

large. When frequencies higher than ca. 1000i cm^{-1} are involved and the barrier heights are of reasonable magnitude (<25 kcal/mol), the tunnel correction factor starts to increase rather rapidly so that an overestimated frequency leads to a still more overestimated tunnel factor. This tendency is amplified the higher the frequency for a given barrier height.

For *ab initio* calculations it has been found that an empirical scaling factor for force constants should be introduced in order to obtain agreement with experiment (17). As a test on the effect of scaling of the frequencies in the present case, we have calculated tunnel correction factors with the absolute values of the imaginary frequencies scaled down by 10% (a rough estimation of the mean value of the deviation for all types of vibrations from experimentally determined values according to ref. 14), see Table 5. The scaling is seen to have most effect on reactions with high imaginary frequencies. In the first row Q_{tH}/Q_{tD} is 7.70 compared to 24.8 without scaling (Table 3), and in the last row the corresponding value is 1.06 compared to 1.07 (Table 4).

Scaling of the frequencies might also influence the semiclassical isotope effect. As an example we calculated the semiclassical isotope effect for the proton transfer from trifluoroethanol to trifluoroethoxide with all the frequencies (both in the reactant complex and transition state) reduced by 10%. The effect turned out to be a reduction of the calculated $(k_H/k_D)_s$ from 8.04 to 6.68, which is a very slight change.

Conclusions

In some aspects the calculation of proton transfer reactions by the MNDO method turns out to give results that qualitatively agree well with notions commonly used by physical organic chemists. We now have confirmed that a quantitative analysis (according to the Marcus equation) of some MNDO calculated proton transfers turns out in a reasonable way.

The results of our isotope effect calculations, however, are rather unexpected, at least if the tunnel corrections are included. The reason for this stems from MNDO's known overestimation of frequencies and from the overestimation of $\Delta E^{\ddagger}$. The tunnel correction function turns out to be especially sensitive to changes in the frequencies in the region of interest in this investigation.

In order to make the MNDO method usable for quantitative isotope effect calculations, either the program should be modified to give frequencies very close to experimental ones, or a separate function for correction of frequencies should be determined and applied to the MNDO-calculated frequencies.

Received September 17, 1985

This paper is dedicated to Professor Arthur N. Bourns

CLIFFORD A. BUNTON and ANGELA CUENCA. Can. J. Chem. **64**, 1179 (1986).

Cationic micelles of cetyltrimethylammonium chloride and bromide (CTACl and CTABr) speed attack of water upon the 2,2′,4,4′,4″-pentamethoxytrityl cation by a factor of ca. 5. The first-order rate constant in water is 5.51 s^{-1} at 25.0°C. Anionic micelles of sodium dodecyl sulfate (SDS) have little effect on this reaction, but they strongly inhibit attack of OH^-. In water, second-order rate constants for attack of OH^-, CN^-, and N_3^- are, respectively, 235, 177, and 2.8 × 10^5 M^{-1} s^{-1}. Rate constants of reaction in CTACl go through maxima with increasing [surfactant] and analysis of the data shows that second-order rate constants at the micellar surface are similar to those in water.

CLIFFORD A. BUNTON et ANGELA CUENCA. Can. J. Chem. **64**, 1179 (1986).

L'addition de micelles cationiques des chlorure ou bromure de cétyltriméthylammonium (ClCTA et BrCTA) augmente la vitesse d'attaque de l'eau sur le cation pentaméthoxy-2,2′,4,4′,4″ trityle par un facteur d'environ 5. Dans l'eau, à 25,0°C, la constante de vitesse du premier ordre est égale à 5,51 s^{-1}. Les micelles anioniques du dodécylsulfate de sodium (DSS) n'ont que peu d'effet sur cette réaction; toutefois, elles inhibent fortement l'attaque par OH^-. Dans l'eau, les constantes de vitesse pour les attaques par OH^-, CN^- et N_3^- sont respectivement 235, 177 et 2,8 × 10^5 M^{-1} s^{-1}. Les constantes de vitesse pour les réactions du ClCTA passent par un maximum lorsqu'on augmente la quantité d'agent de surface et l'analyse des données démontre que les constantes du deuxième ordre à la surface micellaire sont semblables à celles dans l'eau.

[Traduit par la revue]

Introduction

Aqueous ionic micelles speed bimolecular reactions of counterions by bringing substrate and ionic reagent together in the small volume of the micelles (1–6). The dependence of rate on [surfactant] can be treated quantitatively assuming that reactants are distributed between aqueous and micellar pseudophases, which are treated as distinct reaction media. Second-order rate constants can be calculated for reaction in the micellar pseudophases, and for many bimolecular ionic reactions these second-order rate constants are similar to those in water. Thus the micellar rate enhancements are due largely to concentration of reactants in the micellar pseudophase.

Reactions of dinitrohaloarenes with azide ion are major exceptions to this generalization, and second-order rate constants in cationic micelles are greater than those in water by factors of 10^2–10^3 (7). We found similar large micellar effects for reactions of azide ion with hydrophobic *N*-alkyl-2-bromopyridinium ions. However, rate constants of deacylation and S_N2 displacements by azide ion are similar in micellar and aqueous pseudophases (7), so that these unusual rate effects are not simply characteristic of azide ion as a nucleophile.

Azide ion is very reactive towards carbocations, either preformed (8, 9) or generated in S_N1 solvolyses (10, 11). The present investigation had the aim of comparing second-order rate constants for reaction of azide ion with a carbocation in water and micelles. Micellar effects upon nucleophilic addition to triarylmethyl dye cations have been well studied (12, 13), but we could not use such cations as Malachite Green or Crystal Violet because of the unfavorable equilibria with azide ion (14). The tri-*p*-anisylmethyl cation is also unsatisfactory, because it binds weakly to cationic micelles (13) and even in water the reaction is so fast that it can only be followed in very dilute azide ion (9). However, the 2,2′,4,4′,4″-pentamethoxytrityl cation, **1**, reacts at a convenient rate with azide ion and other nucleophiles (Scheme 1).

The surfactants were cetyltrimethylammonium chloride and bromide (CTACl and CTABr). The chloride was generally used because of the relatively low solubility of CTABr. Reactions of water and OH^- were also followed in solutions of sodium dodecyl sulfate (SDS).

Results

Rate constants for reactions of **1** in the absence of surfactants are given in Table 1. Reaction with N_3^- does not go to completion in water because the alkyl azide dissociates, c.f. ref. 14. Reaction goes to completion in aqueous MeCN, and second-order rate constants are 10^{-5} k_2 = 2.6, 2.4, 2.1, and 1.7 M^{-1} s^{-1} in 90, 80, 70, and 60 wt% H_2O, respectively, and the reaction is first order in [N_3^-]. Linear extrapolation of k_2 against mole fraction of H_2O or log k_2 against Y (15) gave k_2 = 2.8 × 10^5 M^{-1} s^{-1}.

The decrease of k_2 with decrease of water content was unexpected for a reaction between oppositely charged anions (10, 16), but reactions of **1** with OH^- and CN^- are also slowed by addition of MeCN to H_2O.

Micellar effects upon the spontaneous reactions are shown in Tables 2 and 3, and for reactions of anions are shown in Fig. 1.

Discussion

Micellar effects upon spontaneous reactions can be analyzed using eq. [1] as applied to the reactions of Scheme 2 (1–7, 17), where water is the nucleophile, Nu.

Scheme 2 gives:

$$[1] \quad k_\psi = \frac{k'_W + k'_M K_s([D] - cmc)}{1 + K_s([D] - cmc)}$$

where k'_W and k'_M are first-order rate constants in aqueous and micellar pseudophases respectively, K_s is the substrate binding

[a]At 25.0°C with 10^{-5} M **1**; 0.21 M NaOH was mixed with 0.01 M HCl. In absence of SDS $k_\psi = 29$ s^{-1}. Values in parentheses are for the water reaction using NaOAc.

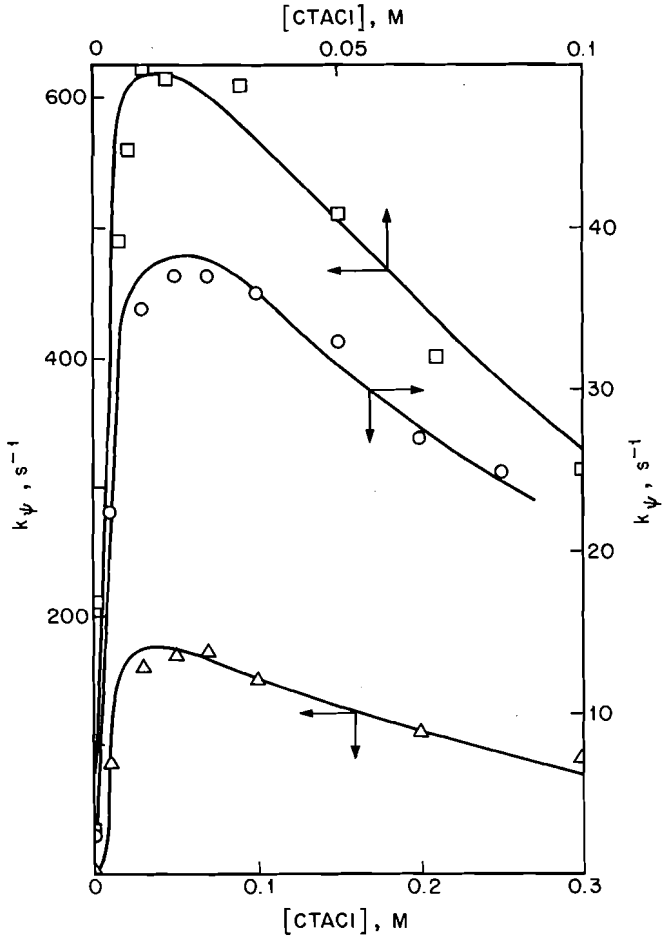

FIG. 1. Reactions of 2,2′,4,4′,4″-pentamethoxy trityl cation with nucleophilic anions in CTACl. ○, 0.01 M NaOH; △, 0.01 M NaCN; □, 10^{-4} M NaN_3. The curves are predicted from the parameters in Table 4 and eqs. [1]–[5].

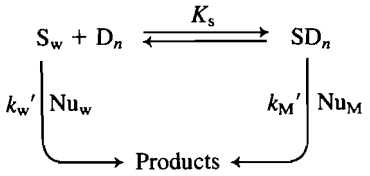
constant, written in terms of micellized surfactant, [D] − cmc, where D is total surfactant and cmc is the critical micelle concentration.

The value of K_s is assumed to be independent of [surfactant] and [salt]. This assumption is reasonably satisfactory for dilute surfactant and salt, but K_s is expected to increase with increasing [salt] (13, 18).

Values of k'_M and K_s (eq. [1]) can be calculated by simulation or by rearranging eq. [1] into a reciprocal form. We calculated values of K_s and k'_M of 7 M^{-1} and 27 s^{-1}, respectively, for reaction in CTACl using the reciprocal form (17) and the fit is illustrated in Table 2.



SCHEME 2

The kinetic data were not fitted for reaction in CTABr, because of the limited concentration range. However, reaction is slightly faster in CTABr than in CTACl (Table 2) probably because ion pairing slightly increases substrate binding, and Br^- should be more effective than Cl^- in this regard (13, 18). Consistently, addition of 0.5 *M* NaCl to CTACl also modestly speeds reaction (Table 2).

Rates of bimolecular attack by water are generally unaffected or slightly reduced by ionic micelles, and micelles of SDS have no effect on rates of water addition to **1** (Table 3) or to other carbocations (13). Consistently, bimolecular water additions to nonionic substrates are faster in cationic than in anionic micelles, although generally both give overall inhibition (19–21).

It has been pointed out elsewhere that spontaneous hydrolyses in which bond making predominates are faster in cationic than in anionic molecules, whereas the opposite is true when bond breaking predominates (19). For example, in spontaneous hydrolyses of 4-nitrophenyl chloroformate and 3,5-dinitrobenzoyl chloride, where bond making predominates, reaction in cationic micelles is faster than in water, whereas reaction is slower in anionic micelles (19, 20). In these reactions there is a partial compensation between bond making and breaking, whereas only bond making at the reaction center is involved in water addition to **1**, and the rate enhancement by micellized CTACl is larger than those with the acid chlorides (19, 20). Thus, the results for water addition to **1** (Table 2 and 3) support the generalization that the water addition step is assisted by cationic micelles.

Reaction occurs in the water-rich region at the micellar surface (1–7, 22) and involves a transfer of positive charge from the reaction center, in the micelle, to water molecules adjacent to its surface. This transfer should be more favorable in a cationic than in an anionic micelle. The overall effect of the micelle will depend upon this "charge effect" and also upon effects due to a lowered polarity at the micellar surface to that of water.[2] Micelles may lower the activity of bound water, but the effects are small at most, and there is no evidence for lowered nucleophilicity (20). These "solvent" and "polarity" effects of the micelle are probably not large and, in the absence of surfactant organic solvents (e.g. MeCN), inhibit water addition to cation **1**.[3]

Quantitative analysis of micellar rate enhancements for reactions of ionic nucleophiles, Nu^-, involves modification of eq. [1]. The first-order rate constants are written as:

$$[2] \quad k_w' = k_W[Nu_W^-]$$

$$[3] \quad k_M' = k_M m_{Nu}^s = k_M[Nu_M^-]/([D] - cmc)$$

where m_{Nu}^s is the mole ratio of micellar-bound nucleophile to micellized surfactant (1, 3). Reaction with water is sufficiently slow to be neglected.

These equations give:

$$[4] \quad k_\psi = \frac{k_W[Nu_W^-] + k_M K_s[Nu_M^-]}{1 + K_s([D] - cmc)}$$

The competition between Nu^- and the inert counterion, X^-, is written as (1, 3, 6):

$$[5] \quad K_X^{Nu} = \frac{[Nu_W^-][X_M^-]}{[Nu_M^-][X_W^-]}$$

Values of K_{Cl}^{Nu} are known or can be estimated (1, 3–7, 24, 25) and, provided that the micellar fractional charge, α, is independent of [surfactant] and the nature or concentration of the ions, values of k_M (eq. [4]) can be calculated by computer simulation of the data. The procedure and assumptions in the treatment have been discussed (1, 3, 6, 25). We write binding of the carbocation, neglecting its charge–charge interaction with the micelle and the effect of added salts on this interaction, and to this extent we probably underestimate the extent of micellar binding. However, this approximation has not caused serious problems in micellar reactions of other ionic substrates in the presence of dilute salt (13, 25).

Values of k_M and K_s are given in Table 4. There is uncertainty in k_M, because reasonably good fits can be obtained with a range of values of k_M, K_s, and α. This problem has been discussed (1, 3), but the uncertainties in k_M do not affect our overall conclusions. In addition, k_ψ for reaction with N_3^- is close to the limit of the stopped-flow spectrophotometer.

The rate constants, k_W and k_M, cannot be compared directly because of the difference in dimensions, but k_M can be converted into k_2^m, $M^{-1}\,s^{-1}$, using eq. [6] (3, 13):

$$[6] \quad k_2^m = 0.14\, k_M$$

where 0.14 is the assumed molar volume (L) of the region at the micellar surface in which reaction takes place. Other estimates of the molar volume range up to ca. 0.37 L, which would give an approximately two-fold increase of k_2^m (2, 4–6).

Values of k_2^m/k_W are given in Table 4. Despite the uncertainties in k_2^m, the micellar rate enhancements are clearly due largely to increased reactant concentrations in the micelles. There seems to be a slight dependence of K_s upon the nucleophilic ion, which may be due to ion pairing assisting substrate binding. Second-order rate constants for reactions of OH^- and N_3^- are lower in micelles than in water, but that for reaction of CN^- appears to be higher. This behavior is not observed in other reactions of CN^- (25) and our tentative explanation is that it interacts preferentially by ion pairing with cation **1** in the micelle.

There is no unusual micellar effect upon reaction of azide ion (Table 4). Very large second-order rate constants in the micelles have been observed only for reactions of 2,4-dinitrochlorobenzene and naphthalene (7) and of *N*-alkyl-2-bromopyridinium ions. We have no simple explanation for this behavior, although second-order rate constants for several aromatic nucleophilic substitutions are slightly higher in micelles than in water, whereas for deacylations and dephosphorylations rate constants are often slightly lower in micelles than in water (1–7).

Aromatic substitution by azide ion is faster in cationic micelles than in water, but this result may be due to this reaction

[2] Mukerjee and co-workers have observed a dependence of micellar polarity, or effective dielectric constant, upon micellar charge (23).

[3] This solvent effect is opposite to that upon water addition to tri-*p*-anisylmethyl cation (16).

TABLE 4. Rate constants for reactions in cationic micelles[a]

Nucleophile	K_s, M	K^X_{Cl}	k^m_2 M^{-1} s^{-1}	k^m_2/k_W
H_2O	7		27[b]	5[b]
OH^-	7	3.5	33	0.15
CN^-	7	0.5	ca. 600	3
N_3^-	10	1.3	4×10^4	0.15

[a]In CTACl; calculated with $\alpha = 0.2$ and cmc $= 10^{-3}$ M.
[b]Rate constants for reactions in H_2O are in Table 1.

being unusually slow in water, rather than fast in micelles. Ritchie and Sawada (26) have compared nucleophilicities for several reactions in terms of the N_+ scale, which was initially based on rates of addition to preformed carbocations. They found that the scale applied reasonably well to aromatic nucleophilic substitution, except that azide ion was much less reactive than predicted from its N_+ value. Thus, unusual micellar effects in aromatic nucleophilic substitution may be due to azide ion being abnormally unreactive in the absence of micelles.

Anionic micelles suppress attack of OH^- upon **1**. The inhibition is observed with [SDS] much lower than its cmc of ca. 8×10^{-3} M (Table 3), suggesting that the cation induces formation of anionic aggregates that exclude OH^- (27). The value of k_ψ becomes constant at high [SDS] and is slightly lower than that for reaction with water. The differences are probably due to differences in [electrolyte] in the two reaction systems.

Ritchie *et al.* (28) found that 2,2′,2″,4,4′,4″-hexamethoxytrityl cation was unusually reactive towards H_2O, relative to such anions as OH^-, and that CN^- was more reactive than OH^-. These rate differences are unusual, and we observe qualitatively similar behavior in reactions of **1** in water (Table 1). The introduction of *o*-methoxy groups seems to be affecting relative reactivities towards nucleophiles and an effect of *o*-methoxy groups on the local structure of water has been suggested (28). The *ortho* groups could also affect reactivity of a carbocation by increasing the out-of-plane twisting of the aryl groups, which will reduce their electron-donating ability. There will then be steric effects upon attack of the nucleophile and hybridization at the reaction center will change from sp^2 towards sp^3. There is thus considerable interplay between steric and electronic effects, and *p*-methoxy groups very sharply retard attack of H_2O upon trityl cations. *o*-Methoxy groups have much less effect, although they have a larger effect upon the stability of the carbocation relative to that of the alcohol (9, 16, 28, 29). For example, the first-order rate constants for reactions of H_2O with the 4-methoxy trityl, tri-*p*-anisylmethyl, 2,2′,4,4′,4″-pentamethoxy trityl, and 2,2′,2″,4,4′,4″-hexamethoxy trityl cations are ca. 10^3, 12, 5.51, and 2.00 s^{-1}, respectively. But values of pK_{R+} are −3.4, +0.82, +2.02, and +3.80[4] (refs. 9, 16, 28, 29), respectively, and this sequence is consistent with electron release by both *ortho* and *para* methoxy groups stabilizing the cation, relative to the alcohol. Carbocation stability is not closely related to its reactivity towards water, which appears to be governed largely by electron release from the *para* methoxy groups.

Experimental

Materials

The preparation or purification of the surfactants has been described (13) and the cmc values agreed with those in the literature (30). 2,2′,4,4′,4″-Pentamethoxytriphenyl methanol was from Aldrich. All solutions were made up using redistilled, deionized water.

Kinetics

Reactions were followed spectrophotometrically at 474 nm and 25.0°C using a Durrum stopped-flow spectrophotometer. The carbocation, in dilute HCl (0.05–0.01 M) was in one drive syringe and the nucleophile in the other. For the water reaction, HCl was neutralized with an equivalent amount of NaOH, or with excess NaOAc, which does not affect reaction, cf. refs. 13 and 16. An equivalent amount of NaOH was used for reaction of N_3^-, but excess NaCN was used for reaction of CN^-.

Reaction of N_3^- could not be followed to completion in water because of its reversibility, and the rate constant was obtained by extrapolation from data in aqueous MeCN; however, reaction goes to completion in aqueous surfactant. Reactions of OH^- and CN^- in water were second order: the concentration ranges were up to 0.1 and 0.15 M for OH^- and CN^-, respectively.

The first-order rate constants, k_ψ, are in reciprocal seconds (s^{-1}).

The rates of aminolyses of *p*-toluenesulfonyl chloride with primary and tertiary amines have been determined both in acetonitrile and in ethanol. The Brönsted plots of log k_{rel} again $pK_{a'}$ values of amines (except hydrazine and 1,8-naphthyridine in acetonitrile) gave a good correlation when the aminolyses were carried out in acetonitrile. In ethanol, however, although Brönsted plots with all tertiary amines show a good correlation, less basic hydrazine shows a higher reactivity than *n*-butylamine. The abnormal rate enhancement found with hydrazine is undoubtedly due to the α-effect, while that with 1,8-naphthyridine in acetonitrile is considered to be due to the repulsion of two lone electron pairs on the two nitrogen atoms in 1,8-naphthyridine.

SHIGERU OAE et YOSHIHITO KADOMA. Can. J. Chem. **64**, 1184 (1986).

On a déterminé les vitesses d'aminolyse du chlorure de *p*-toluènesulfonyle par des amines primaires ainsi que tertiaires, tant dans l'acétonitrile que dans l'éthanol. Lorsque les aminolyses sont effectuées dans l'acétonitrile, il existe une bonne corrélation pour les courbes de Brönsted du log k_{rel} vs. les valeurs de $pK_{a'}$ des amines (excepté dans les cas de l'hydrazine et de la naphtyridine-1,8 dans l'acétonitrile). Dans l'éthanol, les courbes de Brönsted des amines tertiaires présentent toutes une bonne corrélation; toutefois, l'hydrazine qui est moins basique présente une réactivité qui est supérieure à celle de la *n*-butylamine. La vitesse de réaction anormalement élevée qui a été observée avec l'hydrazine est sans doute due à un effet α, alors que l'on considère celle de la naphtyridine dans l'acétonitrile comme étant due à une répulsion des deux paires libres d'électrons des deux azotes de la naphtyridine-1,8.

[Traduit par la revue]

The enhanced reactivity of nucleophiles containing one or more lone electron pairs adjacent to the reacting center has been known as the α-effect (2–4). Among the following three major factors responsible for the α-effect, namely, (*1*) destabilization of the ground state of the α-nucleophile by repulsion between the adjacent lone electron pairs (5), (*2*) stabilization of the transition state by the extra pair of electrons, and (*3*) reduced solvation of the α-nucleophile by the adjacent lone electron pair, the last two factors have been fairly well substantiated by both theoretical (6–9) and experimental studies (10–13). Stabilization of the transition state by the α-nucleophile, namely the second factor, has recently been considered quite important and possibly the major factor for the enhanced reactivity in the nucleophilic attack of the α-nucleophile on the electropositive reacting center, especially in solution. Evidence supporting the third factor has become especially convincing now, since no α-effect was observed in the reaction of HOO^- with methyl formate in the gas phase (13), where HOO^- shows a strong α-effect in solution.

Not much significance has been given to the first factor, i.e., destabilization of the ground state of the α-nucleophile by repulsion between the lone pairs on adjacent atoms, and practically no convincing evidence has yet been shown, although repulsion between lone electron pairs on adjacent heteroatoms is considered to be quite substantial in view of the well-known "rabbit ear effect" (14) of lone electron pairs on nonadjacent atoms.

A nonbonding unshared electron pair, namely, a lone electron pair, is large and takes up more space than a bonding pair (15). Therefore, if there is no electron pair other than a lone electron pair, the unshared pair of electrons would occupy a "*s*" type spherical orbital, spreading widely on the surface of the particular heteroatom (16). Even when the central heteroatom is bound to other atoms, the lone electron pair on the heteroatom tends to spread out, as exemplified by the decrease in the bond angle in the following three representative compounds: CH_4, which has no lone electron pair on the central atom, has a bond angle, $<\mathrm{C}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{H}\end{smallmatrix} = 109.5°$; NH_3, in which there is one lone electron pair on the central atom, has $<\mathrm{N}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{H}\end{smallmatrix} = 107.3°$; while H_2O, which has two lone electron pairs, is more angular, i.e., $<\mathrm{O}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{H}\end{smallmatrix} = 104.7°$. When bonding pairs are replaced successively by a lone electron pair, the bond angle between the bonding pairs decreases, since the lone electron pair takes up more space than the bonding electron pair. Since the lone electron pair engenders an electronic dipole, two lone electron pairs placed in proximity or in parallel must create a considerable electrostatic, and also even some steric, repulsion. The "rabbit ear effect" is caused by such a repulsion between two vicinal lone electron pairs on heteroatoms placed at the β-position to disfavor the conformations in which lone electron pairs on nonadjacent atoms are placed at parallel or at the *syn-axial* position (14), as shown below.

In 1,8-naphthyridine two lone electon pairs on the two nitrogen atoms of the heterocyclic compound are placed in parallel, as shown below.

Therefore, due to the repulsion, this compound should have a considerable internal strain. However, if one of the nonbonding lone electron pairs is used for bonding, such a repulsion would be released, since one of repulsive dipoles would disappear and the steric requirement of a bonding electron pair is less than that of a nonbonding electron pair. Hence, if 1,8-naphthyridine is used as a nucleophile in the nucleophilic reaction and the conventional Brönsted plot of logarithm of rate constant against $pK_{a'}$s of attacking nucleophiles, 1,8-naphthyridine would show a positive deviation from the plotted line, since the release of repulsion between the two lone electron pairs would occur in the transition state by forming a new σ-bond between the nucleophile and the substrate, thus lowering the energy of activation. One earlier report (5*b*) suggested, based on others' work, that 1,8-naphthyridine would show fourfold rate acceleration in the reaction with methyl iodide. One might propose, however, that protonation of one of the two lone electron pairs would result in the release of this unfavorable repulsion, which in turn would result in the increase of the $pK_{a'}$ value of 1,8-naphthyridine. These two opposing effects, i.e., lowering of the activation energy and increasing $pK_{a'}$ value, should cancel out much of the anticipated positive deviation from the Brönsted slope. However, this consideration has been suggested to be not very significant in nucleophilic displacements (17), since the lone electron pairs are more fully removed in the transition state than when perturbed by protonation. The result of our SCF MO calculation also supports this argument (6).

Therefore, if one finds a substantial positive deviation from the Brönsted slope for 1,8-naphthyridine, similar to that for some α-nucleophiles, e.g., hydrazine, it may serve as supporting evidence that repulsion between lone electron pairs is at least partially responsible for the rate enhancement in the nucleophilic reactions. An observation by Zoltewicz and Deady (5*b*) seems to show the possibility of the above argument. However, in order to substantiate the argument, further data such as the solvent effect on the α-nucleophile and 1,8-naphthyridine, as well as quantitative measurements of deviations of both nucleophiles from the slope, should be necessary. Meanwhile, since 1,8-naphthyridine has a low $pK_{a'}$ value, it does not react readily with ordinary esters and hence a more reactive *p*-toluenesulfonyl chloride was used as substrate for the nucleophilic reaction. Thus, we have carried out a kinetic study on the reaction of *p*-toluenesulfonyl chloride with 1,8-naphthyridine, its isomer, 1,5-naphthyridine, hydrazine, and other amines in both ethanol and acetonitrile, observing substantial rate enhancements with both 1,8-naphthyridine and hydrazine in acetonitrile.

Results and discussion

In the reaction of *p*-toluenesulfonyl chloride with amines, the following two reaction paths, i.e., (a) and (b), are conceivable. However, the product analysis indicates the absence of *p*-toluenesulfinate ion and only the presence of the sulfonate ion in the reaction mixture. Thus, path (b) has been ruled out and the reaction is purely a nucleophilic substitution on the sulfonyl S atom.

Earlier, Kice and Legan (18) observed a marked α-effect in the nucleophilic substitution on the sulfonyl sulfur atom with hydroperoxide ion, and hence a substantial rate enhancement has been expected in the nucleophilic substitution of arenesulfonyl chloride with the α-nucleophile. Thus, we have carried out a kinetic study on the nucleophilic substitution of *p*-toluenesulfonyl chloride with various amines.

Although *p*-toluenesulfonyl chloride is quite reactive as compared to ordinary esters, the amines used for this study have a wide range of basicity from low basic 1,5-naphthyridine to highly basic piperidine, the rate of the reaction was found to vary widely in the range of $10^{7.5}$. Therefore, two different analytical procedures were necessary for kinetic measurements in order to compare all the rates. For the reaction with amines of low basicities, such as naphthyridines, quinolines, and pyridine, the reactions were carried out so that the amine concentration was maintained usually 100 times higher than that of the substrate in the reaction cell, and pseudo-first-order rate constants thus obtained were divided by the amine concentration to obtain bimolecular rate constants. In this case, the rate measurement was followed by monitoring the amount of chloride ion liberated in the reaction by conductometry. In the reactions with amines of high basicities from pyridine to piperidine, the conventional uv measurement of the absorption of *p*-toluenesulfonyl chloride was quite applicable, and concentrations of both the amine and the substrate can be kept nearly equal in this procedure. In both procedures, pyridine was used as the reference base and practically identical rate constants were obtained.

Since the repulsion between the vicinally situated lone electron pairs is expected to change considerably, both sterically and in dipole interaction, due to the possible change of solvation, the reaction was carried out in both protic and polar aprotic solvents, i.e., ethanol and acetonitrile. *p*-Toluenesulfonyl chloride is stable in both solvents at these kinetic temperatures and kinetic concentrations for over 10 days, while the concentrations of amines were not affected by these solvents. Thus, the rate constants obtained in acetonitrile are listed in Table 1.

In Fig. 1, the values of log k_{rel} in Table 1 were plotted against the $pK_{a'}$ values of amines used. Apparently, there is a good correlation and the β-value, 0.89, obtained from the Brönsted slope seems to suggest that the reaction is highly dependent on basicity, while there is a high degree of bond formation in the transition state.

The rate constants obtained with 1,8- and 1,5-naphthyridines

Amine	k_2	log k_{rel}	$pK_{a'}$[a]
Piperidine[b]	101 ± 3	7.69	18.92
n-Butylamine[b]	64.4 ± 0.5	7.49	18.26
Monoethanolamine[b]	20.4 ± 0.3	6.99	17.53
Hydrazine[b]	74.0 ± 0.5[c]	7.55	16.61
Ammonia[b]	$(8.73 \pm 0.1) \times 10^{-1}$	5.62	16.46
Isoquinoline[d]	$4.3–2.0 \times 10^{-4}$	2.0–2.35	12.50[e]
Pyridine[b,d]	$(2.34 \pm 0.06) \times 10^{-4}$	1.20	11.98[e]
1,8-Naphythyridine[d]	$(2.08–7.04) \times 10^{-4}$[c]	2.5–3.0	10.44[e]
1,5-Naphythyridine[d]	$(2.08 \pm 0.3) \times 10^{-6}$	0.0	9.92[e]

[a]$pK_{a'}$ values are taken from Coetzee and Padmanabhan (19).
[b]Rate constant was obtained by conductometry.
[c]Obtained rate constant was divided by 2 because these amines have two nucleophilic centers.
[d]Rate constant was obtained by uv spectrophotometry.
[e]Estimated value from a linear plot of $pK_{a'}$ in water vs. $pK_{a'}$ in acetonitrile.

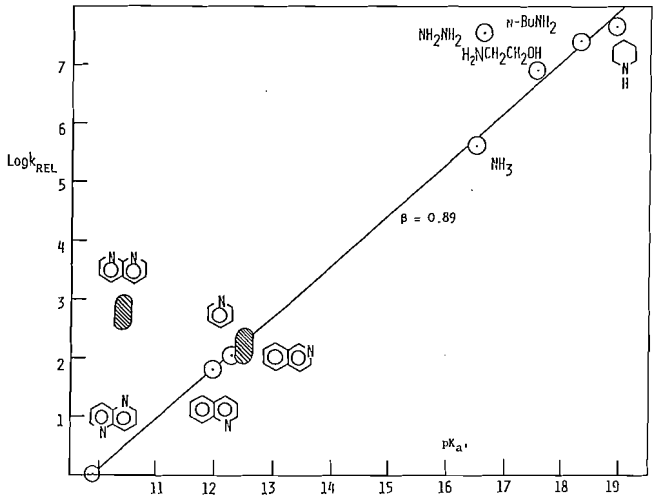

FIG. 1. Brönsted plot for the reaction of *p*-toluenesulfonyl chloride with amines in acetonitrile.

are divided by 2, since these amines have two nucleophilic centers (20). The plot for 1,5-naphthyridine lies well on the slope; however, hydrazine and 1,8-naphthyridine exhibit considerable deviations from the slope. The deviation of the plot with hydrazine is undoubtedly due to the α-effect, while that with 1,8-naphthyridine cannot be assigned to the α-effect but is obviously due to the repulsion of the two lone electron pairs, very likely in the ground state, since vicinally situated lone electron pairs, particularly in parallel positions, would result in a considerable repulsion. In this connecton, it is interesting to see the first $pK_{a'}$ values of substituted diaminonaphthalenes (21); namely, 4.61 for 1,8-diaminonaphthalene, 5.6 for 1,8-bis(monomethylamino)naphthalene, 6.43 for 1-dimethylamino-8-monomethylaminonaphthalene, and 12.34 for 1,8-bis(dimethylamino)naphthalene. The first $pK_{a'}$ value for 1,8-bis(dimethylamino)naphthalene is thus higher than those of normal aliphatic amines. This compound is apparently a highly strained molecule in which the conjugative resonance between the amino group and the naphthalene ring is considerably inhibited and, despite the high van der Waals repulsion, both dipolar repulsion and the strain would be effectively relieved by protonation. Since the unfavorable strain produced by repulsion is expected to be relieved more by forming a σ-bond at the transition state of

Amine	k_2 (L mol^{-1} s^{-1})	log k_{rel}	$pK_{a'}$[a] in water
Hydrazine[b]	1.63 ± 0.05	1.89	7.96
n-Butylamine	0.860 ± 0.03	1.61	10.59
Monoethanolamine	0.605 ± 0.03	1.46	9.50

[a]$pK_{a'}$ values are taken from Perrin (23).
[b]Obtained rate constant was divided by 2 because these amines have two nucleophilic centers.

nucleophilic substitution than when perturbed by protonation, 1,8-bis(dimethylamino)naphthalene is considered to be more reactive than anticipated from its basicity. However, because of the sterically crowded center of the amino groups, it is not a good nucleophile for substitution.

As for 1,8-naphthyridine, the repulsion of lone electron pairs is considered to be effectively reduced at the transition state; thus the compound is 100-fold more reactive than anticipated from its basicity. The rate enhancement observed with 1,8-naphthyridine seems to indicate that the σ-bond formation is nearly complete at the transition state. This is also a favorable condition for hydrazine to exhibit its α-effect, as observed by the markedly positive deviation from the Brönsted slope, the rate enhancement being 40-fold (see Fig. 1).

Our earlier data (22)[4] revealed that the α-effect was not observed in the aminolyses of alkyl, allyl, and benzyl iodides, nor in the hydrolyses of benzylic bromides with hydroperoxide ion, although the aminolyses of allyl and benzyl iodides give nearly identical Brönsted values (0.60 and 0.55, respectively) to that (0.54) obtained with *p*-nitrophenyl acetate. This lack of α-effect in the aminolyses on the sp^3 carbon atom and also in the S_N2 reaction of benzylic bromides with hydroperoxide ion may be explained on the basis of the inability to form tight σ-bonds at the transition state of these S_N2 processes. The tight σ-bond formation, as observed in the formation of a tight tetrahedral intermediate in the ester hydrolysis, seems to be quite essential in releasing repulsion between lone electron pairs, thus enhancing the rate and exhibiting a marked α-effect.

Since large rate enhancements can be observed in the aminolyses of *p*-toluenesulfonyl chloride with 1,8-naphthyridine and hydrazine in such an aprotic solvent as acetonitrile, it is interesting to see how the change of solvent from acetonitrile to

[4]Also, S. Oae and Y. Kadoma, unpublished results.

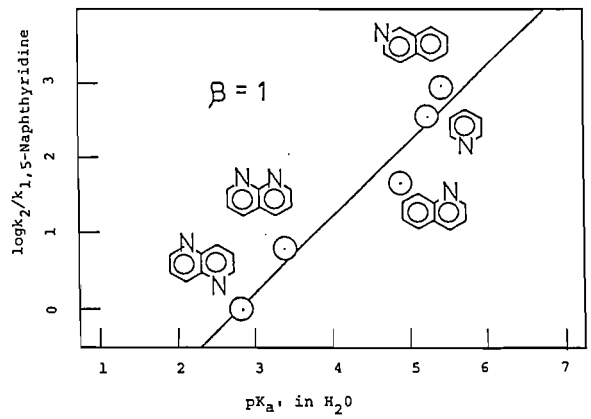

FIG. 2. Brönsted plot for the reaction of tertiary amines to *p*-toluenesulfonyl chloride in ethanol.

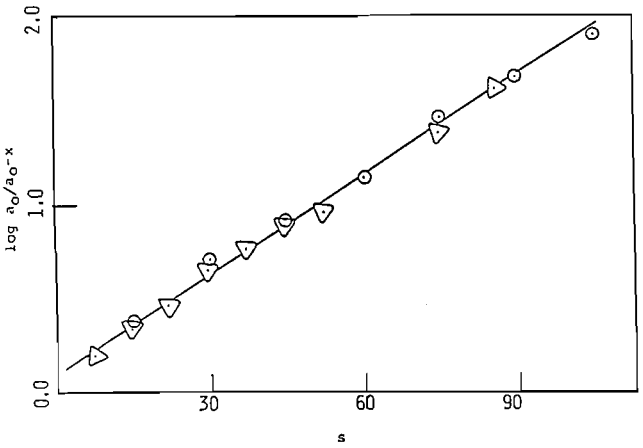

FIG. 3. Kinetic plots of the rates of aminolysis of *p*-toluenesulfonyl chloride with pyridine in ethanol. The log $a_0(a_0 - x)$ values are obtained by the plot of $[Cl^-]$ vs. conductivity of the reaction cell; ⊙ by uv spectrophotometry; △ by conductivity.

a protic solvent such as ethanol would affect the rate of the reaction. Thus, a kinetic study on the aminolyses of *p*-toluenesulfonyl chloride with tertiary as well as primary and secondary amines has been carried out and the results are summarized in Tables 2 and 3, respectively. The Brönsted plot for aminolysis with tertiary amines is also illustrated in Fig. 2. Since it has been known that the relative basicities are little affected by the change of solvent from water to alcohol (24), the rate constants are plotted against $pK_{a'}$ values of amines used in water.

In the aminolyses of *p*-toluenesulfonyl chloride with tertiary amines in ethanol (see Table 2 and Fig. 2), there is also a good correlation between the rate constants and $pK_{a'}$ values of amines used, and the Brönsted β-value of $\simeq 1$ indicates that the bond formation between the nucleophile and the substrate is nearly complete at the transition state, very likely expanding the valence shell of the central sulfur atom. However, in the aminolyses in ethanol, 1,8-naphthyridine does not show any positive deviation from the Brönsted slope, due mainly to solvation, since the lone electron pairs on two nitrogen atoms in the heterocycle are substantially solvated in ethanol by strong hydrogen bonding. Because of this solvation, orbitals of the lone electron pairs would be so contracted that the size of lone electron pairs would be reduced, thus reducing the unfavorable steric interaction, while the unfavorable dipolar repulsion would also be reduced substantially. These repulsive interactions are considered to be removed by formation of a σ-bond between the sulfur atom and the nucleophile. However, the reacting center of 1,8-naphthyridine has vicinally situated lone electron pairs on the two nitrogen atoms, which would be solvated by ethanol molecules, far more in number than in the aminolyses with other tertiary amines. Hence this sterically unfavorable condition created by the strong hydrogen bonding would cancel out any positive deviation from the slope.

In general, the α-effect seems to be somewhat larger in protic solvents than in aprotic media, while it is also considered to be affected markedly by the change of solvent (20). However, there are not many data to substantiate the argument. Therefore, aminolyses of *p*-toluenesulfonyl chloride with primary amines have been carried out, just to see if the α-effect would depend on the solvent change as was observed with 1,8-naphthyridine. The results are shown in Table 3.

One finds in Table 3 that hydrazine reacts faster than other more basic primary amines, due obviously to the α-effect. In the reaction in ethanol the transition state would be well solvated by the solvent ethanol, and further solvation by the vicinally situated lone electron pair will not increase the stability, whereas the presence of the vicinial lone electron pair would rather decrease the solvation at the transition state by repelling some ethanol molecules. Thus in ethanol the ground state destabilization would be cancelled out by the transition state destabilization; the net result is no rate enhancement. The α-effect is solvent independent, while the lone pair – lone pair repulsion is solvent dependent. These observations suggest that while the lone pair – lone pair repulsion is an important factor, it is not the sole cause of the α-effect.

Experimental

Preparation of materials

1,8-Naphthyridine was prepared by the Skraup reaction (25). Five repeated sublimations at 80°C (0.2 Torr; 1 Torr = 133.3 Pa) gave glassy colorless needles, mp 99.5°C (lit. (25) mp 98–99°C). 1,5-Naphthyridine was prepared similarly (26); mp 75°C (lit. (26) mp 75°C). Other amines were prepared by distillation (19), or by recrystallization.

Product analysis

One gram of a given amine (pyridine or 1,8-naphthyridine) was added into the solution containing 1 g of *p*-toluenesulfonyl chloride in 20 g of acetonitrile. After keeping the solution for 5–30 min at room temperature, the reaction mixture was poured onto ice-water, acidified with HCl, and extracted with ether. In the ether solution, there was no *p*-toluenesulfinic acid present and only a trace of the unreacted sulfonyl chloride was detected. *p*-Toluenesulfonic acid in the remaining water layer was identified by adding a solution of *S*-benzylthiouronium chloride to obtain the crystalline *S*-benzylthiouronium salt of *p*-toluenesulfonic acid. After recrystallization from ethanol, the salt gave mp 178°C (lit. (27) mp 178°C).

Product analyses for the reaction of *p*-toluenesulfonyl chloride with primary and secondary amines in ethanol were also carried out using the same method as described above. In the case of a primary amine, the corresponding sulfonamide was isolated quantitatively, while the reaction product with a tertiary amine was the *p*-toluenesulfonic acid ester, which was also obtained quantitatively. The lack of the sulfonic acid ester among the products in the reaction with primary amines in ethanol suggests that at the rate-determining step the unfavorable influence of ethoxide anion can be neglected.

Kinetic measurements

Since a wide variety of amines were used, the rate constant changed widely over the range of $10^{7.5}$. Therefore, two kinetic procedures have

been applied. For the aminolyses with reactive primary and secondary amines, the reactions have been followed by uv spectrophotometry using the absorption of *p*-toluenesulfonyl chloride at 245 nm, while for the tertiary amines, the rates of the reactions have been followed by conductometry, by monitoring the conductivity change in the reaction cell that is caused by the change of chloride ion, liberated during the aminolysis. In the latter method, the concentration of the amine was usually maintained 100 times higher than that of the sulfonyl chloride. Thus, the pseudo-first-order rate constants obtained were divided by the concentration of the amine used, to estimate the second-order rate constant of the aminolysis. For all the kinetic measurements both in ethanol and in acetonitrile, the concentration range of the amine for conductometry was in the range of 1–0.5 mol/L, while *p*-toluenesulfonyl chloride was kept between 0.01 mol/L and 0.005 mol/L; also for the uv spectrophotometry the concentration of amine was between 0.5 mol/L and 5×10^{-4} mol/L, while the concentraton of *p*-toluenesulfonyl chloride was between 0.2 mol/L and 1×10^{-4} mol/L. A typical run is shown in Fig. 3. The apparatus used for the conductivity is the same as that used previously (28). Meanwhile, the rate of the reaction with pyridine was measured by both uv spectrophotometry and conductometry and there was a good agreement in both.

In the aminolysis of sulfonyl chloride with pyridine in ethanol, $\Delta E^{\neq}$ and $\Delta S^{\neq}$ values are calculated to be 14.7 kcal/mol (61.61 kJ) and −15.9 eu, respectively, while $\Delta E^{\neq}$ and $\Delta S^{\neq}$ for the reaction with 1,8-naphthyridine are 17.2 kcal/mol (72.2 kJ) and −15.6 eu, respectively.

Received October 18, 1985

This paper is dedicated to Professor Arthur N. Bourns

OLGA BORTOLINI, LETANZIO BRAGANTE, FULVIO DI FURIA, and GIORGIO MODENA. Can. J. Chem. **64**, 1189 (1986).

The effect of the lipophilicity and coordinating ability of neutral ligands, belonging to the classes of phosphoric amides and pyridine oxides, on the extraction of the neutral oxidants molybdenum(VI)–peroxo complexes from an aqueous acidic phase to an organic one, has been studied. The nature of the Mo(VI)–peroxo species present both in aqueous and organic phase has also been investigated. Sizable amounts of mineral acid, added to adjust pH, may be extracted into the organic phase. The various factors affecting this process such as the nature of the acid added, the organic solvent and the neutral ligand, as well as the effect of this feature on the partition of the oxidant between the two phases are briefly discussed.

OLGA BORTOLINI, LETANZIO BRAGANTE, FULVIO DI FURIA et GIORGIO MODENA. Can. J. Chem. **64**, 1189 (1986).

On a étudié les effects, sur l'extraction d'oxydants neutres comme les complexes peroxo–molybdène(VI), du caractère lipophile et de l'habilité à coordonner des ligands neutres que possèdent les phosphoramides et les oxydes de pyridine. On a aussi examiné la nature des espèces peroxo-molybdène(VI) tant dans la phase aqueuse que dans la phase organique. De grandes quantités d'acides minéraux, qui sont ajoutés pour ajuster le pH, peuvent être extraites dans la phase organique. On discute brièvement des divers facteurs qui affectent ce processus, tel que la nature de l'acide qui est ajouté, la nature du solvant organique et du ligand neutre ainsi que l'effet de cette caractéristique sur la répartition de l'oxydant entre les deux phases.

[Traduit par la revue]

Introduction

Selective oxidations by dilute hydrogen peroxide, catalyzed by transition metal derivatives, present several attractive features (1). In fact, aqueous hydrogen peroxide is a readily available and safe oxidant which has the additional advantage of producing no other by-products than water. Moreover, novel procedures recently proposed, based on biphasic systems (2, 3), allow to overcome the main drawback encountered in the homogeneous catalytic reactions, that is the need of using polar solvents such as water, alcohols, or ethers where the oxidation rates by peroxometal complexes are usually much slower than those in non-polar media (1).

Two main approaches to the development of biphasic systems have been used (2, 3), both based on the acid–base properties of some peroxometal species, namely peroxomolybdenum and peroxotungsten complexes, formed by addition of hydrogen peroxide to Mo(VI) or W(VI) derivatives in protic solvents. In fact, both Mo(VI) and W(VI) peroxo complexes are fairly acidic (4). Thus, it is possible to transfer, by means of a lipophilic quaternary ammonium cation or similar cationic phase-transfer agents, the peroxo anions from the aqueous to the organic phase (2) where the oxidation of the substrate takes place.[2] Alternatively, we have proposed (3) the transfer of neutral peroxo complexes to the organic phase, generally a chlorinated hydrocarbon, by employing neutral lipophilic ligands such as phosphoric amides or pyridine oxides.

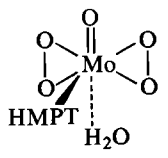
Our system has been tested in two model reactions (3), the oxidation of organic sulfides and the epoxidation of olefins. This system exhibits fairly good rates and selectivities under the appropriate experimental conditions, particularly with a Mo(VI) catalyst. Clearly, the efficiency of the oxidation was found to depend on several factors, a very important one of which is the nature of the ligand employed.

We have therefore deemed worthwhile to extend our study by examining in greater detail the chemistry of the peroxo-species formed and transferred. We limited ourselves to Mo(VI) derivatives, and the interactions of such species with the extracting ligands. It may be anticipated that the results reported in the present paper confirm more quantitatively the relevance of both the lipophilicity and the coordinating ability of a ligand in determining the success of the oxidation procedures. Moreover, this study provided evidence of a less known process, *i.e.* the extraction of the mineral acid in the organic phase by the ligand, which affects both the partition of the peroxo complexes and the reactivity of the system.

Results and discussion

Peroxomolybdenum(VI) species in acid aqueous solutions

Early results reviewed by Connor and Ebsworth in 1964 (5) provided evidence that in acid aqueous solutions containing alkali metal molybdates and an excess of hydrogen peroxide, peroxomolybdenum compounds containing two peroxo groups per molybdenum atom are formed. However, no detailed information on the structure and the chemistry of such species was available at that time. Since then, a variety of well characterized peroxomolybdenum complexes has been prepared (6). Among these, we selected, for the purposes of this investigation, the oxo–diperoxo–phosphoro–amido–aquo complex $MoO(O_2)_2.HMPT.H_2O$, **1** (4*c*):



1

In protic solvents, the organic ligand HMPT may be displaced by the solvent itself (4*c*, 7). The displacement

[1]Part 23. O. Bortolini, F. Di Furia, G. Modena, and A. Schionato. J. Mol. Catal. In press.

[2]Addition of phosphoric or arsenic acids in the aqueous phase is essential in this procedure (2) thus suggesting the formation and subsequent extraction of peroxo-heteropolyanions.

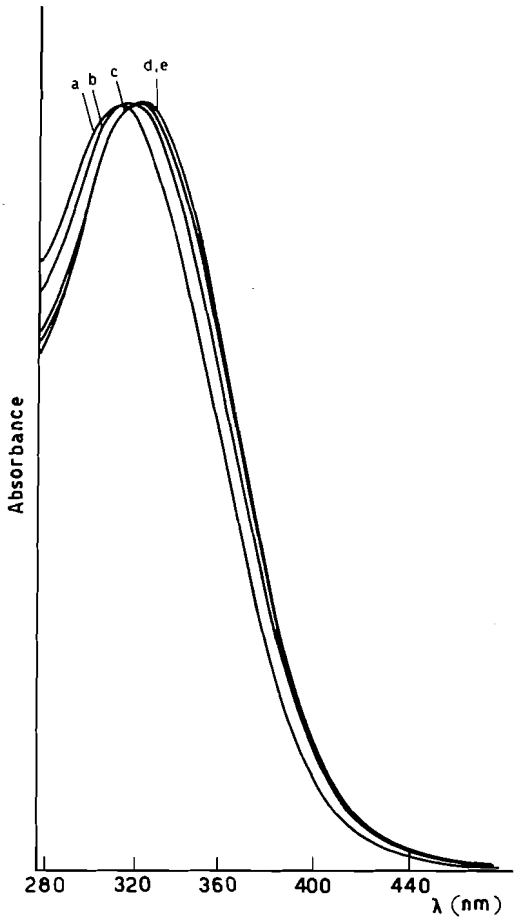


FIG. 1. Electronic spectra of $MoO_5HMPT.H_2O$ (2×10^{-2} *M*) in H_2O at different acidities (H_2SO_4): pH 2.06 (*a*), 1.66 (*b*), 1.24 *c*, 1.17 (*d*), 1.00 (*e*).

equilibrium is easily monitored by ^1H nmr spectroscopy because of the different chemical shifts of the CH_3 group in coordinated and free HMPT, respectively (7). Moreover, the equilibrium is sufficiently slow at room temperature to give two separate signals.

We first determined that in D_2O, 2×10^{-3} *M* solutions of **1** only gave signals (doublet) corresponding to free HMPT. In other words, the ligand was completely displaced. We then measured the electronic spectra of a 2×10^{-3} *M* aqueous solution of **1** at different acidities (H_2SO_4). The pertinent spectra are shown in Fig. 1.

The absorption at ca. 310–320 nm is typical of oxodiperoxomolybdenum complexes (8). Similar features are observed in a series of solvents ranging from protic to hydrocarbon ones (see the following for an example). Moreover, no absorption due to HMPT is observed in this region of the spectrum, as expected. Inspection of the spectra of Fig. 1 indicates that an increase in the acidity of the aqueous solution causes a shift of the peroxide absorption at lower energies, showing acid–base equilibria above pH ~1.2. At higher acidity, on the other hand, no appreciable variation of the band is observed.

It is also observed that in the presence of H_2O_2, at pH values below 1.2, aqueous solutions of H_2MoO_4 or MoO_3 exhibit an absorption spectra which are identical to those shown in Fig. 1, within experimental error. $\lambda_{max} = 324$ nm, $\epsilon_{max} = 1060\,cm^{-1}\,M^{-1}$.

From these data we conclude that the same peroxomolybdenum species occur in solutions, whatever the precursor, provided that the pH values are sufficiently low. The species is most likely an aquo–oxo–diperoxo complex $MoO(O_2)_2(H_2O)_n$.

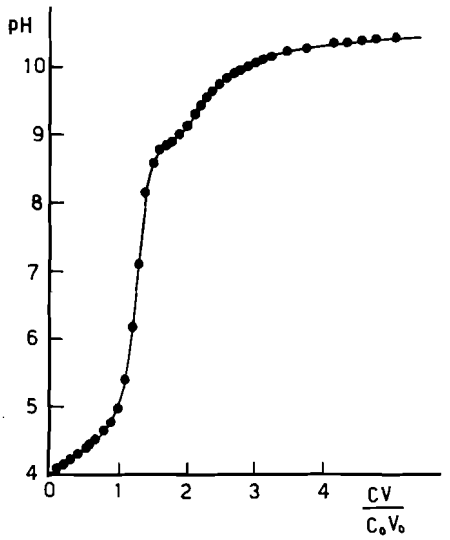

FIG. 2. Potentiometric titration of $MoO_5HMPT.H_2O$ (1×10^{-4} *M*) with NaOH (1×10^{-2} *M*) in H_2O at 25°C, under argon.

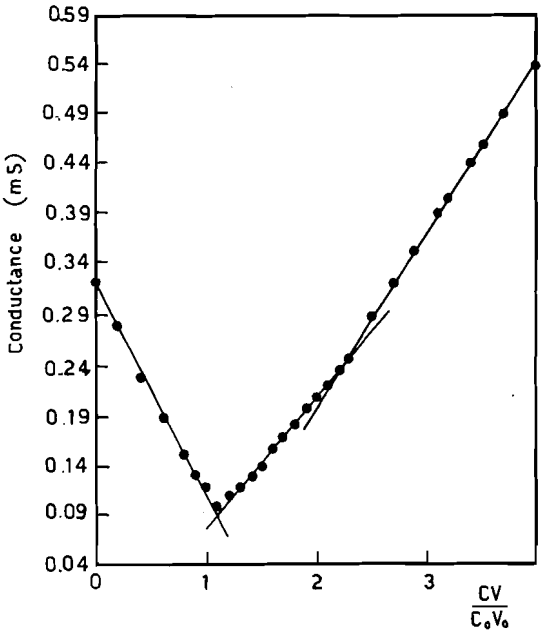

FIG. 3. Conductometric titration of $MoO_5HMPT.H_2O$ (1.25×10^{-4} *M*) with NaOH (1×10^{-2} *M*) in H_2O at 25°C, under argon.

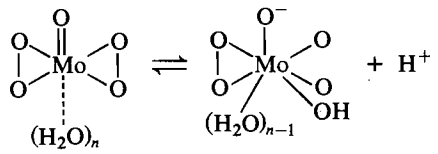
Again using $MoO_5HMPT.H_2O$ as a precursor, we then examined the acid–base behavior of such peroxo complex in aqueous solutions. Figures 2 and 3 show the results of the potentiometric and conductometric titrations of **1**, 1×10^{-4} *M*, with NaOH in aqueous solution. The concentration of **1** in these experiments was such that no HMPT bound to the metal was observed. In both titrations two equivalent points, at [NaOH]/[Mo] ratios of 1 and 2, respectively, are found, in agreement with previous results obtained in very similar systems (4*c*).

The acidic character of Mo(VI)–peroxo species in other protic solvents such as alcohols has been also observed (4*a*, *b*). For comparative purposes, Fig. 4 shows the potentiometric titration of a 1×10^{-4} *M* solution in *i*-PrOH (no HMPT bound to

the metal) with *i*-PrONa. Interestingly, in alcoholic solution only one, fairly acidic, titratable proton is found.

Therefore, the acidity of the peroxo–molybdenum species should not be related to the opening up of the peroxo bridges yielding peracid-like derivatives since such a process should be equally possible in water and in alcoholic solvents.

On the other hand, the titration curve in Fig. 2 clearly shows that the presence of dianionic molybdenum(VI) species in water is confined to basic solution where complicated equilibria involving dimerization and dissociation of hydrogen peroxide are likely to occur (4*c*, 5). Therefore, in aqueous acid solution, where our experiments have been carried out, the only acid–base equilibrium which needs to be considered is that occurring between the neutral peroxomolybdenum species and the mono-anionic one. This might be envisaged as:



Extraction of neutral peroxomolybdenum(VI) species from water to DCE by neutral lipophilic ligands

The experiments reported here were carried out under the following experimental conditions: 2.5 mL of an aqueous solution containing respectively the molybdenum precursor, typically Na_2MoO_4, in the presence of an excess of H_2O_2, at a fixed pH value (obtained by addition of a strong acid) and an equal volume of an organic phase, containing the neutral lipophilic ligand, were mixed together under controlled stirring for 3 min. After this time the stirring was suspended, the two phases were separated, and the peroxomolybdenum complex remaining in the aqueous solution was determined by uv spectroscopy (absorption at ca. 310–320 nm depending on the pH, see preceding paragraph).[3] Control experiments confirmed that, in the absence of the ligand in the organic phase, no appreciable decrease of the concentration of Mo(VI)–peroxo complex in the aqueous phase, after the experiments run under otherwise identical conditions, was observed.

First we examined the yields of extraction as a function of the pH of the aqueous phase, taking two representative neutral ligands, hexaethylphosphoric triamide, HEPT, and phenylpropylpyridine *N*-oxide, RPyNO. (RPy = 4-(C_6H_5—$(CH_2)_3$—C_5H_4N). The pertinent results, concerning aqueous solution of H_2SO_4 and $HClO_4$, are shown in Figs. 5 and 6. A 2-fold excess of the ligand over the peroxomolybdenum complex, under the condition of a 40-fold excess of H_2O_2 over molybdenum, has been used. The curves of Figs. 5 and 6, referring to the extraction from H_2SO_4 aqueous solutions, are in very good agreement with the results reported in the previous paragraph. In fact, the maximum extraction is obtained at a pH value *ca.* 1.5–1.0, roughly corresponding to the invariance of the absorption at 324 nm, see Fig. 1, which has been attributed to the complete neutralization of the anionic peroxomolybdenum species. We observe also that the yields of extraction are larger for RPyNO than for HEPT. This point will be discussed in

[3]It has been confirmed directly that the peroxomolybdenum species in the aqueous phase plus that extracted into the organic one, also determined by uv spectroscopy, as discussed in the next paragraph, correspond to the stoichiometric concentration of molybdenum initially added. Furthermore, under identical conditions, but in the absence of metal derivatives, only negligible amounts of hydrogen peroxide, as determined by iodometric titre, are extracted into the organic phase.

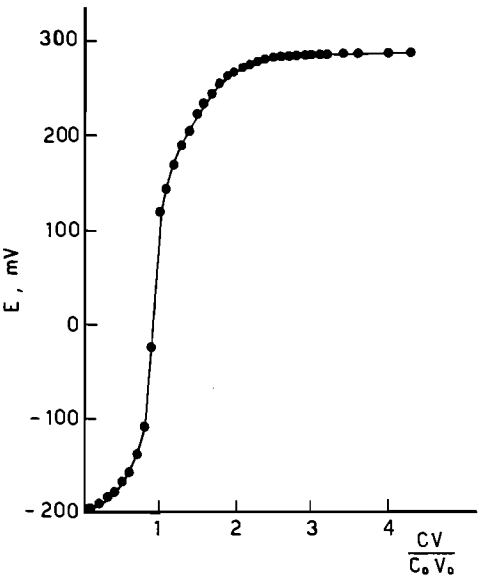


FIG. 4. Potentiometric titration of $MoO_5HMPT.H_2O$ (1×10^{-4} *M*) with $NaOPr^i$ (1×10^{-2} *M*) in Pr^iOH at 25°C, under argon.

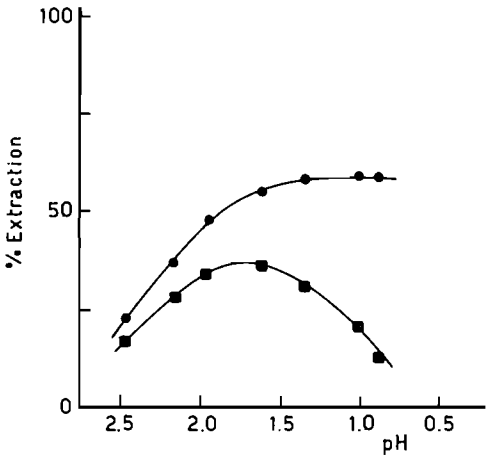

FIG. 5. Extraction (%) of Mo(VI)–peroxo compound in organic phase as a function of pH and the type of acid used: H_2SO_4 (●) or $HClO_4$ (■). $[Mo]_{st} = 2 \times 10^{-2}$ *M*, $[H_2O_2] = 0.8$ *M*, [HEPT] = 4×10^{-2} *M* DCE/H_2O 2.5/2.5 mL at 25°C.

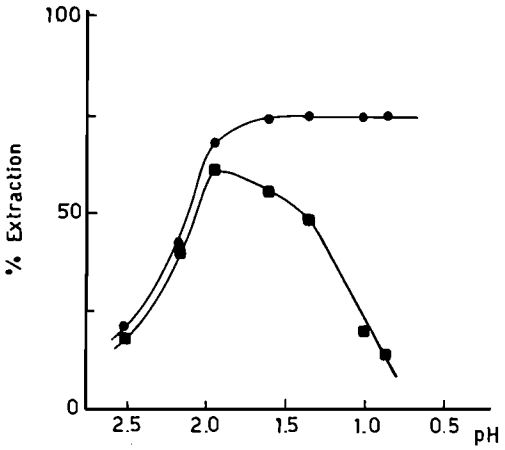

FIG. 6. Extraction (%) of Mo(VI)–peroxo compound in the organic phase as a function of pH and the type of acid used: H_2SO_4 (●) or $HClO_4$ (■). $[Mo]_{st} = 2 \times 10^{-2}$ *M*, $[H_2O_2] = 0.8$ *M*, [RPyO] = 4×10^{-2} *M* DCE/H_2O 2.5/2.5 mL at 25°C.

TABLE 1. Percentage of mineral acid extracted from the aqueous into the organic phase (DCE) $[H_2SO_4]_0 = 7.9 \times 10^{-2}$ mmol, $[HClO_4]_0 = 0.158$ mmol in 2.5 mL of H_2O (pH ~ 1.2)[a]

Ligand	Solvent	% $HClO_4$ in the organic phase		% H_2SO_4 in the organic phase	
		No ligand added	Ligand added	No ligand added	Ligand added
HEPT	DCE	~0.1	14.0	~0.1	0.3
RPyNO	DCE	~0.1	15.4	~0.1	0.6
HEPT	$CHCl_3$	~0.1	1.5	~0.1	~0.1
RPyNO	$CHCl_3$	~0.1	0.5	~0.1	~0.1
HEPT	CH_2Cl_2	<0.1	15.9	~0.1	0.2
RPyNO	CH_2Cl_2	<0.1	17.5	~0.1	0.5
HEPT	Chlorobenzene	~0.1	9.7	~0.1	~0.1
RPyNO	Chlorobenzene	~0.1	17.5	~0.1	0.2

[a]The experiments were carried out under standard conditions (see text) at a fixed (4×10^{-2} *M*) concentration of ligand in DCE. The concentration of the mineral acid in the organic phase was determined by titration (NaOH) after pouring the DCE solution in water.

more detail later on. The shape of the curves of Figs. 4 and 5 concerning extractions from $HClO_4$ solutions is, at first glance, rather puzzling. Also in this case, an increase of the extraction yields is observed upon neutralization of the anionic peroxomolybdenum species. However, at higher acidity of the medium, the yields of extraction sharply decrease. The data reported in Table 1 clearly indicate that in the presence of both ligands HEPT and RPyNO, the concentration of $HClO_4$ in the organic phase is 30- to 40-fold that of H_2SO_4, whereas, in the absence of the ligand, the acid concentration in the organic phase is similar for the two acids and much lower in value. Therefore, it appears that the basic ligands are also able to extract the mineral acids in the organic phase, likely *via* hydrogen bonding or true protonation equilibria (9). Moreover, $HClO_4$ is much more easily extracted than H_2SO_4, possibly because of the known higher solubility of the anion ClO_4^- in organic media. The presence of acid in the organic phase clearly reduces the extracting ability of the ligand toward the peroxomolybdenum species.

For comparative purposes, in Table 1 are reported data referring to other chlorinated solvents. Although the qualitative behavior is the same as that observed for DCE, it may be interesting to note that chloroform appears to be the solvent where less acid is extracted. This feature might be relevant as far as the search for a more efficient oxidizing system is concerned (3). However, we have directly confirmed that, in general, the yields of extraction of Mo(VI)–peroxo complexes are much lower in chloroform compared to other chlorinated hydrocarbons.

Under the best conditions of acidity in the aqueous phase determined by the above experiments, *i.e.* pH 1.2, H_2SO_4, we have studied the increase of extraction yields as a function of the neutral ligand concentration. The pertinent results are shown in Fig. 7 where four different ligands are considered. Beside the two ligands previously employed, HEPT and RPyNO, we have also examined hexabutylphosphoric triamide, HBPT, and tridodecylphosphoric triamide, TDPT. The comparison of the behavior of HEPT and HBPT may give an estimate of the relevance of the lipophilicity of the ligands on their extracting ability. Thus, the similarity of the two curves in Fig. 7 indicates that the efficiency of the two species is largely dominated by the coordinating ability of the oxygen of the P=O group provided that the ligands are sufficiently lipophilic. In fact, control experiments indicate that the water-soluble HMPT is much less effective.

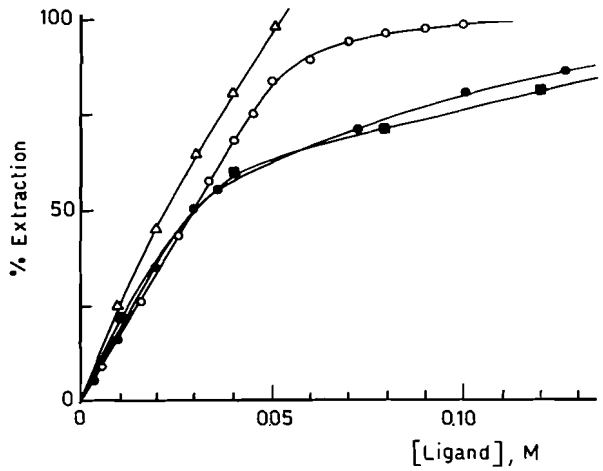

FIG. 7. Effect of increasing concentration of added ligands HBPT (■), HEPT (●), RPyO (○), TDPT (△) on the % extraction of the Mo(VI)–peroxo compound in the organic phase. $[Mo]_{st} = 2 \times 10^{-2}$ *M*, $[H_2O_2] = 0.8$ *M*, pH = 1.2 (H_2SO_4), DCE/H_2O 2.5/2.5 mL at 25°C.

As observed previously, the N-oxide derivative is a better extracting agent than either HEPT or HBPT. Interestingly, TDPT gives the best results under the adopted conditions.

In an attempt to correlate the extraction behavior observed with the coordinating ability of the various classes of ligands we have synthesized two novel model peroxo complexes, $MoO_5(PyNO).H_2O$ (PyNO ≡ 4—CH_3—C_5H_4N → O) and $MoO_5TEPT.H_2O$ (TEPT ≡ $(CH_3CH_2NH)_3P$=O), characterized by a fairly good solubility in alcoholic solvents. We have then studied the displacement equilibria of the ligands for the two complexes, and for $MoO_5HMPT.H_2O$, in the solvent CD_3OD, determining the values of K_{DISS} at 25°C by ^1H nmr technique and standard calculation methods. It should be mentioned that, at variance with $MoO_5HMPT.H_2O$ complex for which, as previously mentioned, two separate signals of the CH_3-group of the coordinated and free HMPT are observed (7), the rates of ligands exchange of the other two complexes are, at 25°C, relatively fast so that a single average signal is observed for the CH_3-group both in $MoO_5(PyNO).H_2O$ and $MoO_5TERP.H_2O$.

$$MoO_5L.H_2O \xrightarrow{CD_3OD} MoO_5L.CD_3OD + H_2O$$

$$MoO_5L.CD_3OD + CD_3OD \rightleftharpoons MoO_5(CD_3OD)_2 + L \qquad K_{DISS}$$

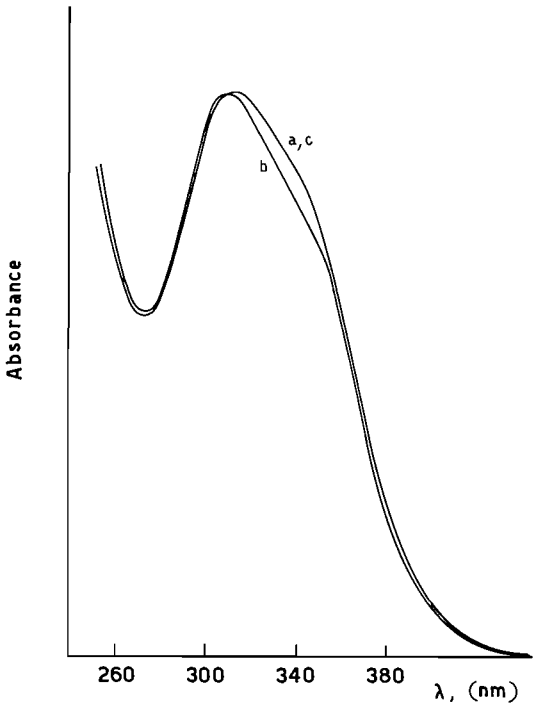

FIG. 8. Electronic spectra of: (*a*) Mo(VI) peroxocompound in DCE extracted from the aqueous phase under standard conditions: $[Mo]_{st} = 2 \times 10^{-2} M$, $[H_2O_2] = 0.8 M$ pH = 1.2 (H_2SO_4); (*b*) $MoO_5HMPT.H_2O$ $1.5 \times 10^{-2} M$ in DCE; (*c*) $MoO_5HMPT.H_2O$ $1.5 \times 10^{-2} M$ in DCE in the presence of acid (H_2SO_4).

The K_{DISS} values thus obtained, $MoO_5(PyNO).H_2O$ (1×10^{-4}), $MoO_5HMPT.H_2O$ (2.4×10^{-4}), and $MoO_5TEPT.H_2O$ (3.7×10^{-4}) follow an order which does not parallel the order of extraction efficiency of the liphophilic ligands containing the same coordinating group. Indeed, the trialkylphosphoric amide ligand TEPT is more easily displaced than PyNO, whereas lipophilic *N*-oxides appear to be less effective as extracting agents than trialkylphosphoric amides. These findings underline the complexity of the biphasic systems where equilibrium processes, other than the partition of the ligands and their coordination to the metal, need to be considered. Among these, an important role is likely played by the interaction between the ligands and the acid in both the organic phase and aqueous phase (9).

Peroxomolybdenum(VI) species extracted into the organic phase

In this part of our investigation we looked for direct evidence that the peroxomolybdenum(VI) complex extracted into the organic phase, independent of the molybdenum precursor present in the aqueous solution, belongs to the well-known family of compounds of the general formula $MoO(O_2)_2L_1L_2$ which were isolated and characterized by Mimoun *et al.* (4*c*). We proceeded by doing spectroscopic and kinetic experiments. We first measured the uv spectrum of the DCE solution after the extraction, using the same conditions as described in the preceding paragraph, from an acidic (pH 1.2) solution of Na_2MoO_4 containing an excess (40-fold) of hydrogen peroxide, employing HEPT as the extracting agent. We then registered the uv spectrum of a DCE solution of $MoO_5HEPT.H_2O$. As shown in Fig. 8, the two spectra are very similar, except for a small red-shift in the extracted peroxo complex. Control experiments have shown that this shift is attributable to a kind of solvent effect caused by the presence of acid in the DCE solution of the extracted peroxo complex.

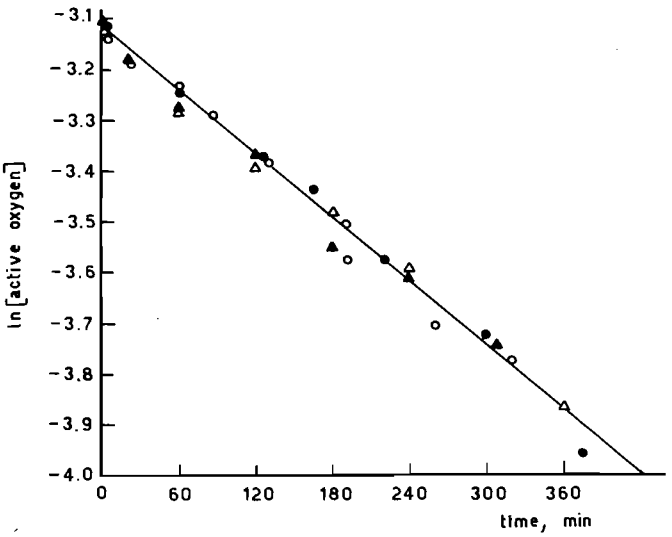

FIG. 9. Rate of disappearance of active oxygen in the oxidation of cyclohexene (0.2 *M*) by Mo(VI)–peroxo compound extracted from the aqueous phase (▲), duplicated reaction (△), or by $MoO_5HMPT.H_2O$ (●), duplicated reaction (○), in DCE in the presence of HEPT $5.76 \times 10^{-2} M$, at 25°C.

Finally, we have tested the oxidizing ability of a solution of the extracted peroxomolybdenum complex by comparing it with that of $MoO_5HEPT.H_2O$ in a model reaction, *i.e.* the epoxidation of cyclohexene. We used identical experimental conditions, particularly the excess of the free ligand over the oxidant since it is known that added ligand reduces the oxidation rates. The results are shown in Fig. 9. Within experimental error, the oxidizing ability of the two systems appears identical thus confirming that the same oxidant is present in solution.

Conclusions

We have shown that the efficiency of the two-phase oxidizing system comprising dilute hydrogen peroxide, Mo(VI) derivatives, and neutral phase-transfer agent depends on several, sometime conflicting, factors. Our results indicate that an increase of the acidity of the aqueous solution is beneficial as far as the neutralization of the anionic peroxo complexes is concerned. On the other hand, the mineral acid, particularly $HClO_4$, may also be transferred into the organic phase. This results in a decrease in the extracting capability of the ligand. Moreover, the presence of an acid in DCE may lower the yields of acid-sensitive products such as some of the epoxides obtained by oxidation of the olefin (3). Although the lipophilicity of the neutral ligands plays a role in the sense that its insolubility in water is a necessary requisite, our studies indicate that the nature of the coordinating group in the ligand itself is more important. On the other hand, the fact that the extraction ability increases in the order hexaalkylphosphoric triamides < *N*-oxides < trialkylphosphoric triamides which is also the order of increasing oxidizing ability of the two-phase systems (3), but is not the order of increasing coordinating ability of the ligands, suggests that other factors, such as the interaction with the acid extracted in the organic phase, may play a relevant role.

Experimental section

Reagents and solvents

Reagent grade MoO_3, Na_2MoO_4, H_2O_2 (36% w/v) were used without further purification. Aqueous solution of peroxo–Mo(VI) complex were prepared by dissolving MoO_3 (10 g, 0.069 mol) in H_2O_2 (100 mL) in the dark at 20°C. Complete dissolution is usually achieved in 4–5 days. DCE, CH_2Cl_2, $CHCl_3$, and chlorobenzene were purified

by standard procedures from highly pure commercial samples. All other chemicals were used as received.

Preparation of the ligands

Hexabutylphosphoric triamide (HBPT). An ethereal solution of PCl_3 (55 g, 0.4 mol) was dropwise added, over a 2-h period, to a solution of dibutyl amine (350 g, 2.71 mol) in 500 mL of anhydrous diethyl ether under vigorous stirring (10). After this time the mixture was allowed to return to room temperature and then refluxed for 6 h. The precipitated amine hydrochloride was filtered off, and carefully washed with ether. From the combined ethereal solutions the solvent was removed in a rotating evaporator. The crude product was dissolved in 200 mL of acetone and oxidized with an excess (ca. 20%) of hydrogen peroxide (36% w/v) slowly added to the reaction mixture maintained at 0°C. The resulting solution was then stirred for 3 h at 40–50°C, cooled, poured into an equal volume of water, and extracted with diethyl ether. The ethereal solution was washed with water, dried over $MgSO_4$, and the solvent removed *in vacuo*. The product was purified by low pressure (4–5 atm) liquid chromatography (11) (silica gel (>0.063 mm), petroleum ether – acetone 90–10) and by subsequent distillation, bp 153°C 0.06 mm Hg, yield 40%. ^{1}H nmr δ 0.93 (t, 18H), 1.28 (m, 12H), 1.49 (m, 12H), 2.90 (m, 12H); ^{31}P nmr δ 23.98 (s) H_3PO_4 30% in D_2O as external reference, broad-band proton-decoupled spectra. *Anal.* calcd. for $C_{24}H_{54}N_3OP$: C 66.77, H 12.61, N 9.73; found: C 66.15, H 12.43, N 9.51.

Hexaethylphosphoric triamide (HEPT). It was obtained in a similar manner from the di-*n*-ethyl amine (10). The product was purified by low pressure liquid chromatography (11) (silica gel > 0.063 mm, petroleum ether – acetone 70–30) followed by distillation bp 107°C 0.3 mm Hg; yield 30%. ^{1}H nmr δ 1.10 (t, 18H) 3.05 (qd, J = 7.2 Hz, J_{P-H} = 10.0 Hz, 12H); ^{31}P nmr δ 23.90 (s) H_3PO_4 30% in D_2O as external reference, broad-band proton-decoupled spectra. *Anal.* calcd. for $C_{12}H_{30}N_3OP$: C 54.70, H 11.50, N 15.90; found: C 54.25, H 11.25, N 15.23.

Triethylphosphoric triamide (TEPT). Precooled $CH_3CH_2NH_2$ (150 mL, 2.29 mol) was rapidly transferred, under stirring, into a round-bottomed flask containing 300 mL of *t*-butyl methyl ether, equipped with a cold-finger condenser and maintained at −10°C. $POCl_3$ (43 mL, 0.17 mol) dissolved in 50 mL of ether was added slowly and the flask allowed to warm at room temperature (12). The reaction was then refluxed for 4 h under stirring. When cooled at room temperature two phases separated spontaneously. The lower layer containing the product was separated and diluted with a 25–30-fold volume of ethylic ether. The amine hydrochloride precipitated and was filtered off. The ethereal solution was concentrated under reduced pressure and the crude product purified by liquid chromatography (silica gel CH_2Cl_2–CH_3OH 97–3), mp 28–29°C, yield 30%. ^{1}H nmr δ 1.15 (t, 9H), 3.05 (m, 6H) 2.35 (s, broad, 3H); ^{31}P nmr δ 19.60 (s) H_3PO_4 30% D_2O reference, proton decoupled. *Anal.* calcd. for $C_6H_{18}N_3OP$: C 40.22, H 10.12, N 23.45; found: C 39.69, H 10.19, N 23.31.

Tridodecylphosphoric triamide (TDPT). $POCl_3$ (11.8 g, 0.078 mol) dissolved in 60 mL of *t*-butyl methyl ether was slowly added, under stirring, to a solution of dodecylamine (93.3 g, 0.05 mol) in 250 mL of ether at 0°C (12).

The temperature was raised to 25°C and the reaction refluxed overnight. The white precipitate formed contained both the amine hydrochloride and the product. The solid was dissolved in hot water and the product separated as an insoluble layer, which was recovered. Recrystallization from ethanol gave a white solid; mp 71–72°C, yield 42%. ^{1}H nmr δ 0.95 (t, 9H), 1.35 (s, 54H), 1.55 (m, 6H), 2.27 (m, 3H) 3.05 (m, 6H); ^{31}P nmr δ 18.01 (s) H_3PO_4 30% D_2O reference, proton decoupled. *Anal.* calcd. for $C_{36}H_{78}N_3OP$: C 72.10, H 13.10, N 7.03; found: C 72.37, H 13.43, N 7.16

CAUTION: HMPT has been proved to be carcinogenic; therefore caution has to be used in handling this and other phosphoric amides.

Preparation of the Mo(VI)–peroxo complexes

$MoO_5.HMPT.H_2O$. The procedure adopted is essentially that reported by Mimoun *et al.* (4*c*). Na_2MoO_4 (8.5 g, 35 mmol) was dissolved in a minimum volume of water and the pH of the solution adjusted with H_2SO_4 (30% w/w) to ca. 2. Then 25 mL of H_2O_2 (0.3 mol) were added at 0°C. To this solution, under stirring, 6.08 mL (35 mmol) of HMPT were added and a yellow precipitate was immediately formed. The product was recrystallized from methanol. If needed, water molecule may be removed by keeping the complex over P_2O_5 under vacuum for one night. The properties of the complex are in agreement with the previously reported data.

$MoO_5.HEPT.H_2O$. HEPT (0.58 g, 2.2 mmol) was slowly added, under stirring at 0°C, to an aqueous solution of MoO_3 dissolved in H_2O_2 (see preceding paragraph). A yellow precipitate was formed immediately, and was stirred for an additional 30 min, then filtered off. The filtrate was washed several times with water and ethylic ether (80% yield). The complex may be dehydrated as previously described; ir (KBr) ν(Mo=O) 950, ν (Mo<O,O>) 542, 590, ν(P=O) 1212 cm^{-1}. *Anal.* calcd. for $C_{12}H_{30}N_3O_6MoP$: C 32.80, H 6.90, N 9.60; found: C 32.93, H 7.07, N 9.59.

$MoO_5.p\text{-}MePyO.H_2O$. A solution of *para*-methyl pyridine *N*-oxide (10.9 g, 0.1 mol) in 5 mL of water was added to a solution of MoO_3 (15 g, 0.1 mol) dissolved in H_2O_2, in an ice-cold bath. A bright yellow precipitate was formed. It was filtered off and washed well with water and ether (70% yield); ir (KBr) ν(Mo=O) 965, ν(Mo<O,O>) 540, 583 cm^{-1}. *Anal.* calcd. for $C_6H_9NO_7Mo$: C 23.78, H 2.99, N 4.62; found: C 23.56, H 2.99, N 4.63.

$MoO_5.TEPT.H_2O$. To a solution of MoO_3 dissolved in H_2O_2 1 equiv. of TEPT was added in a minimum volume of water at 0°C. A pale yellow precipitate was immediately formed. It was filtered off and washed with ether (40% yield). Iodometric titration of active oxygen indicated a purity of 95% based on a molecular weight of 372.99 corresponding to $C_6H_{20}N_3O_7MoP$. Contrary to previously reported compounds this complex decomposes rapidly.

It may be stored at −23°C for 3–4 days.

CAUTION: Dehydration of $MoO_5.TEPT.H_2O$ under vacuum has resulted in a violent decomposition. Such procedure should be avoided. Concentration of the organic phase containing the peroxometal complexes during work-up may also be dangerous.

Apparatus and standard procedures

^{1}H nmr spectra were recorded on a Bruker WP 200 ST, TMS as internal reference; ^{31}P nmr spectra were obtained on a Bruker WP60, H_3PO_4 30% in D_2O as external reference. Ultraviolet–visible spectra were recorded using a Varian Cary 219 or a Perkin-Elmer Lambda 5 spectrophotometer. Infrared spectra were recorded on a Perkin-Elmer PE 580 B in KBr pellets.

The pH values of the solutions were controlled and the potentiometric measurements were carried out on a Metrohm 632, using a standard glass electrode. Conductometric measurements were obtained on RADIOMETER CDM 3. Potentiometric and conductometric acid–base titrations were performed by stepwise addition of freshly prepared 0.01 *M* solutions of NaOH (Normex) or $NaOPr^i$, under argon. Acid–base titrations were carried out using phenolphthalein as indicator. Melting and boiling points are uncorrected. The extraction experiments were carried out as follows: 2.5 mL of an aqueous solution containing Na_2MoO_4 (0.02 *M*) and H_2O_2 (0.8 *M*) at a fixed pH value, obtained by the addition of a strong acid and 2.5 mL of organic phase containing the lipophilic ligand, usually 0.04 *M*, were stirred together for 3 min. After this time the stirring was suspended and the two phases separated. The amount of peroxomolybdenum complex remaining in the aqueous solution was determined by uv spectroscopy using the appropriate λ_{max}, depending on the pH.

This paper is dedicated to Professor Arthur N. Bourns

ROBERT A. MCCLELLAND and POUL E. SØRENSEN. Can. J. Chem. **64**, 1196 (1986).

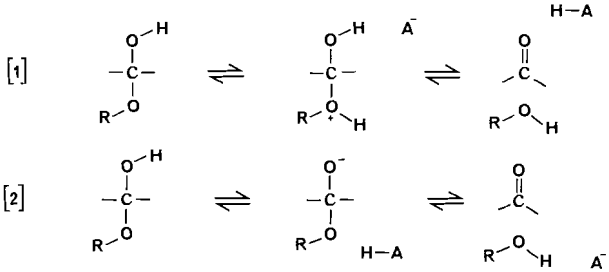
A temperature-jump relaxation study is reported for the equilibration: 3-hydroxyphthalide (SH) ⇄ *o*-formylbenzoate (R^-) ⇄ *o*-formylbenzoic acid (RH). A kinetic analysis is carried out in which SH and R^- interconvert with catalysis in the ring opening direction by water and by added general bases. Excellent Brønsted plots based upon a series of oxyacid buffer catalysts are obtained. These have slopes β for the base-catalyzed ring opening of 0.81 and α for the reverse acid-catalyzed ring closing of 0.19. A mechanism where S^-, the conjugate base of SH, is a discrete intermediate can be ruled out on the basis of the Brønsted values and the magnitudes of the rate constants. The lifetime of S^- is estimated to lie in the range 10^{-11}–10^{-15} s. Two mechanisms can be proposed. A fully concerted mechanism "enforced" by lifetimes less than 10^{-13} s involves direct interconversion of SH and R^- with no intermediate. A preassociated mechanism "enforced" by lifetimes in the 10^{-11}–10^{-12} s range requires, in the ring closing direction, that an acid catalyst be hydrogen bonded to the carbonyl in R^-.

ROBERT A. MCCLELLAND et POUL E. SØRENSEN. Can. J. Chem. **64**, 1196 (1986).

On rapporte une étude sur la relaxation par saut de température de l'équilibre hydroxy-3 phtalide (SH) ⇄ *o*-formylbenzoate (R^-) ⇄ acide *o*-formylbenzoïque (RH). On a effectué une analyse cinétique dans laquelle SH et R^- se transforment l'un dans l'autre sous l'influence d'une catalyse par l'eau et les bases générales qui favorise l'ouverture du cycle. On a obtenu d'excellentes corrélations de Brønsted qui sont basées sur une série de catalyseurs de tampons d'oxyacides. Les pentes, β pour l'ouverture du cycle qui est catalysée par les bases et α pour la réaction inverse de fermeture du cycle sous l'influence des acides, sont respectivement 0,81 et 0,19. En se basant sur les valeurs de Brønsted et sur les amplitudes des constantes de vitesse, on peut éliminer le mécanisme impliquant S^-, la base conjuguée de SH, comme intermédiaire identifiable. On estime que le temps de vie de S^- se situe entre 10^{-11} et 10^{-15} s. On propose deux mécanismes. Un mécanisme complètement concerté et maintenu par des temps de vie de moins de 10^{-13} s implique une interconversion directe de SH et R^-, sans intermédiaire. Un mécanisme pré-associé maintenu par des temps de vie de 10^{-11} à 10^{-12} s nécessite, lors de la fermeture du cycle, qu'un catalyseur acide forme une liaison hydrogène avec le groupement carbonyle de R^-.

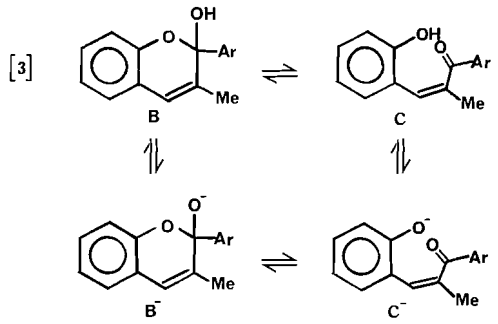
[Traduit par la revue]

Structure–reactivity correlations have provided recent evidence (1–4) that the general acid-catalyzed breakdown of hemiacetals follows the class "e" mechanism (5) of eq. [1] while the general base-catalyzed breakdown follows the class "n" mechanism of eq. [2]. The overall reaction involves three



bonding changes, C—O bond breaking and two proton transfers, and in each of the two reactions one of the proton transfers is usually written coupled with the heavy atom reorganization. A simple explanation as to why the two reactions follow their particular courses is that in so doing they avoid a less stable intermediate, a protonated aldehyde in the case of the acid reaction and an alkoxide ion in the case of the base reaction.

We recently analyzed the base catalysis of the equilibration of the cyclic hemiacetal B (Ar = 4-methoxyphenyl) with its *cis*-chalcone isomer C (6). This system has a phenol leaving



group and thus represents the situation where the anion derived from the leaving group is more stable. Indeed the evidence supported a different mechanism, one in which all three bonding changes were uncoupled and both the hemiacetal anion B^- and the phenolate anion C^- were formed as intermediates. Also of interest were the enormous rates associated with the interconversion of the two anions, ring opening of B^- to C^- for example having a rate constant of 10^9 s^{-1}. The lifetime of the hemiacetal anion is therefore extremely short, and one can imagine a situation with even more stable leaving anions where the lifetime might become so short that the hemiacetal anion could not exist. In this case the reaction would become two steps again, but now as a class "e" mechanism (eq. [4]).

In this paper we present kinetic results pertaining to the buffer

[4] 
catalysis of the reversible ring opening of the hemiacylal 3-hydroxyphthalide, a system with a carboxylate leaving group. Although the equilibration in question is very rapid, it can be studied by the temperature-jump relaxation method (7). A previous study (7) has demonstrated buffer catalysis, but only two buffers, the substrate itself and HF, were investigated. In order to more fully establish mechanistic details we have now looked at a series of carboxylic acid and other oxyacid catalysts.

Experimental

o-Formylbenzoic acid (Aldrich) was recrystallized from water–benzene. Other materials were of Analar grade and were used without further purification. Phosphonic acids were the gifts of A. J. Kresge (8).

The equilibration was studied by use of the temperature-jump method, on a Messanlagen-Studiengesellschaft spectrophotometer. Solutions of the substrate ($(1–6) \times 10^{-4}$ *M*) were prepared in the appropriate buffer, the pH recorded, and the solution placed in the T-jump cell. The spectrophotometer was thermostatted at 21.5°C and a 3.5°C temperature jump applied. The relaxation was observed at 255 nm. The photomultiplier output was digitized (380 points per run), and the digital data transferred to an IBM 3033 computer (NEUCC, Copenhagen), where relaxation constants (τ^{-1}) were evaluated by least-squares fitting. Four to six kinetic runs were carried out for each solution.

Results and discussion

The system in question consists of three species (eq. [5]),

[5] 
whose equilibrium relationships are known (7).

$$[6] \qquad \frac{[SH]}{[RH]} = K_0 = 14.8$$

$$[7] \qquad \frac{[R^-][H^+]}{[RH]} = K_{RH} = 10^{-3.36}\,M$$

$$[8] \qquad \frac{[R^-][H^+]}{[SH]} = \frac{K_{RH}}{K_o} = 10^{-4.55}\,M = \frac{k_0}{k_{H+}} = \frac{k_A K_{HA}}{k_{HA}}$$

Equilibration kinetics were investigated by the T-jump method (7), monitoring changes in absorbance at 255 nm due to the *o*-formylbenzoate ion. Relaxations were observed in a variety of oxyacid buffers; conditions and relaxation constants τ^{-1} are given as supplementary material (see Appendix, Table A1). Data for acetate buffers are plotted in Fig. 1.

Analysis is carried out through the mechanism of eq. [5], where ring opening of SH occurs with general base catalysis to give directly R^- (7). Bases involved are the solvent and the base component of the buffer. R^- itself can also function as a base, and its catalytic coefficient was determined in the previous study with unbuffered solutions (7). At the concentrations employed here, however, its contribution is small. A similar argument applies to hydroxide ion, another possible base catalyst. The assumption is made that simple proton transfers are fast on the time scale of the observed relaxation, so that

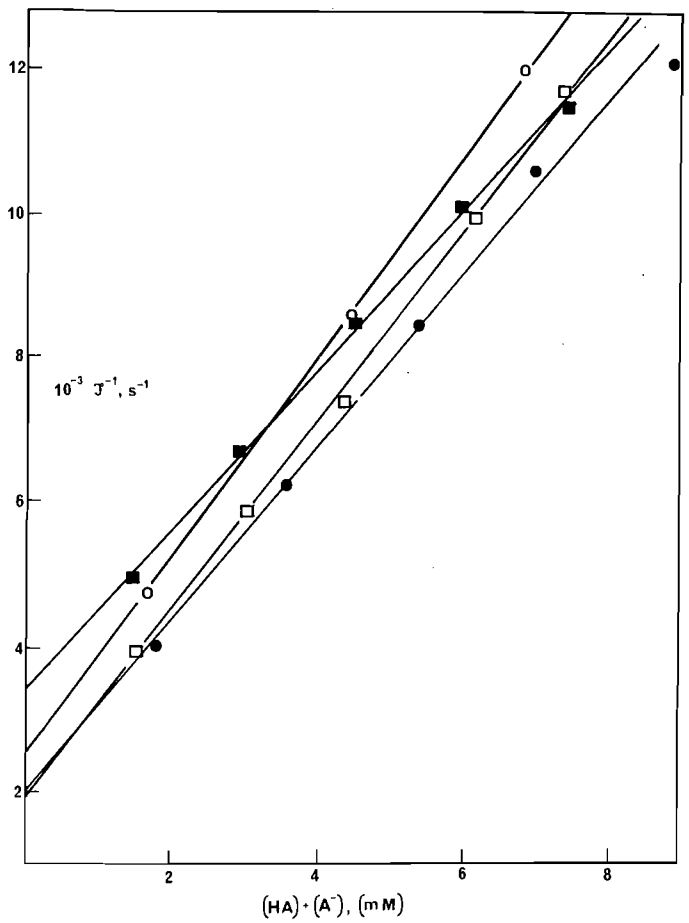


FIG. 1. Relaxation constants as a function of total buffer concentration in acetate buffers. (□), pH = 4.94, [S] = total substrate concentration = 0.155 m*M*; (○), pH = 4.50, [S] = 0.31 m*M*; (●), pH = 4.50, [S] = 0.155 m*M*; (■), pH = 4.22, [S] = 0.31 m*M*.

$$[9] \qquad K_{RH} = \frac{(\bar{H} + \delta_H)(\bar{R} + \delta_R)}{(\overline{RH} + \delta_{RH})}$$

$$[10] \qquad K_{HA} = \frac{(\bar{H} + \delta_H)(\bar{A} + \delta_A)}{(\overline{HA} + \delta_{HA})}$$

where $\bar{X}$ = concentration at equilibrium after the T-jump, δ_X = displacement from equilibrium at any time, and K_{HA} = dissociation constant of buffer. Noting that the following conditions apply: $\delta_{HA} + \delta_A = 0$, $\delta_{SH} + \delta_{RH} + \delta_R = 0$, and $\delta_R + \delta_A = \delta_H$, expressions can then be derived relating all displacements to δ_{SH}. The forward and reverse rate constants are also related (eq. [8]). The appropriate equation is then written for $d\delta_{SH}/dt$, and after some algebra, the following is obtained,

$$[11] \qquad \tau^{-1} = (k_0 + k_A[A^+])\left(1 + \frac{K_0([H^+] + [R^-]X)}{(K_{RH} + [H^+] + [R^-]X)}\right)$$

where $X = (K_{HA} + [H^+])/(K_{HA} + [H^+] + [A^-])$. We define the second term in brackets as C, and plot τ^{-1}/C versus $[A^-]$ (Fig. 2). The validity of this analysis is established by the observation of a common line for the various sets of relaxations obtained in acetate buffers. In addition, a common intercept (k_0)

TABLE 1. Catalytic constants for the general base-catalyzed ring opening of 3-hydroxyphthalide, general acid-catalyzed ring closing of 2-formylbenzoate

Catalyst (acid form)	pK_a	k_A, M^{-1} s^{-1}	k_{HA},[a] M^{-1} s^{-1}

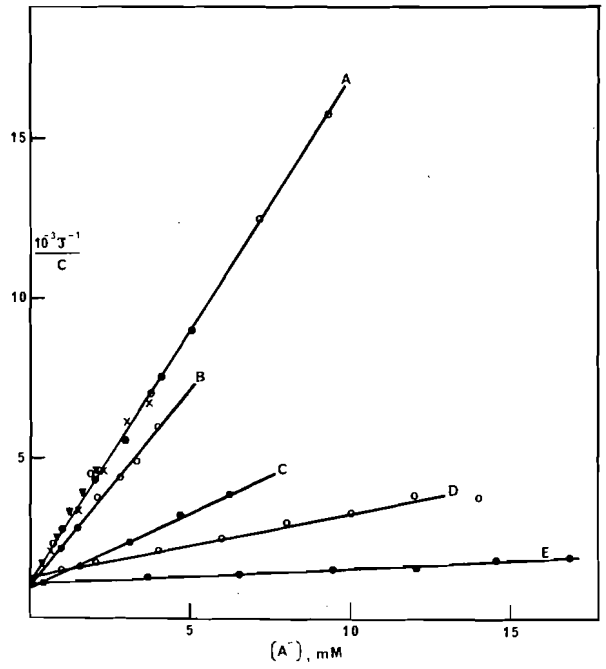

FIG. 2. Corrected relaxation constants (τ^{-1}/C) as a function of the concentration of the base component of the buffer. A: acetate, ●, pH 4.94, [S] = 0.155 mM; ○, pH = 4.50, [S] = 0.31 mM; X, pH = 4.50, [S] = 0.155 mM; ▼, pH = 4.22, [S] = 0.31 mM. B: trichloromethylphosphonate, pH = 4.45, [S] = 0.31 mM. D: methoxyacetate, pH = 4.04, [S] = 0.62 mM. E: chloroacetate, pH = 3.60, [S] = 0.62 mM.

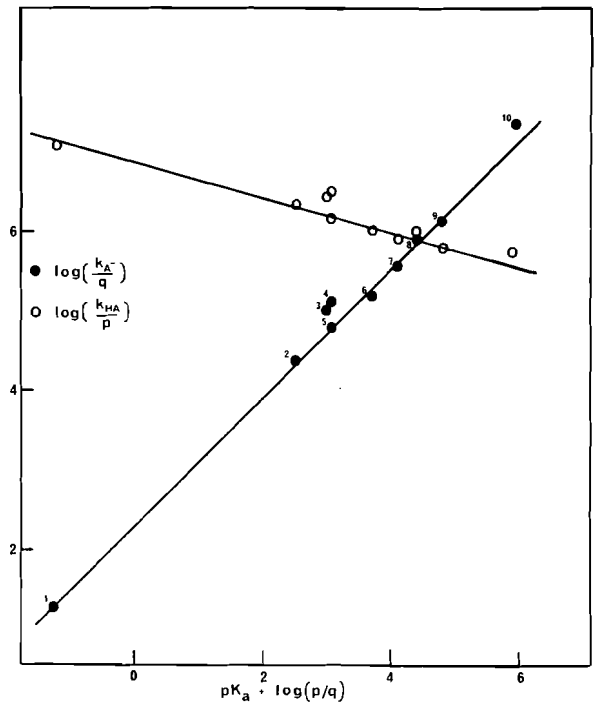

FIG. 3. Brønsted plots for the general base-catalyzed ring opening and microscopic reverse general acid-catalyzed ring closing of the equilibration 3-hydroxyphthalide ⇄ *o*-formylbenzoate. For catalysts see Table 1. Lines drawn are based on linear regression, excluding points 3, 4, and 10.

is found for the data in the different buffers. The slopes of the various lines provide the catalytic coefficients k_A. These and values of k_{HA} calculated using the relationship noted in eq. [8] are listed in Table 1.

Brønsted plots based on the catalytic coefficients are shown in Fig. 3. The cacodylic acid points deviate somewhat, as do the rates obtained previously (7) for HF/F^- and the substrate itself. Otherwise excellent linearity is observed, with the points for RPO_3H^-/RPO_3^{-2}, $RCOOH/RCO_2^-$, and H_3O^+/H_2O falling on a common line. The Brønsted β value for the base plot is 0.81 (correlation coefficient (cc) = 0.9996), ignoring the three deviating points, and shows an insignificant change (0.82, cc = 0.998) if the H_2O point is omitted. Considering all the data, β = 0.83 (cc = 0.994). The Brønsted α value is, as expected, 1−β or 0.19 (ignoring the three points). There is no apparent curvature in these plots. The base rates are becoming extremely fast with the stronger bases, and must soon plateau at the diffusion limit of $\approx 10^{10}$ M^{-1} s^{-1}. Hydroxide presumably would react with a rate constant near this limit, but its catalytic coefficient cannot be measured since at the acidity where the equilibration can be studied (pH 3.5–5) it cannot compete even with the solvent. (With $k_0 = 10^3$ s^{-1}, the value of k_{OH} would have to be 10^{12} M^{-1} s^{-1} or greater for the hydroxide reaction to be important at pH 5.)

In terms of a detailed mechanism we can note first that the class "n" mechanism of eq. [2] is highly improbable, since there

is no need to protonate the carboxylate leaving group. A second possibility is a step-wise mechanism with a discrete hemiacylal anion S^- as an intermediate and, in order to account for the general acid–base catalysis, the proton transfer step rate limiting. This situation will arise if the ring opening of S^- (k_3) occurs faster than its reprotonation, as has now been observed in two cases (6, 9) including that described by eq. [3]. This mechanism can also be rejected. It requires that the observed rate constants k_0 and k_A be equal to k_1 and k_2 of eq. [12],

[12] 
respectively. This, however, predicts a Brønsted β value of 1, since k_1 and k_2 represent proton transfers in the thermodynamically unfavorable direction. The observed β is significantly less than this. Moreover, the observed k_0, k_A values predict an acidity constant for SH ⇄ S^- + H^+ of 7–8 (as pK_{SH}) using the relationship $K_{SH} = k_1/k_{-1} = k_2K_{HA}/k_{-2}$, with k_{-1}, k_{-2} having values near 10^{10} M^{-1} s^{-1}. As discussed in the next paragraph, pK_{SH} is likely considerably greater.

Some idea of the magnitude of pK_{SH} is important for future considerations. A value of 12.3 has been obtained for the hemiacetal AH (10). *Ortho* carbonyl groups are acid strengthening towards a neighbouring carboxylic acid group, decreasing the dissociation constant by about one pK unit, as for example in phthalic acid or RH. Since ρ values for Ar-CRR′ (OH) are close to unity (11), the effect on an alcohol dissociation should be similar, and thus an initial estimate for pK_{SH} is 11.3. For two reasons this may underestimate the effect. Firstly, in SH there is additional inductive transmission through the ring oxygen (12). The magnitude of this effect is difficult to determine; current thinking is that inductive effects are relatively unimportant (12). A second and perhaps more significant effect is a polar one arising from the placement of a partial positive charge on the ring oxygen through its conjugation with the carbonyl. This effect is also difficult to estimate but it should also result in acid strengthening. Considering these uncertainties, we predict that pK_{SH} lies in the range 10.5–11.0.

A further important consideration is the rate constant expected for ring opening of the hemiacylal anion S^- (k_3 of eq. [12]). A rate constant (k_{op} of eq. [13]) of 6×10^5 s^{-1} can be calculated

[13] 
for the hemiacetal anion A^-. This is based upon an observed rate constant of 1.4×10^7 M^{-1} s^{-1} for hydroxide ion catalyzed opening of AH and the pK_a value of 12.3 (10), since $k_{OH} = k_{op}K_a/K_w$. For hydroxide ion catalyzed breakdown of formaldehyde hemiacetals (1) and acetaldehyde hemiacetals (14), β_{1g} values are −1.1 and −0.9, respectively. These contain a contribution from deprotonation of about −0.2 (1), so that β_{1g} values for hemiacetal anion breakdown are −0.9 and −0.7. Such values will obviously depend on the "push" due to the developing carbonyl, more stable carbonyls resulting in an earlier transition state and less negative β_{1g}. For example, for the tetrahedral intermediate $CH_3C(O^-)(SAr)(OAr)$ β_{1g} for aryloxide expulsion is only −0.3 (13). Acetaldehyde provides a better model for the carbonyl group in question here, although it can be noted that geometrical constraints are such that in the ring opening of S^- the developing carbonyl and benzene are not conjugated in the transition state so that the actual "push" may be more like that in a formaldehyde system. The pK_a of the carboxylic acid leaving group in S^- is 11 log units smaller than that of the benzyl alcohol in A^-. The two hemiacetal values then predict ring opening rate constants of 5×10^{15} s^{-1} (−0.9) and 3×10^{13} s^{-1} (−0.7). Both numbers are such that S^- could not exist (14). Considering that there is some uncertainty in β_{1g} and, perhaps more importantly, a rather lengthy extrapolation is involved, the actual number could be smaller. It is, however, difficult to see how it could be much less than 10^{11} s^{-1}.

[14] 
With these considerations two mechanisms can be proposed. One is fully concerted with proton transfer and CO bond making/breaking occurring at the same time, and with no intermediate between SH and R^-. For such a mechanism the position of the transition state with respect to proton transfer is defined by the Brønsted values. In the ring opening direction, proton transfer to the catalyzing base is 8/10 complete. A concerted mechanism would be "enforced" (14) by rate constants for S^- breakdown greater than 10^{13} s^{-1}.

The second possibility is a preassociation mechanism (14, 15). Viewed in the direction of the ring closure, the catalyzing acid is present in the rate-limiting C—O bond-forming step hydrogen bonded to the carbonyl oxygen, and is therefore available to convert the hemiacylal anion into neutral hemiacylal as soon as the anion is formed. This mechanism would also be "enforced", this time by rate constants for S^- breakdown in the range 10^{11}–10^{12} s^{-1}, such that ring opening occurs before diffusional separation. Such a mechanism does fit with the Brønsted data. Previous examples have had α values near 0.15 (13), attributable to a small stabilization of the transition state with increased acidity because of the hydrogen bonding to the developing negative charge.

It is also instructive to consider what the last mechanism requires to explain the observed rate constants. The equilibrium constant $[S^-]/[R^-]$ is equal to $K_{SH}K_0K_{RH}$, and a value of 10^{-6}–10^{-7} is calculated with the known K_0 and K_{RH} and the K_{SH} estimate noted previously. The equilibrium in eq. [15] involves hydrogen bonded anions ($[S^- \ldots HA]/[R^- \ldots HA]$) and will be more favorable towards the stronger base S^-. It seems unlikely, however, that the equilibrium constant can be greater than 10^{-5}. The rate constant k_{-4} cannot be greater than 10^{12} s^{-1}, or otherwise $S^- \ldots$ HA would not exist. Coupling this with the equilibrium constant, k_4 must be less than 10^7. For this mechanism the observed k_{HA} is equal to $K_{as}k_4$, and thus even for the weakest acid, cacodylic acid ($k_{HA} = 1 \times 10^6$ M^{-1} s^{-1}, K_{as} must be greater than 0.1 M^{-1}. Hydrogen bonding association constants for aldehydes are unknown, but since they are weakly basic, it seems unlikely that the value can be much larger than this. The more basic formate ion associates with its conjugate acid $(HCOOH{\cdot}OOCH)^-$, and even here K_{as} is only 0.25 M^{-1}

[15] 
(16). A value of 1/55.5 or 0.02 would pertain to a situation with random encounter.

[16] 
In summary, both the S^- life-time estimate and the requirements for k_4, K_{as} in the preassociation mechanism provide some support for a fully concerted mechanism. However, the uncertainties in the various analyses are such that preassociation cannot be rigorously excluded. The lifetime of S^-, however, must be extremely short, and whichever is the mechanism, it is different from those previously observed. Finally, it can be noted that an anion like S^- is the tetrahedral intermediate of a nucleophilic substitution of a phthalic anhydride. (If $X^- = H^-$, the intermediate is S^-.) If this anion has a lifetime such that it cannot exist, it is not an intermediate but has been transformed into a transition state for a concerted reaction.

This paper is dedicated to Professor Arthur N. Bourns

D. J. MCLENNAN, A. R. STEIN, and B. DOBSON. Can. J. Chem. **64**, 1201 (1986).

Kinetic chlorine isotope effects attending the solvolysis of several ring-substituted 1-phenylethyl chlorides in alcohol–water solvent mixtures are reported. The k_{35}/k_{37} values are insensitive to the identity of ring substituents and to solvent composition. Results are interpreted in terms of an S_N1 heterolytic process incorporating a significant amount of internal return. Theoretical calculations suggest that the incipient chloride ion in the transition state may be strongly hydrogen-bonded.

D. J. MCLENNAN, A. R. STEIN et B. DOBSON. Can. J. Chem. **64**, 1201 (1986).

On a mesuré les effets isotopiques cinétiques du chlore qui accompagnent les solvolyses de plusieurs chlorures de phényl-1 éthyle substitués sur le cycle. Les valeurs de k_{35}/k_{37} sont insensibles à la nature des substituants sur le cycle ainsi qu'à la composition du solvant. On interprète les résultats en fonction d'un processus hétérolytique S_N1 incorporant une part importante de retour interne. Des calcultes théoriques suggèrent que l'ion chlorure qui attaque dans l'état de transition pourrait être fortement lié par des liaisons hydrogènes.

[Traduit par la revue]

Introduction

Much insight into the nature of S_N1 solvolysis has come from studies on 1-phenylethyl halides. Kinetic (1), stereochemical (2), secondary α- and β-deuterium isotope effect (3, 4), and carbon isotope effect (5–8) studies have been reported. Recent work has focussed on the generation and the fate of substituted 1-phenylethyl cations in solution as a function of their lifetimes (9–11).

Leaving group kinetic isotope effects have not been as widely exploited in solvolysis reactions as in other systems. Chlorine isotope effects in the solvolysis of *tert*-butyl chloride (12) and substituted benzyl chlorides (13), and sulfur isotope effects in the solvolysis of the *tert*-butyldimethylsulfonium (14) and benzyldimethylsulfonium (15) cations appear to be the only available examples. In view of our interests in the reactions of 1-phenylethyl derivatives (16–18), in chlorine isotope effects (19, 20), and in isotope effects in general solvolytic processes (21, 22), we decided to measure chlorine isotope effects in the solvolysis of ring-substituted 1-phenylethyl chlorides.

Results

The reactions exemplified by reaction [1] were investigated.

[1] $$\mathrm{Ar{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}Cl + SOH \rightarrow Ar{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}OS + H^+ + Cl^-}$$

Ar = 3,4-$Me_2C_6H_3$, 4-MeC_6H_4, C_6H_5, 4-BrC_6H_4 S = H, Et, CF_3CH_2

Previous investigations have shown that styrene formation is never greater than 3% (3, 5, 18); hence it was neglected. Chloride ion released after partial and complete reaction was quantitatively converted to methyl chloride, and the $^{35}Cl/^{37}Cl$ ratio was assessed in the usual way using an isotope ratio mass spectrometer. Results obtained are shown in Table 1 (for EtOH–H_2O solvents) and Table 2 (for 97% TFE – H_2O solvent). Comment on the accuracy and reproducibility of the isotope effects is in order. The sample 52/50 mass ratios, R, and those for the standard methyl chloride, R_0, are commonly expressed as δ values via eq. [2]. As calculated by repetitive

[2] $$\delta = 1000(R/R_0 - 1)$$

sample/reference comparisons on a single gas sample, δ values were as constant as those previously reported from our laboratory, and varied by no more than 0.5% (19, 20). However, day-to-day variations in δ for the same sample of methyl chloride were of the order of ±2–3%, when compared with the same reference gas. Variations of this nature are not unusual (15) and, so as far as was possible, partial reaction samples and infinity samples were analysed on the same day. Furthermore, samples of methyl chloride independently prepared from the same original sample of AgCl and analysed on different days exhibited variations in δ of up to ±5%, whereas in our previous studies (19, 20), these variations were no greater than ±1%. Limited access to the mass spectrometer precluded a systematic and detailed examination of reasons for this loss of reproducibility under conditions of apparently equal precision.

Constraints of access prevented our analysing all partial reaction and infinity samples of methyl chloride on the same day. Since all infinities were generated from the same sample of 1-arylethyl chloride, it seemed in order to use a mean value obtained from measurements on different days, since δ_∞ values showed no temporal trend. To illustrate the effect of this we recalculated the results for 1-phenylethyl chloride itself, using the individual δ values from Table 1 and mean of the six δ_∞ values, which themselves were calculated from 17 separate 6-fold cycles (see Experimental). In Table 3 we show that the ultimate effect on k_{35}/k_{37} is almost inconsequential. We therefore estimate that the k_{35}/k_{37} values in Tables 1 and 2 are uncertain to the extent of around ±0.0005, which is some ten times the uncertainty established in our earlier work. For this reason we were unable to detect any real variation in k_{35}/k_{37} as (*i*) ring substituents, (*ii*) solvent compositions in EtOH–H_2O, and (*iii*) temperatures, were varied. Within 95% confidence limits, there is no substrate or solvent variation of k_{35}/k_{37}. The same applies to reactions in TFE–H_2O (Table 2) but, when

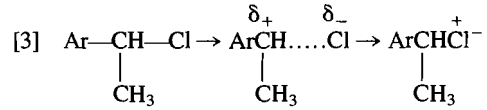
[a]These represent completely independent solvolyses. A common δ_∞ only was used to calculate k_{35}/k_{37}.

standard deviations are taken into account, k_{35}/k_{37} is significantly larger for the EtOH–H_2O solvent system than for reactions conducted in TFE–H_2O.

Discussion

Transition state variation

If all solvolyses are k_C processes, represented by reaction [3]



as the rate-limiting step, then the results suggest that neither ring substituents nor solvent composition (in EtOH–H_2O) affect the degree of bond-breaking and charge development in the transition state (TS). Both ρ^+ (3) and Grunwald–Winstein m values (23) are numerically large for the 1-phenylethyl halide solvolysis system, suggesting that bond rupture and charge transfer are well advanced at the TS. Theory decrees that if simple carbon–chlorine stretching comprises the reaction coordinate the TS should become more reactant-like as electron-donating groups stabilize the carbocationic portion of the ion pair (24, 25) and if such a variation is significant the chlorine isotope effect should become smaller (20, 26, 27). It does not.[2]

Similarly, if C—Cl heterolysis is nucleophilically solvent-assisted (S_N2-like ion pair formation) the same should apply (24, 28). We are therefore left with the alternatives that either the theory is wrong, or that the mechanism is more complex than has been supposed.

Two earlier reports concur. Hill and Fry (13) find that k_{35}/k_{37} for solvolyses in the $ArCH_2Cl$ system is substituent-insensitive. Friedburger and Thornton find the same pattern for sulfur isotope effects in the hydrolysis of $ArCH_2SMe_2^+$ ions. The latter authors have made a detailed enquiry into mechanistic alternatives, and have somewhat tentatively suggested that S_N2 water attack, with TS insensitivity in the tight–loose dimension to substituent changes, may cause constant leaving-group isotope effects. They dismiss the possibility of rate-limiting water

[2]The relationship between chlorine isotope effects and transition state structure in bimolecular S_N2 reactions has recently been examined in detail. See ref. 46. It is not yet certain that all their conclusions can be extrapolated to solvolytic S_N1 reactions, and some of the present results suggest that there may be some differences.

[a]See footnotes to Table 1.

attack on a preformed ion–molecule pair (29). This may indeed be the case for a primary benzylic system, but we will show later that an S_N2 explanation is untenable for our secondary substrates. We recognise that the primary vs. secondary comparison is not in itself sufficient reason to reject nucleophilic solvent assistance to ion pair formation in our system (30).

The suggestion that TS structure (whatever it may be) is insensitive both to substituent and to solvent polarity (EtOH and H_2O have similar nucleophilicities (31)) has a parallel in findings on solvolysis of benzhydryl *p*-nitrobenzoates (32). However, the latter results were eventually interpreted in terms of a multistep mechanism, to which we will later return. In the meantime we recall the rejection by Jencks and Richard (32) of a significant degree of nucleophilic solvent assistance in the solvolysis of mildly activated 1-arylethyl chlorides.

It is of interest to note that the chlorine isotope effect is significantly lower when TFE–H_2O is the solvent (compare Tables 1 and 2). Trifluoroethanol is more electrophilic than EtOH and H_2O (33) and so will hydrogen bond more strongly to an incipient chloride ion in the TS than will the latter. If the degree of negative change development on chlorine is about the same in both solvent systems (and this does not necessarily mean that the solvolysis mechanisms need be identical) one would expect that k_{35}/k_{37} would be diminished by increasingly strong solvent coordination (26, 27). An alternative viewpoint is that the TS is earlier in the "faster" TFE–H_2O solvent, but there is no independent evidence for this. Calculations in the following section and others already reported (26) show that solvent coordination is necessary to obtain reasonable theoretical k_{35}/k_{37} values in the first place, and so an explanation based on relative electrophilicities would appear to be more reasonable.

Model calculations of chlorine isotope effects

Model calculations based on assumed TS structures and force constants for an ionization (k_C) model have been performed in an effort to understand the pattern of chlorine isotope effects. The basic model was as described for *iso*propyl chloride solvolysis (22) except that a point mass of 27 amu replaced a methyl group, and effectively simulated a phenyl group. The possibility that the positive charge on C_α in the TS is not fully delocalized by the phenyl group was simulated by assuming that the charge, equal to $1 - n_1$ in the *i*-PrCl case (22) where n_1 is the C_α....Cl TS bond order, could be replaced by $F(1 - n_1)$, where F is the fraction of charge not delocalized by the phenyl. The phenyl–C_α bond order then becomes $1 + (1 - F)(1 - n_1)$, which simulates partial double bond character for $F \neq 1.0$. Nucleophilic participation by π electrons in 1-phenylethyl halide solvolysis was first proposed by Bourns and Stothers (5) to explain an anomalously low carbon isotope effect, and the idea has re-emerged in more recent isotope effect calculations (34).

In order to obtain chlorine isotope effects of reasonable magnitude, it was necessary to simulate solvation of the incipent chloride ion in the TS, and this was done following the format established for *tert*-butyl chloride isotope effects (27). Three tetrahedrally-disposed HO groups were placed in proximity to the chlorine. The Cl....HO bond was assigned bond orders in the range $0.05(1 - n_1)$ to $0.3(1 - n_1)$, which are somewhat larger than those orginally specified (27, 35).

The reaction coordinate motion for the simple k_C model was visualized as chloride transfer from C_α to the solvent hydrogens:

$$\overset{\qquad f_{11} \qquad f_{22}}{C_\alpha \cdots\cdots Cl \cdots\cdots (HO)_3}$$
$$\leftarrow \qquad \rightarrow \qquad \leftarrow$$

by appropriate formulation of an off-diagonal force constant f_{12} based on the diagonal constants f_{11} and f_{22} (36). A solvent-assistance model was also used, similar to that employed for *i*-PrCl (22). Here the nucleophilic H_2O was viewed either as an entering nucleophile so that O....C_α shortening accompanied C_α....Cl stretching in the TS, or as a solvating spectator. Similar results were obtained for both cases and, since only weak solvent assistance was simulated ($n_{OC} < 0.2$), the inclusion of assistance had little effect on the calculated values of k_{35}/k_{37}. Values of α-k_H/k_D, β-k_{CH_3}/k_{CD_3}, and k_{12}/k_{13} for the central carbon were calculated as well. Details and results will be presented in a forthcoming publication.

It is necessary only to contrast two extreme cases for k_{35}/k_{37}. The first line of Table 4 shows the dependence of k_{35}/k_{37} on n_1 as the TS structure is changed from reactant-like to product-like in a case where (*i*) the choice of parameters for formulation of f_{12} keeps $\nu_L^\pm$, the reaction coordinate frequencies, at low absolute values and (*ii*) only weak hydrogen bonding of the chlorine is similated. The k_{35}/k_{37} values are seen to increase as the TS C_α....Cl bond is made weaker, as expected (20, 22, 26, 27). The second line refers to a case where (*i*) higher absolute values of $\nu_L^\pm$, corresponding to higher barrier curvature, are generated and (*ii*) stronger hydrogen bonding of the chlorine is simulated. The k_{35}/k_{37} values now pass through a flat maximum. Between n_1 values of 0.7 and 0.1 k_{35}/k_{37} is almost constant.

This is then the chlorine analogue of the Westheimer–Melander maximum for proton transfer (37). This is the first theoretical report of such a phenomenon for a leaving group isotope effect; maximal carbon isotope effects in S_N2 alkyl transfers have already been experimentally (38) and theoretically (39) described. It provides a rationale of our results within the framework of substituent-induced TS variation according to the

TABLE 4. Calculated chlorine isotope effects at 25.0°C for two TS models for the unassisted solvolysis of 1-phenylethyl chloride

	k_{35}/k_{37} for n_1 =					
	0.9	0.7	0.5	0.3	0.1	0.05

Model 2[b]	1.00841	1.00968	1.00985	1.00982	1.00981	1.00889

[a] $F = 1.00$, average $\nu_L^{\ddagger}$ 200i cm^{-1}, Cl....HO bond order 0.1 $(1 - n_1)$.
[b] $F = 1.00$, average $\nu_L^{\ddagger}$ 365i cm^{-1}, Cl....HO bond order 0.3 $(1 - n_1)$. Note that k_{35}/k_{37} is relatively insensitive to the value chosen for F over the range 1.00–0.4.

rules (24, 25, 28). The effect of strengthening the hydrogen bonds to chlorine is to lower k_{35}/k_{37} overall; this provides a rationale for the lower isotope effects observed for solvolysis in the more electrophilic TFE–H_2O solvent (Tables 1 and 2). The model also yields values of α-k_H/k_D and β-k_{CH_3}/k_{CD_3} in reasonable agreement with experiment (3). Yet it may well be wrong, for two reasons.

Firstly, the degree of hydrogen bonding needed to generate a maximum without resorting to reaction coordinate formulations which generate unrealistically high absolute values of $\nu_L^{\ddagger}$ is unreasonably high. It is in fact higher than the amount of hydrogen bonding (in bond order terms) estimated for a fully-developed, solvated chloride ion (26, 35).

Secondly, the model fails to reproduce the low carbon isotope effect reported by Bourns and Stothers (5) and the anomalous temperature dependence of this isotope effect reported by Bron and Stothers (7, 8), even when small values of F are employed.

Admittedly, the experimental work pertains to 1-phenylethyl bromide solvolysis, but model calculations on the bromide also yielded larger carbon isotope effects having a normal temperature dependence. We must therefore reject the simple k_C and solvent-assistance models despite the attraction of their reproducing the observed patterns of k_{35}/k_{37} behaviour.

We also note that while theory predicts the possibility of obtaining a maximum in k_{35}/k_{37} as TS symmetry is varied, the impractical parameters needed to force this result mean that experimental demonstration of this effect is unlikely.

Isotope effects in multistep mechanisms

Apparent lack of reactivity-selectivity behaviour in the benzhydryl-*p*-nitrobenzoate reaction series was explained in terms of a multistep mechanism in which opposing effects cancelled (40). We adopt the same approach here in following a treatment proposed by Murr and Donnelly (41). Assume that a stepwise mechanism of minimal complexity can be represented by reaction [4]. If intimate ion pair **2** partitions between internal

$$[4]\quad \underset{\mathbf{1}}{RCl} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\mathbf{2}}{R^+Cl^-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{\mathbf{3}}{R^+ \parallel Cl^-} \xrightarrow[SOH]{k_3} ROS$$

return to **1** and irreversible dissociation to loose ion pair **3**, such that $k_3 \gg k_{-2}$, then the observed chlorine isotope effect is given by eqs. [5] and [6] (41). In these, k_1^{35}/k_1^{37} is the

$$[5]\quad k_{obs}^{35}/k_{obs}^{37} = (k_1^{35}/k_1^{37})(F_2^{35}/F_2^{37})$$

$$[6]\quad F_2^{35}/F_2^{37} = \frac{(k_2^{35}/k_{-1}^{35}) + (k_{-1}^{37}/k_2^{37})/(k_{-1}^{35}/k_2^{35})}{1 + (k_2^{35}/k_{-1}^{35})}$$

ionization isotope effect to which the models in the previous section pertained, and F_2^{35}/F_2^{37} is the partitioning isotope effect for partitioning of **2**. Thus *two* transition states need to be considered: TS(**1** → **2**) for ionization and TS(**2** → **3**) for ion pair interchange. The carbon–chlorine bond should become progressively looser as one proceeds from **1** to **3**.

The introduction of electron-donating substituents into the ring should cause k_1^{35}/k_1^{37} to decrease as TS(**1** → **2**) becomes more reactant-like if theory is correct, and if the more normal of the two models of Table 3 applies. On the other hand, k_2^{35}/k_2^{37} (which should be greater than unity (41)) may well increase in compensation, and the following reason can be advanced. Electron donation will stabilize the carbocationic portion of ion pair **2**, which should increase its selectivity. A stereochemical study suggests that k_2/k_{-1} is less than unity for the unsubstituted ion pair (2*d*) so k_2^{35}/k_{-1}^{35} could decrease further as electron donation renders the ion pair more selective (40). If then the second term in the numerator of eq. [6] is relatively insensitive to ion pair stability, being the quotient of isotope effects for the k_2 and k_{-1} steps, it is easily shown that F_2^{35}/F_2^{37} increases as k_2^{35}/k_{-1}^{35} decreases. Thus the compensating effect sought in eq. [5] can be realised. It is therefore possible that $k_{obs}^{35}/k_{obs}^{37}$ is insensitive to substituents even though chlorine isotope effects on the individual k_1, k_{-1}, and k_2 steps are sensitive because of substituent-induced changes in the character of TS(**1** → **2**) and TS(**2** → **3**).

This argument, insofar as it relates only to $k_{obs}^{35}/k_{obs}^{37}$, is speculative. However, similar considerations based on the same partitioning mechanism allow quantitative rationalization of α-k_H/k_D, β-k_{CH_3}/k_{CD_3}, and both k_{12}/k_{13} and its abnormal temperature dependence, as a forthcoming publication will reveal. A necessary condition is that K_1^{12}/K_1^{13} ($K_1 = k_1/k_{-1}$), the equilibrium carbon isotope effect for **1** ⇌ **2**, is less than unity, and this can be achieved either by using values of F less than unity (nucleophilic donation of π electrons to C_α of the carbocation as originally proposed by Bourns and Stothers (6)), or by nucleophilically solvating the carbocation (the S_N2 (int) mechanism (31)), or both. Thus the present results support the mechanistic arguments advanced by Shiner and co-workers on isotope effect (3) and stereochemical (2*d*) grounds in emphasizing the necessity for an element of internal return in 1-phenylethyl halide solvolysis. We note that competitive internal return is not incompatible with weak nucleophilic solvent assistance (42), nor alternatively with the presence of a pre-associating solvent molecule as a spectator (32).

It must also be mentioned that isotope effect anomalies frequently arise in multistep reactions where no single step is clearly rate-limiting. The present case thus complements a recently reported example from the elimination field, where internal return in a hydrogen-bonded carbanion gives rise to unusual chlorine isotope effects (20). On the other hand, stereochemical results for 1-arylethyl tosylate solvolysis in a variety of solvents have been interpreted in terms of an ion pair

mechanism where one step is clearly rate-limiting in a given solvent (43). It would be interesting to see if the primary carbon isotope effect in this system behaved normally.

Experimental

Substrates and solvents

The 1-phenylethyl chlorides were prepared by standard methods (3) from the corresponding alcohols, which were in turn afforded by reduction of substituted acetophenones. Solvolysis for 10 or more half-lives afforded yields of Cl^- in the 99–101% range, as assessed by precipitation with $AgNO_3$ and weighing. Ethanol was purified by a standard method and TFE as described by Sinnott and Jencks (44).

Isotope effect studies

Chloride ion released after partial and complete reaction was precipitated as AgCl and converted quantitatively to CH_3Cl. The isotope ratio was measured using a Varian-MAT CH7 mass spectrometer operating in the isotope ratio mode. Details are as earlier described in accounts from these (19, 20) and other (12, 13, 45) laboratories. One-point "rate coefficients" could be calculated from the weights of AgCl collected after partial and complete reaction. Where comparison was possible, these were in good agreement with published values of accurate rate constants (3, 23).

In each mass spectrometer measurement, a sample of gas was admitted to the sample inlet reservoir. Gas from a cylinder of methyl chloride was admitted to the reference reservoir and the pressures were equalized. A cycle: sample/purge/reference: (1 min each) was run at least six times and δ values were calculated using eq. [2]. These were concordant to within 0.5%, and a mean was taken. Both sample and reference reservoirs were then evacuated and fresh portions of gas were admitted to each side. The 6-fold cycle was repeated. In most cases two further repeats of the same gas sample were run. Where possible the same sequence was run, on the same day, for the infinity sample from the same reaction.

The uncertainties in δ and δ_∞ shown in Tables 1 and 2 are the mean deviations based on the two or four complete cycles run for the same methyl chloride sample. They are larger than the uncertainties calculated from individual δ values in a single cycle, and day-to-day variations in δ based on methyl chloride generated independently from the same AgCl sample varied more, up to ±5% from the mean. On the basis of the uncertainties in δ and δ_∞ in Tables 1 and 2, and an estimated 1% uncertainty in values of f, we calculate that the maximum experimental error in the derived k_{35}/k_{37} values is ±0.0005, or 0.05%.

Secondary α and β hydrogen–deuterium kinetic isotope effects have been used together to show that the S_N reaction between 1-phenylethyldimethylphenylammonium ion and bromide or iodide ion in chloroform occurs by way of an S_N2 mechanism within a triple ion in spite of the fact that it reacts faster than the primary substrate, benzyldimethylphenylammonium bromide. The very loose transition state and steric effects in the ground state appear to be responsible for the unusually fast S_N2 reactions between 1-phenylethyldimethylphenylammonium ion and halide ions in chloroform.

HELEN ALMA JOLY et KENNETH CHARLES WESTAWAY. Can. J. Chem. **64**, 1206 (1986).

On a fait appel à une combinaison des effets isotopiques cinétiques secondaires des hydrogènes et (ou) deutériums en α ainsi qu'en β pour montrer que le mécanisme de la réaction S_N qui se produit dans le chloroforme entre l'ion diméthyl phényl-1 éthyl phénylammonium et les ions bromure ou iodure est S_N2, dans un ion triple, et ce en dépit du fait que cette réaction soit plus rapide que celle du substrat primaire, le bromure de benzyl diméthyl phénylammonium. Il semble que l'état de transition très lâche et que les effets stériques dans l'état fondamental soient responsables pour la réaction S_N2 exceptionnellement rapide des halogénures de diméthyl phényl-1 éthyl phénylammonium dans le chloroforme.

[Traduit par la revue]

Introduction

Leffek and co-workers have extensively studied the decomposition of aralkyldimethylphenylammonium halides to aralkyl halides and dimethylaniline (the reverse of the Menschutkin reaction) in chloroform (1–5), eq. [1].

[1] $$Ar{-}\overset{|}{\underset{|}{C}}{-}\overset{+}{N}(CH_3)_2C_6H_5\ X^- \xrightarrow{CHCl_3} Ar{-}\overset{|}{\underset{|}{C}}{-}X + (CH_3)_2NC_6H_5$$

These workers concluded that the rate-determining step of the decomposition was the conversion of a quaternary ammonium ion into a carbocation and dimethylaniline inside a positively charged triple ion consisting of the two quaternary ammonium ions and one halide ion, eq. [2] (1–6).

[2] $$3\ ArCH_2\overset{+}{N}(CH_3)_2C_6H_5\ X^- \rightleftarrows [(ArCH_2\overset{+}{N}(CH_3)_2C_6H_5)_2\ X^-]^+ + [ArCH_2\overset{+}{N}(CH_3)_2C_6H_5\ X^-{}_2]^-$$

$$[(ArCH_2\overset{+}{N}(CH_3)_2C_6H_5)_2\ X^-]^+ \xrightarrow{slow} [ArCH_2\overset{+}{N}(CH_3)_2C_6H_5\ X^- + Ar{-}CH_2{}^+ + (CH_3)_2NC_6H_5]^+$$

$$\xrightarrow{fast} ArCH_2N(CH_3)_2C_6H_5 + ArCH_2{-}X + (CH_3)_2NC_6H_5$$

This mechanism was suggested for two reasons, i.e., because (*i*) very large secondary α-deuterium kinetic isotope effects of 1.25 (1.12 per α-D) and 1.20 (1.10 per α-D) were found for the decomposition of benzyldimethylphenylammonium bromide in chloroform and acetone, respectively (3) (the maximum value expected for a secondary α-deuterium kinetic isotope effect in an S_N2 reaction at this time was 1.04 per α-D or 1.08 per CD_2 group (7)), and (*ii*) because the reactivity of these salts was that observed for carbocation ion S_N reactions, i.e., the secondary substrate, 1-phenylethyldimethylphenylammonium bromide, reacted 22.5 times faster than the primary substrate, benzyldimethylphenylammonium bromide in chloroform.

More recent work, however, has shown that the benzyldimethylphenylammonium salts decompose by an S_N2 mechanism in dipolar aprotic solvents (8) and that unusually large secondary α-deuterium kinetic isotope effects are observed in the S_N2 reactions of benzyldimethylphenylammonium ions. In fact, Westaway *et al.* (9, 10) observed a secondary α-deuterium isotope effect of 1.18 (1.09 per α-D) in the S_N2 reaction with thiophenoxide ion in the dipolar aprotic solvent, DMF, eq. [3].

[3] $$C_6H_5S^- + C_6H_5CH_2\overset{+}{N}(CH_3)_2C_6H_5 \xrightarrow[DMF]{0°C} C_6H_5SCH_2C_6H_5 + (CH_3)_2NC_6H_5$$

Thus, the isotope effects for the S_N reactions of benzyldimethylphenylammonium ion in DMF, chloroform, and acetone are very similar, i.e., they vary from 1.09 to 1.12 per α-D and suggest that all three S_N reactions occur by the same mechanism, i.e., an S_N2 mechanism.

Theoretical calculations by Hartshorn and Shiner (11) support this conclusion. Their calculations predict that the maximum secondary α-deuterium kinetic isotope effect for the ionization of the methylammonium ion to a methyl carbocation and ammonia should be 1.19 per α-D (1.42 per CD_2 group). This means the minimum isotope effect for the formation of the methyl carbocation would be $(1.19)^{0.75} = 1.14$ per α-D or 1.30 per CD_2 group (10, 12). In the light of these facts, Westaway and Ali concluded that the substitution reaction in the decomposition of the benzyldimethylphenylammonium bromide in chloroform occurs by a simple S_N2

[1]Author to whom correspondence may be addressed.

reaction within the triple ion (10), eq. [4].

[4] $[(C_6H_5CH_2\overset{+}{N}(CH_3)_2C_6H_5)_2Br^-]^+ \longrightarrow$ 
$\longrightarrow C_6H_5CH_2Br + (CH_3)_2NC_6H_5 + C_6H_5CH_2\overset{+}{N}(CH_3)_2C_6H_5$

Finally, Islam and Leffek in a later publication (5) indicated that they believe the benzyl substrate reacts by the mechanism shown in eq. [4].

If the substitution reaction in the decomposition of benzyldimethylphenylammonium halides in chloroform occurs by an S_N2 mechanism within the triple ion, the observation that the secondary substrate, 1-phenylethyldimethylphenylammonium bromide reacts 22.5 times faster than the primary compound, benzyldimethylphenylammonium bromide, is surprising. This study was undertaken in an effort to determine the mechanism of the faster reaction and to learn why the rate of reaction is greater for the more highly substituted quaternary ammonium salt.

Results and discussion

Four different mechanisms, all occurring within the triple ion, could account for the surprisingly fast rate of decomposition found for the 1-phenylethyldimethylphenylammonium bromide in chloroform, Scheme 1. The first possibility is that this reaction occurs by the same S_N2 mechanism as the benzyldimethylphenylammonium bromide but that there is some factor that makes it faster than expected. The second possibility is that the substitution reaction in the decomposition of the 1-phenylethyldimethylphenylammonium bromide occurs via the carbocation S_N mechanism originally suggested by Leffek and co-workers. If this were the case, the carbocation S_N reaction would simply occur faster than the S_N2 reaction of the benzyldimethylphenylammonium bromide.

The rate constant could also be larger for the 1-phenylethyl compound if the only products of the reaction, 1-phenylethylbromide and dimethylaniline, were produced in a two-step elimination–addition reaction. In the first step, the bromide ion would act as the base and abstract a β-hydrogen from the substrate in an E2 elimination reaction to give styrene, hydrobromic acid, and *N,N*-dimethylaniline in the triple ion complex. In the second step, the hydrobromic acid would add across the π bond of the styrene in a Markovnikov addition to give the observed product, 1-phenylethyl bromide. If the reaction occurred via the elimination–addition mechanism, the first (elimination) step of the reaction would have to be rate determining for several reasons. First, no elimination product (styrene) could be found either during or after the reaction. This means that any hydrobromic acid that formed during the reaction must add quantitatively to the styrene. Since the acid could also react with the other elimination product, dimethylaniline, to form dimethylanilinium bromide in a fast acid–base reaction, the hydrobromic acid would have to react instantaneously with the styrene. Although this might seem unlikely, a simple experiment showed that hydrobromic acid does add instantaneously to styrene in chloroform at room temperature.[2] The addition reaction would be expected to be especially fast in the elimination–addition mechanism because the hydrobromic acid is formed immediately beside the π bond of the styrene and, in fact, the proton of hydrobromic acid is removed from the carbon that accepts the proton in the addition step. Finally, the reaction between hydrobromic acid and dimethylaniline might not occur because the hydrobromic acid is released on the opposite side of the π bond from the dimethylaniline in a *trans*, coplanar E2 elimination reaction.

The last possibility is that the observed rate of decomposition is the sum of the rate constants for the elimination–addition and the substitution reaction. If this was the case, the rate constant for the S_N reaction of the 1-phenylethyldimethylphenylammonium bromide might even be smaller than that found for the S_N2 reaction of the benzyl substrate.

Normally, a kinetic study would distinguish between most of the mechanistic alternatives for this reaction. However, because the reaction occurs within the triple ion, the same kinetic expression would be obtained for all of the mechanisms. As a result, the problem had to be resolved with other mechanistic criteria.

The initial attempt to distinguish between these four mechanisms involved determining the β-deuterium kinetic isotope effect for the reaction. If the substitution reaction occurred via an S_N2 mechanism within the triple ion, a small secondary β-deuterium kinetic isotope effect of between 1.02 and 1.10 would be expected,[3] Table 1. If the substitution reaction involved the formation of a carbocation triple ion intermediate, a large, hyperconjugative secondary β-deuterium isotope effect of between 1.15 and 2.5 should be observed.[3] If the elimination–addition mechanism is followed, the β-hydrogen (deuterium) is removed in the rate-determining step of the overall reaction and a large primary hydrogen–deuterium kinetic isotope effect of between three and ten would be expected (13). Finally, even if a small percentage of the reaction were to proceed via the elimination–addition pathway with a very small primary deuterium kinetic isotope effect of 3.0, a significant β-deuterium kinetic isotope effect would be observed.

The observed β-deuterium kinetic isotope effect for the reaction of the 1-phenylethyldimethylphenylammonium bromide in chloroform at 25°C was 1.144 ± 0.0097 per CD_3 (1.046/β-D), Table 2. This small isotope effect clearly eliminates any appreciable contribution from the elimination–addition mechanism, which would have a primary isotope effect of at least 3.0, Table 1. If one assumes the average secondary β-deuterium kinetic isotope effect found for an S_N2 reaction (1.06/CD_3 group) and an average primary isotope effect of 5.0 for the E2 elimination reaction, the isotope effect would be 1.14 when 9% of the reaction occurred via this route. Even if one uses the minimum secondary β-deuterium isotope effect of 1.02/CD_3 group for the S_N2 reaction and a minimum primary isotope

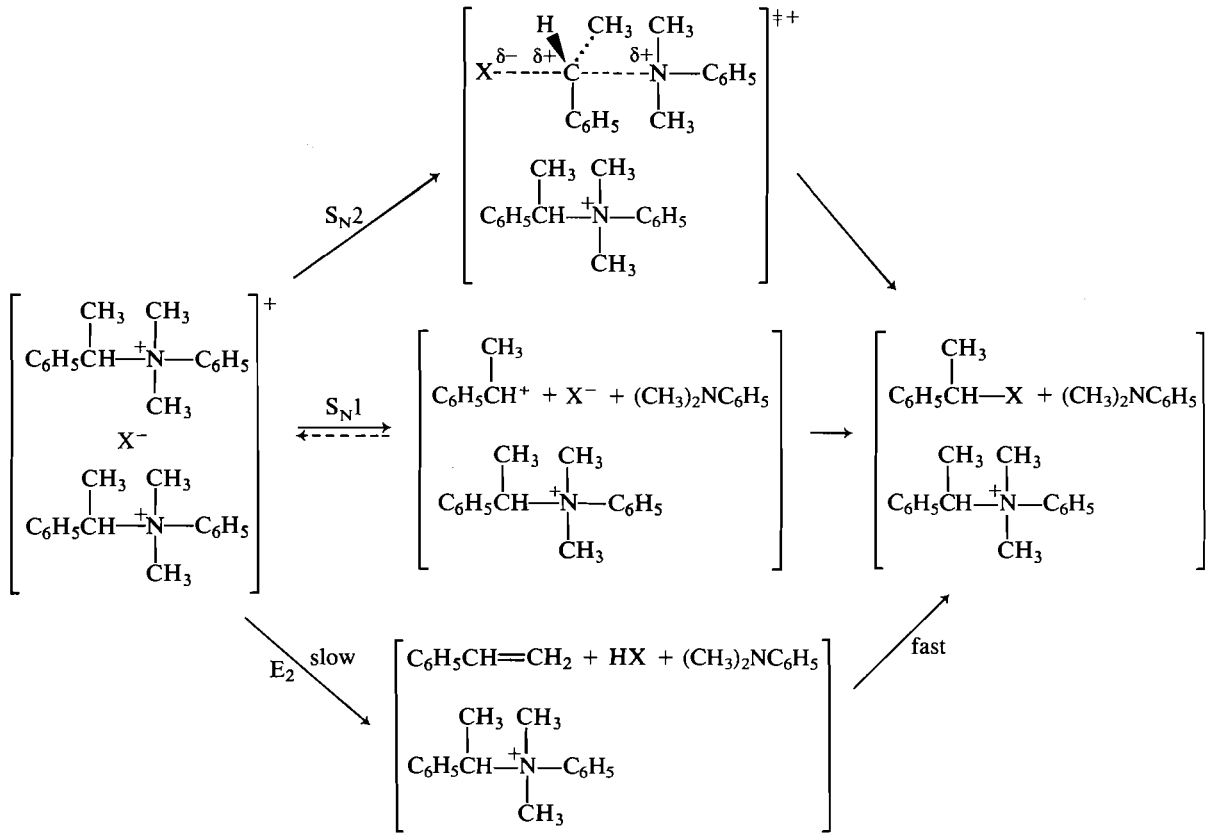

SCHEME 1

TABLE 1. The β-deuterium kinetic isotope effects expected for the different decomposition mechanisms of 1-phenylethyldimethylphenylammonium bromide in chloroform at 25°C.

Decomposition mechanism within the triple ion	Expected $(k_H/k_D)/\beta\text{-}D_3$
S_N2	1.02–1.11
Carbocation S_N	
with k_2 rate determining	1.34–1.52
with k_1, k_3, or k_4 rate determining	1.16–1.34
Elimination–addition	3.0–10
Elimination–addition–substitution with[a]	
$(k_H/k_D)_{\beta S} = 1.02$ and $(k_H/k_D)_{\beta E} = 3.0$ and $P_{HE} = 16\%$	1.14[b]
$(k_H/k_D)_{\beta S} = 1.06$ and $(k_H/k_D)_{\beta E} = 5.0$ and $P_{HE} = 9\%$	1.14[b]

[a] P_{HE} is the percent elimination–addition mechanism for the undeuterated substrate, $(k_H/k_D)_{\beta S}$ and $(k_H/k_D)_{\beta E}$ are the β-deuterium kinetic isotope effects for the substitution and elimination reactions, respectively.

[b] The observed isotope effect is calculated from

$$k_H/k_D = 100[(k_H/k_D)_{\beta S}(k_H/k_D)_{\beta E}]/[(k_H/k_D)_{\beta S} \times P_{HE} + (k_H/k_D)_{\beta E} \times (100 - P_{HE})]$$

effect of 3.0 for the E2 elimination reaction, the observed isotope effect is 1.14 when 16% of the reaction occurs via the elimination–addition pathway. Thus, the β-deuterium isotope effect indicates that less than 16% of the reaction occurs via the elimination–addition pathway and suggests that less than 9% of the reaction occurs via this route if the S_N reaction occurs via an S_N2 mechanism within the triple ion. If the S_N reaction occurs via a carbocation – triple ion intermediate, on the other hand, none of the product forms in an elimination–addition reaction because the secondary β-deuterium isotope effects for carbocation S_N reactions range from 1.05–1.15/β-D (1.16–1.52/CD_3 group),[3] i.e., are larger than the isotope effect observed in this reaction. Thus, the β-deuterium isotope effect demonstrates that the decomposition must occur via one of the S_N mechanisms.

The maximum kinetic isotope effect for a particular leaving group is observed in normal (not occurring in a triple ion) carbocation S_N reactions when the slow step is the formation of the solvent-separated ion pair or the free carbonium ion and hyperconjugation is a maximum (ref. 10 and footnote 3). Smaller isotope effects are found when formation of the intimate ion pair or the destruction of a carbocation intermediate is rate determining. The smaller isotope effect is presumably found in these reactions because the positive charge has not been developed fully or has been partially destroyed in the transition state of the rate-determining step of the reaction and hyperconjugation is not a maximum.[3]

Although a carbocation intermediate in a triple ion cannot exist as a solvent-separated ion pair, the carbocation could react either as an intimate ion–molecule pair or as a free carbocation. Thus, a carbocation S_N reaction occurring within the triple ion, Scheme 2, could have any of the k_1, the k_2, the k_3, or the k_4 steps rate-determining.

In fact, the secondary β-deuterium kinetic isotope effect found when the k_1, the k_3, or the k_4 step of a carbocation reaction is rate determining is only about 1.05/β-D (1.16/CD_3 group) or 60% of the isotope effect found when the k_2 step is rate determining.[3] Since the observed isotope effect of 1.144 is within experimental error of the minimum value expected for a carbocation S_N reaction, one cannot eliminate a carbocation mechanism where the rate-determining step is the formation of

TABLE 2. The α- and β-deuterium kinetic isotope effects for the decomposition of 1-phenylethyldimethylphenylammonium bromide in chloroform at 25°C

$k_H \times 10^4$, s^{-1}	$k_{D_\beta} \times 10^4$, s^{-1}	(k_H/k_D)/β-D_3	$k_{D_\alpha} \times 10^4$, s^{-1}	(k_H/k_D)/α-D

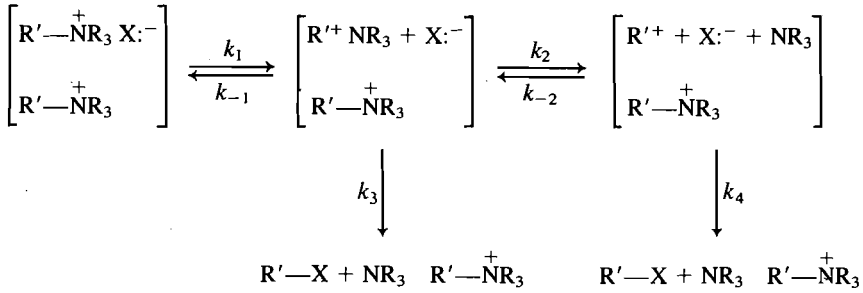
1.153	1.007		9.852	
1.166	1.016		9.857	
1.161±0.007[a]	1.015±0.008[a]	1.144±0.0097[b] (1.046/β-D)	9.857±0.010[a]	1.178±0.006[b]

[a]The error limits are the standard deviation.
[b]The error limits were calculated using the equation
Error = $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2(\Delta k_D)^2]^{1/2}$
where Δk_H and Δk_D are the standard deviations for the rate constants of the undeuterated and deuterated substrate, respectively.



SCHEME 2

the intimate ion–molecule pair or the destruction of a carbocation intermediate.

The secondary β-deuterium isotope effects for S_N2 reactions normally range from 1.01 to 1.03/β-D (1.03–1.09/CD_3 group). However, much larger secondary β-deuterium isotope effects have been found in some S_N2 reactons. For example, an isotope effect of 1.13/CD_3 group was reported for the ethanolysis of isopropyl brosylate[3] and an isotope effect of 1.16/CD_3 group was found in the acetolysis of ethyl triflate at 25°C (14). Although the observed isotope effect of 1.14 is larger than those found in most normal S_N2 reactions, it is smaller than the largest isotope effects that have been found and one cannot rule out the S_N2 mechanism for the reaction within the triple ion. Thus, the β-deuterium kinetic isotope effect eliminates the elimination–addition mechanism as a significant pathway for the reaction and reduces the problem to distinguishing between an S_N2 mechanism and a carbocation S_N mechanism with the k_1 (an S_N1_{lim} mechanism), or the k_3 or k_4 step (S_N2C^+ mechanisms), rate determining.

The second criterion of mechanism that was used to distinguish between the carbocation and the S_N2 mechanisms for the S_N reaction between 1-phenylethyldimethylphenylammonium ion and bromide ion in the triple ion was the secondary α-deuterium kinetic isotope effect. The large isotope effect of 1.178 ± 0.006/α-D found for this reaction, Table 2, is significantly larger than the isotope effect of 1.12 found for the S_N2 reaction of the benzyl derivative in chloroform. In spite of this, the S_N2 mechanism cannot be ruled out for several reasons. Adding a methyl group to the α-carbon of primary substrates that react via S_N2 mechanisms increases the secondary α-deuterium kinetic isotope effect by 1.036 ± 0.003 (15). Adding a methyl group to the α-carbon of the benzyldimethylphenylammonium ion should, therefore, raise the isotope effect for an S_N2 reaction of the 1-phenylethyldimethylphenylammonium bromide from 1.12 to 1.16. Since one would expect the increase in isotope effect to be greater when the substrate is more sterically crowded, i.e., adding a methyl group to the α-carbon of a more crowded substrate would increase the frequency of the out-of-plane C_α—H(D) ground state bending vibrations and the zero-point energy difference more than adding a methyl group to a less crowded substrate, one would expect an even larger isotope effect than 1.16 for the 1-phenylethyl compound. Thus, the expected ($k_H/k_D > 1.16$) and the observed isotope effect ($k_H/k_D = 1.178$) are close enough so that one cannot rule out the S_N2 mechanism. This conclusion is supported by the large secondary α-deuterium isotope effects found in S_N2 reactions by Craze *et al.* (16) and by Knier and Jencks (17). Craze *et al.* reported secondary α-deuterium kinetic isotope effects as large as 1.16/α-D in the S_N2 reactions of 1-methoxymethoxy-2,4-dinitrobenzene and Knier and Jencks found isotope effects as large as 1.18/α-D in the S_N2 reactions of the quaternary ammonium ion, methoxymethyldimethyl-*m*-nitroanilinium ion.

Large secondary α-deuterium kinetic isotope effects at or near the maximum are found in carbocation S_N reactions where the formation of the solvent-separated or the free carbonium ion is rate determining, whereas smaller isotope effects, approximately 75% of the maximum, are found in carbonium ion S_N reactions where the k_1 step is rate-determining (12). The maximum and minimum isotope effect for a carbonium ion mechanism of a primary ammonium salt is 1.19/α-D (11) and $1.19^{0.75} = 1.14$/α-D. The maximum and minimum isotope effects for a secondary substrate would be approximately 1.04 times greater, i.e., 1.24 and 1.17/α-D, respectively. Thus, although the isotope effect of 1.178 is too small to be indicative of a carbocation mechanism where the formation of the free carbocation within the triple ion is rate determining, it is

TABLE 3. The rate constants and Hammett ρ value for a series of *para*-substituted phenyl-1-phenylethyldimethylammonium bromides in chloroform at 34.88°C

[a]The error limits are the standard deviation.

consistent with a carbocation mechanism where the k_1, the k_3, or the k_4 step is rate determining. Unfortunately, both the secondary α- and β-deuterium kinetic isotope effects are at the borderline between the values expected for an S_N2 and a carbocation S_N reaction, with the formation of the intimate ion–molecule pair or the destruction of a carbocation intermediate rate determining. Thus, while measuring these isotope effects limited the mechanistic options to three S_N mechanisms, they did not distinguish between a simple S_N2, an S_N1_{lim}, and an S_N2C^+ mechanism for the triple ion substitution reaction.

The next criterion that was used to determine the mechanism of the triple ion S_N reaction between 1-phenylethyldimethylphenylammonium ion and bromide ion was the Hammett ρ value found by changing the *para* substituent on the benzene ring of the leaving group. If the reaction occurs via an S_N2 or a carbocation mechanism with the k_1 step rate determining, the C—N bond breaks in the slow step of the reaction and a small Hammett ρ value would be observed. If the reaction occurs via a carbocation mechanism with the k_1 step reversible and the k_3 or the k_4 step rate determining, the C—N bond is broken in a fast, reversible step and a large, equilibrium ρ value would be observed. The Hammett ρ value of +2.20, Table 3, is significantly smaller than the ρ values found for the complete destruction of a positive charge on a nitrogen atom. In fact, the ρ values found for the equilibrium dissociation of *para*-substituted *N,N*-dimethylanilinium ions to dimethylanilines and a proton, i.e., for the complete destruction of a positive charge on nitrogen, range from +3.43 to +4.19 in various solvents (8). Thus, one would expect a ρ value of at least 3.4 if the positive charge had been completely destroyed in the transition state of the rate-determining step of the S_N reaction between 1-phenylethyldimethylphenylammonium ion and bromide ion. The much smaller ρ value of +2.20 indicates that the C_α—N^+ bond is breaking in the rate-determining step of the reaction and rules out a carbocation mechanism where the k_3 or the k_4 step is rate determining. Thus, the S_N reaction between the 1-phenylethyldimethylphenylammonium ion and bromide ion in the triple ion must proceed by way of an S_N2 mechanism or a S_N1_{lim} mechanism with the k_1 step rate determining.

The mechanism for the reaction was finally determined by comparing the secondary α- and secondary β-deuterium kinetic isotope effects for the bromide ion reaction with those found when the nucleophile was iodide ion. If the S_N reaction within the triple ion occurred via the rate-determining formation of the intimate ion–molecule pair, the transition state would be independent of the nucleophile and one would find the same α- and β-deuterium isotope effects in both reactions. If the reaction proceeded via an S_N2 mechanism on the other hand, the nucleophiles are a part of the transition states, the transition states would be different, and the magnitude of both the secondary α- and secondary β-deuterium kinetic isotope effects would be different in the two reactions. A comparison of the secondary α- and β-deuterium kinetic isotope effects for the bromide ion (Table 2) and iodide ion reactions, Table 4, show that the isotope effects do change when the nucleophile is changed. In fact, a Wilcoxin test and the Student's *t* test (18, 19) show that the secondary α-deuterium kinetic isotope effects of 1.178 ± 0.006 for the bromide ion reaction and 1.184 ± 0.0077 for the iodide ion reaction, respectively, are significantly different at the 92% confidence level if one uses the average isotope effects obtained by combining each k_H value with each k_D value, and are significantly different at the 53–81% confidence level if one uses the worst and best combinations of the three isotope effects, respectively, in the statistical analysis. While the α-deuterium kinetic isotope effects are not significantly different at a high confidence level, the same two statistical tests indicate that the secondary β-deuterium kinetic isotope effects of 1.144 ± 0.0097 for the bromide ion reaction and 1.172 ± 0.0072 for the iodide ion reaction are significantly different at the 99.9% confidence level. The different isotope effects for these two reactions clearly demonstrate that the nucleophile is in the transition state of the rate-determining step of these reactions and it has been concluded that the decomposition of the 1-phenyldimethylphenylammonium halides in chloroform occurs via an S_N2 mechanism within a triple ion.

Once it had been established that the S_N reaction of both the benzyl- and the 1-phenylethyldimethylphenylammonium bromides in chloroform occurred by an S_N2 mechanism within a triple ion, attention was turned to determining the relative structures of the transition states for these two reactions. The transition states for these two reactions were estimated in two ways. First, the relative lengths of the α-carbon-leaving group transition state bonds were determined by comparing the Hammett ρ values found by changing the substituent in the leaving group. The results in Tables 3 and 5 show that the Hammett ρ values for these two reactions are very different. In fact, the ρ value for the 1-phenylethyl reaction is more than twice that found for the reaction of the benzyl substrate. This clearly indicates that there is a greater change in electron density on the nitrogen atom in going from the reactant to the transition state of the 1-phenylethyldimethylphenylammonium ion reaction and that the α-carbon–nitrogen bond is significantly longer in the 1-phenylethyldimethylphenylammonium bromide transition state.

Next, the relative lengths of the nucleophile–α-carbon bonds in the two transition states were estimated by determining the selectivity of the reactions to a change in nucleophile. Both we (20) and Harris *et al.* (21) have used the selectivity of a reaction to a change in nucleophile to estimate the lengths of nucleophile–α-carbon bonds in S_N reactions. In fact, it is believed that the

selectivity does not indicate the total structure of the transition state but is related to the length of the bond nearest to the point of structural change. The rate constants for the S_N2 reactions of the benzyl and 1-phenylethyl substrates with bromide ion and iodide ion, Table 6, give the selectivity of each reaction to a change in nucleophile. Although the rate constants for the two reactions were measured at different temperatures, the temperature effect on the selectivity (k_I/k_{Br}) for the benzyldimethylphenylammonium ion reaction is small and it is clear that the 1-phenylethyldimethylphenylammonium ion reaction is much less sensitive to change in nucleophile than the benzyldimethylphenylammonium ion reaction. A greater selectivity is indicative of a shorter nucleophile–α-carbon transition state bond because the difference in energy of the two transition states (the rate constants) will be greater when the nucleophile–α-carbon bonds are more complete in the transition state. Thus, the selectivities indicate that the nucelophile–α-carbon transition state bond is significantly longer in the 1-phenylethyldimethylphenylammonium ion transition state than in the benzyldimethylphenylammonium ion transition state.

The selectivities and the Hammett ρ values indicate that the 1-phenylethyldimethylphenylammonium ion reaction has a much looser transition state with longer nucleophile–α-carbon *and* α-carbon-leaving group bonds than the corresponding benzyl salt. In fact, Schowen and co-workers (22) had indicated that adding a methyl group to the α-carbon of the substrate in an S_N2 reaction would lead to a looser transition state and this is what has been found. However, this study has gone further by demonstrating that both of the reacting bonds in the S_N2 transition state become longer when a methyl group is added to the α-carbon.

Finally, it is interesting to speculate on the reason the 1-phenylethyldimethylphenylammonium ion reacts faster than the corresponding primary benzyl substrate. This is unusual because secondary compounds normally react from 25 to 150 times slower than primary compounds in S_N2 reactions (23) because the S_N2 transition state for a secondary substrate is more sterically crowded. It would appear that the 1-phenylethyldimethylphenylammonium ion reacts faster than the benzyl substrate for two reasons. One contributing factor is undoubtedly

that the transition state is very loose. In fact, both the secondary α- and β-deuterium kinetic isotope effects are unusually large for an S_N2 reaction, i.e., they are almost in the range expected for a carbocation S_N reaction and confirm that the transition state for this reaction is very loose. Thus, the steric crowding that is present in the S_N2 transition states of most secondary substrates is not present in the 1-phenylethyldimethylphenylammonium ion S_N2 transition state; the transition state will be lower in free energy and the reaction will be faster than expected. Another factor contributing to the faster rate of reaction is steric crowding in the initial state. Westaway and Ali attributed the very large secondary α-deuterium kinetic isotope effects in the S_N2 reactions of benzyldimethylphenylammonium ions to steric hindrance of the C_α—H(D) out-of-plane bending vibrations in the initial state (10). Obviously, the steric crowding would be greater in the initial state of the 1-phenyl substrate. This would increase the ground state energy of the 1-phenylethyldimethylphenylammonium ion, further reducing the free energy of activation. Thus, the reaction is probably faster than expected for two reasons, steric acceleration due to steric crowding in the initial state and a looser (less sterically crowded) S_N2 transition state within the triple ion.

Experimental

Preparation of reagents

Preparation of 1-phenylethyldimethylphenylammonium bromide

Anhydrous hydrogen bromide gas (Matheson) was bubbled with occasional cooling into 56.80 g (0.546 mol) of styrene for approximately 3 h at room temperature. The product, 1-phenylethyl bromide, was washed several times with distilled water, dried over magnesium sulfate, and distilled, bp 55.5–56.0°C at 3.5 Torr (1 Torr = 133.3 Pa) (lit. (24) bp, 202–203°C). The yield was 91.2 g (90%).

Twenty-five grams (0.135 mol) of 1-phenylethyl bromide was added to 18.2 g (0.150 mol) of freshly distilled *N,N*-dimethylaniline and left under dry nitrogen in the dark for four days. Then the solid product was filtered and washed with anhydrous ether. The crude product (35.4 g (86%)) was recrystallized to a constant melting point of 119.5–120.5°C (lit. (4) mp 125–126°C) by dissolving it in a minimum of acetonitrile at room temperature and precipitating the salt with ether. The discrepancy between the reported and experimental melting point arose because a change in the heating rate of the melting point apparatus altered the melting point markedly. For example, a sample melting between 119.5 and 120.5°C melted at 129–130°C when the heating rate was higher. As a result all of the melting points were determined on the same melting point apparatus at the same heating rate. Finally, all of the quaternary ammonium salts used in this study were stored in a desiccator in the dark until they were used in a kinetic run.

Preparation of 1-phenylethyl-2,2,2-d$_3$-dimethylphenylammonium bromide

This compound was synthesized by adding a mixture of 12.5 g (0.0862 mol) of iodomethane-d_3 (Merck, Sharp and Dohme) in 20 mL of sodium-dried ether, dropwise, to 2.72 g (0.0112 mol) of clean magnesium and 10 mL of sodium-dried ether in a dry, 250-mL three-necked round-bottom flask fitted with a condenser and a dropping funnel. When the addition was complete, the mixture was refluxed for 30 min, cooled to below −5°C with an ice–salt bath, and a solution of 8.74 g (0.0824 mol) of "purified" benzaldehyde (25) in 25 mL of sodium-dried ether was added so that the temperature did not exceed −5°C. When the addition was complete, the reaction mixture was stirred for 30 min and then decanted onto 38 g of crushed ice. After acidification with 10% sulfuric acid, the ether layer was separated. The aqueous layer was extracted with three 20-mL portions of anhydrous ether. Then, the combined ether extracts were washed three times with 10% sodium hydroxide, once with distilled water, and dried with anhydrous magnesium sulfate. A distillation gave 5.38 g (52%) of 1-phenylethyl-2,2,2-d_3 alcohol, bp 62°C at 3 Torr (lit. (26) bp 71–72°C at 2 Torr). The nmr spectrum was identical to that reported for the product (27).

After anhydrous hydrogen bromide (Matheson) had been bubbled through a solution of 5.38 g (0.0423 mol) of 1-phenylethyl-2,2,2-d_3 alcohol in 10 mL of benzene for 90 min, the benzene-1-phenylethyl-2,2,2-d_3 bromide solution was washed several times with water and dried with anhydrous magnesium sulfate. After the benzene had been removed on the rotary evaporator, a distillation gave 3.70 g (69%) 1-phenylethyl-2,2,2-d_3 bromide, bp 50.5°C at 3 Torr (lit. (24) bp 202–203°C at 760 Torr). An analysis of the nmr spectrum indicated that the product was 99% deuterated at the 2 position.

In the third step, 2.93 g (0.0155 mol) of 1-phenylethyl-2,2,2-d_3 bromide was added to 1.65 g (0.0136 mol) of freshly distilled *N,N*-dimethylaniline and left for several days in a dry, nitrogen atmosphere. The product was filtered, washed with several portions of anhydrous ether, and crystallized from a mixture of acetonitrile – anhydrous ether, *vide supra*. This gave 2.59 g (63%) of 1-phenylethyl-2,2,2-d_3-dimethylphenylammonium bromide, mp 119.5–120.5°C.

Preparation of 1-phenylethyl-1-d$_1$-dimethylphenylammonium bromide

A solution containing 15.07 g (0.126 mol) of acetophenone and 150 mL of sodium-dried ether was added dropwise to a mixture of 3 g (0.07 mol) of lithium aluminium deuteride in 200 mL of sodium-dried ether. After refluxing overnight, the reaction mixture was slowly poured onto crushed ice. The solution was made basic by adding sodium hydroxide pellets and the ether layer separated. The aqueous phase was extracted twice with 50-mL portions of ether. Then the ether layers were combined and dried over anhydrous magnesium sulfate. After the ether had been removed on a rotary evaporator, distillation gave 13.31 g (0.1081 mol) of pure 1-phenylethyl-1-d_1 alcohol, bp 66°C at 2 Torr (lit. (26) bp 71–72°C at 2 Torr).

Anhydrous hydrogen bromide was bubbled through 13.31 g (0.1081 mol) of 1-phenylethyl-1-d_1 alcohol for 3 h. The two phases were separated and the organic layer was washed several times with distilled water, dried with anhydrous magnesium sulfate, and then distilled to give 18.5 g (92%) of 1-phenylethyl-1-d_1 bromide, bp 60°C at 2 Torr. An analysis of the C_α-H absorption at 4.56 ppm in the nmr spectrum suggested that the 1-phenylethyl-1-d_1 bromide was 99.4% deuterated.

Finally, 18.03 g (0.0969 mol) of 1-phenylethyl-1-d_1 bromide and 13.29 g (0.109 mol) of freshly distilled *N,N*-dimethylaniline were mixed in a dry nitrogen atmosphere and left at room temperature for 1 week. The solid product was filtered, then washed several times with anhydrous ether. The 25.43 g (85.4%) of crude 1-phenylethyl-1-d_1-dimethylphenylammonium bromide was recrystallized from acetonitrrile – anhydrous ether to a constant melting point of 120–120.5°C.

Preparation of the α-deuterated, β-deuterated, and undeuterated 1-phenylethyldimethylphenylammonium iodides

The α-deuterated, β-deuterated, and undeuterated quaternary ammonium iodides were obtained by converting the appropriate quaternary ammonium bromides into the quaternary ammonium hydroxides with silver oxide and then titrating the hydroxides with hydriodic acid.

Preparation of 1-phenylethyldimethylphenylammonium iodide

A 99% excess (3.255 g, 0.01403 mol) of nitrate-free silver oxide (28) was stirred with a solution of 2.15 g (7.03×10^{-3} mol) of 1-phenylethyldimethylphenylammonium bromide in 60 mL of distilled water for 3.5 h. After the solution was filtered through a 934 AH Reeve Angel glass fiber filter, the filtrate was taken to a pH of 3.9 by adding hydriodic acid and left overnight in the dark. After the solution was filtered through another 934 AH Reeve Angel glass fiber filter, the filtrate was taken to dryness on the rotary evaporator. The crude product (18 g, 74%) was dried in an evacuated desiccator overnight and then recrystallized from an acetonitrile–ether mixture, mp 101–102°C. All of the quaternary ammonium iodides were stored in the dark (28) in a vacuum desiccator until they were used for kinetics.

Preparation of 1-phenylethyl-2,2,2,-d_3-dimethylphenylammonium iodide

1-Phenylethyl-2,2,2-d_3-dimethylphenylammonium bromide, 2.352 g (7.61×10^{-3} mol) was dissolved in approximately 50 mL of distilled water and stirred with 3.53 g (0.0152 mol) of nitrate-free silver oxide for 6 h. Then the solution was filtered through a 934 AH Reeve Angel glass fiber filter and the filtrate acidified to a pH of 3.04 with hydriodic acid. The next day, the solution was filtered through a 934 AH glass fiber filter and the filtrate taken to dryness on the rotary evaporator. The crude product (18 g, 65%) was dried in a vacuum desiccator and recrystallized from acetonitrile–ether, mp 101–102°C.

Preparation of 1-phenylethyl-1-d_1-dimethylphenylammonium iodide

1-Phenylethyl-1-d_1-ammonium bromide, 6.02 g (0.0196 mol), was stirred with 120 mL of distilled water and 9.08 g (0.0391 mol) of silver oxide for 3.5 h, filtered through a 934 AH Reeve Angel glass fiber filter, and the filtrate taken to a pH of 5.40 with hydriodic acid. After the solution had been stored overnight, it was filtered through a 934 AH Reeve Angel glass filter and the water removed on the rotary evaporator. The resulting solid (6.0 g, (86%)) was dried overnight in an evacuated desiccator and recrystallized from acetonitrile–ether, mp 101.5–103°C.

Preparation of a series of 4-substituted phenyl-1-phenylethyldimethylammonium bromides

The 4-methoxy-, the 4-chloro-, and the 4-methylphenyl-1-phenylethyldimethylammonium bromides were prepared by reacting 1-phenylethyl bromide with an excess of 4-methoxy-, 4-chloro-, and 4-methyl-*N,N*-dimethylanilines, respectively. The *N,N*-dimethyl-4-methylaniline (Aldrich) was purified by distillation under reduced pressure. The synthesis of the *N,N*-dimethyl-4-methoxy- and *N,N*-dimethyl-4-chloroanilines are described elsewhere (8).

Preparation of 4-methoxyphenyl-1-phenylethyldimethylphenylammonium bromide

N,N-dimethyl-4-methoxyaniline (4.24 g, 0.280 mol) and 5.31 g (0.0287 mol) of 1-phenylethyl bromide were sealed in an Erlenmeyer flask that had been flushed with dry nitrogen, and stirred overnight. The solid product was filtered, washed several times with anhydrous ether, and dried in an evacuated desiccator. The 9.3 g (99%) of crude 4-methoxyphenyl-1-phenylethyldimethylphenylammonium bromide was recrystallized by dissolving it in a minimum of acetonitrile, placing 4-mL portions into 25 mm × 150 mm test tubes, filling the tubes with anhydrous ether, and allowing the salt to precipitate overnight (recrystallization on a larger scale yielded a sticky oil). Repeated recrystallizations gave a product with a melting point of 107–109°C. The nmr spectrum was consistent with that expected for 4-methoxyphenyl-1-phenylethyldimethylphenylammonium bromide.

Preparation of 4-chlorophenyl-1-phenylethyldimethylphenylammonium bromide

N,N-dimethyl-4-chloroaniline (4.25 g, 0.0273 mol) and 5.04 g (0.0272 mol) of 1-phenylethyl bromide were mixed and left sealed in a dry nitrogen atmosphere overnight. Then the product was filtered, washed with anhydrous ether, and dried in an evacuated desiccator. The 8.88 g (96%) of crude 4-chlorophenyl-1-phenylethyldimethylammonium bromide was recrystallized with acetonitrile – anhydrous ether to a constant melting point of 112.5–113.5°C. The nmr spectrum of the solid was consistent with that expected for the product.

Preparation of 4-methylphenyl-1-phenylethyldimethylphenylammonium bromide

The reactants, 5.06 g (0.0273 mol) of 1-phenylethyl bromide and 4.74 g (0.035 mol) of freshly distilled *N,N*-dimethyl-4-methylaniline were mixed together in a nitrogen atmosphere. The solid that formed in one day was filtered, washed with anhydrous ether, and dried in an evacuated desiccator. Finally, the 6.3 g (72%) of 4-methylphenyl-1-phenylethyldimethylphenylammonium bromide was recrystallized using the method described for the 4-methoxyphenyl-1-phenylethyldimethylphenylammonium bromide. The mp of the pure product was 101–102°C. The chemical shifts and the integration of the peaks in the nmr spectrum were consistent with the structure 4-methylphenyl-1-phenylethyldimethylphenylammonium bromide.

Kinetic measurements

The electrolytic conductivity apparatus used to measure the rate constants for the decomposition of the quaternary ammonium salts consisted of three units, a 1-kHz/s sine wave oscillator (Heath Kit IG-72), a conductivity bridge capable of measuring resistances ranging from 0.1 to 110 000 ohms, and a detector consisting of a 1-kHz low noise, transistorized amplifier and an *X–Y* oscilloscope. The decade resistance of the measuring arm, which was in parallel with variable capacitors to obtain a sharp balance point, measured the resistance to within 0.1%. The conductivity dip cell (cell constant of 0.1) that was used as the unknown arm of the conductivity bridge was equipped with a thermometer adapter and a bushing adapter so that the cell could be sealed completely into the 25 mm × 150 mm ground glass topped test tube that was used as the reaction vessel. These precautions were taken to minimize evaporation of the solvent because the reactions were followed for several hours.

In a typical reaction, approximately 15 mL of distilled chloroform was placed in the reaction vessel. The reaction vessel was sealed with the conductivity dip cell and temperature equilibrated for 30 min at 25.00 ± 0.02°C. Then, a weighed amount (between 0.22 and 0.25 g) of quaternary ammonium salt was dissolved in the temperature equilibrated chloroform. After waiting at least 10 min for the quaternary ammonium salt – chloroform solution to equilibrate, the bridge was balanced and the timer started. Resistance measurements were made every "*x*" minutes according to the Guggenheim method (6, 29). The first-order rate constants were determined from the linear least-squares slope of the Guggenheim plot (6). Care was taken to collect the resistance measurements for each bromide salt over the same range of resistances (concentrations), i.e., from 2747 ± 6 ohms to 44518 ± 1981 ohms, to eliminate any ionic strength effects on the rate constants.

The procedure used to measure the rate constants that were required for determining the Hammett ρ value for the 4-substituted phenyl-1-phenylethyldimethylphenylammonium bromides was slightly different. The changes were (*i*) that 20 mL of distilled chloroform was placed in the reaction vessel, (*ii*) that the temperature was 34.88 ± 0.02°C, (*iii*) that between 0.31 and 0.39 g for the 4-substituted phenyl-1-phenylethyldimethylphenylammonium bromides was used in these runs, and (*iv*) that the time and resistance readings were begun when the quaternary ammonium salt was added to the chloroform and continued every "*x*" minutes until the capacity of the bridge (110 000 ohms) was exceeded or until the concentration of the substrate was less than 0.0246 mol/L. The rate constants for these reactions were obtained by applying the Guggenheim method to the resistances found over the concentrations ranges 0.0508–0.0379 mol/L and from 0.0329–0.0246 mol/L.

Infrared and Raman spectra (4000–100 cm^{-1}) of solid samples of six different methyl substituted thiazolidine products of D-penicillamine and L-cysteine hydrochloride have been observed and assigned. Infrared spectra in D_2O solutions have been obtained for comparison in order to study the amino-acid zwitterion equilibria. Proton and ^{13}C nmr spectra for the compounds have also been measured.

H. E. HOWARD-LOCK, C. J. L. LOCK, M. L. MARTINS, P. S. SMALLEY et R. A. BELL. Can. J. Chem. **64**, 1215 (1986).
On a déterminé et interprété les spectres infrarouges et Raman (4000–100 cm^{-1}) d'échantillons solides de six produits différents de la D-pénicillamine et du chlorhydrate de la L-cystéine avec des thiazolidines substituées par des groupements méthyles. Dans le but d'examiner l'équilibre acide aminé zwitterion, on a mesuré les spectres infrarouges dans le D_2O. On a aussi mesuré les spectres rmn du ^1H et du ^{13}C de ces composés.

[Traduit par le revue]

Introduction

The modes of therapeutic action and adverse side effects of the drug D-penicillamine depend on several biochemical reactions, an important one being the ability to form thiazolidine rings with aldehydes and ketones. Thiazolidine-4-carboxylic acid has also been found to act on the cell membrane of tumour cells, possibly causing a reverse transformation to normal cells through restoration of contact inhibition (1). Therefore, we have been investigating thiazolidine-4-carboxylic acids, and in particular measuring their physical, chemical, and spectroscopic properties, as part of our overall program of studying reactions having biological significance or potential medical applications.

The essential amino acids normally exist in the zwitterion form both in the solid state and in aqueous solutions. Recently, we have shown by vibrational spectroscopy and single crystal X-ray diffraction that (*S*)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid exists in the amino acid form in the solid state and to a minor extent in aqueous solution (2). The unsubstituted thiazolidine-4-carboxylic acid, however, exists in the zwitterion form (2–4). In this work, we attempt to establish by vibrational spectroscopic studies whether methyl substitution at the C2 and C5 positions of the thiazolidine ring affects the amino-acid zwitterion equilibrium. In addition, we have characterized the various species by ^1H and ^{13}C nmr spectroscopy.

Materials and methods

The D-(−)-penicillamine (free base) and L-(+)-cysteine hydrochloride were of reagent grade, as supplied by Sigma Chemical Co., St. Louis, MS. Formaldehyde, 37%, reagent grade was supplied by Sargent Welch Scientific Co., Skokie, IL. Acetaldehyde was distilled from paraldehyde, reagent grade, supplied by BDH; acetone, reagent grade, was supplied by BDH Chemicals, Toronto, Ont. The preparation of the several thiazolidine-4-carboxylic acids was carried out as indicated schematically in Table 1 and outlined in detail as follows:

Thiazolidine-4-carboxylic acid, I

The method of Ratner and Clarke (5) was followed with modification. L-Cysteine hydrochloride hydrate, **A**, 0.5 g (0.003 mol) was dissolved in 2 mL H_2O to which 0.4 ml (0.4 g or 0.003 mol) of 37% (w/w) formaldehyde was added; the mixture was left to react for 15 h at room temperature. Then 0.5 mL pyridine was added. In 30 min, a white solid started separating slowly. Ethanol, 1 mL, was added and the mixture was placed in the refrigerator. Prismatic crystals were separated from the pyridine ethanol mixture by filtration. The compound was recrystallized from ~10 mL hot H_2O to give 0.3 g (0.002 mol, 70%) of a white, crystalline product, mp 185–187°C (dec.), lit. 184–185°C (dec.) (5).

2-Methylthiazolidine-4-carboxylic acid, II

The method of Riemschneider and Hoyle (6) was followed with modification. To 1.4 mL H_2O was added 2.0 g **A** (0.01 mol) 1 mL, glacial acetic acid, followed by 20 mL EtOH. The solution was placed on ice and after 30 min the solid hydroacetate precipitated. This was filtered out, dissolved in water, and the solution placed on ice. Freshly prepared acetaldehyde, 0.5 g (0.013 mol), was added. The clear mixture was allowed to stand in the refrigerator 48 h; then 0.5 mL pyridine was added. A few days later a thick white precipitate was filtered out and air-dried. Weight 1.0 g (yield 60%); mp 153–155°C (dec.), lit. 161–163°C (6).

2,2-Dimethylthiazolidine-4-carboxylic acid, III

The method of Sheehan and Yang (7) was followed with modification. **A**, 0.7 g (0.0057 mol), was added to 180 mL freshly distilled acetone in a 250 mL round bottom flask. The mixture was refluxed for 7 h and then allowed to cool. The undissolved material (0.5 g unreacted cysteine) was removed by filtration. Acetone was removed by distillation and the remaining 10 mL solution was allowed to stand in the refrigerator. Within a few days a cluster of long thin crystals formed in the acetone solution. These were recrystallized from hot acetone to give 0.1 g product, (62% based on the 0.2 g L-cysteine which reacted, 11% based on the initial 0.7 g); mp 163–165°C, lit. 163–165°C (7).

5,5-Dimethylthiazolidine-4-carboxylic acid, IV

The method of Nagasawa *et al.* (8) was followed with modification for **IV** and **V**. D-Penicillamine, **B**, 0.50 mg (0.0034 mol), was mixed with 10 mL EtOH and 2.5 mL H_2O, resulting in a white suspension. Formaldehyde, (37% w/w), 0.5 mL (0.004 mol), was added with stirring and within 30 min the mixture was clear. In 1 h the mixture turned into a white jelly-like solid suspension. This was left at room temperature for approximately 15 h, and then a few drops of pyridine were added. There was no apparent change in the reaction mixture. The white suspension was filtered off and dried in a desiccator for several days. Yield 0.285 g product (0.0018 mol, 53%); mp 194–196°C, lit. 196–197°C (dec.) (8).

2,5,5-Trimethylthiazolidine-4-carboxylic acid, V

B, 1.55 g (0.01 mol), was dissolved in 15 mL H_2O and the mixture was filtered to remove a small amount of undissolved material. The solution was cooled in an ice bath and 1.2 mL (0.02 mol) acetaldehyde was added with stirring; the flask was then sealed with parafilm. In

TABLE 1. Nomenclature and preparation scheme for the thiazolidine-4-carboxylic acids[a]

Reactants	Formaldehyde	Acetaldehyde	Acetone
A, L-cysteine	**I**, thiazolidine-4-COOH	**II**, 2-monomethyl-	**III**, 2-dimethyl-
B, D-penicillamine	**IV**, 5,5-dimethyl-	**V**, 2,5,5-trimethyl-	**VI**, 2,2,5,5-tetramethyl-

Nomenclature: The products are secondary amino acids which are 5-membered heterocyclic rings containing sulfur at atom position 1, nitrogen at position 3, carbons at 2, 4, and 5, and the COOH group attached to the carbon at 4.

[a]Reflux overnight at room temperature or gentle heat (~80°C).

~1½ h a white precipitate started to form and the cold bath was removed. After 3 h stirring at room temperature the mixture became clear. The solvent was evaporated in a Buchi rotoevaporator and the white residue was recrystallized from hot ethyl acetate to give 0.721 g of product (0.004 mol, 40%); mp 161–162°C, lit. 165.5–167.5°C (8).

2,2,5,5-Tetramethylthiazolidine-4-carboxylic acid, VI

The method of Howard-Lock *et al.* (2) was followed: **B**, 3.0 g (0.02 mol), was dissolved in 20 mL H_2O and excess acetone (40 mL) was added. The mixture was stirred for 15 h at room temperature. The solvent was evaporated under N_2 to near dryness, and the resulting solid was filtered off and recrystallized from hot acetone. Yield: 2.70 g product (0.014 mol, 70%).

Spectral measurements

Infrared spectra were recorded on both Nicolet 7199 FT-IR and Perkin-Elmer Model 283 spectrophotometers. The samples were ground with KBr at a concentration of approximately 1% by weight and then pressed into pellets. To confirm that certain peaks were real, and not manifestations of the pelleting procedure, the spectra of certain samples were also run in Nujol and again in hexachlorobutadiene. D_2O solution spectra were run with AgCl windows. Spectra were calibrated with polystyrene. Raman spectra were excited by means of the λ5145 Å radiation from a Spectra-Physics Model 164-02 argon ion laser and recorded on a Spex 14018 double monochromator. Solid samples were contained in glass melting point tubes, and solutions in nmr tubes. The spectrometer was calibrated regularly against an indene standard and had previously been calibrated with a neon lamp; the wavelength readout scale was found not to change (± 1–2 cm^{-1}).

Solutions for nmr studies were prepared in D_2O and concentrations were about 100 mg (solid) mL^{-1} of solvent. Internal TSP (trimethylsilylpropionic acid) was used as the reference. Proton nmr spectra were recorded on a Varian T60 spectrometer, and ^{13}C nmr spectra were recorded on a Bruker WP-80 spectrometer operating at 20.115 MHz.

The p*K*'s of the various thiazolidine-4-carboxylic acids were obtained by titration of an aqueous solution with 0.01 *N* NaOH and 0.01 *N* HCl. The pH's were measured with a Corning Model 130 pH meter which was standardized with Scientific Products potassium hydrogen phthalate pH 4.00 buffer, BDH pH 7.00 buffer, and Scientific Products boric acid/potassium hydroxide pH 10.00 buffer. The pH measurements are reliable to ±0.03.

Results and discussion

The vibrational spectra

The thiazolidine-4-carboxylic acids are secondary α-amino acids which are five-membered heterocyclic molecules having no symmetry elements. There is very little published work relating to the vibrational spectra of thiazolidine-4-carboxylic acids. Some isolated C—S bond frequencies are listed by Freeman (9) for various cyclic sulfides. A study of the vibrational spectra of thiazolidine and ND thiazolidine has been reported, followed by a similar study of three monomethyl thiazolidines (substituted at the C(2), C(4), and C(5) positions (10). These studies did not include work on the 4-carboxylic acids. The infrared spectra of some chelates of thiazolidine acids, including the spectra of free ligands 2-methyl-, 2,2-dimethyl-, 2,2,5,5-tetramethyl- and 2-benzylthiazolidine-4-carboxylic acids have been reported, for the range 4000–400 cm^{-1} (11). Our spectra of these ligands cover a greater cm^{-1} range, and they differ in many details. Detailed spectroscopic studies of D-(−)-penicillamine and its deuterated derivatives, in solid solution, both acid and zwitterion forms (12) and of (*S*)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid and several deuterated species (2) have been reported recently by us.

The spectra of the thiazolidines show many similarities to those of D-penicillamine and its deuterated derivatives, both ref. 12 and this work, and to those for L-cysteine, the main differences being (*i*) the absence of νS—H and δS—H bands; (*ii*) the replacement of bands of the NH_3^+ group by those of the NH group; and (*iii*) the presence of the three unique ring deformations δCSC, δCNC, and δNCS, which are not present in D-penicillamine or L-cysteine.[1]

We discuss here only those features of the spectra which pertain to the CO_2^- (or COOH) and NH_2^+ (or NH) groups; that is, the features relevant to the amino-acid zwitterion equilibria (see Table 2). Strong, broad bands in the infrared spectrum at about 2500 and 1950 cm^{-1}, compounds **IV**, **V** and **VI**, (slightly higher for compounds **I**, **II**, **III**) are typical of fairly strong O—H···N bonding. These bands appear only in the infrared, and not in the Raman spectra for compounds **IV–VI**. They are present in all samples, whether prepared as KBr discs or Nujol or hexachlorobutadiene mulls (and thus are not spurious bands from moisture in KBr). These bands are less consistent in the L-cysteine based compounds, with compounds **I** and **II** showing a single broad band at 2330 and 2630 cm^{-1} and **III** showing bands at 2528 cm^{-1} (ir, Raman) and 2075 cm^{-1} (ir alone).

Bands attributed to the COOH group: The strong infrared bands at 1744–1715, 1330, and 1190–1215 cm^{-1} are assigned as νC=O, δOH, and νC—O, respectively, in **III**, **V**, and **VI**, having mainly the amino-acid form. These assignments are consistent with the findings of the X-ray work for (*S*)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, a compound which exists in the solid in the strongly hydrogen-bonded acid form (2). Bands attributable to the CO_2^- and NH_2^+ groups help identify compounds in the zwitterion form, **I** and **IV**. The specific assignments are in the regions 1620–1555 and 1425–1393 cm^{-1} for $\nu_a CO_2^-$ and $\nu_s CO_2^-$, and 1550–1585 cm^{-1} for δNH_2^+. The spectra of **II** show bands for both forms.

Nuclear magnetic resonance spectra

The ^1H nmr spectra and assignments of the methyl-substituted thiazolidine-4-carboxylic acids are given in Table 3. The

[a]Solutions in D_2O, TSP used as internal standard.
[b]The chemical shift in ppm is followed by peak multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet) and by the integrated peak area.

non-methylated compound has the simplest spectrum with the C2 hydrogens giving rise to a singlet which indicated both protons have the same average chemical environment. The downfield signal is the hydrogen at C4, which is next to an electron-withdrawing carboxyl group having a deshielding effect; the signal is split into a triplet by the two neighbouring protons on C5. The signal of the C5 protons is upfield; these protons have slightly different chemical environments because of their proximity to the carboxyl group; each proton gives rise to a doublet as a result of splitting by the vicinal proton on C4.

2-Methylthiazolidine-4-carboxylic acid, **II**, is a mixture of two stereoisomers: C4 is a fixed chiral center, derived from L-cysteine in this case and with the same *R* conformation, but there is a new chiral carbon, C2, which can be *R* or *S*. The lowest field triplet is the C4 hydrogen. C2-H is split into a quartet by the methyl group attached to the same carbon. The C5 proton signal, of chemical shift 3.5 ppm, is a multiplet because it results from two overlapping doublets of doublets. The doublet of doublets of each proton arises from it being split by the C4 proton and by the geminal proton. The methyl group on C2 gives a doublet and there are two such signals because the methyl group can be on the same side of the ring as the carboxyl group or on the opposite side, because both *R* and *S* isomers are present.

The two methyl groups of the 2,2-dimethyl compound, **III**, give only one singlet in the spectrum, and therefore, they have equivalent chemical environments. They are situated far enough away not to be affected by the carboxyl group, but the two C5 protons, both doublets of doublets, give rise to two distinct signals, split by the C4 proton and in turn by each of the C5 protons, resulting in a quartet of peaks of equal intensity. For the C4 proton, a triplet is observed.

For the 5,5-dimethyl- compound, **IV**, it is somewhat surprising that there are two different C2 proton signals in the spectrum. The two methyl groups appear as two singlets, because there is no plane of symmetry in the molecule.

2,5,5-Trimethylthiazolidine-4-carboxylic acid, compound **V**, also has two chiral centers, and can exist as two diastereomers (*S*,*R* or *R*,*R*) in any proportion. Two sets of resonance signals for each type of proton in the molecule are expected; only one signal was observed for the C2 proton and another one for the methyl group, but the presence of the two diastereomers is shown by the signals for C4.

2,2,5,5-Tetramethylthiazolidine-4-carboxylic acid, compound **VI**, exhibits the expected nmr spectrum. It consists of five singlets, one for each methyl group and one for the single proton bonded to C4. The methyls on C2 are the downfield singlets because they are more deshielded by S and N, both of which are

electron withdrawing. This assignment was confirmed previously by deuteration of the C2 methyl groups (2).

All the C5 methyl groups in Table 2 have very consistent chemical shifts, generally to high field of the C2 methyl groups.

NOE experiments have been carried out with derivatives of penicillin to study thiazolidine ring conformation (13), and have shown that the signals of pro-*R* methyl hydrogens are always at higher field than the hydrogens of pro-*S* methyl groups. By analogy, the 1.68 ppm peak in the spectrum of the 2,2,5,5-tetramethyl compound **VI**, spectrum is assigned to the pro-*R* methyl protons of C5 and the 1.43 singlet to the pro-*S* methyl protons. A study of *erythro* and *threo* sterochemistry of five-membered rings by proton nmr lists also the spectra of tetramethylthiazolidine-4-carboxylic acid, and the assignments agree with those above (14).

Table 4 lists the carbon-13 shifts observed.

The carboxyl carbon is highly deshielded by the two oxygens, and its signal is well downfield, always 170–174 ppm. C4 is expected to be the next most deshielded carbon. As previously discussed with respect to the ^{1}H nmr spectra, the proton on C4 is also the most deshielded because of the proximity to the carboxyl group. C5 is more deshielded than C2 as illustrated by compound **I**, with C2 assigned a chemical shift of 50, and C5, 34.29. This trend continues down the table, although peaks are quite close.

The carbon-13 chemical shifts of compounds **II** and **I** are very similar. C4 and C5 are deshielded to nearly the same extent. The greatest change was observed with C2, with the CH_3 group on C2 causing increased chemical shift, as expected.

In compound **III**, the value of C2 increased only slightly, compared to the same carbon in the 2-methyl compound. C4 has decreased, which cannot be easily explained because the two methyl groups on C2 appear to be too far away from C4 to cause an alteration in the chemical shift unless the conformation of the ring was changed. The carboxyl carbon has its chemical shift lowered by >1 ppm. The methyl carbon on C2 was shifted downfield considerably compared with 2-methylthiazolidine.

For compound **IV**, an increase in the chemical shift of C5 was observed, compared to the values for compounds **I–III** derived from L-cysteine. There is also a large increase in the value for C4; it appears that these methyl groups are close enough to C4 to have an effect similar to that observed for the C5 carbon to which the methyls are directly bound. The chemical shift of C2 has reverted to nearly the same value as in the non-methylated thiazolidine compounds. The C5 methyl groups always occur to slightly higher field than the C2 methyl groups, presumably because of the γ-shielding of the COOH group. This is a general trend which becomes more apparent as more methyl groups are introduced into the molecule.

With compound **V**, C2 again showed an increase in chemical shift relative to compound **IV**. This molecule, **V**, like the 2-methyl compound, **II**, contains two chiral centers, the one at C4 being always *S*, and it can occur in *R*,*S* and *S*,*S* configurations. The compounds are probably about 50:50 mixtures of the two diastereomers, judging from the heights of the duplicated proton nmr signals. The increased chemical shift of C2 relative to that for the compound **IV** reflects the presence of a new methyl group on that carbon. C4 also increased

slightly, which is consistent with the trend previously noted of increasing chemical shifts with every new methyl group added to the thiazolidine ring. The chemical shift of C5 has increased by almost 8 ppm; the presence of one more methyl group on another carbon in the molecule is not a sufficient reason to explain such a large effect, unless the stereochemistry of the ring has changed in such a way as to bring the new methyl spatially close the C5 atom so that the nuclear shielding is altered.

In the compound **VI**, C2 again has a higher value than in the previous compound which only had one C2 methyl group. It should be noted that since there is peak overlap in this compound, either of 61.62 or 76.46 could be assigned to C2 and it is arguable which of the assignments is correct. The chemical shift of C2 is more likely to be 73.46 since it is expected to be higher than that of C5, because of the higher deshielding effects of the N and S atoms around C2 in the ring. For this compound, the methyl group chemical shifts have been assigned previously to C2 and C5 methyl carbons by deuteration of the C2 methyls (2). The 61.62 ppm peak assigned to C5 is of higher chemical shift than expected from the values in ppm assigned to C5 of the other thiazolidine molecules listed in Table 3. Previosly published spectra of *N*-formyl-2,2,5,5-tetramethylthiazolidine compounds (15) helped in the assignment of peaks, as well as the recording of "spin-sort" spectra in which the peaks arising from carbons with an odd number of protons show up below the baseline while carbons with an even number of protons give rise to peaks above the baseline. The methyl group carbons deserve a reference. In thiazolidines that have both C2 and C5 methyl substituents, the methyls on C2 have higher chemical shifts than the C5 methyls, probably because of the proximity of the electronegative N and S. In substituted penicillins the relative shifts were C2 > C5, pro *S* CH_3(C5) > pro *R* (16). If 2,2,5,5-tetramethylthiazolidine-4-carboxylic acid can be considered analogous, the assignments have the same order.

The amino-acid zwitterion equilibria

The p*K* values represent the extent of protonation of ionizable groups, and are presented in Table 5. There is a downward shift of amino group p*K* with increasing CH_3 substitution, especially C2. Increase of COOH group p*K* with methyl substitution is partly caused by inductive effects of the methyl group. Also the anion cannot be solvated so effectively, so that the equilibrium $AH \rightleftarrows A^- + H^+$ is shifted to the left hand side.

From the usual relationship of the Gibbs standard free energy to the equilibrium constant associated with a given reaction in solution, we have calculated the free energy of conversion from the amino acid to the zwitterion form. The values of ΔG^0, also shown in Table 5, vary between -4.2 and -1.8 kcal mol^{-1} for L-cysteine and tetramethylthiazolidine-4-carboxylic acid. If the compounds were tabulated in order of ΔG°, the 2,2-dimethyl-compound, **III**, would be placed below the 5,5-dimethyl compound, **IV**.

Compounds which exist in the amino-acid form in the solid include 2,5,5-trimethyl- and 2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, **V** and **VI**, both derived from D-penicillamine, and the 2,2-dimethyl species, **III**, derived from L-cysteine. When **V** is crystallized from D_2O, howver, it occurs as the zwitterion in the solid state. In D_2O solutions, zwitterion forms are present for all three compounds, although compound **VI** still has a significant concentration of the acid form, as shown by the infrared spectra.

We have shown that methyl substitution at the C2 and C5 positions of the thiazolidine ring does indeed affect the amino-acid zwitterion equilibrium. It was originally assumed that the acidity mght be proportional to the number of CH_3 groups. The shift in equilibrium did not follow this simple relationship, however, since from the infrared spectra the 5,5-dimethyl compound, **IV**, showed no amino acid form in the solid, while the 2-methyl and 2,2-methyl compounds, **II** and **III**, showed evidence for both amino acid and zwitterion forms in the solid. It seems likely that both the number and position of the methyl groups affect the ring conformation and the hydrogen bonding patterns in ways which result in stabilization of either the amino acid or the zwitterion.

The 2-methyl and 2,5,5-trimethyl compounds, **II** and **V**, do have one other feature in common; namely, they can exist as two diastereomers, *RR*, *SR* and *RS*, *SS* respectively. The vibrational spectra of these two compounds show many extra bands, a fact which is consistent with both diastereomers being present. There is, however, no evidence that this factor alone is sufficient to explain the change in the amino acid zwitterion equilibria, although it would mean different entropy values.

Received October 17, 1985
This paper is dedicated to Professor Arthur N. Bourns

RONALD F. CHILDS, BARRY M. DUFFEY, and MAILVAGANAM MAHENDRAN. Can. J. Chem. **64**, 1220 (1986).

Irradiation of the $AlEtCl_2$ complex of *endo*-tricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3-one (**1AL**) yielded the $AlEtCl_2$ complex of *exo*-tricyclo[5.3.0.$0^{2,6}$]deca-4,8-dien-3-one (**3AL**). The structure of **3**, which was obtained on treatment of the irradiated solution with water, was established by its reduction to give the known *exo*-tricyclo[5.3.0.$0^{2,6}$]decan-3-one. The photoisomerization of **1AL** could not be driven to completion as **3AL** underwent a photoisomerization to regenerate **1AL**. Control experiments showed that the interconversions of **1AL** and **3AL** were photochemically and not thermally induced. Irradiation of $AlEtCl_2$ complex of trideutero derivative **6** did not lead to any deuterium scrambling in the starting material, indicating that no hidden skeletal isomerization such as a 2-carbon plus 3-carbon cycloaddition is taking place during this isomerization. The mechanisms of the photoisomerizations are discussed.

RONALD F. CHILDS, BARRY M. DUFFEY et MAILVAGANAM MAHENDRAN. Can. J. Chem. **64**, 1220 (1986).

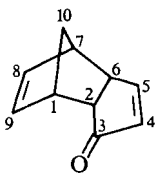
L'irradiation d'un complexe formé de $AlEtCl_2$ et de la tricyclo[5.2.1.$0^{2,6}$] décadiène-4,8 one-3-*endo* (**1AL**) conduit à un complexe du $AlEtCl_2$ avec de la tricyclo[5.3.0.$0^{2,6}$] décadiène-4,8 one-3-*exo* (**3AL**). Le composé **3** est obtenu par traitement de solution irradiée avec de l'eau et sa structure a été déterminée à la suite de sa réduction en tricyclo[5.3.0.$0^{2,6}$] décanone-3-*exo* qui était déjà connue. Le composé **3AL** subissant une photo-isomérisation qui regénère le composé **1AL**, la photo-isomérisation du composé **1AL** ne peut donc jamais être complète. Des expériences de contrôle ont permis de montrer que les interconversions entre les composés **1AL** et **3AL** sont induites photochimiquement et non pas thermiquement. L'irradiation du complexe formé par le $AlEtCl_2$ et le dérivé trideutéré **6** conduit pas à une répartition au hasard des deutérium présents dans le produit de départ; ce résultat suggère que cette isomérisation n'est pas accompagnée d'isomérisations cachées du squelette, comme des cycloadditions de 2 carbones avec 3 carbones. On discute des mécanismes des photo-isomérisations.

[Traduit par le revue]

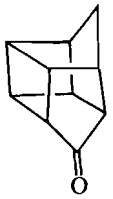
In a continuation of our studies on the photochemistry of oxygen protonated or complexed enones (1) we have examined the effect of Lewis acids on the photochemistry of **1**. Irradiation of **1** under conventional conditions leads to an intramolecular [2 + 2] cycloaddition and the formation of **2** in high chemical and photochemical yield (2). Complexation of the carbonyl oxygen of **1** with a Lewis acid will cause the lowest excited states to be of π,π^* character and we were interested in seeing if the cycloaddition reaction would still occur under these conditions. In addition there is the possibility that a further [2 + 2] cyloaddition could occur with bonding from C_3 and C_5 of the complexed cyclopentenone with the double bond. Such a reaction would correspond to the photoaddition of an allyl cation to a double bond and would extend the range of known photochemical cycloadditions.

Results and discussion

The reaction of **1** with several Lewis acids was examined in $CDCl_3$ solution using ^1H nmr spectroscopy. The changes observed in the nmr spectra of **1** at room temperature in the presence of $[AlEtCl_2]_2$ were consistent with the formation of an oxygen bound complex, Table 1. Spectra obtained at low temperature indicated that the seemingly simple room temperature spectrum was due to a rapid exchange between several closely related complexes resulting from the disproportionation of the aluminum species (3). The uv spectrum of this mixture of complexes showed a strong absorption at 258 nm. The $AlEtCl_2$ complex of **1** was thermally stable at room temperature and **1** could be recovered unchanged on neutralization of the Lewis acid.



1



2

Other Lewis acid complexes of **1** were not so suitable for photochemical studies. The $SnCl_4$ complexes were found to be very insoluble and unsuitable for photochemical work. The $SbCl_5$ complexes were soluble but their uv spectra were complicated by the presence of a strong absorption band due to the Lewis acid (4). In view of the well behaved nature of the $AlEtCl_2$ complexes, it was decided to use these for the photochemical studies.

Irradiation of a $CHCl_3$ solution of complex **1AL** at −50°C led to the formation of a new product. The course of the photoreaction was monitored by ^1H nmr spectroscopy directly on the irradiated solution and by glc after the Lewis acid had been removed. Neutralization of the reaction mixture and separation of the product yielded a new compound, **3**, which was isomeric with the starting material.

The carbon skeleton of **3** and position of the carbonyl group were established by its reduction to **4** which was shown to be identical to authentic material prepared by an independent route (5). The presence of one double bond conjugated to the carbonyl group in **3** was clearly shown by the characteristic chemical shifts of the two vinyl protons (δ 7.71 and 6.29) and their downfield shift when **3** was complexed with $AlEtCl_2$ (δ 8.75 and 7.00). The position of the second double bond was shown by examination of high field ^1H nmr spectra of **3** and shift reagent experiments. At 500 MHz it was possible to resolve all the proton resonances of **3** and with the use of a homonuclear 2D ^1H nmr spectrum completely assign all the signals, Table 2. It was thus shown that the two methylene protons at δ 2.33 and 2.59 were coupled to H(1) (δ 3.04) and not to H(7) (δ 2.36). The

[d]d = doublet, m = multiplet, bt = broad triplet, s = singlet, bs = broad singlet.
[e]1.1–1.2 mol. equiv. $[AlEtCl_2]_2$ was used. This gave rise to (an additional) two signals of lesser intensity for H_4, indicating the occurrence of disproportionation.

addition of shift reagent ($Eu(TFC)_3$) to a solution of **3** caused the resonances of the two methylene protons to be shifted downfield whereas those of the two vinyl protons of the second double bond remained essentially unaffected. The results of both the high field ^{1}H nmr study and the shift reagent experiment show that the second double bond is between C_8 and C_9.

The photoisomerization of **1AL** could not be driven to completion with extended periods of irradiation and it appeared that a photostationary state was being established. This was confirmed by irradiation of a solution of **3AL** when it was found to be converted back to **1AL**. The limiting amount of **3AL** present at the photostationary state was ca. 36% using either 254 nm or 300 nm light sources.

The same interconversion of **1AL** and **3AL** occurred on irradiation at room temperature, however, more material was lost as an insoluble polymer under these conditions. At the lower temperatures typically >85% of the starting ketone could be accounted for in terms of volatile products.

Several control experiments were run. Complexes **1AL** and **3AL** were stable at room temperature and did not interconvert showing that the interconversions of the complexes **1AL** and **3AL** were photochemical and not thermally initiated. It was further shown that the $AlEtCl_2$ complex of **2**, a potential photoproduct in the reaction, was also photochemically and thermally stable under the conditions used for the photochemical reactions of the complexes **1AL** and **3AL**. The cage compound **2** in the absence of the Lewis acid was shown to be inert when irradiated at 254 nm under the conditions used here. It is clear that **2** is not produced under the photochemical conditions used in this work. The irradiation of **1** in the absence of the Lewis acid at 254 nm led only to the formation of **2**.

From the results given above it is clear that the interconversion of **1AL** and **3AL** is a photochemical reaction involving the complexed ketones and that the $AlEtCl_2$ complex of **2** is not an intermediate in these reactions. The isomerizations observed are quite different from those of the neutral ketones when irradiated under the same conditions in the absence of $AlEtCl_2$. The chromophore absorbing the photon in the cases presented here is a complexed cyclopentenone and the lowest energy excited states will be of π,π^* character (6). A further possible difference between the photoisomerizations **1** and **1AL** is the multiplicity of the excited states involved. The conversion of **1** to **2** is known to involve a triplet state (2).

The question arises as to whether a 3-carbon plus 2-carbon (3C + 2C) closure is occurring in **1AL**. The product of such a reaction would be **5** which could reopen to yield **1AL**. Owing to

[1]

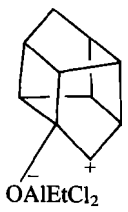
[b]Assignment may be interchanged.

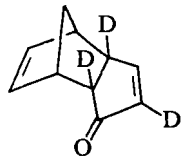
the symmetrical nature of **5**, there are two possible ways it can reopen to yield **1AL**.

To test for the occurrence of this 3C + 2C cycloaddition and subsequent ring opening to give **1AL**, the trideutero derivative **6** was prepared by reacting **1** with $NaOD/D_2O$ in dioxane. It was shown that three deuteriums were incorporated into **6** by mass spectrometric analysis. The ^{1}H nmr spectrum of this compound showed that the resonances attributable to H(2), H(4), and H(6) in **1** were absent.

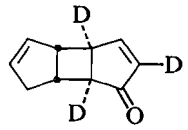
Irradiation of the $AlEtCl_2$ complex of **6** under the same conditions used previously led to the formation of the $AlEtCl_2$ complex of **7**. Ketones **6** and **7** were recovered and separated after neutralization of the irradiated solution and examined by ^{1}H nmr spectroscopy. No scrambling or loss of deuterium was found for **6**. In the case of **7**, deuterium was shown to be at C_2, C_4, and C_6 by the absence of signals corresponding to the proton resonances of the corresponding protio material, Table 2. These results show that there is no reversible formation of the intermediate **5** by a 3C + 2C cycloaddition occurring in these reactions.



5

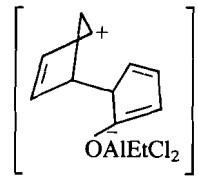


6



7

The interconversion of **1AL** and **3AL** can formally be regarded as a suprafacial 1,3-sigmatropic shift as shown in reaction [1]. It is not clear whether this reaction is concerted or whether it involves an intermediate such as **8**. It has been suggested that twisting about the C_2,C_3 bond of the excited state of the protonated enone leads to a build up of a positive charge at C_3 (7). Cyclopentenone is a fairly rigid system, so that only a partial rotation about the C_2,C_3 bond is possible. Such partial rotation could lead to charge localization at C_3, and a subsequent β-cleavage reaction. The intermediate **8**, which can also be formed by a comparable sequence of events from **3AL**, would be able to revert to **1AL** or close to **3AL**. Comparable thermal interconversions of other substituted derivatives of ring systems corresponding to **1** and **3** have been described (8). The alternative cleavage of the C_1,C_2 bond in a 1,3-sigmatropic shift does not lead to the formation of **3AL**.



8

Overall these results show that the presence of a Lewis acid in solution on irradiation of **1** produces a remarkable change in the course of the photoreaction. It remains to be seen how general this type of Lewis acid catalyzed photorearrangement will be with other cyclic enones.

Experimental

General

^{1}H nmr spectra were obtained on Varian EM-390 or Bruker WM-250 and AM-500 instruments. Gas chromatographic analyses were per-

formed on a Hewlett-Packard 5790A gas chromatograph, using 10% Flourad FC 431 on Chromosorb W-HP 80/100 mesh, packed in a (1 m × 3 mm) stainless steel column. Ultraviolet spectra were measured on Pye Unicam instruments.

Ketone **1** was prepared in 45% yield from dicyclopentadiene according to the method of Woodward and Katz (9). Ethylaluminumdichloride (Ethyl Corporation) was distilled before use and stored under nitrogen in sealed glass ampules. All manipulations were carried out in a nitrogen glove box, using an SMI digital micropipette which was calibrated by weight. Chloroform was used as the solvent, and was dried by storing in a sealed container over activated Linde 4 Å molecular sieves. Irradiations were carried out in quartz apparatus at −50°C using a Rayonet Photoreactor (Southern New England Company) equipped with a magnetic stirrer, and RPR 2540 or 3000 Å lamps.

Preparation of ***3***

The ketone **1** (1.3 g) was added to a solution of $AlEtCl_2$ (1.2 g, 1 mol equiv.) in $CHCl_3$ (50 mL). The solution was cooled to −50°C, and irradiated until a photostationary state was reached (typically 24 h). (The course of the reaction was monitored at regular intervals by gc analysis of quenched aliquots). The solution was then poured into water (5 mL), the organic layer was separated, and the aqueous layer further extracted with $CHCl_3$. The combined organic layers were dried (anhydrous $MgSO_4$), the solvent was removed under reduced pressure, and the resulting residue distilled (120°C, 1 mm Hg) to yield a mixture (1.1 g) containing 64% **1**, and 36% **3**. The latter was separated from the mixture by column chromatography using a 10 cm × 2 cm column packed with tlc grade silica with a petroleum ether/ether mixture as eluent. The product **3** eluted before **1**. The solvent was removed and the product distilled (120°C, 1 mm Hg) to yield **3** (300 mg). Mol. wt. calcd. for $C_{10}H_{10}O$: 146.0732; found (high resolution ms): 146.0732 (Ir (film) ν_{max} 2930, 2850, 1701, 1580, 1350, 1170, 790, 720, and 700 cm^{-1}.

Hydrogenation of ***3***

The ketone **3** (10 mg) was dissolved in methanol (3 mL) containing palladium, 5% on $BaSO_4$ (Koch Light Laboratories) (5 mg). The suspension was stirred under H_2, until 2 mol. equiv. of H_2 was consumed. The suspension was filtered and the catalyst rinsed with methanol. The combined solvents were removed under reduced pressure and the residue distilled (120°C, 1 mm Hg) to yield a clear liquid (8 mg), which was subsequently shown to be tricyclo[5.3.0.$0^{2,6}$]decan-3-one by comparison with an authentic sample prepared by a standard procedure (5).

Preparation of ***6***

D_2O (12 mL) was slowly added to sodium wire (0.6 g) in dioxane (35 mL) under nitrogen atmosphere. A solution of **1** (250 mg) in dioxane (2 mL) was added and the mixture refluxed for 5 days. The mixture was neutralized to pH = 7 with 25% D_2SO_4 in D_2O. The resultant mxture was extracted three times with ether (25 mL) and the combined organic layers dried over anhydrous $MgSO_4$. The solvent was removed under reduced pressure and the residue distilled (120°C, 1 mm Hg), to yield **6** (150 mg) as a clear liquid which slowly turned into white waxy solid upon standing.

This paper is dedicted to Professor Arthur N. Bourns

J. R. KEEFFE, A. J. KRESGE, and J. TOULLEC. Can. J. Chem. **64**, 1224 (1986).

Rates of acid-catalyzed enolization of acetophenone in dilute aqueous solution, measured under conditions where the solvated proton is the only acidic species present, give a hydrogen ion catalytic coefficient, $k^E_{H+} = (1.21 \pm 0.01) \times 10^{-5}\ M^{-1}\ s^{-1}$, that is 35% smaller than the value obtained by X acidity function extrapolation of measurements made in moderately concentrated sulfuric acid solutions. The difference may be attributed to catalysis by bisulfate ion in the sulfuric acid solutions; this is supported by direct measurement of the bisulfate ion catalytic coefficient in dilute sulfuric acid. This revised value of k^E_{H+} leads to new, but only slightly different, values of the keto–enol equilibrium constant for acetophenone in aqueous solution, $pK_E = 7.96 \pm 0.04$, the acidity constant for acetophenone ionizing as a carbon acid, $pK^K_a = 18.31 \pm 0.05$, and the encounter-controlled rate constant for the reaction of acetophenone enol with molecular bromine, $k = (3.2 \pm 0.4) \times 10^9\ M^{-1}\ s^{-1}$.

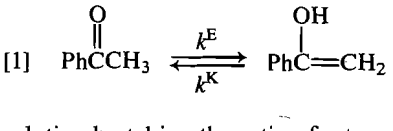
Les vitesses pour les réactions d'énolisations acido-catalysées de l'acétophénone, mesurées en solution aqueuses diluées dans des conditions sous lesquelles le proton solvaté est la seule espèce acide présente, conduisent à une coefficient catalytique de l'ion hydrogène, $k^E_{H+} = (1{,}21 \pm 0.01) \times 10^{-5}\ M^{-1}\ s^{-1}$ qui est environ 35% plus faible que la valeur obtenue à l'aide de l'extrapolation de mesures de la fonction d'acidité X qui ont été faites dans des solutions d'acide sulfurique modérément concentrées. On peut attribuer cette différence à la catalyse de l'ion bisulfate qui est présent dans les solutions d'acide sulfurique; cette conclusion est supportée par des mesures directes du coefficient catalytique de l'ion bisulfate dans des solutions diluées d'acide sulfurique. Cette valeur revisée de k^E_{H+} conduit à de nouvelles, mais que légèrement différentes, valeurs pour: (*a*) la constante céto-énolique de l'acétophénone en solution aqueuse, $pK_E = 7{,}96 \pm 0.04$; (*b*) la constante d'acidité de l'acétophénone qui s'ionise sous forme d'acide du carbone, $pK^K_a = 18{,}31 \pm 0{,}05$ et (*c*) la constante de vitesse contrôlée par les rencontres pour la réaction de l'énol de l'acétophénone avec le brome moléculaire, $k = (3{,}2 \pm 0{,}4) \times 10^9\ M^{-1}\ s^{-1}$.

[Traduit par la revue]

The equilibrium constant for the enolization of acetophenone, eq. [1], was determined recently for dilute aqueous



[1] $PhCCH_3 \underset{k^K}{\overset{k^E}{\rightleftharpoons}} PhC{=}CH_2$ (OH)

solution by taking the ratio of rate constants for this reaction in the forward (enolization) and reverse (ketonization) directions: $K_E = k^E/k^K$ (1). One set of rate constants used for this purpose referred to measurements made in acid solution. The ketonization rate constant was a value determined directy in dilute hydrochloric acid solutions; it was therefore a true hydrogen ion catalytic coefficient, k^E_{H+}. The enolization rate constant, on the other hand, was based upon measurements made in moderately concentrated sulfuric acid; these data were then extrapolated down to dilute solution by using the X acidity function (2). Sulfuric acid of the concentrations used for the rate measurements, however, contains appreciable quantities of bisulfate ion (3), and bisulfate ion in such solutions is known to be a kinetically active proton transfer agent in general acid catalyzed processes such as the enolization of acetophenone (4). The possibility existed, therefore, that the extrapolated rate constant did not represent reaction through H^+ alone, but that it was a combination of H^+ and HSO_4^- catalytic coefficients, and that the keto–enol equilibrium constant based upon it was in error.

To investigate this matter, we have measured the rate of enolization of acetophenone directly in dilute solution under conditions where H^+ is the only acidic species present. The value of k^E_{H+} so obtained is indeed significantly less than the rate constant produced by extrapolating the concentrated sulfuric acid data. We have also measured the rate of enolization of acetophenone in dilute sulfuric acid solutions and from these data have evaluated the HSO_4^- catalytic coefficient for this reaction.

Experimental

Materials

Acetophenone (Fisher, certified reagent) was dried over molecular sieves and then fractionally distilled at reduced pressure through an efficient column. All other substances were best available commercial grades and were used as received. Solutions were made with deionized water that had been purified further by distillation.

Kinetics

Rates of enolization were measured by bromine scavenging in the presence of bromide ion using the absorbance of Br_3^- at 320 nm to monitor the reaction. Runs were performed under zero-order conditions with acetophenone concentrations of ca. $10^{-2}\ M$ and stoichiometric bromine concentrations of ca. $10^{-4}\ M$. Bromide ion was 0.10 M; it was supplied either as HBr, to provide a variable acidity, or as NaBr, to keep ionic strength constant at 0.10 M. Absorbance measurements were made using a Cary Model 118C spectrometer with cell compartment thermostatted at 25.0 ± 0.02°C.

In a typical experiment, 3.0 mL of acid solution contained in a cuvette was brought to temperature equilibrium with the spectrometer

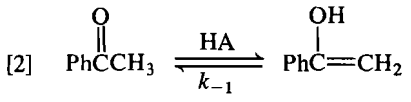
[2]Author to whom correspondence may be addressed.

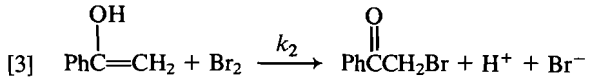
cell compartment. Acetophenone (3.5–4.0 μL) was then added, the mixture was shaken thoroughly to effect solution, and the absorbance at 320 nm was recorded (for the purpose of determining the acetophenone concentration). Saturated bromine water (15–20 μL) was then added to start the reaction. The disappearance of Br_3^- was accurately zero order for ca. 70% of the total absorbance change; this corresponds to 0.8–1.0% consumption of acetophenone on the basis of 1:1 stoichiometry. The rate of change of absorbance was converted to $\Delta[Br_3^-]/\Delta t$ using a value of $\epsilon_{Br_3^-}$ determined here, and thence to $\Delta[Br_2]_{st}/\Delta t$ through the factor $(1 + K_{ass}^{-1}[Br^-]^{-1})$ where $K_{ass} = 16.7\ M^{-1}$ is the equilibrium constant for $Br_2 + Br^- = Br_3^-$.[3] Zero-order rates of disappearance of bromine were then converted to first-order enolization rate constants by dividing by the acetophenone concentration.

Results and discussion

The acid-catalyzed bromination of a ketone such as acetophenone in aqueous solution is known to occur in two stages: formation of the enol, eq. [2], followed by reaction of this intermediate with bromine, eq. [3] (6*a*, 7). Formation of the



[2] $PhCCH_3 \underset{k_{-1}}{\overset{HA}{\rightleftharpoons}} PhC{=}CH_2$ (O over C; OH over C)



[3] $PhC{=}CH_2 + Br_2 \xrightarrow{k_2} PhCCH_2Br + H^+ + Br^-$ (OH over C; O over C)

enol will be the rate-determining stage, and the rate of bromine consumption will consequently measure the rate of the enolization reaction, when the enol reacts with bromine sufficiently more rapidly (say by a factor of 10^2) than it undergoes acid-catalyzed reversion to ketone. This was easily the case in the present study. There is good evidence that the reaction of acetophenone enol with bromine, eq. [3], is an encounter-controlled process (8) whose rate constant is $3 \times 10^9\ M^{-1}\ s^{-1}$ (1), and that the rate constant for the corresponding reaction with Br_3^- as the brominating agent is only a factor of two smaller (8). These values lead to $2 \times 10^5\ s^{-1}$ as the first-order specific rate of bromination of acetophenone enol at the stoichiometric bromine concentration used here, $10^{-4}\ M$. The rate constant for the reketonization of acetophenone enol, k_{-1}, is also known for the case of catalysis by H^+: $k_{H^+} = 1.25 \times 10^3\ M^{-1}\ s^{-1}$ (1), and that value coupled with the highest acidity used in the present study, $[H^+] = 0.1\ M$, leads to $1 \times 10^2\ s^{-1}$ as the maximum first-order specific rate of reversion of the enol to ketone. Bromination of the enol thus occurs at least 2×10^3 times faster than reketonization under the conditions used here.

Although the base-catalyzed halogenation of carbonyl compounds commonly gives polyhalogenated products, only monosubstituted products are generally found in the acid-catalyzed reaction (6*a*). There is direct evidence that this was the case in the present study and that the stoichiometry of the reaction was indeed 1:1 as indicated in eq. [3]. In an early investigation of the acid-catalyzed bromination of acetophenone, phenacyl bromide was the only product isolated (9), and a more recent examination of the reaction product by proton nmr failed to reveal any dibrominated material under circumstances where 4% could have been detected (2, 10). This nmr analysis was carried out on product formed from reaction of roughly equimolar amounts of acetophenone and bromine. Since in the present study acetophenone was always supplied in 100-fold excess over stoichiometric bromine, it seems safe to conclude that under our conditions only one equivalent of bromine was consumed per equivalent of enol formed, and that rates of bromine consumption can therefore be taken to be exactly equal to rates of enolization.

[3]This value of K_{ass} refers to 25°C and ionic strength $\mu = 0.10\ M$; it was obtained by extrapolating determinations reported for 16.5 and 21.5°C (5). Because K_{ass} entered into our data analysis as the factor $(1 + K_{ass}^{-1}[Br^-]^{-1})$, exact knowledge of its value was not critical.

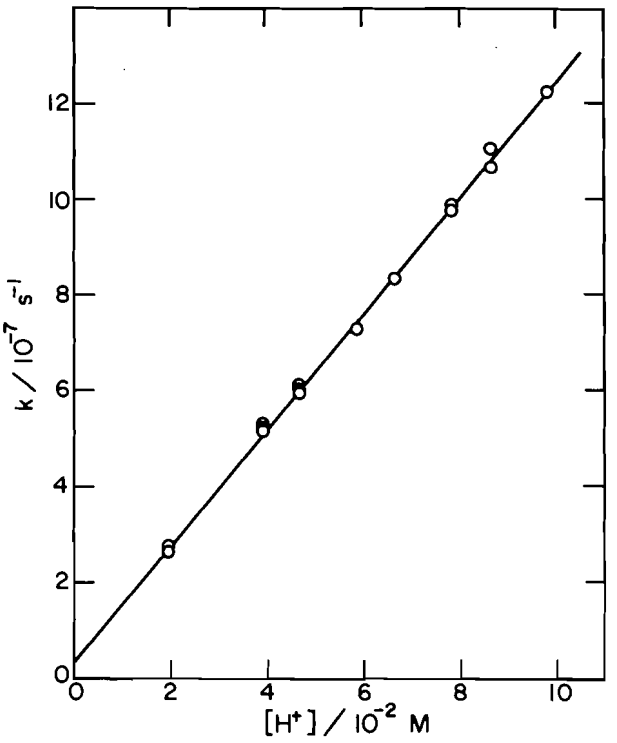

FIG. 1. Relationship between hydrogen ion concentration and observed first-order rate constants for the enolization of acetophenone in aqueous hydrobromic acid solutions at 25°C.

First-order rates of enolization determined in this way were measured in hydrobromic acid solutions over the concentration range $[HBr] = 0.02–0.10\ M$. The data are summarized in Table 1 and are displayed in Fig. 1. It may be seen that these rate constants are accurately proportional to acid concentration; least-squares analysis gives the relationship $k_{obs} = (3.51 \pm 0.86) \times 10^{-8} + (1.21 \pm 0.01) \times 10^{-5}\ [HBr]$. Since hydrobromic acid is completely ionized in dilute aqueous solution (6*b*), the only acidic species present in these solutions is the solvated proton; the bimolecular rate constant determined here is therefore a true hydrogen ion catalytic coefficient.

[a]Stoichiometric concentrations are denoted by the subscript "St"; others are actual (calculated) concentrations. The latter were obtained from the thermodynamic dissociation constant for HSO_4^-, $K_a = 1.05 \times 10^{-2}\,M$ (20), using activity coefficients determined by the Debye–Huckel equation with ion-size parameters of Bates (21); for HSO_4^- this quantity (4.0 Å) was estimated as the average of values for similarily sized and charged ions. This procedure produced the following concentration quotients for HSO_4^- at our experimental ionic strengths: $Q_a = 2.62 \times 10^{-2}\,M$ ($\mu = 0.082\,M$), $2.74 \times 10^{-2}\,M$ ($\mu = 0.100\,M$), and $2.85 \times 10^{-2}\,M$ ($\mu = 0.106\,M$); this spread in Q_a had little effect on the calculated concentrations.
[b]μ = ionic strength.

This result, $k^E_{H+} = 1.21 \times 10^{-5}\,M^{-1}\,s^{-1}$, is 35% less than the rate constant obtained by extrapolation of measurements made in moderately concentrated sulfuric acid solutions, $k = (1.63 \pm 0.03) \times 10^{-5}\,M^{-1}\,s^{-1}$ (2). This suggests that additional catalysis of the enolization reaction by bisulfate ion was indeed taking place in these sulfuric acid solutions, and that extrapolation of the data down the X function did not remove this extra catalysis. Additional evidence in support of this hypothesis may be obtained from some measurements of the enolization of acetophenone made in moderately concentrated perchloric acid solutions (11). This acid is monobasic and fully ionized at the concentrations used, and therefore only catalysis by H^+ is possible. It is thus significant that extrapolation of these data down the X_0 function (12) gives a dilute solution rate constant whose value, $k^E_{H+} = (1.21 \pm 0.01) \times 10^{-5}\,M^{-1}\,s^{-1}$, is identical with the result obtained here by direct measurement in dilute solution.

When this revised value of k^E_{H+} is used to determine the keto–enol equilibrium constant for acetophenone in aqueous solution, the result obtained, $K_E = (9.71 \pm 0.21) \times 10^{-9}$, is still in reasonable agreement with an independently determined value based upon a set of hydroxide ion catalytic coefficients for the enolization and ketonization reactions, $K_E = (1.20 \pm 0.07) \times 10^{-8}$ (1). The current best value of this constant is then the average of these two results, $K_E = (1.08 \pm 0.11) \times 10^{-8}$, $pK_E = 7.96 \pm 0.04$; this differs only marginally from our previous best estimate, $pK_E = 7.90 \pm 0.02$ (1). This change also requires revision of our previous estimate of the equilibrium constant for the ionization of acetophenone as a carbon acid, eq. [4], which

$$[4]\quad \underset{\text{O}}{\overset{\|}{\text{PhCCH}_3}} \overset{K^K_a}{\rightleftharpoons} \underset{\text{O}^-}{\overset{|}{\text{PhC}{=}\text{CH}_2}} + H^+$$

is the product of K_E and the known (13) equilibrium constant for ionization of acetophenone enol as an oxygen acid, K^E_a: $K^K_a = K_E K^E_a$. The new value, $K^K_a = (4.96 \pm 0.59) \times 10^{-19}\,M$, $pK^K_a = 18.31 \pm 0.05$,[4] is again only marginally different from the old: $pK^K_a = 18.24 \pm 0.03$ (1). Another quantity which can be derived from K_E is the rate constant for the encounter-controlled reaction of acetophenone enol with molecular bromine; the new value of this constant, based upon our revised K_E, is $k = (3.2 \pm 0.4) \times 10^9\,M^{-1}\,s^{-1}$, up from the $k = (2.8 \pm 0.02) \times 10^9\,M^{-1}\,s^{-1}$ we had estimated before (1).

In addition to these determinations of the rate of enolization of acetophenone in hydrobromic acid solutions, we also made some measurements of the rate of this reaction in dilute sulfuric acid, at various stoichiometric acid concentrations and with various additions of HBr and Na_2SO_4, to get further variation in the concentrations of solution species. The data are summarized in Table 2. The only acids present in these solutions were H^+ and HSO_4^- (3), and we therefore fitted the data to the rate law shown in eq. [5]. The concentrations of H^+ and HSO_4^- required for this purpose were obtained by calculation, using $K_a = 1.05 \times 10^{-2}\,M$ for the acidity constant of HSO_4^- (14) and activity coefficients determined by the Debye–Hückel equation with ion-size parameters of 9 Å for H^+, and 4 Å for HSO_4^- and SO_4^{2-} (15).

$$[5]\quad k_{obs} = k_0 + k_{H+}[H^+] + k_{HSO_4}[HSO_4^-]$$

We sought to keep ionic strength constant in these sulfuric acid solutions, but this goal was unfortunately incompletely realized: ionic strength varied from $\mu = 0.082$–$0.106\,M$. To determine whether this spread would have a significant effect on the rate of enolization, we performed another series of rate measurements varying ionic strength from $\mu = 0.06$–$0.14\,M$ at a fixed acid concentration, $[HBr] = 0.059\,M$. These data, summarized in Table 3, show no systematic dependence of observed rate constant upon ionic strength: linear least-squares analysis gives a relationship, $k_{obs} = (7.61 \pm 0.11) \times 10^{-7} - (0.04 \pm 1.08) \times 10^{-7}\,\mu$, with zero slope and a predicted value for $\mu = 0.10\,M$, $k = (7.61 \pm 0.03) \times 10^{-7}\,M^{-1}\,s^{-1}$, which is consistent with the rate constant, $k = (7.49 \pm 0.03) \times 10^{-7}\,M^{-1}\,s^{-1}$ predicted for $[H^+] = 0.059\,M$ from the correlation of rate measurements made at variable [HBr] and $\mu = 0.10\,M$.

This result indicates that the variation in ionic strength of our sulfuric acid solutions will have no significant effect on the rate measurements performed in these media. We therefore fit the data to the rate law of eq. [5] with no further adjustment. The result, $k_{obs} = -(0.57 \pm 2.54) \times 10^{-8} + (1.07 \pm 0.20) \times 10^{-5}\,[H^+] + (1.49 \pm 0.40) \times 10^{-5}\,[HSO_4^-]$, gives a hydrogen ion catalytic coefficient in good agreement with the value deter-

[4]This equilibrium constant is a *concentration quotient* which refers specifically to an ionic strength of 0.10 M.

TABLE 3. Rate data for the enolization of acetophenone in aqueous hydrobromic acid solution at 25°C at variable ionic strength[a]

7.55	7.70
9.45	7.56
12.3	7.65
14.0	7.58

$k_{obs} = (7.61 \pm 0.11) \times 10^{-7} - (0.04 \pm 1.08) \times 10^{-7}\ \mu$

[a][HBr] = 5.9×10^{-2} M; ionic strength varied with $NaClO_4$.

mined more precisely in HBr solutions: $k^E_{H+} = (1.21 \pm 0.01) \times 10^{-5}\ M^{-1}\ s^{-1}$. It also gives a bisulfate ion catalytic coefficient that is very similar in magnitude to k^E_{H+}; this shows that appreciable catalysis of the enolization reaction by bisulfate ion can be expected to occur in moderately concentrated sulfuric acid solutions where the concentrations of this ion are large (3).

Such similarity of bisulfate and hydrogen ion catalytic coefficients is unexpected because of the considerable difference in acid strength of these two catalytic species. As the basis for a molecular explanation we can consider two reaction mechanisms. The conventional scheme for acid catalyzed enolization consists of two steps: equilibrium protonation of the carbonyl group followed by rate controlling deprotonation at carbon (6*c*, 7, 16). The other mechanism, alternative or concurrent, is a termolecular reaction in which protonation at oxygen is concerted with deprotonation at carbon (17). The acid–base pair responsible for bisulfate catalysis by this termolecular mechanism could be either H^+/SO_4^{2-} or HSO_4^-/H_2O.[5]

In the two-step mechanism we can account for the surprising catalytic effectiveness of bisulfate by postulating an electrostatic effect (18). The rate controlling transition state is formed from an oxonium ion and a base. For hydrogen ion catalysis the base is water, but for bisulfate ion catalysis the transition state brings together positive oxonium ion and doubly negative sulfate ion. Electrostatic effects on the rates of deprotonation at carbon have been documented (18).

In the termolecular mechanism the transition state for bisulfate catalysis is composed of ketone, hydrogen ion, and sulfate ion, or of ketone, bisulfate, and water. For the former case we note the electrostatic analogy with the transition state of the two-step mechanism. For the latter case the comparison to be made is between the protonation of ketone by hydrogen ion and the protonation of ketone by bisulfate, in both cases with concurrent deprotonation at carbon by water. An unusually high kinetic acidity of bisulfate in proton transfer reactions has been observed before, notably in the acid cleavage of allylmercuric iodide (19) and isobutenylmercuric bromide (20), in the detritiation of 1,3,5-trimethoxybenzene (21), and in the hydrolysis of ethyl vinyl ether (22). The speculation has been advanced that bisulfate ion might be unusually effective in these reactions because the configuration of the solvent molecules in its initial state solvation shell is similar to that required in the transition state, and the need for solvent reorganization during the proton transfer process is thereby minimized.

[5]The first of these pairs consists of the stronger acid and the stronger base; it should therefore be the more effective. In that case the bisulfate-ion catalytic coefficient would be equivalent to a third-order rate constant having the value $(5.6 \pm 1.5) \times 10^{-4}\ M^{-2}\ s^{-1}$.

On démontre que la spectrométrie de masse par bombardement avec des atomes rapides est un outil utile pour étudier les complexes, contenant de fortes liaisons hydrogènes, de l'imidazole avec divers donneurs électroniques.

[Traduit par la revue]

Introduction

The hydrogen-bonding properties of imidazole and its derivatives are of considerable importance in biochemistry (1). Of particular interest is the ability of imidazole to form strong, easily polarizable hydrogen bonds that may play an important role in many biochemical functions (1, 2).

Both nonspectroscopic and spectroscopic techniques have been used for the detection of hydrogen bonds (3). Since the emphasis in recent years has shifted to the use of spectroscopic techniques, a remarkable variety of such methods including infrared, nuclear magnetic resonance, visible, and photoelectron spectroscopy have been successfully applied to the study of hydrogen bonding.

The use of mass spectrometry as a technique for the study of hydrogen bonding has received little attention. The traditional method of electron impact mass spectrometry (EIMS) requires thermal volatilization of the sample and then subjects it to bombardment with electrons, the combination of which effectively precludes the use of EIMS for the study of hydrogen bonding. On the other hand, fast atom bombardment mass spectrometry (FABMS) is a "soft ionization" technique that does not require sample heating (4). In the case of the FABMS experiment the sample is dissolved in a matrix liquid that is relatively involatile under the high vacuum conditions present in the source of the mass spectrometer. The sample is then subjected to bombardment with energetic (6–8 keV) "fast atoms" and by this means both ionization and volatilization of the sample is achieved. Many different matrix liquids may be used in the FABMS experiment and a matrix of the "correct chemistry" is often needed to obtain useful spectra, which in turn can require considerable experimentation. The most commonly used FABMS matrix liquid is glycerol.

Those familiar with the FABMS technique have long known that ions corresponding to protonated dimers and trimers of the matrix liquid are often seen, particularly when using glycerol as the matrix liquid. These ions, containing clusters of molecules, are presumably held together by hydrogen bonding. Despite these observations, FABMS has never been used to systematically study hydrogen bonding *per se*.

Recently, the FABMS of the strongly hydrogen-bonded complex formed between imidazole and trimethylphosphate was reported (5) and an ion corresponding to the hydrogen-bonded complex was observed for this system. We have carried out a further study of hydrogen bonding to imidazole using FABMS with a range of electron donors of varying strength. With the FABMS method, we have studied the effect of the matrix liquid, concentration, and water content on the hydrogen bonding to imidazole. With FABMS the question of how representative of solution behavior the spectrum is must always be considered. Our experiments lead us to conclude that FABMS does indeed give an accurate picture of the hydrogen bonding between the various substrates in the matrix liquid and that FABMS may become a routine method for the analysis of some hydrogen bonded systems.

Experimental

FAB spectra were obtained using an AEI MS-30 (Kratos Ltd., Manchester U.K.) retrofitted with a saddle-field FAB gun (Ion tech, Teddington, U.K.) and a Kratos FAB source in beam 1. Xenon was used as the bombarding atom, the energy of the beam being 6–8 keV and a stainless steel probe tip being used. All the spectra were peak averaged from a minimum of 8 scans using a DS-55 data system. Mass conversion was done off-line based on a tris-perfluoroheptyl-*s*-triazine calibration. Infrared spectra were recorded as hexachlorobutadiene mulls using an Analect FX 6260 FT-IR at 4 wavenumber resolution. The ^{1}H nmr spectra were recorded on a Brüker WP-80 in $CDCl_3$ solution.

meta-Nitrobenzyl alcohol (NBA), imidazole, triphenylphosphine oxide, diphenyl sulphoxide, acetophenone, diphenyl ether, and triphenyl methanol were obtained from BDH and Aldrich (reagent grade), and were used unpurified. Dry *meta*-nitrobenzyl alcohol was obtained by storing NBA over type 4 angstrom molecular sieves activated at 400°C. The hydrogen-bonded complexes were prepared by dissolving 1 g (14.7 mmol) of imidazole in 200 cm^3 of diethyl ether followed by the addition of an equimolar amount of the electron donor. The bulk of the diethyl ether was removed by rotary evaporation to leave an oil. The oil was then pumped dry under vacuum (0.1 Torr; 1 Torr = 133.3 Pa) to leave the solid complex.

Deuteroimidazole was prepared by warming imidazole in D_2O followed by the removal of the water under vacuum. The deuteroimidazole – diphenyl sulphoxide complex was prepared as above, the ^{1}H nmr showing in excess of 90% deuterium incorporation.

Complexes containing a 2:1 electron donor-to-imidazole ratio were prepared as follows. Imidazole (1 g, 14.7 mmol) was dissolved in

[1]Author to whom correspondence may be addressed.

acetonitrile. Concentrated hydrobromic acid (14.7 mmol) was added, generating the protonated imidazole species. Two equivalents of the electron donor were next added, and the acetonitrile was then removed to leave a white crystalline solid in every case.

Results and discussion

Imidazole – electron donor complexes are ideal candidates for the study of hydrogen bonding by FABMS since the complex can be protonated (at N3) without breaking the hydrogen bond. Thus the complex may be easily protonated, generating the quasi-molecular ion observed in the FABMS spectrum. In comparison, we have been unable to observe the H-bonded dimer of benzoic acid by FABMS, presumably because there is no site at which protonation of this species may occur without breakdown of the dimer itself.

We have been able to observe hydrogen-bonded complexes formed between trialkylammonium ions, pyridinium ion, and substituted pyridinium ions with a range of electron donors. These hydrogen-bonded ions, which show 1:1 complex formation, are clearly distinct from clustering caused by electrostatic interaction, which gives rise to ions of the general formula $[\text{cation}(\text{cation}/\text{anion})_n]^+$ where $n = 1, 2, 3 \ldots$.[2]

The choice of the matrix liquid is obviously going to be critical in a hydrogen-bonding FABMS study. Weakly hydrogen-bonded species would not be expected to be observed in a strong H-bonding matrix such as glycerol. The water content of the matrix may also play a critical role in the observation of many H-bonded species by FABMS. Trace amounts of water may be necessary for the generation of protonated species, yet too high a water content may result in breakdown of the complex.

We have found through considerable experimentation that *meta*-nitrobenzyl alcohol (NBA) is the best matrix for the study of hydrogen bonding to imidazole (IM). We were able to obtain spectra over a period of 15 min with no loss in ion current. Cross-scan reports of the spectra showed the very stable nature of the ion current arising from the H-bonded complexes (see Fig. 1).

Preliminary work using glycerol as the matrix liquid showed that only the strongest hydrogen bonds to imidazole were able to survive in this medium, such as those formed with trimethylphosphate and triphenylphosphine oxide. Ions corresponding to glycerol and imidazole or glycerol and electron donor complexes were also observed.[2]

Nitrophenyl octyl ether (NPOE) is another commonly used matrix liquid, but the complexes were found to have low solubility in this matrix. Because of the low solubility only the stronger hydrogen-bonded complex between imidazole and triphenylphosphine oxide was observed. With other electron donors the low concentration of the species present in the matrix resulted in dissociation of the complex, as could be expected. The use of a polyphenyl ether as the matrix liquid was also limited by poor solubility of the complexes.

Sulpholane also proved to be a useful matrix for higher concentrations of the complexes. At low concentration the sulpholane proved to be too volatile in the mass spectrometer and we were only able to obtain spectra over a period of a few minutes (2–3 scans). Because of the transient nature of sulpholane we were unable to obtain quantitative data using this matrix even though peaks due to the H-bonded complexes were in general more intense using sulpholane rather than NBA as the matrix liquid.

[2]Work in progress.

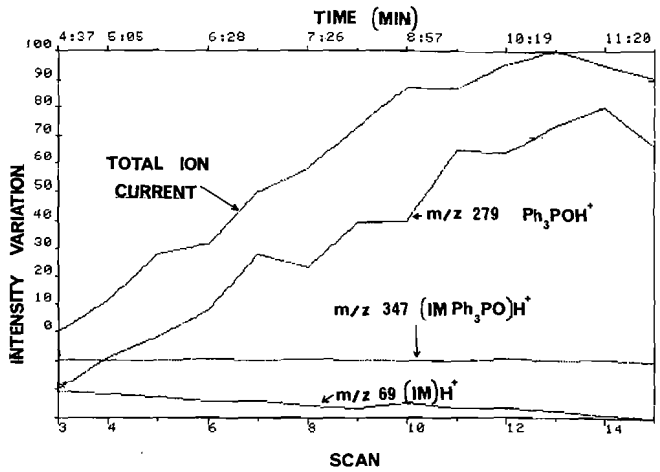

FIG. 1. Cross-scan report of imidazole – triphenylphosphine oxide complex in NBA.

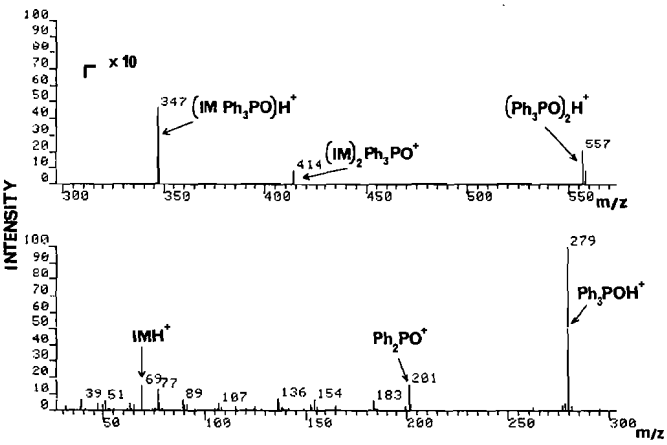

FIG. 2. FABMS of imidazole – triphenylphosphine oxide complex in NBA.

The FABMS of imidazole in NBA at a concentration of approximately 1.3 *M* showed a base peak at m/z 69 corresponding to the quasi-molecular ion $(\text{IM} + \text{H})^+$ for imidazole. Other significant peaks in the spectra included the imidazole dimer (m/z 137, 13% of base) and a peak at m/z 222 (2% of base) corresponding to the imidazole–NBA complex. At this concentration the spectrum due to NBA was relatively weak; the NBA $M + 1$ ion at m/z 154 amounted to only 11% of the base peak. The FABMS spectra of the complexes typically showed peaks at masses corresponding to the H-bonded complex, free imidazole (as an $M + 1$ peak), and the free electron donor (as $M + 1$ peak), except in the case of triphenyl methanol where the base peak corresponds to the Ph_3C^+ ion at m/z 243. In every case H-bond formation was confirmed by ir spectroscopy and the 1:1 ratio of imidazole to electron donor by ^1H nmr. A typical FABMS spectrum is shown in Fig. 2.

Since observation of the imidazole H-bonded complexes by FABMS involves protonation of the imidazole, likely at the N3 position, generating two equivalent H-bonding sites, we have also studied the complexes formed between protonated imidazole and two equivalents of the electron donors triphenylphosphine oxide and diphenyl sulphoxide. In these systems, in addition to the 1:1 complexes in the NBA matrix, we were able to observe the 2:1 donor-to-imidazole H-bonded complexes at low intensity.

*Ratios in terms of absolute intensities of peaks.
†Ph_3COH/IM limited by lower solubility, but H-bonded complex was observed.

The effect of concentration on the intensity of the H-bonded complex peak relative to that of the free imidazole was studied for the triphenylphosphine oxide – imidazole complex and for the diphenyl sulphoxide – imidazole complex, the results of which are shown in Table 1. As expected, we observed a decrease in the intensity of the complex peak relative to that of free imidazole, with decreasing concentration of the complex for both the triphenylphosphine oxide – imidazole and the diphenyl sulphoxide – imidazole complexes. The imidazole peak at m/z 69 was used for the ratio calculation even though the base peak in each case was the quasi-molecular ion from the electron donor, as the ionization efficiency for imidazole was assumed to be closer to that of the complex. The ionization of imidazole and the complex involves protonation at N3 whereas, in the case of the electron donor, ionization involves protonation of a P=O, S=O, or other functional group.

Comparison of the intensity of the H-bonded complex peak relative to that of free imidazole (in terms of absolute intensity) for the range of complexes prepared (at the same concentration) yielded the expected order of H-bond strength (see Table 2), i.e.

$$Ph_3P{=}O/IM > Ph_2S{=}O/IM > Ph_2C{=}O/IM > Ph_3COH/IM > Ph_2O/IM$$

Preparation of a deuterated imidazole – dimethyl sulphoxide complex showed rapid exchange of the deuterium atom involved in the hydrogen bond. This exchange was rapid in both dried and undried NBA. The ^1H nmr of the deuterated complex showed greater than 90% deuteration at the N1 position of imidazole (dissolved in $CDCl_3$). However, FABMS showed approximately 9% deuterium in the complex, using both dried and undried NBA. The $M + 2$ peak of NBA was also larger than the calculated ^{13}C contribution, demonstrating deuterium incorporation in the matrix. Removal of the water from the matrix also resulted in a 23% decrease in the total ion current of the imidazole – diphenyl sulphoxide complex, showing that water plays some part in the generation of the quasi-molecular ions observed by FABMS in these systems.

In conclusion, we believe that FABMS is a promising new technique for the study of hydrogen bonding although the range of complexes that can be studied is clearly limited. The study of hydrogen bonding to preformed anions or cations, which are especially susceptible to FABMS study, should be straightforward. However, the neutral complexes would seem to need to be resistant to protonation if confusion between bonding to the neutral or protonated species is to be avoided. Our studies indicate that semiquantitative information on hydrogen–deuterium exchange and the relative strengths of hydrogen bonds can also be obtained.

The reaction of (*E*)-, (*Z*)-, or a 2:3 mixture of (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[2-^{14}C]vinyl bromide ((*E*)-, (*Z*)-, or (*E*,*Z*)-**3**-Br-2-^{14}C) in HOAc–AgOAc gave a 1:1 mixture of the structurally unrearranged but isotopically scrambled (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[1,2-^{14}C]vinyl acetates ((*E*,*Z*)-**3**-OAc-1,2-^{14}C), with an average of 18.3% scrambling of the ^{14}C label from C-2 to C-1 arising from 1,2-tolyl shifts in the 1,2-diphenyl-2-tolylvinyl cation (**3**). No detectable amount of the structurally rearranged 2,2-diphenyl-1-tolylvinyl acetate (**4**-OAc) was formed. Solvolysis of (*E*,*Z*)-**3**-Br-2-^{14}C in TFE-2,6-lutidine gave as products 62% **4**-OTFE-1,2-^{14}C and 38% of a 1:1 mixture of (*E*)- and (*Z*)-**3**-OTFE-1,2^{14}C. Only (*Z*)-**3**-OTFE-1,2-^{14}C could be isolated as a pure product and it showed an average of 44.7% scrambling of the label from C-2 to C-1. Similar trifluoroethanolyses of (*E*,*Z*)-**3**-Br-2-^{13}C coupled with gas chromatographic – mass spectral analyses of the diphenyl and phenyl tolyl ketones from ozonolysis of the product mixture showed 44.6% scrambling in the (*E*,*Z*)-**3**-OTFE-1,2-^{13}C, confirming the ^{14}C results for the (*Z*) isomer. Nondegenerate rearrangements from 1,2-phenyl shifts before and after the degenerate 1,2-tolyl shifts to give **4**-OTFE-1-^{13}C and **4**-OTFE-2-^{13}C were also observed, demonstrating the occurrence of successive 1,2-aryl shifts in these triarylvinyl cations.

CHOI CHUCK LEE et DAVE WANIGASEKERA. Can. J. Chem. **64**, 1228 (1986).

La réaction du bromure de diphényl-1,2 tolyl-2 vinyle [^{14}C-2]-(*E*), -(*Z*) ou sous la forme d'un mélange 2:3 de -(*E*) et -(*Z*) (**3**-Br ^{14}C-2-(*E*), -(*Z*) ou -(*E*,*Z*)) avec du AgOAc en solution dans de l'acide acétique conduit à un mélange 1:1 des acétates de diphényl-1,2 tolyl-2 vinyle [^{14}C-1,2]-(*E*) et -(*Z*) qui ne sont pas transposés du point de vue de la structure, mais dont le taux moyen de répartition au hasard du marqueur ^{14}C, provenant de glissements-1,2 du groupement tolyle dans le cation diphényl-1,2 tolyl-2 vinyle (**3**), est de 18.3%. Il ne se forme pas de quantités détectables d'acétate de diphényl-2,2 tolyl-1 vinyle (**4**-OAc) qui serait structuralement transposé. La solvolyse du **3**-Br ^{14}C-2-(*E*,*Z*), dans un mélange de TFE–lutidine-2,6, conduit à 62% de **4**-OTFE ^{14}C-1,2 et à 38% d'un mélange 1:1 des isomères (*E*) et (*Z*) du **3**-OTFE ^{14}C-1,2. Seul le **3**-OTFE ^{14}C-1,2-(*Z*) a pu être isolé à l'état pur et, en moyenne, il comportait 44,7% de répartition au hasard du marqueur dans les positions C-2 et C-1. Des trifluoroéthanolyses analogues du composé **3**-Br ^{13}C-2-(*E*,*Z*), couplées à des analyses par spectre de masse/chromatographie en phase gaseuse de la diphénylcétone et de la phényl-tolylcétone qui résultent de l'ozonolyse du mélange, mettent en évidence qu'il s'est produit 44,6% de répartition au hasard du marqueur dans le composé **3**-OTFE ^{13}C-1,2-(*E*,*Z*); ces résultats confirment les résultats de ^{14}C obenus avec l'isomère (*Z*). On a également observé des transpositions non dégénérées provenant de glissements-1,2 de groupements phényles avant et après les glissements-1,2 dégénérés des groupements tolyles qui conduisent aux composés **4**-OTFE ^{13}C-1 et **4**-OTFE ^{13}C-2; ces résultats démontrent l'existence de déplacements-1,2 de groupements aryles dans ces cations triarylvinyles.

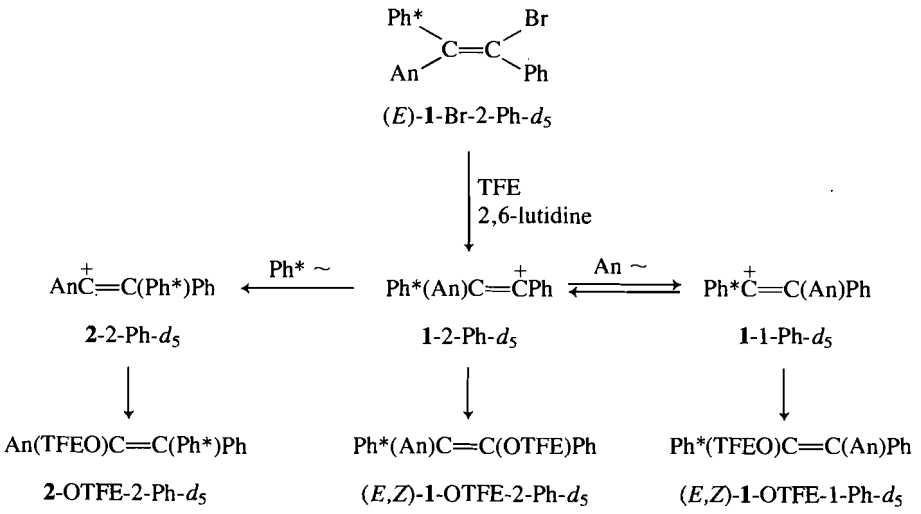
[Traduit par la revue]

Introduction

Rearrangements arising from 1,2-aryl shifts across the double bond in triarylvinyl cations have been studied with various combinations of phenyl (Ph), *p*-tolyl (Tol), and *p*-anisyl (An) groups as the three aryl substituents (2–4). Only one of these triarylvinyl cationic systems that have been investigated so far, namely, the 2-anisyl-1,2-diphenylvinyl cation (**1**), was capable of giving rise to both nondegenerate and degenerate rearrangements (5, 6). Thus, for example, the reaction of (*E*)- or (*Z*)-2-anisyl-1,2-diphenylvinyl bromide ((*E*)- or (*Z*)-**1**-Br) in 2,2,2-trifluoroethanol (TFE) – 2,6-lutidine gave, as major product, the structurally rearranged 1-anisyl-2,2-diphenylvinyl 2,2,2-trifluoroethyl ether (**2**-OTFE), arising from nondegenerate 1,2-phenyl shifts in cation **1** to the more stable 1-anisyl-2,2-diphenylvinyl cation (**2**), and a 1:1 mixture of the structurally unrearranged (*E*)- and (*Z*)-2-anisyl-1,2-diphenylvinyl 2,2,2-trifluoroethyl ethers ((*E*)- and (*Z*)-**1**-OTFE) as minor products (5). Using the pentadeuteriophenyl group as label and analysis by ^1H nmr and mass spectrometry, the trifluoroethanolysis of (*E*)-2-anisyl-1-phenyl-2-($^2H_5$)phenylvinyl bromide ((*E*)-**1**-Br-2-Ph-d_5) was found to give essentially complete scrambling of the label between C-2 and C-1 in the minor products, (*E*)- and (*Z*)-**1**-OTFE-1,2-Ph-d_5, arising from degenerate 1,2-anisyl shifts in the labeled cation **1**, the various rearrangement processes being summarized in Scheme 1.

It may be noted from Scheme 1 that if the nondegenerate 1,2-phenyl shift in cation **1**-1-Ph-d_5, obtained after the degenerate rearrangement, were to take place, cation **2**-2-Ph-d_5 would also be formed. Thus with Ph-d_5 as label, this process could not be demonstrated and was not considered (6). It is also of interest to note that in the reaction of (*E*)-**1**-Br-2-Ph-d_5 with HOAc–AgOAc, only degenerate rearrangement to give (*E*,*Z*)-**1**-OAc-1,2-Ph-d_5 was observed, with no product derived from the more stable cation **2**-2-Ph-d_5 (6). In the present work, we have studied another triarylvinyl cationic system that is capable of giving rise to both nondegenerate and degenerate rearrangements, i.e. the various rearrangement and isotopic scrambling processes in the 1,2-diphenyl-2-tolylvinyl cation (**3**) derived from solvolyses of (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[2-^{14}C]-vinyl or (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[2-^{13}C]vinyl bromides ((*E*)- and (*Z*)-**3**-Br-2-^{14}C or (*E*)- and (*Z*)-**3**-Br-2-^{13}C) in TFE–2,6-lutidine or in HOAc–AgOAc. The results are compared with those obtained from analogous studies with (*E*)-**1**-Br-2-Ph-d_5 and other triarylvinyl cationic systems to show the

[1]Rearrangement studies with ^{14}C. L; for part XLIX, see ref. 1.



SCHEME 1

possibility of successive 1,2-aryl shifts (1,2-tolyl shift followed by 1,2-phenyl shift in cation **3**) and to give information on migratory aptitudes. Moreover, a method of analysis using a gc–ms technique in studies with (*E*)- and (*Z*)-**3**-Br-2-^{13}C has also been developed in the present work.

	or (*E*)- and (*Z*)-**3**-Br-2-^{13}C

Results and discussion

Synthesis of (E,Z)-**3**-*Br-2-*^{14}*C and* (E,Z)-**3**-*Br-2-*^{13}*C*

The synthesis of (*E*)- and (*Z*)-**3**-Br-2-^{14}C was carried out via a series of reactions analogous to those utilized in previous preparations of (*E*,*Z*)-1,2-dianisyl-2-phenyl[2-^{13}C]vinyl (7), (*E*,*Z*)-2-phenyl-1,2-ditolyl[2-^{13}C]vinyl (8), and (*E*,*Z*)-1,2-dianisyl-2-tolyl[2-^{14}C]vinyl (9) bromides. Starting with [^{14}C]-$BaCO_3$, 1,2-diphenyl[1-^{14}C]ethanone (carbonyl labeled desoxybenzoin) was prepared as previously described (10). Treatment of this ketone with TolMgBr gave 1,2-diphenyl-1-tolyl[1-^{14}C]ethanol which, upon reaction with Br_2 in HOAc, gave a 2:3 mixture of (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[2-^{14}C]-vinyl bromides (to be designated (*E*,*Z*)-**3**-Br-2-^{14}C). The pure (*E*) and (*Z*) isomers were then obtained by fractional crystallization from acetone–methanol. In the same way, starting from 1,2-diphenyl[1-^{13}C]ethanone (10), (*E*,*Z*)-**3**-Br-2-^{13}C was also prepared.

Reactions in HOAc–AgOAc

In preliminary work using unlabeled material, reaction of (*E*)- or (*Z*)-**3**-Br in HOAc containing a small amount of Ac_2O to eliminate any moisture, and with the presence of 1.1 molar equivalents of AgOAc under reflux for 24 h, gave an essentially 1:1 mixture of (*E*)- and (*Z*)-1,2-diphenyl-2-tolylvinyl acetates ((*E*,*Z*)-**3**-OAc). No 2,2-diphenyl-1-tolylvinyl acetate (**4**-OAc) was formed, in agreement with the finding that no **2**-OAc-2-Ph-d_5 was obtained in the reaction of (*E*)-**1**-Br-2-Ph-d_5 with HOAc–AgOAc (6).

In similar reactions of (*E*)-**3**-Br-2-^{14}C, (*Z*)-**3**-Br-2-^{14}C, or (*E*,*Z*)-**3**-Br-2-^{14}C in HOAc–AgOAc, the (*E*,*Z*)-**3**-OAc-1,2-^{14}C product was degraded by ozonolysis to give phenyl tolyl[^{14}C]-ketone (**5**-^{14}C), and the difference between the specific activities of the (*E*,*Z*)-**3**-OAc-1,2-^{14}C and the corresponding **5**-^{14}C gave the extent of scrambling of the label from C-2 to C-1. The results are summarized in Table 1, showing a mean scrambling value of 18.3%. The formation of the same 1:1 mixture of (*E*)- and (*Z*)-**3**-OAc-1,2-^{14}C with essentially the same extent of scrambling in the reaction of (*E*)-, (*Z*)-, or (*E*,*Z*)-**3**-Br-2-^{14}C in HOAc–AgOAc would support the dissociated, linear 1,2-diphenyl-2-tolylvinyl cation (**3**) as intermediate in these reactions, with the isotopic scrambling arising from degenerate 1,2-tolyl shifts across the double bond in cation **3** (Scheme 2). Moreover, it is seen from Table 1 that extending the reaction time from 1 day to 2 days for the reaction in HOAc–AgOAc did not affect the extent of scrambling, indicating that the product, (*E*,*Z*)-**3**-OAc-1,2-^{14}C, was stable in the reaction medium.

For the processes depicted in Scheme 2, eq. [1] holds (11), and for a mean scrambling value of 18.3%, from eq. [1], $k_{SOH}/k_r^{Tol} = 3.5$.

$$[1]\quad [(E,Z)\text{-}3\text{-OAc-2-}^{14}C]/[(E,Z)\text{-}3\text{-OAc-1-}^{14}C] = 1 + (k_{SOH}/k_r^{Tol})$$

In the analogous reaction of (*E*)-**1**-Br-2-Ph-d_5 in HOAc–AgOAc, 90.0–94.6% β-anisyl rearrangement (45.0–47.3% scrambling) was reported (6). Using a mean scrambling value of 46.2% and applying eq. [1] to this system, $k'_{SOH}/k_r^{An} = 0.16$. Assuming that k_{SOH} and k'_{SOH} are about the same for the product-forming capture of the 1,2-diphenyl-2-tolylvinyl cation (**3**) and the 2-anisyl-1,2-diphenylvinyl cation (**1**), then the migratory aptitude of An:Tol can be calculated:

$$(k_{SOH}/k_r^{Tol})/(k'_{SOH}/k_r^{An}) = k_r^{An}/k_r^{Tol} = 3.5/0.16 = 22$$

This k_r^{An}/k_r^{Tol} value of 22 may be compared with a similar migratory ratio for An:Tol of 33 obtained from a comparison of data derived from reactions of labeled 1,2-dianisyl-2-tolylvinyl and trianisylvinyl bromides in HOAc–AgOAc (9). While these values differ by 50%, considering the errors that may be involved, the agreement obtained from the two sets of experiments may be considered to be reasonably good. For systems showing very large extents of scrambling, such as the reaction of (*E*)-**1**-Br-2-Ph-d_5 with HOAc–AgOAc, small changes in the extent of scrambling will lead to relatively large variations in k_{SOH}/k_r. For example, if the higher observed value of 47.3% scrambling as reported by Rappoport *et al.* (6) instead of the mean value of 46.2% scrambling were employed in the calculations, k'_{SOH}/k_r^{An} would be 0.11 (instead of 0.16), and

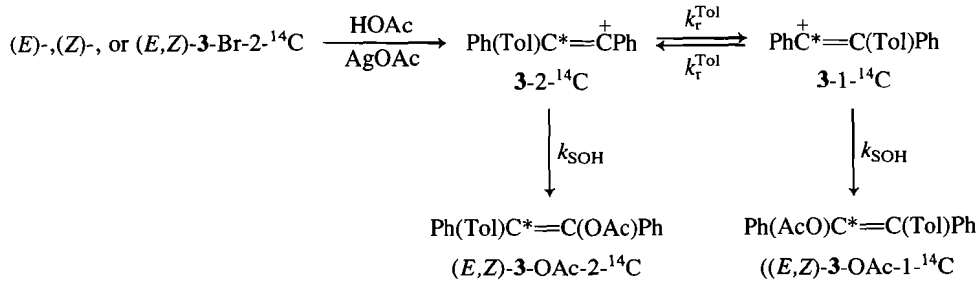
(*E*)-**3**-Br-2-^{14}C	HOAc–AgOAc	26.8	19.7	21.9	16.0	18.2	18.7
(*Z*)-**3**-Br-2-^{14}C	HOAc–AgOAc	7.46	5.00	6.11	4.10	18.1	18.0
(*E*,*Z*)-**3**-Br-2-^{14}C	HOAc–AgOAc	5.10	11.6	4.10	9.48	18.1	18.3
(*E*,*Z*)-**3**-Br-2-^{14}C	HOAc–AgOAc[f]	9.96	6.96	8.15	5.64	18.1	18.9
(*E*,*Z*)-**3**-Br-2-^{14}C	TFE–2,6-lutidine	7.10	1.36	3.89	0.75	44.5	44.9

[a]The substrate was pure (*E*)-, pure (*Z*)-, or a 2:3 mixture of (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[2-^{14}C]vinyl bromides.
[b]The acetolyses were carried out with 0.15 molar concentration of substrate in HOAc containing about 5% Ac_2O and 1.1 equivalents of AgOAc at reflux temperature for 1 day; the trifluoroethanolyses were carried out with 0.15 molar concentration of substrate in TFE containing 1.1 equivalents of 2,6-lutidine in sealed ampoules at 150 ± 2°C for 10 days.
[c]The products analyzed were the 1:1 mixture of (*E*)- and (*Z*)-acetates, (*E*,*Z*)-**3**-OAc-1,2-^{14}C, for the acetolyses, and the pure *Z*-trifluoroethyl ether, (*Z*)-3-OTFE-1,2-^{14}C, for the trifluoroethanolyses.
[d]The degradation product was phenyl tolyl [^{14}C]ketone.
[e]The mean scrambling value is 18.3% for the reactions in HOAc–AgOAc, and 44.7% for the reactions in TFE–2,6-lutidine.
[f]The reaction time was extended to 2 days.



SCHEME 2

k_r^{An}/k_r^{Tol} would be 3.5/0.11 = 32, in almost exact agreement with the previous value of 33 (9).

In another comparison, the 18.3% scrambling arising from 1,2-tolyl shifts in the reaction of *E*,*Z*-**3**-Br-2-^{14}C in HOAc–AgOAc may be considered in conjunction with the 6–7% scrambling observed for the reaction of triphenyl[2-^{14}C]vinyl bromide (**6**-Br-2^{14}C) with HOAc–AgOAc (12). Taking into account the statistical factor of 2 for the 1,2-phenyl shift in the triphenylvinyl cationic system, eq. [2] applies for the reaction of **6**-Br-2-^{14}C in HOAc–AgOAc (11).

$$[2] \quad [\mathbf{6}\text{-OAc-2-}^{14}\text{C}]/[\mathbf{6}\text{-OAc-1-}^{14}\text{C}] = 1 + (k'_{SOH}/2k_r^{Ph})$$

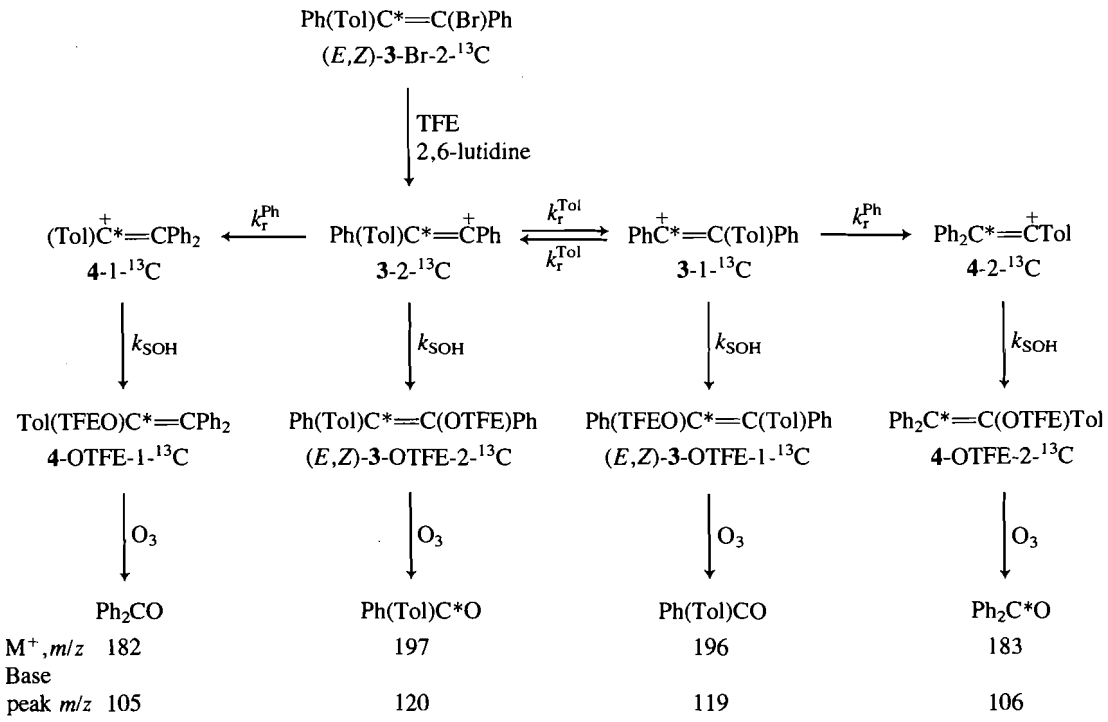
For a mean value of 6.5% scrambling, $k'_{SOH}/k_r^{Ph} = 26$. Again assuming that $k_{SOH} = k'_{SOH}$, $k_r^{Tol}/k_r^{Ph} = 26/3.5$ or about 7, in fairly good agreement with the previously reported value of about 5 (11).

Reactions in TFE–2,6-lutidine

The trifluoroethanolysis of (*E*,*Z*)-**3**-Br-2-^{14}C in the presence of 1.1 equivalents of 2,6-lutidine was carried out in sealed ampoules at 150 ± 2°C for 10 days. In preliminary work with nonlabeled material, such a reaction gave 3 products as identified by ^{1}H nmr. The major product was 2,2-diphenyl-1-tolylvinyl 2,2,2-trifluoroethyl ether (**4**-OTFE, 62%) and the minor component was a 1:1 mixture of the (*E*) and (*Z*) isomers of 1,2-diphenyl-2-tolylvinyl 2,2,2-trifluoroethyl ethers ((*E*)-**3**-OTFE, 38%). The major product, **4**-OTFE, was derived from a nondegenerate 1,2-phenyl shift in cation **3**, while in the structurally unrearranged (*E*)-**3**-OTFE, a degenerate 1,2-tolyl shift may occur and this would be detectable from studies with a labeled substrate.

When the mixture of products, **4**-OTFE and the 1:1 mixture of (*E*,*Z*)-**3**-OTFE, was subjected to fractional crystallization, only the pure (*Z*)-**3**-OTFE could be isolated. Thus in the trifluoroethanolysis of (*E*,*Z*)-**3**-Br-2-^{14}C, the only isolable pure product, (*Z*)-**3**-OTFE-1,2-^{14}C, was degraded by ozonolysis to give phenyl tolyl [^{14}C]ketone (**5**-^{14}C) and, from the specific activities of this (*Z*) isomer and its degradation product, the extent of scrambling of the label from C-2 to C-1 was obtained. The results, as summarized in Table 1, show an average of 44.7% scrambling arising from 1,2-tolyl shifts across the double bond in the 1,2-diphenyl-2-tolylvinyl cation (**3**).

Since only one of three products obtained in the trifluoroethanolysis of (*E*,*Z*)-**3**-Br-2-^{14}C was analyzed for isotopic scrambling, the experiments were repeated using (*E*,*Z*)-**3**-Br-2-^{13}C as substrate with the object of analyzing the extents of possible isotopic scramblings in both the major nondegenerate rearrangement product, **4**-OTFE-1,2-^{13}C, and in the minor products (*E*,*Z*)-**3**-OTFE-1,2-^{13}C. This mixture of products was degraded by ozonolysis to give a mixture of labeled and unlabeled diphenyl and phenyl tolyl ketones which were analyzed by gas chromotography – mass spectrometry (gc–ms), with the mass spectra of the separated ketones obtained by the electron impact method. The extents of scrambling were then evaluated by comparing the relative intensities of the base peaks and the molecular ions of the respective labeled and unlabeled ketones,



SCHEME 3

121	7.41	7.51						

[a]Molecular ions for [TolCOPh]$^+$ and [Tol^{13}COPh]$^+$ at m/z 196 and 197, respectively; the base peak is [Tol^{13}CO]$^+$ at m/z 120.

[b]Percentages for m/z 196 ([TolCOPh]$^+$) and for m/z 119 ([TolCO]$^+$) correspond to % scrambling from C-2 to C-1 in the (*E*,*Z*)-3-OTFE-1,2-^{13}C (see Scheme 3); mean value = (45.2 + 44.3 + 44.6 + 44.4)/4 = 44.6 ± 0.3%.

the relative intensities being correted for $(M+1)^+$ absorption and for the fact that the ^{13}C enrichment was 90%. The processes involved in the trifluoroethanolysis of (*E*,*Z*)-3-Br-2-^{13}C are summarized in Scheme 3. The results from the mass spectral analyses of the degradation products, diphenyl and phenyl tolyl ketones, are given in Tables 2 and 3.

As an illustration of the calculations, consider, for example, the relative intensities of the peaks in the molecular ion region of run 1 for the phenyl tolyl ketones (Table 2). Since the intensity of m/z 198 is 12.9% of the intensity of m/z 197, the $(M+1)^+$ correction should be 12.9% of the intensity of the M^+ ion. Thus correcting for $(M+1)^+$, the intensities of m/z 196 and 197 should be $(32.35 - 0.129 \times 2.01) = 32.09$ and $(35.39 - 0.129 \times 32.35) = 31.22$, respectively.

Since the reaction was carried out using materials with 90% ^{13}C enrichment, 10% of the total reaction would only give rise to TolCOPh (m/z 196) and 90% would give Tol^{13}COPh (m/z 197) and TolCOPh (m/z 196). Therefore, 10% of the total intensity should be subtracted from the m/z 196 peak to give the actual intensity of m/z 196 derived from the 90% enriched reactant. Thus, correcting for the 90% enrichment, the m/z 196 intensity should be $32.09 - [0.1(32.09 + 31.22) = 25.76$.

Since TolCOPh (m/z 196) was derived from the rearranged (*E*,*Z*)-3-OTFE-1-^{13}C, the percentage scrambling of the label from C-2 to C-1, as given in Table 2, would be $(100 \times 25.76)/(25.76 + 31.22) = 45.2\%$.

It is of interest to note that the mean value of 44.6% scrambling of the ^{13}C label from C-2 to C-1 arising from degenerate 1,2-tolyl shifts (Table 2) is in very good agreement with the mean value of 44.7% scrambling (Table 1) obtained from the use of ^{14}C labelling. The formation of unrearranged and rearranged products given in Scheme 3 is summarized again

TABLE 3. Data from the mass spectra of PhCOPh and Ph^{13}COPh

	Observed intensity		Corrected for $(M+1)^+$		Corrected for 90% ^{13}C enrichment		% Distribution[b]	
m/z[a]	Run 1	Run 2	Run 1	Run 2	Run 1	Run 2	Run 1	Run 2

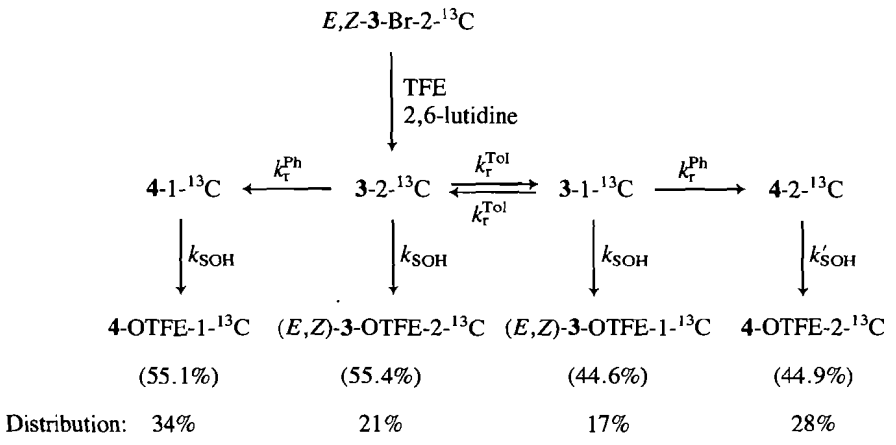
106	64.87	61.43	59.38	56.33	59.38	56.33	45.4	45.5
107	4.15	3.86						

[a]Molecular ions for $[PhCOPh]^+$ and $[Ph^{13}COPh]^+$ at m/z 182 and 183, respectively; the base peak is Ph^+ at m/z 77, although for the unlabeled pure sample of PhCOPh, the base peak was $[PhCO]^+$ at m/z 105. Presumably, in the labeled system, the benzoyl ions appear as 2 peaks at m/z 105 and 106, each of which showed a relative intensity of less than that at m/z 77.

[b]Percentages for m/z 183 ($[Ph^{13}COPh]^+$) and for m/z 106 ($[Ph^{13}CO]^+$) correspond to % of the isotopically rearranged product, **4**-OTFE-2-^{13}C (see Scheme 3); mean value = (44.3 + 44.3 + 45.4 + 45.5)/4 = 44.9 ± 0.5%.



SCHEME 4

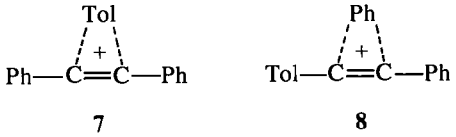
in Scheme 4, with the extents of scrambling of the isotopic label in (*E*,*Z*)-**3**-OTFE-1,2-^{13}C and **4**-OTFE-1,2-^{13}C shown in parentheses. It was indicated earlier that from ^{1}H nmr, the major product (62%) was **4**-OTFE-1,2-^{13}C and the minor product (38%) was (*E*,*Z*)-**3**-OTFE-1,2-^{13}C. Using this 62:38 product ratio and the observed extents of scrambling, a percentage distribution of the products can be calculated. Thus, of the product mixture, the distribution for the unrearranged **4**-OTFE-1-^{13}C and the rearranged **4**-OTFE-2-^{13}C would be 0.551 × 62 = 34% and 0.449 × 62 = 28%, respectively. Similarly, the distribution for (*E*,*Z*)-**3**-OTFE-2-^{13}C and (*E*,*Z*)-**3**-OTFE-1-^{13}C would be 0.554 × 38 = 21% and 0.446 × 38 = 17%. These values are also shown in Scheme 4. Interestingly, the ratios of **4**-OTFE-1-^{13}C/ (*E*,*Z*)-**3**-OTFE-2-^{13}C and **4**-OTFE-2-^{13}C/(*E*,*Z*)-**3**-OTFE-1-^{13}C, or 34/21 = 1.6 and 28/17 = 1.6, are the same, indicating the same extent of rearrangement from the 1,2-diphenyl-2-tolylvinyl cation (**3**) to the more stable 2,2-diphenyl-1-tolylvinyl cation (**4**) before or after the degenerate 1,2-tolyl shift in **3**-2-^{13}C and **3**-1-^{13}C.

From a steady state treatment or with the use of the method of Bonner and Collins (13), it can be shown that eq. [3] applies to the processes given in Scheme 4. The observed results are in agreement with this prediction since the 44.6% scrambling to cation **3**-1-^{13}C is essentially equal to the 44.9% scrambling to cation **4**-2-^{13}C, or 55.4/44.6 = 1.2 and 55.1/44.9 = 1.2 are the same.

$$[3]\quad [(E,Z)\text{-}\mathbf{3}\text{-OTFE-2-}^{13}\text{C}]/[(E,Z)\text{-}\mathbf{3}\text{-OTFE-1-}^{13}\text{C}] = [\mathbf{4}\text{-OTFE-1-}^{13}\text{C}]/[\mathbf{4}\text{-OTFE-2-}^{13}\text{C}]$$

The formation of **4**-OTFE-2-^{13}C, as indicated in Schemes 3 or 4, clearly demonstrated the occurrence of 1,2-phenyl shifts after 1,2-tolyl shifts have taken place. Such successive 1,2-aryl shifts in triarylvinyl cationic systems have recently been shown to occur by the use of doubly labeled triarylvinyl substrates (14, 15). In the present work, the occurrence of both degenerate and nondegenerate rearrangements also provides another route in demonstrating such successive 1,2-shifts.

It has already been noted that in the reaction of (*E*,*Z*)-**3**-Br-2-^{13}C with HOAc–AgOAc, only degenerate rearrangements to give (*E*,*Z*)-**3**-OAc-2-^{14}C and (*E*,*Z*)-**3**-OAc-1-^{14}C were observed, with no detectable amount of nondegenerate 1,2-phenyl shifts to give **4**-OAc-1,2-^{14}C. For a possible explanation of these results, let us consider the transition states involved in these 1,2-aryl shifts. For the degenerate rearrangement, the tolyl bridged transition state **7** may be more stable than the phenyl bridged transition state **8** for the nondegenerate rearrangement. Apparently, in a medium of low nucleophilic



7 8

character such as TFE (16), the lifetime of the cations is sufficiently long for the nondegenerate rearrangement of **3**-2-^{13}C → **4**-1-^{13}C and **3**-1-^{13}C → **4**-2-^{13}C to proceed, overcoming the higher energy barrier via transition state **8**. In HOAc–AgOAc, the lifetime of the cations is shorter and only degenerate rearrangements through the lower energy barrier of **7** could take place.

Experimental

1,2-Diphenyl-1-tolyl[1-^{14}C]ethanol

To a Grignard solution prepared from 8.0 g (47 mmol) of *p*-bromotoluene and 2.0 g (82 mmol) of Mg in 250 mL of dry tetrahydrofuran (THF), and cooled in an ice bath, was added dropwise and with stirring over a period of 1 h a solution of 4.5 g (23 mmol) of 1,2-diphenyl-[1-^{14}C]ethanone (10) in 100 mL of dry THF. The resulting solution was stirred at room temperature for 1 h, refluxed for 2 h, and then poured into 200 mL of H_2O containing 25 g of NH_4Cl and 5 mL of NH_4OH. The organic layer was washed with H_2O (3 × 25 mL) and, after drying over $MgSO_4$, the solvent was evaporated to give 4.1 g (66%) of 1,2-diphenyl-1-tolyl[1-^{14}C]ethanol, which was recrystallized from acetone–methanol. The unlabeled alcohol was prepared in the same way using ordinary desoxybenzoin, mp 87–88°C; ^{1}H nmr ($CDCl_3$) δ: 2.25 (4H, s, CH_3 + OH), 2.29 (sh, OH), 3.57 (2H, s, CH_2), 6.78–7.53 (14H, m, Ar). *Anal.* calcd. for $C_{21}H_{20}O$: C 87.46, H 6.99; found: C 87.17, H 7.04.

(E)- and (Z)-1,2-diphenyl-2-tolyl[2-^{14}C]vinyl bromides

To a solution of 5.00 g (17.4 mmol) of 1,2-diphenyl-1-tolyl[1-^{14}C]-ethanol in 50 mL of HOAc was added dropwise with stirring 3.0 g (19 mmol) of bromine in 20 mL of HOAc over a period of 0.5 h. During this period the temperature of the reaction mixture was maintained below 50°C and any HBr that was produced was flushed out with N_2. The resulting mixture was stirred overnight and the bright yellow solid that was formed was filtered, and washed with 10% $Na_2S_2O_3$ solution and with H_2O. The yield of the dried product was 4.8 g (79%), consisting of an approximately 2:3 mixture of (*E*)-:(*Z*)-1,2-diphenyl-2-tolyl[2-^{14}C]vinyl bromides ((*E*,*Z*)-**3**-Br-2-^{14}C). Degradation of a sample of this (*E*,*Z*)-**3**-Br-2-^{14}C by ozonolysis gave phenyl tolyl [^{14}C]-ketone with the same specific activity, indicating that all the ^{14}C label was located at the C-2 position.

In the same way, (*E*,*Z*)-**3**-Br or (*E*,*Z*)-**3**-Br-2-^{13}C was synthesized from ordinary desoxybenzoin or from 1,2-diphenyl[1-^{13}C]ethanone prepared from 90% enriched [^{13}C]$BaCO_3$. These (*E*,*Z*) isomers could be separated by fractional crystallization from 10% acetone – 90% methanol at room temperature and their (*E*) and (*Z*) structures were assigned based on preliminary crystallographic studies by Professor B. E. Robertson of the University of Regina. The (*Z*) isomer crystallized out first as fluffy colorless crystals, followed by the (*E*) isomer as bright yellow octagons. After further purification by recrystallization from acetone–methanol, the pure (*E*) isomer melted at 131–133°C; ^{1}H nmr ($CDCl_3$) δ: 2.39 (3H, s, CH_3), 7.03–7.51 (14H, m, Ar). *Anal.* calcd. for $C_{21}H_{17}Br$: C 72.21, H 4.91, Br 22.88; found: C 72.04, H 4.92, Br 22.83. The pure (*Z*) isomer melted at 141–143°C; ^{1}H nmr ($CDCl_3$) δ: 2.20 (3H, s, CH_3), 6.87–7.37 (14H, m, Ar). *Anal.* calcd. for $C_{21}H_{17}Br$: C 72.21, H 4.91, Br 22.88; found: C 72.02, H 4.89, Br 23.38.

Reaction of (E)-, (Z)-, or (E,Z)-3-Br-2-^{14}C in HOAc–AgOAc

In a typical experiment, 733 mg (2.10 mmol) of (*E*,*Z*)-**3**-Br-2-^{14}C and 386 mg (2.30 mmol) of AgOAc in 14 mL of HOAc containing about 5% Ac_2O was heated under reflux for 24 h. The excess solvent was then evaporated off under reduced pressure in a rotary evaporator. The residue was disolved in 100 mL of CH_2Cl_2 and washed successively with water (2 × 20 mL), 3% $NaHCO_3$ (2 × 20 mL), and again with water (1 × 10 mL). After drying over $MgSO_4$, the solvent was removed, giving an oil that was purified through an alumina column with elution by 20:80 CH_2Cl_2 – petroleum ether (bp 40–60°C). The first fraction eluted contained some unreacted bromide and the second fraction contained the acetate product. Removal of the solvent gave a white solid, the ^{1}H nmr spectrum of which showed that it was a 1:1 mixture of (*E*)- and (*Z*)-**3**-OAc-1,2-^{14}C on the basis of the tolyl-CH_3 absorptions at 2.27 and 2.35 ppm. Degradation of this product mixture by ozonolysis (17) gave phenyl tolyl [^{14}C]ketone for the determination of the extent of scrambling.

The mixture of (*E*)- and (*Z*)-**3**-OAc could be separated by fractional crystallization from methanol. The first to crystallize and presumably the (*Z*) isomer melted at 91–93°C; ^{1}H nmr ($CDCl_3$) δ: 2.00 (3H, s, OAc), 2.35 (3H, s, CH_3), 7.18–7.31 (14H, m, Ar). *Anal.* calcd. for $C_{23}H_{20}O_2$: C 84.12, H 6.14; found: C 84.30, H 6.11. The other and presumably (*E*) isomer melted at 165–167°C; ^{1}H nmr ($CDCl_3$) δ: 1.95 (3H, s, OAc), 2.27 (3H, s, CH_3), 7.01–7.33 (14H, m, Ar). *Anal.* calcd. for $C_{23}H_{20}O_2$: C 84.12, H 6.14; found: C 84.08, H 6.18.

Reaction of (E,Z)-3-Br-2-^{14}C or (E,Z)-3-Br-2-^{13}C in TFE–2,6-lutidine

In a typical experiment, 800 mg (2.29 mmol) of (*E*,*Z*)-**3**-Br-2-^{14}C in 15 mL of TFE containing 290 mg (2.52 mmol) of 2,6-lutidine in a sealed glass ampoule was heated in an oil bath at 150 ± 2°C for 10 days. After cooling, the dark brown solution was transferred into a round-bottom flask and the excess solvent was distilled off under reduced pressure. The residue was dissolved in 100 mL of ether and the solution was washed successively with H_2O, 1 *M* HCl, and water, and then dried over $MgSO_4$. The excess solvent was removed, giving a brown oil that was passed through an alumina column and eluted with a 20:80 mixture of CH_2Cl_2 – petroleum ether (bp 40–60°C). Removal of the solvent from the eluate under reduced pressure gave 548 mg (65%) of products as a yellow oil. The distribution of products in this oil was estimated from the relative intensities of the tolyl-CH_3 peaks in its ^{1}H nmr spectrum. The two smaller peaks of similar intensity at 2.20 and 2.33 ppm were assigned to the (*E*)- and (*Z*)-1,2-diphenyl-2-tolyl[1,2-^{14}C]vinyl 2,2,2-trifluoroethyl ethers ((*E*,*Z*)-**3**-OTFE-1,2-^{14}C) as minor products. The more intense peak at 2.25 ppm was assigned to the structurally rearranged 2,2-diphenyl-1-tolyl[1,2-^{14}C]vinyl 2,2,2-trifluoroethyl ether (**4**-OTFE-1,2-^{14}C), the ratio of **4**-OTFE-1,2-^{14}C to (*E*,*Z*)-**3**-OTFE-1,2-^{14}C being about 62 to 38.

From a similar solvolysis with unlabeled (*E*,*Z*)-**3**-Br in TFE–2,6-lutidine, the mixture of products as a yellow oil was crystallized from a dilute solution in 95% ethanol. Bright yellow and colorless crystals were formed and these were physically separated. The yellow crystals were recrystallized from 95% ethanol to give pale yellow hexagons, mp 90–91°C; ^{1}H nmr ($CDCl_3$) δ: 2.33 (3H, s, CH_3), 3.73–4.17 (2H, q, CH_2), 7.10–7.37 (14H, m, Ar). *Anal.* calcd. for $C_{23}H_{19}OF_3$: C 74.99, H 5.20; found: C 74.57, H 5.37. This product was assigned the (*Z*) structure based on preliminary crystallographic work by Prof. B. E. Robertson. The major portion of the white crystalline product from the original crystallization was repeatedly recrystallized from 95% ethanol, and the product obtained was **4**-OTFE contaminated by about 10% (*E*)-**3**-OTFE. This mixture melted at 72–74°C, ^{1}H nmr ($CDCl_3$) δ: 2.20 (trace, CH_3, (*E*) isomer), 2.25 (3H, s, CH_3), 3.62–4.06 (2H, q, CH_2), 6.79–7.33 (14H, m, Ar). *Anal.* calcd. for $C_{23}H_{19}OF_3$: C 74.99, H 5.20; found: C 74.51, H 5.26.

In similar reactions of (*E*,*Z*)-**3**-Br-2-^{13}C with TFE-2,6-lutidine, the mixture of products containing (*E*,*Z*)-**3**-OTFE-1,2-^{13}C and **4**-OTFE-1,2-^{13}C, as an oil, was subjected to ozonolysis (17) to give a mixture of unlabeled and labeled diphenyl and phenyl tolyl ketones, which were analyzed by a Model 4000 Finnigan gc–ms system.

Electron transfer and autoxidation kinetics of the bis(imidazole)bis(dimethylglyoximato)iron(II) complex

HENRIQUE E. TOMA[1] AND ANTONIO CARLOS C. SILVA

Instituto de Quimica, Universidade de Sao Paulo, Caixa Postal 20780, Sao Paulo, SP, Brazil

Received October 23, 1985

HENRIQUE E. TOMA and ANTONIO CARLOS C. SILVA. Can. J. Chem. **64**, 1280 (1986).

The properties and reactivity of the bis(imidazole)bis-(dimethylglyoximato)iron(II) complex have been studied based on spectroelectrochemistry, cyclic voltammetry, and stopped-flow kinetics in aqueous solution. The autoxidation reaction was found to be inhibited by the imidazole ligand in excess but susceptible to copper(II) catalysis. In this case a mechanism has been proposed, consisting of a rapid electron transfer followed by the reoxidation of the resulting Cu(I) species by O_2.

HENRIQUE E. TOMA et ANTONIO CARLOS C. SILVA. Can. J. Chem. **64**, 1280 (1986).

Opérant en solution aqueuse et faisant appel à la spectroélectrochimie, à la voltamétrie cyclique et à la cinétique par flux stoppé, on a étudié les propriétés et la réactivité du complexe bis(imidazole) bis(diméthyglyoximato) fer(II). On a trouvé que la réaction d'auto-oxydation est inhibée par le ligand imidazole qui est présent en excès, alors qu'elle est susceptible à la catalyse par le cuivre(II). Dans ce cas, on propose un mécanisme d'après lequel il se produit une transfert rapide d'électron qui est suivi d'une réoxydation, par le O_2, de l'espèce Cu(I) qui résulte.

[Traduit par la revue]

Introduction

Dioxime complexes of iron(II) are interesting examples of coordination compounds which mimic hemoglobin and mioglobin in their ability to reversibly bind carbon monoxide (1–4). Among the several dioxime complexes, the bis(dimethylglyoximato)bis(imidazole)iron(II) complex $[Fe(Hdmg)_2(Him)_2]$, because of its well known molecular structure (5) which resembles the porphyrin species with biologically important ligands, has attracted our attention. On the other hand, in contrast with the pyridine analogues, the imidazole complex is soluble enough in water for comparative studies with the biological hemes.

In this work we have studied the properties and reactivity of the $[Fe(Hdmg)_2(Him)_2]$ complex, with particular emphasis on the electrochemistry and redox kinetics in aqueous solution. We have also investigated the autoxidation mechanisms, including the copper-catalyzed reaction, because of their possible relevance to the understanding of the biological oxidation processes (6–8).

Experimental

The complex $[Fe(Hdmg)_2(Him)_2]$ was synthesized from iron(II) acetate and the corresponding ligands (Aldrich) by the method of Pang and Stynes (3). *Anal.* calcd. for C 39.75, N 26.48, H 5.20; found: C 38.9, N 26.4, H 5.0. $[Co(phen)_3](ClO_4)_3$ dihydrate (phen = *o*-phenanthroline) was prepared according to the procedure of Schilt and Taylor (9). *Anal.* calcd. for C 46.41, N 9.0, H 3.0; found: C 46.4, N 8.8, H 2.7. Imidazole, *o*-phenantroline, $CuSO_4 \cdot 5H_2O$ and other reagent grade chemicals were used as supplied.

The electronic spectra of the complexes in the visible and uv region were recorded on a Cary 17 or a Hewlett-Packard 8451 diode-array spectrophotometer fitted with thermostatted cell compartments. Cyclic voltammetry measurements were carried out with a Princeton Applied Research instrument, consisting of a 173 potentiostat and a 175 universal programmer. A platinum electrode was employed for the measurements, using the conventional Luggin capillary with the Ag/AgCl(1 *M* KCl) reference electrode in a non-isothermic arrangement. A platinum wire was used as the auxiliary electrode.

Spectroelectrochemical measurements were carried out using the diode-array spectrophotometer and the 173 potentiostat, with a transparent electrochemical cell of 0.03 cm internal optical pathlength. A gold minigrid was employed as the working electrode, in the presence of a small Ag/AgCl (1 *M* KCl) reference electrode, and of a platinum auxiliary electrode. The experiments were carried out at 25°C, under semi-infinite diffusion conditions, as described by Kuwana and Winograd (10).

The kinetics of the substitution and electron transfer reactions were investigated with the diode-array spectrophotometer, using a flow cell attached to a rapid mixing system, or with a Durrum D-110 stopped flow apparatus, equipped with a Kel-F flow system.

The $[Fe(Hdmg)_2(Him)_2]$ solutions were freshly prepared under argon atmosphere, by dissolving the solid complex in water, in the presence of an excess of imidazole.

The reactions were followed spectrophotometrically, by monitoring the decay of the absorption band of the $[Fe(Hdmg)_2(Him)_2]$ complex at 530 nm. Pseudo first order rate constants were evaluated from the linear logarithmic plots of absorbance versus time. The reversible reaction between $[Fe(Hdmg)_2(Him)_2]$ or A, and $[Cu(Him)_4]^{2+}$ or B, was analysed according to the following scheme:

$$[1] \qquad A + B \underset{k_r}{\overset{k_f}{\rightleftharpoons}} C + D$$

where

$$[2] \qquad K = \frac{k_f}{k_r} = \frac{[C][D]}{[A][B]}$$

The kinetic constant k_f was evaluated from the plots of eq. [3] versus time (11), for an initial concentration $[B]_0 > [A]_0$, and $[C]_0 = [D]_0 = 0$.

$$[3] \qquad R = \frac{K}{2(K-1)[A]_\infty + \Delta K + 2[A]_0} \times \ln \frac{([A]_0 - [A]_\infty)\{[A] + [A]_\infty + (\Delta K + 2[A]_0)/(K-1)\}}{([A] - [A]_\infty)\{[A]_0 + [A]_\infty + (\Delta K + 2[A]_0)/(K-1)\}}$$

$$\Delta = [B]_0 - [A]_0,$$

$$[A]_\infty = \frac{1}{2(K-1)}\{[(\Delta K + 2[A]_0)^2 + 4[A]_0^2(K-1)]^{1/2} - (\Delta K + 2[A]_0)\}$$

In the case of the copper-catalysed autoxidation reaction, the kinetics were analyzed based on a second order rate law of the type:

$$[4] \qquad -\frac{d[Fe^{II}]}{dt} = k_{obs}\frac{[Fe^{II}]^2}{[Fe^{III}]}$$

where $[Fe^{III}] = [Fe]_0 - [Fe^{II}]$.

[1]To whom all correspondence should be addressed.

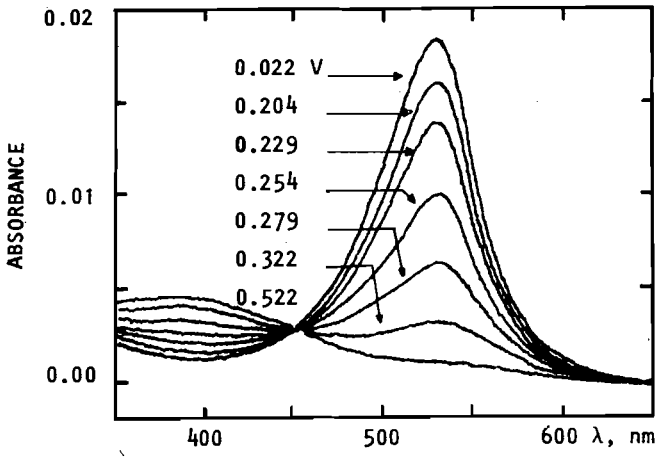

FIG. 1. Absorption spectra of the $[Fe(Hdmg)_2(Him)_2]$ complex (1×10^{-4} *M*) obtained with a spectroelectrochemical cell at several applied potentials versus NHE, [Him] = 0.200 *M*, *I* = 0.100 *M* KCl, 25°C.

The observed rate constant was obtained from the linear plots of eq. [5] versus time.

$$[5] \quad S = \ln [Fe^{II}] + \frac{[Fe]_0}{[Fe^{II}]} = kt + \text{constant}$$

Calculations of kinetic constants and of Marcus theory were carried out using a Microdigital computer.

Results and discussion

The electronic spectrum of the $[Fe(Hdmg)_2(Him)_2]$ complex is characterized by a strong absorption band in the visible (λ_{max} = 530 nm, $\epsilon_{max} = 7.6 \times 10^3\ M^{-1}\ cm^{-1}$) which has been assigned to the Fe-to-Hdmg charge-transfer (CT) transition (12). The spectroelectrochemistry was typically reversible, as shown in Fig. 1. By increasing the applied potential, we observed a systematic decay of the CT band at 530 nm, forming a product which absorbed at 400 nm with an isosbestic point at 445 nm. The measurements led to a Nernst plot with a slope (60 mV) characteristic of a monoelectronic process, and a formal potential of 0.265 V versus NHE (25°C, *I* = 0.10 *M* KCl).

Cyclic voltammograms of the imidazole complex are shown in Fig. 2. The voltammograms of the starting solutions around pH 7 were consistent with the reversibility criteria (13) for a monoelectronic process, with $E_{1/2}$ = 0.268 V versus NHE and $D = 4 \times 10^{-6}\ cm^2\ s^{-1}$, at 25°C and *I* = 0.10 *M* KCl. Above pH 9, however, a systematic cathodic shift was observed in the cyclic voltammograms, with two successive breakpoints in the linear plots of $E_{1/2}$ versus pH, as illustrated in Fig. 2. The observed slopes of 0.058 and 0.110 V/pH were consistent with two successive acid–base equilibria, with pK_a of 9.30 and 10.50, respectively. The assignment of the equilibria involved in the complex was not simple, in view of the following possible reactions:

$$[6] \quad [Fe(Hdmg)_2(Him)_2] = [Fe(Hdmg)(dmg)(Him)_2] + H^+ + e$$

$$[7] \quad [Fe(Hdmg)_2(Him)_2] = [Fe(Hdmg)_2(Him)(im)] + H^+ + e$$

$$[8] \quad [Fe(Hdmg)_2(Him)_2] = [Fe(Hdmg)_2(dmg)(Him)(im)]^- + 2H^+ + e$$

$$[9] \quad [Fe(Hdmg)_2(Him)_2] = [Fe(Hdmg)_2(im)_2]^- + 2H^+ + e$$

$$[10] \quad [Fe(Hdmg)_2(Him)_2] = [Fe(dmg)_2(Him)_2]^- + 2H^+ + e$$

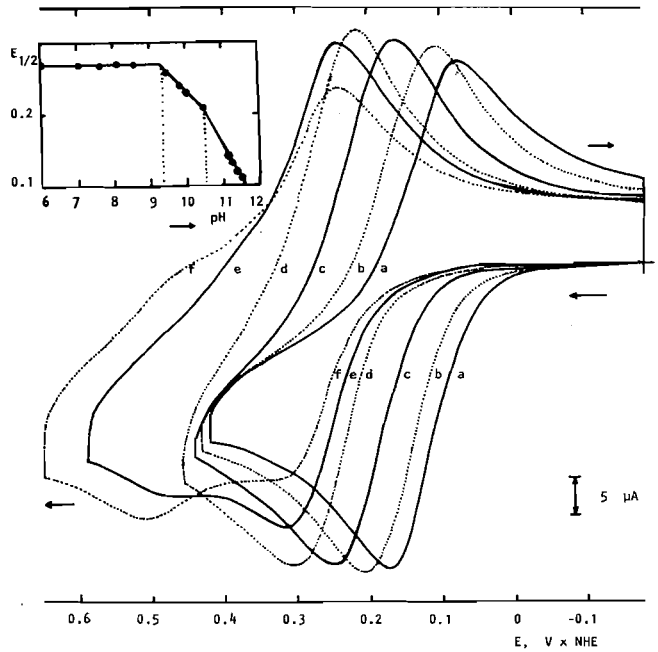

FIG. 2. Cyclic voltammograms of the $[Fe(Hdmg)_2(Him)_2]$ complex (1.8×10^{-4} *M*) in the presence of Him (0.20 *M*), 25°C, *I* = 0.100 *M* KCl, at pH (*a*) 12.08, (*b*) 11.68, (*c*) 11.0, (*d*) 9.65, (*e*) 7.96, and (*f*) 5.94. The dependence of $E_{1/2}$ versus pH is shown in the inset.

It is known that the pK_a of imidazole decreases from 14.2 in the free ligand to 11.0 and 8.9 in the $[Fe(CN)_5(Him)]^{2-}$ and $[(NH_3)_5Ru(Him)]^{3+}$ complexes, respectively (14, 15). On the other hand, pK_a values in the range of 11 to 13 have been reported for the ionization of the hydrogen bonded proton in the O—H···O unit of several bis(dimethylglyoximato)cobalt(III) complexes (16, 17).

Based on these examples, the pK_a of 9.30 would be better ascribed to the deprotonation of the coordinated imidazole ligand in the iron(III)–dioxime complex. However, parallel measurements carried out in this laboratory (18) for the N-methyl imidazole (NMIm) complex led to a single dependence of $E_{1/2}$ versus pH, with a slope of 0.055 V/pH and a pK_a = 9.20 ($E_{1/2}$ = 0.266 V). Since the N-methyl imidazole complexes do not undergo deprotonation reactions below pH 11 (15), we concluded that the observed pK_a in the $[Fe(Hdmg)_2)(Him)_2]^+$ and $[Fe(Hdmg)_2(NMim)_2]^+$ complex should be ascribed to the ionization of the hydrogen bonded proton of the oxyme groups, as in eq. [16]. Analogously, we assigned the pK_a of 10.5 to the deprotonation of the coordinated imidazole ligand in the $[Fe(Hdmg)(dmg)(Him)_2]$ complex, in agreement with the pK_a of 10.3 and 10.45 previously reported for imidazole complexed to Fe(III) porphyrin systems (19, 20).

Below pH 6, a second wave appeared at 0.45 V with a corresponding decrease of the characteristic peaks of the $[Fe(Hdmg)_2(Him)_2]^+$ complex at 0.3 V, as shown in Fig. 2. The intensity of this new wave decreased with the concentration of the imidazole ligand, and was consistent with the presence of $[Fe(Hdmg)_2(Him)(H_2O)]$ species produced in the dissociation equilibrium:

$$[11] \quad [Fe(Hdmg)_2(Him)_2] + H_3O^+ \overset{K}{\rightleftharpoons} [Fe(Hdmg)_2(Him)(H_2O)] + H_2im^+$$

From the relative peak heights we estimated the equilibrium constant *K* as $3 \pm 1 \times 10^4$.

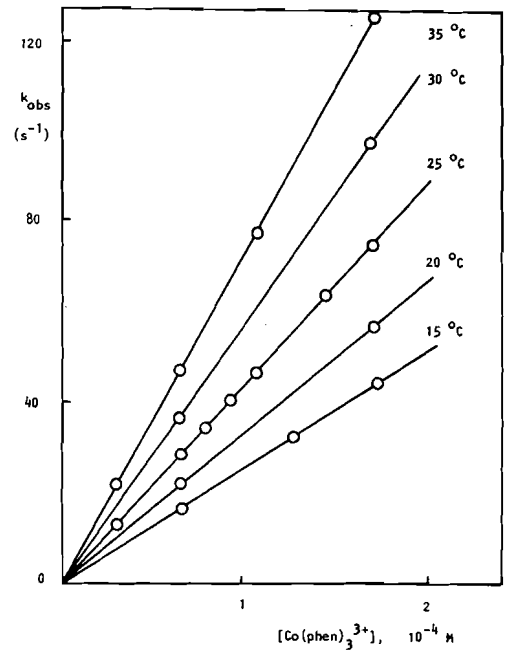

FIG. 3. Plots of the observed rate constants for the electron transfer reaction between $[Fe(Hdmg)_2(Him)_2]$ and $[Co(phen)_3]^{3+}$ at several temperatures, versus the concentation of the cobalt(III) complex (I = 0.100 M KCl, [Him] = 0.20 M).

Electron transfer kinetics

The reaction between $[Fe(Hdmg)_2(Him)_2]$ and $[Co(phen)_3]^{3+}$ followed a first order kinetics, in the presence of an excess of the cobalt complex. The observed rate constants were proportional to the concentration of the reactants, as shown in Fig. 3.

[12] $[Fe(Hdmg)_2(Him)_2] + [Co(phen)_3]^{3+} \rightarrow [Fe(Hdmg)_2(Him)_2]^{+} + (Co(phen)_3]^{2+}$

[13] $$-\frac{d[Fe(Hdmg)_2(Him)_2]}{dt} = k_{12}[Fe(Hdmg)_2(Him)_2] \times [Co(phen)_3^{3+}]$$

The second order rate constant k_{12} measured at 25°C and I = 0.10 M KCl was 4.4 × 10^5 M^{-1} s^{-1}. The activation parameters for the electron transfer reaction were $\Delta H^{\neq}$ = 40 kJ mol^{-1} and $\Delta S^{\neq} = -0.4$ J mol^{-1} K^{-1}.

To evaluate the self-exchange rate constants of the imidazole complex we have performed Marcus theory calculations based on eq. [14] with a pre-exponential factor of 6 × 10^{12} M^{-1} s^{-1}, and using the Wherland-Gray formalism (21) for the work terms W_{ij}.

[14] $$k_{ij} = \kappa_{el}\Gamma_n V\nu_n \exp - (W_{ij}/RT) \exp - (\Delta G_{ij}^{**}/RT)$$

In eq. [14] the product of the electronic and nuclear tunneling factors $\kappa_{el}\nu_n$ is close to unity, $V = 4\pi Nr^3/3000$; ν_n is the nuclear vibration frequency, and $V\nu_n \simeq kTh$.

The self exchange rate constant k_{22} for the $[Co(phen)_3]^{3+}$ complex was measured by Baker *et al.* (22) as 5.5 M^{-1} s^{-1}, at 0°C, and I = 0.10 M KNO_3. The calculated value at 25°C was 45 M^{-1} s^{-1}. The reorganization free energies ΔG_{11}^{**} are given by eq. [15]:

[15] $$\Delta G_{11}^{**} = 2\Delta G_{12}^{**} - \Delta G_{22}^{**} - \Delta G_r^0(1 + \alpha_{12})$$

where

$$\alpha_{12} = \frac{\Delta G_r^0}{4(\Delta G_{11}^{**} + \Delta G_{22}^{**})}$$

and

$$\Delta G_r^0 = -nF\Delta E_{12}^0 - W_{12} + W_{21}$$

The input and output parameters are given in Table 1. The calculated self-exchange rate constant for the $[Fe(Hdmg)_2(Him)_2]$ complex (k_{11} = 5.9 × 10^7 M^{-1} s^{-1}) is similar to those recently reported for several dicyanoiron porphyrins (10^7 M^{-1} s^{-1}) and $[Fe(TPP)(RIm)_2]^{+/0}$ (10^7–10^8 M^{-1} s^{-1}, TPP = tetraphenyl porphyrin). This self exchange rate constant is related to a free energy barrier of 28 kJ mol^{-1}, which is made up of two parts, the inner-sphere and the outer-sphere reorganization energy:

[16] $$\Delta G^{**} = \Delta G_{in}^{**} + \Delta G_{out}^{**}$$

Calculations of the outer-sphere reorganization energy can be made based on eq. [17]:

[17] $$\Delta G_{out}^{**} = \frac{1}{4}\left(\frac{e^2}{2r}\right)\left(\frac{1}{D_{op}} - \frac{1}{D_s}\right)$$

where e is the electronic charge, r is the radius of the complex, D_{op} is the optical dielectric constant, and D_s is the static dielectric constant. Using an average radius of 0.51 nm for the imidazole complex, we obtained ΔG_{out}^{**} = 19 kJ mol^{-1}. The inner sphere reorganization energy was estimated from eq. [16] as 9 kJ mol^{-1}. This value reflects a small change in the equilibrium bond distances, $\Delta r_0 = r_2 - r_1$, as expressed by eq. [18], where f_1 and f_2 are the force constants for the metal–ligand breathing vibrations:

[18] $$\Delta G_{in}^{**} = \frac{3f_1f_2}{f_1 + f_2}(\Delta r_0)^2$$

The estimated value of Δr_0 was 0.007 nm, using an average force constant of 2.0 × 10^5 dyn cm^{-1} taken from the literature (23) for a series of first row transition metal glyoximato complexes.

The reorganization entropy associated with the self-exchange reaction can be calculated from eq. [19],

[19] $$\Delta S_{11}^{**} = \frac{2\Delta S_{12}^{**}}{(1 - 4\alpha_{12}^2)} - \Delta S_{22}^{**} - \frac{\Delta S_r^0(1 + 2\alpha_{12})}{(1 - 4\alpha_{12}^2)}$$

where

$$\Delta S_{ij}^{**} = \Delta S_{ij}^{*} + \frac{dW_{ij}}{dT} + R$$

and

$$\Delta S_r^0 = \Delta S_{rc(Co)}^0 - \Delta S_{rc(Fe)}^0 + \frac{dW_{12}}{dT} - \frac{dW_{21}}{dT}$$

The activation entropy $\Delta S_{22}^{\neq}$ for the $[Co(phen)_3]^{3+/2+}$ system has been reported (22) as 14 J mol^{-1} K^{-1} at I = 0.002 M. Derivation of the work terms dW/dT was carried out as previously described in the literature (24–27). The entropy of the $[Fe(Hdmg)_2(Him)_2]^{+/0}$ redox couple was obtained as 71 J mol^{-1} K^{-1} from careful measurements of $E_{1/2}$ at several temperatures. The corresponding value for the $[Cu(phen)_3]^{3+/2+}$ complex was 92 J mol^{-1} K^{-1}, at I = 0.10 M KCl (28). From these data we calculated the activation parameters shown in Table 1.

These results may involve an appreciable error, due to the uncertainty in the evaluation of the entropy terms and of dW/dT (24). Nevertheless, it is interesting to note that the reorganization entropy for the $[Fe(Hdmg)_2(Him)_2]$ complex, ΔS_{11}^{**} = −50 J mol^{-1} K^{-1}, is similar to those reported for

TABLE 1. Self-exchange rate constants and activation parameters for the $[Fe(Hdmg)_2(Him)_2]$–$[Co(phen)_3^{3+}]$ electron transfer reaction[a]

[a] Selected data, for comparison purposes. Additional data are available under request.

typical transition metal complexes (27, 29). The contribution of ΔH^{*}_{i} = 14 kJ mol^{-1} to the free reorganization energy is comparable to that of the ΔS^{*}_{i} term. Based on the calculations shown in Table 1, we concluded that the null activation entropy for the cross reaction, $\Delta S^{\ddagger}_{12}$, arises from the compensation of the reorganization entropies of the two complexes.

Autoxidation kinetics

The $[Fe(Hdmg)_2(Him)_2]$ complex is autoxidized in air very rapidly, in the absence of an excess of the imidazole ligand. The rates were proportional to the concentration of O_2, but inversely proportional to the concentration of imidazole, as shown in Table 2 (exps. 1–5).

This inhibiting effect associated with the imidazole ligand was indicative of a dissociative equilibrium, as expressed by reaction [20].

[20] $$[Fe(Hdmg)_2(Him)_2] + H_2O \underset{k_L}{\overset{k_{-L}}{\rightleftharpoons}} [Fe(Hdmg)_2(Him)(H_2O)] + Him$$

Because of the presence of a labile water ligand in the axial position, the $[Fe(Hdmg)_2(Him)(H_2O)]$ intermediate was expected to have pronounced reactivity toward substitution and oxidation by dioxygen. As a matter of fact, the dissociation reaction can be quantitatively reversed by reacting the product with an excess of the imidazole ligand, under argon atmosphere.

In order to evaluate k_L, we have investigated the kinetics of the reverse step, using the stopped-flow technique. The observed rate constants in this case were proportional to the concentration of the imidazole ligand, in the range of 0.02 to 0.20 M. From these experiments we obtained $k_L = 1.7 \pm 0.1 \times 10^2$ M^{-1} s^{-1} (25°C, I = 0.10 M).

The $[Fe(Hdmg)_2(Him)(H_2O)]$ complex produced in the dissociation equilibrium can react with dioxygen via inner-sphere or outer-sphere mechanisms, yielding $[Fe(Hdmg)_2(Him)(O_2)]$ or $[Fe(Hdmg)_2(Him)(H_2O)]^+$ and O_2^- species.

$$[21] \quad [Fe(Hdmg)_2(Him)(H_2O)] + O_2 \xrightarrow{k_{ox}} \text{oxidation products}$$

the superoxide species would then react with the bis-imidazole complex, forming $[Fe(Hdmg)_2(Him)_2]^+$ and H_2O_2.

The derived rate law for the mechanism described by reactions [20]–[21], assuming a steady-state approximation for $[Fe(Hdmg)_2(Him)(H_2O)]$, is given by eq. [22],

$$[22] \quad -\frac{d[Fe(Hdmg)_2(Him)_2]}{dt} = k_{obs}[Fe(Hdmg)_2(Him)_2]$$

where

$$k_{obs} = \frac{k_{ox}k_{-L}[O_2]}{k_{-L} + k_L[Him] + k_{ox}[O_2]}$$

In agreement with eq. [22], the plots of k_{obs}^{-1} versus [Him] were linear, leading to the following parameters, calculated from the slope and intercept, respectively.

$$[23] \quad \frac{k_L}{k_{-L}k_{ox}[O_2]} = 5.0 \times 10^4\ M^{-1}\ s$$

$$[24] \quad \frac{k_{-L} + k_{ox}[O_2]}{k_{-L}k_{ox}[O_2]} = 110\ s$$

By substituting $k_L = 170\ M^{-1}\ s^{-1}$ and $[O_2] = 5.0 \times 10^4\ M$ into eqs. [23] and [24], we obtained $k_{-L} = 0.36\ s^{-1}$ and $k_{ox} = 20\ M^{-1}\ s^{-1}$.

The plots of k_{obs}^{-1} versus $[O_2]^{-1}$ were also linear, with an intercept of 3 ± 2 s, and a slope of $0.093 \pm 0.005\ M$ s. The calculated values were 3 s and 0.097 M s, respectively, in excellent agreement with the experimental results.

From the values of k_{-L} and k_L we have evaluated the dissociation constant $K = k_{-L}/k_L = 2.1 \times 10^{-3}\ M$.

The fact that k_{ox} is one order of magnitude smaller than k_L implies that the electron transfer reaction can be preceded by substitution, as in a typical inner sphere mechanism. Although we can not exclude an outer-sphere mechanism, it seems much less probable to occur in the present case. According to the cyclic voltammograms of Fig. 2, the bis-substituted complex would be more easily oxidized than the dissociated product, which has a high E^0 value. Consequently, electron transfer would be faster in the presence of an excess of the imidazole ligand, in contrast to the results observed in this work.

The autoxidation of the $[Fe(Hdmg)_2(Him)_2]$ complex is accelerated in the presence of copper(II) ions, with a complex kinetic behavior as a function of the concentration of the reactants. At low concentrations of imidazole and of copper(II) ions, the autoxidation reaction proceeds according to a first order kinetics. The observed rate constants increase with the concentration of Him and Cu(II), as shown in Table 2 (exps. 6–11). The mechanism, however, is complicated by the dissociative equilibrium in the $[Fe(Hdmg)_2(Him)_2]$ system, and by the presence of several copper(II) species, e.g., Cu^{2+} (aq), $Cu(Him)^{2+}$, $Cu(Him)_2^{2+}$, and $Cu(Him)_3^{2+}$.

At a high imidazole concentration, e.g. 0.20 M, the only relevant species are the $[Fe(Hdmg)_2(Him)_2]$ and $[Cu(Him)_4]^{2+}$ complexes. In this case, two successive reactions have been observed, as shown in Fig. 4. The first reaction occurs within a millisecond time scale, producing only a partial decay of the $[Fe(Hdmg)_2(Him)_2]$ complex. The second reaction is a thousand times slower and leads the oxidation reaction to completion.

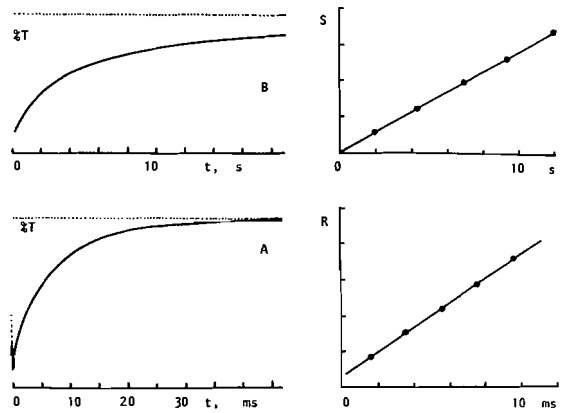

FIG. 4. Oscilloscope traces for the reversible electron transfer reaction (A) and the copper(II) catalyzed autoxidation of the $[Fe(Hdmg)_2(Him)_2]$ complex (B). The plots refer to the analysis described in the Experimental section ($[Fe(II)] = 2.4 \times 10^{-5}\ M$, $[Him] = 0.20\ M$, $[O_2] = 5.0 \times 10^{-4}\ M$, $[Cu(II)] = 7.3 \times 10^{-5}\ M$, 25°C, $I = 0.100\ M$ KCl).

The first rapid reaction was also observed under argon atmosphere, and was assigned to the reversible electron transfer process:

$$[25] \quad [Fe(Hdmg)_2(Him)_2] + [Cu(Him)_4]^{2+} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} [Fe(Hdmg)_2(Him)_2]^+ + [Cu(Him)_4]^+$$

Based on the initial (Fe_T, Cu_T) and equilibrium concentrations (x) measured after 40 ms (Fig. 4), we evaluated $K_1 = k_f/k_r$ as

$$[26] \quad K_1 = \frac{x^2}{[Fe_T - x][Cu_T - x]} = 0.33 \pm 0.01$$

In order to calculate the kinetic constant k_f, we performed a rigorous analysis of the reversible scheme, as described in the Experimental section. The results are shown in Table 2 (exps. 12–18). Based on the calculated second order rate constant $k_f = 1.2 \pm 0.1 \times 10^6\ M^{-1}\ s^{-1}$, and on the calculated work terms, $W_{11} = 1.93$, $W_{21} = 0.79$, $W_{12} = W_{22} = 0$ kJ mol^{-1} ($R_{Cu} = 0.42$ nm, $I = 0.10\ M$, 25°C), we estimated the self exchange rate constant for the $[Cu(Him)_4]^{2+}$ complex as $k_{11} = 4.8 \times 10^4\ M^{-1}\ s^{-1}$.

Preliminary analysis of the second order reaction results in systematic deviations from the first order kinetics. In contrast, the observed pattern was typical of a second order process. Starting from the reversible electron transfer reaction [25], we considered as the next step of the mechanism, the reaction of the Cu(I) species with O_2 leading to superoxide species, as previously described in the literature (30–32). Under the conditions of this work, the $[Cu(Him)_4]^+$ ion dissociates rapidly, producing the catalytically active $[Cu(Him)_2]^+$ complex (30).[2]

$$[27] \quad [Cu(Him)_4]^+ \overset{K_2}{\rightleftharpoons} [Cu(Him)_2]^+ + 2\,Him$$

$$[28] \quad [Cu(Him)_2]^+ + O_2 \overset{K_3}{\rightleftharpoons} [Cu(Him)_2(O_2)]^+$$

Electron transfer between $[Cu(Him)_2(O_2)]^+$ and $[Fe(Hdmg)_2(Him)_2]$ leads the autoxidation reaction to completion, producing H_2O_2 and regenerating the catalyst.

[2]Reversible cyclic voltammograms were obtained for the $[Cu(Him)_4]^{2+}$ complex in the presence of [Him] = 0.1–2.0 M. The half wave potentials varied according to the equation $E_{1/2} = 0.065 - 0.120 \times \log [Him]$. The Nernst slope is consistent with the dissociation of two imidazole ligands from the Cu(I) complex, as expressed by reaction [29].

[29] $[Cu(Him)_2(O_2)]^+ + [Fe(Hdmg)_2(Him)_2] \xrightarrow[2H^+]{k_4} [Cu(Him)_2]^{2+} + [Fe(Hdmg)_2(Him)_2]^+ + H_2O_2$

It should be noted that the reaction of hydrogen peroxide with Cu(I) and Fe(II) species is slower than the corresponding reaction of dioxygen and does not contribute to the derived rate law:

[30] $$-d[Fe^{II}] = k_{obs}\frac{[Fe^{II}]^2}{[Fe^{III}]}$$

where

$$k_{obs} = K_1K_2K_3K_4\frac{[Cu(Him)_4][O_2]}{[Him]^2}$$

The analysis based on eq. [30] was described in the Experimental section, and is illustrated in Fig. 4. The observed rate constants were obtained from the slopes of the second order plots, and incorporate the concentration of the Cu(II), O_2 and Him species used in large excess over the Fe(II) complex. As a matter of fact, the observed rate constants increased linearly with the concentration of the Cu(II) ions and O_2, as shown in Table 2, in agreement with the proposed mechanism.[3]

Another possible reaction to be considered is the oxidation of the $[Cu(Him)_4]^+$ complex by the superoxide species, as in reaction [31].

[31] $[Cu(Him)_4(O_2)]^+ + [Cu(Him)_2]^+ \xrightarrow{k_8} 2[Cu(Him)_2]^{2+} + H_2O_2$

This reaction provides an additional pathway for the regeneration of the Cu(II) species, and has been postulated in the autoxidation of a number of Cu(I) complexes. In the present case, however, it would lead to a quadratic dependence of k_{obs} with respect to the concentration of the Cu(II) ion. Therefore, according to the experimental rate law, reaction [29] should predominate over reaction [31].

It is interesting to compare the mechanism proposed here for the copper catalyzed autoxidation of the $[Fe(Hdmg)_2(Him)_2]$ complex with those previously reported for metalloproteins such as the cytochrome-c (6–8). In the case of the metalloproteins, the rate-determining step is the one electron oxidation of the biomolecule by the copper(II) species. This step is followed by the rapid reoxidation of the resulting Cu(I) products by molecular oxygen. The redox potential of the reacting species becomes the dominant factor in determining the relative rates of the electron transfer reactions (8). In the case of the heme model compounds, the absence of the protein chain facilitates the necessary approach for electron transfer. The reactions are typically adiabatic, with a unity probability factor. For this reason, in contrast with the biological molecules, the electron transfer reaction proceeds very rapidly, and the reoxidation of the resulting Cu(I) species by O_2 becomes the rate-determining step.

[3] An alternative outer-sphere mechanism would lead to the following rate law, assuming a steady state approximation for the concentration of O_2^-:

$$[Cu(Him)_2]^+ + O_2 \underset{k_6}{\overset{k_5}{\rightleftharpoons}} [Cu(Him)_2]^{2+} + O_2^-$$

$$O_2^- + [Fe(Hdmg)_2(Him)_2] \xrightarrow[2H^+]{k_7} [Fe(Hdmg)_2(Him)_2]^+ + H_2O_2$$

$$\frac{-d[Fe^{II}]}{dt} = \frac{KK_2K_5k_7[Fe^{II}]^2[O_2][Cu(Him)_4{}^{2+}]}{[Fe^{III}](k_7[Fe^{II}][Him]^2 + k_6K_2[Cu(Him)_4{}^{2+}])}$$

In order to explain the first order dependence of k_{obs} on the concentration of the $[Cu(Him)_4{}^{2+}]$ complex, the product $k_6K_2[Cu(Him)_4{}^{2+}]$ should be smaller than $k_7[Fe^{II}][Him]^2$. However, in this case, the second order dependence on the concentration of the Fe(II) complex would be reduced to a first order dependence. Therefore, the outer-sphere mechanism is not consistent with the rate law (eq. [30]) observed in this work.

Received October 4, 1985
This paper is dedicated to Professor Arthur N. Bourns

CHOI CHUCK LEE, DAVE WANIGASEKERA, and CHARLES Y. FIAKPUI. Can. J. Chem. **64**, 1235 (1986).

The presence of different amounts of added $LiClO_4$ in the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) or trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C) in 70% HOAc did not materially affect the extent of scrambling of the label arising from 1,2-aryl shifts in the triarylvinyl cation or k_r, the rate constant for the 1,2-aryl shift. Solvolysis of a 2:3 mixture of (*E*)- and (*Z*)-1,2-diphenyl-2-tolylvinyl bromide ((*E*,*Z*)-**3**-Br) in 70% HOAc gave an 85:15 mixture of 1,2-diphenyl-2-tolylethanone (**5**) and 2,2-diphenyl-1-tolylethanone (**6**), the latter product, **6**, being derived from a 1,2-phenyl shift in the 1,2-diphenyl-2-tolylvinyl cation to the more stable 2,2-diphenyl-1-tolylvinyl cation. With (*E*,*Z*)-**3**-Br-2-^{13}C as substrate and analysis by gc–ms, about 26–27% scrambling of the ^{13}C label was found in both products, **5**-1,2-^{13}C and **6**-1,2-^{13}C. Solvolyses of (*E*,*Z*)-**3**-Br-2-^{13}C in 50% and 70% HOAc showed that the extent of scrambling in the major products, **5**-1,2-^{13}C, was lower in 50% HOAc than in 70% HOAc, similar to a trend previously observed for solvolyses of **1**-Br-2-^{14}C. In contrast, solvolyses of **2**-Br-2-^{14}C in 50, 70, or 90% HOAc gave essentially the same extent of scrambling. Mechanistic implications of these results are discussed.

CHOI CHUCK LEE, DAVE WANIGASEKERA et CHARLES Y. FIAKPUI. Can. J. Chem. **64**, 1235 (1986).

L'addition de diverses quantités de $LiClO_4$ lors de la solvolyse du bromure de triphénylvinyle [^{14}C-2] (**1**-Br-^{14}C-2) ou du bromure de trianysylvinyle [^{14}C-2] (**2**-Br-^{14}C-2) dans de l'acide acétique à 70% n'affecte pas matériellement le taux de répartition au hasard du marqueur provenant de glissements-1,2 des groupements aryles dans le cation triarylvinyle ou la constante de vitesse, k_r, des glissements-1,2 des groupements aryles. La solvolyse d'un mélange 2:3 des bromures (*E*) et (*Z*) de diphényl-1,2 tolyl-2 vinyle (**3**-Br-(*E*,*Z*)), dans de l'acide acétique à 70%, conduit à un mélange 85:15 de diphényl-1,2 tolyl-2 éthanone (**5**) et de diphényl-2,2 tolyl-1 éthanone (**6**). Ce dernier composé (**6**) provient d'un glissement-1,2 du groupement phényle dans le cation diphényl-1,2 vinyle pour donner le cation diphényl-2,2 tolyl-1 vinyle qui est plus stable. Dans le cas du **3**-Br-^{13}C-2-(*E*,*Z*), et sur la base d'une analyse par sm/cpg, on note la présence d'un mélange correspondant à environ 26–27% de répartition au hasard du marqueur ^{13}C dans les 2 produits **5**-^{13}C-1,2 et **6**-^{13}C-1,2. Le taux de répartition au hasard du marqueur dans les produits majoritaires, **5**-^{13}C-1,2, qui est obtenu lors de la solvolyse du composé **3**-Br-^{13}C-2-(*E*,*Z*) dans de l'acide acétique à 50% est inférieur à celui observé lors de la même réaction dans de l'acide acétique à 70%; cette tendance est analogue à celle observée antérieurement lors des solvolyses du **1**-Br-^{14}C-2. Par ailleurs, les solvolyses du **2**-Br-^{14}C-2 dans de l'acide acétique à 50, 70 ou 90% donnent essentiellement le même taux de répartition au hasard du marqueur. On discute des implications mécanistiques de ces résultats.

[Traduit par la revue]

α-Arylvinyl cations derived from solvolytic reactions have been extensively discussed (2). Because the solvolysis of triphenylvinyl bromide (**1**-Br) in glacial HOAc without the presence of AgOAc was found to be too slow, isotopic scrambling studies with triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) have been carried out in aqueous acetic acid containing different proportions of HOAc and H_2O as solvent (3). Subsequently, a mixture of 70% HOAc – 30% H_2O (by volume) (to be designated as 70% HOAc) was arbitrarily chosen as solvent in other solvolytic studies on systems such as **1**-Br or **1**-Br-2-^{14}C and trianisylvinyl bromide (**2**-Br) or trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C) (4, 5). In the present paper, further observations on isotopic scramblings are reported for solvolyses in aqueous HOAc of ^{14}C- or ^{13}C-labeled triphenylvinyl, trianisylvinyl, and (*E*,*Z*)-1,2-diphenyl-2-tolylvinyl bromides.

In a previous study (5), the solvolysis of **1**-Br or **2**-Br in 70% HOAc in the presence of $LiClO_4$ was found to give a normal salt effect (6), with the specific rate constant increasing linearly with increasing concentrations of the added salt. In the initial part of the present work, the effect of added $LiClO_4$ on the extent of isotopic scrambling arising from 1,2-aryl shifts in a triarylvinyl cation was investigated. When **1**-Br-2-^{14}C or **2**-Br-2-^{14}C was solvolyzed in 70% HOAc in the presence of different concentrations of added $LiClO_4$, the product, 1,2,2-triphenyl[1,2-^{14}C]-ethanone or 1,2,2-trianisyl[1,2-^{14}C]ethanone, degraded to give the extent of isotopic scrambling (3, 4), showed that the added $LiClO_4$ did not significantly affect the extent of scrambling of the ^{14}C-label from C-2 to C-1 (Table 1).

For the scrambling processes as depicted in Scheme 1, it has been shown that eq. [1] holds (7). When Ar and Ar′ are the same, e.g., with **1**-Br-2-^{14}C or **2**-Br-2-^{14}C, a statistical factor of 2 applies and eq. [1] is modified to eq. [2] (8). While $LiClO_4$ could affect the rate-determining ionization step and gave rise to a normal salt effect, the finding that it did not influence the extent of scrambling indicated that k_{SOH}/k_r did not change significantly in the presence of added $LiClO_4$. Since the medium in all of these experiments is 70% HOAc, k_{SOH} is not expected to vary. A model of the transition state for the 1,2-aryl shift process is an aryl-bridged vinyl cation with dispersal of the positive charge, and hence k_r might be expected to show a decrease with increasing polarity of the medium (9). However, this effect is apparently very small since k_{SOH}/k_r remained essentially constant in the presence of different concentrations of $LiClO_4$.

$$[1] \quad [RY]/[R'Y] = 1 + (k_{SOH}/k_r)$$

$$[2] \quad [RY]/[R'Y] = 1 + (k_{SOH}/2k_r)$$

In the preceding paper of this series (1), we studied the solvolysis of a 2:3 mixture of C-2 labeled (*E*)- and (*Z*)-1,2-diphenyl-2-tolylvinyl bromides (to be designated as (*E*,*Z*)-**3**-Br) in HOAc–AgOAc and in 2,2,2-trifluoroethanol (TFE)–

[1]Rearrangement studies with ^{14}C, LI; for part L, see ref. 1.

TABLE 1. Isotopic scrambling data from solvolyses of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-1-^{14}C) or trianisyl[2-^{14}C]vinyl bromide (**2**-Br-1-^{14}C) in 70% HOAc in the presence of added $LiClO_4$

RX	[RX] (mmolar)	[$LiClO_4$] (mmolar)	Scrambling from C-2 to C-1 (%) Run 1	Run 2	k_{SOH}/k_r[a]
1-Br-1-^{14}C[b]	15	0	15.8[c]	15.3[c]	8.8
	15	15	15.2	15.8	8.9

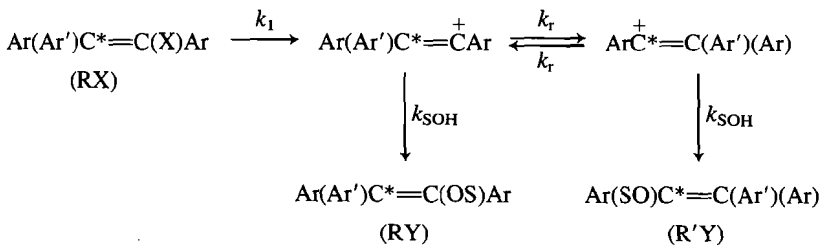
	6	100	30.7	30.9	2.5

[a]Calculated from eq. [2] using the average scrambling values for the duplicate runs.
[b]Solvolyses of **1**-Br-1-^{14}C were carried out at 150 ± 2°C for 10 days, giving essentially complete reaction.
[c]Previously reported (3) mean scrambling value for similar reactions was 15.3%.
[d]Solvolyses of **2**-Br-2-^{14}C were carried out at 120 ± 2°C for 3 days, giving essentially complete reaction.
[e]A previously reported (4) mean scrambling value for similar reactions was somewhat lower at 27.7%.



SCHEME 1

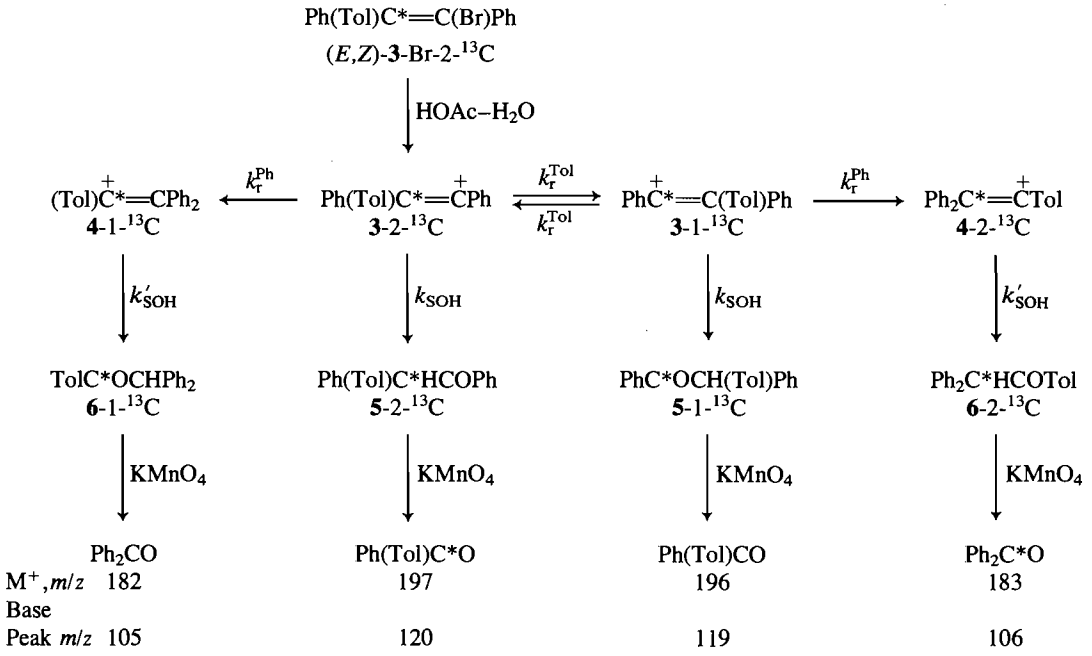
2,6-lutidine. In the present work, the solvolysis of (*E,Z*)-**3**-Br-2-^{13}C in aqueous HOAc was investigated. In preliminary work with nonlabeled (*E,Z*)-**3**-Br, solvolysis in 70% HOAc was found to give, according to ^{1}H nmr, a mixture of 85% 1,2-diphenyl-1-tolylethanone (**5**) and 15% 2,2-diphenyl-1-tolylethanone (**6**), the latter product, **6**, being derived from a 1,2-phenyl shift in the 1,2-diphenyl-2-tolylvinyl cation (**3**) to the more stable 2,2-diphenyl-1-tolylvinyl cation (**4**). An analogous reaction of (*E,Z*)-**3**-Br-2-^{13}C in 70% HOAc gave a mixture of isotopically scrambled products, **5**-1,2-^{13}C and **6**-1,2-^{13}C. Oxidation of this product mixture to give nonlabeled and labeled diphenyl and phenyl tolyl ketones, followed by gc–ms analyses as described previously for the solvolysis of (*E,Z*)-**3**-Br-2-^{13}C in TFE–2,6-lutidine (1), gave the extents of scrambling of the ^{13}C-label between C-1 and C-2 in **5**-1,2-^{13}C arising from degenerate 1,2-tolyl shifts in the 1,2-diphenyl-2-tolylvinyl cation (**3**), and in **6**-1,2-^{13}C arising from nondegenerate 1,2-phenyl shifts in cation **3** before and after the degenerate 1,2-tolyl shifts. The processes involved are depicted in Scheme 2.

The extents of scrambling were calculated from the intensities of the ms absorptions in the molecular ion region and in the base peak region. The observed data are summarized in Tables 2 and 3, and the method of calculation has been described previously (1). A steady-state treatment of the scrambling processes in Scheme 2 gives eq. [3], an equation analogous to that used previously for the reaction of (*E,Z*)-**3**-Br-2-^{13}C with TFE–2,6-lutidine (1).

[3] [**5**-2-^{13}C]/[**5**-1-^{13}C] = [**6**-1-^{13}C]/[**6**-2-^{13}C]

From Tables 2 and 3, it is seen that the mean scramblings in **5**-1,2-^{13}C and **6**-1,2-^{13}C are 26.3 ± 0.9% and 27.5 ± 0.5%, respectively, and these values are identical within experimental errors, in agreement with eq. [3]. Again, analogous to the treatment of data from trifluoroethanolysis (1), the distribution of unrearranged and rearranged products **5**-2-^{13}C, **5**-1-^{13}C, **6**-1-^{13}C, and **6**-2-^{13}C (Scheme 2) can be calculated. Since the ratio of **5** to **6** was 85:15, and since the mean scrambling values were 26.3% from **5**-2-^{13}C to **5**-1-^{13}C and 27.5% from **6**-1-^{13}C to **6**-2-^{13}C, in the product mixture, there would be 85 × 0.263 = 22% **5**-1-^{13}C, 85 × 0.737 = 63% **5**-2-^{13}C, 15 × 0.275 = 4% **6**-2-^{13}C, and 15 × 0.725 = 11% **6**-1-^{13}C. As depicted in Scheme 2, nondegenerate 1,2-phenyl shifts gave **4**-1-^{13}C from **3**-2-^{13}C and **4**-2-^{13}C from **3**-1-^{13}C, respectively, before and after the degenerate 1,2-tolyl shifts in cation **3**. since the ratios of [**6**-1-^{13}C]/[**5**-2-^{13}C] = 11/63 = 0.17 and [**6**-2-^{13}C]/[**5**-1-^{13}C] = 4/22 = 0.18 are essentially the same, the product distribution observed thus indicated that in cation **3**, the same extent of nondegenerate 1,2-phenyl shifts occurred before or after the degenerate 1,2-tolyl shifts, a conclusion that was also reached in the previous study on the trifluoroethanolyis of (*E,Z*)-**3**-Br-2-^{13}C (1).

It is of interest to note that from the present work, reaction of (*E,Z*)-**3**-Br in 70% HOAc gave, as major product, ketone **5** derived from the less stable cation **3**, while the minor product, ketone **6**, was derived from the more stable cation **4**. In contrast, for the trifluoroethanolysis of (*E,Z*)-**3**-Br (1), the major product was derived from the more stable cation **4** while the minor product was derived from the less stable cation **3**. Moreover, in the reaction of (*E,Z*)-**3**-Br with HOAc–AgOAc, the only



SCHEME 2

product was derived from cation **3**, with no detectable amount of product derived from the more stable cation **4**. As was suggested (1), the nucleophilic character of the reaction medium and the lifetime of the vinyl cations may play a role in determining these variations. In TFE with its low nucleophilic character and long cationic lifetime, the nondegenerate 1,2-phenyl shifts from **3** to **4** could be extensive, while in HOAc–AgOAc, the cationic lifetime was short and there was no detectable amount of rearrangement from **3** to **4**. In 70% HOAc, the cationic lifetime would be intermediate between HOAc–AgOAc and TFE and only a small extent of rearrangement from **3** to **4** could take place, resulting in the formation of a minor amount of product derived from **4**.

Another method, involving analysis by ^{13}C nmr, may also be utilized to determine the extent of scrambling arising from degenerate 1,2-tolyl shifts in the solvolysis of (*E,Z*)-**3**-Br-2-^{13}C. Experiments were carried out in 70% and in 50% aqueous HOAc. The major product, **5**-1,2-^{13}C, was recovered after separation by thin-layer chromatography and then reduced with $LiAlH_4$ to give a mixture of *erythro*- and *threo*-1,2-diphenyl-2-tolyl[1,2-^{13}C]ethanol (**7**-1,2-^{13}C). The ^{13}C enrichments at C-2 and C-1, and hence the extent of scrambling, were determined from the ^{13}C nmr spectrum of **7**-1,2-^{13}C by the intensity ratio method as previously described (10, 11). From duplicate solvolyses of (*E,Z*)-**3**-Br-2-^{13}C in 70% HOAc, the scramblings from C-2 to C-1 in **5**-1,2-^{13}C, as measured by ^{13}C nmr, were 26.1 and 27.0%, in good agreement with the data obtained from gc–ms analyses given in Tables 2 and 3. In similar solvolyses in 50% HOAc, 22.3 and 23.2% scramblings from C-2 to C-1 were observed for duplicate runs. It is seen that a higher proportion of H_2O in the HOAc–H_2O solvent mixture gave rise to a lower extent of scrambling (mean scrambling values of 26.6% and 22.8%, respectively, in 70% and 50% HOAc). This trend was also observed in the earlier study on the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in different mixtures of HOAc and H_2O (3). For comparison, some of the data from the earlier work with **1**-Br-2-^{14}C (3) and the present results from reactions of (*E,Z*)-**3**-Br-2-^{13}C in 50% and 70% HOAc are summarized in Table 4.

In Table 1, it is shown that solvolysis of trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C) in 70% HOAc gave a product with 29.5 and 30.5% scrambling in duplicate runs. It is of interest to note that similar reactions of **2**-Br-2-^{14}C in 50% or 90% HOAc also gave essentially the same extent of about 30% scrambling, the results being included in Table 4. These results for **2**-Br-2-^{14}C, therefore, do not follow the same trend of decreasing amounts of scrambling with increasing proportions of H_2O in the HOAc–H_2O solvent mixture that was observed with **1**-Br-2-^{14}C or (*E,Z*)-**3**-Br-2-^{13}C. Recently, isotopic scramblings from reactions of C-2 labeled (*E,Z*)-1,2-dianisyl-2-tolylvinyl bromides ((*E,Z*)-**8**-Br) with HOAc–AgOAc or with TFE–2,6-lutidine have been reported (12). It may also be of interest to note that preliminary work on the solvolysis of (*E,Z*)-**8**-Br-2-^{13}C in aqueous HOAc also indicates no significant changes in the extent of scrambling for different proportions of HOAc and H_2O.

To account for the difference in behavior for the solvolysis of **1**-Br-2-^{14}C, (*E,Z*)-**3**-Br-2-^{13}C, and **2**-Br-2-^{14}C in aqueous HOAc containing different amounts of H_2O, the nature of the triarylvinyl cations involved may be considered. As given in Table 4, a lower extent of scrambling corresponds to a higher value for k_{SOH}/k_r. For the α-phenyl substituted triarylvinyl cations generated from **1**-Br-2-^{14}C or (*E,Z*)-**3**-Br-2-^{13}C, a higher H_2O content in the solvent would increase the nucleophilic character of the reaction medium and would give a higher value for k_{SOH}. As well, a higher H_2O content would also increase the polar character of the solvent and may give rise to a lower k_r, although this effect may be small since it was shown earlier that the presence of $LiClO_4$ in 70% HOAc did not materially influence k_{SOH}/k_r. Thus for solvolyses of **1**-Br-2-^{14}C or (*E,Z*)-**3**-Br-2-^{13}C in HOAc–H_2O, a higher proportion of H_2O in the solvent would increase k_{SOH}/k_r and hence decrease the extent of scrambling as observed. For the reaction of **2**-Br-2-^{14}C, however, the α-anisyl substituted triarylvinyl cation that is generated is more stable than an α-phenyl substituted triarylvinyl cation and would have a longer lifetime and a lower value for k_{SOH}. Apparently, changes in H_2O content in the HOAc–H_2O solvent did not greatly affect the relatively low value of k_{SOH} and since the effect of k_r would also be small,

[c]Reaction of (*E*,*Z*)-1,2-diphenyl-2-tolyl[2-^{13}C]vinyl bromides ((*E*,*Z*)-**3**-Br-2-^{13}C) in HOAc–H_2O at 150 ± 2°C.
[d]Reaction of trianisyl[2-^{14}C]vinyl bromide (**2**-Br-1-^{14}C) in HOAc–H_2O at 120 ± 2°C.
[e]Mean scrambling values from ref. 3.
[f]Calculated from eq. [1] or eq. [2] using the mean scrambling values. For (*E*,*Z*)-**3**-Br-2-^{13}C, steady-state treatment of Scheme 2 gave $k_{SOH}/k_r = [RY]/[R'Y] - 1 - k_{Ph}/k_{Tol}$, but eq. [1] is used since k_{Ph}/k_{Tol} may be quite small.
[g]Scramblings for duplicate runs in the major product, 1,2-diphenyl-2-tolyl[1,2-^{13}C]ethanone (**5**-1,2-^{13}C).
[h]Scramblings for duplicate runs in the product, trianisyl[1,2-^{14}C]ethanone.

the net result is a relatively constant k_{SOH}/k_r, giving rise to about the same extent of scrambling for solvolyses in HOAc–H_2O of α-anisyl substituted triarylvinyl systems such as the trianisylvinyl and (*E*,*Z*)-1,2-dianisyl-2-tolylvinyl bromides.

Since the degenerate rearrangement processes in the triphenylvinyl and 1,2-diphenyl-2-tolylvinyl cations differ only in the migrating phenyl and tolyl groups, a comparison of the data from **1**-Br-2-^{14}C and (*E*,*Z*)-**3**-Br-2-^{13}C in Table 4 would give a measure of the Tol:Ph migratory aptitude. The k_{SOH}/k_r values in Table 4 may be more specifically designated as k_{SOH}/k_r^{Ph} and k'_{SOH}/k_r^{Tol}, respectively, for the triphenylvinyl and 1,2-diphenyl-2-tolylvinyl systems. If k_{SOH} and k'_{SOH} for the capture of the two ions in a given solvent system were assumed to be about the same, then $(k_{SOH}/k_r^{Ph})/(k'_{SOH}/k_r^{Tol}) =$

k_r^{Tol}/k_r^{Ph} would be 17.0/2.4 or about 7 and 8.8/1.8 or about 5, respectively, for solvolyses in 50% and 70% HOAc. These values of about 5–7 are of the same magnitude as previously reported Tol:Ph migratory ratios of 4–5 from comparisons of scrambling data for the tritolyvinyl and 2-phenyl-1,2-ditolylvinyl cations (8), and a k_r^{Tol}/k_r^{Ph} ratio of about 7 from comparisons of the scramblings observed in reactions of **1**-Br-1-^{14}C and (*E,Z*)-**3**-Br-2-^{14}C with HOAc–AgOAc (1).

Experimental

*Solvolyses with triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C)*

Solutions of **1**-Br-2-^{14}C (15 mmolar) in 70% HOAc containing different amounts of $LiClO_4$ (Table 1) were heated in sealed tubes at 150 ± 2°C for 10 days. Each reaction mixture was worked up to give 1,2,2-triphenyl[1,2-^{14}C]ethanone (α,α-diphenylacetophenone), which was in turn degraded to diphenyl [^{14}C]ketone, using procedures previously described (3). The difference in specific activities between each sample of 1,2,2-triphenyl[1,2-^{14}C]ethanone and the corresponding diphenyl [^{14}C]ketone gave the extents of scrambling of the ^{14}C label from C-2 to C-1.

*Solvolyses with trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C)*

Solutions of **2**-Br-2-^{14}C (6.0 mmolar) in 50, 70, or 90% HOAc or in 70% HOAc containing different amounts of $LiClO_4$ (Table 1) were heated in sealed tubes at 120 ± 2°C for 3 days. Each reaction mixture was worked up to give 1,2,2-trianisyl[1,2-^{14}C]ethanone, which was subsequently degraded to give dianisyl [^{14}C]ketone using procedures reported previously (4). The difference in specific activities between each sample of 1,2,2-trianisyl[1,2-^{14}C]ethanone and its degradation product, dianisyl [^{14}C]ketone, gave the extents of scrambling of the ^{14}C label from C-2 to C-1.

*Solvolyses with (E,Z)-1,2-diphenyl-2-tolyl[2-^{13}C]vinyl bromide ((E,Z)-**3**-Br-2-^{13}C)*

The substrate, (*E,Z*)-**3**-Br or (*E,Z*)-**3**-Br-2-^{13}C, consisting of an approximately 2:3 mixture of the (*E*) and (*Z*) isomers, was prepared as described in the preceding paper (1).

A solution of 1.00 g (2.86 mmol) of (*E,Z*)-**3**-Br in 100 mL of 70% HOAc in a sealed tube was heated in an oil bath at 150 ± 2°C for 10 days. After cooling, the tube was opened and the contents extracted 3 times with ether. The extract was washed with H_2O and dried over $MgSO_4$. Removal of the ether under reduced pressure gave about 700 mg of a mixture of 1,2-diphenyl-2-tolylethanone (**5**) and 2,2-diphenyl-1-tolylethanone (**6**) as an oil. Its ^{1}H nmr spectrum indicated that the ratio of **5**:**6** was about 85:15 based on the relative area of the tolyl-CH_3 peaks at δ 2.24 and 2.33 ppm and the CH peaks at δ 6.06 and 6.40 ppm, respectively, for **5** and **6**. The major product, **5**, was purified by preparative thin-layer chromatography using silica gel G/UV_{254} (Brinkmann Instruments (Canada) Ltd.) as the stationary phase and 80% $CHCl_3$ – 20% petroleum ether (bp 40–60°C) as the moving phase. The major band was scraped off, thoroughly washed with 300 mL of $CHCl_3$, and filtered. After removal of the $CHCl_3$ from the filtrate, the colorless residue was recrystallized from methanol to give 320 mg (overall yield of 46% based on a product ratio of 85:15 for **5**:**6**) of **5**, mp 94–95°C; ^{1}H nmr ($CDCl_3$) δ: 2.24 (s, 3H, CH_3), 6.06 (s, 1H, CH), 7.2–8.1 (m, 14H, Ar). *Anal.* calcd. for $C_{21}H_{18}O$: C 88.07, H 6.34; found: C 88.58, H 6.58. Oxidation of a sample of this product gave phenyl tolyl ketone, confirming its structure as **5**. If the product were **6**, its oxidation would give rise to diphenyl ketone.

In analogous solvolyses in 70% HOAc of (*E,Z*)-**3**-Br-2-^{13}C, prepared from 90% enriched [^{13}C]$BaCO_3$, the mixture of products, **5**-1,2-^{13}C and **6**-1,2-^{13}C, was oxidized without prior separation to give a mixture of phenyl tolyl ketone, phenyl tolyl [^{13}C]ketone, diphenyl ketone, and diphenyl [^{13}C]ketone for analysis using a Model 4000 Finnigan gc–ms system. In contrast to the degradation of 1,2,2-triphenyl[1,2-^{14}C]ethanone and 1,2,2-trianisyl[1,2-^{14}C]ethanone, which involved reduction with $LiAlH_4$ to the corresponding ethanol followed by oxidation with alkaline $KMnO_4$ (3, 4), the mixtures of **5**-1,2-^{13}C and **6**-1,2-^{13}C were oxidized directly by $KMnO_4$ in the presence of H_2SO_4 to give the unlabeled and labeled phenyl tolyl and diphenyl ketones for gc–ms analyses.

In another set of experiments, (*E,Z*)-**3**-Br-2-^{13}C, with 45% ^{13}C enrichment, was solvolyzed in 50, 70, or 90% HOAc at 150 ± 2°C for 10 days. From each run, the major product, **5**-1,2-^{13}C, was recovered after separation by thin-layer chromatography and then reduced with $LiAlH_4$ (3, 4) to give a mixture of *erythro*- and *threo*-1,2-diphenyl-2-tolyl[1,2-^{13}C]ethanol (**7**-1,2-^{13}C), which, after crystallization from 95% ethanol, melted at 87–88°C; ^{1}H nmr ($CDCl_3$) δ: 2.17, 2.28 (4H, two s, CH_3 + OH), 2.21 (shr, OH), 4.10, 4.25 (1H, two d, C-2 CH), 5.23, 5.38 (1H, two d, C-1 CH), 6.97–7.35 (14H, m, Ar). *Anal.* calcd. for $C_{21}H_{20}O$: C 87.46, H 6.99; found: C 87.17, H 7.04. Determinations of the ^{13}C enrichments at C-2 and C-1 of **7**-1,2-^{13}C, and hence the extents of scrambling from C-2 to C-1 as recorded in Table 4, were carried out using the ^{13}C nmr spectrum of **7**-1,2-^{13}C by the intensity ratio method as previously described (10, 11). Although the ^{1}H nmr of **7**-1,2-^{13}C gave separate peaks for the *erythro* and *threo* diastereomers, the peaks of interest in the ^{1}H-decoupled ^{13}C nmr spectrum of **7**-1,2-^{13}C, in a 60-MHz instrument, appear as nearly overlapping doublets at 21.0, 60.6, and 76.9 ppm, respectively, for tolyl-CH_3, C-2, and C-1. Ratios of the integrated intensities for C-2 or C-1 relative to the integrated intensity of tolyl-CH_3 containing ^{13}C in its natural abundance as internal reference standard are utilized in the calculations (10, 11).

Dipole interactions in models of the dense part of the electrical double layer

PANAGHIOTIS NIKITAS[1]

Laboratory of Physical Chemistry, Department of Chemistry, University of Thessaloniki, Thessaloniki, Greece

Received September 30, 1985

PANAGHIOTIS NIKITAS. Can. J. Chem. **64**, 1286 (1986).

Since Monte-Carlo studies on freely oriented dipoles suggest that at zero external field the dipoles are oriented preferentially in-plane in ordered configurations, an attempt is made here to incorporate dipole in-plane interactions in the multi-state model of the inner layer. It is found that the predictions of the model become unsatisfactory as ordered structures are taken into consideration. Polarization catastrophe and concentration dependent adsorption maxima are the main problems. Analysis of the polarization behaviour of the inner layer at the adsorption maximum of an adsorbate suggests that in aqueous interfaces and possibly in other real interfaces the dipole in-plane interactions should be quite weak. This is attributed to rotational barriers leading to an almost random distribution of the dipoles in the monolayer.

PANAGHIOTIS NIKITAS. Can. J. Chem. **64**, 1286 (1986).

Des études effectuées par la méthode de Monte Carlo sur des dipôles d'orientation libre suggère que, à un champ externe qui est nul, les dipôles s'orientent d'une façon préférentielle dans des configurations ordonnées; on a donc fait un essai dans le but d'incorporer le dipôle dans les interactions planes d'un modèle à plusieurs états de la couche interne. On a trouvé que les prédictions du modèle deviennent insatisfaisantes lorsqu'on prend des structures ordonnées en considération. Les principaux problèmes sont la catastrophe de la polarisation et les maxima d'absorption qui dépendent de la concentration. Une analyse du comportement de la substance adsorbée, sous polarisation de la couche interne et à un degré maximal d'adsorption, suggère que, dans les interfaces aqueux et possiblement dans d'autres interfaces réelles, le dipôle dans les interactions planes doit être très faible. On attribue cette propriété à des barrières à la rotation qui font que les dipôles de la mononcouche sont pratiquement distribués au hasard.

[Traduit par la revue]

I. Introduction

The conventional methodology followed for the microscopic modelling of the electrical double layer is characterized by the formal division of the double layer into a dense part and a diffuse layer. The former is modelled as a two-dimensional monolayer of dipoles which can take up only a finite number of orientations. In the first molecular treatments the solvent dipoles may have two positions normal to the adsorbing surface (1–5). The multi-state models are reasonable developments of this approach (6–8).

In all these models the dipole–dipole interactions, which predominately determine the properties of the inner layer, are considered as limiting only perpendicular to the electrode surface. Non-nearest-neighbour interactions as well as effects of imaging are incorporated indirectly by introducing an effective coordination number. Dipole interactions parallel to the electrode surface are neglected in all cases. This interpretation overlooks the dipole interaction energy arising from the parallel component of the dipoles and it can be considered a reasonable approximation only if the dipole components in-plane are randomly oriented. However, Monte-Carlo studies (9) clearly indicate that freely oriented dipoles are oriented preferentially parallel to the plane, showing a definite structure when the external field is zero. Therefore, for freely oriented dipoles the in-plane interaction energy cannot be considered negligible. This interaction energy, its incorporation in molecular models for the inner part of the electrical double layer, the problems arising, and their origin are the object of the present paper.

II. Dipole interactions

The dipole–dipole interactions have been made the subject of a number of publications (4, 10–14). However, many problems are still unsolved. There is no work on the effect of imaging on in-plane interactions and, as we show below, the contribution from imaging in interactions normal to the electrode surface is taken erroneously. Here, for reasons of simplicity and continuity with the inner layer models, we consider only point dipoles. The dipoles are arranged on a planar regular lattice with coordination number c and lattice constant d.

The field strength $\mathbf{E}$ caused by an ideal dipole $\mathbf{P}$ at $\mathbf{r}$ is given by (15).

$$[1] \quad \mathbf{E} = \frac{3\mathbf{P}\cdot\mathbf{r}}{r^5}\mathbf{r} - \frac{\mathbf{P}}{r^3}$$

Since the dipole moment $\mathbf{P}$ can be split in a perpendicular and a planar component, relatively to the plane of the dipoles, we examine these two cases separately.

(a) Interactions normal to the plane

The electric field $\mathbf{E}$ caused by an hexagonal array of infinite extent of ideal dipoles at any position (x, y, z) along an outward perpendicular to the surface can be calculated from the work of MacDonald and Barlow (11). Alternatively one may use eq. [1] which results in

$$[2] \quad E = c_e P/d^3$$

where

$$[3] \quad c_e = \sum_{n=m=-\infty}^{\infty} \left(\frac{3\xi^2}{m^2 + n^2 + \xi^2 - nm} - 1\right) \times (m^2 + n^2 + \xi^2 - nm)^{-3/2}$$

for an hexagonal array of dipoles and

$$[4] \quad c_e = \sum_{n=m=-\infty}^{\infty} \left(\frac{3\xi^2}{n^2 + m^2 + \xi^2} - 1\right)(n^2 + m^2 + \xi^2)^{-3/2}$$

in a square plane. $\xi = z/d$. n and m take all negative, zero, and positive integer values except the values $m = n = \xi = 0$.

[1]This work was carried out at the Electrochemistry Research Laboratories, Department of Physical Chemistry, University of Newcastle-upon-Tyne, Newcastle-upon-Tyne, NE1 7RU, England.

Printed in Canada / Imprimé au Canada

Here we should note that the work of MacDonald and Barlow concerns the electrostatic properties of an hexagonal array with a single vacancy. The electric field and the electrostatic potential are calculated along a perpendicular axis to the surface taken through the position of a missing array element. Therefore, to calculate the field strength at any position outside the plane we have to add the contribution arising from the missing element. This detail, unfortunately, has been overlooked by Levine *et al.* (4, 16) in their calculation of the effective coordination number, z_e. In the LBS theory (4) the dipole–dipole interactions between non-nearest neighbouring pairs as well as interactions arising from dipole images are incorporated indirectly into the model by increasing the coordination number of the lattice, c, to an effective value z_e. For the calculation of z_e Levine *et al.* (4, 16) take into account all the interactions arising from the surrounding dipoles and their images on both sides of the interface, but they ignore the contribution from the images of the test dipole. Thus, a number of papers appeared in the literature (4, 6–8, 17–26) make use of an incorrect value of z_e.

Table 1 shows the obtained values of c_e. To calculate c_e with eqs. [2] and [3] the first $n = m = 500$ nearest-neighbours are summed in an IBM 370-168 computer and the remainder of the sum replaced by an integral. It is seen that the field strength falls rapidly out of the plane and dipoles outwards the monolayer, only adjacent to it, can feel very weak repulsive interactions.

The effective coordination number for lateral dipole–dipole interactions due to dipole imaging at an interface formed by a conductor and an electrolyte solution can now be calculated from

$$[5] \quad z_e = 11.034 - 0.226(1 + f)$$

for an hexagonal lattice and

$$[6] \quad z_e = 9.034 - 0.326(1 + f)$$

for a square one. $f = (\epsilon - 1)/(\epsilon + 1)$, ϵ being the dielectric constant of the bulk electrolyte solution. For aqueous electrolyte solutions we have $\epsilon = 78.3$ (at 25°C) and eqs. [5], [6] give $z_e \approx 10.6$ and 8.4 for an hexagonal and a square lattice, respectively. We see that the effective coordination number is smaller than the Topping's values of 11.03 and 9.03 in the two lattice, as first noticed by Guidelli (5). However, he used different arguments.

(b) Interactions in plane

The interpretation of the dipole in plane interactions is the most difficult task, since we can hardly accept that the parallel component takes up few orientations. Here we make use of the Monte-Carlo results (9). It has been found that for freely oriented dipoles and in the configuration with minimum energy the dipoles line up head-to-tail in rows of opposite orientation. Configurations of rows of dipoles with the same orientation should be considered possible, since such configurations present minimum energy as well (12, 13). For these configurations the field strength parallel to the dipoles at the position (x, y, z) can be calculated from eq. [2] with

$$[7] \quad c_e = \sum_{n=m=-\infty}^{\infty} (-1)^{|m|} \left(1 - \frac{3}{4} \cdot \frac{(2n - m)^2}{n^2 + m^2 + \xi^2 - nm}\right) \times (n^2 + m^2 + \xi^2 - nm)^{-3/2}$$

in an hexagonal lattice, whereas in a square one we have

$$[8] \quad c_e = \sum_{n=m=-\infty}^{\infty} (-1)^{|m|} \left(1 - \frac{3n^2}{n^2 + m^2 + \xi^2}\right) \times (n^2 + m^2 + \xi^2)^{-3/2}$$

TABLE 1. Values of c_e calculated from eqs. [3] and [4]

ξ	c_e ($c = 4$)	c_e ($c = 6$)	c_e ($c = 6$)*
0	−9.034	−11.032	−11.034
1	+0.326	+0.226	+0.224
2	-7×10^{-4}	+0.002	$+7 \times 10^{-4}$
3	−0.001	+0.002	-2×10^{-4}

*Calculated from the work of Macdonald-Barlow (11).

Equations [7] and [8] hold for "anti-parallel" configurations, i.e. when the rows of the oriented dipoles have opposite orientations. For "parallel" configurations the term $(-1)^{|m|}$ should be omitted.

The values of c_e obtained from eqs. [7] and [8] are summarized in Table 2. The minus sign indicates that the field E parallel to a row of oriented dipoles is in an opposite direction to that of the dipoles leading to attractive interactions. To calculate the sums we used the same method as previously except for the parallel configurations where the long distance effect is small and estimated by a least-squares procedure. It is seen that the field drops rapidly out of the dipole layer and practically becomes zero after one molecular diameter. Therefore, dipole imaging effects should have a small contribution. This becomes apparent if we calculate the effective coordination number. For aqueous electrolyte solutions in the hexagonal lattice with parallel orientation we have

$$[9] \quad z_e^{\uparrow\uparrow} = -5.516 - 0.114(1 + f) = -5.74$$

and with anti-parallel

$$[10] \quad z_e^{\uparrow\downarrow} = -4.095 - 0.179(1 + f) = -4.45$$

In a square lattice we have, correspondingly

$$[11] \quad z_e^{\uparrow\uparrow} = -4.158 - 0.163(1 + f) = -4.84$$

$$[12] \quad z_e^{\uparrow\downarrow} = -5.099 - 0.127(1 + f) = -5.35$$

Therefore, a value of $z_e \approx -5$ for well oriented in-plane configurations seems appropriate. However, in real interfaces the thermal motion and rotational barriers should increase its value.

An alternative approach to treat in-plane dipole interactions is to evaluate the average dipole–dipole interaction energy from

$$[13] \quad \langle w_{12} \rangle = \frac{\int_0^{2\pi} w_{12} \exp(-w_{12}/kT) d\varphi_1 d\varphi_2}{\int_0^{2\pi} \exp(-w_{12}/kT) d\varphi_1 d\varphi_2}$$

where

$$[14] \quad w_{12} = -\frac{P_1 P_2}{d^3} (2 \cos \varphi_1 \cos \varphi_2 - \sin \varphi_1 \sin \varphi_2)$$

φ_1, φ_2 being the angles of the dipoles in the plane containing the line joining them.

If $|w_{12}| \ll kT$ then eq. [13] results in a two-dimensional Keesom equation (27, 28)

$$[15] \quad \langle w_{12} \rangle = -\frac{5}{4} \cdot \frac{P_1^2 P_2^2}{d^6 kT}$$

However, for an aqueous solution interface we have $d = 3 \times 10^{-10}$ m, $P_1 = P_2 = 6.12 \times 10^{-30}$ Cm and therefore $\langle w_{12} \rangle = -11.5kT$. In this case the numerical evaluation of the integrals in eq. [13] gives

TABLE 2. Values of c_e calculated from eqs. [7] and [8]

	c_e			
	$c = 4$		$c = 6$	
ξ	Parallel	Anti-parallel	Parallel	Anti-parallel
0	−4.518	−5.099	−5.516	−4.095
1	+0.163	+0.127	+0.114	+0.179
2	-7×10^{-4}	$+1 \times 10^{-4}$	+0.001	$+2 \times 10^{-4}$
3	−0.001	-1×10^{-4}	+0.001	-1×10^{-4}

[16] $\langle w_{12} \rangle = -1.62P^2/d^3$

which, for an hexagonal lattice without imaging effects, results in an effective coordination number equal to $z_e \approx -9.7$. This value should be considered high enough, probably because this approach emphasizes the interactions of the central dipole with its neighbours while it ignores the interactions of the neighbouring dipoles with each other.

III. Application to inner layer models

The above results can be easily incorporated in the multistate models of the inner layer (7, 26). Here we consider site-parity for the solvent molecules, i.e. we restrict our treatment in unassociated solvents. Fawcett (6, 8) claims that such behaviour is evident in certain solvents like alcohols, formic acid, and dimethylformamide, whereas water and *N*-methylformamide should be described in terms of clusters. However, in one of our previous publications (26) we have shown that the lattice models and possibly every model of the inner layer is not compatible with the existence of clusters, since their presence as definite units leads to models which predict a concentration-dependent adsorption maximum, in disagreement with most experimental data. For this reason we modelled the inner part of the electrical double layer as a planar monolayer of solvent dipoles, each of them occupying one lattice site. The dipole vector may take a finite number of orientations. If P_s is the absolute value of the solvent dipole moment, then we have

[17] $P_{jn} = P_s \cos \varphi_j \qquad \text{and} \qquad P_{jp} = P_s \sin \varphi_j$

where the subscripts n and p denote the normal and the parallel component of P_s. This notation will be used throughout this paper. φ_j is the angle formed between the dipole vector and a vector normal to the electrode surface. Adsorbate molecules with dipole moment P_A may be present in the lattice occupying r sites.

In a site-parity model the in-plane dipole–dipole interaction energy, under mean field approximation, may be calculated from

[18] $$U_p^{d-d} = \frac{z_{ep}}{2Nd^3}\left(\sum_{i=1}^{N} P_{ip}^t N_i\right)^2 = \frac{1}{2} Y_m \sum_{i=1}^{N} P_{ip}^t N_i$$

where Y_m is the electric field parallel to the adsorbing surface in a site occupied by a monomer dipole, N_i the number of dipoles of type i, N the total number of dipoles equal to the number of the lattice sites, and P_{ip}^t the total (permanent plus induced) in-plane dipole moment of the ith dipole. Note that eq. [18] may include adsorbate molecules with $r = 1$ and dipole moment P_{Ap}. If a_i is the polarizability of the ith type dipoles we have

[19] $P_{ip}^t = P_{ip} - a_i Y_m$

In site-disparity models (say due to absorbate molecules with $r \neq 1$) eq. [18] is easily generalized to

[20] $$U_p^{d-d} = \frac{z_{ep}}{2N_q d^3}\left(\sum_{i=1}^{N} q_i P_{ip}^t N_i/n_i\right)^2 = \frac{1}{2}\sum_{i=1}^{N} P_{ip}^t N_i Y_i$$

where

[21] $Y_i = q_i Y_m/n_i$

[22] $$N_q = \sum_{i=1}^{N} q_i N_i$$

n_i is the number of sites occupied by one dipole of ith type and q_i is defined so that the product $q_i c$ is the number of first neighbour sites surrounding each ith dipole.

Equation [20] results in

[23] $$Y_m = \frac{\sum_{i=1}^{N} q_i P_{ip}\vartheta_i/n_i^2}{\sum_{i=1}^{N} q_i\left(\frac{d^3}{z_{ep}} + a_i q_i/n_i^2\right)\vartheta_i/n_i}$$

where

[24] $$\vartheta_i = n_i N_i \Big/ \left(\sum_{i=1}^{N} n_i N_i\right)$$

Also, by differentiating eq. [20] with respect to N_1 we can obtain the contributions of in-plane interactions to the chemical potentials of the absorbed molecules. We have

[25] $$\mu_{ip}^{el} = P_{1p}Y_1 - \frac{1}{2} Y_1^2(a_1 + d^3 n_1^2/q_1 z_{ep})$$

The contribution to the chemical potentials from all the other sources, i.e. dipole interactions normal to the adsorbing surface, short-range interactions, interactions with the boundaries of the interface and entropy effects have been calculated in an earlier paper (26). The result, for the ith type solvent dipoles, is

[26] $$\mu_{is}/kT = \ln \vartheta_i - \vartheta/r - (1/r)\sum_{i=0}^{r-1}(1/b_i')\ln(1 - b_i'\vartheta) + \frac{A^{AS}(q/r)^2\vartheta^2}{(1 - \vartheta + q\vartheta/r)^2} + \left\{(4\pi\sigma^M + X_m)P_{in} - 4\pi\sigma^M a_{in}X_m - \frac{1}{2}a_{in}(4\pi\sigma^M)^2 - \frac{1}{2}X_m^2\left(\frac{d^3}{z_{en}} + a_{in}\right)\right\}\Big/ kT + U_{is}/kT$$

For the adsorbate molecules we have

[27] $$\mu_A/kT = \ln\vartheta + 1 - \vartheta - \sum_{i=0}^{r-1}\frac{1 - b_i'}{b_i'}\ln\frac{1 - b_i'\vartheta}{1 - b_i'} + \frac{A^{AS}q(1 - \vartheta)^2}{(1 - \vartheta + q\vartheta/r)^2} + U_A/kT + \left\{(4\pi\sigma^M + qX_m/r)P_{An} - 4\pi\sigma^M a_{An}qX_m/r - \frac{1}{2}a_{An}(4\pi\sigma^M)^2 - \frac{1}{2}X_m^2\left(\frac{d^3q}{z_{en}} + a_{An}q^2/r^2\right)\right\}\Big/ kT$$

Here, ϑ_i, ϑ are the surface coverages of the solvent ith state and the adsorbate, respectively; b_i' are lattice constants depending on the geometrical characteristics of the adsorbate; A^{AS} is a constant related to the short-range interactions; σ^M is the electrode charge density; and X_m is the electric field normal to the adsorbing surface at every solvent site. It is given by

$$[28]\quad X_m = \frac{\sum_{i=1}^{N} (P_{in} - a_{in}4\pi\sigma^M)q_i\vartheta_i/n_i^2}{\sum_{i=1}^{N}\left(\frac{d^3}{z_{en}} + a_{in}q_i/n_i^2\right)q_i\vartheta_i/n_i}$$

Finally, U_{is} and U_A are residual energies of the solvent in the ith state and the adsorbate, respectively, at the interface.

Equations [26] and [27] enable us to calculate the equilibrium properties of the model. First we examine the case where there are no adsorbate molecules in the lattice ($\vartheta = 0$). The equilibrium relationships may be written as

$$[29]\quad kT\ln\frac{\vartheta_1}{\vartheta_k} = U_k - U_1 + (P_{kn} - P_{1n})(4\pi\sigma^M + X_m) + (P_{kp} - P_{1p})Y_m$$

From these equations we can obtain

$$[30]\quad \vartheta_1 = (1/q_0)\exp\{-(U_1 + P_{1n}\epsilon + P_{1p}Y_m)/kT\}$$

where

$$[31]\quad \epsilon = 4\pi\sigma^M + X_m$$

$$[32]\quad q_0 = \sum_{i=1}^{N}\exp\{-(U_i + P_{in}\epsilon + P_{ip}Y_m)/kT\}$$

Equation [30], in combination with eqs. [23] and [28], gives

$$[33]\quad q_0Y_m(a_s + d^3/z_{ep}) = \sum_{i=1}^{N} P_{ip}\exp\{-(U_i + P_{in}\epsilon + P_{ip}Y_m)/kT\}$$

$$[34]\quad \epsilon = \frac{d^3 4\pi\sigma^M/z_{en}}{a_s + d^3/z_{en}} + \frac{\sum_{i=1}^{N} P_{in}\exp\{-(U_i + P_{in}\epsilon + P_{ip}Y_m)/kT\}}{q_0(a_s + d^3/z_{en})}$$

where a mean polarizability, a_s, for all solvent states, is assumed. At every σ^M value eqs. [33], [34] can be solved numerically for ϵ and Y_m. Then the surface composition can be calculated by means of eq. [30].

The inner layer differential capacity may be calculated from (6, 8)

$$[35]\quad C_i^{-1} = 4\pi\left(\alpha + \frac{2d}{z_{en}\sqrt{3}}\cdot\frac{\partial X_m}{\partial\sigma^M}\right)$$

where we have accepted that the inner layer thickness, α, is different from the lattice constant, d. Equation [35] after some algebra results in

$$[36]\quad C_i^{-1} = 4\pi\left\{\alpha - \frac{8\pi d}{z_{en}\sqrt{3}}(1 + d^3/\Phi z_{en})^{-1}\right\}$$

where

$$[37]\quad \Phi = a_s + P_s^2 f_1/kT - (P_s^2 f_{12}/kT)^2/(d^3/z_{ep} + a_s - P_s^2 f_2/kT)$$

$$[38]\quad f_1 = \left(\sum_{i=1}^{N}\vartheta_i\cos\varphi_i\right)^2 - \sum_{i=1}^{N}\vartheta_i\cos^2\varphi_i$$

$$[39]\quad f_2 = \left(\sum_{i=1}^{N}\vartheta_i\sin\varphi_i\right)^2 - \sum_{i=1}^{N}\vartheta_i\sin^2\varphi_i$$

$$[40]\quad f_{12} = \left(\sum_{i=1}^{N}\vartheta_i\cos\varphi_i\right)\left(\sum_{i=1}^{N}\vartheta_i\sin\varphi_i\right) - \sum_{i=1}^{N}\vartheta_i\cos\varphi_i\sin\varphi_i$$

When adsorbate molecules are present at the interface the equilibrium equations [29] are still valid. The adsorption isotherm may be calculated from eqs. [25]–[27] and it is given by

$$[41]\quad \ln(\vartheta/\vartheta_{\uparrow}^r) + \sum_{i=0}^{r-1}\ln(1 - b_i'\vartheta) + A_nX_m + B_nX_m^2 + A_pY_m + B_pY_m^2 + A^{AS}q \times \frac{(1-\vartheta)^2 - q\vartheta^2/r}{(1 - \vartheta + q\vartheta/r)^2} = \ln(\beta c_A) + \ln\beta^{el}$$

$$[42]\quad A_n = \{P_{An}q/r - 4\pi\sigma^M a_A q/r - rP_{\uparrow n} + r4\pi\sigma^M a_s\}/kT$$

$$[43]\quad A_p = \{P_{Ap}q/r\}/kT$$

$$[44]\quad B_n = \{r(a_s + d^3/z_{en}) - q^2(a_A + d^3r^2/qz_{en})/r^2\}/2kT$$

$$[45]\quad B_p = \{r(a_s + d^3/z_{ep}) - q^2(a_A + d^3r^2/qz_{ep})/r^2\}/2kT$$

$$[46]\quad \ln\beta = \{\mu_A^0 - r\mu_s^0 + r\mu_{\uparrow}^{0,sr} + r\mu_{\uparrow}^{0,ent} - \mu_A^{0,sr} - \mu_A^{0,ent} + rU_{\uparrow} - U_A\}/kT - \ln c_s - 1 - \sum_{i=0}^{r-1}\frac{1 - b_i'}{b_i'} \times \ln(1 - b_i')$$

$$[47]\quad \ln\beta^{el} = -4\pi\sigma^M\{P_{An} - rP_{\uparrow n} - 4\pi\sigma^M(a_A - ra_s)/2\}/kT$$

Here c_j (j = A, S) is the bulk concentration of the jth component, ($\uparrow$) denotes the solvent state with dipole vector pointing to the solution, and $\mu_j^{0,1}$ represents chemical potentials of the j component in their standard states (26).

Numerical examples were performed for the three-state model (6) only. Here we used for z_{en} the corrected value 10.6. However, as is also expected from the work of Borkowska and Stafiej (29), this value causes polarization catastrophe problems. The polarization catastrophe can be avoided, at least for values of z_{ep} close to zero, if we assume that the thickness of the inner layer is greater than the lattice constant. This is a reasonable assumption, since the plate separation should be equal to one solvent diameter plus one radius of the electrolyte ion and possibly one atomic radius of the metal electrode (30). For an aqueous electrolyte interface the thickness of the inner layer should range from 4×10^{-10} to 4.5×10^{-10} m. Figures 1–4 show some of the obtained results. It is seen that the inclusion of in-plane dipole interactions results in the considerable increase of the parallel state, around the pzc, even at no highly ordered structures. For intermediate z_{ep} values this configuration breaks at relatively high fields and causes polarization catastrophe problems.

Problems appear also when adsorbate molecules are present at the inner layer. At the adsorption maximum the total dipole moment, P, normal to the adsorbing surface, should be independent of the adsorbate surface concentration (26). Since

$$[48]\quad P/M = P_{An}\vartheta/r + (1 - \vartheta)\sum_{i=1}^{N_s}P_{in}g_i - a_A\vartheta(4\pi\sigma^M + X_A)/r - (1 - \vartheta)\sum_{i=1}^{N_s}a_ig_i(4\pi\sigma^M + X_m)$$

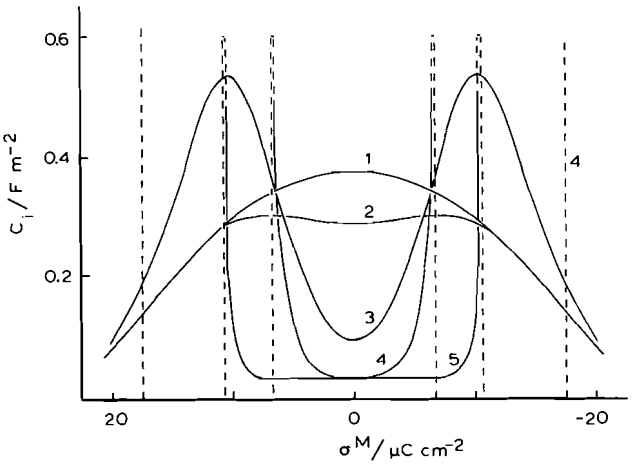

FIG. 1. Plots of the inner-layer capacity C_i against electrode charge density σ^M according to the three-state model. The parameters used were $T = 298$, $P_s = 6.12 \times 10^{-30}$ Cm, $a_s = 1.5 \times 10^{-30}$ m^3, $\alpha = 4.2 \times 10^{-10}$ m, $d = 3 \times 10^{-10}$ m, $U_\uparrow = U_\downarrow = U_\rightarrow$. Values of z_{ep}: (*1*) 0; (*2*) −0.5; (*3*) −1; (*4*) −2; (*5*) −5.

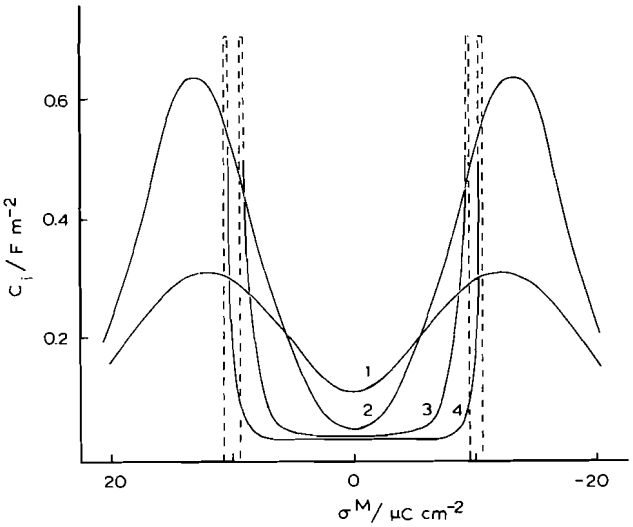

FIG. 2. Plots of the inner-layer capacity C_i against electrode charge density σ^M according to the three-state model. Parameters as in Fig. 1 except $\alpha = 4 \times 10^{-10}$ m and $U_\downarrow - U_\rightarrow = 3kT$. Values of z_{ep}: (*1*) 0; (*2*) −0.5; (*3*) −2; (*4*) −5.

where

$$[49] \quad M = \sum_{i=1}^{N} n_i N_i$$

$$[50] \quad g_i = \vartheta_i/(1 - \vartheta)$$

the condition

$$[51] \quad \left(\frac{\partial P/M}{\partial \vartheta^M}\right)_{\sigma^M_{max}} = 0$$

results in

$$[52] \quad P_{An}/r - \sum_{i=1}^{N_s} P_{in} g_i - a_A(4\pi\sigma^M + X_A)/r + a_s(4\pi\sigma^M + X_m) = 0$$

$$[53] \quad (\partial g_i/\partial\vartheta) = 0$$

$$[54] \quad (\partial X_m/\partial\vartheta) = 0$$

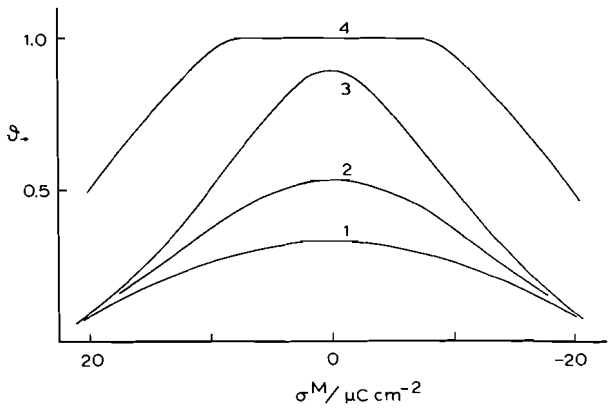

FIG. 3. Plots of the surface coverage of the parallel (→) state against electrode charge density. Parameters as in Fig. 1. Values of z_{ep}: (*1*) 0; (*2*) −0.5; (*3*) −1; (*4*) −5.

However, eqs. [53] and [54] are compatible with the equilibrium equations [29] only when

$$[55] \quad (\partial Y_m/\partial\vartheta) = 0$$

Equations [29], [52]–[55] and the obvious one

$$[56] \quad \sum_{i=1}^{N} \vartheta_i = 1$$

constitute a system of $N_s + 3$ equations, N_s being the number of solvent states. However, there are only $N_s + 2$ unknowns, namely $\vartheta_1, \vartheta_2, \ldots, \vartheta_{N_s}, \vartheta, \sigma^M_{max}$. Therefore, in general, it is impossible to find a solution which would give σ^M_{max} independent of ϑ. Figure 5 shows that the dependence of σ^M_{max} on ϑ is strong even for values of z_{ep} close to zero. Moreover as z_{ep} decreases phase transitions appear in all cases (Fig. 5).

IV. Discussion and conclusions

The above results show that the agreement between the predictions of the model and experimental behaviour is unsatisfactory when ordered in-plane configurations are taken into consideration. This disagreement could be attributed to the following two points of the present treatment:

(*1*) The increase of solvent states with dipoles normal to the adsorbing surface (at intermediate and high fields) as well as adsorbate molecules with small or zero parallel dipole component is expected to unfavour ordered in-plane configurations. Therefore z_{ep} should be a function of both ϑ and σ^M. However, it can hardly be accepted that the use of a variable z_{ep} would improve the results. In this case it is expected that a more pronounced dependence of the parallel state population on σ^M results in polarization catastrophe problems. In the case of σ^M_{max}, a more rapid convocation of σ^M_{max} to its value corresponding to $z_{ep} = 0$ as $\vartheta \rightarrow 1$ would be expected. But at low ϑ values σ^M_{max} would be close to the values of the present treatment. Therefore, a strong dependence of σ^M_{max} on ϑ would also be expected.

(*2*) From a strict theoretical point of view the treatment presented here lacks self-consistency. If we accept a random distribution for the dipoles normal to the electrode it is reasonable to accept the same random distribution for the parallel dipoles as well. However, such an approach is in disagreement with the Monte-Carlo results (9). Therefore, the present results seem to point out the failure of the mean field approximation and the need to find more realistic models.

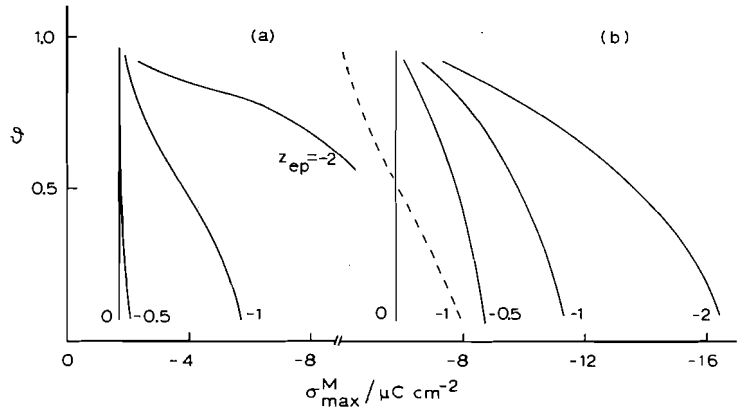

FIG. 4. Dependence of adsorption maximum, σ^{M}_{max}, on ϑ. Parameters used: $T = 298$; $r = 3$; $b'_0 = 0$; $b'_1 = 0.333$; $b'_2 = 0.5$; $A^{AS} = 0$; $P_s = 6.12 \times 10^{-30}$ Cm; $a_s = 1.5 \times 10^{-30}$ m^3; $a_A = 5 \times 10^{-30}$ m^3; $d = 3 \times 10^{-10}$ m; $\alpha = 4 \times 10^{-10}$ m and for (*a*) $P_{Ap} = 5 \times 10^{-30}$ Cm; $P_{An} = 0$; $U_\downarrow - U_\uparrow = U_\downarrow - U_\rightarrow = 3kT$; for (*b*) $P_{Ap} = 0$; $P_{An} = 3 \times 10^{-30}$ Cm; $U_\uparrow = U_\downarrow$; $U_\downarrow - U_\rightarrow = 3kT$. The broken line corresponds to $\alpha = 4.2 \times 10^{-10}$ m, $P_{Ap} = 0$, $P_{An} = 3 \times 10^{-30}$ Cm, $U_\uparrow = U_\downarrow = U_\rightarrow$.

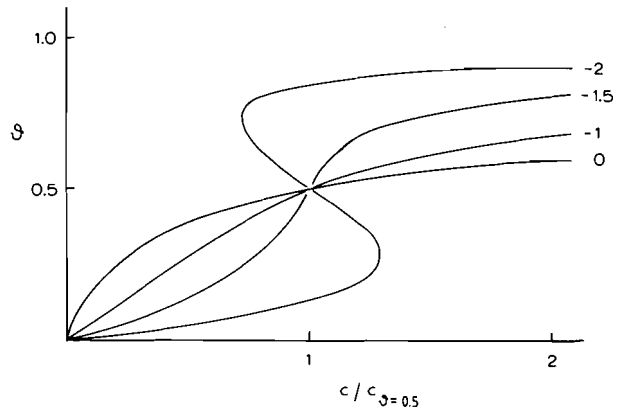

FIG. 5. Dependence of the surface coverage ϑ on the relative concentration at $\sigma^M = -2\,\mu C\,cm^{-2}$ calculated from eq. [41] for different values of z_{ep} indicated by the lines. Other parameters as in Fig. 4 (*a*).

Let us now concentrate our attention on two points; the dependence of σ^{M}_{max} on ϑ and the Monte Carlo results. We have proved that the model predicts a concentration-dependent σ^{M}_{max} even for z_{ep} values close to zero. We can easily extend the above results for every model of the inner layer which assumes ordered in-plane configurations. At the adsorption maximum the total dipole moment normal to the adsorbing surface should be independent of ϑ. That is, the order parameters g_i for the solvent states with perpendicular dipole component should be constant at σ^{M}_{max}. Now, if we assume a Y field parallel to the electrode, having a detectable effect on the population of the various solvent states in the inner layer, then the constancy of g_i should lead to the constancy of Y. However, this is impossible in general. For example, if the dipole moment vector of the adsorbate is oriented normal to the electrode then $Y \rightarrow 0$ as $\vartheta \rightarrow 1$. Perhaps the dependence of σ^{M}_{max} on ϑ would not be as strong as in the model examined, but it should be experimentally detectable. Therefore, at least for the Hg/aq. solution interface, where we have the most accurate data, the constancy of σ^{M}_{max} from ϑ should indicate very weak Y interactions.

The Monte–Carlo treatment of Schmickler (9) deals with freely oriented dipoles. It has been found that at zero external field the dipoles are oriented preferentially in-plane. This means that, at the pzc or around it, the differential capacity of a monolayer of freely oriented dipoles should present a minimum. However, this behaviour does not characterize the Hg/water interface and it further supports the view that at this interface there are no freely oriented dipoles, probably because of the presence of hydrogen bonds. A shallow minimum in the capacity vs. charge curves is the principal feature of alcohols, formic acid, ammonia, and dimethylformamide (6). However, this does not in itself prove the existence of freely oriented dipoles or strong Y fields at the interfaces. Theoretically a minimum in the capacity curves can be predicted even by using the mean field approximation without assuming ordered in-plane structures (6–8). Moreover, adsorption studies at the mercury–methanol interface carried out in our laboratory show a concentration independent adsorption maximum (31–35). Consequently, at this interface Y dipole interactions should not predominate. However, more precise data are needed to clarify the behaviour of non-aqueous solvents at charged interfaces.

The final problem arising from the above discussion is whether the existence of rotational barriers can lead to a random (or an almost random) distribution of the dipoles. It is easily seen from the results of the dipole interactions in section II that a monolayer of dipoles, oriented or not, does not interact or interacts very weakly with a dipole outside the layer. Therefore, a dipole, even near a dipole layer, does not feel strong directional interactions. Now if we take into account that the inner layer of real interfaces is not an isolate system but in continuous competition with the solvent dipoles in the bulk of the electrolyte solution, then it is very likely for the dipoles to enter almost in random the inner layer and the existence of barriers to stabilize such random configurations.

The rate–pH profile for detritiation from the C-2 position of 1-methylimidazole has been determined in aqueous solution at 85°C. The profile is consistent with a mechanism involving attack by hydroxide ion on the conjugate acid of the substrate to give an ylid intermediate in the rate-determining step. At higher pH, hydroxide-catalyzed exchange of the neutral species becomes increasingly important. Comparison of the second-order rate constants derived from the rate–pH profiles of imidazole, 1-methylimidazole, benzimidazole, and 1-methylbenzimidazole showed that methyl substitution caused the rate to increase by 2- to 3-fold while benzo annelation increased the rate by 10- to 20-fold. Frontier molecular orbital (FMO) analysis of the reaction scheme for proton transfer from imidazole, benzimidazole, and their 1-alkyl derivatives has been used to explain the rate-accelerating effect of methyl substitution and benzo annelation in these processes.

ERWIN BUNCEL, HELEN A. JOLY et JOHN R. JONES. Can. J. Chem. **64**, 1240 (1986).

Opérant à 85°C et dans une solution aqueuse, on a déterminé un profil de la vitesse/pH pour la réaction de détritiation de la position C-2 du méthyl-1 imidazole. Le profil est en accord avec un mécanisme impliquant une étape déterminante dans laquelle un ion hydroxyde attaque l'acide conjugué du substrat pour conduire à un ylide intermédiaire. A des pH plus élevés, l'échange catalysé par des bases des espèces neutres devient de plus en plus important. Une comparaison des constantes de vitesse du deuxième ordre, obtenues à partir des profils de vitesse/pH, des imidazole, méthyl-1 imidazole, benzimidazole et méthyl-1 benzimidazole a permis de montrer que la substitution par des groupements méthyles multiplie la vitesse par 2 à 3 alors que l'annelation par un noyau benzénique multiplie les vitesses par 10 à 20. Dans le but d'expliquer l'accélération de la vitesse lors de substitutions par des groupements méthyles et lors de l'annelation par des cycles benzéniques, on a utilisé une analyse, par les orbitales moléculaires frontières, du schéma réactionnel des transferts protoniques de l'imidazole, du benzimidazole et de leurs dérivés substitués par un groupement méthyle en position 1.

[Traduit par la revue]

The rate of hydrogen isotope exchange from the C-2 position of the imidazole ring is of interest, in part because of its presence in biologically important systems such as adenine and guanine, fundamental components of nucleic acids, and in drugs such as puromycin. Imidazole is also the primary component of histidine which is present at the active site of many enzymes. The importance of the imidazole ring can be coupled with the use of deuterium and tritium labels as probes in the investigation of chemical and biochemical processes. For instance, the rate of hydrogen isotope exchange from the C-2 position of the imidazole nucleus present in the histidine residues of the enzymes β-lactamase II and superoxide dismutase has been used to identify the specific histidine residues which act as ligands towards metal ions (1, 2). It is useful therefore to have some knowledge of the factors which can influence the rates of deuterium or tritium loss from the imidazole moiety in different structural environments.

Past studies (3) of proton abstraction from compounds containing the imidazole nucleus suggest that reaction occurs via rate-determining hydroxide attack on either the protonated or the neutral forms of the substrate to form an ylid intermediate. On the basis of such a mechanism one would expect the rate of isotopic hydrogen exchange to be dramatically increased on introduction of a positive charge at sites adjacent to the exchanging hydrogen.

Isotopic exchange involving 1-methylimidazole has previously been studied by two groups of workers but the results obtained are at variance. Harris and Randall (4) reported that the rate–pH profile for deuteration of the C-2 position of 1-methylimidazole at 26°C in the pH region 0–14 was sigmoid. Between pH values 0–4 the rate was undetectable but increased sharply between pH 4–8, beyond which the rate leveled off. This study was qualitative in the sense that the overall rate was not dissected into constituent second order rate constants. Wong and Keck (5) also determined a rate–pH profile for C-2 hydrogen/deuterium exchange between pH 0–14 at 81°C. This study showed some discrepancy with the findings of the previous workers in that the rate increased from pH 2 until pH 8.

The rate–pH profiles obtained for detritiation of 9-alkylpurines (6), 1-methylguanosine (7), and 1-methylinosine (7), which are structurally similar to 1-methylimidazole in that they possess the imidazole nucleus and the pyrrole nitrogen adjacent to C-2 is substituted by an alkyl group, show some deviation in highly basic media from the profile reported for 1-methylimidazole (4, 5), since the rates of proton exchange for the former compounds increase with pH in this region. A re-investigation of the 1-methylimidazole system using a more sensitive means of obtaining rate data was desirable and the results of the detritiation study are reported herein. The resulting reactivity relationships involving imidazole (**1**, R = H), 1-methylimidazole (**1**, R = Me) and the corresponding benzimidazole derivatives (**2**, R = H or Me) which have come to light in

Experimental

Preparation of [2-^{3}H]-1-methylimidazole

Tritiated water (5 μL, 50 Ci/mL) was added to freshly distilled 1-methylimidazole (100 μL) in a small glass ampoule. After sealing, the ampoule was submerged in an oil bath at 85°C for 72 h. The ampoule was then opened, 1 mL of methanol was added to exchange labile tritium and the solvent was removed by lyophilization. Addition of 1 mL portions of methanol was continued until the activity of the lyophilized methanol was found to be insignificant. The purity of the [2-^{3}H]-1-methylimidazole as well as the specificity of labelling of the tritium in the C2 position was checked by ^{1}H and ^{3}H nmr.

Kinetics

The rates of detritiation of [2-^{3}H]-1-methylimidazole in a series of aqueous buffer solutions of known pH – temperature dependence (8) were determined by measuring the increase in the radioactivity of the reaction medium with time in a fashion similar to that used for imidazole (9) and benzimidazole (10). [2-^{3}H]-1-methylimidazole (10 μL) was dissolved in 20 mL of an aqueous buffer solution previously thermostatted at 85.0 ± 0.2°C. Ten 0.5 mL aliquots of the reaction mixture were withdrawn individually at specific time intervals, placed into small round bottom flasks and cooled in liquid nitrogen. Lyophilization of the quenched samples enabled separation of the water from the substrate. A 0.1 mL aliquot of the water collected was placed in 6 mL of Unisolve E liquid scintillator and assayed for tritium (C_t) on a Beckman 100 liquid scintillation counter. The exchange reaction was generally followed for at least two half-lives. The infinity reading (C_∞), i.e., the activity of the water after complete exchange, was obtained by counting the activity of 0.1 mL of the original reaction mixture. All samples were counted for 2 min to ensure statistical accuracy. The pseudo first order rate constant, k_{obs}, was obtained from the slope ($-2.303k_{obs}$) of the plot of log ($C_\infty - C_t$) as a function of time t. The rate constant data in Table 1 are average values of two or more determinations which generally agreed to within 2–3%. For very slow reactions an initial rate method was employed wherein the tritium content of the water (C_t) was measured for only the first 3–5% of the reaction. A linear plot of C_t vs. t is obtained with slope equal to the zero-order rate constant (k_0). The first order rate constant k_{obs} for the slow reactions was obtained by dividing k_0 by the total radioactivity of the substrate (C_∞) obtained as before.

Potassium hydrogen phthalate and sodium borate buffers were used for kinetic measurements carried out at low and intermediate pH ranges, respectively, while sodium hydroxide solutions were used for measurements at higher pH values.

Results and discussion

Kinetic analysis and reaction mechanism

The results obtained for detritiation of [2-^{3}H]-1-methylimidazole in aqueous buffers at 85°C are listed in Table 1 and shown graphically in Fig. 1 in the form of a rate–pH profile for the pH range 2.5–11.5. Exchange rates in more basic media (pH > 11.5) were too fast to be reliably determined by the kinetic technique used.

The rate profile for 1-methylimidazole is similar to that obtained (10) for 1-methylbenzimidazole (Fig. 1) as well as for

TABLE 1. Rates of detritiation of [2-^{3}H]-1-methylimidazole as function of pH at 85.0 ± 0.2°C

pH at 85.0°C	$k_{obs} \times 10^4$ (s^{-1})	pH at 85.0°C	$k_{obs} \times 10^4$ (s^{-1})

7.70	30.3	11.51	34.5

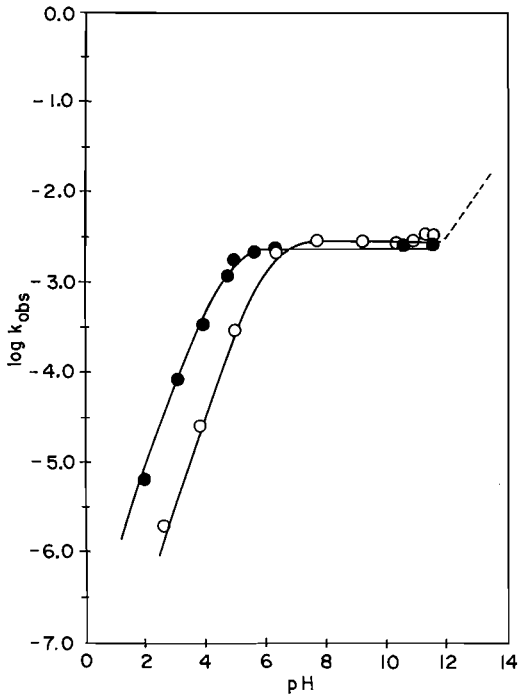

FIG. 1. Rate–pH profiles for the detritiation of [2-^{3}H]-1-methylimidazole ○ and [2-^{3}H]-1-methylbenzimidazole ●. The solid lines represent the theoretical profiles calculated from eq. [9] using the values from the text and the dashed line is the theoretical behaviour expected on the basis of eq. [5].

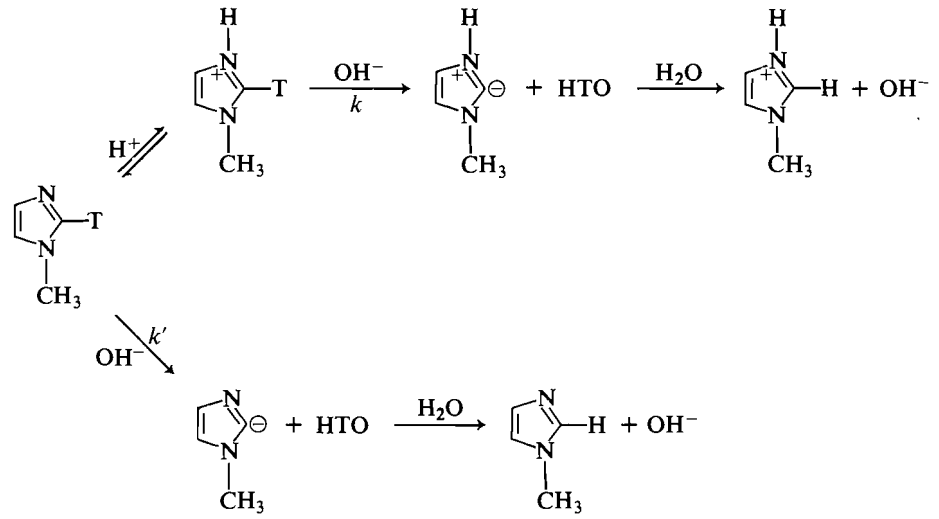
1-methylguanosine, 1-methylinosine (7), and 9-alkylpurines. Initially the rate increases with increasing pH until a pH-independent region is obtained, extending between pH 7 and 10. Such behaviour is consistent with a mechanism in which the conjugate acid of the substrate is being attacked by hydroxide ion in the rate determining step. At pH > 11 the rate increases again with increasing pH. This has been attributed to rate-determining attack by hydroxide ion on the neutral form of the substrate (Scheme 1). Though the rate of tritium exchange in more highly basic media (pH > 11.5) could not be determined, one would expect 1-methylimidazole to behave in a manner similar to that of the 9-alkylpurines (6), namely that the rate would increase with increasing pH. The expected behaviour is indicated by a dashed line in Fig. 1.

The rate expression for the isotopic exchange reaction over the entire pH region is given by eq. [1] from which eq. [2] follows,

$$[1] \quad \text{Rate} = k[\text{ImH}^+][\text{OH}^-] + k'[\text{Im}][\text{OH}^-] = k_{obs}[\text{Im}]_T$$

$$[2] \quad k_{obs} = (k[\text{ImH}^+] + k'[\text{Im}])[\text{OH}^-]/[\text{Im}]_T$$



SCHEME 1

where $[ImH^+]$ and [Im] represent the concentration of the protonated and neutral forms of 1-methylimidazole, respectively, k and k' are the corresponding second order rate constants, and k_{obs} is the pseudo-first order rate constant for the detritiation of [2-^{3}H]-1-methylimidazole. The $[ImH^+]$ and [Im] terms can be expressed by means of experimentally measurable quantities, i.e.

$$[3] \quad [ImH^+] = [Im]_T/(1 + K_a/[H^+])$$

$$[4] \quad [Im] = [Im]_T/(1 + [H^+]/K_a)$$

Now $[Im]_T = [ImH^+] + [Im]$, where $[Im]_T$ is the total concentration of 1-methylimidazole in solution. Also, the acid association constant of protonated 1-methylimidazole is given by $K_a = [Im][H^+]/[ImH^+]$. Substitution of eqs. [3] and [4] into [1] gives

$$[5] \quad k_{obs} = \frac{k[H^+][OH^-]}{K_a + [H^+]} + \frac{k'K_a[OH^-]}{K_a + [H^+]}$$

At low pH, $[H^+] \gg K_a$ and eq. [5] reduces to

$$[6] \quad k_{obs} = k[OH^-] + \frac{k'K_a[OH^-]}{[H^+]}$$

Since K_a is small, and at low pH, [OH] is small while $[H^+]$ is large, the second term can be neglected and eq. [7] follows.

$$[7] \quad k_{obs} = k[OH^-]$$

In accord with eq. [7], plotting k_{obs} versus $[OH^-]$ for the first three data points in Table 1 (pH 2.56–4.94) gave an excellent linear plot which yielded $k = 1.01 \times 10^4\ L\ mol^{-1}\ s^{-1}$ as the rate constant for deprotonation of the conjugate acid (Scheme 1). The rate constant k' corresponding to deprotonation of the neutral substrate is usually derived by plotting data in the high pH region (see eq. [5]) but this could not be evaluated in the present study as noted above.

At the intermediate pH values, corresponding to the plateau region in Fig. 1, $K_a \gg [H^+]$ and eq. [5] reduces to eq. [8], neglecting the second term.

$$[8] \quad k_{obs} = kK_w/K_a$$

Using the values of k ($1.01 \times 10^4\ L\ mol^{-1}\ s^{-1}$), k_{obs} for the pH-independent region ($2.95 \times 10^{-3}\ s^{-1}$) and K_w at 85°C (3.16×10^{-13}) (11), enables K_a for 1-methylimidazole to be estimated as $1.08 \times 10^{-6}\ mol\ L^{-1}$, i.e. $pK_a = 5.96$ at 85°C. The experimentally (12) determined pK_a value is ca. 7.2 at 25°C. Typical temperature coefficients (13) for nitrogen acids of similar acidities are $-0.022\ pK_a$ units per °C rise, and hence the experimental pK_a at 85°C should be 5.88. Extrapolation of pK_a versus temperature data (12) collected for 1-methylimidazole between 10 and 45°C suggests that the pK_a at 85°C for 1-methylimidazole is 6.09. These values are in good agreement with the calculated value from the rate data as given above.

The solid curve drawn for the 1-methylimidazole rate data in Fig. 1 is the result of calculating, for various $[H^+]$ values, theoretical k_{obs} values by means of eq. [9], using $k = 1.01 \times 10^4\ L\ mol^{-1}\ s^{-1}$, $K_w = 3.16 \times 10^{-13}$, and $K_a = 1.08 \times 10^{-6}\ mol\ L^{-1}$.

$$[9] \quad k_{obs} = kK_w/(K_a + [H^+])$$

Equation [9] is obtained from [5] assuming that the contribution from the hydroxide-catalyzed exchange of the neutral species is small and that the second term can hence be neglected. The agreement with the experimental data is satisfactory.

Reactivity relationships

One can compare the second order rate constant corresponding to the rate-determining attack of hydroxide ion on the conjugate acid of 1-methylimidazole with the corresponding rate constants previously reported for imidazole (9), benzimidazole (9, 10), and 1-methylbenzimidazole (9), Table 2. Thus inclusion of the results for 1-methylimidazole allows for a more complete discussion of the effect of methyl substitution and benzo annelation on proton transfer from heterocycles containing an imidazole nucleus. Substitution of N-1 of imidazole and benzimidazole with a methyl group causes the rate of proton transfer to increase by a factor of 2 and 3 respectively, while annelation of a benzo group to the imidazole and 1-methylimidazole nucleus results in a 10- or 20-fold rate increase, respectively (Table 2).

It is also noteworthy that substitution by a methyl group at the N-1 position of imidazole and benzimidazole has no effect on the magnitude of the pK_a for N_3-protonation, i.e. a pK_a value of 6.0 was found for both imidazole and 1-methylimidazole, while a pK_a value of 4.6 was found for both benzimidazole and 1-methylbenzimidazole. On the other hand, benzo annelation

TABLE 2. Comparison of pK_a and rate constants derived from rate–pH profiles for imidazole (Im); benzimidazole (ϕIm) and their 1-methyl derivatives

Compound	pK_a	k ($L\ mol^{-1}\ s^{-1}$)	k_{Me}/k_H	$k_{\phi Im-X}/k_{Im-X}$ (X = Me or H)
Imidazole (**1**, H)	5.9	6.0×10^3	2	10 (X = H)
1-Methylimidazole (**1**, Me)	6.0	1.0×10^4		20 (X = Me)
Benzimidazole (**2**, H)	4.6	6.2×10^4	3	
1-Methylbenzimidazole (**2**, Me)	4.6	2.0×10^5		

does have a substantial effect on the pK_a, which decreases by 1.3 pK units for both imidazole and 1-methylimidazole.

An interesting point in these systems is that they lack a saturation effect, that is, the effect of methyl substitution on the rate of C(2)–H exchange, is not diminished by benzo annelation ($k_{MeIm}/k_{Im} = 2$ and $k_{Me\phi Im}/k_{\phi Im} = 3$). Conversely the effect of benzo annelation on the rate of C(2)–H exchange is not reduced by methyl substitution ($k_{\phi Im}/k_{Im} = 10$ and $k_{Me\phi Im}/k_{MeIm} = 20$).

Conventional arguments, such as those based on the inductive effect of the methyl substituent, do not suffice to explain reactivity diferences in these systems. For example, a methyl group acting as an inductively electron-releasing substituent would be expected to destabilize the ylid intermediate and thereby lead to a rate decrease, whereas the opposite is found to be the case. However, Jones and co-workers (3*a*, 11) showed that there is a linear correlation between log k, the second order rate constant for C-2 proton exchange in azoles, and pK_a for N_3-protonation, which is adhered to by imidazole and benzimidazole. We have found that frontier molecular orbital (FMO) theory provides an explanation of reactivity in the series imidazole, benzimidazole and their 1-methylated analogs, as described below.

FMO analysis of reactivities

The effect of benzo annelation and methyl substitution on the rate of proton transfer from these imidazole derivatives can be rationalized by means of the FMO approach (14, 15). We consider the rate-determining step of the reaction and apply FMO theory to obtain the relative energies of the reacting species and of the intermediates involved, as a result of the structural change which is effected.

Thus considering the exchange process as involving abstraction of the C(2)-hydrogen from the reactant species (R), i.e., the protonated substrate, to form the ylid intermediate (I), one can dissect the reactant and intermediate into fragments whose FMOs are known and estimate the relative intramolecular stabilization energies resulting from interaction of the LUMO of one fragment with the HOMO of the other. The magnitude of the stabilization energy (SE) is dependent on the difference in energy between the HOMO and LUMO of the respective fragments; the smaller the energy gap, the greater the orbital overlap and the greater the stabilization energy. In this system, the degree of stabilization increases significantly in going from the reactant to the intermediate, because of the much smaller energy gap and the consequent enhanced LUMO/HOMO interaction present in the latter. If a structural change results in greater stabilization of the intermediates as compared to the reactants, then an increase in rate is expected since the transition state should also be stabilized on effecting the structural change.

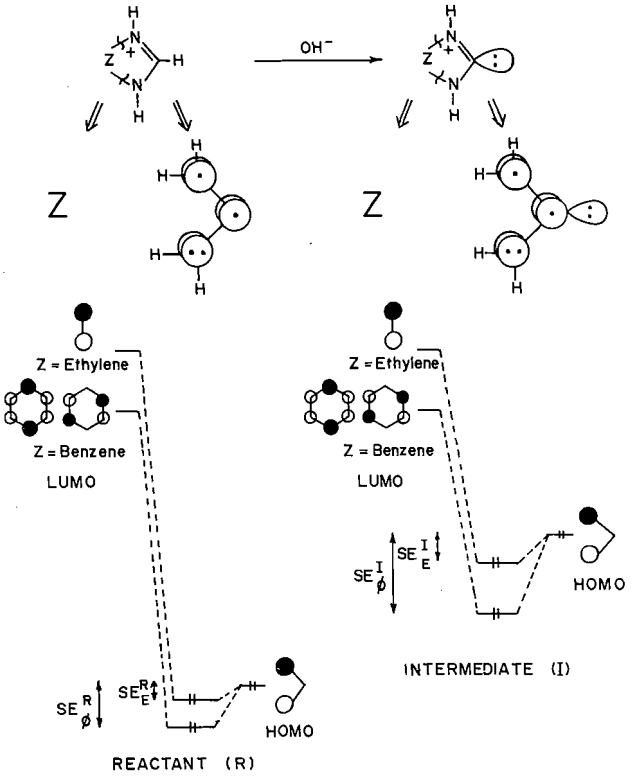


FIG. 2. FMO analysis of the effect of benzo annelation on proton transfer from imidazole showing the interaction between the HOMO of the allyl fragment and the LUMO of ethylene or benzene fragments for the reactant (R) and intermediate (I).

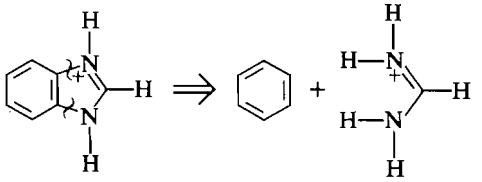
1. Effect of benzo annelation

The FMO analysis of the reaction scheme for benzimidazole and imidazole is shown in Fig. 2. The relative energies of the FMOs of the two reactant species and their corresponding intermediate structures can be estimated by fragmenting the molecules into two moieties whose FMOs are known. Thus benzimidazole is dissected into a benzene and a pseudo allyl fragment;



while imidazole is fragmented into an ethylene and the pseudo allyl fragment:

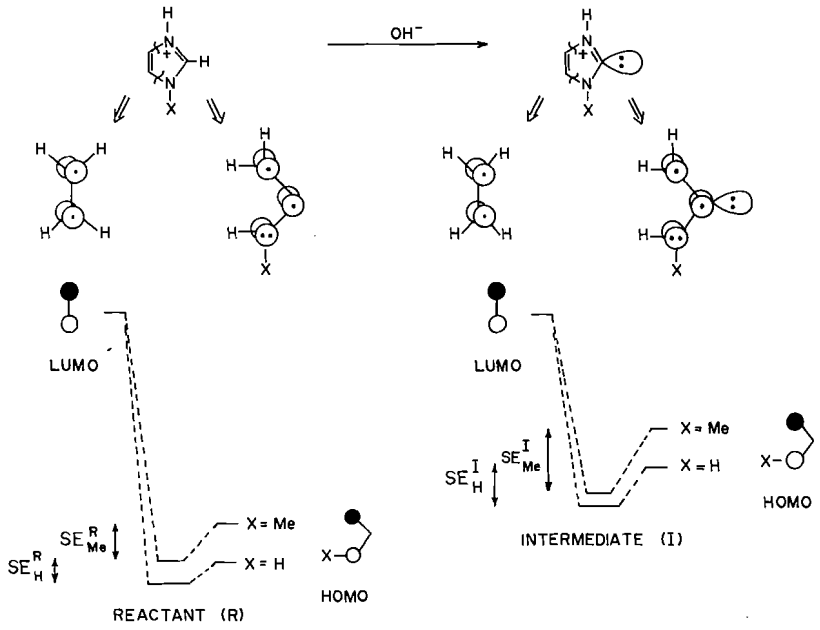


FIG. 3. FMO analysis of the effect of 1-methylation on proton transfer from imidazole.

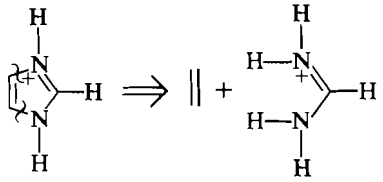

The same procedure is followed for the intermediate structures. This is shown in Fig. 2 with Z corresponding to benzene or ethylene.

The LUMOs of benzene and of ethylene are allowed to interact with the HOMO of the allyl fragment, resulting in molecular orbitals for the benzimidazole and imidazole reacting species, and similarly for the intermediate structures. The relative energies of the LUMOs of ethylene and of benzene can be estimated from the respective electron affinities ($E_{LUMO} = -EA$), which have the values -1.78 and -1.15 eV as determined from electron transmission spectroscopy (16, 17). It follows that greater orbital interaction results between the LUMO of benzene and the HOMO of the allyl fragment, as compared with the corresponding interaction between the ethylene (LUMO) and allyl (HOMO) fragments. The differential stabilization energy for the two reactant species is $\delta SE^R = SE^R_\phi - SE^R_E$, where SE^R_ϕ and SE^R_E are the stabilization energies for the benzene and ethylene cases.

Considering the intermediate structures, the energies of the HOMOs can be taken as corresponding to the ionization potentials (15), i.e. $E_{HOMO} = -IP$. One would expect the energy required to remove an electron from a molecule RH to be much greater than that from the deprotonated species R^-. For example, the first ionization potentials of CH_4 and $CH_3{:}^-$ are 12.99 and 1.08 eV, respectively (18, 19). This would imply that the HOMO of the deprotonated fragment must be significantly higher in energy than that of the parent allyl fragment. The consequent smaller energy gap between the HOMO of the deprotonated allyl fragment and the LUMO of ethylene, or the LUMO of benzene, leads to greater orbital interaction and thus enhanced stabilization in the intermediate structures relative to the reactants. The differential stabilization energy for the two intermediate structures, $\delta SE^I = SE^I_\phi - SE^I_E$, is thus greater than for the reactant species, i.e. $\delta SE^I > \delta SE^R$.

It follows from the above that the transition state for reaction of the benzo annelated reactant will be of lower energy compared to the parent imidazole, thus accounting for the increased reaction rate. A similar analysis can be performed for 1-methylimidazole vs. 1-methylbenzimidazole, which would account for the reactivity difference between these two substrates in an analogous fashion.

2. Effect of methyl substitution

To account for the effect of methylation at N-1 of imidazole and benzimidazole on the rate of C(2)–H exchange, we examine the effect of methyl substitution on the energy of the HOMO of the allyl and the deprotonated allyl fragment. The relative energies of the HOMOs of the allyl and 1-methylallyl fragments is afforded through comparison of the ionization potentials (20) of methylamine (8.97 eV) and dimethylamine (8.24 eV), as well as of methyl (9.95 eV) and ethyl (8.78 eV) radicals (21, 22). Thus the introduction of a methyl group is associated with a decrease in ionization potential, which indicates that the energy of the HOMO for the 1-methylallyl fragment in our system is higher than that for the unsubstituted allyl fragment, in both the reactant and the intermediate.

The FMO analysis for methyl substitution in imidazole is shown in Fig. 3. For the reactants, the orbital interaction is between the ethylene (LUMO) and the allyl (HOMO) fragment for imidazole, as compared with the corresponding interaction between the ethylene (LUMO) and the 1-methylallyl (HOMO) fragments for 1-methylimidazole. The energy of the HOMO for X = Me is greater than for X = H, which results in a greater stabilization energy for the methyl case. The differential stabilization energy for the two reactants is given by $\delta SE^R = SE^R_{Me} - SE^R_H$.

In the intermediate structures, the orbital interactions are now between an ethylene (LUMO) fragment and the deprotonated allyl (HOMO) fragment for imidazole, and between ethylene and deprotonated 1-methylallyl for 1-methylimidazole. The HOMO energies in the intermediates will be significantly higher

than in the reactants, following the argument as applied in Fig. 2. The differential stabilization energy for the intermediates, $\delta SE^I = SE^I_{Me} - SE^I_H$, is hence greater than in the reactants, i.e. $\delta SE^I > \delta SE^R$. The change in structure from X = H to X = Me will hence lead to an intermediate of lower energy. The transition state for the process should thus be stabilized, accounting for the increase in rate on methyl substitution. A similar argument would apply to the case of benzimidazole versus 1-methylbenzimidazole.

Thus FMO analysis provides a satisfactory explanation of relative reactivities in these series of substrates. To our knowledge, this is the first application of FMO theory to reactivity differences in such processes.

Surface photochemistry: the photolysis of α-methoxy acetophenones on silica gel[1]

PAUL DE MAYO AND N. RAMNATH
Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 22, 1986

PAUL DE MAYO and N. RAMNATH. Can. J. Chem. **64**, 1293 (1986).

The photolysis of α-methoxy acetophenones **1***a*–**1***e* adsorbed on silica gel show a significant deviation from the course of reaction in methanol. The results are discussed in terms of conformational control and restricted movement of the radical through adsorption on silica gel. Factors affecting the efficiency of modification of photochemical reactivity on silica gel surface have been examined.

PAUL DE MAYO et N. RAMNATH. Can. J. Chem. **64**, 1293 (1986).

On a effectué la photolyse des α-méthoxy acétophénones **1***a*–**1***e* adsorbées sur du gel de silice; les résultats obtenus diffèrent grandement de ceux obtenus lorsque la même réaction a été réalisée dans du méthanol. On discute des résultats en fonction du contrôle conformationnel et de la restriction du mouvement des radicaux par adsorbtion sur le gel de silice. On discute des facteurs affectant l'efficacité de la modification de la réactivité photochimique sur une surface de gel de silice.

[Traduit par la revue]

Introduction

Specificity in organic reactions is of considerable interest to the synthetic chemist and any general technique by which the course of a reaction may be modified is worthy of attention. We have examined, with this purpose in mind, the way the fact of adsorption of a molecule on a silica gel surface may alter its photochemistry (1–5).

The silica gel surface is composed of siloxane and silanol functional groups. The silanol groups, which may be isolated, vicinal or geminal, are not uniformly distributed. These groups constitute the principal sites for the adsorption of organic molecules on the silica gel surface (6, 7). Electrostatic interactions (8), dispersion forces (11), and hydrogen bonding (8–10) which result in heats of adsorption of 8–40 kJ/mol are assumed to be the forces responsible for the adsorption. In general, the degree of adsorption is a function of the polarity of the organic molecule as well as the activity of the silica gel (12).

It has been shown earlier that adsorption on silica gel imposes constraints on the movement of both closed-shell molecules (1, 13) and radical pairs (14–18). That such constraints lead to a significant deviation of the course of benzoin methyl ether, **1***d*, when adsorbed on a silica gel surface has also been demonstrated (3). In this paper we describe the Norrish type I and II photochemical reactions of variously substituted α-methoxy acetophenones **1***a*–**1***e*. The choice of the substrates was motivated by the desire to study the generality and degree of conformational control and restricted movement that can be brought about through the use of silica gel.

Results

Silica gel irradiations were carried out by tumbling degassed samples in Pyrex tubes before a 450-W medium pressure mercury lamp. The results from silica gel irradiations were compared with the photochemical behaviour of the corresponding ketones in a hydroxylated solvent, viz. methanol, chosen because its polarity approaches that of silica gel (19, 20). The product distributions are shown in Table 1.

Scheme 1 outlines the possible reaction pathways and products thereof. The ketones react by way of a triplet excited $n\pi^*$ state which leads to a triplet radical pair (Norrish type I) to give type I products **4**–**8** and/or a 1,4-biradical intermediate by virtue of a γ-hydrogen abstraction (Norrish type II) to give products **9** and **10**.

Compounds **1***a* and **1***b* react exclusively via the type II pathway in solution and give the corresponding products **9** and **10**. Irradiation on silica gel does not lead to any significant change in the nature of products other than a marginal decrease in percentage cyclization. On the other hand α-disubstituted ketones **1***c*–**1***e* react primarily via the type I pathway. Irradiation in methanol leads almost exclusively to type I products with a very small percentage of type II products ($< 4\%$) which decreases even further at lower temperatures. Photolysis on silica gel leads to a pronounced change in the course of the reaction.

Irradiation of **1***c* in methanol yields type I products, benzaldehyde and benzil. Other products with very low retention times, presumably derived from the 2-methoxy propyl radical, were also observed. Type II products isobutyrophenone and the oxetanol are formed to the extent of $\sim 1\%$. On silica gel, type II products rise nearly ten-fold at 25°C and to nearly 17% at −50°C.

Irradiation of **1***d* and **1***e* in methanol leads to a number of α-cleavage products with a small percentage of products contributed to by the type II process. The major product in either case is the corresponding pinacol ether (*dl* and *meso*) derived from geminate pair escape and combination. Benzaldehyde and benzyl methyl ethers are formed in varying amounts. Rearrangement of the radical pair gives **8**, **1***d*, and **1***e* although the amount formed in solution is very small for the latter. Photolysis on silica gel leads to a significant difference. The amount of type II reaction increases to approximately 10% and the rearranged radical pair combination products **8***d* and **8***e*, respectively, are formed more efficiently, especially in the latter case.

The mass balance in all the above cases is not entirely satisfactory. Reasons for this have been described in the Experimental section.

Discussion

The results obtained bring out the generality of conformational reactions and constraints imposed on adsorbates/radical intermediates upon adsorption on silica gel, albeit in a limited way.

Based on earlier studies (3) this work was aimed at testing the generality of two main features of the consequences of

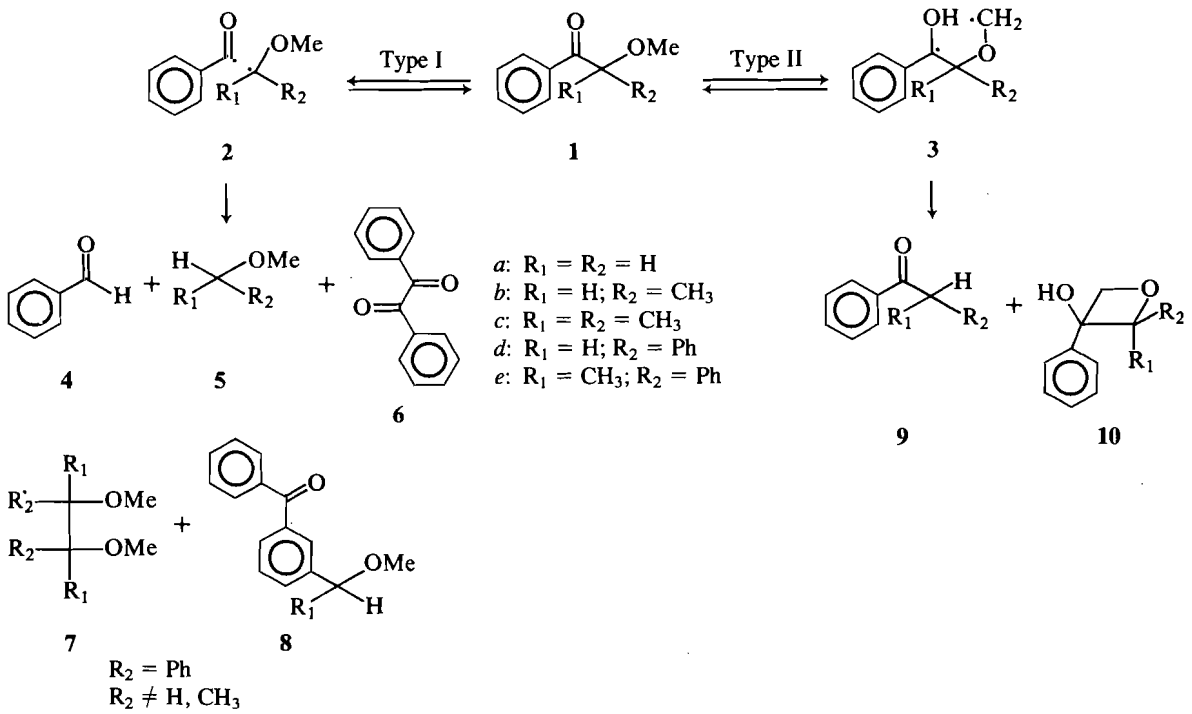
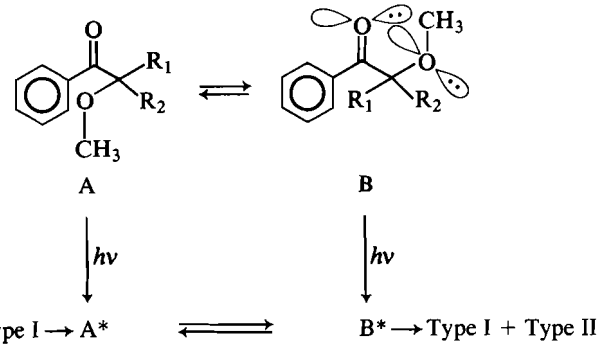


SCHEME I

adsorption on silica gel. (*i*) Restriction of translational movement in radical pairs to permit other forms of recombination. (*ii*) Modification of photochemical reactivity by bringing about a change in conformation through hydrogen bonding forces.

Restriction in translational movement of radical pairs is evident in the reaction of **1***d* and **1***e* with the increased formation of the rearranged product **8***d* and **8***e*, respectively, and a decrease in the formation of the pinacol ethers. In **1***d*, at lower temperatures, the pinacol ethers become minor products while **8***d* is the major rearranged product (3). This has been interpreted as an indication of the suppression of translational motion in the radical pair **2***d*, but not of their rotational motion.

The ketones **1***a*–**1***e* were chosen by virtue of their ability to exist as, at least, two possible conformers. Owing to nonbonded interactions of the electron pairs on the oxygen atoms, the ketones may undergo anomerization (21) in solution so as to



SCHEME 2

exist in the transoid form **A** rather than the cisoid form **B** (Scheme 2).

Lewis and co-workers (22) have examined aspects of conformational control on the photochemical behaviour of α,α-dimethylvalerophenone, α-methyl cyclopentyl- and cyclohexylphenyl ketone. They found that photochemical reactions of cyclohexyl phenyl ketone are more rapid than ring inversion and as a consequence, product compositions are determined by ground state conformational populations (Case I). On the other hand, bond rotations in acyclic ketones are more rapid than photochemical reactions, in which case product compositions are determined by relative rates of the competitive photoprocesses rather than conformational populations (Case II). In the present investigation, adsorption of ketones **1***a*–**1***e* on silica gel could shift the equilibrium in favor of **B** (Scheme 2) owing to hydrogen bonding to the oxygen atoms and the phenyl groups. In such a case an increase in type II products would be expected. The extent of deviation of the course of reaction may depend on whether Case I or Case II operates on the adsorbed ketones.

Results show an encouraging increase in type II products on silica gel in the case of compounds **1***c*–**1***e*. However, type I α-cleavage reactions continue to be more efficient than the type II reactions for these compounds. This indicates that, conformational changes notwithstanding, product compositions are still determined by relative rates of the competitive α-cleavage and γ-hydrogen abstraction processes (Case II) as in solution. Compounds **1***a* and **1***b* react almost exclusively via the type II pathway whereas **1***c*–**1***e* undergo efficient α-cleavage. The rate of α-cleavage is related to the stability of the radicals produced. For different molecules of similar structure, the more stable the radical pair produced by α-cleavage, the faster is the absolute rate constant for reaction (23). Since stability of radicals increases with substitution, the rates for α-cleavage increase with increasing α-substituents. Thus, in solution, the rate constants for α-cleavage should increase from **1***a*–**1***e* with a net decrease in type II reaction. Rate constants for type II reactions of **1***a* and **1***b* are in the order of $10^9\ s^{-1}$ (24). Exclusive type II reaction in these cases has been attributed to the absence of α-methylphenyl eclipsing interactions which permits a favorable conformation for γ-hydrogen abstraction (25). Similarly, it has been observed in the case of *exo*-2-benzoyl-2-norbornane and *exo*-2-benzoyl-2-methylnorbornane that the former undergoes γ-hydrogen abstraction to undergo photoelimination while the latter undergoes efficient α-cleavage (26). This has also been attributed to the presence of eclipsing 1,2-methylphenyl interactions that retard γ-hydrogen abstraction. Thus radical stability as well as 1,2-eclipsing interactions may influence competitive α-cleavage and γ-hydrogen abstractions in solution.

1*d* and **1***e* undergo very efficient α-cleavage. Lewis *et al.* (24) have found that α-cleavage of **1***d* is a rapid process with a rate constant $\sim 10^{10}\ s^{-1}$. Type II reactions for these ketones have not been observed in solution before and were not expected to compete with the α-cleavage of benzoin ethers (24). However, we have observed type II products in solution to the extent of ~4% thus suggesting that rates of type II reaction must be smaller than that of **1***a* ($\sim 10^9\ s^{-1}$). The increase in type II products of **1***c*–**1***e* on silica gel indicates the influence exerted on the competitive α-cleavage and γ-hydrogen abstraction as a consequence of adsorption on silica gel.

Reasons for this change could be partly attributable to a change in the conformation of the ketone to one more favorable for γ-hydrogen abstraction and/or greater stabilization of the 1,4-biradical on silica gel as compared to conditions in solution. The increase in type II products could thus be due to an increase in the efficiency of type II product formation. Conversely, increased formation of type II products may occur because of a decrease in the efficiency of α-cleavage product formation. This decrease could arise because of the restrictions imposed on the translational motion of radicals on silica gel leading to more efficient cage recombination of the radicals resulting from α-cleavage. This increase in cage recombination is shown by the increasing amounts of the rearranged product **8**. This process will not affect the efficiency of α-cleavage or the rate of α-cleavage but merely decreases the efficiency of formation of geminate pair escape products, thus increasing the probability for type II reaction. In the absence of any kinetic parameters and quantum yields of these processes on silica gel (because of the experimental problems involved in devising methods for such measurements under the conditions involved), it is not possible to distinguish clearly between the factors that affect the reactivity of these ketones. For these reasons, this phenomena remains far from predictable. Turro *et al.* (27) have recently described the elegant use of diffuse reflectance laser flash photolysis to measure the lifetimes of some aryl alkyl ketones adsorbed on silica gel. These measurements reveal an increase in the lifetimes of these ketone triplets and has been attributed to restrictions in the accessibility of the conformations required for intramolecular hydrogen abstraction as a result of binding to the silica gel surface. Such measurements for the ketones described in this paper may shed valuable information on the phenomena described here.

Experimental

Silica gel (Merck 60, 35–70 mesh) was used for all experiments. Baker analyzed spectrograde solvents were used. Infrared spectra were recorded on a Beckman IR 4250 and proton nmr spectra were recorded on a Varian XL-200 (MHz) spectrophotometer. Gas chromatography was carried out on Varian 3700 (2 m × 2 mm glass column packed with 3% OV-101 on 80/100 mesh Chromosorb W-HP) fitted with flame ionization detectors and using a Hewlett-Packard 5890 A integrator. Irradiations were carried out with a 450-W medium pressure mercury lamp housed in a Pyrex sleeve.

Preparation of ketones

Compound **1***a* was obtained commercially (Aldrich, 95%) and purified to ~99% purity by fractional distillation. Compounds **1***b* (28) and **1***c* (29) were prepared by the reaction of 2-methoxypropionitrile (28) and 2-methoxyisobutyronitrile (30), respectively, with phenylmagnesium bromide. Compounds **1***d* and **1***e* were prepared by the method of Fisher (31) and Heine (32), respectively. All ketones were purified by column chromatography on silica gel and (or) vacuum distillation prior to use. **1***d* was purified by recrystallization from benzene–ether. All the synthesized compounds had ir, nmr, and uv spectra consistent with the assigned structures.

Irradiations

Photolysis in solution: 0.05 *M* methanolic solutions of the ketones were purged with nitrogen and irradiated to 20–35% conversion of the starting material. Larger conversions did not affect the product ratios significantly. The products of the reaction were estimated by gas chromatography using the appropriate internal standards (C_{11}–C_{16} *n*-alkanes).

Photolysis of silica gel samples: Silica gel samples containing, typically, 20 mg per g of silica gel (5–10% coverage) and were prepared as described in earlier reports (1, 4) in Pyrex cylinders. The cylinders were rotated horizonally on their long axis during irradiations. Conversions were held at 20–35%. After completion of irradiation the products were extracted with 5% methanol in chloroform and estimated by gas chromatography as before.

Identification of products

The identity of all compounds other than **10***a*–**10***e* was confirmed by coinjection with authentic samples that were either obtained commercially (**4**, **6**, **5***d*, and **9***a*–**9***c*) or synthesized (**5***e*, **8***d*, **9***d*, **9***e*, and **10***d*) or isolated from the reaction mixture (**7***d*, **7***e*, **8***e*, and **10***a*). The oxetanols were formed in very small yields and were tentatively identified by comparing the glc retention time patterns with those of the isolated **10***a* and synthesized **10***d*, respectively. Although this may lead to a degree of error, it is not likely to affect the conclusions darwn by virtue of their low yields.

Material balance

As mentioned earlier, the mass balances are not entirely satisfactory. Undetected low molecular weight compounds resulting from α-cleavage and subsequent radical termination reactions, combination or cleavage reactions to form low boiling ethers, alkanes, and alkenes could be a major reason. Although formation of other compounds could be detected by low temperature glc, their estimation and identification proved to be inconsistent and cumbersome and were therefore not attempted.

To investigate proton transfer processes in non-aqueous media, two procedures have been developed of general applicability for the measurement of detritiation rates of carbon acids. One method is a variation of an existing solvent extraction procedure but with inclusion of a trace of trifluoroacetic acid, while the other involves the simple modification of a gas chromatograph so as to function as a radio-gas chromatograph. They have been established by studying the detritiation of [2-$^3H_1$]diethyl malonate in six different solvents (dimethylformamide, dimethyl sulfoxide, sulfolane, hexamethylphosphortriamide, tetrahydrofuran, ethanol) as catalyzed by various heterocyclic bases (substituted pyridines, imidazoles, benzimidazoles, pyrrole, pyrazole, purine, adenosine). The results are discussed in terms of solvation effects and catalyst structure. An approximate Brønsted correlation is found to exist between log k_B^T for detritiation determined in DMSO and the pK_a of the conjugate base measured in water at 25°C.

J. P. DAVEY, J. R. JONES et E. BUNCEL. Can. J. Chem. **64**, 1246 (1986).

Dans le but d'étudier les processus de transferts protoniques dans des milieux non-aqueux, on a développer deux méthodes d'application générale pour mesurer les vitesses de détritiation d'acides carboniques. Une des méthodes est une variation d'une procédure existante d'extraction par les solvants impliquant l'inclusion d'une trace d'acide trifluoroacétique; par ailleurs, l'autre implique une modification simple d'un chromatographe en phase gazeuse de façon à le faire fonctionner comme une chromatographe en phase gazeuse radio. On a établi la validité de ces méthodes en étudiant la réaction de détritiation du malonate de diéthyle [$^3H_1$-2] qui a été effectuée dans six solvants différents (diméthylformamide, diméthylsulfoxyde, sulfolane, hexaméthylphosphoretriamide, tétrahydrofuranne et éthanol) et catalysée par diverses bases hétérocycliques (pyridines substituées, imidazoles, benzimidazoles, pyrrole, pyrazole, purine, adénosine). On discute des résultats en fonction d'effets de solvatation et de structure du catalyseur. On a trouvé qu'il existe un corrélation approximative de Brønsted entre le log k_B^T pour la réaction de détritiation effectuée dans le DMSO et le pK_a de la base conjugée, mesuré dans l'eau, à 25°C.
[Traduit par la revue]

Proton transfer from one atom to another is a fundamental process in chemistry, present in the elementary steps of many reactions (1). In acid, base and enzyme catalyzed reactions, proton transfer between catalyst and substrate is often a key step in the mechanism (2, 3). In many organic reactions in particular, proton transfer from carbon plays a central role and has led to an appreciation of the factors governing the kinetic and thermodynamic properties of carbon acids (4, 5). However, despite an awareness of the importance of the solvent in proton transfer reactions (6) this is a relatively unexplored area. This may be due in part to the fact that the most widely used method of measuring the rates of such reactions, namely halogenation, cannot be readily adapted to non-aqueous conditions.

Hydrogen isotope exchange is particularly suited for studying proton transfer from carbon acids under a variety of conditions, for example as catalyzed by acids, bases and metal ions (7–12), but in the past such investigations have also been largely limited to aqueous media. In this paper we report on the development of two procedures which have general applicability for measurement of detritiation rates of carbon acids in non-aqueous media.

The first method is a variation of an existing extraction procedure with the difference that the exchange is carried out in the presence of a trace amount (0.01% v/v) of trifluoroacetic acid. This addend serves as a source of exchangeable protium in the system (*vide infra*), but does not alter the properties of the solvent to a measurable degree.

[1]Hydrogen exchange studies, Part 16: for Part 15, see ref. 12.

The second procedure takes advantage of the fact that commercial gas chromatographs usually have two flame ionisation detectors, a variable post-column splitter and dual pen recorder, and by attaching a second electrometer capable of measuring currents down to 10^{-12}–10^{-14} A, it is possible to use the second ionisation chamber as a radiation detector (13). Such a simple modification converts the instrument to a radio-gas chromatograph with good sample throughput, ideal for measuring the decrease in the tritium radioactivity of a labelled carbon acid. This method is particularly useful when no satisfactory solvent extraction procedure is available.

Both procedures have been established through investigating the detritiation of [2-$^3H_1$]diethyl malonate, which was previously studied only in aqueous media. In the present study, six different solvents have been employed, namely dimethylformamide (DMF), dimethyl sulfoxide (DMSO), sulfolane, hexamethylphosphortriamide (HMPT), tetrahydrofuran (THF), and ethanol. The catalysts used are heterocyclic nitrogen bases, namely substituted pyridines, imidazoles, benzimidazoles, pyrrole, pyrazole, purines, and adenosine. Because a solvent extraction procedure could be established for all the different solvent systems, the large majority of the experimental results were obtained using the first procedure.

Experimental

Materials

Stringent precautions were employed to ensure high solvent purity and the elimination of water from the experimental systems. Sulfolane

Printed in Canada / Imprimé au Canada

was purified by heating the solvent (2 L) to 210°C in the presence of polyethylene sulfone (20 g) and anhydrous potassium fluoride (10 g); the mixture was then stirred for 24 h under a constant stream of dry nitrogen so as to remove any volatile impurities prior to distillation under reduced pressure. Dimethyl sulfoxide was partially frozen, the remaining liquid decanted off, and the solvent distilled under reduced pressure before storing over Linde type 4A molecular sieve. Dimethylformamide was stored in a similar manner prior to distillation under reduced pressure. Tetrahydrofuran was refluxed over lithium aluminum hydride prior to distillation and storing over calcium hydride. Ethanol was refluxed in the presence of magnesium turnings and iodine for 3 h before the fraction that distilled at 78.4°C/760 mm was collected.

All the organic bases used, with the exception of 6-aminobenzimidazole, were obtained commercially and their purity checked prior to use; this compound was prepared by the catalytic hydrogenation of 6-nitrobenzimidazole using a 5% Pd/C catalyst in methanol.

Tritiation procedure

Diethyl malonate was tritiated by adding freshly distilled material (1 mL) to a small ampoule containing sodium carbonate (0.3 g) and dioxane (0.5 mL); after adding tritiated water (5 μL, 50 Ci mL^{-1}) the ampoule was sealed and left at room temperature for 72 h. The tritiated substrate was isolated by extraction into chloroform (10 mL), which was washed with water (10 mL) and dried over anhydrous Na_2SO_4. After removing the solvent by carefully passing N_2, the tritiated product was taken up in a small volume (100 μL) of $CDCl_3$, a trace of internal standard (TMS) was added and the sample subjected to both ^1H and ^3H nmr analysis.

Kinetic measurements

Method 1

To a known volume (usually 50 mL) of the base solution thermostatted in a constant temperature bath at 50.0°C was added 5 μL of trifluoroacetic acid followed by 10 μL of a stock solution of the labelled diethyl malonate. At given time intervals, aliquots (2 mL) of the solution were withdrawn and injected into tubes containing 10 mL of 0.1 *M* hydrochloric acid and 10 mL of liquid scintillator (3.4 gL^{-1} of 2,5-diphenyl oxazole in toluene). After shaking, most of the toluene layer was extracted and dried over anhydrous Na_2SO_4 before counting 5 mL samples on a Beckman LS 100 scintillation counter. Normally the reaction was followed to more than 90% completion. The rate constants k^T obtained from the plots of $\log_{10}$ (radioactivity) against time (slope = $-2.303k^T$) agreed to within ± 2–3%; dividing k^T by the base concentration (usually in the range 10^{-1}–10^{-3} *M*) gave the second-order rate constant (k_B^T).

In the case of hexamethylphosphortriamide at 50°C there was evidence of catalysis by the solvent. For this reason the results reported for this solvent are limited to 25.0°C.

Method 2

For the radio-gas chromatography procedure (13) the main differences were that the radioactivity of the diethyl malonate was some 10–100 times higher and that the volume of reaction mixture was some ten times smaller than in the solvent extraction method. As mentioned previously the advantage of the method is that it is no longer dependent on our ability of achieving a satisfactory extraction procedure; it is only required to quench the reaction (using 0.1 *M* HCl), inject a sample into the radio-gas chromatograph, and integrate the diethyl malonate radioactivity signal. In the present investigation a 10% OV17 on chromosorb 80–100 mesh column at an oven temperature of 145°C was employed.

In both methods 1 and 2 the base concentration was varied at least ten-fold. In the case of imidazole catalysis where both methods were used the k_B^T values were 0.0224 ± 0.0005 for the solvent extraction procedure and 0.0220 ± 0.001 for the radio-gas chromatographic method.

Results and discussion

Investigation of proton transfer processes in non-aqueous media, while offering insight on solvation effects, also brings into focus the nature of the base to be used for proton abstraction. There is clearly less emphasis on the use of the lyate ion of the solvent compared with hydroxylic media, although work by Bordwell (14, 15), Ritchie (16), and Streitwieser (17, 18) in particular, has shown that the use of the methylsulfinyl anion and the cyclohexylamide anion in dimethyl sulfoxide and cyclohexylamine, respectively, has given forth a wealth of information on kinetic and thermodynamic acidities of carbon acids. However, it appears much less probable that comparable investigations would be undertaken in solvents such as DMF, HMPT, or THF with their lyate ion counterparts. One is hence led to investigate the efficacy of all types of bases when studying proton transfer in non-aqueous media. The goals of such studies will be to determine kinetic and thermodynamic acidities of carbon acids in different media, and to obtain information on inherent properties of the bases, unmasked by solvent effects, thus to improve the understanding of solvent effects on proton transfer processes.

In this first study, we have chosen to investigate the catalytic properties of a range of heterocyclic nitrogen bases, in various solvents, for the abstraction of the acidic proton from diethyl malonate.

The heterocyclic bases were chosen partly as a result of a parallel interest in the kinetic acidities of the C-2(H) proton in compounds such as the imidazoles and benzimidazoles (12, 19) and the equivalent C-8(H) position in purines, and partly because of the opportunity they afforded of investigating structural factors not frequently made available in this kind of study. Thus imidazole, benzimidazole, purine, and pyrrole are all examples of π-excessive N-heteroatoms where the nitrogen is in an electron releasing environment (=CH—NH—CH=). In pyrrole, however, the nitrogen atom contributes its lone pair of electrons to the π-system, completing an aromatic sextet, and

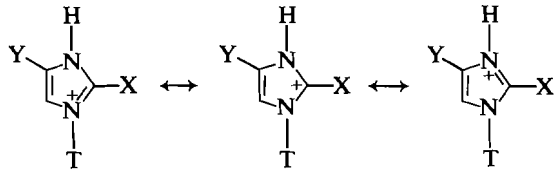
[a]Refers to the structurally similar 2,4-dimethylimidazole.

thus rendering the substance only very weakly basic. The pyridines, on the other hand, are examples of π-deficient heterocycles; here nitrogen has dual character, attracting π-electron density from the ring while making available an unshared electron pair towards a proton.

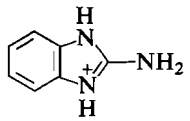
The results on the detritiation of [2-$^3H_1$]diethyl malonate in DMSO are given in Table 1. Analysis of these results reveals the following trend in kinetic basicities: imidazole > benzimidazole > pyridine > pyrazole > pyrrole, purine. However, within each group there are considerable rate variations. Thus in imidazole itself methyl substitution can lead to both rate retardation and rate acceleration, an observation that can be accounted for in the following way. In dimethyl sulfoxide the protonated base formed will be highly solvated and the insertion of electron donating groups X and Y at C-2 and C-4 will stabilise the charge to some degree via the resonance contributions **1***b* and **1***c*:



1*a* **1***b* **1***c*

This would lower the transition state energy for proton abstraction, leading to an increase in reaction rate. On the other hand, bases containing an —N—H group will be highly coordinated to the sulfoxide oxygen, so that N-alkylation will remove this mode of stabilisation, leading to a rate reduction even though the substituent may be electron donating. This would explain why the rate for 1-methylimidazole is lower than that for the parent compound, opposite to what is expected on the basis of pK_a data in water. It would also explain the less than expected rate enhancement for 1,2-dimethylimidazole as well as for 1-benzyl-2-methylimidazole compared with 2-methylimidazole. Steric hindrance in approach of the base (F-strain) is probably the main factor causing the slow rate for 2,4,5-triphenylimidazole.

Introduction of an amino group in both benzimidazole and purine has an accelerating effect, possibly because the amino group is itself able to act as the base in proton abstraction. An alternative possibility[2] is that of a guanidine-like structure whose high basicity is the result of a stabilized conjugate acid, i.e.,



2

No detritiation of the substrate was observed with the π-excessive bases pyrrole and purine, and to this list can be added indole, thymidine, and uridine.

It is interesting that an approximate Brønsted correlation exists between log k_B^T and pK_a (H_2O, 25°C) for the twelve bases for which pK_a data are available, despite the fact that k_B^T refers to DMSO and K_a to the aqueous state. The graph (Fig. 1) covers some 5 pK_a units and only the points for adenine and adenosine deviate significantly. This suggests that any solvation

[2]The authors thank a referee for this suggestion.

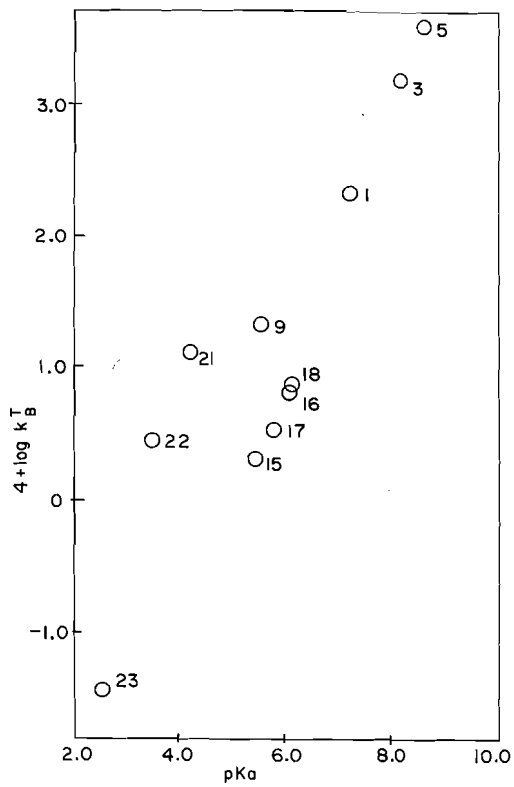


FIG. 1. Brønsted plot for detritiation of [2-$^3H_1$]diethyl malonate by heterocyclic bases: k_B^T values in DMSO at 50°C, K_a values in H_2O at 25°C (Table 1).

type arguments will hold for both media. More importantly, the observation of a Brønsted correlation is in accordance with the proposal that proton transfer is the rate-determining step.

Results on the variation of solvent in detritiation of diethyl malonate using the four imidazole-type bases are given in Table 2. It is seen that the rates vary within relatively narrow limits on solvent change, though the highest rate is generally observed in DMSO. Also noticeable is the regular trend observed for each catalyst, with the possible exception of 1-methylimidazole in tetrahydrofuran, the solvent with the lowest dielectric constant. In this case the possibility of some kind of association causing the unusually low rate cannot be ruled out.

The detritiation of diethyl malonate by the heterocyclic bases represents a reaction between two neutral molecules and hence differential effects of solvents would be expected to be at a minimum, as is borne out in the present investigation. Nevertheless it is somewhat surprising that the vastly different properties of some of the solvents, such as dimethyl sulfoxide, tetrahydrofuran, and ethanol, is not reflected in a wider range of rates.

The reaction mechanism followed in this hydrogen isotope exchange must differ from what operates in hydroxylic media leading to regeneration of base and unlabelled carbon acid, since solvents such as THF contain no exchangeable hydrogen. Radio-gas chromatographic analysis of a reaction mixture showed that the only radioactive peak present not arising from the diethyl malonate originated from the trifluoroacetic acid. Consequently we favour the following scheme in which the trifluoroacetic acid acts as the proton donor towards the carbanion formed on triton abstraction, generating unlabelled carbon acid and the neutral base via the equilibria in reactions [2] and [3]:

TABLE 2. Rate data for detritiation of [2-$^3H_1$]diethyl malonate with imidazole-type catalysts in various solvents at 50.0°C[a]

Base	Solvent					
	DMSO	DMF	Sulfolane	HMPT[b]	THF	EtOH
Imidazole	(224)[a]	(132)[a]	(89.8)[a]	(48.1)[a]	(108)[a]	(145)[a]
	1.00	1.00	1.00	1.00	1.00	1.00
1-Me imidazole	0.53	0.40	0.18	0.20	.057	0.46
2-Me imidazole	7.5	6.68	7.10	8.11	7.43	4.50
2-Et, 4-Me imidazole	19.6	15.0	13.4	15.8	8.44	8.14

[a]The data given in parentheses are the actual $10^4 k_B^T$ values (M^{-1} s^{-1}) for imidazole catalysis at 50°C (25°C for HMPT). The remaining data are the relative rate constants with respect to imidazole as the reference standard.
[b]At 25.0°C, the extrapolated rate constant for imidazole catalysis at 50°C being 164×10^{-4} M^{-1} s^{-1}.

[1] $RT + B \rightarrow R^- + BT^+$

[2] $R^- + CF_3COOH \rightleftharpoons RH + CF_3COO^-$

[3] $CF_3COO^- + BT^+ \rightleftharpoons CF_3COOT + B$

It is emphasized that the addition of only a trace quantity of trifluoroacetic acid (0.01% v/v) is required, since the substrate is present in extremely small concentration and the properties of the solvent medium are thereby unchanged. The kinetic data thus provide a valid measure of the solvent effect on the proton transfer (10, 13).

The four diones derived from benzo[*a*]pyrene oxidation have been characterized by high-field nuclear magnetic resonance techniques including 2-D COSY and selective nuclear Overhauser enhancement. All the proton chemical shifts for these four quinones have been uneqivocally assigned. The direct photoxidation of benzo[*a*]pyrene gives a product distribution very similar to the TPP photosensitized oxygenation, suggesting singlet oxygen is involved in the former. A major product, which was characterized as the 6-seco derivative **6** and not previously reported, was detected in the singlet oxygen reaction. The presence of this product suggests a possible mechanism for quinone formation in the singlet oxygen reaction. One-electron oxidations of benzo[*a*]pyrene were carried out using tris(*p*-bromophenyl)aminium hexachloroantimonate and quenching of the radical cation with superoxide or water. The product distribution in this case was quite different from that obtained in the direct photooxidation.

E. LEE-RUFF, H. KAZARIANS-MOGHADDAM et M. KATZ. Can. J. Chem. **64**, 1297 (1986).

Utilisant des techniques de résonance magnétique nucléaire à haut champ, y compris des techniques de COSY en 2D et d'effet Overhauser nucléaire sélectif, on a caractérisé les quatre diones qui sont obtenues par oxydation du benzo[*a*]pyrène. On a pu attribuer sans équivoque les déplacements chimiques de tous les protons de ces quatre quinones. La photo-oxydation directe du benzo[*a*]pyrène conduit à une distribution de produits qui est très semblable à celle qui est obtenue par oxygénation photo-sensibilisée par le TPP; ceci suggère qu'un oxygène singulet est impliqué dans le premier cas. Lors de la réaction effectuée sous l'influence de l'oxygène singulet, un produit majeur est le dérivé séco-6 **6** qui n'avait pas été rapporté antérieurement. La présence de ce produit suggère un mécanisme possible pour la formation de la quinone lors de la réaction effectuée sous l'influence de l'oxygène singulet. On a effectué des oxydations mono-électroniques du benzo[*a*]pyrène en faisant appel à l'aminiumhexchloroantimonate de tris(*p*-bromophényle) et en piégeant le radical cation par du superoxyde ou de l'eau. La distribution des produits qui résultent de cette réaction est très différente de celle qui est obtenue par photo-oxydation directe.

[Traduit par la revue]

Introduction

The presence of environmental polynuclear aromatic hydrocarbons (PAH) has been of great concern due to the toxicities as carcinogenic initiators exhibited by a number of these derivatives (1). Various oxidized species have been implicated as being responsible in the molecular binding with vital biopolymers such as DNA, proteins, and polysaccharides (2). Benzo[*a*]pyrene (BaP) (**1**) is a classical example of such PAHs. It has been well established that epoxides and diol epoxides, metabolites of this derivative, bind with DNA to form stable adducts and are responsible for the mutagenic activity. Certain peroxidase systems are also known to catalyze the oxygenation of BaP to a mixture of quinones. Whereas most of the metabolic studies on BaP have focussed on the 7,8-epoxide and 7,8-diol-9,10-epoxide, interest in the oxidation to the 1,6- 3,6- and 6,12-quinones has recently picked up (3) as the result of the observation that these quinones themselves exhibit moderate mutagenic activity (4). The 3,6- and 6,12-benzo[*a*]pyrene quinones are as active as the classical mutagen 3-methylcholanthrene and a little less active than the parent BaP. Recently, Tso and co-workers (5) have shown that all three quinones caused degradation of DNA and that this process is oxygen dependent. Electron spin resonance (esr) studies have shown that the semiquinones of these derivatives covalently bind to DNA and polyglutamic acid (6). Katz and co-workers have shown that the three benzo[*a*]pyrene quinones are also produced by oxidation of BaP adsorbed on cellulose acetate plates and on glass under simulated environmental conditions (7, 8) involving a high-intensity visible light source. In these studies, the half-life of BaP was found to be 5 h, significantly more inert than benzo[*a*]anthracene.

Introduction of ozone to the system led to a marked rate enhancement of BaP decomposition, leading to the same mixture of quinones. Recently, Eisenberg *et al.* (9) have obtained evidence that certain PAHs sensitize production of singlet oxygen under environmental conditions and that the oxidation of these PAHs, including BaP, involves the self-sensitized singlet oxygenation of these compounds (10). However, to our knowledge, no systematic study of the singlet oxygen reaction of BAP has been reported. We undertook a study of the oxidation of benzo[*a*]pyrene, under photosensitized singlet oxygen production as well as the use of one-electron oxidations, to establish whether singlet oxygen is responsible for the photooxidation process. Furthermore, we report that the photooxidation and photosensitized singlet oxygenation of BaP produces a major product that has not been previously reported, and which suggests a possible mechanism for quinone production by singlet oxygen reaction. Heretofore, the structures of three isomeric 1,6-, 3,6-, and 6,12-benzo[*a*]pyrene diones **2–4** were all assigned by comparison of uv and mass spectra with "authentic" material obtained from chromium trioxide oxidation of BaP based on an early literature report (11) that predates nmr spectroscopy. Neither uv nor mass spectrometry represent absolute molecular structure characterization methods and, in order to confirm the original structural assignments, we carried out a detailed structural analysis of the above-mentioned three quinones, as well as 4,5 BaP quinone, based on ^{1}H 2-D COSY and selective nOe (nuclear Overhauser enhancement) nmr studies.

Results

Confirmation of benzo[a]pyrene quinone structures by high-field nuclear magnetic resonance studies

The mixture of 6,12-, 1,6-, and 3,6-benzo[*a*]pyrene diones (**2–4**) was prepared according to an early literature procedure (11). The mixture was separated on a dry column of flash-grade silica gel. The order of elution according to previous reports is

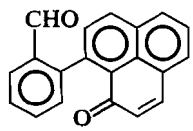
2, followed by **3** and **4**. All three compounds were obtained as crystalline materials with identical melting points, as reported. Of the three quinones, only the 6,12-dione **2** had been prepared by independent synthesis (12). We have repeated this synthesis and the product obtained was identical in all respects with the faster eluting component in the dione mixture. Benzo[*a*]pyrene-4,5-dione **5** was also prepared by literature methods (13, 14) for comparison with products obtained in the oxidation studies of BaP. The confirmation of structures of all four benzo[*a*]pyrene diones **2–5** was established by the mapping of all vicinally coupled and proximal protons by a combination of the 2-D COSY and selective nOe difference spectroscopy methods (15) and checking for self-consistency. In this manner, all of the proton nmr chemical shifts for each of the isomers **2–5** have been unequivocally established and listed in Table 1 and the original structural assignments have now been confirmed. One feature of note is that bay-region hydrogen signals (H-11, H-10), which appear at lowest field in benzo[*a*]pyrene **1**, are shifted to higher fields by about 0.5–0.7 ppm in the four quinones. This can be rationalized in terms of decreasing ring current effects brought about by the decrease in π-electron density in the quinones. The lowest-field signals in the nmr spectra appear to be for those protons at the *peri* position relative to the carbonyl groups. The sensitivity of the high-field nmr method now permits analysis of trace photooxidation products of PAHs by an absolute method. (The sensitivity of the uv–visible spectrometric analysis still exceeds the nmr method by at least two orders of magnitude; however, the latter is limited by the reliance of authentic material for comparison purposes.)

Oxidation studies of benzo[a]pyrene

It has been suggested that the environmental oxidation of PAHs proceeds via self-sensitized singlet oxygen reaction (16). Evidence for gas-phase singlet oxygen formation using heterogeneous gas-phase photosensitization involving PAHs has been obtained from trapping experiments with known singlet oxygen scavengers such as 9,10-diphenylanthracene (9). To establish that singlet oxygen is involved in the direct photooxidation reaction and to elucidate the mechanism of quinone formation, we analyzed and compared the product distribution of the direct photooxidation with those derived from photosensitized singlet oxygen reaction using the common sensitizers, tetraphenylporphyrin (TPP) and methylene blue. Furthermore, it has been suggested that certain reactions involving singlet oxygen proceed via electron transfer processes involving superoxide O^-_2. To establish whether such a mechanism operates in the photooxidation of benzo[*a*]pyrene, we prepared the benzo[*a*]pyrene radical cation by reaction of BaP with tris(4-bromophenyl)aminium hexachloroantimonate and subjected the radical cation to reaction with potassium superoxide. The product distribution was compared with those of the direct photooxidation and photo-sensitized singlet oxygen reaction.

The direct photooxidations of BaP were carried out in one of two ways: aerated benzene solutions of **1** (10^{-3} *M*) were irradiated with an uv source (450-W medium-pressure Hg lamp) using a Pyrex filter (>300 nm). Alternatively, aerated solutions of **1** (10^{-3} *M*) in $CHCl_3$ were irradiated using a visible light source (500 W) with a Pyrex filter. The only products in the uv irradiations are the diones **2–4** with a small amount of product having the identical hplc (high performance liquid chromatography) retention time as the 4,5-dione (**5**). Infrared and nmr spectral comparisons of this minor product with authentic 4,5-dione **5** showed that the two were not identical. The uv data of this minor product were also not compatible with those of an 11,12-benzo[*a*]pyrene dione (17) and no further attempts at identifying this compound were made. The product mixture obtained from irradiation with visible light consisted of the three quinones **2–4** and a *major product that constituted 48% of this mixture*. This product was identified as the 6-seco-benzo[*a*]pyrene derivative **6** and has not been previously



6

$(4\text{-}BrC_6H_4)_3N^{\cdot+}SbCl_6^-$

7

reported in benzo[*a*]pyrene photooxidations. This assignment was based on high-field nmr 2-D COSY correlations, which indicate a vicinal proton coupling system very similar to benzo[*a*]pyrene; however, a low-field proton at 9.7 ppm assigned to the aldehydic C-6 proton was found to be long-range coupled to the C-7 proton. Furthermore, the unusually shielded C-5 proton at 6.5 ppm is characteristic of the α-proton (next to carbonyl) in phenalenones (18). The uv spectrum of this compound was similar to that of phenalenone. Further confirmation of this assignment was obtained from comparison of spectral data with those reported for the same compound obtained in 0.03% yield from the oxidative γ-radiolysis of benzo[*a*]pyrene (19).

In addition, the hplc chromatogram showed the presence of nonpolar components (20%) that could not be resolved. This nonpolar fraction was analyzed by mass spectrometry and showed parent ions corresponding to dimethylbenzo[*a*]pyrenes. Evidence for this suggestion was obtained from experiments in which the photooxidation was performed in CH_2Cl_2 in place of $CHCl_3$ and noticing the absence of this nonpolar fraction. The use of chloroform as a photolysis medium could result in methylation of PAHs by free-radical or cationic pathways. Up to 65% quenching of the oxidation occurred in the presence of 1 equiv. of DABCO (1,4-diazabicyclo[2.2.2]octane), implying presence of $^1O_2$ as the reactive species. The photosensitized oxidation was carried out using either TPP or methylene blue. A filter had to be used for selective excitation of the sensitizer. The filter chosen was a chemical filter solution (21) consisting of $CuSO_4$ and $NaNO_3$ in ammonium hydroxide with a transparent window between 405 and 520 mm. Benzo[*a*]pyrene **1** showed a weak tail-end absorption in this region. Using a 2-cm path width of filter solution, the direct photooxidation of **1** proceeds at 1/20

†Balance consisted of only unreacted BaP.

of the rate in the absence of the filter. This was used as the control for the photosensitized oxygenation experiments. TPP exhibits strong absorption at 416 mm so that, using the filter assembly, the sensitizer (TPP) absorbs greater than 95% of the light. Methylene blue, on the other hand, has a maximum absorption at 610 mm; however, this band extends into the filter window. In both instances the photosensitized oxygenation rate was at least twice as fast as that in the absence of photosensitizer. The product mixture consisted of the nonpolar fraction obtained in the direct photooxidation, a mixture of the diones **2**–**4**, and the seco product **6**. The relative yields of the products are listed in Table 2.

The one-electron oxidation of benzo[*a*]pyrene was carried out using the oxidant tris(4-bromophenyl)aminium hexachloroantimonate **7**. When a chloroform solution of benzo[*a*]pyrene **1** was added to a solution of **7**, an instant rose-coloured mixture was developed. This species was attributed to the radical cation of **1**. The uv–visible spectrum exhibited peaks at 450 and 560 mm. The radical cation of **1** was reported to show a peak at 450 mm (20). In air, the coloured solution faded after a few minutes. The coloured species was instantly quenched with water. It was also quenched by addition of powdered potassium superoxide. In each case, the reaction mixture consisted of the three quinones, with no detectable trace of the seco product **6**. The product distributions of the quinone mixture obtained in all of the oxidations are listed in Table 2.

Discussion

The possibility that PAHs can sensitize singlet oxygen formation has been aptly demonstrated by Eisenberg *et al.* (9). On energetic grounds (see Fig. 1) both the first excited singlet as well as the triplet states of benzo[*a*]pyrene **1** can result in singlet oxygen formation by energy transfer by mechanisms shown in Scheme 1. The lifetimes of both excited states of **1** permit bimolecular collisions with oxygen to take place for energy transfer and it has been shown for other PAHs that fluorescence and phosphorescence can be quenched by oxygen.

In other readily reducing aromatic derivatives, it has been suggested that singlet oxygen reactions occur by way of single electron transfer processes involving PAH radical cation formation (22). Electron transfer from BaP to either singlet (Δg) or ground state oxygen would be endoergonic and not likely to

$$\mathrm{BaP} \xrightarrow{h\nu} \mathrm{BaP}^1$$

$$\mathrm{BaP}^1 + {}^3\mathrm{O}_2 \longrightarrow \mathrm{BaP}^3 + {}^1\mathrm{O}_2$$

$$\mathrm{BaP}^1 \longrightarrow \mathrm{BaP}^3$$

$$\mathrm{BaP}^3 + {}^3\mathrm{O}_2 \longrightarrow {}^1\mathrm{O}_2 + \mathrm{BaP}^1$$

$$\mathrm{BaP} + {}^1\mathrm{O}_2 \longrightarrow \text{reaction products}$$

SCHEME 1

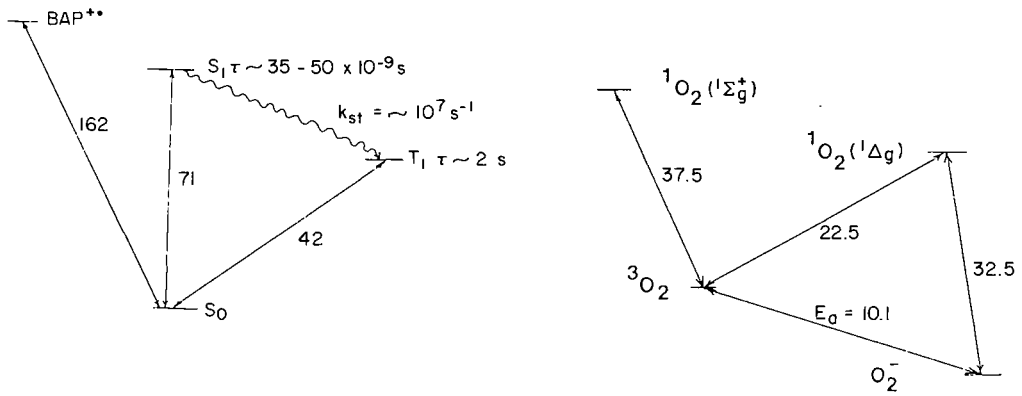

FIG. 1. Excited states of BaP and O_2 (29, 30; see also ref. 26); numbers are in kcal/mol.

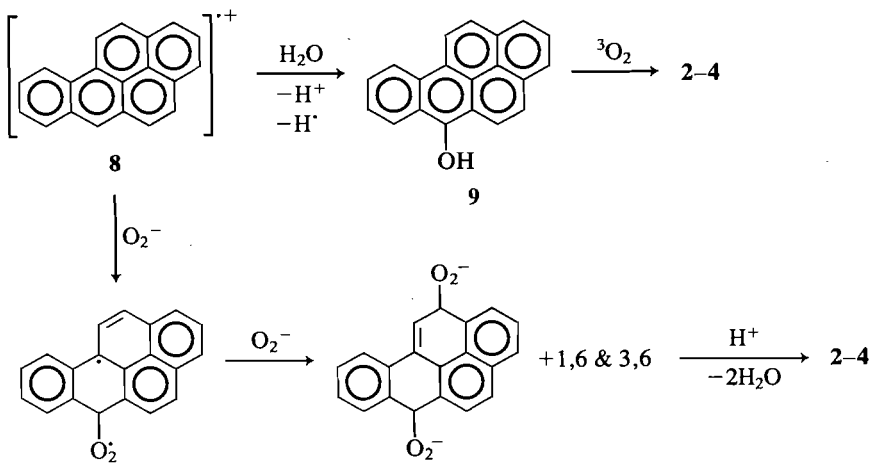
occur on the basis of the high ionization potential of BaP (162 kcal/mol) (23). Similar consideration even for the excited states of BaP would preclude electron transfer to oxygen. To test this, we have shown that the *BaP radical cation, generated independently, reacts with superoxide or water to give a significantly different product distribution* (see Table 2). The 6,12-dione in this case is formed only as a minor product. These relative yields are very similar to ones reported for the electrochemical oxidation of BaP (24). Greenstock and Ruddock have reported that neutral BaP reacts with superoxide generated by pulse radiolysis (25). In our hands, mixtures of BaP with KO_2 were found to be stable indefinitely. It is likely that under conditions of pulse radiolysis, ionization of **1** to the radical cation takes place and that the decomposition of BaP with O_2 takes place by way of this radical cation. The direct photooxidation of BaP **1** produces a mixture that is similar to one obtained from the TPP sensitized oxidations in which the 6,12-dione **2** and seco product **6** predominate. Evidence that the direct photooxidation proceeds via singlet oxygen was shown from DABCO quenching and the trapping of diphenylanthracene-9,10-peroxide when diphenylanthracene, a known singlet oxygen quencher, was added to the photomixture.

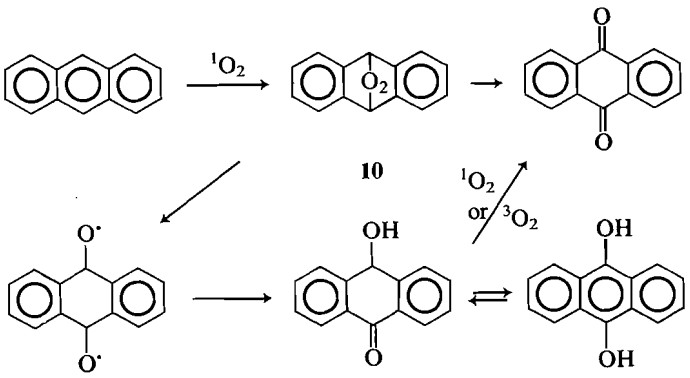
The different product distributions observed in the one-electron and photooxidations of BaP suggest that two fundamentally different mechanisms operate in quinone formation in the two reactions. Adams has suggested (24) that quinone formation by way of electrochemical oxidation proceeds through the intermediacy of the radical cation **8**, which, in aqueous solution, is trapped by water leading to 6-hydroxy BaP **9**. Further oxidation by way of the corresponding oxyradical leads to the mixture of quinones (Scheme 2). Formation of the quinones from reaction of the radical cation with superoxide could proceed by nucleophilic trapping at position 6 and formation of dihydroperoxides. These dihydroperoxides, under basic conditions, could conceivably rearrange to the diones.

It is interesting that the enzymatic oxidation of 6-hydroxybenzo[*a*]pyrene using rat liver homogenates has been reported to produce a mixture of diones **2–4** with a distribution almost identical to one we obtained from the one-electron oxidation of **1** and subsequent quenching with water (28).

The formation of diones from singlet reaction of arenes is believed to proceed via the intermediacy of *meso*-endoperoxides, which represent Diels–Alder adducts of singlet oxygen (26). This is illustrated by the example of anthracene, which undergoes cycloaddition with singlet oxygen to produce the *meso*-peroxide **10**. Formation of 9,10-anthraquinone from the peroxide could involve homolytic O—O bond cleavage and subsequent rearrangement to the half-oxidized hydroquinone **11**. Further oxidation to the dione could be initiated either by ground state or singlet oxygen. The formation of diones **2–4** from benzo[*a*]pyrene is unlikely to involve a mechanism as described above. It would be unlikely for a peroxo bridge to span the 6,12, 1,6, and 3,6 centers. The formation of the seco derivative **6** as the major product in the singlet oxygen reaction of benzo[*a*]pyrene suggests that a dioxetan **12** or perepoxide **13** is involved in the formation of this product. Such an intermediate may also be responsible for quinone formation. It is conceivable that these intermediates could lead to the zwitterion

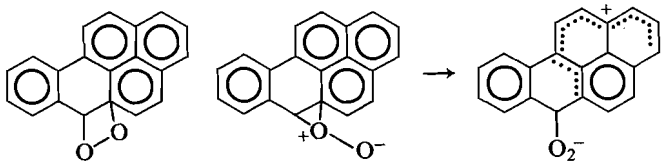


SCHEME 2



SCHEME 3

13. Subsequent trapping of this species by water and further oxidation could lead to the observed quinones. It is interesting that the relative amount of seco derivative **6** and the quinones is dependent on the rigour to which the solvent has been subjected in drying.



Conclusion

Structures of the three major isomeric diones **2–4** formed from benzo[*a*]pyrene **1** oxidation have been confirmed by 2-D COSY and selective nOe nmr techniques. The relative distribution of diones is markedly dependent on the nature of the oxidation. One-electron oxidation of benzo[*a*]pyrene using tris(4-bromophenyl)aminium hexachloroantimonate as a one-electron oxidant produces exclusively a mixture of diones **2–4** with **3** predominating and **2** present as a minor component. On the other hand, direct photooxidation or photosensitized oxgenation of **1** produces a mixture of diones with dione **2** as the major product. Another major product identified as the seco derivative **6** was isolated in these reactions. The presence of **6** suggests a mechanism involving a dioxetan or perepoxide as the probable precursor to diones **2–4** under conditions of singlet oxygen reaction. It is interesting to note that biochemical systems in which singlet oxygen has been implicated catalyze the oxidation of BaP to give a similar mixture of diones as reported by us for the direct or photosensitized oxidations. Marnett *et al.* (27) have reported that **1** is oxidized by sheep seminal vesicals arichodonate-dependent system to a mixture of diones **2–4** with a relative distribution of 45:25:35. On the other hand, oxidation of **1** by rat-liver homogenate (28) (cytochrome dependent) produces a dione mixture **2–4** with relative yields 5:41:44, which is similar to our observed product distribution from the one-electron oxidation. Oxidized cytochromes contain complexed ferric ions that would initiate one-electron oxidation processes with aromatic derivatives with sufficiently low oxidation potentials.

The environmental analysis of benzo[*a*]pyrene is complicated by its oxidation to the diones **2–4** during sampling. In our study we find that a new major product **6** is also present in simulated environmental oxidations. Thus a complete analysis of environmental benzo[*a*]pyrene would have to include analysis of diones **2–4** as well as aldehyde **6**.

Experimental

Benzo[*a*]pyrene and tris(4-bromophenyl)aminium hexachloroantimonate were obtained from Aldrich.

Dry column chromatography was performed with silica gel, Merck Kieselgel 60, 230–400 mesh ASTM, deactivated with water (15% w/w). High performance liquid chromatography (hplc) was carried out with a Waters Associate chromatography equipped with a Model 6000A pump, a model U6K injector, and a model 440 absorbance detector set at 254 nm. A Waters straight-phase μ-Porasil column (3.9 mm × 30 cm/10 μm) was used with a mixture of hexane and chloroform as the mobile phase.

The diones **2–4** were prepared according to the literature and their separation was carried out using dry column chromatography with chloroform as the eluant. The 6,12-dione **2** was first to elute, followed by the 1,6 and 3,6 isomers **3** and **4**, respectively. The purity of the individual fractions was tested by hplc and their retention times are: 6,12-dione **2**, 8.78 min; 1,6-dione **3**, 13.43 min; 3,6-dione **4**, 15.21 min.[3]

Benzo[*a*]pyrene-4,5-dione (**5**) was synthesized according to literature methods (13, 14). The uv and mass spectra data of **2–5** were in good agreement with those reported in the literature.

The nmr acquisitions were performed on a Brüker AM-300 spectrometer.

Selective nOe and 2-D COSY acquisitions

The Brüker pulse sequence 90_{PH1}–t_1–90_{PH2}–F1D(t_2) was used for the 2-D COSY experiment with a 1K × 1K array of data points. The sweepwidth was restricted to the aromatic region 900 Hz. The 2-D plot allows the correlation of vicinally coupled protons. The selective nOe experiments were carried out using a decoupler power of 45–50 L and a decoupler pulse approximately equal to the longest proton T_1 (7 s) to ensure maximum saturation and polarization transfer. The nOe enhancements ranged from 3–15% with bay-region protons exhibiting the largest effects. In all cases a marker proton was established (H-11 in **2**, H-2 in **3**, H-2 in **4**, and H-6 in **5**) and bay-region as well as *peri* relationships of protons determined by this method.

Photooxidation reactions

General: All photooxidations were performed in glass-distilled solvents in Pyrex tubes equipped with a gas purger.

For the uv radiations, the tube was strapped around a quartz cooling well and the assembly was placed in an ice-water bath. A Pyrex inner filter was used and a Hanovia 450-W medium-pressure lamp served as the light source. Dry oxygen was bubbled through the solution during the photolysis.

For the visible light irradiation, the sample tube was placed in the inner well of the cooling vessel. A GE 500-W quartzline lamp was used as the light source and placed exterior to the photolysis assembly. Irradiations with a chemical filter solution were run using a concentric tube placed in the interior of the cooling well, which was filled with a Cu^{+2} ammonia complex solution (21).

Ultraviolet irradiation of benzo[a]pyrene (1)

A solution of 30 mg (0.12 mmol) of **1** in 120 mL AnalaR benzene was irradiated for 16 h with the uv assembly. The solvent was removed under reduced pressure and unreacted **1** was separated using a silica gel column, employing a 50:50 mixture of hexane:benzene as the eluant. The reaction was 60% complete based on the recovery of unreacted benzo[*a*]pyrene. The photomixture was eluted off the column (18 mg) and reapplied on another silica gel column. The quinone mixture of **2–4** (16 mg) was separated and characterized by uv, mass spectroscopy, and 1H nmr, which were identical with authentic samples. The hplc analysis of the product mixture gave the following distribution: 34.6% 6,12-dione **2**, 8% of yellow crystalline material, 21.4% of 6,1-dione **3**, and 24.0% of 3,6-dione **4**. The remaining 11.4% consisted of thirteen

[3]The response of all four diones was identical to within 2% when standard solutions were analysed.

minor components. The unidentified crystalline material, which had the same retention time as the 4,5-dione **5**, exhibited different ^1H nmr and mass spectra. No further attempt was made to characterize this compound.

Visible light irradiation of 1

A solution of 10 mg of **1** (0.039 mmol) in 80 mL of chloroform was photolyzed using a visible light source for 48 h. The solvent was removed and the residue applied to a dry column of silica gel. The unreacted **1** (3.5 mg) was eluted with 50:50 hexane:benzene mixture and the photomixture was eluted with chloroform (6.4 mg). The hplc analysis (90:10 *n*-hexane:chloroform; 1.3 mL/min) indicated the following distribution: 25% of nonpolar unidentified material (ms, $M^+ + 2CH_2$), 11% of **2**, 9.4% of **3**, 5.5% of **4**, and 24.0% of secobenzo[*a*]pyrene derivative **6**. The remaining 23.7% consisted of fourteen minor components. The isomeric quinones **2–4** and seco derivative **6** were separated by dry column chromatography, further purified by hplc, and subjected to spectral analysis. The ir, uv, and ^1H nmr data for **6** were identical to those reported by Gibson and Smith (19). The quinones exhibited identical spectral data with those of the authentic samples.

When the photolysis was carried out in CH_2Cl_2 under identical conditions as above, the nonpolar fraction was absent as evident by hplc. The reaction mixture consisted of 15.8% of **2**, 16.1% of **3**, 15.5% of **4**, and 13.5% of **6**. The remaining 39.1% consisted of at least ten minor components.

Triethylene diamine (DABCO) quenching studies

A solution of 10 mg of **1** in 80 mL of $CHCl_3$ containing 10 mg of DABCO was irradiated with the visible light source for 48 h. The usual work-up yielded 2.7 mg of photooxidized products and hplc analysis showed a reduction of 50% of each of the quinones **2–4** and 60% of the seco product **6**.

9,10-Diphenylanthracene trapping experiment

A solution of 20 mg of diphenylanthracene and 5 mg of **1** in 80 mL of $CHCl_3$ was irradiated for 24 h using the visible light source and the inorganic filter solution. In addition to quinone **2–4** formation, a new product identified as the 9,10-diphenylanthracene peroxide was isolated and its structure confirmed by comparison of its ir spectrum with that of an authentic sample. A control experiment without benzo[*a*]pyrene present was carried out under identical conditions and, in this case, no detectable amount of the peroxide was obtained. The photomixture consisted only of unreacted starting material, by tlc analysis.

Photosensitized oxidation of benzo[a]pyrene (1)

A solution of 10 mg of **1** and 5 mg of methylene blue in 80 mL of $CHCl_3$ was irradiated with the visible light source for 48 h using the inorganic filter solution. After separating unreacted **1** from the photomixture, continued elution with $CHCl_3$ on a silica gel column gave a mixture which was analyzed by hplc (60:40 hexane:$CHCl_3$; 1 mL/min). The following distribution of products was observed: 11.6% (4.45 min) unidentified, 9.5% (4.64 min) unidentified, 7.2% 6,12-dione **2** (8.78 min), 15.1% 1,6-dione **3** (12.97 min), 13.2% 3,6-dione **4** (14.34 min), and 19.8% 9-(2-formylphenyl)phenalenone **6** (18.78 min). The remaining 23.6% consisted of ten minor components.

In a control experiment, in the absence of methylene blue, no seco derivative **6** was detected. Only trace amounts of **2–4** were detected, along with the two less polar components.

The above experiment was repeated with tetraphenylporphyrin as the photosensitizer under identical conditions. A 20% conversion to photooxygenated products was observed by hplc analysis, with the following distribution: 40% nonpolar dimethylated material, 7.5% 6,12-dione **2**, 5.6% 1,6-dione **3**, 6.5% of 3,6-dione **4**, and 35% of seco derivative **6**.

Oxidation of benzo[a]pyrene (1) with tris(4-bromophenyl)aminium hexachloroantimonate and quenching with O_2^-

To a solution of 20 mg of benzo[*a*]pyrene in 50 mL of dry CH_2Cl_2 was added slowly a solution of 65.2 mg of tris(4-bromophenyl)aminium hexachloroantimonate in 50 mL of dry CH_2Cl_2. The solution turned to a rose-purple colour. To this solution was added a suspension of KO_2 in dry CH_2Cl_2, at which point the colour changed to a yellow solution. The solution was stirred for 3 min and poured over crushed ice. The organic layer was separated and washed with 3 × 30 mL of 10% HCl, followed by 3 × 30 mL of water, and dried over magnesium sulphate. The solvent was removed under reduced pressure and the residue was applied to a dry silica gel column. The unreacted benzo[*a*]pyrene (5 mg) was eluted with 50:50 hexane:benzene mixture. Following elution with $CHCl_3$ the quinone fraction **2–4** (15 mg) was obtained; hplc analysis showed the following distribution: 3.4% of 6,12-dione **2**, 54.3% of 1,6-dione **3**, and 42.3% and 3,6-dione **4**. No other peaks were observed by hplc.

In a control experiment, no reaction was observed between KO_2 and benzo[*a*]pyrene in the absence of tris(4-bromophenyl)aminium hexachloroantimonate.

Repetition of the above experiment, using water instead of KO_2 as the quenching agent, led to 2.85 mg (12.6%) conversion to quinones **2–4**. The balance of the mixture was unreacted **1**. The hplc of the oxidation mixture showed the following distribution of products: 13.1% of 6,12-dione **2**, 37.6% of 1,6-dione **3**, and 49.3% of 3,6-dione **4**.

The chlorination of acetone: a complete kinetic analysis

J. Peter Guthrie[1] and John Cossar
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 25, 1985

This paper is dedicated to Professor Arthur N. Bourns

J. Peter Guthrie and John Cossar. Can. J. Chem. **64**, 1250 (1986).

Rate constants are reported for all of the major steps followed in the chlorination of acetone, including the chlorination of mono- and 1,1-dichloroacetone, the chlorination of hydroxyacetone, the chlorination and hydroxide-catalyzed rearrangement of 1,1-dihydroxyacetone, and the haloform cleavage of trichloroacetone. pK_a values are reported for hydroxyacetone and monochloroacetone. Rate constants for the hydrolyses of chloroacetone and 1,1-dichloroacetone are reported; these reactions are probably not S_N2 displacements but proceed by addition of hydroxide and intramolecular displacement.

J. Peter Guthrie et John Cossar. Can. J. Chem. **64**, 1250 (1986).

On a déterminé les constantes de vitesses pour chacune des étapes principales de la chloration de l'acétone, y compris la chloration des mono- et dichloro-1,1 acétones, la chloration de l'hydroxyacétone, la chloration et la transposition catalysée par les bases de la dihydroxy-1,1 acétone ainsi que le clivage haloformique de la trichloroacétone. On rapporte aussi les valeurs de pK_a de l'hydroxyacétone et de la monochloroacétone. On rapporte aussi les constantes de vitesse pour l'hydrolyse de la chloroacétone et de la dichloro-1,1 acétone. Ces réactions ne sont probablement des substitutions S_N2 et elles se produisent probablement par une addition d'hydroxyde qui est suivie d'une substitution intramoléculaire.

[Traduit par le revue]

Introduction

The haloform reaction has long been used both as an analytical procedure (1–3) and as a synthetic method (3–8). Despite this long history of its use we were surprised to discover that the major product from the room temperature reaction of acetone with hypochlorite was lactate and not acetate (9). Clearly this familiar reaction was imperfectly understood. We have now carried out a detailed study of the course of the reactions which occur when acetone reacts with alkaline hypochlorite solutions. It has become clear that at several points the course of the reaction depends on a delicate balance between competing paths, so that minor changes in structure can alter the qualitative outcome of the reaction.

Results

The reactions which we have found to be significant in the chlorination of acetone are shown in Scheme 1. We will now describe experiments leading to rate or equilibrium constants for almost every step in the scheme. In the case of acetone itself the results of earlier work (9, 10) are summarized.

Chlorination of acetone

The rate constant[2] for hydroxide-catalyzed enolization of acetone is $k_{12} = 0.173\ M^{-1}\ s^{-1}$ (10). The equilibrium constant for the reaction of hydroxide with acetone to give the enolate may be calculated from the pK_a of acetone, 19.37 ± 0.51 (9). This allows calculation of the rate constants for the reaction of water with the enolate as $k_{21} = 4.1 \times 10^4\ s^{-1}$. The rate constant for the reaction of the enolate with OCl^- is $k_{23}^- = 2.0 \times 10^4\ M^{-1}\ s^{-1}$ and that for reaction with HOCl is $k_{23}^0 = 1.7 \times 10^9\ M^{-1}\ s^{-1}$, i.e. diffusion controlled (9).

Hydrolysis of monochloroacetone and 1,1-dichloroacetone

The hydrolysis reactions of haloacetones could be studied by the pH stat technique, measuring the consumption of hydroxide ion. The experimental data are given in Tables 1 and 2.[3] From these results we obtain the second order rate constants for reaction with hydroxide ion given in Tables 1 and 2. The kinetics were studied over a range of one pH unit; the range was restricted by the need for a reasonably slow reaction in order to be able to monitor it conveniently, and for a reasonably fast reaction in order to avoid confusion with the continual drift from uptake of atmospheric CO_2. Over the range studied the rates of these reactions were linearly dependent on hydroxide ion concentration. We anticipate that there could be a second order dependence on hydroxide at some higher hydroxide concentration, but saw no evidence for it in these experiments.

Chlorination of monochloroacetone

The chlorination of monochloroacetone was inevitably accompanied by hydrolysis leading to the more slowly reacting hydroxyacetone. This led to biphasic kinetics (Table 3) with the faster phase reflecting hydrolysis plus halogenation, and the slower phase reflecting halogenation of hydroxyacetone. For the faster phase, graphical analysis suggested that there were the following terms in the rate law: zero order in hypochlorite and first order in hydroxide (corresponding to hydrolysis); and first order in hypochlorite, zero or first order in hydroxide (corresponding to halogenation). Since the concentrations of both hydroxide and hypochlorite were low, it was difficult to make up solutions with fixed values of one concentration while the other was varied; this meant that both variables changed from experiment to experiment. The hydroxide concentration was determined by titration for each run. The hypochlorite concentration was determined from the initial absorbance; comparison with direct titration showed that this is a reliable measure. To perform a graphical analysis it was necessary to use data where the hydroxide or hypochlorite concentration, although nominally fixed, actually varied considerably. This meant that the simple graphical analysis could only provide rough approximation to the desired rate constants. To extract rate constants we used a non-linear least-squares treatment with two independent variables and one dependent variable (11), fitting to the three parameter equation [1].

$$[1] \quad k_{obs} = (a + b[OH^-])[OCl^-] + c[OH^-]$$

In addition to the data for chlorination in hydroxide/hypo-

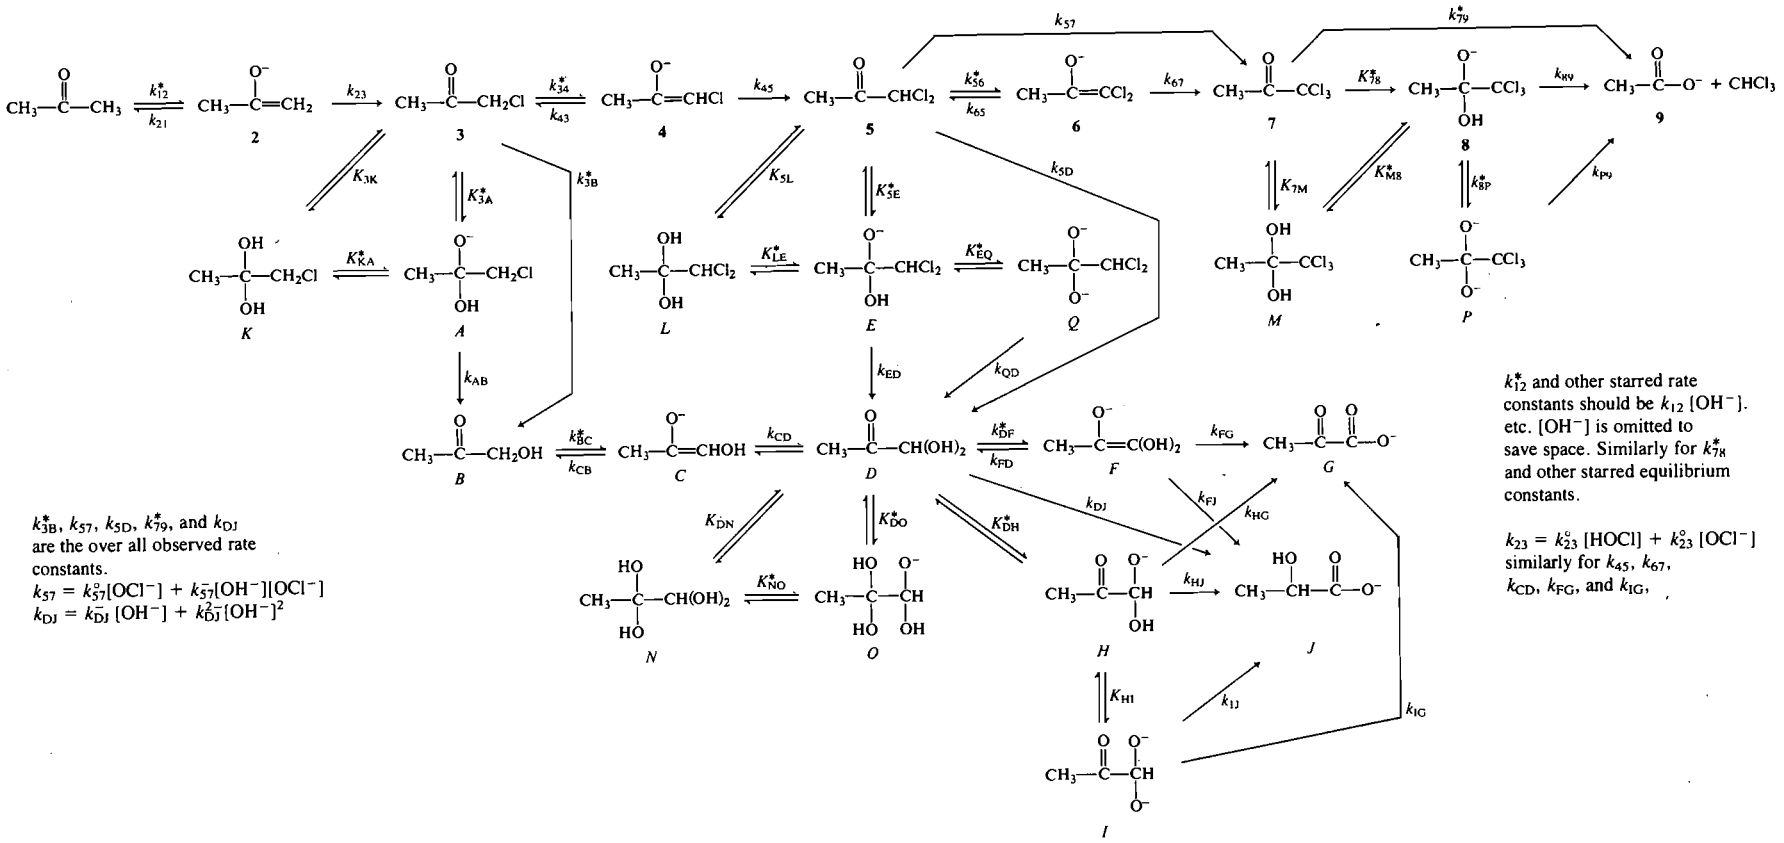

SCHEME 1.

chlorite solutions we used the data for chlorination in pH 10.3 buffers and for hydrolysis of monochloroacetone. With the full data set of 31 points the rate constant for the term first order in both hydroxide and hypochlorite was not well defined; the error limits calculated by the least-squares program were larger than the value:

$$a = 10.1 \pm 1.76$$
$$b = 261 \pm 524$$
$$c = 1.14 \pm 0.94$$

where

$$a = k_{34}k_{45}{}^{0}K_w/k_{43}K_a{}^{HOCl}$$
$$b = k_{34}k_{45}{}^{-}/k_{43}$$
$$c = K_{3A}k_{AB}/(1 + K_{3K})$$

If points deviating by more than 20% were deleted from the data set, one could end up with a set of 22 points for which all three parameters were well defined, and agreed with the parameters defined by the full set within the uncertainty limits calculated by the least-squares program:

$$a = 10.0 \pm 0.64$$
$$b = 224 \pm 179$$
$$c = 1.32 \pm 0.43$$

Alternatively we could try fitting the data to a two-parameter equation, [2], with the same interpretations for the parameters:

[2] $$k_{obs} = a[OCl^-] + b[OH^-]$$

Using the full data set we obtained:

$$a = 10.5 \pm 1.86$$
$$b = 1.41 \pm 0.87$$

Using the reduced data set which allowed the three parameters of eq. [1] to be determined we obtained:

$$a = 10.3 \pm 1.12$$
$$b = 1.65 \pm 0.62$$

Although the parameters are well defined in both cases, the fits are inferior to those obtained with eq. [1]. For the full data set, fitting with eq. [2], there were 10 points deviating by more than 20%; for the reduced data set there were three points deviating by more than 20%. The corresponding values for fits to eq. [1] were eight points deviating by more than 20% for the full data set, and none deviating by more than 20% for the reduced set. The quality of the fit is shown in Fig. 1.[4]

Since other compounds have normally shown hydroxide-dependent as well as hydroxide-independent chlorination we conclude that the corresponding term in the rate law is probably real. Although the data set obtained by discarding deviant points does define the rate constant we have no independent basis for discarding these points, and it seems ill advised to do so. Accordingly we conclude that although the term is real it is ill defined by our data, and we will use the value suggested by the full data set.

Experiments involving the chlorination of monochloroacetone at pH 10.33–10.55 led to rate constants which were first order in hypochlorite; the corresponding second order rate constant was 9.80 ± 0.89 which is indistinguishable from the value obtained above from the full data set. These experiments were unbuffered to avoid possible complications from interactions of buffer and hypochlorite, but as a consequence the pH changed during a set of runs as successive portions of ketone were added. The hydroxide concentration was calculated by interpolation between the initial and final values.

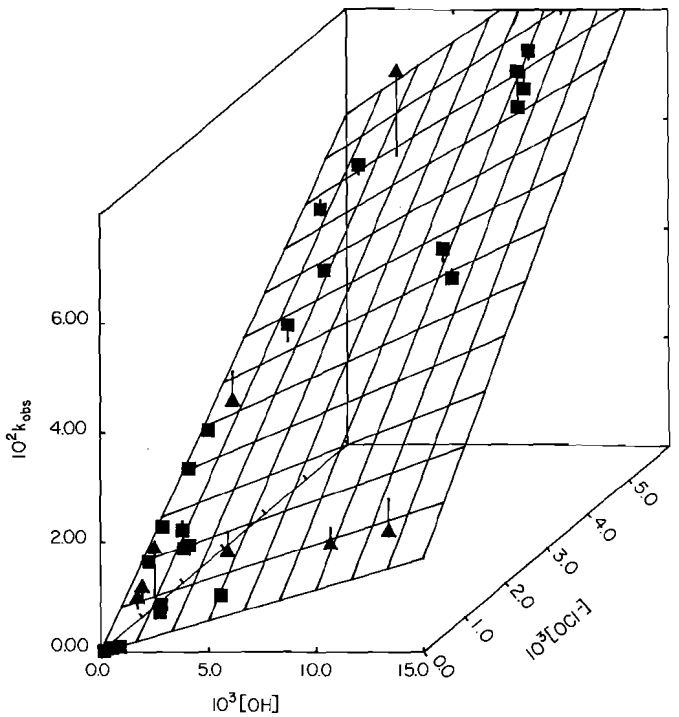

FIG. 1. Rate constants for the combined chlorination and hydrolysis of monochloroacetone, fitted to $k = \{(10.1 \pm 1.76) + (261 \pm 524)[OH^-]\}[OCl^-] + (1.14 \pm 0.94)[OH^-]$. (■) points falling within 20% of the calculated surface; (▲) points falling more than 20% off the calculated surface.

Experiments involving the bromination of monochloroacetone in carbonate buffers at pH 8.82 led to rate constants which were zero order in hypobromite and first order in hydroxide and in carbonate. The corresponding second order rate constants were 0.25 $M^{-1}s^{-1}$ for carbonate and $k_{34} = 136\ M^{-1}s^{-1}$ for hydroxide. These were taken as the rate constants for enolization. From experiments in buffered solutions at lower pH Bell had reported a value of 9.3 $M^{-1}s^{-1}$ (12). We were surprised at the discrepancy, but note that Bell's value is based on experiments in buffer solutions of pH less than 7.

From the rate constant for hydroxide-independent chlorination we can calculate the pK_a of monochloroacetone (subject to the assumption that the halogenation of the enolate of monochloroacetone by hypochlorous acid is diffusion controlled (9)) as 15.76 ± 0.51. We then calculate the rate constant for protonation of the enolate by water, from the rate constant for hydroxide-catalyzed enolate formation and the pK_a, as $k_{43} = 7.8 \times 10^3 s^{-1}$. Finally we estimate $k_{45}{}^-$, the rate constant for the reaction of the enolate with hypochlorite ion, from the value of the rate constant for hydroxide dependent chlorination, as ca. $2 \times 10^4\ M^{-1}s^{-1}$.

Chlorination of hydroxyacetone

The halogenation of hydroxyacetone was, as reported previously (9), faster than the halogenation of acetone. We have

[4]For the cases where we have fitted k_{obs} simultaneously as a function of $[OH^-]$ and $[OCl^-]$, we present three dimensional graphs, with a grid showing the calculated surface and a perpendicular line from the center of each point to the surface, to make clear which points deviate significantly.

extended the range of the kinetics over that previously reported in an attempt to evaluate the rate constant for the term in the rate law first order in hypochlorite and zero order in hydroxide with sufficient accuracy to calculate the pK_a. These additional rate constants are found in Table 4.

The data, including the rate constants reported previously, were subjected to a graphical analysis based on the use of Eadie–Hofstee (13, 14) type plots to analyze the $[OCl^-]$ dependence of k_{obs} at "fixed" $[OH^-]$. The approach is based on the assumed mechanism shown in Scheme 1, which leads to the following expression for the observed rate constant:

$$k = a[OH^-](b/[OH^-] + c)[OCl^-]/\{d + (b/[OH^-] + c)[OCl^-]\}$$
$$= a[OH^-]/\{d/(b/[OH^-] + c)/[OCl^-] + 1\}$$

with

$$a = k_{BC}$$
$$b = k_{CD}{}^0K_w/K_a{}^{HOCl}$$
$$c = k_{CD}{}^-$$
$$d = k_{CB}$$

and at fixed $[OH^-]$ this can be simplified to:

$$k = A/(1 + B/[OCl^-])$$

Then $k + kB/[OCl^-] = A$, $k = A - B\{k/[OCl^-]\}$, and a plot of k_{obs} vs. $k_2 = k_{obs}/[OCl^-]$ will give A and A/B as the y- and x-intercepts.

When the analysis was carried out, the data showed considerable scatter, but were in rough accord with the mechanism of Scheme 1.

The data could also be analyzed directly by least squares, determining all three parameters at once by fitting to the equation:

[3] $$k_{obs} = (e + f[OH^-])/(1/[OCl^-] + e/g[OH^-] + f/g)$$

with

$$e = k_{BC}k_{CD}{}^0K_w/k_{CB}K_a{}^{HOCl}$$
$$f = k_{BC}k_{CD}{}^-/k_{CB}$$
$$g = k_{BC}$$

With the full set of 28 points we found that the parameter "e" was not well defined. If seven points deviating from the curve by more than 20% were deleted from the set, all three parameters were better defined, but the "e" parameter still had errors larger than its value. The values for the parameters obtained by least squares are:

	Full set	Truncated set
e	0.210 ± 0.274	0.176 ± 0.191
f	19.9 ± 6.70	20.8 ± 3.67
g	0.0480 ± 0.0258	0.0473 ± 0.0117

We conclude that although the data almost define the "intercept" parameter, this parameter is really not yet properly defined and little confidence can be placed in it. It is at best a limit, since it might be smaller, but would be readily determined if it were larger.

Since the three-parameter equation was not well defined by the data, attempts were made to fit the data using a simpler equation, corresponding to negligible reaction of the enolate with hypochlorous acid.

$$k = f[OH^-]/(1/[OCl^-] + f/g)$$

A reasonable fit was obtained with the full data set and a better fit was obtained if eight points deviating by more than 20% from the curve were deleted:

	Full set	Truncated set
f	22.5 ± 9.19	22.4 ± 4.06
g	0.0467 ± 0.035	0.0462 ± 0.01371

The three parameter equation gives a better fit, and there is adequate justification for using it based on the results obtained with other ketones, even though one parameter is not well defined.

We can calculate the pK_a on the assumption that the intercept has been determined. As has been previously shown (9):

$$pK_a = \log k_{diffusion} + pK_a^{HOCl} - \log (k^0) \geqslant 17.61$$

k^0 might be smaller, in which case pK_a would be higher; we can only put a lower limit on it. It seems certain that hydroxyacetone will be more acidic than acetone because of the electron-withdrawing effect of the hydroxyl group. This puts an upper limit on pK_a, namely, that of acetone.

Since $k_{BC} = 0.0473 \pm 0.0117\ M^{-1}\,s^{-1}$, we may calculate from the pK_a of the ketone that $k_{CB} \geqslant 190\ s^{-1}$, and that $k_{CD}{}^- \geqslant 8.55 \times 10^4\ M^{-1}\,s^{-1}$.

The values for the rate constants for the second phase of the kinetics measured starting with monochloroacetone are also in qualitative agreement with values calculated from eq. [3]. The second phase rate constants were of low precision because they are based on a small absorbance change and may be accompanied by other side reactions, including the slow decomposition of hypochlorite. In some cases the reactions were not followed long enough to determine the rate constant very well. Accordingly rate constants from these experiments were not included in the least-squares fit. Figure 2 shows a three-dimensional representation of the dependence of k_{obs} on $[OH^-]$ and $[OCl^-]$.

Chlorination of dichloroacetone

The halogenation of 1,1-dichloroacetone was also studied. It was possible to determine the stoichiometry of the reaction and show that it was often close to unity. From the absorbance change accompanying reaction we could determine the amount of OCl^- consumed by a known amount of dichloroacetone. The data in Table 5 show that for low concentrations of hydroxide the stoichiometry was very close to one OCl^- consumed per mole of ketone, consistent with almost complete conversion to acetate by way of trichloroacetone.

At pH 10 reaction with hypobromite was very fast. The amount of bromine consumed (Table 5) was 1.12 moles per mole of ketone, based on the change in absorbance. Except for a small absorbance change with a rate constant of around $3 \times 10^{-2}\ s^{-1}$, attributed to impurities, the consumption of bromine was complete within the time of mixing. This implies a pseudo-first order rate constant greater than $0.1\ s^{-1}$, and a second order rate constant for hydroxide catalyzed enolization greater than $1000\ M^{-1}\,s^{-1}$.

Enolization rates were determined by measuring the rate of bromination in phosphate and acetate buffers as well as $10^{-3}\ M$ HCl; these data are also found in Table 5. The reactions were

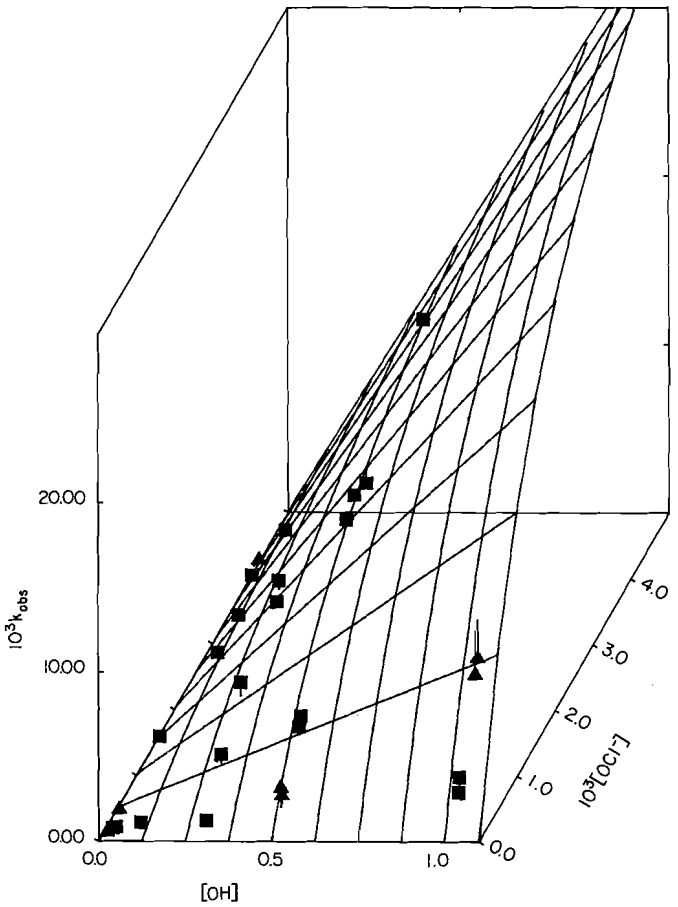

FIG. 2. Rate constants for the chlorination of monohydroxyacetone, fitted to $k = \{(0.210 \pm 0.274) + (19.9 \pm 6.70)[OH^-]\}/\{1/[OCl^-] + (0.210 \pm 0.274)/(0.0480 \pm 0.0258)[OH^-] + (19.9 \pm 6.70)/(0.0480 \pm 0.0258)\}$. (■) points falling within 20% of the calculated surface; (▲) points falling more than 20% off the calculated surface.

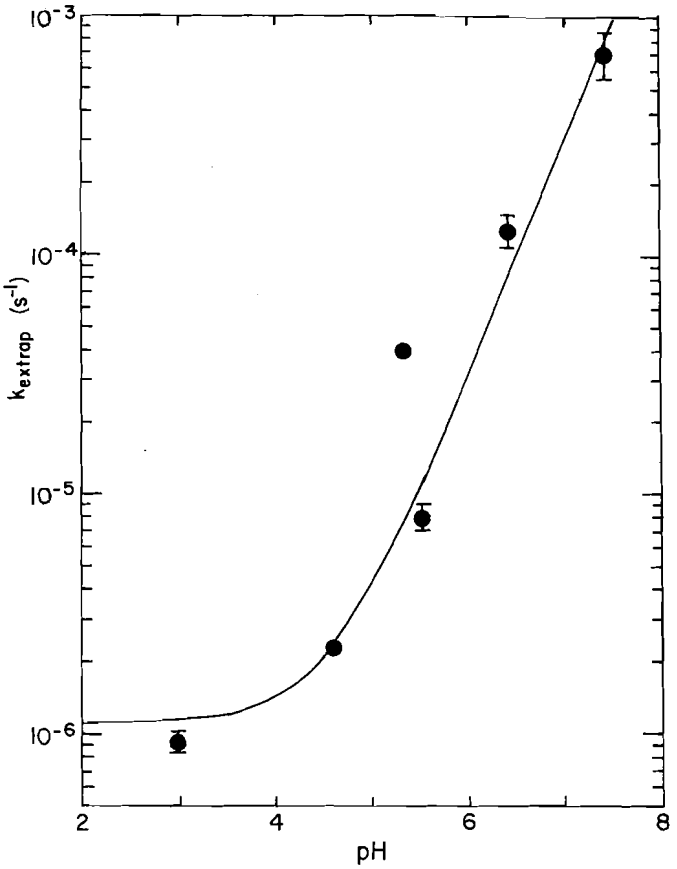

FIG. 3. pH rate profile for the enolization of dichloroacetone; all rate constants extrapolated to zero buffer concentration. The calculated line is based on $k = 1.11 \pm 0.20 \times 10^{-6} + (3010 \pm 514)[OH^-]$.

initially zero order in bromine, but at long times became first order in bromine. The initial slopes were used as a measure of the enolization rate, and were first order in buffer. Extrapolation to zero buffer gave rate constants which contained only the water and hydroxide rates, from which we determined by weighted least squares

$$k_{extrap} = \{(1.1 \pm 0.2) \times 10^{-6} + (3010 \pm 514)[OH^-]\}\ s^{-1}$$

The phosphate catalyzed enolizations at pH 5.33 were anomalous, in that both slope and intercept were out of line with the results of phosphate-catalyzed reactions at higher pH. Since we had only three runs at pH 5.33 and these happened to fall very close to a straight line, the weights based on least-squares fitting were very high. Results at pH 5.33 were not used for further calculations. Figure 3 shows the corresponding pH rate profile.

Our value for the rate constant for uncatalyzed reaction (the water rate) is $(1.1 \pm 0.2) \times 10^{-6}\ s^{-1}$ where Bell reported $7.3 \times 10^{-7}\ s^{-1}$ (12). Our value for the rate constant for acetate-catalyzed enolization is $(5.3 \pm 0.2) \times 10^{-4}\ M^{-1}\ s^{-1}$ where Bell reported $5.7 \times 10^{-4}\ M^{-1}\ s^{-1}$ (12). Our value for the phosphate dianion rate constant is $0.018 \pm 0.005\ M^{-1}\ s^{-1}$; a value of $0.0122\ M^{-1}\ s^{-1}$ can be estimated from the Bell's (12) Brønsted equation using a pK_a of 6.42 for phosphate. For all of these rate constants the agreement is reasonable considering that it was necessary to use initial slopes, and that lines were fitted to limited numbers of points. For the hydroxide-catalyzed reaction, our value for the rate constant is $3010\ M^{-1}\ s^{-1}$ where Bell reported $450\ M^{-1}\ s^{-1}$; here the disagreement is more serious, and again we have no satisfactory explanation for the anomaly.

Product ratios were determined by ^{1}H-nmr analysis of product solutions. The results of these experiments are summarized in Table 6. The only products seen were acetate and lactate.

Graphical analysis showed that the product ratio, r = [acetate]/[lactate], was roughly linear in [OCl$^-$] (lines passing through the origin) for fixed [OH$^-$], and $1/r$ was linear in [OH$^-$] (lines passing through the origin) for fixed [OCl$^-$]. When r was plotted as a function of [OCl$^-$]/[OH$^-$], a line passing through the origin with slope 156 was obtained. The only serious deviation was for the point at [OH$^-$] = 0.049 and [OCl$^-$] = 0.0071, which is also the point with the largest value of r, based on the most dissimilar peak areas.

The rate of the combined halogenation/hydrolysis could be followed by monitoring the uv absorption of hypochlorite. The rate constants so obtained are listed in Table 5. These rate constants could be fitted to:

$$k_{obs} = a + b[OH^-] + c[OCl^-]$$

where, in terms of Scheme 1,

$$a = k_{ED}$$
$$b = k_{QD}K_{EQ}$$
$$c = k_{57}^-/K_{5E} = k_{67}^-k_{56}/k_{65}K_{5E}$$

with

$a = 0.00445 \pm 0.00535$

$b = 0.0333 \pm 0.0134$

$c = 3.33 \pm 1.74$

Figure 4 shows the quality of the fit. The terms a and b are identified with hydrolysis of dichloroacetone. At the hydroxide concentrations used the ketone is entirely converted to the anionic hydroxide adduct, so that the "a" term corresponds to the hydroxide-catalyzed hydrolysis observed at low pH while the "b" term corresponds to hydrolysis via the dianion. In order to fit the entire pH rate profile for hydrolysis we calculated the contribution for hydrolysis alone for each of the observed rate constants by subtracting $c[OCl^-]$. We then fitted all the data to:

$$\frac{k_{obs}}{[OH^-]} = \frac{d + e[OH^-]}{1 + f[OH^-]}$$

where in terms of Scheme 1,

$d = k_{ED}K_{5E}/(1 + K_{5L})$

$e = k_{QD}K_{EQ}K_{5E}/(1 + K_{5L})$

$f = K_{5E}/(1 + K_{5L})$

with

$d = 4.77 \pm 0.60$

$e = 25.3 \pm 15.8$

$f = 992 \pm 216$

The quality of this fit is shown in Fig. 5.

The corresponding values from these two equations are:

$a = d/f$ and $b = e/f$

$a = 0.00445 \pm 0.0054$

$d/f = 0.0048 \pm 0.0034$

$b = 0.0333 \pm 0.0134$

$e/f = 0.0255 \pm 0.0114$

The agreement is satisfactory. Although we have not been able to determine precise values for the parameters, we have a consistent picture fitting the data in hand. From the parameters we can calculate the microscopic rate and equilibrium constants. From $f = 992$, we calculate $K_{5E} = 3.8 \times 10^3\ M^{-1}$. The value which we had estimated is $670\ M^{-1}$, which differs by 0.8 pK units. The difference is larger than one would wish but not outside the range to be expected for estimation procedures. Since $d/f = k_{ED}$, the latter is taken as $0.0048 \pm 0.0034\ s^{-1}$. From $e/f = k_{QD}K_{EQ} = 0.0255 \pm 0.0114$, we can calculate k_{QD} by using an estimated K_{EQ}, which we obtained using Pauling's rule (15) to estimate the second pK_a of 1,1-dichloro-2,2-dihydroxypropane. The value so obtained is $k_{QD} \cong 2.6\ s^{-1}$.

The product ratio, r = [acetate]/[lactate], could be calculated from the absorbance change, ΔA, assuming that the absorbance change represented reaction of part of the dichloroacetone with one equivalent of hypochlorite to give acetate, while the rest underwent hydrolysis followed by rearrangement to give lactate.

The product ratios, r, calculated from the values of ΔA determined by least squares are not in good agreement with those determined by nmr for experiments at low $[OH^-]$. If r values are calculated from the total absorbance change calculated from the infinity value and the absorbance before addition of ketone (corrected for dilution) then the agreement is much better. This suggests that an important amount of reaction

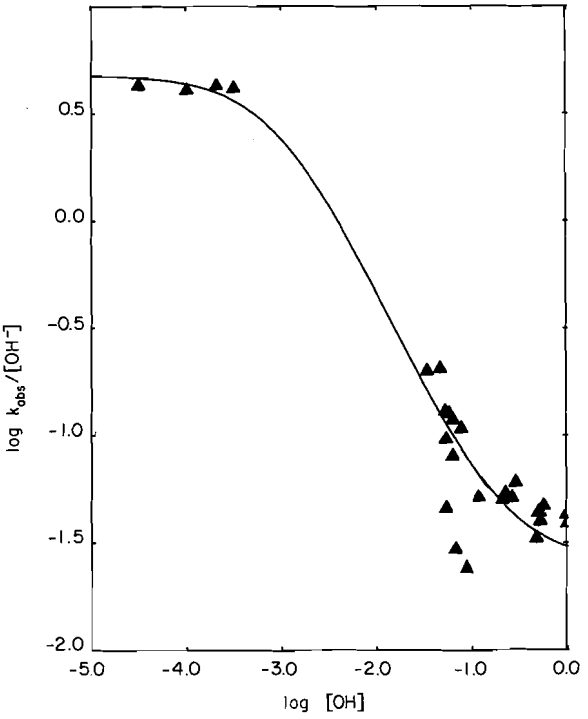

FIG. 5. Rate constants for the hydrolysis of 1,1-dichloroacetone. Values at low $[OH^-]$ by direct measurement, values at higher $[OH^-]$ calculated from rate constants for combined hydrolysis and chlorination by subtracting the contribution from chlorination. The data were fitted to $k_{obs}/[OH^-] = \{(4.77 \pm 0.60) + (25.3 \pm 15.8)[OH^-]\}/\{1 + (992 \pm 216)[OH^-]\}$.

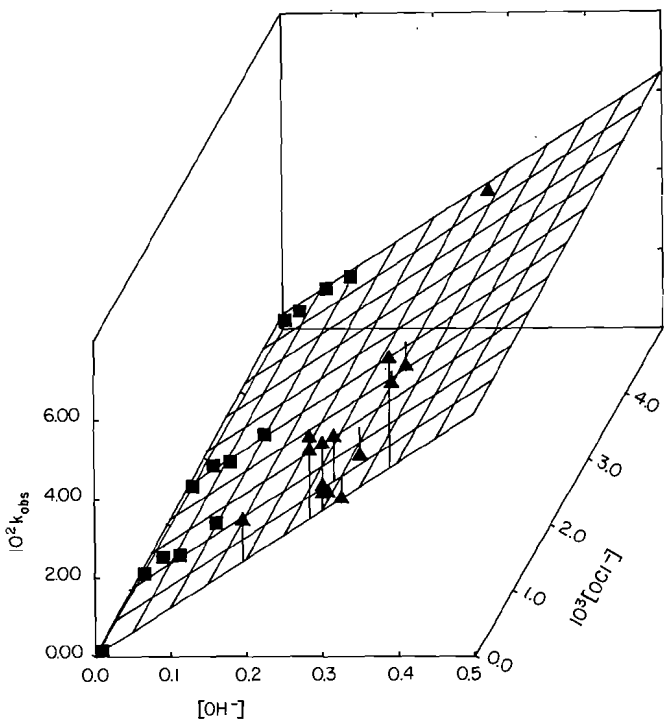

FIG. 6. Rate constants for the combined chlorination and rearrangement of 1,1-dihydroxyacetone, fitted to $k = (0.00034 \pm 0.00027) + (0.673 \pm 0.151)[OCl^-] + (0.122 \pm 0.0155)[OH^-]$. (■) points included in the least squares fit; (▲) points which were not included in the least squares fit, and which fall off the calculated surface.

occurs before measurements begin. This could be the result of the reaction of the keto form of dichloroacetone with hypochlorite before there was time for keto–hydrate anion equilibrium to be established. The phenomenon, a total absorbance change corresponding to the expected stoichiometry, while the measurable kinetic process corresponds to a smaller amount of reaction, has been seen repeatedly in these experiments.

One explanation which must be considered immediately is that the fast reaction, completed before the recording of absorbance time data begins, is the actual reaction of dichloroacetone, while the measurable process is some subsequent reaction. We reject this explanation because the reaction subsequent to chlorination of dichloroacetone, namely haloform cleavage, is rapid and is not expected to lead to any absorbance change, and the reaction subsequent to hydrolysis, namely the chlorination/rearrangement of dihydroxyacetone, shows quite different kinetics and very small consumption of hypochlorite.

There is clearly something complicated going on which will reveal further details of the reaction upon suitable investigation. For the purpose of defining the behaviour of fully equilibrated dichloroacetone the kinetic parameters are adequate. For the immediate purpose of defining the behavior of dichloroacetone generated in situ in the course of the chlorination of acetone, the rate ratio implied by the nmr studies, and the total absorbance changes, is a better guide to the partitioning of this intermediate.

The clear implication of this work is that the major form of dichloroacetone in solution in dilute hydroxide is the hydrate monoanion, and that halogenation will occur at a rate inversely proportional to $[OH^-]$.

Chlorination and rearrangement of 1,1-dihydroxyacetone

2-Oxopropanal (pyruvaldehyde, methylglyoxal) is shown by ^{1}H-nmr to be a mixture of two species in aqueous solution. The major species has a signal at 2.30 attributed to the methyl of 1,1-dihydroxyacetone, and the minor species has a signal at 1.37 attributed to 1,1,2,2-tetrahydroxypropane. Form the areas of the peaks we calculate that the dimensionless equilibrium constant for hydration of 1,1-dihydroxyacetone is 0.61. The chlorination of 1,1-dihydroxyacetone was studied in order to determine the rates of its reaction, the stoichiometry, and the rate of the rearrangement to lactate. These kinetics results are found in Table 7. This latter reaction was difficult to study directly because the absorbance change accompanying rearrangement is small, making it difficult to perform studies at low concentrations. Unfortunately kinetics at higher values of $[OH^-]$, greater than $0.2\,M$, with or without hypochlorite present, gave fast and irreproducible kinetics, with $k_{obs} > 0.04\,s^{-1}$. These kinetics did not fit the general pattern seen at lower hydroxide concentrations, and were subject to a scatter of 25–30%. The data for $[OH^-] < 0.2\,M$ were fitted to:

$$[4] \quad k = a + b[OCl^-] + c[OH^-]$$

where, in terms of Scheme 1,

$$a = k_{HJ}$$
$$b = k_{HG}$$
$$c = k_{IJ}K_{HI}$$

This gave a very good fit; the parameters determined by least squares were:

$$a = 0.00034 \pm 0.00027$$
$$b = 0.673 \pm 0.151$$
$$c = 0.122 \pm 0.0155$$

It should be noted that eq. [4] assumes that the major substrate species in solution is the anionic form of methylglyoxal hydrate, either rearranging with or without hydroxide catalysis or else reacting with ClO^-. Under most conditions relevant to the present study, halogenation is a minor side reaction. The quality of the fit is shown in Fig. 6.

Haloform cleavage of trichloroacetone

The kinetics of this reaction were followed by the pH-stat technique. The data are found in Table 8. These values led to a second order rate constant for hydroxide-catalyzed breakdown of $48.2\,M^{-1}\,s^{-1}$.

Summary of rate constants

All of the rate and equilibrium constants for processes shown in Scheme 1 which are currently known or estimated are given in Table 9.

Discussion

Hydrolysis of chloroacetone

The hydrolysis of chloroacetone is a rapid reaction. Although substitution reactions of powerful nucleophiles with α-halo ketones are normally considered to occur by the S_N2 mechanism (16, 17) with some special accelerating effects attributed to the carbonyl group (18–21), it seemed worthwhile to test whether the present reaction was occurring at a rate which was plausible for the classical mechanism. To do this we endeavored to estimate the rate of the substitution from rates of reaction of other nucleophiles which must react by direct displacement.

The closest available data to the rate constants we wish to estimate are for reactions of nucleophiles with α-halo ketones in aqueous dimethyoxyethane at 54.8°C (16). No temperature

dependence studies were done for chloroacetone itself; the closest model is the reaction of AcO^- with 1-bromo-2-butanone for which the $\Delta S^{\ddagger}$ is -5. We will assume that $\Delta S^{\ddagger}$ is the same for the reactions of simple ionic nucleophiles with chloroacetone. The rate constant for the reaction of acetate with chloroacetone is $1.14 \times 10^{-3}\ M^{-1}\ s^{-1}$ (16). For bromoacetone, rate constants for acetate ($1.46 \times 10^{-3}\ M^{-1}\ s^{-1}$) and azide ($94.8 \times 10^{-3}\ M^{-1}\ s^{-1}$) were reported (16). We will assume that the rate ratio is the same, and so estimate a rate constant for the reaction of chloroacetone and azide as $7.4 \times 10^{-2}\ M^{-1}\ s^{-1}$. We then correct to 25°C and get rate constants for acetate ($3.78 \times 10^{-5}\ M^{-1}\ s^{-1}$) and azide ($3.74 \times 10^{-3}\ M^{-1}\ s^{-1}$). Then using Swain–Scott n values (acetate, 2.72; azide, 4.00; hydroxide, 4.20; all from Wiberg (22) we get $k = 0.0077\ M^{-1}\ s^{-1}$ for hydroxide. This is clearly slower than the observed value ($1.19\ M^{-1}\ s^{-1}$). Unfortunately there are a number of weak points in the estimation procedure which we had to use, and so we cannot have high confidence that the mechanism is not S_N2, although there is a basis for very strong doubt.

The observed rate constant for the reaction of hydroxide with chloroacetone to give hydroxyacetone presumably represents the reaction of the hydroxide adduct, so it is the product of a rate and an equilibrium constant. The equilibrium constant can be estimated as $1.7\ M^{-1}$. The equilibrium constants for hydration of mono- and dichloroacetone have been reported (23); the pK_a's for the hydrates can be calculated using Hine's equation ($pK_a = 14.19 - 1.32\Sigma\sigma^*$) (24); the equilibrium constants for addition of hydroxide then come from a simple cycle; see Table 10.

The rate constant for the intramolecular reaction can now be calculated to be $0.78\ s^{-1}$. This is somewhat faster than what might have naïvely been expected. For $^-O—CH_2—CH_2—Cl$, the rate constant is $0.022\ s^{-1}$ (25). One can, however, anticipate that the cyclization should be favored by the additional substituents present in $^-O—C(OH)(CH_3)—CH_2—Cl$ (26), so that a rate constant greater than $0.022\ s^{-1}$ is to be expected, although it is not clear how much greater. Base-catalyzed cyclization of $HOC(CH_3)_2—CH_2—Cl$ is 252 times faster than that of $HO—CH_2—CH_2—Cl$ (26, 27). Once again the arguments are suggestive but not compelling.

TABLE 10. Equilibrium constants for addition of water and hydroxide to mono-, di-, and trichloroacetone[a]

Ketone	K_{hyd}[b]	K_a[c]	K_{OH}
$MeCOCH_2Cl$	0.11	12.80	1.7
$MeCOCHCl_2$	2.86	11.63	670
$MeCOCCl_3$	50	10.69	1.0×10^5

[b]Values from ref. 23; value for trichloroacetone estimated after ref. 23.
[c]$pK_a = 14.19 - 1.32\Sigma\sigma^*$ (24).

Thus for chloroacetone a plausible case can be made for reaction by an addition–intramolecular displacement mechanism, rather than direct S_N2 attack, but the case cannot be considered proven.

Other, closely related, reactions have been attributed to the addition-intramolecular displacement mechanism. Addition of alkoxide and formation of an alkoxy-oxirane (or products derived from it) is a well-known side reaction in the Favorskii rearrangement (28–31). For secondary α-halo ketones (but not primary) an alternative mechanistic path is available for hydrolysis, namely, solvolysis of the α′-enol (32). Fortunately this additional path is unlikely (32) for the present system, which is already sufficiently complicated.

We may estimate rate constants for the addition of hydroxide to the carbonyl groups of mono- and dichloroacetone from the

TABLE 11. Rate constants for addition of hydroxide to mono-, di-, and trichloroacetone[a]

Compound	K^b (M^{-1})	$k_{on}{}^c$ ($M^{-1}\,s^{-1}$)	k_{off} (s^{-1})

[a]In water at 25°C.

[b]Equilibrium constant for the addition of hydroxide to ketone, producing an anionic adduct; values from Table 10.

[c]k_{on} is the rate constant for the addition of hydroxide to carbonyl; k_{off} is the rate constant for the expulsion of hydroxide from the anionic adduct. Values were calculated using the appropriate Marcus equation (33), for which $b = 6$. b is the "intrinsic barrier" expressed in units of log k.

equilibrium constants calculated above and the Marcus correlation for rate and equilibrium constants for addition of hydroxide to carbonyl compounds (33) (see Table 11):

$$\log k = 10 - b(1 - \log K/4b)^2$$

Note that these rates make the addition reaction the fastest reaction channel available. The peculiar behavior observed in the kinetics of halogenation/hydrolysis of dichloroacetone suggest that for dichloroacetone there may be steric hindrance to the addition of hydroxide, leading to slower reaction than predicted in Table 11.

Hydrolysis of dichloroacetone

Although we could not find any information allowing an estimation of the rate constant to be expected for simple S_N2 attack of hydroxide on 1,1-dichloroacetone, we can state that this reaction would be expected to be considerably slower than the S_N2 attack of hydroxide on monochloroacetone. Streitwieser (34) gives relative rate data for the reactions of methoxide ion in methanol at 50°C with dibromomethane and bromoethane; the rates are in the ratio 0.0078:1. This comparison is for the effect of the second halogen atom with steric effects roughly compensated; since methyl bromide reacts 23 times faster than ethyl bromide with ethoxide in ethanol the rate ratio for dibromomethane and monobromomethane would be more like 0.0003:1. Although these data represent an imperfect model for the case of 1,1-dichloroacetone vs. monochloroacetone, it is clear that for the S_N2 mechanism the former must be much slower. In fact, as was shown above, 1,1-dichloroacetone is somewhat *more* reactive; this demands the conclusion that it does not react by the S_N2 pathway. If, as we suggested was likely, monochloroacetone does not react by the S_N2 pathway either, this conclusion becomes even stronger.

From the fit of the experimental rate constants to the appropriate portions of the mechanism in Scheme 1, we obtained $k_{ED} = 0.0048\ s^{-1}$. It should be noted that this is almost 1000 times slower than the analogous rate constant for monochloroacetone. As shown above, one expects approximately this ratio based on the analogy with mono- and dibromomethane. Thus the proposal that both reactions proceed by the addition–intramolecular displacement mechanism is consistent with the facts.

Chlorination of chloroacetone

From the total change in absorbance due to hypochlorite ion accompanying reaction of monochloroacetone it is possible to calculate the stoichiometry. These measurements are complicated by the slow second phase of the reaction representing halogenation of the hydroxyacetone produced as a byproduct in the fast phase of halogenation. Furthermore there is a very slow pseudo-zero order decrease in absorbance, probably due to decomposition of the hypochlorite ion. For experiments where reaction was relatively rapid the stoichiometry was in the range of 1.5–2.0 moles of OCl^- per mole of monochloroacetone. This is consistent with competing chlorination and hydrolysis, since hydrolysis to hydroxyacetone is followed by consumption of a single mole of OCl^- and then rearrangement to lactate.

The stoichiometry for the initial rapid phase can be estimated from the absorbance change for this phase alone. Values so calculated show considerable scatter, but a plot of n (moles of OCl^- consumed per mole of ketone reacting) vs. $[OCl^-]/[OH^-]$ is in approximate accord with a line calculated from the rate law for the reactions of monochloroacetone, making the simplifying assumption that all dichloroacetone formed consumes another mole of OCl^-.

The equilibrium constant estimated for the addition of OH^- to monochloroacetone implies that for $[OH^-]$ less than 1 M, the anionic adduct is not present as a significant fraction of the total ketone.

Although no products attributable to Favorskii rearrangement were observed, it seems worthwhile to examine the question of why this common reaction of α-haloketones is not a competing side reaction accompanying the halogenation in alkaline solution.

We will first estimate rates of enolization at the α and α′ carbons. The pK_a for chloroacetone at the carbon bearing a chlorine has been calculated above as 15.8 (subject to the assumption that the enolate of chloroacetone reacts with hypochlorous acid at a diffusion-controlled rate). To estimate the pK_a at the other α′ carbon we need an estimate for the effect of a chlorine on the other side. The only available data are rate constants for enolization of 1,3-dichloroacetone from Bell's study (12), which led (35) to a pK_a of 11.04 ± 0.20, based on four carboxylic acids. The same pK_a estimation procedure applied to Bell's data for monochloroacetone led to a pK_a of 14.1 (35), which is quite different from the value calculated in this work. One possible explanation is that there is a different intrinsic barrier associated with deprotonation of a chloromethyl ketone than for a methyl ketone. If one determines a b value (intrinsic barrier in log k units) from the rate constants for carboxylate-catalyzed enolization of chloroacetone using the pK_a derived from the present work, one obtains a value of 7.4 (as opposed to the value of 9.9 for simple alkyl ketones (35)). If this new b value is used for the data for 1,3-dichloroacetone, one estimates a pK_a of 12.7. This means that there is a 3.1 pK_a unit effect of a chlorine on the opposite side of the carbonyl. The effect of a chlorine at the α carbon is 3.3 units (pK_a acetone = 19.1 (9)). We now estimate the pK_a at the α′-carbon of monochloroacetone to be 16.0.

The rate constant for reaction at the α-carbon has been determined in this work as $367\ M^{-1}\,s^{-1}$. For the α′-carbon, using the Marcus relation from ref. 35, with $b = 9.9$ (since there is no chlorine on the carbon bearing the enolizable hydrogen) and a pK_a for H_2O of 15.74, we get $k_{cor} = 0.89\ M^{-1}\,s^{-1}$, which leds to $k_{obs} = 2.7\ M^{-1}\,s^{-1}$, and a rate constant for reprotonation of $270\ s^{-1}$.

For use with Bordwell's results (29, 36), we will do the same for 1-chloro-3-phenylacetone. For phenylacetone the pK_a values are α-, 15.91; α′-, 18.27 (35). Then for the chloro compound, C-1, $pK_a = 18.27 - 3.3 = 15.0$; C-3, $pK_a = 15.91 - 3.1 = 12.8$. When rate constants for hydroxide-catalyzed

enolization are estimated using the appropriate b values in each case, we estimate them as C-1, $k_{OH} = 1200\,M^{-1}\,s^{-}$; C-3, $k_{OH} = 45\,M^{-1}\,s^{-}$. These are necessarily quite approximate estimates, but in fact the exchange results say that they are in the correct order because there is more exchange next to the chlorine, although the two exchange rates are close. The reverse rate constants can be estimated as C-1, $k_w = 1.2 \times 10^4\,s^{-1}$; C-3, $k_w = 2.8\,s^{-1}$.

In order to estimate rate constants for the Favorskii rearrangement, we start with the studies of Bordwell *et al.* (29), (36). Bordwell gives rate constants for the rearrangement of 1-chloro-3-phenylacetone in water–methanol mixtures with up to 50% water present (29). The rate-determining step is changing as the solvent changes because the fraction of exchange is varying. We will correct for this solvent effect by using a log k vs. Y correlation to extrapolate to water; the data employed are given in Table 12. We then use the fraction of exchange to determine the partitioning ratio between reprotonation and rearrangement, and assume that this rate ratio follows Y as well, to extrapolate to water. Then in water, using our estimated rate constant for reprotonation, we calculate a rate constant for the Favorskii step in water. We then consider the probable magnitude of the effect of the phenyl substituent on the rate constant for the ionization step, in order to calculate a rate constant for the reaction of chloroacetone from the rate constant for 1-chloro-3-phenyl-2-propanone.

A plot of log k for the rearrangement vs. Y gives log $k = -0.775 + 0.648Y$, $r = 0.995$, which leads to $k = 31.7\,M^{-1}\,s^{-1}$ in water at 0°C. In pure methanol the temperature effect is such that the rate at 25°C is 34 times the rate at 0°C. This rate ratio leads to a value of the apparent rate constant for the Favorskii rearrangement of 1-chloro-3-phenylacetone in water at 25°C of $1080\,M^{-1}\,s^{-1}$. It is subject to the assumption that the rate-determining step is the same in methanol as in water, and that the partitioning of the intermediate is not a function of temperature. Both assumptions are questionable. The value estimated is the overall rate constant $= k_{deprot}/[1 + (k_{reprot}/k_{ion})]$. As we will see k_{reprot}/k_{ion} is likely to be less than 1 in water so that the overall rate constant should be essentially the rate of deprotonation, for which the temperature coefficient k_{25}/k_0 is likely to be small; a value of $k_{25}/k_0 = 7.67$ is reported for acetone in water (10). Using this value as an estimate of the effect of temperature on the overall rate of the Favorskii rearrangement in water would lead to $k_{observed} = 243\,M^{-1}\,s^{-1}$; we had estimated above that k_{deprot} would be $45\,s^{-1}$.

We next consider the partitioning of the intermediate. We assume that α′ deuterium exchange represents reprotonation of the enolate, which partitions between reprotonation and solvolysis, and that reprotonation in deuterated medium leads to deuterated product. Then from the observed percent exchange (29) we can calculate the rate ratio, $r = k_{reprot}/k_{Fav}$, and extrapolate to water assuming log (r) is linear in Y, as shown in Table 13; since only two exchange experiments were done the assumption cannot be tested.

We can estimate the rate constant for the Favorskii step, based on the partitioning ratio, which is for the moment assumed to be temperature independent. If the rate constant for the reprotonation step is $2.8\,s^{-1}$ in water (*vide supra*) and the rate ratio is 0.102, then the microscopic rate constant for the Favorskii ionization is $27\,s^{-1}$.

One must now consider the effect of the phenyl group in 1-chloro-3-phenylpropanone on the rate of the Favorskii ionization. Streitwieser (37) gives rates for phenylallyl chloride relative to allyl chloride. The rate ratio is solvent dependent, being 139:1 at 100% EtOH at 44.6°C and 7700:1 in 50% EtOH at 44.6°C. Once again we must do an extrapolation making the untested assumption that the rate ratio is linear in Y; see Table 14. The extrapolated value for water is 58000:1.

If we use this rate ratio, and assume that it is insensitive to temperature, we predict that the rate of the Favorskii ionization for the enolate of chloroacetone would be $27/58\,000 = 5 \times 10^{-4}\,s^{-1}$. An argument in favor of this rate ratio is that ρ for 1-aryl-3-chloroacetones is −5. Nevertheless it is very possible that the rate ratio overestimates the effect of the phenyl substituent, because an oxyallyl cation should be sufficiently much more stable than an allyl cation to make less demand upon the substituents for stabilization. It is known that solvolysis of the enol of 3-chloro-1-phenyl-2-butanone readily leads to methoxyketone products, while analogous products are not seen in the reactions of 1-chloro-3-phenyl-2-propanone (32); clearly stabilization of the "carbocation" is still very important at least in the enol. Since 1-chloro-3-phenyl-2-propanone undergoes Favorskii rearrangement, ionization of the enolate is facile in

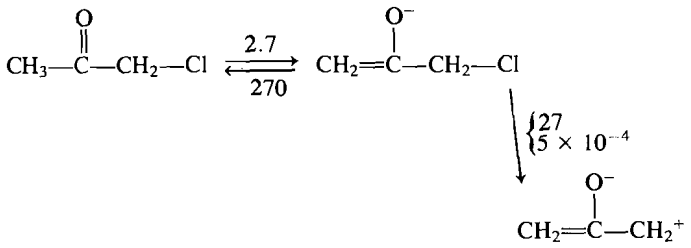
this system. Thus we can only estimate upper and lower limits on the rate of Favorskii ionization for the α′-enolate of monochloroacetone, and the pattern is:



with an overall rate constant, $k_1k_2/(k_{-1} + k_2)$, of $0.27[OH^-]$ s^{-1} estimated if the effect of the phenyl substituent in 1-chloro-3-phenyl-2-propanone is negligible, and $5 \times 10^{-6}[OH^-]\,s^{-1}$ using the large effect of the phenyl substituent estimated using the allyl system as a model. Both of these estimates are smaller than the observed rate constant for hydrolysis, namely, $1.19\ [OH^-]\,s^{-1}$.

The facts of the matter are clearly that the Favorskii rearrangement does not happen, because the nmr shows no sign of propionate, which would be clearly detectable if it were 10% of the total, and probably so even if it were less. The competing reactions are trapping of the α-enolate by halogen and intramolecular displacement by the hydroxide adduct, with the latter often being the dominant reaction. This suggests that the estimation procedure which we used for the upper limit on the rate of the Favorskii rearrangement has led to too high a value. Unfortunately there does not seem to be information available which would permit a better estimate of the value to be expected for our system.

Chlorination of hydroxyacetone

The stoichiometry of the hydroxyacetone reaction appears to be a function of $[OH^-]$; at $0.486\,M$ $[OH^-]$ it is 1.25 while at $0.0129\,M$ $[OH^-]$ it is 1.85 (9). This suggested that there is a competition between rearrangement, which is hydroxide-dependent and leads to a stoichiometry of 1, and a hydroxide-independent second halogenation which leads to a stoichiometry of 2. One must be cautious because the lower hydroxide concentrations lead to slower reactions which may also have more drift, giving spuriously high stoichiometries. Product studies (9) revealed only lactate as a detectable product in the nmr, but the intensity of the peaks was less than expected. There was no acetate.

A plot of n_{app} vs. $[OCl^-]/[OH^-]$, using data from Table 4, showed a possible tendency to increase with increasing $[OCl^-]/[OH^-]$ masked by very considerable scatter. A line calculated on the basis of the observed rate law for the reaction of 1,1-dihydroxyacetone was consistently too low.

One possible explanation would be competing reaction at the methyl group. The proportions of reaction of the methyl and methylene of hydroxyacetone will depend upon the hypochlorite concentration, because at high concentration only the relative rates of ionization matter, and at low concentration only the rates of trapping of the enolate by hypochlorite matter. Using the rate constant for hydroxyacetone enolization evaluated above, i.e. $0.048\,M^{-1}\,s^{-1}$ as the value for the methylene group, and taking the value for acetone (corrected for the number of hydrogens) as an estimate for the methyl group, i.e. $0.087\,M^{-1}\,s^{-1}$, we calculate that at high hypochlorite, reaction would be 64% at the methyl and 36% at the methylene. However, these values are of purely theoretical interest because from the values of the microscopic rate constants for acetone in Table 9 we can calculate that "high hypochlorite" for reaction at the methyl group would be in excess of $20\,M$. At low hypochlorite concentration, and high enough $[OH^-]$ that the reaction of hypochlorite ion dominates, the rate constant for halogenation involving the enolate derived from the hydroxymethylene is $19.2\,M^{-1}\,s^{-1}$ (9), and half the rate constant for acetone, taken as an estimate for the value for reaction involving the enolate derived from the methyl of hydroxyacetone, is $0.044\,M^{-1}\,s^{-1}$. Thus at low hypochlorite less than 0.5% of the reaction is by way of the methyl group.

Chlorination of dichloroacetone

We found that the rate law for the chlorination/hydrolysis kinetics required terms for intramolecular nucleophilic attack by both the mono- and dianionic hydrates of dichloroacetone. The results described above led to a rate constant for the intramolecular reaction of the monoanion of $0.0048\,s^{-1}$, while the intramolecular reaction of the dianion had a rate constant of $2.6\,s^{-1}$. The rate ratio is 531, although it should be borne in mind that the ratio is dependent upon a quite uncertain estimate for the second pK_a of 1,1-dichloroacetone hydrate. For the, admittedly quite different, rearrangement of phenylglyoxal to mandelate, the rate ratio can be estimated as 2000 (*vide infra*).

We did not detect a term in the rate law corresponding to reaction of the enolate of dichloroacetone with hypochlorous acid. Consequently we cannot make any estimate of the pK_a of the ketone. In any case such an estimate would be of doubtful validity, because it is by no means certain that the reaction would be diffusion-controlled (9). The equilibrium constant estimated for the halogenation reaction is distinctly smaller than for the earlier halogenations (9), even though it is still 10^{24}. Thus even if we had a rate constant permitting an estimation of the pK_a, the value so estimated would only be an upper limit.

The rate constants for hydroxide catalyzed enolization of acetone, monochloroacetone, and dichloroacetone are $0.173\,M^{-1}\,s^{-1}$ (10), $136\,M^{-1}\,s^{-1}$, and $3800\,M^{-1}\,s^{-1}$, respectively. These should be corrected for the number of reactive hydrogens in order to compare reactivity; the corrected values are $0.0288\,M^{-1}\,s^{-1}$, $68\,M^{-1}\,s^{-1}$, and $3800\,M^{-1}\,s^{-1}$, respectivley, for relative rates of $1{:}2.4 \times 10^3{:}1.3 \times 10^5$. For comparison Cox and Warkentin (38) report rate constants for acetate-catalyzed enolization of acetone, monobromoacetone, and dibromoacetone at 30°C in aqueous solution as 7.38×10^{-8}, 3.27×10^{-4}, and 5.05×10^{-3} respectively (all $M^{-1}\,s^{-1}$, and corrected for the number of reactive hydrogens). The relative rates are $1{:}4.4 \times 10^3{:}6.8 \times 10^4$. The relative rates are similar to those we found for the chloro ketones. In contrast Bell and Lidwell reported rate constants for acetone, monochloroacetone, and dichloroacetone of 0.042, 4.7, and 450, respectively (all converted to $M^{-1}\,s^{-1}$ and corrected for the number of reactive hydrogens). The corresponding relative rates are $1{:}1.1 \times 10^2{:}1.1 \times 10^4$. These relative rates suggest a distinctly smaller effect for replacement of hydrogen by halogen than what we found or what Cox and Warkentin found for bromine.

For dichloroacetone, the rate constant for phosphate dianion catalyzed enolization which we determined is very close to the value predicted by Bell's Brønsted correlation (12): observed, $0.018\,M^{-1}\,s^{-1}$; predicted $0.0122\,M^{-1}\,s^{-1}$. For monochloroacetone, the rate constant for carbonate anion catalyzed enolization which we determined is actually somewhat slower than the value predicted by Bell's Brønsted correlation (12) (although this represents a much longer extrapolation than for phosphate

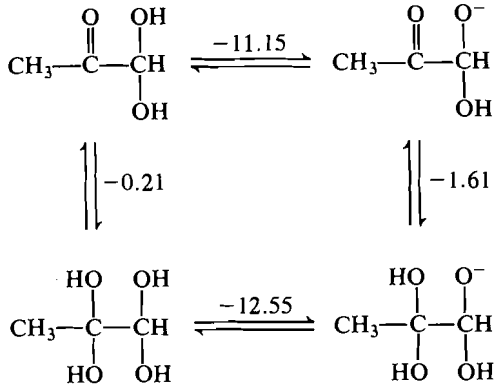
and dichloroacetone): observed, $0.25\,M^{-1}\,s^{-1}$; predicted 1.5 $M^{-1}\,s^{-1}$.

Rearrangement of 1,1-dihydroxyacetone

We may estimate pK_a values for dihydroxyacetone and tetrahydroxypropane using the Hine equation (24):

$$pK_a = 14.19 - 1.32\Sigma\sigma^*$$

For dihydroxyacetone we use $\sigma^*_{MeCO} = 1.81$ and $\sigma^*_H = 0.49$. For tetrahydroxypropane we use $\sigma^*_{MeC(OH)2} = 2 \times \sigma^*_{CH2OH} = 2 \times 0.62 = 1.24$. With these σ^* values, and the experimental value for hydration of neutral dihydroxyacetone, we estimate the equilibrium constants for the reaction cycle:



We also tried estimating the equilibrium constants for hydration of methylglyoxal and dihydroxyacetone, using the Greenzaid equation (23), $\log K_{hydration} = 1.70\Sigma\sigma^* + 2.03\Delta - 2.81$. For methylglyoxal this leads to $K_{hydration} = 1350$. For dihydroxyacetone the equation leads to $K_{hydration} = 0.198$; this is somewhat smaller than the observed value of 0.61 but is not bad, especially considering that the σ^* value had to be estimated.

The empirical rate law, expressed in terms of Scheme 1, gives $k_{IJ}K_{HI} = 0.122\,M^{-1}\,s^{-1}$ and $k_{HJ} = 0.00034$. The pK_a value of 11.15 estimated above leads to $K_{DH} = 708\,M^{-1}$. We may make a crude estimate of the second pK_a using Pauling's rules (15) as 16.2, and hence calculate $K_{HI} = 0.007$, and $k_{IJ} = 17\,s^{-1}$. At low pH, the apparent rate constants will be $k_{DJ} = k_{HJ}K_{DH}/(1 + K_{DN}) = 0.15\,M^{-1}\,s^{-1}$ and $k_{DJ}^- = k_{IJ}K_{HI}K_{DH}/(1 + K_{DN}) = 54\,M^{-2}\,s^{-1}$.

For 1,1-dihydroxyacetone rate constants at 37.5°C are available from the work of Ariyama (39). His values are given in Table 15. For 25°C we estimate that the rate constant will be 0.7 ± 0.4; this estimate was obtained using a factor of 2 in rate for a 12.5°C decrease in temperature, while giving error limits large enough to allow for the possiblity that the temperature effect is small; see below for phenyl glyoxal.

For phenyl glyoxal, a careful study at 35°C by Hine and Koser (40) is available. The apparent rate constant depends on the fraction of substrate which has ionized (K_1 (expressed as K_b) = 247 ± 17 M^{-1}) and is the sum of contributions for reaction of the monoanion and the dianion. The acid dissociation constant for the monoanion to give the dianion could not be determined. For conditions where the monoanion is the major species,

$$k_{app} = 2.95 \times 10^{-4} + 9.14 \times 10^{-2}[OH^-]\,s^{-1}$$

At pH 12, these values lead to a fraction of monoanion = 0.71, and an overall pseudo-first order rate constant = $8.61 \times 10^{-4}\,s^{-1}$.

A study of substituent effects at pH 12 was reported by Vanderjagt *et al.* (41). It should be noted that at pH 12 both monanion and dianion pathways are important, and that the proportions of these paths may depend on the substituent. For phenyl glyoxal itself a rate constant at pH 12, 25°C, of $7.6 \times 10^{-4}\,s^{-1}$ was reported. This is only slightly smaller than the value calculated from data (40) at 35°C, suggesting that the temperature dependence for this reaction may be small.

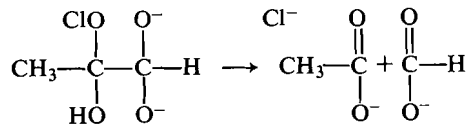
Our results lead to a predicted second order rate constant at low pH of $0.24\,M^{-1}\,s^{-1}$. This is somewhat smaller than the value estimated from the results of Ariyama, but depends on an estimated pK_a. For our rate constant from experiments at $[OH^-] > 0.01\,M$ to be consistent with the value calculated from Ariyama's data, i.e. $0.7\,M^{-1}\,s^{-1}$ the pK_a of dihydroxyacetone would have to be 10.3 and not 11.15. The difference is disturbing, but not impossible, especially when the acid strengthening substituent is a directly bonded carbonyl group which might exert a direct inductive effect as well as the field effect allowed for by a σ^* treatment.

There is a serious interpretational problem for the kinetics, because an alternative mechanism for the rearrangement of 1,1-dihydroxyacetone to lactate is enolization followed by reprotonation. The question is then whether this is competitive with intramolecular hydride transfer. If this were the mechanism, then the hydroxide-independent rate of rearrangement observed in dilute hydroxide solutions would represent enolization and not hydride transfer in the monoanion. The enolization would have to be a hydroxide-catalyzed reaction of the unionized substrate, with

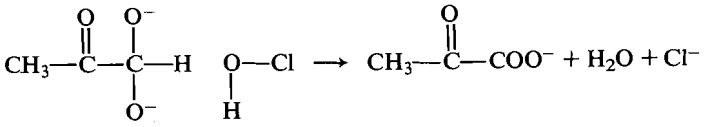
$$k_{obs} = k_{enolization}[OH^-]/K_{DH}[OH^-]$$
$$k_{enolization} = 0.00034 \times 708 = 0.21 \text{ (using } pK_a = 11.15)$$
$$= 0.00034 \times 5000 = 1.5 \text{ (using } pK_a = 10.3)$$

In either case the rate constant for enolization seems far too large compared to the trend observed for acetone and hydroxyacetone ($k_{enolization} = 0.0288\,M^{-1}\,s^{-1}$ and $0.0235\,M^{-1}\,s^{-1}$, respectively, on a per hydrogen basis). One would expect a rate constant of about $0.02\,M^{-1}\,s^{-1}$ for dihydroxyacetone as well. Since the pK_a value is likely to be less than 11.15 rather than greater, it seems improbable that the enolization mechanism is of major importance.

This has immediate consequences for the halogenation path; it clearly cannot involve enolization because in that case the observed halogen dependence of the rate constant would imply preequilibrium proton transfer. If the enolate formed, it would rapidly and irreversibly be converted to lactate (which is known to be inert under our conditions.) The hypochlorite-dependent reacton must then represent some other process; one could imagine either fragmentation of a hypochlorite adduct:



or hydride transfer from the monoanion to hypochlorite or from the dianion to hypochlorous acid:



A product study by nmr showed only lactate; acetate would be inert and should have persisted, but pyruvate would be expected

TABLE 15. Rate constants for rearrangement of methyl glyoxal[a]

pH	k (min^{-1})	k_2 ($M^{-1}\,s^{-1}$)
8.5	2.4×10^{-4}	1.27
9.5	3.22×10^{-3}	1.70
10.5	1.77×10^{-2}	0.93
		Av. 1.3 ± 0.4

[a]Rate constants from ref. 39; kinetics in water at 37.5°C.

to react further by halogenation on the methyl. Thus a hydride transfer mechanism looks more likely at this time.

Cleavage of trichloroacetone

The observed rate constant for the cleavage of trichloroacetone can be expressed in terms of the mechanism shown in Scheme 1 as:

$$k_{obs} = \frac{(k_{89}K_{78}[OH^-] + K_{78}K_{8N}k_{N9}[OH^-]^2)}{(1 + K_{7M} + K_{78}[OH^-] + K_{78}K_{8N}[OH^-]^2)}$$

At low hydroxide concentrations, where the anionic adduct is present in small amounts, and the dianionic adduct is not kinetically important, this can be simplified to

$$k_{obs} = (k_{89}K_{78}[OH^-])/(1 + K_{7M})$$

Using the equilibium constants from Table 10, we can calculate that $k_{89} = 0.023\ s^{-1}$. This value may be somewhat low because it implies that some signs of levelling off should have been observable in the measured portion of the pH rate profile for the reaction, while in fact there was no levelling off seen. The pK_a estimation may be imperfect because of steric effects of the bulky trichloromethyl group.

It seems distinctly possible that cleavage reactions involving the dianion will be significant in dilute hydroxide solutions, but we have not yet devised a way to follow the cleavage reaction under such conditions.

For chloral the reaction is distinctly slower (42); this probably reflects the smaller driving force for generating a formate rather than an acetate anion. For the monoanion $k = 1.29 \times 10^{-4}\ s^{-1}$. The p$K_a$ of the hydrate is 9.76; estimating the second pK_a of the hydrate as 14.8 (using Pauling's rule of 5 pK_a units for successive pK_a's (15)) we estimate that for the dianion $k = 18\ s^{-1}$, which is 1.4×10^5 faster than for the monoanion.

The monoanion reaction of trichloroacetone hydrate has $k_{89} = 0.023\ s^{-1}$ which is 178 times faster than the corresponding rate constant for chloral hydrate. If the same ratio holds for the rate constant for the dianions, we would expect that for trichloroacetone the dianion would react with a rate constant of $k_{P9} = 3000\ s^{-1}$. All we can say on the basis of our results is that this rate constant is less than $4.2 \times 10^5\ s^{-1}$, assuming that a 20% increase would have been visible.

Stoichiometry of the reactions

The overall stoichiometry, $n_{acetone}$, i.e., the number of moles of OCl^- consumed per mole of acetone reacting, can be expressed in terms of partitioning fractions as:

$$n_{acetone} = 1 + f_1(1 + f_2) + [(1 - f_1) + (1 - f_2)]f_3$$

where

f_1 = partitioning fraction for monochloroacetone
= halogenation/(hydrolysis + halogenation)

f_2 = partitioning ratio for dichloroacetone
= halogenation/(hydrolysis + halogenation)

f_3 = partitioning ratio for dihydroxyacetone
= halogenation/(hydrolysis + halogenation)

A similar expression can be derived for n_{mono}, the stoichiometry number for reaction of monochloroacetone, with the complicating factor that the reaction occurs in two phases; rapid reaction involving halogenation of monochloroacetone, and slower reaction of the hydroxyacetone formed by hydrolysis.

$$n_{mono} = f_1(1 + f_2) + (1 - f_1) + [(1 - f_1) + f_1(1 - f_2)]f_3$$

The same complication applies to n_{di}, the stoichiometry number for reaction of dichloroacetone.

$$n_{di} = f_2 + (1 - f_2)f_3$$

The stoichiometry numbers for hydroxyacetone, $n_{hydroxy}$, and dihydroxyacetone, n_{glyox}, are quite simple.

$$n_{hydroxy} = 1 + f_3$$

$$n_{glyox} = f_3$$

The three partitioning fractions may be expressed in terms of the mechanism in Scheme 1 as:

$$f_1 = \frac{\dfrac{k_{34}[OH^-]\{(k_{45}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{45}^{-}\}[OCl^-]}{\{(k_{45}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{45}^{-}\}[OCl^-] + k_{43}}}{\dfrac{k_{34}[OH^-]\{(k_{45}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{45}^{-}\}[OCl^-]}{\{(k_{45}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{45}^{-}\}[OCl^-] + k_{43}} + k_{AB}K_{3A}[OH^-]}$$

$$= \frac{1}{1 + \dfrac{k_{AB}K_{3A}[OH^-]\{1 + \{(k_{45}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{45}^{-}\}[OCl^-]/k_{43}\}}{(k_{34}/k_{43})\{(k_{45}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{45}^{-}\}[OCl^-]}}$$

$$f_2 = \frac{\dfrac{k_{56}[OH^-]\{(k_{67}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{67}^{-}\}[OCl^-]}{\{(k_{67}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{67}^{-}\}[OCl^-] + k_{65}}}{\dfrac{k_{56}[OH^-]\{(k_{67}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{67}^{-}\}[OCl^-]}{\{(k_{67}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{67}^{-}\}[OCl^-] + k_{65}} + k_{ED}K_{5E}[OH^-]}$$

$$= \frac{1}{1 + \dfrac{k_{ED}K_{5E}[OH^-]\{1 + \{(k_{67}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{67}^{-}\}[OCl^-]/k_{65}\}}{(k_{56}/k_{65})\{(k_{67}^{0}K_w/K_a^{HOCl}[OH^-]) + k_{67}^{-}\}[OCl^-]}}$$

$$f_3 = \frac{k_{HG}[OCl^-]}{k_{HG}[OCl^-] + K_{DH}[OH^-]\{k_{HJ} + k_{IJ}K_{HI}[OH^-]\}} = \frac{1}{1 + \dfrac{\{k_{HJ} + k_{IJ}K_{HI}[OH^-]\}K_{DH}[OH^-]}{k_{HG}[OCl^-]}}$$

The product ratios, [acetate]/[lactate], may be expressed in terms of the same partitioning fractions as:

$$([Acetate]/[lactate]_{acetone} = f_1f_2/\{[(1 - f_1) + f_1(1 - f_2)](1 - f_3)$$
$$= ([Acetate]/[lactate])_{monochloro}$$
$$([Acetate]/[lactate]_{dichloro} = f_2/[(1 - f_2)(1 - f_3)]$$

Figures 7–9 show the dependence of the stoichiometry numbers upon the concentrations of hydroxide and hypochlorite calculated using the rate and equilibrium constants in Table 9. The major uncertainty in these stoichiometry numbers is probably our uncertain knowledge of f_3, since the kinetics of the dihydroxyacetone reaction were less thoroughly explored. However, for most conditions this reaction is almost entirely rearrangement. There is also an uncertainty in f_2 at low $[OH^-]$ because we were not able to determine the rate constant for the term in the rate law corresponding to reaction of hypochlorous acid with the enolate of dichloroacetone.

When the ketone is in excess, one of the competitions which governs the stoichiometry is the competition for halogenating agent among the unhalogenated ketone, less reactive but at higher concentration, and the halogenated intermediates, more reactive, but present at low concentrations. This question may be addressed in terms of the steady-state concentrations of the halogenated ketone intermediates, because if the ratio of concentrations of two ketones becomes less than the reciprocal of the ratio of their reactivities under the same conditions, then the less abundant though more reactive ketone will lose out, and will undergo reactions other than halogenation, or simply accumulate if there is no facile reaction path other than halogenation. The steady-state concentrations of monochloroacetone and dichloroacetone may be expressed as:

$$[mono]_{ss} = \frac{\dfrac{k_{12}[OH^-]\{(k_{23}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{23}{}^-\}[OCl^-]}{\{(k_{23}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{23}{}^-\}[OCl^-] + k_{21}}}{\dfrac{k_{34}[OH^-]\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{45}{}^-\}[OCl^-]}{\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{45}{}^-\}[OCl^-] + k_{43}} + k_{AB}K_{3A}[OH^-]}$$

$$[di]_{ss} = \left\{\frac{k_{34}[OH^-]\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{45}{}^-\}[OCl^-]}{\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{45}{}^-\}[OCl^-] + k_{43}}\right\} \Bigg/ \left\{\frac{k_{56}[OH^-]\{(k_{67}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{67}{}^-\}[OCl^-]}{\{\{(k_{67}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{67}{}^-\}[OCl^-] + k_{65}\}\{1 + K_{5L} + K_{5E}[OH^-]\}} + \frac{k_{ED}K_{5E}[OCl^-]}{\{1 + 1/K_{5L} + 1/(K_{5E}[OH^-])\}}\right\}$$

Now we derive expressions for the relative rates of halogenation

$$k_{acetone}/k_{mono} = \frac{\dfrac{k_{12}[OH^-]\{(k_{23}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{23}{}^-\}[OCl^-]}{\{(k_{23}{}^0K_w/K_a{}^{HOCl}[OH^-] + k_{23}{}^-\}[OCl^-] + k_{21}}}{\dfrac{k_{34}[OH^-]\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{45}{}^-\}[OCl^-]}{\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-] + k_{45}{}^-\}[OCl^-] + k_{43}}}$$

$$k_{acetone}/k_{di} = \frac{\dfrac{k_{12}[OH^-]\{(k_{23}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{23}{}^-\}[OCl^-]}{\{(k_{23}{}^0K_w/K_a{}^{HOCl}[OH^-] + k_{23}{}^-\}[OCl^-] + k_{21}}}{\dfrac{k_{56}[OH^-]\{(k_{67}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{67}{}^-\}[OCl^-]}{\{\{(k_{67}{}^0K_w/K_a{}^{HOCl}[OH^-] + k_{67}{}^-\}[OCl^-] + k_{65}\}\{1 + K_{5L} + K_{5E}[OH^-]\}}}$$

$$k_{mono}/k_{di} = \frac{\dfrac{k_{34}[OH^-]\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{45}{}^-\}[OCl^-]}{\{(k_{45}{}^0K_w/K_a{}^{HOCl}[OH^-] + k_{45}{}^-\}[OCl^-] + k_{43}}}{\dfrac{k_{56}[OH^-]\{(k_{67}{}^0K_w/K_a{}^{HOCl}[OH^-]) + k_{67}{}^-\}[OCl^-]}{\{\{(k_{67}{}^0K_w/K_a{}^{HOCl}[OH^-] + k_{67}{}^-\}[OCl^-] + k_{65}\}\{1 + K_{5L} + K_{5E}[OH^-]\}}}$$

Examination of these expressions shows that the problem was incorrectly phrased; the steady-state concentration is that concentration at which the intermediate *does* compete effectively for the halogenating agent, unless other reactions provide the major channel for consumption of the intermediate. Thus in assessing the partitioning of the intermediate with ketone in excess only the partitioning fractions matter.

Conclusions

Although some of the component reactions are not yet completely understood, and some terms in the rate law have not yet been detected, we have now a far more detailed picture of the overall kinetics of the alkaline chlorination of acetone. The most striking conclusion is that for this "well-known" reaction there are numerous competing paths with closely similar activation

energies, so that small changes in conditions can lead to new and unexpected products.

Experimental

Materials

1-Chloro-2-propanone (Eastman practical grade) was shown by proton nmr to be 93 mol% monochloroacetone, 5 mol% 1,1-dichloroacetone, and 1–2 mol% acetone. As these were not separable by fractional distillation, the impure compound was used for the initial kinetics. A 0.10 *M* stock solution was made up in 1 *M* KCl containing 0.00001 *M* HCl and stored in a refrigerator; fresh stock solutions were made up every 2–3 weeks. For each run, 2.0 mL of the stock solution was made up to 50 mL with 1 *M* KCl to make 0.004 *M* chloroacetone.

Chloroacetone dimethyl ketal. 1-Chloro-2-propanone (Eastman practical grade), 30.3 g (0.3 mol), trimethyl orthoformate, 35 mL (34.1 g, 0.3 mol), methanesulphonic acid, 0.5 mL, and methanol, 1 mL, were refluxed for ½ h. Distillation yielded 20 mL of methyl formate, bp 32–34°C and 20 mL of a mixture, bp 102–112°C, found by ^{1}H-nmr analysis to contain chloroacetone, chloroacetone dimethyl ketal, and methanol as well as other unidentified impurities. This mixture was stirred overnight with 20% aqueous Na_2CO_3, 40 mL, and extracted with ether, 3 × 10 mL. The extracts were dried, Na_2CO_3, and distilled at atmospheric pressure, yielding 3 mL of material with bp 132–134°C, and 3 mL with bp 134–136°C; higher boiling residues began to decompose before distilling and were discarded. ^{1}H-nmr analysis of these distillates showed that the fraction boiling at 132–134°C was about 90% ketal, with about 3% chloroacetone, and the fraction boiling at 134–136 was about 80% ketal with about 1–2% chloroacetone. The ketal fraction boiling at 132–134°C was purified by preparative gas chromatography using a 20′ by ⅜″ od column of 20% SE-30 on chromosorb A and a helium flow rate of 135 mL/min. A total of six injections, 200–300 μL each, yielded about 1 mL of product. ^{1}H-nmr analysis showed that the peaks assigned to the ketal accounted for 95% of the total protons. This material was redistilled, bp 50°C/15 Torr, yielding about 0.75 g of colorless product. Literautre bp: 132–134°C (43).

Stock solutions of monochloroacetone prepared from the ketal. For all of the later kinetics of chlorination of monochloroacetone, chloroacetone dimethyl ketal was used as the source of chloroacetone. Stock solutions prepared from the ketal were made 0.002 *M* in HCl and were allowed to stand for 24 h at room temperature to hydrolyze. ^{1}H-nmr showed that hydrolysis was complete after this period. The stock solutions were then neutralized (1 *M* NaOH) to pH 5. The ^{1}H-nmr spectra subsequently remained unchanged after 3 days at room temperature. The stock solutions were stored in a refrigerator.

Bromoacetone stock solutions were made in a similar manner from the dimethyl ketal (Aldrich 97% 1-bromo-2,2-dimethyoxypropane).

1,1-Dichloroacetone (Aldrich 98%) was used without purification. The proton nmr in chloroform was clean except for a small (less than 3%) extra signal at 2.6 ppm, 0.2 ppm downfield from the methyl signal at 2.4 ppm. The stock solution (0.116 *M* in 1 *M* KCl) had a pH of 3.2 immediately after preparation. The stock solution was stored in a refrigerator when not in use. For each run, 1.0 mL of stock was diluted to 50 mL with 1 *M* KCl, making 0.0023 *M* ketone.

1,1,1-Trichloroacetone was prepared according to the method of Winston *et al.* (44) in 10% yield from sodium trichloroacetate and acetic anhydride, and purified by column chromatography on silica gel with 20:80 ether/petroleum ether as eluant, followed by distillation at 60°C/40 Torr. The proton spectrum in water showed two signals assigned to methyl groups, a larger one at 1.9 ppm for the hydrate, and a much smaller one at 2.6 ppm for the ketone. The stock solution (0.345 *M* in water) was made 0.0005 *M* in HCl as a protection against premature hydrolysis. For each titration, 0.50 mL of the stock was diluted to 50 mL with 1 *M* KCl, making 0.00345 *M* ketone.

All the stock solutions in water appeared to be stable for up to two months at room temperature, as their proton nmr spectra did not change.

Methods

pH-state kinetics with mono-, di-, and trichloroacetone. The reactions were followed for 50 mL portions of substrate solution in 1 *M* aqueous KCl made from freshly degassed water. The reaction vessel was a water-jacketed beaker kept at 25.0°C by a circulating water bath. Standardized 0.102, 0.512, or 1.027 *M* NaOH was used as titrant. The apparatus used consisted of a Radiometer pH meter 25, titrator 11, and glass electrode GK2301C, standardized with Fisher buffers at pH 4, 7, and 10 (±0.02) Points were taken manually and then typed into a computer file which was fitted by least squares to a single exponential with a linear term to accommodate CO_2 uptake. The pH was maintained constant to within 0.03 pH units during a run. Runs were followed to at least 10 half-lives, often 20 or more, except for one of the trichloroacetone runs, which was stopped because of leakage in the system; for this run a calculated infinity parameter was used.

Chloroacetone and dichloroacetone kinetics with OCl^- and OBr^-. All hypochlorite and hypobromite solutions were made using water redistilled from permanganate, reagent grade NaOH and chlorine or bromine, and were made up to 1 *M* ionic strength with KCl and KBr, respectively. All values of hydroxide concentrations were obtained by titration against aqueous HCl standardized with vacuum-dried TRIS. Hypochlorite concentrations were determined by absorbance measurements at the uv maximum, 292 nm, using an extinction coefficient of 352 (45). Some OCl^- concentrations were determined by titration using thiosulfate solution standardized against KIO_3. For 22 solutions where comparisons of titration values with absorbance values were made (concentrations 0.0005 *M* – 0.005 *M*), the discrepancy was always less than 2%, with an average of 0.7%. Hypobromite concentration were determined by absorbance at 331 nm using the published (46) extinction coefficient of 326.

Buffers. Carbonate buffers (ionic strength 1 *M*) were prepared from $KHCO_3$ (Fisher A.C.S. Reagent), KBr (Baker reagent), NaOH (Baker reagent), and redistilled water. Phosphate buffers (ionic strength 1 *M*) were prepared from KH_2PO_4 (Baker analytical reagent), KBr (Baker reagent), NaOH (Baker reagent), and redistilled water. Acetate buffers (ionic strength 1 *M*) were prepared from glacial acetic acid (Baker reagent), NaOAc (Fisher certified reagent), and KBr (Baker reagent). Less concentrated buffers in a buffer-dilution series were made by diluting the more concentrated buffer with 1 *M* KBr and making fine adjustments with 1 *M* NaOH and 1 *M* HCl (pH meter) if necessary to keep the pH constant. Such adjustments were not usually necessary.

Bromination of mono- and 1,1-dichloroacetone. A solution of KBr in redistilled water was made approximately 0.025 *M* in bromine (Merck ultra-pure). For runs involving the most dilute carbonate buffers (0.001 *M* CO_3^{2-}), the 0.025 *M* bromine was adjusted to the pH of the buffer being used by adding 0.05 *M* NaOH. This was done so that the bromine addition would not alter the buffer ratio. Measured volumes of buffer in 1- or 2-cm uv cells were brought to temperature equilibrium in the thermostatted cell holder of a Cary-210 spectrophotometer and the balance control brought to zero absorbance at 267 nm. A small volume (less than 1.5% of total volume) of 0.025 *M* bromine was added and the absorbance at 267 nm recorded. Reactions were initiated by injecting a portion (less than 1% of the total volume) of an aqueous stock solution of ketone and shaking the cell for 2–3 s before returning it to the cell compartment. The absorbance was followed at 267 nm. Bromine was present in 5- to 10-fold excess over ketone.

The apparent extinction coefficient of bromine in 1 *M* KBr or in 1 *M* KBr buffered at pH 8.82 (0.015 *M* CO_3^{2-}) was determined using solutions of ca. 1×10^{-4} *M* bromine which had been allowed to stand for several days and then titrated against freshly standardized 0.01 *N* thiosulphate solution. For pH 8.82 buffer the concentration of the solution was 1.57×10^{-4} *M*, the absorbance was 2.999 at 267 nm and the extinction coefficient was 19 000 M^{-1} cm^{-1}. For 1 *M* KBr the total bromine concentration was 6.16×10^{-5} *M*, the absorbance was 2.396 at 267 nm and the extinction coefficient was 38 900 M^{-1} cm^{-1}. In the same way apparent extinction coefficients were determined for phosphate buffers at each pH and for acetate buffers at pH 5.53 at least at the highest and lowest buffer concentrations; the main factor influencing the apparent extinction coefficient is presumed to be the bromide ion concentration. The values found are given in the footnotes to Table 5.

Dihydroxyacetone kinetics. Stock solutions for kinetics were prepared from pyruvic aldehyde dimethyl acetal (Aldrich 99%). A 60 MHz proton spectrum of the acetal in chloroform showed only three singlets: δ 4.6 (1H), 3.6 (6H) and 2.3 (3H). The acetal (0.900 g, 0.0076 mol) was dissolved in 1 *M* HCl, 250 mL, and heated on a steam bath for 3 h. 1 *M* NaOH was then added, with efficient stirring, until the pH reached 6.8. The resulting solution, made up to 500 mL, was 0.0152 *M* in product and did not decolorize bromine water. A ^{1}H-nmr spectrum showed three singlets: δ 3.49 (6H), MeOH; 2.67 and 1.75 (3H for the two together), MeCO- and $MeC(OH)_2$- in a ratio of 1.63:1. UV (water) $\lambda_{max} = 282.5$, $\epsilon = 15$; Lit $\lambda_{max} = 282.5$ $\epsilon = 27.5$ (47). All hydroxide concentrations were determined by titration. Cells were filled with the hydroxide solution, a base line recorded on the Cary, adjusted to zero absorbance and then injected with concentrated NaOCl. The volume of added hypochlorite was small compared to the cell volume (maximum 1.3% volume change). The hypochlorite concentration was taken as absorbance at 292 just before the reaction divided by the extinction coefficient, 352. Reactions were initiated by injecting ketone stock solutions: 40–100 μL with a 100 μL syringe into 3 mL of base-hypochlorite solution or 400 μL with a 500 μL syringe into 25 mL. Concentrations of OH^- and OCl^- were corrected for the volume change accompanying injections.

Product studies on dihydroxyacetone. (*i*) Stock dihydroxyacetone, 1 mL, was added to 0.294 *M* NaOH, 34 mL, stirred for 200 s and then neutralized to pH 7 with HCl containing a small proportion of phosphate. Initial concentrations: $[OH^-]$ 0.285; [ketone] 4.34×10^{-4} *M*. (*ii*) Stock dihydroxyacetone, 1 mL, was added to a solution 0.294 *M* in NaOH and 0.0018 *M* in NaOCl, 34 mL, stirred for 300 s, then hypochlorite was destroyed by adding sodium bisulphite, 7 mg, and the solution neutralized as before. Initial concentrations: $[OH^-]$, 0.285 *M*; $[OCl^-]$, 0.0017 *M*; [ketone], 4.34×10^{-4} *M*. The second procedure was repeated using lithium lactate, 1.45 mg, instead of dihydroxyacetone. Initial concentration: [lactate] 4.32×10^{-4} *M*. When the solutions were evaporated to dryness, the salts could not be dissolved by adding less than 2 mL of water. The resulting product concentration, less than 0.01 *M*, could not be seen by ^{1}H nmr at

Pyrrolyl complexes of the early transition metals. 3. Preparation and crystal structure of $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$ and $Zr(\eta^1\text{-}NC_4H_2Me_2)_4$

The title compounds were synthesized by the reactions of $NaNC_4H_2Me_2$ with the appropriate complex metal chloride in THF. The crystal structures have been determined from X-ray data measured by counter methods. $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$ crystallizes in the orthorhombic space group Pbca with cell dimensions $a = 15.797(6)$, $b = 14.327(5)$, $c = 16.417(6)$ Å, and $\rho_{calcd} = 1.46$ g cm^{-3} for $Z = 8$. Full-matrix least-squares refinement led to a final R factor of 0.041 based on 536 observed reflections. $Zr(\eta^1\text{-}NC_4H_2Me_2)_4$ belongs to the monoclinic space group $P2_1/n$ with $a = 14.065(5)$, $b = 10.717(4)$, $c = 15.733(6)$ Å, $\beta = 90.61(4)°$, and $\rho_{calcd} = 1.31$ g cm^{-3} for $Z = 4$. A final R value of 0.029 resulted from the refinement on the basis of 2649 observed reflections. The dicyclopentadienyl derivative exhibits two features of importance. The Zr—N—centroid angles are 159 and 168°, and the Zr—N bond lengths are 2.24(2) Å. In the homoleptic complex the corresponding values are 164–169° and 2.069(3)–2.090(3) Å. In both cases the bonding parameters are indicative of a substantial amount of π overlap between the zirconium atom and the pyrrolyl nitrogen atom.

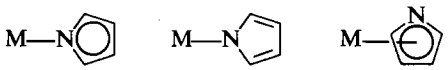
R. VANN BYNUM, H.-M. ZHANG, WILLIAM E. HUNTER et JERRY L. ATWOOD. Can. J. Chem. **64**, 1304 (1986).

On a synthétisé les composés mentionnés dans le titre par réaction, dans du THF, du $NaNC_4H_2Me_2$ avec le complexe du chlorure métallique approprié. On a déterminé les structures cristallines à partir de données de diffraction de rayons x obtenues par les méthodes des compteurs. Le $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$ cristallise dans le groupe d'espace orthorhombique Pbca avec $a = 15,797(6)$, $b = 14,327(5)$ et $c = 16,417(6)$ Å et $\rho_{calcd} = 1,46$ g cm^{-3} pour $Z = 8$. On a affiné la structure par la méthode des moindres carrés (matrice entière) jusqu'à une valeur finale de R de 0,041 pour 536 réflexions observées. Le $Zr(\eta^1\text{-}NC_4H_2Me_2)_4$ cristallise dans le groupe d'espace monoclinique $P2_1/n$ avec $a = 14,065(5)$, $b = 10,717(4)$, $c = 15,733(6)$ Å, $\beta = 90,61(4)°$ et $\rho_{calcd} = 1,31$ g cm^{-3} pour $Z = 4$. On a affiné la structure jusqu'à une valeur finale de R égale à 0,029 pour 2649 réflexions observées. Le dérivé dicyclopentaniényle présente deux caractéristiques importantes. Les angles 2r—N—centroïdes sont égaux à 159 et 168° alors que les longueurs des liaisons Zr—N sont égales à 2,24(2) Å. Dans le complexe homoleptique, les valeurs correspondantes sont de 164–169° et 2,069(3)–2,090(3) Å. Dans les deux cas, les paramètres de liaison sont une indication d'une quantité importante de recouvrement π entre l'atome de zirconium et l'azote du cycle pyrrolyle.

[Traduit par la revue]

Introduction

The pyrrolyl anion can interact with a metal ion in three different ways, **1**–**3**. Compared to the isoelectronic cyclopenta-



1 **2** **3**

dienyl ion, the σ bonding modes are expected to be preferred. However, under an appropriate combination of steric and electronic environments the π-attachment should be accessible to early transition metals. We have previously characterized several Group IVb pyrrolyl complexes: $(\eta^5\text{-}C_5H_5)_2M(\eta^1\text{-}NC_4H_4)_2$ (M = Ti (1), Zr (1), and Hf (2)), $[Na(THF)_6]_2[Zr(\eta^1\text{-}NC_4H_4)_6]$, and $[Li(DME)_3][(\mu\text{-}Cl)(\mu\text{-}O)\{(\eta^5\text{-}C_5Me_5)Zr(\eta^1\text{-}NC_4H_4)(Cl)\}_2]$ (3). In each case the σ interaction, **1**, was found. Since the existence of four cyclopentadienyl-like ligands about Zr or Hf clearly presents a delicate balance of steric and electronic effects,[3] we have undertaken a study of several hindered pyrrolyl anions. Specifically, substitution of bulky groups for the hydrogen atoms in the 2- and 5-positions on the parent molecule should make a π-bonding mode more attractive. Herein we present work with the 2,5-dimethylpyrrolyl anion,

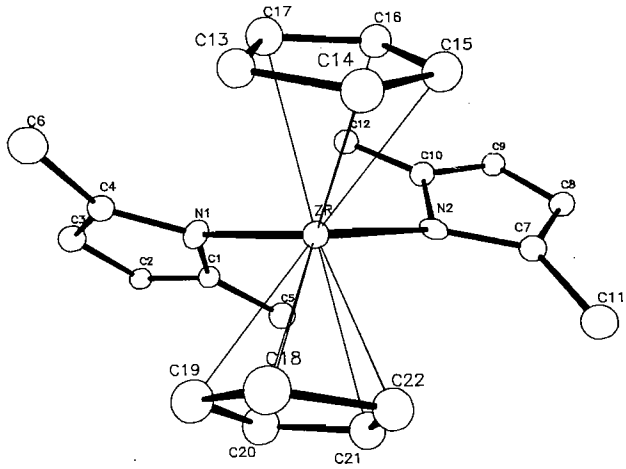


FIG. 1. Molecular structure and atom numbering scheme for $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$.

and show that under the conditions employed bond type **1** is again dominant.

Results and discussion

Dicyclopentadienylbis(2,5-dimethylpyrrolyl)zirconium(IV) was prepared by the straightforward addition of $NaNC_4H_2Me_2$ to $(\eta^5\text{-}C_5H_5)_2ZrCl_2$ in THF. The deep red complex was obtained by extraction with and recrystallization from benzene. The structure presented in Fig. 1 illustrates the σ bonding mode of the pyrrolyl ligand. **1** rather than **2** is designated by the

Zr---N(1)---Cnt(1)	164.1	Zr---N(3)---Cnt(3)	165.9
Zr---N(2)---Cnt(2)	1667.	Zr---N(4)---Cnt(4)	169.4

Zr—N—centroid angles of 159 and 168°. The average is virtually identical to that found for $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_4)_2$, 164° (1). The presence of the methyl substituents on the ligand apparently serve to weaken the Zr—N bond. The length is 2.169(3) Å in the dipyrrolyl complex, but 2.24(2) Å in $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$. Other bond lengths and angles are given in Table 1.

Encouraged by the evidence of a weaker Zr—N σ bond in $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$, we sought tetrakis(2,5-dimethylpyrrolyl)zirconium(IV). Perhaps here the need for coordinative saturation would force one or more π-bonded pyrrolyl groups on the metal. The complex was prepared by the reaction of THF-free $NaNC_4H_2Me_2$ with $ZrCl_4$ in benzene. The structure of the red–orange air-sensitive compound is shown in Fig. 2. The ligand obviously has the bulk to prevent the formation of an anion such as that found for $NC_4H_4^-$ itself, $Zr(\eta^1\text{-}NC_4H_4)_6^{2-}$, but the nitrogen atom is still available for the formation of Zr—N σ bonds. Indeed, the Zr—N lengths of 2.069(3) → 2.090(3) Å are among the shortest yet reported.[4]

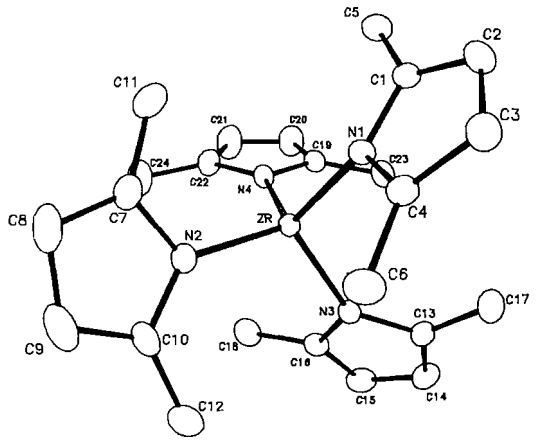

FIG. 2. Molecular structure of $Zr(\eta^1\text{-}NC_4H_2Me_2)_4$.

Before a comparison is made between the Zr—N distances in $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$ and $Zr(\eta^1\text{-}NC_4H_2Me_2)_4$, a few general comments on metal–ligand σ bond lengths are in order. Over the past several years our group has studied a large number of compounds which contain M—C(σ) bonds. Of the many factors governing bond lengths one seems dominant: the electronic environment at the metal as simply evidenced by the electron count. For example, Mo—C(σ) bond lengths range from 2.291(5) Å in $(\eta^6\text{-}C_6H_5Me)MoMe_2(PPhMe_2)_2$ (6) to 2.397(19) Å in $(\eta^5\text{-}C_5H_5)MoEt(CO)_3$ (7) for 18-electron situations. However, typical 12-electron cases reveal much shorter bond distances: 2.110(16) Å in $Mo(CH_2SiMe_3)_3(PMe_3)(Cl)$ (8) and 2.131 Å in $Mo_2(CH_2SiMe_3)_6$ (9). There exists a large body of data to support this view, and the examples given above are simply representative. One should expect a shorter Zn—N length in the formally 8-electron situation, $Zr(\eta^1\text{-}NC_4H_2Me_2)_4$, relative to the 16-electron $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$. One finds average values of 2.079(8) and 2.24(2) Å, respectively.

The Zr—N distance of 2.079(8) Å (or even the one at 2.24(2) Å is indicative of a substantial d_π–p_π interaction. The value is one of the shortest reported for a Zr^{4+} complex (5), and is significantly shorter than the Zr—C(carbonyl) distance of 2.187(4) Å in $(\eta^5\text{-}C_5H_5)_2Zr(CO)_2$ (10). Further evidence for π overlap is found in the Zr—N—centroid angles which range from 164 to 169° and average 167°. Table 1 contains additional bond lengths and angles.

Present work centers on the 2,5-di-*t*-butylpyrrolyl ligand, and the elusive η^5-attachment may soon be available.

Experimental

All reactions were carried out by Schlenk techniques under argon or in a Vacuum Atmospheres drybox. Solvents were distilled from $LiAlH_4$ (tetrahydrofuran, THF) or sodium and degassed before use. $(\eta^5\text{-}C_5H_5)_2ZrCl_2$ and purchased from Alfa Inorganics and used without further purification. 2,5-Dimethylpyrrolyl was purchased from Aldrich and distilled prior to use.

Synthesis of 2,5-dimethylpyrrolylsodium

Excess sodium hydride and THF (*ca.* 500 mL) were placed in a Schlenk flask fitted with an overhead stirrer and a dropping funnel.

[4]The literature contains a Zr—N length of 2.081(4) Å in the Zr^{2+} compound $[(\eta^5\text{–}C_5Me_5)_2ZrN_2]_2N_2$ (5*a*). We have recently characterized $(\eta^5\text{–}C_5H_5)_2Zr(Cl)$ (N=CHPh) in which the Zr=N distance, 2.013(5) Å, implies the existence of a Zr=N linkage (5*b*).

Freshly redistilled 2,5-dimethylpyrrole (95 g, 1 mol) as a 50% solution in THF was then added dropwise over several hours. Gas evolution was noted, and heat was given off. After the mixture was stirred overnight, the excess sodium hydride was removed by filtration and the solution diluted to 1.0 L with THF. Aliquots were hydrolyzed and titrated with standardized HCl to confirm a 1.0 *M* solution.

Synthesis of dicyclopentadienylbis(2,5-dimethylpyrrolyl)zirconium(IV)

$(\eta^5\text{-}C_5H_5)_2ZrCl_2$ (1.46 g, 5 mmol) was dissolved in *ca.* 100 mL of THF. 2,5-Dimethylpyrrolylsodium (1.17 g, 10 mmol) was added via syringe. The solution immediately changed from colorless to red–orange. After 24 h, the solvent was removed under vacuum and the residue extracted with benzene. The solution thus obtained was filtered and on cooling produced deep red, mildly air-sensitive crystals (1.25 g, 61%).

Synthesis of tetrakis(2,5-dimethylpyrrolyl)zirconium(IV)

2,5-Dimethylpyrrolylsodium (2.34 g, 20 mmol) was syringed into a Schlenk flask and the THF removed under vacuum. The flask was then warmed under vacuum overnight to ensure complete removal of the THF. Benzene (*ca.* 100 mL) and $ZrCl_4$ (1.16 g, 5 mmol) were added and the solution brought to reflux. After 24 h, the resulting orange solution was filtered and cooled, and the red–orange air-sensitive crystals were collected (1.14 g, 49%).

X-ray data collection, structure determination, and refinement for $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$

Single crystals of the compound were sealed under N_2 in thin-walled glass capillaries. A well-formed crystal of dimensions 0.10 × 0.10 × 0.20 mm was selected. Final lattice parameters were determined from a least-squares refinement of $(\sin\theta/\lambda)^2$ values for 15 reflections ($\theta > 15°$) accurately centered on the diffractometer.

Data were collected on an Enraf-Nonius CAD-4 diffractometer by the θ–2θ scan technique. The method has been previously described (11). Three check reflections were measured after every 297 reflections and they showed only random fluctuations. A total of 1504 reflections were measured of which 536 were deemed observed ($I/\sigma(I) \geq 3.0$). The intensities were corrected for Lorentz and polarization effects, but not for absorption.

Calculations were carried out with the SHELX system of computer programs (12). Neutral atom scattering factors for Zr, N, and C were taken from Cromer and Waber (13). Scattering factors for H were from ref. 14.

The structure was solved by the application of the direct methods program MULTAN (15). Least-squares refinement with isotropic thermal parameters led to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.092$. Hydrogen atoms on the cyclopentadienyl rings were placed in calculated positions and not refined. At this point it should be noted that only very small crystals could be grown. The data were therefore quite limited: only 36% of the measured reflections were considered observed, and virtually no data could be obtained beyond $2\theta = 36°$. While the small data set was good (as evidenced by the *R* factors), it would support only a limited refinement, and high standard deviations for the derived parameters were obtained. Only the Zr and N atoms were refined with anisotropic thermal parameters. The value of *R* was 0.041 and $R_w = \{\Sigma(|F_o| - |F_c|)^2/\Sigma w(F_o)^2\}^{1/2}$, 0.049. A final difference Fourier map showed no significant feature. Unit weights were used at all stages of refinement. The positional parameters are given in Table 2.[5]

Crystal data

$C_{22}H_{26}N_2Zr$ $M = 409.7$

Orthorhombic, space group *Pbca*, $a = 15.797(6)$, $b = 14.327(5)$, $c = 16.471(6)$ Å, $U = 3727.8$ Å^3, $Z = 8$, $D_c = 1.46$ g cm^{-3}, MoK_α radiation, $\lambda = 0.71069$ Å, $\mu(MoK_\alpha) = 5.89$ cm^{-1}, $F(000) = 1696$.

[5]The tables of structure factors, anisotropic thermal parameters, hydrogen atom coordinates, and complete bond lengths and angles for both compounds are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

X-ray data collection, structure determination, and refinement for $Zr(\eta^1\text{-}NC_4H_2Me_2)^4$

The compound was manipulated and data collected in the same manner as for $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}NC_4H_2Me_2)_2$. However, an excellent crystal gave rise to a superb data set, and faith can be placed in the derived parameters. The crystal of dimension 0.20 × 0.30 × 0.40 mm gave 2649 observed reflections out of a total of 3100 measured to 2θ cut-off of 46°. Three check reflections were measured after 297 reflections and only random fluctuations were noted. All hydrogen atoms were located with the aid of a difference Fourier map, but the coordinates were not refined. The nonhydrogen atoms were refined with anisotropic thermal parameters. The final reliability factors were $R = 0.029$ and $R_w = 0.031$. A final difference Fourier showed no feature greater than $0.3\ e^-/Å^3$. Unit weights were used at all stages of refinement. The atomic coordinates are given in Table 3.[3]

Crystal data

$C_{24}H_{32}N_4Zr$ $M = 467.8$

Monoclinic, space group $P2_1/n$, $a = 14.065(5)$, $b = 10.717(4)$, $c = 15.773(6)$ Å, $\beta = 90.61(4)°$, $U = 2377.4$ Å^3, $Z = 4$, $D_c = 1.31\ g\ cm^{-3}$, MoK_α radiation, $\lambda = 0.71069$ Å, $\mu(MoK_\alpha) = 4.74\ cm^{-1}$, $F(000) = 976$.

SADANAND V. PATHRE, WILLIAM B. GLEASON, YIN-WAN LEE, and CHESTER J. MIROCHA. Can. J. Chem. **64**, 1308 (1986).

An isolate of *Fusarium roseum* "Graminearum" obtained from overwintered oats in Alaska produced toxic cultures when grown on rice. The toxic principle called fusarochromanone isolated from these cultures reproduced the signs of tibial dyschondroplasia in poultry and also reduced hatchability of fertile eggs. Spectroscopic data (nmr, ir, and ms) indicated the mycotoxin to be a chromanone derivative. The chromanone ring structure was also confirmed by single crystal X-ray.

SADANAND V. PATHRE, WILLIAM B. GLEASON, YIN-WAN LEE et CHESTER J. MIROCHA. Can. J. Chem. **64**, 1308 (1986).

Un produit, isolé du *Fusarium roseum* "Graminearum" et qui a été obtenu à partir d'avoine de l'Alaska gardée pour l'hiver, a donné lieu à des cultures toxiques lorsqu'on l'a fait croître sur du riz. Le principe toxique, qui se nomme fusarochromanone et qui a été isolé de ces cultures, permet de reproduire la dyschondroplasie tibiale chez les poules et a aussi réduit la possibilité d'éclosion des oeufs fertiles. Les données spectroscopiques (rmn, ir et sm) indiquent que la mycotoxine est un dérivé de la chromanone. La structure du cycle chromanone a aussi été confirmée par diffraction des rayons X par un cristal unique.
[Traduit par la revue]

Introduction

Species of *Fusarium* are worldwide in distribution and are capable of causing plant disease such as wilt, scab, and rot in the field (1). They also produce a wide variety of mycotoxins such as zearalenone (2), an estrogen, and the trichothecenes. The latter cause complications to farm animals when ingested in animal feeds and have been also found in "Yellow rain" (3).

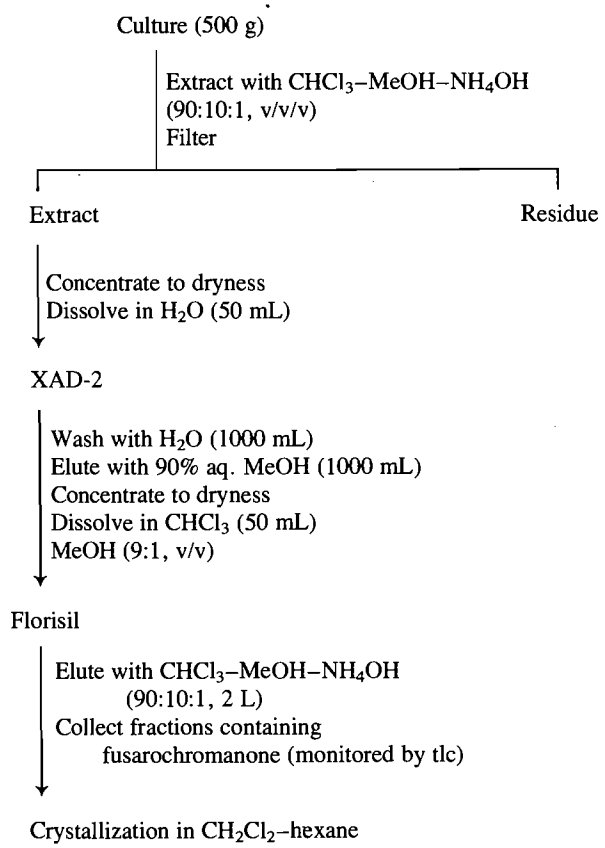
Since *Fusarium* fungi infect important agricultural plants and products, they have been associated with human and animal intoxications (4). Notable among these reports are bone malformation (tibial dyschondroplasia) in poultry and the incidence of low hatchability of fertile eggs when birds were fed diets containing *Fusarium* infected feed (5, 6). Tibial dyschondroplasia (TDP) is characterized by the presence of a cone of cartilage which extends distally from the proximal tibiotarsal physis (7, 8). Similar lesions occur in swine, horses, bulls, and dogs (9).

Recently we isolated a mycotoxin (herein called fusarochromanone) from rice cultures of *Fusarium* grown in the laboratory. Purified fusarochromanone reproduced the signs of TDP in chicks and also reduced hatchability of fertile eggs (10). This report describes the elucidation of the structure of this mycotoxin.

Results and discussion

Several isolates of *Fusarium roseum* "Graminearum" were collected from the overwintered oats in Fairbanks, Alaska, during 1978. All these isolates were screened for the toxicity by growing them on rice. Rice cultures of one of the isolates were found to be toxic to chickens and elaborated lesions of TDP. Several kilograms of rice cultures were extracted with chloroform–methanol – ammonium hydroxide (90:10:1, vol/vol/vol). The extract was subsequently chromatographed to give pure toxin as shown in Scheme 1.

Mass spectral analyses of fusarochromanone (**1**) yielded an ion at nominal mass of 292 (measured at 292.1421 to fit $C_{15}H_{20}N_2O_4$ within 1 ppm). Fast atom bombardment (FAB) mass spectrometry indicated a protonated species at m/z 293, which was peak matched to 293.1524 to fit a composition of $C_{15}H_{21}N_2O_4$ within 7.8 ppm. The FAB also showed an ion at m/z 558.2960, which fitted to within 6.3 ppm for a composition of $C_{30}H_{41}N_4O_8$, presumably due to a dimer.



SCHEME 1. Isolation and purification of fusarochromanone.

[1]Revision received February 7, 1986.

TABLE 1. ^{1}H nuclear magnetic resonance assignment for fusarochromanone and its derivatives

	Chemical shifts (ppm)					Coupling constants (Hz)			
	1	**2**	**3**	**4**	Multiplicity	**1**	**2**	**3**	**4**

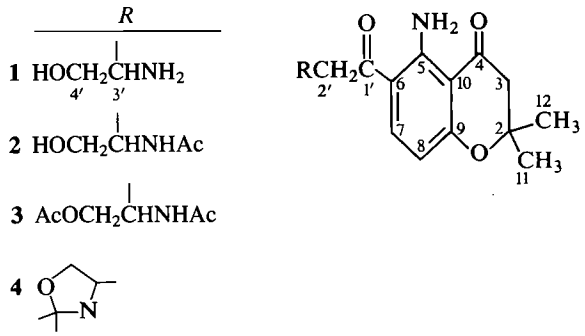
			1.98						
N*H*Ac		6.42	6.40				d, 6	d, 6	

The ^{1}H nmr spectrum of **1** (Table 1) shows two aromatic *ortho* protons (J = 8 Hz), a *gem*-dimethyl, an isolated methylene, and five exchangeable protons, three of which were readily exchanged with D_2O in $CDCl_3$. The remaining two are those observed near 9 ppm as broad singlets. In addition, the spectrum displayed several multiplets between 2.8 and 3.8 ppm representing five protons. This five-proton multiplicity pattern



was assigned to a three-carbon unit **A** consisting of a methine flanked by two methylenes.

OH—CH_2—$CH(NH_2)CH_2$—

A

This assignment was deduced by acetylation of **1** with *N*-acetylimidazole, which afforded two major products identified as mono (**2**) and di (**3**) acetates of **1** by ^{1}nmr (Table 1).

The ^{13}C nmr spectrum of fusarochromanone (Table 2) exhibits 14 carbon signals including a single resonance for *gem*-dimethyl carbons, three methylenes, one aliphatic methine, two aromatic methines, and seven quaternaries. The two-dimensional carbon–proton correlation (HETCOR) spectrum of the toxin established the attachment of protons at 3.5 (isolated methylene singlet), 6.08, and 7.86 ppm to the carbons at 48.96, 104.10, and 140.16 ppm, respectively. The methylene (42.44 ppm) and methine (49.71 ppm) carbons were correlated to the proton multiplets near 3.0 and 3.5 ppm, respectively. Among the quaternaries, two of them were carbonyls. Chemical shifts and ir data indicate these carbonyls are conjugated. One of the carbonyls (193.70 ppm) gave a 3-Hz triplet in the proton-coupled carbon spectrum; this triplet was collapsed to a singlet when the isolated methylene proton singlet was selectively

decoupled. Since no other changes in the carbonyl triplet were observed during coherent low-power irradiation of other protons, this carbonyl should be adjacent to the isolated methylene carbon and well removed from the other protonated carbons. Single frequency low-power irradiation also permitted assignment of most of the quaternary carbons by virtue of their long range coupling with protons. For instance, the resonance at 165.99 ppm was observed as a doublet of doublets (J = 10 and 2.5 Hz) in the undecoupled spectrum. Irradiation of the 6.08-ppm proton resulted in the collapse of the smaller couplings to give a 10-Hz doublet, whereas the 7.86-ppm proton irradiation caused the 10-Hz doublet to collapse to yield a broad singlet. The magnitude of coupling constants indicates that the aromatic protons at 6.08 and 7.86 ppm must be situated *ortho* and *meta*, respectively, to this quaternary carbon. The aliphatic quaternary carbon at 79.32 ppm exhibited a complex multiplet, which reduced to a 2.5-Hz triplet upon irradiation of the *gem*-dimethyl proton singlet. This observation, together with the fact that the decoupling of the dimethyl resonance also caused removal of the long range couplings observed for the isolated methylene carbon, provided a contiguous arrangement of the isopropyl carbon, isolated methylene, and the 193.70-

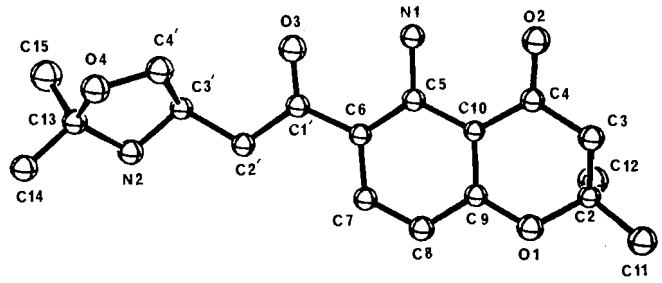

FIG. 1. Labelled drawing of **4** (50% probability).

ppm carbonyl. The chemical shift of the isopropyl quaternary carbon indicated it to be an ether carbon. The other end of this ether substituent was readily deduced to be the 165.99-ppm quaternary carbon since there was only one oxygen left to be accounted for (*vide infra*); the arrangement also provided a clue to the chromanone (3,4-dihydro-4*H*-1-benzopyra-4-one) system. Bookkeeping of all hetero atoms considered so far showed that $-NH_2$ should be one of the substituents, which was assigned to the 154.71-ppm quaternary carbon. The remaining quaternary carbons at 111.71 and 104.16 ppm were identified with the 198.80-ppm carbonyl bearing the three-carbon unit **A** and the γ-pyrone carbonyl, respectively, as substituents.

The substitution pattern in fusarochromanone is unique. A naturally occurring chromanone with an amino substituent at C6 has not been reported in the literature. The placement of the side chain at C7 is also unique. Although the nmr data is quite convincing in proving the structure of fusarochromanone, it was desirable to obtain a single crystal X-ray analysis of fusarochromanone.

Many solvents were used in an attempt to grow crystals of **1** suitable for the analysis, without any success. Finally, an acetone solution of **1** yielded pale yellow needle-shaped crystals. Unfortunately, these crystals were very thin and the best crystal that could be obtained was $0.18 \times 0.26 \times 0.05$ mm. Data of sufficient quality to solve the structure could not be obtained except at low temperature. Further, the ^1H nmr spectrum of these crystals in $CDCl_3$ indicated incorporation of acetone; however, there was no evidence of modification of the ring structure. Since our objective was to confirm the chromanone ring system, no further attempts were made to produce a more accurate structure.

Crystal data

$C_{18}H_{24}N_2O_4$ fw = 332.39

Orthorhombic, $P2_12_12$ (#18), $a = 11.282(4)$, $b = 23.265(6)$, $c = 6.246(4)$ Å^3, $Z = 4$, $V = 1639.4$ Å^3, $\mu = 0.89$ cm^{-1}, $\rho = 1.35$ g cm^{-1} (−100°C, Mo K_α, $\lambda = 0.71073$ Å, graphite monochromator). A labeled drawing of the molecule is given in Fig. 1. Atomic coordinates for non-hydrogen atoms are given in Table A, bond lengths and angles are summarized in Table B, and bond angles in Table C.[2]

Experimental

Infrared spectra were recorded on a Perkin Elmer 283 spectrophotometer. Proton nmr spectra were obtained on Varian XL-100 and XL-200 nmr spectrometers operating at 100 MHz and 200 MHz, respectively, using chloroform-*d* solutions. Carbon-13 nmr spectra were recorded on the Varian XL-200 spectrometer operating at 50.306 MHz using standard acquisition parameters. To obtain undecoupled carbon spectra the decoupler was kept on during a delay of 1 s and was gated off during acquisition to maintain maximum nOe (nuclear Overhauser enhancement). The 2D-nmr experiment was run using the pulse sequence HETCOR resident in the spectrometer system. Ultraviolet spectra were recorded on a Perkin Elmer 554 spectrophotometer in MeOH solutions. Mass spectra were obtained on a Kratos MS-50 high resolution mass spectrometer operating at 10 000 resolution. The standard Kratos FAB source were used. Thin-layer chromatographic analyses were carried out on precoated silica gel-254 (EM Reagents) and KC_{18} (Whatman) glass plates; components were visualized under uv light (either 254 or 356 nm).

For single crystal X-ray analysis, a crystal (obtained by slow evaporation of solvent from an acetone solution) was mounted on an Enraf–Nonius CAD4 diffractometer. Intensity data were collected at low temperature (−100°C) using an ω–2θ scan. Data were collected in the $+h, k, l$ octant to a maximum 2θ value of 48.0°. Three standard reflections measured every two hours during data collection showed a total loss of intensity of 10.3%. A linear decay correction was applied. Lorentz and polarization corrections were applied to the data. Since the linear absorption coefficient is small, an absorption correction was not made.

A total of 1662 reflections were collected (1608 unique and not systematically absent) and the space group of the crystal was determined to be $P2_12_12$ (#18 International Tables) from the systematic absences $h00$: $h = 2n$, and $0k0$: $k = 2n$ and subsequent least-squares refinement. The structure (**4**) was solved by direct methods (11). A total of 19 atoms were located from an *E*-map and the remaining atoms located in succeeding difference Fourier syntheses. Because of a paucity of data, isotropic temperature factors were used for C, O, and N. It was not possible to locate a hydrogen on N2 in difference maps although N1 had two peaks of reasonable intensity (0.4 e/Å^3) and distances (0.6, 1.2 Å). Therefore, hydrogen atoms were included at calculated positions (C—H bond length = 0.95 Å and N—H = 0.90 Å) but their positions were not refined. Hydrogen atoms were assigned fixed isotropic *B* values approximately equal to the *B* value of the atom to which they were attached. The structure was refined using full-matrix least-squares techniques where the function minimized was:

$$\sum w(|F_o| - |F_c|)^2$$

and the weight, w, is defined as:

$$w = 4F_o^2/\sigma^2(F_o^2)$$

All calculations were carried out on Digital Equipment Corporation PDP 8A and 11/34 computers using the Enraf–Nonius CAD4-SDP programs (12). The values of the atomic scattering factors were taken from the International Tables and effects of anomalous scattering were included (13). The model converged for 912 reflections $F_o^2 > 3.0\sigma(F_o^2)$ and 97 variables with agreement factor:

$$R = \sum||F_o| - |F_c|/\sum|F_o| = 0.093$$

$$R_w = \{\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2\}^{\frac{1}{2}} = 0.108$$

In the final cycle, the maximum shift/error was 0.01, the goodness of fit 2.45, and the largest peak in the difference map 0.5 e/Å^3.

Isolation and purification of fusarochromanone (1)

Five hundred grams of crude cultures (10) was extracted 5 times with the solvent system described in the scheme. The extracts were pooled and concentrated *in vacuo* at 40°C to give an oily residue, which was dissolved in 50 mL methanol in 200 mL of distilled water. This mixture was further concentrated to approximately 150 mL of solution and applied to an XAD-2 column (3.5 × 60 cm), rinsed with 1 L of distilled water, and eluted with 1 L of 90% methanol. The methanol fraction was concentrated *in vacuo* at 40°C, and reconstituted in 50 mL $CHCl_3$–MeOH (9:1, v/v). This solution was mixed with 50 g of

[2]A complete set of structure factor listings, thermal parameters, atomic coordinates including hydrogen atom positions, bond distances, bond angles, and torsional angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

anhydrous sodium sulfate and the mixture was dried at room temperature. The dry yellow powder was then packed on the top of a column (3.5 × 60 cm) containing 150 g of Florisil, and eluted with 2 L of $CHCl_3$–MeOH (9:1, v/v) followed by 2 L of $CHCl_3$–MeOH–NH_4OH (90:10:1, v/v/v). Fusarochromanone was detected by irradiating the column with long-wave uv (365 nm) light since the toxin produces an intense blue fluorescence under the uv light. The fractions containing fusarochromanone were concentrated (40°C) and subsequently purified by tlc using $CHCl_3$–MeOH–NH_4OH (80:20:2, v/v/v).

Fusarochromanone (**1**): mp 132–134°C; uv λ_{max} (MeOH) (nm): 248 (ε 21 800), 277 (ε 8 800), 383 (ε 11 700); ir λ_{max} (KBr) (cm^{-1}): 3373, 3267, 3160 (NH_2, OH), 1655 (CO), 1562 (CO, -H bonded); nmr ($CDCl_3$) (see Tables 1 and 2); ms (M^+ 292.1421 calcd. for $C_{15}H_{20}N_2O_4$).

Acetylation of ***1***

Fifty milligrams of 1-acetylimidazole was added to a solution of **1** (50 mg) in $CHCl_3$ (2 mL). The reaction mixture was kept at room temperature for 2 h. The mixture was then chromatographed on preparative tlc ($CHCl_3$–MeOH; 9:1). Two major bands corresponding to R_f of 0.7 and 0.4 were scraped and eluted with $CHCl_3$; removal of solvent gave gummy solids.

*Monoacetate (**2**)*: ir λ_{max} (KBr) (cm^{-1}): 3380, 3280 (NH, OH), 1660 (CO), 1560 (amide II); nmr ($CDCl_3$) (see Table 1); ms (M^+ 334, M − AcO 275).

Methylene chloride extracts of the bryozoan *Flustra foliaceae* show strong antimicrobial activity. Chemical investigation of the metabolites has led to the identification of a series of new bromoalkaloids belonging to the physostigmine class, which are responsible for this activity.

MAURICE V. LAYCOCK, JEFFREY L. C. WRIGHT, JOHN A. FINDLAY et ASHOK D. PATIL. Can. J. Chem. **64**, 1312 (1986).

L'extraction du bryozoaire *Flustra foliaceae* par du chlorure de méthylène fournit des produits qui présentent une activité antimicrobienne très forte. Une étude chimique des métabolites a conduit à l'identification d'une série de nouveaux bromoalcaloïdes de la classe de la physostigmine, qui sont responsables de cette activité.

[Traduit par la revue]

Introduction

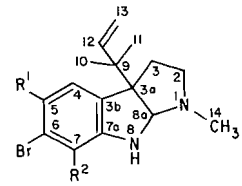
A few of the marine invertebrates belonging to the phylum Bryozoa have been the subject of chemical investigations (1) and these studies have revealed several unusual compounds, most of which display interesting biological activity. A chemical study of the bryozoan *Flustra foliacea L.* from Scandinavian waters revealed the presence of a remarkable variety of bromine-containing metabolites representing the physostigmine (2), tryptamine (3), and quinoline (4) alkaloid types. The bryozoan *F. foliacea* also grows abundantly in several areas of the Bay of Fundy and the methylene chloride extract of this organism showed strong antibacterial activity against an indicator bacterium, *Bacillus subtilis*. Assay-guided fractionation of this crude extract has led to a series of bromoalkaloids and we now wish to report in detail the isolation and structure elucidation of these compounds, two of which occur as N-oxides.

Results and discussion

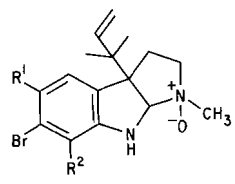
The methylene chloride fraction of the aqueous methanol extract of fresh or frozen *Flustra foliacea* showed significant antibacterial activity against the indicator bacterium *Bacillus subtilis* in a disc diffusion assay (0.5 mg/disc). Large-scale reversed-phase separation (Waters Prep Pak) of the partially purified extract yielded several early fractions displaying antibacterial activity and containing uv-active compounds. Further adsorption chromatography of these active fractions, followed by a final reversed-phase hplc step, yielded the following series of related physostigmine bromoalkaloids.

Dihydroflustramine C, 1

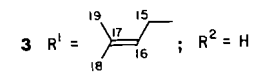
Details of the structure analysis of dihydroflustramine C have already been published (5) but the nmr data are reproduced here for comparison (Tables 1 and 2). This metabolite was the major bromoalkaloid and consistently accounted for at least 60% of the alkaloid mixture. It is very closely related to flustramine C, **6**, obtained as a minor component from the Scandinavian strain, but remarkably we have not identified this latter compound in any of the Fundy samples.



1 R^1, R^2 = H



2 R^1, R^2 = H



3 R^1 = ; R^2 = H

Flustramine D, 3

This metabolite was the next most abundant component (ca. 40%) of the alkaloid mixture. The general shape of the uv spectrum (λ 231, 292 nm) was similar to that of dihydroflustramine C. The mass spectrum of flustramine D showed parent ions at *m/z* 390 and 388 ($C_{21}H_{29}N_2Br$). The base peaks at *m/z* 321 and 319 arise by a loss of 69 mass units from the parent ions and correspond to the loss of an isoprene unit. This is followed by a further loss of 68 mass units from the base peaks corresponding to cleavage of a second isoprene unit. The peaks at *m/z* 347 and *m/z* 345 arise by the loss of 43 mass units from the corresponding parent ions. A similar loss was observed in the mass spectrum of dihydroflustramine C and is accounted for by ejection of a CH_3—N=CH_2 fragment following partial cleavage of the pyrrole ring.

The ^{1}H nmr data for flustramine D are presented in Table 1. By comparison with dihydroflustramine C, **1**, and other related alkaloids (2) the 1H singlet at δ_H 4.39 ppm and the 3H singlet at δ_H 2.38 ppm were assigned to H-8a and the N-methyl group respectively. Irradiation of the N-methyl group resulted in nuclear Overhauser enhancement (nOe) of H-8a. The resonance for H-2 appeared as a 2H multiplet at δ_H 2.56 and the two H-3 protons resonated at δ_H 2.28 and 1.81 ppm. These latter assignments were confirmed by decoupling experiments. After irradiation of the H-2 protons the resonance for each H-3 proton appeared as a doublet due to geminal coupling (^2J = 12 Hz). Irradiation of either H-3 proton caused the H-2 multiplet to collapse to an ill-defined doublet. The spectrum of this second

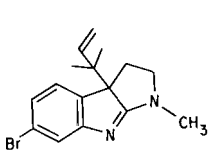
[1]NRCC No. 25516.

[2]Author to whom correspondence should be addressed.

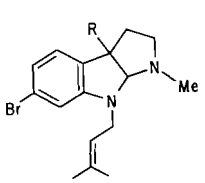
alkaloid also displayed the characteristic resonances for a "reversed" γ,γ-dimethylallyl group (2, 6): two 3H singlets at δ_H 0.98 and 1.02 ppm and the easily recognised ABM pattern at δ_H 4.99, 5.06, and 5.95 ppm. Methyl singlets at δ_H 1.70 and 1.73 ppm together with a methylene doublet at δ_H 3.31 (J = 7.1 Hz) and an olefinic methine at δ_H 5.22 (J = 7.1 Hz) revealed the presence of a second "regular" isoprene unit. The aromatic region contained only two proton resonances and both appeared as singlets, δ_H 6.74 and 6.93 ppm.

All twenty-one carbons of flustramine D, **3**, could be accounted for in the ^{13}C nmr spectrum (Table 2). In many respects the ^{13}C spectrum was very similar to that of **1** except for the five additional resonances (δ_c 17.97, 25.72, 34.26, 122.63, and 132.80 ppm) due to the second isoprene unit. The signals for C-2, C-3, and C-14 could be assigned by comparison of the chemical shift data with model and related compounds. The characteristically large coupling constant ($^1J_{CH}$ = 152.7 Hz) defined the resonance for the methine carbon C-8a. The quaternary carbon C-3a resonates at δ_c 64.12 ppm and must be substituted with a "reversed" γ,γ-dimethylallyl group; the resonance for C-3a is more shielded (ca. 56 ppm) when substituted with a regular γ,γ-dimethylallyl group. The position of this isoprene unit was further established upon irradiation of the methyl resonances H-10 and H-11, which resulted in nOe of H-8a, confirming *cis* fusion of the two heterocyclic rings. The same experiment also resulted in nOe of the H-3 proton resonating at δ_H 2.28 ppm; hence this proton is located on the same side of the pyrrole ring as H-8a and the "reversed" isoprene unit.

The second isoprene unit could be located by consideration of the ^1H and ^{13}C nmr data, and by a series of long-range heteronuclear decoupling experiments that unequivocally assigned the aromatic resonances. The ^1H chemical shift (δ_H 3.31 ppm) of the allylic methylene group H-15 precludes attachment of the C-5 unit at N-1. Because C-3a is already substituted and C-2, C-3, and C-8a all carry the requisite number of hydrogens, the second isoprene unit must be attached to the aromatic ring. Since there is no evidence in the ^1H spectrum of coupling between the aromatic protons, the isoprene unit was placed at C-5. This was consistent with the undecoupled ^{13}C nmr spectrum. The aromatic methine at C-7 (δ_c 112.62) appeared as a clean doublet (J = 164.07 Hz), whereas the resonance for C-4 (δ_c 126.34) appeared as a doublet of triplets (^1J = 157 Hz; ^3J = 4.8 Hz) through long-range coupling with the methylene protons at C-15. This was confirmed by single frequency irradiation of H-15, which removed the long-range coupling to C-4. The same decoupling experiment removed the two-bond coupling to C-5, which now appeared as a narrow doublet ($^3J \approx$ 4.0 Hz) due to coupling with H-7. Conversely, irradiation of



6



7 R =

8 R =

H-7 reduced the resonance for C-5 to a triplet ($^2J \approx$ 5.0 Hz) due to coupling with H-15. The same decoupling experiments indicated long-range coupling to C-6 but this was harder to interpret due to overlap with the resonance for C-16.

Dihydroflustramine C N-oxide, 2

This minor and somewhat unstable component was isolated from the more polar bromoalkaloid fractions. Both it and the other N-oxide, **4**, were present in the initial MeOH extract. The ^1H spectrum of **2** was very similar in overall appearance to that of **1** except for certain chemical shift differences (Table 1). Thus the spectrum displayed two aromatic resonances that integrated for three protons, as well as all the resonances associated with the inverted γ,γ-dimethylallyl group. However, the resonance assigned to H-8a in dihydroflustramine C, **1**, was now considerably deshielded (Δ 0.86 ppm) in this minor component, as was the resonance for the N-methyl group (Δ 0.1 ppm). Furthermore, one H-2 proton was deshielded (Δ 0.17 ppm) and the second one was shielded (Δ 0.18 ppm), whereas both H-3 proton resonances were deshielded by smaller amounts. These assignments were confirmed by a series of decoupling experiments. Irradiation of the 1H multiplet at δ_H 2.0 ppm assigned to H-3 removed a small vicinal coupling to the low-field H-2 resonance at δ_H 2.70 ppm, which now appeared as a clean doublet of doublets due to residual geminal (^2J = 11 Hz) and vicinal (^3J = 6.4 Hz) coupling. Similarly, irradiation at δ_H 2.70 ppm reduced the broadened multiplet at δ_H 2.00 ppm to a doublet of doublets (^2J = 13.1 Hz; ^3J = 4 Hz). Finally, irradiation of the 2H multiplet at δ_H 2.35 ppm collapsed the two resonances at δ_H 2.00 and 2.70 ppm to broad singlets.

In the ^{13}C nmr spectrum the chemical shifts of most resonances of the minor component were essentially the same as those for **1** except for marked shifts of certain resonances associated with the second pyrrole ring (Table 2). In particular, the resonances for C-3, C-8a, and C-14 were considerably deshielded (ca. 11.5, 8, and 9.5 ppm respectively), whereas the signal for C-3a was shielded (Δ ca. 13 ppm).

The mass spectrum showed parent ions at m/z 336 and 338, 16 mass units higher than the corresponding peaks for dihydroflustramine C, **1**. The hrms data established a molecular formula with an extra oxygen, and the fragmentation pathway was characterized by a strong $M - 16$ ion, a feature of amine oxides (7). This characteristic loss of 16 mass units from the parent ion was confirmed in a series of daughter-ion experiments. Thus the accumulated evidence suggests this new compound is an N-oxide of dihydroflustramine C but does not unequivocally discriminate between an N-1 oxide or an N-8 hydroxy function. The evidence favours N-1 substitution since H-8a, H-3, and the N-methyl protons are deshielded and there is little or no perturbation of the aromatic resonances in the ^1H and ^{13}C spectra. Placement of the oxide grouping at N-1 was confirmed by reinspection of the daughter-ion experiments, which showed that in addition to the characteristic loss of 16 mass units from the molecular ions, there is also a loss of 59 mass units from the molecular ions, giving rise to ions at m/z 277 and 279. This corresponds to elimination of a [CH_3—$N^+(O^-)$=CH_2] fragment arising by a fragmentation pathway analogous to the expulsion of [CH_3—N=CH_2] in dihydroflustramine C, **1**, and flustramine D, **3**. This fact also precludes an alternate structure for this minor component based on the structure of geneserine, **9**, a plant alkaloid isolated from *Physostigma venenosum* (8). Long believed to be the N-8 oxide of physostigmine, the structure of geneserine was revised to **9** following the observation that the mass spectrum of the alkaloid did not display a characteristic $M - 16$ loss. Instead, one of the major frag-

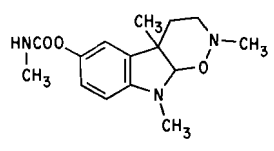
mentations is a loss of 45 mass units corresponding to ejection of [CH_3—N═O]. No such loss is observed for the bryozoan alkaloid. Final structural proof was obtained by oxidation of **1** with *m*-chloroperoxybenzoic acid to yield a product with identical chromatographic (tlc and hplc) and spectroscopic properties (uv and ^{1}H nmr) to the naturally occurring N-oxide.

*Flustramine D N-oxide, **4***

This unstable compound was isolated as a very minor constituent of the alkaloid mixture. Except for a few resonances, the ^{1}H nmr spectrum of this material was very similar to that of flustramine D, **3** (Table 1). In particular, the resonance for H-2 now appeared as two 1H doublets (δ_H 2.33 and 2.69) and the signals for H-3 were deshielded (δ_H 2.0 and 2.69 ppm), as was C-8a (δ_H 5.23 ppm) and the N-methyl group (δ_H 2.46 ppm). Since these chemical differences between **3** and **4** were the same as those observed between **1** and **2** it appeared that this minor component was the N-oxide of flustramine D. This was substantiated by the mass spectral data, which displayed molecular ions at *m/z* 406 and *m/z* 404, 16 mass units higher than those for flustramine D. More significantly, the mass



9

spectrum of this minor component displayed the characteristic losses of 16 mass units and 59 mass units from the molecular ions confirmed in a series of daughter-ion experiments and previously observed in the mass spectrum of dihydroflustramine C N-oxide, **2**.

This N-oxide could be prepared by oxidation of flustramine D with *m*-chloroperoxybenzoic acid. The synthetic material was identical by chromatographic (tlc and hplc) and spectroscopic (uv and ^{1}H nmr) comparisons.

*Isoflustramine D, **5***

One fraction was obtained that was an inseparable mixture of flustramine D, **3**, and another minor related component. The ^{1}H nmr spectrum of the mixture was almost identical with that of **3**, except for several additional resonances that suggested that the second minor component possessed the same basic skeleton as **3**, but that the C_5 isoprene unit was repositioned on the benzene ring. This followed from the observation that the two aromatic resonances of the minor component now appeared as an AB quartet due to *ortho* coupling (J = 8.4 Hz), the allylic methylene protons H-15 were somewhat deshielded (δ_H 3.40; J = 6.7 Hz), and the olefinic methyl protons were shifted to δ_H 1.72 and 1.81 ppm. In addition, the N-methyl, H-8a, and the methyl resonance H-10 were slightly shifted (see Table 1) but the remaining proton resonances for both isoprene units and the multiplets for H-2 and H-3 were unchanged. Based on this evidence and the similarity of the mass spectral data between flustramine D and the mixture, which was obtained over a wide temperature range, the structure of this minor component is tentatively proposed as **5**, a positional isomer of **3**.

Flustrabromine A, **7**, and B, **8**, were reported as the two main physostigmine alkaloids from *F. foliacea* collected from the North Sea (2). In our studies with *F. foliacea* collected from around the Bay of Fundy we did not detect these physostigmine derivatives. Instead our investigations serve to underscore the ability of *F. foliacea* to produce a variety of brominated alkaloids. It is not uncommon to find bromoalkaloids from marine invertebrates, though they appear to occur more frequently among sponges and tunicates (1), two of the most widely

of bromoalkaloids from *Flustra foliacea**

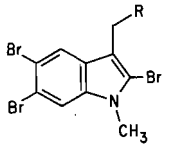
studied phyla. Studies with bryozoans are less common, mainly due to the difficulty in collecting enough material for analysis. However, of the marine bryozoans that have been investigated, a member of the genus *Zoobotryon*, which belongs to the family Flustridae, contains the brominated gramine derivative **10** as well as the N-oxide **11** (9). Thus, the discovery of **2** and **4** from *F. foliacea* is, to our knowledge, only the second time N-oxides have been isolated from marine sources. It will be interesting to learn if other members of the family Flustridae contain further variants of these unusual bromoalkaloids.



10 R = $N(CH_3)_2$

11 R = $\overset{+}{N}(CH_3)_2\ \overset{-}{O}$

The alkaloids from our local *F. foliacea* also display a wide antibacterial spectrum. The alkaloid fraction containing mainly **1** and **3** showed activity against *Enterobacter cloacea*, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, *Salmonella typhimurium*, *Serratia marcescens*, *Staphylococcus aureus* and *Staphylococcus epidermidis* in disc diffusion assays (0.5 mg/disc) using procedures already described (10).

Experimental

Optical rotations were measured with a Perkin–Elmer polarimeter. Ultraviolet and infrared spectra were recorded with a GCA-MacPherson Series 700 and a Perkin–Elmer 283B spectrophotometer. ^1H and ^{13}C nuclear magnetic resonance spectra were all recorded in $CDCl_3$ with TMS as internal standard on the Nicolet 360 NB spectrometer of the Atlantic Region Magnetic Resonance Centre. Mass spectra were obtained with a Dupont model 21-110B double-focussing spectrometer used in the electrical detection mode (8 kV accelerating voltage, 70 eV ionizing energy). Accurate mass measurements were made by peak matching against a perfluorokerosene reference. Large scale hplc was performed with a Waters Associates Prep System 500 and semi-preparative hplc was carried out using Waters Associates model 6000 pumps, U6K injector, and a model 450 variable wavelength detector. Rotating-disc chromatography was performed using a Chromatotron model 7924.

The bryozoan *Flustra foliacea* was collected in the Bay of Fundy off the New Brunswick and Nova Scotian shores. A voucher specimen is on deposit at the Department of Biology, Acadia University, Wolfville, N.S.

Isolation of flustramine alkaloids

The bryozoan (3 kg), either fresh or frozen material, was extracted with methanol at room temperature for 3 days. The methanolic extract (18 L) was concentrated under reduced pressure until most of the methanol was removed and the residue was shaken against methylene chloride. The methylene chloride soluble fraction (12.8 g) was divided into 4 equal portions and each one was chromatographed on a pad ($1\frac{3}{4}$ in. × $3\frac{3}{4}$ in. diam.) of silica gel (Merck, Kieselgel GF_{254}, Type 60) and eluted with a solvent gradient system from hexane through ether, methylene chloride, ethyl acetate, and methanol. Several fractions (2.8 g) displaying antibacterial activity were combined and subjected to large-scale reversed-phase liquid chromatography. The bioactive fractions, eluted with 15% aqueous methanol, all contained uv-active (254 nm) spots and these were further separated by rotating-disc adsorption chromatography on silica gel using solvent mixtures of methylene chloride, methanol, and acetone. The uv-active bands were collected as they were eluted from the disc and from these fractions the individual bromoalkaloids were obtained in a final hplc purification step using Spherisorb ODSII (5μ; Regis, 10 mm × 25 cm) with 10% aqueous methanol containing 0.1% triethylamine.

Dihydroflustramine C, 1

Crystallized from ether – petroleum ether mixtures, mp 82–84°C; $[\alpha]_D^{25}$ −110° (c = 1.5, CH_2Cl_2); λ_{max} (MeOH): 213 (ε 2 × 10^4), 250 (ε 5.6 × 10^3), 309 (ε 3.4 × 10^3) nm; ν_{max} (KBr): 3200, 1600, 1590, 1475, 1350, 1150, 1050 cm^{-1}; ^1H (360 MHz) and ^{13}C (98.2 MHz) nmr data in Tables 1 and 2; m/z (rel. int.): 320/322 (M^+, 50%), 305/307 (8%), 227/229 (15%), 251/253 (100%), 208/210 (66%), 172 (90%), 129 (40%). Accurate mass measurement M^+ at m/z 322.0875 (calcd. for $C_{16}H_{21}N_2{}^{81}Br$: 322.0869).

Dihydroflustramine C N-oxide, 2

Obtained as an oil; $[\alpha]_D^{25}$ −67.1° (c = 0.38, CH_2Cl_2); λ_{max} (MeOH): 226 (ε 3.8 × 10^3), 283 (ε 2 × 10^3) nm; ν_{max} (thin film): 3400–3200 br, 1610, 1460, 1270, 1120, 1010 cm^{-1}; ^1H and ^{13}C nmr data in Tables 1 and 2; m/z (rel. int.): 336/338 (M^+, 17%), 320/322 (34%), 277/279 (44%), 268/270 (17%), 251/253 (100%), 209/211 (76%). Accurate mass measurement M^+ at m/z 336.0843 (calcd. for $C_{16}H_{21}N_2O^{79}Br$: 336.083).

Flustramine D, 3

Obtained as an oil; $[\alpha]_D^{25}$ −86.5° (c = 1.03, CH_2Cl_2); λ_{max} (MeOH): 231 (ε 7.1 × 10^3), 292 (ε 3.1 × 10^3) nm; ν_{max} (thin film): 3180, 1610, 1475, 1355, 1240, 1140, 1010 cm^{-1}; ^1H and ^{13}C nmr data in Tables 1 and 2; m/z (rel. int.): 388/390 (M^+, 26%), 373/375 (2%), 345/347 (4%), 319/321 (100%), 276/278 (7%), 251/253 (14%). Accurate mass measurement M^+ at m/z 390.1498 (calcd. for $C_{21}H_{29}N_2{}^{81}Br$: 390.1494).

Flustramine D N-oxide, 4

Obtained as an oil; λ_{max} (MeOH): 224 (ε 7.1 × 10^3) and 285 (ε 3.1 × 10^3) nm; ν_{max} (thin film): 3400, 1610, 1485, 1467, 1383, 1285, 1127, 1075 cm^{-1}; ^1H nmr data listed in Table 1. The ^{13}C nmr data in Table 2 were obtained on the synthetic material; m/z (rel. int.): 404/406 (M^+, 2%), 388/390 (26%), 373/375 (2%), 345/347 (10%), 319/321 (100%), 277/279 (15%). Accurate mass measurement M^+ at m/z 404.1286 (calcd. for $C_{21}H_{29}N_2O^{79}Br$: 404.12873).

Isoflustramine D, 5

Obtained as a 65:35 mixture with **3**; $[\alpha]_D^{25}$ −14.6° (c = 0.07, CH_2Cl_2); λ_{max} (MeOH): 230 and 290 nm; ν_{max} (thin film): 3400, 1610, 1490, 1450, 1380, 1255, 1160, 1010 cm^{-1}; ^1H nmr data in Table 1; m/z (rel. int.): 388/389 (M^+, 39%), 319/321 (100%), 276/278 (5%), 263/265 (22%), 251/253 (2%), 241 (9%).

Preparation of N-oxides

Dihydroflustramine C (32 mg; 0.01 mmol) or flustramine D (39 mg; 0.01 mmol) in CH_2Cl_2 (5 mL) was stirred and cooled on ice for several minutes preceding addition of an equimolar amount of *m*-chloroperoxybenzoic acid in CH_2Cl_2 (2.5 mL). Stirring was continued until oxidation was complete (1–2 h). The reaction mixture was partially purified by flash chromatography followed by further purification by reversed phase hplc using Spherisorb ODS II (5μ; Regis; 10 mm × 25 cm) and elution with 10% aqueous MeOH containing 0.1% triethylamine.

This paper is dedicated to Professor Arthur N. Bourns

OSWALD S. TEE, JANA PIKA, M. JUDITH KORNBLATT, and MICHAEL TRANI. Can. J. Chem. **64**, 1267 (1986).

The kinetics of bromination of the title compound (**1**) have been measured in aqueous solutions of pH 0–6. The change in the order of reaction which occurs around pH 2.5 is explained by **1** reacting via its covalent hydrate, **3**. Furthermore, there is sufficient **3** present at equilibrium that the kinetics of its equilibration with **1** were also measured. From these two studies the extent of covalent hydration of **1** is estimated to be 5%.

Kinetic studies of the bromination of the dimethyl cation **5** and of its equilibration with the pseudobase **6** were also carried out for the purposes of comparison.

The present results for **1**, **3**, **5**, and **6** are compared to earlier results for 2-pyrimidinone and analogous derivatives.

OSWALD S. TEE, JANA PIKA, M. JUDITH KORNBLATT et MICHAEL TRANI. Can. J. Chem. **64**, 1267 (1986).

Opérant en solutions aqueuses et à des pH allant de 0 à 6, on a mesuré les cinétiques de bromation du composé (**1**) mentionné dans le titre. A un pH de 2,5, il se produit un changement dans l'ordre de la réaction qui est expliqué par le fait que le composé **1** réagit alors par le biais de son hydrate covalent, **3**. De plus, la concentration à l'équilibre du composé **3** est telle que l'on peut aussi mesurer la cinétique de son équilibre. Sur la base des résultats obtenus au cours de ces deux études, on peut évaluer à 5% le taux d'hydratation covalente du composé **1**.

Pour fins de comparaison, on a aussi effectué des études cinétiques de la bromation du cation diméthylé **5** et de son équilibre avec la pseudobase **6**.

On compare les résultats obtenus avec les composés **1**, **3**, **5** et **6** avec ceux obtenus antérieurement avec la pyrimidinone-2 et ses dérivés analogues.

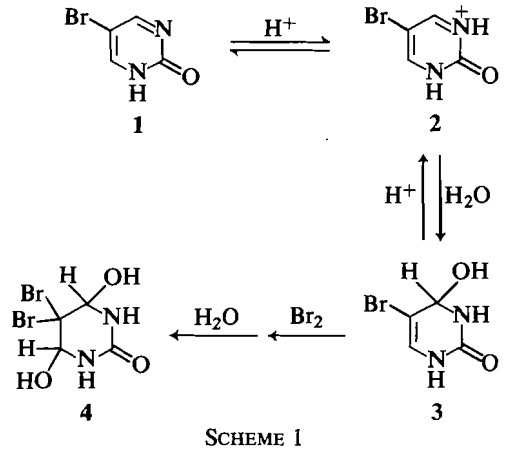
[Traduit par la revue]

Previous studies from this laboratory have shown that covalent hydrates are involved in the aqueous bromination of 2-pyrimidinone (1, 2), 4-pyrimidinone (3), and 4-quinazolinone (4). In contrast, evidence against their involvement was adduced for the bromination of the closely related pyrimidines: uracil (5) and cytosine (6).

From kinetic and equilibrium measurements on the parents and on their *N*-methyl derivatives it was estimated that the extent of hydration of 2-pyrimidinone is ~0.05% (2) and that of 4-pyrimidinone is ~0.0003% (3). The hydrates are involved in the bromination because they are enamines and as such they are very reactive towards bromine ($k_2 \sim 10^9 M^{-1} s^{-1}$) (2, 3, 7).

Since these covalent hydrates are only present at very low levels, they are not observable by normal spectroscopic means (8). However, from the earlier work on 5-bromo-2-pyrimidinone (**1**) and its *N*-methyl derivatives (1) it is possible to estimate[2] that its covalent hydrate (**3**) is present to the level of a few percent and so it might be observable.

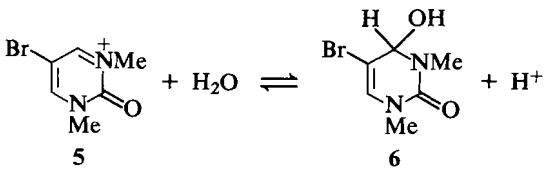
The previous study of the bromination of **1** (Scheme 1) was carried out in strong aqueous acid in which the reaction is slow enough to be followed by conventional spectrophotometry (1). In such media **1** is almost solely present as its conjugate acid, **2**, and it shows a reactivity towards bromine which is very similar to that of the related *N*,*N*′-dimethyl cation, **5**. Since the quaternary ion **5** reacts via its pseudobase **6**, it was concluded that **1** reacts as its covalent hydrate **3** (1).



SCHEME 1

Subsequently much stronger evidence for this type of mechanism was obtained for 2- and 4-pyrimidinones by carrying out stopped-flow kinetic studies in the pH region (2, 3). In particular, it was found that the order of the reaction changes with pH (2, 3, 7). At low pH bromine attack on the hydrate is rate-limiting and so the reaction is first order in substrate and in bromine. However, at intermediate pH the formation of the hydrate is the slow step and consequently the reaction is zero order in bromine (2, 3).

The present paper reports a similar study of the bromination of **1** carried out in the pH region which corroborates the earlier conclusions derived from the study in strong acid (1). More-



[1]To whom correspondence should be addressed.

[2]For the reaction of the pseudobase **6** with bromine the previous work in strong acid at 30°C gave $k_2 \sim 4 \times 10^6 M^{-1} s^{-1}$ (1). *If* one assumes that the same value applies to reaction of the covalent hydrate **3** then the equilibrium constant K_2 (defined later) = 0.012 *M*. However, the literature value of the acid dissociation constant (20°C) of **1** is K_1 = 0.36 *M*. Therefore, the hydration ratio K_h = [**3**]/[**1**] = $K_2/K_1 \sim 0.03$.

over, we have been able to observe the small percentage of the covalent hydrate **3** and to measure its equilibration with **1**. For comparison we have also studied the equilibration of the dimethyl cation **5** with its pseudobase **6**. These studies became necessary because of work in this laboratory in which it has been found that **1** and **3** are inhibitors of the enzyme, cytosine deaminase (9). In particular, we needed to know the equilibrium constant between **1** and **3** and the rate constants for their interconversion as a function of pH.

Results

For the most part the approach taken was as in our earlier studies on 2-pyrimidinones (2, 7) and similar results have been obtained. Accordingly, the present study will not be described in the same detail, except where necessary. The covalent hydrate **3** was detected using uv spectrophotometry and so its equilibration with **1** was studied. Attempts to observe **3** using nmr spectroscopy were thwarted by the low solubility of **1** in water and even in 50% aqueous DMSO.

Bromination studies

The rates of bromination of **1** and of its dimethyl cation **5** were measured by stopped-flow methods (2, 3, 5–7). The results resemble those obtained for 2-pyrimidinone (2) in that there is a change of kinetic order with pH. For **1** they can be explained by Scheme 1 and using a rate expression based on the constants in eq. [1]. Assuming that the covalent hydrate **3** is present in steady

$$[1]\quad \mathbf{1} \underset{K_1}{\overset{H^+}{\rightleftharpoons}} \mathbf{2} \underset{k_H, H^+}{\overset{k_1}{\rightleftharpoons}} \mathbf{3} \xrightarrow[Br_2]{k_2}$$

state amounts[3] leads to eq. [2] for the rate of disappearance of bromine:

$$[2]\quad \text{Rate} = \frac{k_1 k_2[Br_2]}{(k_H[H^+] + k_2[Br_2])} \cdot \frac{[\mathbf{1}]_t[H^+]}{(K_1 + [H^+])}$$

where $[\mathbf{1}]_t = [\mathbf{1}] + [\mathbf{2}]$ and $K_1 = [\mathbf{1}][H^+]/[\mathbf{2}]$. Obviously, the observed kinetic order and the variation of rate with pH will depend on the dominant terms in each of the two bracketed parts of the denominator of eq. [2].

In the pH range 0–2 the bromination of **1** and its dimethyl cation **5** both exhibit second-order kinetics. For **5** the values of k_2^{obs} (Table 1) increase regularly[4] with pH whereas for **1** they give a curved rate profile (see Fig. 1). As previously (1), the results for **5** are attributed to rate-limiting attack of bromine on its pseudobase **6**:

$$[3]\quad \mathbf{5} \underset{H^+}{\overset{K_2}{\rightleftharpoons}} \mathbf{6} \xrightarrow[Br_2]{k_2}$$

For this reaction scheme $k_2^{obs} = k_2K_2/[H^+]$ and from the data we estimate[5] that $k_2K_2 = 9400\ s^{-1}$. From equilibrium measurements we have $pK_a = 3.47$ and so $k_2 = 2.8 \times 10^7\ M^{-1}\ s^{-1}$.

The curved rate profile for **1** is expected since the literature value of $pK_a = 0.44$ (10). The data can be explained by eq. [2] with the condition that $k_H[H^+] \gg k_2[Br_2]$. In this case eq. [2] simplifies to a second-order rate expression (at fixed pH) and the form of the rate constant is:

$$[4]\quad k_2^{obs} = k_2k_2/k_H(K_1 + [H^+]) = k_2K_2/(K_1 + [H^+])$$

TABLE 1. Rate constants for the reaction of bromine with **1** and **5** (bromide salt) at low pH[a]

[b]$[S]_0$ = 0.2 mM, $[Br_2]_0$ = 0.01 mM.
[c]$[S]_0$ = 0.422 mM.

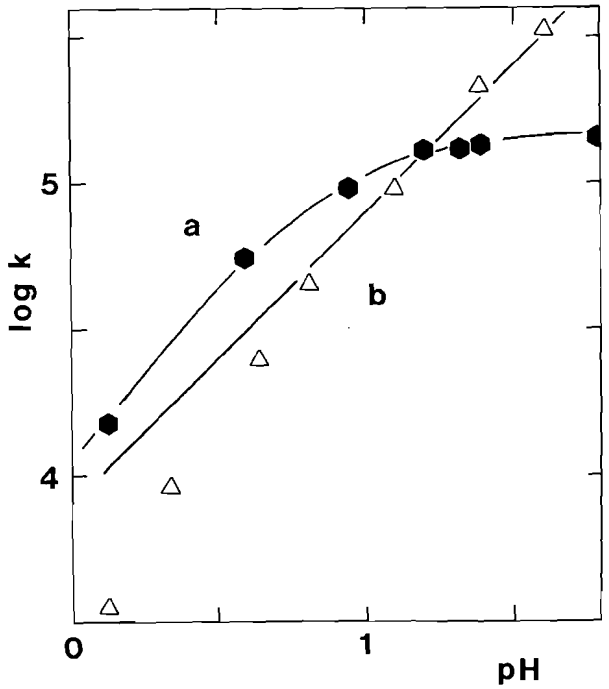

FIG. 1. Second-order rate constants for the bromination of: (*a*) **1**; (*b*) **5** (as bromide ion salt). Conditions are given in Table 1.

[3]This is not strictly true in that **3** is not always present at very low levels. However, at low pH as **3** is consumed by bromine more **1** (present in large excess) is converted to **3** and so its level remains relatively constant. At higher pH values, the initial amount of **3** is consumed rapidly (see later, Fig. 2*a*) and then its formation becomes rate-limiting, as described later. Furthermore, most of the experiments at higher pH values were carried out in such a way that *no* **3** was present initially. In view of the foregoing, we retain eqs. [1] and [2] for the convenience of their use, rather than using a more rigorous (and more abstruse) treatment which takes account of the fact that **3** is present to the level of a few percent at equilibrium.

[4]The pH–rate profile deviates from ideality (slope = 1) as the pH decreases to 0. This is due to the increase in ionic strength which accrues from the higher concentrations of HCl.

[5]The value of k_2K_2 is estimated from the four higher pH values where the ionic strength is reasonably constant (see footnote 4).

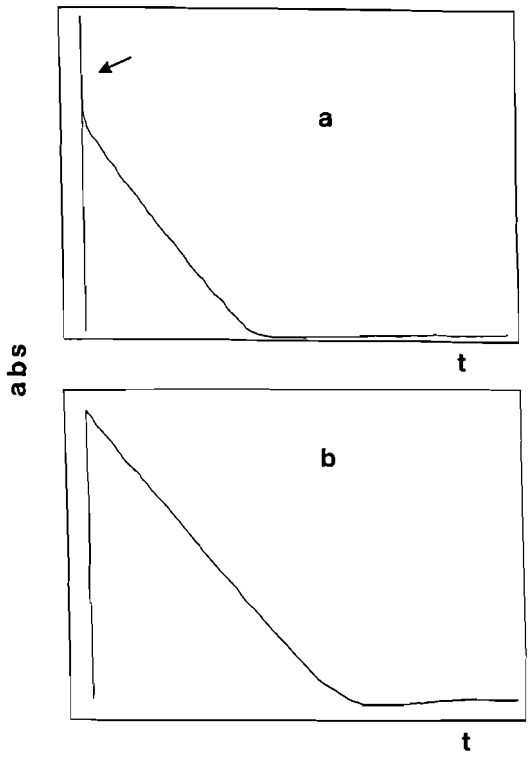

FIG. 2. Sketches of typical absorbance-time traces obtained for the reaction of bromine with **1** in the pH range 3.5–6.0. (*a*) When **1**, at equilibrium in acidic buffer, is mixed with bromine in the same buffer. (*b*) When **1** is generated *in situ* by mixing the anion $\mathbf{1}^-$ with acidic buffer containing bromine. Conditions are given in Table 2.

where $K_2 = k_1/k_H = [\mathbf{3}][H^+]/[\mathbf{2}]$ is the equilibrium constant relating the cation **2** and the hydrate **3**. From the plateau in the rate profile $k_2K_2/K_1 = 1.4 \times 10^5\ M^{-1}\,s^{-1}$. Taking a value of $pK_1 = 0.70$[6] leads to $k_2K_2 = 28\,000\ s^{-1}$.

Above pH 2 the rate of bromination of **5** is too fast to follow by the stopped–flow method. This arises because the increase in the amount of **6** does not level off until after pH 3.5 ($\simeq pK_2$). In the pH range 2–3 the bromination of **1** shows mixed-order kinetics, as was found earlier for the parent, 2-pyrimidinone (**2**). Above pH 3.5 the kinetics are more straightforward and, for an excess of the substrate **1**, the disappearance of bromine follows zero-order kinetics but with an illuminating complication.

When a solution of bromine is mixed with a ten-fold excess of **1** *two* distinct kinetic phases are seen in the absorbance decay curve (Fig. 2*a*). There is an initial rapid phase during which about 30% of the starting absorbance disappears followed by a slower phase which is clearly zero-order. This behaviour we take as direct evidence for the presence of the covalent hydrate **3** and that it is present to a level of *approximately*[7] 3% (since [**1**] is 10× that of Br_2). We argue that when the solution of **1** is mixed with a bromine solution there is a fast initial phase during which the equilibrium amount of the hydrate **3** is consumed. Thereafter, the rate of reaction is determined by the rate of formation of more **3** from **1** and so zero-order behaviour (with respect to bromine) is observed.

TABLE 2. Rate constants for the reaction of bromine with **1** at intermediate pH values[a]

pH	$k_0^{obs} \times 10^5$ ($M\,s^{-1}$)	$k_1^{obs} \times 10^2$ (s^{-1})
3.67	12.2	24.4
4.17	4.33	8.66
4.73	1.55	3.10
5.10	0.764	1.53
6.17	[b]	0.091[b]

[a]At 25°C, $I = 0.11\ M$ (KBr + buffer), $[\mathbf{1}]_0 = 0.5\ mM$, $[Br_2]_0 = 0.05\ mM$. Solutions of $\mathbf{1}^-$ at pH 9–10 were mixed with acidic buffers containing bromine (see text).
[b]See footnote 8.

Confirmation of this interpretation was obtained by carrying out experiments in which *no* hydrate was present initially and so the initial fast phase was absent. Substrate solutions were prepared at pH 9–10 so that **1** was present as its anion $\mathbf{1}^-$, the deprotonation pK_a of **1** being 7.36 (10). Such solutions were then mixed with acidic buffers (pH 3.5–6.5) containing bromine. Upon mixing, the anion $\mathbf{1}^-$ is rapidly protonated (within the dead-time of the instrument) to give **1** in the absence of any of its hydrate **3**. Consequently, no initial fast phase is seen and one simply observes the zero-order disappearance of bromine (Fig. 2*b*) corresponding to rate-limiting formation of the covalent hydrate **3**:

$$[5] \quad (\mathbf{1}^- \xrightarrow[\text{fast}]{H^+})\,\mathbf{1} \xrightarrow[\text{slow}]{} \mathbf{3} \xrightarrow[\text{fast}]{Br_2}$$

Analysis of the absorbance traces obtained at various pHs yielded the zero-order rate constants given in Table 2.[8]

The kinetic behaviour described above and the pH dependence of the rate constants are accommodated by eq. [2] with the conditions that $k_2\,[Br_2] \gg k_H[H^+]$ and $K_1 \gg [H^+]$ ($pH > pK_1$), both of which are reasonable. With these conditions imposed eq. [2] simplifies to an expression which is zero-order in bromine when the substrate **1** is in large excess and constant:

$$[6] \quad \text{Rate} = k_0^{obs} = k_1[\mathbf{1}]_t[H^+]/K_1$$

Accordingly, the expected form of the pH dependence of the first-order rate constant (with respect to **1**) is given by:

$$[7] \quad k_1^{obs} = k_0^{obs}/[\mathbf{1}]_t = k_1[H^+]/K_1$$

As shown by Fig. 3*a* (data from Table 2) the observed values of k_1^{obs} vary with pH in the manner prescribed by eq. [7]. The decrease in rate with increasing pH arises because the rate-limiting step of the formation of the hydrate **3** involves the attack of water (k_1) on the protonated form of the substrate (see **2** → **3**,

[6]The literature value of $pK_1 = 0.44$ is for 20°C at low ionic strength (10). A value of 0.70 is more appropriate for the present work at 25°C and $I = 0.1\ M$. It is derived from the pH at which the observed rate is half of the plateau rate.

[7]The estimate is only approximate since the apparent extinction coefficients for the two phases of the reaction are not the same. The initial fast decrease in absorbance is due to the consumption of **3** and bromine whereas the second is due to the disappearance of **1** and bromine. Furthermore, because of the speed of the first phase it is difficult to accurately measure the absorbance value at time zero.

[8]Around pH 6 the absorbance changes again start to show mixed-order behaviour. This is most probably due to the onset of reaction of bromine with the anion $\mathbf{1}^-$. The absorbance–time data can be analyzed in terms of a combination of pseudo-zero- and pseudo-first-order processes in the manner described by Paventi (19). He found similar behaviour in the bromination of 2- and 4-pyrimidinone, both of which react via their anions at pH > 5.

TABLE 3. Rate constants for the equilibration of the cation **5** with its pseudobase **6**[a]

pH	k_{obs} (s^{-1})	k_f (s^{-1})	k_d (s^{-1})
3.29	158	62.9	95.1
3.60	121	69.5	51.5
3.78	107	69.1	33.9
4.13	102	87.0	19.0
4.41	85.2	76.4	8.77
4.97	79.3	76.9	2.43
5.29	81.2	80.0	1.21
5.58	81.5	80.9	0.628
5.89	82.8	82.5	0.314
6.06	80.9	80.7	0.207
6.50	81.2	81.1	0.0757
6.75	76.3	76.3	0.0400
6.95	80.2	80.2	0.0265
7.90	101	101	0.00375
8.25	123	123	0.00204
8.52	149	149	0.00133

[a]At 25°C, $I = 0.11\,M$ (NaCl + buffer). Values of k_f and k_d were calculated from k_{obs} and K_2 as described in the text.

Scheme 1). Analysis of the data in Table 2 in terms of eq. [7] gives $k_1/K_1 = 1\,500\,M^{-1}\,s^{-1}$, from which $k_1 = 300\,s^{-1}$ for $pK_1 = 0.70$.[6]

Overall, the kinetic behaviour displayed by the bromination of the 5-bromo compound **1** is very similar to that observed previously for its parent, 2-pyrimidinone (2): (*a*) at low pH bromine attack on the covalent hydrate **3**, in equilibrium with **1**, is rate-limiting; (*b*) at higher pH, where dehydration of **3** is slow relative to bromine attack, the formation of **3** from **1** is rate-limiting. However, in the present case of **1** there is sufficient of the hydrate **3** present at equilibrium that its rapid consumption by bromine can be observed (Fig. 2*a*) prior to the zero-order disappearance of bromine due to (*b*).

Equilibration studies

The equilibration of the cation **5** with its pseudobase **6** was studied using established procedures (7, 11). The reaction is quite fast and the observed first-order rate constants (k_{obs}, Table 3) are only just within the range accessible by the stopped–flow method. Between pH 4.5 and 7.0 values of k_{obs} are invariant with pH but at lower and higher pHs they rise beyond the limits of the apparatus.

For such an equilibration (11) the observed rate constant is the sum of the forward and backward rate constants (12), $k_{obs} = k_f + k_d$:

$$[8]\quad \mathbf{5} \underset{k_d}{\overset{k_f}{\rightleftarrows}} \mathbf{6}$$

Using the measured equilibrium constant $K_2 = 3.4 \times 10^{-4}\,M$ ($pK_2 = 3.47$) these contributions are accessible through the expressions derived by Bunting (11): $k_f = k_{obs}K_2/(K_2 + [H^+])$ and $k_d = k_{obs}[H^+]/(K_2 + [H^+])$. Table 3 lists values of k_f and k_d obtained in this way for the pH range 3–9. As expected from previous studies of pseudobase formation (3, 7, 11), they have pH-dependent and pH-independent components which may be described by the following equations:

$$[9]\quad k_f = k_1 + k_{OH}[OH^-]$$

$$[10]\quad k_d = k_H[H^+] + k_0$$

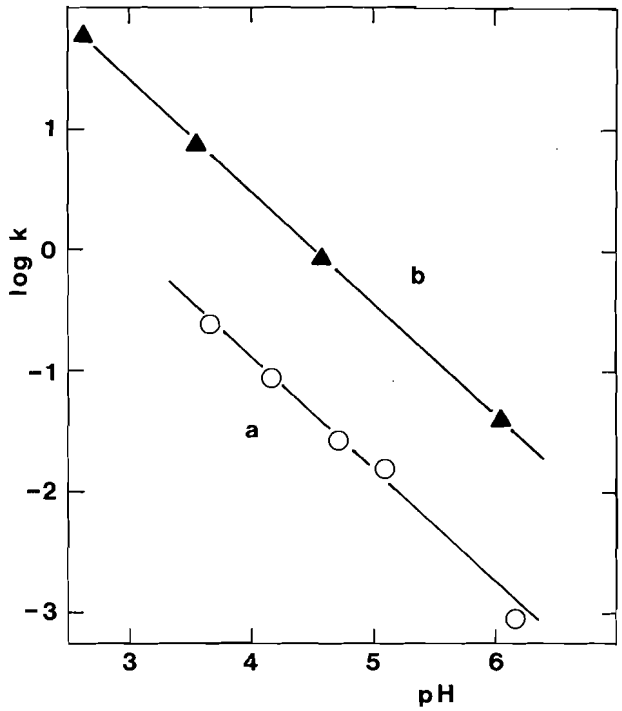

FIG. 3. First-order rate constants for: (*a*) rate-limiting formation of **3** from **1**. Obtained from zero-order bromination studies (see Table 2); (*b*) equilibration of **1** with **3**. The substrate **1** was generated *in situ* in the absence of **3** by mixing solutions of the anion $\mathbf{1}^-$ with acidic buffers. Conditions as in Table 2 except that no bromine was present in the acidic buffer.

In these equations the rate constants on the right-hand side refer to the processes depicted below:

$$[11]\quad \mathbf{5}\ (+\ H_2O) \underset{k_H}{\overset{k_1}{\rightleftarrows}} \mathbf{6} + H^+$$

$$[12]\quad \mathbf{5} + OH^- \underset{k_0}{\overset{k_{OH}}{\rightleftarrows}} \mathbf{6}$$

Appropriate values[9] of these rate constants obtained by fitting eqs. [9] and [10] to the observed values of k_f and k_d are presented later.

From the bromination studies described above it appeared that sufficient of the covalent hydrate **3** is present at equilibrium that a study of its equilibration with **1** might be possible and, fortunately, such was the case. The pseudobase **6** has a uv absorption maximum at 252 nm (ϵ = 7 600) (13) and so the covalent hydrate was anticipated to have a similar absorption in the same region. In contrast, the parent **1** has its long wavelength maximum at 322 nm (ϵ = 3 470) (10, 13) and a *minimum* at 259 nm ($\epsilon \sim 370$). Thus, it appeared quite feasible to observe the formation of **3** in the region of 250 nm.

Solutions of $\mathbf{1}^-$, the anion of **1**, at pH 9–10 were mixed with strong buffers of pH < 7.5. Immediately after mixing, the uv spectrum obtained closely resembles that of **1** at equilibrium, as one expects for the rapid protonation of the anion (14). However, with time there is a modest increase in absorbance at 250 nm and a concomitant small decrease in the 322 nm maximum of **1**. These spectral changes are consistent with the relatively slow formation of a small percentage of the covalent hydrate **3** following the rapid protonation of $\mathbf{1}^-$.

[9]These constants are, of course, interdependent since $k_1 = k_HK_2$ and $k_{OH} = k_0K_2/K_w$ (11).

Figure 3*b* shows the pH dependence[10] of the pseudo-first-order rate constants (k_{obs}) obtained by monitoring the increase at 250 nm. Note well that these rate constants are *not* simply due to the slow formation of **3** from **1**, being substantially faster than the values measured for this process in the bromination studies (Fig. 3*a*). Rather, they are for the equilibration of **1** and **3**:

$$[13]\quad \mathbf{1} \overset{H^+}{\underset{K_1}{\rightleftharpoons}} \mathbf{2} \overset{k_1}{\underset{k_H[H^+]}{\rightleftharpoons}} \mathbf{3}$$

and so k_{obs} is the sum of the forward and backward rate constants (12). For the situation depicted above this means that:

$$[14]\quad k_{obs} = k_1[H^+]/K_1 + k_H[H^+]$$

(since $K_1 \gg [H^+]$, $pK_1 = 0.70$). Of the two contributing terms in this equation, the second one due to the back reaction of **3** to **2** is dominant, as will be made apparent below.

Obviously, the two terms in eq. [14] are not immediately separable since they have the same dependence on acidity. However, the constants k_1 and k_H are related through the constant K_2 ($= k_1/k_H$). To aid subsequent discussion we define the covalent hydrate/parent ratio as $K_h = [\mathbf{3}]/[\mathbf{1}] = K_2/K_1 = k_1/k_HK_1$. With this definition eq. [14] can be rewritten as:

$$[15]\quad k_{obs} = k_H(K_h + 1)[H^+]$$

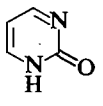
Again, as with eq. [14], it is the second term which is dominant since $K_h \ll 1$ as $[\mathbf{3}] \ll [\mathbf{1}]$, at equilibrium.

Fitting eq. [14] to the equilibration data gives $(k_1/K_1 + k_H) = 31\,000\ M^{-1}\,s^{-1}$. From the zero-order bromination results we have a value of k_1/K_1, whence $k_H = 29\,500\ M^{-1}\,s^{-1}$ and so $K_h = 0.051$. This value means that at equilibrium in water 4.9% of **1** is present as its covalent hydrate **3**.

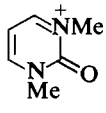
Discussion

The present studies of the bromination of **1** and **5** extend into the pH region the behaviour previously observed in strong acid (1). Moreover, the change to a different kinetic order which occurs around pH 2.5 is consistent with earlier proposals (1, 13) that **1** reacts via its covalent hydrate **3**. The direct observation of **3** and the study of its equilibration with **1** further consolidates this mechanism. Combining results from the bromination and equilibration studies provides a fairly reliable estimate of the proportion of **3** present at equilibrium in aqueous solution.

Taken as a whole, the behaviours exhibited by **1** and its dimethyl cation **5** are qualitatively similar to those observed for 2-pyrimidinone (**7**) and its dimethyl cation (**8**) (2, 7). This is



7



8

most clearly seen by reference to Table 4 in which are collected various constants for the two systems. Table 4 also serves to show the quantitative differences between them.

Firstly, it is noted that the 5-bromo substituent of **1** results in a 100-fold increase in the extent of covalent hydration. In a sense this arises from destabilization in the cation **2** (Scheme 1). This cation is more difficult to form ($\Delta pK_1 = 1.74$) but is much more easily attacked by water ($\Delta pK_2 = 3.70$). Comparable behaviour is displayed by the dimethyl cations for which $\Delta pK_2 = 3.69$.

[10]Beyond pH 6.1 we have not studied the kinetics of equilibration of **1** and **3** in detail because of the complications due to the deprotonation of **1** ($pK_a = 7.36$). At pH 7.5, $k_{obs} \simeq 1.9 \times 10^{-3}\,s^{-1}$.

TABLE 4. Summary of rate and equilibrium constants for 2-pyrimidinone (**7**), 5-bromo-2-pyrimidinone (**1**), and their respective *N*,*N*′-dimethyl cations (**8** and **5**)[a]

Constant	**1**	**5**	**7**[b]	**8**
k_1 (s^{-1})	300	77	10	1.3
k_H ($M^{-1}\,s^{-1}$)	3×10^4	2.3×10^5	5×10^6	2×10^7
k_0 (s^{-1})		7×10^{-4}		0.31
k_{OH} ($M^{-1}\,s^{-1}$)		2.4×10^7		2.1×10^6
k_2K_2 (s^{-1})	28000	9400	1900	135
k_2K_h ($M^{-1}\,s^{-1}$)	1.4×10^5	n.a.	5.2×10^5	n.a.
k_2 ($M^{-1}\,s^{-1}$)	2.8×10^7	2.8×10^7	10^9	2×10^9
pK_1	0.70[c]	n.a.	2.44[c]	n.a.
pK_2	2.00	3.47[d]	5.70	7.16[d]
K_h	0.05	n.a.	0.0005	n.a.

[a]The value for **1** and **5** are from the present work, at 25°C, $I = 0.1\ M$. Those for **7** and **8** are from earlier work at 30°C (2, 7).

[b]Some of the constants in this column are based on an assumed value of k_2 (2).

[c]Obtained from the kinetics. Literature values measured at 20°C and at weaker ionic strengths are lower (2, 10).

[d]Measured spectrophotometrically.

The actual rate of bromine attack (k_2) is about 100 times slower for **1** and **5** where this attack (on **3** and **6**) is occurring *ipso* to the 5-bromo group (Scheme 1). Nevertheless, the *apparent* reactivity of **1** towards bromine is about the same as that for **7** since the former is 100 times more hydrated. Furthermore, this apparent reactivity of **1** ($k_2K_h \sim 10^5\ M^{-1}\,s^{-1}$), which is perfectly reasonable for reaction via its covalent hydrate **3**, is not explicable by a conventional mechanism involving direct bromine attack. Such attack on **1** should be slower than that for 5-bromo-2-pyridinone, for which $k_2 = 380\ M^{-1}\,s^{-1}$ (15).

The effect of *N*-methylation on the protonated forms of **1** and **7** is much the same. In both cases it reduces the rate of water attack (k_0) and increases the rate of proton-catalyzed loss of hydroxyl (k_H) (Table 4). As a result, the pK_2 values are higher for the dimethyl cations **5** and **8**. These effects are probably as much steric as electronic in origin (2).

The present work shows that the rates of bromine attack (k_2) on the hydrate **3** and the pseudobase **6** are the same (Table 4). In other words, the effect of *N*-methylation on the reactivity of **3** is negligible. This is reasonable since *N*-methylation likewise has very little effect on the rates of bromination of pyridinones (15, 16), uracils (5), cytosines (6), and their 5-bromo derivatives. Moreover, the fact that k_2 comes out to be the same for the covalent hydrate **3** as for the pseudobase **6** is excellent evidence that **1** reacts via **3**.

In the case of 2-pyrimidinone (**7**), k_2 was not directly available since K_h was not measurable as here. Accordingly, a value half that for the pseudobase **8** was assumed which allowed us to estimate $K_h \simeq 0.0005$ for **7**. If, as in the present work, k_2 is the same for the hydrate of **7** and the pseudobase of **8**, then this estimate of K_h should be reduced by a factor of 2.

The results summarized in Table 4 are perfectly reasonable, then, for both the effects of 5-bromo substitution and *N*-methylation. More importantly, the overall consistency which is seen there means that the bromination of 2-pyrimidinones via covalent hydrates is now firmly established. As required also, the present study provided valuable information for our study of **1** and **3** as inhibitors of the enzyme, cytosine deaminase (20).

Experimental

The substrates **1** and **5** (bromide ion salt) were synthesized as previously (13). Buffer solutions and bromine solutions were made up

according to standard practice in this laboratory (5–7). For the bromination studies all of the aqueous solutions contained a fixed concentration of KBr for reasons given earlier (5). In the equilibration studies ionic strength was maintained with NaCl.

Kinetics were followed using the stopped–flow apparatus (7) and data acquisition system (17) described elsewhere. The observation cell was thermostatted at 25.0 ± 0.1°C. Bromination reactions were monitored at 267 nm (Br_3^- maximum) and analysis of the absorbance/time data was as in previous studies (5–7). The values of k_2^{obs} given in the text are corrected for the formation of tribromide ion (5). The equilibration of **5** with **6** was monitored as decreases in the long wavelength bands of **5** or of **6**, depending on the pH. The equilibration of **1** with its hydrate **3** was measured as an increase at 250 nm, in the region where **3** should have a maximum (see text). Solutions of **1**, present as its anion, at pH 9–10 were mixed in the stopped–flow apparatus with acidic buffers. For the measurement of zero-order kinetics similar solutions were mixed with acidic buffers containing bromine (see text). Note that this technique would not work if the anion of **1** was more reactive towards bromine. That it does not interfere over most of the pH range studied[8] is evidenced by the order of the reaction and the pH dependence of the rate constants.

The determination of pK_2 for **5** was carried out by making spectrophotometric measurements in 9 buffers spanning pH 2.5–4.5. Analysis of the data obtained at 250 nm (pseudobase maximum) and 345 nm (cation maximum) by standard means (18) gave $pK_2 = 3.47 \pm 0.10$ in both cases.

Structure et conformation du complexe du *N*-acétyl-aspartate avec un cation lanthanide. Étude par résonance magnétique nucléaire du ^{1}H et du ^{13}C

DANIEL BARON ET NICOLE LUMBROSO-BADER

Laboratoire de spectrochimie infrarouge et Raman, Centre national de la recherche scientifique, 2, rue Henri Dunant, 94320 Thiais, France[1] et Université Pierre et Marie Curie, 4, place Jussieu, 75230 Paris 05, France

Reçu le 5 novembre 1985

D. BARON et N. LUMBROSO-BADER. Can. J. Chem. **64**, 1317 (1986).

Les déplacements induits dans les complexes 1:1 de NAcAsp (0,14 *M*) avec Lu^{3+}, Yb^{3+}, Tm^{3+}, Er^{3+}, Ho^{3+} et Dy^{3+} sont déterminés dans du D_2O à un pH 5 pour 10 sites ^{1}H et ^{13}C. La constante de complexation moyenne (pour une concentration en chlorure d'environ 0,05 *M*) est 72 M^{-1}. La détermination du facteur géométrique du terme de pseudo-contact de chaque site (approximation d'une symétrie axiale) nécessite de tenir compte d'un terme de contact et d'écarter les données concernant Tm^{3+}.

Six structures du résidu Asp correspondant à une chélation par les deux carboxylates sont compatibles avec les données obtenues pour ce résidu; la distance $O_\beta^- \ldots C_\alpha'$ semble être critique tandis que l'orientation du COO_α^- est secondaire. L'analyse utilisant tous les sites étudiés permet de sélectionner les trois structures du résidu pour lesquelles l'azote est éloigné au maximum de l'interaction et, parmi les rotamères autour de la liaison C_α—N, ceux qui favorisent les conformations les plus étendues. La chélation implique trois oxygènes dont deux appartiennent au COO_β^-. L'existence d'un équilibre avec un autre complexe minoritaire ne peut cependant pas être totalement exclue.

D. BARON and N. LUMBROSO-BADER. Can. J. Chem. **64**, 1317 (1986).

Lanthanide induced shifts by Lu^{3+}, Yb^{3+}, Tm^{3+}, Er^{3+}, Ho^{3+}, and Dy^{3+} in NAcAsp (0.14 *M* in D_2O, pH 5) are observed for ten magnetic sites (^{1}H and ^{13}C). The averaged binding constant for 1:1 complexes is 72 M^{-1} (for chloride solutions of ca. 0.05 *M*). Determination of the pseudo-contact geometrical factors (under axial symmetry approximation) requires taking into account a contact term and discarding the Tm^{3+} results. Data from the Asp residue are in agreement with 6 structures of this residue such that chelation occurs through the two carboxylates. $O_\beta^- \ldots C_\alpha'$ length seems to be the main factor while COO_α^- orientation is a minor one. The entire set of results is consistent with only three structures where the nitrogen atom is far from the carboxylates, and the C_α—N rotamers have extended conformations. Three oxygen atoms (two from the COO_β^- group) appear to be involved in the chelation. However, the data do not exclude another minor conformational species.

Introduction

La détermination des conformations adoptées préférentiellement par les résidus aspartate ou glutamate en interaction avec un cation est une étape nécessaire pour analyser la structure locale du peptide ou de la protéine complexée par ces ions, qu'il s'agisse d'expliquer les structures obtenues par radiocristallographie ou, éventuellement, de faciliter l'interprétation des cartes de densité électronique. Dans le cas des polypeptides naturels, les cations étant généralement complexés par des chélations impliquant plusieurs groupements carboxylates et des ligandes non chargés (1), il paraît a priori difficile d'analyser ce type d'interaction à partir des contributions individuelles de chaque résidu. Il faut cependant rappeler que les calculs conformationnels peuvent conduire à des résultats très intéressants (2). Par exemple, dans le cas de l'inhibiteur trypsique BPTI, petite protéine fréquemment étudiée dans le domaine de la physicochimie biologique, les résultats obtenus par Levitt, à partir d'un modèle relativement simplifié (3), ont pu être raffinés en prenant en compte de façon plus précise des propriétés des chaînes latérales, notamment la possibilité de formation des ponts disulfures, ce qui a récemment conduit à des structures très proches de celle du cristal (4).

Le but de ce travail est donc d'obtenir des données expérimentales fiables, utilisables, le cas échéant, dans des calculs théoriques, sur la répercussion d'une interaction carboxylate–cation, tant au niveau de la chaîne latérale du résidu, Asp ou Glu, qu'à celui du squelette peptidique. Dans une première étude (5), certaines caractéristiques de la monocomplexation du carboxylate de la chaîne latérale avaient été dégagées, notamment la structure étendue du résidu et l'absence de chélation avec le squelette peptidique, du moins en ce qui concerne les deux carbonyles adjacents à la chaîne latérale. Le présent travail a pour objet l'étude d'une chélation par deux groupements carboxylates proches. Le choix du composé dérivé N-acétyl-aspartate est justifié par le fait que l'amino-acide non bloqué aurait présenté les inconvénients d'avoir un groupe NH_3^+ trop proche du COO_α^- et de ne pas posséder de liaison peptidique. En outre, NAcAsp semble jouer un rôle dans le métabolisme du cerveau (6, 7).

La méthode utilisée est basée sur l'interprétation des déplacements chimiques induits sur les sites ^{1}H et ^{13}C dans les complexes formés par des ions lanthanides paramagnétiques en solution aqueuse. L'étude précédente sur des dérivés monocarboxylates (5) avait montré que les données ^{1}H et ^{13}C obtenues avec l'ytterbium (Yb^{3+}), corrigées des termes diamagnétiques déterminés à l'aide du lutétium (Lu^{3+}), permettaient l'analyse structurale du résidu complexé en se basant sur un modèle de pseudo-contact. En effet, bien que des contributions de contact aient été systématiquement décelées pour les deux carbones proches de Yb^{3+} (COO_β^- et C_β), l'utilisation, ou non, de leurs déplacements induits ne modifiait pas les résultats concernant la conformation moyenne du résidu dans le complexe ni la distance oxygène–lanthanide; elle influait par contre sur la détermination de l'ange $\widehat{C—O—Yb}$ et la qualité du paramétrage.

Dans le présent travail, l'analyse structurale devait s'avérer plus délicate en raison de deux nouveaux éléments : (a) l'axe magnétique principal du complexe ne peut plus être assimilé à une direction $Yb^{3+} \ldots COO^-$ puisque deux groupements carboxylates sont impliqués dans le chélate; (b) un équilibre est possible entre le chélate et un complexe monodentate ne mettant en jeu qu'un seul COO^-. En conséquence, il était indispensable que les données de tous les sites ^{1}H et ^{13}C du résidu puissent être

utilisées sans réserves dans une analyse structurale basée sur un modèle de pseudo-contact. La détermination des déplacements induits par plusieurs lanthanides permet, en appliquant les méthodes proposées par Reilley *et al.* (8, 9), de calculer les termes de contact affectant chaque site. Outre les effets dus à Yb^{3+} et du Lu^{3+}, ceux du thullium (Tm^{3+}), de l'erbium (Er^{3+}), de l'holmium (Ho^{3+}) et du dysprosium (Dy^{3+}) ont donc été déterminés.

Récemment, Shelling *et al.* (10) ont publiés les déplacements induits des protons dans les complexes de NAcAsp avec ces mêmes ions lanthanides, mais d'une part ces données étaient en nombre insuffisant (4 sites) pour tenter une analyse structurale et d'autre part nos résultats expérimentaux diffèrent sensiblement en ce qui concerne H_α.

Partie expérimentale

Systèmes

Produits

Origine commerciale : NAcAsp (Sigma); $LnCl_3$, *x* H_2O (Johnson et Mathey); D_2O deutérié à 99,8% (CEA, France).

Teneur des chlorures de lanthanide en $LnCl_3,6H_2O$

Dosage par NaOH des acidités fortes libérées par $EDTAH_2^{2-}$ (en excès) lors de la complexation avec Ln^{3+} (Ln^{3+} + $EDTAH_2^{2-}$ → $LnEDTA^-$ + 2 H^+); teneurs obtenues : Lu^{3+} (93,5%), Yb^{3+} (93,2%), Tm^{3+} (95,3%), Er^{3+} (97,4%), Ho^{3+} (97,6%), Dy^{3+} (97,4%).

Solutions

NAcAsp : ≃ 0,14 *M*; DSS (référence rmn : diméthyl 4,4-silapentane 4-sulfonate de sodium) : ≃ 0,02 *M*; pH : ajusté à 5,0 (±0,1), à l'aide de NaOD, valeur brute non corrigée de l'effet isotopique (11); Ln^{3+} : concentration variable jusqu'à ρ = $[Ln^{3+}]/[NAcAsp]$ ≃ 0,5 (cf. tableau 1); pour les systèmes tamponnés par Lu^{3+}, $\rho_{tot} = \rho_{Lu} + \rho_{para} \simeq$ 0,35 avec $\rho_{para} \leqslant 0{,}15$ (cf. tableau 2).

Résonance magnétique nucléaire

Spectromètre Brüker WH 90 (^1H : 90 MHz; ^{13}C : 22,63 MHz); température 303 K; référence DSS, les variations à champ faible sont comptées positives; résultats : tableaux 1 et 2.

Attribution des spectres ^1H

Deux problèmes principaux ont été rencontrés :

(a) H_β. Impossibilité d'attribuer de façon univoque les sites $H_{\beta1}$ et $H_{\beta2}$ aux protons $H_{\beta R}$ et $H_{\beta S}$ (ou réciproquement); cependant, ce problème n'a d'incidence que dans les modèles d'analyse structurale basés sur plusieurs complexes 1:1. Par ailleurs, on observe une coalescence des signaux de ces deux sites dans le cas de Lu^{3+} et dans ceux des ions paramagnétiques Ho^{3+} et Dy^{3+}, coalescence partiellement due, pour ces derniers, à l'élargissement des signaux.

(b) H_α. Disparition du signal (largeur trop importante) avec Tm^{3+} (à partir de ρ = 0,38) et avec Er^{3+} (à partir de 0,30); malgré ce problème, nous attribuons sans ambiguïté H_α à un signal se déplaçant à champ fort avec ces deux ions, contrairement à d'autres auteurs (10).

Attribution des ^{13}COO (faible différence de déplacements chimiques dans la solution sans lanthanide : 0,15 ppm)

[a] $\Delta\delta$/solution sans Ln^{3+}; en ppm; positif pour un déplacement à champ faible.
[b] [P] = [NAcAsp] en m*M*.
[c] ρ = [Ln]/[NAcAsp]; $\rho_{tot} = \rho_{para} + \rho_{Lu}$.
[d] Signal sous H_{Me}.
[e] Signal sous CH_2 du DSS.
[f] Signal sous HDO.
[g] Par rapport à la moyenne $H_{\beta1}$, $H_{\beta2}$.
[h] Signal sur le flanc du $CH_{2\beta}$.

L'attribution est d'abord basée sur les résultats obtenus avec NAcGlu[2] pour lequel les signaux COO_α et COO_γ sont suffisamment distincts ($\Delta\delta$ = 2,15 ppm) et attribués sans ambiguïté. Avec NAcGlu, on observe systématiquement, pour une même variations de ρ, $|\Delta\delta_\gamma| > |\Delta\delta_\alpha|$, sauf dans le cas de Er^{3+}. Compte tenu des résultats obtenus avec les dérivés monocarboxylates (5), la relation précédente semble pouvoir être valablement appliquée au problème de NAcAsp. Dans le système NAcAsp–Lu^{3+}, les signaux des deux carboxylates se déplacent à champ faible en se croisant pour ρ = 0,04, ce qui permet d'attribuer le pic à champ fort dans la solution sans lanthanide au COO_β.

Calculs

Programmes d'analyse conçus et exploités au laboratoire (Digital PDP 11/34).

Analyse thermodynamique (systèmes avec Lu^{3+}, Yb^{3+} ou Tm^{3+})

(a) Normalisation des variations de déplacements chimiques, site par site et cation par cation, par rapport à la variation maximale observée pour $\rho \simeq 0,5$: $\Delta\delta_{ij(norm)} = \Delta\delta_{ij(exp)}/\Delta\delta_{ij(\rho\simeq0,5)}$. Quand $\Delta\delta_{ij(\rho\simeq0,5)}$ n'a pas été obtenu, une valeur approchée est définie à l'aide des données du carboxylate β :

$$\Delta\delta_{ij(\rho\simeq0,5)} = \Delta\delta_{ij(\rho)} \cdot \Delta\delta_{COO\beta,j(\rho\simeq0,5)}/\Delta\delta_{COO\beta,j(\rho)}.$$

(b) Minimisation de la variance V pour l'ensemble des 10 sites et des 3 cations, $V = \Sigma_i \Sigma_j p_{ij} (\Delta\delta_{ij(norm)} - \Delta\delta_{ij(calc)})^2$, en fonction de la valeur de K, constante de complexation 1:1; p_{ij} est un facteur de poids, dépendant de la déviation standard σ_{ij}.

(c) Pondération $(p_{ij}) \cdot \sigma_{moy} = \Sigma \sigma_{ij}/n$ (n étant le nombre de déplacements induits calculés); $p_{ij} = 1$ si $\sigma_{ij} \leq \sigma_{moy}$ et $p_{ij} = \sigma_{moy}/\sigma_{ij}$ si $\sigma_{ij} > \sigma_{moy}$.

(d) Elimination des données si $\sqrt{p_{ij}}(\Delta\delta_{ij(norm)} - \Delta\delta_{ij(calc)}) > 2\,\sigma_{ij}$ (dans la limite de 10% du nombre total de données).

2. Étude en cours.

Vérification de l'additivité des effets dans les systèmes comportant un tampon de Lu^{3+}

Pour Er^{3+}, à partir des données pour lesquelles $0,3 < \rho < 0,4$, calcul des moyennes $\Delta\delta_{iEr}/\rho_{Er}$ et des gradients moyens $\Delta(\Delta\delta_{iEr})/\Delta\rho_{Er}$, ce qui permet d'estimer $(\Delta\delta_{iEr}/\rho_{Er})$ pour toute valeur autour de ρ = 0,351; pour Lu^{3+}, calcul des moyennes $\Delta\delta_{iLu}/\rho_{Lu}$ dans le domaine $0,25 \leq \rho \leq 0,53$ (les gradients ne sont pas significatifs pour cet ion); pour une solution mixte Lu^{3+}–Er^{3+}, avec $\rho_{tot} = \rho_{Lu} + \rho_{Er}$:

$$\Delta\delta_{i(calc)} = \rho_{Er} \cdot (\Delta\delta_{iEr}/\rho_{Er})_{\rho tot} + \rho_{Lu} \cdot (\Delta\delta_{iLu}/\rho_{Lu})$$

Facteur d'accord (12)

$$[1] \quad R = \Sigma\,(\Delta\delta_{exp} - \Delta\delta_{calc})^2/\Sigma\,\Delta\delta^2_{exp}$$

Symétrie non axiale du tenseur d'anisotropie magnétique du complexe

Le système d'équations (10, 13)

$$[2] \quad \Delta\delta_{Pij}/D_j = F \cdot G_i + F \cdot G_i'(D_j'/D_j) + F \cdot A_i(\langle S_z\rangle_j/D_j)$$

est résolu par une méthode de moindres carrés en fonction des paramètres D_j', avec itérations sur les termes D_j' supposés non nuls et recherche du minimum de la variance.

Remarques : (a) tous les calculs ont été effectués avec au départ $D_j' = 0$ pour tous les cations; (b) les estimations de D_j' (13) n'ont pas été utilisées.

Déplacements induits dans les complexes

Méthode

L'analyse des résultats expérimentaux (variations des déplacements chimiques des 10 sites magnétiques de NAcAsp en fonction de la concentration en lanthanide) est basée sur l'égalité des constantes de complexation ligande –Ln^{3+} pour les différents lanthanides utilisés dans cette étude. Cette approxima-

TABLEAU 3. Déplacements induits dans les complexes $\Delta\delta_{Cij}$ [a]

[c]Série de données non utilisée dans l'analyse thermodynamique (Lu, Yb, Tm).

tion (14–16) a été fréquemment vérifiée et utilisée dans des travaux de rmn (10, 17–20); elle semble particulièrement justifiée lorsqu'il s'agit, comme ici, de chélates de lanthanides lourds (21).

Trois systèmes pour lesquels les variations de déplacements chimiques ont été étudiées dans le domaine $0 < \rho = [Ln]/[NAcAsp] \leqslant 0{,}5$ (Lu^{3+}, Yb^{3+}, Tm^{3+}; cf. tableau 1) sont analysés simultanément, c'est-à-dire en recherchant la constante K_1 qui minimise la variance pour l'ensemble des séries de données $\Delta\delta_{ij}$ (i: site magnétique; j: cation) pour lesquelles on calculera un déplacement chimique induit dans le complexe $\Delta\delta_{Cij}$. Les avantages d'une analyse simultanée ont déjà été discutés (5) : prise en compte effective d'un plus grand nombre de données pour la détermination de K_1 et meilleure cohérence des valeurs de Δ_{Cij}, ce qui est particulièrement important pour l'analyse structurale. Pour cela, il est nécessaire de normaliser les résultats expérimentaux et de tenir compte des différences de précision entre les séries de données $\Delta\delta_{ij}$ en introduisant des facteurs de poids p_{ij} en fonction des déviations standards σ_{ij} (cf. Partie expérimentale, § Calculs).

Les résultats sont interprétés en utilisant le modèle qui s'était avéré valable dans l'étude des dérivés monocarboxylates (5) : complexes 1:1 et 2:1 (peptide:lanthanide). En effet, il n'est pas possible, à partir de données obtenues à une seule concentration en peptide (0,14 M), de discriminer efficacement divers modèles de solution. Mais il faut remarquer que les données ^1H et ^{13}C proviennent des mêmes solutions et qu'en conséquence les valeurs de $\Delta\delta_{Cij}$, calculées pour différents modèles thermodynamiques vraisemblables, restent pratiquement proportionnelles pour les divers sites. Ce mode d'analyse simplifié ne peut donc, en principe, perturber les conditions de l'analyse structurale; il en est de même de l'utilisation des approximations $\delta(P_2Ln) = \delta(PLn)$, égalité des déplacements chimiques dans les deux types de complexes, et $K_1 = 4\ K_2$ (K_2, constante de l'équilibre $P + PLn \rightleftarrows P_2Ln$). Bien qu'inattendues dans un problème d'interaction entre cations et ligandes, de telles relations ont déjà été observées dans certains travaux sur la complexation d'ions lanthanides par des acides aminés (20, 22).

Compte tenu des approximations du modèle, les valeurs de K_1 et des $\Delta\delta_{Cij}$ doivent être considérées comme des moyennes, d'autant plus valables que l'on se rapproche de $\rho \simeq 0{,}34$, ceci dû au fait que le processus de minimisation est basé sur la somme des carrés des déviations. Or, pour les besoins de l'analyse structurale, les déplacements induits par les différents lanthanides doivent être obtenus à partir de domaines d'étude comparables, ce qui n'est pas possible avec Ho^{3+} et Dy^{3+} pour lesquels de nombreux signaux disparaissent pour des valeurs de ρ inférieures à 0,3. On peut alors utiliser un tampon de Lu^{3+} qui permet de ne pas restreindre l'étude au domaine des faibles concentrations en lanthanide paramagnétique : $\rho_{tot} = \rho_{Lu} + \rho_{para}$. Pour déterminer $\Delta\delta_{Ci,para}$, K_1 et $\Delta\delta_{Ci,Lu}$ étant par ailleurs connus, il suffit de faire varier ρ_{para} jusqu'à 0,15 par exemple tout en maintenant ρ_{tot} à environ 0,34. L'emploi de tampon de lanthanides diamagnétiques est une méthode qui a déjà été utilisée pour maintenir la force ionique constante (23).

Résultats et discussion

Les résultats finaux, K_1 et $\Delta\delta_{Cij}$ (j = Lu^{3+}, Yb^{3+}, Tm^{3+}) sont obtenus à partir de 135 données, certaines d'entre elles ayant été éliminées (voir Partie expérimentale, § Calculs). La déviation standard moyenne, relative aux données normalisées et pondérées, est très satisfaisante (4,1%) compte tenu de la simplicité du modèle. En ce qui concerne la pondération des résultats expérimentaux, on remarque une certaine corrélation entre p_{ij} et $\Delta\delta_{Cij}$ (dans le tableau 3, on a signalé les sites pour lesquels p_{ij} est maximum), mais les exceptions sont trop nombreuses (cas de Lu^{3+} notamment) pour que cette pondération puisse être liée a priori aux valeurs maximales de $\Delta\delta_{ij}$; d'autres facteurs interviennent, dont, en particulier, l'élargissement des signaux dû à l'ion paramagnétique, ce qui justifie un mode de calcul de facteurs de poids basé sur la précision effective des paramétrages. Par ailleurs, signalons que les données relatives à C_{Me}—Yb ayant dû être écartées de l'analyse générale, le déplacement induit, dans ce cas, a été calculé de façon indépendante, en utilisant la valeur de K_1 précédemment déterminée.

Les valeurs de $\Delta\delta_{Cij}$ (tableau 3) peuvent être comparées, pour Lu^{3+} et Yb^{3+} du moins, à celles des dérivés monocarboxylates de Asp (5) : apparemment, la chélation augmente d'environ 50% les effets de Yb^{3+} sur les sites COO_β, C_β et H_β. Précisons qu'une analyse de nos résultats, basée sur un modèle de solution à un seul complexe (PLn ou P_2Ln), conduirait à des valeurs de déplacements induits anormalement élevées (par exemple, $|\Delta\delta_C| \simeq 88$ ppm pour COO_β avec Yb^{3+}) et, on le verra, incompatibles avec la plupart des résultats de Shelling *et al.* (10). Enfin, la nette différence entre les effets de Lu^{3+} sur les deux carboxylates montre que les forces d'interaction ne sont pas identiques et reflètent sans doute les pK des fonctions ($COO_\alpha \simeq 2$ et $COO_\beta \simeq 4$).

La constante moyenne K_1, déterminée à partir des données relatives aux ions Lu^{3+}, Yb^{3+} et Tm^{3+} est de 72 M^{-1}; pour la comparer avec la valeur obtenue dans le système NAcAspOMe $-Yb^{3+}$, 70 M^{-1} (5), il faudrait pouvoir effectuer des corrections qui concourraient toutes à augmenter le rapport K_1 (NAcAsp)/

K_1 (NAcAspOMe) : corrections de méthode d'analyse (K_1/K_2 a été fixé à 4 dans ce travail, alors qu'il était de 11 pour NAcAspOMe), d'anion (Cl^- pour ce travail, ClO_4^- précédemment) et de force ionique, la majeure partie des déplacements chimiques du proton du système NAcAspOMe–Yb^{3+} ayant été obtenue à la concentration de 10^{-2} *M* en acide aminé. Récemment d'ailleurs, pour des concentrations en lanthanide de 10 à 20 m*M* (soit une cinquantaine de fois plus faibles que dans cette étude), Shelling *et al.* (10) obtenaient, pour la complexation de NAcAsp avec des lanthanides lourds, une valeur moyenne de K_1 d'environ 5000 M^{-1}. Cette variation de la valeur du quotient de complexation devrait pouvoir être attribuée, pour l'essentiel, à un effet de la force ionique sur les coefficients d'activité des ions impliqués dans le complexe. Ainsi, d'après les résultats de Hurlen (24), en passant du domaine moyen de concentration utilisé par Shelling *et al.* au nôtre, le coefficient d'activité du seul ion lanthanide serait divisé par un facteur 30, ce qui expliquerait l'essentiel de la divergence des résultats thermodynamiques. L'incidence éventuelle du domaine de concentration en lanthanide sur les valeurs de $\Delta\delta_{Cij}$ sera examinée après avoir discuté de la détermination des grandeurs relatives à Er^{3+}, Ho^{3+} et Dy^{3+}.

Pour tester la validité de la méthode utilisant des solutions tamponnées par le lutétium, on a comparé les résultats expérimentaux obtenus avec l'erbium seul (domaine $0{,}3 < \rho < 0{,}4$; tableau 1) et le système mixte Lu^{3+}–Er^{3+} ($\rho_{tot} \simeq 0{,}35$; $\rho_{Er} < 0{,}15$; tableau 2); voir Partie expérimentale, § Calculs. L'erbium a été choisi car il permettait d'obtenir (sauf cas du H_α déjà signalé) des spectres rmn exploitables jusque vers $\rho = 0{,}4$. La comparaison entre les valeurs expérimentales et calculées est très satisfaisante, le facteur d'accord de Wilcott (cf. éq. [1]) étant de 3,6%. Par ailleurs, incidemment, cette étude a permis de confirmer l'attribution des variations de déplacements chimiques des carboxylates par effet des ions Er^{3+} (dans ce cas particulier, l'effet à champ fort est plus important sur le COO_α que sur le COO_β). Précisons encore qu'une vérification similaire de la validité de la méthode a été effectuée avec les systèmes NAcGlu–Tm^{3+} et Lu^{3+}–Tm^{3+}.[3] Finalement, le procédé a été appliqué à Ho^{3+} et Dy^{3+} (tableau 2). Le calcul des valeurs de $\Delta\delta_{Cij}$ pour les complexes de Er^{3+}, Ho^{3+} et Dy^{3+} est effectué en utilisant les valeurs de K_1 et des $\Delta\delta_{CiLu}$ précédemment obtenues (tableau 3). Aucune déviation significative n'est observée lors de ces déterminations de déplacements induits.

Nos valeurs de $\Delta\delta_{Cij}$ sont comparables à celles de Shelling *et al.* (10) pour les sites H_{Me}, $H_{\beta 1}$ et $H_{\beta 2}$ en dépit de la différence des domaines de concentrations en lanthanides (cf. *supra*); par contre le désaccord est très important pour H_α, tant en grandeur qu'en signe (cas de Tm^{3+} et de Er^{3+}); voir Partie expérimentale, § Résonance magnétique nucléaire. Il parait improbable que notre modèle d'analyse des données soit en cause puisque pour 3 des 4 sites ^1H, l'accord entre les déplacements induits déterminés dans les deux travaux est en moyenne de 7%. Enfin, il est possible de vérifier que, dans les conditions expérimentales utilisées, l'influence du pH sur ces grandeurs est négligeable (cf. Appendice).

Facteurs géometriques

Principe

La détermination des déplacements induits dans les complexes pour une série de lanthanides paramagnétiques doit permettre de calculer, pour chaque site, le facteur géométrique de l'équation de McConnell et Robertson (25), ($3\cos^3\theta_i - 1)/r_i^3$, θ_i et r_i se référant aux coordonnées du site *i* de la molécule, par rapport à la position de l'ion lanthanide et à la direction de l'axe magnétique principal du complexe; à partir d'un ensemble suffisant de valeurs de facteurs géométriques, on peut entreprendre une analyse structurale de ce complexe. Les grandeurs utilisées dans les calculs sont les termes paramagnétiques $\Delta\delta_{Pij}$ (déplacements induits corrigés de l'effet diamagnétique du lutétium) :

$$[3] \quad \Delta\delta_{Pij} = \Delta\delta_{Cij} - \Delta\delta_{CiLu}$$

La prise en compte d'un effet de contact étant indispensable pour disposer d'un maximum de valeurs fiables des facteurs géométriques (cf. Introduction), les termes paramagnétiques sont analysés suivant (8–10, 13) :

$$[4] \quad \Delta\delta_{Pij} = F(G_i \cdot D_j + A_i\langle S_z\rangle_j)$$

$G_i \cdot D_j$ est le terme de pseudo-contact, $A_i\langle S_z\rangle_j$ celui de contact, G_i le facteur géométrique recherché, A_i la constante hyperfine de contact du site (ou sa valeur relative), D_j et $\langle S_z\rangle_j$ des paramètres calculés théoriquement (26–29) et fréquemment utilisés dans ce type d'analyse (8–10, 13, 20); enfin F est un facteur d'échelle tenant compte de la normalisation des valeurs de D_j et $\langle S_z\rangle_j$ à $D_{Dy} = 100$. On rappelle que cette méthode est basée d'une part sur l'isostructuralité des complexes et la constance de A_i à l'intérieur de la série d'ions considérés (9) et d'autre part sur la symétrie axiale du tenseur de susceptibilité magnétique dans le complexe. Lorsque cette dernière approximation est discutable (13, 30), il convient d'utiliser la relation (10, 13) :

$$[5] \quad \Delta\delta_{Pij} = F(G_i \cdot D_j + G_i' \cdot D_j' + A_i\langle S_z\rangle_j)$$

G_i' est un second facteur géométrique qui dépend de θ_i et de r_i mais également de l'angle entre la direction Ln^{3+} – site *i* et l'un des axes secondaires du tenseur d'anisotropie magnétique (31). Des valeurs de D_j' ont été évaluées pour les ions lanthanides (13).

Résultats et discussion

En premier lieu, il faut remarquer que les termes paramagnétiques ne peuvent être expliqués par un seul effet de pseudocontact axial, l'incertitude moyenne sur les facteurs géométriques G_i étant nettement trop importante (tableau 4).

[b]Calculées pour le modèle symétrie axiale, analyse avec 4 cations (sans Tm).

Par contre, lorsque l'analyse tient compte de l'effet de contact (éq. [4]), la précision est fortement améliorée bien qu'une déviation systématique soit encore observée, au niveau de chaque site, dans le cas de l'ion Tm^{3+}. Ces déviations peuvent être dues à une absence de symétrie axiale du tenseur d'anisotropie magnétique, comme cela avait déjà été suggéré pour cet ion (10, 30). On a essayé de vérifier cette hypothèse en supposant que pour un ou plusieurs cations l'approximation de la symétrie axiale ne soit pas valable. Les termes paramagnétiques sont alors analysés suivant l'éq. [5] (cf. Partie expérimentale pour la méthode de calculs) en postulant que seuls certains cations entrainent un effet non-axial important et que pour les autres on a $D_j' \simeq 0$. Dans chacun des groupes de combinaisons avec 1, 2 ou 3 cations pour lesquels $D_j' \neq 0$, les meilleurs résultats (plus faible incertitue moyenne sur les facteurs géométriques, par exemple) impliquent toujours l'ion Tm^{3+} (cf. tableau 4).

Il faut remarquer que lorsque $D_j' \neq 0$ pour un seul cation k les résultats obtenus avec l'éq. [5] sont équivalents à ceux de l'analyse basée sur l'éq. [4] dans un système n'incluant pas les données du cation k; c'est en particulier le cas pour Tm^{3+} (tableau 4). Par ailleurs, toutes les combinaisons de 3 cations à symétrie non-axiale qui impliquent l'ion Tm^{3+} conduisent à des variances très proches, ce qui semble indiquer que l'on atteint, à ce niveau, la limite des possibilités d'une telle analyse de nos données. Pour discuter des différents modes d'interprétation des termes paramagnétiques, on a choisi de se référer à la moyenne des facteurs géométriques obtenus à partir de ces 6 combinaisons avec Tm^{3+} et deux autres cations non-axiaux; cf. tableau 5. On constate le très bon accord entre ces moyennes de référence et les valeurs obtenues avec l'éq. [4], à partir d'un système à 4 cations (sans Tm^{3+}); ces derniers résultats ont donc été utilisés dans l'analyse structurale.

Il faut également noter que les facteurs géométriques calculés à partir des seules données de Yb^{3+} et Dy^{3+} et du modèle à symétrie axiale et effet de contact (éq. [4]) sont également très cohérents avec les résultats précédents (tableau 5). Si ce résultat peut être corroboré par des études ultérieures, sur des dérivés du glutamate notamment,[4] on disposerait d'une méthode beaucoup plus rapide pour la détermination des facteurs géométriques. Par contre, les termes paramagnétiques relatifs à Yb^{3+} ne sont pas exempts d'effets de contact et d'importantes déviations apparaissent sur les valeurs de G_i calculées à partir de ces seules données, particulièrement au niveau des carbones adjacents aux carboxylates, ce que l'on peut expliquer par les valeurs relatives des constantes hyperfines de contact.

Les variations de A_i sont relativement cohérentes (tableau 6), ce qui valide, a posteriori, le modèle : les effets sont d'autant plus importants que le site est proche du lanthanide et on observe l'alternance de signe attendue lorsque le phénomène de polarisation de spin est prépondérant :  (réf. 9); par ailleurs, le contact est apparemment négligeable pour les noyaux du groupement N-acétyle. Enfin, deux observations importantes sont à souligner : les effets de contact sont plus grands du côté du carboxylate β que du COO_α et, par ailleurs, la proportion de contact dans le terme paramagnétique est relative-

4. Étude en cours.

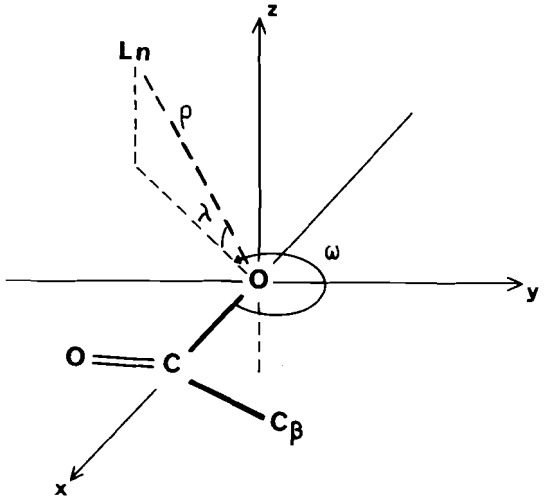

FIG. 1. Définition des coordonnées du lanthanide (ρ, ω, λ) par rapport au carboxylate.

ment plus importante pour les carbones β et α que pour les carboxylates eux-mêmes, ce qui explique que, dans une étude antérieure basée sur les seules données de Yb^{3+}, les déviations les plus importantes provenaient justement des C_β (5).

Structure et conformation du complexe

Les facteurs géométriques précédemment déterminés (tableau 5), ainsi que les constantes hyperfines relatives à l'effet de contact (tableau 6), montrent clairement que les deux carboxylates sont impliqués dans l'interaction mais que les effets sont plus importants au niveau du COO_β que du COO_α; il peut donc s'agir d'un chélate dissymétrique.

La méthode générale de calcul, ainsi que les longueurs et angles de liaison utilisés, ont été détaillés dans un travail antérieur (5). En ce qui concerne les rotamères, nous avons conservé également les approximations suivantes: rotations d'ordre 3 autour des liaisons C_{sp^3}—C_{sp^3} (positions alternées), C_{sp^3}—COO^- (avec éclipse du C=O); rotation d'ordre 6 autour de C_α—N. La position de l'ion Ln^{3+} (ρ, ω, λ) est définie dans le chélate par rapport au COO_β (fig. 1) et la direction de l'axe magnétique principal est déterminée en fonction de l'inverse du carré des distances Ln^{3+} ... O_α^- et Ln^{3+} ... O_β^-, ce que nous discuterons ultérieurement. Enfin, la variance est exprimée sous la forme du facteur d'accord R (éq. [1]).

Résultats

Dans un premier temps, l'analyse a été limitée aux noyaux proches des interactions avec le lanthanide (les 7 sites du résidu Asp) dans le but de préciser les structures possibles parmi les 27 conformations du résidu. Seules 6 structures (tableau 7) permettent d'obtenir des valeurs acceptables de R (entre 9,8 et 12,7%) et de ρ (entre 2,45 et 3,15 Å). Dans tous les autres cas R est supérieur à 14% (ρ étant limité à 3,2 Å) et il paraît statistiquement impossible que ces autres structures aient une quelconque importance dans le complexe.

La distance O_β^- ... C_α' semble le facteur essentiel de discrimination entre ces conformations: les arrangements correspondant aux deux carboxylates en position *anti* par rapport à la liaison C_β—C_α sont évidemment défavorisés (fig. 2c), mais ceux pour lesquels le C—O_β^- ne pointe pas directement vers le carboxylate α le sont également (fig. 2a, e, f). Par contre, on observe peu de différence pour les 3 rotamères autour de C_α—C', ce qui peut s'interpréter par une quasi-équivalence des

TABLEAU 7. Conformations du résidu Asp dans le chélate

deux oxygènes du carboxylate α, en relation peut-être avec la faible basicité de ce groupement ($pK \simeq 2$).

L'analyse finale peut donc être restreinte aux conformères dérivés, par rotation d'ordre 6 autour de C_α—N, des 6 structures possibles du résidu, soit 36 conformères sur les 162 théoriques. Une exploration préalable a été effectuée avec des pas de 0,2 Å pour ρ ($2,2 \leqslant \rho \leqslant 3,0$ Å) et des pas de 10° pour les angles ω et λ; les résultats sont alors affinés pour chaque sous minimum obtenu (résolution finale: 0,05 Å et 2,5°). Le meilleur résultat est relatif à des conformères de structure **10** ou **11** pour lesquels R = 11,7% (respectivement 11,6 et 11,3% lors de l'analyse à 7 sites). Cette légère augmentation du facteur d'accord R n'est pas surprenante: les sites du N-acétyl ont des déplacements induits faibles et les répercussions des incertitudes du modèle y seront relativement plus importantes.

L'analyse permet de déterminer le conformère prédominant, les 3 coordonnées du lanthanide (ρ, ω, λ) et le facteur d'échelle de l'équation de McConnell et Robertson (25). Compte-tenu des 10 sites considérés, on peut admettre qu'il reste 5 degrés de liberté et que la valeur maximale admissible pour R est (32) $R_{max} = R_{mini}(1 + 1/5)^{1/2}$ soit 12,8%. Quatorze conformères (sur 36) répondent à cette condition (tableau 8) et ne diffèrent que par des rotations autour de C_α—C' (tableau 7) et de C_α—N (angle ϕ). Ils correspondent donc au même squelette $^-$O—C—C_β—C_α—C' et sont issus des structures **10**, **11** et **12** du résidu, le groupement N-acétyle étant en position *anti* par rapport au COO_β (fig. 2d), donc éloigné au maximum des deux carboxylates en interaction avec le cation, contrairement à leur situation dans les structures **4**–**6** (fig. 2b). Ainsi, l'introduction des données du N—Ac permet une sélection parmi les précédentes conformations du résidu et montre, comme dans les complexes de monocarboxylates (5), la tendance à l'extension des groupements de la molécule ne participant pas à l'interaction.

L'orientation du lanthanide par rapport au carboxylate β est pratiquement constante dans cette série de 14 conformères: ω = 256° (±7°), λ = −67° (±4°); par contre ρ varie de 2,6 à 3,2 Å avec une valeur moyenne de 2,95 Å (±0,19). Les meilleurs résultats sont obtenus avec les structures **10** et **11** où deux oxygènes sont à des distances de 2,9 à 3,2 Å du lanthanide (l'un est le O^- du COO_β, l'autre appartient au COO_α); un troisième oxygène, le C=O du COO_β, est à environ 3,4 Å (**11**) ou 3,8 Å (**10**). Dans les structures **12**, la distance moyenne du lanthanide aux 3 oxygènes les plus proches est comparable aux cas précédents mais par contre l'interaction se fait préférentiellement avec le COO_β (2,6 et 3,2 Å) tandis que le plus proche oxygène du COO_α est à environ 3,7 Å. Cette structure moins chélatée semble être défavorisée puisque 3 conformères seule-

[a]Dont le facteur d'accord est $R \leq 12{,}8\%$.
[b]Voir tableau 7.
[c]Angle C′—C_{α}/N—C(O); voir (*a*), tableau 7 et réf. 33.

ment ont un facteur $R \leq 12{,}8\%$. La figure 3 illustre ces 3 types de structures.

Par rapport à la complexation monodentate du carboxylate d'un résidu aspartate (5), on observe donc dans le chélate, outre la structure repliée du résidu, deux modifications significatives qui favorisent l'interaction avec 3 oxygènes : l'allongement de la distance O_{β}^{-} ... Ln^{3+} et le positionnement du cation à proximité du plan bissecteur du COO_{β} et nettement en dehors du plan du carboxylate.

Enfin, en ce qui concerne le groupement N-acétyle, l'oxygène de l'amide étant toujours à plus de 5,7 Å du lanthanide (tableau 8), les rotamères les moins étendus (ϕ = 90° et +30°) semblent légèrement moins stables, comme le suggère les facteurs d'accord (tableau 8). Pour ces conformères défavorisés, le groupe CH_3CO est proche à la fois du C′ et du C_{β} (fig. 4); ces résultats, s'ils sont significatifs, sont en accord avec les valeurs théoriques ou expérimentales de l'angle ϕ dans les protéines (2).

Discussion

Le facteur d'acord, près de 12%, peut sembler relativement élevé pour ce type d'analyse et rappelle les valeurs obtenues pour les complexes monocarboxylates–Yb^{3+} lorsque tous les sites, y compris le carboxylate et son carbone adjacent, étaient

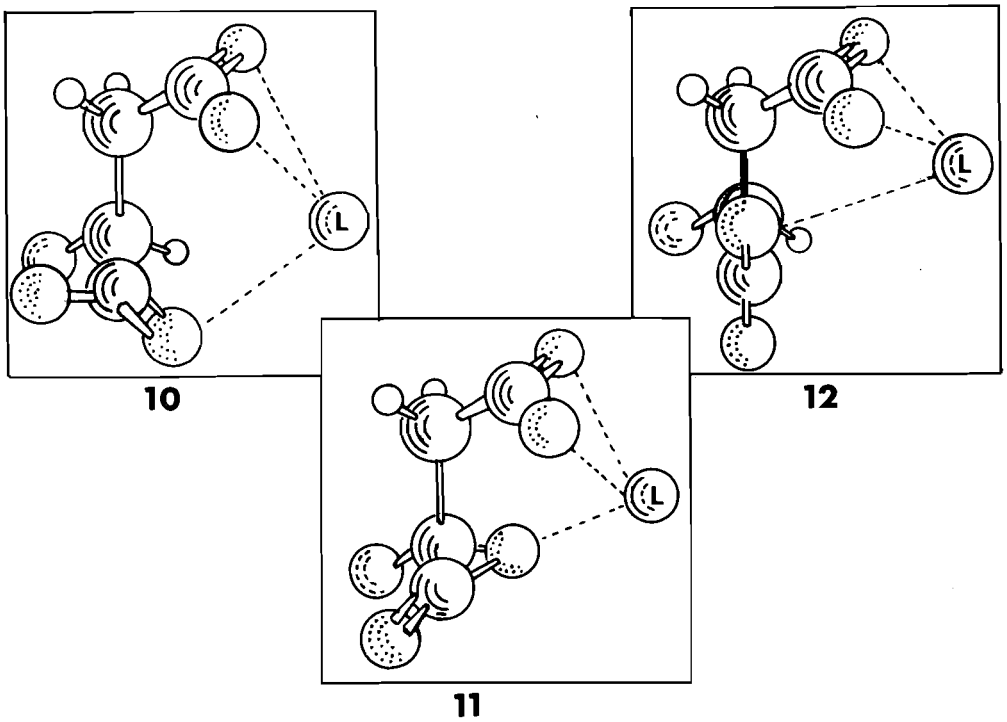

FIG. 3. Structures du chélate (le groupement acétyle n'est pas représenté).

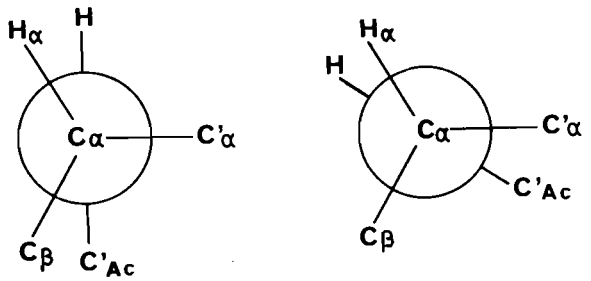

FIG. 4. Conformères défavorisés (rotamères autour de C_α—N).

inclus dans l'analyse (5). Toutefois, la détermination des facteurs géométriques du NAcAsp a été effectuée en tenant compte, pour l'essentiel, des effets de contact et d'ailleurs les déviations les plus importantes observées dans l'analyse structurale concernent les sites $H_{\beta 1}$ et $H_{\beta 2}$ et non les carbones proches du lanthanide. Nous avons donc recherché d'autres causes possibles de ces déviations et, en particulier, examiné successivement l'influence d'une variation sensible de la direction de l'axe magnétique et celle d'un équilibre entre plusieurs types de complexes 1:1.

Dans les analyses précédentes, la direction de l'axe magnétique principal du complexe avait été déterminée par une pondération en fonction de l'inverse du carré des distances entre le cation et les deux oxygènes O_α^- et O_β^-. On pouvait penser qu'un paramétrage de la direction de cet axe permettrait de tenir compte de l'intervention des 3 oxygènes les plus proches du cation. En fait, les calculs montrent que l'amélioration du facteur d'accord est relativement négligeable ($R \simeq 11\%$) et statistiquement insuffisante. Il ne faut cependant pas en déduire que la direction de l'axe magnétique ne soit pas un élément important pour l'analyse : en fixant par exemple l'axe dans la direction $Ln^{3+} \ldots O_\beta^-$, ce qui correspondrait à un complexe monodentate, le facteur d'accord minimum atteindrait 27%.

En ce qui concerne l'existence de complexes secondaires, plusieurs modèles ont été testés : deux complexes monodentates (« α » et « β »), un équilibre entre un chélate et un monodentate « β » et enfin un équilibre entre conformations du chélate. Précisons que lorsqu'un complexe monodentate est impliqué, on a fait l'hypothèse que l'ion Ln^{3+} était sur l'axe C—O^- (5). Il est facile d'éliminer le modèle avec deux complexes monodentates : la variance décroit régulièrement lorsque les distances ρ_α et ρ_β tendent vers des valeurs inférieures à 2,0 Å; les calculs ont été effectués avec les 7 données relatives au résidu Asp, pour les 81 combinaisons possibles (9 conformères « α » et 9 conformères « β »).

Dans le cas d'un équilibre chélate – monodentate β, l'analyse préliminaire limitée aux 7 sites du résidu Asp montre encore que seules les 6 structures du chélate précédemment évoquées (**4–6** et **10–12**) sont compatibles avec nos résultats. Les calculs finaux ont donc été restreints aux combinatisons entre 36 conformères du chélate et 54 du monodentate « β » pour lequel on a fixé ρ à 2,7 Å, valeur obtenue pour les complexes de la chaîne latérale de Asp (5). Dans ces conditions, la meilleure combinaison conduit à $R = 5{,}1\%$. Ce résultat n'est pourtant pas réellement significatif étant donné la réduction du degré de liberté du système due aux déterminations du type de conformère pour le monodentate « β » et du poids relatif de ce complexe ouvert. La valeur du test statistique F (34) n'est que de 4,2 alors qu'un seuil de 9,0 est nécessaire pour que ce modèle soit probablement significatif (niveau de confiance de 90%) par rapport à celui n'impliquant que le chélate. D'autres arguments (nombre de sous-minima apparus lors de l'analyse, poids de chacun des complexes) concourrent également à ne pas retenir ce modèle.

Enfin, deux conformères du chélate pourraient être en équilibre, mais, comme dans le cas précédent, il est actuellement difficile d'effectuer une analyse quantitative significative, même en imposant, par exemple, des valeurs identiques de ρ et de ω dans les deux conformères. Pourtant, un équilibre

conformationnel de ce type permettrait d'expliquer les déviations observées pour les sites $H_{\beta 1}$ et $H_{\beta 2}$ lorsqu'on ne considère qu'un seul conformère. En effet, si les variations d'angle ϕ et les rotations autour de la liaison C_α—C′ sont apparemment sans effet important sur la valeur des facteurs géométriques de ces deux protons, par contre leur ordre est inversé lorsque l'on passe d'une structure de type **10–12** à une autre de type **4–6** et, compte tenu des signes des déviations pour ces deux sites proton, un tel équilibre conformationnel devrait améliorer le facteur d'accord. En considérant un modèle de 2 conformères (**4–6**, **10–12**) pour lesquels ρ et ω sont supposés identiques, il est possible d'abaisser R en dessous de 8%.

Conclusion

Un modèle de solution simplifié, n'impliquant que deux complexes, PLn et P_2Ln, est suffisant pour interpréter les résultats obtenus pour des solutions relativement concentrées en NAcAsp (0,14 *M*) et en sel de lanthanide (0,05 *M* en moyenne) et déterminer les déplacements induits dans le complexe 1:1. Une plus grande cohérence des résultats est obtenue à l'aide d'une méthode de pondération des données dans laquelle intervient la déviation standard de chaque série de résultats expérimentaux. Enfin, l'utilisation de solutions tamponnées par les ions Lu^{3+} résoud les problèmes posés par l'élargissement des signaux dans le cas de certains lanthanides.

Pour la détermination des facteurs géométriques, il est nécessaire de ne pas utiliser les données relatives au thullium, en raison sans doute d'une forte déviation par rapport au modèle à symétrie axiale en ce qui concerne le terme de pseudo-contact. Pour certains sites, l'effet de contact n'est jamais négligeable, même avec l'ytterbium; par contre, il semble suffisant de combiner les données relatives à Yb^{3+} et à Dy^{3+} pour obtenir les facteurs géométriques avec une bonne approximation.

D'après les données du seul résidu Asp, les deux carboxylates du chélate sont en conformation *gauche* par rapport à la liaison C_α—C_β et O_β^- est dirigé vers COO_α. Les résultats relatifs au N-acétyle introduisent une condition supplémentaire, ce groupement devant être éloigné au maximum du cation et des carboxylates. Les conformères finalement retenus ne diffèrent que par des rotations autour de C_α—C′ et C_α—N; la chélation implique toujours 3 oxygènes (un pour le COO_α à 3,25 Å du cation en moyenne, deux pour le COO_β à environ 2,95 et 3,55 Å), le cation se rapprochant du plan bissecteur du carboxylate β par rapport à la situation observée dans les complexes de monocarboxylates. Ces conformères pourraient cependant ne correspondre qu'à l'espèce majoritaire d'un équilibre conformationnel; dans l'autre forme le groupement N-acétyle serait alors en conformation *gauche* par rapport au carboxylate β.

Appendice

Variation de la constante de complexation apparente et du déplacement induit en fonction du pH

On considère un système constitué par 2 espèces acido-basiques AH^- et A^{2-} (cette dernière étant prédominante) et les 2 complexes $(AHLn)^{2+}$ et $(ALn)^+$.

$$AH^- \rightleftarrows A^{2-} + H^+ \qquad [AH^-]/[A^{2-}] = [H^+]/K_A = h$$

$$AH^- + Ln^{3+} \rightleftarrows (AHLn)^{2+} \qquad [(AHLn)^{2+}]/[AH^-] = K_1\,[Ln^{3+}]$$

$$[(AHLn)^{2+}]/[A^{2-}] = K_1 h\,[Ln^{3+}]$$

$$A^{2-} + Ln^{3+} \rightleftarrows (ALn)^+ \qquad [(ALn)^+]/[A^{2-}] = K_2\,[Ln^{3+}]$$

Déplacements chimiques

$AH^- : (\delta_1)$ $\quad A^{2-} : (\delta_2)$ $\quad (AHLn)^{2+} : (\delta_{C_1})$ $\quad (ALn)^+ : (\delta_{C_2})$

$$\delta = \Sigma(C_i\delta_i)/\Sigma C_i = \Sigma(C_i\delta_i/[A^{2-}])/\Sigma(C_i/[A^{2-}])$$

$$\delta = \{h\delta_1 + \delta_2 + (K_1 h\delta_{C_1} + K_2\delta_{C_2})[Ln^{3+}]\}/\{h + 1 + (K_1 h + K_2)[Ln^{3+}]\}$$

pour $[Ln^{3+}] = 0$

$$\delta = (h\delta_1 + \delta_2)/(h + 1)$$

$$\Delta\delta = \delta_{[Ln^{3+}]\neq 0} - \delta_{[Ln^{3+}]=0} = \frac{K'\cdot\Delta\delta'_C\cdot[Ln^{3+}]}{1 + K'\cdot[Ln^{3+}]}$$

avec

$$K' = K_2(1 + hK_1/K_2)/(1 + h)$$

$$\Delta\delta'_C = (K_1 h\delta_{C_1} + K_2\delta_{C_2})/(K_1 h + K_2) - (h\delta_1 + \delta_2)/(h + 1)$$

Déplacement paramagnétique :

$$\Delta\delta'_P = \Delta\delta'_{C(Ln\ para)} - \Delta\delta'_{C(Ln\ dia)}$$

avec

$$\Delta\delta'_{C(Ln\ dia)} = \Delta\delta'_{C(Lu^{3+})}$$

$$\Delta\delta'_P = \frac{(\delta_{C2P} - \delta_{C2D})\{1 + [(\delta_{C1P} - \delta_{C1D})/(\delta_{D2P} - \delta_{C2D})] \cdot (K_1 h/K_2)\}}{1 + K_1 h/K_2}$$

Remarques :

(a) K' dépend du pH même si $K_1 = 0$

(b) $\Delta\delta'_P$ dépend du pH si $K_1 \neq 0$ *et* si $(\delta_{C1P} - \delta_{C1D}) \neq (\delta_{C2P} - \delta_{C2D})$

Cas de NAcAsp à pH 5 : $h \simeq 0{,}1$ ($pK_2 \simeq 4$)

Situation la plus défavorable : les 2 carboxylates complexent le cation de façon équivalente : $K_1/K_2 = 0{,}5$ et $0 \leqslant (\delta_{C1P} - \delta_{C1D})/(\delta_{C2P} - \delta_{C2D}) \leqslant 2$ (suivant les sites). Dans le pire des cas, l'incertitude introduite en assimilant $\Delta\delta'_P$ à $\delta_{C2P} - \delta_{C2D}$ est de 4,8%. En réalité l'importance du chélate dans les complexes $(ALn)^+$ doit abaisser l'incertidue maximale aux environs de 1%.

Ionization of 9-cyanofluorene in Me_2SO–water mixtures. The role of solvent reorientation in proton tranfers

CLAUDE F. BERNASCONI AND FRANÇOIS TERRIER[1]

Thimann Laboratories of the University of California, Santa Cruz, CA 95064, U.S.A.

Received October 23, 1985

This paper is dedicated to Professor Arthur N. Bourns

CLAUDE F. BERNASCONI and FRANÇOIS TERRIER. Can. J. Chem. **64**, 1273 (1986).

Rate constants of the reversible deprotonation of 9-cyanofluorene by primary aliphatic amines were measured in 10%, 50%, and 90% aqueous Me_2SO (v/v) by the stopped-flow method. Intrinsic rate constants defined as $k_0 = k_1^B/q = k_{-1}^{BH+}/p$ at $\Delta pK + \log(p/q) = 0$ were obtained from Brønsted plots. The values for $\log k_0$ are 3.60 ± 0.15 in 10%, 3.81 ± 0.10 in 50%, and 3.61 ± 0.05 in 90% Me_2SO. The constancy of k_0 with increasing Me_2SO content of the solvent contrasts with results obtained by Ritchie (C. D. Ritchie, J. Am. Chem. Soc. **91**, 6749 (1969)) who found that k_0 for the ionization of 9-carbomethoxyfluorene by carboxylate ions in Me_2SO is much higher than for the ionization of the same carbon acid by methoxide ion in methanol. Our findings suggest that it is mainly early desolvation of the oxyanions in the hydroxylic solvent which accounts for Ritchie's results.

CLAUDE F. BERNASCONI et FRANÇOIS TERRIER. Can. J. Chem. **64**, 1273 (1986).

Faisant appel à une méthode par flux stoppé et opérant dans des solutions aqueuses à 10, 50 et 90% (v/v) de DMSO, on a mesuré les constantes de vitesse pour la déprotonation réversible du cyano-9 fluorène par des amines primaires. En se basant sur des courbes de Brønsted, on a pu évaluer les constantes de vitesse intrinsèque qui sont définies par l'équation $k_0 = k_1^B/q = k_{-1}^{BH+}/p$ lorsque $\Delta pK + \log(p/q) = 0$. A 10, 50 et 90% de DMSO, les valeurs de $\log k_0$ sont respectivement $3{,}60 \pm 0{,}15$, $3{,}81 \pm 0{,}10$ et $3{,}61 \pm 0{,}05$. La relative constance de k_0 avec une augmentation de la concentration en DMSO est en opposition avec les résultats obtenus par Ritchie (C. D. Ritchie, J. Am. Chem. Soc. **91**, 6749 (1969)) qui a trouvé que le k_0, dans le DMSO, de l'ionisation du carbométhoxy-9 fluorène en ions carboxylates est beaucoup plus élevé que pour l'ionisation du même acide carboné sous l'influence de l'ion méthylate dans le méthanol. Nos observations suggèrent que les résultats de Ritchie sont principalement expliqués par une désolvatation précoce des oxyanions dans le solvant hydroxylique.

[Traduit par la revue]

The study of solvent effects on the rates of proton transfer between aromatic hydrocarbons and oxyanions has led to some unorthodox notions about the role played by the solvent in these reactions. In 1968 and 1969 Ritchie (1, 2) reported that, for a given ΔpK, the rates in Me_2SO were substantially higher than in methanol. If one defines k at $\Delta pK = 0$ as the *intrinsic* rate constant, k_0, it appeared that in Me_2SO k_0 was approximately 10^2 fold higher than in methanol, based on the deprotonation of 9-carbomethoxyfluorene for which the most accurate data were available (2).

Ritchie (1, 2) interpreted these results in terms of a rate retarding effect of solvent reorientation in methanol. The basic idea was that the amount of energy required to reorganize methanol (or hydroxylic solvents in general) around reactants and products, as they interconvert, is greater than in Me_2SO, because of the presence of strong oriented hydrogen bonds.

The notion that solvent reorganization or reorientation may affect intrinsic rates in the manner envisioned by Ritchie is an intriguing one.[2] Similar ideas had been expressed earlier by Caldin (4) and by Ogg and Polanyi (5). In the intervening years since Ritchie's proposal, a number of workers have reported results that confirm the importance of solvent reorganization effects (6–17). Many of these studies have shown that at least part of the rate retarding effects of solvent reorientation can be understood as a consequence of early desolvation of reactant ions and/or late solvation of product ions. For example, in reactions of oxyanions acting as bases or nucleophiles, strongly basic ions show marked negative deviations from Brønsted plots. These deviations, which are tantamount to a lowering of k_0, have been attributed to the strong solvation of these ions, coupled with the requirement that their desolvation is ahead of bond formation in the transition state[3] (11, 12, 16, 17). In reactions that lead to resonance stabilized carbanions, with the negative charge localized on oxygen as in nitronate (14, 15) and enolate ions (16, 17), the late development of the solvation of the negative charge, for which there is independent evidence (10, 13, 15), leads to a lowering of k_0 (10, 13–17).[3]

The ionization of 9-substituted fluorenes provides a particularly nice system in which to demonstrate the effect on k_0 of early desolvation of the oxyanion. This is because, in contrast to nitronate and enolate ions, the negative charge in the carbanion is highly dispersed and thus is only subject to small solvation effects of its own. In other words, most of the observed solvent effect on k_0 should come from the early desolvation of the oxyanion. We have tested this idea by studying the solvent effect on the ionization of 9-cyanofluorene by primary aliphatic amines, a series of bases that are much less strongly solvated than oxyanions.

Our results in 10%, 50%, and 90% aqueous Me_2SO (v/v), obtained by the stopped-flow method, are summarized in Table 1. In 10% Me_2SO only two amines were amenable to study, because the rates with the other amines were too fast for the

[1]On leave from Département de Chimie, Faculté des Sciences de Rouen, 76130 Mont Saint Aignan, France.

[2]There is a distinct analogy between this proposal and current notions about how outer sphere electron transfer reactions occur (3).

[3]This lowering of k_0 is the consequence of a general principle that we have called the Principle of Imperfect Synchronization (13).

[a](v/v).

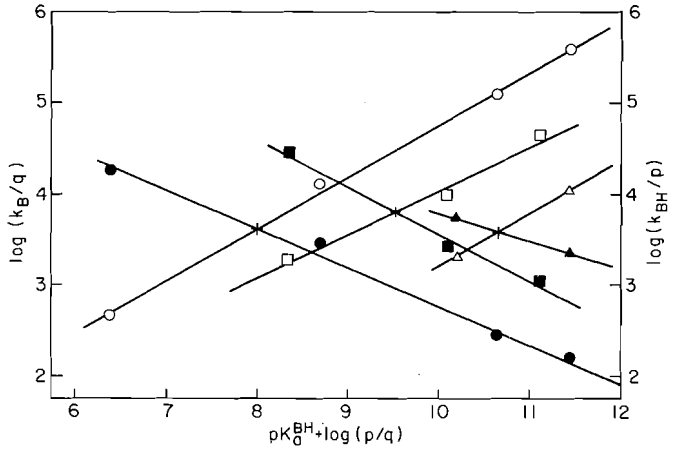

FIG. 1. Brønsted plots for the ionization of 9-cyanofluorene by amines in aqueous Me_2SO at 20°C. Open symbols: k_B; filled symbols: k_{BH}. Circles: 90% Me_2SO; squares: 50% Me_2SO; triangles: 10% Me_2SO. log k_0 is obtained where log (k_B/q) = log (k_{BH}/p) indicated by crosses.

stopped-flow technique; the same is true for oxyanions in all solvents.[4]

Figure 1 shows the Brønsted plots from which the following log k_0 values[5] were obtained: 3.60 ± 0.15 in 10% Me_2SO, 3.81 ± 0.10 in 50% Me_2SO, 3.61 ± 0.05 in 90% Me_2SO. It is quite apparent that, within experimental error, k_0 is solvent independent. These results contrast with Ritchie's finding of an approximately 100-fold increase in k_0 upon transferring the reaction of 9-carbomethoxyfluorene with oxyanions from methanol to Me_2SO. This difference between amine and oxyanion reactions is reminiscent of recent results with 1,3-indandione (17) and acetylacetone (16): log k_0 for the deprotonation of the former by carboxylate ions increases from 2.64 in 10% aqueous Me_2SO to 4.53 in 90% Me_2SO, while for the deprotonation by primary aliphatic amines the increase is only from 2.27 to 2.97; similar results were obtained for acetylacetone. Note that in these examples there is still some increase in k_0 for the amine reactions because of the effect of late solvation of the enolate ions.

It would appear then that the major conclusion to be drawn from the present study is that a large fraction, and perhaps most of the solvent effect observed by Ritchie, is caused by the requirement of early oxyanion desolvation. But closer scrutiny of our results suggests an additional solvent reorientation factor may be present, one that is more in keeping with Ritchie's original formulation[6] and related to what has been called "dynamic solvent effects" (18). The reason why this additional factor does not manifest itself as a modest increase in k_0 for the amine reactions in the Me_2SO-rich solvents, is that it is masked by other effects of nonsynchronous solvation/desolvation that tend to depress k_0 in Me_2SO. One such effect is the solvation of the developing ammonium ion that probably lags behind proton transfer, as has been suggested by Bell (19) and Jencks (20). This should lead to a lowering of k_0 which is expected to be somewhat more pronounced in the Me_2SO-rich solvents, due to the stronger solvation of ammonium ions by Me_2SO than by water (21, 22).[3]

If solvation of the developing carbanion is also retarded in the transition state,[7] this, too, would lower k_0 in both solvents. But because of the somewhat stronger solvation of fluorenyl ions in Me_2SO compared to water or methanol (2), this decrease in k_0 would again be somewhat more pronounced in the Me_2SO-rich mixtures. Finally, early desolvation of the carbon acid could also lower k_0 (17). Work is in progress to develop a more quantitative assessment of all these factors along lines suggested elsewhere (13, 17).

[4]In Me_2SO-rich solvents ionizations of carbon acids by oxyanions are generally substantially faster than ionizations by amines (16, 17).

[5]Since our Brønsted plots are statistically corrected, k_0 is defined as $k_B/q = k_{BH}/p$ at $pK_a^{BH} - pK_a^{CH} + \log(p/q) = 0$.

[6]In the original formulation there was more emphasis on solvent–solvent as contrasted to solvent–solute interactions.

[7]Work by Murdoch *et al.* (9) suggests that this is the case for fluorenyl ions just as for nitronate and enolate ions.

Comprehensive equations for the thermodynamic properties of aqueous NaI, CsF, CsCl, CsI, $NaIO_3$, KIO_3, $CsIO_3$, $KClO_4$, and HCl are generated by combining the heat capacity and density measurements reported by the first author with literature data for the enthalpy and Gibbs energy, or activity, as a function of molality at 298 K. The composition dependence is represented by the equations of Pitzer, which combine a theoretical form and Debye–Hückel terms with empirically evaluated parameters for short-range ion interactions. Temperature dependencies are represented by simple empirical equations, which should be reliable to 413 K or a little higher.

PREET P. S. SALUJA, KENNETH S. PITZER et RAMESH C. PHUTELA. Can. J. Chem. **64**, 1328 (1986).

Si l'on combine les données de capacité calorifique et de densité, qui sont rapportées par le premier auteur, avec les données rapportées dans la littérature pour l'enthalpie et l'énergie de Gibbs, ou l'activité en fonction de la molalité à 298 K, on peut générer des équations étendues pour les propriétés thermodynamiques de solutions aqueuses de NaI, de CsF, de CsCl, de CsI, de $NaIO_3$, de KIO_3, de $CsIO_3$, de $KClO_4$ et de HCl. On peut représenter la dépendance sur la composition par les équations de Pitzer qui combinent une forme théorique et des termes de Debye–Hückel avec des paramètres évalués d'une façon empirique pour les interactions ioniques à courte distance. On représente la dépendance sur la température à l'aide d'équations empiriques simples qui devraient être fiables au moins jusqu'à 413 K.

[Traduit par la revue]

Introduction

Thermodynamic properties of various mixed aqueous electrolytes are of great practical interest in a number of engineering and geological situations. It has been shown (1–4) that a good estimate of the properties of a mixed electrolyte can be obtained from knowledge for each cation–anion interaction present and this is given in turn from the properties of the various pure electrolytes. Small terms for the mixing of ions of the same sign, if available, should be added to obtain more accurate prediction of the properties of mixtures.

Preliminary analysis of the various chemical processes in the vicinity of a deep underground nuclear fuel waste-disposal vault (5) has shown the radiological importance of ^{129}I, ^{135}Cs, ^{99}Tc, and ^{90}Sr. Thus, our current interest lies in understanding the interactions of several singly charged ions, including the fission products I^- (or IO_3^-) and Cs^+ with the major constituents of ground water.

While the thermodynamic properties of aqueous electrolytes have been studied extensively at room temperature and low pressure, only recently have a few electrolytes been investigated at higher temperature and pressure. For the most abundant components of most natural waters, there are comprehensive and accurate data through 473 K or higher temperature for NaCl (6, 7), KCl (8), and Na_2SO_4 (9). For $MgCl_2$ there are excellent isopiestic data (10) and further studies are now in progress. Measurements at Berkeley have been completed and a paper is (33) for $MgSO_4$. Thus, information is now, or soon will be, available for the most abundant ions in ground water, and the present paper presents data for other singly charged ions important for radio-active waste disposal studies. Similar studies for multiple charged ions are in preparation.

In addition to the practical interest in these particular ionic species, it is of interest to compare the thermodynamic properties of various ions from a theoretical viewpoint.

Since the Gibbs energy (and activity) and the enthalpy are known as a function of molality for most aqueous electrolytes at room temperature (298.15 K), it is an efficient procedure to measure the apparent molar heat capacity as a function of temperature, ${}^{\phi}C_p(T, m)$. Then the apparent molar enthalpy ${}^{\phi}L$ is found by integration

$$[1] \quad {}^{\phi}L(T, m) = \int_{298}^{T} [{}^{\phi}C_p(T', m) - {}^{\phi}C_p(T', 0)]\, dT' + {}^{\phi}L(298, m)$$

where 298 is an abbreviation of 298.15 K. The total excess enthalpy $H^{EX} = L = n_2{}^{\phi}L$ with

$$[2] \quad L = H - n_1H_1^0 - n_2\bar{H}_2^0$$

Here n_1 and n_2 are numbers of moles of components 1 and 2 (H_2O and salt, respectively) with standard molar enthalpies H_1^0 for pure water and $\bar{H}_2^0$ for the salt at infinite dilution.

A second integration yields the excess Gibbs energy per mole of solute G^{EX}/n_2.

$$[3] \quad G^{EX}(T, m)/n_2T = -\int_{298}^{T} [{}^{\phi}L(T', m)/(T')^2]\, dT' + G^{EX}(298, m)/298n_2$$

Appropriate derivatives of G^{EX} with respect to m yield the activity and osmotic coefficients. The treatment of aqueous Na_2SO_4 by Rogers and Pitzer (9) is a prototype investigation of this type in which heat capacities were integrated twice to yield Gibbs energy data.

The equations of Pitzer (2, 11) give an accurate and concise representation of the molality dependence, and the ion-interaction parameters for those equations are now available for several electrolytes as a function of temperature (2, 6–10). Furthermore, these equations have proved to be quite accurate in predicting the properties of complex mixed electrolytes (3, 4).

TABLE 1. General definitions[a] and composition-dependent (Pitzer) equations for a 1:1 electrolyte[b]

Gibbs energy functions

[5] $G^{EX} = G - n_1G_1^0 - n_2\tilde{G}_2^0 + 2n_2RT(1 - \ln m)$
$= 2n_2RT(\ln \gamma_\pm + 1 - \phi)$

[6] $1 - \phi = (\partial G^{EX}/\partial n_w)_{T,P,n_2}/RTm$

[7] $\ln \gamma_\pm = (\partial G^{EX}/\partial n_2)_{T,P,n_1}/2RT$

[8] $G^{EX}/n_wRT = -A_\phi(4m/b) \ln (1 + bm^{1/2}) + 2m^2(B_{MX} + mC_{MX})$

[9] $B_{MX} = \beta_{MX}^{(0)} + 2\beta_{MX}^{(1)}g(\alpha m^{1/2})$, $C_{MX} = C_{MX}^{\phi}/2$

[10] $g(x) = [1 - (1 + x) \exp (-x)]/x^2$

[11] $\phi - 1 = -A_\phi m^{1/2}/(1 + bm^{1/2}) + m[\beta_{MX}^{(0)} + \beta_{MX}^{(1)} \exp (-\alpha m^{1/2})] + m^2C_{MX}^{\phi}$

[12] $\ln \gamma_\pm = -A_\phi[(2/b) \ln (1 + bm^{1/2}) + m^{1/2}/(1 + bm^{1/2})]$
$+ m\{2\beta_{MX}^{(0)} + 2\beta_{MX}^{(1)}[1 - (1 + \alpha m^{1/2} - \alpha^2 m/2) \exp (-\alpha m^{1/2})]/\alpha^2 m\} + 3m^2C_{MX}$

Apparent molar enthalpy

[13] ${}^{\phi}L = (A_H/b) \ln (1 + bm^{1/2}) - 2RT^2(mB_{MX}^L + m^2C_{MX}^L)$

[14] $B_{MX}^L = \beta_{MX}^{(0)L} + 2\beta_{MX}^{(1)L}g(\alpha m^{1/2})$

[15] $\beta_{MX}^{(0)L} = (\partial\beta_{MX}^{(0)}/\partial T)_P$, $\beta_{MX}^{(1)L} = (\partial\beta_{MX}^{(1)}/\partial T)_P$
$C_{MX}^L = (\partial C_{MX}/\partial T)_P$

Apparent molar heat capacity

[16] ${}^{\phi}C_p = \tilde{C}_{p,2}^0 + (A_J/b) \ln (1 + bm^{1/2}) - 2RT^2(mB_{MX}^J + m^2C_{MX}^J)$

[17] $B_{MX}^J = \beta_{MX}^{(0)J} + 2\beta_{MX}^{(1)J}g(\alpha m^{1/2})$

[18] $\beta_{MX}^{(0)J} = (\partial\beta_{MX}^{(0)L}/\partial T)_P + (2/T)\beta_{MX}^{(0)L}$
$\beta_{MX}^{(1)J} = (\partial\beta_{MX}^{(1)L}/\partial T)_P + (2/T)\beta_{MX}^{(1)L}$
$C_{MX}^J = (\partial C_{MX}^L/\partial T)_P + (2/T)C_{MX}^L$

Apparent molar volume

[19] ${}^{\phi}V = \tilde{V}_2^0 + (\partial G^{EX}/\partial P)_{T,n_1,n_2}/n_2$

[20] ${}^{\phi}V = \tilde{V}_2^0 + (A_V/b) \ln (1 + bm^{1/2}) + 2RT(mB_{MX}^V + m^2C_{MX}^V)$

[21] $B_{MX}^V = \beta_{MX}^{(0)V} + 2\beta_{MX}^{(1)V}g(\alpha m^{1/2})$

[22] $\beta_{MX}^{(0)V} = (\partial\beta_{MX}^{(0)}/\partial P)_T$, $\beta_{MX}^{(1)V} = (\partial\beta_{MX}^{(1)}/\partial P)_T$
$C_{MX}^V = (\partial C_{MX}/\partial P)_T$

Debye-Hückel slopes

[23] $A_\phi = (2\pi N_0d_1/1000)^{1/2}(e^2/4\pi\epsilon_0DkT)^{3/2}/3$

[24] $A_H = 4RT^2(\partial A_\phi/\partial T)_P$

[25] $A_J = (\partial A_H/\partial T)_P$

[26] $A_V = -4RT(\partial A_\phi/\partial P)_T$

[a]Definitions of symbols: n_w = No. of kg of water ($n_w = n_1/M_1$), $b = 1.2$ kg$^{1/2}$ mol$^{-1/2}$ and $\alpha = 2.0$ kg$^{1/2}$ mol$^{-1/2}$ are parameters which are constant for all 1:1 electrolytes (and more generally), m is molality (which is equal to ionic strength for a 1:1 electrolyte), $\beta_{MX}^{(0)}$, $\beta_{MX}^{(1)}$, C_{MX} are fitting parameters specific to the salt MX, $\tilde{C}_{p,2}^0$ and $\tilde{V}_2^0$ are the apparent or partial molar heat capacity and volume, respectively, of the solute at infinite dilution.
[b]See ref. 7 or 9 for the more general equations for other charge types.

Hence these equations are used for the present research. Table 1 presents the equations in the form simplified for pure 1:1 electrolytes. Equations for mixed electrolytes were derived by Pitzer and Kim (1) and are now available from several sources (2–4).

Somewhat similarly, the apparent molar volume is related to the pressure dependence of the Gibbs energy. Thus

$$[4] \quad G^{EX}(T, P, m)/n_2 = \int_{P_0}^{P} {}^{\phi}V(T, P', m)\, dP' + G^{EX}(T, P_0, m)/n_2$$

In general, the apparent molar volume should be known as a function of pressure, but at moderate pressures it is a satisfactory approximation to neglect the pressure dependency and to measure the volume or density at any convenient and moderate pressure.

Review of available data

Heat capacity data

The development of flow microcalorimeters has made heat capacity measurements easier and more accurate for aqueous solutions at room temperature and more recently at high temperature. For aqueous NaCl and Na_2SO_4 measurements have been reported to 473 K or higher temperature (9, 12, 13). For the electrolytes discussed in this paper, measurements through 373 K are reported in reference 14. In addition there are published data, primarily near room temperature, for several of these systems (15–20). Table 2 gives the references for the literature data actually used in our calculations and the ranges of temperature, pressure, and concentration.

Literature data reported for other pressures, usually 0.1 MPa, were converted to 0.6 MPa for the present calculations by use of the available volumetric data for these systems. The change in heat capacity is very small for this pressure change.

Since the primary purpose of this research concerned proper-

TABLE 2. Literature heat capacity data for aqueous 1:1 electrolytes

Electrolyte	Reference	Temperature range (K)	Pressure (MPa)	Concentration range (Molal)	Standard deviation of fit ($J K^{-1} mol^{-1}$)

[a]Data for temperatures below 298 K were not used in our final calculations.

ties at higher temperatures, we did not burden our calculations with the very large number of room-temperature measurements of varying precision which were available in some cases. One or two of the best sets of measurements sufficed to determine the properties at 298 K.

Of the literature data for temperatures higher than 298 K, only those of Allred and Woolley (16) for HCl were included in the final calculations.

Other sets of measurements (17–19) were considered carefully, but it was concluded that their inclusion with more than negligible weight would only distort the results from the recent measurements (14–16).

After the present calculations were essentially complete, we became aware of the very recent measurements extending to 413 K for HCl by Tremaine *et al.* (21) which have subsequently been published. Since these authors offer an excellent treatment for HCl in terms of the same (Pitzer) equations used here, there seemed to be little reason to repeat our calculations with the addition of their data. As indicated below, there is good agreement between the two investigations.

Volumetric data

In comparison with heat capacity, there are even fewer investigations of the volumetric properties of the systems of present interest at high temperature. Again, we used enough of the best measurements at room temperature to be sure the properties at 298 K were accurately determined without including all data in all cases. In addition to the measurements reported in ref. 14, the data of Allred and Woolley (16) for HCl at several temperatures and of Fortier *et al.* (15) for NaI, CsCl, and HCl at 298 K were included in the present calculations. All these data arise from modern instruments and have comparable precision.

Calculations and results

Heat capacity

Equation [16] (see Table 1) was fitted to the measured values of the apparent molar heat capacity. The Debye–Hückel parameters for various functions, including A_J, were calculated from the equation of Bradley and Pitzer (22) for the dielectric constant of water as a function of T and P and from the equations in Table 1. The other properties of water were taken from the equation of Haar *et al.* (23).

Exploratory calculations were made of the data at a single temperature to assure that the composition dependence was accurately reproduced by eq. [16]. Indeed, it was found that, for the limited range of molality of measurement, the third virial coefficient C^J_{MX} was not needed. Also the precision at very low molality was not high enough to justify inclusion of the term in $\beta^{(1)J}_{MX}$. Thus, equation [16] was reduced in practice to

$$[27]\quad {}^{\phi}C_p = \tilde{C}^0_{p,2} + (A_J/b)\ln(1 + bm^{1/2}) - 2mRT^2\beta^{(0)J}_{MX}$$

Next, the temperature dependence of $\tilde{C}^0_{p,2}$ and $\beta^{(0)J}_{MX}$ were considered. Three-term expressions were found to be adequate:

$$[28]\quad \tilde{C}^0_{p,2}(T) = A^C_c/T + B^C_c + C^C_c T$$

$$[29]\quad \beta^{(0)J}_{MX}(T) = A^C_\beta/T + B^C_\beta + C^C_\beta T$$

The entire array of data at all temperatures was then fitted in a single least-squares calculation adjusting the six parameters in eqs. [28] and [29].

Initially, all data were given equal weight. With the guidance of the calculations at a single temperature, it was then decided whether certain literature data were accurate enough to be retained. Also, a very few individual values were sufficiently deviant as to suggest error, and these were assigned greatly reduced weights. While the precision of apparent molar quantities decreases at low molality, we did not generally reduce weight with molality because we wanted to maintain as high accuracy as possible for the limiting $\tilde{C}^0_{p,2}$. Also, we found that the resulting function usually agreed very well with the measurements at high molality, even with full weight for the low-molality data. The exception was $CsIO_3$, where the data at very low molalities showed substantial deviations. In this case the weight was greatly reduced for all measurements below 0.016 mol kg^{-1}. The resulting equation for $CsIO_3$ then fitted quite accurately all of the measurements above 0.016 mol kg^{-1}.

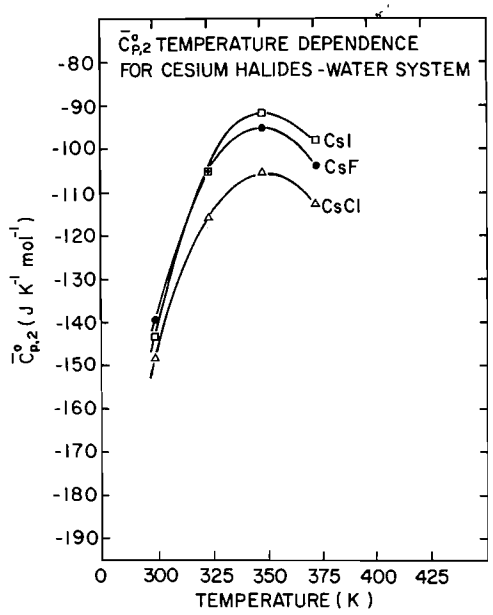

FIG. 1. Temperature dependence of the partial molar heat capacities, $\bar{C}^0_{p,2}(T)$, of cesium halides in water at 0.6 MPa. ●, △, and □ are isothermal $\bar{C}^0_{p,2}$ values from present work.

TABLE 3. Coefficients for eq. [28] for the partial molar heat capacity function, $\bar{C}^0_{p,2}(T)$, at 0.6 MPa

System	$A^C_c \times 10^{-5}$ / J mol^{-1}	$B^C_c \times 10^{-3}$ / J mol^{-1} K^{-1}	C^C_c / J mol^{-1} K^{-2}
NaI–H_2O	−6.3812	3.71181	−5.5301
CsF–H_2O	−6.4956	3.63455	−5.3536
CsCl–H_2O	−6.0076	3.33271	−4.9190
CsI–H_2O	−6.8489	3.80083	−5.5296
$NaIO_3$–H_2O	−10.1759	5.83106	−8.2159
KIO_3–H_2O	−10.3330	5.89793	−8.3571
$CsIO_3$–H_2O	−11.4674	6.43049	−9.0063
$KClO_4$–H_2O	−6.4708	3.81151	−5.5555
HCl–H_2O	−2.8802	1.61240	−2.5884

Figure 1 shows the resulting curves for $\bar{C}^0_{p,2}$ for the cesium halides as typical examples of the results. The points on Fig. 1 are the values arising from separate fits of the data at each temperature. It is evident that the three terms of eq. [28] are adequate to express the temperature dependence of $\bar{C}^0_{p,2}$.

The resulting values for these parameters for each system are given in Table 3 for the $\bar{C}^0_{p,2}$ function and in Table 4 for the $\beta^{(0)V}_{MX}$ function. The standard deviation of fit in each case is given in Table 2.

Although there are measurements for HCl below 298 K, these were not included in our calculations. The rapid change in heat capacity near 273 K is well-known. It did not seem worthwhile to complicate the present equations in order to represent exactly this effect below 298 K. Thus the present equations for HCl and for all of the various salts apply with full accuracy only from 298 to 373 K. As indicated below, the integrated functions of enthalpy and Gibbs energy will be quite accurate over an extended range.

Volumetric properties

The treatment of the data for the apparent molar volume was similar in every respect to that for the heat capacity. The terms in C^V_{MX} and $\beta^{(1)V}_{MX}$ in eqs. [20] and [21] were not needed. The

System	$A^V_v \times 10^{-4}$ / cm^3 K mol^{-1}	$B^V_v \times 10^{-2}$ / cm^3 mol^{-1}	$C^V_v \times 10$ / cm^3 mol^{-1} K^{-1}
NaI–H_2O	−4.4628	2.9548	−3.718
CsF–H_2O	−3.3511	2.2740	−3.184
CsCl–H_2O	−2.8035	2.0855	−2.525
CsI–H_2O	−2.8844	2.1904	−2.179
$NaIO_3$–H_2O	−4.7505	2.8997	−3.532
KIO_3–H_2O	−5.2419	3.2927	−3.982
$CsIO_3$–H_2O	−4.0960	2.6899	−2.852
$KClO_4$–H_2O	−3.6628	2.4669	−2.375
HCl–H_2O	−3.7806	2.6361	−3.992

temperature dependencies of $\bar{V}^0_2$ and $\beta^{(0)V}_{MX}$ were represented by the following three-term expressions:

$$[30]\quad \bar{V}^0_2(T) = A^V_v/T + B^V_v + C^V_v T$$

$$[31]\quad \beta^{(0)V}_{MX}(T) = A^V_\beta/T + B^V_\beta + C^V_\beta T$$

The resulting values of the parameters for each system are given in Table 5 for $\bar{V}^0_2$ and in Table 6 for $\beta^{(0)V}_{MX}$. For the four cesium salts, the C^V_β term was not needed, while for $NaIO_3$ and $KClO_4$ only one term was required for $\beta^{(0)V}_{MX}$. The standard deviations of fit for the apparent molar volume range from 0.06 to 0.38 cm^3 mol^{-1}. The highest value, 0.38, is for CsF. In this case there is a systematic deviation at all temperatures between the measurements for 0.658 and those for 1.06 mol kg^{-1}. The inclusion of the third virial coefficient term in C^V_{MX} would substantially reduce this deviation, but we are reluctant to introduce this term for data extending only to 1.06 mol kg^{-1} and for just the one salt. For most of the other salts, the standard deviation is 0.2 cm^3 mol^{-1} or less.

Pressure dependence of thermodynamic properties

From the volumetric results one has a measure of the pressure dependency of various thermodynamic properties through the relationships:

$$[32]\quad (\partial G/\partial P)_T = V$$

$$[33]\quad (\partial H/\partial P)_T = V - T(\partial V/\partial T)_P$$

$$[34]\quad (\partial C_p/\partial P)_T = -T(\partial^2 V/\partial T^2)_P$$

$$[35]\quad (\partial \beta^{(0)V}_{MX}/\partial P)_T = (\partial^2 \beta^{(0)V}_{MX}/\partial T^2)_P + (2/T)(\partial \beta^{(0)V}_{MX}/\partial T)_P = 2C^V_\beta/T$$

Equation [34] may be used to obtain the effect of pressure on the standard-state heat capacity at infinite dilution $\partial\bar{C}_{p,2}^0/\partial P$. The results, which are given in Table 7, are subject to considerable uncertainty since they arise from the second temperature derivative of $\bar{V}_2^0$ as expressed by eq. [30]. It is clear that pressures of several MPa (or several tens of bar) will have a significant effect on heat capacity, but that a few tenths of MPa will have only a very small effect. At very high pressures, the pressure coefficient will decrease significantly and the present treatment is no longer adequate.

Enthalpy and Gibbs energy

The enthalpy is obtained by integration of the heat capacity, eq. [1]. In terms of the ion-interaction parameters, one has

$$[36]\quad T^2\beta_{MX}^{(0)L}(T) = \int_{298}^{T} (T')^2\beta_{MX}^{(0)L}dT' + 298^2\beta_{MX}^{(0)L}(298)$$

where the last term is the value of the enthalpy parameter at 298.15 K. The pressure dependency may also be introduced by the relationship

$$[37]\quad \beta_{MX}^{(0)L}(P) = \int_{P_0}^{P} (\partial\beta_{MX}^{(0)V}/\partial T)_P dP' + \beta_{MX}^{(0)L}(P_0)$$

where P_0 is the pressure at which $\beta_{MX}^{(0)L}$ is known. Similar equations apply for $\beta_{MX}^{(1)L}$ and C_{MX}^L, but we have found those terms unnecessary for the heat capacity or the volume. If we substitute eqs. [29] and [31] and integrate, we obtain

$$[38]\quad \beta_{MX}^{(0)L} = [(T^2 - 298^2)A_\beta^C/2 + (T^3 - 298^3)B_\beta^C/3 + (T^4 - 298^4)C_\beta^C/4 + 298^2\beta_{MX}^{(0)L}(298, P_0) - A_\beta^V(P - P_0)]/T^2 + C_\beta^V(P - P_0)$$

A second integration yields the excess Gibbs energy as given in eq. [3]. Again, for the ion-interaction parameter, this yields

$$[39]\quad \beta_{MX}^{(0)}(T) = \int_{298}^{T} \beta_{MX}^{(0)L}dT' + \beta_{MX}^{(0)}(298)$$

and for the particular temperature dependency of eqs. [29] and [38]

$$[40]\quad \beta_{MX}^{(0)} = A_\beta^C(T/2 + 298^2/2T - 298) + B_\beta^C(T^2/6 + 298^3/3T - 298^2/2) + C_\beta^C(T^3/12 + 298^4/4T - 298^3/3) + [A_\beta^V/T + B_\beta^V + C_\beta^V T](P - P_0) + (298 - 298^2/T)\beta_{MX}^{(0)L}(298, P_0) + \beta_{MX}^{(0)}(298, P_0)$$

Strictly, the pressure for the heat capacity equation should be the same as that for the integration constants $\beta_{MX}^{(0)L}(298, P_0)$ and $\beta_{MX}^{(0)}(298, P_0)$. The effect of pressure differences of a fraction of one MPa, however, will be negligible. Hence, values for one bar or another low pressure can be used without significant error. Again, for $\beta_{MX}^{(1)}$ and C_{MX}, only the last two terms remain, i.e., $\beta_{MX}^{(1)}(298)$ and $(298 - 298^2/T)\,\beta_{MX}^{(1)L}(298)$, and similarly for C_{MX}.

The integrations of $\bar{C}_{p,2}^0$ to yield the enthalpy and Gibbs energy as a function of temperature and pressure for the salt in its standard state are similar and yield

$$[41]\quad \bar{H}_2^0(T, P) = A_c^C \ln(T/298) + B_c^C(T - 298) + (C_c^C/2)(T^2 - 298^2) + (P - P_0)[-A_v^V/T^2 + C_v^V] + \bar{H}_2^0(298, P_0)$$

$$[42]\quad \bar{G}_2^0(T, P)/T = A_c^C\left[\frac{\ln T}{T} + \frac{1}{T} - \frac{1}{298} - \frac{\ln 298}{T}\right] + B_c^C\left[1 - \frac{298}{T} - \ln\left(\frac{T}{298}\right)\right] + \frac{C_c^C}{2}\left[596 - T - \frac{298^2}{T}\right] + (P - P_0)\left[\frac{A_v^V}{T^2} + \frac{B_v^V}{T} + C_v^V\right] + \bar{H}_2^0(298, P_0)\left[\frac{1}{T} - \frac{1}{298}\right] + \bar{G}_2^0(298, P_0)/298$$

where again the P_0 of the integration constants and that of the heat capacity and volume measurements should be the same. But again the effects of small differences will be negligible.

Table 8 gives the enthalpy and Gibbs energy parameters at 298 K, which are needed as integration constants in eqs. [36] and [38]. All values for $\beta^{(0)}_{MX}$, $\beta^{(1)}_{MX}$, and C_{MX} were obtained from Pitzer and Mayorga (24). The enthalpy parameters for CsF, CsI, and HCl were taken from Silvester and Pitzer (25) while the remaining enthalpy parameters were obtained in the present work – NaI, CsCl, and $NaIO_3$ from the NBS tables (26); $KClO_4$ from the NBS report (27); and KIO_3 from the recent work of Vanderzee *et al.* (28). Unfortunately, there appear to be no measurements from which the Gibbs-energy parameters can be calculated for $NaIO_3$, KIO_3, or $KClO_4$. For $CsIO_3$ neither type of parameter is available. Appropriate heat-of-dilution and activity or osmotic measurements should be made to provide this information.

Except for the cases with missing values for the integration constants, the tables of this paper provide comprehensive equations for the various thermodynamic properties over the temperature range 298–373 K and for pressure variation in the low-pressure range where such effects are linear.

Since this treatment gives the second temperature derivative up to 373 K, one expects the equations to extrapolate upward in temperature with considerable accuracy for the enthalpy and especially for the Gibbs energy. This accuracy of extrapolation was demonstrated for the activity coefficients of Na_2SO_4 by comparison with the solid solubility (29). Tremaine *et al.* (21) discuss this type of extrapolation for HCl.

Single ion and standard state properties

Since the standard state properties at infinite dilution must be additive for the ions present, it is convenient to assign the value zero to the H^+ ion and give relative values for the other ions. For $\tilde{C}^0_{p,2}$ and $\tilde{V}^0_2$ at 298 K, this has been done recently by Desnoyers *et al.* (30) and by Millero (31), respectively. Roux *et al.* (32) added values for several additional ions. Table 9 compares our results with the values calculated from these tables of individual ion values (30–32).

Since the literature values are for a pressure of 0.1 MPa whereas ours are for 0.6 MPa, exact agreement is not expected, but the difference from this source is very small. The agreement in Table 9 is excellent for the volumes and as good as reasonably expected for the heat capacities. Thus the published values of single ion properties at 298 K are confirmed by the present research.

At higher temperatures, our results can be compared with those of Holmes and Mesmer (8) for CsCl and those of Tremaine *et al.* (21) for HCl. For CsCl, Holmes and Mesmer (8) carried out a comprehensive treatment of various types of thermodynamic data, including the high-temperature heat capacity measurements of Rüterjans *et al.* (17). Their values of $\tilde{C}^0_{p,2}$ at 298 and 373 K are −145 and −114 J K^{-1} mol^{-1}, respectively, compared to our values of −149 and −113. Thus, the agreement is essentially perfect at 373 K and quite good at 298 K where one also has the value −150 from Desnoyers *et al.* (30). For HCl, Tremaine *et al.* (21) report -118.7 ± 3.3 from a series of measurements at 349.43 K and −114.5 J K^{-1} mol^{-1} from their general equation fitted over their range of temperature. The

value from our equation at that temperature is $-116.3\ J\ K^{-1}\ mol^{-1}$, in excellent agreement. Even at 412.61 K our extrapolated value of −154 agrees reasonably well with Tremaine's results of -149.2 ± 0.8 and $-150.4\ J\ K^{-1}\ mol^{-1}$.

Discussion

While the primary value of these results will lie in their use in various applications, it is of interest to consider briefly the pattern of behavior displayed. The three curves on Fig. 1 for $\tilde{C}^0_{p,2}$ for the cesium halides are typical of all of the systems studied in that they show maxima near 353 K. Indeed, the standard state volumes $\tilde{V}^0_2$ also show similar curves with maxima. Clearly, this similarity of behavior must arise from the properties of ions in water without regard to the details of the ionic structure. It is the effect of the ionic charge on the water structure that yields this similarity.

Table 10 lists the temperatures for these maxima and the maximum values of $\tilde{C}^0_{p,2}$ and $\tilde{V}^0_2$ for each of the solutes measured. The temperatures for the maxima for HCl are somewhat lower than those for the various salts where there appears to be a slight upward trend with ion size. But there is considerable uncertainty in these temperatures and the differences are rather small, hence one should be cautious in more detailed interpretation. The relative values of the volumes and heat capacities at their maxima follow essentially the same pattern as that for values at 298 K. The 298 K values have been available for some time, although we are not aware of any very detailed theory that yields good agreement. The Born theory for an ion in a dielectric gives the sign and magnitude of the effects correctly. While the aqueous standard-state volumes generally increase with the intrinsic ion size, the behavior of the heat capacities is more compex. The large decrease of about $45\ J\ K^{-1}\ mol^{-1}$ from Na^+ to Cs^+ is striking as is the large negative value for any halide. The complex anions have internal heat capacity which probably accounts for the positive values for salts containing these ions. More detailed discussion of these aspects is beyond the scope of this paper.

Sulphite-promoted delignification of wood: identification of paucidisperse lignosulphonates

ALEC M. BIALSKI, CORINNE E. LUTHE, JENNY L. FONG, and NORMAN G. LEWIS. Can. J. Chem. **64**, 1336 (1986).

Paucidisperse lignosulphonates, previously described as a distinct group of compounds called "hemilignins" ($\bar{M}_w \sim 2\,000$), were conclusively shown to be a complex mixture of monomeric (C_9) sulphonic acids. Since these compounds are rapidly solubilized only during the early stages of delignification from softwoods (≤30% lignin removal), it can be concluded that they are selectively removed from the secondary wall and not from the middle lamella. This result gives chemical support to the hypothesis that morphological differences in lignin structure exist. It is proposed that the generation of monolignols and their sulphonated derivatives may occur via an α-O-aryl bond cleavage rather than β-O-aryl cleavage as previously suggested. For softwoods, several other major constituents were isolated, which may be derived from sulphonation of a β-hydroxylated form of coniferyl alcohol.

ALEC M. BIALSKI, CORINNE E. LUTHE, JENNY L. FONG et NORMAN G. LEWIS. Can. J. Chem. **64**, 1336 (1986).

Les lignosulfonates, mélange de macromolécules monodispersées, ont été préalablement décrit. Ils sont formés de groupes de composés séparables appelés "hémilignines" ($\bar{M}_w \sim 2\,000$); on démontre sans ambiguïté qu'il s'agit d'un mélange complexe d'unités (C_9) d'acides sulphoniques monomères. Puisque ces composés ne se solubilisent rapidement que lors des premières étapes de la delignification du conifère (au plus 30% de la lignine est eliminée), on en conclut qu'ils sont selectivement éliminés de la paroi secondaire et non de la lamelle centrale. Ce résultat fournit un support chimique à l'hypothèse selon laquelle des différences morphologiques existent au sein de la structure de la lignine. Le méchanisme suivant a été proposé: la génération des monolignols et de leur derivés sulfonés serait préférentielle lors de la coupure de la liaison α-O-aryl et non lors de la coupure de la liaison β-O-aryl comme ce fut préalablement suggéré. Chez les conifères, plusieurs autres constituents ont été isolés, ce qui pourrait provenir de la sulfonation de l'alcool conifèrylique hydroxylé en β.

Introduction

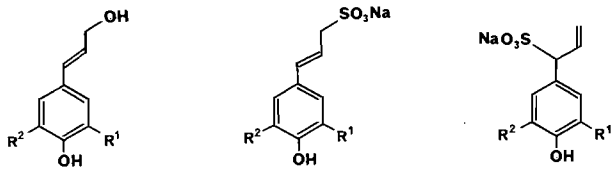
The structure and biosynthesis of the terrestrial plant polymer, lignin, is not well understood because of its molecular complexity and intractable nature. The most widely held view of lignin, as it exists in nature, is that of a random, three-dimensional, infinite polymeric network (1–7) derived from the three basic monomeric building blocks, *p*-coumaryl alcohol **1**, coniferyl alcohol **2**, and sinapyl alcohol **3**.

This concept has been directly challenged by the reported finding that sulphonated lignin from softwoods is composed (~80%) mainly of an homologous series of lignin sulphonates having *identical* repeating units, with the remainder (~20%) being described as a distinct group of compounds, called "hemilignins," of weight-average molecular weight $\bar{M}_w \sim 2\,000$ (8).

Clearly, these two postulates, i.e., random versus regular structure, are incompatible.

In our recent studies (9), we reported that during the sulphite-promoted delignification of the softwood, black spruce (*Picea mariana*), two broad classes of sulphonated lignins appeared to be formed: Type I (paucidisperse) and Type II (widely polydisperse). Lignin heterogeneity has also been reported for the acidolysis products from poplar (*Populus euramericana*) obtained under lengthy isolation conditions (10).

We now wish to extend our observations regarding Type I lignosulphonates and "hemilignins" in terms of their chemical structures, point of formation, and anatomical origin.



1, $R^1, R^2 = H$ **4**, $R^1, R^2 = H$ **7**, $R^1, R^2 = H$
2, $R^1 = OCH_3, R^2 = H$ **5**, $R^1 = OCH_3, R^2 = H$ **8**, $R^1 = OCH_3, R^2 = H$
3, $R^1, R^2 = OCH_3$ **6**, $R^1, R^2 = OCH_3$ **9**, $R^1, R^2 = OCH_3$

Results

The hplc (high performance liquid chromatographic) separation of paucidisperse lignin sulphonates for both the softwood, black spruce (*Picea mariana*), and the hardwood, poplar (*Populus tremuloides*), can be seen in Figs. 1A and 1B. These samples were produced by mild sulphonation of each species under conditions which effect ~30% and 45% delignification, respectively. Following isolation by chromatography, it was established that H, I, and J (see Fig. 1A) from black spruce corresponded to the sulphonates **8**, **4**, and **5**, respectively. The structural elements of these monomers contribute to about 4–5% of the total lignin in wood. Structural confirmation of **5** and **8** was achieved by total synthesis from eugenol **10** (Scheme 1), via a combination and modification of previously reported routes (11, 12). For the hardwood lignin sulphonates, compo-

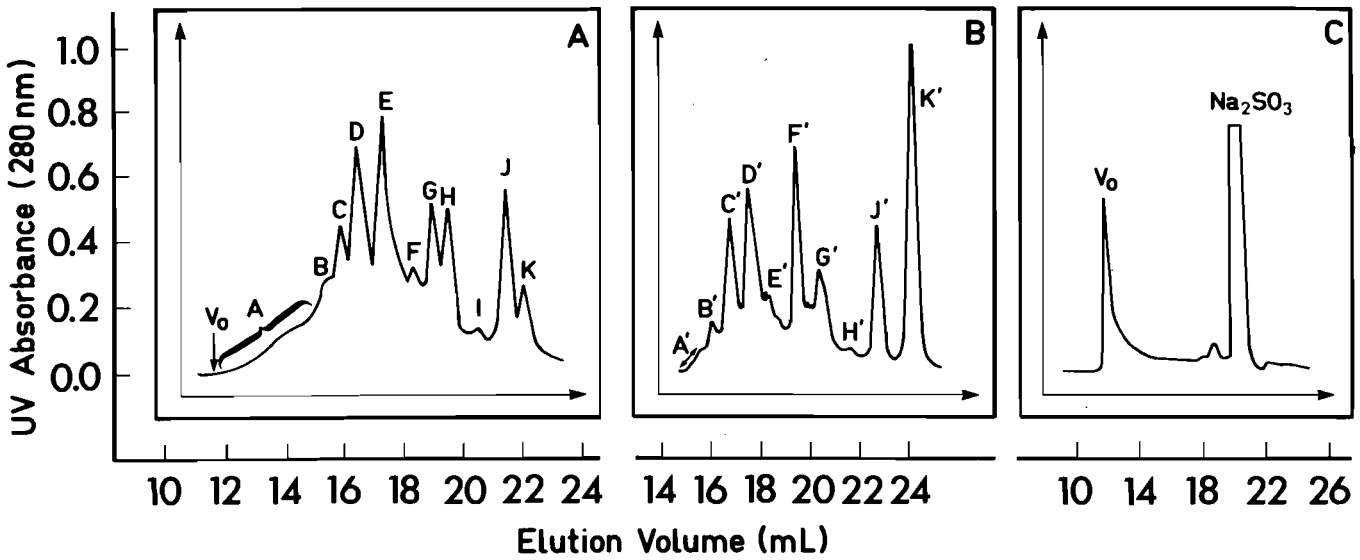

FIG. 1. Chromatograms of dissolved uv-absorbing paucidisperse lignosulphonates from (A) black spruce (*Picea mariana*) and (B) poplar (*Populus tremuloides*). Fig. 1C is an hplc trace of spruce polydisperse lignosulphonates produced during continuous flow experiments (see experimental section). Elution details: Waters I-125 and I-60 protein columns in series eluted with 50 m*M* citric acid/Na_2HPO_4 buffer, pH 3.0. Flow = 1 mL/min, V_0 = void volume. (Note: retention times in Fig. 1B are slightly longer due to the use of a guard column.)

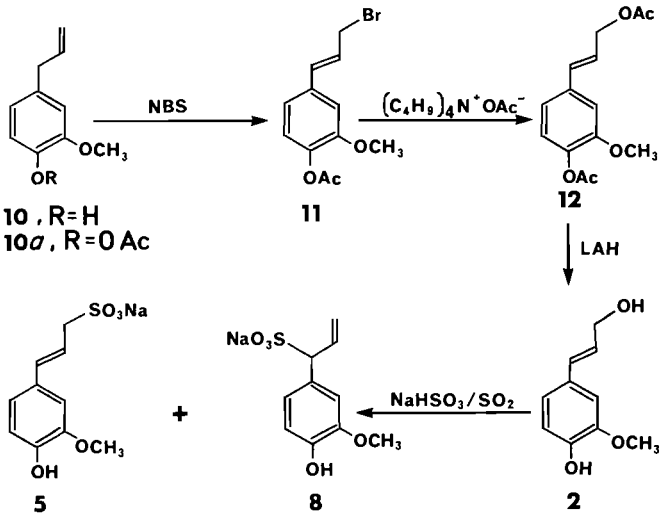

SCHEME 1. Synthesis of sulphonates **5** and **8** from eugenol **10**.

nents G′, H′, and J′ (Fig. 1B) were also shown to be the sulphonates **8**, **4**, and **5**. In addition, the corresponding sinapate sulphonates **6** and **9** were also isolated (same peak *K*′) reflecting the known differences in hardwood lignin composition (13). Structural proof was achieved by comparison with synthetic material produced from *E*-sinapic acid **13** (Scheme 2).

It was of interest to establish whether these monomers were produced continuously or only at specific stages of delignification. To resolve this particular point, black spruce wood was delignified at pH 3.0 in a "continuous-flow" reactor (14) scaled down for micropulping experiments (15). In this experiment, any soluble sulphonated lignin is removed almost immediately, thus reducing the possibility of further degradation/condensation reactions. These soluble materials were then collected at various time intervals and analysed following separation on high performance liquid chromatographic columns (9), previously calibrated with lignosulphonates of known $\bar{M}_w$ (16). Using this approach, it could be concluded that essentially only Type I (paucidisperse) lignin sulphonates, with a $\bar{M}_w \leq 3\,300$, were solubilized during the early stages of delignification (<30–40% lignin removal) (cf. Fig. 1A). Beyond this point only widely polydisperse (Type II) lignin sulphonates ($\bar{M}_w > 3\,300$) of increasing $\bar{M}_w$ (Fig. 1C) were removed, i.e., the monomeric moieties **4**, **5**, and **8** were produced just during the release of the paucidisperse lignin sulphonates. Similar findings were also noted at pH 2, 5, and 7, the only observable difference being the rate at which delignification took place. These findings were also true for hardwoods, i.e., monomers were removed only during the initial stages of delignification.

One severe drawback to the handling of paucidisperse lignosulphonates is that all manipulations are performed in aqueous media. We have therefore developed methodology for their derivatization into organic soluble compounds. To date, the most frequently used method was to prepare the corresponding acetyl lignin sulphonic acid methyl esters (17). However, we found this procedure to be cumbersome and consequently developed alternate strategies. Sulphonic acids were thus converted specifically to their methyl or ethyl esters using methyl or ethyl orthoformate, respectively (18), or treated with ethereal diazomethane, thereby alkylating both phenolic and sulphonic acid moieties directly. Surprisingly, diazomethane has been reported to only incompletely methylate lignosulphonates (19). However, no such difficulties were experienced in this study.

Prior to methylation, paucidisperse lignosulphonates from either softwoods (Fig. 1A) or hardwoods (Fig. 1B) were *exhaustively* extracted with *n*-butanol to remove the monomeric sulphonic acids (12, 20). These monomers were converted to their free acid (H) form using Amberlite IR-120 (H) resin and then methylated with ethereal diazomethane. Figure 2A and 2B show the hplc profile of these methylated monomers from both softwoods and hardwoods, respectively. Monomers **16**–**22** were then each isolated following separation on a semi-preparative hplc column and their structures determined using

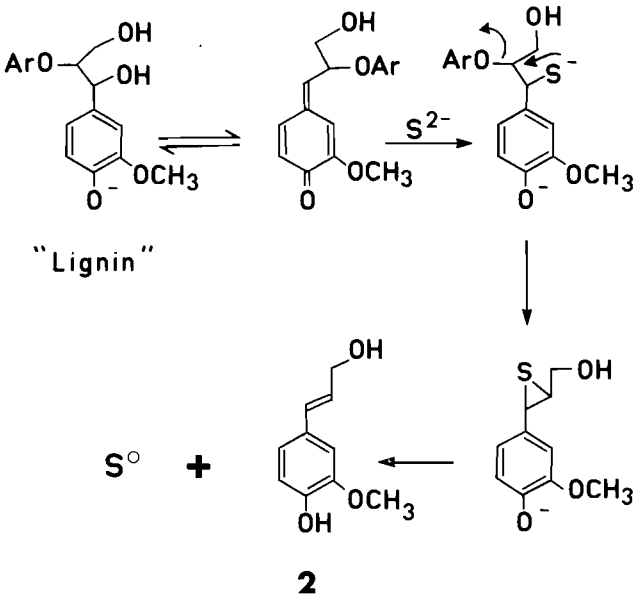

SCHEME 3. Gierer's mechanism for the formation of coniferyl alcohol **2** formed during alkaline (kraft) pulping.

standard spectroscopic techniques (see Experimental). In particular, ^{13}C DEPT analysis (21) of these monomers was most useful.[2] The unambiguous assignment of near or overlapping carbon signals containing different numbers of hydrogen atoms (e.g., CH_2SO_3H vs. OCH_3, etc.) is exactly the type of precise information required for assigning signals in the more complex polydisperse lignosulphonates.

[2]Preliminary findings using DEPT ^{13}C nmr for the analysis of sulphonated lignins were presented at the ACS Chemistry Meeting, Philadelphia, September 1984 (ref. 21*b*).

The remaining paucidisperse lignosulphonates from the spent softwood pulping liquors were further purified by a complexation/decomplexation procedure using dicyclohexylamine as previously described (9). We then converted these substances to their fully methylated derivatives and separated them by hplc (as before). The major components in these mixtures have now been isolated (see Fig. 3) and their structures determined by spectroscopic techniques (see Experimental). It is important to note that all of the substances identified to date in this category are disulphonic acids of lignin-derived monomers (i.e., **23–26**). The other remaining uncharacterized substances are also monomeric in character, having molecular weights <450. Additional work is in progress to establish their structures.

Discussion

It is well known that the monomers (**5**, **6**, **8**, and **9**) are produced in minute quantities during the extensive delignification (~95%) of wood, carried out under strongly acidic sulphonation conditions (12, 20, 22).

There appears to be a striking correlation between their formation and the presence of minute quantities of the monolignols **2** and **3** in soluble lignin fractions obtained by treatment of wood at elevated temperatures with either THF/H_2O (23–25), dioxane/H_2O (24), or sodium sulphide/H_2O solutions (kraft) (26–30). With the exception of kraft lignin, which is removed under strongly alkaline treatment, these preparations are all produced under mildly acidic conditions. A feature common to all, however, is the fact that these monolignols are liberated during the early stages of delignification. This suggests that their genesis might be the consequence of a common bond-breaking process. For kraft lignin, coniferyl alcohol **2** is considered to be formed only via β-O-aryl cleavage as shown in Scheme 3 (31, 32). However, since such cleavages are less likely under sulphonation conditions (32), it seems more

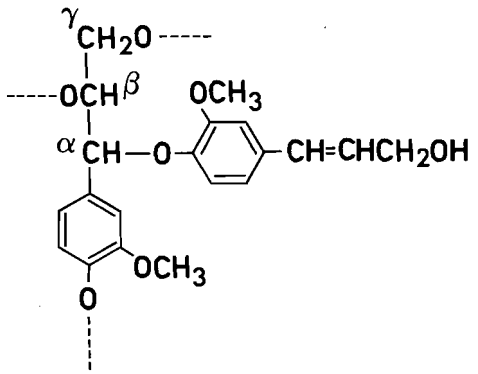

FIG. 4. Possible bonding pattern of coniferyl alcohol **2** to the lignin macromolecule.

reasonable that, during the early stages of delignification, the formation of these monolignols is, instead, a consequence of α-O-aryl bond cleavage (Fig. 4). This interpretation would unify the various experimental observations, and would be consistent with the known lability of α-O-aryl bonds.

It was also interesting to note that the monolignols **1–3** were essentially absent from the side-chain oxygenated monomeric products produced following lengthy acidolysis of poplar (10). This can simply be attributed to the instability of compounds **1–3** under these conditions.

It is now also clear that Forss' "hemilignins" ($\bar{M}_w \sim 2\,000$) are in fact monomeric sulphonic acids of the type **22–26**. The high $\bar{M}_w$ values previously reported for these hemilignins (8, 16) may be due to a limitation of the ultracentrifugation technique used, and (or) simply nonideal chromatographic behaviour of these substances.

From a wood anatomical viewpoint, it is well documented that earlywood tracheids from black spruce contain 72% of the *total lignin* in the secondary wall versus 28% in the compound middle lamella (33). (It should be noted, though, that the *concentration of lignin* is much higher in the middle lamella (~50–85%) than in the secondary wall (22%).)

Of importance, however, was the observation that the rates of acid-sulphite promoted delignification of the secondary wall and middle lamella were different (34); e.g., by 30% total delignification of spruce wood, the total lignin content of the secondary wall was reduced from 72 to 45% whereas the middle lamella was almost the same (from 28 to 25.5%). This clearly suggests that softwood paucidisperse lignosulphonates, including the monomers, are removed from the secondary wall. A similar proposal has been made by Forss for hemilignins ($\bar{M}_w \sim 2\,000$) (8). If this morphological observation is correct, then our results clearly show that secondary wall lignin contains more easily hydrolysable linkages. This further supports the contention that lignin in black spruce is heterogeneous (8, 9). Additional support for this hypothesis can also be found from the results obtained from the alkaline (kraft) pulping of black spruce wood tissue fractions *enriched* in either secondary wall or middle lamella material respectively (29). In that particular study, it was clearly demonstrated that, following correction for lignin contents, 14–16 times more coniferyl alcohol **2** was liberated from the secondary wall tissue than from the middle lamella.

These findings not only support the concept of heterogeneity but again appear to mitigate against coniferyl alcohol **2** formation being simply the consequence of β-O-aryl bond cleavage (31, 32). In addition, these results with isolated tissue fractions are also important in addressing discussions concerning diffusion through the cell wall. For example, it has been argued that the differences in the rate of delignification from the secondary wall and middle lamella may be due to differences in diffusion of the pulping chemicals into, or diffusion of the lignin degradation products out of, the wood cell (35). Such penetration problems are likely to be substantially reduced with isolated tissue fractions.

The steps involved in lignification beyond the monolignols, e.g., coniferyl alcohol **2**, are poorly understood (36). However, speculation as to the nature of the precursors that, after sulphonation, lead to the disulphonic acids **23–26** is important. This is because it may provide some insight into the biosynthetic conversions beyond **2**.

Hibbert originally suggested (37) that the first biosynthetic step beyond coniferyl alcohol **2** occurred via a free radical β-hydroxylation to give ketone **27** (Scheme 4). According to this hypothesis, the genesis of compound **23** could be envisaged via sulphonation, dehydration, and methylation. Hibbert's proposal was, however, subsequently modified (38, 39) to include results from the acidolysis of the lignin model compound, guaiacyl glycerol β-guaiacyl ether. In those experiments, it was demonstrated that phenyl glycerol type compounds could afford a series of keto and hydroxyketo compounds (38, 39). Presumably ketone **27** is formed as an acidolytic intermediate. Thus, by means of this modified route, the precursors of compounds **24–27** could be produced.

There are, however, additional experiments that do not appear to be in agreement with this latter hypothesis: (*i*) the acidolysis pathway is *not* considered to be important under the conditions of sulphonation (31, 32) and (*ii*) sulphite-promoted delignificaton of *borohydride*-reduced wood meal (40, 41) proceeds at a considerably slower rate, suggesting the involvement of ketonic functionalities during delignification.

It is therefore clear that these inconsistencies require further examination in order to fully understand the pathway of sulphite-promoted delignification.

In closing, it should also be mentioned that while the purported existence of an identical repeating unit in the high molecular weight (Type II) polydisperse material (8) is appealing, we have to date found no evidence supporting that statement. This hypothesis will be investigated more deeply.

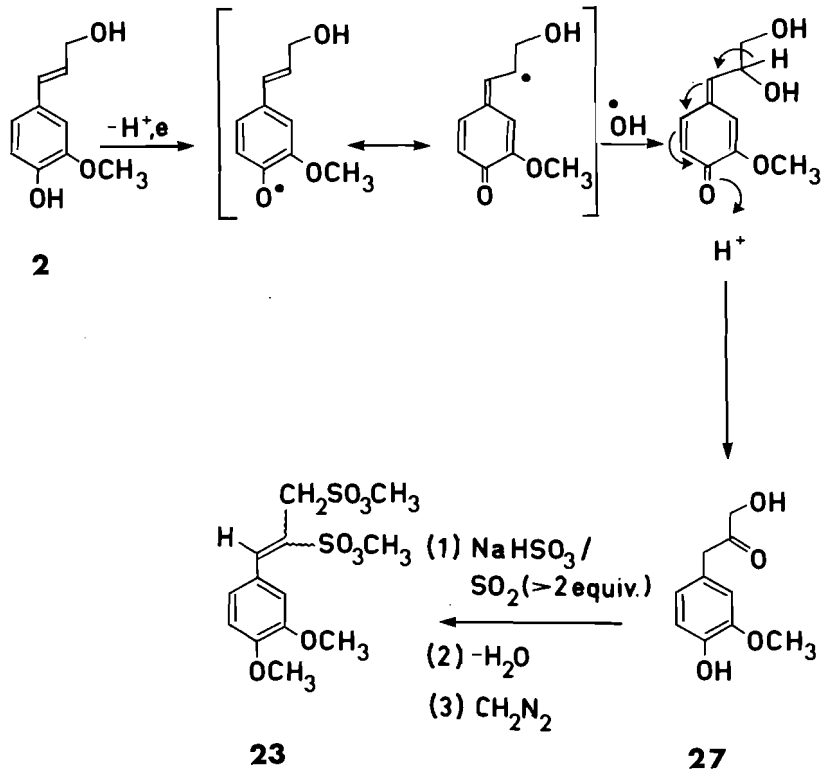
Conclusions

We have investigated the sulphite-promoted delignification of the softwood, black spruce (*Picea mariana*), and the hardwood, poplar (*Populus tremuloides*), and have concluded that:

(*i*) Paucidisperse lignosulphonates (Type I), previously called "hemilignins," are only solubilized during the initial stages of delignification. These materials have been characterized and have been shown to be either monomeric or disulphonic acids of lignin monomers. No oligomeric material with M_w approaching 2 000 has been isolated.

(*ii*) A unified hypothesis for the hydrolytic removal of *p*-hydroxycinnamyl alcohols **1–3** during the initial stages of delignification can now be made. This uses simple α-O-C cleavage (Fig. 4) of the lignin macromolecule and removes the necessity to involve β-O-cleavages (Scheme 3), which are less likely under the conditions employed.

(*iii*) The acidolysis products from poplar (10) bear certain similarities to our findings in the sense that the substances removed are mainly monomeric. One major difference noted,



SCHEME 4. Postulated formation of disulphonic acids from coniferyl alcohol **2**.

however, was the essential absence of the *p*-hydroxycinnamyl alcohols **1**–**3**. These substances are significant delignification products and are stabilized in solution by sulphonation.

(*iv*) Based upon previous studies, it can be concluded that these soluble paucidisperse substances are removed exclusively from the secondary wall and not the middle lamella. It therefore follows that softwood lignin is chemically heterogeneous. This places a substantial constraint on the random, infinite polymeric network theories (1–7).

(*v*) To account for the formation of the disulphonic acids **23**–**26**, it appears that no hypothesis can be presented that is in agreement with all of the experimental observations accumulated to date.

Experimental

The hplc analyses and separations were carried out using a Hewlett–Packard or a Waters liquid chromatograph equipped with a variable wavelength detector set at 280 nm. Columns used were of the protein I-125 and I-60, as well as μ-Porasil types, purchased from Waters Associates. Nuclear magnetic resonance spectra were obtained on Varian XL-200 or XL-300 instruments. Carbon-13 assignments are tentative unless unambiguously determined using ^{13}C-DEPT techniques. Low and high resolution mass spectra were run on Hewlett–Packard 5984 and Dupont 21-492B instruments, respectively. Ultraviolet analyses were carried out using a Unicam SP-800 spectrophotometer. All solvents (and dicyclohexylamine) were distilled prior to use.

trans-*3-(4-Acetoxy-3-methoxyphenyl)-2-propenyl acetate (12)*

Bromide **11** was prepared from **10***a* exactly as described (11) in 65% yield and used without further purification. A solution of crude bromide **11** (57 g, 0.2 mol) and tetra-*n*-butylammonium acetate (72.2 g, 0.24 mol) (42) in chloroform (300 mL) was stirred at reflux temperature for 0.5 h. The chloroform was then removed under reduced pressure and the residual oil extracted (magnetic stirring) with diethyl ether (3 × 500 mL). The combined ether extracts were washed with water (3 × 500 mL), each water wash being reextracted with ether (450 mL). The ether fractions were then dried over magnesium sulphate and evaporated to afford, as an oil, the desired acetate **12** (44.9 g, 85%).

trans-*3-(4-Hydroxy-3-methoxyphenyl)-2-propenol (2)*

Diacetate **12** (26.4 g, 100 mmol) was reduced with lithium aluminium hydride (7.6 g, 200 mmol) exactly as described (11). Immediate flash chromatography (43) of the crude product on silica eluted with EtOAc–hexane (1:1) gave fractions containing pure coniferyl alcohol **2**. Recrystallization from diethyl ether – petroleum ether afforded pure alcohol **2** (11.7 g, 65%), mp 74–75°C (lit. (44) mp 74–76°C).

*Sodium-1-(4-hydroxy-3-methoxyphenyl)-2-propene-1-sulphonate 8 and sodium-*trans*-3-(4-hydroxy-3-methoxyphenyl)-2-propene-1-sulphonate 5*

The sulphonation procedure used was based upon previously reported work (12, 20), and the crude mixture of sulphonates **8** and **5** recovered as described.

Sulphonates **8** and **5** (200 mg) were dissolved in 50 m*M* citric acid/Na_2HPO_4 (4 mL, pH 3.0). This solution was applied to two preparative liquid chromatographic columns (Waters I-125) in series, and then eluted with 50 m*M* citric acid/Na_2HPO_4 buffer solution (pH 3.0) at 50 mL min^{-1}. Fractions containing either pure **5** or **8** were combined, neutralized (1.0 *M* NaOH), and freeze-dried. The resulting material (~3–4 g for each isomer), was then dissolved in water (~52 mL) and subsequently extracted with *n*-butanol (6 × 30 mL). The *n*-butanol extracts for each isomer were combined and azeotroped as before to yield a white amorphous material. Each was then applied to 20 × 20 cm silica plates eluted with *n*-butanol to afford the sulphonates **5** (35 mg, 16.6%) and **8** (27 mg, 12.8%).

3-(4'-Acetoxy-3',5'-dimethyoxyphenyl)-prop-2-enoic acid (14)

Sinapic acid **13** (5 g, 22.32 mmol) was converted to its corresponding acetate **14** as before (5.58 g, 94%), mp 202–203°C.

Ethyl-(4'-acetoxy-3',5'-dimethoxyphenyl)-prop-2-enoate (15)

Acetate **14** (5.498 g, 20.67 mmol) was taken and placed in a 250-mL round-bottomed flask under an atmosphere of nitrogen. Dry thionyl chloride (~55 mL, 0.765 mol) was added and the resulting solution heated until reflux began. This was maintained for 1 h, following which

the solution was cooled (to 20°C) and the excess thionyl chloride removed under reduced pressure. Dry redistilled ethanol (125 mL, 2.14 mol) was added and the solution then allowed to stir at room temperature for 1.25 h, following which the solvent was removed. Recrystallization of the product from CH_3OH–H_2O afforded the required ethyl ester **15** (4.31 g, 71%), mp 120–121°C (lit. (44) mp (120–121°C).

trans-*3-(4'-Hydroxy-3',5'-dimethoxyphenyl)-2-propenol (3) (44)*

Starting from ethyl ester **15** (8 g, 27.2 mmol), sinapyl alcohol (2.95 mg, 51.7%) was prepared exactly as described (44), mp 66–67°C (lit. (44) mp 66–67°C).

*Sodium-*trans*-1-(3,5-dimethoxy-4-hydroxyphenyl)-2-propene-1-sulphonate (6) and sodium-3-(3,5-dimethoxy-4-hydroxyphenyl)-2-propene-1-sulphonate (9)*

Sinapyl alcohol **3** (144 mg, 0.686 mmol) was converted to the corresponding sulphonates **6** and **9** exactly as previously described for coniferyl alcohol **2**. An aliquot (20 mg) of the resulting butanol soluble material (156 mg) was then applied to silica gel plates (20 × 20 cm) and eluted with *n*-butanol to afford **6** (3 mg); ^{1}H nmr (D_2O) δ: 3.57 (2H, d, $J \sim 7$ Hz, CH_2), 3.61 (3H, s, OCH_3), 6.05–6.23 (1H, m, CH=CH_2), 6.43 (1H, $J = 21.6$ Hz, CH=CH—CH_2), 6.64 (2H, s, ArH), and **9** (2 mg); ^{1}H nmr (D_2O) δ: 3.57 (3H, s, OCH_3), 4.51 (1H, d, $J = 9$ Hz, $CHSO_3Na$), 5.18–5.26 (2H, m, CH_2), 6.05–6.23 (1H, m, CH=CH_2), 6.64 (2H, m, ArH).

*Lignosulphonates from black spruce (*Picea mariana*)*

Black spruce chips were delignified as described previously (9). The lignosulphonates so obtained were freeze-dried as described below.

*Lignosulphonates from Poplar (*Populus tremuloides*)*

Poplar chips (5.0 kg dry weight, Klason lignin = 22.1 g/100 g) were steam-pretreated (pressure = 138 kPa, 3 min, 3 cycles) in a 56-L batch digester. The wood was then exposed to a sodium-based bisulphite solution (27.5 L; total SO_2 = 4.99%, free SO_2 = 2.48; pH = 3.91). Pulping conditions were as follows: temperature raised from 20 to 160°C over 120 min and then held for 45 min at 160°C with a maximum pressure of 627 kPa. The resulting pulp (3.85 kg, 77% yield), with a Klason lignin content of 16 g/100 g, was then removed by filtration to recover the crude lignosulphonate solution. The solution was then concentrated to half-volume, neutralized (1 *N* NaOH), and freeze-dried.

General experimental procedure to remove lignin-derived butanol solubles

A solution of crude freeze-dried spent sulphite liquor (50 g/225 mL H_2O) was extracted with *n*-butanol (5 × 200 mL). Following removal of the butanol by azeotroping with water, the organic extracts were freeze-dried. The butanol soluble lignosulphonates were further purified by modification of a complexation/decomplexation procedure with dicyclohexylamine (DCHA), previously described (9). Thus an aqueous solution of butanol solubles (1.5 g/20 mL H_2O) adjusted to pH 2.0 with 18 *M* H_2SO_4 was extracted with CH_2Cl_2–*n*BuOH–DCHA (25:1.3:0.5, 25 mL) and the organic layer separated (Fraction 1); three additional fractions were obtained in an analogous manner. In order to effect decomplexation of the various fractions, water (20 mL) was added and the pH adjusted to 11 with 1 *N* NaOH; the mixture was washed with ether (5 × 100 mL) and the aqueous layer was then freeze-dried after neutralization with Amberlite IR-120 (H^+) resin.

Sulphonates 8 and 5 from black spruce butanol solubles

An aliquot (304 mg) of butanol solubles from black spruce was taken and dissolved in a minimum amount of 50 m*M* citric acid/Na_2HPO_4 buffer at pH = 3.0. Separation and purification as described previously afforded sulphonate **8** (29 mg) and sulphonate **5** (37 mg), identical to synthetic material in all respects.

Sulphonates 5, 6, 8, and 9 from poplar butanol solubles

An aliquot (353 mg) of butanol solubles separated as before from poplar was taken and sulphonates **5** (11 mg), **8** (15 mg), **6** (16 mg), and **9** (14 mg) were isolated as described above.

Note: In all cases, extensive losses were experienced using this procedure. Consequently, methylation was chosen instead.

General experimental procedure for methylating butanol-soluble lignosulphonates

To a suspension of lignosulphonates – sodium sulphate (100 mg) in MeOH (4 mL) was added Amberlite-120 (H^+) resin (2 g, prewashed with MeOH). The lignosulphonates were thus rendered MeOH soluble, and the solution was stirred at room temperature for 10 min. After this time, the resin was filtered off and washed with MeOH (2 × 1 mL); to the combined filtrate and washings was added freshly distilled ethereal diazomethane (25 mL). After 2 h, the excess diazomethane and solvents were removed under reduced pressure. The methylated adducts were redissolved in CH_2Cl_2 and filtered; solvent removal afforded CH_2Cl_2-soluble material in yields ranging from ~50–90%. The major components were separated by hplc, on a Waters μ-Porasil column (7.8 mm × 30 cm) using 60% hexanes:40% (0.90% MeOH/CH_2Cl_2) as eluant.

Methylated butanol-soluble lignosulphonates from black spruce

Characterization data for each compound is given below:

*Methyl-*trans*-3-(4'-methoxyphenyl)-2-propene-1-sulphonate (19)*, uv λ_{max}(MeOH): 267, 215 nm; ^{1}H nmr ($CDCl_3$) δ: 3.77 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 3.94 (2H, dd, $J_{1,2} = 7.5$ Hz, $J_{1,3} = 1.2$ Hz, $CH_2SO_3CH_3$), 6.03 (1H, dt, $J_{1,2} = 7.5$ Hz, $J_{2,3} = 15.7$ Hz, CH=$CHCH_2$), 6.64 (1H, bd, $J_{2,3} = 15.7$ Hz, CH=$CHCH_2$), 6.82–7.36 (4H, bABq, $J = 8.8$ Hz, ArH); ms (*m/e*): 242 (M^+, 13%), 147 ($M^+ - SO_3CH_3$, 100%), 132 ($M^+ - SO_3CH_3$, —CH_3, 6.8%), 91 ($M^+ - CH_2$=CH—$CH_2SO_3CH_3$, —CH_3, 18.9%). *Exact Mass* calcd. for $C_{11}H_{14}SO_4$: 242.0613; found; 242.0611.

General experimental procedure to isolate paucidisperse lignosulphonates

Freeze-dried spent sulphite liquor (20 g) from a high yield bisulphite cook was dissolved in H_2O (100 mL) and washed with *n*-BuOH (5 × 200 mL; 125 mL H_2O added during extraction). The volume of the aqueous layer was then adjusted to 300 mL and its pH adjusted to 6.3 with 18 *M* H_2SO_4. Dicyclohexylamine (20 mL) and CH_2Cl_2–BuOH (5:1; 200 mL) were added, and the resultant mixture was shaken very gently for 5 min. After separation of the organic layer, the aqueous fraction was readjusted to pH 6.3 and an analogous extraction was performed. To the combined organic layers were added H_2O (150 mL) and 1 *N* NaOH (~30 mL; pH of aqueous layer ~11). After vigorous shaking, the aqueous layer was separated, washed with diethyl ether (5 × 100 mL), neutralized with Amberlite-120 (H^+) resin, and freeze-dried. The solid thus obtained was redissolved in H_2O (10 mL), washed with BuOH (7 × 20 mL), neutralized, and freeze-dried to afford ~2.5 g of material.

General experimental procedure for methylating paucidisperse lignosulphonates

This methylation procedure is analogous to that described for the corresponding BuOH-soluble lignosulphonates and afforded CH_2Cl_2-soluble material in ~70% yield. The major components were separated by hplc, on a Waters μ-Porasil column (7.8 mm × 30 cm) using 5% hexanes:95% (0.35% MeOH/CH_2Cl_2) as eluant. The solvent polarity was adjusted slightly from the above value, depending on the age and activity of the silica gel.

Continuous flow micropulping

The apparatus used was based upon a previous report (14) and scaled down for our purposes (15). Black spruce wood (500 mg) was taken and allowed to sit in water under vacuum for 1 h. The resulting material was then packed into a cylindrical stainless-steel tube (80 × 5 mm). A solution of sodium sulphite (250 mL, 13.6 g/L Na_2SO_3, 0.5% Na^+) in nitrogen-sparged water, previously adjusted to pH 3.0 with gaseous sulphur dioxide, was placed in the reservoir. The micropulping apparatus was then flushed with nitrogen gas and assembled. The flow of the pulping solution was adjusted to 1 mL min^{-1} after which the digester and coils were immersed in the heating bath oil at 155°C for 4 h. Fractions (1.5–2 mL) were collected and analysed by hplc. After 4 h, the bomb was removed, cooled, and the resulting pulp washed, filtered, and freeze-dried. Weight of pulp = 222 mg, 44%. (Pulping experiments were also repeated at pH 2, 5, and 7 and with poplar.) Micro-Klason determinations were carried out according to the described method (45).

Received December 19, 1985

G. BOUCHOUX, I. HANNA, R. HOURIET, and E. ROLLI. Can. J. Chem. **64**, 1345 (1986).

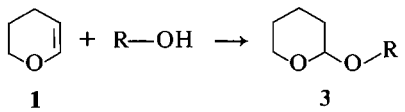
The gas phase basicity (GB) of dihydropyran **1** and dihydro-1,4-dioxin **2** is measured in equilibrium proton transfer reactions conducted in an ion cyclotron resonance spectrometer. GB(**1**) is found to be greater than GB(**2**) by 37 kJ mol^{-1}, this difference parallels the lower reactivity of **2** observed in solution under acidic condition. Conclusion as to the favoured protonation of the C—C double bond, giving rise for both **1** and **2** to oxycarbonium cations, is drawn from comparison with analogous compounds and substantiated by molecular orbital calculations (MNDO) on the protonated structures.

G. BOUCHOUX, I. HANNA, R. HOURIET et E. ROLLI. Can. J. Chem. **64**, 1345 (1986).

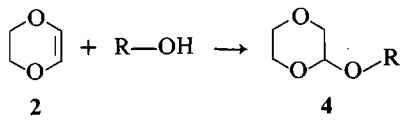
Les basicités gazeuses (BG) du dihydropyrane **1** et de la dihydrodioxine-1,4 **2** ont été mesurées à partir d'équilibres de transferts de protons dans un spectromètre à résonance cyclotronique ionique. BG(**1**) est supérieure à BG(**2**) de 37 kJ mol^{-1}, cet écart est à comparer à la plus faible réactivité de **2** en solution acide. Pour les deux composés, le site de protonation est la double liaison C=C, l'ion résultant possède une structure oxycarbonium. Ceci est établi par comparaison avec des composés voisins et par des calculs d'orbitales moléculaires (méthode MNDO).

Introduction

Dihydropyran **1** and dihydro-1,4-dioxin **2** undergo acid-catalyzed addition of alcohols affording 2-tetrahydropyranyl (THP) **3** and 1,4-dioxan-2-yl **4** ethers, respectively. However, whereas tetrahydropyranylation of alcohols readily occurs under very mild conditions (pyridinium *p*-toluenesulfonate (1) or iodotrimethylsilane (2)), more acidic catalysis (TsOH or $CuBr_2$) (3) are necessary for the preparation of **4**:



1 **3**



2 **4**

In order to account for this unexpected observation, we have examined the intrinsic basicity of compounds **1** and **2** by the method of equilibrium proton-transfer reaction in an ion cyclotron resonance (ICR) spectrometer.

For each molecule the favoured site of protonation was unambiguously determined by comparison with the basicity data of molecules containing closely analogous substructures (4). The conclusions were strengthened by molecular orbital calculations on the five possible protonated forms of **1** and **2**, i.e. cations *a*–*c* and *d*, *e*, respectively.

Results

Experimental

Determination of the equilibrium constant K for the proton transfer reaction:

[1] $[MH]^+ + B \rightleftarrows [BH]^+ + M$

was carried out for M = **1** and **2** and several reference bases B in the ICR cell. The latter was operated in the trapped mode under a total pressure of ca. 10^{-6} Torr and at a temperature of 313 K (5). The gas phase basicity of M is given by GB(M) = GB(B) − RT ln K where K is the equilibrium constant for reaction [1], with an accuracy better than 1 kJ mol^{-1}. Experimental data are given in Table 1.

TABLE 1. Experimental ΔG_r^0 for reaction $[MH]^+ + B \rightleftarrows M + [BH]^+$ and related gas phase basicities GB (kJ mol^{-1})

M	Reference base B	ΔG_r^0	GB(B)	GB(M)[a]
1	2,4-Pentanedione	−0.4	837[b]	
	Diisopropyl ether	+4.2	831[b]	836±1
	3,4-Dimethylfuran	−3.8	839[c]	
2	Methyl acetate	+2.1	797[b]	799±1
	para-Nitrotoluene	+3.3	795[d]	

[a]Standard experimental deviation 0.8 kJ mol^{-1}.
[b]From ref. 12.
[c]From ref. 9*b*.
[d]A revised value, ref. 15.

The corresponding proton affinity, PA(M) is obtained after introduction of the appropriate entropic term:

$$PA(M) = GB(M) + T\Delta S^0$$

For the first molecule **1**, ΔS^0 may be satisfactorily approximated by the translational entropy for the isolated proton ($T\Delta S^0$ = 33 kJ mol^{-1} at 313 K) if structures *a* or *b* are produced.

Conversely $T\Delta S^0$ should be reduced by RT ln 2 for the symmetrical molecule **2** yielding *d* or *e*. The PA values deduced this way from the experimental GB are collected in Table 2. The heats of formation of $[MH]^+$ are estimated using $\Delta H_f^0[H]^+$ = 1530 kJ mol^{-1} and experimental heat of formation for **1**, an additivity method was used in order to determine ΔH_f^0(**2**) (Table 2).

Molecular orbital calculation

The five possible structures *a*–*e* resulting from protonation of dihydropyran **1** and dihydro-1,4-dioxin **2** were examined using the semiempirical MNDO method (8). This calculation procedure gives satisfactory estimates of relative heats of formation for isomeric oxygenated closed-shell cations (9). Thus it can be

TABLE 2. Experimental proton affinities PA(M) and heats of formation of M and $[MH]^+$ for dihydropyran and dihydro-1,4-dioxin

M	PA(M)	$\Delta H_f^0(M)$	$\Delta H_f^0[MH]^+$
1	870[a]	−125[c]	535
2	829[b]	−234[d]	467

[a] $T\Delta S^0 = 33\,kJ\,mol^{-1}$, see text.
[b] $T\Delta S^0 = 30\,kJ\,mol^{-1}$, see text.
[c] Reference 6.
[d] Reference 7. A ring correction of $17\,kJ\,mol^{-1}$ was applied. This value is estimated using the ring correction term associated to 1,4-dioxan (i.e. $14\,kJ\,mol^{-1}$) and taking into account a strain energy of $3\,kJ\,mol^{-1}$ due to the C=C double bond. This latter value is obtained by comparison with the ring correction terms of tetrahydropyran ($2\,kJ\,mol^{-1}$) and 2,3-dihydropyran ($5\,kJ\,mol^{-1}$).

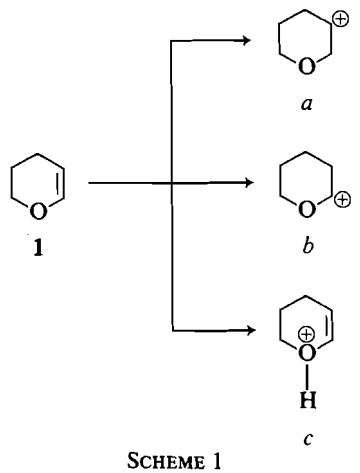
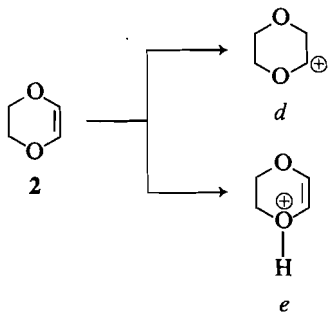


SCHEME 1



SCHEME 2

used for predicting the most favoured protonation site on **1** and **2**.

The heats of formation presented in Table 3 were obtained after complete geometry optimisation of the corresponding species *a*–*e* (optimized geometrical parameters are available upon request to the authors).

Discussion

Protonation of dihydropyran **1** and dihydro-1,4-dioxin **2** may occur either on an unsaturated carbon atom or on conjugated oxygen atom as illustrated by Schemes 1 and 2.

The assignment of the protonation site under equilibrium proton transfer conditions can be made using the following arguments.

Firstly, the gas phase basicities of **1** and **2** are greater than those of their saturated analogs:[1]

$$GB(\mathbf{1}) - GB(\text{tetrahydropyran})\ (10) = 34\,kJ\,mol^{-1}$$

$$GB(\mathbf{2}) - GB(\text{1,4-dioxane})\ (10, 11) = 19\,kJ\,mol^{-1}$$

It is well known that the introduction of a conjugated carbon–carbon double bond tends to lower the basicity of an oxygen atom (4, 12). Since protonation of tetrahydropyrane and 1,4-dioxane certainly occurs on one oxygen atom, the present results dismiss protonation on the oxygen atom both in **1** and **2**.

Thus we conclude that formation of ions *c* and *e* by protonation of **1** and **2** can be excluded under our experimental conditions.

Secondly, the experimentally determined GB values for 2,3-dihydrofuran and ethyl-vinyl ether (4) are exactly the same as GB(**1**), i.e. $836\,kJ\,mol^{-1}$ (Table 1). This observation constitutes a strong support in favour of the same protonation site for the three afore-cited compounds which contain the same α,β-unsaturated ether moiety. Owing to earlier conclusions (4) protonation on the β carbon is thermodynamically favoured. This leaves little doubt that *b* is obtained from **1** during equilibrium proton transfer.

A *third* indication confirms that oxygens are not involved in the low energy protonation process of **1** and **2**. Bloch *et al.* (13) have demonstrated that the highest occupied molecular orbital (HOMO) in neutral molecules **1** and **2** is a π-orbital mainly centred on the CC double bond. Approximately 2.5 eV above, the second band of the photoelectron spectra is due to ejection of an electron from a delocalized σ-orbital involving mainly the in-plane oxygen lone pair.

The final arguments will be given by molecular orbital calculations. In agreement with the preceding indications, MNDO calculation predict that structures *b* and *d* are the most stable protonated forms of **1** and **2**.

One may note that the corresponding oxygen protonated form *c* and *e* are less stable by 75 and $54\,kJ\,mol^{-1}$, respectively. The difference between these two values constitutes an illustration of the withdrawing effect of the second oxygen atom destabilizing the positive charge in *d* with respect to *b*. Experimentally, GB(**2**) is lower than GB(**1**) by $37\,kJ\,mol^{-1}$ (Table 1) in agreement with the lower ability of *d* to bear the positive charge. Moreover the relative proximity in energy of *d* and *e* is in keeping with the participation of this latter ion in the acid-catalyzed hydrolysis of **2** in solution (14).

Conclusion

The most thermodynamically favoured protonated forms of dihydropyran **1** and dihydro-1,4-dioxin **2** are the oxycarbonium ions *b* and *d*. This fact is established from experimental as well

[1] Using $PA(NH_3) = 205.0\,kcal\,mol^{-1}$, one obtained a revised PA value of $193.6\,kcal\,mol^{-1}$ for 1,4-dioxane.

as theoretical arguments. In addition, the lower basicity of dihydro-1,4-dioxin **2** with respect to dihydropyran **1** in the gas phase is clearly established. This inherent property attributed to the base-weakening effect of the second oxygen atom in **2** is probably also operative in solution.

^{2}H nuclear magnetic resonance studies of motions in tetramethylammonium salts: the question of methyl reorientation[1]

CHRISTOPHER I. RATCLIFFE AND JOHN A. RIPMEESTER
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9
Received November 28, 1985

CHRISTOPHER I. RATCLIFFE and JOHN A. RIPMEESTER. Can. J. Chem. **64**, 1348 (1986).

The ^{2}H nmr lineshapes of a number of tetramethylammonium salts have been studied as a function of temperature. It is shown from this and previous evidence that in certain cases the lowest temperature motions should be assigned to whole ion C_3' or pseudo-isotropic motion, rather than to methyl group motions as has been assumed in previous ^{1}H nmr studies. Steric potential calculations have been used to investigate a previously suggested model of concerted partial reorientations of methyl groups.

CHRISTOPHER I. RATCLIFFE et JOHN A. RIPMEESTER. Can. J. Chem. **64**, 1348 (1986).

On a déterminé les spectres rmn du ^{2}H d'un certain nombre de sels de tétraméthylammonium et on a étudié la forme des raies en fonction de la température. En se basant sur ces données et sur des données antérieures, on tire des conclusions relativement à la nature des mouvements se produisant aux températures les plus basses; alors que des études antérieures basées sur la rmn du ^{1}H laissaient croire que ces mouvements devraient être attribues à des mouvements des groupements méthyles, on doit plutôt les attribuer à l'ion global C_3' ou à un mouvement pseudo-isotrope. On a utilisé des calculs de potentiels stériques pour étudier un modèle qui avait été suggéré antérieurement et qui implique des réorientations partielles concertées des groupements méthyles.
[Traduit par la revue]

Introduction

In a recent study of deuterated *tert*-butyl compounds (1) we demonstrated the utility of ^{2}H nmr in discriminating between C_3 methyl group reorientation, and reorientation of the *tert*-butyl group about its principal C_3' axis when the methyls do not rotate internally. ^{1}H spin-lattice relaxation time (T_1) and second moments (M_2) measurements cannot distinguish between the two and, although this was known, it had generally been assumed that C_3 methyl motion always occurred at lower temperatures than C_3'. Using ^{2}H nmr we were able to show, in agreement with recent neutron scattering results (2), that this is not true in all cases.

Numerous ^{1}H nmr T_1 and M_2 studies of $(CH_3)_4N^+$, tetramethylammonium (TMA), salts have appeared in the past (3–21). In almost all of the T_1 studies it has again been *assumed* that C_3 methyl reorientation is always responsible for the relaxation at the lowest temperatures, followed by pseudo-isotropic motion at higher temperatures, or in some cases at about the same temperature as the methyl motion. (Since isotropic motion strictly implies random reorientation among all directions in space of any vector within the molecule, the term pseudo-isotropic motion is used here to imply rapid reorientation between specific equilibrium positions about many or all of the threefold and twofold axes of the $(CH_3)_4N^+$. ion. In either case the lineshape is narrowed to a single sharp line.) Through a number of arguments, which we discuss later, it became apparent to us that some of the activation energies claimed for the methyl C_3 reorientation are *much lower* than should be anticipated. This suggested that in some cases (just as in some of the *tert*-butyl compounds) the lower temperature T_1 behaviour might be explained better by whole ion C_3', C_2', or pseudo-isotropic motions, occurring before any methyl C_3 motion begins. There are similar complications in the interpretation of the ^{1}H nmr results for the lowest temperature phase of neopentane (5, 22–24). Results for this material will be presented elsewhere.

Another novel reorientation process has recently been proposed to account for an unusually shallow T_1 minimum that has been observed only in the $PtBr_6^{2-}$, $TeBr_6^{2-}$, $SnBr_6^{2-}$, and $TeCl_6^{2-}$ salts of TMA (18, 19) at low temperatures; the model interprets this minimum in terms of a partial and symmetrical rotation of all the methyl groups around their C_3 axes between two positions about 15° on either side of the all-staggered configuration of the ion. While this model (which we will refer to from here on as the "twisted methyls" model) is interesting and worthy of consideration, we felt that there may be another simpler explanation of the T_1 results. Furthermore, one might question the existence of the two equilibrium positions necessary for this model.

All these motions should give different characteristic ^{2}H nmr powder lineshapes (in the fast motion limit), so this seemed to be an ideal method for attempting to sort out exactly which motions do occur in several selected TMA salts.

Experimental

TMA-d_{12} chloride was obtained from M.S.D. isotopes. TMA-d_9 iodide was prepared by condensing $(CD_3)_3N$ (MSD isotopes) into a tube containing an ethanol solution of methyl iodide at liquid nitrogen temperatures (by means of a vacuum line). The tube was sealed and allowed to warm up to room temperature, by which time the solids had melted, mixed, and reacted. The ethanol was then removed. TMA-d_9 OH·5H_2O was prepared from TMA-d_9I as follows: An excess of a freshly prepared suspension of silver oxide was stirred into a solution of TMA-d_9I. The silver iodide and excess silver oxide were filtered off. The resulting solution of TMA-d_9 hydroxide was then concentrated and left in a desiccator until crystals of the pentahydrate had formed. This hydroxide was later neutralized with HBr solution to give TMA-d_9Br, which was used to prepare the $SnBr_6^{2-}$ and $TeBr_6^{2-}$ salts. [TMA-d_9]$_2$$SnBr_6$ was prepared by mixing the appropriate amounts of TMA-d_9Br (dissolved in a minimum amount of water at 80°C) and $SnBr_4$ (in a small amount of concentrated hydrobromic acid at 80°C). The yellow precipitate was cooled, filtered, and washed with absolute ethanol (19).[TMA-d_9]$_2$$TeBr_6$ was prepared in a similar manner, except TeO_2 was substituted in the place of $SnBr_4$ (19). [TMA-d_{12}]$_2$$ZnCl_4$ was prepared by mixing concentrated solutions of the appropriate amounts of dried TMA-d_{12}Cl and $ZnCl_2$. The resulting precipitate was filtered and dried. A second sample of $(CD_3)_4$NOH·5-H_2O was prepared at a later date from a sample of perdeuterated TMAOD hydrate obtained from Cambridge Isotopes Ltd.

The ^{2}H nmr powder lineshapes were obtained at 27.63 MHz using a

[1]NRCC No. 25524.

[a]Authors (18) suggest alternatively that this is overall reorientation.
[b]Two types of TMA ion in unit cell, *assumed* (17).
[c]Assumes one methyl (E_a = 1.6 kcal/mol) is unique (12).

Brüker CXP 180 spectrometer, a Brüker/Oxford Instruments cryomagnet, and a variable temperature N_2 gas-flow probe with a Brüker B-VT-1000 temperature controller. Spectra at liquid nitrogen temperature were obtained with a separate probe designed to hold liquid nitrogen around the coil and sample. A quadrupole echo pulse sequence (25) was used, with a delay time of 35 μs between X and Y pulses of 2.5 μs, and phase alternation. The cycle repetition times varied from 0.4–20 s depending on T_1. The second sample of TMA-d_{12} hydroxide was investigated below 77 K using liquid helium coolant in an Andonian cryostat, with a different probe and a Brüker 1.41 Tesla electromagnet. Spectra were then obtained at 9.2 MHz using the CXP spectrometer.

Discussion

Previously determined methyl rotation barriers

Table 1 lists all the claimed activation energies for methyl reorientation in TMA obtained from T_1 versus temperature studies. The values range widely from 1.6 to 6.8 kcal/mol, which itself seems rather unusual. Inelastic neutron scattering (INS) studies of the methyl torsional modes in the TMA halide salts (26) indicate threefold barriers of 7.9, 7.5, and 6.7 kcal/mol for the chloride, bromide, and iodide respectively. Allowing for the zero point energies, the INS barriers correspond quite well with the activation energies (7) given in Table 1, and help to substantiate the interpretation of those nmr results. Methyl torsional mode assignments in the infrared and Raman spectra of the $PtCl_6^{2-}$, $PtBr_6^{2-}$, $TeBr_6^{2-}$, and $NiCl_3^-$ salts (27) also lead to barrier values of the order of 5 kcal/mol. Now, there is no reason why the *internal* barrier to methyl reorientation should change drastically from one salt to another, though small changes in the total methyl barrier would be expected to arise from differences in the external barriers, as indicated by the halide salts. This cannot account, however, for the large range of claimed methyl activation energies. The barrier to methyl rotation in $(CH_3)_3N$ in its clathrate hydrate has been determined from ^1H nmr tunnelling lineshapes to be 4.17 kcal/mol (28). Any external contribution to the barrier in this hydrate should be extremely small, and the internal barrier would be lower than that in $(CH_3)_4N^+$ since there is less steric crowding. Furthermore, since the barriers to methyl reorientation in $(CH_3)_4X$ species increase with decreasing C—X distance (29, 30), the barrier in TMA^+ should be higher than that in neopentane, $(CH_3)_4C$, for which the barrier has been determined by infrared, INS, and thermodynamics studies (summarized in ref. 29) to be no lower than 4.3 kcal/mol. The barrier determined from the tunnelling lineshape of neopentane clathrate hydrate is also 4.26 kcal/mol (28). The implication is that the values lower than this for TMA salts, obtained from ^1H T_1 studies, do not represent methyl reorientation. Consequently those values in the right hand column of Table 1 probably represent either pseudo-isotropic reorientation or preferred reorientation about specific axes (C_3' or C_2') of internally rigid TMA ions.

Second moment discrepancies

When methyl groups have barriers of ~4.5–3.5 kcal/mol, tunnelling processes produce lineshapes, at low temperatures, that are quite distinct from the rigid lattice lineshape, and for barriers lower than 3.5 kcal/mol the lineshapes are the same as for the classical rotor. Consequently the observed ^1H second moments may never reach their anticipated rigid lattice values (31). This being the case, there are obvious discrepancies between the low activation energies claimed for methyl rotation from T_1 results and the observation of rigid lattice lineshapes and second moments: this is particularly clear in the case of TMA $CdCl_3$ (12). In fact all the second moment values reported at sufficiently low temperatures are very close to the expected rigid lattice values (4, 6, 9, 10, 18, 19), though most of these studies do not go right down to liquid helium temperatures.

For whole ion motions the moments of inertia are *much* higher than for methyl reorientation. Consequently energy level splittings due to barrier tunnelling are very much smaller than for methyl and hence have no observable effect on the lineshape.

Considerations of the "twisted methyls" model

The model involving the "twisted methyls" appears to have originated with Lassettre and Dean (32), who calculated potentials using semi-empirical bond dipole and quadrupole interactions. Their calculations for neopentane suggested that the minimum energy configuration occurs when the methyls are all twisted symmetrically away from the all-staggered configuration by an angle between 0 and 30°. However, it has been suggested from the analysis of the different energy contributions, calculated more recently by *ab initio* methods, that internal barriers are not simply due to bond dipole–quadrupole interactions (33); the similarity between observed barriers and those calculated using the bond dipole–quadrupole interactions may therefore be more fortuitous than realistic.

Berg (27) revived the model to attempt to explain some features of his infrared and Raman spectra of the hexahalometallate salts of TMA, and following this the model seemed to provide a plausible explanation of the corresponding ^1H T_1 results (18, 19). Berg's statements (27) are misleading, however, in that they imply that the torsional barriers in the isolated TMA ion are due entirely to electrostatic repulsions between the protons. In fact, although H–H interactions must certainly play a part, they are only one contributor to the total torsional potential.

We considered it worthwhile doing some simple empirical calculations for TMA to attempt to clarify the situation. We used the following potential and empirical parameters (34, 35).

$$V(r) = a \exp(-br) - c/r^6$$

for	H—H	a = 2171	b = 3.74	c = 24.39
	C—H	a = 8503	b = 3.67	c = 111.82

TABLE 2. Calculated frequency separations of the pairs of discontinuities (kHz) for various reorientations in the fast motion limit based on the rigid parameters given in the first row

	q_{zz}	q_{yy}	q_{xx}	η	e^2qQ/h (kHz)

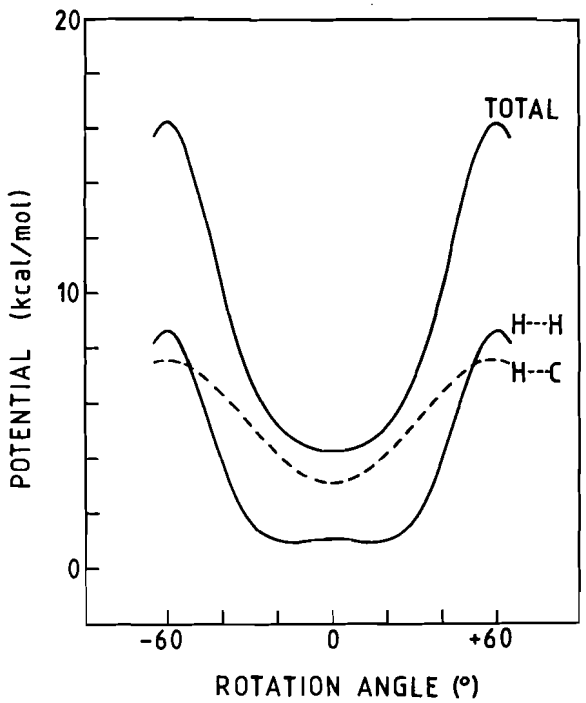

FIG. 1. Steric potential contributions for $(CH_3)_4N^+$ when *all* CH_3 groups are rotated simultaneously in the same direction with respect to their C—N axes. (Angle 0° = all-staggered configuration.)

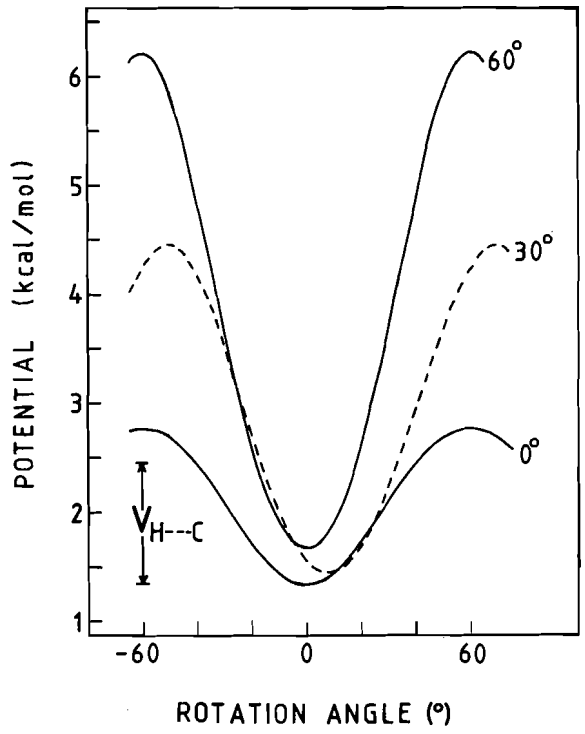

FIG. 2. Steric potential for one CH_3 group of $(CH_3)_4N^+$ when the three other CH_3 groups have all been rotated, in the same direction with respect to their C—N axes, to 0, 30, or 60° from the all-staggered configuration.

(The potential is in kcal/mol if r is in Å, using these parameters.) We assumed C—H = 1.09 Å, C—N = 1.5 Å, and all bond angles to be tetrahedral.

We first calculated the *total* steric interaction potential for the whole molecule as *all* 4 methyls are rotated by the same angle, Fig. 1. The H—H interactions do indeed produce potential minima at about ±16° on each side of the all-staggered configuration, but note that the barrier between the two positions is *very* small. The C—H interactions, however, produce a symmetrical 3-fold potential with its minimum at the all-staggered configuration (indeed because of symmetry this must occur). The *total* potential then has only one broadened minimum (in a 120° rotation) at the all-staggered configuration. It should also be pointed out that the C—H interactions may be underestimated by this kind of interaction potential, because the internal barrier involves the electron distributions in the C—H and N—C bonds as well as the interatomic interactions.

Secondly we calculated the steric potential for reorientation of *one* methyl group with the other 3 groups all rotated by angle α, for a range of values of α, Fig.2. The H—C term is again a constant 3-fold potential with a minimum at the all-staggered configuration. The H—H term is a 3-fold potential with a minimum at the all-staggered configuration only for α = 0 or 60°; for $0 < \alpha < 60$ the minimum shifts first away from and then back to the all-staggered configuration. Note that the height of the barrier increases as α increases. Perhaps the most significant aspect of this second set of calculations is that the minimum is always single, and hence it appears that the double minimum will only appear in the total H—H potential when there are simultaneous symmetric twists of all 4 methyl groups.

Obviously these calculations are very simplistic and depend both on the molecular dimensions and the potential function and parameter set chosen. They do indicate, however, that even if the parameters were chosen (and weighted in favour of the H—H interactions) so as to produce a double minimum in the total potential, then the barrier between the two would likely be

much smaller than the 7.7–12.8 kJ/mol (1.83–3.05 kcal/mol) assigned to the "twisted methyls" motion in the earlier nmr studies (18,19). We thus have good reason for investigating alternative explanations of the low temperature relaxation minimum for those hexahalometallate salts concerned.

^2H lineshape calculations

Values for the rigid lineshape quadrupole coupling constant $e^2qQ/h = 168$ kHz and asymmetry parameter $\eta = 0.0635$ were used in calculating the motionally averaged lineshapes for a number of cases. The results are given in Table 2 and shown in Fig. 3. All bond angles were assumed to be tetrahedral and the rigid lattice q_{zz} tensor component was assumed to be along the C—D bond axis. The narrowed lineshapes were calculated by averaging the tensor components at all the equilibrium positions sampled by a deuteron during the motion (see ref. 36). The calculations apply to the fast motion limit, i.e. when the reorientation rate is much faster than the reciprocal of the quadrupole coupling constant of the unnarrowed lineshape.

For the "twisted methyls" model we calculated the motional averaging for in-plane flips between two sites for two cases, where the sites are separated by angles of 20 and 30° respectively. Translated into methyl torsional angles these correspond to 21.2 and 31.9°. The larger angle is closer to the values suggested by the ^1H nmr study (19), but we wished to see whether the reduced effect of the smaller angle on the lineshape would still be detectable if it occurred. (Other angles were considered but are not shown here.) It was found that q_{zz} changes the most rapidly at low flip angles. The lineshape for most flip angles retains a non-zero asymmetry parameter but the overall width is reduced.

For the C_3' motion, 9 of the deuterons are averaged in exactly the same way as the deuterons in a C_3 methyl rotation would be, i.e. the lineshape is narrowed by a factor of about 1/3 to give the inner doublet of Fig. 3(d). However, the 3 deuterons whose C—D axes lie parallel to the C_3' axis show very little narrowing, since q_{zz} remains unchanged and q_{xx}, q_{yy} are averaged. Note that the two sets of doublets that thus make up the total lineshape for this motion both have $\eta = 0$. For TMA-d_9 ions $(CD_3)_3CH_3N^+$ the result will be exactly the same as for $(CD_3)_4N^+$; even the intensity ratio of 3:1 of inner:outer doublet is unchanged (consider the average of the four possible C_3' axes of the ion).

The C_2' twofold reorientation produces an unmistakable averaged lineshape with a very large η. Perhaps of more interest is the lineshape produced when reorientation occurs about C_2' among more than the 2-fold positions (e.g. 4-fold is plausible). The line in this case is almost completely narrowed, a result which arises because all the C—D bonds are oriented at the magic angle with respect to the C_2' axis. (In fact if the rigid lattice η were zero then the narrowing *would* be complete.)

Observed ^2H lineshapes

The experimental ^2H lineshapes at various temperatures are shown in Figs. 4–8. Our efforts to determine which motion occurs first at low temperatures are generally hampered because of (*1*) dynamic effects on the lineshape, and (*2*) the overlap of other line-narrowing processes at higher temperature, i.e. the pure lineshape as calculated for the fast motion limit above may not necessarily be seen. Fortunately the lineshape changes occurring are sufficiently well defined in most cases that we may be unambiguous in assigning the motions.

We can briefly summarize some general observations before considering each case in more detail:

TABLE 3. Observed ^2H nmr lineshapes: estimated quadrupole coupling constants and asymmetry parameters

TMA salt	e^2qQ/h (kHz)	η	T (K)
Rigid lineshape components:			
Cl	169	0.0512	77
I	165	0.0484	77
$ZnCl_4$	167	0.0637	77
$OH{\cdot}5H_2O$	165	0.0687	69
$TeBr_6$	169	0.0630	77
$SnBr_6$	170	0.0706	77
C_3 or C_3' reduced doublet components			
Cl	49	0	270
I	51	0	170
$ZnCl_4$	53	0	100
$OH{\cdot}5H_2O$	54	0	69

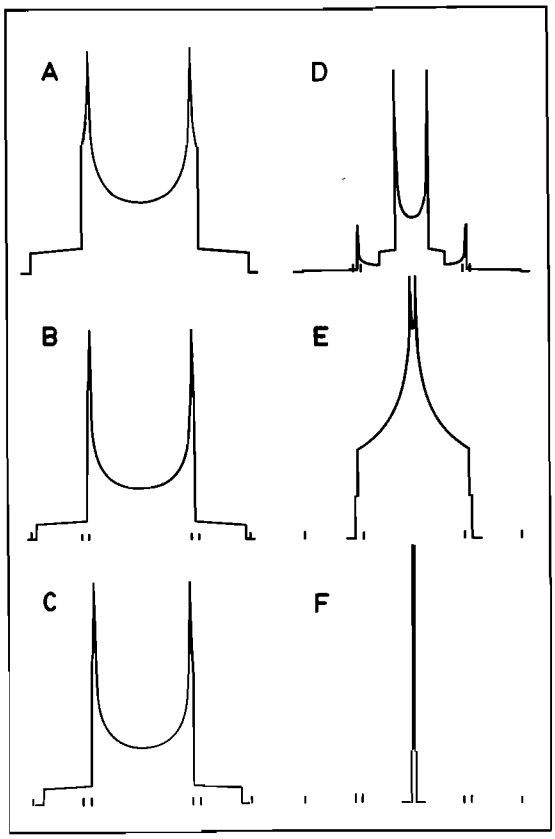

FIG. 3. Calculated ^2H nmr lineshapes. A, rigid lattice; B, C, "twisted methyls" model, rotation angle between 2 sites 20° and 30° respectively; D, C_3' motion; E, C_2' 2-fold motion; F, C_2' n-fold motion ($n > 2$). The short vertical marks indicate the positions of the rigid lineshape singularities. (Note: the inner singularities of the doublets have been truncated, since no broadening functions have been convoluted with the pure lineshapes.) All lineshapes (except rigid) in the fast motion limit.

1. In most of the cases studied (except for the OH^- salt) we have largely the rigid lattice lineshape at 77 K. This is basically the same in all the salts, though it may be significant that for the Cl and I salts, where motional barriers are highest, the asymmetry parameters are lower. Values of e^2qQ/h and η are given in Table 3.

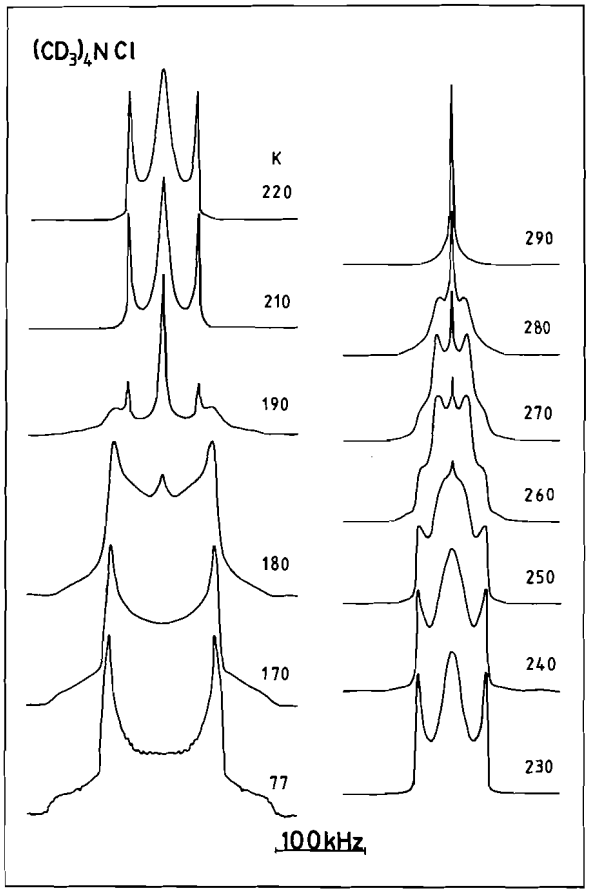

FIG. 4. The ^2H nmr lineshapes of (TMA)Cl as a function of temperature. Note there is a phase change between the lineshapes at 180 and 190 K.

2. There is no evidence in any of the spectra of the C_2' 2-fold rotation lineshape.

3. Features due to the roughly 1/3 reduced doublet characteristic of C_3 or C_3' appear in the spectra of the Cl^-, I^-, $ZnCl_4^-$, and OH^- salts.

4. In all cases as temperature increases we see the development of the pseudo-isotropic lineshape. (Note this could include C_2' 4-fold reorientation.)

5. There is no evidence for the reduced lineshape for 20–30° "twisted methyls" flipping in the $TeBr_6^{2-}$ and $SnBr_6^{2-}$ salts.

TMA Cl and I

In the ^2H lineshapes of both these salts (Figs. 4 and 5) we can observe the appearance of the features of the reduced lineshape due to C_3 methyl reorientation (see Table 3), over a wide temperature range, as the rigid lattice features become less well defined and eventually disappear. It is perhaps here where we can distinguish between C_3 and C_3' motion, since for C_3' we should retain a well-defined outer doublet (cf. C_3' motion in certain *tert*-butyl compounds and $(CD_3)_3N$ (ref. 1). Of course for these two salts we do not question the previous studies, which show that C_3 motion is the first to occur (7). In both salts the C_3 fast motion limit lineshape is never attained, since the pseudo-isotropic lineshape begins to develop before this occurs. Another feature that distinguishes these halide salts is that the pseudo-isotropic lineshape begins to appear, and finally becomes the only lineshape, at much higher temperatures than in the other salts.

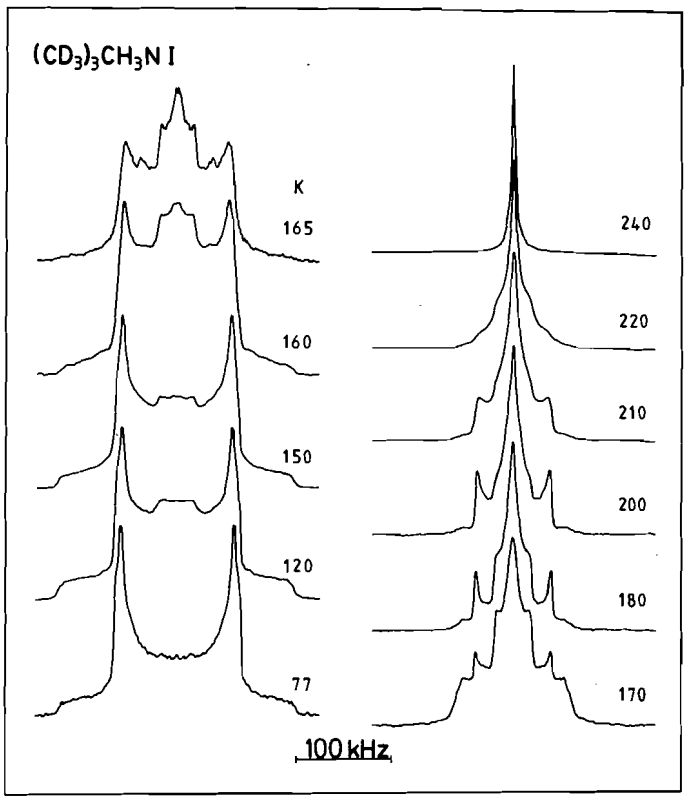

FIG. 5. The ^2H nmr lineshapes of (TMA)I as a function of temperature.

$(TMA)_2$ $ZnCl_4$

All the lineshapes we are concerned with for this salt are for the lowest temperature phase VI, which is stable below 161 K (37). The lineshape is almost completely rigid at 77 K, by 90 K we can see features due to both pseudo-isotropic and C_3 or C_3' motions, but by 120 K virtually all the intensity is in the sharp central pseudo-isotropic line, Fig. 6. Ignoring the central line, if we focus on the spectra above 100 K where the inner doublet has more intensity than the outer doublet, the outer doublet now appears to have $\eta = 0$. Whether this is simply a dynamic effect in the narrowing region or the expected effect due to C_3' motion (see calculations) cannot be resolved. However, since we have already argued that the activation energies derived from the ^1H T_1 results for this salt are too low for methyl $C3$ reorientation, it is quite clear from the ^2H lineshapes that the motions involved are C_3' reorientation about one axis followed very closely by pseudo-isotropic reorientation.

The crystal structure of phase VI is not known so one should also consider the possibility of having inequivalent TMA ions. Some ions may reorient by C_3' followed by pseudo-isotropic motion and others might go straight to pseudo-isotropic motion. This would be reflected in the relative line intensities and the depths of the two observed T_1 minima (17).

$(TMA)\,OH{\cdot}5H_2O$

The lineshapes shown in Fig. 7 were all obtained at 9.2 MHz. The one spectrum of $(CD_3)_3CH_3NOH{\cdot}5H_2O$ that was obtained at 77 K and 27.63 MHz was virtually identical to that at 9.2 MHz except it showed the outer singularities of the broad doublet more clearly. (This is on account of the higher pulse power attainable in the 27.63 MHz probe.)

Even at 69 K the ^2H lineshape of this material clearly shows evidence of a great deal of motion. Again there are features due

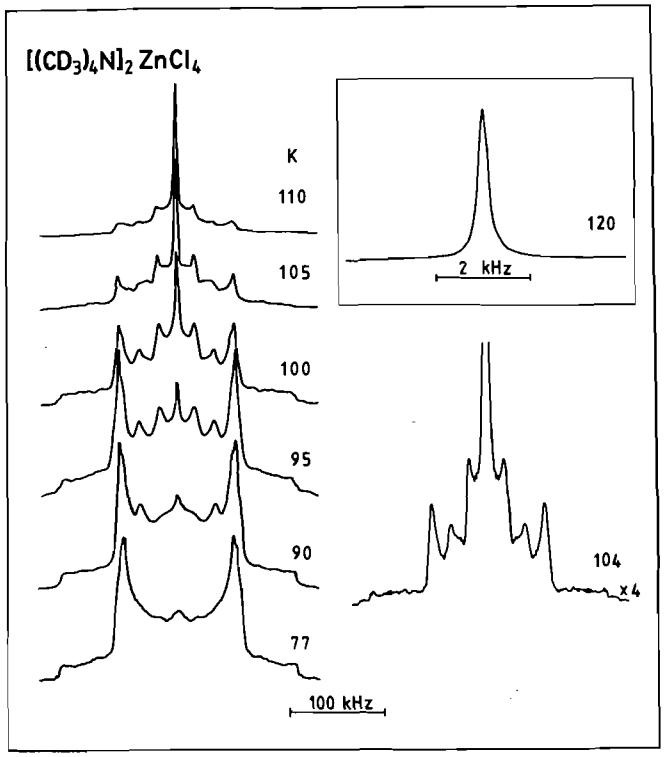

FIG. 6. The ^2H nmr lineshapes of $(TMA)_2ZnCl_4$, phase IV, as a function of temperature.

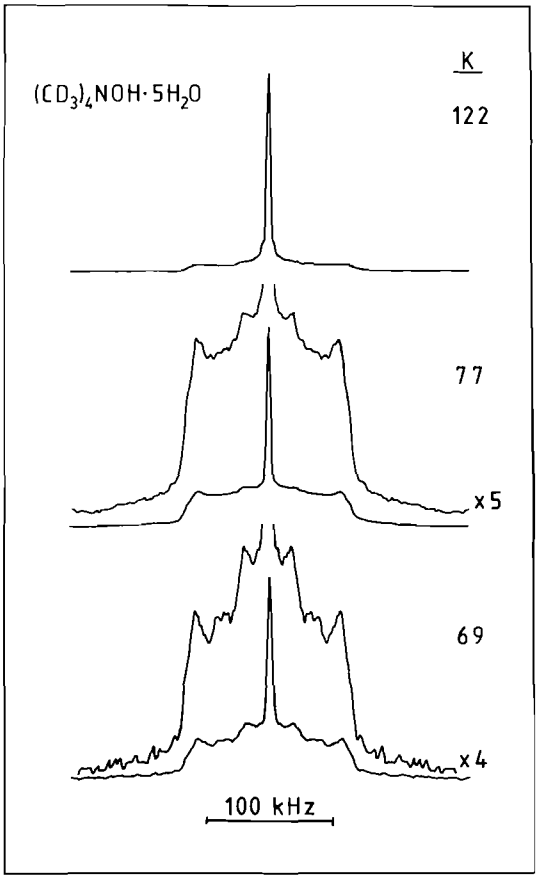

FIG. 7. The ^2H nmr lineshapes of $(TMA)OH\cdot 5H_2O$ at low temperatures (9.2 mHz).

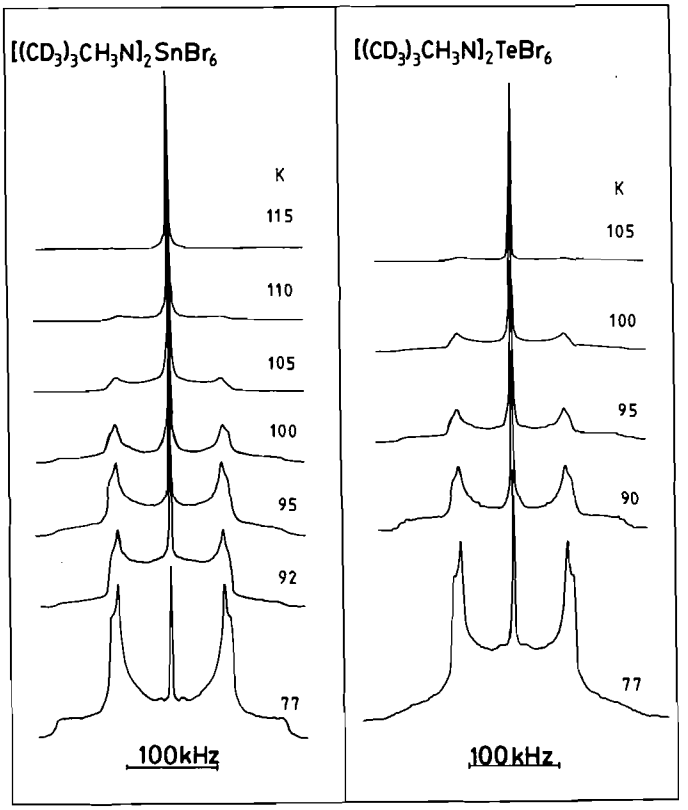

FIG. 8. The ^2H nmr lineshapes of $(TMA)_2SnBr_6$ and $(TMA)_2TeBr_6$ below 120 K.

to C_3' and pseudo-isotropic motions. The broad outer doublet must consist of a small contribution from the broad component of the C_3' lineshape, but it can be largely attributed to the rigid lattice lineshape (showing dynamic effects). Note that the C_3' lineshape is most prominent at the lowest temperature and together with the rigid lineshape loses intensity to the pseudo-isotropic line as the temperature increases. This suggests that although C_3' motion may occur first it is closely followed by pseudo-isotropic motion.

In this particular case one would anticipate a C_3' motion based on X-ray structure information (38); the TMA ion is enclathrated in a cage consisting of water molecules incorporating the OH^- ion and it has a unique C_3' symmetry axis. Also, as with most clathrate hydrates (39), reorientation of the ion within the cage would be expected to have a very small barrier, and it is quite possible that there is disorder of the protons of the cage structure at low temperatures. This latter feature can lead to a distribution of cage potentials and reorientational correlation times. From ^1H T_1 and second moments studies (in progress in this laboratory) it is also clear that C_3 methyl motion is not observed (i.e. (*1*) motional narrowing gives the second moment values expected for pseudo-isotropic motion, below 110 K; (*2*) at 4 K one obtains a rigid lattice lineshape (no methyl tunnelling effects); and (*3*) the activation energy obtained from T_1 for the lowest temperature motion is too low for methyl reorientation).

$(TMA)_2SnBr_6$ and $TeBr_6$

The ^2H lineshape changes for these two salts are very similar, Fig. 8, and are quite distinct from the others we have considered so far. In both salts the rigid lattice lineshape simply seems to diminish in intensity while a sharp central line grows, as the temperature is increased. In fact there is a trace of the central

line even at 77 K. Note that phase transitions have been detected at 84 K ($TeBr_6^{2-}$ salt) and 90 K ($SnBr_6^{2-}$ salt) (19), so that except for the 77 K spectra all the lineshapes shown belong to the phase which is also stable at room temperature. There is obviously no evidence for C_3, C_3', or C_2' (2-fold) reorientation in these lineshapes. It is also clear that the broad doublet of the rigid lattice does not show any significant narrowing as temperature increases, and certainly not to the degree expected for the "twisted methyls" flipping motion.

Since the only motion indicated is pseudo-isotropic (or perhaps C_2' (4-fold)), we must now find an alternative explanation for the observed T_1 minima. At room temperature all the $(TMA)_2MX_6$ salts, where M = Pt, Te, Sn and X = Cl, Br, belong to space group $Fd3c$ (19, 40, 41), and whenever this phase is stable down to low enough temperatures the shallow ^1H T_1 minimum appears (previously ascribed to "twisted methyls" motion), i.e. in $TeCl_6^{2-}$, $PtBr_6^{2-}$, $TeBr_6^{2-}$, and $SnBr_6^{2-}$. (In the $TeCl_6^{2-}$ case the phase appears to be metastable in the temperature range of the shallow T_1 minimum, and the lower temperature phase does not show this minimum (18).) In general, the shallow minimum does not appear in the other solid phases.

The detailed $Fd3c$ structure of the $TeBr_6^{2-}$ salt (41) shows two crystallographically inequivalent types of TMA ion in the ratio 3:1. We propose that the most plausible reinterpretation of the T_1 behaviour for these salts is that both observed minima are due to pseudo-isotropic reorientation, but with motion of the rarer type of TMA ion occurring at lower temperature and hence producing a separate shallow minimum. In fact the ratio of the two T_1 minima roughly fits a 1:3 ratio. The observation that the deeper minimum is not very symmetrical is most probably due to the *pseudo*-isotropic nature of the motion. Pseudo-isotropic motion for this ion really implies a combination of C_3' and C_2' motions about all such axes, and some of these motions may have slightly different rates (though insufficiently distinct to separate them).

In conclusion, we have demonstrated by way of old and new results that methyl group reorientation is not the lowest temperature motion occurring in a number of TMA salts. This once again shows that careful consideration must be given to all the known results concerning structure and motion for any case before a complete understanding can be attained.

The structure of the nucleoside 5-methoxymethyl-1-(2′-deoxy-β-D-lyxofuranosyl)uracil (MMdLU) was deduced by X-ray crystallographic analysis. MMdLU crystallized in space group $P2_1$ with a = 8.719(4), b = 13.188(3), c = 5.701(3) Å, β = 109.56(2)° and Z = 2; R = 0.040 for 1208 unique reflections with net $I > 2\sigma(I)$. The furanose ring adopts the rare C(4′)—*exo* envelope conformation ($_4E$). The glycosyl linkage is *anti* (χ = 243.5°) and the C(5′) side chain has the *t* conformation. The conformation was also determined in solution by nmr analysis. The sugar ring exists in the *N*-conformation (97 ± 5%), the populations of the three rotamers about the exocyclic C(4′)—C(5′) bond were estimated to be $g^+:t:g^-$ = 23%:59%:18% and the glycosidic conformation is predominantly *anti*.

J. WILSON QUAIL, IRENA EKIEL, OSSAMA A. L. EL-KABBANI, GUY TOURIGNY, LOUIS T. J. DELBAERE, ALLAN L. STUART et SAGAR V. GUPTA. Can. J. Chem. **64**, 1355 (1986).

Faisant appel à la diffraction des rayons X, on a déterminé la structure du nucléoside méthoxyméthyl-5 (déoxy-2′ β-D-lyxo-furannosyl)-1 uracil (MMdLU). Le MMdLU cristallise dans le groupe d'espace $P2_1$ avec a = 8,719(4), b = 13,188(3) et c = 5,701(3) Å. β = 109,56(2)° et Z = 2; R = 0,040 pour 1208 réflexions uniques avec $I > 2\sigma(I)$. Le cycle furannose adopte la configuration enveloppe C(4′)-*exo* ($_4E$) qui est rare. La liaison glycosidique est *anti* (χ = 243,5°) alors que la chaîne latérale C(5′) adopte une conformation *t*. On a aussi déterminé la conformation en solution en se basant sur une analyse par rmn. Le cycle du sucre existe dans la conformation-*N* (97 ± 5%) et on a évalué que les populations des trois rotamères autour de la liaison exocyclique C(4′)—C(5′) sont $g^+:t:g^-$ = 23%:59%:18% et la conformation glycosidique est principalement *anti*.

Introduction

Our laboratory has been interested in viral chemotherapy, and, more specifically, the effect of nucleoside analogs on herpes simplex virus infections (1–8). The nucleoside, 5-methoxymethyl-2′-deoxyuridine (MMdUrd), was synthesized (9) and its selective activity against herpes simplex virus was discovered in the early seventies (2). In order to understand the molecular basis for selective action of antiherpes drugs, analogs of MMdUrd were synthesized and the structural modifications were related to the antiviral activity (7, 10). The 3′-epimer of MMdUrd, *5-methoxymethyl-1-(2′-deoxy-β-D-lyxofuranosyl)uracil* (MMdLU), which has the 3′-OH group in the *endo* position (1′*R*,3′*R*,4′*R*-configuration), was synthesized. MMdLU was essentially devoid of activity against herpes simplex virus (11). The selective activity of MMdUrd is due to preferential phosphorylation by virus-induced pyrimidine deoxyribose kinase (viral-K). The nucleotide, after conversion to its triphosphate, is a competitive inhibitor of viral DNA-dependent DNA polymerase (12). The substrate specificity of MMdUrd is most likely a reflection of the amino acids at the active center of the viral-K enzyme and the lack of activity of MMdLU is related to differences in the stereochemistry of the two analogs. Furthermore, since no 2′-deoxy*lyxo*nucleoside (or 2′-deoxy*xylo*nucleoside) has been subjected to X-ray analysis, the crystal structure determination of MMdLU was considered to be relevant. In order to compare the conformation in solution with that found in the solid state, the structure of MMdLU was also determined in D_2O by nmr spectroscopy.

[1]Author to whom all correspondence should be addressed.

Results and discussion

The synthesis of MMdLU was accomplished by a four-step reaction sequence. The 5′-OH group of MMdUrd was protected by tritylation (7). Treatment of the triphenylmethyl derivative with methanesulfonyl chloride in pyridine at 4°C gave the 3′-mesyl ester, which upon hydrolysis in base yielded 5′-tritylated MMdLU. Detritylation was done in 80% acetic acid at 50°C. The structural formula with atomic numbering for MMdLU is shown in Fig. 1.

X-ray analysis.

The bond lengths and angles determined for MMdLU are given in Tables 1 and 2, respectively, and a stereoscopic view of the molecule is shown in Fig. 2. The bond distances in MMdLU and most of the bond angles are very similar to those in MMdUrd. However, the bond angles involving C(3′) differ considerably due to the difference in configuration. The

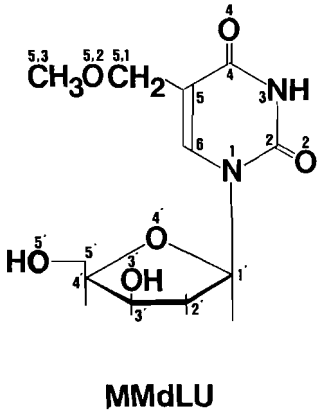

FIG. 1. Structure and atomic numbering of MMdLU.

respective values for MMdLU and MMdUrd are C(1′)—C(2′)—C(3′) 104.0(3)° and 101.4(2)°, C(2′)—C(3′)—O(3′) 112.0(3)° and 106.8(2)°, O(3′)—C(3′)—C(4′) 108.1(3)° and 111.6(2)°, O(4′)—C(4′)—C(3′) 103.6(3)° and 106.2(2)°. Selected torsion angles are shown in Table 3. The glycosidic torsion angle χ, O(4′)—C(1′)—N(1)—C(2), is 243.5° which is within the usual range of pyrimidine nucleosides that have the *anti* configuration (13). The χ values found in MMdUrd and in 5-hydroxymethyl-2′-deoxyuridine (HMdUrd) were 233.3° and 236.4°, respectively (14, 15). Torsion angles for the 5-methoxymethyl group C(5)—C(5,1)—O(5,2)—C(5,3) and C(6)—C(5)—C(5,1)—O(5,2) are 170.7° and −2.7° for MMdLU. The corresponding values are −114.2° and −99.2° in MMdUrd (14). The change in these torsion angles reflect the relatively flexible nature of the 5-methoxymethyl group and differences in intermolecular hydrogen bonding.

The values calculated for the two pseudorotational parameters (16) of the furanose ring are $P = 55.8°$ and $\tau_m = 41.8°$ for the phase angle of pseudorotation and the amplitude of puckering, respectively. Each of the deoxyribose rings of MMdLU, MMdUrd, HMdUrd, and 2′-deoxythymidine (dThd) in the crystalline state exhibit differences in their envelope conformation. The conformations and corresponding displacements from the mean plane through the other four ring atoms are C(4′)—*exo*, 0.76 Å for MMdLU; C(2′)—*endo*, 0.58 Å for MMdUrd (14); C(1′)—*exo*, 0.42 Å for HMdUrd (15); C(3′)—*exo*, 0.57 Å for dThd (17). It is interesting to note that the C(4′)—*exo* conformation observed has not been reported previously for pyrimidine nucleosides.

The crystal structure is stabilized by three intermolecular hydrogen bonds. The first one is O(5′)—H(05′) ... O(4) [2 − x, 1/2 + y, 2 − z] with distances O(5′) ... O(4) 2.655(4) Å, H(05′) ... O(4) 1.74(8) Å, O(5′)—H(05′) 1.04(6) Å, and angle O(5′)—H(05′) ... O(4) of 144(7)°; the second one is O(3′)—H(03′) ... O(5′) [1 − x, 1/2 − y, 1 − z] with distances O(3′) ... O(5′) 2.649(5) Å, H(03′) ... O(5′) 1.80(9) Å, O(3′)—H(03′) 0.93(9) Å, and angle O(3′)—H(03′) ... O(5′) 150(7)°; the third one is N(3)—H(3) ... O(3′) [1 + x, y, z] with distances N(3) ... O(3′) 2.878(4) Å, H(3) ... O(3′) 2.01(5) Å, N(3)—H(3) 0.87(5) Å, and angle N(3)—H(3) ... O(3′) of 174(4)°.

Nuclear magnetic resonance analysis

The ^1H and ^{13}C parameters are summarized in Tables 4 and 5, respectively. The conformation of the sugar ring was obtained from the relationship between the proton–proton coupling constants and the pseudorotational properties of the ring using a computer program (SPACEJ) based on the method described by Haasnoot *et al.* (18). The calculated coupling constants for the full pseudorotational circuit ($P = 0°$ to 360°) at a puckering amplitude (τ_m) of 39° are shown in Fig. 3. Based on nmr and X-ray evidence (13, 16) as well as theoretical calculations (19), the furanose ring in nucleosides exists in solution in a dynamic equilibrium between two puckered conformations centered around $P = 18°$ (*N*-conformer) and $P = 162°$ (*S*-conformer). The observed vicinal coupling constants represent time-averaged coupling which are linearly related to the couplings of the two conformers and their relative populations by eq. [1], where X_N is the mole fraction of the *N*-conformer.

$$[1] \quad J_{obs} = X_N J_N + (1 - X_n) J_S$$

Using this model, it was calculated that in solution, MMdLU exists in the *N*-conformation (97 ± 5%). Similarly, a strong preference for *N*-type puckering has been reported for 2′-deoxy-*lyxo*-furanosyladenine (20). A shift of the conformational equilibrium toward the C(3′)—*endo* conformer (*N*-type) was also reported for lyxonucleosides (16, 21) and xylonucleosides (22–24). These results suggest that the 2′-OH group in lyxo- and xylonucleosides is much less important than 3′-OH in determining the conformation of the furanose ring. The cisoidal relationship between the 3′-OH and 5′-CH_2OH groups shifts the equilibrium towards the *N*-type conformation. Since the X-ray crystallographic analysis showed an unusual C(4′)—*exo* envelope conformation ($P = 55.8°$), the possibility of such a conformation in the solution was also considered. There is a greater difference between observed and calculated coupling constants when a τ_m value of 39° (the average value reported for nucleosides (16, 25)) is used. However, if the value of $\tau_m = 41.8°$, found in the solid state, is used for these calculations the correlation between experimental and calculated values is improved for the C(4′)—*exo* conformation.

The population of the three rotamers about the exocyclic C(4′)—C(5′) bond was estimated from the $J_{4',5'}$ and $J_{4',5''}$ coupling constants using the method of Haasnoot *et al.* (26). The weighted time-averaged nmr couplings are related to the couplings of the individual conformers and their relative populations by eqs. [2] and [3] where x denotes the mole fraction of each conformer present.

$$[2] \quad {}^3J_{4'5'} = X_{g^+} J'_{g^+} + X_{g^-} J'_{g^-} + X_t J'_t$$

$$[3] \quad {}^3J_{4'5''} = X_{g^+} J''_{g^+} + X_{g^-} J''_{g^-} + X_t J''_t$$

The relative populations for the g^+, t, and g^- modes are 23%, 59%, and 18%, respectively. Assignment of protons H(5′) and

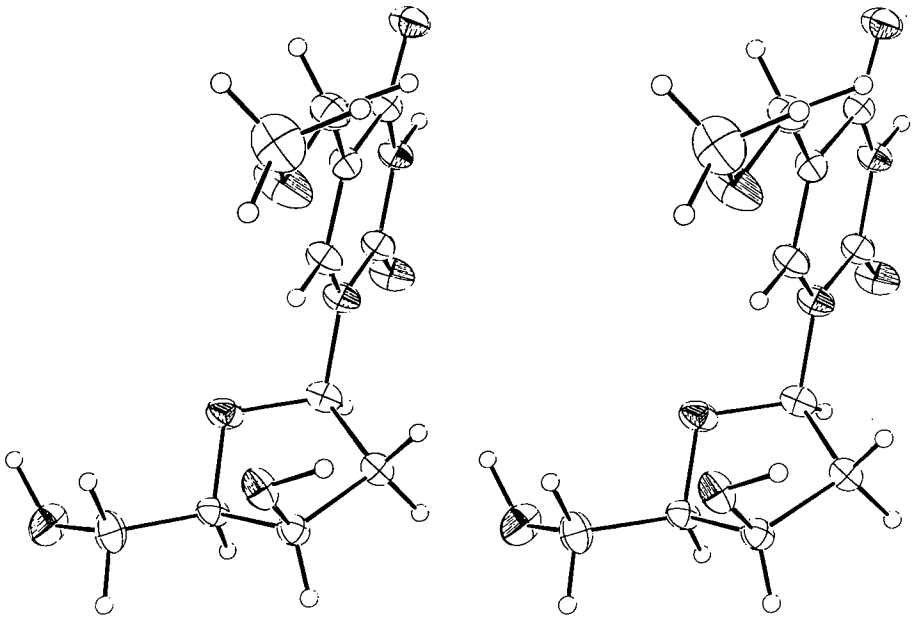

FIG. 2. Stereoscopic view of MMdLU.

H(5″) was done according to Remin and Shugar (27). The reverse assignment leads to values of 29%, 13%, and 58%, respectively. In contrast, the biologically active epimer MMdUrd exists predominantly in the g^+ mode (14). The strong destabilization of the g^+ mode in MMdLU is typical for nucleosides having the 3′-OH group cisoidal to the exocyclic C(5′) group (27). Most likely this is due to the steric and/or electrostatic effects of the cisoidal configuration.

The nmr signal for C(2) is a form of a doublet with $J_{C(2),H(6)}$ = 8.8 Hz but $^3J_{C(2),H(1')}$ is not resolved. The value of the latter coupling constant can be estimated to be less than 2 Hz which is consistent with an *anti* conformation about the glycosidic bond. The relationship between the 5-methoxymethyluracil and furanose rings seems to be independent of whether the 3′-OH group is *endo* or *exo*.

The two hydrogens of the methylene in the 5-methoxymethyl substituent have different chemical shifts. However, since both protons of the methylene group have the same coupling constant with H(6), the methoxy group does not seem to have any preference to be on one particular side of the pyrimidine ring. The anisotropic effects are stronger in MMdLU than in its epimer because the methoxy group is closer to the sugar moiety in MMdLU.

Experimental

5-Methoxymethyl-1-(2′-deoxy-β-D-lyxofuranosyl)uracil

Epimerization at the 3′-carbon was accomplished using the procedure described previously for thymidine (28, 29). Methanesulfonyl chloride (0.94 mL, 12.4 mmol) was added to a cooled solution of 2.0 g (3.4 mmol) of 5-methoxymethyl-5′-triphenylmethyl-2′-deoxyuridine (7) in 20 mL of pyridine at 4°C and the solution was stirred for 16 h. Water (0.4 mL) was added and after stirring for 1 h, the reaction mixture was added dropwise to ice-water. The precipitate was dissolved in 70 mL of $CHCl_3$, washed successively with 0.1 *M* HCl, 5% $NaHCO_3$, and dried over Na_2SO_4. The solvent was removed *in vacuo* and the amorphous powder (2.2 g) was dissolved in a solution of 60% ethanol–water containing 1 equiv. of NaOH. The reaction mixture was stirred at room temperature for 16 h to yield the O^2,3′-cyclic intermediate monitored by the disappearance of the 265

nm peak and the appearance of shoulders at 231 and 255 nm (29). After addition of 2 equiv. of NaOH, the mixture was refluxed for 5 h, cooled, the pH adjusted to 5 with HCl, and the solvent was evaporated *in vacuo*. The gummy residue was triturated with water and filtered. The amorphous power was added to 20 mL of 80% acetic acid and incubated at 50°C for 2 h to remove the trityl group. After chilling, triphenylmethanol was removed by filtration. The solvent was evaporated and crystallization from absolute ethanol gave 0.7 g of *5-methoxy-1-(2′-deoxy-β-D-lyxofuranosyl)uracil* (yield 75%); mp 155–156°C; uv (0.1 *M*, phosphate buffer, pH 7.0) λ_{max} 264 nm (10,300). *Anal.* calcd. for $C_{11}H_{16}O_6N_2$: C 48.52, H 5.93, N 10.29; found: C 49.15, H 6.10, N 10.36.

X-ray crystallography

Suitable crystals were obtained from a saturated solution of MMdLU in methanol/ethyl acetate over a period of one month. The colorless crystals of MMdLU, empirical formula $C_{11}H_{16}O_6N_2$ have the space group $P2_1$ with a = 8.719(4), b = 13.188(3), c = 5.701(3) Å, β = 109.56(2)°, V = 6.77 Å^3, Z = 2, μ = 10.4 cm^{-1}, observed density = 1.44 g cm^{-3}, calculated density = 1.46 g cm^{-3}. Quantitative data collection was done on an ENRAF-NONIUS CAD4F Diffractometer with an ω/2θ scan and Ni-filtered copper radiation (λ = 1.5418 Å). Three standard reflections were checked every 5000 s for intensity variations and every 100 reflections for orientation. The maximum variation of the intensity standard was 3.1%. There was no significant decay of the crystal over the entire data collection. The octants ±*h*, *k*, *l* were measured. Observational weights for the reflections were derived from

[4] $w = 1/\sigma((F_0))^2$.

The crystal was 0.825 × 0.375 × 0.150 mm in size and exhibited the forms (101), (010), (001), (031), and (100). A total of 2768 reflections were collected out to θ = 70°; of 1224 unique reflections, 1208 had net $I > 2\sigma(I)$. X-ray data were processed and the structure was solved using the XTAL83 system (30) using atomic scattering factors from Cromer and Mann (31). All four figures of merit by GENTAN were used to choose the best set of phases in the structure determination (RFOM = 1.04, RFAC = 0.12, PSIO = 0.79, NEGQ = 96, and CFOM = 0.83). All 19 nonhydrogen atoms in the molecule were found on the *E* map.

Least-squares isotropic refinement gave an *R* value of 0.117. Anisotropic refinement was then carried out and gave an *R* value of 0.068. The positions of the hydrogen atoms were located by using a difference Fourier map. Finally, full-matrix least-square refinement of anisotropic temperature factors for the non-hydrogen atoms and isotropic refinement for the hydrogen atoms converged to an *R* index of 0.040. The quantity minimized in refinement was $\Sigma W\Delta F^2$.

[5] $R = \Sigma||F_0| - |F_c||/\Sigma|F_0|$

[6] $R_w = [\Sigma w\Delta F^2/\Sigma wF_0^2]^{1/2}$

[7] $S = [\Sigma w\Delta F^2/(m - n)]^{1/2}$

R_w was 0.059 and S was 4.1. The largest and average shift/error ratios

for the parameters in the final cycle of refinement were 0.47 and 0.014, respectively. A final difference Fourier map showed a largest peak of 0.23e. A stereoscopic representation of the molecule is shown in Fig. 2 and all final coordinates are given in Table 6.* A VAX 11/780 computer at the University of Saskatchewan was used to carry out all crystallographic computations.[2]

Nuclear magnetic resonance spectroscopy

The nmr experiments were carried out using a Brucker CXP300 spectrometer. Spectra were recorded in the Fourier transform mode at 26°C. Solutions were made to a concentration of 0.2 M in D_2O. Chemical shifts were measured relative to internal trimethylsilyl propanesulfonic acid, sodium salt (TSP) for ^1H and relative to tetramethylsilane (TMS) in a concentric capillary for ^{13}C. ^1H nmr spectra were simulated with the aid of the LAOCOON III program and final coupling constants have a precision of 0.1–0.2 Hz.

Synthèses, réactivité et études structurales en série thiophéno[*b*]homotroponique

BERNARD HANQUET ET ROGER GUILARD[1]

Laboratoire de synthèse et d'électrosynthèse organométallique associé au Centre national de la recherche scientifique (Unité associée 33), Faculté des sciences « Gabriel », 6, Boulevard Gabriel, 21100 Dijon, France

Recù le 26 avril 1985[2]

B. HANQUET et R. GUILARD. Can. J. Chem. **64**, 1360 (1986).

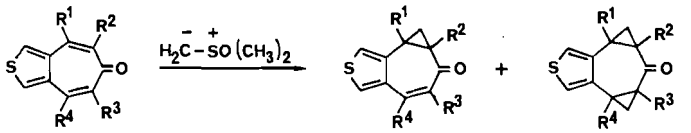
Les thiophéno[*b*]mono et bishomotropones sont préparées par action du méthylure de diméthylsulfoxonium sur les thiophéno[*b*]tropones. La position, la nature des substituants du carbocycle et le solvant réactionnel sont les paramètres qui gouvernent l'évolution de la réaction de cyclopropanation. La structure des monohomotropones obtenues est établie en mettant en oeuvre des analogues deutériés et l'analyse des spectres rmn des thiophéno[*b*]bishomotropones permet de préciser la configuration *cis* ou *trans* des composés bishomotroponiques. La réduction, selon Clemmensen, de ces dérivés livre des cycloocta et cyclonona[*b*]thiophénones dont la structure est déterminée par rmn à deux dimensions.

B. HANQUET and R. GUILARD. Can. J. Chem. **64**, 1360 (1986).

Thiopheno[*b*]mono and bishomotropones are readily synthesized from thiopheno[*b*]tropones and dimethyloxosulfonium methylide. The position, the nature of the seven-membered ring substituents, and the reaction medium are the most important parameters of the cyclopropanation reaction. The structure of the monohomotropones is established by comparison with deuteriated analogues. The *cis* or *trans* configuration of the bishomotropones is determined by nmr data analysis of the corresponding alcohols. Clemmensen reduction leads to cycloocta or cyclonona[*b*]thiophenones. The structure of the latter is proved by 2D nmr.

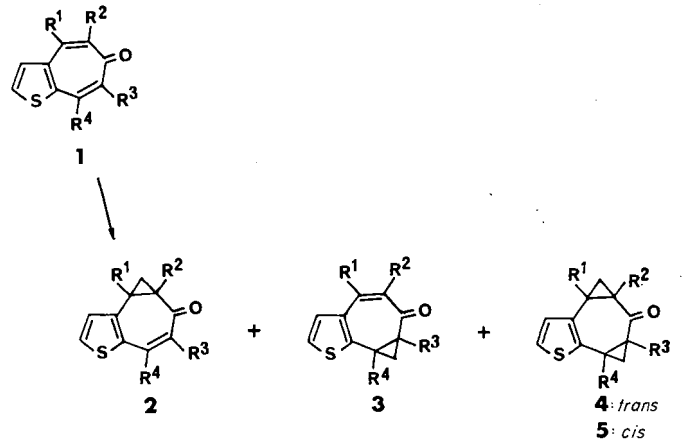
Introduction

Dans un mémoire précédent (1), nous avons décrit les modalités d'accès aux thiophéno[*c*]mono et bishomotropones et examiné les problèmes liés à la détermination de leur structure. La préparation de ces composés est réalisée avec de bons rendements (jusqu'à 87%) par condensation du méthylure de diméthylsulfoxonium sur les thiophéno[*c*]tropones. Le bilan réactionnel peut être résumé selon le schéma suivant :



cis/trans

Lors des recherches effectuées dans cette série nous avons montré que le nombre et la nature des thiophéno[*c*]homotropones obtenues dépendaient pour l'essentiel du nombre, de la nature et de la position des substituants présents sur le carbocycle. Nous avons voulu étendre les résultats obtenus en série [*c*] à la série des thiophéno[*b*]homotropones pour laquelle l'asymétrie introduite par la position de l'atome de soufre entraîne, *a priori*, l'existence de deux thiophéno[*b*]monohomotropones isomères et pour laquelle subsistent les problèmes structuraux liés à l'isomérie *cis/trans* des systèmes bishomotroponiques.



Ce mémoire sera donc consacré à la synthèse, l'étude de la réactivité et la détermination structurale des thiophéno[*b*]homotropones. Nous montrerons que trois paramètres ont une incidence sur l'évolution de la réaction : la nature et la position des substituants présents sur le carbocycle, le rapport agent de cyclopropanation/substrat et le solvant réactionnel. Nous aborderons enfin quelques aspects de la réactivité des thiophénohomotropones synthétisées ayant trait à la présence du groupement carbonyle en envisageant l'action de réducteurs tels que l'hydrure double de lithium et d'aluminium et l'amalgame de zinc. Ces derniers résultats complètent ceux que nous avons publiés par ailleurs (2, 3) concernant l'action des agents protecteurs de la fonction carbonyle.

Synthèses

Le nombre et la structure des composés obtenus dépendent de la structure des thiophéno[*b*]tropones mises en oeuvre et des conditions opératoires. Les transformations sont conduites, sauf indication contraire, dans le *N,N*-diméthylformamide (DMF) à la température ambiante.

(1) *Influence des substituants du carbocycle*

Au départ de la thiophéno[*b*]tropone non substituée **1***a* il ne nous a pas été possible d'isoler d'homotropones, quelles que soient les conditions de température et de solvant. En revanche la thiophéno[*b*]tropone diméthylée **1***b* conduit à deux thiophéno[*b*]monohomotropones isomères **2***b* et **3***b*. Un analogue deutérié **1'***b* de **1***b* a été mis en oeuvre pour démontrer la structure des deux isomères. Lors de la réaction de cyclopropanation, aucun phénomène d'échange isotopique n'intervient.

Au départ des thiophéno[*b*]tropones triméthylées **1***c* et **1***d* une seule monohomotropone est obtenue. On retrouve ici un résultat déjà observé en série [*c*] : l'encombrement stérique de deux groupements méthyle vicinaux induit la formation de la monohomotropone la moins encombrée.

De même qu'en série [*c*] la présence de substituants électroattracteurs identiques sur le reste troponique ($R^2 = R^3 = CO_2C_2H_5$ ou Ph) conduit simultanément aux deux monohomo-

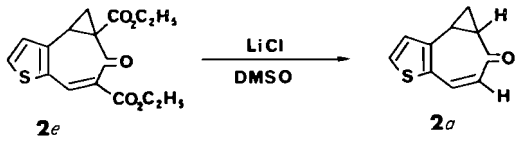
a. **5***f*: composé *cis*.

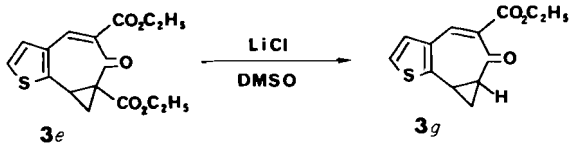
tropones isomères et à une bishomotropone de configuration *trans*. La cyclopropanation des analogues deutériés **1′***e*, **1′***f* et **1″***f* a été également réalisée.

Même si la température de la réaction est abaissée, les rendements en thiophéno[*b*]homotropones diester restent faibles (~33%) alors que la transformation des dérivés diphénylés s'effectue avec des rendements comparables à ceux obtenus en série [*c*] (~77%). Lorsque les deux thiophéno[*b*]monohomotropones sont obtenues, le composé **2** est souvent en quantité plus importante que son isomère **3**. La cyclopropanation de la double liaison située du côté de l'atome de soufre semble donc moins aisée. Les résultats sont en accord avec les caractéristiques rmn ^{13}C du substrat de départ. Ainsi dans le cas de la thiophéno[*b*]tropone **1***f* le déblindage plus important de C_4 (132,5 ppm) par rapport à C_8 (130,6 ppm) privilégie l'attaque du réactif sur ce sommet. Cependant la valeur faible de cette différence des glissements chimiques explique que les proportions relatives des isomères **2** et **3** sont parfois très voisines.[3] Le tableau 1 indique les différentes thiophéno[*b*]homotropones synthétisées (le tableau 5 de la partie expérimentale précise leurs proportions relatives).

Bien que la thiophéno[*b*]tropone **1***a* n'ait pu subir avec succès l'addition d'ylure de diméthylsulfoxonium, nous avons accédé à certaines thiophéno[*b*]homotropones non substituées au départ des homotropones diester. Ainsi, en présence d'un sel alcalin, le dérivé **2***e* livre la monohomotropone non substituée **2***a*. En revanche, et dans les mêmes conditions expérimentales, **3***e* conserve un groupement ester pour donner **3***g* :



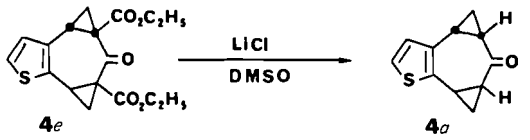
2*e* **2***a*



3*e* **3***g*

3. Une étude théorique par les méthodes de Hückel étendu et CNDO/4 est en cours. Les calculs portent essentiellement sur les intermédiaires résultant de l'addition de l'ylure sur les thiophéno[*b*]tropones et conduisant aux composés **2** et **3**.

La thiophéno[*b*]bishomotropone **4***e* conduit avec un bon rendement (61%) au dérivé non substitué **4***a* :



4*e* **4***a*

(2) *Influence du rapport ylure/tropone et du solvant réactionnel*

Le tableau 2 regroupe les résultats observés en faisant varier la quantité relative d'ylure mise en oeuvre et le solvant. Le substrat mis en jeu est la thiophéno[*b*]tropone diphénylée **1***f*.

Lorsque la réaction est effectuée dans le DMF et sur des quantités équimoléculaires (exp. 1), la transformation n'est pas totale et seules les deux monohomotropones isomères apparaissent. Lorsque la proportion d'ylure augmente (exp. 2), le dérivé bishomotroponique *trans* est obtenu simultanément avec les deux composés monohomotroponiques et le rendement global de la réaction est très voisin du précédent (76%). Si le solvant réactionnel est le DMSO (exp. 3), le mélange des monohomotropones n'apparaît qu'avec un rendement de 4% et le produit majoritaire est la bishomotropone *trans*. Il convient également de souligner que l'isomère *cis* apparaît simultanément (2%). Enfin, si la proportion d'ylure est plus importante (exp. 4), le rendement global diminue car l'on observe une dégradation partielle des produits de la réaction.

Ces constatations expérimentales suggèrent que la monohomotropone ne subit que difficilement une nouvelle attaque d'ylure de diméthylsulfoxonium dans le DMF même avec un rapport élevé de réactif. Un effet cinétique important est mis en évidence en substituant le DMSO au DMF. Dans ce cas la transformation est, pour des rapports de réactif comparables, beaucoup plus importante.

Action des reducteurs

Les réactions de réduction des thiophéno[*b*]homotropones ont été essentiellement étudiées au départ des composés diphénylés pour lesquels nous disposions du plus grand nombre de représentants. Deux types de réducteurs ont été mis en oeuvre : l'hydrure double de lithium et d'aluminium et l'amalgame de zinc en milieu chlorohydrique.

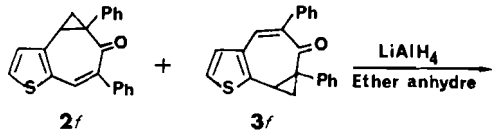
(1) *Hydrure double de lithium et d'aluminium*

Comme en série thiophéno[*c*]homotroponique, opposé à

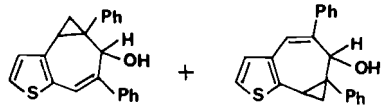
TABLEAU 2. Influence du rapport ylure/tropone et rôle du solvant

Exp.	Solvant réactionnel	Rapport ylure/tropone	Rendements en produits formés (ou récupérés) Tropone 1*f*	Monohomos 2*f* + 3*f*	Bishomo *trans* 4*f*	Bishomo *cis* 5*f*
1	DMF	1:1	8	75	0	0
2	DMF	5:1	0	51	25	0
3	DMSO	4:1	0	4	71	2
4	DMSO	5:1	0	0	74	0

l'hydrure double de lithium et d'aluminium, le mélange des thiophéno[*b*]monohomotropones, non séparées, conduit au mélange d'alcools attendus. Seuls les dérivés d'addition-1,2 sont obtenus :



2*f* **3***f*

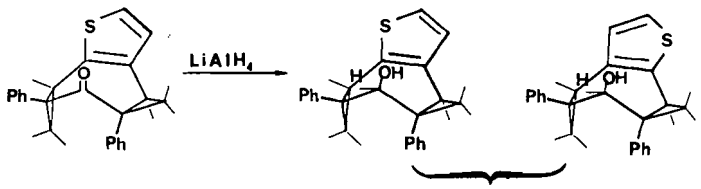


6*f* **7***f*

La réduction des thiophéno[*b*]bishomotropones procède également d'une addition-1,2. Mais au départ du composé **5***f* un seul alcool est obtenu, alors que deux alcools isomères en proportions voisines sont isolés au départ de **4***f*.

Nous avons déjà signalé dans un précédent mémoire (1) que l'on observait lors de la réduction des thiophéno[*c*]bishomotropones une très grande stéréosélectivité, un seul alcool étant obtenu au départ de chacune des thiophéno[*c*]bishomotropones *cis* et *trans*. Cette même stéréosélectivité conduit à un seul alcool au départ du composé *cis* **5***f* alors que deux alcools diastéréoisomères sont produits au départ de **4***f*.

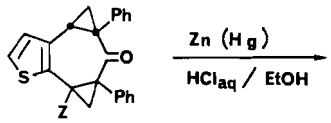
5*f* **9***f*



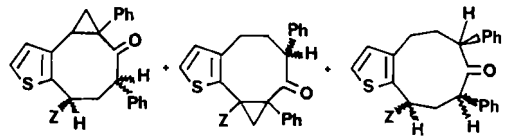
4*f* **8***f*

(2) *Amalgame de zinc*

La réduction selon Clemmensen (4) de la thiophéno[*b*]homotropone **4***f* conduit aux deux composés isomères **10** et **11** (non séparés) dans les proportions relatives de 40 et 60%. Ce résultat est observé pour un rapport zinc/substrat voisin de 40:1 mais si la quantité de réducteur est augmentée (100:1) on note également l'apparition d'une cyclonona[*b*]thiophénone **12**, dérivé ultime de la réaction de réduction.



4*f*: Z=H
4*f'*: Z=D



10 **11** **12**
10' **11'** **12'**

Ces résultats font clairement apparaître que pour la série de composés étudiés, l'hydrure double de lithium et d'aluminium ne conduit qu'à des dérivés d'addition-1,2 alors que par réduction selon Clemmensen seuls les produits d'addition-1,4 sont obtenus. Enfin, pour aucun des systèmes étudiés nous n'avons pu mettre en évidence la formation de thiophénohomotropilidènes.

Détermination des structures

La détermination de la structure des thiophéno[*b*]homotropones ou de leurs dérivés est rendue délicate en raison de l'absence de symétrie du substrat de départ. Ainsi pour les monohomotropones la position du cycle à trois chaînons ne peut généralement être établie que par comparaison du spectre du composé avec celui de son analogue deutérié. Pour les bishomotropones le recours à l'examen radiocristallographique a été nécessaire (5). L'analyse des spectres rmn à haut champ a permis de lever certaines incertitudes structurales.

(1) *Thiophéno[*b*]monohomotropones*

Les caractéristiques rmn de ces dérivés apparaissent dans le tableau 3. L'analyse des spectres de rmn protonique des deux thiophéno[*b*]monohomotropones triméthylées **2***c* et **3***d* (fig. 1) est très aisée : pour chaque composé les protons du motif cyclopropanique apparaissent sous la forme d'un système ABX. Il s'ensuit que le cycle à trois chaînons a été introduit au niveau de la double liaison la moins encombrée. Les deux spectres présentent par ailleurs des caractéristiques très proches tant pour les déplacements chimiques que pour les constantes de couplage. Les deux protons thiophéniques de **2***c* donnent un système AB classique alors que ces mêmes protons sont équivalents dans **3***d*.

L'analyse comparative des spectres de **2***b* et de son analogue deutérié **2'***b* (fig. 2) permet d'établir sans ambiguïté la structure de **2***b*. L'absence de proton éthylénique sur le spectre de **2'***b* et la disparition simultanée du couplage avec les protons du

a. $^5J_{H_3-H_7}$ = 0,50 Hz.
b. $^4J_{H_{4a}-H_6}$ = 1,70 Hz.
c. $^5J_{CH_3-CH_3}$ = 1,00 Hz.
d. $^5J_{H_3-H_7}$ = 0,72 Hz.
e. E = $CO_2C_2H_5$, Ph = C_6H_5.
f. $^5J_{H_3-H_7}$ = 0,89 Hz.

groupe méthyle voisin permet de fixer la position du cycle à trois chaînons du côté opposé à l'atome de deutérium.

Dans le cas des deux thiophéno[*b*]monohomotropones **2***e* et **3***e*, l'analyse des couplages à longue distance permet de conclure. Ainsi pour l'isomère **2***e* on note un couplage ^5J en « zig-zag » entre le proton thiophénique H_3 et le proton éthylénique H_7. Ce couplage n'apparaît pas dans le cas de **3***e* pour lequel la disposition des liaisons est telle que le zig-zag est « cassé ». L'analyse comparative des spectres de **2***e* et **2′***e* d'une part et **3***e* et **3′***e* d'autre part confirme cette attribution structurale (voir tableau 3).

(2) *Thiophéno[b]bishomotropones*

L'ensemble des données de rmn des thiophéno[*b*]bishomotropones figure dans le tableau 4.

Si les spectres de rmn des thiophéno[*c*]bishomotropones (1) présentent une grande symétrie tant pour les composés *cis* que pour leurs isomères *trans*, il n'en est plus de même pour les thiophéno[*b*]bishomotropones par suite de la dissymétrie intrinsèque à la série [*b*].

Le dérivé *trans* **4***f* présente deux systèmes AMX entre 1,0 et 3,0 ppm. Dans le même domaine de fréquence l'isomère *cis* **5***f* montre deux systèmes plus fortement couplés de type ABX. Cependant l'examen comparatif de ces données est insuffisant pour préciser la nature *cis* ou *trans* de ces thiophéno[*b*]bishomotropones. Aussi, nous avons analysé les spectres rmn des alcools dérivés. Leur examen comparatif (voir fig. 3) montre que deux alcools isomères sont isolés au départ de **4***f* alors qu'un seul alcool apparaît lors de la réduction de **5***f*.

(3) *Cycloocta et cyclonona[b]thiophénones*

L'examen comparatif des données de rmn des composés **10**, **11** et **12** et celles de leurs analogues deutériés **10′**, **11′** et **12′** a permis de préciser la structure de ces dérivés.

Dans le cas de la cyclonona[*b*]thiophénone **12** l'existence de

et des dihydro-4,4a 3b*H*-cyclopropa [3,4]cyclohepta[2,1-*b*]thiophénones-5, **3**

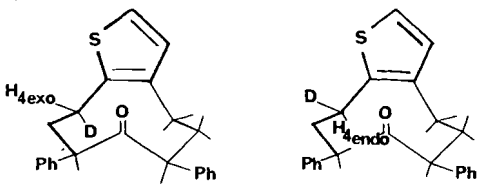
deux motifs —CH_2—CH_2—CHPh— inéquivalents et indépendants rend l'analyse spectrale délicate.

Le recours à un spectre COSY[4] est nécessaire pour préciser les connexions des dix protons inéquivalents. Nous avons fait figurer de part et d'autre de la diagonale les connexions relatives à chacun des deux systèmes de cinq protons (voir fig. 4).

Le spectre calculé[5] avec les valeurs mesurées sur le spectre à une dimension coïncide parfaitement avec ce dernier (voir fig. 5). Nous avons également fait figurer le spectre de **12'**, analogue deutérié de **12**. On constate ainsi :

(*i*) que les signaux des protons H_{4endo} et H_{4exo} sont tous deux concernés par la présence d'un atome de deutérium en position 4,



(*ii*) qu'il est possible d'assigner les deux motifs —CH_2—CH_2—CHPh— sur la base de la comparaison des deux spectres.

L'examen attentif des valeurs des constantes de couplage (voir partie expérimentale) permet de préciser la conformation

4. Le spectre COSY a été obtenu à l'aide du micro-programme BRÜKER COSY .AU. Paramètres introduits : 512 expériences; 32 signaux collectés; 4 signaux ignorés; deuxième dimension 2K; première dimension 1K; multiplication sinusoïdale déphasée de $\pi/10$ dans les deux dimensions; délai de recyclage 2 s; délai initial entre les deux impulsions : 3 μs; angles d'impulsion 90° et 90° (8 μs).

5. Programme de simulation PANIC (Bibliothèque BRÜKER). Largeur des raies : 0,5 Hz. Ce program est limité à 9 spins inéquivalents. On peut cependant dans notre cas scinder le calcul en traitant successivement deux systèmes *indépendants* de 5 spins non équivalents et en additionnant les deux sous-spectres ainsi obtenus.

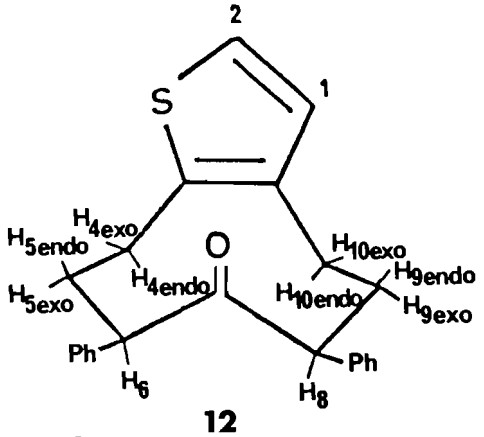
a. E = $CO_2C_2H_5$, Ph = C_6H_5.
b. $^4J_{H_3-H_{6a}}$ = 1,21 Hz.



12

$^3J_{H_{4endo}-H_{5endo}}$ = 7,29 Hz
$^3J_{H_{5endo}-H_6}$ = 12,38 Hz
$^3J_{H_{10endo}-H_{9endo}}$ = 7,47 Hz
$^3J_{H_{9endo}-H_8}$ = 12,34 Hz

privilégiée qu'adopte cette molécule. Pour l'un des motifs —CH_2—CH_2—CHPh—, un seul des cinq protons échange trois couplages importants et un couplage plus faible. Il s'agit nécessairement du proton H_{5endo}. En effet, outre la constante géminée (13,81 Hz) échangée entre ce proton et H_{5exo}, H_{5endo} présente deux couplages vicinaux importants (12,38 et 7,29 Hz) correspondant à des interactions diaxiales respectivement avec H_6 et H_{4endo}. Enfin la valeur peu élevée de la constante H_{5endo}–H_{4exo} (3,73 Hz) est attribuable à une interaction de type axial–équatorial. Un raisonnement identique peut être tenu à propos du proton H_{9endo} et la conformation privilégiée qu'adopte cette molécule peut alors être proposée et représentée selon le schéma ci-dessous.

Conclusion

La réactivité des thiophéno[*b*]tropones vis-à-vis du méthylure de diméthylsulfoxonium ne diffère pas fondamentalement de celle de leurs isomères [*c*]. La structure des thiophéno[*b*]monohomotropones obtenues découle de l'examen comparatif des spectres de rmn à champ moyen des composés et de leurs analogues deutériés. L'analyse spectrale à haut champ des produits de réduction a contribué à élucider les problèmes structuraux liés à l'isomérie *cis*/*trans* des systèmes bishomo-

3b*H*,5a*H*-dicyclopropa[3,4:6,7]cyclohepta[1,2-*b*]thiophénones-5, **4** et **5**

troponiques. L'action de l'amalgame de zinc conduit à des cycloocta et cyclonona[*b*]thiophénones dont la structure est déterminée par analyse des spectres de rmn à haut champ.

Partie expérimentale

Les analyses élémentaires ont été effectuées par le Service Central d'Analyse du C.N.R.S. Les spectres de rmn ^1H ont été enregistrés à 100 MHz sur un appareil JEOL FX 100 et à 400 MHz sur un appareil Brüker WM 400. Un échantillon de 5 mg est, sauf indication contraire, dissous dans 0,2 cm^3 de $CDCl_3$. Les déplacements chimiques sont donnés en ppm par rapport à $SiMe_4$ et les constantes de couplage en Hz (résolution digitale : 0,01 Hz). Les multiplicités sont indiquées comme suit : s (singulet), d (doublet), t (triplet), q (quadruplet), m (multiplet).

A. Matières premières

1. *Thiophéno[*b*]tropones*

Les thiophéno[*b*]tropones mises en oeuvre ont été préparées par les méthodes décrites dans la littérature (6) : cyclohepta[*b*]thiophénone-6, **1***a*, *F* = 94°C; diméthyl-5,7 cyclohepta[*b*]thiophénone-6, **1***b*, *F* = 83°C; triméthyl-5,7,8 cyclohepta[*b*]thiophénone-6, **1***c*, *F* = 73°C; triméthyl-4,5,7 cyclohepta[*b*]thiophénone-6, **1***d*, *F* = 80°C; oxo-6 cyclohepta[*b*]thiophéne dicarboxylate-5,7 de diéthyle, **1***e*, *F* = 103°C; diphényl-5,7 cyclohepta[*b*]thiophénone-6, **1***f*, *F* = 140°C (rmn ^{13}C, 100 MHz, δ ppm/TMS : 187,2 (CO), 132,5 (C4), 131,6 (C3), 130,6 (C8), 128,5 (C2).

2. *Thiophéno[*b*]tropones deutériées*

*Diméthyl-5,7 cyclohepta[*b*]thiophénone-6 (D-8), 1'*b

La préparation est identique à celle de son analogue non deutérié **1***b*. Au départ de diformyl-2,3 thiophène (CDO-3) (14 g, 100 mmol) et de 13 g (150 mmol) de pentanone-3 on isole 16,5 g (Rdt = 87%) de **1'***b*; *F* = 80°C. *Anal.* calc. pour $C_{11}H_9DOS$: C 69,08, H 4,74, D 1,05, O 8,37, S 16,77; trouvé : C 69,3, H 4,8, D 1,0, O 8,6, S 16,5.

*Oxo-6 cyclohepta[*b*]thiophène dicarboxylate-5,7 de diéthyle (D-8), 1'*e

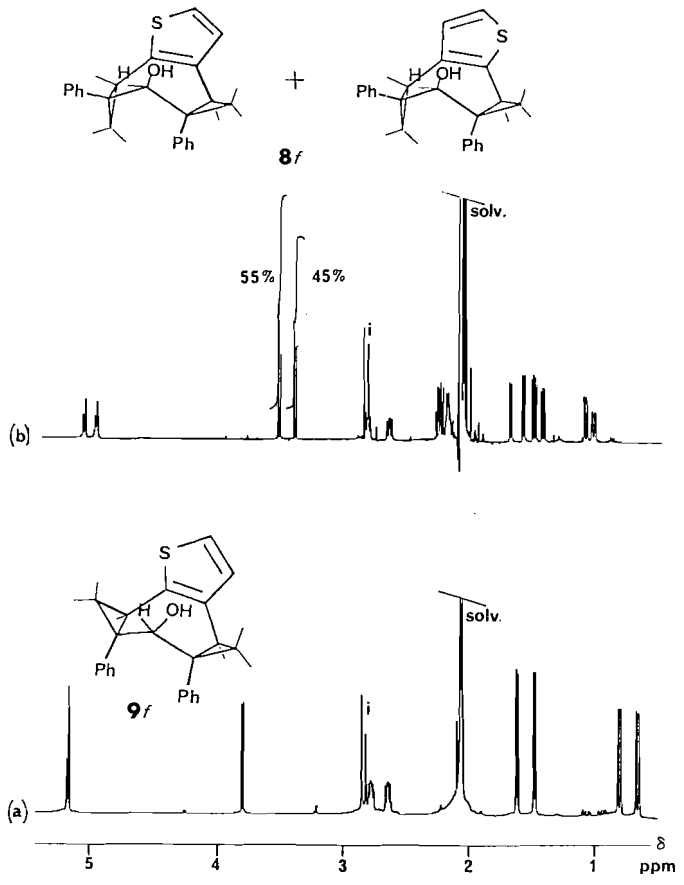

FIG. 3. Spectres rmn ^1H (400 MHz, $(CD_3)_2CO$) des thiophéno[*b*]-bishomotroponols; (a) **9***f*, (b) **8**. i : impureté du solvant deutérié.

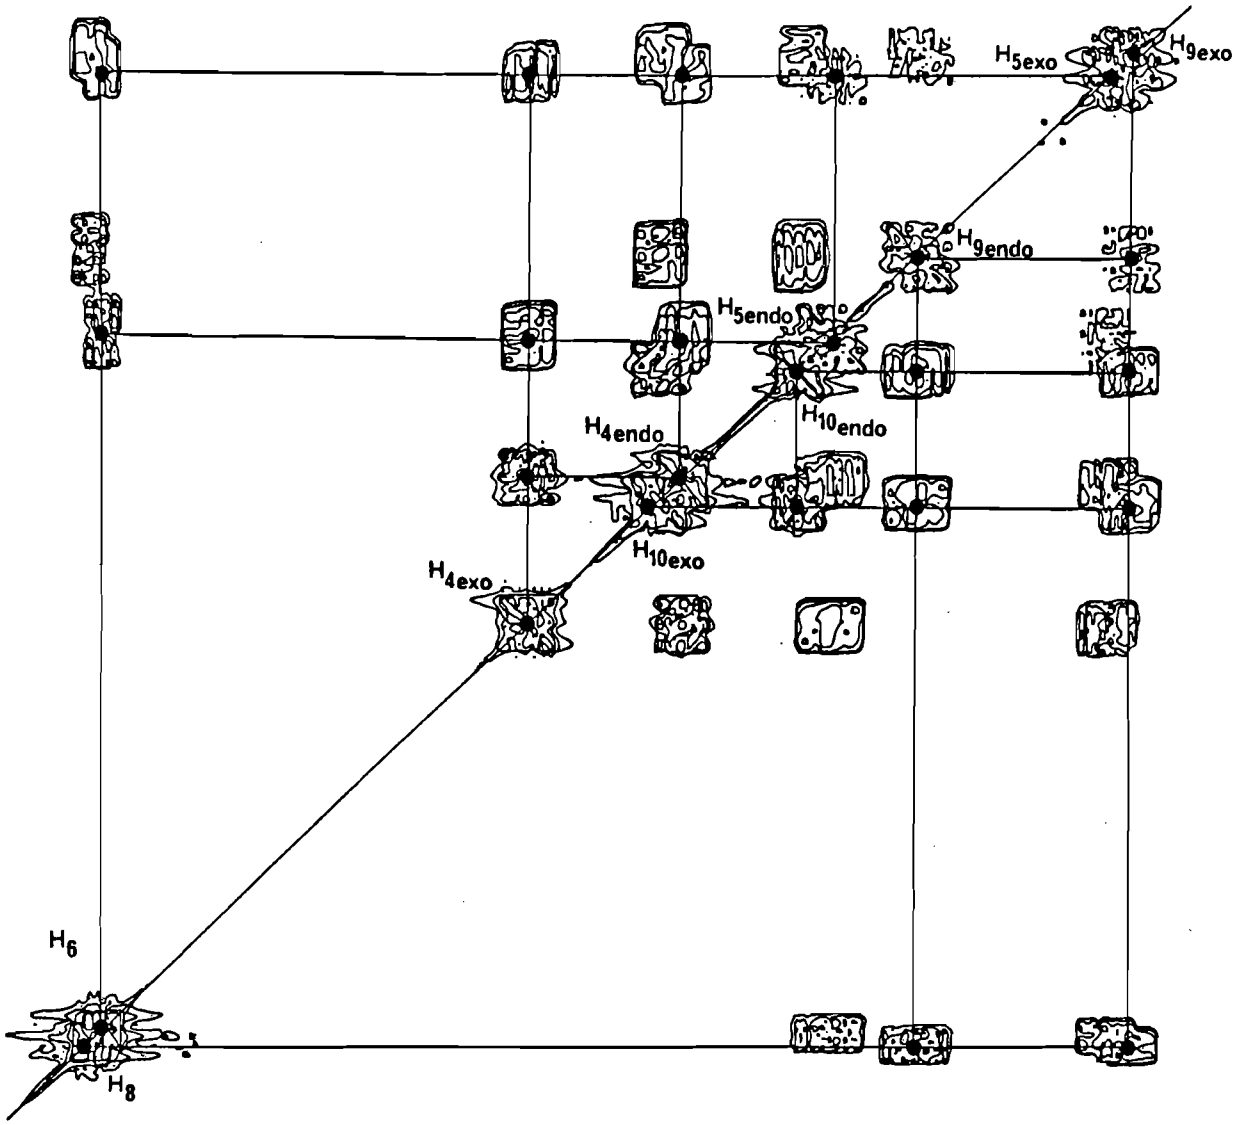

FIG. 4. Spectre COSY (400 MHz, $CDCl_3$) du composé **12** montrant les connexions des deux motifs —CH_2—CH_2—CHPh indépendants.

Dans les mêmes conditions que **1***e*, au départ de diformyl-2,3 thiophène (CDO-2), **1′***e* est obtenu avec un rendement de 78%; F = 103°C. *Anal.* calc. pour $C_{15}H_{13}DO_5S$: C 58,62, H 4,26, D 0,65, O 26,03, S 10,43; trouvé : C 58,6, H 4,2, D 0,6, O 26,2, S 10,5.

*Diphényl-5,7 cyclohepta[*b*]thiophénone-6 (D-8), 1′*f *et diphényl-5,7 cyclohepta[*b*]thiophénone-6 (D-4), 1″*f

On procède comme pour **1***f* respectivement au départ de diformyl-2,3 thiophène (CDO-2) ou (CDO-3) (Rdts = 79 et 68%); F = 138 et 138°C. *Anal.* calc. pour $C_{21}H_{13}DOS$: C 79,97, O 5,07, S 10,16; trouvé pour **1′***f* : C 80,5, O 5,1, S 10,0; trouvé pour **1″***f* : C 80,1, O 5,0, S 10,1.

*B. Cyclopropa et dicyclopropa cyclohepta[*b*]thiophénones-5*

Les thiophéno[*b*]homotropones ont été préparées dans des conditions voisines (voir tableau 5) qui ne seront détaillées que dans l'exemple suivant.

*Triméthyl-4a,6,7 dihydro-4,4a 3b*H*-cyclopropa[3,4]cyclohepta-[2,1-*b*]thiophénone-5,* **3***d*

À une suspension de 1,92 g (40 mmol) d'hydrure de sodium (50% dans l'huile minérale), préalablement lavée par trois fois 50 cm^3 d'éther de pétrole on ajoute 8,80 g (40 mmol) d'iodure de triméthylsulfoxonium (7) et 50 cm^3 de *N,N*-diméthylformamide (DMF). Après 1 h de contact l'ylure obtenu est filtré et additionné à une solution de 2,04 g (10 mmol) de **1***d* dans 50 cm^3 de DMF. Le milieu se colore progressivement en brun. L'agitation est poursuivie 12 h, puis le mélange est versé sur 200 cm^3 d'eau acidifiée (pH ~2). La phase aqueuse est extraite à l'éther et les phases organiques réunies sont lavées à l'eau jusqu'à neutralité, séchées sur sulfate de magnésium et les solvants sont évaporés. Le solide brut obtenu est chromatographié sur acide silicique (éluant : éther–hexane 1:2), puis recristallisé dans 40 cm^3 de ce même mélange de solvants. On obtient 1,57 g (Rdt = 72%) du composé **3***d*; F = 119°C.

Trois autres thiophéno[*b*]homotropones ont été obtenues par décarboalkoxylation des homotropones correspondantes selon les protocoles suivants :

*Dihydro-4,4a 3b*H*-cyclopropa[3,4]cyclohepta[1,2-*b*]thiophénone-5,* **2***a*

Au départ de 0,96 g (3 mmol) de **2***e* et 0,25 g de chlorure de lithium dans 60 cm^3 de DMSO à reflux on isole 0,25 g (Rdt = 47%) de **2***a*; F = 57°C; rmn δ (400 MHz) : 7,35 (d, H_2, J = 4,98 Hz), 7,13 (2d, H_3, J = 4,98 et 0,70 Hz), 6,91 (2d, H_7, J = 12,57 et 0,70 Hz), 5,94 (2d, H_6, J = 12,57 et 1,70 Hz), 2,60 (3d, H_{3b}, J = 8,41, 9,02 et 6,98 Hz), 2,54 (4d, H_{4a}, J = 8,41, 9,19, 6,28 et 1,70 Hz), 1,93 (3d, H_{4exo}, J = 9,02, 9,19 et 4,60 Hz), 1,47 (3d, H_{4endo}, J = 6,98, 6,28 et 4,60 Hz). *Anal.* calc. pour $C_{10}H_8OS$: C 68,15, H 4,58, O 9,08, S 18,20; trouvé : C 68,3, H 4,6, O 9,2, S 18,1.

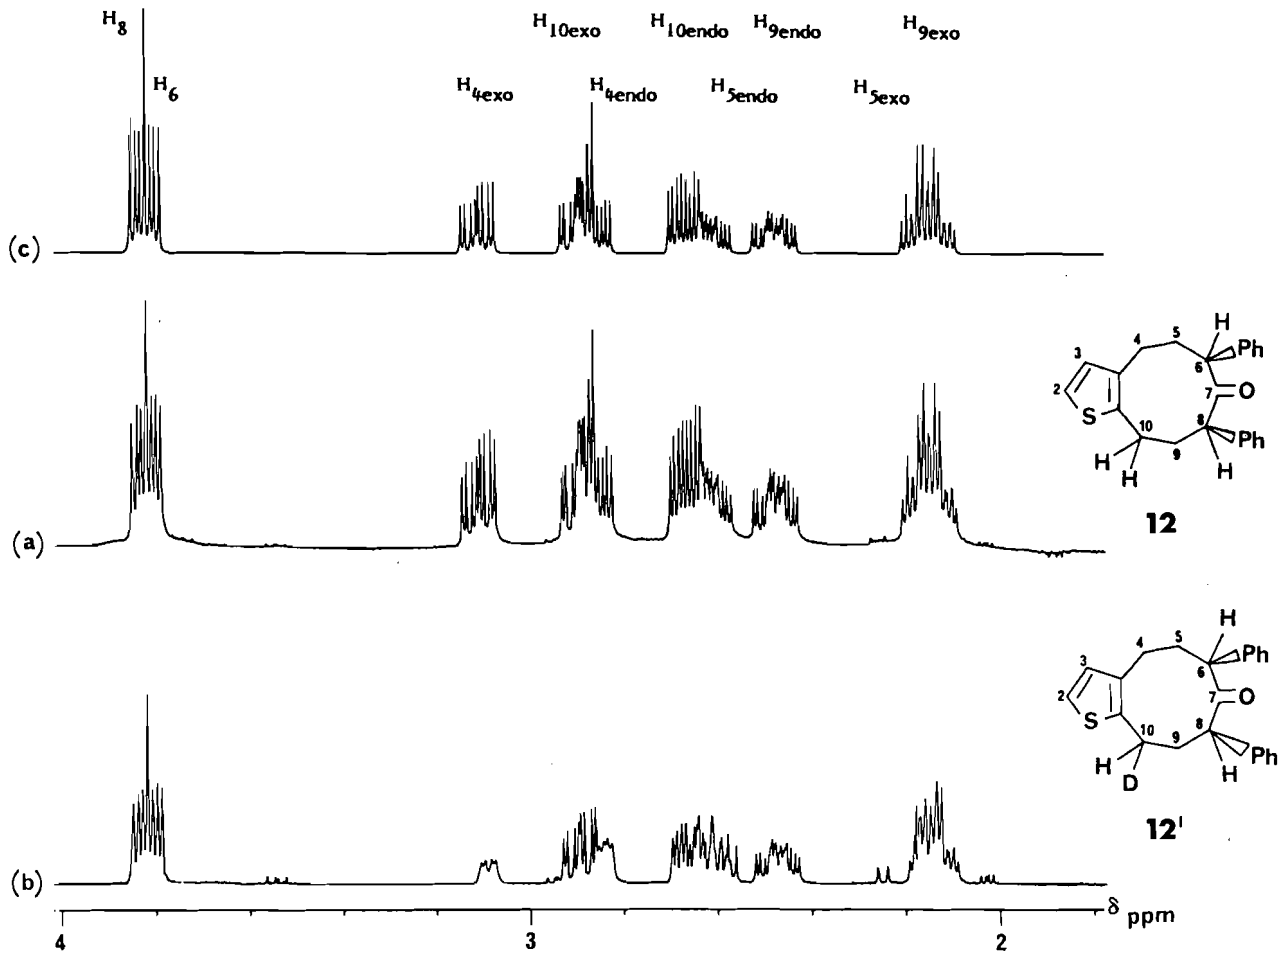

FIG. 5. Spectres rmn ^1H (400 MHz, $CDCl_3$) : (a) du composé **12**; (b) de **12'**, analogue deutérié de **12**; (c) spectre calculé de **12**.

*Oxo-5 dihydro-4,4a 3b*H-*cyclopropa[3,4]cyclohepta[2,1-*b*]thiophènecarboxylate-6 d'éthyle, 3*g

Au départ de 0,18 g de **3***e*, 0,05 g de chlorure de lithium et en opérant comme précédemment on isole 0,09 g (Rdt = 43%) de **3***g*. Ce composé a été uniquement caractérisé par son spectre de rmn protonique; rmn δ (400 MHz) : 7,72 (s, H_7), 7,07 (d, H_2, J = 5,35 Hz), 7,00 (d, H_1, J = 5,35 Hz), 4,29 (q, —OCH_2—, J = 7,08 Hz), 2,91 (3d, H_{3b}, J = 8,99, 8,51 et 6,63 Hz), 2,75 (3d, H_{4a}, J = 8,99, 8,62 et 6,92 Hz), 1,97 (3d, H_{4exo}, J = 8,51, 8,62 et 5,38 Hz), 1,93 (3d, H_{4endo}, J = 6,63, 6,92 et 5,38 Hz).

trans *Tétrahydro-4,4a,6,6a 3b*H,*5a*H-*dicyclopropa[3,4:6,7]cyclohepta[1,2-*b*]thiophénone-5, 4*a

Le composé **4***a*, 1,83 g (6 mmol) et 0,51 g (12 mmol) de chlorure de lithium conduisent après 2 h de chauffage à reflux dans 120 cm^3 de DMSO à 0,70 g (Rdt = 61%) de **4***a*; F = 88°C. *Anal.* calc. pour $C_{11}H_{10}OS$: C 69,44, H 5,30, O 8,41, S 16,85; trouvé : C 69,8, H 5,3, O 8,4, S 16,3. Les caractéristiques rmn de ce composé apparaissent dans le tableau 3.

*C. Dérivés de reduction des cyclopropa et dicyclopropa cyclohepta[*b*]-thiophénones-5*

*1. Cyclopropa et dicyclopropa[*b*]thiophène-ols-5*

*Diphényl-4a,6 dihydro-4,4a 3b*H-*cyclopropa[3,4]cyclohepta[1,2-*b*]thiophène-ol-5, 6*f *et diphényl-4a,6 dihydro-4,4a 3b*H-*cyclopropa[3,4]cyclohepta[2,1-*b*]thiophène-ol-5, 7*f

À une suspension de 0,76 g (20 mmol) de $LiAlH_4$ dans 40 cm^3 d'éther anhydre on ajoute goutte à goutte à 0°C une solution de 1,64 g (5 mmol) du mélange **2***f* + **3***f*. Après 2 h de contact l'excès d'hydrure est détruit par 2 cm^3 d'eau. Le précipité formé est filtré et lavé par trois fois 10 cm^3 d'éther. Les phases éthérées sont lavées, séchées et le solvant est évaporé. On obtient 1,3 g (Rdt = 80%) du mélange **6***f* + **7***f*; rmn δ (400 MHz, $(CD_3)_2CO$) : 7,20–7,50 (M, 24H arom.), 4,92 (d, C*H*OH (**6***f*), J = 5,08 Hz), 4,88 (d, C*H*OH (**7***f*), J = 5,13 Hz), 3,93 (d, CHO*H* (**7***f*), J = 5,13 Hz), 3,92 (d, CHO*H* (**6***f*), J = 5,08 Hz), 2,93 (2d, H_{3b} (**7***f*), J = 5,93 et 9,81 Hz), 2,26 (2d, H_{3b} (**6***f*), J = 6,09 et 10,07 Hz), 1,75 (2d, H_{4endo} (**7***f*), J = 4,00 et 5,93 Hz), 1,71 (2d, H_{4endo} (**6***f*), J = 4,09 et 6,09 Hz), 1,06 (2d, H_{4exo} (**7***f*), J = 4,00 et 9,81 Hz), 1,01 (2d, H_{4exo} (**6***f*), J = 4,09 et 10,07 Hz).

trans-*Diphényl-4a,5a tétrahydro-4,4a,6,6a 3b*H,*5a*H-*dicyclopropa[3,4:6,7]cyclohepta[1,2-*b*]thiophène-ol-5, 8*f

Au départ de 2,00 g de **4***f* (5,85 mmol) et de 1,14 g de $LiAlH_4$ (30 mmol) on isole 1,52 g (Rdt = 76%) de **12***f*; F = 110°C; rmn δ (400 MHz, $(CD_3)_2CO$) : 7,1–7,6 (M, 24H arom.), 5.05 (d, CHO*H*, J = 7,08 Hz), 4,96 (d, CHO*H*, J = 7,32 Hz), 3,52 (d, C*H*OH, J = 7,08 Hz), 3,39 (d, C*H*OH, J = 7,32 Hz), 1,0–3,0 (M, 12H aliph.). *Anal.* calc. pour $C_{23}H_{20}OS$: C 80,19, H 5,85, O 4,65, S 9,31; trouvé : C 80,2, H 5,9, O 4,6, S 9,2.

The internal rotational potential in benzyl chloride

TED SCHAEFER, RUDY SEBASTIAN, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2
Received December 2, 1985

TED SCHAEFER, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **64**, 1372 (1986).

The ^{1}H nmr spectra of benzyl chloride in dilute CS_2 and acetone-d_6 solutions are analyzed. The long-range coupling constants are consistent only with a low-energy conformation in which the C—Cl bond lies in a plane perpendicular to the benzene plane. Geometry optimized computations at the STO 3G level of molecular orbital theory agree with this conclusion and yield a nearly pure twofold barrier to internal rotation of 8.6 kJ/mol. In CS_2 solution the long-range couplings yield 8.8 kJ/mol, rising to 11.2 kJ/mol in acetone solution. This increase in the internal barrier in a polar solvent is similar to that found for benzyl fluoride, but in the latter the barrier itself is very much smaller than in benzyl chloride.

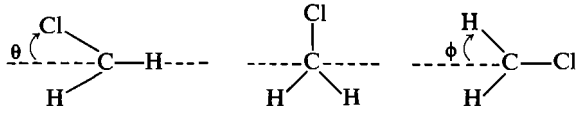
TED SCHAEFER, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **64**, 1372 (1986).

On a analysé les spectres rmn du ^{1}H du chlorure de benzyle qui ont été déterminés dans des solutions diluées de CS_2 et d'acétone-d_6. Les constantes de couplage à longue distance ne sont en accord qu'avec une conformation de basse énergie dans laquelle la liaison C—Cl serait dans une plan perpendiculaire au plan du benzène. Des calculs optimisés de la géométrie, effectués au niveau STO 3G de la théorie des orbitales moléculaires, sont en accord avec cette conclusion et conduisent à une barrière binaire pratiquement pure, de 8,6 kJ/mol, pour la rotation interne. Cette augmentation de la barrière interne dans un solvant polaire est semblable à celle qui a été observée dans le cas du fluorure de benzyle; toutefois, dans ce dernier cas, la barrière elle-même est beaucoup plus faible que dans le cas du chlorure de benzyle.

[Traduit par la revue]

Introduction

Early Raman (1) and Kerr constant (2) data implied that **1** is the low-energy conformer of benzyl chloride in solution, while an infrared and Raman spectral study apparently detected all three conformers (3). For the 3,5-dichloro derivative in benzene-d_6 solution the long-range proton–proton coupling constants were interpreted to mean that **2** is of lowest energy and that the internal barrier to rotation, assumed twofold, was 8.8 ± 1.7 kJ/mol (4).



1 **2** **3**

The electron diffraction pattern of benzyl chloride in the gas phase was consistent with essentially **1** as the average structure or with **2** and a concomitant twofold internal barrier to rotation of 6.3 kJ/mol (5). Reconsideration of the data suggested that V_2 is nearer 8.8 kJ/mol (6). Recent ^{1}H nmr spectra of benzyl chloride dissolved in two nematic phases are consistent only with conformer **1**, apparently to the exclusion of **2** and **3** (7). It was stated, however, that independent information about the shape of the potential function for internal motion was required for a more rigorous discussion.

In this paper we report extensive geometry optimized STO 3G MO calculations for the internal potential of benzyl chloride. The ^{1}H nmr spectra in CS_2 and acetone-d_6 are analyzed in order to investigate solvent perturbations of the internal barrier.

Experimental

A 2.5 mol% solution of benzyl chloride in CS_2, containing 10 mol% of C_6D_{12} and 0.5 mol% of TMS, was transferred to a 5-mm od nmr tube. The solution was degassed by several cycles of the freeze–pump–thaw technique and the nmr tube was flame-sealed. The same treatment was given to a 2.2 mol% solution of benzyl chloride in acetone-d_6, which also contained 0.5 mol% TMS.

The ^{1}H nmr spectra were accumulated at a probe temperature of 300 K and at 300 MHz on a Bruker AM300 spectrometer. Wide sweepwidths referenced the spectra with respect to TMS. Each spectral region was examined in detail, the sweepwidth and data region being adjusted to give acquisition times of about 40 s. The digital resolution was about 0.025 Hz. Four to sixteen scans were acquired. Zero filling to twice the original data region was done before transforming the FIDs using a small amount of gaussian multiplication. The linewidths at half height were approximately 0.04 Hz. STO 3G MO (9) computations employed the computer program MONSTERGAUSS (10) and utilized an Amdahl 470/V8 system. INDO and CNDO/2 computations (11, 12) were also done on this system.

Results and discussion

Spectral analyses

These were done with a locally modified version of the computer program NUMAR1T (13). The spectral parameters are collected in Table 1, where they are compared with those obtained (14) from a self-assigning analysis of an ^{1}H nmr spectrum at 100 MHz for a 20 mol% solution in acetone. Considering that the linewidth at half height of the peaks in the latter spectrum was 0.148(2) Hz, compared to the ca. 0.04 Hz at 300 MHz, the agreement between the parameters is very good. However, the small long-range couplings are expected to be more accurately given by the present analyses because of the larger number of resolved splittings observable in the spectra at 300 MHz.

Figure 1 displays the observed and calculated spectra of the methylene protons in CS_2 solution.

STO 3G MO calculations

When all bond angles and lengths were allowed to vary, with the proviso that the carbon framework of the benzene moiety remained a regular hexagon, the relative energies of the conformers could be fit by eq. [1]. The angle θ is 90° for **2** above

$$[1]\quad V(\theta)/\text{kJ mol}^{-1} = 8.58 \pm 0.01 \sin^2(\theta + 90°) - 0.24 \pm 0.01 \sin^2 2\theta$$

[g]Because the linewidth in this spectrum was 0.15 Hz, these long-range couplings are probably considerably less reliable than those in the other columns, extracted from spectra with linewidths of about 0.04 Hz.

and seven values were used in the fit, the errors being given at the 95% confidence level. The completely optimized structure of the low-energy conformer **2** is shown in Fig. 2.

According to these computations the barrier is predominantly twofold, with a very small fourfold component. In the discussion below of the long-range couplings, the internal barrier will be taken as twofold.

Long-range couplings and the internal potential

(i) CS_2/C_6D_{12} solution

It has been demonstrated that $^6J(H,CH_2) \equiv {}^6J$ is directly proportional to $\sin^2\phi$, where ϕ is the angle by which the C—H bond of the sidechain twists out of the benzene plane (15–17). If the value of ^6J is known at $\phi = 90°$, then the observed ^6J yields the expectation value, $\langle\sin^2\phi\rangle$. The latter can be related to the twofold barrier by a hindered rotor model (17). A recent precise analysis of the ^{1}H nmr spectrum of toluene yields ^6J as −1.204(4) Hz at $\phi = 90°$ (8).

However, the magnitude of this number decreases in the presence of electronegative α-substituents. Recent detailed studies of benzyl fluoride (18) and benzyl methyl ether and some derivatives (19) show that ^6J is −1.02 Hz for a CH_2OR group at 90° and is −0.95 Hz for CH_2F. The assumption of a linear dependence of ^6J on the electronegativity of the α-substituent yields ^6J as −1.06 Hz for CH_2Cl if the chlorine substituent has an electronegativity of 3.0 on the scale for which fluorine is placed at 3.92, OR at 3.31, and H at 1.78 (20–22).

Because ^6J is −0.358(1) Hz in CS_2 solution, $\langle\sin^2\phi\rangle$ follows

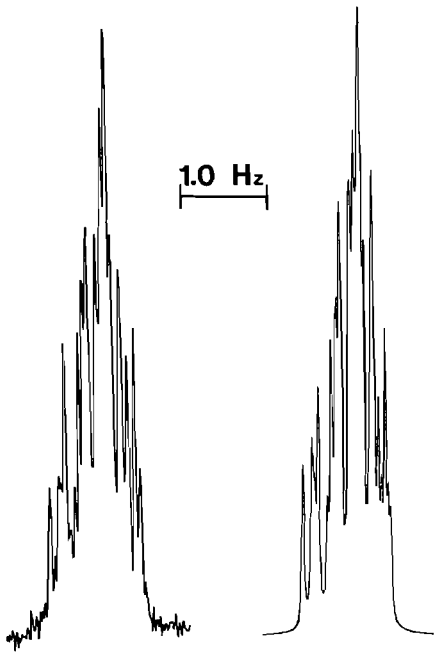

FIG. 1. The observed and computed ^{1}H nmr spectra of the methylene protons of benzyl chloride, for a 2.5 mol% CS_2 solution containing 10 mol% of C_6D_{12} and 0.5 mol% of TMS. The probe temperature is 300 K and the spectrometer frequency is 300.135 MHz. The linewidth at half height is between 0.03 and 0.04 Hz. The computed spectrum is based on the parameter values in Table 1.

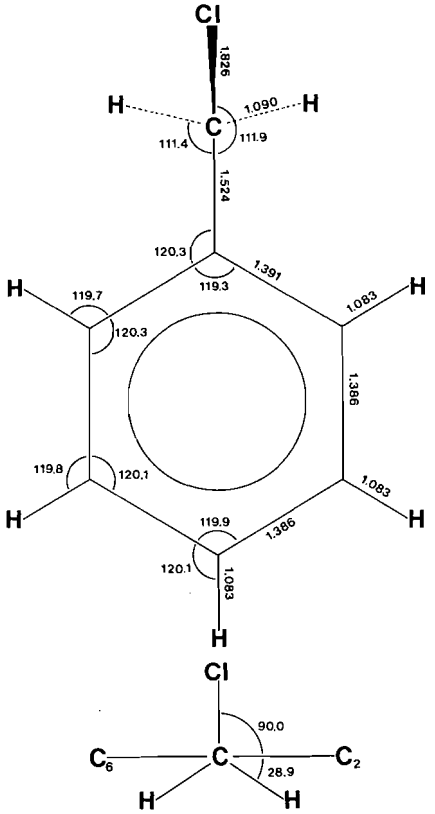

FIG. 2. The fully optimized structure of the stable conformer of benzyl chloride at the STO 3G level of molecular orbital theory. Its energy is −720.475480 au. The C(1)—C(α) bond makes an angle of 0.2° with the C(1)—C(4) axis. When the C—Cl bond lies in the benzene plane, the C(1)CCl angle increases to 114.75° and the C(2)C(1)C(α) angle is computed to increase also, to 123.2°. Therefore steric strain is indicated as at least one contribution to the internal barrier of rotation about the sp^2–sp^3 bond.

as 0.358/1.06 or 0.338. This value corresponds to a V_2 of 8.8 ± 0.4 kJ/mol in a table relating $\langle \sin^2 \theta \rangle$ to V_2, the temperature, and to the reduced moment of inertia of benzyl chloride (23), *if* it is assumed that the conformation of lowest energy is **2**. The quoted error assumes an error of 0.01 Hz in ^6J at $\phi = 90°$. This barrier in CS_2 solution agrees rather well with the 8.6 kJ/mol calculated by STO 3G MO methods above. Furthermore, it coincides with the 8.8 kJ/mol deduced by Scharfenberg from the electron diffraction data for the vapor (6). The average torsional angle associated with this barrier corresponds, not to 60° as in **1**, but to 67.5° (6). Such an average is also compatible with a hindered rotor model (24).

The dipole moment of benzyl chloride is 1.74 D in decalin (25) and is reported as 1.75–1.89 D in benzene solution (26). INDO MO computations for the STO 3G MO geometries give 2.21 D for **2** and 2.18 D for **3**, whereas the STO 3G MO values are 2.66 and 2.42 D, respectively. Both sets of data suggest an increase in the dipole moment as the C—Cl bond twists out of the ring plane but are clearly overestimates of the dipole moment magnitudes. Assuming a dipole moment of 1.7 D for **3** and 1.9 D for **2**, the dielectric continuum model (27), and allowing for the polarizability of the solute predicts an increase of at most 0.3 kJ/mol in the stability of **2** relative to **3** when benzyl chloride is dissolved in CS_2. The same model predicts a stabilization of **2** in acetone by about 0.5 kJ/mol, rather less than found below.

(ii) Acetone-d_6 solution

In this solution, ^6J is −0.337 (1) Hz and V_2 becomes 11.2 ± 0.4 kJ/mol, an increase of 2.4 ± 0.8 kJ/mol relative to the CS_2 solution. It happens that the J method (17) for internal barriers is most sensitive in this region of barrier magnitudes. The increase of 2.4 kJ/mol is reliable because its value is insensitive to the value taken for ^6J at $\phi = 90°$. Furthermore, a detailed study of long-range $^{13}C,^{19}F$, $^1H,^{19}F$, and $^1H,^1H$ couplings of benzyl fluoride in a range of solvents established that the conformer analogous to **2** became 2 kJ/mol more stable than that analogous to **3** when passing from CS_2 to acetone solution (18). It may also be noted that the dipole moment of benzyl fluoride (28) is equal to that of benzyl chloride within experimental error.

The notable difference between the two compounds is that the internal barrier in benzyl fluoride must be very small, probably less than 1 kJ/mol in CS_2 solution (18). Therefore the change in internal barrier caused by the polar acetone solvent is apparently independent of the intrinsic barrier, implying that for benzyl chloride the low-energy conformer **2** is being stabilized by the polar solvent and probably leaving the high-energy form **3** (steric barrier?) unchanged (see Fig. 2).

*(iii) **1** cannot be of lowest energy*

The discussion above assumes **2** as the stable conformer. However, suppose **1** were stable, as deduced from a classical approach to the ^1H nmr spectra in nematic solvents (7). For this conformer $\langle \sin^2 \phi \rangle$ is $(\sin^2 60° + \sin^2 0°)/2$ or 0.375, assuming that the barrier is not so high that averaging of the two ^6J values is prevented. Then ^6J becomes -1.06×0.375 or −0.398 Hz. Any internal motion in conformer **1** will cause this number to change towards −0.53 Hz because, in the limit of free internal rotation, $\langle \sin^2 \phi \rangle$ equals 0.5. Because the observed ^6J values are well below 0.398 Hz in magnitude, **1** cannot be the preferred conformer for benzyl chloride in CS_2 or acetone solutions. Only if ^6J at $\phi = 90°$ were less than 0.90 Hz in magnitude in CS_2 solution, would **1** be stable, and then only if the barrier in **1** were very large indeed.

(iv) Concerning $^5J(H,CH_2)$ and $^4J(H,CH_2)$

The orthobenzylic coupling in toluene has been written as (29)

$$[2] \quad {}^4J(H,CH_2)/Hz = -1.08 \sin^2 \phi - 0.32 \cos^2 \phi$$

For toluene the expectation values of $\sin^2 \phi$ and $\cos^2 \phi$ are both 0.5, so that ^4J should be −0.70 Hz, precisely as found in a recent analysis (8). It was also shown (29) that ^4J decreases in magnitude as the electronegativity of the α-substituent increases, at least for acenaphthene derivatives in which the substituent has a fixed orientation with respect to the π plane of the aromatic system.

If the multiplier of $\sin^2 \phi$ represents the σ–π or hyperconjugative term in the coupling mechanism, then it may be reasonable to assume a reduction in its magnitude in the same proportion suffered by ^6J, a sole σ–π coupling. If this assumption is correct, then it follows from the −0.518 Hz for ^4J in the CS_2 solution of benzyl chloride that the term in $\cos^2 \phi$ must also be reduced, by a factor of 0.92. For the acetone solution the calculated ^4J becomes −0.494 Hz, somewhat different from the observed −0.483 Hz.

Whatever the merit of the assumptions in this discussion, qualitatively it is clear that ^4J should be smaller in magnitude in acetone than in CS_2 solution, simply because ^4J is dominated by the $\sin^2 \phi$ term in eq. [2] and its expectation value is smaller in the acetone solution because **2** is stabilized. In other words, the

observed changes in ^4J and ^6J are both consistent with an increased V_2 in acetone solution if **2** is the stable conformer.

Turning to ^5J, it has been postulated (8) to obey eq. [3] for toluene.

[3] $^5J(H,CH_2) = 0.336\langle\sin^2\phi\rangle + 0.322\langle\sin^2(\phi/2)\rangle$

The first term represents the $\sigma-\pi$ term and in benzyl chloride should also be reduced, presumably by a factor of 1.06/1.20. It is not known whether the σ electron term, in $\sin^2(\phi/2)$, increases or decreases in the presence of an electronegative α-substituent.

An electronegative *ortho* substituent increases the σ electron component of ^5J, for example in 2,6-difluorotoluene (30). If the ^5J of 0.287 Hz for benzyl chloride in CS_2 solution is to be reproduced by an equation like [3], then the α-chlorine substituent must increase the σ electron term. One might write $^5J = 0.287 = 0.336(1.06/1.20)(0.338) + 0.322(0.5)R$ because for a twofold barrier $\langle\sin^2(\phi/2)\rangle$ is 0.5. The factor R becomes 1.16. Application of this factor to the acetone solution yields 0.281 Hz as compared to the observed 0.280(1) Hz.

In other words, the observed decrease of ^5J in going from the CS_2 to the acetone solution is interpreted to arise from the decreased $\sigma-\pi$ component in the latter, the σ electron term being a constant whatever the value of R. Qualitatively, this interpretation is consistent with the behaviour of ^4J and ^6J in the two solvents.

(v) Concerning the barrier in 3,5-dichlorobenzyl chloride

In benzene-d_6 solution, $^6J(H,CH_2)$ is $-0.40(1)$ Hz (4). It was assumed (4), on the basis of arguments now known to be incorrect, that ^6J at $\phi = 90°$ was -1.14 ± 0.02 Hz, from which it followed that 8.8 ± 1.7 kJ/mol represented the internal barrier to rotation. The value of $-1.06(1)$ Hz for the extremum of ^6J yields an internal twofold barrier of 5.7 ± 0.9 kJ/mol.

In CS_2 solution, V_2 is 8.8 ± 0.4 kJ/mol for benzyl chloride. The difference of 3.1 ± 1.3 kcal/mol is most likely real because, for benzyl fluoride, a variety of coupling data show that the conformer analogous to **3** is stabilized by 2 kJ/mol by chlorine substituents at the two *meta* positions. In other words, because **2** is the most stable conformer of benzyl chloride, the two *meta* chlorine substituents *lower* the internal barrier. The stabilization of the conformer with the halogen substituent in-plane may well be very similar for benzyl chloride and benzyl fluoride if intramolecular dipole interactions are responsible; the dipole moments of the two compounds are so very similar. Yet, it is interesting that the in-plane conformer of benzenethiol is also stabilized by *meta* chlorine substituents (31). The barrier in benzenethiol is presumably dominated by conjugative interactions.

Conclusions

In CS_2 solution the only reasonable interpretation of the long-range proton coupling constants in benzyl chloride is that the conformation of lowest energy is the one in which the C—Cl lies in a plane perpendicular to the benzene ring. The derived twofold internal barrier is in agreement with that computed by STO 3G MO methods and with the latest treatment of electron diffraction patterns. In acetone-d_6 solution the barrier increases by about 2 kJ/mol, according to the long-range couplings.

A recent discussion of the vibrational spectra of liquid benzyl chloride (32) concludes that the internal barrier is sixfold with an upper magnitude of 16.0 kJ/mol.

Motion about the C_{sp^2}—S bond in thioanisole and some derivatives by the *J* method

TED SCHAEFER AND JAMES D. BALEJA[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 21, 1986

TED SCHAEFER and JAMES D. BALEJA. Can. J. Chem. **64**, 1376 (1986).

Conformations about the C_{sp2}—S bond in thioanisole and eight of its derivatives in solution are investigated by means of long-range spin–spin coupling constants over six bonds between the sidechain ^{13}C nucleus and the *para* ring proton or ^{19}F nucleus. According to geometry optimized STO 3G MO calculations the internal barrier to rotation is predominantly twofold in the gas phase in thioanisole and is 6.2 kJ/mol. In benzene solution the coupling constant yields 5.5(4) kJ/mol. *Para* fluorine and methyl substituents reduce the magnitude of the internal barrier, but *meta* methyl or chlorine substituents cause significant increases. In the presence of two *ortho* fluorine substituents the conformation of lowest energy has the C—S bond in a plane perpendicular to the aromatic plane, but the barrier may now contain a fourfold component. Addition of further fluorine substituents in the *meta* or *para* positions causes characteristic changes in conformational preferences of the thiomethyl group.

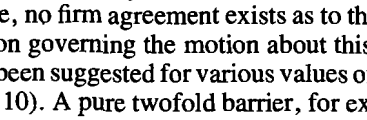
TED SCHAEFER et JAMES D. BALEJA. Can. J. Chem. **64**, 1376 (1986).

En se basant sue les constantes de couplage à longue distance à travers six liaisons entre les noyaux ^{13}C de la chaîne latérale et le proton ou un noyau ^{19}F en position *para* du cycle, on a étudié les conformations autour de la liaison C_{sp2}—S du thioanisole et de huit de ses dérivés en solution. Dans le cas du thioanisole en phase gazeuse et d'après des calculs d'OM au niveau STO 3G effectués sur des géométries optimisées, la barrière interne à la rotation est principalement binaire et s'élève à 6,2 kJ/mol. En solution dans le benzène, l'évaluation faite sur la base de la constante de couplage est égale à 5,5(4) kJ/mol. La présence de substituants fluor ou méthyle en position *para* réduit l'amplitude de la barrière interne; toutefois, la présence de substituants chlore ou méthyle en position *méta* provoque une augmentation importante de cette valeur. En présence de deux substituants fluor en position *ortho*, la conformation de plus basse énergie comporte une liaison C—S dans un plan qui est perpendiculaire au plan aromatique; toutefois, dans ce cas, la barrière peut maintenant contenir une composante quaternaire. L'addition d'autres substituants fluor en position *méta* provoque des changements des changements caractéristiques dans les préférences conformationnelles du groupement thiométhyle.

[Traduit par la revue]

Introduction

Although most experimental and theoretical methods (1–10) agree that the low energy conformation of thioanisole has all heavy atoms coplanar, the estimates of the barrier to rotation about the C_{sp2}—S bond vary from 1 kJ/mol (10) to 26 kJ/mol (2). Furthermore, no firm agreement exists as to the form of the potential function governing the motion about this bond, *local* minima having been suggested for various values of θ between 0 and 90° in **1** (3, 10). A pure twofold barrier, for example, has a



1

maximum at 90°, as would a barrier consisting of twofold and fourfold terms if the latter is relatively small. If it is substantial, then a local minimum can occur at 90°.

In thiophenol, in which the internal barrier is determined by $3p...\pi$ conjugation across the C—S bond, the potential hindering rotation is adequately described as twofold (11–13). In thioanisole, modification of such a simple form may be caused by interactions of the methyl group with, say, the *ortho* C—H bonds.

In view of the present uncertainties concerning the shape and magnitude of the barrier governing motion about the C_{sp2}—S bond in thioanisole, it seems reasonable to apply an independent method to this problem.

It is known that certain long-range spin–spin coupling constants between sidechain and ring nuclei have a simple conformational dependence (14). For example, ^6J(H,H) in toluene is proportional to $\sin^2\theta$, where θ is the angle by which the C—H bond twists out of the benzene plane (15). In a benzyl compound, then, the expectation value of $\sin^2\theta$ can be calculated in terms of the hindering potential and the temperature via a hindered rotor model, or classically, if preferred. If the value of ^6J(H,H) is known at $\theta = 90°$, then the measured value of ^6J(H,H) for the compound yields the expectation value of $\sin^2\theta$ and hence the magnitude of the potential barrier, whose form is assumed in the model (14).

In thioanisole the coupling constant of choice is $^6J(^1H,^{13}C)$. It is calculated to obey a $\sin^2\theta$ law. In 4-fluorothioanisole, the useful parameter would be $^6J(^{13}C,^{19}F)$, again involving the ^{13}C nucleus of the methyl group. Some success has been had with the corresponding couplings in anisole derivatives as indicators of conformational preferences (16).

Accordingly, this paper reports on the use of $^6J(^1H,^{13}C)$ and $^6J(^{13}C,^{19}F)$ in the measurement of internal barriers in thioanisole and a number of its derivatives. STO-3G MO computations, using fairly full geometry optimization procedures, are employed to provide hints about the form of the internal potentials.

Experimental

Compounds

^{13}C enriched thioanisole and its 2,6-dichloro, 3,5-dichloro, 3,5-dimethyl, and sym-tetrafluoro derivatives were prepared by adding (17) iodomethane-^{13}C (99 at.%, MSD Isotopes) to a mixture of the appropriate commercial thiophenol and anhydrous K_2CO_3 in dry acetone. The products were identified by nmr and mass spectroscopies.

Pentafluoro- and 4-methylthiophenol were methylated by addition of dimethyl sulfate to the aqueous sodium thiolate.

The 2,6-dibromo, 2,6-difluoro, 2,4,6-trifluoro, 2,6-dibromo-4-fluoro, and 2,6-dibromo-4-methyl derivatives of thioanisole were prepared from the corresponding anilines by treatment of the aqueous diazonium hydrosulfate salt with cuprous methylmercaptide, as devel-

oped in this laboratory (18). Product identity was confirmed by ^{1}H,^{13}C,^{19}F nmr spectroscopies and by the mass spectra.

Sample preparation

Sampes for ^{1}H and ^{19}F nmr measurements were prepared by weight to consist of ca.2 mol% solutions in acetone-d_6 or benzene-d_6. Each solution was filtered through a pipette, containing cotton wool cleaned with CCl_4, into a 5-mm od nmr tube fitted with a ground-glass joint. Sample tubes were then degassed by at least five freeze–pump–thaw cycles and were flame-sealed.

Samples for ^{13}C nmr studies were prepared by volume or by weight as solutions in acetone-d_6 and were treated as above, except that 10-mm od sample tubes were employed.

Nuclear magnetic resonance measurements

^{1}H,^{13}C, and ^{19}F free induction decays were recorded on a Bruker WH90-DS spectrometer at a probe temperature of 305 K and at transmitter frequencies of 90.02, 84.70, and 22.63 MHz, respectively. The B_2 fields for multiple resonance experiments were calibrated with off-resonance techniques and could be regulated in 1-db steps (19). Some ^{1}H and ^{13}C nmr spectra were accumulated on a Bruker AM300 spectrometer when it became available in the later stages of the work.

In order to measure long-range couplings from protons to the ^{13}C nucleus of the methyl group, the INEPT pulse sequence was used (20). Other measurements used methods adequately described previously (16, 21). For the determination of very small splittings, resolution enhancement was obtained by multiplication with an increasing exponential function combined with a negative line broadening parameter, or by sine multiplication.

Computations

Ab initio molecular orbital calculations, using geometry optimization procedures, were performed at the STO-3G level (22) with the program MONSTERGAUSS (23). INDO MO FPT (24, 25) computations of spin–spin coupling constants employed the STO 3G optimized geometries. All computations were done with an Amdahl 470/V8 system.

Results and discussion

These were carried out with the programs LAME (26, 27) and NUMARIT (28) in iterative and non-iterative modes. Table 1 gives the ^{1}H nmr spectral parameters for thioanisole-α-^{13}C in benzene-d_6 solution. The ^{1}H nmr spectrum of unenriched thioanisole had previously been analyzed (21) and the comparison in Table 1 gives an indication of the precision obtainable. Figure 1 displays part of the nmr spectrum of the *meta* protons of the enriched compound.

Figures 2 and 3 illustrate how the signs of $^5J(^1H,^{13}C)$ and $^6J(^1H,^{13}C)$ were determined for 2,6-dichlorothioanisole. They are positive and negative, respectively, relatives to $^1J(^1H,^{13}C)$ in the methyl group. The latter is positive (29).

Figure 4 displays one of the four multiplets of the INEPT spectrum of the methyl ^{13}C nucleus in 2,6-dibromothioanisole. The large spacing arises from coupling to the *para* proton.

Table 2 gives the coupling parameters relevant to the discussion below.

The extrema in $^6J(^1H,^{13}C)$ and $^6J(^{13}C,^{19}F)$

In the equation $^6J = {}^6J_{90}\langle\sin^2\theta\rangle$, in which $^6J_{90}$ is the value of ^6J at $\theta = 90°$ and $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$ for a particular barrier, it is assumed that ^6J vanishes at $\theta = 0$. This assumption is valid for $^6J(^1H,^1H)$ couplings (14).

The assumption that $^6J(^1H,^{13}C)$ and $^6J(^{13}C,^{19}F)$ are proportional to $\sin^2\theta$ can be tested with INDO MO FPT calculations, which usually yield a reliable functional form of such long-range couplings even when the magnitudes of the couplings are not reproduced. For thioanisole, the calculations give $^6J(^1H,^{13}C)/Hz = -0.05 - 0.49\sin^2\theta$. As usual (15, 30, 31), the angle-independent term is taken as an artifact of the computation.

For 2,6-dichlorothioanisole, $^6J(^1H,^{13}C)$ is measured as −0.51(1) Hz and the barrier to internal rotation is calculated as 31.3 kJ/mol by STO 3G MO. Such a barrier, if twofold, corresponds to a $\langle\sin^2\theta\rangle$ of 0.96, suggesting a $^6J_{90}$ of −0.53 Hz. In 2,6-dibromothioanisole, $^6J(^1H,^{13}C)$ is −0.541(5) Hz. In this compound, the barrier to internal rotation must be larger than in the chloro derivative, so that −0.54 Hz appears as a reasonable approximation to $^6J_{90}$.

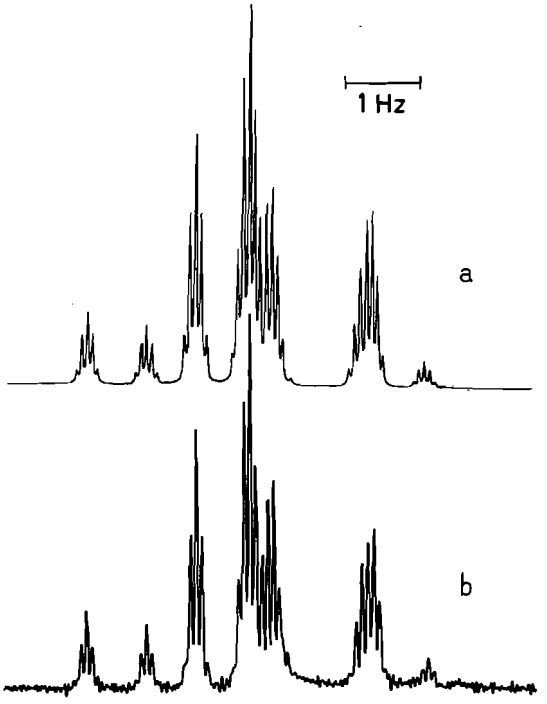

FIG. 1. Part of the *meta* ^{1}H nmr spectrum at 300 MHz and 300 K for a 1.7 mol% solution of thioanisole-α-^{13}C in benzene-d_6 solution. The smallest splittings in the observed spectrum in b are near 0.08 Hz and, according to the full analysis, are due to coupling over five bonds to the ^{13}C nucleus with a magnitude of 0.078(1) Hz. The quintet structure of some of the multiplets arises because the coupling over six bonds to the methyl protons also has a value near 0.08 Hz (see Table 1).

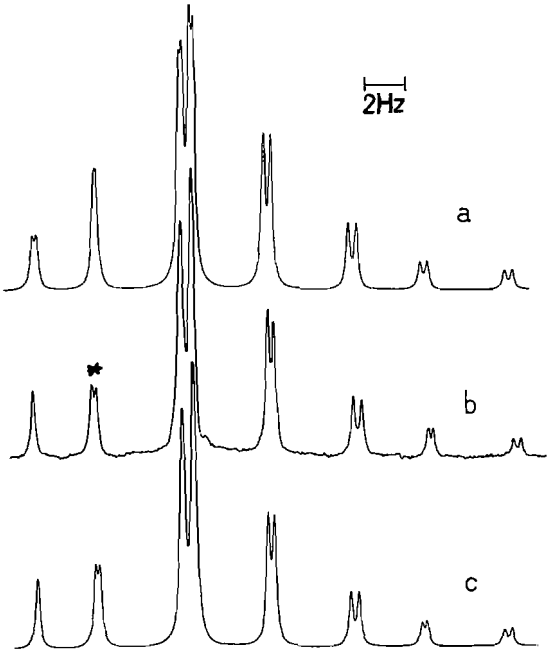

FIG. 2. The ^{1}H nmr spectrum of the ring protons of a 4 mol% solution of 2,6-dichlorothioanisole-α-^{13}C in acetone-d_6 at 300 K and 90 MHz is shown in b. In a the simulated spectrum has $^5J(^1H,^{13}C)/^6J(^1H,^{13}C)$ positive whereas in c this ratio is negative. Clearly, the couplings are of opposite sign. The band marked by an asterisk is shown with higher resolution in Fig. 3.

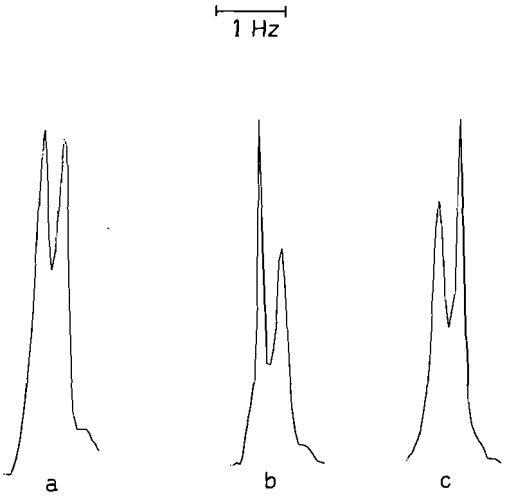

FIG. 3. In a is shown the band marked with an asterisk in Fig. 2, arising from the *meta* protons in 2,6-dichlorothioanisole-α-^{13}C. The peaks are broadened by coupling to the methyl protons. In b the methyl protons (those at high frequency) are being decoupled for one spin state of the ^{13}C nucleus, whereas in c the low frequency methyl proton band is being irradiated. The experiments show that $^1J(^1H,^{13}C)/^5J(^1H,^{13}C) > 0$.

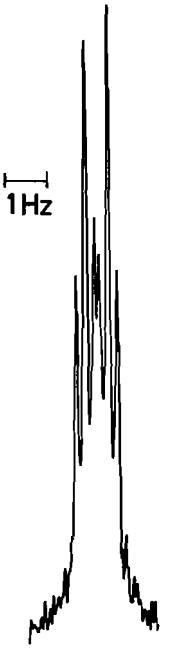

FIG. 4. One multiplet of the INEPT spectrum of the methyl ^{13}C nucleus of a 2 mol% solution of 2,6-dibromoanisole in acetone-d_6 at 300 K and 75.486 MHz. The large splitting arises from coupling to the *para* proton and is 0.541(5) Hz in magnitude. The triplets arise from a coupling of 0.217(5) Hz to the *meta* protons.

However, in a 2,6-dibromo-4-methylthioanisole, $^7J(^1H,^{13}C)$ becomes 0.606(5) Hz. If $^6J(^1H,^{13}C)$ is a pure σ–π coupling, then one expects that $^7J = -^6J$. Three possible reasons for the absence of this equality suggest themselves. First, it is known that a *para* methyl group decreases the $3p\ldots\pi$ conjugation in thiophenol and thereby decreases the twofold barrier by 1 kJ/mol (11). In the present thioanisole derivative the 4-methyl substituent would therefore further stabilize the $\theta = 90°$ conformation, leading to an increase in the magnitude of the hypothetical ^6J and therefore in ^7J. The observed increase of

[g]This is $^7J(^1H,^{13}C)$.
[h]Based on $^6J(^1H,^{13}C) = -0.56 \pm 0.02$ Hz at $\theta = 90°$ and $^6J(^{13}C,^{19}F) = 1.54 \pm 0.04$ Hz at $\theta = 90°$.
[i]These twofold barriers follow from tables of $<\sin^2\theta>$ as a function of the barrier, the temperature, and reduced moment of inertia (42).
[k]These barriers are based on the assumption of a twofold barrier. See text.
[l]Based on geometry optimized structures.

10% is really rather too large, however. Second, it is conceivable that ^6J contains a *positive* non σ–π component and, because ^7J measures only the σ–π component, its magnitude is then larger than that of ^6J. Thirdly,it is possible that for the present couplings the equality in magnitudes is not to be expected, it having been postulated and observed (32–34) originally for $^1H,^1H$ couplings. Yet, to within experimental error (16) the equality holds for the corresponding anisole derivatives.

In view of these uncertainties about the value of $^6J_{90}$ and because a value of −0.54 Hz holds only if the barrier in the bromo derivative is infinite, it shall be assumed that $^6J_{90}$ has a value of -0.56 ± 0.02 Hz in the derivation of barriers below, and can be compared to the -0.63 ± 0.01 Hz deduced for anisole (16). The magnitude of the latter would be expected to be larger because hyperconjugation would be more efficient in anisole, the shorter bond lengths leading to larger overlap integrals.

Turning to $^6J(^{13}C,^{19}F)$, its value in 2,6-dibromo-4-fluorothioanisole is 1.48(1) Hz, actually equal to that observed in the corresponding anisole derivative (16). The INDO MO FPT calculations again support a $\sin^2\theta$ dependence of this coupling, but underestimate its magnitude, as they do for $^6J(^{13}C,^{19}F)$ in 4-fluoroanisole (16) and for $^6J(^1H,^{19}F)$ in 4-fluorotoluene (15). In the absence of more definite information, $^6J_{90}$ will be taken as 1.54(4) Hz to allow for the finite barrier in the compound above. Furthermore, any possible ^6J at $\theta = 0$ will be ignored. The same assumption for anisole derivatives led to reasonable conformational deduction (16).

The form of the hindering potential

When bond lengths and angles are allowed to vary, with the constraint that the carbon network of the benzene ring remain a planar hexagon, the STO 3G MO energies can be fit by $V_2/\text{kJ} = (6.23 \pm 0.24)\ \sin^2\theta$ at the 95% confidence level. The geometries are optimized at 15° intervals in θ, giving seven values in all. If a fourfold potential is assumed to be present, one has $V/\text{kJ} = (5.95 \pm 0.18)\ \sin^2\theta + (0.43 \pm 0.17)\ \sin^2 2\theta$. Perhaps a small fourfold component, amounting to about 7% of the twofold, is present. However, such a magnitude of V_4 will alter $<\sin^2\theta>$ by very little, less than the uncertainty introduced by that in $^6J_{90}$.

For 3,5-difluorothioanisole, the STO 3G MO energies are reproduced by $V_2/\text{kJ mol}^{-1} = 8.84 \pm 0.26\ \sin^2\theta$. The increase in the calculated barrier relative to thioanisole is expected on the basis of the perturbational approach to molecular orbital theory (35) and parallels that observed (12) for V_2 in the corresponding thiophenols.

It will be assumed below that, in the absence of *ortho* substituents, the rotational barrier is adequately described as twofold.

For 2,6-difluoroanisole the computed energies are fit by $V/\text{kJ} = (9.7 \pm 0.6)\ \sin^2\phi - (2.7 \pm 0.6)\ \sin^2 2\phi$ where φ is zero when the methyl group lies perpendicular to the benzene plane. The expectation value of $<\sin^2\theta>$ is 0.788 for this potential and is 0.844 if a twofold barrier with a magnitude of 9.7 kJ/mol is assumed. Therefore, for some of the compounds below, a barrier derived on the basis of a twofold potential will contain an error to be discussed further below.

The derived barriers and conformations

Table 2 contains the magnitudes of the internal barriers to rotation about the C_{sp2}—S bond for thioanisole and eight of its derivatives.

(*i*) *Thioanisole*

The present STO 3G MO results indicate a predominantly twofold barrier in the gas phase, only a little higher than the 5.4(4) kJ/mol deduced for the benzene solution. The latter number implies that the barrier lies towards the low end of the range of some 25 kJ/mol in the values found in the literature. In some of these experiments, an angle θ is computed. Thus, from dipole moment and induced birefringence data in CCl_4 solution, θ is deduced as 23 ± 5° (1), in agreement with deductions based on X-ray fluorescence spectra (8) at liquid nitrogen temperature.

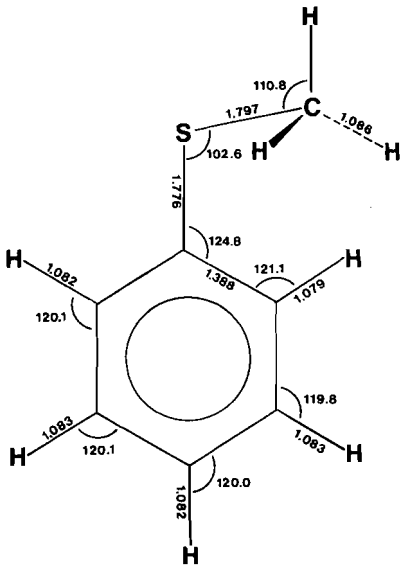

FIG. 5. The STO 3G MO geometry of the planar ground state of the thioanisole molecule with the carbon framework of the phenyl group as a regular haxagon. Note the deformation from 120° of the C2C1S angle, which becomes 120° of course for the perpendicular conformer. In the latter the C—S—C angle becomes 97.9° and the aromatic C—H bonds become 1.083 Å; the C_{sp2}—S bond increases to 1.787 Å and the C_{sp3}—S bond length becomes 1.803 Å. The electron diffraction structure (36) has a C—C bond length of 1.391(2) Å, a C_{sp2}—S bond length of 1.749(4) Å, and a C_{sp3}—S length of 1.803(4) Å. The C—S—C angle is 105.6(7)°, the S—C—H angle is 110.2(1.7)°, and the methyl group is apparently twisted out-of-plane by 45.3(2.8)°.

Electron diffraction patterns in the gas phase apparently fit a θ of 45 ± 10° (36). For a V_2 of 5.4(4) kJ/mol, the classical expectation value of θ is 27.6 ± 1.0° at 300 K, not very different from the value calculated (37) quantum mechanically from a hindered rotor model. A value of 45° is obtained for a zero barrier, of course. That out-of-plane populations are significant is also confirmed by nmr spectroscopy on thioanisole dissolved in liquid crystals (9).

Figure 5 gives the STO 3G MO structure for thioanisole in its lowest energy conformation. The figure caption compares the structure with that deduced from electron diffraction data and with the structure of the computed high energy form.

(ii) 4-Fluoro- and 4-methylthioanisole

Because the methylthio group is a π electron donor, the fluorine and methyl substituents act to decrease the $3p...\pi$ conjugation. If much of the barrier arises from this conjugation, as expected because the low-energy form is clearly planar, then the barriers to internal rotation in these two compounds should be lower than in thioanisole.

This decrease in V_2 is observed via the coupling constants and is also calculated by STO 3G MO methods (Table 2). A reduction of V_2 of thiophenol, caused by *para* fluorine or methyl substituents, has been noted (11).

The microwave barrier for 4-fluorothioanisole is 3.0 ± 1.0 kJ/mol and is based on the relative intensities of two band series in the low resolution spectrum in the gas phase at ambient temperatures (38). This value agrees with the 3.8(4) kJ/mol found in acetone solution in the present work.

(iii) 3,5-Dichloro- and 3,5-dimethylthioanisole

The increases in the internal barrier to rotation of the sulfhydryl group in the analogous thiophenols (relative to thiophenol) are the same as those found for the thioanisole in Table 2 (12). The change in the barrier caused by *meta* substituents has been discussed for the thiophenol derivatives in terms of perturbation molecular orbital theory and will not be repeated here. Qualitatively, the STO 3G MO barriers in Table 2 agree with the observed increases in barrier in solution for the two molecules.

(iv) 2,6-Difluorothioanisole

The two *ortho* fluorine substituents destabilize the planar (θ ± 0) conformation. In fact, $\langle\sin^2\theta\rangle$ becomes 0.75(2) in Table 2. If the barrier is purely twofold, then this number implies that the perpendicular (θ = 90°) conformation is of low energy and that the internal barrier is 5.9(8) kJ/mol. According to the STO 3G MO numbers, however, the magnitude of the fourfold component is about 30% of that of the twofold component. If a fourfold component exists, then a set of calculations of the classical expectation values of $\langle\sin^2\theta\rangle$ shows that the experimental value of 0.75 can be accommodated by a variety of combinations of twofold and fourfold potentials (note that the value of $\langle\sin^2\theta\rangle$ is not in question). If the restriction that $|V_4/V_2| \sim 0.3$ is applied, then 1.6/4.8 and −2.4/8.0 can be accommodated for V_4/V_2, for example.

In any event, it is clear that a significant barrier to internal rotation exists and that a given SCH_3 group spends much of its time nearer θ = 90° than θ = 0 at 300 K in acetone solution.

(v) Tri-, tetra-, and pentafluoro thioanisoles

When a *para* fluorine substituent is added to 2,6-difluorothioanisole, it is expected that the perpendicular conformer is further stabilized and that $\langle\sin^2\theta\rangle$ will increase, the *para* substituent causing a decrease in $3p...\pi$ conjugation. Although the errors in $\langle\sin^2\theta\rangle$ are rather large in Table 2, there is the consistency that V_2 drops by about 1 kJ/mol in moving from thioanisole to 4-fluorothioanisole, as it should because the planar conformer is stable for both compounds, whereas in moving from 2,6-difluoro- to 2,4,6-trifluorothioanisole an apparent increase occurs in $\langle\sin^2\theta\rangle$.

If two *meta* fluorine substituents are added to 2,6-difluorothioanisole, then by analogy to 3,5-dichlorothioanisole lower values of θ are expected to be more heavily populated. Indeed, the value of $\langle\sin^2\theta\rangle$ drops to 0.66(2), corresponding to an *apparent* V_2 of 3.3(7) kJ/mol.

Then, addition of one more fluorine substituent to tetrafluorothioanisole must again raise the magnitude of $\langle\sin^2\theta\rangle$. This occurs, to a value of 0.77(2), and it appears that a *para* fluorine substituent dominates the two *meta* substituents. Exactly the same phenomenon is observed for thiophenol derivatives in the sense that, although two *meta* chlorine substituents cause a remarkable increase in V_2, the addition of a *para* hydroxy substituent to 3,5-dichlorothiophenol brings V_2 back to a value similar to that in 4-methoxythiophenol (12). In terms of perturbation molecular orbital theory, it may be that the *para* substituent causes a first-order perturbation and, when it is present, the *meta* substituents are second-order perturbers. However, we have no more detailed interpretation of such a possibility.

Because of the rather large errors in the $\langle\sin^2\theta\rangle$ values for these fluorine derivatives, it is useful to have another set of parameters that substantiate the tentative conclusions about the conformational properties of these fluorine derivatives of thioanisole given in this section. Such a set is provided by $^5J(CH_3{}^{19}F)$, the long-range couplings between the methyl protons and the ^{19}F nuclei in the *ortho* C—F bonds.

The long-range $^5J(CH_3,{}^{19}F) \equiv {}^5J$

There is very little doubt that this coupling in anisole (16) and acetophenone (39) derivatives is a "through-space" (40) or proximate coupling. As such, its magnitude depends critically on the distance between the coupled nuclei. For ^5J in 2-fluoroacetophenone, for example, a semiempirical approach relates the magnitude of ^5J to $\cos^4\theta$, defined between $\theta = 0$ (methyl group *cis* to the C—F bond) and $\theta = 90°$ (39). In other words, ^5J decreases rapidly as the methyl group moves out of the benzene plane.

It appears eminently reasonable that ^5J in thioanisole derivatives is also a proximate coupling. If so, then it is arguable that, relative to its value in 2,6-difluorothioanisole, 0.746(5) Hz, its magnitude should decrease in 2,4,6-trifluorothioanisole because larger values of θ are now preferred. Indeed, ^5J is 0.588(1) Hz in the latter. Again, in 2,3,5,6-tetrafluorothioanisole the two *meta* substituents induce lower values relative to the 2,6-difluro derivative and ^5J increases to 0.907(2) Hz. The addition of a *para* fluorine substituent to yield the pentafluoro compound should now cause ^5J to drop. It does, to 0.722 Hz.

Quantitatively, the ^5J values support the arguments in the previous section concerning the degree of nonplanarity of the thiomethyl group. Indeed, if the V_2 values in Table 2 are used to calculate classical expectation values of θ, one finds a correlation coefficient of 0.903 (significant at the 90% confidence level) between ^5J and $\cos^4\theta$. The relationship implies a ^5J of 4.5 Hz at $\theta = 0$, a reasonable value. Of course, this correlation does not constitute a proof of the correctness of the barriers tabulated in Table 2, nor indeed that they are twofold. Parenthetically, the expectation value of 65° for θ in pentafluorothioanisole based on V_2 happens to agree with the conformational angle of 64 ± 5° deduced from Kerr constants (41) and X-ray fluorescence measurements (8).

Acknowledgments

We are grateful to Dr. James Peeling for the measurements on 4-fluorothioanisole and to the Natural Sciences and Engineering Research Council of Canada for financial support.

A study of chromium-exchanged zeolites as potential catalysts for thermolysis of water

K. M. MIEDZINSKA AND B. R. HOLLEBONE
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6
Received July 5, 1985[1]

K. M. MIEDZINSKA and B. R. HOLLEBONE. Can. J. Chem. **64**, 1382 (1986).

Evidence was found that the Cr(III)/Cr(II) redox cycle previously described to occur upon dehydration and rehydration of exchanged zeolite 13X, does not occur reversibly. Data suggest dimerization of the metal ion at high levels of exchange. The bridging provided by the oxygen atoms of the lattice probably stabilize these dimers and lead to initial but irreversible reduction at very low temperatures. Evidence also indicates irreversible formation of new lattices at very high dehydration temperatures.

K. M. MIEDZINSKA et B. R. HOLLEBONE. Can. J. Chem. **64**, 1382 (1986).

D'après des rapports antérieurs, les réactions de déshydratation et de réhydratation de réolites 13X échangées sont accompagnées d'un cycle rédox Cr(III)/Cr(II); on a trouvé que ce cycle ne se produit pas d'une façon réversible. Les données suggèrent que, à des niveaux élevés d'échange, il se produit une dimérisation de l'ion métallique. Le pontage qui est fourni par les atomes d'oxygène du réseau stabilise probablement ces dimères et, à des températures très basses, il conduit à une réduction initiale qui est irréversible. Les données indiquent aussi que, à des températures de déshydratation élevées, il se produit aussi une formation irréversible de nouveaux réseaux.

[Traduit par la revue]

Introduction

Amongst the many chemical systems which have been identified as potential systems for energy storage, metal ion doped zeolites which catalyse the thermolysis of water have been extensively studied (1–9). Both natural and synthetic zeolites absorb up to 30% by weight of water. The sites occupied by sodium ions and water bound within these lattices of various stoichiometries (10) have been characterized by crystallographic studies (1, 2, 4, 8) and infrared spectroscopy (3, 7, 11), epr (7) and nmr (12) as points of high symmetry in both the sodalite and supercages of the structure. These sites may be occupied by either aquated sodium ions or water but range in thermodynamic stability from the greatest in the sodalite cage to the least in the supercage as an approximate function of the availability of lattice oxygen binding sites at each position (13–15) (Fig. 1).

A large proportion of both the lattice sodium ions and water molecules can be displaced by exchange with a wide variety of transition metal or rare earth ions (7, 16). The degree of exchange depends on the critical dimension of the exchanging ion (17) and for the larger ions may involve the loss of some water ligands during insertion into the lattice (18). This can result in the stabilization of unusual coordination numbers (1, 7, 9, 19) or oxidation states (1, 7, 20, 21) which are of potential interest as catalytic sites. In particular, chromium(III) has been examined as a potential catalyst for thermolysis of water because of its facile reduction to the divalent form (22–24). In particular, studies of water thermolysis on Cr doped zeolites showed oxygen production under moderate temperature conditions (25, 26). However, the detailed behaviour of the chromium ion was not clarified and the overall reversibility of the system was not established.

In this work zeolites 13X and Y52 have been doped at many levels up to saturation with trivalent chromium. The structures both before and after thermal treatment have been examined by a variety of probes to determine the role played by the chromium ion. Using the same probes the systems have been recycled to examine reversibility and to discover whether they offer any potential as working catalysts for thermolytic energy conversion.

Experimental

Sample preparation

Synthetic zeolites of the X lattice 13X (lot 139450 30049) and of the Y lattice LZ-Y52 (lot 020580) (previously known as SK-40) were obtained from Union Carbide Corporation Linde Division. Both powder samples were washed free of sodium silicates before use. All water was doubly distilled and deionized, all chemicals were reagent grade. Both zeolites were exchanged by overnight stirring in with trivalent chromium nitrate ($Cr(NO_3)_3.9H_2O$) solutions at concentrations of either 0.06 or 0.03 *M* in 300 mL of H_2O depending on the degree of exchange desired. The pH was maintained at 5 to 6 with 6 *N* NH_4OH and samples were mixed with Teflon stirrers while protected from light. With a minimum molar ratio of Cr/NH_4OH of 20:1 there was no evidence of the formation of $Cr(OH)^{2+}$. After exchange, samples were filtered and air dried to constant weight. Details may be found in Table 1.

Sample analysis

All samples were digested in a mixture of HF, NHO_3, and H_2SO_4 in Teflon vessels to dryness, then redissolved in 10% HF solution. Sodium was analysed gravimetrically as the magnesium uranyl acetate (27). Aluminum and chromium were determined by atomic absorption on a Perkin-Elmer, Model 5000, with HGA 500 graphite furnace atomic absorption spectrophotometer. Sample notation and data are given in Table 2.

Structural methods

Magnetic susceptibilities were measured by the Gouy method on a custom built magnetic balance incorporating a Cahn electrobalance, evacuated sample chamber with thermal control from 4 to 278 K and an electromagnet of variable field up to 9.2 kG. The instrument was calibrated with Mohr's salt.

Infrared spectra were obtained at low resolution on a Perkin Elmer Model 257 and at high resolution on a Perkin Elmer Model 257 spectrophotometer as Nujol mulls.

Thermogravimetric analysis were performed on a Dupont Model 950 Thermogravemetric Analyser. Samples in platinum boats were heated at 10°C/min with a gravimetric time constant of 1 s. The instrument was standardized with calcium oxide under nitrogen using chrome alumel thermocouples.

Differential thermal analysis were performed on the Dupont Model 900 Differential Thermal Analyser. In HEAT mode, samples were heated at 20°/min with a baseline slope of zero. The instrument was standardized daily against glass, KNO_3 (127.7°), $KClO_4$ (299.5°C), and Ag_2SO_4 (412°).

Dehydration of exchanged zeolites

Samples in the area of 1 g were dehydrated to temperatures of 110, 150, 200, and 250°C. All samples were dehydrated on a vacuum line

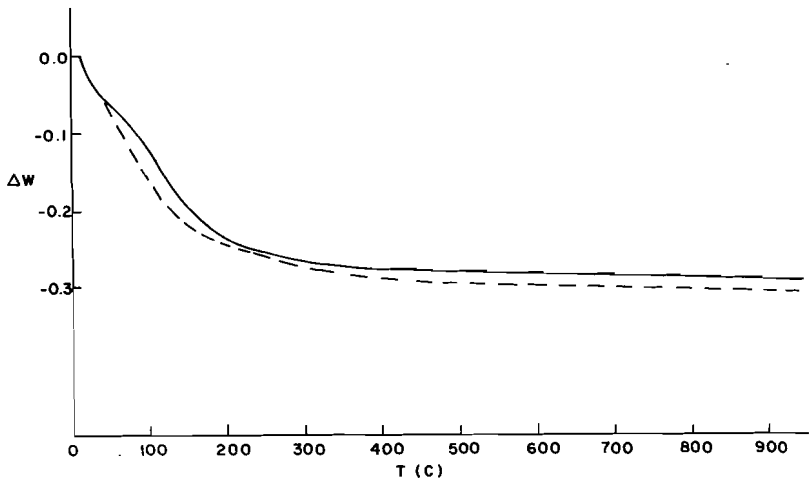

FIG. 2. Thermogravimetric analysis of Cr zeolite 13X (- - -) and zeolite 13X (——).

with a fore-pump and mercury diffusion pump system capable of pumping down to 10^{-3} mbar. Samples were evacuated in an electrically heated sand bath monitored by a thermometer in the sand at a depth equivalent to that of the sample. Samples were protected from the light and evacuated with heating up to as long as 60 h with continual evacuation. Samples were then cooled to room temperature (24°C) over a 24 h period under vacuum but with no further pumping. They were then transferred under nitrogen into sealed tubes.

Rehydration of exchanged zeolites

Samples were weighed out under nitrogen and immersed in 20 mL water for 48 h, being warmed to ~50°C. They were then filtered with tarred Whatman #42 paper and air dried under cover.

Results

Exchange and structures

In every case, all of the chromium of the first exchange was placed onto the lattice (as is evidenced by a colourless filtrate). Although the second filtrate remained green, and indicated that not all of the chromium made available to the lattice was exchanged, it was possible to place more chromium onto the frame in further exchanges. This was proven by analysis of the filrates, which showed high levels of sodium and significantly decreased levels of chromium.

The results in Table 1 show exchange levels from 18 to 36%. The framework structure of the samples was monitored by X-ray powder diffraction. It is known that in powder samples many X-ray intensities of zeolites are lost in the background or are confused by overlapping diffraction lines (11). The results indicated that all the samples remaind intact after exchange. Previous studies have shown exchange levels of only 6 Cr per zeolitic unit (28), yet this study has successfully exchanged 8.1 Cr^{3+} on Y52, 10.4 on 13X.

Thermogravimetric analysis

Water loss was calculated from the percentage weight loss of the samples. Samples were run both entirely hydrated and partially dehydrated (i.e. at 120°C). It was found that the total percentage weight losses of the partially dehydrated samples were equivalent to the percentage weight loss as extrapolated to the appropriate temperature of dehydration of fully hydrated sample.

Shown in Fig. 2 is an example of a TGA spectrum, specifically of unexchanged 13X and a chromium exchanged 13X.

The exchanged zeolites lose water more rapidly and continue to lose water at higher temperatures. The endothermic shift of water loss at moderate temperatures also seen in DTA spectra, indicates that the water is more loosely bound in exchanged systems (Table 3).

Differential thermal analysis

Spectra were obtained on all samples of exchanged, unexchanged, dehydrated, and rehydrated zeolites. All samples were run against a glass reference and against the corresponding unexchanged zeolite where applicable. Characteristics are shown in Table 4.

Shown in Fig. 3 is an example of a DTA spectrum of unexchanged 13X and of chromium exchanged 13X with the 13X background removed by the differential operation of the instrument. Both the X and Y zeolite samples displayed plateaus in the 750°C range, indicating a phase transition and probable structural collapse. However, none of the samples showed any evidence of the intense exothermic peak expected. It is reasonable to assume that the framework is unstable upon dehydration and that the exothermic process of lattice destruction occurs between 100 and 350°C and is thus masked by the endothermic process of dehydration (6). This assumption was substantiated by X-ray crystallography of the sample at 500°C.

The 13X sample reveals three major areas of slow endother-

mic dehydration between 50 and 300°C (29). Upon dehydration to 120°C only the last region is seen and is shifted up to 225 to 300°C, suggesting that the remaining water molecules are very strongly bonded. The samples dehydrated at 150 to 200°C show endothermic peaks at the low temperature scale.

The Y52 on the other hand shows an exothermic peak in the midst of the endothermic area. As the sample is dehydrated the endothermic area remains relatively stable but the exothermic shifts up in temperature and becomes split.

When the chromium is exchanged onto 13X only one large endothermic area covering the same range as the 13X is observed within which there is a smaller area of faster loss. Upon dehydration to 120°C there is a shift to lower temperature as for 13X. Upon removal of the 13X background, the effect of the chromium is resolved into three endothermic peaks within the range shown by the entire sample. Upon elimination of the background of a similarly treated (13X)120, a sharp exothermic peak at 75–100°C and a large endothermic peak at 200–310°C, with the major portion at 200 to 230°C are observed. This would again suggest that there has been an internal phase transition (or perhaps another migration) and that the remaining water is very strongly bonded.

The DTA spectra of rehydrated samples show a strong exothermic peak immediately previous to three areas of *endo* activity, which lie within the endothermic area of the original sample. After removal of the zeolitic sample background one sees two endothermic areas appear, each preceded by a strong exothermic peak, again indicating internal migration. There is also a further endothermic area at a higher temperature than expected. There are clearly differences between the original exchanged samples and the de- and re-hydrated samples (30). The same pattern appears with the 150 and 200°C samples and also holds for the Y zeolites.

Magnetic susceptibilities

The instrument was calibrated with Mohr's salt (ferrous ammonium sulphate, $Fe(NH_4)_2(SO_4)_26H_2O$ MW 392.15, $\chi'_m = 32.04 \times 10^{-6}$ cgs at 22°C). Samples of Cr exchanged zeolites were run at three temperatures (room, helium and nitrogen) to determine if the magnetic susceptibilities were temperature independent. Thereafter all samples were run at room temperature. Samples were run at four field strengths, 0.65, 0.75, 0.84, and 0.92 Tesla. The gram and molar susceptibilities derived after applying instrument calibration factors and molecular weights respectively are given in Table 5. Errors are assessed from the initial weight, the standard deviation and the errors in molecular weights in Table 1.

The standard spin-only value for $\mu_{eff}(Cr^{3+})$ is 3.87 BM. All

[a] μ_{eff} of the metal ion alone is obtained by dividing the μ_{eff} of the total metal ion per mole of exchanged zeolite by the number of metal ions per unit cell as obtained from Table 1.

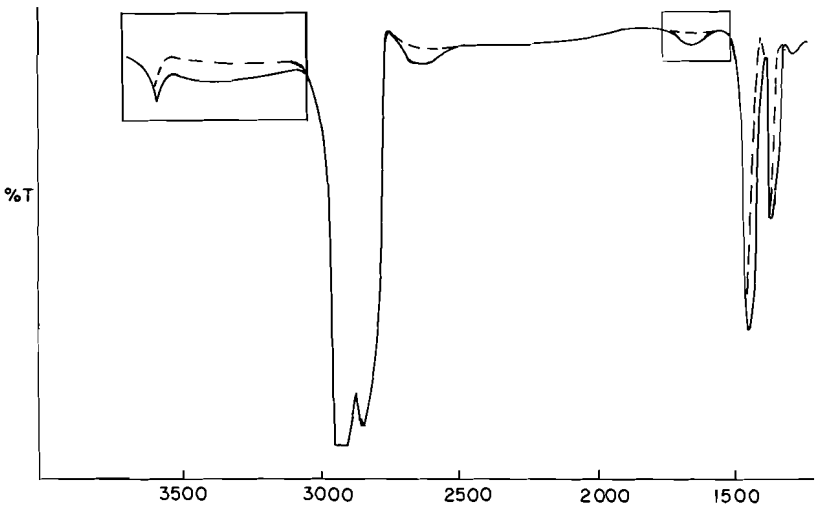

FIG. 4. Infrared spectra of Cr zeolite to 1500 cm^{-1}.

the results in Table 4 lie well below this value, decreasing with increasing dehydration temperature in most cases. The sharpest decrease is observed for dehydration at 120°C for the singly exchanged 13X is coincident with the first large endothermic peak in differential thermal analysis (Table 3). It also accompanies a distinct colour change from green to light grey. In the Y52 samples susceptibilities were also well below those expected in isolated Cr^{3+} but show an increase in samples dehydrated at 200°C.

Infrared spectra

Infrared spectra were obtained on all samples before and after dehydration or exchange. Typical low resolution spectra of 13X and Cr^{3+} 13X are shown in Figs. 4 and 5. High resolution spectra, reported in Table 6, were obtained in the ranges indicated on the low resolution spectra to observe the features which changed with treatments more closely.

Hydroxyl stretching bands occur in the range from 3000 to 3800 cm^{-1} for O—H bonds in various environments. The weak sharp band at 3750 cm^{-1} is exhibited by all zeolites and has been assigned to a terminal hydroxyl stretch (31). It disappears on dehydration and does not return during rehydration under the conditions of these experiments.

Bands appearing in the 3650 to 3680 cm^{-1} have been assigned to bridging hydroxyl stretching modes (31) in both zeolite 13X and Y52. Like the terminal stretch mode, they disappear on dehydration and do not return with rehydration. These bands are also altered by the extent of Cr^{3+} exchange. At 24% exchange, the 2680 cm^{-1} band in Y52 is lost but the 3650 band in both lattices is retained. Since initial exchange involves substitution in the sodalite cage at site I the 3680 cm^{-1} band is assigned to labile water in the sodalite cage bridging between Na^+ ions and the lattice. At 36% exchange in both lattices, the 3650 cm^{-1} disappears from 13X and is shifted to 3630 cm^{-1} in Y52. At this level of exchange sites in the supercages are occupied suggesting that the 3650 cm^{-1} band represents bridging hydroxyl groups in the supercage. The supercage of 13X is smaller than that of Y52 and having a lower Si/Al ratio as well, appears to lose all bridging water at this level of exchange while in Y52 some labile water is retained but the bridges are weaker.

A third band type near 3575 cm^{-1} is observed in all lattices and is persistent through all heat treatments. They are assigned as local Cr—OH hydroxyl stretch modes (31) of the exchanged ion or possibly those of occluded silica residues in the zeolite lattice.

A set of bands in the 1600 to 1700 cm^{-1} range is assigned to

water bending modes (31–33). Like the stretching modes they are lost on dehydration and do not reappear on rehydration. Their dependence on exchange is difficult to interpret. Similar results and difficulties are encountered with the low energy bands between 700 and 1100 cm^{-1}. The absence of any characteristic NH_4^+ bands is evidence of the purity of the zeolite with respect to the NH_4OH buffer.

Discussion

The structure of Na13X is well established by single crystal Na13X X-ray diffraction (8). The sites occupied by Na^+ ions are I and I′ with the water in I′ and II′ (8, 34). The sites occupied by replacement ions are also well documented on zeolite A (Cu^{2+}, Cu^+) (1) and zeolite A (Zn^{2+}) (2) by crystallography and many ions by infrared and epr spectroscopy (7, 13, 22, 23). The arrangements fall naturally into a progressive pattern of substitution which represent occupation of successively less stable sites (13). This corresponds directly with the decreasing availability of lattice oxygen ligands in sites I, I′, II′, and finally II (Fig. 1).

This theoretical sequence appears to be confirmed by the current experiments. The infrared spectra show the progressive

loss of lattice hydroxyl with increasing exchange levels in both X and Y lattices. At the same time, the spectra of the Y lattice suggest the free volume occupied by bridging hydroxyls of the supercage decreases. The thermal data show that there is an increase in the lattice water content on substitution but a decrease in its stability, since the endothermic peaks all shift to lower temperature.

All of these facts are consistent with the initial occupation of Site I by the dehydrated exchange ion (18). This site was formerly occupied by a four coordinate, tetrahedral $[Na^+(H_2O)_4]^+$ complex ion and the waters of coordination were hydrogen bound to the lattice oxygen of the sodalite cage. From the spectroscopic evidence, the infrared bands attributed to this hydrated ion have disappeared and the complexed sodium ion appears to have been expelled by the much larger deaquated chromium exchange ion, binding directly to the lattice oxygen. When the hydrogen bonds between the lattice and the water bound to the sodium ion are broken and the sodalite cage contains no coordinated water, molecules in the supercage from both the exchanged ion and the displaced sodium ions are more weakly bound. This is shown by the endothermic shifts in exchanged zeolite thermal data and the long wavelength shifts in the infrared of bridging hydroxyl.

While this exchange is occurring, it has been demonstrated that some hydroxyl oxygen may exchange with the lattice (35), probably because the lattice silicon remains a strong Lewis acid permitting splitting of the six rings (14). The processes of dehydration and exchange lead to symmetry reductions at the aluminum (12) when this exchange occurs.

For the exchange ion, the next most stable site is I′ or II′ (13) both of which provide three lattice oxygen and three waters of coordination in the supercage (36). Site II′ is probably occupied first if Site I is occupied because of Coulomb repulsion. Up to this level of exchange one would expect dilute magnetic behaviour. Immediately Sites I and I′ (37) are occupied, because II′ is also occupied, exchange ions become adjacent in the lattice, sharing lattice oxygen bridges on alternate faces of the 6-ring. This provides the opportunity for shared oxidation states (mixed valence states in partly reduced species) and the formation of metal–metal bonded dimers. Such dimers do not form between pairs of Cr^{3+} ions, but can form in mixed valence pairs or pairs of tetragonal d^4 Cr^{2+} ions (38). This is in sharp contrast to most doped zeolites in which the electronic configurations of the transition metal ions are not conducive to dimerization. As observed in iron doped lattices, bridging then occurs through lattice oxygen atoms (39).

The bridging provided by the lattice can stabilize these dimers and lead to reduction at very low temperatures. Evidence of this is seen in the progressively greying colour of the doped materials and the falling magnetic susceptibility, to be expected in the formation of deep red diamagnetic Cr^{2+} dimers.

At the highest levels of exchange, Site II must also be occupied (13). This can displace the ion in Site II′ towards that in Site I providing a further opportunity for dimerization. Such metal–metal bond formation could readily distort the supercage, as is observed at the highest exchange achieved in these experiments by powder crystallography.

There are distinct differences seen in the DTA spectra of the original exchanged zeolites and the rehydrated zeolites for both X and Y. The infrared spectra do not show the expected regrowth of water bending bonds, again indicating a breakdown of the bridging hydroxyls. This is further indication of lattices which have been irreversibly altered.

In conclusion, it appears that the reduction suggested by the earlier thermolysis research (25) proceeds very easily once the characteristic dimer formation of the d^4 system becomes possible at the higher levels of exchange. It appears to be completely irreversible. This is because the lattice under the stress of the dimer bonding collapes to a new form and is incapable of breaking the Cr^{2+}—Cr^{2+} bond when reoxydation is attempted.

Reçu le 25 novembre 1985

DIEGO CORTES, REYNALD HOCQUEMILLER, ANDRÉ CAVÉ, JAIRO SAEZ et ADRIEN CAVÉ. Can. J. Chem. **64**, 1390 (1986).

Les alcaloïdes pseudoxandrine, pseudoxandrinine, oxandrine et oxandrinine ont été isolés d'une Annonacée colombienne, *Pseudoxandra* aff. *lucida*. Ces alcaloïdes appartiennent au petit groupe des bisbenzylisoquinoléines à pont biphénylique, C(11)—C(11′) et ils sont les premiers α ou α′ mono-céto-bisbenzyltétrahydroisoquinoléines. Ces structures ont été élucidées par sm, par des expériences de double résonance et nOe en rmn de ^{1}H, et par ^{13}C rmn.

DIEGO CORTES, REYNALD HOCQUEMILLER, ANDRÉ CAVÉ, JAIRO SAEZ, and ADRIEN CAVÉ. Can. J. Chem. **64**, 1390 (1986).

The alkaloids pseudoxandrine, pseudoxandrinine, oxandrine, and oxandrinine have been isolated from a Colombian Annonaceous, *Pseudoxandra* aff. *lucida*. These bases belong to the small group of bisbenzyisoquinolines with a C(11)—C(11′) biphenyl bond, and are the first α or α′ mono-keto-bisbenzyltetrahydroisoquinolines. These structures were elucidated by ms, ^{1}H nmr (including double resonance and nOe experiments), and ^{13}C nmr.

Introduction

Parmi les alcaloïdes isolés des écorces de l'espèce colombienne *Pseudoxandra* aff. *lucida* (1), il faut remarquer la présence de plusieurs bisbenzyltétrahydroisoquinoléines à pont biphénylique, dont l'antioquine, **1** (alcaloïde majeur (2)), qui a montré une intéressante activité spasmolytique;[3] la sécantioquine, première *seco*-bisbenzyltétrahydroisoquinoléine à pont biphénylique (3); et la medelline, première bisbenzyltétrahydroisoquinoléine à pont méthylènedioxy intramoléculaire (4). Quatre autre bisbenzyltétrahydroisoquinoléines mineures ont été isolées; elles sont caractérisées par la présence d'une cétone conjuguée en position α ou α′ : il s'agit de la pseudoxandrine, **2**, la pseudoxandrinine, **8**, l'oxandrine, **9**, et l'oxandrinine, **13**.

Résultats et discussion

La pseudoxandrine, **2**, est obtenue sous forme de poudre amorphe, $[\alpha]_D$ +23° (*c* 1,13, $CHCl_3$). Le spectre ir, montre la présence d'un groupement carbonylé de type arylcétone (ν(C=O) : 1680 cm^{-1}); ceci est confirmé par le spectre de ^{13}C rmn : 1 singulet à 205,1 ppm (voir Tableau 1). Son spectre de masse en impact électronique ($M^{+\cdot}$ 622, 100%) confirme sa nature dimérique. Les fragmentations principales conduisent

[3]D'après une étude pharmacologique préliminaire, l'antioquine a montré sur duodénum isolé de Rat, à la concentration de 0,1 mg/mL, une inhibition de près de 50% des spasmes induits par l'acétylcholine et le chlorure de baryum.

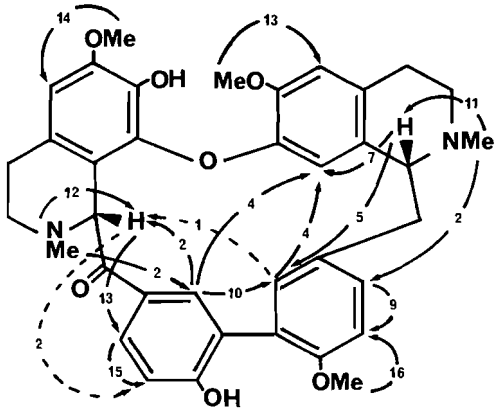
3 : $R^1 = R^2 = Ac$

4 : $R^1 = R^2 = Me$

par rupture de deux liaisons benzyliques (1–α et 1′–α′) à un ensemble bisisoquinoléique se traduisant sur le spectre par des pics à *m/z* 382, 192 et 191 correspondant respectivement aux ions monochargé et doublement chargé (5). Cette fragmentation est en faveur (*i*) d'une bisbenzyltétrahydroisoquinoléine à deux ponts, l'un diaryl-éther entre les unités isoquinoléines, l'autre biphénylique (6); (*ii*) d'une partie bisisoquinoléique diméthoxylée; (*iii*) de la présence de deux groupements phénoliques, l'un sur la partie bisisoquinoléique, l'autre sur la partie biphénylique.

Le spectre de ^1H rmn de la pseudoxandrine, **2**, montre que la molécule possède deux N-méthyles et trois méthoxyles. Les signaux correspondant aux protons en 1 et 1′ apparaissent l'un sous forme d'un doublet à 4,05 ppm, et l'autre sous forme d'un singulet à 4,25 ppm, laissant ainsi supposer que le groupement carbonyle de **2** est porté soit par le carbone α, soit par le carbone α′. Des expériences de découplage sélectif ont montré la présence de deux systèmes AMX appartenant aux noyaux C et C′.



2 : pseudoxandrine, nOe

——→ nOe +

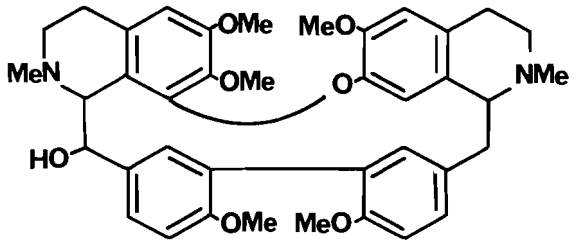
- - - - → nOe −

Par ailleurs, l'étude des dérivés diacétylé, **3**, et diméthylé, **4**, de la pseudoxandrine, a permis de confirmer l'existence, dans **2**, de deux OH phénoliques et de fixer leur position en 7 et en 12 (ou 12′).

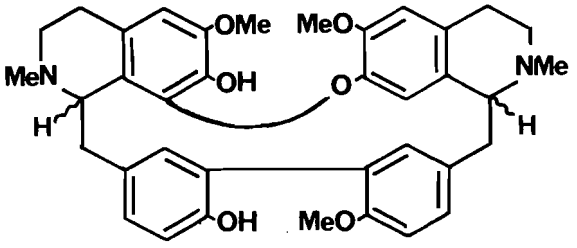
L'analyse structurale de la pseudoxandrine, **2**, est complétée par la mesure des effets Overhauser nucléaires (7, 8), enregistrés à 360 MHz sous forme de spectres de différences (2). L'irradiation successive des singulets N—Me à 2,27 et 2,39 ppm fait apparaitre un effet de 11% sur le doublet H-1′ à 4,05 ppm et un effet de 12% sur le singulet H-1 à 4,25 ppm. Un effet plus faible de l'ordre de 2% indique la proximité de ce dernier groupe N—Me avec le proton aromatique H-10. L'irradiation des protons H-1 et H-1′ permet d'identifier les protons proches, 10 et 14 pour le premier et 8′ et 10′ pour le second. La proximité des protons 10 et 10′ découle de l'irradiation du signal de H-10 qui donne un effet de 10% sur H-10′, permettant ainsi de relier les deux unités benzylisoquinoléïques. Le positionnement du méthoxyle en 12′ découle d'un effet de 16% avec le proton aromatique 13′ déjà identifié lors des expériences de double irradiation. L'identification du H-5 et du méthoxyle 6 résulte de l'observation d'un effet de 14% sur le singulet à 6,42 ppm lors de l'irradiation sélective du méthoxyle à 3,85 ppm. L'irradiation du signal du méthoxyle 6′ à 3,63 ppm permet de localiser le proton 5′ à 6,66 ppm. Les deux OH phénoliques sont placés par déduction en 12 et en 7.

Un effet Overhauser négatif est observé sur H-13 lors de l'irradiation de H-1. Il met en évidence une disposition « en ligne » (9) des protons 1, 14 et 13. Un effet comparable est observé sur H-1 lors de l'irradiation de H-10′. On peut noter les proximités de NMe-2 avec H-10 et de H-1 avec H-14 qui traduisent un arrangement structural bien défini dans cette partie de la molécule. Ces expériences permettent donc de placer le carbonyle en position α.

La présence du groupe carbonyle a été confirmée soit par réduction au $NaBH_4$, soit par réduction de Clemmensen. En effet, la réduction de la diméthylpseudoxandrine **3**, par $NaBH_4$, conduit à la dihydrodiméthylpseudoxandrine, **5**. Quant à la réduction de la pseudoxandrine **2** par la méthode de Clemmensen (Zn/HCl), elle conduit, avec un faible rendement, à deux produits, **6** et **7**. L'examen des spectres de ^1H rmn et de masse (sm), montre qu'il s'agit de stéréoisomères. Le sm de ces deux



5



6 : 1*S*, 1′*R* : tiliageine

7 : 1*R*, 1′*R*

produits présente les mêmes fragmentations que celles de l'antioquine, **1** (2), et de la tiliageine, **6** (6). L'examen des courbes de dc (dichroïsme circulaire) de **2** et de **6** et **7** permet de proposer les stéréochimies. La courbe de dc de la pseudoxandrine, **2**, est identique à celle de l'antioquine, **1**, dont la configuration a été établie comme étant 1*S*, 1′*R* (1, 2). De plus, la courbe de dc de l'un des dérivés, **6**, obtenu par réduction de

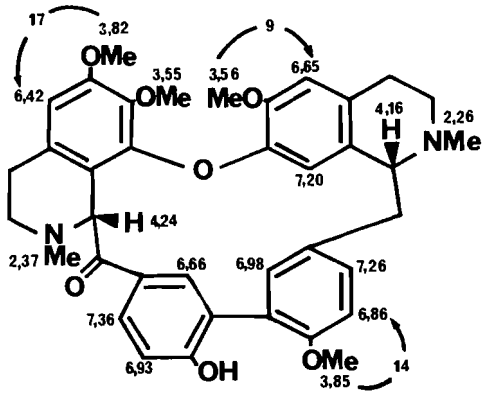


FIG. 1. Composé **8**: pseudoxandrinine, ^{1}H rmn et nOe; $J_{10-14} = J_{10'-14'} = 2$ Hz; $J_{14-13} = J_{14'-13'} = 8{,}5$ Hz.

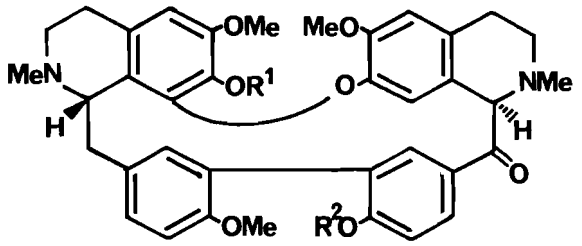
Clemmensen de la pseudoxandrine, **2**, est identique à celle de l'antioquine, **1**, permettant de conclure que ce produit correspond à la tiliageine, **6**, dont la stéréochimie a été établie par biosynthèse (6). Le signe et la valeur du pouvoir rotatoire du dérivé **6** sont en accord avec cette hypothèse. La courbe de dc du deuxième produit, **7**, obtenu lors de la réduction de Clemmensen est inverse de celle de l'antioquine, **1**; ceci permet de supposer que par réduction au Zn/HCl de **2** on obtient les deux isomères, l'un **6** étant 1*S*, 1′*R*, l'autre **7** étant de configuration 1*R*, 1′*R*. Au vu des résultats de cette réduction, on peut envisager que celle-ci se fait par l'intermédiaire d'un énol, expliquant ainsi la non conservation de la stéréochimie en position 1.

La pseudoxandrinine **8** a une structure très proche de celle de la pseudoxandrine, **2**, comme le montre l'analyse de ses différents spectres. Le sm de **8** révèle un pic moléculaire ($M^{+\cdot}$ 636, $C_{38}H_{40}N_2O_7$), et des fragmentations qui montrent que la pseudoxandrinine, **8**, est une *O*-méthyl-7 pseudoxandrine. En effet, le spectre de ^{1}H rmn vient à l'appui de cette hypothèse (voir **8**, fig. 1). Une corrélation avec le dérivé diméthylé, **4**, de la pseudoxandrine, **2**, confirme la position des différents substituants. La configuration absolue de **8** est déduite de sa courbe de dc; celle-ci, identique à celles de la pseudoxandrine, **2**, et de l'antioquine, **1**, permet d'attribuer à **8** la configuration 1*S*, 1′*R*.

La troisième cétoamine isolée de *P.* aff. *lucida*, l'oxandrine, **9**, présente un $[\alpha]_D$ négatif en $CHCl_3$ (−11°) et positif en MeOH (+9°). Ses spectres uv, ir (C=O, 1680 cm^{-1}), ^{13}C rmn (s, 205,5 ppm; voir Tableau 1) et masse ($M^{+\cdot}$ 622 et *m/z* 381, 192, 191), présentent une grande similitude avec ceux de la pseudoxandrine, **2**. L'examen du spectre de ^{1}H rmn de **9** (fig. 2), et de celui de ses dérivés diacétylé, **10**, et diméthylé, **11**, confirme la parenté entre la pseudoxandrine, **2** et l'oxandrine, **9**. La structure de **9**, a été confirmée par mesure des effets Overhauser en ^{1}H rmn (voir **9** nOe). Lorsque le singulet à 4,21 (H-1 ou H-1′, voisin du carbonyle en α ou α′) est irradié, on note un nOe sur un des NMe (δ 2,32), sur un dd à δ 7,25 (H-14 ou H-14′) et sur le singulet à δ 7,12 correspondant au H-8′. Par contre l'irradiation du doublet à δ 3,80 (H-1 ou H-1′, voisin du CH_2 en α ou α′), provoque des effets Overhauser sur l'autre NMe (δ 2,33) et sur les protons du méthylène benzylique (H-α). Ces expériences montrent que le carbonyle de l'oxandrine appartient au monomère benzylisoquinoléine porteur du proton libre en position 8′. Il est à noter que les effets Overhauser observés par irradiation du H-1′ sont nettement moins intenses sur le H-8′ et plus prononcés sur le H-14′ pour l'oxandrine, **9**, que pour l'antioquine, **1** (2), et

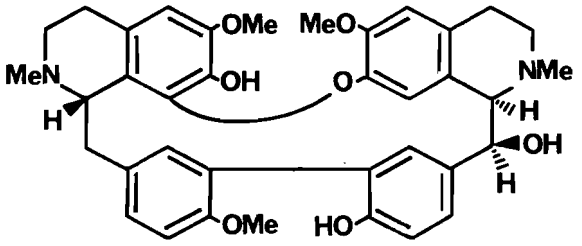


9: $R^1 = R^2 = H$: oxandrine

10: $R^1 = R^2 = Ac$

11: $R^1 = R^2 = Me$

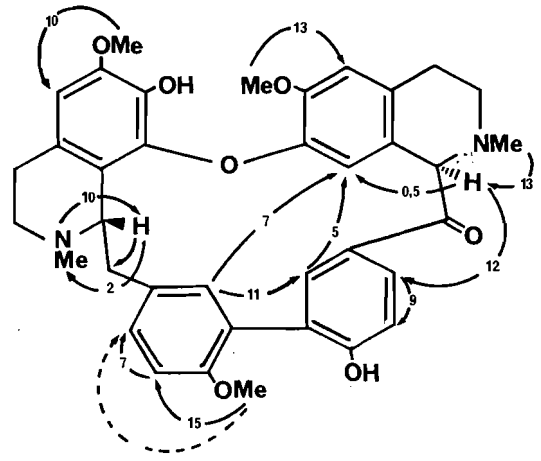
13: $R^1 = H$; $R^2 = Me$: oxandrinine



12: dihydrooxandrine

la pseudoxandrine, **2** (voir fig. 3). Comme le montre l'étude sur le modèle Dreiding, ces différences peuvent s'expliquer si la configuration en 1′ est inverse chez l'oxandrine, c'est-à-dire 1′*S*. Si cet argument est insuffisant à lui seul pour affirmer que l'oxandrine, **9**, a la configuration 1*S*, 1′*S* (les effets nOe en 1 sont identiques pour l'antioquine, **1** (2), et pour l'oxandrine, **9**), il est conforté par l'aspect de la courbe de dc de **9**, qui présente des effets Cotton opposés à ceux de l'antioquine, **1**.

De plus, si la réduction de **9**, par $NaBH_4$, conduisant à l'alcool majoritaire, **12**, ne confirme que l'existence du carbonyle en α′,[4] la réduction de **9** par Zn/HCl permet d'obtenir



9: oxandrine, nOe

——→ nOe +

- - - - → nOe −

[4]La disposition en *cis* des H-1′ et H-α′ est démontrée d'une part par ^{1}H rmn ($J = 4$ Hz), d'autre part par déshydratation ($POCl_3$) et formation de l'énamine correspondante.

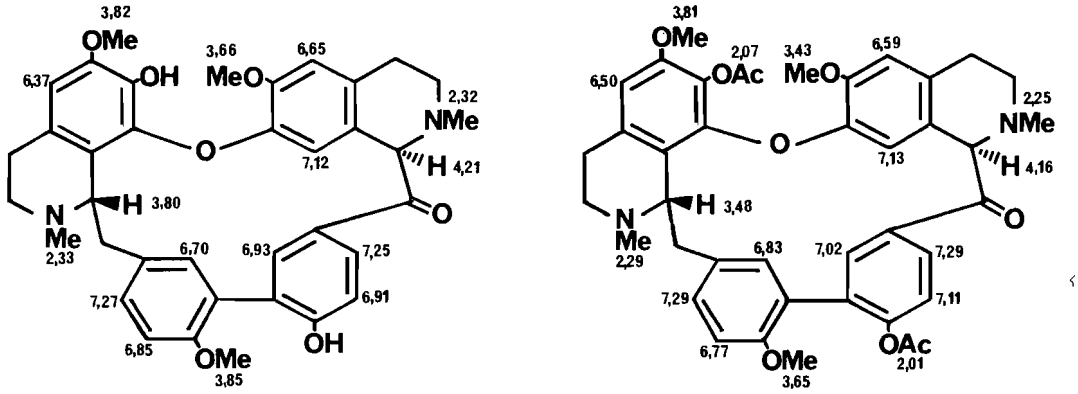


FIG. 2. Composé **9** : oxandrine, ^{1}H rmn; $J_{14-13} = J_{14'-13'} = 8{,}5$ Hz; $J_{10-14} = J_{10'-14'} = 2$ Hz. Composé **10**, ^{1}H rmn; $J_{14-13} = J_{14'-13'} = 8{,}5$ Hz; $J_{10-14} = J_{10'-14'} = 2$ Hz.

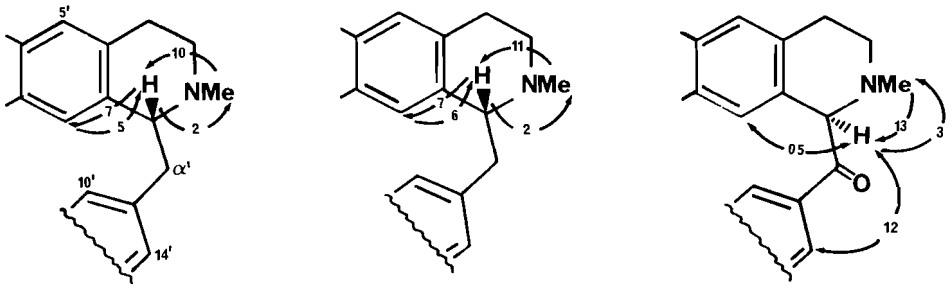

antioquine, **1** pseudoxandrine, **2** oxandrine, **9**

FIG. 3

deux produits isomères, dont l'un est identique à la (*S,R*)-antioquine, **1** (ccm, ir, dc, ^{1}H rmn, sm). Or, il a été montré pour la pseudoxandrine, **2**, que la réduction de Clemmensen menait à la formation de deux épimères. Il est donc logique que l'un des deux produits obtenus ait acquis la configuration 1′*R* et ait la même configuration que l'antioquine (1*S*, 1′*R*).

La configuration inverse en 1′ de l'oxandrine, **9**, par rapport à l'antioquine, **1**, pourrait être expliquée par l'existence d'un intermédiaire ènamine lors du processus oxydatif.

L'oxandrinine, **13**, a été obtenue en très faible quantité (0,1% des A.T. (alcaloïdes totaux)). L'ensemble de ses données spectrales (uv, ir, ^{1}H rmn, masse), montrent qu'il s'agit de la *O*-méthyl-12′ oxandrine. Ceci a été confirmé par la préparation de la méthyloxandrinine identique à la diméthyloxandrine, **11**. La courbe de dc de **13** est superposable à celle de l'oxandrine, **9**, et permet donc de lui proposer la configuration 1*S*,1′*S*.

La pseudoxandrine, **2**, et l'oxandrine, **9**, constituent les premiers exemples d'alcaloïdes α ou α′ céto-bisbenzyltétrahydroisoquinoléiques rencontrés jusqu'ici (10, 11). Elles peuvent être considérées comme des intermédiaires biogénétiques d'oxydation des bisbenzyltétrahydroisoquinoléines à pont biphénylique, dont la position α ou α′ est rendue favorable à des oxydations par la présence d'un hydroxyle phénolique en position *para*. Ce stade intermédiaire d'oxydation n'a jamais été décrit. En effet les structures des céto-bisbenzyltétrahydroisoquinoléines, décrites auparavant, ont été récemment révisées; il s'agit en réalité de *N*-formyl-bisbenzyltétrahydroisoquinoléines.[5] Cependant, des produits d'oxydation plus poussée ont été signalés, tels que les cétoimines (13) et les *seco*-bisbenzyltétrahydroisoquinoléines (14, 3).

Partie expérimentale

Pouvoirs rotatoires mesurés sur polarimètre Schmidt–Haensch, type Polartronic I. Spectres enregistrés sur les appareils suivants: uv, Unicam SP 1800; ir, Perkin Elmer 257; dc, auto-dichograph Mark V; sm, VG Micromass 70 et Nermag R10-10C; ^{1}H rmn, Cameca (250 MHz) et Brüker (360 et 500 MHz); ^{13}C rmn, Varian CFT 20 (25,2 MHz).

Extraction des alcaloïdes

Les écorces de *Pseudoxandra* aff. *lucida* (Annonaceae) ont été récoltées à San Luis, Antioquia (Colombie). L'extraction menée de façon habituelle fournit 1,5% d'alcaloïdes totaux non quaternaires. Les alcaloïdes totaux ont été chromatographiés sur colonne de Kieselgel 60. L'élution a été réalisée par des mélanges de polarité croissante de dichlorométhane et méthanol. (1, 2).

(4), 311 (11 [$M^{+\bullet}$/2]), 192 (8), 191,5 (8), 191 (30), 190 (9), 175 (4), 174 (3).

O,O-*diacétylpseudoxandrine, 3*

Préparée à partir de **2** (Ac_2O/Pyr); $[\alpha]_D$ +47° (*c*, 0,53, $CHCl_3$); uv, λ_{max}, EtOH, nm (log ϵ) : 212 (4,75), 281 (3,92); ir, ν_{max}, film : 1760, 1685, 1610, 1500 cm^{-1}; ^1H rmn, $CDCl_3$, 250 MHz, δ : 1,75 (s, 3H, OAc-7), 2,12 (s, 3H, OAc-12), 2,28 (s, 3H, NMe-2′), 2,72 (s, 3H, NMe-2), 3,62 (s, 3H, OMe-6′), 3,68 et 3,83 (2s, 6H, OMe-12′ et OMe-6), 4,29 (s, 1H, H-1), 6,50 (s, 1H, H-5), 6,71 (s, 1H, H-5′), 6,59–7,30 (7H, Ar–H); sm, IC (NH_3), *m/z* : 707[$M^{+\bullet}$+ 1]; sm, IE, *m/z* (%) : 706 (100 [$M^{+\bullet}$]), 705 (55), 691 (13), 664 (28), 663 (34), 622 (3), 621 (8), 423 (2), 381 (4), 368 (2), 206 (3), 204 (2), 191 (34), 175 (4).

O,O-*diméthylpseudoxandrine, 4*

Préparée à partir de **2** (CH_2N_2/Et_2O); $[\alpha]_D$ +6° (*c* 0,66, $CHCl_3$); uv, λ_{max}, EtOH, nm (log ϵ) : 210 (4,70), 286 (3,95); ir, ν_{max}, film : 1680, 1605 cm^{-1}; ^1H rmn, $CDCl_3$, 250 MHz, δ : (signaux doublés, déplacements chimiques moyens) 2,29 (3H, NMe-2′), 2,39 (3H, NMe-2), 3,52 (3H, OMe-7); 3,56 (3H, OMe-6′), 3,73, 3,79 et 3,84 (9H, OMe-6, OMe-12 et OMe-12′), 4,25 (1H, H-1), 6,02–7,26 (9H, Ar–H); sm, IC (NH_3) *m/z* : 651 [$M^{+\bullet}$ + 1]; sm, IE, *m/z* (%) : 650 (100, [$M^{+\bullet}$]), 649 (89), 635 (61), 621 (21), 607 (10), 395 (10), 382 (12), 381 (17), 368 (5), 354 (7), 325 (26), 311 (15), 206 (98), 198,5 (17), 198 (67), 192 (14), 191 (15), 190 (27), 175 (27), 174 (21).

Dihydrodiméthylpseudoxandrine, 5

Préparée à partir de **4** ($NaBH_4$/MeOH) selon la méthode décrite pour **12**; ir, ν_{max}, film : 1605, 1585, 1500 cm^{-1}; sm, IC, *m/z* : 653 [M^+ + 1], 652 [M^+], 639, 621, 395, 369, 206.

Réduction de la pseudoxandrine, 2, par Zn/HCl : produits 6 et 7

À 40 mg de **2** en solution dans 4 mL d'acide acétique sont additionnés 6 g de Zn pulvérisé et 12 mL de HCl 10 *N*; le mélange est porté à reflux pendant 68 h. Après extraction et purification du milieu réactionnel par ccm préparative, on obtient 3 mg du dérivé **6** et 2 mg du dérivé, **7**. Dérivé **6** : Tiliageine; [α] +192° (*c*, 0,12, $CHCl_3$) (litt. (6) [α] +132, Pyr); ir, ν_{max} film : 1610, 1580, 1500 cm^{-1}; dc, MeOH (*c*, $3,7 \times 10^{-4}$), $\Delta\epsilon$ (nm) : 0 (320), +1,9 (291), +3,8 (249), 0 (231), −3,9 (217); sm, IC, *m/z* : 609 [M^+ + 1], 608 [$M^{+\bullet}$], 381, 367, 191. Dérivé **7** : dc, MeOH (*c* $3,5 \times 10^{-4}$), $\Delta\epsilon$ (nm) : 0 (297), −4 (246), 0 (240), +25 (223), 0 (214); sm, IC, *m/z* : 609 [$M^{+\bullet}$ + 1], 608 [$M^{+\bullet}$], 381, 367, 191.

Pseudoxandrinine, 8

Amorphe (0,1% des A.T. (1, 2)); $C_{38}H_{40}N_2O_7$; $[\alpha]_D$ +7° (*c* 0,7, $CHCl_3$); uv, λ_{max}, EtOH, nm (log ϵ) : 208 (4,44), 224 ép. (4,34) 280 (3,80); EtOH + NaOH : 220 (4,90), 2,96 (4,33); ir, λ_{max}, film : 3340, 1675, 1600, 1500, 1270, 1230, 1120, 1070, 1020 cm^{-1}; dc, MeOH (*c* $5,1 \times 10^{-4}$), $\Delta\epsilon$ (nm) : 0 (362), −2,9 (341), 0 (313), +2,9 (296), +19 (249), 0 (232), −21,7 (219); ^1H rmn, 360 MHz, $CDCl_3$: voir fig. 1; sm, IE, *m/z* (%) : 636 (100, [$M^{+\bullet}$], 635 (85), 621 (28), 607 (12), 593 (6), 411 (2), 396 (1), 395 (2), 381 (5), 367 (1), 365 (9), 198,5 (5), 198 (19), 191 (3), 175 (6), 174 (6).

O-*méthylpseudoxandrinine*

Préparée à partir de **8** (CH_2N_2/Et_2O). Le produit méthylé obtenu est identique à la diméthylpseudoxandrine, **4**.

Oxandrine, 9

Amorphe (1% des A.T. (1, 2)); $C_{37}H_{38}N_2O_7$; $[\alpha]_D$ −11° (*c* 0,9, $CHCl_3$); $[\alpha]_D$ +9° (*c* 0,96, MeOH); uv, λ_{max} EtOH, nm (log ϵ) : 209 (4,73), 282 (4,02); EtOH + NaOH : 224 (4,92), 296 (4,30); ir, ν_{max}, film : 3320, 1670, 1605 cm^{-1}; dc, MeOH (*c* $2,57 \times 10^{-4}$), $\Delta\epsilon$ (nm) : 0 (310), −4,6 ép. (293), −25 (250), 0 (233), +80 (221), 0 (211); ^1H rmn, $CDCl_3$, 360 MHz : voir fig. 2 et **9**, nOe; ^{13}C rmn, voir Tableau 1; sm, IC (NH_3), *m/z* : 623 ($M^{+\bullet}$ + 1); sm, IE, *m/z* (%) : 622 (16 [$M^{+\bullet}$]), 381 (3), 367 (1), 192 (100), 191 (30), 175 (5).

O,O-*diacétyloxandrine, 10*

Préparée à partir de **9** (Ac_2O/Pyr); $[\alpha]_D$ +88° (*c* 0,9, $CHCl_3$); uv λ_{max}, EtOH, nm (log ϵ) : 224 (4,62), 282 (3,69); ir, ν_{max}, film : 1765, 1680, 1605 cm^{-1}; ^1H rmn, $CDCl_3$, 360 MHz : voir fig. 2; sm IC (isobutane), *m/z* : 707 [$M^{+\bullet}$ + 1]; sm, IE, *m/z* (%) : 706 (100, [$M^{+\bullet}$]), 664 (50), 663 (58), 649 (19), 437 (5), 381 (5), 368 (4), 353 (9), 191 (30).

O,O-*diméthyloxandrine, 11*

Préparée à partir de **9** (CH_2N_2/Et_2O); sm, IE, *m/z* (%) : 650 (100, [$M^{+\bullet}$]), 396 (1), 381 (12), 198 (60), 175 (39); ^1H rmn, 500 MHz, $CDCl_3$, δ : 2,26 (s, 3H, NMe-2′), 2,27 (s, 3H, NMe-2), 3,41 (s, 3H, OMe-7), 3,69 (s, 3H, OMe-6′), 3,74 et 3,76 (2s, 6H, OMe-12 et OMe-12′), 3,83 (s, 3H, OMe-6), 3,45 (m, 1H, H-1), 4,13 (s, 1H, H-1′), 6,44 (s, 1H, H-5), 6,58 (s, 1H, H-5′), 6,77 (d, 1H, H-10), 6,81 et 6,85 (2d, 2H, H-13 et H-13′), 7,02 (d, 1H, H-10′), 7,12 (s, 1H, H-8′), 7,26 (dd, 1H, H-14′), 7,28 (dd, 1H, H-14); $J_{14-13} = J_{14'-13'}$ = 8,5 Hz; $J_{10-14} = J_{10'-14'}$ = 2 Hz.

Dihydrooxandrine, 12

Du $NaBH_4$ (100 mg) est additionné en petites portions à une solution d'oxandrine, **9** (100 mg) dans le méthanol (10 mL) sous agitation, à température ambiante, pendant 30 min. Après évaporation, le résidu est redissous par HCl dilué, alcalinisé par l'ammoniaque et extrait par CH_2Cl_2. L'extrait est purifié par ccm (chromatographie sur couche mince) préparative sur silice (CH_2Cl_2/MeOH/NH_4OH 100 : 10:1). On obtient 30 mg de l'alcool majoritaire, **12**; $[\alpha]_D$ +140° (*c* 0,38, $CHCl_3$); uv, λ_{max}, EtOH, nm (log ϵ) : 210 (4,99), 285 (4,02); EtOH + NaOH : 220 (5,00), 292 (4,09); ir, ν_{max}, film : 3350, 1610 cm^{-1}; ^1H rmn, $CDCl_3$, 360 MHz, δ : 2,08 (s, 3H, NMe-2′), 2,35 (s, 3H, NMe-2), 3,42 (s, 3H, OMe-6′), 3,70 (s, 3H, OMe-6), 3,82 (s, 3H, OMe-12); système AB : 3,67 (d, 1H, H-1′), 5,30 (d, 1H, H-α′), $J_{1'-\alpha'}$ = 4 Hz, 6,32 (s, 1H, H-5), 6,57 (s, 1H, H-5′), 6,88 (d, 1H, H-13), 6,90–7,41 (6H, Ar-H); sm, IE, *m/z* (%) : 624 (100 [$M^{+\bullet}$]), 623 (60), 609 (34), 381 (3), 206 (14), 191 (27).

Réduction de l'oxandrine, 9, par Zn/HCl

La réduction de **9** selon la méthode précédemment décrite pour la pseudoxandrine, **2**, mène à deux produits, dont l'antioquine, **1** (ccm, ir, dc).

Oxandrinine, 13

Amorphe (0,1% des A.T. (1, 2)) : $C_{38}H_{40}N_2O_7$; $[\alpha]_D$ +60° (*c* 0,5, $CHCl_3$); uv, λ_{max}, EtOH, nm (log ϵ) : 208 (4,50), 282 (3,64); EtOH + NaOH : 216 (4,78), 290 (4,00); ir, ν_{max}, film : 3340, 1675, 1600, 1500; dc, MeOH (*c* $4,32 \times 10^{-4}$), $\Delta\epsilon$ (nm) : 0 (355), +1 (330), 0 (281), −2,5 (252), 0 (236), +8,5 (223), 0 (210); ^1H rmn, $CDCl_3$, 360 MHz, δ : 2,27 (s, 6H, NMe-2 et NMe-2′), 3,74 (s, 3H, OMe-6′), 3,80 (s, 3H, OMe-6), 3,84 (s, 6H, OMe-12 et OMe-12′), 4,18 (s, 1H, H-1′), 6,43 (s, 1H, H-5), 6,65 (s, 1H, H-5′), 6,81–7,32 (m, 7H, Ar-H); sm, IC, (NH_3), *m/z* : 637 [$M^{+\bullet}$ + 1]; sm, IE, *m/z* (%) : 636 ($M^{+\bullet}$), 635, 621, 607, 417, 411, 381, 368, 191, 190, 175, 174.

O-*méthyloxandrinine*

Préparée à partir de **13** (CH_2N_2/Et_2O). Le produit méthylé obtenu est identique à la diméthyloxandrine, **11**.

Remerciements

Les auteurs expriment leur gratitude au Dr. C. Merienne, de l'Institut d'Electronique Fondamentale d'Orsay, pour l'enregistrement des spectres de ^1H rmn à 250 MHz.

FARID R. AHMED, FRANCIS M. F. CHEN, and N. LEO BENOITON. Can. J. Chem. **64**, 1396 (1986).

A side product accompanying the reaction of *N*-methoxycarbonyl-L-valine anhydride with an amino acid anion in aqueous dimethylformamide has been characterized by an X-ray analysis as *N*,*N*′-bismethoxycarbonyl-L-valyl-L-valine, $C_{14}H_{24}N_2O_7$. The crystals are orthorhombic, space group $P2_12_12_1$, $a = 14.581(2)$, $b = 17.110(2)$, $c = 6.970(1)$ Å, $Z = 4$. The structure was determined by the direct method, and refined by block-diagonal least squares to $R = 0.046$, $R_w = 0.053$ for 1759 reflections with $I \geq 3\sigma(I)$. The carboxy-terminal part of the dimer is in the *gauche* conformation while the other part is *trans*. Each molecule at (x, y, z) makes two hydrogen bonds O...H—O and N—H...O to the molecule at $(1 - x, y - 1/2, 1/2 - z)$ and similarly to that at $(1 - x, 1/2 + y, 1/2 - z)$ to form infinite ribbons along y.

FARID R. AHMED, FRANCIS M. F. CHEN et N. LEO BENOITON. Can. J. Chem. **64**, 1396 (1986).

Faisant appel à la diffraction des rayons-X, on a déterminé que le produit secondaire, qui accompagne la réaction de l'anhydride de la *N*-méthoxycarbonyl L-valine avec un anion d'acide aminé dans du diméthylformamide aqueux, est de la *N*,*N*′-bisméthoxycarbonyl L-valyl-L-valine, $C_{14}H_{24}N_2O_7$. Les cristaux sont orthorhombiques, groupe d'espace $P2_12_12_1$, avec $a = 14{,}581(2)$, $b = 17{,}110(2)$ et $c = 6{,}970(1)$ Å et $Z = 4$. On a déterminé la structure par la méthode directe et on l'a affinée par la méthode des moindres carrés (blocs diagonaux) jusqu'à des valeurs de $R = 0{,}046$ et $R_w = 0{,}053$ pour 1759 réflexions avec $I \geq 3\sigma(I)$. La portion carboxy terminale du dimère est dans une conformation *gauche* alors que l'autre partie est *trans*. Chacune des molécules dans l'environnement x, y, z forme deux liaisons hydrogènes O...H—O et N—H...O avec la molécule qui se trouve dans l'environnement $(1 - x, y - 1/2, 1/2 - z)$ et, de la même manière, avec celle en $(1 - x, 1/2 + y, 1/2 - z)$ pour former des rubans infinis le long de l'axe y.

[Traduit par la revue]

Introduction

The reaction of an *N*-alkoxycarbonylamino acid anhydride **1** with the amino acid anion **2** in aqueous dimethylformamide gives, after acidification, the expected *N*-protected dipeptide acid **3** and the *N*-alkoxycarbonylamino acid **4** (1). However, it also gives a third product which is strongly retained by a reversed phase high performance liquid chromatography column. Further investigation of the reaction using *N*-methoxycarbonyl-L-valine anhydride (**1***a*) revealed that the same product was generated in aqueous dimethylformamide containing sodium hydrogen carbonate in the absence of nucleophile **2**. Successive fractionation of an organic solvent extract of the acidified mixture led to the isolation of crystalline material, mp 149–150°C. It is this third product which is the subject of the present study.

[2]L-Valine = (2*S*)-2-amino-3-methyl-butanoic acid.

Experimental

Preparation of N,N′*-bismethoxycarbonyl-L-valyl-L-valine (6a)*

Crystalline *N*-methoxycarbonyl-L-valine anhydride (**1***a*) (1 mmol), obtained from the parent acid **4***a* using a soluble carbodiimide followed by aqueous washes (2, 3), was dissolved in dimethylformamide–water (3:1, 4 mL) containing $NaHCO_3$ (1.1 mmol). After 2 h at room temperature, the mixture was acidified with 1 *N* HCl, and extracted with dichloromethane (20 mL × 2). The extract was dried ($MgSO_4$), the solvent was removed with a rotary evaporator, and the final traces of dimethylformamide were removed with a vacuum pump. The residue was fractionated by crystallization from dichloromethane – light petroleum. **6***a* had mp 149–150°C; $[\alpha]_D^{22}$ −26.4° (*c*, 1 in $CHCl_3$); ir (KBr pellet): 3360, 3320, 2970, 1750 (urethane), 1730 (urethane), 1710 (acid), 1680 (amide) cm^{-1}; ^{1}H-nmr ($CDCl_3$) δ ppm vs. Me_4Si: 0.80, 0.81, 1.18, 1.26 (12H, 4 × d, $J = 7$ Hz, CH_3CH), 2.30 (2H, m, $(CH_3)_2CH$, 3.68 (3H, s, OC(1)H_3), 3.83 (3H, s, OC(16)H_3), 4.88 (1H, d, $J = 9$ Hz, αC(17)*H*), 5.48 (2H, b, α*CH*, N*H*; after D_2O exchange, 1H, d, $J = 4$ Hz, αC(6)*H*), 7.35 (1H, b, CO_2H); ms: *m*/*e* 332 (M* absent), 314 (M* − H_2O).

X-ray structure analysis of (6a)

Suitable crystals were obtained after four crystallization attempts from dichloromethane – light petroleum. The crystal selected for the

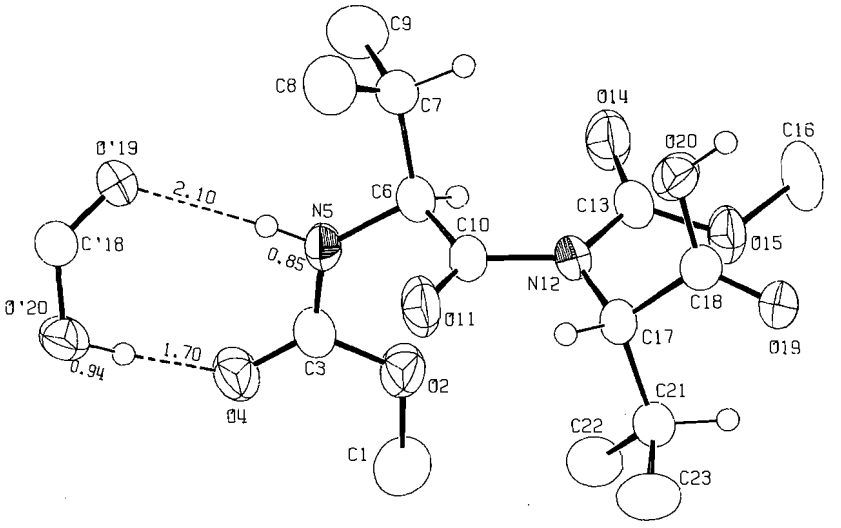

FIG. 1. ORTEP diagram of (**6***a*) showing the molecular structure with thermal ellipsoids drawn at 50% probability. The hydrogen bonds (dotted lines) have O(4)···O′(20) = 2.642(3) Å, O(4)···H—O′(20) = 174(5)°, N(5)···O′(19) = 2.929(3) Å, and N(5)—H···O′(19) = 164(3)°.

*$U_{eq} = (1/3)\sum_i\sum_j U_{ij}\, a_i^* a_j^* a_i a_j$.

X-ray analysis was in the shape of a triangular prism of dimensions 0.13 × 0.27 × 0.33 mm. The X-ray data were measured on an Enraf-Nonius CAD-4F diffractometer using Ni-filtered Cu radiation, λ(Kα$_1$) = 1.54056 Å. Crystal data at 22°C are:

$C_{14}H_{24}N_2O_7$ fw = 332.36

Orthorhombic, $P2_12_12_1$, a = 14.581(2), b = 17.110(2), c = 6.970(1) Å, V = 1738.9 Å^3, Z = 4, D_c = 1.269 g cm^{-3}, F(000) = 712, μ(Cu Kα) = 8.2 cm^{-1}.

The unit-cell parameters were derived by a least-squares fit of the 2θ values for 22 reflections with 25° < θ < 51°. Intensities were measured for the 2070 non-equivalent reflections within 2θ = 150°, in the ω–2θ scan mode with Δω = (0.7 + 0.14 tan θ)° plus 25% at each end for the background. Three standard reflections measured every hour showed minor variations of ±2% in their intensities. Corrections were applied for the scale variations and for Lorentz and polarization effects, but not for absorption. Of the measured reflections, 1759 with $I \geq 3\sigma(I)$ were considered observed and were employed in the analysis.

The structure was determined by the direct method with the aid of MULTAN (4), but the atom types were identified from the bond lengths after partial refinement. All the H atoms were located from a difference map and included in the refinement with isotropic temperature factors. Refinement was by block-diagonal least squares minimizing $\Sigma w(|F_o| - |F_c|)^2$ with $w = [1 + (|F_o|/20)^2]^{-1}$ for the observed reflections, but excluding the (200) reflection which showed extinction effect. Convergence was reached at $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.046$ for the observed reflections, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.053$, $S = [\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2} = 0.53$, mean shift = 0.03σ and maximum shift = 0.54σ. The final difference map showed small fluctuations within −0.24 and 0.16 e Å^{-3}. Scattering factor curves were from refs. 5 and 6, and the computations were performed with the NRC system of crystallographic programs (7) and ORTEP (8).

Final atomic parameters are presented in Tables 1, 4, and 5.[3]

Results and discussion

The ^{1}H-nmr spectrum showed two methoxy singlets of equal intensity at δ 3.68 and 3.83 ppm, two non-equivalent isopropyl groups (four C*H*$_3$CH-doublets) and one D$_2$O-exchangeable acidic proton, thus indicating the compound to be a dimer of **4***a* with no D$_2$O-exchangeable N—H proton. On the other hand, the molecular ion at *m/e* 314 in the mass spectrum corresponded to that of a dimer of 2-methoxy-5(4*H*)-oxazolone **5***a* or **4***a* which had lost a molecule of water. The ir spectrum (KBr pellet) showed four sharp peaks in the 1680–1750 cm^{-1} carbonyl region. Our inability to arrive at a structure based on this information prompted an analysis by single crystal X-ray diffraction which characterized the compound as *N,N′*-bis-methoxycarbonyl-L-valyl-L-valine (**6***a*). It transpires that the mass spectrum of **6***a* does not indicate the molecular ion but M* − 18, and that the N—H proton is only slowly exchangeable by deuterium, requiring 24 hours for complete exchange. The compound is sensitive to alkali, being completely destroyed in 20 min in aqueous sodium hydrogen carbonate.

*Numbers in parentheses are estimated standard deviations.

The molecular structure depicted in Fig. 1 is shown to correspond to formula **6***a*. The corresponding bond lengths and valence angles are listed in Table 2. The bond lengths occur in the narrow ranges 1.520(4)–1.554(4) Å for C—C, 1.199(4)–1.223(4) Å for C=O, 1.322(3)–1.340(4) for C—O near a carbonyl group, otherwise 1.443(4)–1.446(3) Å. However, the C—N show wider variations, where the shortest is C(3)—N(5) = 1.328(4) Å and the longest is N(12)—C(17) = 1.480(4) Å.

In this dimer molecule, the conformation at C(6)—C(7) is *gauche* with H(6)—C(6)—C(7)—H(7) = −61(3)°, while that at C(17)—C(21) is close to *trans* with H(17)—C(17)—C(21)—H(21) = −147(3)°. Similarly, two different conformations were reported (9) for the two independent molecules in the unit cell of L-valine. Other torsion angles describing the molecular conformation are presented in Table 3.

Each molecule at (x, y, z) forms two intermolecular hydrogen bonds O(4)...H′(20)—O′(20) and N(5)—H(5)...O′(19) to the molecule at $(1 - x, y - 1/2, 1/2 - z)$, and two similar bonds to the molecule at $(1 - x, 1/2 + y, 1/2 - z)$ thus connecting the molecules into ribbons along y. The ribbons are held together in the structure by van der Waals interactions. The geometry of the hydrogen bonds is given in Fig. 1 and its legend. It should be noted that the observed intermolecular distances O(4)...O′(20) = 2.642(3) Å and N(5)...O′(19) = 2.929(3) Å of the hydrogen bonds are shorter than the sums of the corresponding van der Waals radii which were derived in a recent publication (10) as r(O) = 1.54 Å and r(N) = 1.60 Å.

The nmr data indicate that the conformations at C(6)—C(7) and C(17)—C(21), which are *gauche* and *trans* respectively in the crystal, are similar in the molecule in solution in deuterochloroform. A *trans* relationship with the isopropyl proton is indicated by the 9 Hz coupling constant for the proton on the α-carbon which is not linked to N—H, i.e. H(17). A *cis* relationship with the isopropyl proton is indicated by the coupling constant of 4 Hz, which becomes apparent after deuterium exchange, for the proton on the α-carbon which is linked to N—H, i.e. H(6).

Urethane acylation producing **6** has been encountered as a side-reaction in mixed anhydride couplings of *N*-protected glycine derivatives (11–14). The present work is the first characterization of a diacylimide **6** with $R^2 \neq H$, and the first

demonstration that urethane acylation occurs in aqueous solvents. It also confirms, as suggested (11, 14–16), that anhydride **1** is an immediate precursor of **6**. A subsequent publication will address in detail the chemistry implicated in the formation and decomposition of compound **6**.

Fluorination of protected mannose derivatives using diethylaminosulfur trifluoride

IAN P. STREET AND STEPHEN G. WITHERS
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6
Received November 29, 1985

IAN P. STREET and STEPHEN G. WITHERS. Can. J. Chem. **64**, 1400 (1986).

3,4,6-Tri-*O*-benzyl-D-mannose and methyl 3,4,6-tri-*O*-benzyl-α-D-mannopyranoside were subjected to fluorination by diethylaminosulfur trifluoride and each produced two products. The former suffered fluorination at the anomeric centre to give the α-fluoride and, to a lesser extent, additionally at C-2 to give the 2-fluoro-2-deoxy-β-D-glucopyranosyl fluoride. The methyl mannoside underwent a methyl ether migration reaction to produce a 1:1 mixture of the α- and β-2-*O*-methyl glucosyl fluorides. A mechanism for this rearrangement is proposed and ^1H and ^{19}F nmr data are presented for all products.

IAN P. STREET et STEPHEN G. WITHERS. Can. J. Chem. **64**, 1400 (1986).

On a soumis le tri-*O*-benzyl-3,4,6 D-mannose et le tri-*O*-benzyl-3,4,6 α-D-mannopyrannoside de méthyle à une fluoration par le diéthylamino trifluorure de soufre; chacune des réactions conduit à deux produits. L'ose est fluoré au centre anomérique pour conduire au fluorure-α et à un degré moindre au fluorure de fluoro-2 déoxy-2 β-D-glucopyrannosyle, un produit qui a subi une fluoration supplémentaire au niveau du carbone-2. Le mannoside de méthyle subit une réaction de migration de l'éther méthylique qui conduit à un mélange 1:1 des fluorures des α- et β-*O*-méthyl-2 glucosyles. On propose un mécanisme pour cette transposition et on présente des données de rmn du ^1H et du ^{19}F pour tous les produits.

[Traduit par la revue]

Introduction

Considerable effort has been expended recently in the synthesis of fluorinated sugars, particularly of 2-fluoro-2-deoxy-D-glucose and 2-fluoro-2-deoxy-D-mannose (1–3). One reason for this has been the widespread use of [^{18}F]-labelled carbohydrates as probes for studying energy metabolism in the brain by means of positron emission tomography (4). In addition, fluorinated carbohydrates have been suggested to possess antitumour activity (5) and have also been used as probes of the active sites of proteins and enzymes that bind sugars (6).

Several different approaches to the synthesis of 2-deoxy-2-fluoro carbohydrates have been adopted, which fall into the two general categories of addition reactions to glucals and of nucleophilic displacement reactions (or epoxide ring openings) using fluoride (7). A particularly promising approach has been the use of diethylaminosulfur trifluoride (DAST) to convert a hydroxyl group to a fluorine with inversion of stereochemistry (8). In connection with our project on the use of fluorodeoxy sugars to probe the active sites of enzymes, we embarked upon a study of the use of DAST to effect fluorinations of 3,4,6-tri-*O*-benzyl-D-mannopyranose (**1**) and methyl 3,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**2**) with a view to achieving a convenient and rapid synthesis of 2-fluoro-2-deoxy-D-glucose. Previous studies (9, 10) have suggested that displacement reactions at C-2 of mannosides proceed more efficiently with the β- than the α-mannosides. However, since the latter are more readily synthesized, possible routes through such intermediates would be considerably more convenient. This paper describes the results of these investigations.

Results and discussion

Since characterization of these compounds relies to a considerable extent upon ^{19}F nmr data on the fluorinated products, it is pertinent to review some relevant information (1) on this topic prior to discussion of results. In general, a fluorine attached to the anomeric centre will resonate well downfield (Φ = 136–151 ppm) of fluorine attached elsewhere on the sugar rings. In addition, α-D-pyranosyl fluorides tend to resonate at lower field strengths than the corresponding β-anomer. Geminal couplings to fluorine tend to be large (≈50 Hz) and vicinal ^1H–^{19}F couplings range from 0 Hz up to ≈30 Hz in a *trans*-diaxial relationship.

Reaction of DAST with 3,4,6-tri-O-benzyl-D-mannose (1)

Treatment of 3,4,6-tri-*O*-benzyl-D-mannose (**1**) (11) with three equivalents of DAST for 24 h at room temperature resulted in the formation of two major products, which were separated by column chromatography. The chromatographically more mobile fraction was identified as 2-deoxy-2-fluoro-3,4,6-tri-*O*-benzyl-β-D-glucopyranosyl fluoride (**3**) (30% isolated yield) while the slower product (18% isolated yield) was shown to be 3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl fluoride (**4**).

Proof of structure for the former compound (**3**) was obtained from mass spectral data (m/z = 454) and from both ^1H and ^{19}F nmr spectroscopic data since, for example, two fluorine resonances were observed (Φ = 141.05 and 197.78) consistent with a 2-fluoro-2-deoxy-β-D-hexopyranosyl fluoride. Further, the fluorine resonance at C-2 showed only relatively small ^1H–^{19}F and ^{19}F–^{19}F couplings, other than the geminal coupling. All nmr data were very similar to those published for 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-β-D-glucopyranosyl fluoride (12). Additional proof of structure was provided by removal of the blockings groups via catalytic hydrogenolysis with Pd catalyst to yield the free sugar, since this compound was shown to be identical to an authentic sample of 2-deoxy-2-fluoro-β-D-glucosyl fluoride prepared by an alternative route (12), as demonstrated by tlc analysis and nmr spectroscopic data. No difluorinated product possessing the α-anomeric configuration was observed.

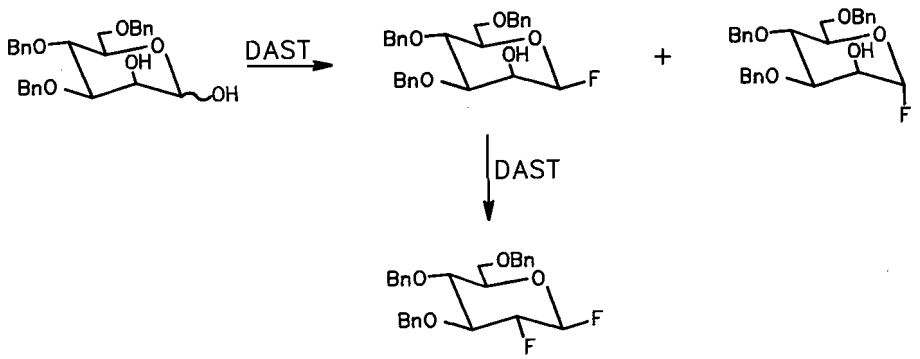


SCHEME 1

Only one resonance was observed (Φ = 140.98) in the ^{19}F nmr spectrum of the second compound, showing it to be a glycosyl fluoride, probably α-linked. The ^{1}H nmr data suggest it to be a mannosyl fluoride, since no large coupling was observed between H-2 and F-1 and between H-2 and H-3 as required for the glucosyl fluoride. Further, the ^{19}F nmr chemical shift measured is very close to that observed previously (13) for the compound 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl fluoride (Φ = 138.8) and for α-D-mannopyranosyl fluoride itself (Φ = 138.8). Thus the compound was identified as 3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl fluoride (**4**).

This mixture of products suggests that the initial reaction involves the formation of an anomeric mixture of mannopyranosyl fluorides of which only the β-anomer can then undergo a second, much slower, displacement reaction with DAST at C-2 to produce a difluorinated product (Scheme 1). Indeed, recent studies (14, 15) have shown that DAST is a very efficient reagent for the synthesis of appropriately protected glycosyl fluorides. It has also been noted by several authors (10, 11) that displacement reactions at C-2 of mannopyranosyl derivatives, with a charged nucleophile such as azide or fluoride, occur much more readily on sugars possessing the β-anomeric configuration than those of α-configuration. This is exemplified by the reaction of DAST with benzyl 3,4,6-tri-*O*-benzyl-β-D-mannopyranoside (16), which gave the desired displacement product in 80% yield, with a reaction time of only 5 min. Similar success has been achieved in effecting displacement of trifluoromethanesulfonate from C-2 of β-D-mannopyranosides using cesium fluoride (17), tetrabutylammonium fluoride (18), and tris(dimethylamino)sulfonium difluorotrimethyl silicate (19). In contrast, an attempt to displace trifluroromethanesulfonate from C-2 of methyl α-D-mannopyranoside using azide gave only a 30% yield of the desired 2-deoxy-2-azido-α-D-glucosyl derivative (20). In this case the major product was the result of a competing elimination reaction.

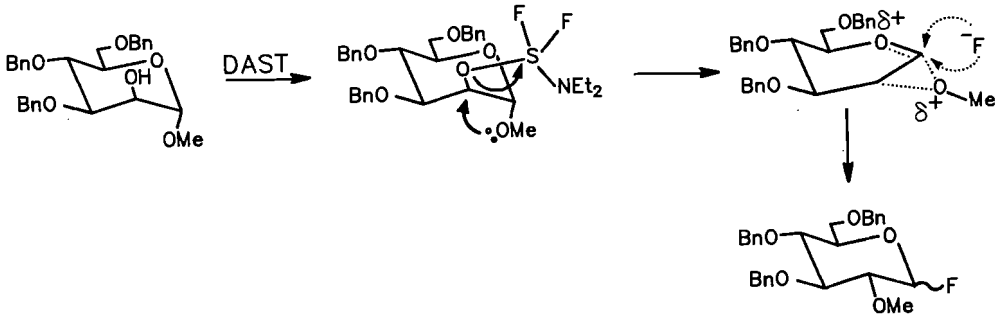
The reluctance of α-mannosides to undergo displacements at C-2 has been attributed to a variety of closely related factors. These include the high concentration of electron density in the required path of the incoming nucleophile due to the lone pair present on the α-anomeric substituent and, secondly, the unfavorable dipolar interactions that occur in the transition state between an axial anomeric substituent and the approaching nucleophile. Given the highly polar nature of the carbon–fluorine bond, it would be expected that the presence of an axial fluorine substituent at the anomeric centre would increase the magnitude of this latter effect. However, since the electron density associated with the fluorine would be held very close to the nucleus relative to the case for oxygen, it might be expected on this basis that such displacements would occur relatively more readily for a glycosyl fluoride than for an α-linked *O*-glycoside. Since all attempts to effect a displacement at C-2 of the α-mannopyranosyl fluoride (**4**) by DAST were unsuccessful, as were attempts to force the reaction of **1** with DAST towards a greater yield of the difluorinated sugar (**3**) by extending the reaction time or by heating, it must be concluded that the dipolar argument is probably the more reasonable in this case.

*Reaction of DAST with methyl 3,4,6-tri-*O*-benzyl-α-D-mannoside (2)*

In an effort to see if DAST could effect a displacement from C-2 of an α-mannopyranoside, methyl 3,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**2**) was prepared as described (11) and treated with 3 equivalents of DAST in dichloromethane at reflux for 90 min. Instead of the expected displacement products, a 46% yield of a 1:1 anomeric mixture of 2-*O*-methyl-3,4,6-tri-*O*-benzyl-D-glucopyranosyl fluorides **5** and **6** was obtained. These were identified by a number of techniques as follows. The data are consistent with fluorine substitution at C-1 rather than C-2 since the ^{19}F nmr resonances appear well downfield in a region characteristic of glycosyl fluorides. A *gluco* rather than a *manno* configuration was assigned, since in the case of the α-fluoride (**5**) a large (25.61 Hz) coupling constant is observed between H-2 and F-1, a magnitude which is only observed for *trans*-diaxially related substituents, particularly at C-2. Similarly, for the β-anomer a large H-1 – H-2 coupling of 6.7 Hz is observed, which is again consistent only with a *trans*-diaxial arrangement of the two protons. Additionally, a long-range coupling between fluorine and the protons of the 2-*O*-methyl substituent (J = 1.05 Hz) is observed in the β-anomer (**6**). A similar fluorine–proton coupling over 5 bonds is observed in the two 2-*O*-methyl-3,4,6-tri-*O*-acetyl-D-glycosyl fluorides (13).

Mass spectral data are also consistent with these structures since the parent ion mass (m/z = 466) is identical for the two compounds isolated and in agreement with the proposed structure. Moreover a major peak (parent − 20) due to the loss of hydrogen fluoride is observed, consistent with the expected ready loss of fluoride from the anomeric centre. Further, acid catalysed hydrolysis of the product produces a single compound that contains no fluorine, as evidenced by the lack of ^{19}F–^{1}H couplings in the ^{1}H nmr. Such behaviour would be expected for a glycosyl fluoride but not for a 2-fluoro-2-deoxy sugar.

Thus, rather than effecting a displacement reaction at C-2, a methyl ether migration has occurred with the concomitant, or subsequent, attack of fluoride at the anomeric centre. A likely



SCHEME 2

mechanism for this would involve the initial formation of the sulfoxo derivative at the axial hydroxyl group (see Scheme 2). Rather than suffer displacement by free fluoride ion, this highly reactive leaving group is instead displaced by intramolecular attack of the glycosidic oxygen atom to produce a 2-*O*-methyl glycosyl oxocarbonium ion intermediate, which undergoes attack by fluoride at the anomeric centre, apparently with equal ease from either face, to produce the (1:1) mixture of glycosyl fluorides. It is not, therefore, a thermodynamically controlled reaction. A concerted mechanism in which the sulfoxy derivative at C-2 provides a concerted intramolecular delivery of fluoride to the anomeric centre would not appear to be likely in this case since this would result in exclusive formation of the β-fluoride.

A migration of this type, to our knowledge, has not been reported before in fluorination attempts using DAST, although eliminations are common competing side reactions (1, 20). Indeed, in the case mentioned previously involving azide displacement of the highly reactive triflate from C-2 of a protected methyl-α-D-mannopyranoside, no evidence was obtained for a migration product, simply a product of an elimination reaction. However, migration has been observed in attempts to perform displacements of the highly reactive triflate leaving group (21), where a methyl ether migration from the anomeric centre to C-5 of a pentopyranosyl 5-triflate occurred.

Experimental

Thin-layer chromatography (tlc) was performed on Merck Silica Gel 60 F_{254} aluminum backed plates. Chromatograms were visualized by charring with 10% sulfuric acid in methanol. Flash chromatography was carried out on Merck Silica gel (230–400 mesh). The ^{1}H nmr spectra were recorded on a Brüker WH-400 spectrometer using $CDCl_3$ solutions and tetramethylsilane as an internal standard. Chemical shifts are expressed in δ and coupling constants (*J*) are given in hertz (s = singlet, d = doublet, t = triplet, m = multiplet). The ^{19}F nmr spectra were recorded on a Brüker HXS-270 operating at 254 MHz using a $CDCl_3$ solution and trifluoroacetic acid as an external standard. Chemical shifts are expressed in Φ, i.e. ppm upfield from $CFCl_3$, and coupling constants in hertz. Diethylaminosulfur trifluoride was obtained from Aldrich Chemical Co.

3,4,6-Tri-O-*benzyl-2-deoxy-2-fluoro*-β-D-*glucopyranosyl fluoride (3) and 3,4,6-tri*-O-*benzyl*-α-D-*mannopyranosyl fluoride (4)*

The compound 3,4,6-tri-*O*-benzyl-D-mannopyranose, 500 mg (1.1 mmol), was dissolved in dry dichloromethane (10 mL) and cooled to −20°C. Anhydrous conditions were maintained while DAST, 0.4 mL (3.3 mmol), was added and the reaction mixture allowed to slowly warm to room temperature. After a period of 24 h the reaction mixture was cooled to 0°C and, after cautious addition of 5 mL of methanol, stirred at room temperature for a further 2 h. The solvents were removed *in vacuo* and the resulting oil purified by flash chromatography using 95% methylene chloride/5% ethyl acetate. The chromatographically more mobile fraction was further purified on a second flash column using 90% *n*-pentane/10% ethyl acetate to yield 183 mg (0.4 mmol 36%) of the 2-deoxy-2-fluoro-β-D-glucopyranosyl fluoride (**3**); ^{19}F nmr data, Φ: 141.05 (dt, *J* = 52.71, 13.81 Hz, F-1), 197.78 (m, *J* = 50.6, 15.06, 3.47 Hz, F-2); ^{1}H nmr data δ: 5.33 (ddd, *J* = 52.74, 6.52, 3.89 Hz, 1H, H-1), 4.89, 4.83, 4.72, 4.59, 4.54, 4.51 (6 benzylic protons), 4.49 (m, *J* = 51 Hz, 8.0, 13.0 Hz, 1H, H-2), 3.79 (dt, *J* = 8.2, 10.3 Hz, 1H, H-3), 3.78–3.70 (m, 3H, H-4, H-6, H-6′), 3.61 (m, 1H, H-5), 7.34–7.14 (m, 15 aromatic protons). Mass spectrum, *m/z*: 454.

The second fraction (from the first column) yielded 92 mg (0.2 mmol, 18%) of the α-D-mannopyranosyl fluoride (**4**). ^{19}F nmr data, Φ: 140.98 (d, *J* = 49.47 Hz); ^{1}H nmr data, δ: 7.35–7.17 (m, 15H, aromatic protons), 5.66 (dd, *J* = 1.7, 49.56, 1H, H-1), 4.82–4.52 (m, 6H, 6 benzylic protons), 4.08 (m, 1H, H-2), 3.92 (t, *J* = 8.5 Hz, 1H, H-4), 3.90 (m, 1H, H-5), 3.86 (dd, *J* = 8.1, 1.9 Hz, 1H, H-3), 3.77 (dd, *J* = 3.9, 11.0 Hz, 1H, H-6), 3.70 (dd, *J* = 1.8, 11.0 Hz, 1H, H-6′), 2.82 (br s, removed on addition of D_2O, C-2—O*H*). Mass spectrum, *m/z*: 452.

3,4,6-Tri-O-*benzyl-2*-O-*methyl*-α- *and* β-D-*glucopyranosyl fluorides (5 and 6)*

Methyl 3,4,6-tri-*O*-benzyl-α-D-mannopyranoside, 222 mg (0.48 mmol), was dissolved in 10 mL of anhydrous methylene chloride and cooled to −20°C under anhydrous conditions. DAST, 0.180 mL (1.24 mmol) was added and the reaction temperature maintained at −20°C for 30 min. After allowing the reaction mixture to warm to room temperature it was heated gently to reflux for 90 min. The mixture was then cooled to 0°C and, after cautious addition of 5 mL of methanol, stirred for 1 h at room temperature. After removal of the solvents the product mixture was separated by flash chromatography using 10% ethyl acetate/90% *n*-pentane. The first compound eluted was found to be 3,4,6-tri-*O*-benzyl-2-*O*-methyl-β-D-glucopyranosyl fluoride (**6**) (48 mg, 0.11 mmol, 23%); ^{19}F nmr data, Φ: 138.61 (dd, *J* = 53.29, 12.21 Hz); ^{1}H nmr data, δ: 7.35–7.13 (m, 15H, aromatic), 5.15 (dd, *J* = 6.7, 52.0 Hz, 1H, H-1), 4.88–4.54 (6H, 6 benzylic protons), 3.72, 3.67, 3.57 (5H, H-3, H-4, H-5, H-6, H-6′), 3.58 (d, *J* = 1.05 Hz, 3H, C-2—OCH_3), 3.25 (m, *J* = 6.5, 8.1, 12.1 Hz, 1H, H-2). Mass spectrum, *m/z*: 466.

Further elution with the same solvent system gave the chromatographically less mobile compound 3,4,6-tri-*O*-benzyl-2-*O*-methyl-α-D-glucopyranosyl fluoride (54 mg, 0.12 mmol, 24%); ^{19}F nmr data, Φ: 149.87 (*J* = 53.45, 25.65 Hz); ^{1}H nmr data, δ: 7.36–7.13 (m, 15H, 15 aromatic protons), 5.73 (dd, *J* = 2.7, 54.0, 1H, H-2), 4.91–4.50 (6H, 6 benzylic protons), 3.95–3.66 (m, 5H, H-3, H-4, H-5, H-6, H-6′), 3.55 (s, 3H, C-2—OCH_3), 3.55 (m, *J* = 2.67, 9.46, 25.61 Hz, 1H, H-2). Mass spectrum, *m/z*: 466.

Use of camphor in pseudoguaianolide synthesis

JOHN H. HUTCHINSON, THOMAS MONEY,[1] AND SUSAN E. PIPER
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received December 18, 1985

JOHN H. HUTCHINSON, THOMAS MONEY, and SUSAN E. PIPER. Can. J. Chem. **64**, 1404 (1986).

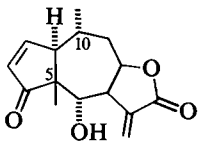
Stereoselective alkylation of a bicyclic lactone (**9**) derived from (+)-camphor (**5**) is the basis of a synthetic route to bicyclic enone (**3**) which could be used as a key intermediate in helenanolide synthesis.

JOHN H. HUTCHINSON, THOMAS MONEY et SUSAN E. PIPER. Can. J. Chem. **64**, 1404 (1986).

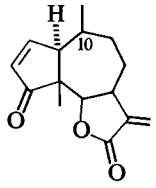
On utilise l'alcoylation stéréosélective de la lactone bicyclique **9**, provenant du (+)-camphre (**5**), pour préparer l'énone bicyclique **3** qui peut être utilisée comme intermédiaire clé dans la synthèse de l'hélènanolide.

[Traduit par la revue]

Pseudoguaianolides are sesquiterpenoid lactones which are classified as helenanolides (cf. helenalin (**1**)) or ambrosanolides (cf. ambrosin (**2**)) on the basis of their configuration at the C(10) position. The cytotoxic activity (1) and structural complexity of the helenanolides and ambrosanolides has stimulated considerable interest in their total synthesis and several imaginative routes to specific sesquiterpenoids of each class have been reported (2–13). A recent report (13) by Lansbury and co-workers describing the synthesis of a pseudoguaianolide intermediate by ring cleavage of 9-iodocamphor oxime prompts us to record our synthetic studies in this area.

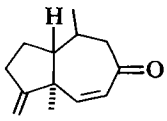


1

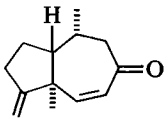


2

As part of our general investigations on the use of camphor as a chiral starting material in natural product synthesis (**9**) (14, 15) we have recently been involved in the development of simple synthetic routes from (+)-camphor (5) to epimeric dienones, **3** and **4**, which have considerable potential as intermediates in the



3



4

synthesis of *ent*-helananolides and *ent*-ambrosanolides, respectively.[2] The synthetic route to dienone (**3**) involves an intermediate bicyclic lactone (14, 15) which is readily synthesized from 9,10-dibromocamphor (**7**) (14*a*)[3] by the previously reported procedure (15) (cf. Scheme 1). Subsequent alkylation of **9** with methyl iodide provided the expected 4 β-methyl derivative **10** as the only isolable product in ~55% yield. The stereochemistry of the methyl group in this compound was supported by nmr evidence, i.e. the 4α-hydrogen signal, on irradiation with the C(4)-methyl resonance frequency, collapsed to a doublet with a coupling constant (J = 12 Hz) consistent with its *anti* relationship with the 5 β-hydrogen atom.[4] Methanolysis of lactone (**10**) followed by protection of the alcohol group and reduction of the ester provided monocyclic alcohol (**11**) in ~65% overall yield from **9**. Conversion of **11** to the corresponding iodide (**12**) followed by treatment with the carbanion derived from 2-methyl-1,3-dithiane (19) yielded an intermediate which was hydrolyzed ($CH_3I/CH_3CH{:}H_2O/CaCO_3$) (20*a*, 20*b*,[5] 20*c*) to provide silyloxyketone (**13**) in 45% overall yield. Removal of the silyl protective group followed by oxidation (PDC/CH_2Cl_2) (21) and intramolecular aldol condensation [(*i*) (KOH/MeOH; (*ii*) $MsCl/Et_3N$/DMAP/24 h)] of the intermediate keto-aldehyde (**14**) provided dienone **3** in ~70% yield.[6]

Dienone (**3**)[7] is structurally similar to racemic intermediates (**15***a*, *b*) used by other research groups in published synthetic routes to helenanolides and it is expected that this synthetic intermediate will be convertible to optically pure helenanolides by adaptation of previously published procedures (2, 5).

Experimental

Unless otherwise stated, the following are implied. Melting points (mp) were determined on a Kofler micro heating stage and are uncorrected. For gas–liquid chromatography a Hewlett-Packard gas chromatograph (Model 5830A) was used with 6 ft × ⅛ in. column (3% OV-17). Capillary glc analysis was carried out on a Hewlett-Packard 5880A gas chromatograph employing a flame ionization detector and using a W.C.O.T. narrow bore (0.21 mm × 12 m) Carbowax 20 M column. Helium was used as the carrier gas. The ^1H nmr spectra were recorded on Bruker WH-400, Nicolet Oxford H-270 or Bruker WP-80 instruments. Signal positions are given in delta (δ) with tetramethylsilane (TMS) as an internal reference. Signal multiplicity and integrated areas are indicated in parentheses. The solvent used was deuteriochloroform. Infrared spectra were recorded on a Perkin-Elmer 137 spectrophotometer and optical rotations were measured using a Perkin-Elmer 141 polarimeter. Low resolution mass spectra were obtained using a Varian/MAT Kodel CH4B mass spectrometer and high resolution mass spectra using a Kratos MS50 instrument. Microanalysis were

[1]To whom all correspondence should be addressed.

[2]Dienones (**3**) and (**4**) are synthons for the *ent*-helenanolides and *ent*-ambrosanolides, respectively. To synthesize enantiomers of (**3**) and (**4**) would involve C(3)-bromination (Br_2/HOAc) of commercially availible (−)-camphor as the first step in the sequence. (−)-Camphor is relatively expensive and although this extra expense can be avoided to some extent by oxidizing commercially available (−)-borneol with hypochlorite (16–18), the convenience of starting with (+)-3-bromocamphor (**6**) prompted us to conduct our initial investigations in the *ent*- series.

[3]Our published (14*a*) yield (~60%) for the conversion of 3,9,10-tribromocamphor to 9,10-dibromocamphor (**7**) has been increased to ~90% by conducting the selective debromination (Zn/HOAc/ether) in an ice-bath for 30 min.

[4]Structure (**10**) has recently been confirmed by X-ray chrystallographic analysis; S. J. Rettig and J. Trotter, unpublished results.

[5]In the absence of $CaCO_3$ the double bond was isomerized to the endocyclic position and the silyl protective group was removed.

[6]The synthesis of dienone (**3**) was previously described at the C.I.C. Conference, Montreal, June 3–6, 1984.

[7]The conversion of (+)-9,10-dibromocamphor (**7**) to epimeric dienone (**4**), a potential intermediate in ambrosanolide synthesis, is currently being investigated in our laboratory.

performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

Methyl lactone (10)

LDA was generated at 0°C under argon by adding *n*-butyllithium (1.6 *M* in hexane; 2.5 mL; 4.0 mmol) dropwise to a stirred solution of diisopropylamine (0.56 mL) in dry THF (30 mL) and stirring for 30 min. The mixture was cooled to −78°C and a solution of lactone (**9**) (15) (0.65 g, 3.92 mmol) in THF (26 mL) was added dropwise by means of a cannula. After 30 min at −78°C, methyl iodide (0.75 mL; 12 mmol) was added and the mixure warmed to room temperature and stirred for 1.5 h. Addition of saturated aqueous ammonium chloride followed by extraction with ether, drying ($MgSO_4$) and removal of solvent gave a yellow solid (0.70 g) which was shown by capillary glc to consist of one major (~60%) component. Column chromatography (silica gel; petroleum-ether:ether, 4:1) of the crude product afforded methyl lactone (**10**) as white needles (0.39 g; 55% yield). ν_{max} (CCl_4) 1730, 1645, 890 cm^{-1}; δ ($CDCl_3$, 400 MHz) 1.08 (d, 3H, $J \sim 1$ Hz), 1.31 (d, 3H, $J = 7$ Hz), 4.22 (d, 1H, $J = 10$ Hz), 4.34 (d, 1H, $J = 10$ Hz), 4.61 (t, 1H, $J = 2.5$ Hz), 4.82 (1H, t, $J = 2$ Hz). M.W. calcd. For $C_{11}H_{16}O_2$: 180.1150; found (high resolution mass spectrometry): 180.1149. *Anal.* calcd. for $C_{11}H_{16}O_2$: C 73.29, H 8.95; found: 73.22, H 9.01.

Silyl ether alcohol (11)

A solution of methyl lactone (**10**) (0.521 g, 2.89 mmol) in anhydrous methanol (15 mL) containing 1 drop of concentrated H_2SO_4 was stirred at room temperature for 1.5 h. The mixture was quenched with saturated aqueous sodium hydrogen carbonate, poured into saturated brine, extracted several times with ethyl acetate, and the organic layers dried ($MgSO_4$) and evaporated to give the corresonding hydroxy-ester as a colorless oil (0.61 g, 99% yield). δ ($CDCl_3$, 80 MHz) 0.875 (s, 3H), 1.2 (d, 3H, $J = 6$ Hz), 3.2 (D) and 3.55 (D) (AB quartet, $J = 12$ Hz), 3.7 (s, 3H), 4.85 (t, 1H, $J = 2$ Hz), 4.97 (t, 1H, $J = 2$ Hz).

Freshly sublimed *t*-butyldimethylsilyl chloride (2.89 g; 19.15 mmol) was added to a mixture of the above hydroxy-ester (1.35 g; 6.38 mmol) and dimethylaminopyridine (DMAP) (2.34 g; 19.14 mmol) in dry CH_2Cl_2 (50 mL) at room temperature. After 48 h the mixture was poured into ice-cold dilute hydrochloric acid (0.5 *M*) and extracted several times with CH_2Cl_2. Washing (water) and drying ($MgSO_4$) of the organic layers afforded, after solvent removal, a pale yellow oil. Column chromatography (silica gel; petroleum ether:ether 24:1) provided the TBDMS etherester as a colorless mobile oil (1.93 g, 93% yield). δ ($CDCl_3$, 80 MHz): 0.025 (s, 6H), 0.875 (s, 9H), 0.9 (s, 3H), 1.15 (d, 3H, $J = 6$ Hz), 3.25 (d) and 3.40 (d) (AB quartet, $J = 10$ Hz), 3.7 (s, 3H), 3.78 (t, 1H, $J = 2$ Hz), 3.88 (t, 1H, $J = 2$ Hz).

Lithium aluminum hydride (0.156 g; 4.1 mmol) was added portionwise to a stirred solution of the above ester (1.35 g; 4.13 mmol) in dry THF (30 mL) at 0°C. After 1 h at 0°C the mixture was poured into ice-cold brine, acidified with dilute hydrochloric acid (0.5 *M*), and extracted several times with ethyl acetate. Drying ($MgSO_4$) and removal of the solvent afforded a pale yellow oil (1.2 g; 98% yield). Column chromatography (silica gel; petroleum ether:ether 9:1) provided pure alcohol (11). $[\alpha]_D$ −45.0 (c, 0.22, CH_2Cl_2); *M/e* (relative intensity): 241 (16) ($M^+ - C_4H_9$), 149 (76), 107 (94), 89 (62), 75 (100); δ ($CDCl_3$, 400 MHz): 0.03 (s, 3H), 0.05 (s, 3H), 1.08 (s, 9H), 1.1 (s, 3H), 1.16 (d, 3H, $J = 7$ Hz), 1.74 (s, 1H, disappears on addition of D_2O), 3.64 (1H, dd, $J = 10$ Hz), 3.68 (d) and 3.77 (d) (2H, AB quartet, $J = 10$ Hz), 3.85 (1H, dd, $J = 10$ Hz and 5 Hz), 4.92 (br, s, 1H), 5.07 (br s, 1H). *Anal.* calcd. for $C_{17}H_{34}OSi$: C 68.39, H 11.48; found: C 68.60, H 11.50.

Silyl ether iodide (12)

Mesyl chloride (0.35 mL; 4.5 mmol) was added dropwise to a stirred mixture of alcohol (**11**) (1.22 g; 4.09 mmol), triethylamine (0.63 mL; 4.5 mmol), and DMAP (0.244 g; 2 mmol) in dry CH_2Cl_2 (30 mL) at 0°C. Stirring for 1.5 h followed by pouring into ice-cold dilute HCl (0.5 *M*), extraction with CH_2Cl_2, drying ($MgSO_4$), filtration and evaporation afforded the corresponding mesylate as a pale yellow oil (1.5 g, 97% yield), which was used without further purification. *M/e* (relative intensity): 361 ($M^+ - CH_3$), 319 (1.2), 281 (0.5), 244 (0.8), 153 (49.3), 149 (100); δ ($CDCl_3$, 80 MHz): 0.05 (s, 6H), 0.92 (s, 9H), 0.98 (s, 3H), 0.98 (d, 3H, $J = 7$ Hz), 3.00 (s, 3H), 3.32 (d) and 3.45 (d) (2H, AB quartet, $J = 10$ Hz), 3.85–4.38 (m, 2H), 4.75 (t, 1H, 2 Hz), 4.80 (t, 1H, 2 Hz).

Sodium iodide (5.31 g; 35.4 mmol) was added portionwise to a stirred solution of the above mesylate (2.22 g; 5.9 mmol) in HMPA (dry; 60 mL) at 0°C under argon. The mixture was allowed to warm to room temperature and stirred in the dark for 25–48 h while being monitored at regular intervals by tlc (petroleum ether:ether, 4:1, silica). The reaction was worked up by pouring into saturated brine, extracting several times with ether and washing the organic layer with aqueous sodium hydrogen sulphite and water. Removal of the solvent provided a pale-yellow oil which, after column chromatography (silica; petroleum ether:ether, 9:1) afforded pure iodide (**12**) as a colorless oil (1.96 g; 82% yield). *M/e* (relative intensity): 393 (0.3, $M^+ - CH_3$), 351 (43.8), 309 (1.25), 281 (0.6), 263 (5.07), 223 (9.03), 185 (18.28), 149 (87.56), 107 (100); δ ($CDCl_3$, 400 MHz): 0.02 (s, 3H), 0.04 (s, 3H), 0.9 (s, 9H), 0.94 (s, 3H), 0.98 (d, 3H, $J = 7$ Hz), 1.37 (m, 1H), 1.8 (m, 2H), 2.05 (m, 1H), 2.31 (m, 2H), 3.13 (dd, 1H, $J = 10$ Hz and $J = 8$ Hz), 3.36 (dd, 1H, $J = 10$ Hz and 4 Hz), 3.34 (1H, d, $J = 10$ Hz), 3.43 (1H, d, $J = 10$ Hz), 4.75 (t, 1H, $J = 2$ Hz), 4.88 (t, 1H, $J = 2$ Hz). *Anal.* calcd. for $C_{17}H_{33}OSiI$: C 49.99, H 8.14; found: C 50.46, H 8.33.

Silyl ether ketone (**13**)

n-Butyllithium (1.6 *M* in hexane, 2.36 mL, 3.77 mmol) was added, dropwise over 10 min, to a stirred solution of 2-methyl-1,3-dithiane (0.5 g; 3.77 mmol) in dry THF (10 mL) at −20°C under argon. After 3 h a solution of iodide (**12**) (0.52 g; 1.274 mmol) in THF (10 mL) was added and the mixture stirred at −20°C for 1 h and 20°C for 15 h. Acidification with aqueous ammonium chloride followed by extraction with ether and workup in the usual way afforded a yellow oil which was purified by column chromatography (silica; petroleum ether:ether,

100:1) to provide the dithiane silyl ether as a colorless oil (0.42 g; 80% yield); δ (400 MHz) 0.01 (s, 3H), 0.015 (s, 3H), 0.88 (s, 9H), 0.90 (d, 3H, $J = 7$ Hz), 1.04 (s, 3H), 1.46 (s, 3H), 2.36 (m, 2H), 2.84 (m, 4H), 3.16 (1H, d, $J = 10$ Hz), 3.33 (1H, d, $J = 10$ Hz), 4.75 (br s, 1H), 4.84 (br s, 1H).

The above dithiane derivative (0.2 g; 0.48 mmol) and anhydrous calcium carbonate (145 mg, 1.45 mmol) was heated in a solution (13 mL) of acetonitrile, water, and methyl iodide (v/v, 10:2:1) at ~80°C for 1.5 h. Excess acetonitrile and methyl iodide were removed *in vacuo*, water added, and the mixture extracted several times with ethyl acetate. Removal of solvent afforded a colorless oil (0.13 g; 82% yield) which, after column chromatography (silica, petroleum ether:ether, 24:1), afforded pure methyl ketone (**13**) (0.11 g, 71% yield); ν_{max} (cm^{-1}, film): 1720, 1650, 840. $[\alpha]_D = -35.00$, (c 0.4, CH_2Cl_2); *M/e* (relative intensity): 225 (16.7), 210 (29.5), 175 (15.7), 159 (18.5); δ (400 MHz): 0.01 (s, 3H), 0.015 (s, 3H), 0.83 (d, 3H, $J =$ 6 Hz), 0.88 (s, 9H), 0.97 (s, 3H), 1.59 (m, 1H), 1.74 (m, 1H), 1.87 (m, 1H), 2.12 (s, 3H), 2.26 (m, 3H), 2.56 (dd, 1H, $J = 15$ Hz and 5 Hz), 3.28 (d, 1H, $J = 10$ Hz), 3.39 (d, 1H, $J = 10$ Hz), 4.74 (br s, 1H), 4.86 (br s, 1H). *Anal.* calcd. for $C_{19}H_{36}O_2Si$: C 70.31, H 11.18; found: C 70.38, H 11.20.

Keto aldehyde (14)

Tetrabutylammonium fluoride (TBAF) (1.0 *M* in THF; 3.21 mL, 3.21 mmol) was added to a flask containing ketone (**13**) (0.52 g, 1.6 mmol) under argon at room temperature and the mixture stirred for 3 h. The reaction mixture was extracted with ethyl acetate, and worked up in the usual way to provide crude keto alcohol (400 mg) as a yellow oil. ν_{max} (cm^{-1}, film): 3600–3150, 1710, 1650. δ ($CDCl_3$, 80 MHz) 0.9 (d, 3H, $J = 7$ Hz), 0.95 (s, 3H), 2.15 (s, 3H), 3.5 (d, 2H, $J =$ 7 Hz), 4.8 (t, 1H, $J = 2$ Hz), 4.95 (t, 1H, $J = 2$ Hz).

To a stirred solution of the crude keto alcohol (0.335 g; 1.6 mmol) in dry CH_2Cl_2 (15 mL) was added pyridine dichromate (PDC) (2.0 g, 5.32 mmol). The mixture was stirred at room temperature for 20 h before filtering through a pad of celite/silica gel/$MgSO_4$. Evaporation of the organic solution afforded a yellow oil which, after column chromatography (silica; petroleum ether:ether, 4:1) provided keto-aldehyde (**14**) (0.246 g, 74% yield over two steps) as a colorless oil. ν_{max} (cm^{-1}, film): 1710, 1700, 1640, 890. δ ($CDCl_3$, 80 MHz): 0.95 (d, 3H, $J = 7$ Hz), 1.1 (s, 3H), 2.1 (s, 3H), 4.68 (t, 1H, $J = 2$ Hz), 5.08 (t, 1H, $J = 2$ Hz), 9.28 (s, 1H). *M/e* (relative intensity): 208 (1.2 M^+), 194 (1.8), 136 (13.7), 121 (20.6), 43 (40.9).

Bicyclic enone (3)

A potassium hydroxide solution (10%, 3.0 mL) was added to a stirred solution of keto-aldehyde (**14**) (0.327 g; 1.572 mmol) in methanol (20 mL) at room temperature and the mixture stirred for 3 h. After this time acidification of the reaction mixture followed by extraction with ethyl acetate and workup in the usual way gave crude aldol (0.327 g) as a white crysalline solid.

Mesyl chloride (0.27 g, 0.183 mL; 2.36 mmol) was added dropwise to a stirred mixture of crude aldol (0.327 g, 1.572 mmol), triethylamine (0.328 mL; 2.36 mmol) and DMAP (0.192 g, 1.572 mmol) in dry CH_2Cl_2 (10 mL) at 0°C. Stirring was continued at 0°C for 3.5 h, after which time DBU (0.469 mL, 3.14 mmol) was added. The mixture was allowed to warm to room temperature and stirred for 20 h before removal of solvent *in vacuo*. Column chromatography (silica; petroleum ether:ether, 19:1) of the resultant brown oil provided enone (**3**) (0.223 g, 75% yield) as a colorless oil. ν_{max} (cm^{-1}, film): 1670, 1640, $[\alpha]_D = -102.42$ (c 0.33, CH_2Cl_2). δ ($CDCl_3$, 400 MHz): 1.11 (d, 3H, $J = 7$ Hz), 1.18 (s, 3H), 1.43 (m, 1H), 1.72 (6 line multiplet, 1H), 1.98 (m, 2H), 2.28–2.4 (m, 2H), 2.49–2.58 (m, 1H), 3.06 (dd, 1H, $J =$ 12 Hz and 8 Hz), 4.92 (t, 1H, 2 Hz), 4.95 (t, 1H, 2.5 Hz), 5.96 (dd, 1H, $J = 12$ Hz and 1 Hz), 6.8 (d, 1H, $J = 12$ Hz). *M/e* (relative intensity): 190.1358 (41.9), 175.1123 (35.24), 161.0977 (17.32), 120.0939 (54.07), 105.0704 (79.71), 91.0550 (100). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.53; found: C 82.15, H 9.50.

Improved syntheses of hydroxy acid precursors of macrolide pheromones of cucujid grain beetles[1,2]

A. C. OEHLSCHLAGER,[3] E. CZYZEWSKA, R. AKSELA, AND H. D. PIERCE, JR.
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received May 27, 1985[4]

A. C. OEHLSCHLAGER, E. CZYZEWSKA, R. AKSELA, and H. D. PIERCE, JR. Can. J. Chem. **64**, 1407 (1986).

Syntheses of 11- and 12-hydroxy-(*Z*)-3-dodecenic, 11- and 12-hydroxy-(*Z*,*Z*)-3,6-dodecadienic, and 13-hydroxy-(*Z*,*Z*)-5,8-tetradecadienic acids are reported. These unsaturated hydroxy acids are precursors of male-produced macrolide aggregation pheromones of grain beetles of the genera *Cryptolestes* and *Oryzaephilus*. The sequence of reactions for synthesis of the hydroxy-(*Z*)-3 acids was carboxylation of the dilithium salt of 10- or 11-hydroxy undecyne, deconjugation of the resulting carboxylic acids with $NaNH_2$ in THF/liquid ammonia to a mixture of 2,3-allenic and 3-alkynoic acids, and hydrogenation of the mixture with P-2 nickel catalyst. This latter reaction gave only the desired hydroxy-(*Z*)-3-alkenoic acids. The convergent point in the syntheses of the diunsaturated hydroxy-(*Z*,*Z*) acids was the coupling of the dimagnesium salt of 3-butyn-1-ol or 5-hexyn-1-ol to the appropriate functionalized propargylic bromide. The resulting 1,4-diacetylenic alcohols were oxidized with Jones reagent to the corresponding carboxylic acids, which were hydrogenated over P-2 nickel catalyst and deprotected.

A. C. OEHLSCHLAGER, E. CZYZEWSKA, R. AKSELA et H. D. PIERCE, JR. Can. J. Chem. **64**, 1407 (1986).

On rapporte des synthèses des acides hydroxy-11 (et 12) dodécène-3(*Z*) oïques, hydroxy-11 (et 12) dodécadiène-3(*Z*),6(*Z*) oïques et hydroxy-13 tétradécadiène-5(*Z*),8(*Z*) oïque. Ces acides hydroxylés et insaturés sont des précurseurs de phérémones d'aggrégation, produites par les mâles de coléoptères des classes génériques *Cryptolestes* et *Oryzaephilus*. La synthèse des acides hydroxylés portant une double liaison en position 3(*Z*) implique la carboxylation du sel de dilithium de l'hydroxy-10 (ou 11) undécyne, puis une déconjugaison des acides carboxyliques qui en résultent, à l'aide de $NaNH_2$ dans du THF/ammoniac liquide, qui conduit à un mélange d'acides allèniques-2,3 et alcyne-3 oïques et finalement une hydrogénation du mélange sur un catalyseur P-2 de nickel. Cette dernière réaction ne conduit qu'aux hydroxy-acides alcène-3(*Z*) oïques désirés. Le point de convergence des synthèses des hydroxy-acides di'insaturés-(*Z*,*Z*) est le couplage du sel de dimagnésium du butyne-3 ol ou de l'hexyne-5 ol avec le bromure propargylique fonctionnalisé d'une façon appropriée. On a oxydé les alcools di-acétyléniques-1,4 qui en résultent avec le réactif de Jones; on a hydrogéné les acides carboxyliques correspondants sur un catalyseur P-2 de nickel et on les a ensuite déprotégé.

[Traduit par la revue]

Introduction

During the past several years, we have reported (1–6) the discovery of seven macrolide aggregation pheromones for five species of grain beetles (Table 1). These well-known cucujids are economically-important pests during grain storage, food processing and distribution, and in households. The beetles infest a wide variety of stored-product commodities such as grain, cereal-based foods, nuts, chocolate, oil seeds and cake, raisins and other dried fruits, and spices.

Our initial syntheses (7–9) of these macrolides were long and, in cases, inefficient, but furnished sufficient amounts of the pheromones for laboratory bioassays. In order to supply selected macrolides for laboratory trap tests and limited field trials, we have devised more efficient syntheses of the ω and ω − 1 hydroxy acid precursors of macrolides **1**–**4** and **6**. As in previous approaches, we have utilized functionalized alkynes for carbon–carbon bond formation by coupling with appropriate electrophiles and for conversion into the required *Z*-olefinic bonds. In this paper, we report new syntheses for the hydroxy acid precursors of macrolides **1** and **6** and improved routes to those of macrolides **2**–**4**.

Results and discussion

*Hydroxy (Z)-3-alkenoic acids **8** and **14***

Alkylation of the lithium salt of 1-octyne with methyloxirane gave alkynol **9**, which was isomerized to terminal alkyne **10** with sodium 3-aminopropylamide in 1,3-diaminopropane (11). While carboxylation of the dilithium salt of **10** gave a good yield of hydroxy acid **11**, deconjugation of **11** with sodium amide in liquid ammonia – THF (10, 11) always gave a mixture containing desired **12** and conjugated allenic acid **13** with the former predominating (Scheme 1). Fortunately, this mixture was stereospecifically reduced to (*Z*)-3-alkenoic acid **8** with P-2 nickel (7–9).

The efficiency and ease of execution of the combined sequence of carboxylation, deconjugation, and reduction suggested its use for the synthesis of **14**, the precursor of macrolide **6**. Commercially available 10-undecen-1-ol, **15**, was converted by published methods (12) to 10-undecyn-1-ol, **16**, which was carboxylated to give **17** (Scheme 1). Deconjugation of **17** also gave a mixture of β,γ-alkynoic and allenic acids (**18** and **19**) but the mixture was reduced cleanly with P-2 nickel to the (*Z*)-3-acid **14**.

Reduction with P-2 nickel of conjugated allenes **13** and **19** to (*Z*)-3 acids **8** and **14** depends upon the presence of the carboxyl group since reduction under similar conditions of disubstituted allenes bearing a carbomethoxy, hydroxymethylene, or acetoxymethylene gave mixtures of regioisomers and stereoisomers of the possible alkenes (E. Czyzewska, unpublished results). Apparently, the polar carboxyl group or carboxylate anion (generated from ethylene diamine in the catalytic system) complexes with the nickel surface so that only the least hindered side of the allene bond is reduced.

Our new five-step routes to acids **8** and **14** proceed in overall yields of 40–50%, a 2- to 3-fold improvement upon our previously reported syntheses (7, 8), and avoid protection and

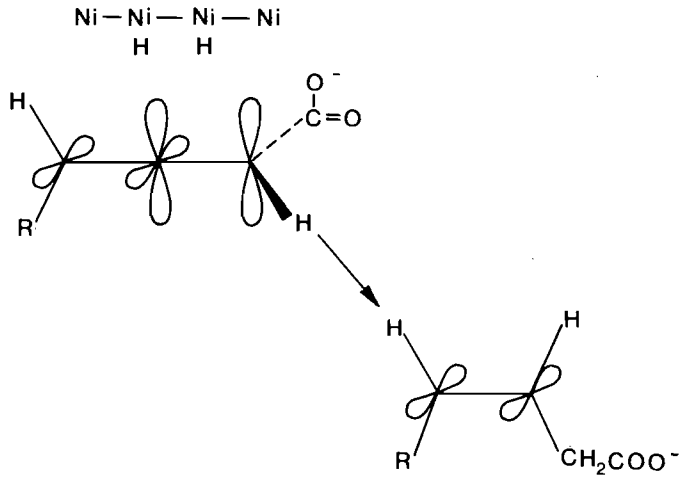
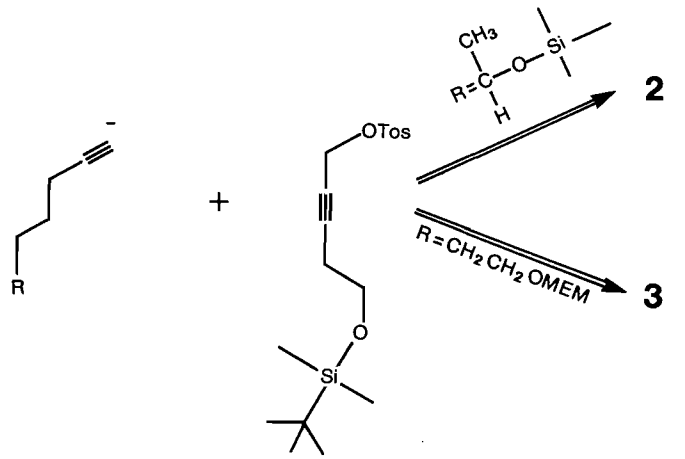
deprotection of hydroxyl groups, and chromic acid oxidation for generation of 3-alkynoic acids from homopropargylic alcohols. Use of (*R*)- or (*S*)-methyloxirane would permit synthesis of chiral isomers of **8**.

*Hydroxy (Z,Z)-dienic acids **26**, **35**, and **41***

The convergent point of our previous syntheses of **26** and **35** (Schemes 2 and 3) was the coupling of **20** with the appropriately substituted alkyne. This procedure, while efficient, required for **26** the selective removal of a *tert*-butyldimethylsilyl group in the presence of a MEM-protected hydroxyl. This process gave only moderate yields, and we desired a route to avoid these steps. Recently, Nicolaou *et al.* reported that the dimagnesium salt of 3-butyn-1-ol coupled efficiently to propargylic bromides in the presence of CuCl (14). Thus we redirected our effects to the syntheses of substituted propargylic bromides.



For the synthesis of **26** (Scheme 2), commercially available 3-heptyn-1-ol was isomerized to 6-heptyn-1-ol, which was protected to give the known (13) MEM derivative, **21**. Chain extension of **21** with formaldehyde (10) gave propargylic alcohol **22**, which was converted to bromide **24** via tosylate **23**. Bromide **24** coupled with the Grignard dianion of 3-butyn-1-ol in HMPA/THF using cuprous chloride catalysis to give the previously prepared (9) diyne **25** in excellent yield. It is noteworthy that the reaction failed to yield any coupled product if HMPA was omitted. Diyne **25** was oxidized to the carboxylic acid, which was deprotected and reduced to **26**. The present route to **26** through intermediate **25** requires nine steps and proceeds in 14% overall yield, a 60% improvement over our previous synthesis (9).



20

For the synthesis of **35**, bromide **32** was prepared in 35% overall yield from chloroalcohol **27** and was coupled with the dianion of 3-butyn-1-ol to give diynic alcohol **33** in 80% yield (Scheme 3). However, conversion of **33** to **35** by several different routes gave low yields. For example, deprotection of **33** and subsequent oxidation of **34** with chromic acid to the intermediate keto acid, which was sequentially reduced with $NaBH_4$ and P-2 nickel, gave **35** in 14% overall yield. We have been able to increase the yield of **35** to 24% by careful monitoring of the P-2 nickel reduction of **34**. Chromic acid oxidation of **33** prior to deprotection of the C-11 hydroxyl led to a mixture of products in which no component exceeded 30%. Diyne to diene reduction of **34** with P-2 nickel proceeded well (67–74%) but subsequent Jones oxidation (inverse addition) (16) of the resulting dienic, 1,11-diol to the corresponding dienic keto acid proceeded in only 30% yield.

The synthesis of acid **41** commenced with conversion of **36** (17) to bromide **37**, which was coupled with the Grignard dianion of 5-hexyn-1-ol (Scheme 4). Oxidation of **38** with Jones reagent gave keto acid **39**, which was sequentially reduced with $NaBH_4$ and P-2 nickel to hydroxy (*Z*,*Z*)-dienic acid, **41**. Our new synthesis of **41** proceeds with an overall yield of 46%, which is considerably better than the 27% obtained by our previous route.

Experimental

Hewlett–Packard 5880A and 5890A gas chromatographs fitted with capillary inlet systems, flame-ionization detectors, and WCOT columns (15 or 30 m × 0.25 mm id) of glass or fused silica were employed for analyses by gas–liquid chromatography (gc). Columns were coated with OV-101, SP-2100, or DB-1 liquid phases. Injection port and detector temperatures were 260 and 275°C, respectively. Helium was the carrier gas.

Column chromatography was performed by the flash chromatography method on silica gel (Kieselgel 60, 40–63 μm, E. Merck, Darmstadt). Solvents were distilled before use.

Low-resolution mass spectra were obtained on a Hewlett–Packard 5985B coupled gas chromatograph – mass spectrometer using electron-impact ionization at 70 eV or chemical ionization (CI) with isobutane as the ionizing gas. High resolution mass spectra were obtained on a Kratos MS80 RFA mass spectrometer interfaced with a Carla Erba gas chromatograph equipped with a 15 m × 0.25 mm id, DB-1 fused silica column. The ir spectra of neat samples between NaCl plates were determined on a Perkin–Elmer 599B spectrophotometer. The ^1H nmr spectra were recorded in $CDCl_3$ on Varian EM 360 or Brüker 400 WM spectrometers.

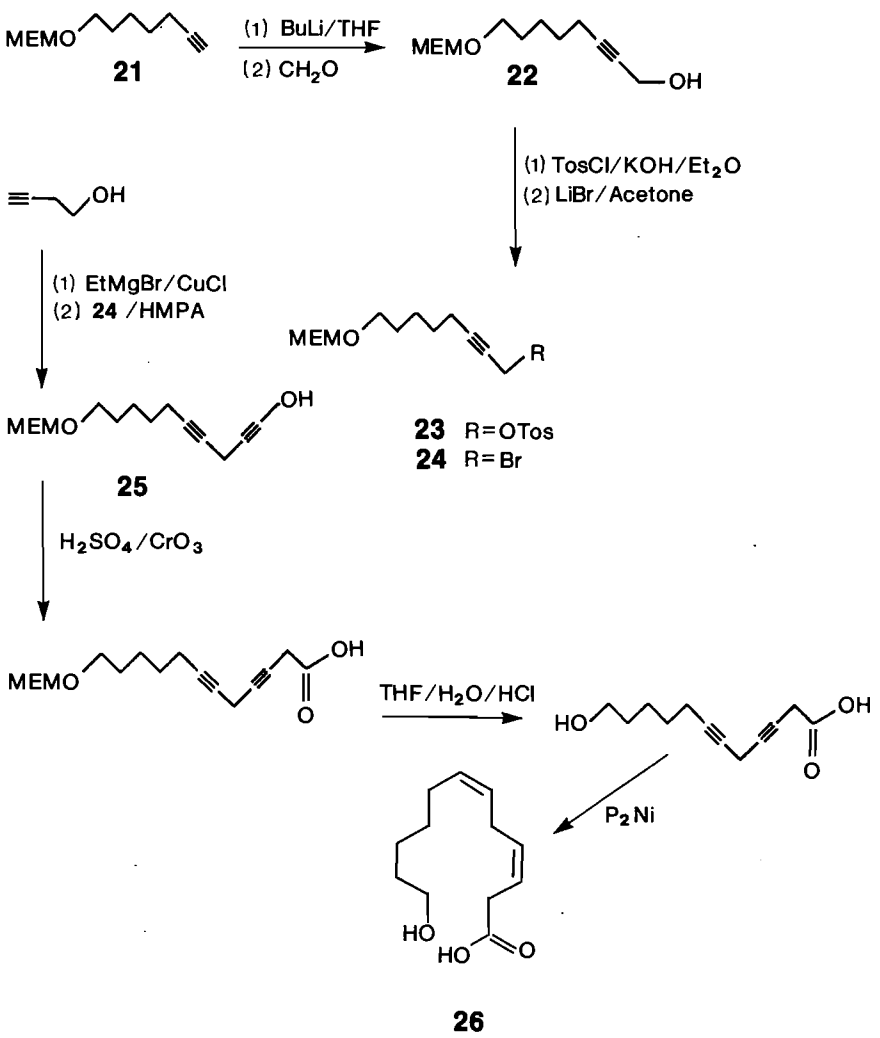
All reactions requiring anhydrous and (or) oxygen-free conditions were run in flame-dried glassware under a positive pressure of nitrogen or argon. Tetrahydrofuran (THF) was freshly distilled from lithium aluminum hydride. Dimethylformamide (DMF) and hexamethylphosphoramide (HMPA) were distilled from calcium hydride under reduced pressure. 1,3-Diaminopropane (1,3-DAP) was distilled from barium oxide. Rotary evaporation at water aspirator pressure was employed to concentrate or remove solvent from solutions obtained by extractive work-up of reactions. Due to instability of the 1,4-diyne intermediates, all subsequent reactions on these intermediates were carried out without purification.

Preparation of 4-undecyn-2-ol (9)

To a solution of 1-octyne (15 g, 0.136 mol) in 120 mL of dry THF under argon at −40°C was added dropwise 78 mL of 2.1 *M* *n*-BuLi in hexane (0.164 mol). After completion of addition, the mixture was warmed to 0°C over 30 min, and then cooled to −20°C. Dry HMPA (45 mL) was added, followed by dropwise addition over 45 min of racemic methyloxirane (9.5 g, 0.164 mol) in HMPA (45 mL). The reaction was stirred at −20°C for 30 min, warmed to 20°C over 4 h, and stirred an additional 12 h. The mixture was poured into ice-water (100 mL) and extracted with ether (4 × 50 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated with no heating. Distillation of the residue gave **9** (18) (21.5 g, 94%); bp 65–72°C (0.2 Torr; 1 Torr = 133.3 Pa). Mass calcd. for $C_{11}H_{20}$: 168 (M^+); found: 169 ($M^+ + 1$, CI, isobutane).

Preparation of 10-undecyn-2-ol (10)

To a suspension of $NaNH_2$ (41.2 g, 1.1 mol, 6 equiv.) in 500 mL of liquid ammonia (10) was added 250 mL of 1,3-DAP (dried over KOH). Most of the ammonia was then evaporated at 50°C (water bath), and the last traces were removed at water pump pressure while maintaining the contents of the flask at 40°C for 15 min. 4-Undecyn-2-ol, **9** (29.6 g, 0.176 mol), was added and the reaction heated at 80°C for 2 h. The reaction mixture was then poured into 400 mL of ice-water and extracted with ether (4 × 50 mL). The ether extracts were dried ($MgSO_4$) and concentrated to yield **10** (21.5 g, 72.5%, 98% pure by gc), which was used in the subsequent reaction without further



SCHEME 2

purification; ir (film): 2135 (s, C≡C) cm^{-1}. *Exact Mass* calcd. for ($C_{11}H_{20}O - CH_3$): 153.1279; found: 153.1297.

Preparation of 11-hydroxy-2-dodecynoic acid (11)

To 400 mL of dry THF under argon at −10°C was added 141 mL of 2.1 *M n*-butyllithium (0.296 mol) in hexane. To this was added 19.8 g (0.118 mol) of **10** in 50 mL THF. The temperature was raised to 0°C, and CO_2 from a cylinder was bubbled in for 30 min. The reaction was warmed to room temperature and quenched by the sequential addition of 50 mL saturated aqueous NH_4Cl solution and 200 mL 5 *N* HCl. The resulting solution was extracted with ether (4 × 200 mL). The combined extracts were dried ($MgSO_4$) and concentrated to give a 95% yield of **11**. An analytical sample (>90% pure by gc) of the methyl ester of **11** was prepared by treatment of a small portion of the product with diazomethane. Ester: ^1H nmr ($CDCl_3$) δ: 1.18 (d, 3H, J = 6 Hz, C(12) H), 1.20–1.66 (m, 13H, CH_2, OH), 2.32 (t, 2H, J = 7 Hz, C(4) H), 3.76 (s, 3H, OCH_3), 3.80 (m, 1H, C(11) H). Carboxylic acid: ir (film): 3350 (br, COOH), 2240 (s, C≡C), 1720 (s, C=O) cm^{-1}.

Preparation of 12 and 13 from 11

To the suspension of $NaNH_2$ (8.4 mmol) in 50 mL liquid ammonia was added **11** (0.3 g, 1.4 mmol) in 5 mL THF. After 30 min, 4 g of powdered ammonium chloride was added, and the ammonia was removed by heating at 50°C. The reaction was cooled to room temperature, and ether (100 mL), crushed ice (20 g), and sufficient 5 *N* HCl to lower the pH to 1 were added. The solution was saturated with NH_4Cl and extracted with ether (3 × 50 mL). The ether extracts were combined, dried ($MgSO_4$), and concentrated to yield nearly quantitative amounts of **12** and **13**. A small sample (0.1 g) of the product mixture was esterified with diazomethane. Gas chromatographic analysis of the esterified mixture revealed two principle (>90%) peaks in a ratio of 6:1–2:1 (depending on the run): ^1H nmr ($CDCl_3$) δ: 1.19 (d, J = 6 Hz, C(12) H), 1.2–1.6 (m, 10H, CH_2, OH), 3.26 (t, 1.5 H, C(2) H), 3.57 (s, 3H, OCH_3), 3.80 (m, 1H, C(11) H), 5.58 (d, 0.25H, J = 15 Hz, C(2) H), 5.62 (q, ≈0.25H, J = 9.5, 15 Hz, C(4) H). Mass calcd. for $C_{13}H_{22}O_3$ (both compounds): 226 (M^+); found: 227 (M^+ + 1, CI, isobutane, both compounds).

Reduction of 12 and 13 to 8

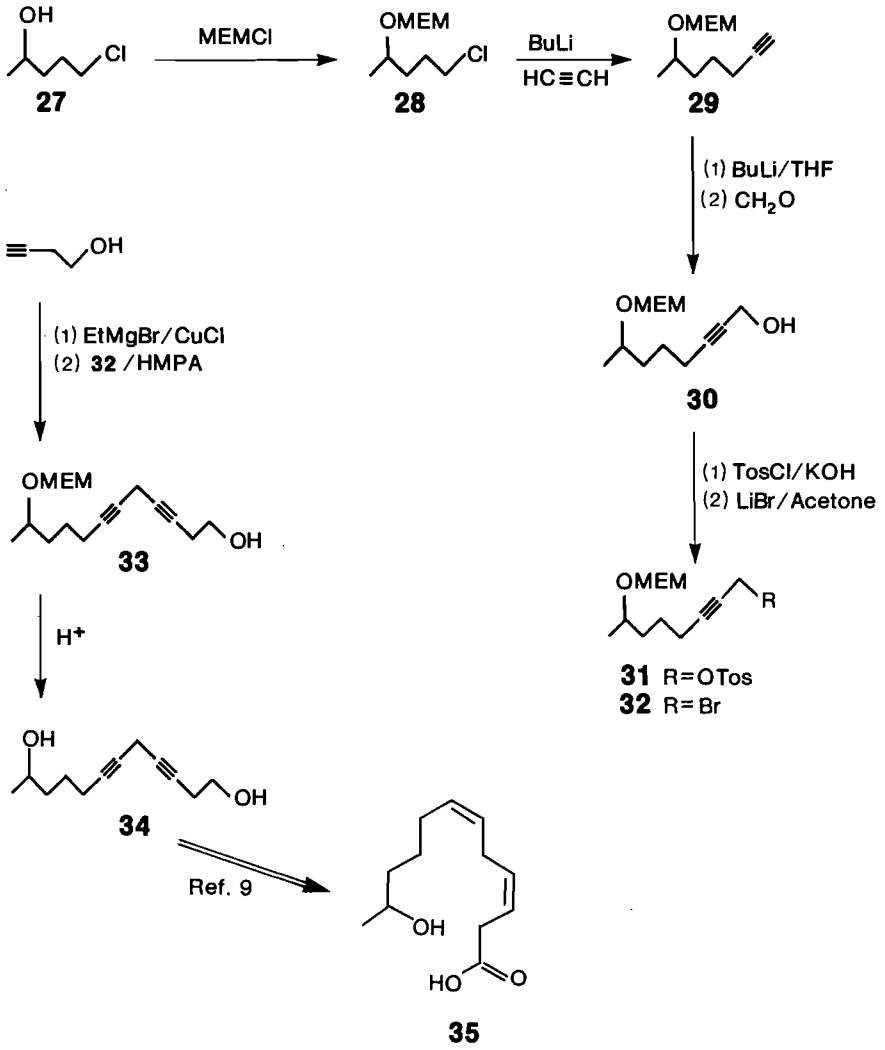
A mixture of **12** and **13** (2.8 g, 13 mmol) was reduced with P-2 nickel by the procedure previously reported (7). The product (2.5 g, 89%) was identical to 11-hydroxy-(*Z*)-3-dodecenoic acid, **8**, prepared earlier (8).

Preparation of 10-undecyn-1-ol, 16

To a solution of 26 g (0.153 mol) of 10-undecen-1-ol, **15**, in 100 mL of CH_2Cl_2 at 4°C was added slowly 24.5 g (0.153 mol) of bromine in 100 mL of CH_2Cl_2 (12). Removal of solvent gave 46.7 g (92%) of 10,11-dibromoundecan-1-ol as a liquid that was a single component by gc. To a solution of crude product in 800 mL of heptane was added powdered KOH (19.9 g, 0.301 mol, 2.12 equiv.) and 18-crown-6 (0.375 g, 1.42 mmol). The reaction was carried out and worked up according to the published procedure (12) to give 18.8 g (80%) of alkynol **16**; ir (film): 3360 (br, OH), 3320 (s, C≡CH), 2130 (s, C≡C) cm^{-1}.

Preparation of 12-hydroxy-2-dodecynoic acid, 17

Alkynol **16** (2.3 g, 13.7 mmol) was carboxylated in nearly quantitative yield by the procedure described above for **10**. The methyl



SCHEME 3

ester (CH_2N_2) of **17** (96% pure by gc) gave acceptable nmr and ir spectra. *Exact Mass* calcd. for ($C_{12}H_{20}O_3$ − CH_3O): 195.1385; found: 195.1370.

Preparation of 18 and 19 from 17

The deconjugation of **17** (6.1 g, 19 mmol) was conducted (Na, 8 equiv., 50 mL liquid NH_3, 80 mL THF) according to the procedure described for **11** to yield 5.6 g (92%) of a mixture (3:2–4:1, by gc of methyl esters) of **18** and **19**. The mixture of methyl esters (CH_2N_2) of **18** and **19** gave acceptable nmr and ir spectra.

Reduction of 18 and 19 to 14

Reduction of the mixture of **18** and **19** from the above preparation (5.6 g) with P-2 nickel yielded 5.5 g of **14**, which was identical by gc–ms (as the methyl ester) and nmr with that prepared previously (7).

Preparation of [(2-methoxyethoxy)methoxy]-6-heptyne, 22

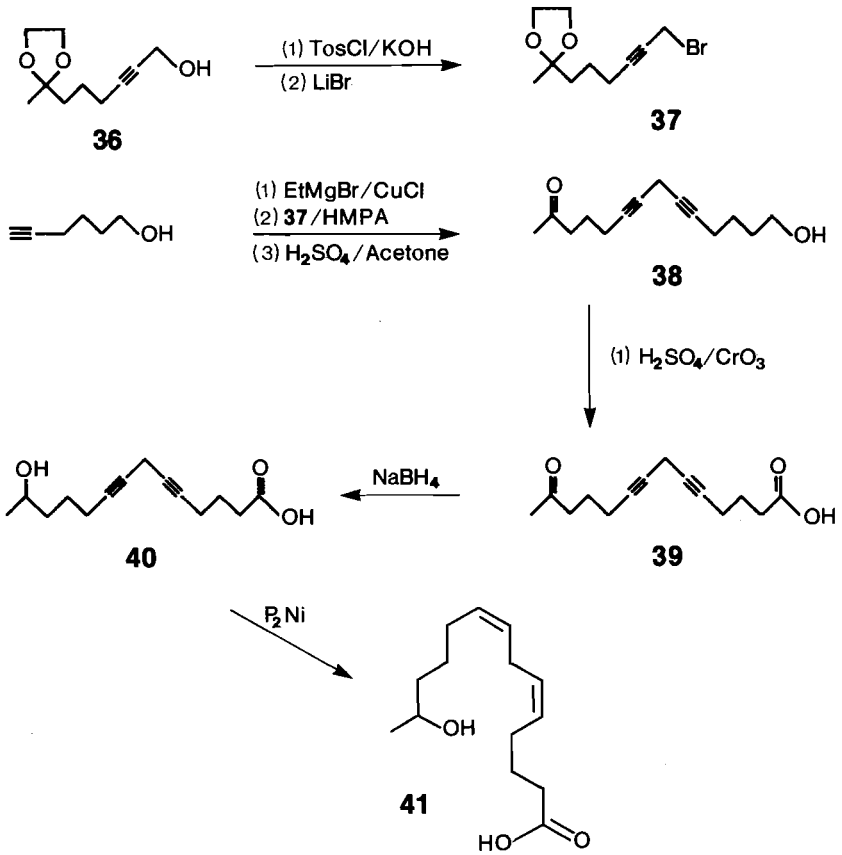
3-Heptyn-1-ol was isomerized to the terminal alkyne in 90% yield as described for **9**, which was then protected as the (2-methoxyethoxy)methyl ether in 81% yield (15). Compound **21** gave ^1H nmr and mass spectra identical to that prepared previously (9). To a solution of **21** (32 g, 0.16 mol) in THF (500 mL) under argon, while maintaining the temperature below 0°C, was added dropwise *n*-BuLi in hexane (96 mL, 2.5 *M*, 0.24 mol). The resulting solution was stirred at 0°C for 30 min. Dry paraformaldehyde (7.7 g, 0.26 mol) was added in one portion. The mixture was warmed to 20°C over several hours and stirred at 20°C for 12 h. The reaction was worked up by pouring into ice-water (100 mL) and extracting with ether (4 × 50 mL). The ether extract was dried ($MgSO_4$) and concentrated to give 25.7 g (70%) of **22** (75% pure by gc). *Exact Mass* calcd. for ($C_{12}H_{22}O_4$ − CH_3O): 199.1334; found: 199.1333.

Preparation of 8-[(2-methoxyethoxy)methoxy]-2-heptyn-1-yl p-toluenesulfonate, 23

The crude product (38.6 g,0.17 mol) from the previous reaction was stirred with *p*-toluenesulfonyl chloride (35.2 g, 0.185 mol) and powdered KOH (47.1 g, 0.84 mol) in 500 mL dry ether at 0°C. After 30 min the reaction was poured into ice-water (300 mL) and the organic layer removed. The aqueous layer was extracted with ether (2 × 150 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated without heating. Final traces of solvent were removed under vacuum (0.1 Torr) for 4 h, yielding the tosylate **23** as an oil (60.28 g, 93%). Tosylate **23** gave one spot on tlc (hexane:EtOAc, 3:1) and was used without further purification.

Preparation of 8-[(2-methoxyethoxy)methoxy]-2-heptyn-1-yl bromide, 24

Tosylate **23** (40 g, 0.104 mol) and LiBr (18 g, 0.21 mol) in 600 mL dry acetone were stirred at room temperature for 1 h. The solution was concentrated at room temperature, diluted with 500 mL of water, and extracted with ether (2 × 200 mL). The combined ether extracts were dried ($MgSO_4$) and concentrated to yield 31 g (100%) of crude product, which was purified by flash chromatography on silica gel (200 g;



SCHEME 4

hexane:EtOAc, 4:1) to yield 15 g (50%) of **24** (80% pure by gc). *Exact Mass* calcd. for ($C_{12}H_{21}O_3Br$ − Br): 213.1490; found: 213.1468.

Preparation of 12-[(2-methoxyethoxy)methoxy]-3,6-dodecadiyn-1-ol, 25

A 2.25 *M* solution of EtMgBr (7.1 mL, 15.95 mmol) in THF was added dropwise to 3-butyn-1-ol (0.58 g, 8.24 mmol) in 40 mL dry THF. The resulting suspension was refluxed for 2 h. Cuprous chloride (0.85 g, 8.64 mmol) was added to the cooled (room temperature) mixture, which was stirred a further 0.5 h. Bromide **24** (1.06 g, 3.75 mmol) in 10 mL dry HMPA was added at ice-bath temperature. The ice bath was removed. The reaction mixture was stirred for 2.5 h, poured into 50 mL cold saturated NH_4Cl solution, and extracted with ether (3 × 50 mL). The combined ether extracts were washed with saturated NH_4Cl solution (50 mL) and brine. The ether extract was dried ($MgSO_4$) and concentrated to yield 1.1 g (92%) of the crude **25** (89% pure by gc). The ^1H nmr, ms, and ir data of **25** were equivalent to those previously obtained (9).

Preparation of 5-chloro-2-pentanol, 27

To a stirred solution of $NaBH_4$ (10.0 g, 0.264 mol) in 200 mL of 95% EtOH at 0°C was added dropwise over 2 h a solution of 5-chloro-2-pentanone (30 g, 0.249 mol) in 50 mL of 95% EtOH. After 1 h, acetone (50 mL) was added and most of the solvent was evaporated. Water (250 mL) was added to the residue, and the solution was extracted with ether (3 × 100 mL). The ether extracts were combined, dried ($MgSO_4$), and evaporated. The residue was distilled to give 27.5 g (90%) of **27** (98% pure by gc); bp 89–90°C (25 Torr).

Preparation of 5-chloro-2-[(methoxyethoxy)methoxy] pentane, 28

Reaction of chloro alcohol **27** with MEM chloride by the literature procedure (13) gave **28** in 89% yield (93% pure by gc); bp 60–70°C (0.1 Torr); ^1H nmr ($CDCl_3$) δ: 1.16 (d, 3H, J = 6.6 Hz, CH_3), 1.55–1.65 (m, 2H, C(3)), 1.80–1.91 (m, 2H, C(4)), 3.36 (s, 3H, OCH_3), 3.50–3.58 (m, 4H, OCH_2CH_2O), 3.66–3.76 (m, 3H, C(2), C(5)), 4.68–4.76 (dd, 2H, OCH_2); ms, *m/e* (%, rel. int.): 105 (55%), 89 (100%), 73 (18%), 59 (78%).

Preparation of 6-[(2-methoxyethoxy)methoxy]-1-heptyne, 29

A stream of dry acetylene was used to saturated 180 mL of dry THF at ice-bath temperature. To this solution, 2.1 *M* *n*-BuLi in hexane (65 mL, 0.136 mol) was added dropwise while maintaining the temperature at 5–10°C. After stirring the mixture for 0.5 h at 10°C, 5-chloro-2-[(2-methoxyethoxy)methoxy]-pentane, **28** (20.4 g, 0.097 mol), in 50 mL of dry HMPA was added dropwise. The reaction mixture was warmed to room temperature and stirred under an acetylene atmosphere for 24 h. The reaction was quenched by pouring into ice-water (150 mL) and extracting with ether (5 × 50 mL). The combined ether extracts were washed with water (75 mL) and brine (2 × 75 mL), dried ($MgSO_4$), and concentrated. Distillation of the residue gave 19.5 g (94%) of **29** (93% pure by gc); bp 65–70°C (0.2 Torr); ir (film): 3295, 2118 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.13 (d, 3H, J = 6.6 Hz, CH_3), 1.50–1.67 (m, 4H, C(4), C(5)), 1.95 (t, 1H, J = 2.5 Hz, C(1)), 2.18 (tt, 2H, J = 7, 2.5 Hz, C(3)), 3.40 (s, 3H, OCH_3), 3.56 (m, 2H, OCH_2CH_2O), 3.70 (m, 2H, OCH_2CH_2), 3.75 (m, 1H, C(6)), 4.70–4.78 (dd, 2H, OCH_2O). *Exact Mass* calcd. for ($C_{11}H_{20}O_3$ − CH_3O): 169.1229; found: 169.1248.

Preparation of 7-[(2-methoxyethoxy)methoxy]-2-octyn-1-ol, 30

6-[(2-Methoxyethoxy)methoxy]-1-heptene, **29**, was chain-extended to **30** in 62% yield by the procedure described above for **22**: bp 120–130°C (0.3 Torr); ir (film): 3360, 2220 cm^{-1} (90% pure by gc); ^1H nmr ($CDCl_3$) δ: 1.14 (d, 3H, J = 6.6 Hz, C(8)), 1.50–1.66 (m, 4H, C(5), C(6)), 2.18 (tt, 2H, J = 7, 2.5 Hz, C(4)), 2.32 (br s, 1H, OH), 3.40 (s, 3H, OCH_3), 3.56 (m, 2H, OCH_2CH_2O), 3.70 (m, 2H, OCH_2CH_2O), 3.75 (m, 1H, C(7)), 4.18 (br s, 2H, C(1)), 4.70–4.78 (dd, 2H, OCH_2O). *Exact Mass* calcd. for ($C_{12}H_{22}O_4$ − CH_3O): 199.1334; found: 199.1376.

Preparation of 1-bromo-7-[(2-methoxyethoxy)methoxy)-2-octyne, 32

Bromide **32** was prepared from **30** in 69% yield by the procedure described for **24** and was purified by distillation; bp 120–130°C (0.1 Torr); ir (film): 2200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.14 (d, 3H, J = 6.6 Hz, C(8)), 1.50–1.66 (m, 4H, C(5), C(6)), 2.18 (tt, 2H, J = 7, 2.5 Hz, C(4)), 3.40 (s, 3H, OCH_3), 3.56 (m, 2H, OCH_2CH_2O), 3.70

(m, 2H, OCH_2CH_2O), 3.75 (m, 1H, C(7)), 3.92 (t, 2H, J = 2.6 Hz, C(1)), 4.70–4.78 (dd, 2H, OCH_2O); ms, m/e (%, rel. int.): 173 (12%), 171 (12%), 159 (7%), 157 (7%), 144 (23%), 146 (23%), 107 (35%), 79 (50%), 65 (45%), 55 (40%), 45 (100%). *Exact Mass* calcd. for ($C_{12}H_{21}O_3Br$ − Br): 213.1491; found: 213.1504.

Preparation of 11-[(2-methoxyethoxy)methoxy]-3,6-dodecadiyn-1-ol, 33

Bromide **32** was coupled to 3-butyn-1-ol as described above for **25** to give **33** (83% pure by gc) in 98% crude yield; ^{1}H nmr ($CDCl_3$) δ: 1.13 (d, 3H, J = 6.6 Hz, C(12)), 1.50–1.66 (m, 4H, C(9), C(10)), 1.95 (t, 1H, J = 5, 3 Hz, OH), 2.17 (m, 2H, C(8)), 2.43 (m, 2H, C(2)), 3.13 (quint., 2H, J = 2.2 Hz, C(5)), 3.40 (s, 3H, OCH_3), 3.56 (m, 2H, OCH_2CH_2O), 3.69–3.78 (m, 5H, OCH_2CH_2O, C(1), C(11)), 4.70–4.78 (dd, 2H, OCH_2O).

Preparation of 3,6-dodecadiyn-1,11-diol, 34

The crude diyne **33** prepared above (5.44 g, 0.019 mol) was stirred for 18 h at 20°C in 195 mL of THF:H_2O:conc. HCl (8:2:1 by volume). The reaction was quenched by pouring into 200 mL of ice-water and extracted with ether (2 × 100 mL). The ether extract was washed with brine (2 × 100 mL), dried ($MgSO_4$), and concentrated to yield 3.7 g (100%) of **34**, which gave ^{1}H nmr and mass spectra identical to those obtained previously (9).

Preparation of 2-methyl-2-(6-bromo-4-hexynyl)-1,3-dioxolane, 37

Bromide **37** was prepared in 89% yield from **36** by the procedure used to prepare **24**. The crude product (82% pure by gc) was employed for the following reaction; ir (film): 2220 cm^{-1}; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 1.53–1.82 (m, 4H, $2CH_2$), 2.12–2.40 (m, 2H, $CH_2C{\equiv}C$), 3.90 (br s, 4H, OCH_2CH_2O), 3.95 (br s, 2H, CH_2Br). *Exact Mass* calcd. for ($C_{10}H_{15}O_2Br$ − Br): 167.1072; found: 167.1070.

Preparation of 13-oxo-5,8-tetradecadiyn-1-ol, 38

To 5-hexyn-1-ol (0.64 g, 6.5 mmol) in 40 mL of THF was added 5.6 mL of 2.25 *M* EtMgBr (12.6 mmol) in THF. The mixture was refluxed for 2 h and cooled to ice-bath temperature, whereupon CuCl (0.64 g, 6.5 mmol) was added. After 0.5 h of stirring, **37** (0.94 g, 3.8 mmol) in 10 mL of dry HMPA was added. The reaction was stirred overnight and then poured into 50 mL of saturated NH_4Cl solution. The product was isolated by extraction with ether (3 × 25 mL). The combined ether extracts were worked up with saturated NH_4Cl solution (2 × 25 mL) and brine (2 × 40 mL), dried ($MgSO_4$), and concentrated to give 1.1 g of the crude hydroxy ketal, which was 95% pure by gc. To this ketal in 40 mL of acetone was added 3 drops of 3.5 *M* H_2SO_4. After 5 h of stirring at 25°C, K_2CO_3 (1 g) was added. The solution was then filtered and concentrated to give 0.85 g of **38**, which was 85% pure by gc analysis; ir (film): 2238 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.53–1.68 (m, 4H, C(2), C(3)), 1.75 (quint., 2H, J = 7.3 Hz, C(11)), 2.15 (s, 3H, C(14)), 2.16–2.23 (m, 4H, C(4), C(10)), 2.55 (t, 2H, J = 7.3 Hz, C(12)), 3.08 (quint., 2H, J = 2.1 Hz, C(7)), 3.65 (t, 2H, J = 7 Hz, C(1)). *Exact Mass* calcd. for $C_{14}H_{20}O_2$: 220.1463; found: 220.1455.

Preparation of 13-oxo-5,8-tetradecadiynoic acid, 39

Crude keto-alcohol **38** (0.8 g, ≈3.8 mmol) in reagent acetone (40 mL) was added dropwise over 1 h at ice-bath temperature to CrO_3 (1.64 g, 16.4 mmol) dissolved in 3.5 *M* H_2SO_4 (16.5 mL). The ice bath was removed, the reaction stirred at 20°C for 4 h, poured into ice-water (300 mL), and extracted with ether (4 × 50 mL). The ether extract was washed with brine (2 × 50 mL), dried ($MgSO_4$), and concentrated to give 0.87 g of **39** (78% overall from **37**), which was 80% pure by gc (as the methyl ester, CH_2N_2); ^{1}H nmr ($CDCl_3$) δ: 1.75 (quint., 2H, J = 7 Hz, C(3)), 1.83 (quint., 2H, J = 7 Hz, C(11)), 2.16 (s, 3H, C(14)), 2.17–2.29 (m, 4H, C(4), C(10)), 2.52 (t, 2H, J = 7 Hz, C(2)), 2.56 (t, 2H, J = 7 Hz, C(12)), 3.08 (quint., 2H, J = 2.1 Hz, C(7)). *Exact Mass* calcd. for ($C_{15}H_{20}O_3$ − CH_3): 233.1177; found: 233.1209.

Preparation of 13-hydroxy-5,8-tetradecadiynoic acid, 40

Keto-acid **39** (0.69 g, 2.9 mmol) was dissolved in 95% ethanol (10 mL) and cooled to −20°C, whereupon $NaBH_4$ (0.16 g, 4.1 mmol) was added in one portion. The reaction was slowly warmed to 0°C, cooled to −20°C, and acidified with 3.5 *N* HCl. Brine (40 mL) was added and the solution extracted with ether (4 × 40 mL). The ether extract was washed with brine (2 × 40 mL), dried ($MgSO_4$), and concentrated to give 0.76 g (87%) of **40**, which was 80% pure by gc when analyzed as the methyl ester (CH_2N_2); ir (film): 3600–2500, 2240, and 1710 cm^{-1}. *Exact Mass* calcd. for ($C_{15}H_{22}O_3$ − CH_3): 235.1334; found: 235.1325.

Preparation of 13-hydroxy-(Z,Z)-5,8-tetradecadienoic acid, 41

Reduction of hydroxy acid **40** (0.66 g, 1.8 mmol) with P-2 nickel (7) gave, after work-up, 0.69 g (73%) of crude **41** whose nmr and mass spectra matched those previously reported (9).

A CIDEP study of the photooxidation of benzoquinone in trifluoroacetic acid

MARJORY T. CRAW, M. CATHERINE DEPEW, AND JEFFREY K. S. WAN[1]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 1, 1985

MARJORY T. CRAW, M. CATHERINE DEPEW, and JEFFREY K. S. WAN. Can. J. Chem. **64**, 1414 (1986).

The combined techniques of electron spin resonance and CIDEP have been used to probe the reactions of 1,4-*p*-benzoquinone in trifluoroacetic acid. The results led to the establishment of two distinct mechanisms, a thermal and a photochemical pathway, for the formation of the one-electron oxidized species in this solvent. In addition it has also been found that by using time-resolved CIDEP the neutral 1,4-*p*-benzohydroquinone radical may be readily observed under various conditions.

MARJORY T. CRAW, M. CATHERINE DEPEW et JEFFREY K. S. WAN. Can. J. Chem. **64**, 1414 (1986).

On a fait appel à une combinaison de techniques de résonance paramagnétique électronique et CIDEP pour étudier les réactions de la benzoquinone-1,4 dans l'acide trifluoroacétique. Les résultats tendent à suggérer l'existence de deux mécanismes distincts, une voie thermique et une autre photochimique, pour la formation des espèces oxydées par un électron que l'on retrouve dans ce solvant. De plus, l'utilisation de la technique CIDEP résolue en fonction du temps permet d'observer facilement le radical benzohydroquinone-1,4 dans ces conditions.

[Traduit par la revue]

Introduction

Thermal and photoredox reactions involving benzoquinones have long been the subject of considerable general interest (1, 2). The intermediates in many of these reactions are commonly referred to as "semiquinones," which include the neutral and charged forms. Of the charged semiquinone radicals, the radical anion is readily observed by both optical and esr (electron spin resonance) spectroscopy; the corresponding one-electron oxidized species have, however, been more difficult to observe and are thought to be stable only in strongly acidic media (3, 4). Thus, trifluoroacetic acid, TFA, generally acknowledged for its ability to solvate and stabilize organic cations due to its acidity and low nucleophilicity (5, 6), has been used in this laboratory for the time-resolved CIDEP[2] studies of organic radical cations (7–9). Both a theoretical investigation (10) and an experimental study (7, 11) have concluded that the major stabilization effect arises from an interaction of the trifluoromethyl group and the organic cation.

The photochemical formation of polarized benzoquinone radical cations in TFA has been used as a model system for the charge transfer process involving heterocyclic sulfur-containing compounds (8). It was confirmed that secondary polarization observed in the radical cations of heterocyclic sulfur compounds resulted directly from the rapid charge transfer process:

$$BQ^{\ddagger} * + S \rightarrow BW + S^{\ddagger} *$$

An alternate, direct primary photochemical process such as

$$^3BQ^* + S \rightarrow \dot{S}^+ * + BQ^{\dot{-}} *$$

is unlikely, as the resultant $BQ^{\dot{-}} *$ radical anion was never observed in these systems. It was also clear that the primary polarized benzoquinone radical species is the radical cation, since neither a neutral nor an anion radical could lead to a charge transfer process resulting in the formation of the sulfur radical cation.

While the polarized benzoquinone radical cation in TFA provided a model system for CIDEP study of charge transfer reactions, the mechanism for the thermal and photochemical production of the radical cation in TFA remained unresolved. Because of the great deal of general interest in the radical cation studies in TFA, we have systematically investigated the photooxidation of benzoquinone in TFA and related solvents by the combination of esr and time-resolved CIDEP methods.

The results provide some insight into the complex mechanism for the formation of the benzoquinone radical cation in trifluoroacetic acid. It was further unambiguously established that the trifluoroacetyl moiety served only to enhance the stabilization of the radical cation and was not involved in the formation steps. These conclusions will be of great interest to organic reactions in TFA in general.

Experimental

Benzoquinone was supplied by Aldrich and repeatedly recrystallized from ethanol and sublimed before use. Trifluoroacetic acid was obtained from Alfa Chemicals. All other chemicals were reagent grade and used without further purification. All samples were purged with oxygen-free nitrogen before experimentation.

For the variable temperature studies, oxygen was evacuated from the samples by the freeze-thawing technique. The esr spectra were recorded on a Varian E3 spectrometer with a variable temperature control accessory. The samples were irradiated inside the cavity using a 200-W super pressure mercury arc lamp. CIDEP experiments were also conducted on the Varian E3 spectrometer using a 1-MW Molectron N_2 laser; the CIDEP transients were directly detected without modulation using a Hewlett Packard wide-band preamplifier and a Princeton Applied Research model 162 boxcar integrator. The polarization spectra were then displayed and stored on a Nicolet microcomputer-controlled oscilloscope connected to a Hewlett Packard 7475A digital plotter. In some cases the microwave signal was increased to a significant extent by using a "homemade" amplifier that essentially magnified the microwave signal prior to modulation and utilized a Narda solid-state GaAs preamplifier narrowly tuned to the cavity frequency.

Kinetic measurements were carried out using the Nicolet computer oscilloscope, the intensity of the esr signal being monitored before, during, and after irradiation. The decay rates of the radicals were calculated assuming pseudo-first-order kinetics.

Results and discussion

When a solution of benzoquinone (BQ) in TFA was placed in the cavity of the esr spectrometer at room temperature, a fairly weak signal consisting of 5 lines was observed. Photolysis of this solution resulted in an increase in the signal intensity; the *g* factor and hyperfine splitting constant were the same as those observed thermally. The splitting pattern is indicative of a

[1]Author to whom correspondence may be addressed.

[2]CIDEP: chemically induced dynamic electron polarization.

1:4:6:4:1 quintet, consistent with the formation of a radical with 4 equivalent protons. The proposed structure of this species is that shown (**1**), with the unpaired electron being delocalized over the whole π system.

1

The g factor (2.0040) and splitting constant (a_H = 2.22 G) measured for this species are very similar to those reported previously (12) for the radical anion, i.e. g = 2.0046 and a_H = 2.36 G, suggesting that, as with the anion (13), the cation has a quininoid structure with planar geometry. The assignment of **1** was further supported by an INDO calculation using the structural parameters given by Shinagawa and Shinagawa (13). In addition, benzoquinone-d_4 was synthesized and the radical cation spectrum showed a major single peak with unresolved hyperfines due to the d-atoms.

It is not immediately obvious why the benzoquinone radical cation and the radical anion have such similar proton hyperfine splittings, granted that they are produced in very different media. This point deserves some further examination. We have thus listed in Table 1 all our experimental observations and the standard INDO molecular orbital calculations of all three charged forms of possible paramagnetic intermediates of p-benzoquinone. It is apparent that in all three cases the ring protons have similar hyperfine splittings, which do not seem to be sensitive to the charges they carry. Another example of the insensitivity of splittings of atoms in the ring to the charges is that of phenoxazine (T. S. Liu and J. Retsky, private communication). Since in the case of benzoquinone radicals all the ring protons lie in the nodal plane of the unpaired π-electron, we thought that a more reliable test for differentiating the changes in hyperfine splitting with charge would be the symmetrical 2,5-dimethyl-p-benzoquinone. The experimental observations of both the 2,5-dimethyl-p-benzoquinone radical cation in TFA and the corresponding radical anion in IPA are given in Table 1. Although both have the same hyperfine pattern (septet of triplets), it is clear that the major septet splitting due to the six equivalent methyl protons is substantially different. As well, we should also mention that many of the substituted p-benzoquinones we tested do not form radical cations, although the corresponding radical anions are usually observable in basic medium. These include duroquinone and tetrachloro-p-benzoquinone.

Returning to the esr parameters of p-benzoquinone radicals, it is further worthwhile to point out that the radical cation and the radical anion have rather different relaxation times. In both cw (continuous wave) and time-resolved polarized esr spectra, the line width of the radical cation is several times greater than the corresponding radical anion. This phenomenon is also exhibited by comparing the line width of the phenoxazine radical cation and its neutral counterpart, as well as for the 2,5-dimethyl-p-benzoquinone radical cation and anion systems.

The significant line-broadening effect in the radical cation spectrum observed in TFA is probably caused by the strong interaction of the radical cation with the trifluoromethyl moiety. The phenomenon thus lends further support to the importance of the unique stabilization effect of TFA towards radical cations.

The cw optical spectra of p-benzoquinone in three different solvents, IPA, ethanol with NaOH, and TFA, have also been recorded. In separate esr measurements, the NaOH solution showed a strong signal of the radical anion while the TFA solution exhibited the weaker signal of the radical cation. Although some different appearances in the near uv band around 300 nm are evident in all three different spectra, little conclusion can be drawn in these experiments as the solvent effect in such systems can be dominating.

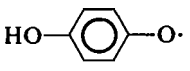
TABLE 1. Calculated and experimental proton hyperfine splittings (gauss) of p-benzoquinone radical ions

	INDO results	Experimental observations
	a_H = 2.56	a_H = 2.33 (in alcohol)
	a_H = 2.14	a_H = 2.22 (in TFA)
	a_H = 1.67 a_{OH} = 5.08	a_H = 2.24 a_{OH} = 5.08 (in H_2SO_4)
	—	a_{CH3} = 3.30 a_H = 0.90 (in TFA)
 [a]	—	a_{CH3} = 2.30 a_H = 1.70 (in water)

[a]Taken from ref. 19.

The presence of the benzoquinone radical cation was further established by chemical evidence given below. When photolysis ceased, the photochemically generated signal decayed to an intensity similar to that detected before irradiation. The rate constant for this decay was calculated as 3.83×10^3 s^{-1}, assuming pseudo-first-order kinetics. However, when the temperature was raised in stages from 23 to 60°C the thermal signal intensity increased more than sevenfold, reflecting the increasing radical steady-state concentration.

When the solvent was changed from TFA to acetic acid, no signal was observed before photolysis. Irradiation of this sample resulted in the observation of only the neutral semiquinone radical (**2**) (14), with splitting constants as shown.



$a_H ortho$ = 5.11 G
$a_H meta$ = 0.28 G
a_{OH} = 1.79 G

2

Although the radical cation may possibly form, it may not persist long enough for cw observation due to a lack of solvent stabilization. On the other hand, if the radical species observed in TFA was to be assigned to the unlikely radical anion, there would have been no reason at all why the same radical anion could not be observed in acetic acid. The photochemical production of the neutral semiquinone radical can be accounted for by the triplet abstraction from the methyl group of acetic acid.

In time-resolved CIDEP experiments with benzoquinone in TFA, the broadened polarized radical cation spectrum observed is given in Fig. 1. The strong, totally emissive polarization is characteristic of the photochemical triplet mechanism but a minor contribution of E/A polarization from the radical pair mechanism is clearly evident. Thus, the low-field lines are

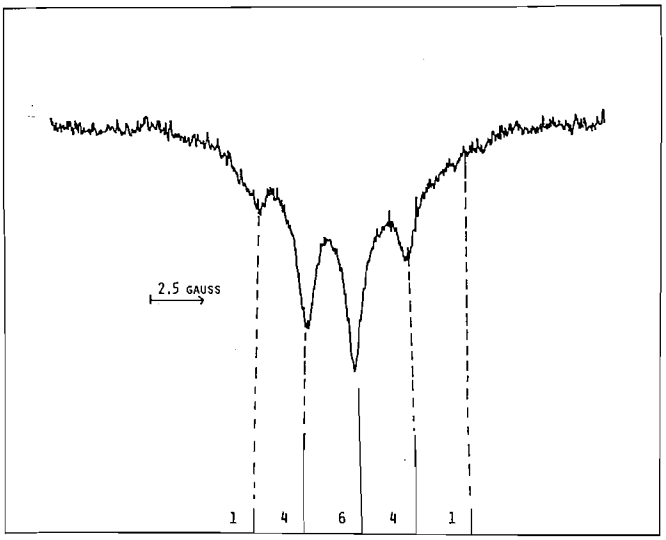


FIG. 1. The polarization spectrum of the 1,4-*p*-benzoquinone radical cation ($B\dot{Q}^+$) in TFA recorded 1.0 μs after the laser flash.

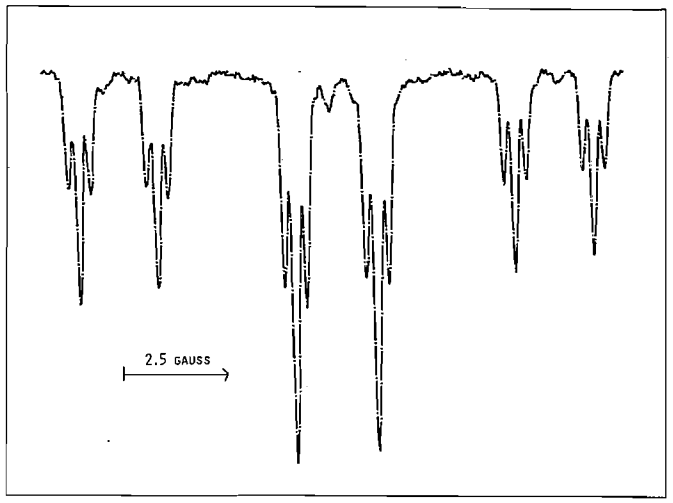

FIG. 2. The polarization spectrum of the neutral radical of 1,4-*p*-benzoquinone ($B\dot{Q}H$) in CH_3COOH/IPA recorded 1.0 μs after the laser flash.

relatively stronger in emission than the high field lines. The "thermalized" radicals produced simultaneously during the CIDEP experiments are not detected in the time-resolved observations. A simple mechanism, which can account for both the thermal and photochemical observations involving oxidation of benzoquinone in TFA, can be represented by the following:

[1] $BQ + CF_3COOH \rightleftharpoons BQH^+ + CF_3COO^-$

[2] $BQ + BQH^+ \xrightarrow{\Delta} B\dot{Q}^+ + B\dot{Q}H$

[3] $BQ + h\nu \rightsquigarrow {}^3BQ^*$ (*denotes spin polarization)

[4] ${}^3BQ^* + BQH^+ \longrightarrow B\dot{Q}^{+}* + B\dot{Q}H^*$

[5] $B\dot{Q}H^* + H^+ \longrightarrow B\dot{Q}H_2^+$

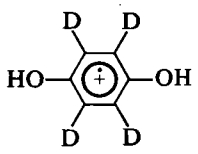
Benzoquinone, having two reactive carbonyl groups, is likely to undergo some degree of protonation at thermal equilibrium:

$$\rangle C{=}O + H^+ \rightleftharpoons \rangle \overset{+}{C}{-}OH$$

As well, protonation can also occur at the quininoid ring. Thus, Davies and co-workers (16) have proposed the intermediacy of a carbenium ion in the photolysis of cyclopentadiene derivatives in TFA. Once formed, this species is thought to rapidly lose a hydrogen atom to form the cyclopentadienyl radical cation.

In the thermal oxidation of benzoquinone in TFA, reaction [2] may involve either a hydrogen atom transfer from BQH^+ to BQ or a direct charge transfer between the two. Since the product radicals are the same and the thermal radicals do not exhibit CIDEP, we are not able to distinguish the detailed step involved. It is obvious that reaction [2] is endothermic but the activation energy barrier may not have to be substantial, since the reactants and the products are almost structurally degenerate. Nevertheless, the thermal reaction [2] is indeed temperature dependent, as evidenced by the experimental results. While the $B\dot{Q}^+$ would be stabilized by the trifluoromethyl moiety, the companion neutral semiquinone radical $B\dot{Q}H$ decayed rapidly in acidic medium (17).

In the photochemical oxidation, reaction [3] involved the intersystem crossing to the triplet sublevels of benzoquinone, ${}^3BQ^*$, causing the spin polarization to be in the emissive mode (15). Subsequent reaction of the polarized triplet in reaction [4] will conserve the spin polarization in the primary radicals, provided the reaction is faster or comparable to the triplet spin lattice relaxation, which is normally in the nanosecond region in liquid medium. Again, *we are not able to distinguish whether reaction [4] is a charge transfer or a H atom abstraction process*. The counter radical, $B\dot{Q}H^*$, was not evident in the "integrated" time-resolved CIDEP spectrum (Fig. 1), although in the benzoquinone-d_4 experiments a minor triplet component due to the dihydroxysemiquinone radical cation, **3**, became observable. The formation of **3**,



3

can be accounted for in reaction [5].

In order to confirm the necessary protonation step in reaction [1] and the role of the trifluoroacetyl group, experiments were conducted with BQ in trifluoroacetic anhydride [$(CF_3CO)_2$] instead of TFA. In this case we could not detect any esr signal at all before or after irradiation, but by adding one drop of water to the sample the esr spectrum corresponding to the benzoquinone radical cation was immediately observed. This clearly shows that this reaction requires hydrogen ions in solution and not merely the presence of the trifluoroacetyl moiety. On the other hand, when formic acid was used as solvent, *no thermal signal was detected*. During photolysis a relatively weaker cw and polarized radical cation spectrum was observed. The rate of decay of the $B\dot{Q}^+$ in formic acid was measured as $1.03 \times 10^4\ s^{-1}$, some three times faster than that observed in TFA. Thus, formic acid is capable of protonating the quinone; however, the difference in the decay rate of the radical cation in this solvent and in TFA suggests that the cation radical is considerably more stable in the presence of CF_3COO^-. This agrees well with results we obtained previously where it was found that as one descends the series CF_3COOH, CF_2COOH, and CFH_2COOH stabilization of radical cations decreases (7).

The photochemical observation of $B\dot{Q}^+$ in both TFA and formic acid and not in acetic acid may be accounted for by the

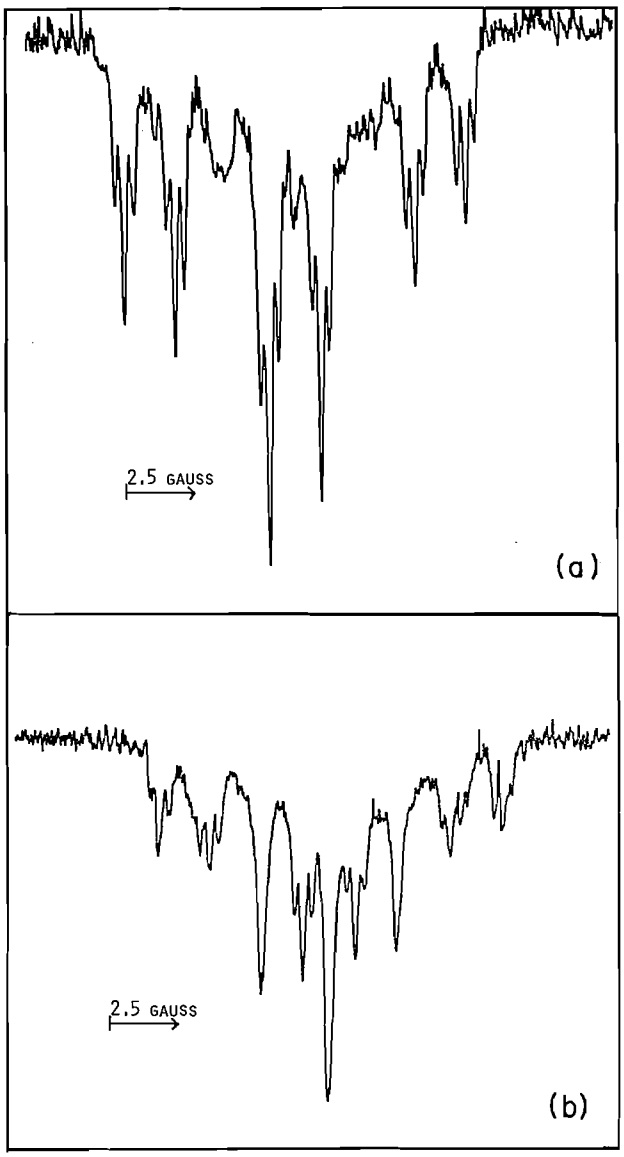


FIG. 3. The polarization spectrum of 1,4-*p*-benzoquinone in ethanol recorded (a) 0.5 μs and (b) 1.5 μs after the laser flash; see text.

somewhat lower p*K*a values of the former two acids and the lack of stabilization of $B\dot{Q}^+$ in acetic acid. The inability to observe polarization from $B\dot{Q}H$ in acetic acid may result from a decrease in the rate of $\dot{H}$ abstraction in this solvent compared with, for example, isopropyl alcohol. Indeed, if the solvent used consists of a 1:1 mixture of acetic acid/isopropyl alcohol intense emissive polarization (Fig. 2) corresponding to the neutral hydroquinone radical is observed. The slower rate of H abstraction in acetic acid relative to alcohol solvents may be explained in terms of a switching of the lowest lying excited states to the π,π^* character (1, 18). The observation of such an intense polarization signal for the neutral hydroquinone radical was rather surprising since this species is not very stable and was difficult to observe in the conventional esr experiment.

We have conducted further CIDEP experiments with BQ in ethanol solvent. The polarization spectra obtained for this system 0.5 μs and 1.5 μs after the laser pulse are shown in Figs. 3. As may be seen, only the neutral semiquinone radical is observed after 0.5 μs, whereas increasing the delay time led to a spectrum that becomes the superposition of two species, the neutral semiquinone and $BQ^{\dot{-}}$, suggesting that in this case the neutral radical is the precursor to the anion radical.

It is rather satisfying that in the laboratory one can indeed control the experimental conditions to yield CIDEP spectra of all the three forms of the benzoquinone radicals: the neutral semiquinone radical, the benzoquinone radical anion, and the benzoquinone radical cation. The present study of the oxidation of 1,4-*p*-benzoquinone provides a model system for which further investigations of structurally similar molecules, particularly those of biological significance such as vitamin K and vitamin E, will be developed.

Electrochemical nucleation in the electroreduction of silver(I) from molten calcium nitrate tetrahydrate

SURENDER K. JAIN[1] AND KEITH E. JOHNSON[2]

Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received February 26, 1985[3]

SURENDER K. JAIN and KEITH E. JOHNSON. Can. J. Chem. **64**, 1418 (1986).

The electroreduction of silver(I) on a platinum electrode from its solution in molten calcium nitrate tetrahydrate has been studied using voltammetric, chronopotentiometric, and chronoamperomeric techniques. The early stages of metal deposition appear to be controlled by a nucleation step as indicated by potential overshoots in chronopotentiometric and maxima in chronoamperometric transients. From the rising portion of the current–time transients, the number-density of the surface nuclei has been estimated. Diffusion coefficients calculated from the data obtained from different techniques are in good agreement.

SURENDER K. JAIN et KEITH E. JOHNSON. Can. J. Chem. **64**, 1418 (1986).

Utilisant des techniques voltamétriques, chronopotentiométriques et chronoampérométriques, on a étudié l'électro-réduction de l'argent(I) sur une électrode de platine à partir de sa solution dans du nitrate de calcium tétrahydraté, à l'état fondu. Il semble que les premières étapes de la déposition du métal sont controlées par une étape de nucléation qui est indiquée par des excès de potentiel dans la chronopotentiométrie et par des maxima dans les espèces transitoires de la chronoampérométrie. En se basant sur la portion qui augmente des espèces transitoires de la courbe du courant en fonction du temps, on a pu évaluer la densité numérique des noyaux de surface. Les coefficients de diffusion qui ont été calculés à partir des données obtenues à l'aide de ces diverses techniques sont en bon accord.

[Traduit par la revue]

Introduction

Physico-chemical studies of hydrated melts have been reported over recent years by various workers (1–11). Braunstein *et al.* (12) reported the polarographic diffusion coefficients of Cd^{2+} in aqueous nitrate melts. Moynihan and Angell (13) measured the diffusion coefficients of Ag^+, Tl^+, and Cd^{2+} in molten calcium nitrate tetrahydrate by chronopotentiometry using a mercury pool electrode for Tl^+ and Cd^{2+} and a platinum foil electrode for Ag^+. Lovering (14, 15) for the first time studied systematically the electro-reduction of a large number of inorganic cations in a variety of molten hydrates and reported their polarographic half-wave potentials and diffusion coefficients.

Recently, Bansal and Plambeck (16, 17), have investigated the electrochemical reduction of various cations in molten calcium nitrate tetrahydrate using chronopotentiometric and cyclic voltammetric techniques. These authors have also studied the reduction of Ag^+, Tl^+, and Cd^{2+} by ac chronopotentiometry (18). It is noticeable that while the authors presented ac and dc chronopotentiograms for Tl^+ and Cd^{2+}, only the ac chronopotentiogram was included for the reduction of Ag^+. Moynihan and Angell (13) did not report any abnormality in the potential–time transients for the reduction of Ag^+ on a platinum electrode. These observations prompted us to investigate in detail the electroreduction of Ag^+ from its solutions in molten calcium nitrate tetrahydrate. Our results concerning electroreduction of Ag^+ on a platinum electrode using voltammetric, chronopotentiometric, and chronoamperometric techniques, presented in this paper, show that the electrodeposition of silver from molten calcium nitrate tetrahydrate involves the formation and growth of nuclei in the early stages of the reaction, i.e. before a uniform deposit has been formed over the electrode surface.

Experimental

Calcium nitrate tetrahydrate (BDH, AnalaR) and silver nitrate (Shawinigan Reagent) were used without further purification. The gravimetric analysis of calcium nitrate hydrate gave the water-to-salt mole ratio as 4.00 ± 0.005. Densities of the melt corresponding to this composition were obtained from the works of Ewing and Mikovsky (19). About 140 g of the melt were used for each experiment. As the solubility of oxygen in this melt is negligible (13, 16), no precaution was taken to exclude air from the system, save for tightly capping the cell to avoid loss of water.

The cell containing the melt was kept immersed in an oil bath thermostated to ± 0.1°C. The bath stirrer was turned off to avoid mechanical vibrations only during the measurements. The working electrode consisted of a 0.5 mm diameter bright platinum wire sealed into a 6 mm diameter soda–lead glass tubing so that about 9 mm length of wire protruded from the seal. The exact length and diameter were measured by optical micrometry. The auxiliary electrode was a platinum flag of large area and the reference electrode was a 0.8 mm diameter silver wire loosely coiled at one end and immersed in a silver nitrate (0.05 mol kg^{-1}) solution in molten calcium nitrate tetrahydrate held in a fritted glass tube. All electrochemical work was done using a PAR Electrochemical system (model 170) and x-y recorder (Houston Instruments-Type 2000).

After each scan, the electrode was held at an anodic potential for a few minutes to strip off the deposited metal and the solution stirred well before recording the next scan. Each scan was repeated at least twice.

Results

Linear sweep and cyclic voltammetry

The theoretical treatment of linear sweep voltammetry for the electrode processes involving the reversible deposition of a soluble or insoluble product is available (20). Berzins and Delahay (21) treated the case where reversible charge transfer resulted in the deposition of an insoluble product. From their treatment it can be shown that the peak current (i_p) for the reversible deposition of an insoluble metal at any temperature is given by the equation

$$[1] \quad i_p = 6346\, n^{3/2} A C D^{1/2} v^{1/2} T^{-1/2}$$

where i_p is the peak current in amperes, n is the number of electrons involved in the charge transfer process, A is the area of the electrode in cm^2, C is the concentration (mol L^{-1}), D is the diffusion coefficient ($cm^2\ s^{-1}$), and v is the voltage scan rate ($V\ s^{-1}$).

[1]On leave from Hindu College, University of Delhi, Delhi-110007, India.

[3]Revision received February 10, 1986.

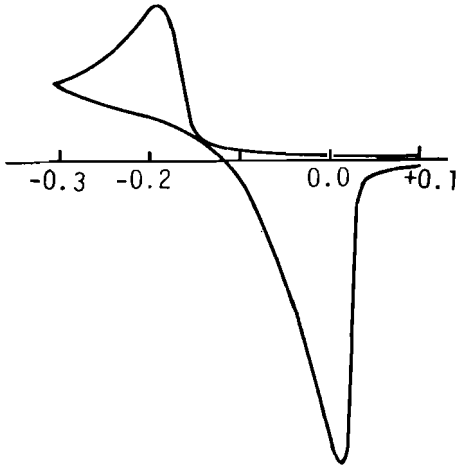

FIG. 1. A typical cyclic voltammogram for Ag^+ in molten calcium nitrate tetrahydrate at 30.7°C. Scan rate: 100 mV s^{-1}; $C_{Ag+} = 15.72 \times 10^{-3}$ mol/L. X axis values are in volts against Ag/Ag^+ (0.05 mol kg^{-1}) reference electrode.

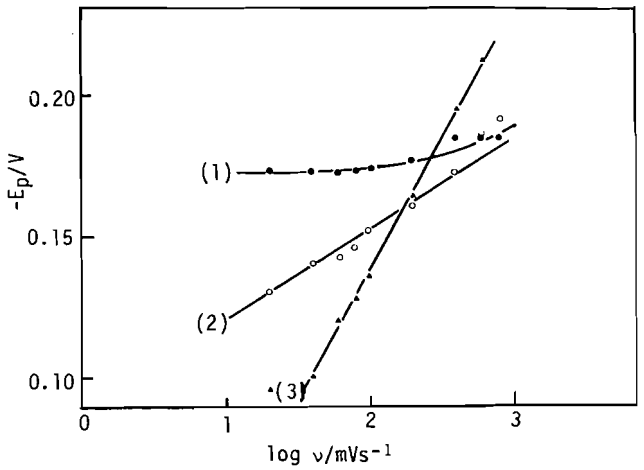

FIG. 2. Plots of E_p vs. log v for the voltammetric reduction of Ag^+ at 55°C. C_{Ag+}: (*1*) 2.62×10^{-3}; (*2*) 15.72×10^{-3}; (*3*) 58.17×10^{-3} mol L^{-1}.

Assuming that the activity of the deposited metal remains constant and equal to unity, the peak (20, 21) and half-peak (22) potentials are given by:

$$[2] \quad E_p = E^0 + \frac{RT}{nF} \ln fC - \frac{0.854RT}{nF}$$

$$[3] \quad R_{p/2} = E^0 + \frac{RT}{nF} \ln fC - \frac{0.0815RT}{nF}$$

where f is the activity coefficient of the solute and all other terms have their usual significance.

Combining eqs. [2] and [3], one can write,

$$[4] \quad \Delta E = E_p - E_{p/2} = -\frac{0.7725RT}{nF}$$

Thus, the peak and half-peak potentials depend upon the concentration of the electroactive species, and would shift to more positive (anodic) values with an increase in solute concentration. The difference, $E_p - E_{p/2}$ ($= \Delta E$) on the other hand is independent of the concentration. For a reversible process, E_p, $E_{p/2}$, and ΔE are independent of the scan rate.

A typical cyclic voltammogram for the reduction of Ag^+ from its solution in molten calcium nitrate tetrahydrate at 55°C is presented in Fig. 1. It illustrates two important features, namely the unusually steep rise in current as the cathodic peak potential is approached and the equally sharp fall in current after the anodic peak. This latter characteristic is consistent with the stripping of an insoluble deposit from the electrode surface. The anodic peak current exceeds that for the cathodic process, being simply a function of the reversal potential, but within measurable limits the quantities of charge involved in cathodic and anodic half-cycles are always the same. However, the rising part of the cathodic peak is too steep and the peak potential is at too cathodic a value relative to the reversible potential for a simple diffusion-controlled process. In the multicyclic runs, the peak potentials for the reduction process in the subsequent cycles shift to more anodic values.

The peak and half-peak potentials were estimated from the recorded voltammograms and presented in Table 1. The peak and half-peak potentials for the reduction process showed a cathodic shift with an increase in the scan rate while the anodic peak potential remained practically unaltered. However, at low

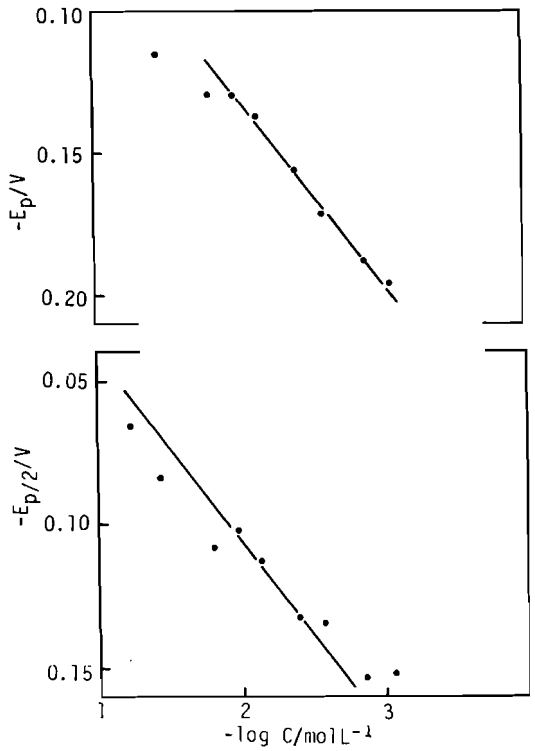

FIG. 3. $E_{p/2}$ and E_p shown as a function of log C for voltammetric reduction of Ag^+ at 55°C. Sweep rate 20 mV s^{-1}.

concentration E_p and $E_{p/2}$ remained virtually constant over the scan rate 20–200 mV s^{-1}. The differences $E_p - E_{p/2}$ showed a considerable scatter but were in the vicinity of 40 ± 20 mV as compared to the theoretical value of 21.8 mV calculated from eq. [4] for a one-electron process at 55°C. The variation of E_p with scan rate does not obey any simple relationship. However, the linear dependence of E_p on log v predicted for an irreversible process is evident at higher concentrations (Fig. 2). Although the peak and half-peak potentials shifted to more anodic values with an increase in the concentration of Ag^+ at any given scan rate, the plots of $E_{p/2}$ and E_p vs. log C resulted in straight lines with the theoretical slopes predicted by eqs. [2] and [3] only at low scan rates. Typical plots for the reduction of silver at a scan rate of 20 mV s^{-1} are shown in Fig. 3. At higher scan rates, the straight line plots exhibited lesser slopes. The

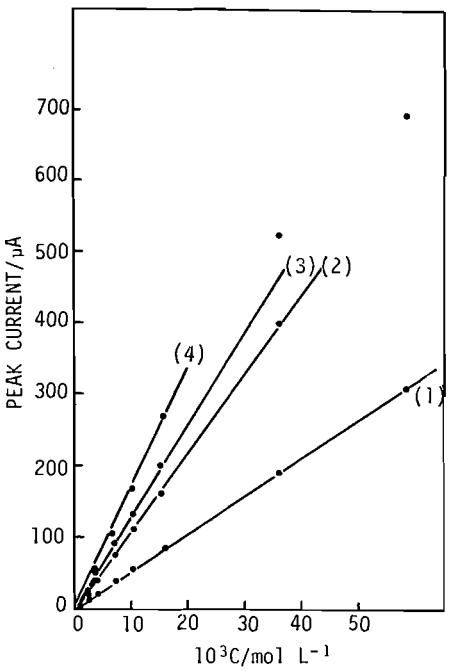

FIG. 4. Voltammetric peak current (i_p) shown as a function of concentration at various sweep rates: (*1*) 20; (*2*) 100; (*3*) 200; (*4*) 400 mV s^{-1}.

peak current (i_p) versus $v^{1/2}$ plots (not shown) for different Ag^+ concentrations were linear only up to a scan rate of about 200 mV s^{-1}, as is to be expected for a simple diffusion-controlled process. At all concentrations above this scan rate negative deviations were observed.

The i_p vs. concentration plots were linear (Fig. 4) in the low concentration region and up to a sweep rate of about 400 mV s^{-1}. The diffusion coefficients of Ag^+ were evaluated from the linear part of the i_p vs. $v^{1/2}$ plots. The calculated values are recorded in Table 2.

It was shown by Mamantov *et al.* (22) that for a reversible deposition of an insoluble substance at the electrode surface, the plot of log $(i_p - i)$ vs. E approaches linearity in the approximate range $(0.5–0.9)i_p$ with a slope equal to $2.2nF/RT$. The present results show that while such a correlation is found to hold good at low sweep rates, the range of linearity of such plots is very narrow at higher sweep rates. A typical set of data is presented in Fig. 5 to illustrate this point.

E_D (Arrhenius equation) = 47.7 kJ mol^{-1}

In view of the experimental evidence presented here, it can be concluded that some other factor, kinetic or otherwise, is involved in the reduction of Ag^+ on the platinum electrode.

In Table 3 are presented the voltammetric diffusion coefficients at different temperatures. The Arrhenius equation described adequately the temperature dependence of the diffusion coefficients over the temperature range 304–343 K: the activation energy for the diffusion process was found to be 47.7 kJ mol^{-1}.

Chronopotentiometry

The reduction of Ag^+ on a platinum electrode from its solutions in molten calcium nitrate tetrahydrate was also investigated by chronopotentiometry. A typical chronopotentiometric transient is shown in Fig. 6. Apart from a small maximum at the beginning of the transition time, the transient has a characteristic shape. Another feature frequently observed during the recording of chronopotentiometric transients was the appearance of a small, second transition at more cathodic potentials during the deposition of silver from its solutions in calcium nitrate tetrahydrate melt.

The theoretical potential of the working electrode during constant current electrolysis is given by (20),

$$[5] \quad E = E^0 + \frac{RT}{nF} \ln \left[c - \frac{2it^{1/2}}{nF\pi^{1/2}D^{1/2}} \right]$$

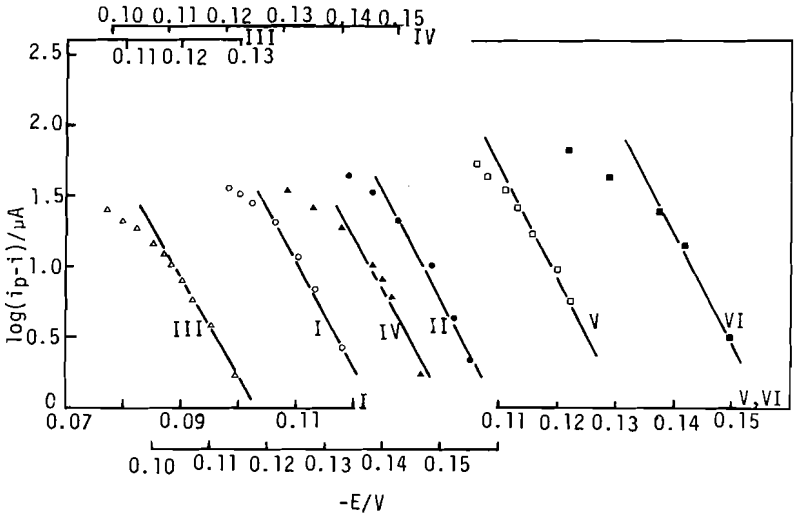

FIG. 5. Plots of log $(i_p - i)$ vs. E constructed from voltammograms at different concentration and sweep rates at 55°C. Sweep rates: I, III, and V: 20 mV s^{-1}; II, IV, and VI: 200 mV s^{-1}. Concentration: III and IV, 7.19 × 10^{-3}; I and II, 10.46 × 10^{-3}; V and VI, 15.72 × 10^{-3} mol L^{-1}.

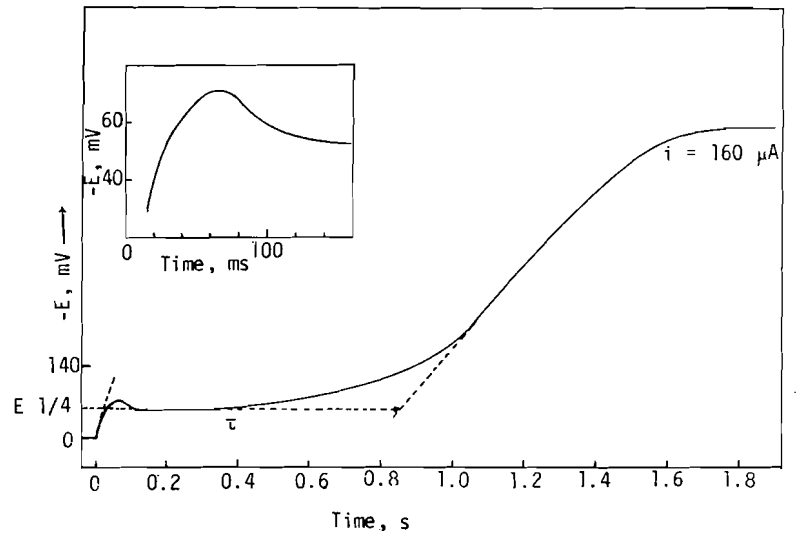

FIG. 6. Chronopotentiogram for the reduction of Ag^+ from its solution in molten calcium nitrate tetrahydrate at 55°C. The concentration of $AgNO_3$ = 17.108 × 10^{-6} mol cm^{-3}.

where E^0 is the standard electrode potential of the metal–metal ion couple, n is the number of electrons involved in the electron-transfer step, i is the current density (A cm^{-2}), D is the diffusion coefficient (cm^2 s^{-1}), c is the bulk concentration (mol cm^{-3}) of the reducible species, and R, T, F have their usual significance. From eq. [5], it can be seen that the potential of the microelectrode would approach infinity at the time τ (called the transition time) which is defined as

$$[6] \qquad \tau^{1/2} = \frac{n\pi^{1/2}FcD^{1/2}}{2i}$$

In actual practice, the potential of the microelectrode rapidly increases to such a value that some other electrode process, such as deposition of another ion or the electrolysis of the solvent itself, takes over. Thus, from eq. [6], the square root of the transition time, at any concentration, should vary linearly with i^{-1}.

In the present work, the square root of the transition time, evaluated using the method of Delahay and Berzins (23), for concentrations over the range 17.08 × 10^{-6} – 42.08 × 10^{-6} mol cm^{-3} varied linearly with the inverse of the current and the plots passed through the origin (Fig. 7). However, the deviations from linearity at the lowest concentration, 9.15 × 10^{-6} mol cm^{-3}, are apparent. The ratio of transition times for the reduction and oxidation processes was 1:1, which is a typical value for the deposition of an insoluble product. This is confirmed by the logarithmic plots in Fig. 8 in which, however, the marked deviations from linearity at the beginning of the transient are a reflection of the overshoot in the beginning of the potential–time transients. The τ values and the related parameters for the reduction of Ag^+ from its solutions in molten calcium nitrate tetrahydrate at various concentrations and current densities at 55°C are included in Table 4. The average values of diffusion coefficients for Ag^+ compare reasonably well with those obtained from the voltammetric data (Table 2). These observations indicate that the conditions for semi-infinite linear diffusion were operative during the measurements.

The present chronopotentiometric results have been analyzed to determine whether an adsorption process is responsible for

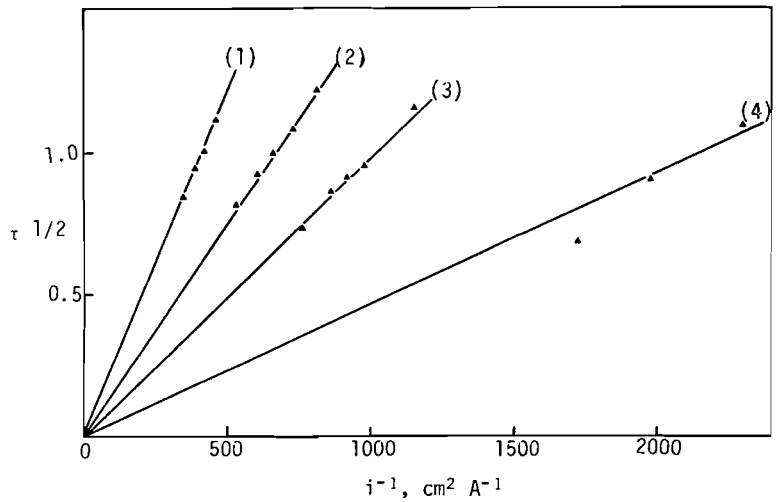

FIG. 7. Plots of $\tau^{1/2}$ vs. i^{-1} for the chronopotentiometric reduction of Ag^+ from calcium nitrate tetrahydrate melts (at 55°C) at different concentrations. The c_{Ag+} are: (*1*) 42.08×10^{-6}; (*2*) 26.45×10^{-6}; (*3*) 17.08×10^{-6}; (*4*) 9.15×10^{-6} mol cm^{-3}. Pt-wire electrode area 0.1379 cm^2.

the observations recorded in the present study. The plots of $i\tau$ vs. i^{-1} and vs. $\tau^{1/2}$ according to the AR, SR, and SAR models of adsorption (24) were constructed. These plots for different concentrations as shown in Fig. 9, are linear and pass through the origin, thereby indicating that an adsorption phenomenon is not operative in the present case. The slopes of $i\tau$ vs. i^{-1} and $\tau^{1/2}$ plots yielded diffusion coefficients of Ag^+ identical to those obtained from Sand's equation (Table 5).

Chronoamperometry

The electroreduction of Ag^+ was also studied by the potential step technique. In the present work, the magnitude of the applied potential step (η) was varied systematically by -5 to -10 mV from the equilibrium potential (against 0.05 mol kg^{-1} Ag^+). The resultant current–time transients for a typical concentration are shown in Fig. 10. For a simple diffusion-controlled process, the current response to a potentiostatic pulse should decay with time for all values of η. In the present study, the I–t curves show maxima at potentials close to the potential of Ag^+ reduction, but are of normal shape both at potentials less cathodic than the reduction and in the region of diffusion control. The position and the height of the maxima are very sensitive to both the applied potential and the concentration of Ag^+.

The current–time relationship for semi-infinite cylindrical diffusion is given by (20)

$$[7] \quad I(t) = \frac{zFADc}{r_0}\left(\frac{1}{\sqrt{\pi\phi}} + \frac{1}{2} - \frac{1}{4}\left(\frac{\phi}{\pi}\right)^{1/2} + \frac{\phi}{8}\cdots\right)$$

where r_0 is the radius and A the area of cylindrical wire electrode, and $\phi = Dt/r_0^2$. For ordinary times, all but the first

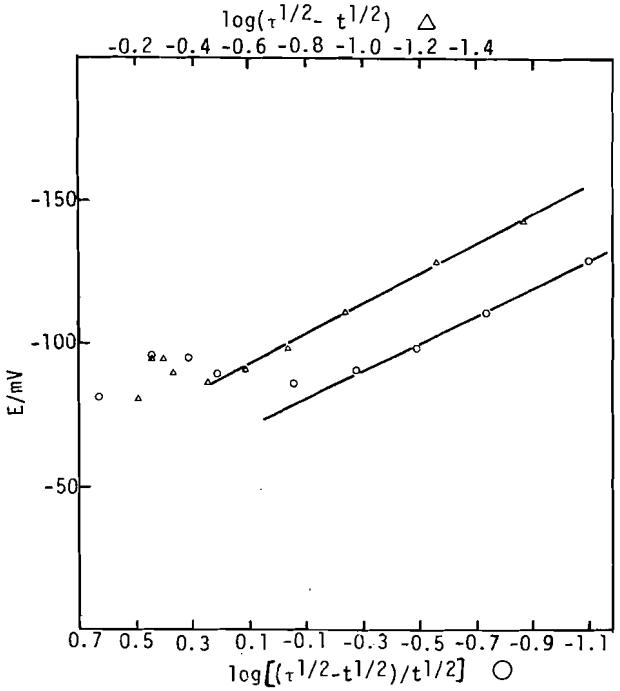

FIG. 8. Plots of E vs. $\log\{(\tau^{1/2} - t^{1/2})/t^{1/2}\}$ and $\log(\tau^{1/2} - t^{1/2})$ for the reduction of Ag^+ from calcium nitrate tetrahydrate at 55°C. $c_{Ag+} = 17.08 \times 10^{-6}$ mol cm^{-3}; $i = 13.05 \times 10^{-4}$ A cm^{-2}; $\tau = 0.56$ s.

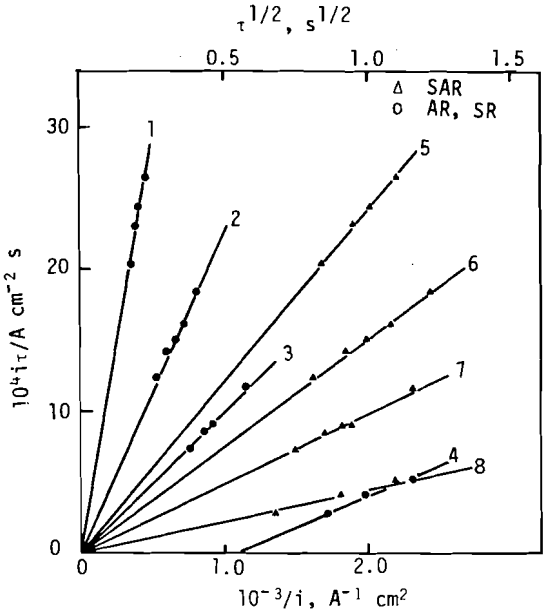

FIG. 9. Plots of $i_0\tau$ vs. i^{-1} and $\tau^{1/2}$ constructed from chronopotentiometric data for the reduction of Ag^+ from molten calcium nitrate tetrahydrate. $c_{Ag+} = (1, 5)\,42.08 \times 10^{-6}$; $(2, 6)\,26.45 \times 10^{-6}$; $(3, 7)\,17.08 \times 10^{-6}$; $(4, 8)\,9.15 \times 10^{-6}$ mol cm^{-3}.

two terms in the parentheses can be neglected, and the current is still a linear function of $t^{-1/2}$ as in the case of linear diffusion. Figure 11 shows a typical current–time$^{-1/2}$ correlation in which, for $6 \geq t \geq 0.4$, a linear relationship is observed. The diffusion coefficient calculated from the linear portion of the plot was estimated to be 3.14×10^{-7} cm^2 s^{-1}. Using this value for the diffusion coefficient, the value of the intercept ($= FADc/2r_0$) was calculated and is compared with that

obtained by extrapolating the linear portion. The two values were, respectively, 3.7 μA and 7 μA. In view of the uncertainty involved in the extrapolation, the disagreement cannot be considered significant. The diffusion coefficient obtained by this method is also given in Table 2. The average values for the diffusion coefficient of Ag^+ obtained in the present study at 55°C appear to be in reasonably good agreement with the value of 2.15×10^{-7} cm^2 s^{-1} (at 50°C) reported by Lovering (14). The slightly lower value of Lovering could be due to the combined effects of a slightly lower temperature of measurement and the possible loss of water during his measurements (25). The rising portion of the current–time transients followed the I–$t^{1/2}$ relationship. All I–$t^{1/2}$ plots (not shown) in the present study passed through the origin and had slopes which were strongly dependent on the applied potential step. Our studies, however, did not show the existence of any "induction period" necessary before the nucleation and growth processes could proceed, as observed by Hills *et al.* (26) in their studies. As apparent from the work of these authors, the induction period decreased rapidly as the potential step became more cathodic.

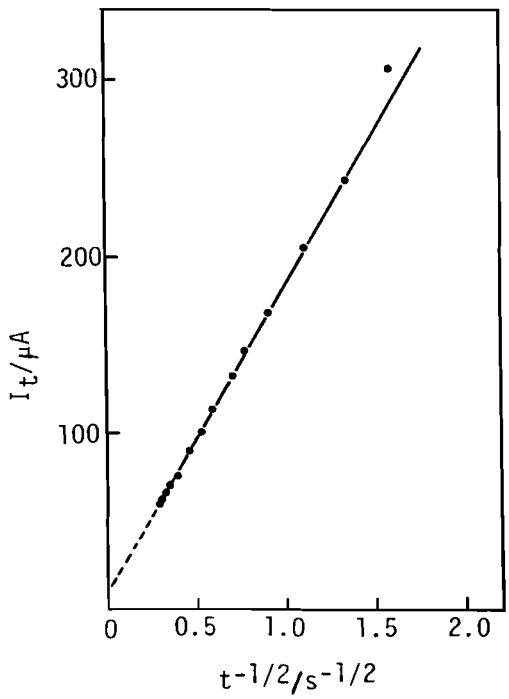

FIG. 11. I_t vs. $t^{1/2}$ plot constructed from the chronoamperometric curve at an applied potential of −160 mV at 55°C. $c_{Ag+} = 42.08 \times 10^{-6}$ mol cm^{-3}.

We feel that the potential steps applied in the present study are probably such that the induction period becomes too short to be observed.

Discussion

The unusual behavior of Ag^+ upon reduction in molten calcium nitrate tetrahydrate as observed in the present study indicates that the electrode process is not a simple reversible one. One possible explanation could be the existence of adsorption phenomena, which are well known in aqueous electrodeposition as well as in molten salts (27–31). The $i\tau$ vs. i^{-1} and $\tau^{1/2}$ plots for different concentrations, constructed from the chronopotentiometric data obtained in the present study (Fig. 9) pass through the origin, thereby speaking against the adsorption process influencing the mechanism of Ag^+ reduction under the conditions of the present investigations. As the usual effect of nucleation is the appearance of a maximum in the chronoamperometric and chronopotentiometric curves, another convincing and probably physically more relevant explanation is the existence of a nucleation step at the beginning of the electrodeposition of the metal. Hills *et al.* (26) have observed almost identical phenomena during the reduction of Ag^+ from molten nitrates and also during the electrodeposition of silver on platinum and graphite and of mercury on graphite from aqueous solutions (26). Mamantov and co-workers have also observed a nucleation step in the electrodeposition of aluminum (31), zirconium (31), and iron (33) on solid microelectrodes in chloroaluminate melts.

The formation and growth of an electro-deposited phase is a complex process. Fleischmann and Thirsk (34) have reviewed the different possible types of growth mechanisms when the electrodeposited metal is the same as that of the substrate. According to Hills *et al.* (26) for a hemispherical diffusion, the potentiostatic time transient for *instantaneous* nucleation can be described through the equation,

TABLE 6. The number-density of silver nuclei (N_0/cm^2) evaluated through eq. [10]

and that for *progressive* nucleation through the expression,

$$[9] \quad I(t) = \frac{4nFk_nN_0\pi(Dc)^{3/2}M^{1/2}t^{3/2}}{3\rho^{1/2}}$$

in which N_0 is the number of nuclei formed, M and ρ are the molar mass and density of the electro-deposited metal, D and c are the diffusion coefficient and concentration of the electroactive species, t is the time, and k_n is the rate constant for the formation of nuclei. All other terms have their usual significance.

In a subsequent publication, Gunawardena, Hills, and Montenegro (35) showed that a more appropriate equation representing the middle rising portion of the current-time transient is

$$[10] \quad I(t) = \frac{1.04nF\pi(2Dc)^{3/2}M^{1/2}N_0t^{1/2}}{\rho^{1/2}}$$

As predicted by eq. [10], the I vs. $t^{1/2}$ linear plots pass through the origin in the present case, thereby indicating that the deposition of silver under these conditions is a process involving instantaneous three-dimensional nucleation followed by growth controlled by the hemispherical diffusion of Ag^+ from the melt. The potential dependence of the growth current at any given concentration implies that the total number of available nucleation sites is potential dependent, i.e., there is a distribution of nucleation sites of different energies which nucleate at different overpotentials.

The number-density of the nuclei at the electrode surface, as calculated from the slopes of I–$t^{1/2}$ plots, are presented in Table 6.

In view of the observations resulting from the analysis of the current–time transients, it is possible to explain the abnormal chronopotentiometric and voltammetric behaviour relating to the electrodeposition of silver from molten calcium nitrate tetrahydrate. The small overshoot observed at the beginning of each chronopotentiogram can be seen as the nucleation overpotential, which must be attained before bulk deposition can proceed. Once nucleation has taken place, the charge-transfer process, being rapid, no longer requires this overpotential and as a result the potential of the working electrode falls to normal before the transient of the expected shape is completed. The *frequent* appearance of a small second overpotential at more cathodic potentials during the deposition of silver from this hydrate melt may be due to a secondary nucleation process.

Examining for such a possibility during the electrodeposition of silver on platinum from molten nitrates by scanning electron micrographs, Hills *et al.* (26) could actually see that, at lower overpotentials, the deposit grows only in patches over the electrode surface and that the remainder of the surface is not nucleated until higher overpotentials are reached.

Although at the moment we are unable to correlate the cathodic shift of cathodic peak-potentials at higher sweep rates with the chronopotentiometric and chronoamperometric results, the near constancy of the anodic peak potentials appears to be consistent with the existence of a nucleation step, for during anodic stripping no overpotential would be required. The anodic shift of the reduction peak potentials in subsequent cycles of multicyclic runs, which has been suggested as one of the criteria for nucleation (32), further supports the occurrence of a nucleation step during initial stages of Ag^+ reduction.

Detection of deuterium labelling by two-dimensional $^{1}H,^{13}C$ nuclear magnetic resonance shift correlation with ^{2}H decoupling

PAUL B. REESE, LAIRD A. TRIMBLE, AND JOHN C. VEDERAS[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 13, 1985

PAUL B. REESE, LAIRD A. TRIMBLE, and JOHN C. VEDERAS. Can. J. Chem. **64**, 1427 (1986).

Methylene groups that are stereospecifically labelled with deuterium can be easily observed using deuterium-decoupled 2-dimensional proton/carbon nmr shift correlation spectroscopy in either normal or CH-selective mode. Application of the technique to [3-^{2}H]camphors **2**, **3**, and **4** shows that overlap of other ^{13}C resonances does not interfere with the ^{2}H detection. Such experiments with [3-^{2}H]-*N*-benzoylphenylalanine methyl esters **6** and **7** demonstrate that identification of labelled diastereotopic hydrogens can be done if they are separated by 0.1 ppm in the ^{1}H nmr spectrum. Fully deuterated carbons (e.g., CD_3 methyl, CD_2 methylene, CD methine) cannot be observed by this approach, as seen by the study of pregnenolone acetate (**9**) randomly deuterated at C-17 and C-21. The technique is ideal for cases with extensive overlap of other proton and carbon resonances because high chemical shift dispersion in two dimensions separates the signals of interest. This nmr method was used to show that hydrogenation of cholesteryl acetate (**10**) with deuterium gas and palladium catalyst exchanges the C-7 α-hydrogen to give **12**. The detection limit is estimated at 10% deuterium per site unless ^{13}C-labelled compounds are used.

PAUL B. REESE, LAIRD A. TRIMBLE et JOHN C. VEDERAS. Can. J. Chem. **64**, 1427 (1986).

Utilisant la spectroscopie de corrélation des déplacements rmn proton/carbone bidimensionnelle, découplée pour le deutérium et opérée soit en mode normal ou en mode sélectif pour le CH, on peut facilement observer les groupements méthylènes qui sont marqués d'une façon stéréospécifique avec du deutérium. L'application de cette technique aux camphres-[^{2}H-3] **2**, **3** et **4** permet de montrer que le recouvrement des autres résonances ^{13}C n'interfère pas avec la détection du ^{2}H. De telles expériences avec les esters méthyliques de la *N*-benzoylphénylalanine-[^{2}H-3] **6** and **7** permet de démontrer que l'identification des hydrogènes diastéréotopes marqués peut être faite s'ils sont séparés par 0,1 ppm dans le spectre rmn du ^{1}H. En se basant sur une étude réalisée sur de l'acétate de pregnénolone (**9**) deutéré au hasard dans les positions C-17 et C-21, on peut conclure que les carbones complètement deutérés (par exemple, méthyles CD_3, méthylènes CD_2 et méthine CD) ne peuvent pas être observés par cette approche. Dû au fait que les déplacements chimiques subissent une grande dispersion lorsqu'on opère en deux dimensions et que cette propriété permet de séparer les signaux qui présentent de l'intérêt, la technique est toutefois idéale pour les cas où il existe beaucoup de recouvrement avec les résonances d'autres protons ou carbones. On a utilisé cette méthode rmn pour démontrer que l'hydrogènation de l'acétate de cholestéryle (**10**) avec du deutérium gazeux en présence d'un catalyseur de palladium échange l'hydrogène-α en C-7 pour conduire au composé **12**. On a évalué que la limite de détection est égale à 10% de deutérium par site, à moins que l'on utilise des composés marqués au ^{13}C.

Introduction

Labelling studies employing nmr detection of hydrogen isotopes are increasingly popular because they provide considerable insight into biological and chemical mechanisms (1, 2). The most widely used isotope, deuterium, is routinely observed by changes induced in ^{1}H nmr spectra and by direct ^{2}H nmr measurements (3). Alternatively, it may be detected by differences in the ^{13}C nmr spectra of carbons that are directly attached to deuterium (e.g., α-isotope shifts) (2, 4, 5) or two bonds away (β-isotope shifts) (4, 6, 7). However, determining which of two diastereotopic hydrogens on a methylene group is deuterium labelled is often difficult by any of these techniques even if the ^{1}H nmr assignment is known. At low levels of isotopic enrichment ^{1}H nmr differences are normally obscured by intense signals due to unlabelled material, whereas ^{2}H nmr spectra frequently suffer from extensive overlap of resonances because chemical shift similarities are exacerbated by quadrupole broadening. Although addition of lanthanide shift reagents can sometimes overcome the latter problem (8), the procedure does involve contamination of a potentially valuable sample. Use of normal ^{1}H-decoupled ^{13}C nmr spectroscopy for stereochemical analysis is even more limited since ^{2}H-induced isotope shifts (4) are often of similar magnitude for each of the diastereotopic methylene hydrogens. In principle, tritium labelling in combination with ^{3}H nmr can circumvent these difficulties because of the excellent spectral characteristics of this isotope; however, the accompanying high levels of radioactivity have restricted its use so far (9, 10).

Modern nmr pulse methods[2] possess considerable promise for defining the position and extent of deuterium labelling. Among such techniques that have been applied to deuterated systems (12), two-dimensional chemical shift correlation of deuterium with carbon-13 (13) or correlation of deuterium with protons (14) could potentially provide information on the stereochemistry of labelling at a methylene group. Recently we reported in preliminary form (15) the use of two-dimensional proton/carbon-13 nmr shift correlation with deuterium decoupling to examine stereospecifically deuterated systems. This approach has already proved valuable in analyzing the stereochemistry of an enzymatic reaction (16). In the present work, full experimental details of this method, its limitations, and additional applications to more complex systems are described.

Results and discussion

In order to test the utility as well as the shortcomings of the deuterium-decoupled $^{1}H,^{13}C$ nmr shift correlation method, four systems were examined. These are (*1*) [3-^{2}H]camphor, in which the ^{1}H resonances of interest are well separated in the ^{1}H nmr spectrum, but another interfering carbon signal (C-4) appears within 0.1 ppm of C-3 in the ^{13}C nmr spectrum; (*2*) *N*-benzoyl-[3-^{2}H]phenylalanine methyl ester, in which the

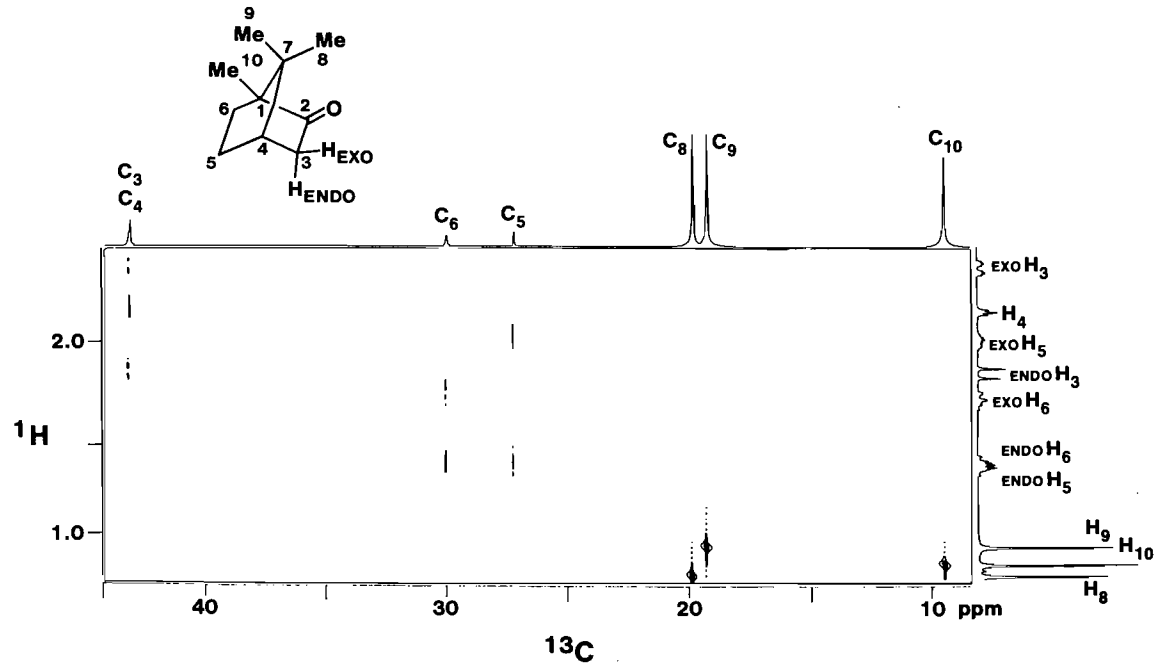

FIG. 1. Normal $^1H,^{13}C$ shift correlation spectrum of unlabelled camphor (**1**). Corresponding sections of the ^1H nmr (400 MHz) and ^{13}C nmr (100.6 MHz) are shown on the vertical and horizontal axes, respectively.

^1H nmr chemical shifts of the C-3 methylene hydrogens are within 0.1 ppm, but the attached carbon signal is well separated; (*3*) [17,21-^2H]pregnenolone acetate, in which methine and methyl groups are partially deuterated; and (*4*) [5,6,7-^2H]cholestanyl acetate, in which the hydrogen resonances of interest are buried in the ^1H nmr "steroidal envelope" and the corresponding carbon signals are flanked by numerous other peaks. Use of a selective $^1H,^{13}C$ correlation pulse sequence (17) that gives signals only for carbons bearing a single hydrogen (CH plots) is also described.

Camphor

Since a number of ^{13}C nmr assignments of camphor (**1**) in various solvents have been reported (18–20), spin echo Fourier transform (SEFT) (21) and 2D INADEQUATE (11, 22) techniques were employed to confirm an earlier assignment (19).[3] A previous ^1H nmr assignment (20) was verified by normal heteronuclear proton–carbon shift correlation (11, 23) (Fig. 1), homonuclear proton–proton decoupling experiments, and examination of $Eu(fod)_3$-induced shifts[3] in proton and carbon spectra. The resulting values given in Table 1 are in complete agreement with a very recent nmr study (24) of camphor (**1**).[4] The exchangeable C-3 methylene hydrogens of camphor (**1**) are well resolved in the ^1H nmr spectrum (*endo* at 1.84 ppm, *exo* at 2.36 ppm). However, the C-3 and C-4 carbon resonances appear within 0.1 ppm of each other in ^{13}C nmr spectra, and slight temperature or concentration changes can shift their positions sufficiently to cause complete overlap.

Endo-, *exo-*, and bis-deuterated camphors **2**, **3**, and **4**, respectively, were prepared by literature procedures (26). Each of these compounds was separately mixed with unlabelled camphor (**1**) in a 2:1 ratio (labelled:unlabelled). Normal two-dimensional $^1H,^{13}C$ chemical shift correlations (23) with broad-band deuterium decoupling were done on each of these samples. The portions of the spectra containing the C-3 methylene and C-4 methine groups are shown as the CH_n plots in the top row of Fig. 2. Application of the selective heteronuclear correlation pulse sequence (17) with deuterium decoupling and the variable pulse angle θ set to 90° produced the simpler CH plots in the bottom row of Fig. 2. These display only those carbons bearing a single proton. In each case A and B are signals due to correlation of the C-3 methylene carbon of unlabelled camphor (**1**) with the attached *exo* and *endo* hydrogens, respectively. Resonance X results from the C-4 methine group of **1**. Comparison of the complete and the CH-only correlation plots of pure **1** to the corresponding plots of mixtures of **1** with **2** or **3** shows the appearance of two additional signals: Y and either C or E. Signal Y results from the C-4 methine being shifted upfield on the horizontal ^{13}C chemical shift axis due to the presence of single deuteriums at C-3 (β-isotope shift) (4, 6).

TABLE 1. Chemical shifts of camphor (**1**)[a]

Position	δ ^1H	δ ^{13}C
1	—	57.6 (s)
2	—	217.9 (s)
3	2.36 (*exo*) 1.84 (*endo*)	43.4 (t)
4	2.10	43.5 (d)
5	1.96 (*exo*) 1.41 (*endo*)	27.4 (t)
6	1.68 (*exo*) 1.34 (*endo*)	30.2 (t)
7	—	46.8 (s)
8	0.83	19.8 (q)
9	0.95	19.3 (q)
10	0.91	9.3 (q)

[4]Our results and those in ref. 24 show that a different ^1H nmr assignment (25) is incorrect.

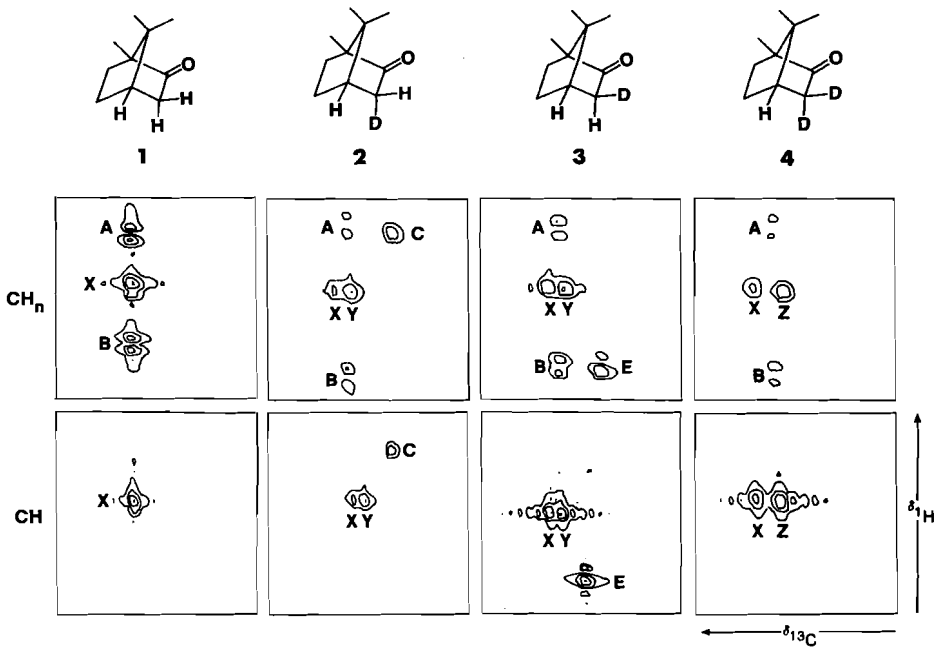

FIG. 2. Deuterium-decoupled normal (CH_n) and selective (CH) proton/carbon shift correlation plots of the C-3 methylene and C-4 methine region of camphor. In each plot the chemical shift increases from 1.76 to 2.43 ppm for ^1H on the vertical axis and from 42.76 to 43.93 ppm for ^{13}C on the horizontal axis (right to left).

The signals labelled C and E arise from C-3 carbons bearing a single proton in the *exo* or *endo* positions, respectively. The large upfield α-isotope shift caused by deuterium on directly-bonded carbon (2, 4) effects the substantial separation of undeuterated (A, B) and deuterated (C, E) methylene signals. In the bis-deuterated camphor (**4**), *Z* is the C-4 methine resonance that is shifted upfield by the two deuteriums on C-3.

The spectra depicted in Fig. 2 clearly demonstrate that stereospecific deuterium labelling can be easily determined by either the normal or selective correlation method even if other interfering carbon resonances are present. The main advantage of the selective correlation is simplification of the plots for easier visualization. However, it is generally necessary to run complete correlation spectra with unlabelled material present as internal standard to be certain of correct assignment of new signals arising from the deuterated compound. With either full or selective correlation techniques, complete broad-band deuterium decoupling is essential, and normally requires a ^{19}F lock (C_6F_6). It is also extremely important to use a relaxation delay (ca. 3 s) between pulse sequences to guarantee optimal observation of correlation signals.

In order to estimate the lower limit of detection of singly deuterated methylene groups by this method, the ratio of unlabelled camphor (**1**) to labelled compounds **2** or **3** was varied. Correlation experiments done using the same conditions as before (see Experimental) on samples containing 20% monodeuterated camphor and 80% unlabelled **1** still gave clean correlation plots similar to those in Fig. 2. These results in combination with normal one-dimensional broad-band $^1H,^2H$-decoupled ^{13}C nmr spectroscopy suggest that the lower detection limit may be in the range of 10% deuterium on natural abundance carbon-13 (1.1%) if the number of scans and experiment time are considerably increased.

N-*Benzoylphenylalanine methyl ester*

Frequently the resonance of a methylene carbon is well resolved in the ^{13}C nmr spectrum, but the chemical shifts of attached diastereotopic hydrogens are very similar. To test the deuterium-decoupled correlation method in such circumstances, a racemic mixture of (2*S*,3*S*)- and (2*R*,3*R*)-*N*-benzoyl[2,3-$^2H_2$]phenylalanine methyl esters (**6**) was prepared by literature procedures (27) and mixed with the corresponding unlabelled compound **5** (28) in a 2:1 ratio. A mixture of all possible stereoisomers of the C-3 monodeuterated derivative **7** was generated by enolization of **6** and quenching with unlabelled acetic acid. This was mixed with unlabelled material **5**, in the same fashion, before nmr analysis.

In the normal ^1H nmr spectrum ($CDCl_3$) the diastereotopic hydrogens of *N*-benzoylphenylalanine methyl ester (**5**) appear at 3.20 and 3.29 ppm as the A and B parts of an ABX system. The corresponding methylene carbon displays a well-separated resonance at 38.0 ppm. Two-dimensional proton/carbon shift correlation experiments with deuterium decoupling on **5** and its mixtures with **6** and **7** produced the plots shown in Fig. 3. These expansions of the C-3 methylene region of the full (CH_n) and selective (CH) correlations clearly display additional signals for **6** and **7** due to the presence of CHD groups. The correlation of the upfield hydrogen of **6** with an isotope-shifted carbon resonance shows that the downfield methylene hydrogen has been replaced by deuterium. Since **7** is nonstereospecifically labelled, the CHD group exists in both possible relative configurations. As a result, two isotope-shifted correlation signals are observed.

The observed deuterium-induced α-isotope shift on the horizontal carbon axis is the essential feature that allows detection of deuterated methylenes. However, a small upfield shift in the position of the deuterated species can also be seen on the vertical proton chemical shift axis. Deuterium isotope shifts on ^1H nmr resonance positions have been reported previously (4, 29), but are usually too small to be readily noticed. They seem to be a general phenomenon, which is easily observed in the deuterium-decoupled $^1H,^{13}C$ shift correlation spectra.

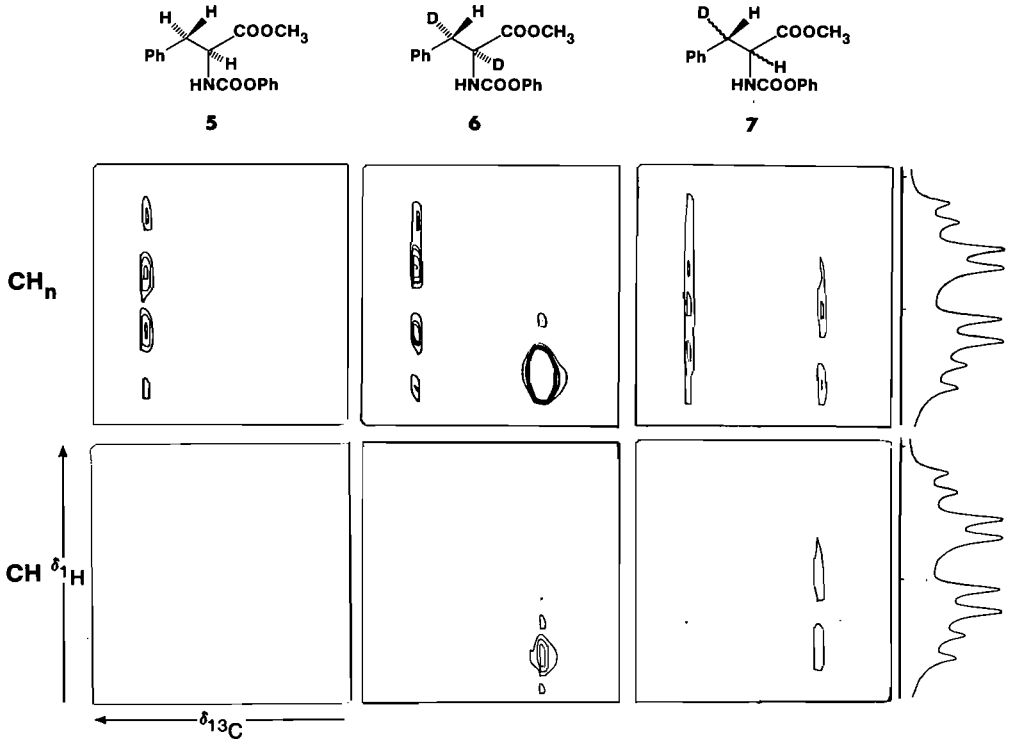

FIG. 3. Normal (CH_n) and selective (CH) proton/carbon correlations (deuterium decoupled) of the C-3 region of *N*-benzoylphenylalanine methyl esters. Compound **6** is racemic and **7** is a mixture of all stereoisomers. The corresponding ^1H nmr of **5** is shown on each vertical axis (3.12–3.36 ppm).

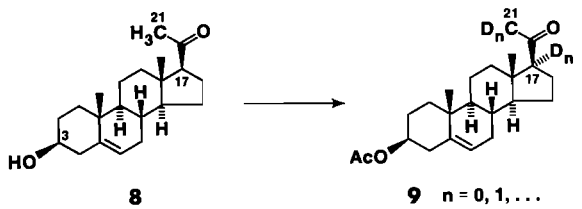
Pregnenolone acetate

In order to examine use of this method with other types of deuterated systems, the hydrogens at C-17 and C-21 of pregnenolone (**8**) (Scheme 1) were partially exchanged in basic media containing 50% labile deuterium. Acetylation afforded **9** as a statistical mixture of d_0, d_1, d_2, d_3, and d_4 species. Although deuterium substitution at C-17 produces the expected changes in the ^1H nmr and fully decoupled (^1H,^2H) ^{13}C nmr spectra of **9**, the ^1H,^{13}C shift correlation methods are ineffective at detecting the methine label because only species bearing hydrogen at C-17 give signals. Similarly, molecules having three deuteriums at the C-21 methyl cannot be seen in the correlation spectra of that region (Fig. 4). However, the CHD_2, CH_2D, and CH_3 species are all readily visible in the full deuterium-decoupled proton/carbon correlation spectrum (CH_n) because of the additive nature of the α-isotope effect of deuterium on carbon (4). Unfortunately, the presence of deuterium unfavorably alters Overhauser enhancement and relaxation of directly attached carbons (2, 30) such that not all the peak areas are a direct measure of the extent of ^2H labelling. This is also true in the regular fully decoupled (^1H,^2H) ^{13}C nmr spectrum. The β-isotope shift method developed by Staunton and co-workers (6) may be the most widely applicable approach to examine deuterium content at methines and methyl groups (7). The deuterium/carbon-13 shift correlation technique recently reported by Wesener and Günther (13) could be advantageous in cases of extensive ^{13}C resonance overlap, and should give signals for all deuterated methine and methyl species.



SCHEME 1

Cholestanyl acetate

One of the most common problems in measuring deuterium content at labelled methylene groups is overlap of other proton resonances. This overlap can make definitive identification of labelled sites impossible by routine one-dimensional nmr methods. To rigorously test the present technique in such a situation, cholesteryl acetate (**10**) was reduced to unlabelled and deuterated cholestanyl acetates **11** and **12**, respectively (Scheme 2). The reaction of **10** with deuterium gas and palladium on charcoal (5%) in ethyl acetate containing acetic acid-d_4 labelled C-5, C-6, and C-7 of **12**, in analogy to the previously reported (31) reduction with platinum catalyst. Carbons bearing deuterium could be identified from α- and β-isotope shifts in the normal fully decoupled (^1H,^2H) ^{13}C nmr spectra of a 1:2 mixture of **11** and **12**. Thus C-4, C-8, and C-10 exhibited smaller β-isotope shifts (4), whereas C-5, C-6, and C-7 each showed a larger α-isotope shift as well as the small β-shifts (Table 2). The ^{13}C nmr spectral assignments are in accord with those previously reported by two other groups (32, 33). The known configuration at C-5, the preference for *syn* addition of hydrogen, and the well-precedented interaction of the steroid α-face with palladium (34) suggested that the deuteriums at C-6 and C-7 were on the α-side. However, this cannot be directly determined by routine ^1H nmr, ^2H nmr, or ^{13}C nmr analysis because the resonances of interest are buried in the "steroid envelope".

The deuterium-decoupled proton/carbon correlation spec-

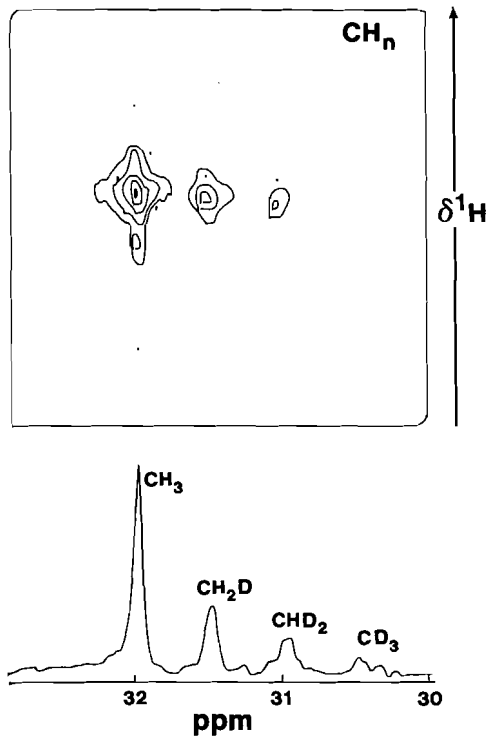


FIG. 4. Deuterium-decoupled proton/carbon correlation of the C-21 methyl region of **9** showing various labelled species. The fully decoupled (^1H,^2H) ^{13}C nmr spectrum is displayed underneath for comparison. The chemical shift increases from 1.40 to 2.73 ppm for ^1H on the vertical axis.

Position	Shift type[b]	Magnitude (ppm)[c]
4	β	0.12
5	α	0.57
	β	0.10
6	α	0.50
	β[d]	0.10
7	α	0.48
	β	0.13
8	β	0.12
10	β	0.12

[a]For measurement conditions see Experimental.
[b]α refers to directly attached ^2H, β refers to ^2H two bonds away.
[c]All shifts upfield.
[d]Shifts due to ^2H at C-7 and to ^2H at C-5 are same size.

trum of the 1:2 mixture of **11** and **12** clearly shows that the upfield axial (α-face) hydrogen at C-7 is deuterium labelled (Fig. 5). In the expansion of section A from the large plot (Fig. 6), signals F and G are due to correlation of the C-7 carbon to the directly attached equatorial (downfield) and axial (upfield) hydrogens (35) of unlabelled cholestanyl acetate (**11**). Signals H and J result from the same correlation in molecules of the deuterated derivative **12**, which have no deuterium at C-7 but do bear a deuterium two bonds away at C-6 that causes an upfield β-isotope shift on the carbon axis. Signal K arises from molecules of **12** having axial deuterium at C-7 (large α-isotope shift), but no deuterium at C-6. The intense peak L is due to molecules of **12** having axial deuterium at C-7 (large α-isotope shift) and a single deuterium at C-6 (smaller β-isotope shift). Lack of any correlation between the axial hydrogen at C-7 and any carbon signal having an α-isotope shift demonstrates that deuterium labelling is completely stereospecific at that site (i.e., all C-7 ^2H is axial).

Unfortunately the axial and equatorial hydrogens at C-6 of cholestanyl acetate (**11**) could not be resolved in the ^1H nmr spectrum. These diastereotopic protons give rise to a single resonance in the proton/carbon shift correlation spectrum of unlabelled **11** in either chloroform-*d* (Fig. 5) or benzene-d_6. Examination of the spectra of cholestan-3-one gave a similar result. A recent report on correlation experiments with a different steroid system also showed that the C-6 hydrogen resonances have essentially identical chemical shifts (36). The region of the deuterium-decoupled proton/carbon correlation spectrum containing the C-6 methylene is expanded in section B of Fig. 6. Resonance M comes from unlabelled material **11**, whereas the other additional signals (N, P, Q) are due to carbons of **12** having deuterium directly attached (P, Q) and (or) two bonds away (N, Q). Although no stereochemical information about the deuterium at C-6 is available from this two-dimensional spectrum, it does remove interference from the overlapping carbon resonances of C-16 and C-25. In contrast, the stereospecific labelling at C-7 can be clearly seen.

Conclusions

The deuterium-decoupled proton/carbon nmr shift correlation technique is ideal for observation of stereospecifically ^2H-labelled methylene groups in complex systems (e.g., **12**). This method takes advantage of the high chemical shift dispersion available in ^{13}C nmr to separate signals of interest, and avoids obscuring the methylene proton AB system through resonance broadening common in ^2H nmr. The large upfield deuterium-induced α-isotope shift on ^{13}C resonance positions cleanly separates the correlation peaks of partially deuterated carbons from corresponding signals of unlabelled material. Key resonances due to monodeuterated methylenes can be isolated further through application of a selective pulse sequence (17), which generates correlation plots containing only CH groups. The technique is also excellent for detecting small ^2H-induced isotope shifts on ^1H nmr resonances. Some resolution of the methylene AB signals in ^1H nmr is essential for stereochemical identification, but this separation of resonances can be much smaller (≤0.1 ppm) than with ^2H nmr or correlation of deuterium with other nuclei (13, 14). Of course, as with other nmr methods, determination of the absolute stereochemistry must be done by independent means.

The major current limitation of this technique is instrumental; it is necessary to lock on ^{19}F while decoupling ^2H and pulsing

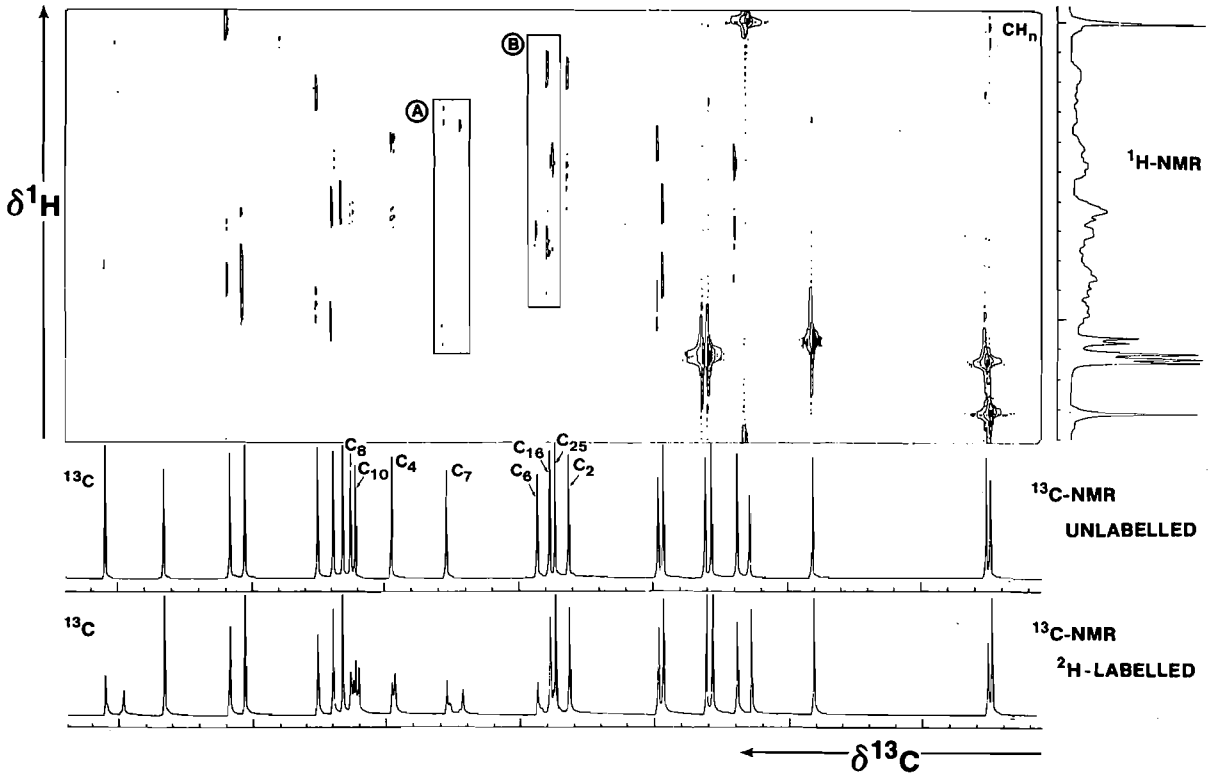

FIG. 5. Deuterium-decoupled proton/carbon correlation of deuterated 3β-acetoxycholestane (**12**). The corresponding 400-MHz ^{1}H nmr spectrum (0.59–2.05 ppm) is shown on the vertical axis and the 100.6-MHz ^{13}C nmr spectra (10.6–47.0 ppm) of unlabelled and ^{2}H-labelled material are displayed on the horizontal axis. See Fig. 6 for expansions of the regions labelled A and B.

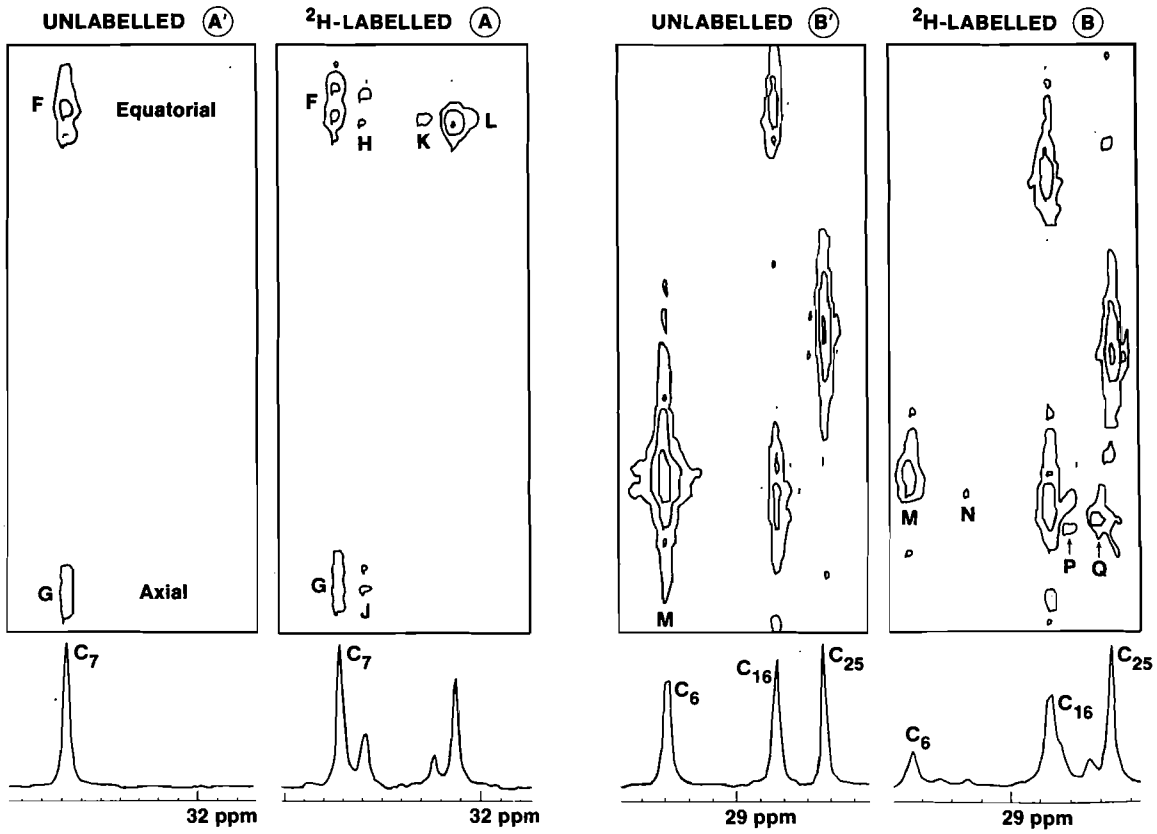

FIG. 6. Deuterium-decoupled proton/carbon correlations of the regions containing C-7 (A′ and A) and C-6 (B′ and B) of unlabelled 3β-acetoxycholestane and the ^{2}H-labelled analog **12**. The sections A and B are also shown in Fig. 5 for comparison.

^1H and ^{13}C frequencies. Wider distribution of commercially-available triple resonance probes in the future will overcome this difficulty. This method is not applicable to fully deuterated carbons that bear no hydrogen (e.g., CD_3), and is generally not ideal for quantitative determination of deuterium content. As with other 2D nmr spectra, another limitation is the amount of material available for study. A correlation experiment on a sample whose concentration is 0.8 *M* in a 5-mm tube takes about 1 h (400 MHz for ^1H). It is clear that 64 t_1 points are sufficient to obtain the required information. The appearance of the spectra could certainly be improved by use of more t_1 values, but only at the expense of valuable spectrometer time. At least 10% ^2H per site is necessary for detection at natural abundance levels of ^{13}C (1.1%). However, shorter instrument time and much greater sensitivity can be achieved if the compound is enriched with ^{13}C at the deuterated carbons. Such double labelling of precursors is now routine in biochemical investigations. One application of this nmr method has already been described (16), and work on its use in biosynthetic studies will be reported shortly.

Experimental

Melting points were recorded on a Thomas Hoover apparatus and are uncorrected. Infrared (ir) spectra were measured on chloroform solutions using a Nicolet 7199 FT spectrometer. Mass spectra were obtained on a KRATOS A.E.I. MS50 spectrometer using electron impact (70 eV) and chemical ionization (NH_3) modes. Commercial chemicals were of reagent grade and were purified as necessary according to standard procedures (37).

Nuclear magnetic resonance spectra

A Brüker WH400 spectrometer (400 MHz ^1H, 100.6 MHz ^{13}C) was used to obtain spectra on samples in $CDCl_3$ (unless otherwise noted) using 5-mm tubes at 25°C. All chemical shifts are reported in parts per million (δ scale) from tetramethylsilane as internal standard. All ^2H-decoupled nmr spectra were done using a ^{19}F lock on C_6F_6 (5–20% v/v added to sample). Heteronuclear proton/carbon shift correlations with broad-band deuterium decoupling employed previously described pulse sequences to obtain the complete (23) and selective (17) two-dimensional plots. For the latter, the variable pulse angle θ was set to 90°. All correlation experiments used: a relaxation delay = 3 s between scans; 1 K FID's for 64 values of t_1; zero filling to 512 points in f_1 (^1H) and 2 K in f_2 (^{13}C). In each case a Gaussian window function was applied to both f_1 and f_2 with the line broadening set equal to the number of Hz/pt after zero filling, and the Gaussian broadening was set to zero. For camphor (2.36 *M* solution): f_1 (^1H) = 1060 Hz; f_2 (^{13}C) = 5000 Hz; acquisition time 0.10 s; 4 scans/t_1 increment. For *N*-benzoylphenylalanine methyl esters (1.29 *M*): f_1 (^1H) = 800 Hz; f_2 (^{13}C) = 1800 Hz; acquisition time = 0.28 s; 8 scans/t_1 increment. For pregnenolone acetates (3β-acetoxypregn-5-en-20-one) (0.89 *M*): f_1 (^1H) = 1400 Hz; f_2 (^{13}C) = 1700 Hz; acquisition time = 0.31 s; 12 scans/t_1 increment. For cholestanyl acetates (3β-acetoxycholestane) (0.81 *M*): f_1 (^1H) = 585 Hz; f_2 (^{13}C) = 3600 Hz; acquisition time = 0.14 s; 16 scans/t_1 increment.

Deuterated camphors 2, 3, and 4

The monodeuterated compounds **2** and **3** were prepared by the procedures of Joshi and Warnhoff and the bis-deuterated camphor **4** was made according to Thomas and Wilholm (26). All three were sublimed before use to give chromatographically pure materials with the expected physical and spectral properties.

For [3-*endo*-^2H]camphor (**2**): ^1H nmr signal at δ 1.78 reduced by 80%. *Exact Mass* calcd. for $C_{10}H_{15}{}^2HO$: 153.1265; found: 153.1274.

For [3-*exo*-^2H]camphor (**3**): ^1H nmr signal at δ 2.29 (3 *exo* H) reduced by 75%, at 1.78 (3 *endo* H) relative intensity unchanged. *Exact Mass* calcd. for $C_{10}H_{15}{}^2HO$: 153.1265; found: 153.1273.

For [3,3-$^2H_2$]camphor (**4**): ^1H nmr signals at δ 1.78 and 2.29 completely absent. *Exact Mass* calcd. for $C_{10}H_{14}{}^2H_2O$: 154.1317; found: 154.1327.

N-Benzoylphenylalanine methyl esters 5, 6, and 7

The unlabelled compound **5** was prepared by literature procedures (28). The racemic mixture of (2*S*,3*S*)- and (2*R*,3*R*)-*N*-benzoyl[2,3-$^2H_2$]phenylalanine methyl esters (**6**) was synthesized by the method of Battersby and co-workers except that the intermediate azlactone was cleaved by methanol according to Buckles *et al.* (27). For the preparation of **7** a solution of **6** (2.0 g, 7.0 mmol) in tetrahydrofuran (THF) (15 mL) was added to a cold (−78°C) solution of THF (20 mL) and lithium diisopropylamide (1.5 *M* *n*-BuLi (14 mL, 20 mmol), diisopropylamine (3.0 mL, 21 mmol)) under Ar atmosphere. Stirring was continued for 30 min, acetic acid (5.0 mL, 80 mmol) was added, and the mixture was allowed to warm to 20°C. The solution was diluted with ether and washed with concentrated aqueous NaCl and sodium bicarbonate. The organic phase was dried, concentrated *in vacuo*, filtered through a short column of silica gel (70–230 mesh), and recrystallized from ethyl acetate–ether to give 1.95 g (97%) of *N*-benzoyl[3-^2H]phenylalanine methyl ester (**7**) as a mixture of all possible stereoisomers. This material showed the expected physical and spectral properties. For **7**: mp 84–86°C; ^1H nmr signals at δ 3.20 and 3.29 (1H total, d, J = 6 Hz, H at C-3), 5.06 (1H, br t, J = 6 Hz, H at C-2). *Exact Mass* calcd. for $C_{17}H_{16}{}^2HNO_3$: 284.1272; found: 284.1272.

[17,21-^2H]-3β-Acetoxypregn-5-en-20-one (9)

Commercially available (Sigma) pregnenolone (**8**) (2.0 g, 6.3 mmol) in THF (20 mL) was mixed with a solution of NaOH (50 mg), H_2O (1 mL), D_2O (1 mL), methanol (2 mL), and methanol-d_1 (2 mL). This was heated to reflux for 48 h, the solvent was removed *in vacuo*, and the steroid was extracted with ethyl acetate. This extract was washed with water, dried, and concentrated *in vacuo* to give 2.0 g of pregnenolone deuterated randomly in the 17 and 21 positions. A portion of this (1.5 g, 4.2 mmol) was dissolved in pyridine (8 mL) and treated with acetic anhydride (2 mL, 20 mmol) at 20°C overnight. The mixture was poured into excess cold (4°C) aqueous hydrochloric acid, and the steroid was extracted with ethyl acetate. The extract was washed with water and sodium bicarbonate solution, dried, and concentrated *in vacuo*. Recrystallization from ethyl acetate gave 1.5 g (ca. 88%) of pregnenolone acetate **9** randomly deuterated at C-17 and C-21. Comparison to authentic unlabelled material (38) showed the expected physical and spectroscopic properties: mp 147–149.5°C (lit. (38) mp 149–150°C); ^1H nmr signals at δ 2.1 (H-21) and 2.55 (H-17) reduced. The mass spectrum (ms) exhibits ions (M^+ − HOAc) at 302.2538, 301.2486, 300.2427, 299.2366, and 298.2301 for tetra-, tri-, di-, mono-, and non-deuterated compounds, respectively. Pure unlabelled compound gave *Exact Mass* calcd. for ($C_{23}H_{34}O_3$ − CH_3COOH): 298.2298; found: 298.2301.

3β-Acetoxy-5α-cholestanes 11 and 12

Palladium (5% on carbon) (200 mg) was stirred in dry ethyl acetate (2.5 mL) under deuterium gas (1 atm.) for 10 min. A solution of 3β-acetoxycholest-5-ene (**10**) (1.00 g, 2.33 mmol) in warm ethyl acetate (5 mL) was added, followed by acetic acid-d_1 (5 mL). The mixture was stirred under deuterium for 48 h, filtered, and concentrated *in vacuo*. The ^1H nmr showed that the reaction was 95% complete but purification was difficult. The mixture was therefore dissolved in dichloromethane (15 mL), cooled to 4°C, treated with *m*-chloroperoxybenzoic acid (800 mg), and allowed to stir at 20°C for 10 h. The solution was washed with aqueous sodium sulfite and sodium bicarbonate, dried, concentrated *in vacuo*, and redissolved in acetone. A solution of periodic acid dihydrate (500 mg) in water (5 mL) was added and the mixture was heated to reflux 1 h. Sodium bicarbonate (185 mg) was added to the cooled solution; the mixture was then concentrated *in vacuo* and partitioned between concentrated aqueous NaCl and ethyl acetate. The organic phase was dried, concentrated *in vacuo*, and chromatographed on silica gel (70–230 mesh) with 10% ethyl acetate – light petroleum ether. The resulting 600 mg (60%) of pure [5α,6α,7α-$^2H_3$]-3β-acetoxycholestane (**12**) was recrystallized from ethyl acetate. The undeuterated compound **11** was prepared analogously, and showed physical and spectral properties in accordance with literature reports (32, 33, 39, 40). For deuterated compound **12**: mp 99–102°C;

^{1}H nmr almost indistinguishable from that of unlabelled analog **11** (40); ms *m/e* (*relative intensity*): 433.3985 (*61*), 432.3925 (*55*), 431.3858 (*21*), 430.3795 (*6*).

This paper compares bond lengths deduced from the methods of surface crystallography with predictions from the Pauling–Schomaker–Stevenson approach and from a new alternative approach suggested by recent work of Brown and Altermatt. Examples considered are specifically for X—M surface bond lengths where atoms X from groups 16 or 17 are adsorbed on well-defined surfaces of a metal M. The alternative approach introduced here is parametrised with reference to structural data from solid compounds of formula MX. The two predictive approaches considered, when used together, appear to be quite adequate for guiding choices of trial model structures to be included in surface crystallographic analyses with low-energy electron diffraction (LEED); also they seem reasonable for checking the general reliability (or otherwise) of surface bond length data. Two further features introduced by this work are (*i*) evidence that the Cl—Ag distance reported by LEED for Cl adsorbed on the Ag(100) surface is broadly consistent with the structure of solid AgCl; (*ii*) evidence for S adsorbed on the Fe(110) surface that these analyses can guide investigations of lateral relaxations of surface metal atoms. As more reliable structural data become available, extensions of these analyses should help to identify the finer details in X—M bond lengths which result from the special coordination arrangements occurring at surfaces.

K. A. R. MITCHELL, S. A. SCHLATTER et R. N. S. SODHI. Can. J. Chem. **64**, 1435 (1986).

Dans ce travail, on compare les longueurs des liaisons déduites à l'aide de méthodes de cristallographie de surface avec les prédictions qui peuvent être faites à l'aide de l'approche de Pauling–Schomaker–Stevenson ainsi qu'à partir d'une nouvelle approche qui a été suggérée par un travail de Brown et Altermatt. Les exemples qui sont considérés sont reliés spécifiquement aux longueurs des liaisons X—M de surface, dans lesquelles les atomes X provenant des groupes 16 et 17 sont adsorbés sur des surfaces bien définies d'un métal M. Dans l'approche alternative introduite dans ce travail, on attribue les paramètres par référence avec des données de structure de composés solides de formule MX. Lorsqu'on utilise ensemble les deux méthodes de prédiction, elles semblent assez adéquates pour guider dans le choix de structures modèles qui peuvent être introduites dans des analyses de surfaces cristallographiques établies à l'aide de la diffraction électronique à basse énergie (LEED); elles semblent aussi raisonables pour vérifier la fiabilité générale (ou autre) des données relatives aux longueurs de liaison de surface. Dans ce travail, on a aussi introduit les deux caractéristiques suivantes: (*i*) les données relatives au fait que la distance Cl—Ag déterminée par LEED pour du Cl adsorbé sur la surface (100) de l'argent est généralement en accord avec la structure du AgCl solide; (*ii*) le fait que les analyses des données relatives au S adsorbé sur la surface (110) du fer peuvent servir de guide dans des études de relaxations latérales d'atomes métalliques de surface. Au fur et à mesure que des données de structure deviendront disponibles, des extensions de ces analyses devraient aider à identifier les détails plus fins des longueurs des liaisons X—M qui résultent d'arrangements spéciaux de coordinations se produisant sur les surfaces.

[Traduit par la revue]

Introduction

Structural information now becoming available for chemisorption on well-defined metal surfaces is opening a new dimension for structural chemistry. A recent review (1) discussed some approaches for assessing the general reasonableness, or otherwise, of structural data being produced by the methods of surface crystallography. This discussion emphasised the near-neighbour X—M interatomic distances observed when main-group atoms (X) are chemisorbed on crystallographically well-defined surfaces of metals (M). The approach of utilising bond order – bond length relations of the type used by Pauling, in combination with the Schomaker–Stevenson scheme for determining single-bond distances (2), often worked quite well for estimating surface X—M bond lengths, although a few instances remained of more substantial discrepancies between predicted and experimental values. The discrepancy for O adsorbed on the (111) surface of aluminum was identified as a problem for the Pauling–Schomaker–Stevenson (PSS) approach, although the situation was somewhat ambiguous in other cases, including that for Cl adsorbed on the (100) surface of silver. For the latter, the structural determination with low-energy electron diffraction (LEED) (3) appears basically reliable, but in terms of Pauling-type atomic radii the reported Cl—Ag distance seems long compared with the corresponding Cl—Cu distance for Cl adsorbed on Cu(100) (4, 5).

Another approach for predicting surface bond distances is to use bond valence – bond length relations deduced from computer analyses of solid state structures (6). A recent application to O—M interatomic distances at surfaces with specific expressions so given by Brown and Altermatt (7) showed improvements compared with the PSS approach, especially for predicting nearest-neighbour and next-nearest-neighbour bond lengths for O adsorbed on long-bridge sites of (110) surfaces of face-centered cubic metals (8). Models for the common adsorption sites observed in surface crystallography are detailed in ref. 9.

Potentially the Brown–Altermatt approach seems likely to provide a powerful scheme for interpreting surface structures, although the range of combinations of X and M for which bond valence – bond length expressions have been reliably established is still restricted. The expressions used in ref. 8 were for examples where the oxidation states of M were comparatively low (e.g. 1 or 2), however many of the other expressions provided by Brown and Altermatt are for M with oxidation states which seem too high for applications to chemisorption structures. Nevertheless, for future reference, it is noted that Brown and Altermatt also proposed an algorithm for estimating these expressions for wider ranges of atom combinations and oxidation states (7).

The present paper explores a new procedure which contains the gist of the Brown–Altermatt approach, while enabling estimates to be made for X—M surface bond lengths for a wide

TABLE 1. X—M interatomic distances from surface crystallographic techniques for adsorption of X atoms belonging to either group 16 or 17, and compared with values predicted by the PSS approach and by eq. [1]; n identifies the numbers of near-neighbours for atom X on the surface, and the values of r_0 for use in eq. [1] have been estimated for compounds of formula MX

				X—M distances (Å)		
X	Surface	r_0 (Å)	n	PSS	Eq. [1]	Surface crystallography
O	Ag(110)	1.84*	2	2.07	2.05	2.06(12)

*Values estimated with Brown and Altermatt's algorithm (7); see text.

range of chemisorption systems and coordination arrangements. Several reasons can be identified for needing to predict surface bond lengths. One is to indicate reasonable structural models for testing with multiple-scattering calculations during LEED crystallographic analyses. A second reason involves assessing the general reliability of a determined surface structure. Finally, a third, but prospective, reason involves probing the finer details of determined bond distances to identify aspects of the surface chemical bonding. The latter is required as a step toward understanding energetics and important molecular processes on surfaces, including catalysis.

Calculations and results

The Brown–Altermatt (BA) method (7) depends on the expression

[1] $r = r_0 - 0.85 \log s$

for a particular interatomic distance of bond valence s, where r_0 is the corresponding distance for a bond of unit valence. Given r_0, X—M bond lengths can be calculated with eq. [1] on the assumption that the sum of bond valencies at each X equals the atomic valence v, which in the following is taken as the normal group value (e.g. 1 for F, Cl, ...; 2 for O, S, ...). For the case that X adsorbs on a metallic surface with n equivalent neighbouring M atoms, all the bond valencies equal v/n.

The present work explores ways for deducing plausible values of r_0 in situations which have not yet been assessed in detail by the type of procedures discussed by Brown and Altermatt. Specifically an attempt is made to deduce r_0 from the known coordination numbers of X and the corresponding sets of X—M neighbouring interatomic distances in a reference solid of formula MX. This particular choice is made in part because there is an appreciable amount of reference data available for this formula type, and therefore many systems can be readily compared on an equal footing. Other factors encouraging this choice are (*i*) the metal's oxidation state is necessarily fairly low (e.g. +1 or +2 when X is a halogen or chalcogen respectively), which seems appropriate for surface metal atoms, and (*ii*) this approach is broadly consistent with that which recently used detailed BA expressions for investigating structural data for oxygen chemisorption (8).

When information is available for more than one structure for a particular reference compound, such as AgI (10), a value of r_0 is determined for each and an average taken. Also, when structural information is unavailable (or uncertain) for a compound MX, the required value of r_0 is estimated with Brown and Altermatt's algorithm (7), except for metal sulphides where each BA estimate is systematically reduced by 0.08 Å (since otherwise the M—S surface bond lengths predicted by the algorithm appear to be too long when compared with experimental data or with predictions with the PSS approach). X—M bond lengths from surface crystallography are compared in Table 1 with predicted values for examples where X is either a group 16 or group 17 atom. The predicted values are from the PSS approach, as discussed in ref. 1, and from the use of eq. [1] as outlined above. For the latter, entries in Table 1 identify the value of r_0 used in each case for parametrising the analysis. Wherever possible values of r_0 were estimated with structural data compiled by Wyckoff (11), but where such data are unavailable the r_0 values were estimated from Brown and Altermatt's algorithm as described above (such values are identified with an asterisk in Table 1).

Discussion

For O adsorbed on the surfaces of Ag(110), Cu(110), Fe(100), and Ni(110), for S adsorbed on Fe(100), Ni(110), and Rh(110), and for Se adsorbed on Ni(110), two sets of X—M bond lengths are given in Table 1; these are to M atoms in the top metal layer and to those in the second metal layer. The latter are often predicted less well than for bonds to top layer M atoms, and in part this is because the calculations always assume that the topmost interlayer spacing in the metal equals the bulk value. Some distortions from bulk vertical spacings are now being recognised experimentally in this context, and this forms a topic of increasing interest; nevertheless, it probably remains premature to include such effects in an analysis (extensions from the treatment here would need to consider X—M and M—M bonding simultaneously). Even with the less reliable predictions for X—M bond distances to second metal layers, the average discrepancy between predicted surface bond distances and experimental values is about 0.05 Å with this use of eq. [1]; the average discrepancy for the PSS model as applied in ref. 1 is about 30% larger.

Overall the level of correspondence found with eq. [1] is more than sufficient for guiding choices of trial structures for LEED crystallography. Further, predictions from the two methods together appear to provide a helpful framework for assessing the general reliability of a surface structural determination. For example the problem associated with the PSS approach for O on Al(111) is avoided by using eq. [1]; additionally the comparison in Table 1 for this equation apparently supports the essential reliability of the LEED structural analysis for Cl on Ag(100). Thus the surface bond lengths for Cl adsorbed on the (100) surfaces of silver and copper are shown here to be generally consistent with the bulk structural data for AgCl and CuCl. Excluding bond distances to second layer metal atoms, there is just one example (S adsorbed on Ni(111)) where both approaches give predictions which disagree with the experimental value by 0.10 Å or more. For the use of eq. [1] alone, larger discrepancies occur for I on Cu(111) and for the adsorption of S on surfaces of rhodium. Incidentally, for the latter, if the solid $Rh_{17}S_{15}$ (54) is used to parametrise eq. [1], a value of r_0 equal to 2.01 Å is suggested. Then the predicted S—Rh bond distances on the (100), (110) (two), and (111) surfaces are 2.27, 2.45, 2.11, and 2.16 Å respectively, and the average discrepancy from the experimental values is reduced markedly compared with the values given for the use of eq. [1] in Table 1. For the latter, the estimated value of r_0 has already been reduced by 0.08 Å from that given by the BA algorithm. This reduction is empirical, and the evidence for S—Rh bonds may indicate that some further refinement could be advantageous; in any event the fundamental reasons for the need for this correction factor are not clear at present.

The LEED crystallographic analysis for S adsorbed on Fe(110) shows that the surface metal atoms relax laterally (28), and accordingly our analysis allows the top layer metal atoms to relax so that the two pairs of neighbouring S—Fe distances become more similar. The calculations made here for this system considered metal distortion from the unrelaxed (bulk) structure through to the fully "jammed" structure for the topmost layer, which is the structure observed by LEED (28). The average calculated S—Fe bond distances are found to decrease monotonically from the unrelaxed to the jammed structure according to both the PSS model and the use of eq. [1]. The distortion induced by S in the Fe(110) surface layer is appreciable. For the unreconstructed model, eq. [1] predicts pairs of bond lengths equal to 2.14 and 2.58 Å. The latter are significantly different from the values 2.21 and 2.40 Å which minimise the average S—Fe bond distance (and therefore are assumed to approximate the circumstances for maximum adsorption energy).

The values of r_0 used in this work for O—M bonds are generally close to those taken from Brown and Altermatt's tables and used in the recent analysis by two of the authors (8) (where common systems are treated the predicted O—M bond lengths in Table 1 equal those in ref. 8 to within 0.01 Å on average). To elaborate for O—Ni bonds, a value of r_0 equal to 1.67 Å (suggested by the structure of solid NiO) is used here, whereas 1.654 Å was used previously. One addition to the information in Table 1 for O adsorbed on Ni(100) should be noted, and this concerns the LEED analysis by Demuth *et al.* (55) which suggests that O atoms may be displaced from the 4-fold centre sites toward the bridge-bonding positions. No

confirmation has yet been provided for this structure, which has two pairs of O—Ni interatomic distances at 1.75 Å and 2.14 Å for each O atom. However, the structure proposed by Demuth *et al.* corresponds to a total bond valence of 2.17 at O when eq. [1] is used with r_0 equal to 1.67 Å. Indeed r_0 would just need to be reduced to 1.64 Å to give exact consistency with the conventional group valence of 2; therefore this structure is broadly consistent with the requirements of the BA relations.

Concluding remarks

This study, along with that published previously (1), should be seen as a preliminary investigation to interpret the structural data which are now emerging from the methods of surface crystallography. A very close overall correspondence between experiment and prediction cannot be expected at this stage, in part because of uncertainties which necessarily occur in the surface structural determinations. These are difficult to estimate in general, but the most recent and carefully made structural analyses yield X—M bond lengths which are likely to be accurate to within 0.03 Å. The choice made here of the reference compounds for parametrising eq. [1] is arbitrary, although the note made above for S adsorbed on rhodium suggests that refinements may be appropriate as more reliable structural data become available. However, for now, there is consistency in using a constant formula type, and, in any event, the bonding arrangement for X adsorbed on a well-defined crystallographic plane of a solid metal M is normally different from that occurring in any actual solid formed by X and M. Nevertheless, with carefully-made surface structural analyses, there remains the hope that extensions to the basic approach reported here should help to identify the finer details in X—M bond lengths which result from the special coordination arrangements required at surfaces.

^{13}C magnetic resonance studies. 124.[1] Preparative ring expansions of bicyclic ketones by homoketonization of cyclopropoxide analogs

VIJAY PATEL,[2] ARTHUR J. RAGAUSKAS,[3] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 14, 1986

VIJAY PATEL, ARTHUR J. RAGAUSKAS, and J. B. STOTHERS. Can. J. Chem. **64**, 1440 (1986).

Homoketonization of some readily prepared cyclopropoxides provides a new synthetic method for ring expansion of the [2.2.1] and [2.2.2] ring systems. Cyclopropanation of the trimethylsilyl enol ethers derived from a variety of polycyclic ketones affords the required cyclopropyl silyl ethers, which may be ketonized directly or hydrolyzed to the corresponding cyclopropanols before ketonization. The results for fourteen examples serve to define the scope of the ring expansion process, and the silyl enol ethers, cyclopropyl silyl ethers, and most of the corresponding cyclopropanols have been characterized by ^{13}Cmr. The stereochemistry of the ketonization leading to ring expansion has been established by deuterium labelling experiments.

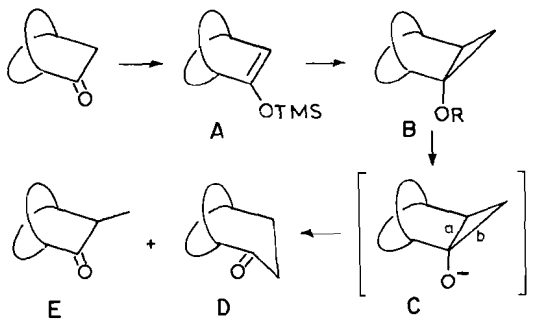
VIJAY PATEL, ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **64**, 1440 (1986).

L'homocétonisation de quelques éthers cyclopropaniques facilement accessibles fournit une nouvelle méthode de synthèse pour l'extension de cycle des systèmes [2.2.1] et [2.2.2]. La cyclopropanation des éthers énoliques triméthylsilylés, obtenus à partir de diverses cétones bicycliques, conduit aux éthers cyclopropyl/silyles requis qui peuvent soit être transformés en cétones directement soit être hydrolysés en cyclopropanols correspondants avant de les soumettre à la réaction de cétonisation. Les résultats obtenus avec quatorze exemples permettent de définir la généralité de ce processus d'extension de cycle; de plus, on a caractérisé les éthers énoliques silylés, les éthers cyclopropyle/silyles et la plupart des cyclopropanols correspondants en faisant appel à la rmn du ^{13}C. En se basant sur les résultats d'expériences réalisées à l'aide de produits marqués au deutérium, on a pu établir la stéréochimie de la réaction de cétonisation qui conduit à l'extension de cycle.

[Traduit par la revue]

Introduction

Efficient regiospecific homologation of unsymmetrical ketones has been the objective of many synthetic procedures and although the treatment of ketones with diazoalkanes (1), diazoacetic esters (2), and the Tiffeneau–Demjanov reaction (3) often proceeds in good yield these processes generally lead to mixtures of two regioisomers. Recently, in the course of an examination of the homoketonization of some highly substituted polycyclic cyclopropoxides (4), we found that the analogous derivatives of less highly substituted bicyclic [2.2.1] and [2.2.2] systems undergo ring expansion preferentially upon homoketonization (5), thereby affording an attractive new method of regiospecific homologation since the direction of ring expansion is predetermined by the structure of the cyclopropoxide species as outlined in Scheme 1. This sequence, developed by Girard and Conia (6) for a series of acyclic and monocyclic ketones, was utilized to generate several polycyclic



SCHEME 1

cyclopropanol derivatives to examine their behavior upon cleavage via homoketonization. Treatment of a given ketone with lithium diisopropylamide (LDA) followed by reaction with trimethylsilyl chloride (TMSCl) and triethylamine afforded the trimethylsilyl enol ether **A**; this procedure is a modification of that described by House *et al.* (7). Cyclopropanation with methylene iodide and a zinc–silver couple gave **B** (R = Me_3Si) which may be converted to the corresponding cyclopropanol **B** (R = H) with dilute HCl in tetrahydrofuran. In each case, a single cyclopropyl ether was formed in the cyclopropanation reaction and the orientation of the three-membered ring was deduced from the ^{13}C shielding data. Homoketonization via **C** can be accomplished directly from the ether **B** (R = Me_3Si) by base-catalyzed cleavage or by deprotonation of the cyclopropanol **B** (R = H) with dilute base. In either case, **C** is rapidly ketonized to a mixture of ketones with the ring-expanded isomer **D** as the major component for systems having one- or two-carbon bridges in the bicyclic skeleton. The minor product **E** is the α-methyl derivative of the initial ketone. For systems having one 3-carbon bridge the α-methyl ketone is the major product. The ^{13}Cmr spectra served to identify the ketonic products in each case. Protonation of the carbanion leading to **D**, generated upon ketonization of **C**, can occur with either retention or inversion of configuration and the stereochemistry of the process has been established by ^{13}C studies of the product from the requisite deuterium labelling experiments in four systems. We wish to describe the results of this study in this paper.

Results and discussion

Originally our interest in an examination of homoketonization of cyclopropoxide units in polycyclic systems arose from our ongoing investigation of homoenolization in polycyclic ketones. As an initial step, the sequence outlined in Scheme 1 was carried out with norcamphor (**1***a*) as a model compound for the development of the required preparative procedures for related ketones. The conversion of **1***a* to its trimethylsilyl enol ether followed by cyclopropanation and treatment with dilute

acid gave tricyclo[3.2.1.$0^{2,4}$]octan-2-ol in 60% overall yield, which, upon treatment with base at room temperature, afforded an essentially quantitative yield of bicyclo[3.2.1]octan-2-one. Clearly, we had observed a simple *regiospecific* ring expansion under mild conditions. To explore the potential of this process, ketones **2***a*–**10***a* were selected for further examination, since these provide a systematic series through the [2.2.1], [2.2.2], [3.2.1], [3.2.2], and [3.1.1] ring systems. The ketonization of **C** (Scheme 1) involves cleavage of either bond *a* or *b*, leading to either ring expansion to **D** (via *a* cleavage) or the α-methyl derivative **E** of the starting ketone (via *b* cleavage). The results for the series **1***a*–**10***a* should shed light on the balance between these two modes of cleavage.

Ketones **1***a*–**10***a* were converted to their trimethylsilyl enol ethers by reaction with LDA and TMSCl in 75–98% yields upon isolation by short-path distillation under reduced pressure. These enol ethers were characterized by their ^{13}Cmr spectra and the data are collected in Table 1, which includes precise mass measurements for most of the products. Cyclopropanation with CH_2I_2 and a Zn–Ag couple afforded the expected Simmons–Smith product, in each case as a single isomer as revealed by glc analysis and ^{13}Cmr; the ^{13}C data are listed in Table 2. Mild acid-catalyzed ether cleavage of these substituted cyclopropyl ethers furnished the corresponding cyclopropanols in high yield. For several examples, the cyclopropanol was isolated and examined by ^{13}Cmr; these shielding data are included in Table 2, from which it is evident that the trimethylsilyl group on oxygen in the ether has very minor effects on the skeletal carbon shieldings.

The orientation of the methylene group introduced by the Simmons–Smith cyclopropanation reaction was evident for **11***a*, derived from norcamphor (**1***a*), by the ^{13}C shielding data since the cyclopropyl methylene has marked effects on the methano bridge carbon in polycyclic systems as shown by the data for **15**–**17**. The *exo*- and *endo*-cyclopropyl rings produce major shielding and deshielding effects, respectively, at the methano bridge carbon. Exactly analogous trends have been observed for the saturated analogs of **15**–**17** (8), the tricyclo[3.1.1.$0^{2,4}$]- and tetracyclo[4.1.0.$0^{2,4}0^{3,5}$]heptane (9), and the tricyclo[3.3.1.$0^{2,4}$]- and tetracyclo[3.3.1.$0^{2,4}0^{6,8}$]nonane (10) systems. The observed methylene signals for **11***a* at δ_C 9.8, 24.7, 29.1, and 31.2, therefore, clearly show that this product arises by *exo*-cyclopropanation. In the event of *endo* cyclopropanation, the methano carbon would appear in the range of 45–50 ppm; the absence of such absorption in the spectra of **11***a*–*f*, **13***a*,*b* and *e*,*f* established the *exo* orientation of the cyclopropyl ring in each case. For **12***c*,*d* and *g*,*h* derived from the bicyclooctenones **5***a* and **5***b*, the *endo* disposition of the cyclopropyl ring is based on the observed olefinic shieldings in the range δ_C 129.6–132.8, which are upfield from those in bicyclooctene, δ_C 134.1 (11), and the upfield shift exhibited by C-8 in **12***c*,*d*, ascribable to a γ-*gauche* interaction with the neighboring oxygen nucleus; the data for several bicyclooctene derivatives (11) support this assignment. Cyclopropanation of **18**, derived from nopinone (**8***a*), was expected to favor formation of **14***a* since addition to the other side of the double bond would be hindered by the *syn* methyl group; strong support for the assigned structure is provided by the data for a series of 6,6-dimethyltricyclo[4.1.1.$0^{2,4}$]octanes (12). Specifically, the shieldings for the 2,6,6-trimethyl derivative are remarkably similar to those for **14***b*, as expected, since the shielding effects of hydroxyl and methyl substituents are known to be very similar, apart from the α-effects. The orientation of the cyclopropyl ring in **13***c*,*d*, **14***c*, *d*, and *e* is more difficult to assign with certainty although an examination of molecular models led us to the indicated assignments. It may be noted that epimerization of *exo*-3-methylbicyclo[2.2.1]octan-2-one (**9***b*) fails to produce detectable amounts of the *endo*-3-methyl isomer (13), which clearly suggests that isomers **14***c*, *d*, and

e are significantly more stable than their *endo* counterparts, thereby precluding formation of the latter. The lack of appropriate model data renders the assignments for **13***c*,*d* more tenuous and these indeed may have *endo*-cyclopropyl rings but, in any event, the cyclopropanation reaction gave a single isolable addition product.

In the early stages of this project, the cyclopropanols were obtained from the trimethylsilyl ethers to permit direct generation of the corresponding cyclopropoxide for examination of the homoketonization process. While the acid-catalyzed ether cleavage proceeds in essentially quantitative yield, the cyclopropanols are much less stable than their corresponding trimethylsilyl ethers and, consequently, do not store well. Furthermore, these cyclopropanols tend to decompose on attempted analysis by glc, yielding the α-methyl derivative of the initial ketone. As examples, it was found that a single α-methyl ketone was found in >80% yield for **11***b* → **1***b*, **12***d* → **5***b*, **13***b* → **6***b*, and **14***b* → *exo*-**8***b*. Since the α-methyl ketones are not epimerized on the glc columns, this shows that their stereochemistry is predetermined by the structure of the cyclopropanol. Thus these transformations confirm the stereochemical assignments for these cyclopropanols. Treatment of the cyclopropyl ethers with base, however, accomplishes cleavage and homoketonization of the resulting cyclopropoxide in one step and was shown to give the same mixture of products. For preparative purposes this is clearly the method of choice for cleavage of the cyclopropyl ring.

The results for homoketonization of the cyclopropanated

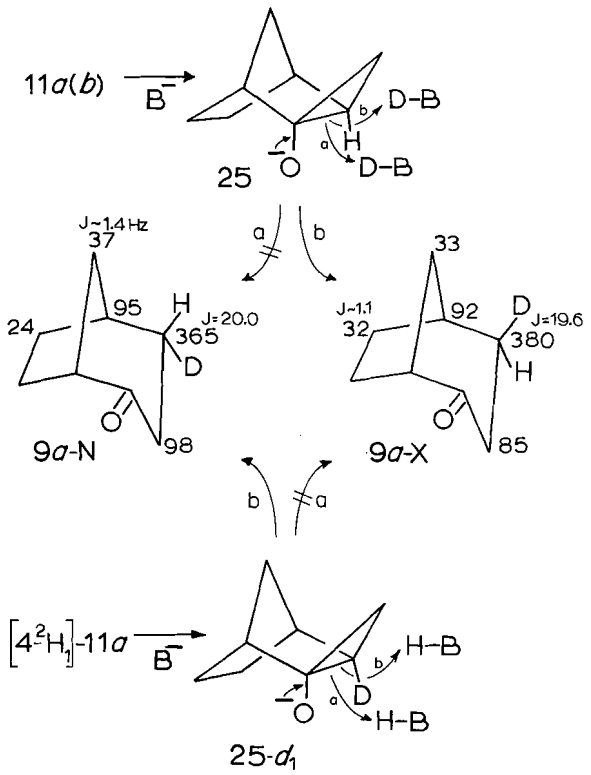
[c]Data previously reported (4) but not assigned.
[d]For analytical samples obtained by glc.

derivatives of the ten ketones **1***a*–**10***a* are summarized in Table 3; for five of these cases the trimethylsilyl cyclopropyl ethers and their corresponding cyclopropanols were examined to establish that both routes give the same product mixture within experimental error. In each case, the α-methyl ketones were readily identified by their ^{13}C spectra, all of which had been reported previously: **1***b* (15), **2***b*, **3***b*, and **10***b* (11), **4***b* and **5***b* (17), **6***b*–**9***b* (13). The ring-expanded ketones were shown to be isomeric by ms and their ^{13}C spectra lacked methyl absorption; the ^{13}C shieldings are listed in Table 4 except for **19** (16) and **21** (18) for which these data have been published.

From the product mixtures for the derivatives of **1***a* and **2***a* it is readily apparent that ring expansion is the highly favored mode for ketonization in these [2.2.1] systems. In fact, the efficacy of this new process for ring expansion in **1***a* led to the examination of **2***a* as a model system for a proposed synthesis of hirsutene, which required an analogous ring expansion of the Δ^3-derivative of **2***a* as a key step and was subsequently found to work well (14). For **3***a*, the third member of the [2.2.1] family, ring expansion is clearly favored although to a lesser extent than the others. For both of the [2.2.2] systems, **4***a* and **5***a*, ring expansion is favored, more highly so in the unsaturated case. With the isomeric bicyclo[3.2.1]octanones, **6***a* and **9***a*, however, the proportion of ring-expanded product decreases significantly, especially for the latter in which the initial carbonyl group is in the 3-carbon bridge. For the remaining examples **7***a*, **8***a*, and **10***a*, their α-methyl derivatives were obtained in >95% yields. In the case of **7***a*, the ring-expanded product was clearly identified, although it was not obtained in a pure state because all separation attempts with glc failed to resolve the product mixture, and the proportions of **22** and **7***b* were estimated from the ^{13}C spectrum of the mixture. For **8***a*, the only product was **8***b*, as a 5:1 mixture of *exo* and *endo* isomers. The minor component (<5%) formed from **10***a* appeared to be a condensation product from its ^{13}C spectrum, but this material was not fully characterized.

The results in Table 3 show clearly that there is a delicate balance between the two modes of ring opening for these cyclopropoxides with the ratio of bond cleavage *a*:*b* (see **C**, Scheme 1) varying from ~100:1 to ~1:100. It is also apparent that cleavage leading to ring expansion is increasingly favored with decreasing reaction temperature for **11***a*–*c*, **12***a*–*d*, and **13***a*. Two major opposing factors governing the regioselectivity in a given system can be envisaged. Cleavage of bonds *a* and *b* will lead to incipient secondary and primary carbanions, respectively, and the latter may be inherently favored because of the greater stability of the 1° species and the fact that it should be less hindered for protonation. On the other hand, cleavage of bond *a* can be expected to relieve ring strain in some systems thereby rendering it the favored mode of reaction, i.e. a dependence on product stability. Presumably the importance of this factor will diminish as the size of the bridges in the ring system increase, and the proportion of ring-expanded product will reflect this trend. It is apparent that ring expansion is decreasingly favored in the saturated series in the order: [2.2.1], [2.2.2], [3.2.1], [3.2.2], and the unsaturated [2.2.2] skeleton gives a higher proportion of ring expansion than its saturated counterpart; these trends agree with expectations. It may be noted that ring expansion is less favored in the **3***a* system than in the isomeric **2***a* system. This also fits nicely with expectations, since **10***a* formed in the latter case will be more stable than the isomeric **19** arising from **3***a* because the favored conformation of the six-membered ring in each will be different. The chair form, readily adopted in **10***a*, would be destabilized by nonbonded interactions with the *endo*-3- and -5-methylenes in **19** rendering a boat-like conformation more favorable, thereby destabilizing **19** relative to **10***a*. In any event, the homoketonization results show that the sequence in Scheme 1 is useful for preparative ring expansions in the [2.2.1], [2.2.2], and related systems. As examples we have utilized this sequence for the corresponding homologations of the tricyclo[3.2.1.$0^{2,4}$]octan-6-ones (10) and of tricyclo[5.2.1.$0^{1,5}$]decan-8-one (**24**) (19).

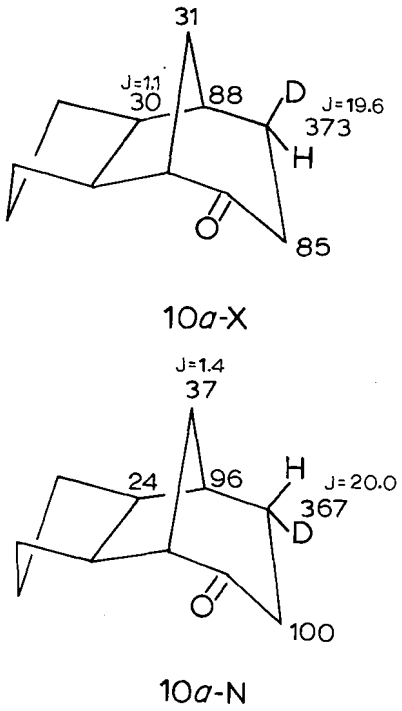
The opening of cyclopropoxide **C** to the ring-expanded ketone **D** (Scheme 1) can proceed with retention or inversion of configuration at the carbanionic site and the stereochemistry of the process can be determined by cleavage in a deuterated medium as illustrated by *a* and *b*, respectively, in Scheme 2 for cyclopropoxide **25** formed from **11***a* and **11***b*. In general, ketonizations of cyclopropoxides in polycyclic systems are found to undergo inversion of configuration, but some strained systems exhibit retention (20) and it was, therefore, of interest to determine the stereoselectivities in the **1***a*, **2***a*, **5***a*, and **6***a* systems. To distinguish between paths *a* and *b*, **11***a* was cleaved in KOD/*t*-BuOD at 25°C and the product treated with KOH/MeOH to back-exchange the α-deuterium incorporated after the cleavage. The ^{13}Cmr spectrum of a 1:1 mixture of **9***a* with the **9***a*-d_1 obtained in this manner was recorded to observe the effects of the 4-deuterium on its neighboring carbon absorptions to determine its stereochemistry. The orientation of the deuterium is revealed by the magnitude of the vicinal



SCHEME 2

^2H–^{13}C coupling interactions and the ^2H-induced isotope shifts (21). From this spectrum *exo*-deuterium incorporation was revealed; the observed isotope effects on the ^{13}C shieldings in ppb and the resolved vicinal couplings are shown in **9***a*-**X**. A key feature is the observation of vicinal ^{13}C–^2H coupling for C-6 with $J = 1.1$ Hz, while C-8 is only slightly broadened; this is indicative of deuterium antiperiplanar to C-6 and, therefore, in the *exo* orientation. To confirm this conclusion, a sample of [3,3-$^2H_1$]-**1***a* was converted to [4-$^2H_1$]-**11***a*, which was subsequently opened with NaOH/MeOH to form **9***a*-d_1. The ^{13}C spectrum of a 1:1 mixture of this material and **9***a* exhibited the ^2H effects shown for **9***a*-**N** (Scheme 2). In this case, the C-8 pattern revealed a vicinal coupling of 1.4 Hz while the C-6 signal was slightly broadened by the deuterium, indicating that C-8 and ^2H-4 are antiperiplanar, i.e. *endo*-^2H-4. These data establish that the cleavage of **25** proceeds with inversion. It may be noted that the patterns for C-3 and C-5 exhibited resolved geminal couplings of 0.6 Hz with ^2H-4; thus an upper limit of ca. 0.3 Hz may be suggested for the C-6, ^2H-4 vicinal interaction. The analogous experiments with **11***c* and [10-$^2H_1$]-**11***c* gave the isomeric monodeuterated ketones **10***a*-**X** and **10***a*-**N**, respectively, exhibiting the ^2H–^{13}C couplings and ^2H-induced shifts noted in the structural formulas. These constitute good evidence of the presence of *exo*- and *endo*-deuterium, respectively, at C-10 and, hence, for inversion of configuration upon homoketonization of the cyclopropoxide generated from **11***c*.

Treatment of **13***a* with KOD/*t*-BuOD, followed by back-exchange with KOH/MeOH, furnished a sample of **21**-d_1, tentatively identified as **21**-**X**, having the ^2H effects in the ^{13}C spectrum indicated. A sample of [4-$^2H_1$]-**13***a*, prepared from [7,7-$^2H_2$]-**6***a*, was opened with NaOH/MeOH to form **21**-d_1, which displayed the ^2H effects shown in **21**-**N** in its ^{13}C spectrum. These assignments required reversal of the shieldings



originally ascribed (18) to C-6 and C-9, but followed from the fact that the methylene absorption at δ_C 32.5 (C-6) exhibits vicinal ^{13}C-^2H coupling in both monodeuterated samples while that at δ_C 32.0 (C-9) has resolvable coupling in only one. For each of these samples, geminal couplings of 0.5 Hz were readily resolved for C-3 and C-5. The six-membered ring containing the carbonyl group in **21** will be a mixture of chair and skew-boat forms, thereby rendering the ^2H effects different from those found for the isomeric pairs of [4-$^2H_1$]-**9***a* and [10-$^2H_1$]-**10***a* described above. In either conformation, an *endo*-4-deuterium atom (**21**-**N**) will be antiperiplanar to C-9 and resolvable vicinal coupling would be expected. For the *exo*-4-^2H isomer, however, the dihedral angles relating the deuterium atom and C-9 will be ca. 60° and ca. 90° for the chair and skew-boat forms for which the vicinal coupling is expected to be small. On this basis, we conclude that ketonization of **13***a* also proceeds with inversion.

The stereochemistry of cyclopropoxide cleavage was also examined in the unsaturated [2.2.2] system. Treatment of **12***c* with KOD/*t*-BuOD, followed by back-exchange with KOH/MeOH, gave a sample of the monodeuterated ring-expanded ketone **26**-**N**. Its ^{13}C spectrum exhibited distinctive ^2H effects in four of the signals while the olefinic absorption at δ_C 136.7 was slightly broadened. In contrast, the spectrum of a sample of this ketone obtained by cleavage of [4-$^2H_2$]-**12***c* with NaOH/MeOH revealed vicinal ^{13}C–^2H coupling of 1.1 Hz for this olefinic signal whereas the C-6 signal was only broadened, but shifted by 32 ppb; this is consistent with structure **26**-**X**. Thus, homoketonization of **23***c* proceeds with inversion of configuration.

The ^2Hmr spectra of each of the monodeuterated ketones obtained in these homoketonization experiments were recorded to determine the stereoselectivity of the cleavages. In each case, a single ^2H signal was observed, indicating that the stereoselectivities are >98% favoring inversion of configuration for each system. The positions of these signals in $CHCl_3$ solutions were (δ): 1.70 (**9***a*-**X**), 1.79 (**9***a*-**N**), 1.67 (**10***a*-**X**), 1.83 (**10***a*-**N**), 2.06 (**21**-**X**), 1.79 (**21**-**N**), 1.91 (**26**-**N**), and 1.79

TABLE 5. Base-catalyzed homoketonizations of **11***e*,*f*, **12***f*,*h*, and **13***f*

Initial ketone	Cyclopropyl derivative	Temperature (°C)	Products: Ring-expansion Compound	Ring-expansion %	α,α-Dimethyl derivatives Compound	α,α-Dimethyl derivatives %
1*b*	**11***e*	25	4-Me-**9***a*[a]	37	**1***c*	63

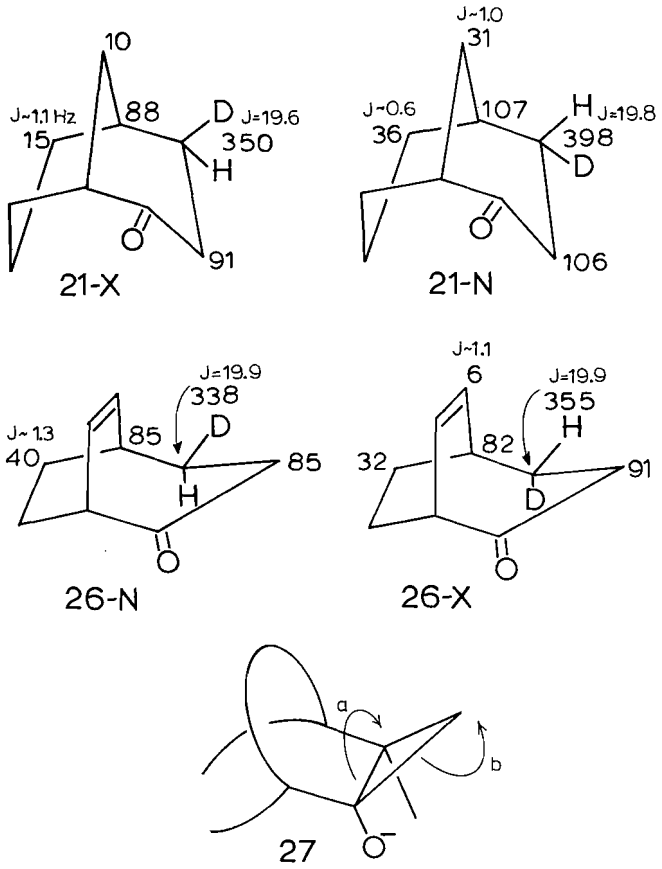
[a]Reference 4.
[b]The proportion of ring-expanded product (?) was estimated by glc but the material was not identified.



(**26-X**). Thus, in each case, the presence of product arising by opening with retention would give rise to a separately resolved ^2H signal; the absence of such signals establishes the high stereoselectivity noted.

After the discovery of homoenolization (22) in camphenilone (**1***c*), Nickon, Lambert, and Oliver showed that β-proton abstraction also occurred at the α-methyl carbons (23) and a homoenolate anion such as **27** was suggested as a possible intermediate for α-methyl exchange. Subsequently, many examples of this exchange process under homoenolization conditions have been found for mono-, bi-, and tricyclic ketones, having *gem*-dimethyl substitution at the α-methylene positions (20). Although **27** can open in two ways, with ring expansion (path *a*) or to regenerate the initial α,α-dimethyl ketone (path *b*), ring-expanded products have not been detected for any of the cyclic systems examined; path *a*, however, has been found to be important in acyclic systems. Our original examination of **1***a* was intended to develop the preparative procedures for an investigation of **1***b* and related ketones to test for the possible intermediacy of species such as **27** in the α-methyl exchange process. In fact, four systems were examined and the results are listed in Table 5, while the ^{13}C shieldings for the trimethylsilyl enol ethers and their cyclopropanated derivatives are included in Tables 1 and 2. In each case the α,α-dimethylated ketones were readily identified by ^{13}Cmr (**1***c* (15), **4***c*, **5***c* (17), and **6***c* (13)), which also served to characterize the new ring-expanded ketones 4-Me-**9***a*, **20***b*, and Δ[6]-**20***b* (Table 4); it can be noted that the generation of the trimethylsilyl enol ether from **6***b* proved difficult and a pure product was not isolated. However, the cyclopropanation reaction led to a mixture of components of which the major one could be isolated by preparative glc and was characterized as **13***e* (Table 2). From the results in Table 5 it is apparent that cleavage leading to the α,α-dimethyl ketones is strongly favored, indicating that **27** opens preferentially via a primary carbanion (path *b*) rather than a tertiary species (path *a*), which is consistent with the greater stability of the former. This mode is increasingly favored with increasing temperature, suggesting that **27** is a reasonable intermediate for α-methyl exchange under typical homoenolization temperatures of 185°C or higher. Since α-methyl exchange is known (20) to be very slow ($k \sim 10^{-7}\ s^{-1}$), small amounts of ring-expanded products, formed by the less-favored opening of **27**, may have escaped detection; presumably these could readily undergo aldol condensation under homoenolization conditions.

In summary, the sequence outlined in Scheme 1 provides an efficient method for regioselective ring expansion in [2.2.1], [2.2.2], and related systems and can be carried out under mild conditions. Furthermore, the homoketonization of the cyclopropoxides proceeds with high stereoselectivity, thereby providing a means of generating selectively deuterated ring-expanded products that may be useful for other studies.

Experimental

Boiling points are uncorrected. Gas–liquid chromatography was carried out on Varian 920 and 3700 instruments using columns of 6% FFAP or 10% SE-30 on Chromosorb W, as indicated. Tetrahydrofuran (THF) and ether were dried over sodium and freshly distilled before

use. Diisopropylamine, triethylamine, and pyridine were distilled from CaH_2 and stored over 4A molecular sieves. Norcamphor (**1***a*) and bicyclo[5.2.1.$0^{2,6}$]decan-8-one (**2***a*) are commercially available (Aldrich). All other starting ketones were prepared in earlier studies and additional material was generated using the same procedures: **1***b* (15), **3***a*, **10***a* (16), **4***a*,*b*, **5***a*,*b* (17), **6***a*,*b*, **7***a*, **8***a*, **9***a* (13).

Infrared spectra were recorded with a Beckman 4250 instrument and mass spectra were obtained on a Varian MAT-311A system at 70 eV (direct inlet). Routine ^{1}Hmr spectra were obtained with either Varian T-60 or EM-360 instruments while data for pure samples were collected with a Varian XL-200 instrument. The latter spectrometer and a Varian XL-300 were employed to record the ^{2}H and ^{13}Cmr spectra and comparison of the fully decoupled ^{13}C spectra with those obtained with either the APT (24) or DEPT (25) sequences identified the methyl, methylene, methine, and fully-substituted carbon signals.

General procedure for the preparation of the trimethylsilyl enol ethers

Freshly distilled THF (20 mL) and diisopropylamine (30 mmol) were added to a flame-dried flask under nitrogen and cooled to −78°C. Upon the addition of *n*-butyllithium (25 mmol) in *n*-hexane via syringe, the mixture was stirred for 30–45 min before dropwise addition of a solution of the ketone (20 mmol) in THF (5 mL). While the stirring continued, a quenching solution of chlorotrimethylsilane (30 mmol), triethylamine (10 mmol), and THF (7 mL) was prepared in a flame-dried, nitrogen-purged centrifuge tube. The precipitate was removed by centrifugation and the clear solution added to the enolate solution. The reaction mixture was stirred at −78°C briefly and then allowed to warm to room temperature while stirring was continued for 0.5–3 h before cooling to 0°C. A cold, saturated aqueous Na_2CO_3 solution (30 mL) was added with vigorous stirring; the product was isolated by pentane extraction and purified by Kugelrohr distillation. With the exception of the enol ether from **6***b*, which could not be obtained in a pure form, the trimethylsilyl enol ethers were characterized by ^{13}Cmr and precise mass measurements, which are listed in Table 1 together with the isolated yields for each enol ether; the purity of each product was assessed by glc analysis (FFAP) and found to be ≧95% in each case. The product from **1***a*, bp 85–90°C/10 Torr (1 Torr = 133.3 Pa); ir (film): 1605 cm^{-1}; from **1***b*, bp 75–80°C/6 Torr; ir (film): 1670 cm^{-1}; from **2***a*, bp 92–94°C/0.4 Torr; ir (film): 1610 cm^{-1}; from **3***a*, bp 89–94°C/0.2 Torr; ir (film): 1614 cm^{-1}; from **4***a*, bp 62–66°C/17 Torr; ir (film): 1642 cm^{-1}; from **4***b*, bp 85–90°C/14 Torr; ir (film): 1640 cm^{-1}; from **5***a*, bp 60–64°C/17 Torr; ir (film): 1657 cm^{-1}; from **5***b*, bp 45–50°C/1 Torr; ir (film): 1685 cm^{-1}; from **6***a*, bp 100–115°C/15 Torr; ir (film): 1622 cm^{-1}; from **7***a*, bp 110–115°C/4 Torr; ir (film): 1665 cm^{-1}; from **8***a*, bp 95–100°C/10 Torr; ir (film): 1646 cm^{-1}; from **9***a*, bp 90–95°C/4 Torr; ir (film): 1660 cm^{-1}; from **10***a*, bp 85–90°C/0.2 Torr; ir (film): 1660 cm^{-1}.

Cyclopropanation of the trimethylsilyl enol ethers

A modification of the procedure described by Girard and Conia (6) was employed. To a flask fitted with a reflux condenser, nitrogen purge, and magnetic stirrer was added a zinc–silver couple (55 mmol). The apparatus was flame-dried and then cooled to room temperature before the addition of CH_2I_2 (30 mmol) in anhydrous Et_2O (10 mL). The mixture was warmed until refluxing occurred without external heating. Upon cessation of reflux a solution of enol ether (16 mmol) in Et_2O (35 mL) was added and this mixture was heated under reflux for several hours before cooling to 0°C. Pyridine–ether (1:1) solution was added until no further precipitation occurred and the precipitate was removed by filtration and washed with Et_2O. After evaporation of the solvent, the residue was taken up in *n*-pentane and the last traces of precipitate were removed before drying over $MgSO_4$. After the solvent was evaporated, the product was isolated by Kugelrohr distillation and its purity assessed by glc (FFAP or SE-30). Analytical samples were obtained by glc and characterized by ^{13}Cmr and precise mass measurements, listed in Table 2 with the isolated yields. For each ether, the reflux time, purity, bp, and principal ir absorption were:

11*a*: 25.5 h; >96%; bp 110–115°C/15 Torr; ir (film): 3085, 2980, 1340, 1245, 835 cm^{-1}; **11***c*: 25.5 h; >95%; bp 56–58°C/0.3 Torr; ir (film): 3060, 2940, 1250, 833 cm^{-1}; **11***d*: 14 h; >90%; isolated without distillation; ir (film): 3060, 2950, 1250, 870 cm^{-1}; **11***e*: 20 h; >95%; bp 64–68°C/2 Torr; ir (film): 3060, 2975, 1250, 845 cm^{-1}; **12***a*: 6 h; >94%; bp 75–80°C/15 Torr; ir (film): 3078, 2945, 1250, 1195, 840 cm^{-1}; **12***c*: Zn–Ag (40 mmol), CH_2I_2 (20 mmol), 24 h; >93%; bp 75–80°C/5 Torr; ir (film): 3050, 3008, 2950, 1255, 1198, 840 cm^{-1}; **12***e*: 50 h; >90%; bp 80–85°C/1 Torr; ir (film): 3025, 2950, 1245, 1190, 835 cm^{-1}; **12***g*: Zn–Ag (30 mmol), CH_2I_2 (16 mmol), 20 h; >90%; bp 80–85°C/2 Torr; ir (film): 3050, 3000, 2950, 1250, 1188, 840 cm^{-1}; **13***a*: 18 h; >93%; bp 130–135°C/15 Torr; ir (film): 3020, 2955, 1254, 879, 840 cm^{-1}; **13***c*: 20 h; >90%; bp 125–130°C/4 Torr; ir (film): 3075, 2950, 1250, 830 cm^{-1}; **13***e*: 25 h; >85%; bp 135–140°C/8 Torr; ir (film): 3065, 2950, 1250, 835 cm^{-1}; **14***a*: 2 cycles of 23 h each; >98%; bp 75–80°C/2 Torr; ir (film): 3078, 2920, 1240, 1185, 840 cm^{-1}; **14***c*: 25 h; >90%; bp 100–105°C/2 Torr; ir (film): 3080, 2950, 1250, 840 cm^{-1}; **14***e*: 18 h; >90%; isolated by preparative glc without distillation; ir (film): 3000, 2950, 1190, 850 cm^{-1}.

Preparation of cyclopropanols

To a solution composed of 10% 0.1 *M* aqueous HCl and 90% THF was added the pure cyclopropyl silyl ether, obtained by preparative glc, and the reaction mixture stirred at room temperature for 0.5–3 h. After removal of THF under reduced pressure, the residue was taken up in pentane and dried over $MgSO_4$. Evaporation of the pentane yielded the corresponding cyclopropanol in essentially quantitative yield, which was characterized by ^{13}Cmr and, in several cases, precise mass measurement. These data are collected in Table 2. **14***b* crystallized on standing: mp 92–95°C (from pentane–methanol); ir (CCl_4): 3160, 3079, 2918, 1185 cm^{-1}.

Homoketonization experiments

(a) Cyclopropanols

The cyclopropanol (20 mmol) was added to a solution of KOH/*t*-BuOH (1.26 *M*, 10 mL) at the desired temperature and the solution was stirred for 0.5 h (83°C), 2 h (25°C), 24 h (0°C). After the addition of H_2O (15 mL), the ketonic products were isolated by pentane extraction (3 × 20 mL) and the combined extracts dried over $MgSO_4$. The oily residue (>85% yield in each case) remaining after removal of solvent was analyzed by glc (FFAP) to determine the composition of the product mixture. In each case, the α-methylated ketones were known from earlier studies in these laboratories and were readily identified by coinjection. Preparative glc provided samples of each component for examination by ^{13}Cmr to confirm their identities. The ^{13}C data for the ketones that had not been previously encountered in our earlier work are listed in Table 4 together with precise mass measurements. For each cyclopropanol, triplicate runs were done at a given temperature and the average compositions of these product mixtures are collected in Tables 3 and 5; the results were reproducible within limits of ±2%.

(b) Trimethylsilyl cyclopropyl ethers

To methanolic NaOH solution (3 *M*, 5 mL), maintained at the desired temperature, was added the silyl cyclopropyl ether (15 mmol, glc collected) and the mixture was stirred for 20–25 h (0°C, 25°C) or 2 h (83°C) before the addition of aqueous NaCl solution (10 mL). The ketonic products were isolated in >85% yields and assessed as described above for the corresponding cyclopropanols. The compositions of the product mixtures (averaged from triplicate runs) are listed in Tables 3 and 5 while the ^{13}C data for new ketones are collected in Table 4.

*Homoketonizations of the monodeuterated cyclopropyl ethers (**11**a–d_1, **11**c–d_1, **12**c–d_1, **13**a–d_1)*

*(i) Preparation of **1**a–d_2, **2**a–d_2, **5**a–d_2, and **6**a–d_2*

A modification of the procedure described by Hunter *et al.* (26) was employed. To a solution of anhydrous potassium carbonate (2.7 g) in D_2O (22.7 mL, 99.8% D, minimum isotopic purity, Merck, Sharp & Dohme) was added ketone **1***a* (5.0 g) under nitrogen and the mixture refluxed for 18 h. The ketone was recovered by pentane extraction (3 × 15 mL) and the extracts dried over $MgSO_4$ before evaporation of the solvent. After an additional cycle (18 h), [3,3-$^2H_2$]-**1***a* (4.3 g,

84%) was recovered and its ^{13}C spectrum indicated nearly complete exchange at the α-methylene site.

An analogous sample of [9,9-$^2H_2$]-**2***a* (2.2 g, 55% yield) was obtained upon treatment of **2***a* (4.0 g) with K_2CO_3 (1.2 g) in D_2O (12 mL) after four cycles with reflux times of 11, 40, 158, and 83 h.

Essentially complete exchange of the α-methylene hydrogens in **5***a* (0.5 g) was realized by refluxing with K_2CO_3 (0.2 g) in D_2O (2.0 mL) for 17 h under nitrogen. Pentane extraction furnished a solid product that upon sublimation gave [3,3-$^2H_2$]-**5***a* (0.46 g, 90% yield).

The same treatment of **6***a* (2.0 g) with K_2CO_3 (2.5 g) in D_2O (25 mL) at reflux for 12 h yielded **6***a*-d_x (2.0 g) for which the ^{13}C spectrum indicated ca. 50% exchange of the α-methylene hydrogens. Hence, a solution of **6***a*-d_x (2.0 g) in anhydrous dioxane (4 mL) was added to a 1 *M* NaOD/D_2O solution (25 mL) and refluxed under nitrogen for 16 h. Pentane extraction furnished [7,7-$^2H_2$]-**6***a* (1.5 g, 75% yield) for which the ^{13}C spectrum indicated essentially complete exchange of the α-methylene hydrogens.

(*ii*) The trimethylsilyl enol ethers of the dideuterated ketones just described were generated following the same procedures used for the parent ketones using 1.5 molar equivalents of LDA and TMSCl. Treatment of these enol ethers with the Simmons–Smith reagent (Zn–Ag, CH_2I) gave the corresponding cyclopropyl silyl ethers in the same yields as those obtained for their unlabelled counterparts.

(*iii*) Cyclopropyl ether **11***a*-d_1 (45 mg, 2.3 mmol) was added to methanolic NaOH solution (3 *M*, 7 mL) and the mixture was stirred overnight at room temperature. After the addition of H_2O (7 mL)), the product was extracted with pentane (3 × 15 mL) and the combined extracts were washed with H_2O (2 × 15 mL) before drying over $MgSO_4$. Removal of the solvent by evaporation gave an oil (28 mg, 98% yield), which by glc (FFAP) was >99% pure **9***a*-d_1; ms: 3.4% d_0, 97.6% d_1 (0.976 D/molecule); which was shown to be [*endo*-4-$^2H_1$]-**9***a*-**N**) by ^{13}Cmr (see text); ^2Hmr ($CHCl_3$) δ: 1.79.

The same treatment of **11***c*-d_1 (48 mg) gave [*endo*-10-$^2H_1$]-**10***a* (32 mg, 95% yield, >99% pure); ms: 6.8% d_0, 93.2% d_1 (0.932 D/molecule); ^2Hmr ($CHCl_3$) δ: 1.83; shown to be **10***a*-**N** by ^{13}Cmr (see text).

For **12***c*-d_1 and **13***a*-d_1, the product mixture isolated by pentane extraction was separated by preparative glc (FFAP) to obtain the requisite samples of the deuterated ketones: [*exo*-4-$^2H_1$]-Δ^6-**20***a* (88% yield, >98% pure); ms: 8.8% d_0, 91.2% d_1, (0.912 D/molecule); ^2Hmr ($CHCl_3$) δ: 1.79 and shown to be **26-X** by ^{13}Cmr (see text); [*endo*-4-$^2H_1$]-**21** (51% yield); ms: 3.3% d_0, 96.7% d_1 (0.967 D/molecule); ^2Hmr ($CHCl_3$) δ: 1.79; and found to be **21**-**N** by ^{13}Cmr (see text).

Homoketonizations of **11**a, **11**c, **12**c *and* **13**a *in deuterated base*

To a solution of KOD/*t*-BuOD (95% deuterated, 1 *M*, 6 mL) was added **11***a* (0.32 g) and the mixture stirred at room temperature under nitrogen overnight. After the addition of H_2O (4 mL), the product was extracted with pentane (4 × 10 mL) and the combined extracts washed with 10% NaCl solution (2 × 10 mL) and H_2O (10 mL) before drying over $MgSO_4$. Removal of the solvent gave an oil (0.20 g), which was treated with methanolic NaOH (3 *M*, 6 mL) and stirred at room temperature overnight. Pentane extraction, as in the first step, gave [*exo*-4-$^2H_1$]-**9***a* (140 mg, 70%); ms: 50.5% d_0, 49.5% d_1 (0.495 D/molecule); ^2Hmr ($CHCl_3$) δ: 1.70; identified as **9***a*-**X** by ^{13}Cmr (see text).

The same sequence with **11***c* (100 mg) using KOD/*t*-BuOD (95% deuterated, 1 *M*, 1.6 mL) followed by methanolic NaOH solution (1 *M*, 1.6 mL) gave [*exo*-10-$^2H_1$]-**10***a* (67 mg, 96%); ms: 28.5% d_0, 68.7% d_1, 2.8% d_2 (0.743 D/molecule); ^2Hmr ($CHCl_3$) δ: 1.67; shown to be **10***a*-**X** by ^{13}Cmr (see text).

Cyclopropyl ether **12***c* (55 mg) was stirred with NaOD/CD_3OD solution (99.8% deuterated, 1 *M*, 5 mL) at room temperature under nitrogen overnight. The product isolated by pentane extraction as described above was treated similarly with methanolic NaOH solution (3 *M*, 5 mL) and reisolated by pentane extraction to afford [*exo*-4-$^2H_1$]-Δ^6-**20***a* (33 mg, 91%); ms: 4.2% d_0, 95.1% d_1, 0.7% d_2 (0.965 D/molecule); ^2Hmr ($CHCl_3$) δ: 1.91; identified as **26**-**N** by ^{13}Cmr (see text).

Exactly analogous treatment of **13***a* gave [*exo*-4-$^2H_1$]-**21** in 70% yield; ms: 3.2% d_0, 92.2% d_1, 4.6% d_2 (1.014 D/molecule); ^2Hmr ($CHCl_3$) δ: 2.06; identified as **21-X** by ^{13}Cmr (see text).

Structural studies of 1,3-dioxa-2-silacycloalkanes[1,2]

A. W. HANSON, A. W. MCCULLOCH, AND A. G. MCINNES

Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford St., Halifax, N.S., Canada B3H 3Z1

Received October 24, 1985

A. W. HANSON, A. W. MCCULLOCH, and A. G. MCINNES. Can. J. Chem. **64**, 1450 (1986).

Crystal structure analyses of 1,3-dioxa-2,2-diphenyl-2-sila-5,6-benzocycloheptane (**1**), 2,9-disila-1,3,8,10-tetraoxa-2,2,9,9-tetraphenyl-5,6,12,13-dibenzocyclotetradecane (**2**), 2,10-disila-2,2,10,10-tetramethyl-1,3,9,11-tetraoxa-5,7,13,15-dibenzocyclohexadecane (**3**), 2,7-disila-2,2,7,7-tetramethyl-1,3,6,8-tetraoxa-4,5,9,10-dibenzocyclodecane (**4**), and 2,4-disila-2,2,4,4-tetraphenyl-1,3,5-trioxa-6,7-benzocycloheptane (**11**) are reported. Facile acid-catalyzed reaction of 2,7-disila-1,3,6,8-tetraoxa-2,2,7,7-tetraphenyl-4,5,9,10-dibenzocyclodecane (**8**) with water gives 1,3-di(2-hydroxyphenoxy)-1,3-disila-2-oxa-1,1,3,3-tetraphenylpropane (**12**). The latter in turn decomposes in a base-catalyzed reaction to give a mixture of **11** and catechol.

A. W. HANSON, A. W. MCCULLOCH et A. G. MCINNES. Can. J. Chem. **64**, 1450 (1986).

On rapporte des analyses des structures cristallines des dioxa-1,3 diphényl-2,2 sila-2 benzo-5,6 cycloheptane (**1**), disila-2,9 tétraoxa-1,3,8,10 tétraphényl-2,2,9,9 dibenzo-5,6,12,13 tétradécane (**2**), disila-2,10 tétraméthyl-2,2,10,10 tétraoxa-1,3,9,11 dibenzo-5,7,13,15 cyclohexadécane (**3**), disila-2,7 tétraméthyl-2,2,7,7 tétraoxa-1,3,6,8 dibenzo-4,5,9,10 cyclodécane (**4**) et disila-2,4 tétraphényl-2,2,4,4 trioxa-1,3,5 benzo-6,7 cycloheptane (**11**). Le disila-2,7 tétraoxa-1,3,6,8 tétraphényl-2,2,7,7 dibenzo-4,5,9,10 cyclodécane (**8**) réagit facilement avec l'eau, sous l'influence des acides, pour donner le di(hydroxy-2 phénoxy)-1,3 disila-1,3 oxa-2 tétraphényl-1,1,3,3 propane (**12**). Ce dernier composé, par réaction catalysée par les bases, se décompose pour donner un mélange de **11** et de catéchol.

[Traduit par la revue]

Introduction

The rather diverse literature on the intriguing chemistry of 1,3-dioxa-2-silaheterocycles has been summarised in a recent review by Cragg and Lane (1). These workers have undertaken a comprehensive investigation of the preparation and spectroscopic properties of such compounds. As part of an ongoing study in this laboratory of the biological role of silicon, we have over the past few years conducted a study of model interactions of dihydroxy compounds with dichlorosilanes which in many respects closely parallels that of Cragg and Lane.

1,3-Dioxa-2-silacycloalkanes are usually prepared by reaction of diols with difunctional silanes. Monomeric, dimeric, and polymeric products are obtained, with the stability of the product being dependent on ring size and substitution. Physical studies, such as nmr and X-ray diffraction, of such products have been extremely limited. In this article we therefore wish to describe the X-ray structure analyses of five compounds: the 7-membered monomer **1**, 14-membered dimer **2**, 16-membered dimer **3**, and 10-membered dimer **4**, as well as the trioxa derivative **11** (see Figs. 1–5). We have also studied in detail the chemistry of the dimeric compound **8**, obtained by reaction of catechol with dichlorodiphenylsilane.

Results and discussion

Preparation of 1,3-dioxa-2-silacycloalkanes

Birkofer and Stuhl have reported (2) that reaction of 1,2-benzenedimethanol with dichlorodiphenylsilane yields the benzodioxasilacycloheptane **1**. Since the submission of this manuscript Cragg and Lane have reported details of the isolation of **1** and its dimer **2** from a similar reaction (15). In our hands the predominant reaction product was the monomer **1**, mp 128–130°C, with **2**, mp 251–253°C, being obtained as a minor product.

The reactions of 1,3-benzenedimethanol with dichlorosilanes have not previously been investigated. Steric constraints in this case preclude monomer formation. We have isolated in good yield the crystalline dimer **3**, mp 162–164°C, from reaction of 1,3-benzenedimethanol with dichlorodimethylsilane.

The reactions of catechol with dichlorosilanes have received considerable attention (1), and it has been shown that the monomeric 1,2-phenylenedioxysilanes (e.g. **9**) undergo reversible dimerisation (e.g. to **4**): dissociation to monomer is favoured at elevated temperatures (3). X-ray diffraction studies have been carried out on a number of *o*-phenylenedioxy siliconates in which the silicon atom is either pentacoordinated (4–7) or hexacoordinated (8). Myer and Nagorsen have also presented X-ray diffraction data for the tetracoordinated bis(*o*-phenylenedioxy)silane (9), although the planar structure they propose has been subsequently questioned by Dunitz (10). No X-ray study has been carried out on compounds of type **4** or **9**. Hence we have also prepared and analysed **4**, mp 87–90°C, from reaction of catechol with dichlorodimethylsilane.

12 $R_1 = R_2 = \phi$
13 $R_1 = R_2 = Me$

Carbon-13 and silicon-29 nmr data for **1** and **3** are presented in Table 1. Compound **2** was not sufficiently soluble to permit high-resolution nmr investigation. Carbon-13 nmr also confirmed that the analogous reactions of 1,2-benzenedimethanol with dichloromethylphenylsilane and dichlorodimethylsilane afforded chiefly the monomeric products **5** and **6**. The chemical shifts of the methylene carbon and the aryl carbon geminal to oxygen are very similar to those of the corresponding carbons of **1** (Table 1).

Through comparison with the ^{13}C spectrum of **4** we have likewise identified the dimeric compounds **7** and **8** as major products of reaction of catechol with dichloromethylphenylsilane and dichlorodiphenylsilane (Table 2). When a solution of **4** was allowed to stand at room temperature new low-intensity ^{13}C signals were observed for the monomer **9**. In particular, the chemical shifts of the aryl carbons bonded to or geminal to oxygen resemble those of 1,3-benzodioxole, while in the more flexible **4** the shifts of these carbons correspond more closely to those of catechol itself. Creation of the five-membered ring results in a downfield shift of ~3 ppm in the oxygen-bonded carbon and an upfield shift of ~8 ppm in the carbon geminal to oxygen. Analogous small signals presumably due to **10** were observed at 113.90 and 148.85 ppm in freshly-prepared $CDCl_3$ solutions of **8**.

Chemistry of dimer 8

Cragg and Lane have reported that reaction of catechol with dichlorodiphenylsilane affords dimer **8**, for which they report a melting point of 126–130°C (11). They were unable to explain why the mp was significantly lower than those (157–171°C) previously reported by other workers (11).

In our hands the reaction yielded two major solid products. The first, with low solubility in acetone and mp 167–172°C, has all the ^1H, ^{13}C, and ^{29}Si nmr features reported by Cragg and Lane for **8** (11). Using X-ray analysis we have established the structure of the second product, which crystallized from petroleum ether/ethyl acetate with mp 136–138°C, as **11**, a compound postulated by Cragg and Lane as a product of distillation of **8** (11). The ^{29}Si shift of −32.71 ppm is very close to that (−32.58 ppm) quoted by them for their distillate.

These discrepancies led us to closely examine the chemistry of dimer **8**. As a consequence, we have further observed that **8** reacts readily with moisture to give the dihydroxy derivative **12**, mp 128–130°C. The closeness of this mp to that reported for **8** by Cragg and Lane suggests that during the crystallization process they inadvertently caused conversion to **12**.

These authors did produce ^{13}C spectra showing the initial stages of decomposition of **8** (11). When a $CDCl_3$ solution of

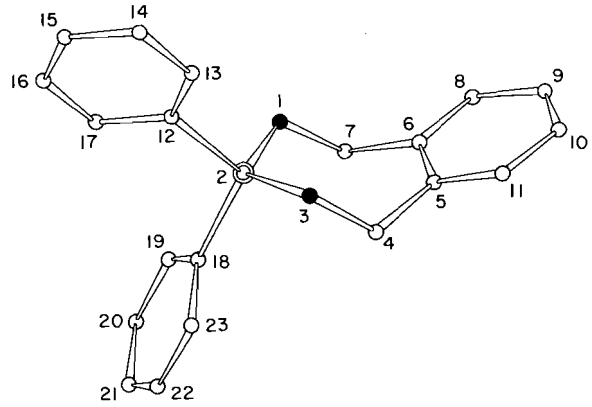

FIG. 1. 1,3-Dioxa-2,2-diphenyl-2-sila-5,6-benzocycloheptane, **1**. In this and other figures carbon, oxygen, and silicon atoms are represented by open, solid, and open double circles, respectively.

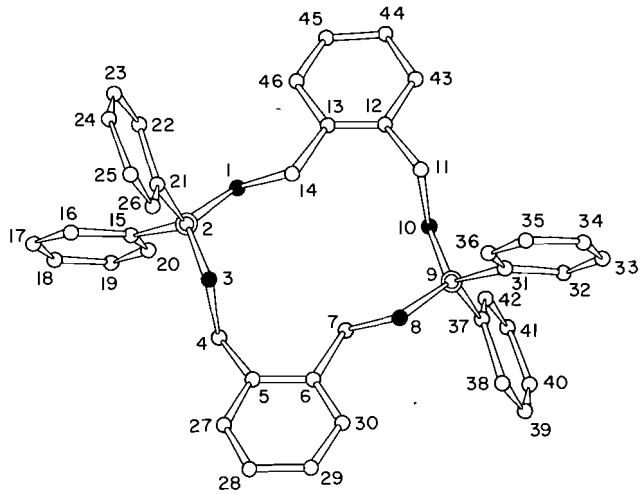

FIG. 2. 2,9-Disila-1,3,8,10-tetraoxa-2,2,9,9-tetraphenyl-5,6,12,13-dibenzocyclotetradecane, **2**.

our **8** was allowed to stand at room temperature and monitored by ^{13}C nmr, we observed the same type of initial change. However, after 15 days the spectrum showed only signals for **12**. A similar conversion was obtained when an acetone or benzene suspension of **8** was refluxed for 2–3 h. Atmospheric

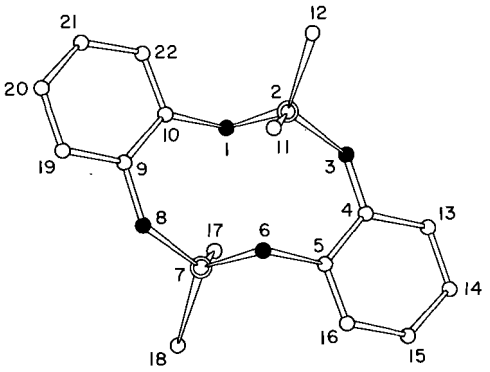

FIG. 4. 2,7-Disila-2,2,7,7-tetramethyl-1,3,6,8-tetraoxa-4,5,9,10-dibenzocyclodecane, **4**.

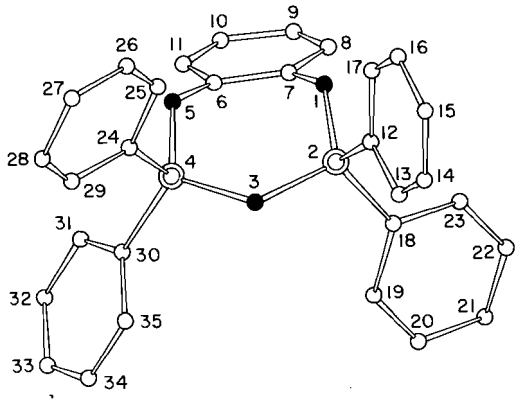

FIG. 5. 2,4-Disila-2,2,4,4-tetraphenyl-1,3,5-trioxa-6,7-benzocycloheptane, **11**.

moisture is responsible for the slow conversion of **8** to **12** in organic solvents. The time required for complete conversion in chloroform at room temperature can be reduced to 6 h by addition of a few drops of water.

The generality of the process was demonstrated by the analogous conversion of **4** to **13** (21 days in $CHCl_3$ at room temperature), the ^{13}C nmr of which is given in Table 2.

The structure of **12** follows from consideration of its ^1H, ^{13}C, and ^{29}Si nmr spectra and from its facile breakdown to **11** and catechol, in the presence of a small amount of pyridine. The same products were obtained from the pyridine-promoted breakdown of **8**. ^1H, ^{13}C, and ^{29}Si nmr spectra have been obtained for **8**, **11**, and **12**. The ^1H nmr data (Table 3) reveal the ratio of catechol ring hydrogens to Si-phenyl hydrogens, as well as the presence of OH groups in **12**. The ^{13}C spectra (Table 2) establish the symmetrically substituted catechol rings of **8** and **11** and the equivalence of both such rings in **8**, as well as the asymmetrically substituted catechol rings of **12**, and their equivalence. As expected, the ring methine carbon geminal to the hydroxyl group in **12** was three-bond coupled to both the hydroxyl proton and the hydrogen at the *meta* ring carbon, thus appearing as a doublet of triplets. The remaining three methine carbons on the catechol ring each appeared as a doublet of doublets, showing three-bond coupling to only a single *meta* hydrogen. Finally, the ^{29}Si nmr spectra confirmed that all three compounds possessed only tetra-coordinated Si atoms.

The conversion of **8** to **12** (and of **4** to **13**) presumably involves protonation and formation of a transient silanol the oxygen of which attacks the second silicon atom (Fig. 6). It seems likely that hydrogen-bonding (involving the phenolic proton, silanol group, and the oxygen under attack as in Fig. 6) determines the direction of the final rupture of the Si—O bond to give the second phenolic group of **12**, since no **11** was detected in the reaction products. Base-catalyzed reaction of **12** leads directly to **11** and catechol as shown in Fig. 6.

The isolation of **11** as a major product of reaction of catechol with dichlorodiphenylsilane can be explained on the basis of the facile base-catalyzed conversion of **8**. Not unexpectedly, we have found that the ratio of these two products is very sensitive to the reaction conditions, since this would be controlled by factors such as the concentration of moisture and free pyridine available to catalyze conversion of **8** to **11**.

Crystallography

All procedures were executed at a nominal temperature of 24°C, using Ni-filtered CuKα radiation ($\lambda\alpha_1$ = 1.54056 Å). The space groups were deduced from single-crystal photographs. The unit-cell constants were derived by least-squares analysis of the diffractometer (Picker four-circle) angles of a sufficient number of automatically centred reflections in the range $100° < 2\theta < 130°$. The intensities of all independent reflections with $2\theta < 130°$ were measured with θ–2θ scans, and individual reflection profiles were analysed as described by Grant and Gabe (12). There was no evidence of decay during these measurements for any of the specimens. Absorption corrections (Gaussian integration) were applied for **1**, **3**, **4**, and **11**. Crystals of **2** were invariably found to be twinned on $(\bar{1}\,0\,1)$. For the specimen studied the volume ratio of twin elements was estimated to be 0.63:0.37. The intensities corresponding to the larger element were recorded and used in the analysis. Because of the twinning, absorption correction was not considered feasible for this specimen. The problem of overlapping reflections was treated pragmatically. For the $(\bar{h}\,0\,h)$ reflections the overlap of (equivalent) reflections was total, and the observed intensities could be appropriately scaled. Two instances of incomplete overlap (of non-equivalent reflections) were revealed by anomalous profiles, and the reflections affected were excluded from the analysis. Complete, or nearly-complete overlaps could not be detected in this way, however, and the intensities of some reflections were undoubtedly overestimated. At a late stage in the refinement, therefore, all reflections with $F_c \gg F_o$ (an additional 33, or 2% of the data set) were also excluded. The structure determined for this compound is undoubtedly correct, but the possibility of unusual systematic errors in the final atomic parameters should not be disregarded. All structures were solved uneventfully by direct methods (MULTAN (13)). Refinement was by block-diagonal least-squares, minimizing $\Sigma w\Delta F^2$, where $1/w = \sigma^2(F_o) + kF_o^2$. The hydrogen atoms were either assigned reasonable positions (C—H = 1.08 Å) or located in ΔF syntheses. The thermal motion was assumed to be isotropic for the hydrogen atoms, and anisotropic for the others. Refinement was terminated when all indicated parameter shifts were acceptably small ($<0.1\sigma$). The final ΔF syntheses indicated no detail inconsistent with the proposed structures (Figs. 1–5). The atomic coordinates are given in Tables 4 to 8, and selected bond lengths, bond angles, and torsion angles in Tables 9 to 13. The computer programs and the source of atomic scattering factors are identified in ref. 14. Cragg and Lane have suggested (1) that large SiOC bond angles may be a characteristic of all 1,3,2-dioxasilacycloalkanes. This is certainly true for **4** (126.0° and 137.0°) but for **1**, **2**, and **3** these angles range from 118.6° to 125.1° (mean 121.6°). In the *trioxa* derivative **11**, the corresponding values are 126.1° and 131.1°, while the SiOSi angle is 134.9°.

*In this and following tables, $B_{eq} = 8\pi^2(U_{11} + U_{22} + U_{33})/3$.

Crystal and other numerical data[3]

(1) $C_{20}H_{18}O_2Si$ fw = 318.4
Monoclinic, a = 19.735(1), b = 8.4424(6), c = 10.3032(4) Å, β = 102.08(1)° (25 reflections), V = 1678.6 Å^3, space group $P2_1/n$ (alt. $P2_1/c$, No. 14), Z = 4, ρ_c = 1.259 g cm^{-3}. Nominal crystal dimensions 0.5 × 0.2 × 0.07 mm, μ = 12.6 cm^{-1}, absorption corrections 1.08 to 1.32. A total of 2858 reflections were scanned ($\pm h$, $+k$, $+l$), giving 1950 with $I > 2\sigma(I)$. Final R = 0.035 (0.064 including the unobserved), R_w = 0.048, k in weighting scheme, 0.0005. H atom parameters were refined.

(2) $C_{40}H_{36}O_4Si_2$ fw = 636.9
Triclinic, a = 9.334(3), b = 12.179(3), c = 7.724(3) Å, α = 91.22(2), β = 103.54(2), γ = 99.24(2)° (23 reflections), V = 841.0 Å^3, space group $P\bar{1}$ (No. 2), Z = 1, ρ_c = 1.257 g cm^{-3}, molecular symmetry, centre. Nominal crystal dimensions 0.4 × 0.13 × 0.07 mm, μ = 12.7 cm^{-1}, no absorption corrections. A total of 2853 reflections were scanned ($\pm h$, $+k$, $\pm l$) giving 1595 with $I > 2\sigma(I)$, but 35 were omitted from the refinement procedure. Final R = 0.055 (0.133 for all reflections), R_w = 0.075, k in weighting scheme, 0.001. H-atom parameters were not refined (U_{iso} = 0.10 Å^2).

(3) $C_{20}H_{28}O_4Si_2$ fw = 388.6
Monoclinic, a = 10.914(1), b = 11.646(3), c = 8.094(2) Å, β = 95.28(2)° (36 reflections), V = 1024.4 Å^3, space group $P2_1/c$ (No. 14), Z = 2, ρ_c = 1.259 g cm^{-3}, molecular symmetry, centre. Nominal crystal dimensions 0.4 × 0.27 × 0.27 mm, μ = 17.0 cm^{-1}, absorption corrections 1.42 to 1.66. A total of 1749 reflections were scanned ($\pm h$, $+k$, $+l$), giving 1581 with $I > 2\sigma(I)$. Final R = 0.032 (0.036 including the unobserved), R_w = 0.052, k in weighting scheme, 0.0002. H atom parameters were refined.

Experimental

The ^{13}C (20 MHz) nmr spectra were recorded in $CDCl_3$ on a Varian FT-80A spectrometer with internal ^{2}H lock to the solvent and at a temperature of 35°C. The spectra were acquired with SW 4132, AT 0.99, FA 23°, ^{1}H irradiation at 80 Hz, $\gamma H_2/2H\pi \sim 4000$ Hz, modulation bandwidth 2000 Hz (broadband decoupling). ^{29}Si nmr spectra with broadband ^{1}H-decoupling were obtained at 71.73 MHz using a Nicolet Magnetics 360 spectrometer. Samples ($CDCl_3$; 10 mm tubes) were treated with $Cr(acac)_3$ (5 mg/mL) to decrease spin–lattice relaxation time T_1 and suppress the nuclear Overhauser enhancement which has the potential to cause nulling of ^{29}Si signals. Other conditions were as follows: temperature 21°C, spectral width ±10 kHz, quadrature phase detection, acquisition time 0.41 s, 90° pulses (40 µs), delay between acquisitions 1 s to 10 s.

(50 mL) was added to a stirred, hot (~100°C) mixture of 1,2-benzenedimethanol (13.82 g, 0.10 mol) and pyridine (16 mL, 0.198 mol) in toluene (200 mL). After refluxing for 3 h the precipitated solid was filtered and the toluene evaporated. Trituration of the residue with ether gave colorless solid (29.68 g). Treatment of the latter with refluxing ethyl acetate gave **2** as insoluble solid (2.67 g, 8.4%). The pure compound was obtained as colorless prisms, mp 251–253°C (toluene) (lit. 245–250°C (1)).

Successive concentrations of the ethyl acetate-soluble fraction gave **1** as a colorless solid (20.57 g, 64.7%): the pure compound was obtained as colorless prisms, mp 128–130°C (ethyl acetate) (lit. 129–131°C (1)).

Analogous reactions of 1,2-benzenedimethanol with dichloromethylphenylsilane and dichlorodimethylsilane afforded viscous oils. Compounds **5** and **6** were identified as the major components by ^{13}C nmr (Table 1).

2,10-Disila-2,2,10,10-tetramethyl-1,3,9,11-tetraoxa-5,7,13,15-dibenzocyclohexadecane, ***3***

Dichlorodimethylsilane (13.3 g, 0.103 mol) in toluene (50 mL) was added to a stirred, hot (100°C) solution of 1,3-benzenedimethanol (13.82 g, 0.10 mol) and pyridine (16 mL, 0.198 mol) in toluene (200 mL). Work-up after 3 h as above gave a viscous oil which crystallized on cooling. Trituration with ether gave **3** as an insoluble solid (11.77 g, 60.7%): the pure compound was obtained as colorless prisms, mp 162–164°C (ethyl acetate).

2,7-Disila-2,2,7,7-tetramethyl-1,3,6,8-tetraoxa-4,5,9,10-dibenzocyclodecane, ***4***

A solution of dichlorodimethylsilane (26.6 g, 0.206 mol) in toluene (50 mL) was added to a hot (~80°C), stirred mixture of catechol (22.0 g, 0.20 mol) and pyridine (32 mL, 0.396 mol) in toluene (200 mL). After refluxing for 3 h and standing overnight at room temperature the precipitate was filtered off. Toluene was distilled from the filtrate to give a semi-crystalline mass (29.08 g): compound **4** was obtained as colorless prisms (16.42 g, 49.5%), mp 87–90°C (petroleum ether) (lit. 84–88°C (11)).

Crystalline **7**, mp 117–121°C (lit. 109–115°C (11)), was isolated from an analogous reaction of catechol with dichloromethylphenylsilane.

2,7-Disila-1,3,6,8-tetraoxa-2,2,7,7-tetraphenyl-4,5,9,10-dibenzocyclodecane, ***8****, and 2,4-disila-2,2,4,4-tetraphenyl-1,3,5-trioxa-6,7-benzocycloheptane,* ***11***

Analogous reaction of dichlorodiphenylsilane (25.28 g) and catechol (11.01 g) in the presence of pyridine (15.65 g) and toluene (250 mL) was carried out at 100°C for 3 h. The precipitated pyridine hydrochloride was filtered off and the filtrate concentrated by evaporation under reduced pressure. A colorless precipitate (11.39 g) was collected. This was washed with warm acetone to leave dimer **8** as a colorless solid (11.045 g, 38%), mp 167–172°C.

Distillation of toluene from the filtrate gave a viscous oily residue which gradually crystallized. The trioxa derivative **11** was obtained as colorless prisms (7.06 g, 29%), mp 136–138°C (petroleum ether/ethyl acetate).

1,3-Di(2-hydroxyphenoxy)-1,3-disila-2-oxa-1,1,3,3-tetraphenylpropane, ***12***

A solution of dimer **8** (2.00 g) in chloroform (20 mL) was allowed to stand at room temperature for 15 days. Evaporation of the solvent and

crystallization gave **12** as colorless prisms (1.602 g, 78%), mp 128–130°C (petroleum ether/ether acetate).

Complete conversion to **12** was obtained after **8** (500 mg) was stirred for 6 h at room temperature in chloroform (10 mL) to which water (4 drops) had been added. Complete conversion was also obtained when suspensions of **8** (1 g) in 30 mL of acetone or benzene were refluxed for 2 or 4 h, respectively: the solid slowly dissolved as the reaction progressed.

*Pyridine-catalyzed decomposition of **12***

A solution of **12** (1.00 g) in chloroform (20 mL) containing pyridine (1 drop) was stirred at room temperature for 30 min. The petroleum ether insoluble portion of the product afforded catechol as a colorless solid (88 mg, 48%) identified by mp (100–106°C), mixed mp (100–105°C) and nmr. Crystallization of the petroleum ether soluble component gave **11** (371 mg, 46%), mp 134–137°C (petroleum ether/ethyl acetate). When the reaction time was increased to 1 h the isolated yields of catechol and **11** were 86% and 74%, respectively.

The same breakdown products (**11** and catechol) were isolated after a solution of **8** (1 g) in chloroform (20 mL) was treated with 1 drop of pyridine and allowed to stand at room temperature for 24 h.

*1,3-Di(2-hydroxyphenoxy)-1,3-disila-2-oxa-1,1,3,3-tetramethylpropane, **13***

When a solution of **4** in $CDCl_3$ was allowed to stand at room temperature for 21 days, essentially quantitative conversion to **13** was observed.

The reactions of $O(^3P)$ with 2-propanone, 2-butanone, and 3-pentanone

JOHN M. ROSCOE
Department of Chemistry, Acadia University, Wolfville, N.S., Canada B0P 1X0

Received July 30, 1985[1]

JOHN M. ROSCOE. Can. J. Chem. **64**, 1458 (1986).

The reactions of $O(^3P)$ with 2-propanone, 2-butanone, and 3-pentanone have been studied kinetically as a function of temperature and substrate concentration. The absolute rate constants for these reactions in the gas phase, in the units $M^{-1}\,s^{-1}$, obey the following relations.

$$O + \text{2-propanone: } \ln k = 20.28\pm0.18 - (2.1\pm0.2) \times 10^3/T$$

$$O + \text{2-butanone: } \ln k = 20.02\pm0.19 - (1.3\pm0.3) \times 10^3/T$$

$$O + \text{3-pentanone: } \ln k = 19.48\pm0.32 - (1.0\pm0.5) \times 10^3/T$$

The activation energies for these reactions are comparable to those for the reactions of $O(^3P)$ with alcohols, but the preexponential factors for the reactions of $O(^3P)$ with these ketones are significantly smaller than those for the analogous reactions with alcohols. The available data indicate that the reactivity of $O(^3P)$ toward ketones shows a variation with polar effects of substituents which is similar to that found for the reactions of OH with ketones.

JOHN M. ROSCOE. Can. J. Chem. **64**, 1458 (1986).

On a étudié la variation de la cinétique des réactions du $O(^3P)$ avec la propanone-2, la butanone-2 et la pentanone-3 en fonction de la température et de la concentration des substrats. Les constantes absolues de ces vitesses de réaction en phase gazeuse, exprimées en $M^{-1}\,s^{-1}$, obéissent aux relations suivantes:

$$O + \text{2-propanone: } \ln k = 20{,}28\pm0{,}18 - (2{,}1\pm0{,}2) \times 10^3/T$$

$$O + \text{2-butanone: } \ln k = 20{,}02\pm0{,}19 - (1{,}3\pm0{,}3) \times 10^3/T$$

$$O + \text{3-pentanone: } \ln k = 19{,}48\pm0{,}32 - (1{,}0\pm0{,}5) \times 10^3/T$$

Les énergies d'activation de ces réactions sont comparables à celles des réactions du $O(^3P)$ avec les alcools; toutefois, les facteurs préexponentiels pour les réactions du $O(^3P)$ avec ces cétones sont beaucoup plus faibles que ceux observés pour les réactions analogues avec les alcools. Les données disponibles indiquent que la réactivité du $O(^3P)$ avec les cétones varie avec les effets polaires des substituants d'une façon semblable à celle qui a été observée pour les réactions de OH avec les cétones.
[Traduit par la revue]

Introduction

We recently reported an analysis of kinetic data for the reactions of $O(^3P)$ with C_1 to C_4 alcohols (1). The results indicated that the inductive effect of the OH group was significant at CH bonds which were not α to OH. The Arrhenius preexponential factors for these reactions were consistently smaller than those for reactions of $O(^3P)$ with alkanes and were insensitive to the structure of the alcohol except for a statistical dependence on the number of α-CH bonds. The activation energies for the reactions of $O(^3P)$ with alcohols were some 2 to 4 times smaller than those for the analogous alkane reactions as a result of the strong inductive effect of the OH group. A Taft linear free energy analysis showed that the reactions of $O(^3P)$ with alcohols had a sensitivity to polar effects midway between the analogous reactions with alkanes and aldehydes and that the reactions of $O(^3P)$ consistently showed somewhat stronger polar effects than the corresponding reactions of OH.

The reactions of $O(^3P)$ with ketones described here were investigated for several reasons. Kinetic data for these reactions are very scarce. The only previous study of such reactions of which we are aware (2) reported that, for the reaction of $O(^3P)$ with 2-propanone, the activation energy was comparable to, or somewhat larger than, that for the reaction of $O(^3P)$ with methanol. The Arrhenius preexponential factor, however, was found to be some 5 to 10 times smaller than the recently reported values for the reaction of $O(^3P)$ with methanol (3–5). It seemed useful to test the generality of this result. Ketones also provide the opportunity to investigate the effects of substitution on both sides of a very polar functional group. It was of interest to estimate the extent to which polar effects due to substitution on one side of the carbonyl would be felt on the other side of the carbonyl. Finally, the comparatively wide range of substitution possible in ketones provides an excellent opportunity to seek correlations between Arrhenius parameters and to further explore the sensitivity of reactions of $O(^3P)$ to polar effects.

Experimental

The reactions were studied in a conventional discharge-flow system similar to those used in earlier work in this laboratory (6, 7). The cylindrical reaction vessel was coated with boric acid to inhibit heterogeneous recombination of $O(^3P)$. The substrate entered the reactor through a moveable inlet and the concentration of $O(^3P)$ was monitored at a fixed point at the downstream end of the reaction vessel. The pressures used in the experiments ranged from 0.9 to 1.2 Torr (1 Torr = 133.3 Pa) and linear flow velocities in the reaction vessel ranged from 600 to 1300 cm s^{-1}.

Oxygen atoms were formed by titrating $N(^4S)$ atoms with NO in order to avoid interference from O_2 (6, 8). $N(^4S)$ was produced by dissociating purified N_2 with a microwave-driven discharge. The concentration of $O(^3P)$ produced in this way was kept small by passing only a small part of the total nitrogen flow through the discharge, the remainder of the nitrogen mixing with the products of the discharge upstream from the NO inlet. This arrangement made it possible to achieve more than a 1000-fold excess of ketone. This was essential to avoid secondary reactions of $O(^3P)$, particularly with OH, while permitting a reasonably wide variation in ketone concentration as required in the kinetic analysis. The concentration of $O(^3P)$ was determined by measuring the intensity of the emission from electronically excited NO_2 produced by adding a small amount of NO in excess of that required to completely consume the $N(^4S)$. The rate constants

[1]Revision received February 26, 1986.

obtained in this way were independent of the amount of excess NO used.

The ketones (Fisher, Certified) were purified by repeated fractional distillation until no impurities could be detected by gas chromatography. Their purity was estimated on this basis to be better than 99.995%. Gas chromatographic analysis of both starting materials and reaction products was done on an 8-ft column packed with Porapak Q using a thermal conductivity detector because of the need to measure water. The purity of the starting materials was also confirmed on an 8-ft 1% Carbowax column using a flame ionization detector. Reaction products were trapped with liquid nitrogen, warmed to room temperature, and then removed from the flow system for injection into the gas chromatograph. Because of the large concentration of ketone used in these experiments, the ketone could be used as an internal standard for determination of the reaction products.

Experiments in which a constant amount of NO in slight excess of $N(^4S)$ was added through the moveable inlet at various distances along the reactor in the absence of ketone indicated that heterogeneous recombination of $O(^3P)$ was negligible over the range of reaction times used in the kinetic experiments. However, as in our recent work on the reactions of $O(^3P)$ with the butanols (1), adsorption of the substrate and (or) reaction products on the walls of the reaction vessel produced a substantial extraneous first-order heterogeneous loss route for $O(^3P)$. In an effort to keep this effect constant during a given set of kinetic experiments, the moveable inlet was always moved upstream during a run and was moved slowly enough to allow the system to stabilize between successive measurements of the concentration of $O(^3P)$. After a kinetic experiment, the substrate flow was turned off, the moveable reactant inlet was returned to the downstream end of the reaction vessel, and a new kinetic experiment was not started until the $O(^3P)$ concentration had returned to its previous value in the absence of reactant. The pseudo-first-order plots obtained in this way were reproducible, had linear correlation coefficients better than 0.98, and gave slopes with standard deviations less than 2%. As indicated in Fig. 1, the pseudo-first-order rate constants could be adequately represented by

[1] $$k_{obs} = k_0 + k_R[RC{:}OR']$$

in which k_R is the rate constant for the reaction of $O(^3P)$ with ketone in the gas phase and k_0 refers to the complicating first-order wall loss for $O(^3P)$. Values of k_R were obtained from plots such as those in Fig. 1 covering a factor of up to 8 in ketone concentration. Values of k_R obtained in this way were reproducible to within 20% or better. Both the pseudo-first-order rate constants and the Arrhenius parameters obtained from them were calculated by weighted least squares with weights $y^2/\sigma^2(y)$ where $y = k_R$ in the Arrhenius expression and $y = O(^3P)$ signal in the pseudo-first-order analysis of $O(^3P)$ decay. The data in the pseudo-first-order analysis were within two standard deviations of the regression line while the data used in the Arrhenius expressions were at the 95% confidence level or better.

Results and discussion

The earlier work on the reaction of $O(^3P)$ with 2-propanone (2) demonstrated clearly that the initial step in the reaction is

[2] $$CH_3C{:}OCH_3 + O \rightarrow CH_2C{:}OCH_3 + OH$$

Subsequent reactions that must be considered are

[3] $$O + OH \rightarrow O_2 + H$$

[4] $$OH + CH_3C{:}OCH_3 \rightarrow CH_2C{:}OCH_3 + H_2O$$

[5] $$2\ CH_2C{:}OCH_3 \rightarrow \text{products}$$

[6] $$O + CH_2C{:}OCH_3 \rightarrow \text{products}$$

Reaction [3] may be suppressed relative to reaction [4] by using a sufficient excess of 2-propanone (or of the appropriate ketone in the other reactions studied, assuming they occur by the same kind of mechanism). The concentration ratio of ketone to $O(^3P)$ required to accomplish this will be indicated by $[H_2O]/\Delta[O] = 1$ where $\Delta[O]$ is the reduction in [O] due to reaction. For $[CH_3C{:}OCH_3]/[O]_0 > 150$ the measured yield of H_2O was equal to the consumption of $O(^3P)$ while ratios less than 100 gave yields of H_2O that were clearly less than the consumption of $O(^3P)$. Similar results were obtained for the other ketones although the ketone/$O(^3P)$ ratio required for quantitative elimination of reaction [3] varied somewhat from one ketone to another. The ratio of ketone to $O(^3P)$ was always kept greater than that required to ensure that reaction [3] was negligible.

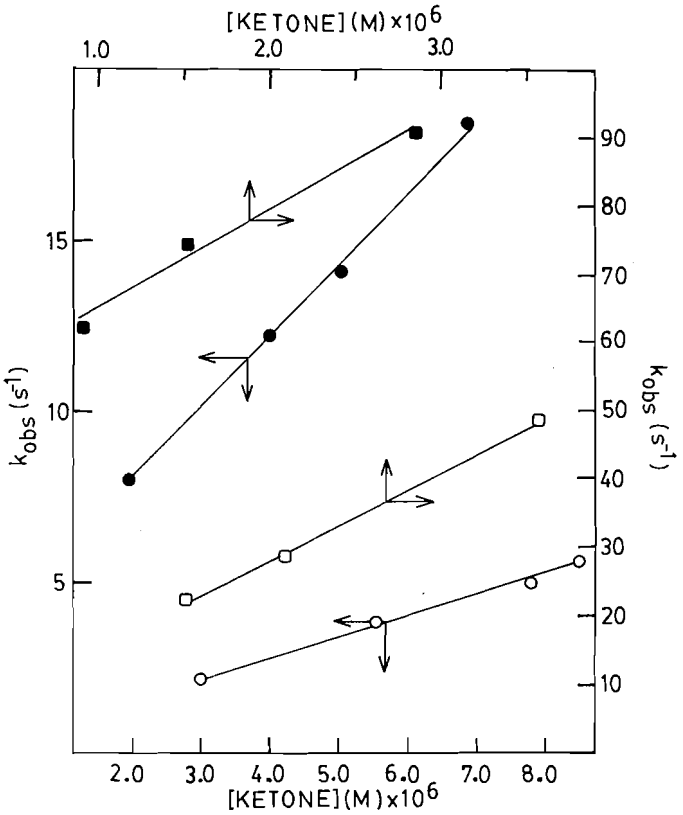

FIG. 1. Concentration dependence of pseudo-first-order rate constants (k_{obs}). ○, O + 2-propanone, 301 K; ●, O + 2-propanone, 371 K; □, O + 2-butanone, 318 K; ■, O + 3-pentanone, 344 K.

The effect on $O(^3P)$ decay kinetics of intervention by reaction [6] is less clear-cut than was the case for reaction [3]. If reaction [6] occurs by addition, it simply represents an extra loss route for $O(^3P)$ that does not lead to H_2O. The observation that, with a sufficiently large excess of ketone, the yield of H_2O could be made equal to the consumption of $O(^3P)$ indicates that addition of $O(^3P)$ to the organic radical formed in the initial step of the reaction is not important under the conditions used to determine the rate constants. It is, of course, possible for reaction [6] to proceed by hydrogen abstraction producing OH, which would then yield H_2O via reaction [4], setting up a chain for removal of $O(^3P)$. Such a mechanistic complication would not be detected by measuring the yield of H_2O. There are, however, both theoretical and experimental reasons to conclude that this version of reaction [6] was also unimportant. The extent of intervention of reaction [6] will depend on the concentration of the organic radical ($CH_2C{:}OCH_3$ in the case of 2-propanone) and this, in turn, will depend on the initial concentration of $O(^3P)$. The initial concentration of $O(^3P)$ was varied by approximately a factor of 5 for each reaction studied with no detectable effect on the value of the rate constant. This

[a]Values of the heterogeneous component of k_{obs} have been listed to indicate the approximate magnitude of the extraneous loss of $O(^3P)$.

[b]These data are included to indicate the effect of an inadequate excess of 2-propanone. The values of k_R at these temperatures require a significant stoichiometric correction.

suggests that reaction [6] was unimportant as a loss route for $O(^3P)$. In order for reaction [6] to be important, the ratio $k_1[CH_3C{:}OCH_3]/k_6[CH_2C{:}OCH_3]$ would need to be less than about 10. This is unlikely for two reasons. The concentration of the organic radical is likely to be substantially smaller than that of $O(^3P)$ during at least the first half-life. Since the ketone/$O(^3P)$ ratio ranges from about 100 to over 1000 this would require k_1/k_6 to be less than 0.01. For comparable preexponential factors, this would require reaction [6] to have an activation energy more than 2.5 kJ/mol less than that for reaction [1]. Alternatively, for comparable activation energies reaction [6] would require a preexponential factor more than 10 times larger than that for reaction [1]. Such large variations in preexponential factor or activation energy between reactions [1]

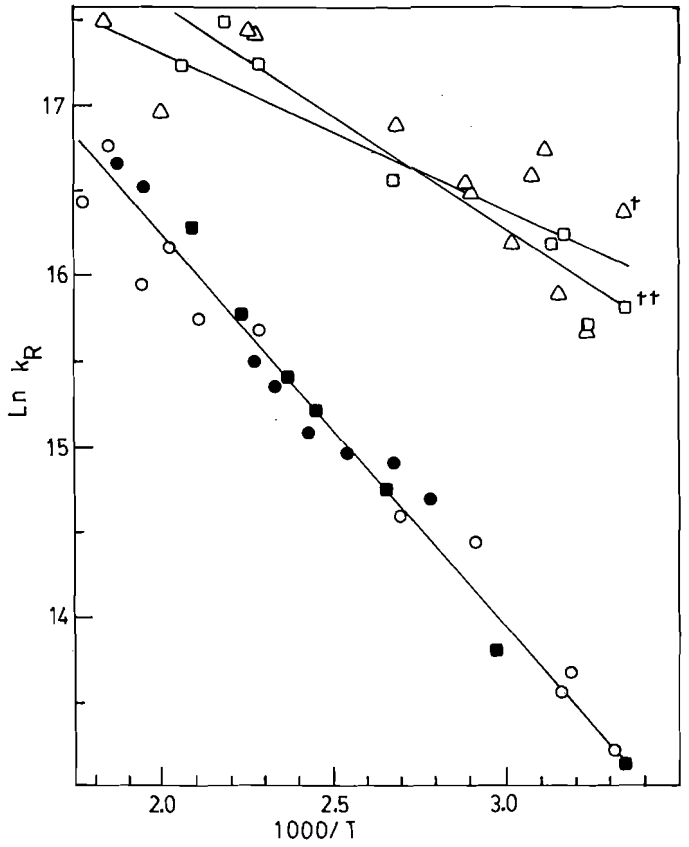

FIG. 2. Arrhenius plots for the reactions of $O(^3P)$ with ketones. O + 2-propanone: ○, this work; ●, ref. 2, mass spectrometric results; ■, ref. 2, esr results, experimental rate constants divided by the suggested stoichiometric coefficient of 3; O + 2-butanone: □, this work; □††, calculated from the linear free energy correlation of ref. 10 using the experimental rate constant for OH + 2-butanone reported in ref. 11; O + 3-pentanone: △, this work; △†, calculated from the linear free energy correlation of ref. 10 using the experimental rate constant for OH + 3-pentanone reported in ref. 12.

and [6] seem unreasonable in view of the similarities in the organic reactant in these reactions. Finally, intervention by reaction [6] as a hydrogen abstraction reaction would increase the rate constants measured experimentally above the correct value for the absolute rate constant by a factor equal to the chain length. This effect would show up as a larger than expected value for the preexponential factors of the reactions. In fact, the preexponential factors are significantly smaller than those for the reactions of $O(^3P)$ with either alcohols or alkanes.

The effect of an inadequate excess of 2-propanone is indicated in the data for the first three temperatures in Table 1. The first data set spans $[CH_3C{:}OCH_3]/[O]_0$ ratios of about 8–35, the second, ratios of about 22–65, and the third, ratios of about 245–641. In all cases, good first-order atom decays were observed and within each range of $[CH_3C{:}OCH_3]/[O]_0$ ratios the pseudo-first-order rate constant was linearly related to the concentration of 2-propanone. It is clear, however, that the slopes of such relations, representing the homogeneous bimolecular rate constant, decrease systematically with decreasing initial concentration of $O(^3P)$ but with 2-propanone concentrations falling in the same range for each data set. As noted earlier, the effect of decreasing the initial concentration of $O(^3P)$ will be to decrease the concentration of the $CH_2C{:}OCH_3$ radical relative to 2-propanone, thereby decreasing the importance of secondary reactions of $O(^3P)$ with $CH_2C{:}OCH_3$. This

TABLE 2. Summary of Arrhenius parameters

Ketone	$A \times 10^{-8}$ ($M^{-1}s^{-1}$)	E_a (kJ mol^{-1})	Reference
2-Propanone	9. ± 3	18. ± 3.	2[a]
2-Propanone	6.4 ± 4	17. ± 2.	This work
2-Butanone	5.0 ± 0.9	10. ± 2.	This work

[a]Recalculated from the mass spectrometric data of ref. 2 by the *y*-weighted least-squares method used for the data obtained in this work.

behaviour may be compared with that observed by Lee and Timmons (2). They found that rate constants for the reaction of $O(^3P)$ with 2-propanone, measured by following the pseudo-first-order loss of $O(^3P)$ by esr spectroscopy, were about a factor of three larger than those obtained by using mass spectrometry to follow the loss of 2-propanone in the presence of a large excess of $O(^3P)$. While they do not quote an absolute concentration of $O(^3P)$, comparison with earlier work from their laboratory (9) suggests that their esr experiments were made with $[O(^3P)] \sim 10^{-7}\,M$ (~4% dissociation of O_2). Their $[CH_3C{:}OCH_3]/[O]_0$ ratios would then fall about in the range 30–100 where we also found significant stoichiometric corrections. Our initial concentrations of $O(^3P)$ are in the range $2 \times 10^{-8}\,M - 3 \times 10^{-9}\,M$ in the experiments with 2-propanone while our absolute concentrations of 2-propanone fall in the same range as those used by Lee and Timmons. A gradual variation in the stoichiometric correction with $[CH_3C{:}OCH_3]/[O]_0$ ratio would not be noticed over a modest range of values of this ratio because of the experimental scatter inherent in such measurements, and reasonably linear dependence of the pseudo-first-order rate constant on the concentration of 2-propanone might be expected. Good linear first-order atom decays would also be observed provided the stoichiometric factor is constant and the consumption of 2-propanone is negligible over the range of reaction times examined. The effects of variable stoichiometric corrections only become evident when the ratio of reactant concentration to atom concentration is varied by several orders of magnitude as in our work and in the comparison of the mass spectrometric and esr results reported by Lee and Timmons.

In view of the above comments, it seems unlikely that extraneous loss routes for $O(^3P)$ had a significant effect on the values calculated for the rate constants of the reactions studied here. At least in the reaction of $O(^3P)$ with 2-propanone, perhaps the most convincing evidence of this is the excellent agreement between our results and those in the literature (2) as shown in Fig. 2. The data falling on that Arrhenius plot cover an overall range of $[CH_3C{:}OCH_3]/[O]_0$ of from 0.015 to 1500, suggesting that both this work and the earlier measurements have adequately eliminated the effects of secondary reactions. There are no data in the literature for the temperature dependence of the reactions of $O(^3P)$ with 2-butanone and 3-pentanone. However, the linear free energy correlation of Gaffney and Levine (10) may be combined with measurements of the rate constants for the reactions of OH with these ketones (11, 12) to estimate the rate constants for their reactions with $O(^3P)$ at 298 K. The values calculated in this way are indicated in Fig. 2 and are in good agreement with our experimental values.

The Arrhenius parameters for the reactions studied are summarized in Table 2. The activation energies are comparable to those found for the reactions of $O(^3P)$ with alcohols (1)

TABLE 3. Summary of data for Taft correlations[a]

Reaction	k_{298} (M^{-1} s^{-1})	σ*	E_s	Reference
O + 2-propanone	4.04×10^5	0.49	1.24	2

OH + 3-hexanone	4.19×10^9	−0.10	−0.07	12

[a]In all cases the reference compound is the one for which σ* = E_s = 0.00 by definition.

[b]For the series of ketones CH_3C:OR, the reference compound is by convention the one for which R = C_2H_5 since both sides of the carbonyl must be bound to carbon to yield a ketone. Similarly, for the series of ketones C_2H_5C:OR, the reference compound is the one for which R = C_2H_5. Thus, 2-butanone is both the reference compound for the series CH_3C:OR and the compound for which R = H in the series C_2H_5C:OR.

and show the expected trend to smaller values with increasing accumulation of secondary α-CH bonds. The preexponential factors show a systematic variation approximately in proportion to the number of α-CH bonds. This is similar to the behaviour observed in the reactions of O(^3P) with alcohols in which the first step is hydrogen abstraction, mainly from the α-CH, and is consistent with a similar initial step in the reactions of O(^3P) with ketones.

The preexponential factors for the reactions of O(^3P) with ketones measured here are some 5–10 times smaller than those for the reactions of O(^3P) with alcohols. They are also an order of magnitude or more smaller than the preexponential factors for the reactions of O(^3P) with alkanes. This kind of behaviour has been observed consistently in the reactions of O(^3P) with organic compounds containing oxygen (e.g. refs. 1–7). It has been postulated that because of the electrophilic nature of the oxygen atom, attack tends to occur preferentially at electron-rich centers such as the OH group in alcohols and the double bonds in ketones and olefins (2). The resulting complex in reactions of O(^3P) with olefins can yield stabilized products such as epoxides. However, such stabilized products are not possible in the reactions of O(^3P) with alcohols and ketones and, at the pressures encountered in experiments in a discharge flow system, these addition complexes simply dissociate again to starting material. Such an explanation would predict that the preexponential factors become smaller with increasing availability of electron density in functional groups such as —OH and >C=O at which O(^3P) is unable to react. This is consistent with the observed decrease in preexponential factor from reactions of O(^3P) with alcohols to the reactions of O(^3P) with ketones.

The transmission of polar effects from the alkyl group on one side of the carbonyl to the one on the other side may be estimated by comparing the rate constants at 300 K for the reactions of O(^3P) with the three ketones studied here. In the reaction of O(^3P) with 2-butanone there are two kinds of α-CH bonds and one kind of β-CH bond so that the composite rate constant for abstraction is

$$[7] \quad k_{C_4H_8O} = k_{CH_3} + k_{C_2H_5}$$

Here k_{CH_3} is the rate constant for abstraction of hydrogen from the CH_3 group bound to the carbonyl and $k_{C_2H_5}$ is the composite rate constant for abstraction from the C_2H_5 group on the other side of the carbonyl. Similarly, the rate constant for reaction of O(^3P) with 3-pentanone can be written

$$[8] \quad k_{C_5H_{10}O} = 2k_{C_2H_5}$$

On the assumption that $k_{C_2H_5}$ is approximately the same for 2-butanone and 3-pentanone, the value of k_{CH_3} at 300 K in 2-butanone is $3 \times 10^6 M^{-1}$ s^{-1}. This is significantly larger than the value of k_{CH_3} ($2.7 \times 10^5 M^{-1}$ s^{-1}) calculated from the rate constant for the reaction of O(^3P) with 2-propanone at 300 K. In fact, operation of polar effects would tend to make the value of $k_{C_2H_5}$ estimated from the reaction of O(^3P) with 3-pentanone larger than the value appropriate to 2-butanone. This suggests that the estimate of $3 \times 10^6 M^{-1}$ s^{-1} for k_{CH_3} in 2-butanone might best be regarded as a lower limit. The estimate of k_{CH_3} in 2-butanone is subject to a probable uncertainty of as much as 70% since it is calculated as the difference between two rate constants of comparable magnitude. The qualitative indication is, however, that extension of the alkyl group in 2-propanone from CH_3 to C_2H_5 increases the reactivity of the remaining CH_3 group.

It is instructive to use the Taft relation (13) to compare the sensitivity to polar effects of the reactions of O(^3P) with ketones. The relevant data are summarized in Table 3. The correlations are less satisfactory than those in the recent analysis of the reactions of O(^3P) with alcohols (1) for two reasons. First, there are too few data for the reactions of O(^3P) with ketones to provide a good correlation. However, comparison of the limited data available provides an estimate of −2 for the value of ρ* for the reactions of O(^3P) with CH_3C:OR and −0.2 for the value of ρ* for the reactions of O(^3P) with C_2H_5C:OR. While there are more data for the reactions of OH with ketones, the Taft correlation suffers from the lack of accurate kinetic data for the reaction of OH with 2-propanone, restricting the analysis to a rather narrow range of values of the substituent parameter. The kinetic data for the reactions of OH with ketones of the type C_2H_5C:OR are also badly scattered, preventing estimation of an accurate value of the reaction parameter, ρ*, for this series of ketones. Nevertheless, a value of −4 may be estimated for ρ* for the reactions of OH with the series of ketones CH_3C:OR and a value of about −0.5 may be estimated for the reactions of OH with the series of ketones C_2H_5C:OR. This indicates a close

parallel between the sensitivities toward polar effects exhibited by the reactions of ketones with OH and with $O(^3P)$. A similar, although less dramatic, dependence of ρ^* on general reactivity was observed in the Taft analysis of reactions of $O(^3P)$ and OH with a wide range of substrates (1). The effect is also consistent with the observation that ρ^* should become less negative as reactivity increases (14).

High-field ^{2}Hmr spectrometry of deuteriated 1,3,3-trimethylbicyclo[2.2.1]heptan-2-ones. Determination of geminal deuterium isotope effects on deuterium chemical shift

NICK HENRY WERSTIUK, GEORGE TIMMINS, AND BRIAN SAYER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received January 24, 1986

NICK HENRY WERSTIUK, GEORGE TIMMINS, and BRIAN SAYER. Can. J. Chem. **64**, 1465 (1986).

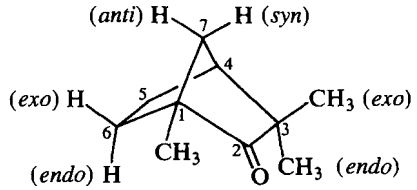
By a high-field ^{2}Hmr study of deuteriated 1,3,3-trimethylbicyclo[2.2.1]heptan-2-ones (fenchones), we have established that the geminal deuterium isotope effects on the *exo*-6-, *endo*-6-, and methyl deuterons are 1.46 ± 0.06 Hz (0.019 ppm), 1.61 ± 0.06 Hz (0.021 ppm), and 1.46 ± 0.06 Hz (0.019 ppm), respectively. From this study it is clear that high-field ^{2}Hmr has the potential of providing directly all the information on the degree of deuterium substitution at carbon previously obtained indirectly by ^{13}Cmr, while retaining the ability to identify chemically nonequivalent deuterons.

NICK HENRY WERSTIUK, GEORGE TIMMINS et BRIAN SAYER. Can. J. Chem. **64**, 1465 (1986).

En appliquant la technique de la rmn du ^{2}H à haut champ à des triméthyl-1,3,3 bicyclo[2.2.1]heptanones-2 (fenchones), on a établi que les effets isotopiques geminaux du deutérium des deutérons *exo*-6, *endo*-6 ainsi que ceux des groupements méthyles sont respectivement 1,46 ± 0,06 Hz (0,019 ppm), 1,61 ± 0,06 Hz (0,021 ppm) et 1,46 ± 0,06 Hz (0,019 ppm). Sur la base de cette étude, il est clair que la rmn du ^{2}H à haut champ possède le potentiel de fournir directement toutes les informations relatives au degré de substitution par des deutérium (jusqu'à maintenant on ne pouvait obtenir cette information qu'indirectement en se basant sur la rmn du ^{13}C) tout en gardant la possibilité d'identifier les deutérons qui ne sont pas équivalents du point de vue chimique.

[Traduit par la revue]

Although many cases of deuterium isotope effects on ^{1}H and ^{13}C chemical shifts have been documented (1), there is a paucity of examples of deuterium isotope effects on deuterium chemical shift, basically because the dispersion of the signals is narrow. By using a high-field spectrometer and resolution enhancement, this problem has been obviated. In this communication, we report on a ^{2}Hmr study at 76.78 MHz of deuteriated 1,3,3-trimethylbicyclo[2.2.1]heptan-2-ones (fenchones (**1**)). We document the first examples of geminal deuterium isotope effects on deuterium chemical shift and establish, because the effects are additive, that this direct method has potential of providing all the information on the degree of substitution at carbon previously obtained indirectly by ^{13}Cmr (1–3) while retaining the ability to identify chemically nonequivalent deuterons. This method should prove to be useful not only for monitoring ^{1}H–^{2}H (H–D) exchange but for determining isotopic enrichment in biosynthetic studies as well.



1

The fenchones used in this study were obtained by homoenolization of the ketone in deuteriated medium (Table 1). The ^{2}Hmr spectra[1] of the fenchones, obtained at identical concentrations (0.040 g/mL in CCl_4) at 30°C, are given in Fig. 1. Spectra A, B, D, and E were obtained by using resolution enhancement. Spectrum C is the original spectrum obtained under standard conditions corresponding to D.

TABLE 1. Preparation of deuteriated fenchones

Entry	Conditions	Deuterium incorporation
1	$(CH_3)_3COD/(CH_3)_3COK^a$ 187°C/40 h	1.00
2	$(CH_3)_3COD/(CH_3)_3COK^a$ 197°C/50 h	1.30
3	$(CH_3)_3COD/(CH_3)_3COK^b$ 220°C/304 h	1.52
4	$(CD_3)_3COD/(CD_3)_3COK^c$ 220°C/304 h	3.75

[a]Fenchone (0.100 g) was reacted in a base solution prepared by dissolving potassium (0.100 g) in $(CH_3)_3COD$ (2.0 mL).
[b]Fenchone (0.255 g) was reacted in a base solution prepared by dissolving potassium (0.255 g) in $(CH_3)_3COD$ (5.0 mL).
[c]Fenchone (0.176 g) was reacted in a base solution prepared by dissolving potassium (0.207 g) in $(CD_3)_3COD$ (4.0 mL).

Signals at δ 1.491 and 1.359 of A, the spectrum of fenchone-$d_{1.00}$ (entry 1), show that, as expected (2), *exo*-6-H undergoes exchange faster than *endo*-6-H. The signals at lower frequency flanking these signals are due to fenchone with two deuterons at C-6 and the isotope shifts for *exo*-3 and *endo*-D are +0.019 ppm (1.46 ± 0.06 Hz) and +0.021 ppm (1.61 ± 0.06 Hz), respectively.

Spectrum B is the resolution-enhanced spectrum of fenchone-$d_{1.30}$ (entry 2). In this case, there is 43% of species with two deuterons at C-6, 7% of species that have a single deuteron (δ 0.997) in the *exo*-3 methyl, and ~1% of species labelled at the bridgehead methyl (δ 1.092). That the weak signal at δ 0.978 is due to species with two deuterons in the *exo* methyl rather than the *endo*-3 methyl deuteriated species is established by the fact that the chemical shift difference is ~0.019 ppm. This conclusion is supported by the fact that the difference in

[1]Deuterium magnetic resonance spectra were obtained at 76.78 MHz on a Brüker AM 500 spectrometer operating at 11.75 *T* with broadband proton decoupling. Four hundred transients were acquired in each case using a 45° pulse with an acquisition time of 4.1 s. Initially, memory size was 16K; this was zero-filled to 64K giving a digital resolution of 0.06 Hz/point. Resolution enhancement was achieved with the "Gaussian multiplication" feature available with Brücker software.

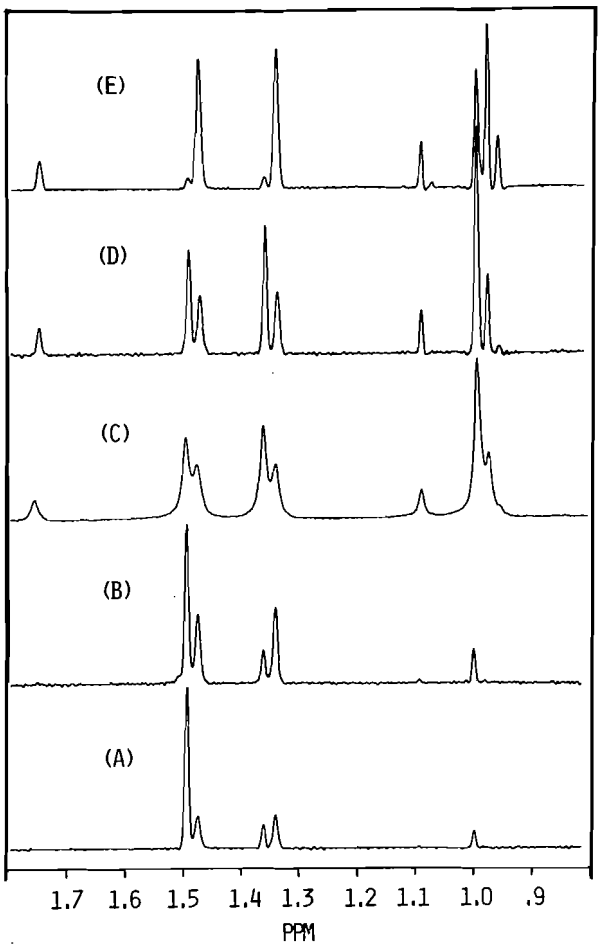


FIG. 1. (A) Resolution-enhanced ^{2}Hmr spectrum (76.78 MHz, CCl_4) of fenchone-$d_{1.00}$. (B) Resolution-enhanced ^{2}Hmr spectrum of fenchone-$d_{1.30}$. (C) ^{2}Hmr spectrum of fenchone-$d_{1.52}$. (D) Resolution-enhanced ^{2}Hmr spectrum of fenchone-$d_{1.52}$. (E) Resolution-enhanced spectrum of fenchone-$d_{3.75}$.

chemical shift between the *exo* and *endo* methyls is only 0.005 ppm as established from the 500-MHz ^{1}Hmr spectrum. In this case, the *exo*-D and *endo*-D shifts also are +0.019 ppm (1.46 ± 0.05 Hz) and +0.021 ppm (1.61 ± 0.06 Hz), respectively.

Spectrum D of fenchone-$d_{1.52}$ (entry 3) shows, as established previously, that the 6-position is equilibrated with the deuterium pool, which is gradually diluted as $(CH_3)_3COD$ is converted to isobutene (4). That is, the intensities of the peaks due to *exo*-6-D, *endo*-6-D, and the 6-d_2 species are roughly equal. The intensity of the peak due to *exo*-6-D is slightly lower than the intensity of the peak due to *endo*-6-D and slightly lower than the sum of the peaks due to the 6-d_2 species. This is so because exchange at the *exo*-6 position is faster than exchange at the *endo*-6 position and thereby more rapidly reflects the dilution of the deuterium pool. The *exo*-D and *endo*-D shifts are the same as the shifts in the previous two cases. The signals of δ 0.997, 0.978, and 0.959, with identical separations of 0.019 ppm, of relative intensity 100, 35, and 4 are due to the *exo*-3 methyl containing one, two and three deuterons, respectively. Close examination of the peak at δ 0.997 indicates that there is a perceptible shoulder on its low frequency side (Δδ 0.01), more pronounced in E, that must be due to deuterium in the *endo* methyl. The signal at δ 1.748 is due to deuterium at the *syn*-7 position (4, 5). By comparison, spectrum C, corresponding to D, obtained under standard conditions clearly shows doubly and triply labelled species as shoulders. It is important to note that in each resolution-enhanced spectrum, the intensities of the signals due to the *exo*- and *endo*-deuterons of the C-6 dideuteriated species are roughly within 90% of each other. This indicates that resolution enhancement does not seriously distort the intensities as the natural line widths of the deuterium resonances are similar. Caution should be exercised when applying this method to resonances of very different line widths.[2]

Spectrum E of fenchone-$d_{3.75}$ (entry 4) shows conclusively that the ketone is essentially fully deuteriated at C-6. The *exo*-D and *endo*-D shifts are identical to the shifts determined in the first three cases. The weak signal on the low frequency side of the peak at δ 1.092 indicates that a small amount of the fenchone is doubly labelled at the bridgehead methyl. The signals at δ 0.997, 0.978, and 0.959 indicate that the *exo*-3 methyl is 36% singly labelled, 48% doubly labelled, and 16% triply labelled. The shoulder on the peak at δ 0.997 due to deuteriated *endo*-3 methyl is more pronounced than it is in D (*vide supra*). The isotope shift of a deuteron of a methyl group by a deuteron is 0.019 ppm and for two deuterons it is 0.038 ppm (2.92 ± 0.06 Hz). On the other hand, from four determinations of the isotope shifts at C-6, it appears that the shift of *exo*-D (1.46 ± 0.06 Hz) is slightly less than the shift (1.62 ± 0.06 Hz) of *endo*-D.

À l'aide de calculs quantiques associés aux données de la spectroscopie photoélectronique ultraviolette (spu), nous montrons que la régiosélectivité des cycloadditions du pyridyl-2 isothiocyanate et de divers dipoles 1–3 est gouvernée par les orbitales frontières. Les différentes cycloadditions (4 + 2, 2 + 3, 2 + 2) dépendent en effet du recouvrement de ces orbitales, ce qui met en relief l'importance des interactions secondaires, c'est-à-dire de la localisation des orbitales sur les atomes adjacents aux liaisons qui se forment au cours de l'addition.

C. GUIMON, G. PFISTER-GUILLOUZO, D. ILAVSKY, M. MARCHALIN, and A. MARTVON. Can. J. Chem. **64**, 1467 (1986).

On the basis of molecular orbital calculations made in association with ultraviolet photoelectron spectroscopy (ups), it is demonstrated that the regioselectivity of the cycloadditions of pyridyl-2-isothiocyanate with 1,3-dipoles is directed by frontier orbitals. The different cycloadditions (4 + 2, 2 + 3, 2 + 2) vary with the overlap of these orbitals and this shows the importance of secondary interactions, namely the localization of the orbitals on the atoms adjacent to the bonds that are formed during the addition.

[Traduit par la revue]

La réactivité du groupement isothiocyanate vis-à-vis de dipoles 1–3 ou de systèmes éthyléniques a été largement étudiée. Cependant, si les réactions de cycloaddition concernant des alkyl ou des aryl isothiocyanates sont relativement bien connues, celles de ce groupement lié à des hétérocycles n'ont fait l'objet que de peu de travaux.

Nous présentons ici, dans le but d'interpréter les nombreuses réactions de cycloadditions présentées par ce composé, une analyse de la structure électronique du pyridyl isothiocyanate. Cette analyse prend comme support une technique expérimentale, la spectroscopie photoélectronique à rayonnement ultraviolet (spu) (He I, He II) associée aux méthodes quantiques, MNDO (avec minimisation de l'énergie par rapport aux paramètres géométriques) et EHT (Extended Hückel Theory).

Nous nous sommes placés dans l'hypothèse de réactions concertées et gouvernées par les orbitales frontières (HOMO : orbitale occupée la plus haute, LUMO : orbitale vacante la plus basse).

Partie expérimentale et théorique

Les spectres photoélectroniques (He I, He II) ont été enregistrés sur un appareil PS 18 Perkin Elmer et sur un spectromètre modèle 0078 des PhotoElectron Spectrometer Laboratories Ltd. La résolution des bandes est en moyenne de 25 meV pour les spectres enregistrés avec la radiation He I (21,21 eV). L'étalonnage a été effectué dans tous les cas par rapport aux pics $^2P_{1/2}$ et $^2P_{3/2}$ du xénon (12,13 et 13,43 eV) et de l'argon (15,76 et 15,94 eV).

Les potentiels d'ionisation ont été calculés dans le cadre de l'approximation de Koopmans (1) à l'aide de la méthode MNDO (2) après une minimisation complète de l'énergie totale par rapport aux paramètres géométriques, ceci pour l'isothiocyanate, le pyridyl-2 isothiocyanate et tous les réactifs envisagés. Dans le cas des pyridyl-3 et -4 isothiocyanates nous avons utilisé les géométries minimisées du fragment isothiocyanate et du cycle pyridinique (3).

I. Structure électronique des pyridyl-isothiocyanates

La structure électronique des divers pyridyl-isothiocyanates peut être facilement déduite de la structure électronique déjà bien connue de la pyridine et de l'isothiocyanate lui-même. Les orbitales moléculaires occupées les plus hautes sont en effet des combinaisons linéaires des orbitales localisées sur les deux fragments, combinaisons pondérées par le recouvrement et l'écart énergétique de ces orbitales. Nous avons schématisé les interactions entre les orbitales localisées sur les fragments dans la figure 1, en se référant aux valeurs expérimentales des potentiels d'ionisation déterminées par spectroscopie photoélectronique (tableau 1).

Les deux orbitales occupées les plus hautes de l'isothiocyanate sont de symétrie π mais orthogonales entre elles (4, 5), l'une (π) se conjuguant avec le système π du cycle, l'autre (π') étant dans le plan σ.

Dans le cas du méthylisothiocyanate, ces deux orbitales sont quasiment dégénérées. En effet, la bande correspondant à l'éjection d'un électron issu de l'orbitale π' apparaît comme un épaulement de la bande associée à l'orbitale π (fig. 2). Du fait de son faible recouvrement avec les orbitales σ du cycle, cette orbitale reste pratiquement pure dans les différents pyridyl-isothiocyanates (9,8, 9,6 et 9,8 eV). La localisation prononcée de cette orbitale sur l'atome de soufre est traduite par une baisse d'intensité de la bande correspondante dans les spectres enregistrés avec la radiation He II (figures 3 et 4). Ceci est en accord avec toutes les observations antérieures et les calculs de section efficace de photoionisation qui prévoient dans les spectres He II, une intensité relative plus faible pour les bandes

1. Part XX de « Application of photoelectron spectroscopy to molecular properties ». Part XIX : réf. 30.

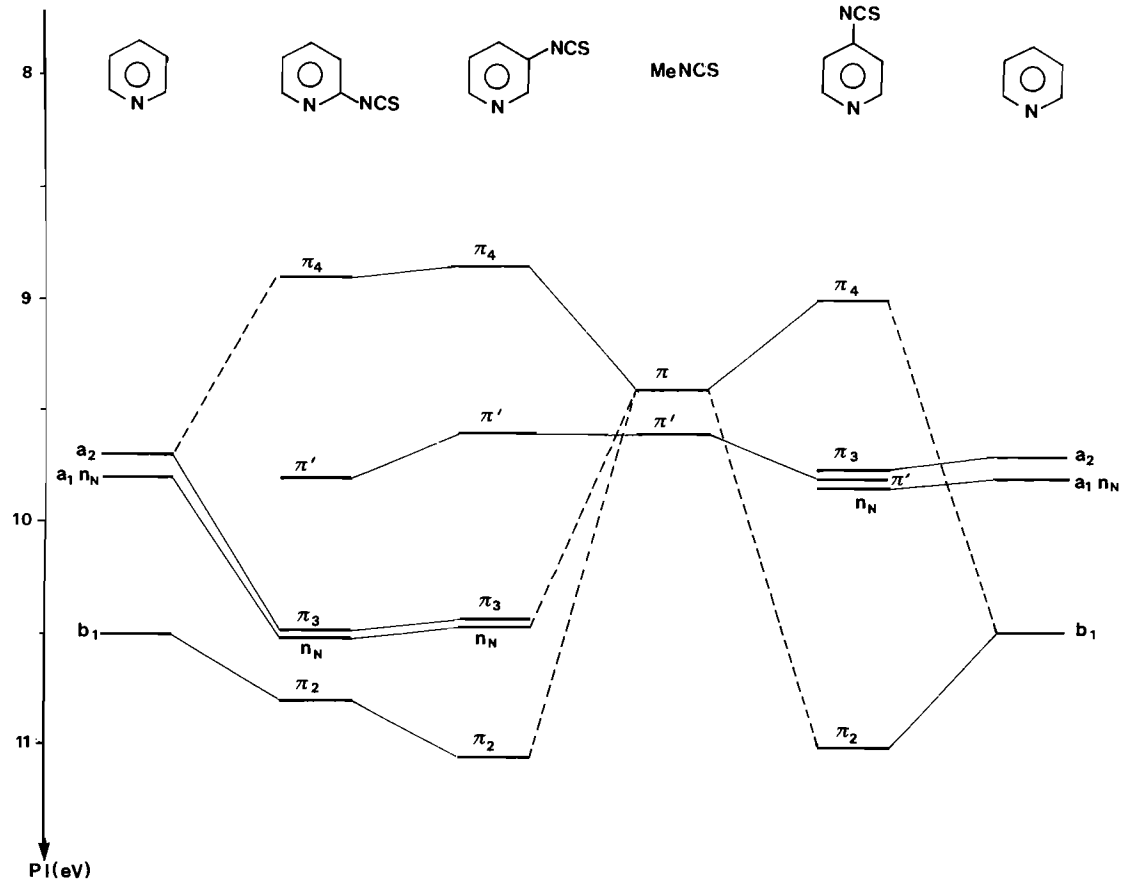

FIG. 1. Diagramme d'interaction entre les orbitales occupées les plus hautes de la pyridine et du groupement isothiocyanate.

associées aux orbitales localisées sur les atomes de la 3ème période (S) par rapport à celles résultant de l'éjection d'un électron plus localisé sur des atomes de la 2ème période (C, N, O) (6–10).

L'orbitale π localisée en grande partie également sur l'atome de soufre mais aussi sur l'atome d'azote (fig. 6) présente un recouvrement important avec les deux orbitales π_{b_1} et π_{a_2} de la pyridine (11, 12). Lorsque le groupement isothiocyanate est placé en position *ortho* ou *méta*, l'interaction de ces orbitales donne trois combinaisons π_2, π_3 et π_4 (fig. 1). Du fait de leur position énergétique, les orbitales π_{b_1}, π_{a_2} et π interviendront de façon majoritaire respectivement dans les combinaisons π_2, π_3 et π_4. Cette dernière est d'ailleurs associée à une bande diminuant d'intensité dans les spectres He II (figures 3, 4 et 5). La stabilisation plus prononcée de l'orbitale π_2 dans le pyridyl-3 isothiocyanate vient d'une localisation supérieure de l'orbitale π_{b_1} de la pyridine sur le sommet 3 (*méta*) par rapport au sommet 2 (*ortho*). Nous remarquons pour ces deux composés, une stabilisation conséquente (0,6 eV) de l'orbitale non liante n_N de la pyridine due selon toute vraisemblance à un effet inductif du groupement isothiocyanate.

Dans le cas du pyridyl-4 isothiocyanate, l'orbitale π interagit seulement avec l'orbitale π_{b_1} (l'orbitale π_{a_1} présentant un noeud sur le sommet *para*) pour donner les combinaisons π_2 et π_4. Les trois autres orbitales (π', n_N et π_{a_2}) restent donc pratiquement pures et se trouvent accidentellement dégénérées (figures 1 et 5).

Les calculs MNDO effectués dans le cadre de l'approximation de Koopmans (PI $\sim -\epsilon_i$) reflètent assez bien cette analyse qualitative et expérimentale, du moins au niveau des orbitales

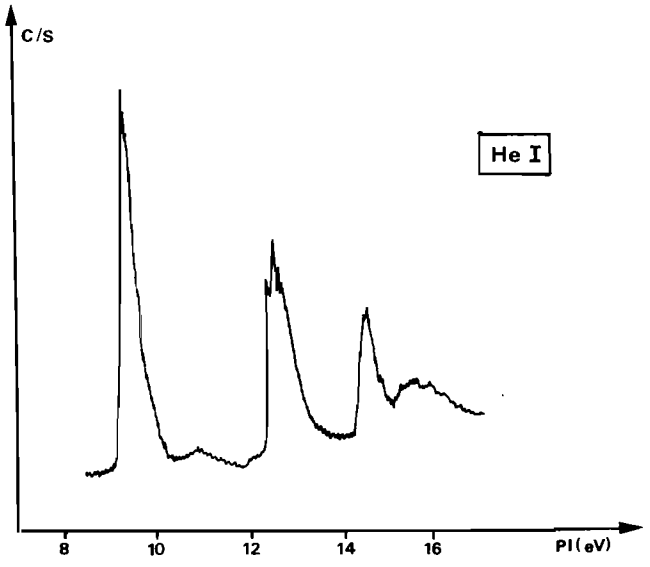

FIG. 2. Spectre photoélectronique (He I) du méthylisothiocyanate.

de type π. En effet la séquence de ces orbitales est bien respectée et les valeurs des potentiels d'ionisation sont reproduites avec un décalage maximum de 0,8 eV, ce qui est un résultat satisfaisant pour une méthode semi-empirique qui ne prend en compte ni les effets de corrélation, ni la réorganisation des ions. Comme pour toutes les autres méthodes cependant, elle a tendance à surestimer d'environ 1 eV les potentiels d'ionisation associés à la paire libre de l'azote pyridinique. Ceci

est dû aux effets de polarisation plus importants dans le cas de l'éjection d'un électron très localisé et qui ne sont pas pris en compte dans l'approximation de Koopmans.

II. Réactivité du pyridyl-2 isothiocyanate

Comme nous le soulignons dans l'introduction, le pyridyl-2 isothiocyanate présente une réactivité très intéressante, que ce soit avec les composés dipolaires 1–3, tel que l'acide hydrazoïque ou le diazométhane ou avec différentes molécules comportant une liaison C=N (imines, isocyanates, isothiocyanates, carbodiimides, hydrazones). Toutes ces réactions conduisent à l'obtention d'hétérocycles à 4, 5 ou 6 chaînons selon le type de cycloaddition (2 + 2, 2 + 3 ou 4 + 2).

De nombreux travaux ont mis en évidence le rôle prépondérant des interactions entre les orbitales frontières HOMO (orbitales occupées les plus hautes) et LUMO (orbitales vacantes les plus basses) des différents réactifs dans la plupart des cycloadditions (13–17). En effet, lors de l'approche des

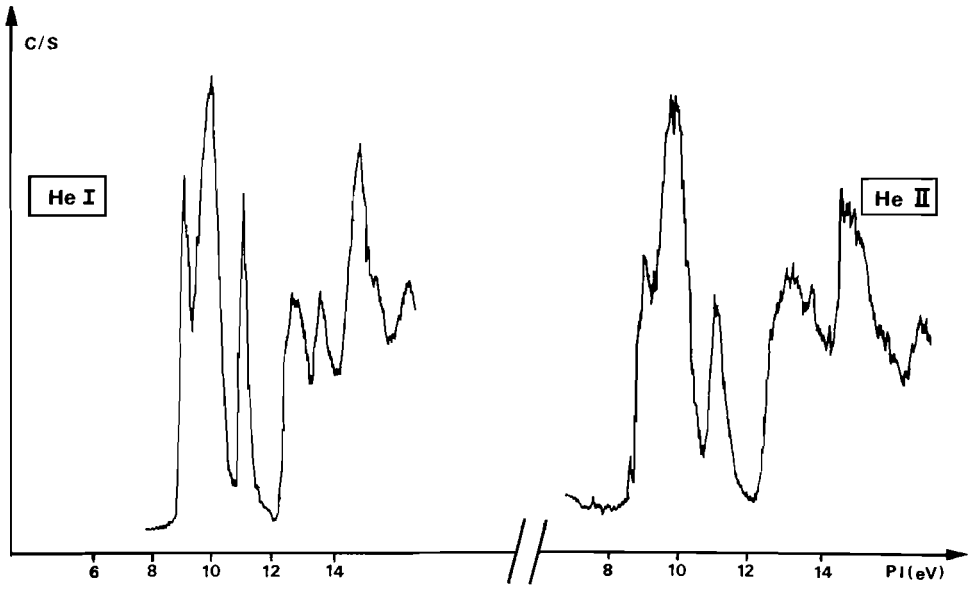

FIG. 5. Spectre photoélectronique (He I, He II) du pyridyl-4 isothiocyanate.

deux réactifs, les orbitales virtuelles les plus basses de chacun d'eux interagissent avec les orbitales occupées les plus hautes de l'autre réactif ce qui conduit à une stabilisation de l'énergie du supersystème. Cette stabilisation est proportionnelle au recouvrement de ces orbitales et inversement proportionnelle à leur écart énergétique. Si l'on admet que les interactions coulombiennes peuvent être négligées (ce qui est généralement le cas pour des réactions concertées), la théorie des perturbations du second ordre permet d'estimer cette énergie de stabilisation.

Dans la plupart des cas, la presque totalité de cette énergie vient de l'interaction de la plus haute orbitale occupée de type π de chaque réactif avec la plus basse vacante π de l'autre réactif, car les autres orbitales de même type sont, ou beaucoup plus stables (pour les occupées) ou beaucoup moins stables (pour les virtuelles), ce qui augmente la valeur du dénominateur et rend donc négligeable le terme correspondant. La régiosélectivité des cycloadditions suit souvent l'ordre donné par l'interaction principale qui correspond à la seule prise en considération des atomes (1 et 2 de la molécule A et 1′ et 2′ de la molécule B) entre lesquels se forment les liaisons (1–1′ et 2–2′).

Ainsi, l'énergie d'interaction principale $\Delta E'$ dans l'état de transition est donnée par la somme des interactions HOMO (A) – LUMO (B) et HOMO (B) – LUMO (A) (18–21) :

$$\Delta E' = \frac{[(C_{\text{HOMO}\,1}\,C_{\text{LUMO}\,1'} + C_{\text{HOMO}\,2}\,C_{\text{LUMO}\,2'})\beta]^2}{E_{\text{HOMO A}} - E_{\text{LUMO B}} - Q} + \frac{[(C_{\text{HOMO}\,1'}\,C_{\text{LUMO}\,1} + C_{\text{HOMO}\,2'}\,C_{\text{LUMO}\,2})\beta]^2}{E_{\text{HOMO B}} - E_{\text{LUMO A}} - Q}$$

$C_{\text{HOMO}\,1}$ et $C_{\text{LUMO}\,1}$ (ou $C_{\text{HOMO}\,2}$ et $C_{\text{LUMO}\,2}$ ou $C_{\text{HOMO}\,1'}$ et $C_{\text{LUMO}\,1'}$ ou $C_{\text{HOMO}\,2'}$ et $C_{\text{LUMO}\,2'}$) représentent les coefficients des orbitales atomïques P_π sur l'atome 1 (ou 2, ou 1′, ou 2′) dans les orbitales moléculaires frontières occupée (HOMO) et virtuelle (LUMO) respectivement d'énergie $E_{\text{HOMO A}}$ et $E_{\text{LUMO A}}$ (ou $E_{\text{HOMO B}}$ et $E_{\text{LUMO B}}$)·β qui est l'intégrale d'échange entre les orbitales atomiques 1 et 1′ ou 2 et 2′ est proportionnelle à l'intégrale de recouvrement de ces orbitales. Comme nous l'avons fait remarquer précédemment, $\Delta E'$ est donc fonction de la structure de l'état de transition à la fois par

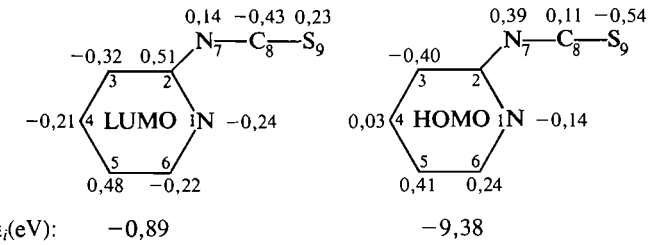

FIG. 6. Valeurs propres et vecteurs propres associés aux orbitales frontières π du pyridyl-2 isothiocyanate calculés par la méthode MNDO (2) avec optimisation de l'énergie totale par rapport à la géométrie moléculaire.

l'intermédiaire de l'intégrale β et par celui du paramètre Q dont la valeur croît lorsque les deux réactifs se rapprochent (21).

Si la prise en compte de cette seule interaction principale suffit à expliquer la régiosélectivité de la cycloaddition de molécules simples, elle est souvent insuffisante pour rendre compte de la réactivité de composés conjugués. Dans ce cas, il faut considérer l'interaction des orbitales frontières dans leur globalité et donc estimer un terme analogue à $\Delta E'$, $\Delta E''$, correspondant à des interactions secondaires et qui tient compte des coefficients des orbitales atomiques sur les autres sommets. Ces interactions secondaires, qui jouent un rôle non négligeable dans le cas d'un recouvrement important de ces orbitales atomiques, sont naturellement fonction de la position respective des réactifs dans l'état de transition. Le terme $\Delta E''$ viendra alors s'ajouter ou se retrancher à $\Delta E'$ selon que le recouvrement sera positif (lobes en phase) ou négatif (lobes en opposition de phase).

Les composés réagissant avec le groupement isothiocyanate sont de deux types, d'une part les imines, d'autre part, les dipoles 1–3. Nous présentons dans les figures 6 et 7 l'énergie et la localisation des orbitales frontières (HOMO et LUMO) de tous les réactifs étudiés, calculées par la méthode MNDO après minimisation de l'énergie totale par rapport à tous les paramètres géométriques. On peut immédiatement remarquer qu'au niveau des sommets entre lesquels s'établissent les liaisons, la forme générale des orbitales frontières est pratiquement iden-

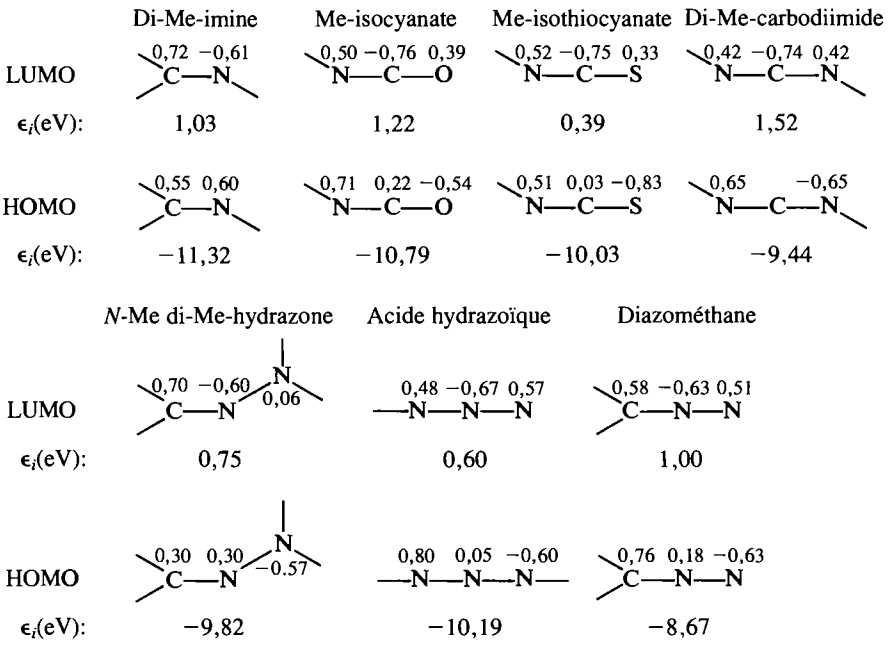

FIG. 7. Valeurs propres et vecteurs propres associés aux orbitales frontières π de différents réactifs impliqués dans la cycloaddition du pyridyl-2 isothiocyanate. Ces valeurs ont été calculées par la méthode MNDO (22) avec optimisation de l'énergie totale par rapport à tous les paramètres géométriques.

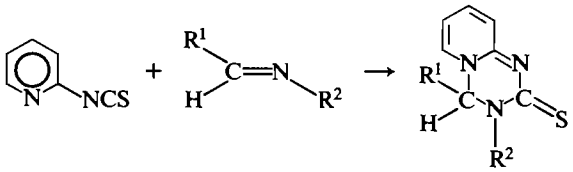
tique pour tous ces composés. Les différences de régiosélectivité relevées dans la littérature ne peuvent donc provenir seulement des interactions principales, mais doivent être liées à l'existence de certaines interactions secondaires. Dans la discussion ci-dessous, nous allons tenter d'analyser l'importance relative de ces deux types d'interactions dans les diverses cycloadditions. Celles-ci peuvent être de trois types, 4 + 2, 2 + 3 et 2 + 2, suivant que les sommets réagissant sont, pour le pyridyl-isothiocyanate, l'atome d'azote intracyclique et l'atome de carbone extracyclique (4 + 2) ou deux atomes contigus du groupement NCS (2 + 3 et 2 + 2) et pour les autres réactifs deux atomes voisins (4 + 2 et 2 + 2) ou deux atomes en position 1–3 (2 + 3).

N-*Éthylydene-methylamine*

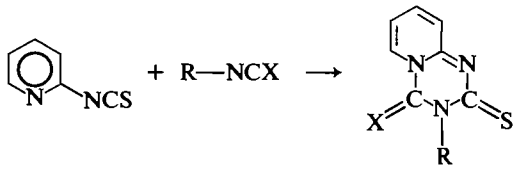
R^1 et R^2 étant des groupements alkyls, la régiosélectivité de cette réaction doit suivre les interactions principales, les interactions secondaires étant pratiquement inexistantes. La cycloaddition 2 + 2 doit être défavorisée de part le faible



recouvrement entre la LUMO du pyridyl-isothiocyanate et l'HOMO de l'imine, la première présentant des lobes en opposition de phase sur les sommets contigus de NCS, la seconde étant en phase sur C—N. Seule est donc envisageable une addition 4 + 2 (les sommets attaqués par l'imine étant le carbone C_8 et l'azote N_1) qui fait intervenir des sommets présentant des lobes en phase entre les LUMO et les HOMO. La régiosélectivité dépend du recouvrement des orbitales frontières dans l'état de transition. Celui-ci sera d'autant plus important que les liaisons se formeront entre les sommets ayant la localisation de ces orbitales la plus élevée, c'est-à-dire, entre l'atome de carbone de l'imine et l'atome d'azote de la pyridine d'une part et l'atome d'azote de l'imine et l'atome de carbone du groupement NCS d'autre part. C'est bien ce qui a été observé expérimentalement (22).

Isocyanates et isothiocyanates

Comme dans le cas précédent, quel que soit l'hétéroatome X (oxygène ou soufre), le type de la cycloaddition observé est 4 + 2 (22). C'est également vrai lorsque R est un noyau pyridinique, c'est-à-dire, lorsque la cycloaddition correspond à une dimérisation (23, 24). Cette dernière s'effectue très facilement pour donner un dimère très stable thermodynamiquement.



Si l'on ne tient compte que des interactions principales (fig. 6), deux types de cycloadditions sont possibles, à savoir 4 + 2 et 2 + 2. Dans ce dernier cas, les atomes de carbone et de soufre du groupement fonctionnel s'accrochent respectivement aux atomes de soufre et de carbone de l'autre groupement. Seuls en effet ces atomes présentent au niveau des orbitales frontières des lobes en phase ce qui augmente le recouvrement entre les LUMO et les HOMO et favorise les interactions stabilisantes. Il apparaît toutefois que la cycloaddition 4 + 2 est favorisée par les interactions secondaires stabilisantes, celles-ci n'existant pas lors de l'approche du type 2 + 2.

Nous avons visualisé ces interactions dans la figure 8. Elles sont particulièrement importantes entre l'HOMO du pyridyl-2 isothiocyanate et la LUMO de R—NSX au niveau des deux atomes d'azote extracycliques et surtout au niveau de l'atome de soufre (dans l'HOMO) et du carbone C_3 du cycle pyridinique (dans la LUMO) du fait de la localisation importante sur ces atomes des orbitales correspondantes (fig. 6).

De façon à apprécier l'importance de ces interactions, nous avons effectué un calcul EHT (25) sur la supermolécule dans

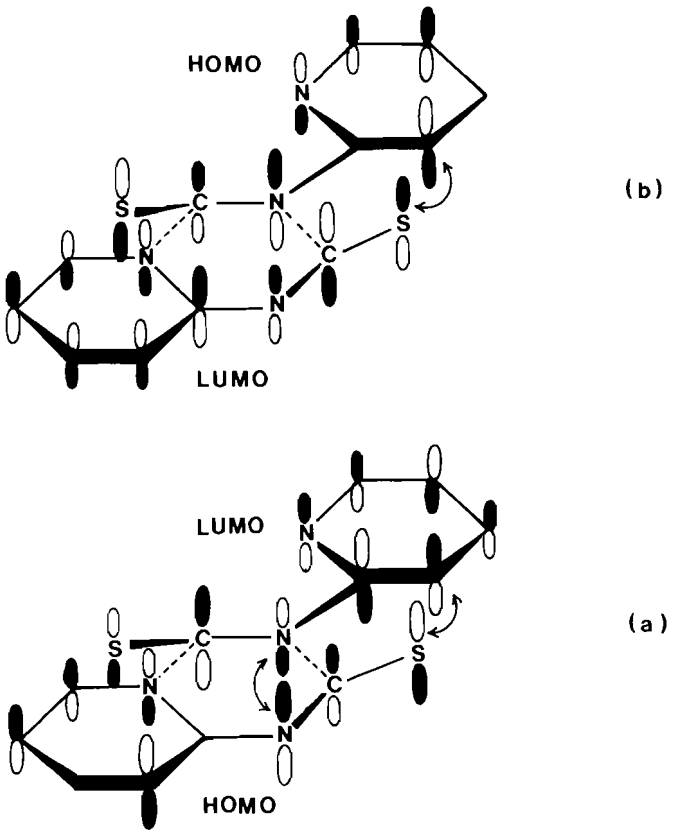


FIG. 8. Interactions primaires (...) et secondaires (↔) stabilisantes lors de la dimérisation du pyridyl-2 isothiocyanate.

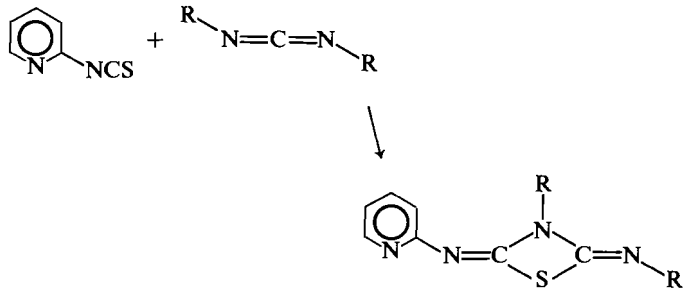
son état de transition supposé, c'est-à-dire les deux molécules étant dans des plans parallèles distants de 2,25 Å l'un de l'autre (fig. 8). D'après diverses études théoriques (26), on peut en effet considérer que cette structure représente approximativement l'état de transition de l'addition dans l'hypothèse d'une réaction concertée. Il semble probable que pour un système donné, la distance entre les plans moléculaires est pratiquement constante lors les différentes approches. Il s'en suit que le terme Q de l'équation donnant $\Delta E'$ peut également être considéré comme constant, ce qui rend possible des corrélations entre la régiosélectivité des réactions étudiées et la valeur des recouvrements entre les orbitales des deux réactifs. Ces recouvrements sont tirés d'un calcul FMO (Fragment Molecular Orbitals) (27).[2]

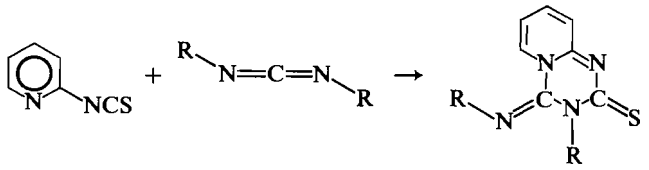
Ainsi, le recouvrement entre l'HOMO d'une pyridyl-2 isothiocyanate et la LUMO de l'autre dans l'approche présentée dans la figure 8 (a) est de 0,1086, tandis que le recouvrement LUMO–HOMO (fig. 8 (b)) est seulement de 0,0104. Cette approche telle qu'elle est schématisée dans la figure 8 semble préférentielle puisque un calcul similaire sur ce système où l'on a fait tourner la molécule supérieure de 180° autour de l'axe C—N exocyclique donne comme recouvrements 0,0898 et 0,0074. Ces recouvrements plus faibles s'expliquent par le décalage des deux cycles, ce qui minimise les interactions secondaires. De plus, l'interaction destabilisante HOMO–HOMO est dans ce cas légèrement supérieure (0,0160 contre 0,0046).

Carbodiimide

Ce composé de symétrie D_{2h} peut en principe, comme les précédents, donner lieu à une cycloaddition 2 + 2 ou 4 + 2. Dans le cas où les groupements substituants R sont des groupements alkyls, les interactions secondaires sont négligeables et seules sont à considérer les interactions principales. Au vu des coefficients reportés dans les figures 6 et 7, il semble que doit être privilégiée l'addition 2 + 2 où les atomes d'azote et de carbone de la diimine se lient respectivement aux atomes de carbone et de soufre du groupement NCS, à cause en particulier de la forte localisation de l'HOMO du pyridyl isothiocyanate sur l'atome de soufre, ce qui renforce l'interaction stabilisante HOMO (NCS) – LUMO (NCN). Cette conclusion est confirmée par diverses études expérimentales (22, 28) :

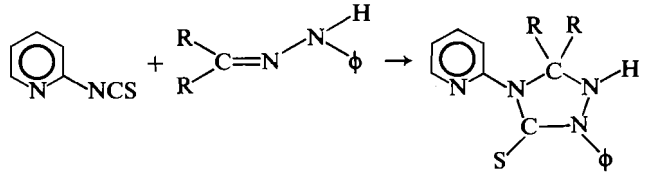


Lorsque R est un groupement conjugué, il faut prendre en compte les interactions secondaires de la même manière que pour l'étude de la dimérisation. Comme dans ce cas donc, l'addition 4 + 2 doit être favorisée grâce en particulier à la proximité de l'atome de soufre et de l'atome de carbone en position *ortho* du groupement aryl (fig. 8). Ce résultat est en accord avec les données expérimentales dont nous disposons (22) :



Hydrazone

Ce composé a la possibilité de s'additionner selon le schéma 4 + 2 mais également selon le schéma 2 + 3 où l'atome d'azote amino se lie à l'atome de carbone de NCS pour donner une triazole-thione après migration de l'atome d'hydrogène de l'azote amino sur l'azote imino :



Si l'on considère la localisation des orbitales frontières au niveau des sommets en compétition (N_1, N_7, C_8 de la pyridine et C, N, N de l'hydrazone) des deux réactifs, il semble que les interactions principales soient plus stabilisantes pour la cycloaddition 2 + 3 que pour la 4 + 2, en particulier au niveau du recouvrement HOMO (NCS) – LUMO (CNN).

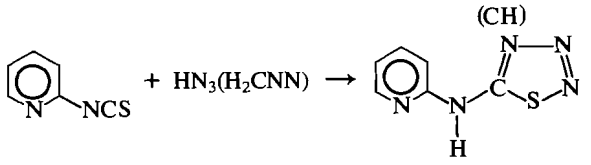
Ceci est bien traduit par le calcul EHT – FMO puisque le

2. Afin d'estimer quantitativement les interactions entre les orbitales ϕ_k localisées sur les différents fragments qui composent une molécule (ou super molécule) donnée, on effectue un calcul EHT sur la molécule complète, ce qui donne les orbitales moléculaires ψ_i sur la base des orbitales atomiques χ_j ($\psi_i = \Sigma_j a_{ij} \chi_j$), puis un calcul identique pour chaque fragment ($\phi_k = \Sigma_j b_{kj} \psi_j$). Un simple produit matriciel donne alors les orbitales moléculaires ψ_i sur la base des orbitales semi-localisées ϕ_k ($\psi_i = \Sigma_k c_{ik} \phi_k$). Il en est de même de la matrice des recouvrements entre les orbitales localisées ϕ_k.

recouvrement de ces deux orbitales est de 0,0094 pour l'addition 2 + 3 et de 0,0021 pour l'addition 4 + 2.[3] De même les recouvrements entre la LUMO (NCS) et l'HOMO (CNN) sont respectivement égaux à 0,0065 (addition 2 + 3) et à 0,0001 (addition 4 + 2). Les résultats concernant la phényl hydrazone (24) font bien état d'une addition 2 + 3 avec le pyridyl-2 isothiocyanate.

Acide hydrazoïque; diazométhane

L'addition de ces deux dipoles 1–3 sur le groupement isothiocyanate donne un thiatriazole ou un thiadiazole après une migration d'un atome d'hydrogène du dipole sur l'azote du groupement NCS (24, 29). À priori deux types d'additions sont



possibles si l'on regarde la forme des orbitales frontières des deux réactifs (figures 6 et 7). D'une part les atomes de carbone et d'azote des extrémités du diazométhane (ou les deux atomes 1 et 3 de l'acide hydrazoïque peuvent se lier respectivement aux atomes de carbone et de soufre du groupement isothiocyanate (résultat expérimental) ou aux atomes de carbone et d'azote de ce groupement. (Cette dernière régiosélectivité semble favorisée par rapport à celle où les deux atomes cités du diazométhane s'accrochent respectivement aux atomes d'azote et de carbone de NCS, ceci grâce à un recouvrement LUMO (NCS) – HOMO (CNN) bien supérieur.)

Ici encore la régiosélectivité de la cycloaddition est bien traduite par les interactions entre les orbitales frontières des deux composés. En effet un calcul EHT–FMO montre que la cycloaddition observée expérimentalement correspond à un recouvrement LUMO (NCS) – HOMO (CNN) dans l'état de transition nettement plus important que pour l'autre approche (0,1164 contre 0,0760).

Conclusion

L'analyse de la structure électronique du pyridyl-2 isothiocyanate nous a permis de rendre compte de manière satisfaisante de la réactivité vis-à-vis de divers dipoles 1–3 et de composés possédant une liaison C=N. La régiosélectivité des cycloadditions semble être gouvernée par les orbitales frontières et plus particulièrement par le recouvrement de celles-ci. Il a toutefois été nécessaire d'inclure dans nos raisonnements qualitatifs à la fois les interactions principales et secondaires, c'est-à-dire de considérer les orbitales dans leur globalité et non, comme il a été souvent proposé, de s'en tenir aux seules interactions principales (correspondant aux sommets entre lesquels se forment les liaisons). On a ainsi pu mettre en évidence l'importance de ces interactions secondaires qui sont souvent à l'origine du type de cycloaddition observé (4 + 2, 2 + 3 ou 2 + 2).

3. Ces recouvrements ont des valeurs plus faibles que ceux calculés pour la dimérisation car nous avons éloigné légèrement les plans moléculaires à cause de la gêne stérique provoquée par les groupements méthyles R de l'hydrazone.

Complexes of hybrid ligands. Comparative studies on two cationic Pt^{2+} complexes of a fluorinated alkoxy-thioether ligand: solid-state structures and evidence for coupled ring-thioether inversion in solution[1]

RENÉ T. BOERÉ, NICHOLAS C. PAYNE, AND CHRISTOPHER J. WILLIS[2]
Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7
Received September 4, 1985[3]

RENÉ T. BOERÉ, NICHOLAS C. PAYNE, and CHRISTOPHER J. WILLIS. Can. J. Chem. **64**, 1474 (1986).

Complete structural determinations are reported for two cationic platinum(II) complexes of the chelating, hybrid, alkoxythioether ligand $CH_3SCH_2O(CF_3)_2O^-$ with phosphine coligands and BF_4^- counterions. Complex **1**, $[Pt(PPh_3)_2\{CH_3SCH_2C(CF_3)_2O\}]BF_4$, $C_{42}H_{37}BCl_2F_{10}OP_2PtS$ (CH_2Cl_2 solvate) is monoclinic, space group $P2_1/c$, with $a = 12.2534(9)$, $b = 18.584(2)$, $c = 19.612(3)$ Å, $\beta = 97.36(1)°$, $V = 4466(1)$ Å^3, $Z = 4$. Complex **2**, $[Pt(PPh_2Me)_2\{CH_3SCH_2C(CF_3)_2O\}]BF_4$, $C_{31}H_{31}BF_{10}OP_2PtS$, is orthorhombic, space group $Pna2_1$, with $a = 23.093(4)$, $b = 11.362(3)$, $c = 12.880(2)$ Å, $V = 3379(2)$ Å^3, $Z = 4$. The structures show the five-membered chelate ring to have similar conformations in the two complexes, the CH_3S and axial CF_3 groups being in an *anti* conformation.

The structural results are discussed in relation to previous nmr studies on these and related complexes. It is concluded that an anisotropic shielding effect on the CH_3S and CF_3 resonances is present in both complexes, but that it is significantly greater in **1**, where PPh_3 is the coligand, and anomalies in the ^{19}F nmr spectra are explained on this basis. A careful consideration of the nmr data, in light of the crystal structures, demonstrates the persistence of preferred chelate ring conformations in solution. Thioether inversion induces ring inversion in these complexes.

RENÉ T. BOERÉ, NICHOLAS C. PAYNE et CHRISTOPHER J. WILLIS. Can. J. Chem. **64**, 1474 (1986).

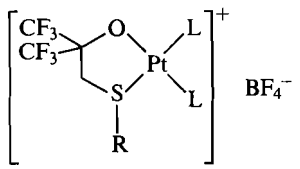
On rapporte les déterminations complètes des structures de deux complexes cationiques du Pt(II) avec du $CH_3SCH_2C(CF_3)_2O^-$ (l'alcoolate d'un thioéther qui est un ligand hydrure, chélatant), des coligands phosphines et des contre-ions BF_4^-. Le complexe **1**, $[Pt(PPh_3)_2\{CH_3SCH_2C(CF_3)_2O\}]BF_4$, $C_{42}H_{37}BCl_2F_{10}OP_2PtS$ (CH_2Cl_2 solvaté), est monoclinique, groupe d'espace $P2_1/c$ avec $a = 12,2534(9)$, $b = 18,584(2)$ et $c = 19,612(3)$ Å, $\beta = 97,36(1)°$, $V = 4466(1)$ Å^3 et $Z = 4$. Le complexe **2**, $[Pt(PPh_2Me)_2\{CH_3SCH_2C(CF_3)_2O\}]BF_4$, $C_{31}H_{31}BF_{10}OP_2PtS$, est orthorhombique, groupe d'espace $Pna2_1$, avec $a = 23,093(4)$, $b = 11,362(3)$, $c = 12,880(2)$ Å, $V = 3379(2)$ Å^3 et $Z = 4$. Les structures comprennent un cycle à cinq chaïnons qui est chélaté de manière a assumer des conformations semblables dans les deux complexes; les groupements CH_2S et CF_3 axial sont dans des conformations *anti*.

On discute des résutats structuraux en relation avec des études rmn qui ont été faites antérieurement sur ces complexes et sur d'atures qui leur sont reliés. On en conclut que l'effet de blindage anisotrope sur les résonances des groupements CH_3S et CF_3 est présent dans les deux complexes: toutefois, il est de beaucoup plus important dans le complexe **1**, dans lequel le PPh_3 est le coligand; on peut expliquer les anomalies du spectres rmn ^{19}F sur cette base. Un examen attentif des données de la rmn, à la lumière des structures cristallines, démontre que les conformations privilégiées du cycle chélate persistent même en solution. Dans ces complexes, l'inversion du thioéther induit une inversion du cycle.

[Traduit par la revue]

Introduction

We have recently reported (1) the preparation and structural characterization by nmr of some cationic Pt^{2+} complexes of the bidentate, anionic, fluoro-alkoxy thioether ligands R—S—CH_2—$C(CF_3)_2$—O^- (R = Me or Ph).[4] The energetics of thioether inversion in complexes **1–7** were investigated by the dynamic nmr method:



R = Me, L = PPh_3 (**1**); L = PPh_2Me (**2**); L = $PPhMe_2$ (**3**); L = PMe_3 (**4**); R = Ph, L = PPh_3 (**5**); L = PPh_2Me (**6**); L = $PPhMe_2$ (7)

In the course of this work, we noted unusual *upfield* coordination chemical shifts for the SCH_3 groups in **1–3**, an effect which has been postulated as due to the aromatic ring anisotropy of a neighbouring phosphine ligand (3, 4). We also noted anomalous effects in the ^{19}F nmr, where the CF_3 groups in compound **1** appeared equivalent at temperatures where all of the other complexes showed the doublet-of-quartets pattern associated with inequivalence.

In order to probe the origin of these two effects, we have determined the solid-state structures of **1** and **2** by single-crystal X-ray crystallography.

The results, reported here, show that both complexes have very similar geometry, and that phenyl rings from the neighbouring phosphines are indeed oriented in such a way as to induce the observed shifts in the ^1H nmr. Consideration of data for the two systematic series of compounds **1–4** and **5–7** shows that the anomalies in the ^{19}F nmr are due to the same effect.

Structure determination

General

The synthesis of the complexes has been described previously (1). Colourless crystals of each compound were grown by slow evaporation from ethanol/dichloromethane solutions; compound **1** crystallized as a dichloromethane solvate.

Compound 2, X-ray data collection and reduction

Preliminary Weissenberg and precession photography showed Laué symmetry and systematic absences consistent with the orthorhombic

space groups *Pnma* (# 62) and *Pna*2$_1$ (# 33) (5). Cell constants suggested four formula units per unit cell, which in *Pnma* requires cations at special positions with either mirror or inversion symmetry, both of which are inconsistent with the assumed cation structure in an ordered crystal. Since there were no signs of disorder, space group *Pna*2$_1$ was chosen. A suitably sized crystal of **2** was cleaved perpendicular to [001] from an elongated prism. Details of crystal parameters, intensity data measurements (6) and data processing (7) are summarized in Table 1. No appreciable crystal decomposition occurred during data collection. Crystal dimensions were measured on an optical microscope, face indices assigned by optical goniometry, and an absorption correction was applied (8). For both structures neutral atom scattering factors were taken from Cromer and Waber (9), with those for hydrogen from Stewart, Davidson, and Simpson (10). Anomalous dispersion contributions were included for Pt, Cl, S, and P atoms (11). The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where the weight w is defined as $4|F_o|/\sigma^2(F_c^2)$, and p values were 0.04 for each structure (12).

Preliminary structure solution and refinement were carried out on a PDP 11/23+ computer (7). The position of the Pt atom and inner coordination sphere were determined by heavy-atom methods. Further solution was hampered by a persistent pseudo mirror-symmetry perpendicular to c, but all the non-hydrogen atoms were eventually located in a series of difference-Fourier syntheses without refinement. Although the CH_2Cl_2 solvent molecule was not disordered, and the carbon and chlorine atoms could be assigned anisotropic thermal parameters, there was significant disorder of the tetrafluoroborate anion, which was finally described by using three rigid groups of varying multiplicities.[5]

In the final stages of the refinement phenyl rings were included as idealized 6-atom rigid groups (C—C = 1.392 Å) with individual isotropic thermal parameters (13). Since *Pna*2$_1$ is an acentric space-group, a preliminary test was performed to determine the hand of the crystal. Inverting the model led to a slight increase in the R factors, and refinement was therefore continued on the original choice of hand.

[5]Computer programs used included local modifications of the following for the CDC Cyber 835 at the University of Western Ontario: WOCLS, full-matrix least-square refinement, from J. A. Ibers' NUCLS; Patterson and Fourier Syntheses, FORDAP, by A. Zalkin: ORFFE, Functions and Errors, by W. R. Busing, K. O. Martin, and H. A. Levy, and ORTEPII, crystal structure illustrations, by C. K. Johnson.

Hydrogen atoms were located in a difference-Fourier synthesis with electron densities ranging from 0.8(3) to 0.3(3) e $Å^{-3}$, and included in subsequent refinements at idealized locations with C—H = 0.95 Å and isotropic temperature factors 110% of that of the attached atom. A further two cycles of refinement with all non-group atoms assigned anisotropic thermal parameters gave $R_1 = 0.034$, $R_2 = 0.044$. The best model for the anion consisted of three tetrahedra of F atoms, with multiplicities of 50, 25, and 25% and the group origins tied to the position of a boron atom assigned an anisotropic thermal parameter. A full description of the different disorder models tried has been deposited.[6] On varying the group orientation angles and individual atom isotropic temperature factors, agreement factors of $R_1 = 0.036$ and $R_2 = 0.045$, with electron density residuals of 0.9(2), 0.9(2), and 0.8(2) e $Å^{-3}$ (top three peaks) were obtained. A final check on the handedness of the crystal was performed at this stage, again showing the inverted model to be inferior. A statistical analysis suggested the presence of secondary extinction, so a correction was applied (14). Two further cycles of least-squares refinement, with appropriate adjustment of the H-atom positions, led to convergence with agreement factors of $R_1 = 0.036$ and $R_2 = 0.045$. The largest parameter shift was 0.215 of its esd, associated with the x-coordinate of the origin of the Ph(4) group. The error in an observation of unit weight was 4.2 electrons. The secondary extinction coefficient refined to $5.9(2) \times 10^{-6}$. A final difference-Fourier map showed a peak of 1.1(2) e $Å^{-3}$ associated with the carbon atoms of one phenyl ring. The largest residual in the vicinity of the anion was only 0.9(2) e $Å^{-3}$. A statistical analysis of R_2 in terms of $|F_o|$, diffractometer setting angles, and $\lambda^{-1} \sin\theta$ showed no unusual trends.

Compound 1, X-ray data collection and reduction

Preliminary Weissenberg and precession photographs showed the space group to be $P2_1/c$. General conditions of data recording (6) and processing (7) were as described for compound **2** and are recorded in Table 1. An analytical absorption correction using the program AGNOST was applied.[7] Preliminary structure solution and refinement were carried out on a PDP 11/23+ computer. The position of the Pt atom was determined from an origin-removed Patterson synthesis, and subsequent difference-Fourier syntheses located all 60 non-hydrogen atoms (7). Two cycles of full-matrix least-squares refinement with the four heaviest atoms assigned anisotropic thermal parameters, and the phenyl rings as idealized groups (13), gave agreement factors $R_1 = 0.60$, $R_2 = 0.065$. Use of absorption-corrected data and the variation of individual temperature factors for the group atoms during two further cycles of refinement gave $R_1 = 0.048$, $R_2 = 0.051$. At this point a Fourier synthesis over the anion region of the unit cell showed only mild disorder, with the electron-density plot dominated by five major peaks consistent with a BF_4^- anion. The anion was therefore refined as individual atoms assigned anisotropic thermal parameters and two further cycles led to $R_1 = 0.044$ and $R_2 = 0.045$. The hydrogen atom positions were located on a total-difference Fourier map, at peak heights ranging from 0.8(3) to 0.3(3) e $Å^{-3}$, and were included in idealized positions as in the refinement of the structure of compound **2**. In the final cycles of refinement, employing 5660 unique data with $F_o \geq 3\sigma(F_o)$, 289 parameters were varied to convergence with $R_1 = 0.041$ and $R_2 = 0.038$. The largest parameter shift was 0.6 of its esd, that of the y-coordinate of $F(10)$. A final difference-Fourier map showed peaks of 1.2(1) e $Å^{-3}$ near the anion, 1.0(1) e $Å^{-3}$ near C(24), and 0.9(1) e $Å^{-3}$ near Cl(2). This suggests that any disorder in the BF_4^- ion is adequately accounted for in the anisotropic model, although the geometry of the model is not that of an ideal tetrahedron.

Final atomic positions and U_{equiv} of non-hydrogen atoms for compounds **1** and **2** are given in Tables 2 and 3, respectively,

TABLE 2. Atomic positional ($\times 10^4$) and thermal ($\times 10^3$) parameters for **1**

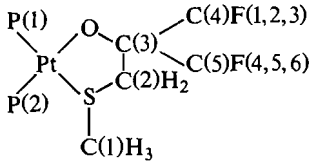
[a]Bond lengths in Å, angles in deg. Estimated standard deviations are given in parentheses and refer to the least significant digit(s).

[b]Observed differences applied to a normal distribution using accepted criteria before averaging (2), estimated standard deviations are the root-mean-square values.

The common atom numbering scheme for the hybrid ligand in both complexes is shown in the line diagram:



In the PPh_3 complex **1**, C(11), C(21), and C(31) are bonded to P(1), and C(41), C(51), and C(61) to P(2). In the PPh_2Me complex **2**, C(6)(Me), C(11)(Ph) and C(21)(Ph) are bonded to P(1), and C(7)(Me), C(31)(Ph), and C(41)(Ph) to P(2). In both cases, F(7), F(8), F(9), and F(10) are bonded to boron in the anion.

Both of the structures are composed of discrete cations and anions. In **1**, the shortest intermolecular contact is 2.33 Å between one of the hydrogen atoms on C(2) and a fluorine atom in the anion. In **2**, one intermolecular H—H contact (2.24 Å) is less than the sum of the covalent radii, and there are also several short contacts between phenyl-ring hydrogens and BF_4^- anions.

The basic geometry of both cations is similar. Coordination around the platinum atom is distorted square-planar in each, with adjacent angles greater than 90° [P(1)—Pt—P(2), S—Pt—P(2)] or less than 90° [P(1)—Pt—O, S—Pt—O]. The large inter-phosphorus angles (97–99°) are consistent with general observations on complexes containing *cis*-coordinated

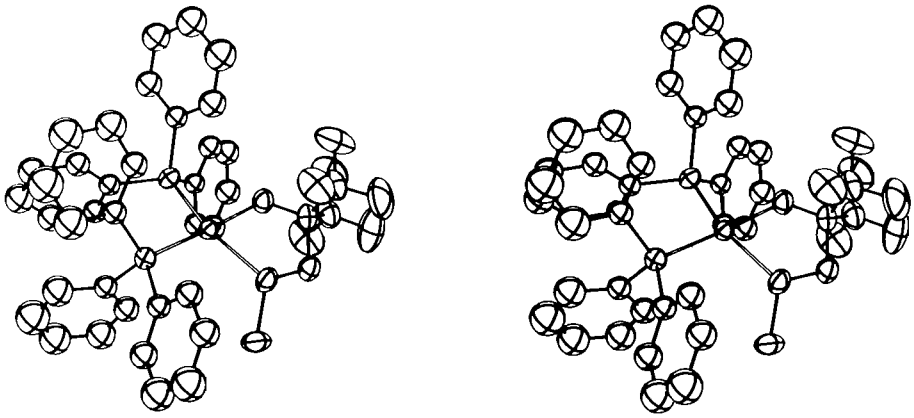


FIG. 1. ORTEP stereoviews of the cation in compound **1**.

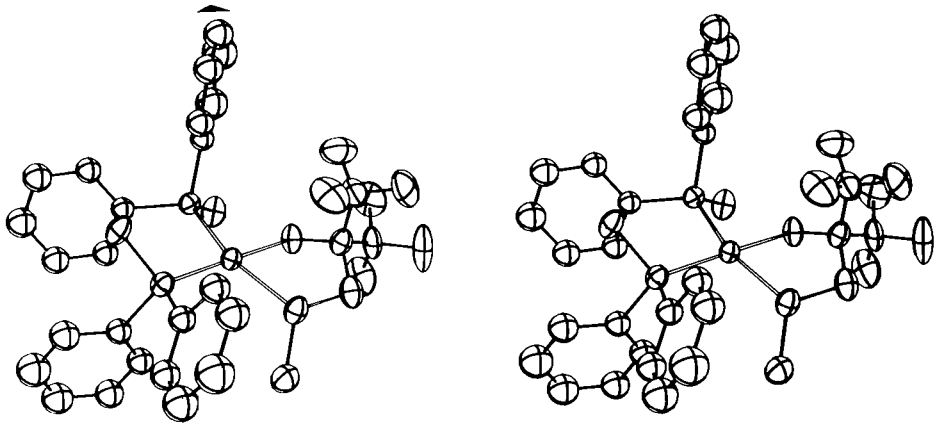

FIG. 2. ORTEP stereoviews of the cation in compound **2**.

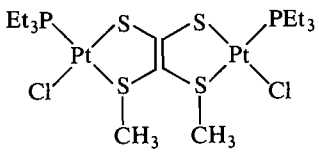
phenyl phosphines. The similar values for the angles between coordinated phosphorus and sulfur (95–97°) suggest that the thioether methyl substituent also has considerable steric bulk, which in turn is likely to influence the chelate ring conformations. The "bite" angle of the chelating ligand does not differ significantly between the two complexes, and the average of 84.1(2)° is similar to other known examples in which Pt^{2+} or Pd^{2+} is incorporated into a five-membered ring with one first-row and one second-row donor atom (16).

The average Pt—S bond length in the two complexes is 2.345(3) Å. This is significantly longer than the range 2.21(1)–2.292(6) Å reported for Pt—S bonds *trans* to halides, amines, or thioethers (17). A longer bond [2.33(1) Å] is found in the complex **8** (18) which is, to our knowledge, the only other structure reported in which a thioether is *trans* to a phosphine on platinum(II):



8

The average Pt—O bond length of 2.050(6) Å in **1** and **2** is within the normal range. A survey[8] of ten crystal structures published in 1980–1983 shows a range of 1.98–2.06 Å, with a mean of 2.02(3) Å. Previously reported values for Pt—O bonds in fluorinated alkoxy derivatives of platinum include 1.992(5) Å in (COD)Pt[—$OC(CF_3)_2$—O—$C(CF_3)_2^-$] (19) and 2.024(21) and 2.032(9) Å in *cis*-$(R_3P)_2$Pt[—O—$C(CF_3)_2$—O—$C(CF_3)_2$—O—], where R_3P = $MePPh_2$ and PPh_3, respectively (20).

For each of the complexes **1** and **2**, the bond from Pt to the phosphine *trans* to the thioether, Pt—P(1), is longer than that to the phosphine *trans* to the alkoxy group, Pt—P(2). The Pt—P(2) distance, at 2.251(3) Å, is identical in **1** and **2** and is marginally longer than the values of 2.223(9) and 2.244(4) Å found previously for R_3P—Pt *trans* to a fluorinated alkoxy group (19). However, there is a significant difference between the Pt—P(1) bond length of 2.292(3) Å found in complex **1** and that of 2.275(3) Å in **2**. This may be attributed to the greater degree of steric crowding, and the associated departure from strict square-planar geometry, that is found with the bulkier triphenylphosphine in **1**.

The average C—O bond length of 1.37(1) Å is significantly shorter than the normal sp^3-carbon to oxygen bond length of 1.43(1) Å. We have found very similar values in several other fluorinated alkoxides (21, 22).

The geometry of the chelate ring is similar in the structures of **1** and **2**. In both, the sulfur methyl substituent is located *anti* to the more axial of the two CF_3 groups, presumably to minimize intramolecular $CH_3 \leftrightarrow CF_3$ repulsion. In other complexes of CF_3-substituted thioether complexes, the least sterically hindered arrangement is found in the solid state (23). For example,

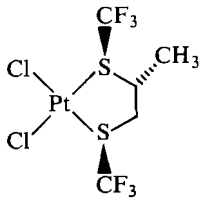
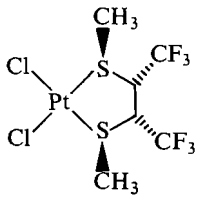
in **9**, the CF_3 group and the CH_3 substituent β to it on the chelate backbone are mutually *anti* (24). Similarly in complex **10**, each of the S—CH_3 groups is *anti* to the adjacent CF_3 group (25).



9



10

As can been seen in the stereoviews, the conformations of **1** and **2**, though similar, do differ significantly. In both structures, four out of the five atoms making up the ring are close to coplanarity. However, in **2** it is the carbon atom carrying the CF_3 groups, C(3), which is 0.51 Å *above* the plane, while in **1** it is the methylene carbon atom, (C)2), which is 0.63 Å *below* the plane. We have observed very similar situations in complexes of the closely-related ligand $Ph_2PCH_2C(CF_3)_2O^-$ (26), and it seems to be a general trend for Pt and Pd complexes of these ligands to adopt a conformation with four coplanar atoms in a five-membered chelate ring. It is unclear whether these differing conformations are due to differing steric requirements of the phosphine ligands, or merely to crystal packing forces, but either points to a low-energy distortion coordinate between them.

Discussion

Anisotropic shielding of the SCH_3 group

We have attributed a large shielding of the methyl resonance in the complex $PtCl(Me—S—O)(PPh_3)$ to the ring-current effect of an *adjacent* PPh_3 group (1). Similar shielding effects are observed in the cationic complexes **1–4**, and our postulate that there is an interaction between the sulfur methyl groups of Me—S—O$^-$ and the phosphine phenyl rings is now substantiated by the structural results on complexes **1** and **2**. As Figs. 1 and 2 show, an aromatic ring makes an almost exactly perpendicular approach to the CH_3—S substituent. In solution, the phosphines would be expected to undergo rapid reorientation about the Pt—P bond, and the methyl groups would therefore experience an average shielding influence from the rotating phenyl rings. The size of the influence will depend upon the number of aromatic substituents on the phosphine and upon their relative freedom to re-orient about their P—C axes. In Table 5, the dependence of $\delta(CH_3S)$ on the coligand is presented.

The shift in $[Pt(Me—S—O)(PMe_3)_2]^+$ was taken as the zero-point, from which we calculate an anisotropic shielding effect, Δδ, which increases with the number of aromatic rings on the adjacent phosphine. The palladium analogue of **1** has $\delta(CH_3—S) = 1.77$ ppm, implying a large Δδ for this complex as well. Ring anisotropy effects have been postulated before to explain upfield shifts; for example, in a series of dimethylcarboxamido platinum complexes (3) and in a ruthenium(II) complex (4), but have not previously been substantiated by a full structural determination.

The perpendicular approach of the phosphine rings to the CF_3 groups is also evident on the stereoviews. For the nmr data (Table 5), we define Δδ as the *difference* in chemical shift between the two CF_3 groups. In the absence of ring anisotropy effects, at temperatures low enough to slow inversion at sulfur, the CF_3 groups in complexes of these ligands give doublet-of-quartet patterns, with $J(F_A, F_B)$ of about 10 Hz. The chemical shift separation, Δδ, varies considerably in different types of R—S—O$^-$ complexes (1, 27), making it essential to consider a systematic range of compounds in order to draw significant conclusions about specific influences on Δδ. We report here two such series, namely **1–4** and **5–7**. In each, there is a systematic variation in $\Delta\delta(CF_3)$ with change in phosphine, such that, in each series, Δδ decreases in the sequence $PMe_3 > PPhMe_2 > PPh_2Me > PPh_3$. This variation closely matches the anisotropic shielding of the methyl groups, and we therefore suggest that the CF_3 groups are also affected by ring currents on adjacent phosphine ligands. Supporting evidence comes from the complex $PtCl(Me—S—O)(PPh_3)$, in which chloro is adjacent to the CF_3 groups and $\Delta\delta(CF_3)$ is 1.6 ppm (1).

In the PPh_3 complex **1**, Δδ = 0, whereas the similar complex of the ligand Ph—S—O$^-$, **5**, has a small, but non-zero, separation. This suggests that the observation of a single resonance for the CF_3 groups on **1** is the result of a *fortuitous* negation of inherently different chemical shifts by the ring current effects. The crystal structures of **1** and **2** substantiate this conclusion, since differences between the two structures are not sufficient to explain the chemical shifts on any other basis.

Preferred conformation in solution

A direct consequence of the observation of ring anisotropy effects on the CF_3 groups is that the chelate rings of complexes **1–7** maintain a preferred conformation in solution; that is, for a

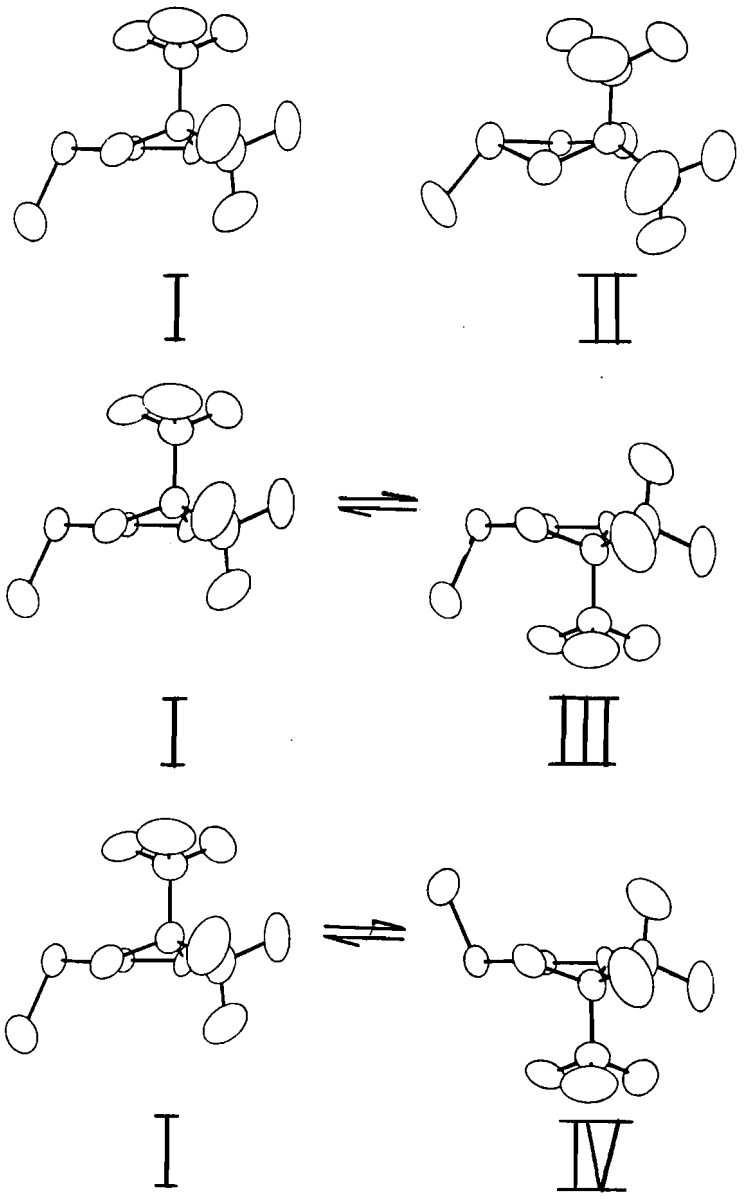


FIG. 3. Possible chelate ring conformations.

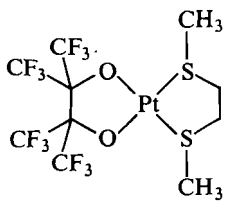
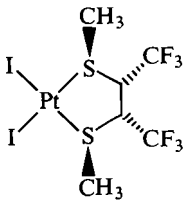
given enantiomer, the axial and equatorial CF_3 groups do *not* exchange in the manner shown by **I** ↔ **III** in Fig. 3, or at least that the lifetime of **I** is long with respect to that of **III**.

Since the two conformations are of different energy, this is perhaps not surprising, but the difference is subtle and not immediately obvious. Configurations **I**, **II**, and **III** are, of course, *representations* of the three static structures; we do not mean to imply that the differences between the solid-state conformations are maintained in solution. All that is required to explain the observed nmr behaviour is that complete ring inversion does not occur at low temperatures, since rapid **I** ↔ **III** exchange would average the CF_3 environments with respect to the adjacent phenyl rings, resulting in no net effect on their chemical shifts. The lower-energy species is probably I, with the CH_3—S group *anti* to the more axial CF_3 group, minimizing CH_3 ↔ CF_3 interactions. This aspect of the solid-state structures *is* maintained in solution, and only when thioether inversion becomes rapid does the complete ring inversion occur (shown as **I** ↔ **IV** in Fig. 3).

Ring conformational changes in five-membered metal–sulfur ring systems are usually very low energy processes, and are thus rapid at temperatures well below those required for thioether inversion (28). For this reason, and because most work has employed symmetrically substituted dithioethers, preferred conformations are rarely seen in such complexes. We have previously reported the nmr parameters of the platinum(II) perfluoropinacolato complex of 2,5-dithiahexane, Pt(PFP)(DTH), **11** (29).



11



12

The *anti*-isomer of **11** has inequivalent CF_3 groups, which indicates a preferred conformation of the PFP ring, presumably

that which minimizes interaction with the CH_3—S groups of DTH.

Preferred conformations have also been reported in complexes of $CF_3SCH_2CH(CH_3)SCH_3$ (24), $CH_3SCH(CF_3)SCH_3$ (30), and $CH_3SCH_2CH(CF_3)SCH_3$ (23, 30). The presence of two chiral centres in the PtX_2 complexes of these ligands means that preferred conformations can be detected through the abundance of specific diastereomers, and **12** exists in solution entirely as the *syn* diastereomer, where $CH_3 \leftrightarrow CF_3$ interactions are at a minimum. There is an excellent correlation between known solid-state structures and the most abundant stereoisomer in solution for these complexes (23–25).

The absence of a second chiral centre in **1** and **2** makes it difficult to follow the chelate ring dynamics in our complexes, as has been done for **12**. The excellent agreement between the activation energies for thioether inversion measured independently from the ^1H and ^{19}F nmr suggests that the CH_3 and CF_3 groups are rendered equivalent by the same process, which we believe to be the coupled ring-thioether inversion represented by **I** ↔ **IV** in Fig. 3.

Conclusions

The crystal structures of **1** and **2** clearly show the origin of the anomalous chemical shifts observed for the SCH_3 and CF_3 groups. In complexes of the thioether ligands Me—S—O^- and Ph—S—O^-, with bulky CF_3 substituents, subtle steric interactions control the conformations of the chelate rings in the solid state and in solution; the power of the combined use of ^1H and ^{19}F nmr to monitor the latter has been demonstrated. As a consequence of the large substituents and the low symmetry, preferred conformations, correlating with solid-state structures, exist in solution.

KÁLMÁN HIDEG, JÓZSEF CSEKÖ, H. O. HANKOVSZKY, and PÁL SOHÁR. Can. J. Chem. **64**, 1482 (1986).

The enhanced reactivity of nitroxide allylic bromides is used for preparation of spin-labelled analogues of biologically active compounds (morphine, Nalorphine, barbituric acid, choline and acetyl choline). Nitroxide α,β-unsaturated aldehydes are reacted with phosphoranes to give nitroxide polyenes. The nitroxides are reduced to diamagnetic *N*-hydroxy hydrochloride salts, which can be converted in the presence of base to *N*-acetoxy derivatives.

KÁLMÁN HIDEG, JÓZSEF CSEKÖ, H. O. HANKOVSZKY et PÁL SOHÁR. Can. J. Chem. **64**, 1482 (1986).

On fait appel à la grande réactivité des nitroxydes des bromures allyliques pour préparer des analogues de composés biologiquement actifs (morphine, Nalorphine, acide barbiturique, choline et acétyl choline) portant des marqueurs de spin. On a fait réagir des nitroxydes d'aldéhydes α,β-non saturés avec des phosphoranes pour obtenir des nitroxydes de polyènes. On a réduit les nitroxydes pour obtenir les chlorhydrates diamagnétiques de dérivés *N*-hydroxylés qui peuvent être transformés, en présence de base, en dérivés *N*-acétoxylés.

[Traduit par la revue]

Introduction

It is essential in spin labelling of various biomolecules (drugs, hormones, and amino acids) to achieve minimal perturbation of their function (1–3). Besides this there are other important factors requiring optimization, such as the use of a spin label reagent with high but selective reactivity, and to achieve a stable labelled molecule in which its nitroxide moiety shows relatively high resistance toward reduction reactions.

In earlier work spin-labelled analogues of drug molecules such as morphine, barbiturate, and acetylcholine have been reported, e.g. morphine was alkylated on its phenolic hydroxyl group with 1-oxyl-2,2,5,5-tetramethyl-3-iodoacetamidopyrrolidine and used for spin-label immunoassay (4). The preparation of diacylated morphines (5), the 6-amino[2,2,6,6-tetramethyl-4-piperidyl-1-oxyl]morphine, and -codeine with marginal biological activity (6) are also known. Commercially available 5-(2-aminoethyl)-5-isopentylbarbituric acid was acylated with ethyl 1-oxyl-2,2,5,5-tetramethylpyrrolidine-3-carbonyl carbonate (7). The spin-labelled acetylcholines having the 2,2,6,6-tetramethylpiperidine-1-oxyl moiety are also known (7–9) and have been used in various membrane studies (10).

Preparation of a spin-labelled diene, 1-oxyl-4-vinyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine in a multistep synthesis started from triacetonamine, and its Diels–Alder reaction with maleic anhydride has been described (11).

Allylic halides offer enhanced reactivity (for reviews, see ref. 12), and therefore we have used nitroxide allylic halides for alkylating biomolecules. For preparation of dienes by the Wittig reaction we used α,β-unsaturated aldehydes, which can conveniently be obtained by oxidation (e.g. by MnO_2) of the corresponding allylic alcohol (13).

Results and discussion

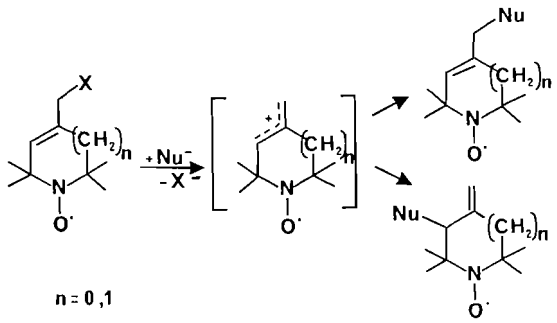
The first objective of the present paper is to give further examples of the advantages of unsaturated aldehydes and allylic halides in preparation of spin-labelled analogues of the aforementioned molecules. In our laboratory the preparation of spin-labelled α,β-unsaturated aldehydes (**1**), (14), (**3**) (15) and allylic halides (**2**) (16), (**4**) (15) have been developed.

1 (R = CHO)
2 (R = CH_2Br)

3 (R = CHO)
4 (R = CH_2Br)

It is an advantage of allylic compounds that they are more reactive in nucleophilic displacement than their saturated analogues, and thus substitution reactions can be carried out more easily under milder conditions. However, it is important to know whether the nucleophilic displacement has taken place with or without allylic rearrangement (12) (Scheme 1). If the compounds are diamagnetic, the structure of the products can be proved by nmr investigation. In the case of paramagnetic compounds it is necessary to convert them to diamagnetic derivatives, most conveniently by reduction. When compounds are not sensitive to hydrogenation the reduction to *N*-hydroxy derivatives could be carried out by catalytic hydrogenation (17). in the case of olefinic nitroxides this method cannot be applied.

Another known convenient method for the reduction of



SCHEME 1

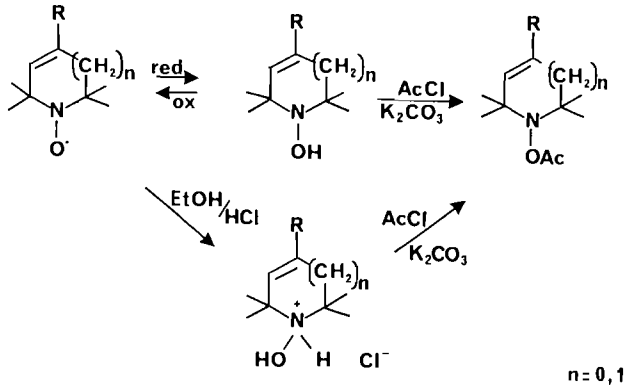
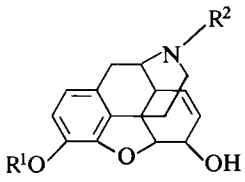
[2]Revision received February 21, 1986.



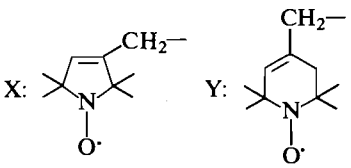
SCHEME 2

nitroxides is the reduction by aqueous ascorbic acid (18). Really, all the types of paramagnetic molecules in this paper can be reduced to the corresponding *N*-hydroxy derivatives by an excess of ascorbic acid. However, during isolation of the *N*-hydroxy compounds some of them are oxidized back spontaneously to nitroxide so quickly that this method could not be used. Since the nitroxides can be converted in alcohol with strong acid to *N*-hydroxy salts (19) we prepared, in most of the cases, the *N*-hydroxy hydrochloride salts, then directly acetylated them to stable *N*-acetoxy derivatives in the presence of base (triethylamine or potassium carbonate).

In this type of substitution reaction the position of the allylic double bond did not change. The ^1H and ^{13}C nmr spectra of compounds obtained from each reaction type showed that reactions with **2** and **4** had taken place without allylic rearrangement (see Table 1 and Experimental). The allyl halides (**2**, **4**) used for alkylation of morphines have not only the advantage of higher reactivity observed in alkylation of morphine, with **2**, on the phenolic hydroxyl to **5** (16), or with **4** to **6**, but in alkylating the normorphine molecule with **2** or **4** the *N*-allyl labelled derivatives (**7**, **8**) can be obtained. When normorphine was reacted with excess of reagents **2** and **4**, the biradicals (**9** and **10**) were obtained.



5 (R^1 = X, R^2 = Me)
6 (R^1 = Y, R^2 = Me)
7 (R^1 = H, R^2 = X)



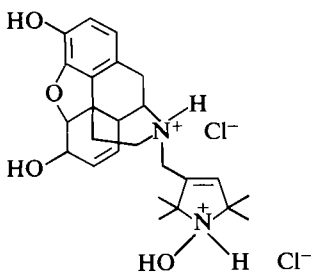
8 (R^1 = H, R^2 = Y)
9 (R^1 = R^2 = X)
10 (R^1 = R^2 = Y)

It turned out that while the *N*-allyl morphine (Nalorphine) is an antagonist of morphine according to Snyder's bioassay method (20), **7** and **8** are moderate agonists. The inhibition of electrically induced contraction of guinea pig intestine (ID_{50}), morphine: 7×10^{-6} mol, normorphine: 7×10^{-6} mol (20); **7**: 3×10^{-6}; **8**: 1×10^{-6} mol. The sodium ion index (Nalorphine 3, morphine 38) (20) of **7** is 7, and of **8** is 20.[3] The 3-*O*-labelled derivatives (**5**, **6**) proved less active than the *N*-allyl derivatives (**7**, **8**). The ^1H and ^{13}C nmr spectra of the dihydrochloride salt of **7** (11) were not informative enough to investigate the question of allylic rearrangement; therefore it was acetylated to **12**, whose nmr spectra proved the structure (Table 1, Experimental).

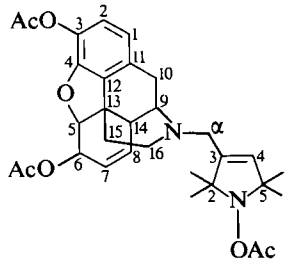
[3]A. Borsodi, unpublished data.

The *N*-hydroxy derivative of **6** was converted into the *N*,*O*-diacetoxy derivative, whose nmr spectra correspond to non-rearranged product (**13**).

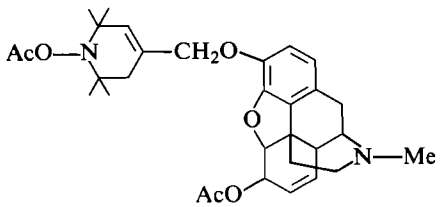
Spin-labelled malonic esters (**14**, **15**) were prepared from the corresponding malonates with **2** or **4** in a phase-transfer (PHT) reaction, using tetrabutylammonium hydrogen sulfate (TBAH) as PHT catalyst. The nmr spectra of *N*-hydroxy hydrochloride salts (**16** and **17**) obtained from **14** and **15** showed that no allylic rearrangement had taken place during the alkylation, because the position of the signal of the olefinic proton (or carbon) and the methylene protons (or carbon) remain as they are in the hydrochloride salts of the allylic alcohols: 1-hydroxy-3-



11

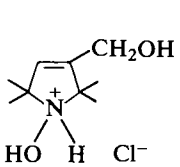


12

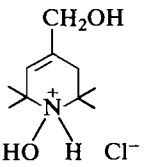


13

hydroxymethyl-2,2,5,5-tetramethyl-3-pyrroline hydrochloride (**18**) and 1-hydroxy-4-hydroxymethyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine hydrochloride (**19**). (The nitroxide allylic alcohols (13, 16) were starting compounds in the synthesis of α,β-unsaturated aldehydes **1** and **3** and allylic bromides **2** and **4**.)



18



19

The ring closure reactions of malonates **14** and **15** with urea in the presence of sodium ethoxide in dry ethanol gave spin-labelled barbituric acids **20** and **21**.

The experience of preparation of spin-labelled maleimides from spin-labelled amines with maleic anhydride showed that the ring closure was always accompanied by the formation of undesired iso-maleimide (**22**) as by-product (21, 22). We wished to utilize the high reactivity of **2** and **4** for preparation of maleimides **23** and **24** from allyl halides (**2**, **4**) with silver maleimide or maleimide (in a PHT reaction). Compounds **23** and **24** could be obtained but the yields were very low; **23** was identical with a sample prepared earlier by the alternative route from amine and maleic anhydride (23).

The advantageous reactivity of allylic halides was also utilized for preparation of spin-labelled choline and acetylcholine with minimal perturbance to either choline or acetylcholine. By quaternization of *N*,*N*-dimethylamino ethanol or its *O*-acetyl

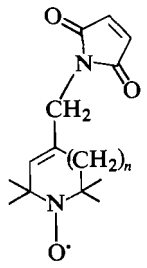
derivative with **2** and **4**, spin-labelled cholines **25**, **26** or acetylcholines **27**, **28** were conveniently prepared. These compounds, showing close resemblance to the Me_3N^+ moiety of the non-labelled compounds, may be useful for biological studies and investigation of the structure – biological activity relationship.

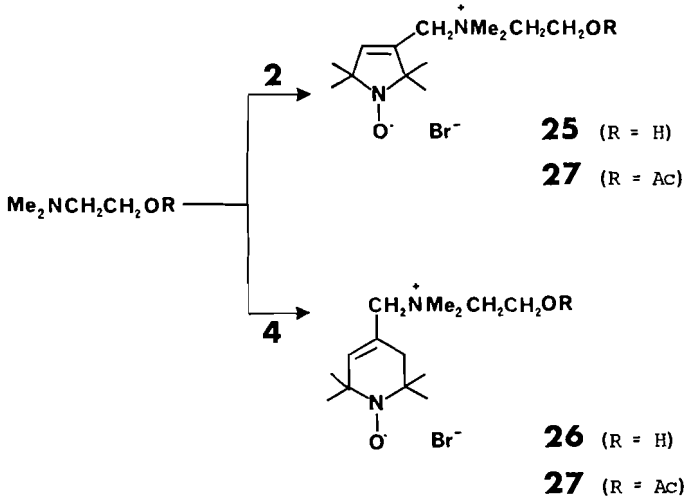


23 (n = 0)
24 (n = 1)

In another set of experiments the unsaturated aldehydes (**1**, **3**) were utilized as convenient synthons for preparation of polyenes. For an ongoing collaboration with polymer chemists we wished to use a spin-labelled diene for investigation of polystyrene polymerization. Utilizing a phase-transfer Wittig reaction (24) of **1** with methylidene phosphorane, formed *in situ* 2,2,5,5-tetramethyl-3-vinyl-3-pyrroline-1-oxyl (**29**) was obtained.

However, the application of paramagnetic dienes in a free radical polymerization procedure might not be possible because of the involvement of the nitroxide moiety in the polymerization as an inhibitor (25).

Therefore the diene (**29**) first was reduced either with ascorbic acid to *N*-hydroxy diene (**30**), then *O*-acetylated to **32**, or else **29** was dissolved in ethanol saturated with HCl, then incubated for several hours at room temperature and precipitated with ether. The $CHCl_3$ solution of *N*-hydroxy hydrochloride **31** in the presence of K_2CO_3 was acylated with excess acetyl chloride to **32**. The *O*-acetyl protecting group as an active ester group can be easily hydrolyzed with aqueous alkali and oxidized again spontaneously, by air or with PbO_2, to nitroxide (**29**). This



SCHEME 4

method of protection was successfully applied in a polystyrene copolymerization study (26).

Compound **29** was reacted with maleic anhydride to a new spin-labelled anhydride reagent (**33**), with the known spin-labelled maleimide **24** to a biradical (**34**). However, it was also necessary to prepare further adducts to determine the configuration of these adducts, because the anhydride **33** is sensitive toward the above-mentioned reduction methods, and the biradical **34** has signals that partly overlap the signals of ring junction protons (or carbons). Therefore **29** was reacted with *N*-methyl maleimide to give **35**, and with *N*-ethyl maleimide to give **36**,

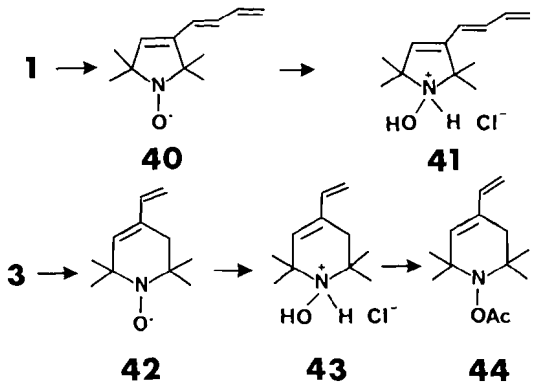

SCHEME 6

which are mixtures of two isomers (*a* and *b*), differing in the configuration of C-3, -7, -8. Diamagnetic *N*-hydroxy salts of **36***a,b* were separated (**38***a,b*) as well as the *O*-acetyl derivatives **39***a,b* obtained via *N*-hydroxy salts (**37***a,b*). Carbon chemical shifts showed that the major isomers formed in the cyclization are the stereochemically more stable ones, while the minor compounds are the more crowded molecules. Determination of the stereostructure of these diastereomers is in progress and will be published elsewhere.

Compound **1**, with allyl triphenylphosphorane, gave a nitroxide triene **40**. The nmr spectra of reduced derivatives **41** showed that the trienes have *E* configuration.

The Wittig reaction of **3** with methylidene phosphorane formed *in situ* gave **42**, which was converted into **43**, then **44**.

Experimental

The compounds were purified by flash column chromatography on Kieselgel 60 (0.040–0.063 mm, Merck). The esr (electron spin resonance) spectra were obtained from 10^{-3} *M* solution on a Zeiss ER9 spectrometer. All of the monoradicals exhibited three equidistant lines a_N = 14.3–15.3 G. The mass spectra were measured on a Varian MAT-SM-1 mass spectrometer. Melting points were measured using a Boetius micro instrument and are not corrected. The ir spectra of radicals were measured with a Zeiss Specord 75 type of instrument; ir spectra of diamagnetic compounds were run in KBr discs on a Brüker IFS-113v FT spectrometer equipped with an Aspect 2000 computer.

The nmr spectra were recorded in 5- or 10-mm tubes at room temperature on a Brüker WM-250 (^{1}H) or WP-80SY FT spectrometer (^{13}C) controlled by an Aspect 2000 computer at 250.13 (^{1}H) or 20.14 MHz (^{13}C) in $CDCl_3$ or DMSO-d_6 solution using the deuterium signal of the solvent as the lock and TMS as internal reference. The most important measuring parameters were as follows: sweep width: 5 kHz; pulse width: 1 (^{1}H) or 3.5 (^{13}C) μs (ca. 20° or 30° flip angle); acquisition time 1.64 s; number of scans: 16 or 2^{10}–2^{16}; computer memory: 16K; Lorentzian exponential multiplication for signal-to-noise enhancement (LB 0.7 or 1.0 Hz) and complete proton noise decoupling (ca. 1.5 W) for ^{13}C measurements were applied.

DEPT[4] experiments (27) were performed (in the case of compounds **13** and **32**) in a standard way (28) using only the θ = 135° pulse to separate CH/CH_3 and CH_2 lines phased "up" and "down", respectively. Typical acquisition data were: number of scans: 128–12 K; relaxation delay for protons: 3 s; 90° pulse width: 10.8 and 22.8 μs for ^{13}C and ^{1}H, respectively. The estimated value for *J*(C,H) resulted in a 3.7-ms delay for polarization.

Spectral data of the common (spin-labelled) part of the compounds investigated were tabulated (Table 1); further parameters of the very different structures are listed separately (the footnotes in Table 1 are also referred to throughout the Experimental). It is to be noted that many of the nmr signals are broadened (lines of multiplets have coalesced) due probably to residual free radical contaminations. Consequently, and because of poor solubilities or coincidences with the solvent peaks, it was not possible to determine proton–proton coupling constants for compounds **38***a,b* and **39***a,b* nor to identify some carbon lines in the case of **38***a,b*. The assignments of carbons of the morphine skeleton are based on literature data (29).

General method for the preparation of hydroxylamine hydrochloride salts (Method A)

The nitroxide compound was dissolved in EtOH saturated with HCl (5 mL) and allowed to stand overnight. Then ether was added and the crystalline product was filtered.

General method for the preparation of N*-acetoxy compounds (Method B)*

To a stirred mixture of hydroxylamine hydrochloride salt (1 mmol) and potassium carbonate (2 mmol) in dry chloroform, acetylchloride (2 mmol) was added. After 20 min water was added, the organic phase washed with a solution of $NaHCO_3$, water, dried, and evaporated.

*Preparation of 3-spin-labelled morphine derivatives (**5**, **6**). General procedure*

The allylic bromo compound (**2** or **4**) (0.50 mmol) was added to a suspension of morphine base (143 mg, 0.50 mmol) and K_2CO_3 (100 mg) in DMF, and the mixture was heated (70°C) for 2 h, diluted with a solution of NH_4Cl, extracted with $CHCl_3$ (3 × 10 mL), dried, and evaporated. The pure product (**5** or **6**) was obtained by preparative thin-layer chromatography (Merck, Kieselgel 60; chloroform:ether: ethanol, 4:4:1). Compound **5** was identical in all respects with the compound prepared from the corresponding mesylate (16). Yield: 110 mg (48%) (**6**); mp 156–157°C; ir (Nujol): 3400–3200 (OH), 1520 (C=C) cm^{-1}; ms, *m/e*: M^+ 451 (9), 437(13), 436(6), 421(13). *Anal.* calcd. for $C_{27}H_{35}N_2O_4$ (451.59): C 71.81, H 7.81, N 6.20; found: C 72.05, H 7.51, N 5.98.

Preparation of N*-spin-labelled normorphine derivatives (**7**, **8**). General procedure*

The nitroxide allylic bromo compound (**2** or **4**) (0.50 mmol) was added to a suspension of normorphine (135 mg, 0.50 mmol) and K_2CO_3 (100 mg) in DMF and the mixture was heated (70°C) for 2 h,

[4]DEPT: Distortionless Enhancement by Polarization Transfer.

diluted with a solution of NH_4Cl, extracted with $CHCl_3$ (3 × 10 mL), and the organic phase was dried and evaporated. The pure product (**7** or **8**) was obtained by preparative thin-layer chromatography (Merck, Kieselgel 60; chloroform:ether:ethanol, 4:4:1). Yield: 125 mg (59%) (**7**); mp > 250°C; ir (Nujol): 3500–3100 (OH) cm^{-1}. *Anal.* calcd. for $C_{25}H_{31}N_2O_4$ (423.54): C 70.94, H 7.38, N 6.61; found: C 70.72, H 7.49, N 7.05. Yield: 100 mg (45%) (**8**); mp > 200°C; ir (Nujol): 3500–3100 (OH) cm^{-1}; ms, *m/e*: M^+ 437(49), 429(100), 407(22), 284(24). *Anal.* calcd. for $C_{26}H_{33}N_2O_4$ (437.56): C 71.37, H 7.60, N 6.40; found: C 71.28, H 7.72, N 6.29.

*Preparation of bis spin-labelled normorphine derivatives (**9**, **10**). General procedure*

The allylic bromo compound (**2** or **4**) (1 mmol) was added to a suspension of normorphine base (135 mg, 0.50 mmol) and K_2CO_3 (100 mg) in DMF, and the mixture was heated (70°C) for 2 h, diluted with a solution of NH_4Cl, extracted with $CHCl_3$ (3 × 10 mL), dried, and evaporated. The pure product (**9** or **10**) was obtained by preparative thin-layer chromatography (Merck, Kieselgel 60; $CHCl_3$:ether:ethanol, 4:4:1). Yield: 140 mg (49%) (**9**); mp 92–93°C; ir (Nujol): 3500–3100 (OH) cm^{-1}. *Anal.* calcd. for $C_{34}H_{45}N_3O_5$ (575.75): C 70.93, H 7.88, N 7.30; found: C 70.96, H 8.05, N 7.33. Yield: 94 mg (31%) (**10**); mp 191–192°C; ir (Nujol): 3500–3100 (OH) cm^{-1}; ms, *m/e*: M^+ 603 (0.2), 152 (100). *Anal.* calcd. for $C_{36}H_{49}N_3O_5$(603.84): C 71.61, H 8.18, N 6.96; found: C 71.93, H 8.34, N 7.02.

*Preparation of hydrochloride salt of **7** (**11**)*

From **7** (450 mg, 1.1 mmol) according to *Method A*. Yield: 500 mg (94%) mp > 250°C; ir ($CHCl_3$): 3400–3200 (OH) cm^{-1}. *Anal.* calcd. for $C_{25}H_{32}N_2O_4 \cdot 2HCl$ (497.47): C 60.36, H 6.89, N 5.63, Cl 14.15; found: C 59.99, H 6.93, N 5.64, Cl 14.59.

Preparation of N*-acetoxy derivative of **7** (**12**)*

From **11** (450 mg, 0.90 mmol) according to *Method B*. Yield: 300 mg (61%); mp 129–130°C; ir (KBr): 1774 (C═O, phenolic ester), 1738 (C═O, allylic ester), 1247, 1207, 1038 (C—O) cm^{-1}; ^1H nmr: CH_3(Ac): 2.14, 2.16, 2.27, 3 × s (3 × 3H); H-9: 3.45, m (1H); H-5: 5.10, dd (5.5, 0.7 Hz); H-6: ~5.15, m (1H); H-8: 5.40, ~d (~10 Hz); H-7: 5.62, ~d (~10 Hz); H-1: 6.58, d (8.2 Hz); H-2: 6.76, d (8.2 Hz); ^{13}C nmr: CH_3(Ac): 19.1, 20.5, 22.1; CH_2(10): 20.5; CH_2(15): 35.4; CH(14): 40.8; CH_2(16): 43.6; C-13: 44.5; CH(9): 57.5; CH(6): 71.3; CH(5): 89.0; CH(1): 119.2; CH(2): 122.0; CH(8): 128.6;[f] C-12: 131.2;[e] CH(7): 132.1;[i] C-11: 132.2;[i] C-3: 141.1; C-4: 149.7; C═O: 168, 170.3, 171.3. *Anal.* calcd. for $C_{31}H_{38}N_2O_7$ (550.68): C 67.62, H 6.96, N 5.09; found: C 67.41, H 6.88, N 4.98.

Preparation of N*-acetoxy derivative of **6** (**13**)*

From **6** (1.5 g, 3.3 mmol) by *Method A*, then *Method B* (without isolation of hydrochloride salt). The pure product (**13**) was obtained by flash chromatography ($CHCl_3$:MeOH, 20:1). Yield: 250 mg (14%); mp 63–64°C; ir ($CHCl_3$): 1750, 1735 (C═O) cm^{-1}; ^1H nmr: CH_3(Ac): 2.10, 2.14, 2 × s (2 × 3H); CH_3N: 2.43, s (3H); H-9: 3.35, m (1H); H-5: 5.10, d (~6 Hz); H-6: 5.16, m (1H); H-8: 5.44, ~d (~10 Hz); H-7: 5.63, ~d (~10 Hz); H-2: 6.50, d (~9 Hz); H-1: 6.64, d (~9 Hz); ^{13}C nmr: CH_3(Ac): 17.4, 19.6;[s] CH_2(10): 19.6;[s] CH_2(15): 34.4; CH(14): 39.5; C-13: 41.5; NCH_3: 41.9; CH_2(16): 45.6; CH(9): 58.1; CH(6): 67.1; CH(5): 86.8; CH(2): 116.5; CH(1): 118.1; C-11: 126.7; CH (8): 127.35;[f] C-12: 129.9; CH(7): 130.5;[e] C-3: 139.5; C-4: 146.3; C═O: 169.0, 169.6. *Anal.* calcd. for $C_{31}H_{40}N_2O_6$ (536.67): C 69.38, H 7.51, N 5.22; found: C 69.48, H 7.80, N 5.52.

*Preparation of spin-labelled diethyl phenylmalonate (**14**)*

A solution of NaOH (2 *N*, 3.6 mL) was added to a CH_2Cl_2 solution (9 mL) of diethyl phenylmalonate (710 mg, 3 mmol), TBAH (1.222 g, 3.6 mmol), and **2** (839 mg, 3.6 mmol) and stirred at room temperature for 16 h. The organic layer was separated, dried, evaporated, and chromatographed on a silica gel column with CCl_4/ether, to give **14**. Yield: 700 mg (60%); mp 100–101°C; ir (Nujol): 1725 (C═O) cm^{-1}. *Anal.* calcd. for $C_{22}H_{30}NO_5$ (388.49): C 68.02, H 7.78, N 3.61; found: C 68.00, H 7.49, N 3.56.

*Preparation of spin-labelled diethyl ethylmalonate (**15**)*

A solution of NaOH (2 *N*, 3.6 mL) was added to a solution of diethyl ethylmalonate (565 mg, 3 mmol), TBAH (1.222 g, 3.6 mmol), and **4** (89 mg, 3.6 mmol) in CH_2Cl_2 (9 mL) and stirred at room temperature for 16 h. The organic layer was separated, dried, evaporated, and chromatographed on a silica gel column with CCl_4/ether, to give **15**. Yield: 400 mg (37%), red oil; ir ($CHCl_3$): 1720 (C═O) cm^{-1}. *Anal.* calcd. for $C_{19}H_{32}NO_5$ (354.48): C 64.38, H 9.10, N 3.95; found: C 64.46, H 8.91, N 3.84.

*Preparation of hydrochloride salt of **14** (**16**)*

From **14** (194 mg, 0.50 mmol) according to *Method A*. Yield: 200 mg (94%); mp 130–132°C; ir (KBr): 3100–2400 (OH + N^+H), 1753, 1725 (C═O), 1240, 1200, 1028 (C—O) cm^{-1}; ^1H nmr: CH_3(OEt): 1.16, t (7.0 Hz), 6H; CH_2(OEt): 4.20, qa (4H); ArH: 7.3–7.5, m (5H); OH + NH: ~11.6, ~12.0, 2 × br s (2 × 1H); ^{13}C nmr: CH_3(OEt): 15.3; C_{quat}: 62.5; CH_2(OEt): 63.4; C_{Ar}-2′, -6′: 129.7,[e] 129.8;[e] C_{Ar}-1′: 137.1; C═O: 170.8. *Anal.* calcd. for $C_{22}H_{31}NO_5 \cdot HCl$ (425.96): C 62.03, H 7.57, N 3.29, Cl 8.32; found: C 61.79, H 7.70, N 3.01, Cl 8.62.

*Preparation of hydrochloride salt of **15** (**17**)*

From **15** (177 mg, 0.50 mmol) according to *Method A*. Yield: 170 mg (91%); mp 130–131°C; ir (KBr): 3100–2400 (OH + N^+H), 1749, 1726 (C═O), 1225, 1182, 1036 (C—O) cm^{-1}; ^1H nmr: CH_3(C-Et): 0.78, t (7.4 Hz, 3H); CH_3(OEt): 1.19, t (7.1 Hz, 6H); CH_2(C-Et): 1.85, qa (2H); CH_2(OEt): 4.13, qa (4H); OH + NH: ~11.5, ~12.4, 2 × br s (2 × 1H); ^{13}C nmr: CH_3(C-Et): 9.9; CH_3(OEt): 15.4; CH_2(C-Et): 26.5; C_{quat}: 59.1; CH_2(OEt): 62.6; C═O: 172.1. *Anal.* calcd. for $C_{19}H_{33}NO_5 \cdot HCl$ (391.94): C 58.23, H 8.74, N 3.57, Cl 9.04; found: 58.57, H 8.60, N 3.47, Cl 9.02.

*Preparation of 1-hydroxy-3-hydroxymethyl-2,2,5,5-tetramethyl-3-pyrroline hydrochloride (**18**)*

From 1-oxyl-3-hydroxymethyl-2,2,5,5-tetramethyl-3-pyrroline (170 mg, 1 mmol) according to *Method A*. Yield: 184 mg (88%) mp 157–159°C; ir (KBr): 3450, 3325, 3200–2500 (OH + N^+H), 1107 (C—O) cm^{-1}; ^1H nmr: OH + NH: ~11.6, ~12.2, 2 × br s (2 × 1H). *Anal.* calcd. for $C_9H_{17}NO_2 \cdot HCl$ (207.70): C 52.05, H 8.73, N 6.75, Cl 17.07; found: C 52.26, H 8.91, N 6.93, Cl 17.19.

*Preparation of 1-hydroxy-4-hydroxymethyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine hydrochloride (**19**)*

From 1-oxyl-4-hydroxymethyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine (184 mg, 1 mmol) according to *Method A*. Yield: 165 mg (90%) mp 176–177°C; ir (KBr): 3425, 3200, 2675 (OH, HN^+ − OH, N^+H) cm^{-1}; ^1H nmr: OH + NH: ~11.4, ~12.5, 2 × br s (2 × 1H). *Anal.* calcd. for $C_{10}H_{19}NO_5 \cdot HCl$ (221.73): C 54.17, H 9.03, N 6.32, Cl 15.99; found: C 53.94, H 9.23, N 6.59, Cl 16.08.

*Preparation of 5-phenyl-5-[(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-yl)methyl]barbituric acid (**20**)*

A solution of **14** (388 mg, 1 mmol) in dry EtOH was added to a solution of urea (300 mg, 5 mmol) in sodium ethoxide (1 *M*, 3 mL, 3 mmol) and refluxed for 15 h. The reaction mixture was acidified with 1 *N* HCl and extracted with $CHCl_3$. The organic phase was washed with water, dried, evaporated, and chromatographed on a silica gel column with chloroform/ether, to give **20**. Yield: 150 mg (43%); mp 138–140°C; ir ($CHCl_3$): 3300–2700 (NH), 1750, 1690 (C═O), 1600 (C═C) cm^{-1}; ms, *m/e*: M^+ 355(5), 288(8), 258(11), 232(50). *Anal.* calcd. for $C_{19}H_{22}N_3O_4$ (356.41): C 64.03, H 6.22, N 11.79; found: C 63.89, H 6.54, N 12.07.

*Preparation of 5-ethyl-5-[(1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyrid-4-yl)methyl]barbituric acid (**21**)*

To a solution of urea (300 mg, 5 mmol) in sodium ethoxide (1 *M*, 3 mL, 3 mmol), a solution of **15** (354 mg, 1 mmol) in dry EtOH was added dropwise. The reaction mixture was refluxed for 15 h, acidified with 1 *N* HCl, and extracted with $CHCl_3$. The organic phase was washed with water, dried, evaporated, and chromatographed on a silica gel column with $CHCl_3$/ether, to give **21**. Yield: 140 mg (43%); mp 156–157°C; ir ($CHCl_3$): 3300–2700 (NH), 1750, 1710 (C═O) cm^{-1};

ms, *m/e*: M^+ 322(33), 308(15), 136(34), 135(17). *Anal.* calcd. for $C_{16}H_{24}N_3O_4$ (322.40): C 59.61, H 7.50, N 13.03; found: C 59.82, H 7.57, N 13.02.

Preparation of spin-labelled maleimides (23, 24) Method I

In a three-necked flask equipped with a nitrogen inlet was placed maleimide (97 mg, 1 mmol), powdered anhydrous K_2CO_3 (83 mg, 0.6 mmol), powdered KOH (73 mg, 1.1 mmol), and 18-crown-6 (26 mg, 0.1 mmol) in toluene (8 mL). The mixture was stirred under nitrogen at room temperature for 24 h, then **2** or **4** (1,1 mmol) in toluene (1 mL) was added. The mixture was stirred for 18 h at reflux. The reaction mixture was cooled to room temperature, and the inorganic salts were filtered off and washed with saturated KCl solution (3 × 20 mL), dried, and evaporated. The product **23** or **24** was obtained with preparative thin-layer chromatography (Merck, Kieselgel 60; CCl_4:ether 4:1). Yield 20 mg (8.0%) (**23**). Compound **23** was identical in all respects with the compound that has been described in the literature (23). Yield: 20 mg (7.6%) (**24**); mp 110–112°C; ir ($CHCl_3$): 1730, 1710 (C=O) cm^{-1}. *Anal.* calcd. for $C_{14}H_{19}N_2O_3$ (263.31): C 63.86, H 7.27, N 10.64; found: C 64.01, H 7.13, N 10.36.

Method II

The silver maleimide was prepared by the method of Schwartz and Lerner (30). A mixture of allylic bromo compound (**2** or **4**) (1 mmol) and silver maleimide (1.1 mmol) in dry benzene (5 mL) was refluxed for 16 h. The silver salts were removed by filtration. After evaporation of the solvent the residue was chromatographed on silica gel to give the spin-labelled maleimide compound. Yield: 23 mg (9.2%) (**23**); 25 mg (9.6%) (**24**).

Preparation of spin-labelled choline derivatives (25, 26). General procedure

Compound **2** or **4** (0.50 mmol) was added to 2-dimethylaminoethanol (45 mg, 0.50 mmol). After a few minutes the crystalline product was filtered, then washed with ether. Yield: 56 mg (35%) (**25**); mp 184–186°C; ir (Nujol): 3500–3100 (OH) cm^{-1}. *Anal.* calcd. for $C_{13}H_{26}BrN_2O_2$ (322.27): C 48.45, H 8.13, Br 24.80, N 8.69; found: C 48.40, H 8.07, Br 24.63, N 8.48. Yield: 72 mg (41%) (**26**); mp 160–162°C; ir (Nujol): 3500–3100 (OH) cm^{-1}. *Anal.* calcd. for $C_{14}H_{28}BrN_2O_2$ (336.29): C 50.00, H 8.39, Br 23.76, N 8.33; found: C 49.90, H 8.56, Br 23.42, N 8.43.

Preparation of spin-labelled acetylcholine derivatives (27, 28). General procedure

Compound **2** or **4** (0.50 mmol) was added to 2-(dimethylamino) ethyl acetate (66 mg, 0.50 mmol). After a few minutes the crystals of product were filtered, then washed with ether. Yield: 82 mg (45%) (**27**); mp 121–123°C; ir (Nujol): 1740 (C=O) cm^{-1}. *Anal.* calcd. for $C_{15}H_{28}BrN_2O_3$ (364.31): C 49.46, H 7.75, Br 21.93, N 7.69; found: C 49.66, H 7.58, Br 21.90, N 7.51. Yield: 81 mg (43%) (**28**); mp 142–144°C; ir (Nujol): 1735 (C=O) cm^{-1}. *Anal.* calcd. for $C_{16}H_{30}BrN_2O_3$ (378.35): C 50.80, H 7.99, Br 21.12, N 7.40; found: C 50.81, H 7.98, Br 21.05, N 7.37.

Preparation of 1-oxyl-3-vinyl-2,2,5,5-tetramethyl-3-pyrroline (29) From 1

Anhydrous K_2CO_3 (3.5 g) and the aldehyde (**1**) (3.36 g, 0.02 mol) were added to a solution of triphenylmethylphosphonium iodide (8.4 g, 0.02 mol) in dioxane, refluxed for 24 h, filtered off, evaporated, and the residue purified by chromatography on a silica gel column with chloroform/ether, to give **29** as a dark red oil. Yield: 1.8 g (54%); ir ($CHCl_3$): 1630, 1590 (C=C—C=C) cm^{-1}; ms, *m/e*: M^+ 166(20), 152(26), 151(30), 136(32). *Anal.* calcd. for $C_{10}H_{16}NO$ (166.25): C 72.25, H 9.70, N 8.43; found: C 71.92, H 9.59, N 8.27.

From 32

To a solution of *N*-acetoxy diene (**32**) (104 mg, 0.50 mmol) in MeOH (2 mL) was added 1 *N* aqueous NaOH (2 mL) and the solution allowed to stand for 30 min. It was then extracted with chloroform, the organic phase dried ($MgSO_4$), stirred with PbO_2 (1 g) for 10 min, filtered, and evaporated. The product is identical with compound **29** obtained by *Method I*. Yield: 50 mg (60%).

Preparation of hydrochloride salt of 29 (31)

From **29** (166 mg, 1 mmol) according to *Method A*. Yield: 186 mg (91%); mp 140–141°C. *Anal.* calcd. for $C_{10}H_{17}NO{\cdot}HCl$ (203.72): C 58.96, H 8.91, N 6.88, Cl 17.40; found: C 59.20, H 9.13, N 6.91, Cl 16.96.

N-*Acetoxy-3-vinyl-2,2,5,5-tetramethyl-3-pyrroline (32) From 29*

A solution of ascorbic acid (3.52 g, 0.02 mol) in water (10 mL) was added to a solution of **29** (1.66 g, 0.01 mol) in methanol (5 mL). After decolorization the solution (10 min) was extracted with chloroform, dried ($MgSO_4$), evaporated, and added to a stirred mixture of acetylchloride (1.17 g, 0.015 mol) and potassium carbonate (2.76 g, 0.02 mol) in dry chloroform. After 20 min water was added, the organic layer washed with a solution of $NaHCO_3$, water, dried, and evaporated to give **32** as a colorless oil. Yield: 1.15 g (55%); ir (KBr): 1774 (C=O), 1202 (C—O), 999 (=CH) cm^{-1}; ^1H nmr: $=CH_2$: 5.14, *d* (*J*(*cis*) = 11.3 Hz), 5.42, *d* (*J*(*trans*) = 17.8 Hz); ^{13}C nmr: CH_3(Ac): 19.1; $=CH_2$: 115.9; C=O: 171.3; ms, *m/e*: M^+ 209(2,2), 194(13), 167(10), 152(100). *Anal.* calcd. for $C_{12}H_{19}NO_2$ (209.29): C 68.87, H 9.15, N 6.69; found: C 68.70, H 8.85, N 7.09.

From 31

From **31** (186 mg, 0.92 mmol) according to *Method B*: the pure product was obtained by flash chromatography (*n*-hexane:ethyl acetate, 4:1), and it was identical with compound **32** obtained with *Method I*. Yield: 189 mg (99%).

1,1,3,3-Tetramethyl-2-oxyl-1,3,4,5,6,9-hexahydroindol-3,4-dicarboxylic anhydride (33)

Maleic anhydride (60 mg, 0.7 mmol) and toluene-4-sulfonic acid (5 mg) were added to a solution of **29** (166 mg, 1 mmol) in dry benzene, then refluxed for 4 h. After this the reaction mixture was evaporated and purified with preparative thin-layer chromatography (Merck, Kieselgel 60; $CHCl_3$:ether, 1:1) to give **33**. Yield: 70 mg (27%); mp 136–137°C; ir ($CHCl_3$): 1870, 1795 ($(CO)_2O$) cm^{-1}; ms, *m/e*: M^+ 264(100), 225(10), 166(18), 151(16). *Anal.* calcd. for $C_{14}H_{18}NO_4$ (264.32): C 63.62, H 6.86, N 5.30; found: C 63.68, H 6.97, N 5.14.

Preparation of adduct of 29 and N-*(1-oxyl-2,2,6,6-tetramethyl-4-piperidyl)maleimide (34)*

N-(1-oxyl-2,2,6,6-tetramethyl-4-piperidyl)maleimide (22) (251 mg, 1 mmol) and toluene-4-sulfonic acid (5 mg) were added to a solution of **29** (166 mg, 1 mmol) in dry benzene, refluxed for 12 h, evaporated, and purified by preparative thin-layer chromatography (Merck, Kieselgel 60; CCl_4:ether, 1:1), to give **34**. Yield: 110 mg (26%); mp 108–110°C; ir ($CHCl_3$): 1860, 1790 (C=O) cm^{-1}; esr: five lines of biradical with $a_{N/2}$ = 8.71G. *Anal.* calcd. for $C_{23}H_{35}N_3O_4$ (417.55): C 66.16, H 8.45, N 10.06; found: C 66.07, H 8.91, N 10.21.

Preparation of adducts of 29 with N-*methylmaleimide (35a, 35b)*

N-Methylmaleimide (1.55 g, 0.014 mol) was added to a solution of **29** (2.25 g, 0.014 mol) in dry toluene and the reaction mixture was refluxed for 12 h, evaporated, and purified with flash chromatograhy (*n*-hexane:ethyl acetate, 2:1) to give two main products. The first product eluting from the column was **35***a*. Yield: 0.2 g (5%); mp 161–162°C; ir ($CHCl_3$): 1775, 1705 (C=O, imide) cm^{-1}. *Anal.* calcd. for $C_{15}H_{21}N_2O_3$ (277.36): C 64.96, H 7.63, N 10.10; found: C 65.08, H 8.00, N 10.30. The second product was **35***b*. Yield: 1.4 g (37%); mp 130–131°C; ir ($CDCl_3$): 1775, 1695 (C=O, imide) cm^{-1}. *Anal.* calcd. for $C_{15}H_{21}N_2O_3$ (277.36): C 64.96, H 7.63, N 10.10; found: C 64.62, H 7.43, N 9.79.

Preparation of adducts of 29 with N-*ethylmaleimide (36a, 36b)*

N-Ethylmaleimide (250 mg, 2 mmol) was added to a solution of **29** (332 mg, 2 mmol) in dry toluene, refluxed for 12 h, evaporated, and purified by flash chromatograhy (*n*-hexane:ethyl acetate, 2:1) to obtain two stereoisomer products. The first product eluting from the column was **36***a*. Yield: 56 mg (9%), mp 164–166°C; ir ($CHCl_3$): 1775, 1690 (C=O, imide) cm^{-1}. *Anal.* calcd. for $C_{16}H_{23}N_2O_3$ (291.37): C 65.96, H 7.96, N 9.61; found: C 66.12, H 8.04, N 9.63. The second product was **36***b*. Yield: 184 mg (31%); mp 131–132°C; ir (in $CHCl_3$): 1770,

1690 (C=O, imide) cm^{-1}. *Anal.* calcd. for $C_{16}H_{23}N_2O_3$ (291.37): C 65.96, H 7.96, N 9.61; found: C 66.04, H 8.17, N 9.90.

Preparation of hydrochloride salts of **35**a *and* **35**b (**37**a, **37***b*)

From **35***a* (200 mg, 0.7 mmol) according to *Method A* to give **37***a*. Yield: 155 mg (70%); mp 209–210°C; ir ($CHCl_3$): 1775, 1705 (C=O, imide) cm^{-1}. *Anal.* calcd. for $C_{15}H_{22}N_2O_3 \cdot HCl$ (314.83): C 57.23, H 7.36, N 8.90, Cl 11.26; found: 57.63, H 7.72, N 8.90, Cl 11.38.

From **35***b* (300 mg, 1 mmol) according to *Method A* to give **37***b*. Yield: 270 mg (86%); mp 163–164°C; ir ($CHCl_3$): 1770, 1695 (C=O, imide) cm^{-1}. *Anal.* calcd. for $C_{15}H_{22}N_2O_3 \cdot HCl$ (314.83): C 57.23, H 7.36, N 8.90, Cl 11.26; found: 57.26, H 7.63, N 8.79, Cl 11.49.

Preparation of hydrochloride salts of **36**a *and* **36**b (**38**a, **38***b*)

From **36***a* (50 mg, 0.17 mmol) according to *Method A* to give **38***a*. Yield: 49 mg (87%); mp 142–144°C; ir (KBr): 3100–2200 (OH + HN^+), 1772, 1690 (C=O, imide) cm^{-1}; ^1H nmr: CH_3(NEt): 1.00, t (7.1 Hz); H-9: ~2.35,[c,m] ~3.5;[c,m] H-8: 3.00,[m] ~s (1H); H-7: 3.25,[m] ~t (broad lines, ^1H); CH_2(NEt): 3.36, qa (2H); ^{13}C nmr: CH_3(Et): 14.2; NCH_2: 34.9; C-7, -8; ?;[k] C-9:[t] NC=O: 180.0.[n] *Anal.* calcd. for $C_{16}H_{24}N_2O_3 \cdot HCl$ (328.84): C 58.44, H 7.66, N 8.52, Cl 10.78; found: C 58.62, H 7.39, N 8.26, Cl 11.02.

From **36***b* (50 mg, 0.17 mmol), according to *Method A* to give **38***b*. Yield: 50 mg (89%); mp 161–163°C; ir (KBr): 3100–2300 (OH + N^+H), 1776, 1699 (C=O, imide) cm^{-1}; ^1H nmr: CH_3(NEt): 1.07, t (7.2 Hz); H-9: 1.90,[m] ~tt (1H), 2.85, m;[m,n] H-8: 2.6, m;[o] H-7: 3.25, dd (~10, ~5 Hz); ^{13}C nmr: CH_3(Et): 14.2; NCH_2: 34.6; C-7, -8: ?;[k] C-9:[t] NC=O: 179.5, 179.9. *Anal.* calcd. for $C_{16}H_{24}N_2O_3 \cdot HCl$ (328.84): C 58.44, H 7.66, N 8.52, Cl 10.78; found: C 58.13, H 7.36, N 8.45, Cl 10.88.

Preparation of N-*acetoxy derivatives of* **35**a *and* **35**b (**39**a, **39***b*)

From **37***a* (150 mg, 0.5 mmol) according to *Method B*. The pure product was obtained by flash chromatography (*n*-hexane:ethyl acetate, 2:1). Yield: 100 mg (62%); (**39***a*); mp 125–126°C; ir (KBr): 1772, 1699 (C=O, imide), 1745 (Ac), 1231 (C—O) cm^{-1}; ^1H nmr: H-9: ~2.2,[s] ~2.85;[s] CH_3(Ac): 2.30, br s (3H); H-8: ~2.5[s] (1H); NCH_3: 2.91, s (3H); H-7: 3.10, t (~8 Hz); ^{13}C nmr: CH_2(9): 18.8; CH_3(Ac): 21.4; NCH_3: 28.1; C-7, -8: 40.3, 41.4; C=O(Ac): 173.3; NC=O: 176.4, 178.4. *Anal.* calcd. for $C_{17}H_{24}N_2O_4$ (320.41): C 63.73, H 7.55, N 8.74; found: C 63.45, H 7.99, N 8.44.

From **37***b* (250 mg, 0.8 mmol) by *Method B*. The pure product was obtained by flash chromatography (*n*-hexane:ethyl acetate, 2:1). Yield: 175 mg (68%) (**39***b*); mp 128–129°C; ir (KBr): 1772, 1701[u] (C=O), 1200 (C—O) cm^{-1}; ^1H nmr: H-9: 1.90,[n] 2.85,[m,n] (2 × *m* (2 × 1H); CH_3(Ac): 2.15, s (3H); H-7: ~2.75, m;[m] H-8: ~2.85, m;[m,n] NCH_3: 3.00, s (3H); ^{13}C nmr: CH_3(Ac): 18.9; NCH_3: 30.4; C-7, -8: 38.7, 39.7; C=O(Ac): 170.7; NC=O: 178.6, 178.9. *Anal.* calcd. for $C_{17}H_{24}N_2O_4$ (320.41): C 63.73, H 7.55, N 8.74; found: C 63.48, H 7.62, N 8.94.

*Preparation of 1-oxyl-3-(1,3-butadienyl)-2,2,5,5-tetramethyl-3-pyrroline (**40**)*

The anhydrous K_2CO_3 (1.75 g) and the aldehyde (**1**) (1.68 g, 0.01 mol) were added to a solution of allyltriphenylphosphonium chloride (3.38 g, 0.01 mol) in dioxane, then refluxed for 24 h, filtered off, evaporated, and the residue purified by flash chromatography (*n*-hexane: ethyl acetate, 9:1) to give **40** as a red oil. Yield: 670 mg (35%); ir ($CHCl_3$): 1620, 1595, 1580 (C=C) cm^{-1}; ms, *m/e*: M^+ 192(53.5), 177(47), 162(53.5), 119(100). *Anal.* calcd. for $C_{12}H_{18}NO$ (192.29): C 74.96, H 9.44, N 7.28; found: C 74.85, H 9.46, N 6.99.

*Preparation of hydrochloride salt of **40** (**41**)*

From **40** (384 mg, 2 mmol) according to *Method A*. Yield: 300 mg (65%); mp 149–151°C; ir (KBr): 3250–2250 (OH + N^+H) cm^{-1}; ^1H nmr: $=CH_2$: 5.12, *d* (*J*(*cis*) = 9.9 Hz); 5.24, d (*J*(*trans*) = 16.6 Hz); =CH(β): 6.54 dd ($J_{\alpha,\beta}$(*trans*) = 15.8 Hz, $J_{\beta,\gamma}$(*vic*) = 10.6 Hz); =CH(γ): 6.30 ~dt ($J_{\gamma,\delta}$(*trans*) = 16.6 Hz, $J_{\gamma,\delta}$(*cis*) ≅ $J_{\beta,\gamma}$(*vic*) = 10.3 Hz); ^{13}C nmr: $=CH_2$: 122.8; =CH(β): 125.1;[e] =CH(γ): 136.8.[e] *Anal.* calcd. for $C_{12}H_{19}NO \cdot HCl$ (229.76): C 62.74, H 8.77, N 6.10, Cl 15.43; found: C 62.82, H 8.61, N 6.02, Cl 15.91.

*Preparation of 1-oxyl-4-vinyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine (**42**)*

Anhydrous K_2CO_3 (1.75 g) and the aldehyde (**3**) (1.82 g, 0.01 mol) were added to a solution of triphenylmethylphosphonium iodide (4.2 g, 0.01 mol) in dioxane, then refluxed for 24 h, filtered off, evaporated, and the residue purified by flash chromatography (*n*-hexane:ethyl acetate, 9:1) to give **42** as a red oil. Yield: 750 mg (42%). Compound **42** was identical in all respects with the compound that has been described in the literature (11).

*Preparation of hydrochloride salt of **42** (**43**)*

From **42** (180 mg, 1 mmol) according to *Method A*. Yield: 150 mg (69%); mp 157–158°C; ir (KBr): 1650, 1610 (C=C—C=C) cm^{-1}. *Anal.* calcd. for $C_{11}H_{19}NO \cdot HCl$ (217.75): C 60.68, H 9.26, N 6.43, Cl 16.28; found: C 60.52, H 9.57, N 6.27, Cl 16.21.

Preparation of N-*acetoxy derivative of **42** (**44**)*

From **43** (108 mg, 0.5 mmol) according to *Method B*. The pure product (**44**) was obtained by flash chromatography (*n*-hexane:ethyl acetate, 9:1) as a colorless oil. Yield: 138 mg (62%); ir (KBr): 1768 (C=O), 1196 (C—O), 989 (=CH, olefin) cm^{-1}; ^1H nmr: CH_3(Ac): 2.12 s (3H); $=CH_2$: 4.99, *d* (*J* (*cis*) = 10.8 Hz), 5.08, *d* (*J* (*trans*) = 17.5 Hz); ^{13}C nmr: CH_3(Ac): 18.6; $=CH_2$: 111.5. *Anal.* calcd. for $C_{13}H_{21}NO_2$ (223.33): C 69.92, H 9.48, N 6.27; found: C 70.17, H 9.61, N 6.13.

Received November 11, 1985

JORGE D. ANUNZIATA, NORMA S. GALAVERNA, JOAQUÍN O. SINGH, and JUANA J. SILBER. Can. J. Chem. **64**, 1491 (1986).

The interaction of several aliphatic amines as *n*-donors with 1,2-, 1,3-, and 1,4-dicyanobenzenes as π acceptors in *n*-hexane has been studied. The spectroscopic behaviour of the mixtures leads us to propose that Electron Donor – Acceptor (EDA) complexes are formed. Correlations of the experimental data with the amine structure were performed for the amine–1,4-dicyanobenzene complexes. By means of free energy related substituents and regression analysis, the electronic and steric effects of three N-substituents were quantitatively separated. Thus, with *K* representing the stability constants of the complexes, the values of log *K* are correlated with Taft's polar substituent constants, σ^*, and Hancock's corrected steric substituent constants, E_s^C. The results allowed the proposal of a probable structure of the complex, at least with respect to the donor orientation.

JORGE D. ANUNZIATA, NORMA S. GALAVERNA, JOAQUÍN O. SINGH et JUANA J. SILBER. Can. J. Chem. **64**, 1491 (1986).

On a étudié l'interaction, dans le *n*-hexane, entre plusieurs amines aliphatiques agissant comme donneurs et les dicyano-1,2 (et -1,3 et -1,4) agissant comme accepteurs π. Le comportement spectroscopique des mélanges nous a conduit à proposer qu'il y a formation de complexes donneur–accepteur d'électrons (DAE). Pour les complexes des amines avec le dicyano-1,4 benzène, on a établi des corrélations entre les valeurs expérimentales et la structure de l'amine. Au moyen de relations d'énergie libre des substituants et d'analyse de régréssion, les effets électroniques et stériques des trois substituants du N ont pu être séparés quantitativement. De cette façon, les valeurs de log *K*, en prenant *K* comme la constante de stabilité des complexes, sont en corrélation avec la constante polaire de Taft du substituant, σ^*, et la constante stérique corrigée de Hancock du substituant, E_s^C. Les résultats permettent de proposer une structure probable du complexe, au moins par rapport à l'orientation du donneur.

[Traduit par la revue]

Introduction

Continuing our work involving the interactions between *n*-electron donors with π-electron acceptors (1, 2), in the presence investigation we wish to report the study of EDA (Electron Donor–Acceptor) complexation between aliphatic amines and 1,2-, 1,3-, and 1,4-dicyanobenzenes (DCB) in *n*-hexane as solvent.

We have previously determined the weak character of the EDA complexes formed between benzonitrile and aliphatic amines in the same solvent (1). The presence of another cyano group in the aromatic ring would be expected to increase its electron acceptor character since its electron affinity is also increased (3).

The π-acceptor properties of dicyano and the polycyanobenzenes in particular have been thoroughly studied in relation to π donors (4–7) with which fairly strong complexes have been encountered. However, in studies of the photochemical reactions of the dicyanobenzenes with some aliphatic amines in polar solvents, it has been proposed that the EDA complex formation in the ground state is either absent or very weak (8, 9) since these systems do not exhibit any charge-transfer absorption band.

In this work we were able to measure the stability constants (*K*) of aliphatic amines with dicyanobenzenes and correlate these values with the amine structure. It is known that the steric properties of the substituents attached to the electron donor can influence the magnitude of the complex association constant, which is smaller than that expected simply from the electronic effects when there is a close approach of the donor and the acceptor (10–12).

The reactivity of the aliphatic amines towards lone-pair acceptors is generally governed by the polar and steric factors of the three N-substituents (13–16). We have analyzed the effect of these types of substituents from a number of aliphatic amines upon complex formation with 1,4-DCB. The analyses were carried out by means of free energy substituent parameters (17), which allowed quantitative determination of the magnitude of the steric effects with respect to the polar effect. The correlations obtained are compared with other types of amine–EDA complexes and as $n-\sigma$ (14, 17) and $n-\upsilon$ (17, 18).

Experimental

n-Hexane (Carlo Erba R.P.) was purified as previously described (1); diethyl, triethyl, *n*-butyl, di-*n*-butyl, tri-*n*-butyl, *n*-propyl, di-*n*-propyl, tri-*n*-propyl, isopropyl, isobutyl, di-isobutyl, *tert*-butyl, and *sec*-butyl amines (Aldrich Chem. Co.) were dried with KOH pellets and distilled in a dry nitrogen atmosphere over metallic sodium.

All the reagents were degassed and distilled in a high vacuum line just before use to ensure anhydrous conditions. To obtain reproducible results special care should be taken to assure the purity of the amine. The latter was controlled by the ultraviolet (uv) cutoff point and gas–liquid chromatography (glc) (Porapak Q., Apiezon L.). 1,2-DCB (Aldrich Chem. Co.), 1,3-DCB (Fluka), and 1,4-DCB (Fluka) were recrystallized several times from triply distilled water and then sublimed under vacuum.

Spectra were obtained in thermostatted cells in a Cary 17 spectrophotometer. The working temperatures were 15, 27, and 40±0.1°C.

Solutions were prepared by weighing. The ranges of concentration used were $0.5 \times 10^{-4} - 6 \times 10^{-4}$ *M* for the DCBs and 0.2–3 *M* for the amines. All solutions were freshly prepared prior to use.

Data processing was performed on a Digital PDP 11/34 computer.

Results

Characterization of the EDA complexes and measurement of stability constants

The spectral characteristics of the mixtures of amines with DCBs show the same general features previously observed for the amine–benzonitrile (1) and amine–dinitrobenzene (2) systems. Thus, although no new band is observed, there is an appreciable deviation from additivity of the optical density with

TABLE 1. Experimental results for the K values and ε_{AD} for diethylamine–DCB complexes in n-hexane and 27°C and λ = 294 nm

Acceptor	K ($dm^3\ mol^{-1}$)[a]	ε_{AD} ($dm^3\ mol^{-1}\ cm^{-1}$)[b]	Correlation coefficient	$E_{1/2}$ (eV)
1,2-DCB	0.060 ± 0.006	2360	0.9980	−2.12
1,3-DCB	0.180 ± 0.010	460	0.9990	−2.17
1,4-DCB	0.088 ± 0.009	3870	0.9988	−1.97

[a]The error in K was calculated as in ref. 1.
[b]$\varepsilon_{AD} = \varepsilon_A + \varepsilon_D + \varepsilon_C$.
[c]$E_{1/2}$ = half-wave potential (ref. 31).

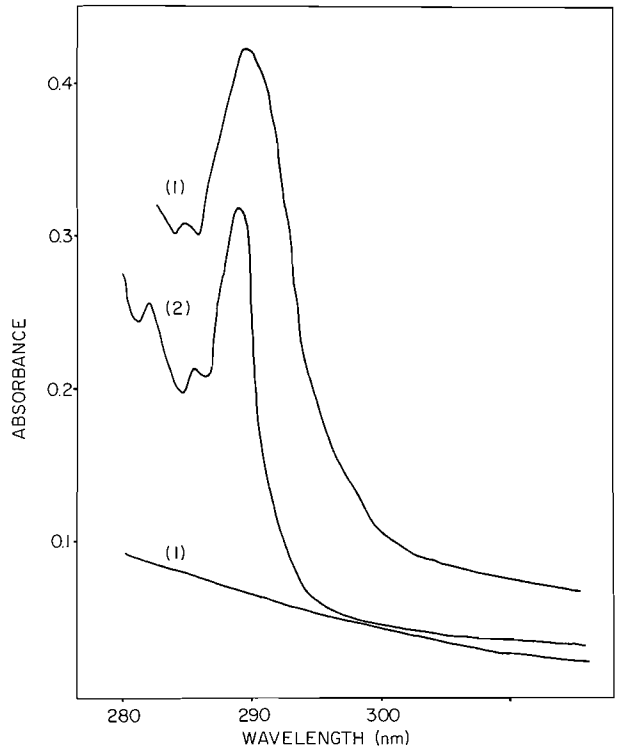

FIG. 1. Typical spectral results: (1) n-BA 3.04 M; (2) 1,4-DCB 1.75×10^{-4} M; (3) mixture of n-BA 3.04 M and 1,4-DCB 1.75×10^{-4} M. Solvent: n-hexane; temperature: 27 ± 0.1°C.

respect to that of either component alone. This effect was best observed in a range of wavelengths from 290 to 320 nm. Typical spectral results are shown in Fig. 1.

The enhanced absorbance for the amine–DCB systems was interpreted as due to a specific interaction of the type of EDA complexation.

Thus if a 1:1 complex is assumed, the observed absorbance, A_T, of a system can then be interpreted as the sum of three components (eq. [1]).

$$[1] \quad A_T = A_A + A_D + A_D$$

where A_A, A_D, and A_{AD} stand for the absorbance of the acceptor (DCB), the donor (amine), and the complex at equilibrium.

A value of absorbance, A_C, can now be defined as a function of the experimental value, A_T, and the corresponding values for the initial concentration of the acceptor, A_{A_0}, and the donor, A_{D_0} (eq. [2]).

$$[2] \quad A_C = A_T - (A_{A_0} + A_{D_0})$$

Hence, A_C is a measure of the deviation from additivity of the mixtures, and in every system was calculated for several ratios of amine–DCB where the amine concentration, D_0, was always at least 500-fold in excess with respect to the DCB concentrations, A_0. The most accurate measurements could be performed at 294 nm, which was therefore the wavelength chosen to calculate K. K can be determined graphically by utilizing a known equation derived (19) for the case in which the absorption of the complex overlaps with that of the donor and the acceptor, such as eq. [3].

$$[3] \quad \frac{A_0 D_0}{A_C(A_0 + D_0)} = \frac{1}{K\varepsilon_C}\frac{1}{(A_0 + D_0)} + \frac{1}{\varepsilon_C}$$

where A_0 and D_0 are the initial concentrations of the acceptor and the donor and $\varepsilon_C = \varepsilon_{AD} - (\varepsilon_D + \varepsilon_A)$, where ε_{AD}, ε_D, and ε_A are the molar extinction coefficients of the complex, the donor, and acceptor, respectively, at the chosen wavelength. The values of K and ε_C, thus calculated, are used to initiate an iterative procedure previously described (1, 2), which provides more reliable values under our experimental conditions. The results obtained for the amine complexes with the three acceptors are depicted in Table 1. On the other hand, Table 2 shows the results for the complexes of 1,4-DCB with the thirteen amines studied, to analyze the effect of the structure of the donor on the stability of the complexes.

The behaviour of K with temperature for every system gives values of $-\Delta H$ of the order of 12 ± 1.0 kJ mol^{-1}, which are consistent with the values expected for the formation of weak EDA complexes (20).

Correlations of K *with the structure of the amines*

Earlier works correlated the reactivity of amines with the total polar effects of the three N-substituents by using the summation of the Taft σ* values ($\Sigma\sigma^*$) (13). The deviation of the data for the "hindered" amines from the apparent correlation for the "unhindered" compounds was only qualitatively attributed to the steric effect of bulky N-substituents (17). Since the steric effect of the three N-substituents is not additive (21), we attempted to separate the polar and steric effects of these N-substituents, namely R^1, R^2, and R^3, by means of the known (14) multiparameter eq. [4].

$$[4] \quad \log K = \rho^*\Sigma\sigma^* + a_1E_S^C(R^1) + a_2E_S^C(R^2) + a_3E_S^C(R^3) + C$$

where $E_S^C(R^1)$, $E_S^C(R^2)$, and $E_S^C(R^3)$ are respectively the Hancock (22) corrected steric constants of N-substituents. R^1, R^2, and R^3 where $E_S^C(R^1) \geq E_S^C(R^2) \geq E_S^C(R^3)$; ρ^*, a_1, a_2, a_3 are the susceptibility constants, and C is the intercept.

The value of E_S^C is a steric constant E_S, corrected by the hyperconjugation effect of α-hydrogen atoms, which is related to the Hancock constant by eq. [5].

[5] $E_S^C = E_S - 0.306(3 - n_H)$

where n_H is the number of α-hydrogen atoms.

In eq. [4], the overall effects of the N-substituents of the aliphatic amines on lone-pair acceptors are quantitatively factored into electronic and steric effects.

The correlation according to eq. [4] and the multiple regression analysis for the equilibrium constants of Table 2 are gathered in Table 3.

Employing the correlation obtained by means of eq. [4], we now compared the values calculated for log K (reported in Table 2) to the experimental data. From this comparison and by considering the high confidence level obtained in the correlation (F-values in Table 3), we were able to presume that this equation takes into account both polar and steric effects in these types of complexes and it therefore has good predictive value.

Discussion

The fact that we were able to determine a finite value of K and a constant value of ε_{AD} for the DCB – aliphatic amine systems is interpreted as though we were actually detecting a complex at equilibrium. However, if these are indeed EDA complexes, they are undoubtedly weak. Furthermore, we expect that these complexes have a 1:1 stoichiometry, as in the n–π systems previously studied (1, 2). Problems of solubility prevented experiments in the presence of an excess of DCB, as were carried out for the benzonitrile systems. Nevertheless, we feel that our conclusions are justified by the fact that the data fit equations derived for 1:1 complexes, even when the concentration of DCBs was varied more than tenfold within the entire range of the donor. Moreover, other types of interaction, such as electrostatic or dipolar forces that may contribute to gain stabilization (23, 24), cannot be altogether disregarded. Previous work performed in our laboratory on the solvatochromism of the uv spectra of π-acceptors such as benzonitrile (25), and more recently with nitrobenzene and DCBs (26), demonstrated that the solvent effects of the aliphatic amines cannot be accounted for only by the dipolar interactions and that EDA complex formation should be postulated.

In agreement with the latter statement we could consider that the charge transfer band of these complexes is not observed due to the overlap of these bands with those of the donor and the acceptor. Therefore, its maximum should appear in a uv region that is not experimentally accessible under the conditions required to detect these weak complexes.

The theory for EDA complexes (20) predicts a correlation of

the position of the maximum of the charge-transfer transition (λ_{max}) with the ionization potential (I_P) of the donor and electron affinity (E_A) of the acceptor.

We could attempt to establish these correlations for the amine–1,4-DCB systems, by considering that $\varepsilon_{AD\,max}$ is not drastically different for the various amines (1, 2) and that it can be assumed the calculated ε_{AD} at 294 nm represents the extinction coefficient of the tail of the charge-transfer band. Consequently, an increase in ε_{AD} reflects the shift in λ_{max}. Then, by inspection of Table 2, it can be observed that ε_{AD} increases as I_P decreases. Moreover, the tendency observed is very similar to the corresponding I_2 – aliphatic amine (14) and 1,3,5-trinitrobenzene – aliphatic amine complexes (27, 28). These correlations lead us to conclude that the interactions of 1,4-DCB–aliphatic amines are the result of intermolecular EDA complexes.

On the other hand, and following the same reasoning for a given donor, a greater value of ε_{AD} would be obtained for an acceptor with a greater E_A. If we compare the half-wave potential, $E_{1/2}$, taken as a measure of E_A (29) with the values of ε_{AD} for the amine complexes with the three DCBs (Table 1), the predicted trend is actually observed.

Then, all the evidence agrees with the assumption of an EDA complex formation. It should be noted that the K values for the amine–DCB complexes are higher than those obtained for the corresponding amines with benzonitrile (1). This is also expected, since the presence of a second electron-withdrawing cyano group increases the acceptor strength of the aromatic ring.

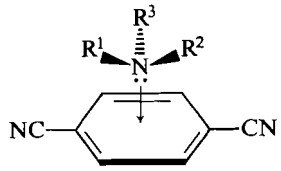
The analysis of the applications of eq. [4] to correlate the K values in the amine–1,4-DCB systems with the structure of the amines yields some interesting results. As shown in Table 3, a negative ρ^* value is obtained; then, the greater the electron-donating ability of the N-substituents, the greater also the association reactivity of the amines. On the other hand, the positive a_1, a_2, and a_3 values show that bulkier substituents give rise to smaller K values. These susceptibility constants of the steric terms decrease in the order of $a_1 > a_2 > a_3$. This means that K values are more sensitive to the steric effect of R^1 (the smallest group) and least sensitive to that of R^3.

If our data are compared with the same type of correlation obtained for other EDA complexes (see Table 3), such as the amine–iodine (14, 17) in *n*-hexane and amine–trimethylboron (17, 18), it is observed that the ratio of $a_1:a_2:a_3$ is nearly 4:3:1 for our systems, while it is 4:2:1 for the iodine systems and 10:3:1 for the trimethylboron complexes. This comparison, in principle, suggests the idea that the relative significance of the steric effects of the component substituents seems to be similar in the 1,4-DCB–amine and iodine–amine complexes but very different from that of the trimethylboron complexes.

A high value of negative ρ^* as observed for the latter complexes indicates strong complexation, which is derived from a closer approach of the donor and acceptor.

However, a much lower value of negative ρ^* for the 1,4-DCB–amine system implies looser complexes, and consequently the susceptibility to steric factors is also lower.

Apparently the steric effects of R^1 and R^2 in the 1,4-DCB–amine complexes are similar but much greater than R^3. This would mean that the bulkier N-substituent, R^3, tends to be at a greater distance from the acceptor moiety than R^1 and R^2. In this manner, if we assume that the approach of the lone-pair electrons of the donor is perpendicular to the benzene ring, the geometry of these complexes would be as in structure **I**.



I

In the case of 1,4-DCB, the more symmetric of the acceptors under study, the geometry of **I** seems to be quite reasonable. In support of this idea, it can be cited that theoretical calculations for the $n-\pi$ complexes between aliphatic amine and *p*-benzoquinones (30) showed that the *n*-donor always approaches in a manner perpendicular to the plane of the ring.

With respect to 1,2- and 1,3-DCB, more data are needed to support certain conclusions. However, the fact that 1,3-DCB gives the greater value of K (Table 1) can be explained only if orientational complexes are proposed (2). In this case, there will be a preferential approach of the donor to the region of the smallest electronic density in the benzene ring. This region would be between both cyano groups where the sum of the inductive and resonance effects is the greatest, that is to say an approach toward position 2 in 1,3-DCB. No preferential region of this type can be postulated for 1,2- and 1,4-DCB by this undoubtedly very simplified analysis. The preferential site of attack has been proposed for other $n-\pi$ complexes (30).

Work is now in progress to gather more data for the 1,2- and 1,3-DCB–amine complexes, together with theoretical calculations to establish the probable geometry of these complexes.

Atomic properties and the reactivity of carbenes

PRESTON J. MACDOUGALL[1] AND RICHARD F. W. BADER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 26, 1985

PRESTON J. MACDOUGALL and RICHARD F. W. BADER. Can. J. Chem. **64**, 1496 (1986).

The properties of the atoms in a number of substituted carbenes and silylene provide an understanding of the relative stabilities of their lowest lying singlet and triplet states and of their differing chemical reactivities. The theory of atoms in molecules defines all of an atom's properties, including its energy. In this research one finds that the methylenic carbon or silicon atom is energetically most stable in the triplet state of each system, while the ligands are most stable in the corresponding singlet state. It is also found that the average electron populations of the carbon and silicon atoms are largest in the triplet states. In systems where the carbon or silicon atom bears a net positive charge, as found in $CHNH_2$, CF_2, and SiH_2, the excess in the transfer of charge to the more electronegative ligands in the singlet states stabilizes the ligands more than it destabilizes the central atom. These systems have singlet ground states. The relative susceptibility of singlet and triplet carbenes to electrophilic and nucleophilic attack is determined by the properties of the Laplacian of the charge distribution. This quantity assimilates the model of localized electrons in terms of local concentrations of electronic charge. It also determines regions from which electronic charge is locally depleted. These regions are found to coincide with those where the lowest-lying vacant orbital is concentrated.

PRESTON J. MACDOUGALL et RICHARD F. W. BADER. Can. J. Chem. **64**, 1496 (1986).

Les propriétés des atomes dans un certain nombre de carbènes et de silylènes substitués fournissent une base pour la compréhension des stabilités relatives de leurs états singulet et triplet de plus basses énergies ainsi que de leurs diverses réactivités chimiques. La théorie l'atome dans les molécules définit toutes les propriétés des atomes, y compris leur énergie. Dans cette recherche, on trouve que les atomes de carbone ou de silicium méthyléniques sont, d'un point de vue énergétique, plus stable dans l'état triplet de chaque système alors que les ligands sont plus stables dans l'état singulet correspondant. On a aussi trouvé que les populations électroniques moyennes des atomes de carbone et de silicium sont plus élevées dans les états triplets. Dans les systèmes les atomes de carbone ou de silicium portent une charge positive nette, comme dans où $CHNH_2$, CF_2 et SiH_2, l'excès dans le transfert de charge vers les ligands plus électronégatifs des états singulets a comme effet de plus stabiliser les ligands que de déstabiliser l'atome central. Les états fondamentaux de ces systèmes sont singulets. En se basant sur les propriétés de la distribution de charge de Laplace, on a déterminé les susceptibilités relatives des carbènes singulet et triplet aux réactions d'attaque électrophile et nucléophile. Cette fonction assimile le modèle des électrons localisés en fonction de concentrations locales de la charge électronique. On détermine aussi les régions à partir desquelles la charge électronique est localement épuisée. On a trouvé que ces régions coïncident avec celles dont l'orbitale basse vacante est concentrée.

[Traduit par la revue]

Introduction

This paper relates the chemistry of carbenes and related compounds to the properties of their constituent atoms and the bonds which link them. The atoms and bonds are in turn defined in terms of salient properties of the charge distribution, properties that are determined by the forces acting within the system. Thus the concepts of atoms and bonds serve to both summarize the physics of a system and provide for its translation into the language of chemistry.

The chemistry of a carbene is dependent upon its spin multiplicity (1). On the basis of *chemical* evidence methylene has been shown to have a triplet ground state (2*a*). This was in accord with Herzberg's earlier spectroscopic findings (2*b*). Difluoromethylene and silylene, SiH_2, on the other hand, possess singlet ground states (3). This paper relates the relative stabilities of the singlet and triplet states to the properties of the central carbon or silicon atom and to the behaviour of the nonbonded charge concentrations in the valence shells of these atoms. These charge concentrations, two in a triplet and one in a singlet, are described not within an orbital model but rather in terms of a property of the total charge density, its Laplacian. The total charge density exhibits local maxima only at the positions of nuclei and its topology, while providing the basis for the definition of atoms and molecular structure (4), gives no indication of concentrations of charge as anticipated in terms of the Lewis electron pair model or localized orbital models of electronic structure. On the other hand, the Laplacian of a scalar function such as ρ, the quantity $\nabla^2\rho$, magnifies any local variations in the function. Just as energy changes of chemical interest are found to be only small fractions of the total energy of a molecular system, so chemically important properties are found to correspond to relatively small local variations in the charge density. These local variations in the otherwise smooth topology of ρ are translated by its Laplacian into the familiar model of localized bonded and nonbonded "electron pairs", i.e. local concentrations of electronic charge (5).

When the Laplacian of ρ is negative at a given point in space ($\nabla^2\rho < 0$), it means that the value of ρ at that point is greater than the average of its values at all neighbouring points. A local maximum in $-\nabla^2\rho$ thus means that electronic charge is concentrated or compressed in the region of the maximum. Correspondingly, a local minimum in $-\nabla^2\rho$ means that charge is locally depleted, or that the charge density is expanded in the region of the minimum. It must be borne in mind that stationary points in the Laplacian of ρ do not determine maxima or minima in ρ itself but rather the points where electronic charge is locally compressed ($\nabla^2\rho < 0$) or expanded ($\nabla^2\rho > 0$).

Singlet carbenes are known to exhibit ambiphilic characteristics. It has been shown that the local charge concentrations and depletions, the lumps and holes in a charge distribution as defined by the Laplacian of ρ, determine the sites of electrophilic and nucleophilic attack, respectively (5). The sizes and shapes of these lumps and holes in the charge distributions of a variety of carbenes, silylenes, and vinylidenes are used to rationalize the predominance of either electrophilic or nucleophilic behaviour in these molecules.

Calculations

The results for the singlet states were obtained from single determinantal calculations using the 6-31G** basis set. Calculation of the triplet state functions used the same basis but employed the unrestricted SCF procedure (the 6-21G** basis was used for singlet and triplet SiH_2). All geometries were optimized at either of these two levels of theory and the results are given in Table 1. The bonds in CLi_2 are ionic with little directional character and the bending force constant for this molecule is very small. The predicted geometries of such triatomic molecules are very dependent upon the adequacy of the basis set used to describe the negatively charged central atom.[2] With the addition of an extra set of diffuse s, p, and d functions on the C atom the CLi_2 molecule in its triplet state is predicted to be bent with a bond angle of 111.9°. The molecule is still a floppy one and the energy difference between the linear and equilibrium geometries is only 1.4 kcal/mol. Convergence difficulties were encountered in the calculation of the singlet state of this molecule, but it has been previously shown that the ground state of CLi_2 is a triplet (7). The singlet state of formylmethylene is calculated to have a nonplanar geometry at the 6-31G** basis set as previously reported by Bouma *et al.* (8). We find a slightly lower energy for this state than that found by Bouma *et al.*, who state that with correlation, formylmethylene isomerizes to ketene.

In the linear geometry of a carbene the $2p_z$ and $2p_x$ orbitals on carbon (the $3a_1$ and $1b_1$ orbitals, respectively, of the bent molecule) are degenerate and of π symmetry. With an increasing departure from linearity the $3a_1$ orbital becomes increasingly more stable than the $1b_1$ orbital. Thus for linear or near linear geometries Hund's rule applies to yield a $^3\Sigma_g$ or $^3B_1$ ground state from the configurations $\ldots\pi^2$ or $\ldots 3a_1 1b_1$. For a strongly bent geometry the ground state will be a singlet, $\ldots 3a^2$,

[2]Grev and Schaefer (6) have found that two sets of d orbitals are necessary to properly describe the ground state of CSi_2, which is bent. We have since calculated that the net charge on C in this molecule is −2.69 e. We employed their expanded basis set for C in our geometry optimization of triplet CLi_2.

$^1A_1$. Thus there is a close connection between the geometry and spin multiplicity of a carbene and one notes in Table 1 that the calculated bond angles of the triplet states are always larger than those of the singlets.

A $^1A_1$ state is also obtained by double occupation of the $1b_1$ orbital and the ground state of a singlet carbene is better described in terms of a linear combination of these two lowest $^1A_1$ determinantal state functions. A two-state CI calculation (at the single-state geometries) was carried out for CH_2, CF_2, and SiH_2 to determine its effect on the properties of the electronic charge distribution. The contribution of the upper state to the total charge distribution was only a few percent in each case. While the effect on the singlet–triplet energy separation was significant, the quantitative changes in ρ amounted to only a few percent and qualitatively the charge distributions were left unaltered. These results are summarized in the Appendix. Our two configuration CI calculations impose the frozen orbital approximation. Two configuration SCF calculations which do not invoke this approximation give smaller singlet–triplet splitting energies, 22.0 and 12.8 kcal/mol for methylene (9, 10). The latter was obtained using a basis of quality similar to ours.

A recent review emphasizes the sensitivity of the singlet–triplet splitting to the level of theory used (11).

Atomic properties and ground state multiplicities

As has been demonstrated (12) and recently reviewed for the chemical reader (13), the atomic boundaries and the network of bonds are determined by the gradient vector field of the charge density (see Fig. 1). The atomic boundaries exhibit a zero flux in the gradient vectors of ρ and they thus satisfy the quantum condition for the definition of a subsystem with well-defined properties. Five atomic properties will be used in the present investigation:

(*a*) atomic charge of atom Ω, $q(\Omega)$ is obtained by integration of ρ over the basin of atom Ω to obtain its average electron population $N(\Omega)$ followed by the subtraction of this average electron population from the nuclear charge, Z_Ω,

$$[1] \quad q(\Omega) = Z_\Omega - \int_\Omega \rho d\tau = Z_\Omega - N(\Omega)$$

(*b*) Atomic dipole $\boldsymbol{\mu}(\Omega)$ is obtained by weighting the integration of ρ with the position vector $\boldsymbol{r}$ with origin at the nucleus of Ω,

$$[2] \quad \boldsymbol{\mu}(\Omega) = \int_\Omega \boldsymbol{r}\rho d\tau$$

(*c*) Spin population $S(\Omega)$, is obtained by integrating the spin density $\sigma(\boldsymbol{r}) = \rho^\alpha(\boldsymbol{r}) - \rho^\beta(\boldsymbol{r})$, the difference between the α- and β-spin densities, over the basin of Ω to give the average number of excess α electrons (if $S(\Omega) > 0$) on atom Ω (14)

$$[3] \quad S(\Omega) = \int_\Omega \sigma(\boldsymbol{r}) d\tau$$

(*d*) The degree of localization of the electrons on atom Ω and denoted by $l(\Omega)$ is obtained by integrating the Fermi hole over the basin of the atom, $F(\Omega,\Omega)$, and comparing it with the average number of electrons in the atom (15*a*)

$$[4] \quad F(\Omega,\Omega) = -\Sigma_{i,j}[\int_\Omega \phi_i \phi_j d\tau]^2$$

Conceptually this is equivalent to averaging, over all reference coordinates within atom Ω, the extent to which the "exchange charge density" (15*b*) is contained within that atom. The limiting value of the integrated Fermi hole, $F(\Omega,\Omega)$, is $-N(\Omega)$. At this limit the $N(\Omega)$ electrons are completely localized on atom Ω, there is no exchange of these electrons with other electrons in the system and the fluctuation in the average population $N(\Omega)$ is zero. Thus the ratio $|F(\Omega,\Omega)/N(\Omega)|$ determines the fraction of the maximum possible localization and when multiplied by 100 determines the percent localization of the electrons on atom Ω, $l(\Omega)$.

(*e*) The energy of atom Ω, $E(\Omega)$, is most simply obtained by integrating the kinetic energy density over the atom to obtain its average kinetic energy, $T(\Omega)$. Since the atom is a quantum subsystem, the virial theorem applies and $E(\Omega) = -T(\Omega)$.[3] For equilibrium geometries, as is true here, the sum of the atomic energies equals the total energy of the molecule,

$$E = \Sigma_\Omega E(\Omega)$$

We begin with a discussion of the atomic properties of the systems listed in Table 2. The ground states of CH_2 and the systems listed above it are triplets, while those of the remaining systems are singlets. The charge distributions of CH_2 and SiH_2 shown in Fig. 1 serve to illustrate the definition of atomic boundaries and how the resulting atomic properties reflect the principal features of a charge distribution. There is an almost equal sharing of bonding density between C and H in saturated hydrocarbons, $q(H) = -0.06$ e in CH_4. This remains true for the two states of methylene where the charges on H are of even smaller magnitude. In SiH_2 there is a substantial transfer of charge from Si to H as is evident in the display of ρ; the distribution on H is expanded and more diffuse compared to that for CH_2, and ρ is separately localized in each atomic basin to a greater extent in SiH_2 than it is in CH_2. This difference in the degree of localization of charge is quantified by the values of $l(\Omega)$ (Table 2) which show that the electrons on the H atoms in SiH_2 are 76% localized compared to a value of only 48% in CH_2.

The properties of ρ at the bond saddle point serve to characterize the nature of the bond (Table 3). The value of ρ at the bond saddle point, the quantity ρ_b, tends to smaller values as the bonding tends towards the ionic limit. Thus ρ_b is greater for CH_2 than it is for SiH_2 which in turn possesses a value greater than that for CLi_2, for which the bonding is ionic. One notes that the remaining core density on each Li atom is highly localized (Table 2). Negative values of $\nabla^2\rho_b$, the value of the Laplacian of ρ at the bond saddle point, indicate that the negative curvatures of ρ (those perpendicular to the bond) dominate the interaction. This behaviour is typical of a shared interaction such as is found in CH_2 — charge is accumulated along the bond path as a result of the perpendicular contractions of ρ (5, 16). In SiH_2, $\nabla^2\rho_b > 0$ indicating that the Si—H interactions are dominated by the contractions of ρ away from the interatomic surface towards each of the nuclei. This behaviour is typical of bonds with substantial charge transfer and localized atomic distributions. The reader is again referred to Fig. 1 to appreciate the differing behaviours associated with a large ρ_b and negative $\nabla^2\rho_b$ value and a low ρ_b and positive $\nabla^2\rho_b$ value.

There is considerable charge transfer from carbon to fluorine and nitrogen (Table 2) and the $\nabla^2\rho_b$ values for the C—F and

[3] Because the approximate state functions used here do not satisfy the Hellmann–Feynman theorem, there are small net forces calculated for the nuclei at the equilibrium geometry. Thus the ratio $|E/T|$ differs slightly from unity. The values of $T(\Omega)$ were multiplied by the $|E/T|$ ratio in order that the sum of the atomic energies would equal E. These are small corrections, the ratios for the triplet and singlet states, respectively, are 1.0001 and 0.9991 for CH_2, 1.0002 and 1.0004 for SiH_2.

*Atomic dipoles in atomic units. 1 au = 2.542 D. A positive value for μ means the negative end of dipole is directed away from ligands.
†All energy differences are in kcal mol^{-1} and all refer to E(triplet state) − E(singlet state).
‡The individual atomic contributions to ΔE from the formyl group are: ΔE(C′) = −59, ΔE(O) = +74, and ΔE(H) = −2 all in kcal mol^{-1}.

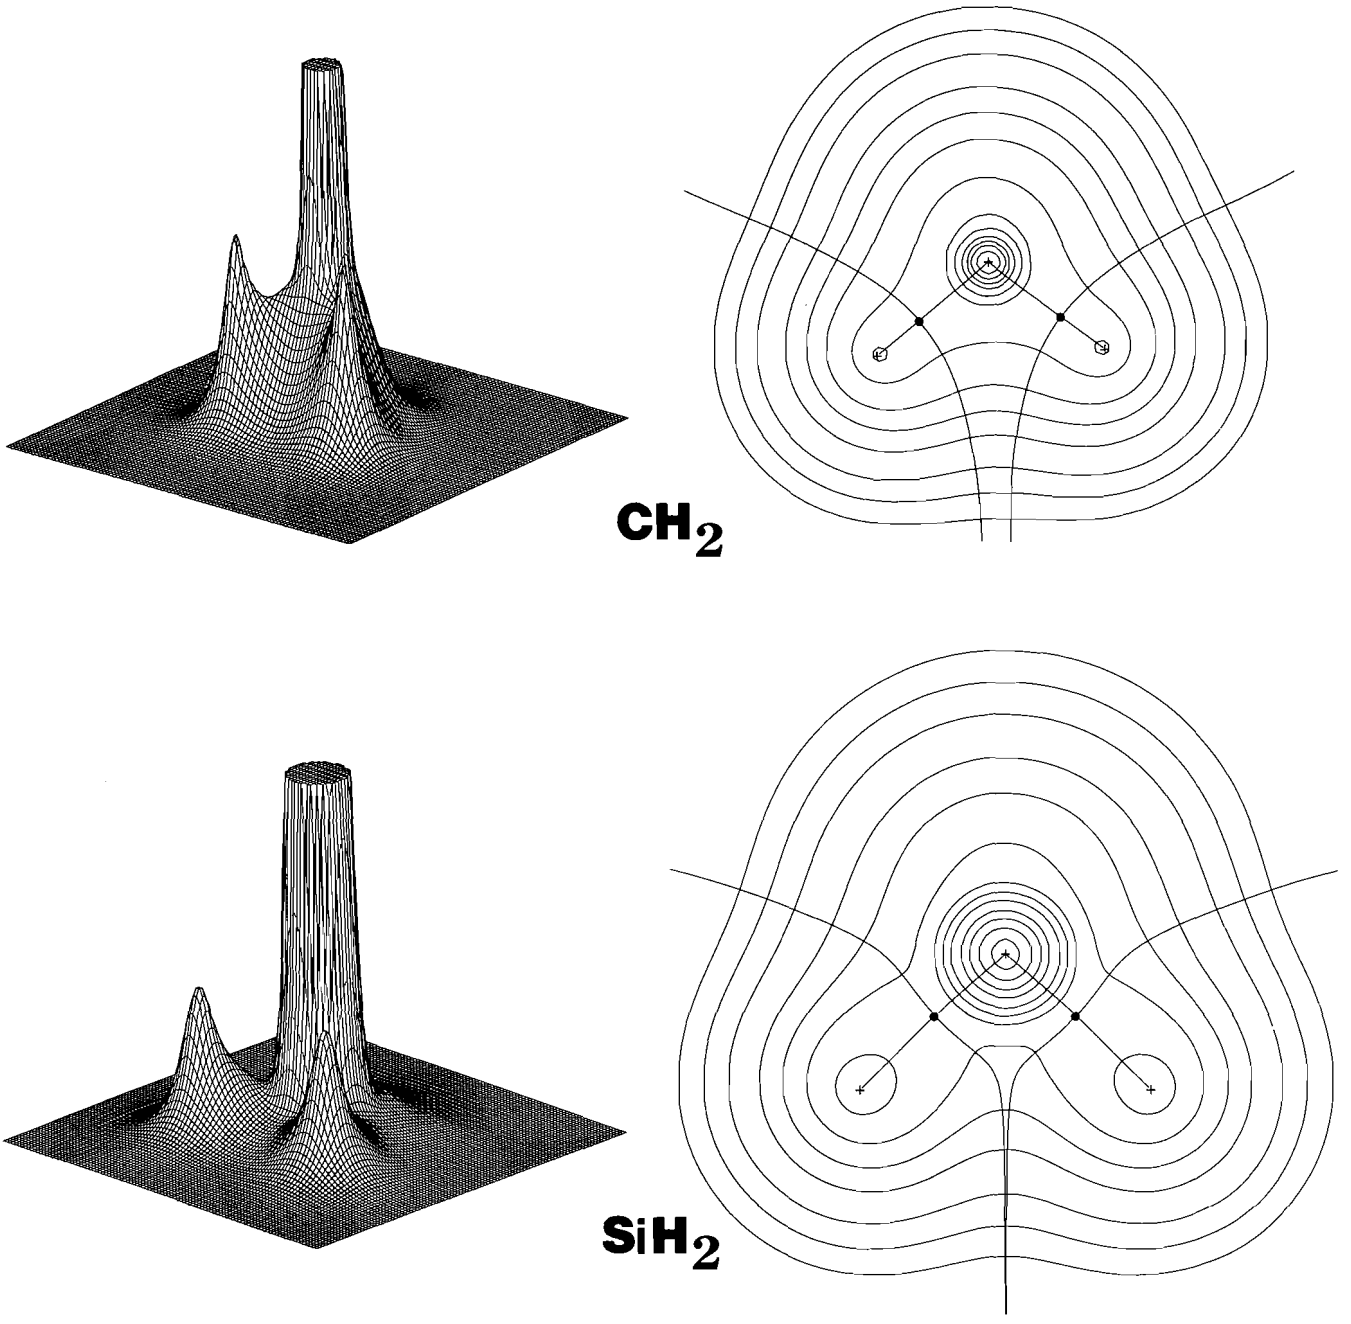

FIG. 1. Contour maps and corresponding relief maps of the singlet charge distributions in the plane of the nuclei for CH_2 and SiH_2. The same vertical scaling is used in the relief maps. The maxima in ρ at the positions of the C and Si nuclei are not shown. The black dots on the contour map denote the positions of the bond saddle points. Also shown are the bond paths and the atomic boundaries defined by the interatomic surfaces. As illustrated in the relief maps, the value of ρ at a bond saddle point ρ_b, is the minimum value attained by ρ along the bond path and the maximum value attained in the interatomic surface. A bond path and its associated surface are defined respectively by the gradient vectors of ρ which originate and terminate at the bond saddle point. The contour values in au are 0.002, 0.004, and 0.008 increasing by powers of 10 to a maximum value of 20 au.

C—N bonds indicate that these interactions are dominated by a contraction of charge towards each of the nuclei. These interactions are, however, not ionic but very polar shared interactions as indicated by the relatively large values of ρ_b.

Essentially all of the unpaired spin density is localized on the carbon atom in the triplet states of CLi_2 and CH_2. There is a small excess in the transfer of β-spin density compared to α-spin density to the carbon atom in these systems with the result that the ligands have small net α spin populations. In $CHNH_2$, CF_2, and SiH_2 there is a significant delocalization of the spin density onto the ligands as a result of the transfer of charge to the ligands from the carbon and silicon atoms in these molecules. There is also a significant delocalization of the spin density in formylmethylene and vinylmethylene into the CH=O and CH=CH_2 fragments. Since there is no net transfer of charge from the methylenic carbon in these two molecules, the spin delocalization is accomplished through a spin polarization rather than by a transfer of charge. From the data given in Table 2 it is seen that the spin populations of the methylenic carbons are reduced from the value of two. Negative spin populations, approximately

†⊥ indicates major axis is perpendicular to the plane of the Y—X—Y′ nuclei. In singlet formylmethylene the major axis of the C′=O bond is perpendicular to the plane of the formyl group. All other bonds have their major axis in the Y—X—Y′ plane.

*There are two such holes in the singlet states of all systems, while only one in the triplet states.

equal to the reduction in S(C), are present on the adjacent carbon atoms. The terminal oxygen and carbon atoms again have positive spin populations. The presence of alternating net spin populations on neighbouring atoms as a mechanism for spin delocalization has been previously noted (14). This mechanism is different from that operative in the amino- and difluoro-molecules where there is a simple transfer of charge and all the atoms exhibit spin populations of the same sign.

The final property listed in Table 3 is the bond ellipticity ϵ defined as $\epsilon = (\lambda_1/\lambda_2 - 1)$ where λ_1 and λ_2 are the magnitudes of the two negative curvatures of ρ at the bond saddle point with $\lambda_1 > \lambda_2$ (17). When these two curvatures are not equal, the charge density in the interatomic surface falls off from its maximum value at the saddle point more slowly in the plane containing the smallest of the two curvatures, indicating that charge density is preferentially accumulated in this particular plane. The C=C bond in ethylene, for example, has $\epsilon > 0$ and the axis of the smaller curvature lies in the plane perpendicular to the plane of the nuclei — charge density is preferentially accumulated in the plane of the "π" orbital. The data in Table 3 indicate that the charge of the methylenic bonds is preferentially accumulated in the plane of the nuclei in the singlet molecules and in the plane perpendicular to this for all of the triplet molecules.

A carbon–carbon bond order n can be defined in terms of the value of ρ_b (17), giving $n = 1, 2, 3$, respectively for ethane, ethylene, and acetylene. In terms of the bond order and bond ellipticity parameters, one can show that in addition to the spin polarization present in the formyl- and vinylmethylenes, there is an essentially complete delocalization of the π density in these systems. The two C—C bonds in vinylmethylene have equal bond orders of 1.6 and similar ellipticities with their major axes in the π plane. The C—C bond order in the triplet state of formylmethylene is 1.5 again indicating a delocalization of the π density. The spin populations, bond orders, and bond ellipticities indicate that vinylmethylene is best described as a vinyl radical with an extra unpaired and localized σ electron resulting from the loss of a terminal hydrogen atom. Hutton *et al.* (18) have arrived at the same description of this molecule on the basis of its esr spectrum.

The perturbation of the nonbonded charge density on carbon is minimal in the methylene systems because of the essentially equal sharing of the bonding charge density between the C and H atoms. This is reflected in the near zero atomic charges on carbon in these systems and in their small atomic dipoles. Hence the triplet state is of lower energy than the singlet state for methylene because of Hund's rule, as it is for the carbon atom itself. Indeed the singlet–triplet energy gaps are of the same order of magnitude for the two systems. The relative singlet–triplet stabilities in the remaining systems will be discussed by comparing the properties of their charge distributions with those for the two corresponding states of CH_2.

The single most distinguishing feature of the examples listed in Table 2 relative to methylene is the extent and direction of charge transfer. A transfer of charge from the ligands to the carbon as in CLi_2 leaves the triplet as the ground state. When charge is transferred to the ligands as in $CHNH_2$, CF_2, and SiH_2, the singlet state is more stable than the triplet. In the two

remaining systems where the methylenic carbon is bonded to another carbon atom, the net charges on C are similar to those found in CH_2 itself and the triplet states are again the ground states. One notes as well that the central carbon and silicon atoms of the triplet states are more electronegative than they are in the corresponding singlets; q(C) is more negative for the triplet than for the singlet state in every system listed in Table 2.

The energies listed in Table 2, $\Delta E(\Omega)$, are the differences in the atomic energies between the triplet and singlet states for each molecular system. We first discuss the systems with a charge transfer from carbon or silicon to the ligands. In each of these systems the central atom is most stable in the triplet state and its energy change is the largest of the atoms in the molecule. The ligands, on the other hand, are most stable in the singlet states. These relative atomic stabilities parallel the differences in the average atomic populations between the triplet and singlet states. The populations for C and Si are largest in the triplet states while those for H, N, and F are largest in the singlet states. In the $CHNH_2$, CF_2, and SiH_2 systems the excess in the transfer of charge to the more electronegative ligands in the singlet states stabilizes the ligands more than it destabilizes the less electronegative central atom and the singlet states are most stable. Given the differing populations in these systems, the favoured state is the singlet as the largest amount of negative charge is placed on the most electronegative atoms in this state.

The singlet–triplet atomic charge and energy differences for formylmethylene follow the same patterns as those already discussed if the formyl group is considered as a single entity. Within this group there is a significant charge transfer from the carbon to the oxygen atom. The oxygen atom has its largest electron population and lowest energy in the singlet state and behaves as do the ligands discussed above. The formyl carbon, however, possesses a larger population and its lowest energy in the triplet state, both differences being greater than for the methylenic carbon. As discussed above there is a polarization of the spin density and a delocalization of the π density in this molecule and in the related vinylmethylene. This delocalization of the charge density and the accompanying alternation of the spin population leads to a greater stabilization of the two neighbouring carbon atoms in the triplet states of these unsaturated carbenes than it does to the terminal carbon and oxygen atoms in the corresponding singlet states, and the ground states are triplets.

The methylenic carbon always possesses a larger electron population and lower energy in the triplet than in the singlet state of a carbene. From the examples studied here it is found that the triplet is the ground state when carbon bears a net negative charge. Thus this extra stabilization of the methylenic carbon in the triplet state dominates the total singlet–triplet energy difference when the net charge on carbon is negative. When there is a substantial transfer of charge to the ligands and carbon bears a net positive charge, the ground state is a singlet.

Previous workers have attributed a triplet ground state in vinylmethylene to a delocalization of π density and a singlet ground state in systems with ligands possessing unshared pairs of electrons as in CF_2 to a back-donation of the π density (19–21). This latter argument does not account for the existence of a singlet ground state in SiH_2. Harrison *et al.* (22) have proposed that electronegative substituents differentially stabilize singlet carbenes, while electropositive substituents stabilize triplet carbenes. It has also been argued that π donors stabilize the singlet more than the triplet, while π acceptors have the opposite effect (23).

The orbital model of π back-donation wherein an electronegative atom such as fluorine or nitrogen donates electronic charge to a less electronegative atom such as carbon is not apparent as such in the properties of a total charge distribution. For example, π back-donation is predicted to occur in the singlet states of CF_2 and $CHNH_2$ and yet the methylenic carbon has a larger electron population in the triplet than in the singlet states of these two systems. Also, as noted in Table 3, the ellipticities of the C—F and C—N bonds in the singlet molecules have their major axes in the plane of the nuclei, opposite to what is found for bonds with partial π character. It is a general observation that in a bond X—Y with significant charge transfer from X to Y there is a polarization of both atomic charge distributions in the direction counter to the direction of the charge transfer (24). What one observes is that the magnitude of the atomic *back-polarization* on Y parallels the anticipated consequences of the π *back-donation* model. Thus, the magnitude of μ(Y) is largest when there is an orbital vacancy on X; in CH_3F, μ(F) = 0.32 au while in singlet CF_2, μ(F) = 0.52 au. Also, within the carbene series, μ(F) and μ(N) are larger in the singlet states than in the triplets (Table 4). The π-donation model is invoked to account for unusually short X—Y bond lengths and the data in Table 4 show that the state, singlet or triplet, with the shortest X—Y bond also has the largest value for μ(Y). In CF_2 or $CHNH_2$ this is the anticipated singlet state while in SiH_2, where the ligand has no unshared electrons, it is the triplet. However, the polarization of H is of the same magnitude as the others despite this difference.

The triplet ground states of formyl and vinylmethylene have been accounted for in terms of the π-acceptor model (23). As already noted, the present theory provides a quantitative assessment of both spin and charge delocalization through the assignment of corresponding atomic populations, bond orders, and bond ellipticities. As demonstrated below, the properties of the Laplacian of ρ provide the mechanism underlying the atomic back-polarizations and charge delocalizations.

Valence charge concentrations and ground state multiplicities

The Laplacian of ρ for a free atom reflects the quantum shell structure by exhibiting a corresponding number of alternating pairs of regions of charge concentration ($\nabla^2\rho < 0$), and charge depletion ($\nabla^2\rho > 0$) beginning with a spike-like concentration at the nucleus. Upon bonding, local maxima and minima are formed in the valence shell of charge concentration (VSCC) and the number of resulting bonded and nonbonded maxima thus formed are in general agreement with localized models of electronic structure.

The local concentrations of charge in the valence shell of an atom as determined by the Laplacian of ρ mimic not only the model of localized bonded and nonbonded pairs, they also reflect the presence of local concentrations of unpaired electrons. In Fig. 2 the Laplacian distribution for triplet CF_2 exhibits two distinct maxima on the carbon atom in the symmetry plane perpendicular to the plane of the nuclei. The singlet state of the same molecule exhibits a single nonbonded maximum on carbon. The magnitude of this single maximum (corresponding to the model of a localized electron pair) is larger than the two identical maxima present in the triplet state, each of which models a single unpaired electron. The values of the nonbonded maxima in the Laplacian of ρ are given in Table 3. Similar observations apply to the other pairs of molecules listed in Table 3 (Fig. 3) with the exceptions of CHCH=O and $CHCH{=}CH_2$. In these molecules the triplet states exhibit a single nonbonded

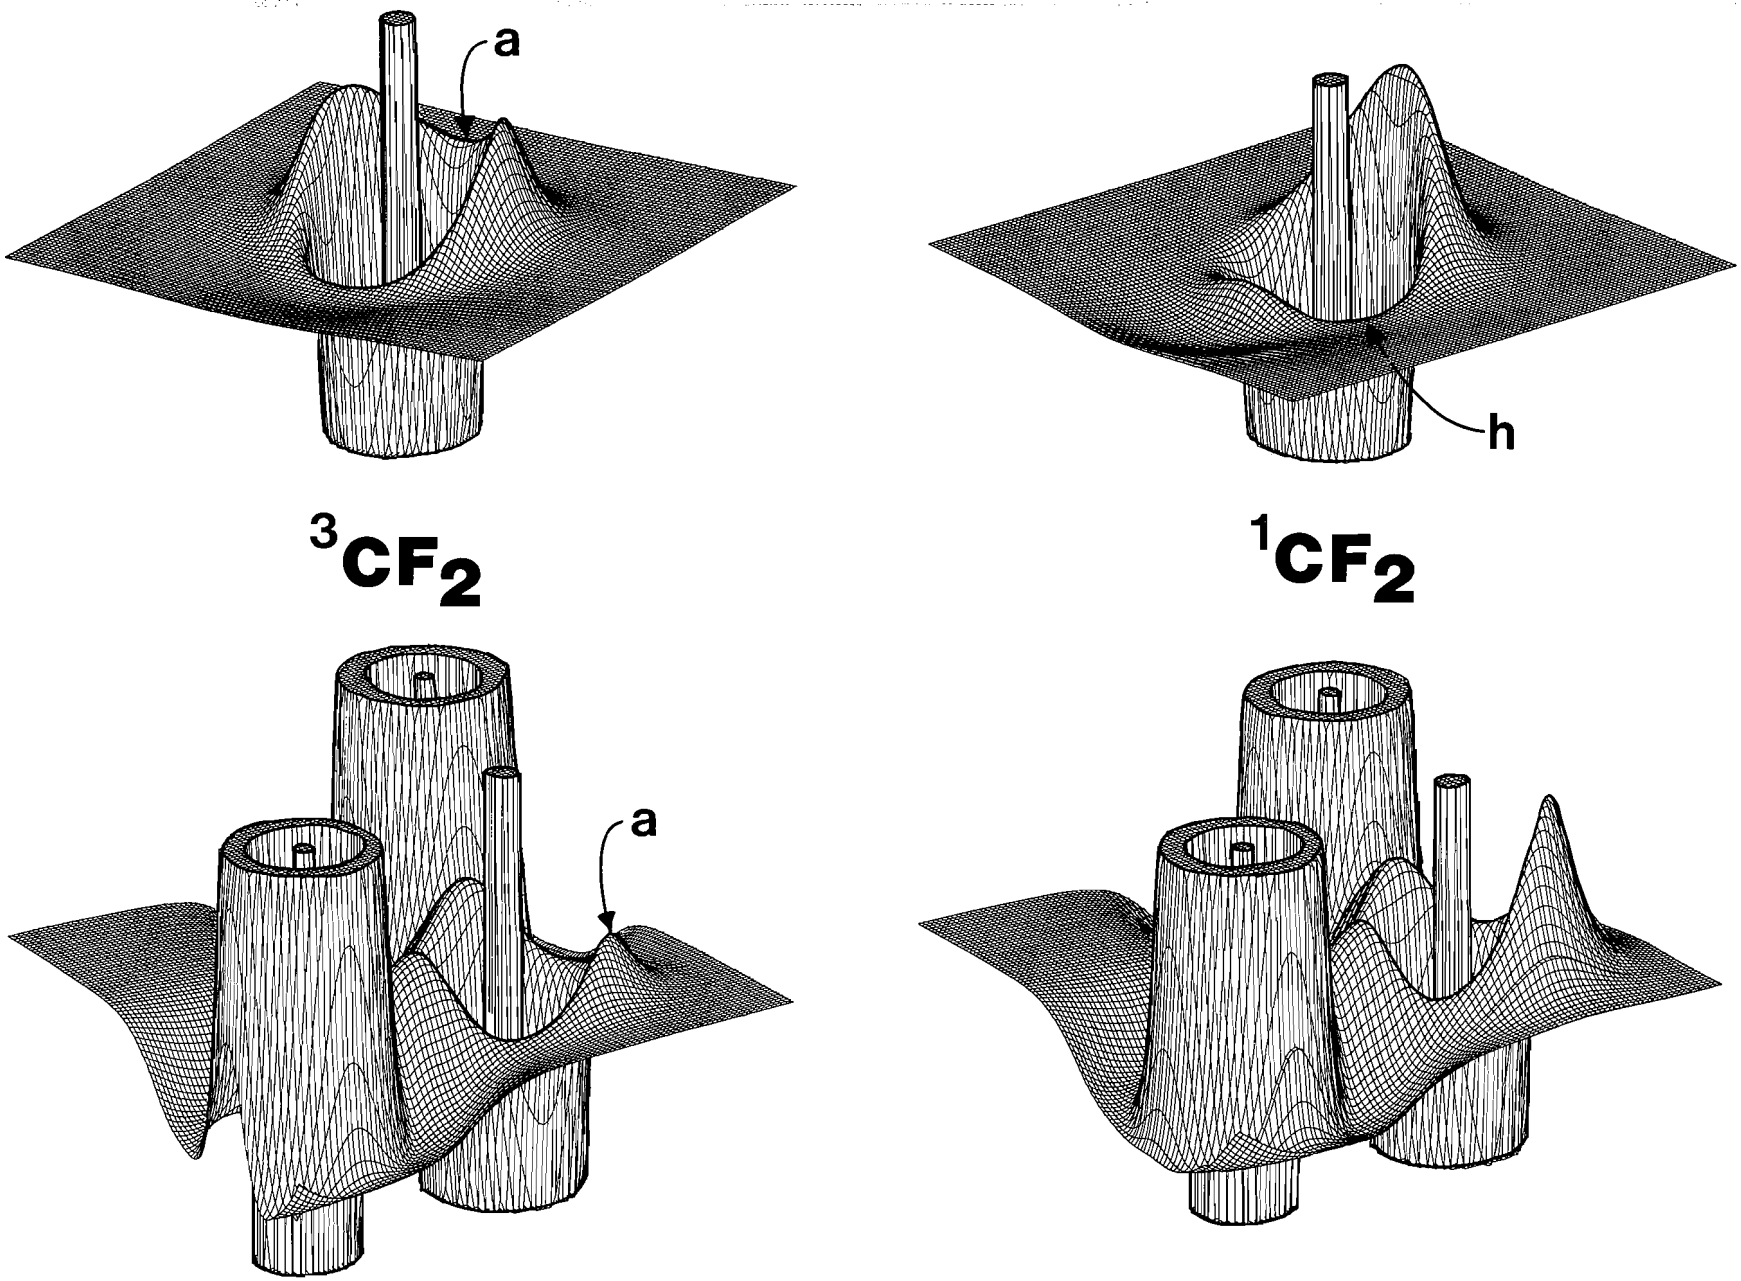

FIG. 2. Displays of the Laplacians of the charge distributions for the triplet and singlet states of CF_2. The lower diagrams are for the plane of the nuclei, the upper ones for the perpendicular symmetry plane containing the C nucleus. The function plotted is $-\nabla^2\rho$, a maximum in this function denoting a maximum in the concentration of charge. The core or first quantum shell of each atom exhibits a spike-like charge concentration at the nucleus surrounded by a deep region of charge depletion. This is followed by the valence shell of charge concentration (VSCC) and the outer or valence region of charge depletion. The VSCC of carbon in the triplet state shows two bonded maxima and two nonbonded maxima in the perpendicular plane. The point labelled **a** in the lower diagram is not a maximum. It is *another* view of the saddle point **a** between the nonbonded maxima. The VSCC of carbon in the singlet state also shows two bonded maxima but only a single, larger, nonbonded maximum. The point labelled **h** and its mirror point are positions where the VSCC on carbon has been broken. There is no radial maximum or lip defining a shell at these points. The maxima present in the VSCC's of the F atoms are not shown as they are larger by a factor of ten than those on the carbons.

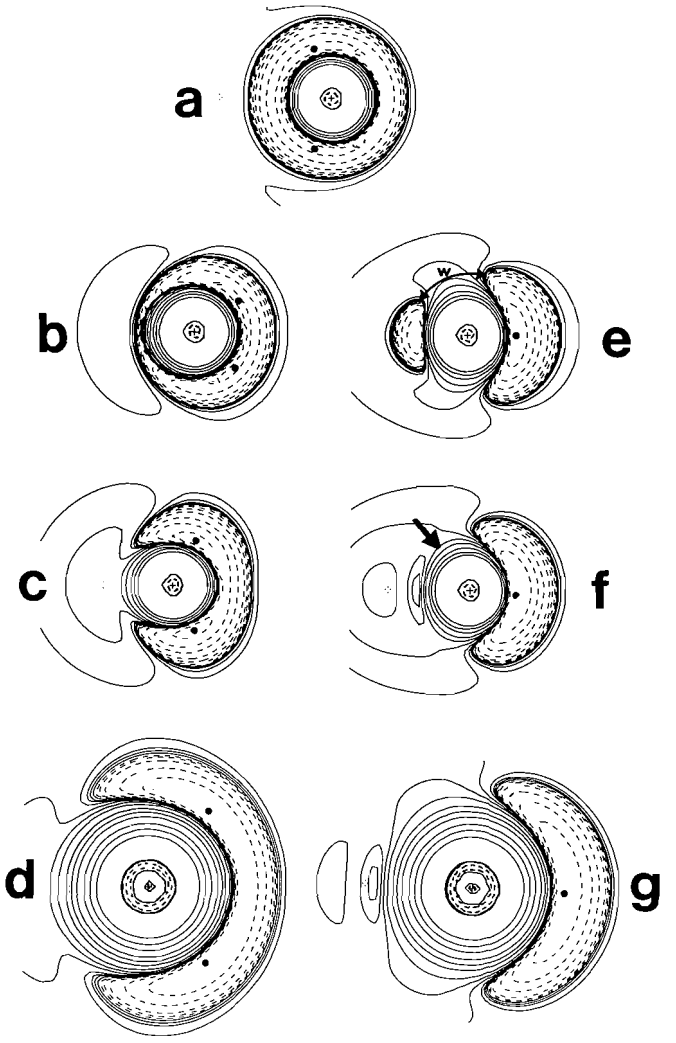

FIG. 3. Contour plots of $\nabla^2\rho$ in symmetry planes perpendicular to the plane of the nuclei containing the C or Si nucleus. For the triplets (*a*) CLi_2, (*b*) CH_2, (*c*) CF_2, and (*d*) SiH_2 and for the singlets (*e*) CH_2, (*f*) CF_2, and (*g*) SiH_2. The right-hand side of each figure corresponds to the nonbonded side of the C or Si atom. Dashed lines denote negative values — regions where charge is concentrated. Solid lines denote positive values — regions of charge depletion. Each dot denotes a maximum in $-\nabla^2\rho$, a maximum in charge concentration. Each triplet state exhibits two and each singlet one such maxima in this plane. Figures (*c*) and (*f*) are the contour maps corresponding to the top two relief diagrams of Fig. 2. Contour values in au are ±0.002, ±0.004, ±0.008 increasing in powers of 10 up to ±8.0.

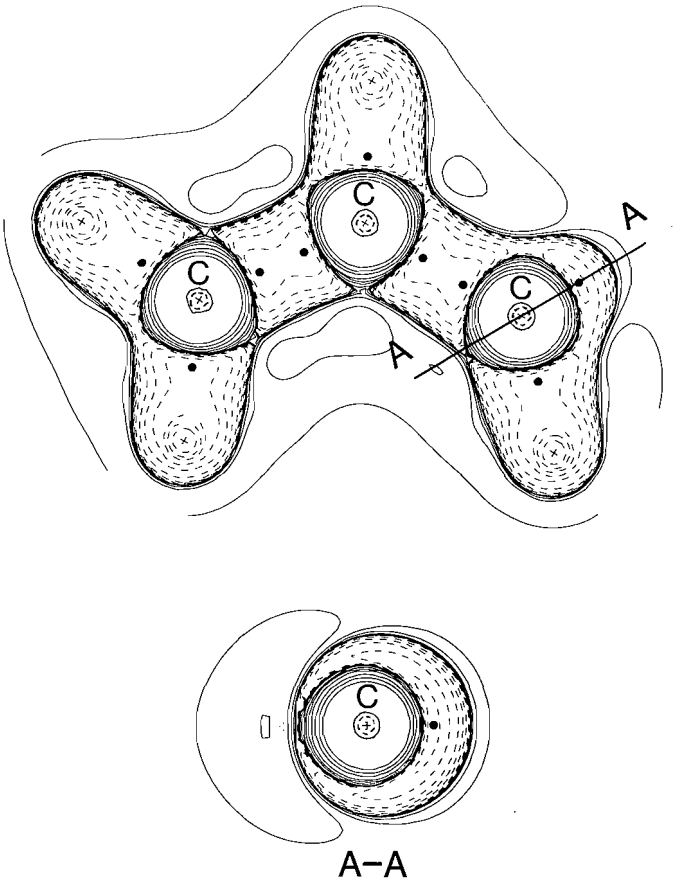

FIG. 4. Contour plot of the Laplacian of ρ for the triplet state of vinylmethylene; in the plane of the nuclei (upper diagram) and the cross-section, A—A, through the divalent carbon. The dots denote the bonded and the single nonbonded maximum in charge concentration.

maximum (Fig. 4) as a result of the delocalization of the π density into the CH=CH_2 and CH=O fragments.

We begin with some general observations. The nonbonded maxima in the singlet states are considerably larger than those in the triplet states. In those molecules which have a triplet ground state there are no regions of charge depletion (or holes as we shall refer to them) in the VSCC and the nonbonded maxima are not pronounced.[4] This behaviour is typified by the methylenic carbon in vinylmethylene as illustrated in Fig. 4. The delocalization of the valence charge concentration is most pronounced in the triplet state of CLi_2 where the C atom bears a large net negative charge (Fig. 3*a*). The VSCC is also polarized towards the ligands in this molecule to the extent that what correspond to nonbonded maxima in the other examples are now maxima on the *bonded* side of the molecule. The nonbonded charge in the singlet states of these molecules on the other hand is very localized (Fig. 3*e*) with the result that regions of charge depletion or holes are also present in the VSCC of the methylenic carbon in the singlet state, in accord with their ambiphilic nature. For the molecules which have singlet ground states, the nonbonded maxima are large and very pronounced in both the singlet and triplet states of each system as illustrated for CF_2 in Fig. 2. In these systems the ligands bear substantial negative charges and the methylenic carbon atom is strongly polarized into its nonbonded region, more so in the singlet than in the triplet states (see μ(C) values in Table 2). Correspondingly the single nonbonded maximum in the singlet is approximately twice the magnitude of either maximum in the triplet. Thus as a consequence of the charge transfer to the ligands, the nonbonded charge concentrations on carbon are localized and holes are present in the VSCC's in both the singlet *and* triplet states of these molecules.

In summary, in carbenes where the methylenic carbon is neutral or negatively charged, there is a delocalization of the nonbonded charge concentration in the triplet state while the nonbonded charge concentration is localized in the singlet state. In these systems the ground state is the delocalized triplet. In carbenes where there is a substantial charge transfer to the

[4]The magnitude of $\nabla^2\rho$ at the intervening saddle points is only a few percent less than its value at the maxima, and the extrema are not pronounced.

ligands the VSCC of the methylenic carbon is very localized into bonded and nonbonded charge concentrations in both the triplet and singlet states. The localization is greatest in the singlet states and these are the ground states in such systems.

Substituent effects on chemical reactivity

The extent of atomic back-polarization of Y in an X—Y bond can be rationalized in terms of the properties of the Laplacian of ρ. Of interest is the case where Y has unshared pairs of electrons, such as fluorine. In an axially symmetric system such as H—F, fluorine exhibits a uniform nonbonded torus of charge concentration subtending an angle at the nucleus of 101.2°. The manner and extent to which this torus of nonbonded charge is polarized in a system without axial symmetry is determined by the properties of the VSCC of the bonded neighbour, X. If X does not possess an orbital vacancy then its VSCC does not exhibit any pronounced regions of charge depletion. In this case the polarization of the nonbonded torus of charge concentration of F is very slight and the small maxima induced in the torus are staggered with respect to the bonded maxima on X.[5] In ClF_5 for example, the axial F exhibits four nonbonded maxima which are staggered with respect to the four bonded maxima on the Cl atom. In CH_3F, fluorine has three nonbonded maxima which are staggered with respect to the three bonded maxima on carbon. The maxima induced in the nonbonded torus by these polarizations exceed in value the resulting minima in $\nabla^2\rho$ by less than 1.0% and correspondingly, the atomic back-polarization of F is relatively small.

In the case where X possesses an orbital vacancy the polarization of the nonbonded torus on F and the resulting back-polarization of its density are very pronounced. In the singlet state of CF_2, the VSCC on carbon exhibits two pronounced holes so positioned as to mimic a vacant $p\pi$ orbital, Fig. 3*c*. The VSCC of carbon in a carbocation exhibits the same pattern of charge depletion. In singlet CF_2 the density on F, including the nonbonded torus of charge concentration, undergoes significant polarization towards the regions of charge depletion on carbon. The result is the formation of two minima and two maxima in the nonbonded torus. Since the minima result from the polarization of the nonbonded charge towards the holes on carbon, the nonbonded maxima on fluorine now eclipse the maxima on carbon. These are large effects; the resulting nonbonded maxima on fluorine exceed the minima in the nonbonded torus of charge concentration by 25% and the atomic dipole is large (Table 4). This situation parallels the model of π back-donation, but as previously noted there is only a polarization of the atomic charge on Y, not a transfer back to the vacancy on X.

The VSCC of carbon in triplet CF_2 has regions of charge depletion in the plane of the nuclei (Figs. 2 and 3*c*). The nonbonded torus on F undergoes a polarization similar to that in the singlet state, but to a lesser extent. The resulting nonbonded charge maxima exceed the minima by 8% and they again eclipse the nonbonded maxima on carbon which are above and below the plane of the nuclei in this case. The atomic polarization on F is also less than in the singlet state. In the orbital model of a triplet carbon every orbital on carbon is at least singly occupied and hence no π back-donation is expected. The Laplacian of ρ, by indicating the presence of regions of charge depletion on carbon, does correctly anticipate atomic back-polarization in the triplet case. Since the holes on carbon are less pronounced in the triplet than in the singlet state, the extent of polarization is less.

These same mechanisms are operative in the $CHNH_2$ system. In the singlet state of this molecule the —NH_2 group is planar so as to align the nonbonded charge concentration on nitrogen with

[5]Cremer and Kraka (25) have proposed that the staggered conformation results from maximum avoidance of vicinal bonded charge concentrations.

TABLE 4. Bond distances and atomic dipoles

*1 au = 2.542 D, a positive μ value means that the negative end of the dipole is directed away from the ligands.
†⊥ indicates that the major axis is perpendicular to the plane of the ring. All other bonds have their major axis in the plane of the ring.

the π-like region of charge depletion on carbon. The nitrogen is polarized towards carbon to such an extent that it no longer possesses a nonbonded charge concentration and its atomic dipole is large, Table 4. In triplet $CHNH_2$ the nitrogen atom is pyramidal and possesses a nonbonded charge concentration as does N in NH_3 (5). The VSCC of carbon in the triplet state has a region of charge depletion in the plane of the H—C—N nuclei and the nonbonded charge concentration on N is aligned with it. As with CF_2, the polarization of the ligand is less pronounced in the triplet than in the singlet.

The shape of the interatomic surface illustrates the effect that such back-polarization has on an X—Y bond (Fig. 5). It is observed that the bulging in these interatomic surfaces is not axially symmetric, but that in the singlet states it is more pronounced above and below the plane of the nuclei. It is also observed that the extent of bulging increases as μ(Y) increases.

In ref. 5 it was proposed that nonbonded maxima in $-\nabla^2\rho(r)$ are sites of electrophilic attack and points of maximum charge depletion in the VSCC are sites of nucleophilic attack. It is generally found that VSCC's of atoms with incomplete valence shells, such as C in carbenes, do not completely envelope the nucleus. In Fig. 2 any radial line from the C nucleus in triplet CF_2 passes through a maximum as it crosses the VSCC, but in the case of the C atom in singlet CF_2 there exist radial paths which do not pass over such a "lip". As a result a critical point corresponding to a point of maximum charge depletion in the VSCC does not exist. To characterize the susceptibility of such atoms to nucleophilic attack we report (Tables 3 and 5) the width of the hole in the VSCC. This measurement is illustrated in Fig. 3*e*. We also report the value of $\nabla^2\rho$ at the hole center. To characterize the susceptibility of the divalent atoms to electrophilic attack, the values of $\nabla^2\rho$ at the nonbonded maxima are reported in Tables 3 and 4.

The triplet states of CH_2 and CLi_2 do not exhibit regions of charge depletion in the VSCC's of the methylenic carbon atoms. Hence the triplet states of these molecules are not susceptible to attack by nucleophiles. They are, however, very susceptible to attack by electrophiles. The delocalized nature of the nonbonded charge concentration in these molecules indicates that it is easily polarized, thereby accounting for their reactive nature towards electrophiles. As pointed out earlier, singlet carbenes have both lumps and holes in their VSCC's, making them susceptible to both electrophilic and nucleophilic attack (Fig. 3). The singlet states of carbenes in which charge is transferred to the ligands are found to be less susceptible to nucleophilic attack than singlet CH_2 (26). The arrow in Fig. 3*f* indicates that the direction of approach of a nucleophile to the VSCC of the C atom in singlet CF_2 is at an acute angle to the C—F bond axes. The resulting electron–electron repulsion between the approaching nucleophile and the negatively charged F atoms creates a barrier to nucleophilic attack. This same argument applies to singlet SiH_2 and singlet $CHNH_2$. Sosa and Schlegel have calculated that indeed the singlet states of CF_2 and SiH_2 have high insertion barriers relative to that of singlet CH_2, and that the angle of approach is as described above for both CF_2 and SiH_2 (27). The small hole width and completion of the VSCC of the C atom in singlet $CHNH_2$ indicate it is less susceptible to nucleophilic attack than singlet CH_2, even before ligand–nucleophile repulsions are considered.

The delocalization of spin and charge density in α,β-unsaturated methylenes was previously discussed. As mentioned, these systems are best described as biradicals with one of the unshared electrons delocalized into the π system. Thus, the reactivity of these systems will be free radical-like. As a result of the presence of a single nonbonded charge concentration (Fig. 4), they are predicted to be less reactive than alkylmethylenes which have two such maxima. Singlet formylmethylene has been predicted to rearrange easily to ketene via an intramolecular αC—H insertion (8). This rearrangement is foreshadowed by the alignment of the αC—H bond with the hole in the VSCC of the divalent C atom and the unusually small angle this bond makes with the C—C bond axis, 108.2° compared to 117.4° in the triplet state. This is an example of a singlet carbene with a ligand which possesses no unshared electrons. In the absence of an unshared pair the density of the C—H bond is polarized towards the hole in the VSCC of the methylenic carbon, as indicated by its low ρ_b value (Table 5). This behaviour is analogous to hyperconjugation in carbocations (17).

The reactivity of the singlet states of two cyclic carbenes and a vinylidene (Table 5) are considered next. Others have shown

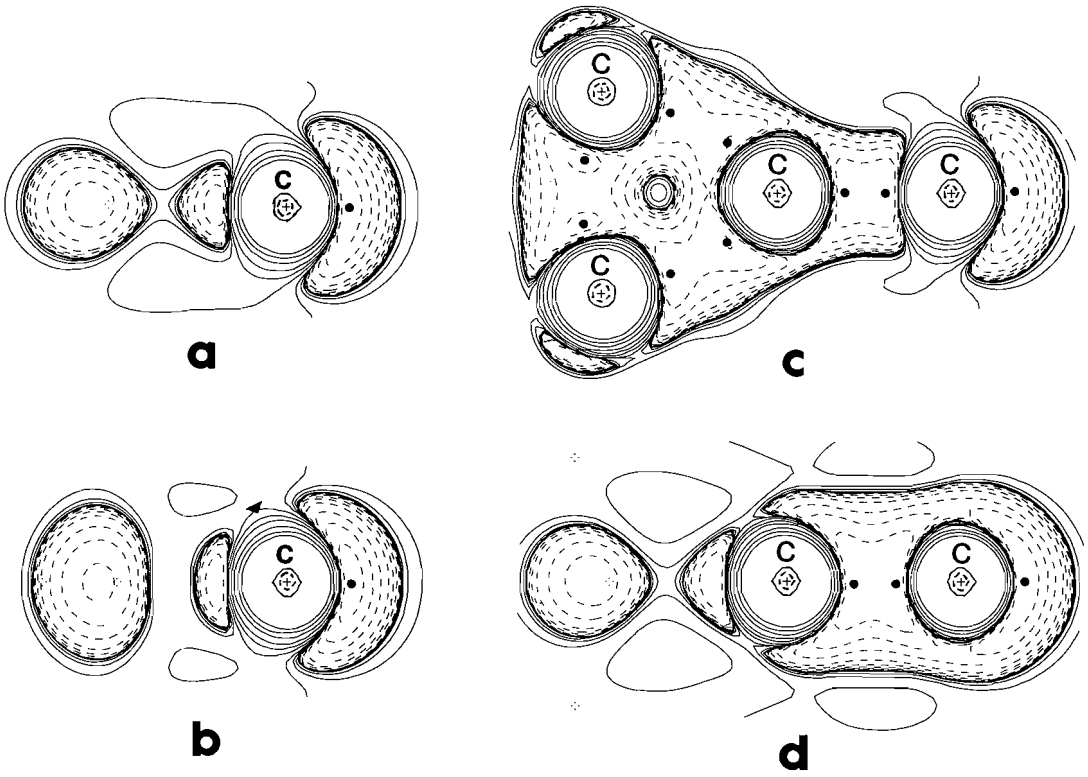

FIG. 6. Contour plots of $\nabla^2\rho$. Local maxima in $-\nabla^2\rho$ are denoted by solid circles. (*a*) The symmetry plane bisecting the ring in cyclopropylidene. Note the delocalization of charge into the center of the ring. (*b*) A similar plane in cyclopropenylidene. The triangle indicates a critical point in the VSCC of the methylenic carbon atom corresponding to a site of nucleophilic attack. There is a mirror site as well. (*c*) The plane containing the ring nuclei in cyclopropylidenecarbene. The sites of nucleophilic attack on the methylenic carbon are also in this plane. (*d*) The plane containing the π bond in cyclopropylidenecarbene.

that they possess singlet ground states (20, 28). Considering the small bond angle in three-membered ring carbenes (59.3° in cyclopropylidene and 55.4° in cyclopropenylidene), one can account for the singlet ground states of these systems by recalling that the $3a_1$ orbital becomes increasingly more stable relative to the $1b_1$ orbital as θ(RCR) decreases. Note that in the latter two examples in Table 5 there is significant charge transfer from the methylenic C atom to its neighbouring atom(s). Hence the singlet ground states of these systems agree with the charge transfer argument as well.

In cyclopropylidene the two types of C—C bonds differ only slightly from the C—C bond in cyclopropane for which n = 0.99 and ϵ = 0.49. On the basis of the data in Tables 3 and 5, the reactivity of the methylenic carbon in cyclopropylidene is predicted to be similar to that of singlet CH_2; susceptible to both nucleophilic and electrophilic attack. A comparison of Figs. 3*e* and 6*a* illustrates this similarity.

Cyclopropenylidene has been predicted to be unreactive towards nucleophiles (29). The bond orders given in Table 5 indicate that there is some delocalization of charge in this system. The effect of this on the VSCC of the methylenic C atom is illustrated in Fig. 6*b*. In this case there is a point of maximum charge depletion in the VSCC of the methylenic C atom, that is, a critical point in $\nabla^2\rho$. Because of this delocalization, charge is much less depleted at this point than in other carbenes. Thus one would predict cyclopropenylidene to be even less susceptible to nucleophilic attack than singlet $CHNH_2$, for example. Even though the data in Table 5 predict the nonbonded charge concentration on cyclopropylidene to be similar in reactivity to that of cyclopropenylidene, nucleophilic behaviour will be dominant in the latter because of its greater selectivity as an electrophile (26).

The final example is cyclopropylidenecarbene. This vinylidene has an unusually short C2=C1: bond (1.275 Å) and a correspondingly high bond order (n = 2.60). The partial triple-bond character of the C1—C2 bond arises from conjugation with the three-membered ring (17). This is suggested by the reduction in the bond order of the adjacent C—C bonds, n(C2—C3) = 0.932. The extent of charge concentration in the π plane (Fig. 6*d*) illustrates the highly nucleophilic nature of this C=C: fragment (30). Figure 6*c* shows the plane containing the hole in the VSCC of the methylenic carbon atom, $\nabla^2\rho$ at the hole center $\approx +0.4$, roughly that for singlet CH_2. However, the hole width is extremely small resulting from the extent that the bonded and nonbonded charge concentrations cover the VSCC, reducing the size of the region a nucleophile can attack.

Conclusions

1. We find the energy of the central atom to be lower in the triplet state while the energy of the ligand is lower in the singlet state. It is also found that the average electron population of the central atom is largest in the triplet state. As a result, transfer of charge to the ligands preferentially stabilizes the singlet state while transfer of charge to the central atom stabilizes the triplet state. We expect these observations to remain valid at higher levels of theory. The trend is supported by performing a two-state CI calculation on singlet methylene, for which ΔE(C) = −68 kcal/mol and ΔE(H) = +21 kcal/mol (cf. Table 2). These observations allow one to rationalize, non-empirically, the

ground state multiplicities of simple carbenes in terms of well-defined atomic properties.

2. The orbital model of π back-donation is found to be inconsistent with the observed properties of the charge density. Instead, back-polarization of negatively charged ligands is found to be the operative mechanism that accounts for the trends in X—Y bond lengths (Table 4).

3. In unsaturated carbenes it is found that spin polarization, and not charge transfer, stabilizes the triplet states.

4. Finally, the properties of the Laplacian distribution allow one to discuss carbene reactivity in terms of an observable property directly related to the energetics of the system.

A previous model based on electronegativity (22) was deemed "unnecessary in understanding substituent effects on ST (singlet–triplet) gaps" in the publication of a more recent model. The latter model was based on empirical π-acceptor and π-donor indices derived from Mulliken population analyses (23). On the basis of conclusions 1, 2, and 3 above, the latter model is unnecessary also.

Appendix

Effect of two state CI on properties of singlet CH_2

Property	Value	
	One configuration	Two configurations
$E(^1T) - E(^0S)$	−30.86 kcal/mol*	−26.72 kcal/mol
$E(^0S)$	−38.8763 au	−38.8829 au
q(H)	−0.0473 e	−0.0438 e
C—H bond		
ρ_b	0.2905 au	0.2899 au
$\nabla^2\rho_b$	−1.1225 au	−1.1182 au
ϵ	0.1746	0.1628
Nonbonded charge concentration		
$\nabla^2\rho(r)$	−1.5537 au	−1.4696 au

*This value reduces to −27.7 kcal/mol when $E(^1T)$ is obtained from a restricted open-shell calculation rather than from UHF. This value compares favourably with the value −26.2 kcal/mol obtained in ref. 10 which used a basis set of similar size, but with different exponents for the *d* functions in the singlet and triplet states.

Convenient synthesis, X-ray crystal structure, and Raman spectrum of the heptasulphide dianion, S_7^{2-}, in $[PPN]_2S_7 \cdot 2EtOH$

TRISTRAM CHIVERS,[1] FRANK EDELMANN, JOHN F. RICHARDSON, AND KENNETH J. SCHMIDT
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received January 13, 1986

TRISTRAM CHIVERS, FRANK EDELMANN, JOHN F. RICHARDSON, and KENNETH J. SCHMIDT. Can. J. Chem. **64**, 1509 (1986).

The S_7^{2-} ion is readily prepared in high yield by the reaction of [PPN]SH with *cyclo*-S_8 in ethanol. The crystal and molecular structures of $[PPN]_2S_7 \cdot 2EtOH$ have been determined by X-ray crystallography. The crystals are monoclinic and belong to the space group $P2_1$, a = 13.199(2), b = 19.414(2), c = 14.046(2) Å, β = 94.027(6)°, V = 3590.3(7) Å^3, Z = 2. The final R and R_w values were 0.064 and 0.060, respectively. The S_7^{2-} ion is an unbranched chain of sulphur atoms in the *cis,trans,cis*-configuration with torsion angles of 89.99(18), 71.84(16), 76.54(16), and 94.19(18)°. The S—S distances (in Å) become progressively smaller in the sequence d(S—S central) [2.072(3) and 2.070(3)] > d(S—S internal) [2.050(2) and 2.037(3)] > d(S—S) terminal [2.044(3) and 2.026(4)]. The Raman spectrum of the S_7^{2-} ion in $[PPN]_2S_7 \cdot 2EtOH$ exhibits characteristic S—S stretching vibrations at 503, 453, 419, and 395 cm^{-1}.

TRISTRAM CHIVERS, FRANK EDELMANN, JOHN F. RICHARDSON et KENNETH J. SCHMIDT. Can. J. Chem. **64**, 1509 (1986).

La réaction du [PPN]SH avec le *cyclo*-S_8 dans l'éthanol permet de préparer facilement et avec un très bon rendement l'ion S_7^{2-}. Faisant appel à la diffraction des rayons-X, on a déterminé les structures cristalline et moléculaire du $[PPN]_2S_7 \cdot 2EtOH$. Les cristaux sont monocliniques, groupe d'espace $P2_1$ avec a = 13,199(2), b = 19,414(2) et c = 14,046(2) Å, β = 94,027(6)°, V = 3590,3(7) Å^3 et Z = 2. Les valeurs finales de R et R_w sont respectivement 0,064 et 0,060. L'ion S_7^{2-} est une chaîne linéaire d'atomes de soufre dans la configuration *cis,trans,cis* avec des angles de torsion de 89,99(18), 71,84(16), 76,54(16) et 94,19(18)°. Les distances S—S (en Å) deviennent de plus en plus courtes dans la séquence d(S—S central) [2,072(3) et 2,070(3)] > d(S—S interne) [2,050(2) and 2,037(3)] > d(S—S terminal) [2,044(3) et 2,026(4)]. Le spectre Raman de l'ion S_7^{2-}, tel qu'il existe dans le $[PPN]_2S_7 \cdot 2EtOH$, présente les vibrations d'élongation caractéristiques aux S—S, soit des bandes à 503, 453, 419 et 395 cm^{-1}.

[Traduit par la revue]

Introduction

Recent developments in the chemistry of transition metal polysulphides have stimulated interest in the characterization of long-chain polysulphide anions, S_x^{2-} ($x > 6$) (1). Several investigations have provided evidence for the formation and instability of such anions in solution (2–4). Solubility and uv–visible spectroscopic measurements indicate that solutions of lithium polysulphides in DMSO or THF contain chains with an *average* of 9–10 sulphur atoms (2). Earlier studies of the electrochemical reduction of *cyclo*-S_8 have established that the S_8^{2-} ion is unstable with respect to disproportionation to S_6^{2-} and sulphur in dilute DMF (3) or DMSO (4) solutions (10^{-3} – 10^{-4} *M*) in the presence of R_4N^+ salts. Long chain polysulphide anions can, however, be stabilized in the solid state by the presence of larger counter-ions.

In 1983 Coucouvanis *et al.* reported the unexpected formation of $[Ph_4P]_2S_7$ in moderate yield from the reaction of MoS_9^{2-} with an excess of sodium diethyldithiocarbamate in the presence of $[Ph_4P]Cl$ (5). The S_7^{2-} ion was shown to be an unbranched chain in the *trans,trans,trans*-configuration by X-ray crystallography (5). Subsequently, more direct routes for the preparation of salts of S_x^{2-} anions ($x > 6$) have been described. The compounds $[Ph_4As]_2S_7$ (6) and $[Ph_4P]_2S_8$ (7) were obtained in 80% yields by addition of $[Ph_4As]Cl$ or $[Ph_4P]Cl$, respectively, to an ethanol solution of Na_2S_4. The S_{12}^{2-} ion was isolated as its PPN^+ salt ($PPN^+ = (Ph_3P)_2N^+$) from the reaction of [PPN]Cl with *cyclo*-S_8 in the presence of potassium carbonate (8).

In an attempt to stabilize the initial product of the nucleophilic cleavage of an S_8 ring we have investigated the reaction of [PPN]SH with *cyclo*-S_8 in ethanol and found that it produces a high yield of $[PPN]_2S_7 \cdot 2EtOH$ rather than $[PPN][HS_9]$. The crystal and molecular structures of $[PPN]_2S_7 \cdot EtOH$ have been determined by X-ray crystallography and the Raman spectrum of this salt is compared with that of $[PPN]_2S_{12}$.

Experimental

Reagents and general procedures

[PPN]Cl (9), NaSH (10), and $[PPN]_2S_{12}$ (8) were prepared by the literature procedures. All solvents were dried and distilled before use: C_2H_5OH (Na/diethylphthalate), CH_3CN (CaH_2, P_2O_5, CaH_2). The preparation of $[PPN]_2S_7$ was carried out under an atmosphere of dry nitrogen, but the manipulation of crystalline samples of this salt was performed in air.

Infrared spectra were recorded as Nujol mulls (CsI windows) on a Perkin-Elmer 467 grating spectrophotometer (4000–250 cm^{-1}). Raman spectra were obtained on a Jarrell-Ash Model 25-100 double monochromator calibrated with carbon tetrachloride. A Coherent Radiation CR4 Argon ion laser fitted with an Innova plasma tube was used to obtain exciting radiation at 514 nm. Samples were mounted in a 6 cm diameter stainless steel ring on a bed of dry KBr, which was rotated at about 1000 rpm to prevent thermal decomposition.

Preparation of $[PPN]_2S_7$

(*a*) A solution of [PPN]SH was prepared by stirring a mixture of NaSH (0.30 g, 5.4 mmol) and [PPN]Cl (3.1 g, 5.4 mmol) in ethanol (30 mL) at 23°C (11) for 2 h. The precipitate of sodium chloride was removed by filtration and ethanol (80 mL) and *cyclo*-S_8 (0.60 g, 2.3 mmol) were added to the clear filtrate with vigorous stirring. The solution turned orange rapidly and a strong smell of H_2S was detected. After 5 min, a small amount of unreacted sulphur (ca. 0.10 g) was removed by filtration and the bright orange filtrate was allowed to stand at 23°C for 1 day whereupon large, ruby red crystals formed. After 2 days these crystals were separated by filtration, washed with ethanol (2 × 30 mL), and dried in air to give $[PPN]_2S_7 \cdot 2C_2H_5OH$ (2.5 g, 1.9 mmol). *Anal.* calcd. for $C_{76}H_{72}N_2O_2P_4S_7$: C 65.49, H 5.21, N 2.01, S 16.10; found: C 64.82, H 5.20, N 2.05, S 16.58. One of these crystals was used in the X-ray structural determination.

(*b*) In order to optimize the yield of $[PPN]_2S_7$ a slightly different procedure was used. A solution of [PPN]SH was prepared as described

above using the same quantities of reagents except that the total volume of ethanol was only 40 mL. Addition of *cyclo*-S_8 (0.50 g, 2.0 mmol) to this solution produced an orange–red precipitate within 1 min. After 15 min some unreacted sulphur was still present, so the mixture was stirred at 23°C for 18 h by which time sulphur was no longer evident in the orange precipitate. The product was isolated by filtration, washed with ethanol (2 × 10 mL), and dried in air to give $[PPN]_2S_7 \cdot 2EtOH$ (2.65 g, 2.0 mmol), which had a Raman spectrum identical to that of the crystalline sample prepared in (*a*). Powdered samples obtained by this procedure sometimes contain small amounts of *cyclo*-S_8 as indicated by Raman bands at 471, 218, and 152 cm^{-1} (12). *Cyclo*-S_8 can be removed from these samples by Soxhlet extraction with *n*-pentane for 24–48 h.

X-ray crystallography

Crystal data:

$C_{76}H_{72}N_2O_2P_4S_7$ fw = 1393.78

Space group $P2_1$, a = 13.199(2), b = 19.414(2), c = 14.046(2) Å, β = 94.027(6)°, V = 3590.3(7) Å^3, Z = 2, ρ_c = 1.29 g cm^{-3} (21(1)°C, MoKα, λ = 0.71069 Å, graphite monochromator), μ(MoKα) = 3.51. $F(000)$ = 1458 and crystal description: red, multi-faceted blocks, approx. 0.30 × 0.30 × 0.33 mm.

An examination of the crystalline sample using both binocular and polarising microscopes showed the bulk of the sample to be composed of twinned crystals. Six crystals were mounted and photographed on an Enraf-Nonius CAD4F diffractometer before one was found having ω scans of suitable quality for data collection. Intensity data were collected using the ω–2θ scan technique with a scan range of 1.5(0.80 + 0.142 tan θ) and scan speeds varying from 0.6 to 3.3° min^{-1}. Three standard reflections measured every 2400 s of X-ray exposure time showed a variation of less than 1% during the data acquisition period. The intensity of the reflection data dropped off rapidly with increasing θ and collection was terminated at a maximum θ of 25°. A total of 6486 unique reflections were measured for the octants $+h, -k, \pm l$, of which 4362 were considered observed ($F_o > 3\sigma(F_o)$, where σ was derived from counting statistics). The data were corrected for background, Lorentz and polarization effects but an absorption correction was not carried out. Details concerning data collection and reduction can be found in ref. 13. The choice of space group as $P2_1$ is ambiguous. The choice of the acentric space group was supported by the distribution of E values (K curve). Although the independent cations almost lie about a centre of symmetry, this is not exact and, more importantly, the anion and solvate molecules do not satisfy the conditions necessary for $P2_1/m$. Examination of the intensity data collected and cell reduction (performed using a modification of TRACER II by S. L. Lawson, see ref. 14) failed to show the presence of a higher symmetry cell.

The coordinates of the S and P atoms were determined by direct methods (MULTAN 78) (15). Structure factor and difference Fourier calculations revealed the positions of the remaining non-hydrogen atoms. The structure was refined by block-diagonal least-squares techniques (4 blocks) based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = [\sigma(F_o)^2 + 0.0001F^2]^{-1}$. All computations were performed using the XRAY 76 system of programs (16). Scattering factors were taken from refs. 17 (non-H) and 18 (H) and anomalous dispersion corrections were included for non-hydrogen atoms (19). Phenyl H atoms were included in calculated positions with isotropic thermal parameters set to 1.1 times B_{eq} of the atom to which they are bonded. H atoms associated with the solvent molecule could not be located. The model did not converge easily, with the average Δ/σ being 0.6 in the final cycle. We attribute this oscillation in parameters to the near-centric distribution of the PPN^+ cations in the cell. In the final cycle there were 5594 observations (observed reflections plus those for which $I_c > 3\sigma(I_o)$) and 458 variables with the agreement factors $R = \Sigma(||F_o| - |F_c||)/\Sigma(|F_o| = 0.064$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|]^{1/2} = 0.060$. The final GOF value was 1.15 and the largest peak of residual electron density was 0.6 e Å^{-3} (in the region of C(3)—C(4)).

The positional and isotropic thermal parameters for the non-hydrogen atoms of $[PPN]_2S_7 \cdot 2EtOH$ are given in Table 1. Tables giving the anisotropic thermal parameters (SI), positional and thermal parameters for H atoms (SII), bond lengths and angles (SIII), and the structure factors (SIV) have been placed in the Depository of Unpublished Data.[2]

The estimated standard deviations quoted in the tables are those derived from counting statistics and least-squares refinement. In view of the relative weakness of the intensity data, these calculated esds are probably underestimated, particularly for bond lengths and angles. It is difficult to evaluate the exact standard deviation, but it should be noted that differences between chemically equivalent bonds may not be significant.

Results and discussion

Synthesis of $[PPN]_2S_7$

The reaction of [PPN]SH with *cyclo*-S_8 in ethanol in a 1:1 molar ratio proceeded rapidly at room temperature to give $[PPN]_2S_7$ and a considerable amount of unreacted sulphur. Presumably the initially formed HS_9^- ion decomposes with loss of H_2S to give S_7^{2-} and sulphur. In subsequent reactions, the stoichiometry was adjusted in order to optimize the yield of $[PPN]_2S_7$ according to the following overall reaction.

$$2[PPN]SH + 6/8S_8 \rightarrow [PPN]_2S_7 + H_2S$$

The product can be recovered from ethanol solution either as large, ruby red crystals or, from more concentrated solutions, as an orange powder in ca. 80% yield. In aprotic donor solvents such as acetonitrile or DMF, $[PPN]_2S_7$ disproportionates to give polysulphur radical ions, e.g. $S_3^{\cdot-}$, cf. $[Ph_4P]_2S_7$ (5). Crystalline samples of this salt can be stored at room temperature for several days without decomposition. After several weeks the deposition of elemental sulphur is noticeable and can readily be detected by Raman spectroscopy (*vide infra*). Samples should be stored under an inert atmosphere at low temperatures in order to minimize the decomposition.

Crystal and molecular structures of $[PPN]_2S_7 \cdot 2EtOH$

An ORTEP drawing of the S_7^{2-} ion in $[PPP]_2S_7 \cdot 2EtOH$ is shown in Fig. 1 and the packing of the ions in the crystal is depicted in Fig. 2. Polysulphide chains, S_x^{2-} ($x \geq 5$), present interesting possibilities of isomerism because the dihedral angles $S_1S_2S_3/S_4S_5S_6$ etc. are normally close to 90° (20). For example, the S_6^{2-} ion can have three isomers, (*cis*,*cis*), (*cis*,*trans*), or (*trans*,*trans*) and there are six possible conformations of the S_7^{2-} ion.[3] Previous X-ray structural investigations have revealed only *all cis*- or, more frequently, *all trans*-conformations for S_x^{2-} (x = 5–7) (22). The former configuration is present in *cyclo*-S_8 while the latter is the configuration of the helices of fibrous sulphur and of the S_7^{2-} ion in $(Ph_4P)_2S_7$ (5). By contrast, the S_7^{2-} ion in the PPN^+ salt adopts a *cis*,*trans*,*cis* arrangement of sulphur atoms and thus provides the first example of a polysulphide chain that is not in either an *all cis*- or an *all trans*-conformation. This conformation is similar to the regular alternating *cis*,*trans* structure of *cyclo*-S_{12} (23).

The bond lengths, bond angles, and torsion angles of the S_7^{2-} ions in $[Ph_4P]_2S_7$ and $[PPN]_2S_7 \cdot 2EtOH$ are compared in Table 2. A trend towards progressively smaller S—S bond distances in the sequence d(S—S central) > d(S—S internal) > d(S—S

[2]Tables SI–SIV may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]These numbers do not include the possible existence of pairs of enantiomers for each isomer. A succinct discussion of the stereochemistry of polysulphide chains is given in ref. 21.

terminal) is observed for both salts, but the attenuation is less pronounced in $[PPN]_2S_7 \cdot 2EtOH$. In contrast, it should be noted that the values of the S—S distances in the *all-trans* S_6^{2-} ion of ethylenediammonium hexasulphide alternate, the shortest being the internal S—S bond (22), whereas no significant difference between internal and terminal S—S bond lengths was found for $[Bu_4N]_2S_6$ (24). The average S—S bond length in $[PPN]_2S_7 \cdot 2EtOH$ is 2.050(3) Å [cf. 2.030(2) Å in $[Ph_4P]_2S_7$ (5)]. The average S—S—S angle of 109.4(2)° in $[PPN]_2S_7 \cdot 2EtOH$ is very similar to the value of 109.3(1)° found for $[Ph_4P]_2S_7$ (5). There are substantial differences, however, in the torsion angles

observed for the S_7^{2-} ion in these two salts. These differences are largest for the outermost torsion angles and can probably be attributed to the different chain conformations (*cis,trans,cis* for the PPN^+ salt vs. *trans,trans,trans* for the Ph_4P^+ salt). Previous structural studies of polysulphide anions have revealed torsion angles of ca. 90° for *all trans*-conformations and torsion angles of ca. 72° for *all cis*-conformations (22). Unlike cyclic sulphur allotropes (25), there appears to be no obvious correlation between S—S bond lengths and torsion angles in anionic polysulphide chains.

Raman spectra of $[PPN]_2S_7 \cdot 2EtOH$ and $[PPN]_2S_{12}$

Raman spectroscopy is the technique of choice for the characterization of cyclic (12) and linear (26) homonuclear sulphur species. A typical Raman spectrum of the S_7^{2-} ion in $[PPN]_2S_7 \cdot 2EtOH$ is shown in Fig. 3*a*. Characteristic S—S stretching vibrations are observed at 503, 453, 419, and 395 cm^{-1} and a strong SS deformation mode occurs at 178 cm^{-1}. The presence of *cyclo*-S_8, which sometimes arises in freshly prepared powders or in the crystalline product upon prolonged standing at room temperature, can be detected readily by the observation of characteristic Raman bands at ca. 470, 216, and 150 cm^{-1} (Fig. 3*b*) (27). Thus the Raman spectrum provides an excellent criterion of purity for samples of $[PPN]_2S_7$. The S_8^{2-} ion in $[Ph_4P]_2S_8$ is reported to exhibit S—S stretching bands at 500, 459, 431, and 390 cm^{-1} and a deformation band at 282 cm^{-1} in the ir spectrum (7).

We also obtained the Raman spectrum of the recently described PPN^+ salt of the dodecasulphide anion, S_{12}^{2-} (8), for

comparison with that of $[PPN]_2S_7$. The characteristic S—S stretching vibrations for $[PPN]_2S_{12}$ appeared at 515, 460 sh, 434, and 350 sh cm^{-1}.

Summary and conclusions

The reaction of [PPN]SH with *cyclo*-S_8 in ethanol provides a rapid, high yield synthesis of either powdered or crystalline samples of $[PPN]_2S_7 \cdot 2EtOH$ of high purity. An X-ray structural investigation of this product showed it to contain the first example of an anionic polysulphide chain which is not in either an *all cis*- or an *all trans*-conformation. This salt could prove to be a convenient reagent for the synthesis of derivatives of *cyclo*-octasulphur in which one sulphur atom is replaced by a transition metal, e.g. $(Me_3P)MS_7$ (M = Ru, Os) (28), or a main group element, e.g. S_7TeX_2 (X = Cl, Br) (29, 30). It is apparent that large cations are not only capable of stabilizing long polysulphide anions, S_x^{2-} ($x > 6$), in the solid state but that, under different reaction conditions, the same cation may stabilize different polysulphide chains e.g. $[PPN]_2S_7$ and $[PPN]_2S_{12}$ or $[Ph_4P]_2S_7$ and $[Ph_4P]_4S_8$.

Preparation of *exo*-6-benzyl-*exo*-2-(*m*-hydroxyphenyl)-1-dimethylaminomethylbicyclo[2.2.2.]octane. A non-peptide mimic of enkephalins

PATRICE C. BÉLANGER AND CLAUDE DUFRESNE

Medicinal Chemistry Department, Merck Frosst Canada Inc., P.O. Box 1005, Pointe Claire/Dorval, P.Q., Canada H9R 4P8

Received December 4, 1985

PATRICE C. BÉLANGER and CLAUDE DUFRESNE. Can. J. Chem. **64**, 1514 (1986).

A model for the active conformation of methionine enkephalin was derived from computer modeling. From this model, a target was designed and synthesized using bicyclo[2.2.2]octane as a structural template. Thus, a key intermediate, *exo*-6-benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene was prepared via a Diels–Alder reaction using ethyl dihydrobenzoate and phenylvinylketone. It was subsequently modified to *exo*-6-benzyl-1-dimethylaminobicyclo[2.2.2]-2-octene. This intermediate was hydroborated and oxidized to the ketone on which the second aromatic group was introduced using a Grignard reaction, eventually giving rise to the desired target, *exo*-6-benzyl-*exo*-2-(*m*-hydroxyphenyl)-1-dimethylaminobicyclo[2.2.2]octane. Biological testing demonstrated weak activity with this compound.

PATRICE C. BÉLANGER et CLAUDE DUFRESNE. Can. J. Chem. **64**, 1514 (1986).

Utilisant un ordinateur, on a déssiné un modèle pour la conformation active de la méthionine encéphaline. À partir de ce modèle, on a choisi une cible que l'on a synthétisée en utilisant le bicyclo[2.2.2]octane comme support de la structure. On a donc préparé un intermédiaire clé, le benzoyl-6-*exo* carboéthoxy-1 bicyclo[2.2.2]octène-2, par le biais d'une réaction de Diels–Alder entre le dihydrobenzoate d'éthyle et la phénylvinylcétone. On l'a subséquemment transformée en benzyl-6-*exo* diméthylamino-1 bicyclo[2.2.2]octène-2. On a procédé à une réaction d'hydroboration de cet intermédiaire et on l'a oxydé en une cétone. En procédant à une réaction de Grignard sur la benzyl-6-*exo* diméthylamino-1 bicyclo[2.2.2]octanone-2, on a éventuellement obtenu le produit désiré, le benzyl-6-*exo* (*m*-hydroxyphényl)-2-*exo* diméthylamino-1 bicyclo[2.2.2]octane. Les tests biologiques exécutés avec ce composé n'ont mis en évidence qu'une faible activité.

[Traduit par la revue]

Introduction

The discovery of the enkephalins (1, 2) has renewed the hope that the development of analgesics without the side effects associated with the narcotic analgesics might be possible. With the help of the Merck Molecular Modeling System (MMMS) (3), a model for the bioactive conformation of the enkephalins was developed. The process involved a combination of the structure–activity relationships known for the opiates (4) and for the enkephalins (5), of the distance between the two aromatic systems (6) (estimated to be approximately 10 Å from fluorescence studies of enkephalin analogs), and of modeling and comparing with known opiates. Another feature of this model is the presence of a β turn, which adds rigidity to the flexible enkephalin backbone and also acts as a template for positioning the key groups (tyrosine and phenylalanine phenyl groups) in space as is found in the very active opiates such as etorphin (7). The bicyclo[2.2.2]octane derivative **2** is such a structure that gave a good fit with the model and also possesses the two aromatic groups found in the enkephalins. The methionine part is absent from the proposed target and justification for this is found in the high degree of analgesic activity in some of the tetrapeptide analogs of the enkephalins (8). Using such a model, it was hoped to obtain activity of the μ-type with compounds having mixed agonist and antagonist activity on oral administration.

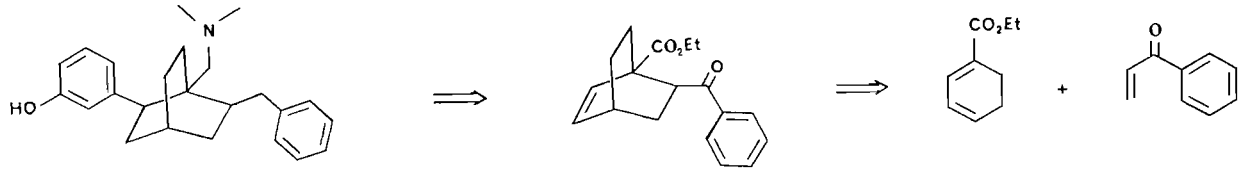
Results and discussion

A retrosynthetic analysis of the bicyclo[2.2.2] structure **2** suggested as a key intermediate the keto ester **3**, the product expected to result from the Diels–Alder reaction of ethyl dihydrobenzoate **4** with vinyl phenyl ketone **5**, followed by functionalizations to the desired target **2**. Four possible geometrical isomers are possible, and a stereospecific approach can reduce the number of possible isomers to give the desired 2,6 *exo* relationship suggested by the modeling experiments.

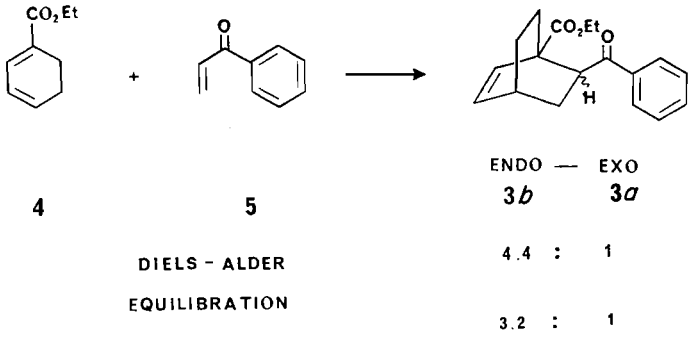
The key intermediate **3** was synthesized via a Diels–Alder reaction. Thus, ethyl dihydrobenzoate **4**, prepared according to the indications of Hünig and Kahanek (9), reacted readily with vinylphenylketone **5** affording **3** in 46% yield as the major compound. Among the other products of this Diels–Alder reaction, the *exo* isomer was also found to be present in 13%, giving rise to a mixture of 4.4:1. Obviously this mixture has not



2 3 4 5

SCHEME 1

reached equilibrium, as the ratio of the *endo*:*exo* mixture was found to be 3.2:1 when pure *endo* or pure *exo* isomers alone were equilibrated by stirring in ethanol containing sodium ethoxide for 3 days at room temperature.



Nuclear magnetic resonance (nmr) spectra can clearly distinguish the *endo* and *exo* relationship, as can be seen by the chemical shift of the olefinic protons that appear to be influenced by the ketone in position 6. In the *exo* isomer, the two protons H-2 and H-3 absorb at 6.20 and 6.45 ppm as a triplet ($J_{3,2}$ = 6 Hz, $J_{3,4}$ = 8 Hz) and as a doublet (J = 4 Hz), whereas in the *endo* isomer, H-2 and H-3 appeared as a doublet (J = 8 Hz) and a triplet ($J_{3,2}$ = 6 Hz, $J_{3,4}$ = 8 Hz), at 6.20 and at 6.85 ppm, the downfield shift of 0.40 ppm being attributed to the influence of the benzoyl carbonyl.

Ortho orientation was easily demonstrated chemically by reducing **3** with sodium borohydride followed by treating the resulting alcohols **6** with phosphorous tribromide. γ-Lactones **7**, readily characterized by their infrared band at 1790 cm^{-1}, were obtained (10).

Base hydrolysis of **3** led to the keto acid **8**, which was submitted to the conditions of the Wolff–Kishner reaction, affording the carboxylic acid **9** in low yield.

Such a result forced us to change the strategy at this stage and, accordingly, the approach outlined in Scheme 3 was used as an alternative route to **2**.

Consequently, the treatment of the *endo* ketoacid **8** with thionyl chloride in chloroform gave the β,γ-unsaturated lactone **10**. This lactone **10** was then ammonolysed by reacting it at room temperature with anhydrous ammonia dissolved in tetrahydrofuran (THF). Analysis of the reaction mixture revealed the formation of the desired *exo* ketoamide **11** as the major product and of the *endo* ketoamide **12** as a minor product. The ratio of *exo* to *endo* was determined to be 2:1. This result is not too surprising as protonation of the intermediate enolate is expected to take place from the least hindered face, which is the face opposite to the ethano bridge. The nmr spectra of the *exo* isomer **11** show the olefinic protons absorbing as a multiplet between 6.35 and 6.55 ppm whereas the *endo* isomer **12** has its corresponding multiplet as a broad and less defined absorption located between 5.7 and 6.7 ppm.

The benzoyl group is now placed with the desired stereochemistry and the reduction of the carbonyl group remains to be carried out to ascertain the proper positioning of the phenylalanine equivalent.

Since the lithium aluminium hydride (LAH) reduction of **11** afforded a mixture of *exo* amino alcohols **13** in variable yields, due most likely to the formation of insoluble salts, it was found that the best approach to achieve this conversion was to carry it out on the nitrile **14**, readily prepared by the treatment of ketoamide **11** with trifluoroacetic anhydride in a mixture of pyridine and dioxane. LAH reduction of the resulting nitrile **14** provided a more reliable higher yielding and efficient preparation of **13**. There were no attempts to separate the diastereoisomers at this stage as, in the next step, the removal of the hydroxyl group eliminated this source of potential problems.

Reduction of **13** by lithium in liquid ammonia according to the indications of Hall *et al.* (11) gave **15**, where the benzyl group is now in place as a phenylalanine equivalent. The Eschweiler–Clark reaction (12) was performed on **15** in a boiling mixture of 37% aqueous formaldehyde solution and formic acid, leading to **16**, a derivative bearing the dimethylamino group that affords the basic nitrogen deemed necessary for analgesic activity.

The remaining problem to tackle was the introduction of the tyrosine equivalent, the *m*-hydroxyphenyl group. This was best achieved by hydroborating the double bond of intermediate **16**. This reaction gave rise to the isomeric alcohols **17***a* and **17***b* after decomposing the amine–borane complex by a base hydrolysis. A mixture of four isomers are possible and were indeed present in the mixture. However, the pair of the two regioisomers were readily separated by preparative hplc (high performance liquid chromatography) from the other pair as the difference of polarity was such that a pair required the incorporation of methanol in the eluent. This behavior is probably due to hydrogen bonding, possible in the case of **17***a* because of the proximity of the hydroxyl group and the dimethylamino group but not possible in the case of **17***b*. Each pair of regioisomers was oxidized to the corresponding ketone by Jones oxidation (13).

The structural assignment of the pair of regioisomers **17***a* and **17***b*, which was based on polarity considerations, was confirmed by the analysis of the nmr spectra of their corresponding ketones **18***a* and **18***b*. Thus, isomer **18***a* has a CH_2 group α to the carbonyl with a bridgehead proton next to it and its nmr shows that H-3a at 2.88 ppm is a doublet of doublets with coupling constants of 3.7 Hz and 14.0 Hz for the coupling of protons H-3a,H-4 and H-3a,H-3b, respectively. On the other hand, isomer **18***b*, having an isolated CH_2 group *ortho* to the carbonyl, shows the absorption of these protons H-2a and H-2b as an AB pair of doublets centered at 2.50 ppm with a coupling constant of 17 Hz.

The Grignard addition of *m*-methoxyphenylmagnesium bromide on ketone **18***a* allowed the introduction of the tyrosine equivalent. The mixture of tertiary alcohols **20** was dehydrated by treating it with *p*-toluenesulfonic acid in refluxing benzene,

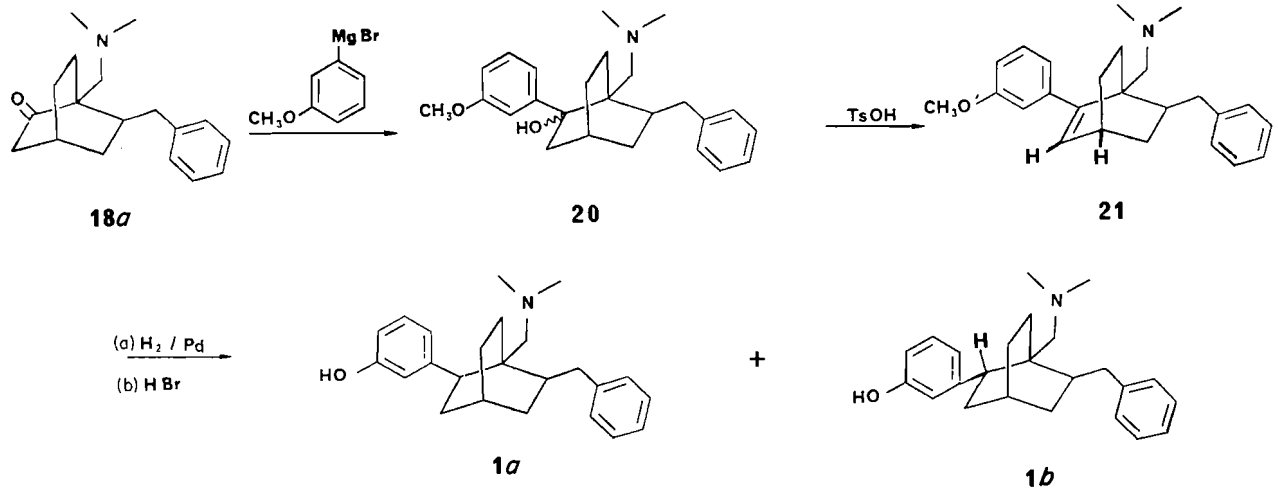

SCHEME 7

thus affording the olefinic product **21**. The olefinic proton absorbs at 5.95 ppm as a doublet having a coupling constant of 6.0 Hz, again in agreement with the proofs of structure of the alcohols **17** and ketones **18**. Hydrogenation of the olefin **21** gave a mixture of two products. Two isomers can be expected from this catalytic hydrogenation but preferential absorption was expected to occur from the least hindered face. Indeed, the reduction gave a major isomer, assigned as the desired isomer, based on the preferential attack of the double bond. The other isomer was assigned as having the *m*-methoxyphenyl group *endo* and was isolated in small amounts.

Deblocking the phenolic function in **22** was carried out by

refluxing **22** in a mixture of concentrated hydrogen bromide in acetic acid, leading to the isolation of the desired target **1**.

Compound **1** and its *endo* isomer were tested in the ^{3}H-Naloxone binding assay (14) and they were found to have only weak binding activity with a IC_{50} (mean inhibitory concentration) of 225 n*M* and 1025 n*M* respectively. Under the same conditions, morphine and methionine enkephalin had a IC_{50} of 4.5 n*M* and 9.0 n*M* respectively. When tested on rats in the hot plate assay (15), both isomers were found to be analgesic at 64 mg/kg when administered orally. Under these conditions, methionine enkephalin was inactive because of poor absorption and morphine was active at 2 mg/kg. Two reasons can be invoked to explain this disappointing biological activity. First of all, there may be a need for the missing methionine portion. Also, the glycine amides are considered as spacers that positioned the key aromatic groups in the correct spatial relationship. The use of the bicyclo[2.2.2]octane system to act as a spacer could be too great a change, as it was shown that slight modifications of the Gly-2 and Gly-3 amide carbonyls result in a marked decrease of the in vitro biological activities (16).

Experimental

Melting points were taken on a Thomas Hoover apparatus in open capillary tubes and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 267 grating spectrophotometer and were recorded as KBr disks unless otherwise noted. A Varian EM-360 spectrometer was used to record nmr spectra in deuterochloroform unless otherwise indicated. Proton chemical shifts are relative to tetramethylsilane (TMS) as internal standard. Elemental analyses were performed by Galbraith and Associates, Knoxville, TN.

All reactions as well as column chromatographic separations were monitored routinely with the aid of thin-layer chromatography (tlc) using precoated 0.25-mm silica gel GF plates, Analtech, visualized by charring with sulfuric acid.

Preparative hplc separations were performed on a Waters PrepLC/System 500 preparative liquid chromatograph using PrepPAK-500/Silica cartridges (5.7 × 30 cm). The peaks were detected with a differential refractive index detector and the flow rate was 200 mL/min, unless otherwise indicated.

endo-*6-Benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene (3)*

Ethyl dihydrobenzoate **4** (335.3 g, 2.21 mol), 1-phenyl-3-propen-1-one **5** (347 g, 2.63 mol), and hydroquinone (32 g, 0.29 mol) were heated under nitrogen at 150°C for 24 h. The mixture was purified by preparative hplc eluting with 10% ether in hexane to yield *endo*-6-benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene **3***a* (286 g, 46%) and *exo*-6-benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene **3***b* (65 g, 13%); *endo*, mp 52–60°C; *exo*: oil.

3*a*: ir: 1725 (CO_2Et), 1680 (C=O) cm^{-1}; ^{1}H nmr (ppm): 0.9–3 (m, 10H, aliphatic protons), 4.15 (m, 3H, OCH_2 + 1 proton), 6.2 (t, 1H, H-3), 6.85 (d, J = 8 Hz, 1H, H-2), 7.45 (m, 3H, *para* and *meta* aromatic protons), 7.95 (m, 2H, *ortho* protons). *Anal.* calcd. for $C_{18}H_{20}O_3$: C 76.08, H 7.09; found: C 76.18, H 7.16.

3*b*: ir: 1725 (CO_2Et), 1680 (C=O) cm^{-1}; ^{1}H nmr (ppm): 0.9–3 (m, 10H, aliphatic protons), 4.15 (m, 3H, OCH_2 + 1 proton), 6.2 (t, 1H, H-3), 6.45 (d, J = 4 Hz, 1H, H-2), 7.45 (m, 3H, *para* and *meta* aromatic protons), 7.95 (m, 2H, *ortho* protons). *Anal.* calcd. for $C_{18}H_{20}O_3$: C 76.08, H 7.09; found: C 76.22, H 7.18.

Equilibrium of endo-*6-benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene (3*a*)*

The *endo* isomer **3***a* (0.1 g, 0.35 mmol) was dissolved in ethanol (3 mL) of a sodium ethoxide solution prepared by reacting sodium (0.2 g) with ethanol (10 mL). The solution was left at room temperature for 3 days. Analysis by hplc, using a μ-Porasil column (Waters Scientific), eluting with hexane – ethyl acetate in a ratio of 8:2 (v/v), gave a ratio of 73:27 in favor of the more polar *endo* isomer **3***a*.

Equilibration of exo-*6-benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene (3*b*)*

The *exo* isomer **3***b* (0.1 g, 0.35 mmol) was dissolved in ethanol (3 mL) of a sodium ethoxide solution prepared by reacting sodium (0.2 g) with ethanol (10 mL). The solution was left at room temperature for 3 days. Analysis by hplc, using the conditions described above, gave a ratio of 76:24 in favor of the more polar *endo* isomer **3***a*.

endo-*6-Benzoylbicyclo[2.2.2]-2-octene-1-carboxylic acid (8)*

endo-6-Benzoyl-1-carboethoxybicyclo[2.2.2]-2-octene (75 g, 0.26 mol) in ethanol (65 mL) was added to a solution of potassium hydroxide (52.8 g, 0.94 mol) in ethanol (200 mL). The mixture was refluxed for 4 h. The solvent was removed under vacuum, and the residue was taken up in water and extracted with ether. The aqueous layer was then acidified, the solid was filtered, and then air-dried to yield *endo*-6-benzoylbicyclo[2.2.2]-2-octene-1-carboxylic acid (**8**) (58.6 g, 87%), mp 249–253°C; ir: 1700 (CO_2H), 1675 (C=O) cm^{-1}; ^{1}H nmr (ppm): 0.9–2.4 (m, 7H, aliphatic protons), 3.95 (mq, J = 6 Hz, H-4, 6.15 (t, J = 8 Hz, 1H, H-3), 6.65 (d, J = 8 Hz, 1H, H-2), 7.50 (m, 3H, *para* and *meta* aromatic protons), 7.85 (m, 2H, *ortho* protons). *Anal.* calcd. for $C_{16}H_{16}O_3$: C 74.98, H 6.29; found: C 74.98, H 6.47.

Enol lactone (10)

endo-6-Benzoylbicyclo[2.2.2]-2-octene-1-carboxylic acid (**8**) (7 g, 27 mmol) was suspended in chloroform (100 mL) and thionyl chloride (14 mL, 0.19 mol) was added. After a reflux period of 3 h, the solution was evaporated to dryness to yield crude enol lactone **10** (6.5 g, 100%). An analytical sample obtained by preparative tlc had mp 100–105°C; ir: 1800 (CO), 1680 (C=C) cm^{-1}; ^{1}H nmr (ppm): 1.75 (m, 4H, aliphatic protons), 2.55 (m, 2H, CH_2), 3.10 (m, 1H, aliphatic proton), 6.40 (m, 2H, olefinic protons), 7.45 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{16}H_{14}O_2$: C 80.65, H 5.92; found: C 80.67, H 5.95.

exo-*6-Benzoylbicyclo[2.2.2]-2-octene-1-carboxamide (11)*

Enol lactone (**10**) (46 g, 0.19 mol) dissolved in tetrahydrofuran (50 mL) was added slowly to a saturated solution of gaseous ammonia in THF (100 mL). After stirring the mixture at room temperature for 6 days, it was evaporated to dryness. Trituration of the mixture of *endo* and *exo* isomers in ether yielded pure *exo* **11**, sparingly soluble in ether (30 g, 61%), mp 165–168°C. The mother liquors contained 16 g of a mixture of the isomers enriched in the *endo* isomer; ir: 3490, 3170 (NH), 1678 (CO), 1670 ($CONH_2$) cm^{-1}; ^{1}H nmr (ppm): 1.55 (m, 5H, aliphatic protons), 2.65 (m, 2H, CH_2), 3.70 (q, 1H), 5.85 (broad peak, 2H, NH_2), 6.45 (d, 2H, olefinic protons), 7.45 (m, 3H, *para* and *meta* aromatic protons), 7.85 (m, 2H, *ortho* protons). *Anal.* calcd. for $C_{16}H_{17}O_2N$: C 75.28, H 6.71, N 5.48; found: C 75.29, H 6.92, N 5.34.

exo-*6-benzoyl-1-cyanobicyclo[2.2.2]-2-octene (14)*

To *exo*-6-benzoylbicyclo[2.2.2]-2-octene-1-carboxamide **11** (2.6 g, 10 mmol) dissolved in anhydrous dioxane (250 mL) and pyridine (23 mL) and maintained at 0°C, was added carefully trifluoroacetic anhydride (2.2 mL). The reaction mixture was heated at 50°C for 3 h and was poured into ice and water. It was then extracted with ether, the organic phases were washed with 5% sodium bicarbonate, with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield, after crystallization from cold ether, *exo*-6-benzoyl-1-cyanobicyclo[2.2.2]-2-octene **14** (2.2 g, 93%), mp 80–81°C; ir: 2240 (CN), 1680 (C=O) cm^{-1}; ^{1}H nmr (ppm): 1.60 (m, 5H, aliphatic protons), 2.70 (m, 2H, CH_2), 3.55 (q, 1H, J = 8 Hz, H-4), 6.35 (m, 2H, J = 2 Hz, olefinic protons), 7.50 (m, 3H, *meta* and *para* aromatic protons), 7.85 (m, 2H, *ortho* aromatic protons). *Anal.* calcd. for $C_{16}H_{15}ON$: C 80.98, H 6.37, N 5.90; found: C 80.80, H 6.32, N 5.84.

exo-*6-(α-hydroxybenzyl)-1-aminomethylbicyclo[2.2.2]-2-octene (13)*

Preparation from keto amide 11

To *exo*-6-benzoylbicyclo[2.2.2]-2-octene-1-carboxamide **11** (1.2 g, 4.7 mmol) dissolved in THF (20 mL) was added slowly a solution of LAH (0.5 g, 13.5 mmol) in THF (10 mL) and the mixture was refluxed for 24 h. The reaction mixture was poured into ice and water. It was then extracted with ether, the organic phases were washed with 5% sodium bicarbonate, with brine, dried (Na_2SO_4), and concentrated *in*

vacuo to yield a residue that was purified by chromatography on alumina to give *exo*-6-(α-hydroxybenzyl)-1-aminomethylbicyclo[2.2.2]-2-octene **13** (0.38 g, 33%), mp 118–120°C; ir: 3365, 3320, 3290 (NH_2, OH) cm^{-1}; ^1H nmr (ppm): 0.9–2.5 (m, 8H, aliphatic protons), 3.05 (m, 2H, CH_2), 3.65 (s, 3H, NH_2, OH), 4.45 (d, J = 10 Hz, 1H, CHO), 6.10 (m, 2H, J = 2 Hz, olefinic protons), 7.20 (s, 5H, aromatic protons). *Anal.* calcd. for $C_{16}H_{21}ON$: C 78.97, H 8.69, N 5.75; found: C 78.70, H 8.90, N 5.55.

Preparation from nitrile ***14***

Similarly, the reduction of nitrile **14** (2.2 g, 9.2 mmol) by LAH (1 g, 26.3 mmol) in THF (40 mL) proceeded well to give 60% yield of **13** whose properties were identical to those of the product obtained from the reduction of the amide **11**.

exo-*6-Benzyl-1-aminomethylbicyclo[2.2.2]-2-octene (**15**)*

exo-6-(α-Hydroxybenzyl)-1-aminomethylbicyclo[2.2.2]-2-octene **13** (11 g, 45 mmol) in THF (75 mL) was added dropwise to a solution of lithium (6 g, 0.86 mol) in liquid ammonia (500 mL). Stirring was maintained for 2 h and then solid ammonium chloride (30 g) was added to the reaction mixture, followed by the careful addition of water. The aqueous mixture was extracted with methylene chloride, the organic phases were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield a residue that was purified by preparative hplc, eluting with 4% methanol in chloroform containing 0.4% NH_4OH to give *exo*-6-benzyl-1-aminomethylbicyclo[2.2.2]-2-octene (**15**) (8.6 g, 84%), mp 102–104°C. The hydrochloride had mp 243–245°C; ir: 3300 (NH_2) cm^{-1}; ^1H nmr (ppm): 1.0–3.0 (m, 14H, aliphatic protons), 6.20 (m, 2H, J = 4 Hz, olefinic protons), 7.15 (s, 5H, aromatic protons). *Anal.* calcd. for $C_{16}H_{21}NCl$: C 72.84, H 8.40, N 5.31, Cl 13.43; found: C 72.70, H 8.37, N 5.21, Cl 13.23.

exo-*6-Benzyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octene (**16**)*

exo-6-Benzyl-1-aminomethylbicyclo[2.2.2]-2-octene **15** (5 g, 22 mmol), formic acid (100 mL), and 35% aqueous formaldehyde (5 mL) were refluxed under nitrogen for 5 h. The volatiles were removed under vacuum and the residue was taken up in water (100 mL). The resulting solution was neutralized with 5% sodium bicarbonate, extracted with methylene chloride, dried (Na_2SO_4), and evaporated to yield **16** (5 g, 89%). Its hydrochloride had mp 237–240°C; ^1H nmr (ppm): 1.0–3.0 (m, 18H, aliphatic protons), 6.25 (m, 2H, J = 4 Hz, olefinic protons), 7.10 (s, 5H, aromatic protons). *Anal.* calcd. for $C_{18}H_{26}NCl$: C 74.02, H 8.98, N 4.80, Cl 12.15; found: C 73.90, H 9.01, N 4.80, Cl 12.34.

exo-*6-Benzyl-2-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**17**a, **17**b)*

exo-6-Benzyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octene (**16**) (9 g, 35 mmol) dissolved in THF (20 mL) was treated with diborane (50 mL, 1 *M* solution in THF, 50 mmol) at 0°C under nitrogen for a period of 2 h. Sodium hydroxide (50 mL, 3 *N*) and 30% hydrogen peroxide (50 mL) were slowly and successively added to the mixture, which was then refluxed for 1 h to hydrolyse the amine–borane complex. The two phases were separated and the aqueous phase was extracted with ether. The organic phases were combined and washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield a residue that was purified by preparative hplc, eluting with 10% methanol in chloroform containing 0.1% NH_4OH to yield 6-benzyl-2-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**17***a*) as the less polar isomer (6.2 g, 65%) and 6-benzyl-3-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**17***b*) as the more polar isomer (1.7 g, 18%).

Isomer ***17***a: ir: 3390 (OH) cm^{-1}: ^1H nmr (ppm): 1.0–2.0 (m, 7H, aliphatic protons), 2.0–3.0 (m, 13H, aliphatic protons), 3.95 (m, 1H, CH), 7.20 (s, 5H, aromatic protons), 7.85 (br s, 1H, OH). *Anal.* calcd. for $C_{18}H_{27}NO$: C 79.12, H 9.89, N 5.12; found: C 79.64, N 9.97, N 4.98.

Isomer ***17***b: ir: 3390 (OH) cm^{-1}; ^1H nmr (ppm): 1.0–2.9 (m, 21H, aliphatic protons), 2.90 (m, 1H, CH), 7.20 (s, 5H, aromatic protons). *Anal.* calcd. for $C_{18}H_{27}NO$: C 79.12, H 9.89, N 5.12; found: C 79.40, H 9.71, N 4.85.

exo-*6-Benzyl-2-keto-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**18**a)*

exo-6-Benzyl-2-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**17***a*) (5 g, 18 mmol) dissolved in acetone (100 mL) was cooled at 0°C and 1.1 *M* Jones reagent (18 mL, 19.8 mmol) was added dropwise to the solution. The mixture was stirred for 4 h at 0°C and was poured into water (50 mL). It was extracted with methylene chloride. The organic phase was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield *exo*-6-benzyl-2-keto-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**18***a*) (4.8 g, 91%) as an oil; ir: 1715 (CO) cm^{-1}; ^1H nmr (ppm): 1.0–2.3 (m, 2H, aliphatic protons), 2.5 (s, 2H, CH_2N), 2.70 (d of d, J = 11.2 Hz, 14 Hz, H-3b), 2.90 (d of d, J = 3.7 Hz, 14.0 Hz, H-3a), 3.03 (s, 3H, CH_3), 3.07 (s, 3H, CH_3), 3.35 (2H, q, J_{ab} = 14 Hz, CH_2), 7.25 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{18}H_{25}NO$: C 79.65, H 9.28, N 5.16; found: C 79.74, H 9.40, N 5.00.

exo-*6-Benzyl-3-keto-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**18**b)*

exo-6-Benzyl-3-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**17***a*) (2.5 g, 9 mmol) dissolved in acetone (100 mL) was cooled at 0°C and 1.1 *M* Jones reagent (9 mL, 9.9 mmol) was added dropwise to the solution. The mixture was stirred for 4 h at 0°C and was poured into water (50 mL). It was extracted with methylene chloride. The organic phase was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield *exo*-6-benzyl-3-keto-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**18***b*) (2.0 g, 90%) as an oil; ir: 1730 (CO) cm^{-1}; ^1H nmr (ppm): 1.0–2.3 (m, 10H, aliphatic protons), 2.40 (d, J = 14 Hz, H-3b), 2.90 (d, J = 14.0 Hz, H-3a), 2.82 (s, 3H, CH_3), 2.88 (s, 3H, CH_3), 3.16 (2H, q, J_{ab} = 14 Hz, CH_2), 7.25 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{18}H_{25}NO$: C 79.65, H 9.28, N 5.16; found: C 79.70, H 9.22, N 5.04.

endo- *and* exo-*6-benzyl-2-(*m*-methoxyphenyl)-2-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**20**)*

To *m*-methoxyphenylmagnesium bromide prepared by the reaction of magnesium (0.97 g, 40 mmol) with *m*-bromoanisole (7.5 g, 40 mmol) in THF (50 mL) was added dropwise a solution of *exo*-6-benzyl-2-keto-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**18***a*) (4 g, 14.7 mmol) at room temperature. After stirring for 30 min, the reaction mixture was quenched by adding water (14 mL). The aqueous mixture was extracted with chloroform. The organic phase was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield a residue that was purified by preparative hplc, eluting with 1% methanol in chloroform containing 1% NH_4OH to give a mixture of *endo*- and *exo*-6-benzyl-2-(*m*-methoxyphenyl)-2-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**20**) (3.3 g, 59%), mp 85–89°C; ir: 3200 (OH) cm^{-1}; ^1H nmr (ppm): 1.0–3.0 (m, 20H, aliphatic protons), 3.75 (s, 3H, CH_3), 6.40 (s, 1H, OH), 7.15 (m, 9H, aromatic protons). *Anal.* calcd. for $C_{25}H_{33}NO_2$: C 79.11, H 8.76, N 3.69; found: C 79.38, H 8.40, N 3.99.

exo-*6-Benzyl-2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**21**)*

The mixture of *endo*- and *exo*-6-benzyl-2-(*m*-methoxyphenyl)-2-hydroxy-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**20**) (0.59 g, 1.55 mmol) was refluxed for 2 h in benzene containing traces of *p*-toluenesulfonic acid. The reaction mixture was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield *exo*-6-benzyl-2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octene (**21**) (0.58 g, 100%), mp 88–100°C. Its hydrochloride had mp 162–164°C; ^1H nmr (ppm): 1.85–2.55 (m, 17H, aliphatic protons), 3.70 (s, 3H, CH_3), 3.75 (d, 1H, CH), 6.00 (d, J = 6 Hz, 1H, H-3), 6.85 (m, 4H, aromatic protons), 7.15 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{25}H_{31}NO$: C 72.84, H 8.15, N 3.39; found: C 73.12, H 8.36, N 3.26.

exo-*6-Benzyl*-exo-*2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**22**a)*

exo-6-Benzyl-*exo*-2-*m*-methoxyphenyl-1-dimethylaminoethylbicyclo[2.2.2]-2-octene (2.9 g, 8 mmol) in ethanol (150 mL) was hydro-

genated at 50 psi (1 psi = 6.9 kPa) over 5% palladium on charcoal (0.35 g) for a period of 1 h. After filtering through Celite, the filtrate was concentrated *in vacuo* to yield 2.9 g of a mixture of epimers. The crude mixture was chromatographed on silica gel, eluting with chloroform treated with 0.1% NH_4OH, giving *exo*-6-benzyl-*exo*-2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**22***a*) (1.8 g, 62%) as the major isomer and *endo*-6-benzyl-*exo*-2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**5***b*) as the minor isomer (150 mg).

The hydrochloride of the major isomer had mp 238–240°C.

Isomer **22**a: ^{1}H nmr (ppm): 1.60–2.10 (m, 21H, aliphatic protons), 3.05 (m, 2H, H-4, H-5), 3.70 (s, 3H, CH_3), 6.85 (m, 4H, aromatic protons), 7.10 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{25}H_{35}NO$: C 75.10, H 8.51, N 3.50; found: C 74.97, H 8.46, N 3.41.

Isomer **22**b: ^{1}H nmr (ppm): 1.60–2.10 (m, 21H, aliphatic protons), 3.05 (m, 2H, H-4, H-5), 3.70 (s, 3H, CH_3), 6.85 (m, 4H, aromatic protons), 7.10 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{25}H_{35}NO$: C 75.10, H 8.51, N 3.50; found: C 75.21, H 8.36, N 3.51.

exo-*6-Benzyl*-exo-*2*-m-*hydroxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (1*a)

exo-6-Benzyl-*exo*-2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**22***a*) (0.46 g, 1.27 mmol) in acetic acid (5 mL) and 48% hydrobromic acid (5 mL) was refluxed under nitrogen for a period of 24 h. The mixture was neutralized with concentrated ammonia, extracted with methylene chloride, the organic phase was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield *exo*-6-benzyl-*exo*-2-*m*-hydroxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**1***a*) (0.43 g, 97%). After purification by tlc, it had mp 155–157°C. Its hydrochloride had mp 264–265°C; ^{1}H nmr (ppm): 1.60–2.10 (m, 19H, aliphatic protons), 3.05 (m, 2H, H-4, H-5), 5.48 (s, 1H, OH), 6.85 (m, 4H, aromatic protons), 7.10 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{24}H_{32}NOCl \cdot 0.5H_2O$: C 73.01, H 8.36, N 3.54; found: C 73.34, H 8.42, N 3.44.

endo-*6-Benzyl*-exo-*2*-m-*hydroxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (1*b)

endo-6-benzyl-*exo*-2-*m*-methoxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**22***b*) (0.10 g, 0.27 mmol) in acetic acid (3 mL) and 48% hydrobromic acid (3 mL) was refluxed under nitrogen for a period of 24 h. The mixture was neutralized with concentrated ammonia, extracted with methylene chloride, the organic phase was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield *exo*-6-benzyl-*exo*-2-*m*-hydroxyphenyl-1-dimethylaminomethylbicyclo[2.2.2]-2-octane (**1***b*) (0.08 g, 80%), isolated as an oil. Its hydrochloride had mp 150–153°C; ^{1}H nmr (ppm): 1.60–2.10 (m, 19H, aliphatic protons), 3.05 (m, 2H, H-4, H-5), 6.85 (m, 5H, aromatic protons, OH), 7.10 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{24}H_{32}NOCl$: C 74.71, H 8.30, N 3.63; found: C 74.41, H 8.58, N 3.41.

Preparation of 1-carboethoxy-6-(α-hydroxybenzyl)bicyclo[2.2.2]-2-octene (6)

To a solution of 1-carboethoxy-6-benzoylbicyclo[2.2.2]-2-octene (280 mg, 1 mmol) in methanol (10 mL) was added sodium borohydride (40 mg) and the reaction mixture was stirred at room temperature for 15 min. The mixture was poured into water and extracted with ether, washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed on silica gel, eluting with benzene to yield 254 mg of 1-carboethoxy-6-(α-hydroxybenzyl)bicyclo[2.2.2]-2-octene; ir: 3480 (OH), 1720 (CO) cm^{-1}; ^{1}H nmr (ppm): 1.60–2.10 (m, 13H, aliphatic protons), 4.00 (m, 3H, CH_2, CHO), 6.35 (m, 2H, olefinic protons), 7.23 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{18}H_{22}O_3$: C 75.49, H 7.74; found: C 75.22, H 7.71.

Preparation of lactone (7)

To a solution of 1-carboethoxy-6-(α-hydroxybenzyl)bicyclo[2.2.2]-2-octene (154 mg, 0.53 mmol) in ether (5 mL) was added phosphorous oxychloride (100 mg) and the reaction mixture was stirred at room temperature for 30 min. The mixture was poured into water and extracted with ether, washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed on silica gel, eluting with benzene to yield 129 mg of lactone (**7**); ir: 1780 (CO) cm^{-1}; ^{1}H nmr (ppm): 1.30–2.70 (m, 8H, aliphatic protons), 4.73 (d, J = 10 Hz, 1H, CHO), 6.10 (d, J = 8 Hz, 1H, H-2), 6.50 (t, J = 6 Hz, 1H, H-3), 7.27 (m, 5H, aromatic protons). *Anal.* calcd. for $C_{16}H_{15}O_2$: C 79.97, H 6.71; found: C 79.78, H 6.90.

Preparation of 1-carboethoxy-6-benzylbicyclo[2.2.2]-2-octene

A solution of 1-carboethoxy-6-benzoylbicyclo[2.2.2]-2-octene (280 mg, 1 mmol) and potassium hydroxide (300 mg) in ethylene glycol (10 mL) was heated at 100°C for a period of 45 min. At this point, all ester was found to be hydrolysed to its corresponding acid. Hydrazine (0.5 mL) was then added and the temperature was brought up to 200°C and maintained at that temperature for 2 h. The reaction mixture was then poured onto water and extracted with ether, washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was taken up in ether and treated with an excess of diazomethane. Evaporation of the ether gave a residue (207 mg) that was purified by chromatography on silica gel, eluting with 10% ether in hexane to yield 17 mg of 1-carbomethoxy-6-benzylbicyclo[2.2.2]-2-octene as an oil; ir: 1730 (CO) cm^{-1}; ^{1}H nmr (ppm): 1.50–2.70 (m, 10H, aliphatic protons), 3.83 (s, 3H, CH_3), 6.30 (m, 2H, H-2 and H-3), 7.27 (m, 5H, aromatic protons); mass spectrum: M^+ 256.

Received August 12, 1985[1]

A. L. De and A. K. Atta. Can. J. Chem. **64**, 1521 (1986).

The thermodynamic first dissociation constants, $({}_sK)_{H_2A}$ of thymolsulfonephthalein (H_2A), an uncharged acid, have been determined at 25°C in aqueous mixtures of 10, 30, 50, 70, and 80 wt% acetonitrile (ACN), 11.52, 20.31, 29.64, and 36.83 wt% urea, 20, 40, 60, and 80 wt% dimethyl sulfoxide (DMSO) by spectrophotometric measurements. The solvent effect represented by $\partial(\Delta G^0) = 2.303RT[p({}_sK)^N - p({}_wK)^N]$ is found to increase in ACN + H_2O system as mol% ACN increases in the solvent. In contrast, the corresponding values in urea + H_2O as well as DMSO + H_2O solvent systems decrease with increase in proportion of organic component in the solvent, the decrease being sharp in urea + H_2O. The results have been discussed in terms of the standard Gibbs energies of transfer of H^+ from water to the mixed solvent, $\Delta G_t^0(H^+)$ and the relative values of the standard Gibbs energies of transfer of HA^-, $\Delta G_t^0(HA^-)$ and of $\Delta G_t^0(H_2A)$ in all the solvent systems. The overall dissociation behaviour of the acid (H_2A) is found to be dictated by the specific solute-solvent interactions of the species participating in the dissociation equilibria.

A. L. De et A. K. Atta. Can. J. Chem. **64**, 1521 (1986).

Faisant appel à des mesures spectrophotométriques et opérant à 25°C, dans des mélanges aqueux à 10, 30, 50, 70 et 80% (poids) d'acétonitrile (ACN), à 11,52, 20,31, 29,64 et 36,83% (poids) d'urée et 20, 40, 60 et 80% (poids) de diméthylsulfoxyde (DMSO), on a déterminé les premières constantes de dissociation thermodynamiques, $({}_sK)_{H_2A}$, de la thymolsulfonephtaléine (H_2A), un acide qui n'est pas changé. On a trouvé que, dans le système ACN/H_2O, l'effet de solvant représenté par l'équation $\partial(\Delta G^0) = 2{,}303RT[p({}_sK)^N - p({}_wK)^N]$ augmente avec une augmentation de la concentration de ACN dans le solvant. Par ailleurs, les valeurs correspondantes dans les systèmes de solvant urée/H_2O et DMSO/H_2O diminuent avec une augmentation de la proportion du composé organique dans le solvant; la diminution est rapide dans le système urée/H_2O. On discute des résultats en fonction des énergies standard de Gibbs pour le transfert des ions H^+ de l'eau vers le solvant mixte, $\Delta G_t^0(H^+)$ et des valeurs relatives des énergies standard de Gibbs pour le transfert des ions HA^-, $\Delta G_t^0(HA^-)$, et de l'acide H_2A, $\Delta G_t^0(H_2A)$, dans tous les systèmes de solvants. On a trouvé que le comportement global de la dissociation de l'acide (H_2A) est dicté par les interactions spécifiques soluté/solvant des espèces qui participent dans l'équilibre de la dissociation.

[Traduit par la revue]

Introduction

Despite extensive (1–9) studies the solvent effect on the dissociation of weak Brønsted acids can hardly be considered completely understood. Previously solvent effect was believed to be chiefly guided by the change of dielectric constant of the solvents. But recent observation that the extent of proton transfer processes differs in different isodielectric solvent systems (8, 9) leads to recognize that the dielectric constant can not be the sole factor but the chemical nature of the cosolvents also plays an important role in dictating the overall solvent effects.

In this paper attempts have been made to examine the solvent effects on proton transfer equilibria of the neutral acid, thymolsulfonephthalein in a series of aqueous binary mixtures of several cosolvents having different physicochemical properties such as urea, dimethyl sulfoxide (DMSO) and acetonitrile (ACN), in light of the solvation behaviour of the species involved in the dissociation equilibria. Unlike DMSO + H_2O (10) and ACN + H_2O (11) mixtures, the dielectric constant (ϵ_s) value of urea + H_2O (12) increases with the increase in organic component of the solvent in the mixture (ϵ_s values are shown in Table 4). Such an analysis is expected to reveal important information on the solvation behaviour of the species involved in the dissociation equilibria, as would be guided by the influence of varying acidity, basicity, dispersion, structural and electronic characteristics of the cosolvents and their aqueous mixtures besides the varying Born-type electrostatic interactions on the ionic species involved. Dissociation constants of monopositively charged acids in urea + H_2O (7*c*, *d*), ACN + H_2O (7*e*), and DMSO + H_2O (13, 14) were reported earlier and the study is now extended to uncharged acid.

The structures of thymolsulfonephthalein may be represented by **I** to **III**.

The probable structure of thymolsulfonephthalein in solution in red colour acid form is **II** or **III**. Kolthoff *et al.* (15) considered acid form of a thymolsulfonephthalein as a hybrid, $A^{\pm}$ (acid–base type $A^{\pm}B^{\pm -}$). While studying the salt effect and medium effect on the dissociation of *m*-cresolsulfonephthalein in methanol–water, Bates *et al.* (16) has indicated that the behaviour of activity coefficient function does not lend support to one of the three possible structures A^0B^-, $A^{\pm}B^-$, or $A^{\pm}B^{\pm -}$.

The neutral thymolsulfonephthalein can be written (17) as H_2A since it has two ionizable hydrogen atoms, one of which undergoes ionization in the acid range (step *i*) and the other in the alkaline range (step *ii*). The two steps may be represented in reaction [1].

$$[1]\quad \underset{\text{(red)}}{H_2A} \underset{\text{step } i}{\overset{-H^+}{\rightleftharpoons}} \underset{\text{(yellow)}}{HA^-} \underset{\text{step } ii}{\overset{-H^+}{\rightleftharpoons}} \underset{\text{(blue)}}{A^{2-}}$$

The first stages of ionization of neutral H_2A in the mixed solvent SH is represented by reaction [2]

$$[2]\quad H_2A + SH \rightleftharpoons HA^- + SH_2^+$$

Experimental

Purification of ACN (18) (BDH), DMSO (19) (Merck), and water (18) have been described. DMSO + H_2O and urea + H_2O mixtures were prepared by weight and dry HCl gas was passed into respective solvents to produce HCl solution. Molal concentration of HCl was obtained by titrating weighed amounts of solution dissolved in water against standard aqueous alkali using phenolphthalein as the indicator. Stock HCl solution in ACN + H_2O mixture was, however, obtained by mixing weighed amounts of standard aqueous HCl solution and pure ACN in suitable proportion to give the desired solvent composition. This procedure in ACN + H_2O was necessary for stable absorbance readings and reproducibility of result. Thymolsulfonephthalein (pro-analysis, E. Merck) was used as such. Dissociation constants were determined spectrophotometrically using the method described for some acids earlier (5*a*, 20, 21). As H_2A is a relatively strong acid, it is possible to achieve considerable variation in the degree of dissociation by varying the concentration of added strong acid, HCl permitting determination of $p({}_sK)_{H_2A}$ without recourse to buffer solution. A series of solutions were prepared in 10 cm^3 amounts by adding weighed amounts of HCl solution, indicator solution, and the appropriate solvent. Simple calculation gave the molalities of HCl. The spectral

absorbances were determined at 25 ± 0.2°C using a PMQ II CARL ZEISS spectrophotometer with 1 cm cells at 548 nm where the absorbance shows a maximum for the acid form in water. The limiting absorbances of the acid form (H_2A) were determined in concentrated solution of HCl (4–6 M), (in ACN + H_2O, the values of m_{HCl} used were much less and for the limiting absorption of the completely acid form, a very much smaller amount of concentrated HCl was required when compared to other solvent systems) but that for the base form (HA^-) was determined in the respective solvents without any addition of alkali (16, 22). The absorbance readings were corrected, where necessary, for the identical total concentration of the indicator. The indicator solution in pure solvent contained virtually exclusively the species HA^- and there was no trace of A^{2-} because measurement at 598 nm (the maximum absorption wavelength of blue form, A^{2-}) showed no absorption at all (21).

Results

For determination of thermodynamic dissociation constant, $({}_sK)_{H_2A}$ (subscript s refers to mixed solvent) an extrapolation function $p({}_sK)'_{H_2A}$ defined by reaction [3] was constructed (20) by combining mass law expression for reaction [2] with the Debye–Hückel expression for activity coefficient.

$$[3]\quad p({}_sK)'_{H_2A} = -\log m_{SH^+_2} - \log (m_{HA^-}/m_{H_2A}) + 2S_f\sqrt{\mu}(1 + Ba_0\sqrt{\mu})^{-2} = p({}_sK)_{H_2A} + f(\mu)$$

where $m_{SH^+_2}$ is the relative molality of H^+ in the solution, $S_f = 1.824 \times 10^6(\epsilon_s T)^{-3/2}$ and $B = 50.29(\epsilon_s T)^{-1/2}$ are the Debye–Hückel constants, a_0 is the ion-size parameter, μ is the ionic strength being equal to $\mu = m_{HCl} \cdot d_s$ where d_s is the density of the solvent. Densities were available from literature (10–12). The concentration of the ionic species obtained from dissociation of H_2A being extremely small compared to that of m_{HCl}, their contribution to the ionic strength can be neglected. As indicator concentration is very small, the value of $m_{SH^+_2}$ is practically the same as that of m_{HCl}. Dielectric constant values (ϵ_s) required for calculation of Debye–Hückel constants were available from literature (10–12). The value of concentration ratio, $m_{HA^-}/m_{H_2A} = (A - A_a)/(A_b - A)$ were obtained (5*a*, 20) from absorbances A_a, A_b, and A of the completely acid form (H_2A), completely base form (HA^-), and the mixture of the two forms measured at an identical total concentration of the indicator in the same cell. In eq. [3], $({}_sK)'_{H_2A}$ is the apparent dissociation constant which becomes equal to thermodynamic dissociation constant, $({}_sK)_{H_2A}$ at an ionic strength of zero. $p({}_sK)'_{H_2A}$ values were calculated by considering $a_0 = 0$, because, this numerical value resulted in linear $p({}_sK)'_{H_2A}$ plots. Other value of a_0 (= 1, 2 etc.) also produces straight lines with different slopes but have no effect on $p({}_sK)_{H_2A}$ values.

The values of m_{HCl}, spectral absorbances (A), and $p({}_sK)'_{H_2A}$ are listed in Tables 1–3. $p({}_sK)_{H_2A}$ values in the molal scale in the three solvent systems are given in Table 4. The uncertainty in the pK values is about ±0.01 unit. pK value of H_2A in water, i.e., $p({}_wK)_{H_2A}$ reported recently (17) agreed completely with the literature value (23).

Discussion

To make a valid comparison (5*b*, 7, 8, 24) of the results in different solvents, it is necessary to use dissociation constants in the mole fraction scale, $p({}_sK)^N_{H_2A}$ which is related to molal scale value by the equation (2, 7) $p({}_sK)^N_{H_2A} = p({}_sK)_{H_2A} + \log 1000/M_{SH}$ where M_{SH} is the average molecular weight of the mixed solvent. Solvent effect on the dissociation can be represented by (8*b*)

$$[4]\quad \text{Solvent effect} = \partial(\Delta G^0) = {}_s\Delta G^0 - {}_w\Delta G^0 = 2.303RT[p({}_sK)^N_{H_2A} - p({}_wK)^N_{H_2A}] = 2.303RT[p({}_sK)_{H_2A} - p({}_wK)_{H_2A} - \log M_{SH}/M_w]$$

[a]Dielectric constant values of ACN + H_2O (11), urea + H_2O (12), and DMSO + H_2O (10) mixtures were taken from literature. Some of the values in ACN + H_2O were obtained by interpolation.

[b]$\Delta G_t^0(H^+)$ values in ACN + water have been obtained from ref. 18 by interpolation and the values in DMSO + water and urea + water have been taken from refs. 28 and 29, respectively. Uncertainty in $\Delta G_t^0(H^+)$ values are ±0.2 kJ mol^{-1}.

[c]Reference 17.

where $({}_wK)_{H_2A}$ and M_w are the dissociation constant in pure water and molecular weight of water, respectively. Values of $\partial(\Delta G^0)$ in mole fraction scale are summarised in Table 4.

Figure 1 depicts the variation of $\partial(\Delta G^0)$ with mol% non-aqueous component. $\partial(\Delta G^0)$ increases gradually with increase in mol% ACN. In contrast, the corresponding value in urea + H_2O and DMSO + H_2O decreases with increase in proportion of organic co-solvent in the mixed solvent, the decrease being sharp in urea + H_2O. Solvent effect on the dissociation of positively charged acids has also been found to be unusually large (7*c*, *d*) in urea + H_2O solvent systems.

Solvent effect is determined by the interactions of H^+, H_2A,

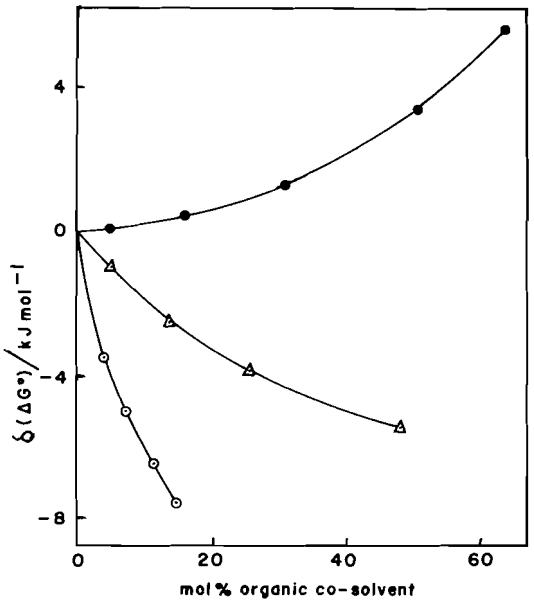

FIG. 1. Variation of $\partial(\Delta G^0)$ of thymolsulfonephthalein in aqueous mixtures of DMSO (△), ACN (●), and urea (○) at 298.15 K.

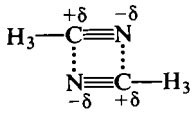
and HA^- with the solvent molecules and is better understood in terms of $\Delta G_t^0(i)$ values in eq. [5] of all the three species involved in the dissociation equilibrium (3, 20)

$$[5] \quad \partial(\Delta G^0) = \Delta G_t^0(H^+) + \Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$$

where $\Delta G_t^0(i)$ is the Gibbs energy change accompanying the transfer of one mole of species i from the standard state in water to the standard state in the solvent concerned, both on the mole fraction scale.

$\Delta G_t^0(H^+)$ values for all the solvent systems based on widely used (25–27) extrathermodynamic method using the reference electrolyte [RE = Ph_4AsBPh_4 (Ph = phenyl)] assumption, $\Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$ are available in literature (18, 28, 29). $\Delta G_t^0(H^+)$ values are found to be increasingly negative in DMSO + H_2O and urea + H_2O indicating increased stabilization of H^+ and the increased solvation of H^+ is dictated by the co-solvent-induced basicity of the solvents (28, 29). $\Delta G_t^0(H^+)$ for ACN + H_2O passes through a minimum. $\Delta G_t^0(H^+)$ for pure ACN is positive (18) (not shown



A

in Fig. 2). In spite of fairly large negative charge on nitrile N atom of ACN molecule, the protophobic character of ACN may arise from the possible formation of dimers (**A**) which are shown from ir studies to exist in pure ACN. Negative charge centres of nitrile N atom is not available for H^+ solvation and ACN behaves as protophobic solvent. Thus, the initial increased solvation of H^+ can be attributed to the increased basicity of aqueous ACN resulting from the breakdown (30) of three-dimensional ice-like water (31) structure releasing more basic monomeric water molecules. The "non-aqueous" water, containing increased number of monomeric water molecules, is effectively a more basic solvent (3). Moreover, these water monomers and ACN molecules may lead to the formation of intercomponent hydrogen-bonded complexes (32) (**B**) and (**C**)

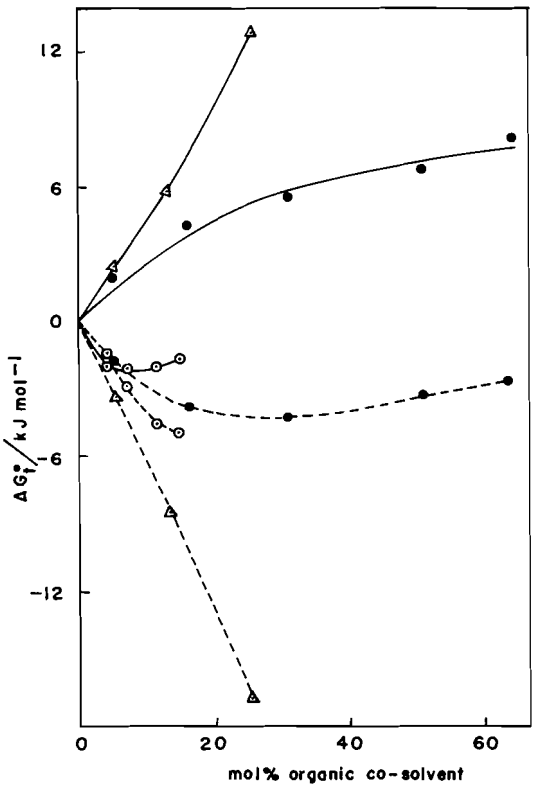


FIG. 2. Variation of $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ of thymolsulfonephthalein [solid line] and $\Delta G_t^0(H^+)$ [dotted line] in aqueous mixtures of DMSO (△), ACN (●), and urea (○) at 298.15 K.

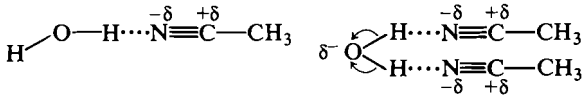
resulting in an increased basicity of the hydroxyl oxygen itself due to the presence of N lone pair.



B C

Increasing trend in $\Delta G_t^0(H^+)$ at higher ACN mol% may be partly attributed to the Born-type electrostatic interaction and partly to the protophobic character of ACN. Values of $\Delta G_t^0(H^+)$ facilitates the evaluation of the combined term $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ from eq. [5]. Variations of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ (Table 4) with mol% organic co-solvent shown in Fig. 2. Value of $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ in urea + H_2O decreases and passes through a minimum. On the other hand, the corresponding value in ACN + H_2O and DMSO + H_2O increases with mol% organic component, the value passing through more positive magnitudes in DMSO + H_2O.

The dispersion interaction contribution to the combined term is expected to be cancelled to a large extent. The solvents, however, differ in their dielectric constant (ϵ_s) values and solvating capabilities. ϵ_s value increases as urea is added to water, but the value decreases on addition of ACN or DMSO. Contribution to Gibbs energy of transfer of HA^- due to Born-type electrostatic interaction (3) is positive in aqueous mixtures of ACN or DMSO and negative in urea + H_2O. Again, ϵ_s value of DMSO + H_2O being greater than that of ACN + H_2O of similar mol% non-aqueous component, electrostatic interaction should impart less positive contribution to $\Delta G_t^0(HA^-)$ in DMSO + H_2O than in ACN + H_2O. Contrary behaviour as reflected in relative positions of $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ curves in DMSO + H_2O and ACN + H_2O (Fig. 2) may be

attributed to stronger anion desolvating capability of DMSO compared to ACN. Destabilization of anion in DMSO + H_2O and ACN + H_2O is likely to stem from the weak H-bond donating capability and the location (33) of positive end of the solvent dipole at a sterically unapproachable position of the molecule. From this point of view, the non-linearity of and increased number of $—CH_3$ groups in DMSO make positive end of the dipole less available to anion than in ACN and this is probably responsible for the observed relative behaviour of $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ in DMSO + H_2O and ACN + H_2O.

In case of urea + H_2O, besides the negative contribution to $\Delta G_t^0(HA^-)$ due to Born electrostatic effect, further stabilization of HA^- is expected from "acid–base type" interaction of the negative charge centre of HA^- with the Zwitterionic form $\overset{+}{N}H_2{=}C(NH_2)O^-$, the actual contributor to the resonating structure of urea. The Zwitterionic structure of urea molecule probably makes it more acidic compared to water molecule. For this reason, hydrogen bond formed by HA^- are expected to be stronger with urea than with water, causing greater stabilization of HA^- and more negative ΔG_t^0 values with increasing proportion of urea in the solvent. The upward trend of $\Delta G_t^0(HA^-) - \Delta G_t^0(H_2A)$ after passing through a minimum is consistent with those observed (28, 29) for some anions like benzoate, Cl^-, OH^-. The upward trend after passing through a minimum is explained by the interaction of the solute species at that structurally critical region of the mixed solvents.

Interaction of H^+ is reflected in $\Delta G_t^0(H^+)$ values which may be considered as a measure of basicities of the solvents relative to water (3). In conclusion it may be said that very large negative magnitude of $\Delta G_t^0(H^+)$ in DMSO + H_2O compared to that in ACN + H_2O is primarily responsible for contrasting dissociation behaviour of H_2A in these two solvent systems and maximum acidic strength of H_2A in urea + H_2O is due primarily to combined effect of stability of both H^+ and HA^- ions in the mixed solvent relative to that in water.

Diaulusterols A and B from the skin extracts of the dorid nudibranch *Diaulula sandiegensis*

DAVID E. WILLIAMS, STEPHEN W. AYER, AND RAYMOND J. ANDERSEN[1]

Departments of Oceanography and Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received January 14, 1986

DAVID E. WILLIAMS, STEPHEN W. AYER, and RAYMOND J. ANDERSEN. Can. J. Chem. **64**, 1527 (1986).

Two new steroids, diaulusterol A (**2**) and diaulusterol B (**3**), have been isolated from skin extracts of the dorid nudibranch *Diaulula sandiegensis*. The proposed structures of **2** and **3** are based on spectral arguments.

DAVID E. WILLIAMS, STEPHEN W. AYER et RAYMOND J. ANDERSEN. Can. J. Chem. **64**, 1527 (1986).

On a isolé deux nouveaux stéroïdes, le diaulustérol A (**2**) et la diaulustérol B (**3**), des écorces de la *Diaulula sandiegensis*. On propose les structures **2** et **3** en se basant sur des données spectrales.

[Traduit par la revue]

Introduction

The intertidal and subtidal regions of the Pacific Coast of North America are inhabited by sizable populations of a large number of species of dorid nudibranchs (1). Many of the species have distributional ranges that extend along the entire coastline from Alaska to Mexico. A series of examinations of the dorid *Cadlina luteomarginata*, collected at several California (2) and British Columbia (3) sites, showed that its skin chemistry differed from one collecting site to another. It was simultaneously shown that the majority of metabolites present in the skin extracts of *C. luteomarginata* were obtained from sponges in the nudibranch's diet, and that the observed variation in skin chemistry was a consequence of changing diet with changing collection site.

Diaulula sandiegensis is another dorid which has a documented distribution range that extends from Alaska to Cape San Lucas, Mexico (1). Walker and Faulkner isolated a series of nine chlorinated acetylenes related to **1** from specimens of *D. sandiegensis* collected at Point Loma, California (4). We have examined specimens of *D. sandiegensis* collected in Barkley Sound, British Columbia, and found them to contain the two new steroids, diaulusterol A (**2**) and diaulusterol B (**3**).

D. sandiegensis was collected by hand using SCUBA (−1 to −15 m) on exposed rocky reefs in Barkley Sound. Freshly collected animals were immediately immersed in methanol and allowed to extract at 2°C for two days. The extraction solvent was decanted from the nudibranchs, evaporated *in vacuo*, and the residue was partitioned between brine and ethyl acetate. Fractionation of the ethyl acetate soluble material by flash, LH20, and reverse-phase chromatography produced pure samples of diaulusterol A (**2**) and diaulusterol B (**3**).

Diaulusterol A (**2**) was isolated as a uv (ultraviolet) absorbing clear oil that showed ir (infrared) bands at 3380, 1722, 1660, and 1620 cm^{-1} appropriate for hydroxyl, saturated carbonyl, unsaturated carbonyl, and alkene functionalities. The electron impact mass spectrum of **2** provided little information since no parent ion was observed. Diaulusterol A (**2**) showed resonances for 31 carbon atoms in its ^{13}C nmr spectrum and its ^1H nmr spectrum showed a series of methyl resonances at 0.65 (s, 3H), 0.96 (d, J = 7 Hz, 3H), 1.17 (s, 3H), and 1.46 (s, 6H) ppm that indicated a steroidal structure. Other notable features in the ^1H nmr spectrum of **2** were an additional methyl resonance at 1.21 (d, J = 7 Hz, 3H), three carbinol methine proton resonances at 3.90 (dt, J = 11, 5 Hz, 1H), 4.15 (m, 1H), and 4.28 (t, J = 5 Hz, 1H), and two olefinic proton resonances at 5.87 (t, J = 1 Hz, 1H) and 6.54 (d, J = 5 Hz, 1H) ppm.

We found that **2** steadily decomposed to give a complex mixture of very polar materials when it was exposed to nmr solvents or other manipulations. Acetylation of **2** with acetic anhydride and pyridine generated the triacetate **4**, which proved to be a very stable substance. Triacetate **4** was shown by mass spectrometry to have a molecular formula of $C_{37}H_{54}O_9$, which represents the addition of six carbon atoms to the 31 that were observed in the ^{13}C nmr spectrum of **2**. Three new methyl resonances at 2.06, 2.08, and 2.12 in addition to the observed downfield shifts of the carbinol methine resonances to 5.14, 5.23, and 5.64 ppm in the ^1H nmr spectrum of **4** confirmed the formation of a triacetate.

Subtraction of the atoms present in the three acetyl residues from the molecular formula of **4** resulted in a molecular formula of $C_{31}H_{48}O_6$ for diaulusterol A (**2**). Three of the oxygen atoms in this formula could be accounted for by the three secondary alcohols (^{13}C nmr 64.4 (d), 65.2 (d), and 66.7 (d)) that underwent acetylation. The ir (1722 and 1660 cm^{-1}) and ^{13}C nmr spectra (172.4 (s) and 188.7 (s) ppm) of **2** revealed that the remaining oxygen atoms were present as ester and cross-conjugated ketone functionalities.

A decoupling experiment further elaborated the ester containing fragment. Thus, irradiation of the carbinol methine resonance at 4.15 in the ^1H nmr spectrum of **2** collapsed the methyl doublet at 1.21 to a singlet, and simplified two resonances at 2.34 (dd, J = 9, 16 Hz, 1H) and 2.42 (dd, J = 4, 16 Hz, 1H) ppm to an AB quartet (J = 16 Hz). This isolated six-proton spin system was assigned to a 3-hydroxybutanoate moiety.

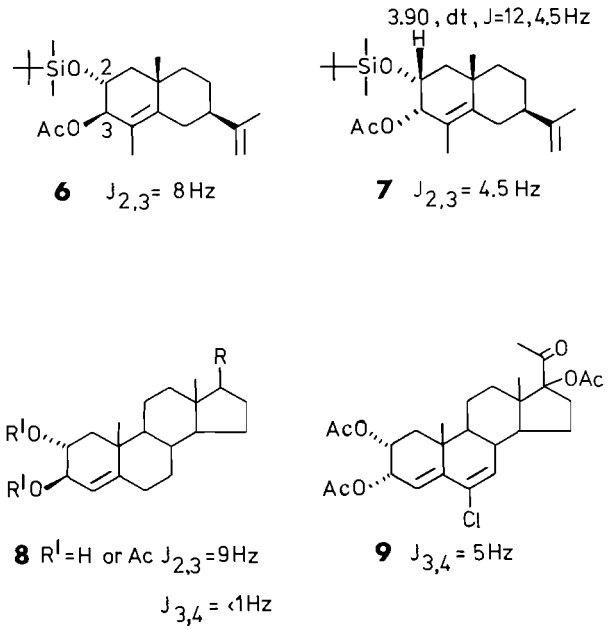

FIG. 1. Models for the ^{1}H spin system in ring A of Diaulusterol A.

Subtraction of the four carbons of this fragment from the molecular formula of **2** leaves the 27 carbons of a basic steroid skeleton, supporting our hypothesis of a steroidal structure for **2**. A ^{1}H nmr resonance at 1.46 (s, 6H) and a ^{13}C nmr resonance at 83.6 (s) ppm indicated that the butanoate fragment was attached to C25 of the steroid sidechain.

A second series of ^{1}H nmr decoupling experiments allowed the placement of much of the remaining functionality on the steroid nucleus. Irradiation of the methine proton at 3.90 in the spectrum of **2** collapsed the methine resonance at 4.28 to a doublet (J = 5 Hz) and simplified a pair of resonances at 1.75–1.85 ppm to an apparent AB quartet. Irradiation of the methine resonance at 4.28 simplified the multiplet at 3.90 to a doublet of doublets (J = 5, 11 Hz) and collapsed the doublet at 6.54 to a singlet, while irradiation at 6.54 simplified the methine resonance at 4.28 to a doublet (J = 5 Hz). The only way to situate this five-proton spin system on a steroid nucleus was to assign the resonances at 1.75–1.85 to a pair of geminal protons at C1, the resonances at 3.90 and 4.28 to carbinol methine protons at C2 and C3, respectively, and the resonance at 6.54 to an olefinic proton at C4. The demonstration of a nOe (nuclear Overhauser enhancement) between the methyl protons at 1.26 (C19) and a methine proton at 5.14 (H2) in the triacetate **4** required that H2 be β. An additional nOe between the methine proton at 5.14 (H2) and its vicinal neighbor, which appears at 5.64 (H3) ppm in the ^{1}H nmr spectrum of **4**, showed that H3 was also β. Comparison of the observed coupling constants for this spin system in **2** and **4** to the corresponding coupling constants in the model compounds **6–9** (5–7) confirmed our assignment (see Fig. 1).

The remaining functionality indicated by the spectral data and required by the molecular formula of **2** was a cross-conjugated ketone and a trisubstituted olefin. Having established the nature of the A ring in **2**, there was no choice but to place the ketone functionality at C6 and the olefin at C7—C8. The resulting proton and ^{13}C nmr assignments for diaulusterol A (**2**), which are given in Table 1, are in good agreement with the proposed structure. Also consistent with the structural assignment is the splitting of the C7 olefinic proton resonance (5.87 ppm) into a

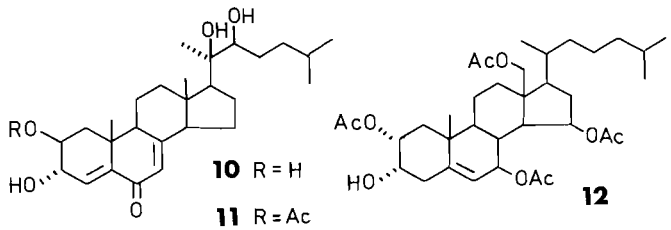
[a]Hydrogen attachments were determined using ADEPT.

triplet (J = 1 Hz) via allylic coupling to the C14 and C9 protons, and the observation of intense fragment ions at m/z 582 (M^+ − HOAc), 522 (M^+ − (2 × HOAc)), 496 (M^+ − (3-acetoxybutanoic acid) via McLafferty), and 265 (M^+ − (sidechain + (2 × HOAc)) daltons in the mass spectrum of **4**.

The observed chemical shifts for the C18 (^{1}H: 0.65; ^{13}C: 12.75 ppm) and C21 (^{1}H: 0.96; ^{13}C: 18.75 ppm) methyl groups in **2** were virtually identical to those reported for cholesterol (C18: 0.67, 12.0; C21: 0.90, 18.8 ppm), suggesting that the relative configurations at C13, C14, C17, and C20 were identical in the two molecules. This information, coupled with the above arguments for ring A, allowed us to assign the relative stereochemistry of diaulusterol A (**2**) as shown. Irradiation of the C18 methyl protons in **4** failed to induce an observable nOe into the C14 proton and irradiation of the C19 methyl protons likewise failed to induce an nOe into the C9 proton. This negative evidence, while not proving the stereochemical assignment, is at least consistent with it.

Diaulusterol B (**3**) was also isolated as a clear oil that was shown by mass spectrometry to have a molecular formula of $C_{27}H_{42}O_4$ (M^+; calcd.: 430.3083; found: 430.3055). The ^{1}H nmr spectrum of **3** was identical to that of **2** in all respects except for the absence of the resonances due to the 3-hydroxybutanoate residue. Diaulusterol B was therefore assigned structure **3**. Treatment of the triol **3** with acetic anhydride and pyridine at room temperature generates the diacetate **5** as expected. We found diaulusterol B (**3**) in rapidly processed extracts of *D. sandiegensis*, thereby eliminating the possibility that it is an artifact formed by hydrolysis of diaulusterol A (**2**).



Diaulusterols A (**2**) and B (**3**) are related to pinnasterol (**10**) and acetylpinnasterol (**11**) (8), which were isolated from the red alga *Laurencia pinnata*. All four steroids share structural features with the ecdysones, and compounds **10** and **11** showed biological activity as insect moulting hormones. The 25-(3-hydroxybutanoate) residue and the 2-α,3-α diol array of the diaulusterols are not commonly encountered in naturally occurring steroids. One of the small number of steroids containing a 2-α,3-α diol is compound **12**, which was recently isolated from the marine hydroid *Eudendrium glomeratum* (9).

Our results, in combination with previous findings of Walker and Faulkner (4), have shown that *Dialula sandiegensis* represents another example of a dorid nudibranch that has different skin chemistry at different collecting sites. It seems reasonable to assume that the steroids found in the British Columbia specimens and the chlorinated acetylenes found in the California specimens are being produced by the different dietary organisms found at the two locations; however, an actual dietary source of the metabolites has not been identified at either collecting site.

Experimental

The ^{1}H nmr spectra were recorded on Varian XL-300 and Brüker WH-400 spectrometers. The ^{13}C nmr spectra were recorded on a Varian XL-300 spectrometer. TMS (tetramethylsilane) was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS902 spectrometer and high resolution mass spectra on an AEI MS50 instrument. The ir spectra were recorded on a BOMEM Fourier Transform spectrometer. The uv–visible spectra were recorded on a Bausch and Lomb Spectronic-2000 spectrometer.

Merck silica gel 230–400 mesh was used for flash and preparative thin-layer chromatography (tlc) and a Whatman Magnum-9 ODS-3 column was used for preparative hplc. Sephadex LH-20 resin was used for molecular exclusion chromatography. R_f's are listed for all compounds in an analytical tlc system using ethyl acetate as an eluent.

Specimens of *Diaulula sandiegensis* (152 animals) were collected on several exposed rocky reefs (−1 to −15 m) in Barkley Sound, British Columbia. Freshly collected animals were immediately immersed in methanol and allowed to extract at 2°C for two days, after which the methanol was decanted off and replaced with fresh solvent. The first and second methanol extracts were combined and evaporated *in vacuo*. The resulting residue was partitioned between brine (200 mL) and ethyl acetate (5 × 125 mL). Evaporation of the combined ethyl acetate extracts gave a brown oil (1.4 g).

Flash chromatography of the brown oil (1:1 acetone – methylene chloride) gave a fraction (90 mg) that contained diaulusterols A (**2**), B (**3**), and fats. LH20 chromatography (1:4 methanol – chloroform) removed most of the fats. The resulting enriched mixture of compounds **2** and **3** (47 mg) was purified via reverse phase hplc (7:3 methanol – water) to yield pure steroids as clear oils (**2**: 24 mg; **3**: 3.2 mg).

Diaulusterol A (2): R_f 0.18; ir (film): 3380, 2940, 2870, 1722, 1660, 1620, 1455, 1375, 875, and 750 cm^{-1}; ^{1}H nmr ($CDCl_3$): 0.65 (s, 3H), 0.96 (d, J = 7 Hz, 3H), 1.17 (s, 3H), 1.21 (d, J = 7 Hz, 3H), 1.46 (s, 6H), 2.34 (dd, J = 9, 16 Hz, 1H), 2.42 (dd, J = 4, 16 Hz, 1H), 3.90 (dt, J = 5, 11 Hz, 1H), 4.15 (m, 1H), 4.28 (t, J = 5 Hz, 1H), 5.87 (t, J = 1 Hz, 1H), and 6.54 (d, J = 5 Hz, 1H); ^{13}C nmr ($CDCl_3$): 12.5, 18.7, 20.4, 21.1, 21.8, 22.3, 22.6, 26.1, 26.2, 27.6, 35.8, 35.9, 38.5, 38.6, 40.6, 41.1, 43.7, 44.5, 47.8, 56.0, 56.2, 64.4, 65.2, 66.7, 83.6, 123.6, 128.1, 146.2, 166.9, 172.4, and 188.7 ppm.

Diaulusterol A triacetate (4): Diaulusterol A (**2**) (24 mg) was stirred overnight at room temperature in a solution of pyridine – acetic anhydride (3:1; 8 mL). Evaporation of the reagents under high vacuum generated a residue that was purified via preparative tlc to give pure acetate **4** (27 mg): clear oil; R_f 0.56; uv (MeOH) λ_{max}: 264 nm (12 800); ^{1}H nmr ($CDCl_3$): 0.68 (s, 3H), 0.99 (d, J = 7 Hz, 3H), 1.26 (s, 3H), 1.32 (d, J = 8 Hz, 3H), 1.46 (s, 6H), 2.06 (s, 3H), 2.08 (s, 3H), 2.12 (s, 3H), 2.46 (dd, J = 6, 18 Hz, 1H), 2.60 (dd, J = 8, 18 Hz, 1H), 5.14 (dt, J = 14, 5 Hz, 1H), 5.27 (m, 1H), 5.64 (m, 1H), 5.92 (bs, 1H), and 6.47 (d, J = 7 Hz); ms: 642 (M^+), 582, 522, 496, 494, 376, 361, 265, 249, 171, 147, 129, 119. *Exact Mass* calcd.: 642.3768; found: 642.3779.

Diaulusterol B (3): clear oil; R_f 0.15; ^{1}H nmr ($CDCl_3$): 0.65 (s, 3H), 0.97 (d, J = 7 Hz, 3H), 1.17 (s, 3H), 1.23 (s, 6H), 3.88 (m, 1H), 4.27 (m, 1H), 5.87 (bs, 1H), 6.54 (d, J = 5 Hz, 1H); ms: 430 (M^+), 412, 397, 394. *Exact Mass* calcd.: 430.3083; found: 430.3055.

Diaulusterol B diacetate (5): Prepared as described above for **4**. Compound **5**: clear oil; R_f 0.55; uv (MeOH) λ_{max}: 264 nm; ^{1}H nmr ($CDCl_3$): 0.67 (s, 3H), 0.98 (d, J = 7 Hz, 3H), 1.24 (s, 9H), 2.04 (s, 3H), 2.08 (s, 3H), 5.12 (m, 1H), 5.61 (m, 1H), 5.89 (bs, 1H), 6.43 (d, J = 7 Hz, 1H).

Reçu le 22 novembre 1985

DANIELLE GONBEAU, JEAN-LUC GARCIA et GENEVIÈVE PFISTER-GUILLOUZO. Can. J. Chem. **64**, 1530 (1986).

Une étude des sections efficaces de photoionisation du phosphazène HP=NH a été réalisée dans le cadre de la méthode MSXα. Les résultats obtenus, concernant les ionisations mettant en jeu les paires du phosphore et de l'azote, ont été confrontés à ceux déduits qualitativement d'un examen des localisations dans la fonction d'état initial. Parallèlement, les phénomènes de réorganisation électronique au niveau des ions générés par photoionisation ont été discutés.

DANIELLE GONBEAU, JEAN-LUC GARCIA, and GENEVIÈVE PFISTER-GUILLOUZO. Can. J. Chem. **64**, 1530 (1986).

A study of photoionization cross sections was undertaken in MSXα on the phosphazene HP=NH. For the ionizations involving the phosphorus and nitrogen lone pairs, the results were discussed and compared with those obtained from examination of localizations in the initial state. In parallel the electronic reorganization effects encountered in the ionic states were also analyzed.

En spectroscopie photoélectronique (ultraviolet) l'analyse des variations d'intensité des bandes observées expérimentalement notamment par passage du rayonnement HeI (21,22 eV) à HeII (40,81 eV) est un outil puissant d'attribution largement utilisé.

Sur la base de règles qualitatives, fondées sur les calculs de sections efficaces atomiques et l'examen des localisations dans les orbitales moléculaires mises en jeu lors des ionisations (1), l'interprétation des variations expérimentales d'intensité a été réalisée avec succès pour de nombreux systèmes moléculaires. Les limites d'une telle démarche apparaissent pour des molécules hétéroatomiques. Dans le cas des triazaphospholes par exemple (2), les variations d'intensité lors du passage HeI/HeII ne peuvent être toutes interprétées à partir des localisations des orbitales ionisées.

Ceci nous a conduit à examiner de façon plus rigoureuse les sections efficaces de photoionisation pour une molécule de petite taille présentant précisément deux hétéroatomes de période différente. Compte tenu des études expérimentales réalisées nous avons fait choix de l'entité modèle HP=NH.

Étant donné les limites mises en évidence d'une interprétation basée sur la considération du seul état initial, nous avons estimé par une approche multiconfigurationnelle l'importance des phénomènes de relocalisation dans les ions.

1. Conditions de calcul

Les calculs de sections efficaces de photoionisation ont été menés dans le cadre de la méthode MSXα particulièrement bien adaptée à ce type de problèmes.

En effet, l'extension de cette méthode à l'étude d'états du continu (3) permet l'évaluation dans un formalisme homogène des fonctions d'état initial et d'état final intervenant au niveau du moment de transition; elle se révèle par là même d'approximation moins grossière que les nombreux calculs effectués sur la base d'une représentation de l'état final par une onde plane.

Nous avons travaillé dans des conditions identiques à celles définies lors d'une étude antérieure (4): (*i*) au niveau des atomes les paramètres α optimisés par Schwarz (5) ont été utilisés avec une moyenne pondérée des α atomiques pour les régions intersphère et outersphère; (*ii*) les rayons des sphères atomiques ont été déterminés de façon non empirique (6) en réduisant de 12% les rayons obtenus à l'itération 0 pour des sphères englobant un nombre d'électrons égal au numéro atomique; (*iii*) l'évaluation des fonctions d'état initial et d'état final a été réalisée avec le même potentiel (prise en compte à chaque itération de calcul MSXα de la correction de Latter (7) pour le calcul des états initiaux); (*iv*) pour chaque atome et pour le calcul de toutes les fonctions d'état initial (i) une valeur $l_{max} = l + 1$ a été adoptée. Pour les fonctions d'état final (f) des valeurs $l_{max\,f} = l_{max\,i} + 1$ ont été choisies. Dans le cas de l'outersphère l_{max} a été déterminée par examen de la convergence des résultats.

Les potentiels d'ionisation ont été évalués selon le formalisme de l'état de transition (8).

Les effets de relocalisation dans l'état final ont été obtenus en Hartree Fock à l'aide d'une méthode de pseudo potentiel (9) (inclue dans le programme Hondo (10) avec des bases de valence d'un niveau double zeta (ζ) et une fonction de polarisation de type *d* sur le phosphore. Les interactions de configurations ont été réalisées dans le cadre de la méthode CIPSI (11) qui met en oeuvre conjointement la méthode des variations (pour les interactions les plus fortes) et une méthode perturbative (pour l'effet des déterminants moins importants).

Les conditions générales de calcul adoptées sont identiques à celles précisées lors d'un précédent travail (12).

2. Calculs MSXα sur H—P=N—H

Les calculs ont été effectués pour les deux conformères *trans* et *cis* de HP=NH.

Récemment le premier dialkyl imino phosphane *t*Bu—P=N—*t*Bu (conformation *trans*) a été détecté par Niecke et Flick (13). Il a été généré et caractérisé en spectroscopie photoélectronique par thermolyse du dimère (14).

La conformation *cis* du phosphazène correspond quant à elle à une disposition intervenant au niveau des hétérocycles à phosphore dicoordiné examinés par ailleurs (2).

2.1. Potentiels d'ionisation

Les résultats obtenus pour les deux isomères sont présentés dans le tableau 1.

Pour l'isomère *trans*, en accord avec des résultats antérieurs (15) les premier et troisième potentiels d'ionisation à 10,95 eV et 14,29 eV sont attribués respectivement à des ionisations

1. Part XXIX de «Application of photoelectron spectroscopy to molecular properties.» Part XXVIII : réf. 21.

	3a′	−13,256	27	25	5	20	16	7	16,78
	2a′	−16,044	33	32	10	7	11	7	19,53

PI expérimentaux (*t*Bu—P=N—*t*Bu, *trans*) (14) 8,11 eV; 9,70 eV; 10,10 eV. Paramètres géométriques de HP=NH *trans* et HP=NH *cis* définis lors d'un précédent travail (15).

mettant en jeu les orbitales 5a′ et 4a′, combinaisons liante (n^+) et antiliante (n^-) des paires libres des atomes de phosphore et d'azote. il faut remarquer une localisation plus grande sur le phosphore en ce qui concerne l'orbitale 5a′ et au contraire un poids plus important sur l'azote pour l'orbitale 4a′ (tableau 1).

Le potentiel d'ionisation à 12,32 eV correspond à l'ionisation faisant intervenir l'orbitale 1a″ caractéristique de la liaison $\pi_{P=N}$.

L'attribution des deux premiers potentiels d'ionisation est en accord avec celle proposée expérimentalement par Elbel *et al.* (14) pour le dérivé tertiobutylé : PI (n^+) (8,11 eV) < PI (π) (9,70–10,10 eV). En dépit de l'effet bien connu des groupements tertiobutylés (stabilisation de l'état ionique) les potentiels d'ionisation obtenus théoriquement sont trop profonds.

En ce qui concerne l'isomère *cis* (tableau 1), une séquence analogue σ, π, σ est observée pour les dernières orbitales occupées avec une interaction des paires en *trans* nettement plus importante qu'en *cis*, respectivement de 3,3 et 1,2 eV. Il faut noter également que les orbitales 5a′ et 4a′ correspondent respectivement aux combinaisons n^- et n^+ des paires des atomes de phosphore et d'azote. Elles présentent toutefois les mêmes localisations que dans l'isomère *trans*, à savoir poids important sur le phosphore pour l'orbitale 5a′, forte localisation sur l'azote pour 4a′.

Nous observons une position quasiment inchangée du potentiel d'ionisation associé à l'ionisation mettant en jeu l'orbitale $\pi_{P=N}$ (isomère *trans* : 12,32 eV, isomère *cis* : 12,46 eV).

2.2. *Sections efficaces et paramètres d'asymétrie*

Les résultats obtenus pour les sections efficaces différentielles de photoionisation (directement comparables aux intensités des bandes expérimentales) et les paramètres d'asymétrie ont été visualisés sous forme de courbes (figures 1 et 2) pour les trois premiers états initiaux de chaque isomère.

Un balayage en énergie cinétique par pas de 5 eV a été effectué dans un domaine compris entre 5 eV et 50 eV et les énergies de photons correspondant aux deux sources de rayonnement HeI (21,22 eV) et HeII (40,81 eV) ont été matérialisées par des traits verticaux.

Dans le cas de l'isomère *trans* une diminution est observée lorsqu'on passe d'un rayonnement HeI à HeII pour les trois états (fig. 1).

Toutefois, des différences apparaissent pour les états initiaux 5a′ et 4a′ mettant en jeu les paires libres des atomes de phosphore et d'azote. En effet, la diminution en passant de $h\nu$ = 21,22 eV à $h\nu$ = 40,81 eV est nettement plus grande pour l'état initial 5a′ correspondant à la combinaison n^+ que pour l'état initial 4a′ associé à la combinaison n^-.

En ce qui concerne les paramètres d'asymétrie leurs variations en fonction de l'énergie des photons, font apparaître également des allures bien différenciées pour les deux états initiaux 5a′ et 4a′.

Les résultats obtenus pour l'isomère *cis* (fig. 2) permettent de remarquer une diminution des sections efficaces en fonction de l'énergie des photons incidents pour les trois premiers états initiaux. Par contre, la plus forte diminution est observée dans ce cas pour l'état initial 4a′. Ce résultat est particulièrement intéressant compte tenu des localisations observées au niveau des orbitales 5a′ et 4a′.

En effet, comme nous l'avons vu, l'orbitale 5a′ présente le poids le plus important sur l'atome de phosphore alors que l'orbitale 4a′ est fortement localisée sur l'azote. Sur la base des règles habituelles, l'ionisation mettant en jeu l'orbitale 5a′ devrait ainsi être associée à une bande diminuant nettement d'intensité en passant d'un rayonnement HeI à HeII vis-à-vis de celle correspondant à l'ionisation faisant intervenir l'orbitale 4a′. Les calculs réalisés conduisent à des résultats inverses puisque la diminution la plus importante de section efficace est notée pour l'état initial 4a′.

Ces résultats mettent ainsi en évidence les limites des règles qualitatives dans ce cas. La seule analyse de la fonction d'état initial est insuffisante pour discuter des variations d'intensité en fonction de l'énergie des photons incidents.

Par ailleurs, l'examen des résultats obtenus pour les isomères *cis* et *trans* montre que la plus nette diminution de section efficace intervient dans les deux cas pour les états initiaux correspondant à la combinaison n^+ des paires du phosphore et de l'azote (5a′ pour l'isomère *trans*, 4a′ pour l'isomère *cis*).

Ainsi, les sections efficaces associées aux états initiaux caractéristiques des paires libres des atomes de phosphore et d'azote paraissent plus affectées par la «symétrie» des combinaisons des paires que par la localisation plus ou moins importante sur l'atome de phosphore dans la fonction d'état initial. Une remarque similaire peut être faite en ce qui concerne

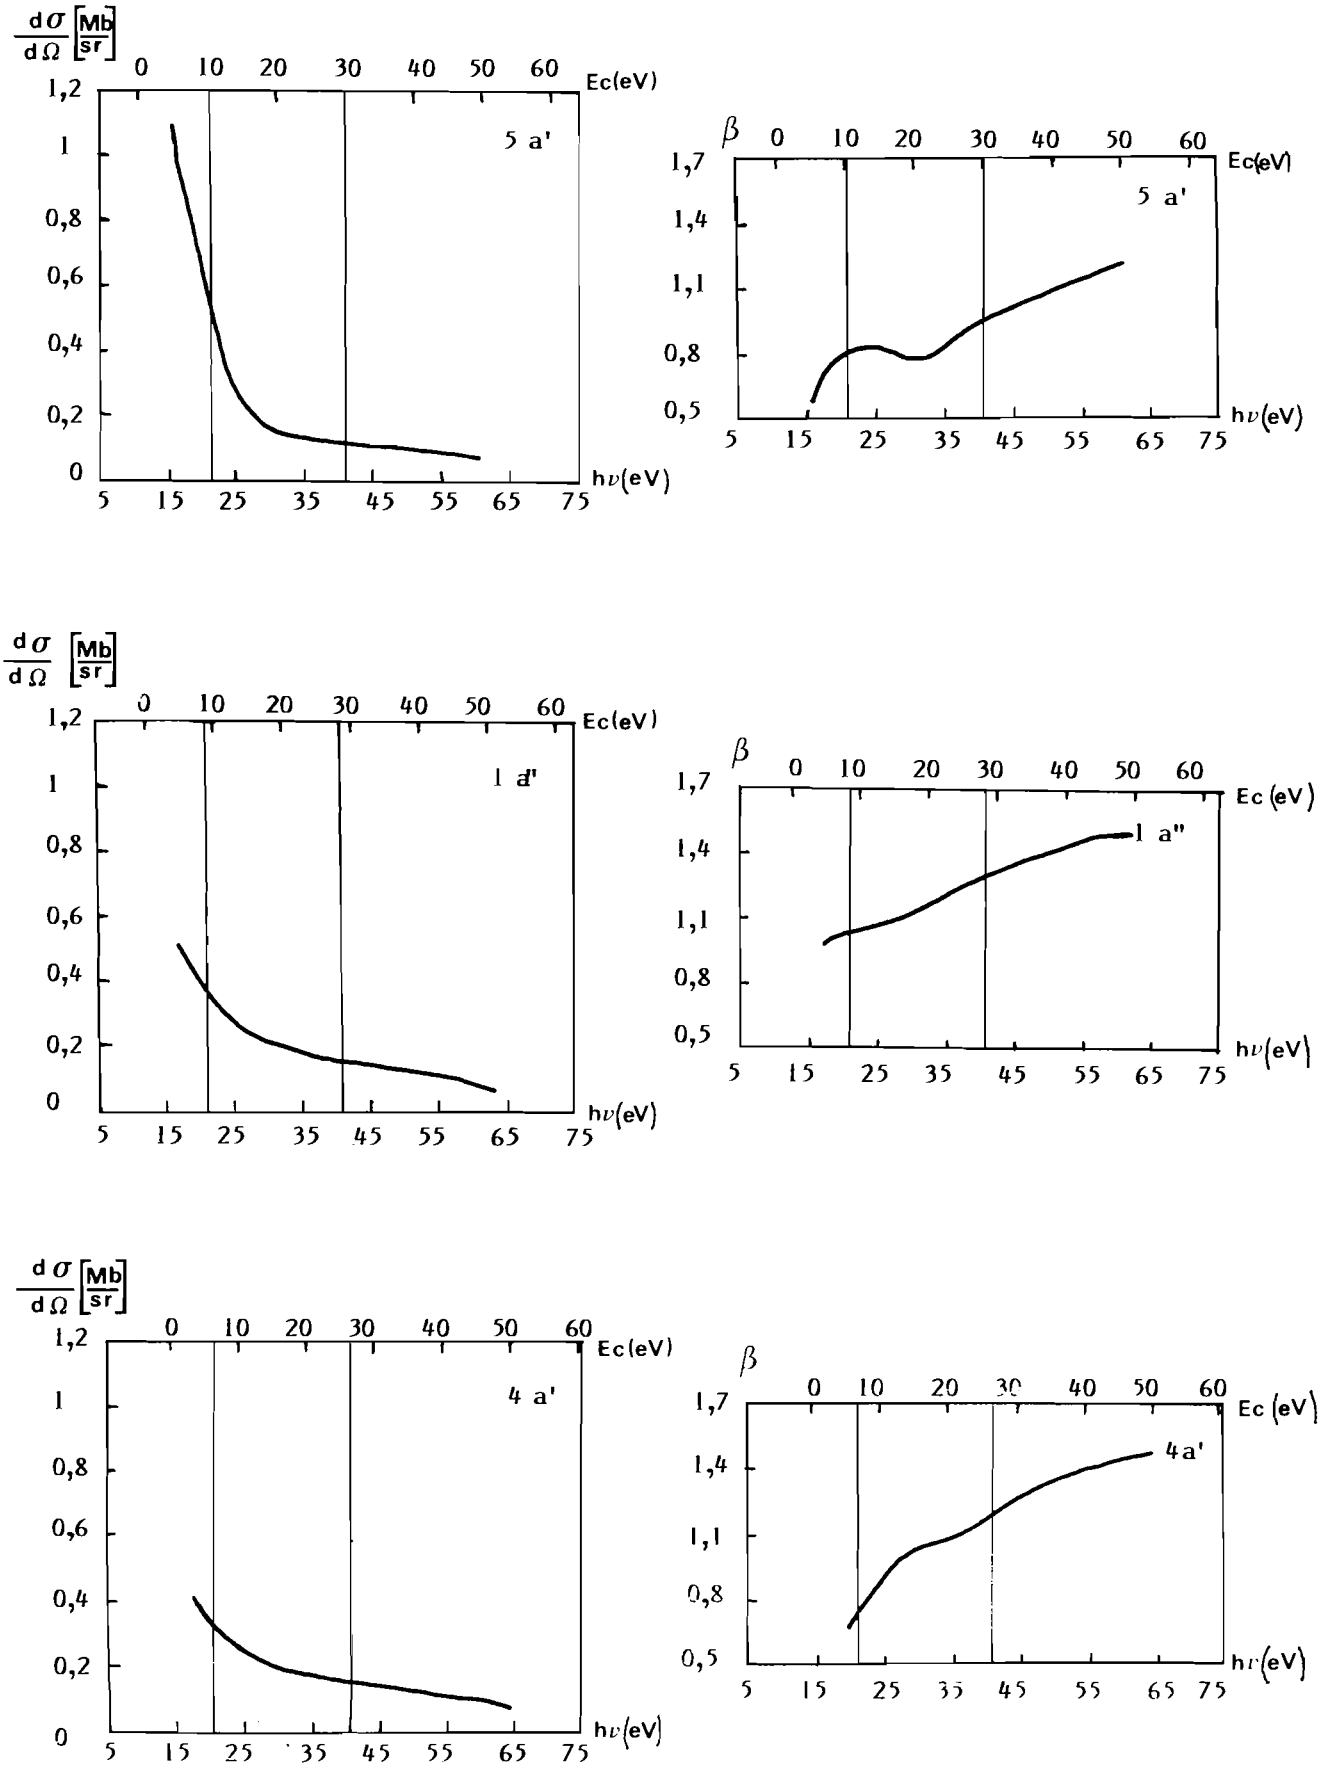

FIG. 1. HP=NH *trans* : orbitales $5a'$, $1a''$, $4a'$. Sections efficaces différentielles de photoionisation et paramètres d'asymétrie.

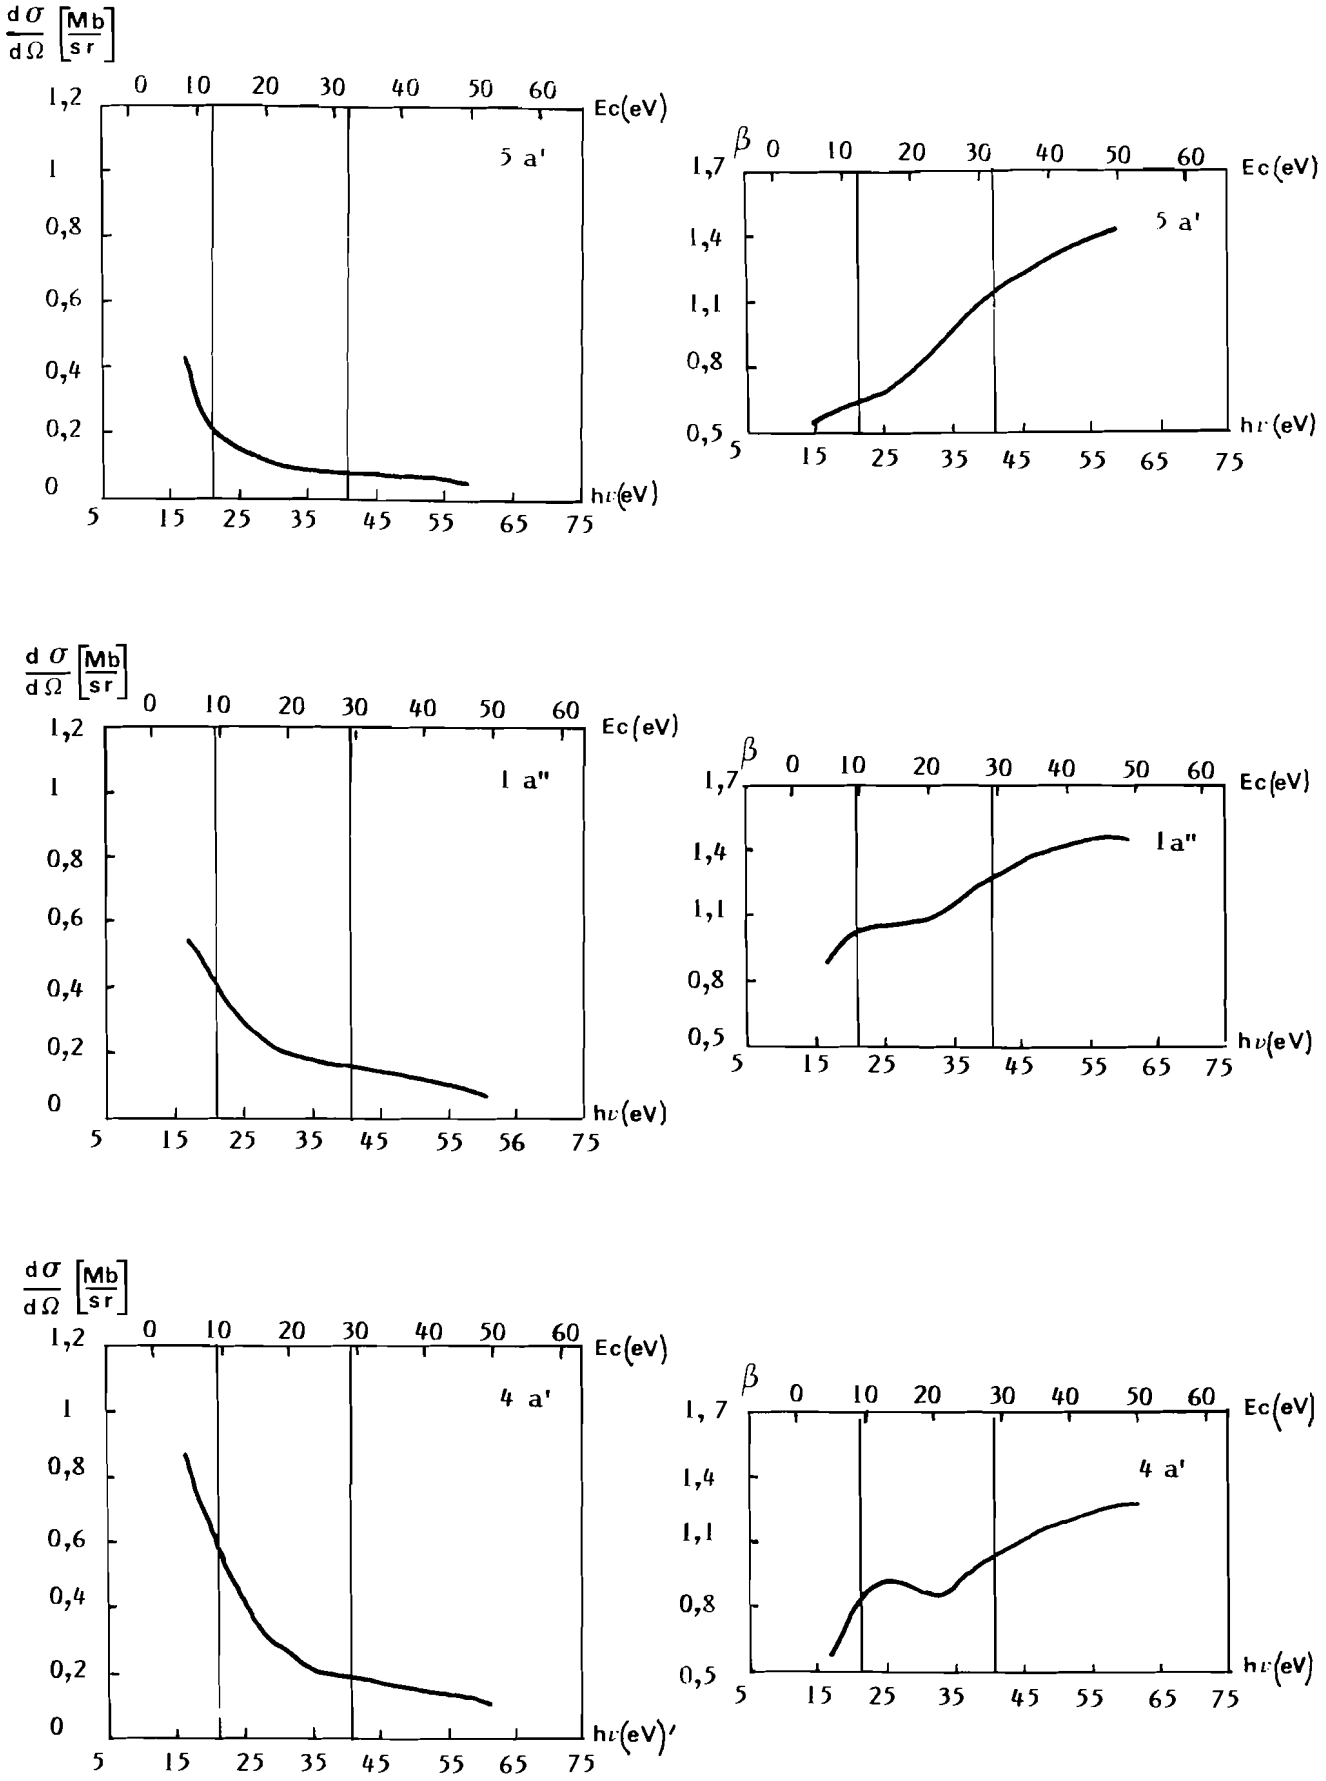

FIG. 2. HP=NH *cis* : orbitales $5a'$, $1a''$, $4a'$. Sections efficaces différentielles de photoionisation et paramètres d'asymétrie.

TABLEAU 2. HP=NH *trans*. Potentiels d'ionisation calculés (CIPSI)

États	PI Koopmans (eV)	Correction de polarisation	Correction de corrélation	PI corrigés (eV)	PI calculés par CIPSI	PI expérimentaux *t*Bu—P=N—*t*Bu
$^2A'$	10,61	−0,37	0,24	10,03	8,878	8,11

$^2A'$	16,08	−0,57	0,23	15,69		

TABLEAU 3. HP=NH *cis*. Potentiels d'ionisation calculés (CIPSI)

États	PI Koopmans (eV)	Correction de polarisation	Correction de corrélation	PI corrigés (eV)	PI calculés par CIPSI
$^2A'$	10,66	−0,26	0,26	10,66	9,34
$^2A''$	11,85	−0,71	0,57	11,71	11,72
$^2A'$	12,86	−0,96	0,21	12,11	11,13
$^2A'$	17,64	−0,49	0,19	17,34	

les paramètres d'asymétrie puisque des variations de β du même type sont observées pour les états $5a'$ (*cis*), $4a'$ (*trans*) d'une part et pour $4a'$ (*cis*), $5a'$ (*trans*) d'autre part.

Ces conclusions rejoignent celles de Price *et al.* (16) et les observations expérimentales sur CS_2, CO_2, COS où les bandes associées aux orbitales $\sigma_g(2p)$ présentent d'appréciables diminutions d'intensité par rapport aux bandes $\sigma_u(2p)$.

3. Phénomènes de relocalisation au niveau des ions générés par photoionisation de H—P=N—H

Les calculs MSXα ont été réalisés dans le cadre d'une approche monoélectronique et, en particulier, le caractère multiélectronique du processus de photoémission n'a pas été pris en compte dans la description de l'état final.

Or, pour interpréter les modifications d'intensité non explicables précisément à partir des localisations calculées dans l'état initial, on invoque parfois des possibilités de réorganisation de l'ion.

Nous avons donc entrepris d'examiner l'importance de ces phénomènes de relocalisation et procéder pour cela à des calculs Hartree Fock avec interaction de configurations.

Au niveau SCF (self-consistent field), nous obtenons pour les dernières orbitales occupées une séquence identique à celle précédemment déterminée en MSXα. Les potentiels d'ionisation dans le cadre de l'approximation de Koopmans sont assez voisins de ceux obtenus avec le formalisme de l'état de transition (tableaux 1–3). Pour l'isomère *trans*, les valeurs des potentiels d'ionisation obtenues sont trop élevées vis-à-vis des données expérimentales.

Il est cependant bien connu que dans cette approximation, on ne prend pas en compte les effets de polarisation et de corrélation qui peuvent affecter différemment les niveaux π et ceux caractéristiques des paires libres de ces systèmes.

Les effets de polarisation sont d'autant plus importants que les «trous» sont localisés et donc attendus les plus forts pour les paires libres; il contribuent généralement à diminuer les potentiels d'ionisation alors que les effets de corrélation les augmentent et ceci particulièrement pour les liaisons π (17).

À l'aide d'un processus déjà utilisé par ailleurs (12, 18) et qui présente l'avantage de ne nécessiter qu'un temps de calcul de l'ordre d'une itération SCF par potentiel d'ionisation nous avons estimé les corrections de polarisation et de corrélation.

Les résultats obtenus (tableaux 2 et 3) ne mettent en évidence que peu de changements sur les écarts respectifs des trois potentiels d'ionisation avec pour les deux premiers une compensation quasi totale des effets de polarisation et de corrélation.

Nous avons donc réalisé des calculs perturbationnels complets à l'aide du programme CIPSI.

Pour l'isomère *trans*, nous constatons (tableau 2), compte tenu de l'effet des groupements tertiobutyles (stabilisation de l'état ionique), un accord satisfaisant avec les données expérimentales, le premier potentiel d'ionisation étant toutefois un peu trop bas.

Dans le cas de l'isomère *cis* (tableau 3), nous observons une inversion des deuxième et troisième potentiels d'ionisation.

Il est important de remarquer que ces modifications notables ont leur principale origine dans l'effet de corrélation spécifique des ions; l'importance de ce terme a déjà été soulignée par Cederbaum (19) et Chong (20) et mise en évidence lors d'une étude réalisée sur le diméthyl diphosphène (12).

Dans les cas considérés ici, il est particulièrement important pour les ionisations mettant en jeu les orbitales combinaisons des paires libres de P et de N, de part la présence d'une orbitale virtuelle π* assez basse.

Après avoir examiné l'importance des effets de polarisation et de corrélation, nous avons analysé à l'aide des matrices densité après interaction de configuration les phénomènes de relocalisation au niveau des deux premiers ions σ.

Les résultats présentés sur la figure 3 pour le phosphazène *trans* font apparaître pour l'ion mettant en jeu l'orbitale $5a'$ un «trou» totalement délocalisé sur les deux atomes de phosphore et d'azote; au niveau de l'ion associé à l'orbitale $4a'$, le «trou» paraît un peu plus localisé sur l'atome de phosphore.

Dans le cas du phosphazène *cis*, des conclusions voisines peuvent être déduites de l'examen de la figure 3 avec toutefois un «trou» plus nettement localisé sur le phosphore en ce qui concerne l'ion correspondant à l'orbitale $4a'$.

Si la structure électronique globale de ces ions est assez différente de l'image que l'on pouvait en avoir à partir du seul examen des localisations des orbitales moléculaires mises en jeu

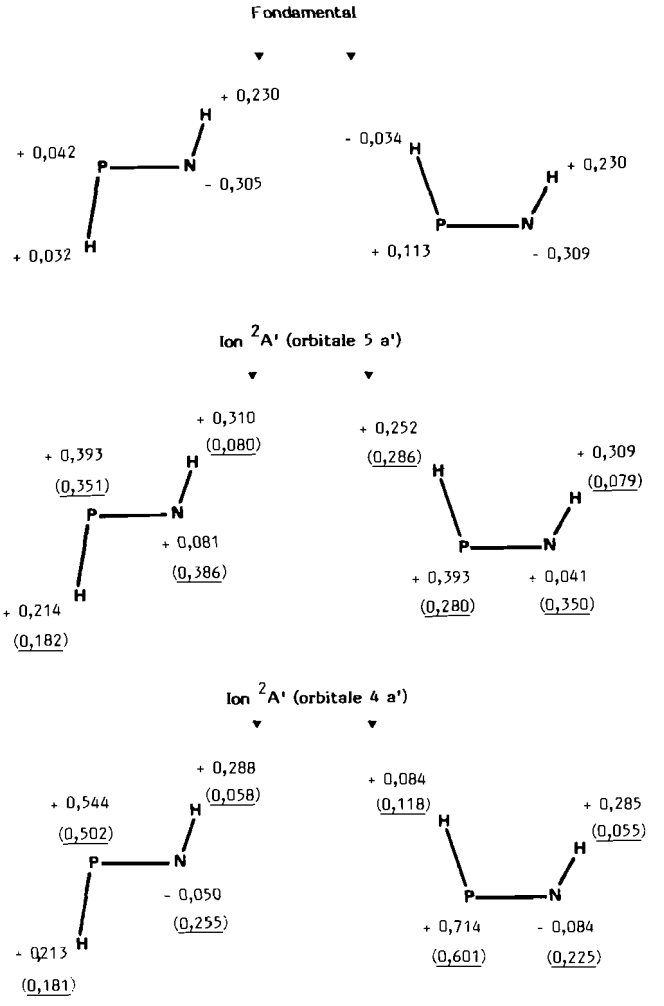

FIG. 3. HP=NH. Isomères *trans* et *cis*. Charges nettes après interaction de configurations. (Ecarts en charges nettes entre les ions et le fondamental.)

lors de l'ionisation, on constate toutefois que ces phénomènes de relocalisation ne sont pas très importants.

Toutefois, les calculs des sections efficaces pour les deux isomères mettent en évidence un comportement similaire pour les états associés respectivement à l'orbitale $5a'$ de l'isomère *trans* et à l'orbitale $4a'$ de l'isomère *cis*. Les résultats obtenus ici ne font apparaître aucune analogie de ce type puisqu'au contraire une localisation du «trou» sur le phosphore n'intervient que pour les ions correspondant aux orbitales $4a'$ des isomères *cis* et *trans*.

Les mêmes remarques avaient pu être déduites de l'analyse de travaux similaires (2) sur les isomères α et β des triazaphospholes. Quel que soit l'ion examiné, aucune corrélation n'avait pu être établie entre les variations d'intensité HeI/HeII observées expérimentalement et la plus ou moins grande localisation du «trou» sur l'atome de phosphore dans les différents ions formés.

4. Conclusion

L'étude réalisée sur le phosphazène HP=NH nous a permis de dégager un certain nombre de points importants concernant les sections efficaces de photoionisation des états ioniques provenant de l'éjection d'électrons des paires libres du phosphore et de l'azote.

Tout d'abord, il apparaît que la seule considération des localisations dans la fonction d'état initial est insuffisante pour interpréter correctement les variations d'intensité. Un des points essentiels mis en évidence apparaît être la phase entre les orbitales atomiques intervenant dans l'orbitale moléculaire ionisée liée à la pseudo symétrie du système.

De plus il semble, d'après l'analyse des phénomènes de réorganisation électronique au niveau des ions générés par photoionisation, que ce type de phénomène ne peut être en corrélation directe avec les variations des sections efficaces.

Remerciements

Les auteurs remercient le Docteur J. P. Flament (Unité Associée 465, École Polytechnique) pour leur avoir communiqué le programme de calcul permettant d'obtenir les matrices densité après interaction de configurations.

Vitamin D relatives. Part I. B-thiophene-des-A-cholestanes. Solvolytic reactions of some derivatives of 2,2-disubstituted cyclohexane-1,4-diol and 4-hydroxycyclohexan-1-one

JACEK W. MORZYCKI
Department of Chemistry, University of Warsaw, Pasteura 1, 02093 Warszawa, Poland

Received December 6, 1985

JACEK W. MORZYCKI. Can. J. Chem. **64**, 1536 (1986).

Some derivatives of des-A-cholestane with a thiophene ring B have been prepared from triketone **2**. The reactions of tosylates of C-10 alcohols (**7***b*, **9***b*, and **8***c*) leading to A-ring ethers (**10** and **11**) and olefin **5**, respectively, have been studied. The solvolysis of tosylate **4***c* and the Bamford–Stevens reactions of *p*-tosylhydrazones **3***c* and **13***b* are also discussed.

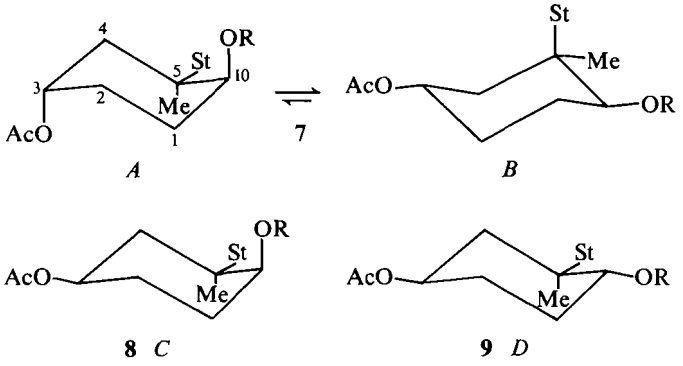
JACEK W. MORZYCKI. Can. J. Chem. **64**, 1536 (1986).

Utilisant la tricétone **2** comme produit de départ, on a préparé quelques dérivés du des-A-cholestane comportant un thiophène comme cycle B. On a étudié les réactions des tosylates des alcools en C-10 (**7***b*, **9***b* et **8***c*) qui conduisent respectivement aux éthers du cycle A (**10** et **11**) et à l'oléfine **5**. On discute aussi des réactions de solvolyse du tosylate **4***c* et des réactions de Bamford–Stevens des *p*-tosylhydrazones **3***c* and **13***b*.

[Traduit par la revue]

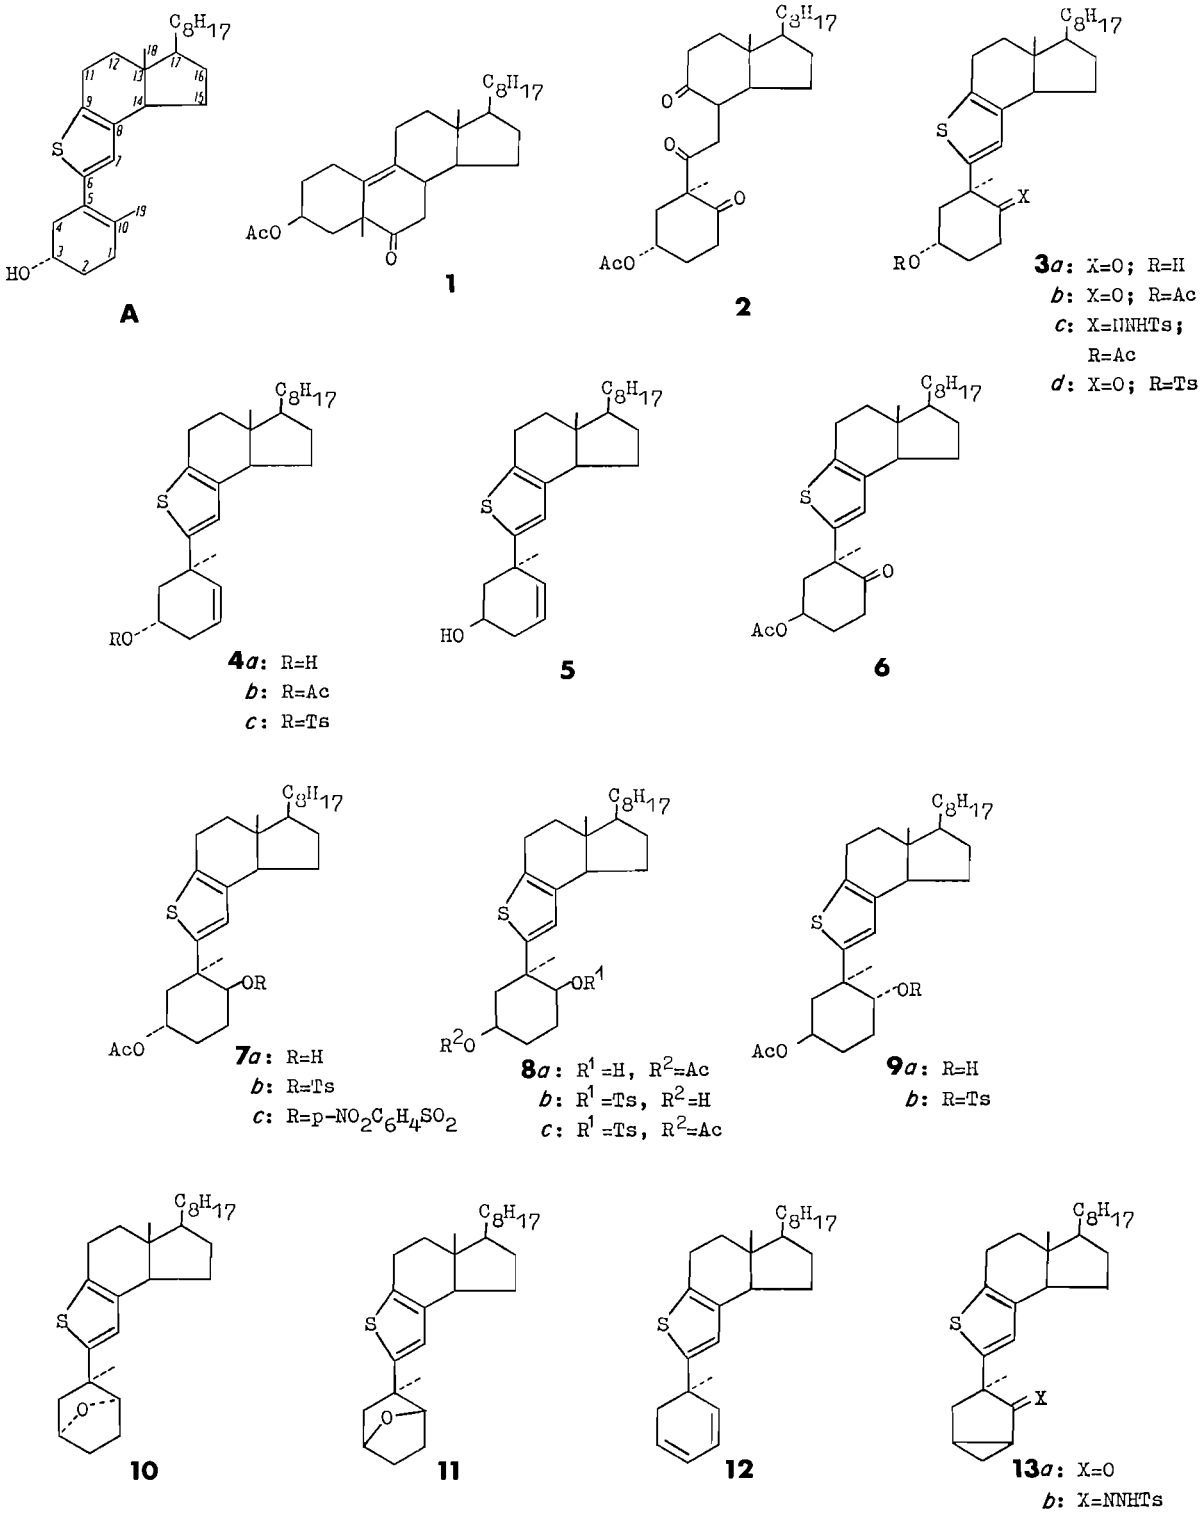
In the course of our studies on the synthesis of vitamin D relatives (1, 2) we have drawn attention to 6,9-epithio-tachysterol **A** as a possible intermediate. The allylic oxidation of this compound, followed by desulfurization, as well as photochemical and thermal isomerization (3) could afford an important, active metabolite of vitamin D_3, i.e. 1α-OH-D_3 (4). In an attempted synthesis of 6,9-epithio-tachysterol **A**, the starting ketone **1** (5) with the double bond C(9)—C(10) was subjected to ozonolysis. The resulting triketone **2** contained a 1,4-dicarbonyl system that reacted with phosphorus pentasulfide to give the thiophene derivative **3***b* (6) in good yield. In the next step the problem of the 19-methyl group migration from the 5β position to its former (in cholesterol) 10β position arose. It was expected that generation of a carbonium ion at C-10 should provide a driving force for the reaction. We assumed that the secondary carbonium ion adjacent to the quaternary carbon C-5 is likely to rearrange, to give a more stable tertiary carbonium ion by migration of a substituent (methyl, thienyl) or ring bond.

The carbon atom C-10 exists in compound **3***b* in the form of a carbonyl group and one of the best ways to the desired carbonium ion seemed to be the decomposition (7*a*) of 10-toluene-*p*-sulfonylhydrazone **3***d* under basic conditions (Bamford–Stevens reaction). The reaction afforded the unrearranged $\Delta^{1(10)}$ olefin **4***a* as the major product. The failure of this reaction prompted us to study the solvolytic reactions (7*b*) of *p*-toluenesulfonates of the C-10 alcohols. The $NaBH_4$ reduction of ketone **3***b* yielded a single epimer of alcohol **7***a*. As expected (attack of hydride from the less hindered side of the molecule), the compound obtained had the 10α-OH configuration. Proton nmr showed the equatorial orientation of both hydroxyl and acetoxyl groups (the broad signals of axial 10β ($w/2$ = 15 Hz) and 3α ($w/2$ = 20 Hz) protons at δ = 3.66 and 5.13, respectively) in the dominating conformation *B*. The alternative chair conformation *A* with the *anti*-coplanar arrangement of 10α-OH and 5β-CH_3 is less stable due to 1,3-diaxial interaction of 3β-acetoxyl and methyl groups. The reaction of 10α-tosylate **7***b* with KOH/diethylene glycol/diglyme (diglyme: diethylene glycol dimethyl ether) at 120°C afforded ether **10** in good yield. The product was apparently formed by an intramolecular attack of the 3β-alkoxyl ion from the back side on carbon C-10 in the boat conformation, which becomes more significant at higher temperature. This S_N2 type reaction unequivocally confirmed the *trans* relationship of 3β-acetate to the leaving group in the starting material **7***b*. Unfortunately the formation of the oxygen bridge precluded the development of a carbonium ion at C-10 and, at the same time, the retropinacolic rearrangement. To avoid this complication and to increase the contribution of the conformation with an axial hydroxyl (or tosyloxyl) group, we decided to study the solvolysis of compound **8***c* with the inverted configuration of acetate at C-3. Acetylation with inversion (8) of hydroxy-ketone **3***a* gave **6**. The $NaBH_4$ reduction of ketone **6** resulted in the formation of two products in the ratio 4:3. The less polar, major product appeared to be the 10α alcohol **8***a*. The ^1H nmr spectra confirmed the domination of the expected conformation *C*, with the axial substituent at C-10 and the equatorial 3α-acetate, either in the case of free alcohol **8***a* or its tosylate **8***c* (δ 5.08 (m, $w/2$ = 24 Hz, 3β-H) and 4.57 ($w/2$ = 6 Hz, 10β-H)).



The second, more polar product was identified as the 10β alcohol **9***a*. The formation of significant amounts of epimeric alcohol **9***a* can be explained by taking into consideration its relative stability. In the preferred conformation *D*, either alcohol **9***a* or its tosylate **9***b* (δ 4.96 (m, $w/2$ = 22 Hz, 3β-H), 4.75 (m, $w/2$ = 18 Hz, 10α-H)) contained three equatorial substitutents, and only the small methyl group that occupied the axial position was involved in the 1,2-ae interaction with a 10β substituent.

The solvolysis of 10α-tosylate **8***c* was carried out under the same conditions as described in the case of compound **7***b*. Although the preferred conformation *C* seemed to be the most favourable for the methyl group migration, the reaction afforded $\Delta^{1(10)}$ olefin **5** and no rearranged products were detected. The



SCHEME 1

minor product of the reaction appeared to be hydroxy-tosylate **8***b* (the elimination of TsOH must be slower than the intramolecular substitution observed in the case of **7***b*). The similar reaction of the 10β-tosylate **9***b* resulted in the formation of α-ether **11** as the only isolable product. This intramolecular displacement proceeded in the same way as described above for compound **7***b*. In this case a nucleophilic attack took place from the opposite, α, side of the molecule as required by the structure of the starting material.

Since we failed to obtain the rearranged products by solvolytic methods from tosylates of the C-10 alcohols, we tried some other reactions that could afford at least partial positive charge at C-10. Such a reaction was the solvolysis of tosylate **4***c*, which should proceed with participation of π-electrons of the double bond. A nonclassical carbocation with a considerable charge at C-10 could be a suitable intermediate for rearrangement. The compound **4***c* was obtained by tosylation of homoallylic alcohol **4***a*, the product of the decomposition of *p*-tosylhydrazone **3***c*

already described. However, the reaction, carried out in the same manner as described previously, yielded only the product of a simple elimination of *p*-TsOH, diene **12**. Another attempt was the Bamford–Stevens reaction of *p*-tosylhydrazone **13***b*. The α-cyclopropyl ketone **13***a* was easily obtained from oxo-tosylate **3***d* by the reaction with sodium isopropoxide in almost quantitative yield. Unfortunately the decomposition of **13***b* under basic conditions led to a complex mixture of products, which were not analysed.

Eventually, we brought about the migration of the 19-methyl group by solvolysis of *p*-nitrobenzenesulfonate **7***c* in refluxing acetic acid in the presence of sodium acetate. Under these conditions, mainly the products of methyl migration were formed, in addition to a small amount of unrearranged olefin **4***b*. However, 6,9-epithio-tachysteryl acetate (λ_{max} 294 nm, δ 1.88 (br s, 19-H)), obtained in low yield, was accompanied by a number of other products (e.g. the $\Delta^{4(5)}$ isomer, nonpolar products of rearrangement with concomitant 3β-acetate elimination). The process requires further studies, which are under way.

Experimental

The melting points were determined on a Boetius micro melting point apparatus and are uncorrected. Optical rotations were measured on a Perkin–Elmer 241 polarimeter in chloroform solutions at $c = 1.0$ unless otherwise stated. The ir spectra were recorded on UR-20 and Unicam SP 1100 spectrophotometers. The ^{1}H nmr spectra were taken at 100 mHz (JEOL INM-4H-100 and Brüker instruments) in $CDCl_3$ solutions with TMS as an internal standard. Column chromatography was performed on silica gel (Kieselgel 60, 70–230 mesh, Merck). Thin-layer chromatograms were developed on aluminium tlc sheets precoated with silica gel F_{254} and visualized with 50% sulfuric acid after heating. All solvents were dried and freshly distilled prior to use. The starting ketone **1** was prepared according to the procedure described in ref. 5.

Triketone 2

A solution of β,γ-unsaturated ketone **1** (2.5 g) in hexane (100 mL) was cooled to −70°C in a Dry Ice – acetone bath and then treated with ozone. An excess of ozone was removed by passing a stream of oxygen, the reaction mixture was allowed to warm up to room temperature, and hexane was evaporated under reduced pressure. The residue was dissolved in acetic acid (30 mL) and stirred with zinc dust (2.5 g) for 45 min. The reaction mixture was diluted with ether (250 mL) and all inorganic material was filtered off. The filtrate was washed with water, sodium bicarbonate solution, again with water, and dried over anhydrous sodium sulfate. The solvent was removed and the crude product was purified on a silica gel column. Triketone **2** (1.9 g) was eluted with benzene–ether (9:1); $[\alpha]_D^{27}$ −68.2°; ν_{max} (neat): 1732, 1713, and 1698 cm^{-1}; δ: 5.42 (m, 1H, 3α-H), 2.08 (s, 3H, CH_3COO—), 1.38 (s, 5β-CH_3), 1.03 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{46}O_5$: C 73.4, H 9.8; found: C 73.5, H 9.7.

β-Oxo-thiophenes 3

To a stirred solution of triketone **2** (500 mg) in anhydrous THF (50 mL) were added phosphorus pentasulfide P_4S_{10} (1 g) and potassium hydrogen carbonate (1 g) and the reaction mixture was refluxed for 1 h. Most of the solvent was distilled off and the residue was dissolved in tetrachloromethane and water. The organic solution was washed with water, dried, and evaporated. Silica gel column chromatography of the crude product afforded compound **3***b* in a pure form (310 mg; 62%) eluted with benzene–ether (1%). At the end of elution some fractions containing **3***b* were contaminated by a slightly more polar furan analog (δ: 6.10 (s, 7-H)). Therefore it is recommended to leave the crude product for a few days in CCl_4 solution before chromatography to get rid of the unstable furan derivative. Compound **3***b*: $[\alpha]_D^{27}$ −72°; ν_{max} ($CHCl_3$): 1730, 1716, and 1261 cm^{-1}; λ_{max} (EtOH): 240 nm (ε 4950); δ: 6.53 (s, 1H, 7-H), 5.43 (m, 1H, 3α-H), 2.08 (s, 3H, CH_3COO—), 1.37 (s, 5β-CH_3), 0.61 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{44}O_3S$: C 73.7, H 9.4; found: C 73.6, H 9.4.

The hydrolysis of **3***b* was carried out in the following way. Compound **3***b* (140 mg) was dissolved in ethanol (20 mL) and a solution of potassium hydroxide (200 mg) in water (1 mL) was added dropwise. The reaction mixture was kept at 40°C for 1 h. The usual work-up afforded hydroxy-ketone **3***a* as an amorphous solid, $[\alpha]_D^{24}$ −76°; ν_{max} (KBr): 3430 and 1721 cm^{-1}; δ: 6.38 (s, 1H, 7-H), 4.30 (m, 1H, 3α-H), 3.41 (bs, 1H, —OH), 1.36 (s, 5β-CH_3), 0.60 (s, 13β-CH_3).

*3β-Hydroxy-olefin 4*a

Compound **3***b* (150 mg) and toluene-4-sulfonic acid hydrazide (250 mg) were dissolved in diglyme (2 mL) – diethylene glycol (5 mL) mixture, and acetic acid (0.5 mL) was added. The reaction mixture was stirred at 70°C for 4 h; tlc control showed the disappearance of all the starting material. A solution of *p*-tosylhydrazone **3***c* obtained in such a way was treated with KOH (2.5 g) and the temperature was increased to 140°C. The reaction was maintained at this temperature until evolution of N_2 stopped (about 30 min). After cooling, the reaction mixture was poured into 3% sulfuric acid and extracted with methylene chloride. The extract was dried over sodium sulfate and evaporated (the rest of the diglyme and glycol was removed under high vacuum) and the residue was chromatographed on a silica gel column. The product, olefin **4***a*, was eluted with benzene–ether (3%). Yield 76 mg; $[\alpha]_D^{24}$ +114°; ν_{max} ($CHCl_3$): 3610 and 1034 cm^{-1}; δ: 6.37 (s, 1H, 7-H), 5.69 (almost s, 2H, 1-H and 10-H), 3.90 (m, 1H, 3α-H), 1.41 (s, 5β-CH_3), 0.61 (s, 13β-CH_3). *Anal.* calcd. for $C_{27}H_{42}OS$: C 78.2, H 10.2; found: C 78.4, H 10.1.

*3β,10α-Diol 3-monoacetate 7*a

A stirred solution of compound **3***b* (200 mg) in benzene (15 mL) – methanol (15 mL) was treated with sodium borohydride (50 mg). After 30 min at room temperature the solvents were removed, chloroform and 5% sulfuric acid were added, and the chloroform layer was separated, washed with water, and dried over sodium sulfate. The evaporation of the solvent afforded essentially pure 10α-alcohol **7***a* in almost quantitative yield; mp 170–171°C (from hexane); $[\alpha]_D^{26}$ +32.5° (*c* 0.9); ν_{max} (KBr): 3474, 1718, and 1272 cm^{-1}; λ_{max} (EtOH): 241 nm (ε 6900); δ: 6.61 (s, 1H, 7-H), 5.13 (m, $w/2 = 20$ Hz, 1H, 3α-H), 3.66 (m, $w/2 = 15$ Hz, 1H, 10β-H), 2.05 (s, 3H, CH_3COO—), 1.83 (s, —OH), 1.42 (s, 5β-CH_3), 0.62 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{46}O_3S$: C 73.4, H 9.8; found: C 73.5, H 9.6.

Compound **7***a* (70 mg) and *p*-TsCl (170 mg) were dissolved in anhydrous pyridine (3 mL) and the solution was allowed to stand at room temperature for 24 h. The usual work-up gave tosylate **7***b*, which was used in the next experiment.

3β,10β-Ether 10

Tosylate **7***b* from the previous experiment was dissolved in diglyme (3 mL), potassium hydroxide (1.2 g) in diethylene glycol (3 mL) was added, and the vigorously stirred reaction mixture was heated at 120°C for 1 h. After cooling, the reaction mixture was poured into dilute hydrochloric acid and extracted with tetrachloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated. The crude product **10** was filtered through a layer of silica gel in a benzene–ether (2%) solution. Yield 39 mg; $[\alpha]_D^{26}$ +18° (*c* 0.86); ν_{max} ($CHCl_3$): 1017 cm^{-1}; λ_{max} (EtOH): 241 nm (ε 7000); δ: 6.42 (s, 1H, 7-H), 4.64 and 4.23 (2 × m, 2 × 1H, —CH—O—CH—), 1.42 (s, 5β-CH_3), 0.62 (s, 13β-CH_3). *Anal.* calcd. for $C_{27}H_{42}OS$: C 78.2, H 10.2; found: C 78.5, H 10.2.

3α-Acetoxy-ketone 6

To a stirred solution of 3β-hydroxy-ketone **3***a* (300 mg) triphenylphosphine (250 mg), and acetic acid (100 mg) in anhydrous tetrahydrofuran (5 mL) was added diethyl azodicarboxylate (180 mg), and the reaction mixture was allowed to stand at room temperature for 24 h. The solvent was evaporated and the residue was chromatographed on a silica gel column. The steroidal product **6** was eluted with benzene–ether (5%). Yield 220 mg; $[\alpha]_D^{24}$ −6.0°; ν_{max} ($CHCl_3$): 1730 and 1705 cm^{-1}; δ: 6.37 (s, 1H, 7-H), 5.24 (m, 1H, 3β-H), 1.93 (s, 3H,

CH_3COO—), 1.49 (s, 5β-CH_3), 0.62 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{44}O_3S$: C 73.7, H 9.4; found: C 73.9, H 9.5.

3α,10α-Diol- and 3α,10β-diol-3-monoacetates ***8***a *and* ***9***a

A solution of compound **6** (200 mg) in benzene–methanol (1:1; 30 mL) was treated with $NaBH_4$ (50 mg) at room temperature for 1 h. The usual work-up of the reaction mixture, followed by the chromatographic separation of products on a silica gel column afforded 10α-alcohol ***8a*** (108 mg) and 10β-alcohol ***9a*** (82 mg); both products were eluted with benzene–ether (6%).

Compound ***8a***: $[\alpha]_D^{24}$ +65.0°; ν_{max} (neat): 3620, 1732, and 1248 cm^{-1}; δ: 6.53 (s, 1H, 7-H), 5.02 (m, 1H, 3β-H), 3.68 (m, 1H, 10β-H), 2.06 (s, 3H, CH_3COO—), 1.78 (s, —OH), 1.39 (s, 5β-CH_3), 0.61 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{46}O_3S$: C 73.4, H 9.8; found: C 73.7, H 9.8.

Compound ***9a***: $[\alpha]_D^{24}$ +63.8°; ν_{max} (neat): 3525, 1739, and 1248 cm^{-1}; δ: 6.56 (s, 1H, 7-H), 5.00 (m, 1H, 3β-H), 3.77 (m, 1H, 10α-H), 2.00 (s, 3H, CH_3COO—), 1.38 (s, 5β-CH_3), 0.62 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{46}O_3S$: C 73.4, H 9.8; found: C 73.6, H 9.7.

Both alcohols were converted into the corresponding tosylates ***8c*** or ***9b*** by dissolving the starting material (70 mg) in anhydrous pyridine (3 mL) together with *p*-tosyl chloride (300 mg). The reactions were allowed to stand at 30°C for 1 week. The standard work-up followed by chromatographic purification (tosylates were eluted with benzene–ether (2%) in both cases) afforded compounds ***8c*** or ***9b*** in almost quantitative yields.

8c: δ: 7.26 (AA′BB′, J = 8.4 Hz, 4H, arom. H), 6.38 (s, 1H, 7-H), 5.08 (m, $w/2$ = 24 Hz, 1H, 3β-H), 4.57 (m, $w/2$ = 6 Hz, 1H, 10β-H), 2.40 (s, 3H, Ar-CH_3), 2.03 (s, 3H, CH_3COO—), 1.35 (s, 5β-CH_3), 0.58 (s, 13β-CH_3).

9b: δ: 7.27 (AA′BB′, J = 8.2 Hz, 4H, arom. H), 6.37 (s, 1H, 7-H), 4.96 (m, $w/2$ = 22 Hz, 1H, 3β-H), 4.75 (m, $w/2$ = 18 Hz, 1H, 10α-H), 2.40 (s, 3H, Ar-CH_3), 1.97 (s, 3H, CH_3COO—), 1.38 (s, 5β-CH_3), 0.58 (s, 13β-CH_3).

3α,10α-Ether ***11***

To a solution of tosylate ***9b*** (67 mg) in diglyme (3 mL) was added potassium hydroxide (1.2 g) in diethylene glycol (3 mL). The reaction mixture was heated at 120°C and stirred for 1 h. The reaction was quenched in cold water, acidified with hydrochloric acid, and extracted with tetrachloromethane. The extract was washed with water, dried (anhydrous Na_2SO_4), and evaporated. The crude produce was purified on a silica gel column. 3α,10α-Ether **11** (37 mg) was eluted with benzene–ether (1%); $[\alpha]_D^{24}$ +33.5°; ν_{max} ($CHCl_3$): 995 cm^{-1}; λ_{max} (EtOH): 240 nm (ε 6200); δ: 6.49 (s, 1H, 7-H), 4.65 and 4.36 (2 × m, 2 × 1H, —CH—O—CH—), 1.42 (s, 5β-CH_3), 0.54 (s, 13β-CH_3). *Anal.* calcd. for $C_{27}H_{42}OS$: C 78.2, H 10.2; found: C 78.5, H 10.1.

3α-Hydroxy-olefin ***5***

The solvolysis of tosylate ***8c*** (70 mg) was carried out in exactly the same manner as in the previous experiment. The reaction products were separated on a silica gel column. The elution with benzene–ether (4%) afforded 3α-hydroxy-olefin **5** (36 mg). With benzene–ether (7%), hydroxy-tosylate ***8b*** (10 mg) was eluted.

Compound **5**: $[\alpha]_D^{24}$ + 61°; ν_{max} ($CHCl_3$): 3618 and 1038 cm^{-1}; δ: 6.47 (s, 1H, 7-H), 5.68 (m, 1H, 1-H), 4.08 (m, 1H, 3β-H), 1.45 (s, 5β-CH_3), 0.63 (s, 13β-CH_3). *Anal.* calcd. for $C_{27}H_{42}OS$: C 78.2, H 10.2; found: C 78.4, H 10.4.

Compound ***8b***: $[\alpha]_D^{24}$ +52°; ν_{max} ($CHCl_3$): 3606, 1178, and 901 cm^{-1}; δ: 7.27 (AA′BB′, J = 8.4 Hz, 4H, arom. H), 6.41 (s, 1H, 7-H), 4.54 (m, 1H, 10β-H), 3.98 (m, 1H, 3β-H), 2.41 (s, 3H, Ar-CH_3), 1.34 (s, 5β-CH_3), 0.59 (s, 13β-CH_3).

Diene ***12***

3β-Hydroxy-olefin ***4a*** (80 mg) and *p*-tosyl chloride (300 mg) were dissolved in anhydrous pyridine and allowed to stand for 16 h. Thin-layer chromatography showed complete conversion and the pyridine was then evaporated at room temperature. The residue was dissolved in diglyme (2 mL) and a solution of KOH (0.8 g) in diethylene glycol was added. The reaction mixture was vigorously stirred and heated at 110°C for 30 min. The reaction was quenched in cold water, acidified with HCl, and extracted with tetrachloromethane. The solvent was removed from the extract dried over sodium sulfate, and the crude product was purified by filtration through a layer of silica gel in a benzene – petroleum ether (1:4) solution. Yield of diene **12**, 56 mg; $[\alpha]_D^{25}$ +155°; ν_{max} ($CHCl_3$): 2965 and 1471 cm^{-1}; λ_{max} (EtOH): 244 (ε 12 000) and 256 (ε 11 600) nm; δ: 6.51 (s, 1H, 7-H), 5.86 (m, 4H, 1-H, 2-H, 3-H, and 10-H), 1.42 (s, 5β-CH_3), 0.64 (s, 13β-CH_3). *Anal.* calcd. for $C_{27}H_{40}S$: C 81.8, H 10.2; found: C 81.5, H 10.0.

α-Cyclopropylketone ***13***a

A solution of compound ***3a*** (140 mg) and *p*-tosyl chloride (500 mg) in anhydrous pyridine (5 mL) was allowed to stand at room temperature for 16 h. Pyridine was removed under high vacuum and a solution of sodium isopropoxide in isopropanol (prepared from 1 g of sodium and 80 mL of i-PrOH) was added. The suspension obtained was refluxed for 1 h. Then water was added and isopropanol was distilled off under reduced pressure. The steroidal product was extracted with benzene, and the extract was dried over sodium sulfate and evaporated. The crude product was purified on a silica gel column, and α-cyclopropylketone ***13a*** (105 mg) was eluted with benzene; mp 69–70°C; $[\alpha]_D^{25}$ +19.8°; ν_{max} ($CHCl_3$): 1699 cm^{-1}; δ: 6.48 (s, 1H, 7-H), 1.42 (s, 5β-CH_3), 0.61 (s, 13β-CH_3). *Anal.* calcd. for $C_{27}H_{40}OS$: C 78.6, H 9.8; found: C 78.5, H 9.8.

The *p*-tosylhydrazone of α-cyclopropylketone ***13b*** was obtained in a manner similar to that described earlier for compound ***3c*** (the reaction was somewhat slower and required more acetic acid). Its decomposition (Bamford–Stevens reaction), however, resulted in the formation of a complex mixture of products, which was not studied further.

The short synthetic route from 3β-acetoxy-5β-methyl-19-norcholest-9(10)-en-6-one (**1**) to 8-methylene-des-AB-cholestan-9-one (**8**) is described. Compound **8** is a convenient intermediate for the synthesis of relatives of vitamin D_3 by the A → CD route.

JACEK W. MORZYCKI, JAROSŁAW JUREK et WŁADYSŁAW J. RODEWALD. Can. J. Chem. **64**, 1540 (1986).

On décrit une voie de synthèse courte pour transformer l'acétoxy-3β méthyl-5β nor-19 cholestène-9(10) one-6 (**1**) en méthylène-8 des-AB cholestanone-9 (**8**). Le composé **8** est un intermédiaire utile pour la synthèse, par le biais de la route A → CD, de composés apparentés à la vitamine D_3.

[Traduit par la revue]

Considerable interest surrounds des-AB- and des-A-B-seco-cholestane derivatives since they serve (2) as intermediates for the synthesis of relatives of vitamin D_3. These systems can be obtained either by total synthesis (3) or by degradation of cholesterol (4). The degradative approach avoids many of the stereochemical problems of a total synthesis and consists of successive cleavage of two bonds in ring B of the cholestane skeleton. Continuing studies (1) on des-A-B-seco steroids, our attention has been drawn to the synthesis of des-AB cholestanes containing one carbon atom substituent attached to C-8. The easily available ketone **1** (5) (from cholesterol in 4 steps)[3] seemed to be an excellent starting material for this purpose. The same compound was used by Lythgoe and co-workers in the synthesis of 8-hydroxymethyl-des-AB-cholest-8-ene (**12***a*) (6). Compound **12***a* was obtained in good yield and then successfully converted to 1α-hydroxy-vitamin D_3 (7). However, the multi-step Lythgoe synthesis of **12**, though efficient, was somewhat troublesome and therefore we considered alternative, more direct, methods of ketone **1** degradation (8). The most promising one seemed to be the oxime **2** fragmentation to an unsaturated nitrile, the reaction that was expected to predominate under Beckmann rearrangement conditions. We assumed that the ozonolysis of the C(9)—C(10) double bond in hypothetic nitrile **A**, followed by HCN elimination, should afford α-methylene ketone **8**.

Compound **2***a* reacted with $POCl_3$/Py to give a chromatographically inseparable mixture of nitriles in addition to a small amount of lactam **3**. However, spectral analysis of the mixture suggested a high content of nitrile **4**. The whole nitrile fraction was ozonized and the complex mixture of products was subjected to column chromatography. The major product appeared to be compound **5**, thus confirming structure **4** as the most significant compound of the nitriles mixture. Since we failed to obtain **8** in this way some changes in our synthetic strategy were necessary. We decided to inverse the order of transformations and to study the oxime **6***a* fragmentation reaction. We planned to obtain compound **6***a* by ozonolysis of the C(9)—C(10) double bond of the protected oxime, followed by hydrolysis of a protective group. It has been found (9) that γ-oxo-ketoximes undergo a heterolytic 5-centre fragmentation reaction to α,β-unsaturated ketones and nitriles. A similar fragmentation could also be expected in the case of **6***a*. The protection of oxime as acetate **2***b* appeared to be sufficient against ozone, and diketone **6***b* was obtained in 80% yield. The oxime acetyl group was selectively and almost quantitatively removed by hydrolysis with $NaHCO_3$/MeOH. Unfortunately, the compound obtained did not react either with TsCl/Py or with TsCl/MeOH/NaOH (9) (except for hydrolysis of 3β-OAc). However, on treatment with $POCl_3$/Py, it unexpectedly underwent fragmentation to α-methylene ketone **8** in about 50% yield. Under these conditions the normal Beckmann rearrangement of compound **6***a* was rather anticipated (10). The A-ring fragment is probably water soluble, as we could not find it in the benzene extract of the reaction products in spite of careful analysis. In some experiments a small amount of slightly more polar by-product **9** was obtained. The formation of oxazine **9** was also unexpected unless the structure **6***a* of the starting material was incorrect. These results prompted us to reexamine a structure of the product of oxime acetate **6***b* hydrolysis. We found that its hydroxyl group (ν_{max} ($CHCl_3$): 3582 cm^{-1}) is resistant to acetylation under mild conditions. This suggested that either the hydroxyl group is strongly engaged in an intramolecular hydrogen bond or, more likely, it is tertiary and the actual structure is **7**. Carbon-13 nmr distinguishes between these two possibilities. The comparison of the C-9 chemical shifts in ^{13}C nmr spectra of **6***b* (δ: 211.3 $\rangle C{=}O$) and the hydrolysis product (δ: 95.7 $\rangle C(OH)(OR)$) unequivocally confirmed the cyclic structure **7** of the latter compound and showed that it is a mixture of two epimers **7***a* and **7***b* in a ratio of approximately 7:3 (calculated from the integration of the anomeric carbon signals at δ 95.7 and 96.0) (11). The mixture is inseparable by chromatographic methods but it may be enriched in α-anomer **7***a* by crystallization from petroleum ether. In further experiments it was checked that oxazine **9** was not an intermediate in the reaction and that the presence of base (pyridine) is important for the fragmentation progress. The tentative mechanism of the reaction is shown in Scheme 1. However, it is also possible that during the reaction there is an equilibrium between **7***a*, **7***b*, and an open chain tautomer, i.e., **6***a*. The hydroxyl group of the free oxime **6***a* is easily accessible and therefore it reacts faster with $POCl_3$ than **7** (*a* or *b*) to give the corresponding ester. The fragmentation of this intermediate could be similar to that shown for the compound **7** derivative.

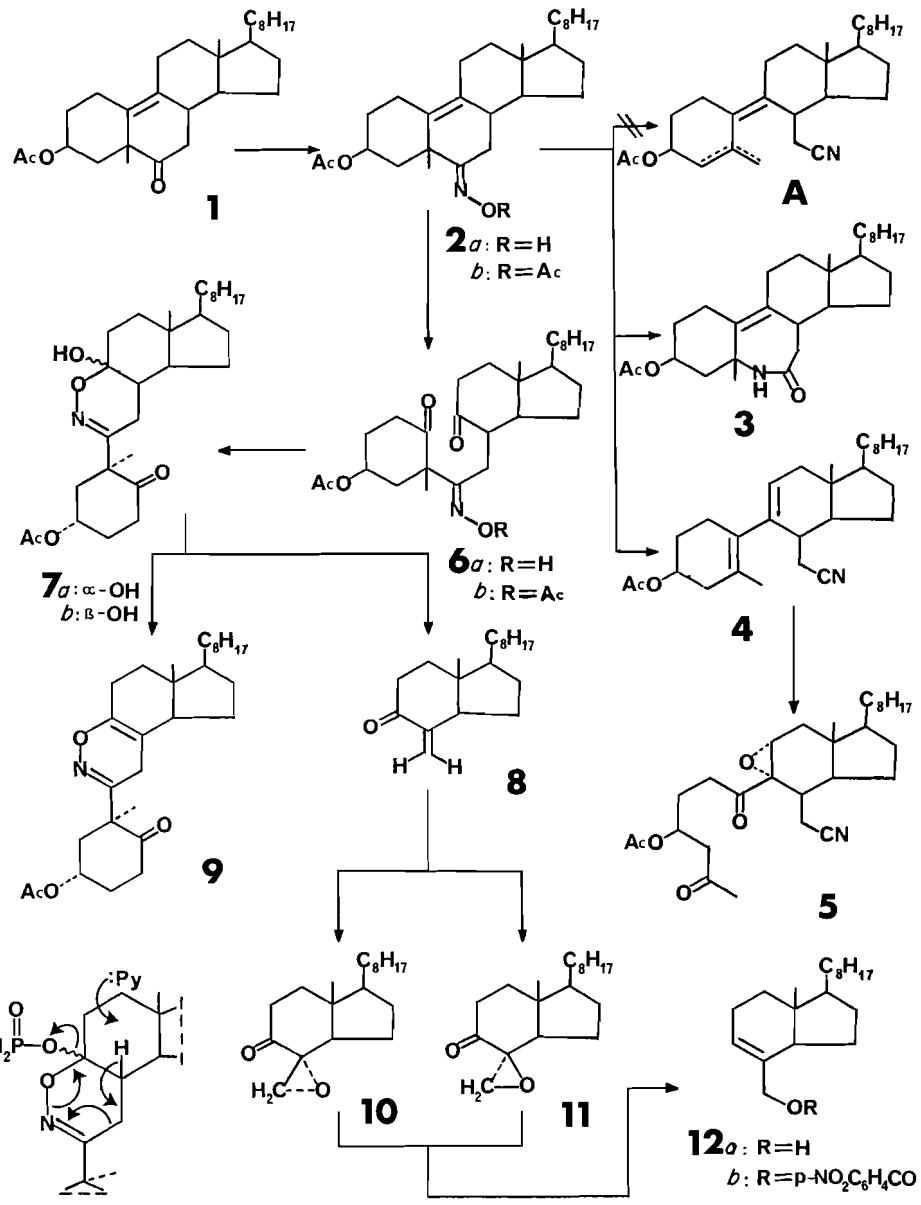
[3]The improved synthesis of **1** from cholesterol was recently elaborated by Szczepek (5*b*).



SCHEME 1

The virtual utility of the des-AB compound **8** for the synthesis of relatives of vitamin D_3 and some analogs of natural steroids seems to be clear (12). To confirm its structure by chemical means and to demonstrate its application in the vitamin D field, the α-methylene ketone **8** was converted to the known allylic alcohol **12***a* by Wharton's two-step procedure (13). In the first step compound **8** was oxidized with hydrogen peroxide/NaOH/MeOH to yield a mixture of epoxy ketones **10** and **11** in the ratio 2:3. Each of them (or a mixture of both epimers) was then reduced with hydrazine at room temperature to give the same product **12***a*. Physical constants and spectral properties of its *p*-nitrobenzoyl derivative **12***b* proved to be almost identical with the data given for this compound in the literature (6).

Experimental

The melting points were determined on a Boetius micro melting point apparatus and are uncorrected. Optical rotations were measured on a Perkin–Elmer 241 polarimeter in chloroform solutions at $c = 1.0$ unless otherwise stated. The ir spectra were recorded on UR-20 and Unicam SP 1100 spectrophotometers. The ^1H and ^{13}C nmr spectra were taken at 100 MHz (JEOL INM-4H-100 and Brüker) in $CDCl_3$ solutions with TMS as an internal standard. The mass spectra were recorded on a LKB 9000 spectrometer at 70 eV. Column chromatography was performed on silica gel (Kieselgel 60, 70–230 mesh, Merck). Thin-layer chromatograms were developed on aluminium sheets tlc precoated with silica gel F_{254} and visualized with 50% sulfuric acid after heating. All solvents were dried and freshly distilled prior to use. The starting ketone **1** was prepared according to the procedure described in ref. 5*b*.

*Oxime 2*a

A solution of ketone **1** (5.0 g) and hydroxylamine hydrochloride (8.0 g) in methanol (100 mL) and pyridine (25 mL) was refluxed for 20 min. After cooling, the reaction mixture was poured into ice-water (400 mL), acidified with dilute hydrochloric acid, and extracted with chloroform (3 × 150 mL). The combined organic extracts were washed with water and dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure and the residue was purified by silica gel column chromatography. The elution with benzene–ether (9:1) afforded oxime **2***a* (4.3 g), which was used in the next step without any further purification. An analytical sample of **2***a* was obtained by

preparative tlc of oxime **2***a* (100 mg) eluted from the column. The plates were developed four times in benzene. This procedure got rid of the more polar *Z* isomer,[4] which makes up about 5% of the crude product. The pure compound **2***a* crystallized from petroleum ether, mp 151–153°C; $[\alpha]_D^{26}$ +39°; ν_{max} ($CHCl_3$): 3589, 3300, 1732, 1667, and 1268 cm^{-1}; δ: 5.11 (m, 1H, 3α-H), 2.07 (s, 3H, CH_3COO—), 1.42 (s, 5β-CH_3), 0.78 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{47}NO_3$: C 76.1, H 10.3; found: C 75.9, H 10.2.

Beckmann rearrangement of oxime **2**a

To a solution of compound **2***a* (900 mg) in pyridine (20 mL) cooled to −10°C a well-chilled mixture of $POCl_3$ (1 mL) and pyridine (20 mL) was added. The temperature (−10°C) was maintained for 10 min, then the reaction mixture was poured into ice-water (400 mL), acidified with dilute HCl, and extracted with chloroform (3 × 70 mL). The chloroform extracts were washed with water and dried over anhydrous Na_2SO_4. The solvent was evaporated and the residue was subjected to column chromatography. The benzene elution afforded a mixture of nitriles (450 mg). The elution with a benzene–ether (3:1) mixture yielded lactam **3** (150 mg), mp (from methanol) 132–135°C; $[\alpha]_D^{26}$ +105°; ν_{max} (neat): 3220, 1740, 1668, 1642 (shoulder), and 1250 cm^{-1}; δ: 5.95 (s, 1H, —NH), 5.03 (m, 1H, 3α-H), 2.05 (s, 3H, CH_3COO—), 1.63 (s, 5β-CH_3), 0.79 (s, 13β-CH_3). *Anal.* calcd. for $C_{29}H_{47}NO_3$: C 76.1, H 10.3; found: C 75.8, H 10.3.

Ozonolysis of the nitriles mixture

The nitrile fraction from the preceding experiment (80 mg) was dissolved in hexane (100 mL), cooled in a Dry Ice – acetone bath, and ozonized until a blue colour appeared. Hexane was removed under reduced pressure and zinc dust (200 mg) in acetic acid (5 mL) was added. The above mixture was stirred for 2 h, diluted with ether (200 mL), and the zinc was filtered off. The filtrate was washed with water, then with sodium bicarbonate solution, again with water, and dried over sodium sulfate. The crude product was chromatographed on a silica gel column. The benzene–ether (4:1) mixture eluted epoxy-diketone **5** (24 mg), $[\alpha]_D^{27}$ +6.2°; ν_{max} (neat): 2259, 1740, 1724, 1712, and 1250 cm^{-1}; δ: 5.26 (m, 1H, 3α-H), 3.15 (m, 1H, 11β-H), 2.15 (s, 3H, CH_3CO—), 2.01 (s, 3H, CH_3COO—), 0.81 (s, 13β-CH_3); *m/e*: 487 (M^+, 0.5%), 427 (M^+ − HOAc, 13%), 314 (M^+ − HOAc − C_8H_{17}, 23%), 124 (100%). *Anal.* calcd. for $C_{29}H_{45}NO_5$: C 71.4, H 9.3; found: C 71.3, H 9.3.

Ozonolysis of oxime acetate **2**b

Oxime acetate **2***b* was obtained by acetylation of oxime **2***a* (4.0 g) under standard conditions (15 mL of Ac_2O, 50 mL of Py, room temperature, 4 h). The usual work-up afforded the crude product, homogenous in tlc (4.25 g); $[\alpha]_D^{26}$ +53°; ν_{max} (neat): 1770, 1739, 1681, and 1637 cm^{-1}; δ: 5.19 (m, 1H, 3α-H), 2.18 (s, 3H, CH_3COON=), 2.07 (s, 3H, CH_3COO—), 1.52 (s, 5β-CH_3), 0.75 (s, 13β-CH_3).

A solution of the above oxime acetate **2***b* (140 mg) in hexane (150 mL) was cooled to −20°C. A stream of ozone (about 10 L/h) was passed through the solution for 3 min. Hexane was removed under reduced pressure and zinc dust (200 mg) in acetic acid (5 mL) was added. The further work-up was identical to the previous experiment. The silica gel column chromatography of crude product afforded diketone **6***b* (119 mg) eluted with benzene–ether (9:1), $[\alpha]_D^{25}$ −30°; ν_{max} ($CHCl_3$): 1770, 1730, 1712, and 1633 cm^{-1}; δ: 5.43 (m, 1H, 3α-H), 2.21 (s, 3H, CH_3COON=), 2.03 (s, 3H, CH_3COO—), 1.34 (s, 5β-CH_3), 1.02 (s, 13β-CH_3); ^{13}C nmr, δ: 211.3 (C-9), 208.9 (C-10), 170.2 (C=O in 3β-acetate), 169.4 (C=O in oxime acetate), 167.6 (C-6), 68.2 (C-3). *Anal.* calcd. for $C_{31}H_{49}NO_6$: C 70.0, H 9.3; found: C 69.8, H 9.3

The selective hydrolysis of compound **6**b

To a solution of compound **6***b* (400 mg) in methanol (100 mL) was added sodium bicarbonate (0.5 g), and the reaction mixture was stirred at room temperature for 1.5 h. $NaHCO_3$ was filtered off, the filtrate was acidified with acetic acid (to pH 6), and methanol was removed under reduced pressure. The residue was redissolved in benzene (150 mL), the solution obtained was washed with water, dried over sodium sulfate, and the solvent was evaporated. The crude product, **7** (361 mg), homogenous in tlc, was crystallized several times from petroleum ether, mp 137–138°C; $[\alpha]_D^{25}$ −29°; ν_{max} ($CHCl_3$): 3582, 1729, 1713, and 1260 cm^{-1}; δ: 5.40 (m, 1H, 3α-H), 2.08 (s, 3H, CH_3COO—), 1.25 (s, 5β-CH_3); ^{13}C nmr, δ: 209.2 (C-10), 170.2 (C=O in acetate), 157.6 (C-6), 95.7 (C-9), 68.3 (C-3). *Anal.* calcd. for $C_{29}H_{47}NO_5$: C 71.1, H 9.7; found: C 70.9, H 9.7.

8-Methylene-des-AB-cholestan-9-one (8) and oxazine **9**

A solution of compound **7** (a crude material was used that is actually a mixture of anomers **7***a* and **7***b*; 104 mg) in pyridine (20 mL) was chilled to 0°C and treated with $POCl_3$ (1.5 mL) in cold pyridine (10 mL). The reaction mixture was allowed to stand in the refrigerator (5°C) for 1 h, then poured into ice-water, acidified with dilute HCl, and extracted with benzene. The extract was washed with water, dried over sodium sulfate, and the solvent was evaporated. The residue was subjected to column chromatography. The least polar compound, α-methylene-ketone **8**, was eluted with benzene (32 mg); $[\alpha]_D^{25}$ +45°; ν_{max} ($CHCl_3$): 3100 (w, CH_2=), 1693, and 1625 cm^{-1}; λ_{max}: 234 nm (ε 4100); δ: 6.15 and 5.20 (2 × m, 2 × 1H, H_2C=), 0.72 (s, 13β-CH_3); *m/e*: 276 (M^+, 10%), 163 (M^+ − C_8H_{17}, 100%). *Anal.* calcd. for $C_{19}H_{32}O$: C 82.5, H 11.7; found: C 82.5, H 11.6.

Further elution with benzene afforded oxazine **9** (7 mg); $[\alpha]_D^{25}$ −14°; ν_{max} ($CHCl_3$): 1730, 1715, 1678, 1620 (w), and 1260 cm^{-1}; δ: 5.21 (m, 1H, 3α-H), 2.09 (s, 3H, CH_3COO—), 1.26 (s, 5β-CH_3), 0.77 (s, 13β-CH_3); *m/e*: 471 (M^+, 10%), 43 (100%). The benzene–ether (9:1) mixture eluted unreacted starting material **7** (21 mg).

The oxidation of 8-methylene-des-AB-cholestan-9-one (8) with hydrogen peroxide

A flask with a solution of α-methylene-ketone **8** (72 mg) in methanol (10 mL) and 30% hydrogen peroxide (1.6 mL) was placed in an ice-water bath. To the vigorously stirred reaction mixture 20% aqueous sodium hydroxide (0.4 mL) was added dropwise during 10 min. After 4 h of continuous stirring the mixture was poured into water and extracted with ether. The usual work-up provided an oily product, which was chromatographed on a silica gel column. The benzene elution afforded α-epoxide **10** (23 mg); $[\alpha]_D^{25}$ +73° (*c* 1.0 in CCl_4); ν_{max} ($CHCl_3$): 1719 cm^{-1}; δ: 3.15 and 2.53 (2 × d, J = 6 Hz, 2 × 1H, H_2C—C—), 0.92 (s, 13β-CH_3); *m/e*: 292 (M^+, 22%), 43 (100%).

The benzene–ether (9:1) mixture eluted β-epoxide **11** (34 mg); $[\alpha]_D^{25}$ +38° (*c* 1.0 in CCl_4); ν_{max} ($CHCl_3$): 1720 cm^{-1}; δ: 3.04 and 2.74 (2 × d, J = 6 Hz, 2 × 1H, H_2C—C—), 0.98 (s, 13β-CH_3); *m/e*: 292 (M^+,

17%), 43 (100%).

Allylic alcohol **12**a *and its* p*-nitrobenzoate* **12**b

To a solution of epoxide (**10** and (or) **11**; 60 mg) in methanol (10 mL) cooled to 0°C in an ice-water bath was added portionwise a solution of anhydrous hydrazine (1 mL) in methanol (4 mL). The reaction mixture was allowed to stand for 1 h at 0°C and for another hour at room temperature, then poured into water and extracted with benzene. The solvent was removed from the dried (anhydrous Na_2SO_4) extract, and the oily product, allylic alcohol **12***a*, was directly subjected to *p*-nitrobenzoylation (60 mg of *p*-$NO_2C_6H_4COCl$, 6 mL of pyridine, room temperature, 4 h). The reaction mixture was diluted with benzene (80 mL), washed several times with an aqueous solution of cupric sulfate, with water, and dried over sodium sulfate. The solvent was evaporated and the crude product was purified by column chromatography. *p*-Nitrobenzoate **12***b* was eluted with hexane–benzene (3:1) and crystallized from ethanol; mp 103–104.5°C (lit. (6) mp 100–103°C); $[\alpha]_D^{25}$ +16.5°; ν_{max} (KBr): 1729, 1670, 1530, 1352, and 1290 cm^{-1}; δ: 8.20 (m, 4H, arom H), 5.70 (m, 1H, 9-H), 4.75 (almost s, 2H, —CH_2OCO—), 0.71 (s, 13β-CH_3); *m/e*: 427 (M^+, 2%), 260 (M^+ −

Infrared spectroscopic studies of solvent effects on the conformation of *n*-alkanes[1]

H. L. CASAL, P. W. YANG, AND H. H. MANTSCH
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received January 27, 1986

H. L. CASAL, P. W. YANG, and H. H. MANTSCH. Can. J. Chem. **64**, 1544 (1986).

The infrared spectra of specifically deuterated *n*-tridecane-7,7-d_2 pure and mixed with several linear and branched hydrocarbons have been measured as a function of temperature. The average *gauche* fraction at the middle of the *n*-tridecane chain has been determined from the intensities of conformation-specific CD_2 rocking bands. The results indicate that the concentration of *gauche* rotamers in the centre of the *n*-C_{13} chains varies with the solvent. For example, when *n*-tridecane is dissolved in other *n*-hydrocarbons the *gauche* concentration decreases when the chain length of the solvent is shorter than *n*-C_{13} and increases when the solvent chains are longer than *n*-C_{13}. However, no simple, direct correlation is found between these solvent-induced changes in *gauche* concentration and measured thermodynamic quantities of mixing.

H. L. CASAL, P. W. YANG et H. H. MANTSCH. Can. J. Chem. **64**, 1544 (1986).

Opérant à diverses températures, on a mesuré les spectres infrarouges du *n*-tridécane-d_2-7,7 soit à l'état pur soit sous forme de mélange avec plusieurs hydrocarbures linéaires ou ramifiés. En se basant sur les intensités des bandes de vibration de rotation du CD_2 qui sont spécifiques aux conformations, on a déterminé la fraction moyenne de conformères *gauche* qui existe au centre de la chaîne du *n*-tridécane. Les résultats indiquent que la concentration de rotamères *gauche* dans le centre des chaînes *n*-C_{13} varie avec le solvant. Par exemple, lorsqu'on dissout du *n*-tridécane dans d'autres hydrocarbures linéaires, la concentration de conformères *gauche* diminue si la longueur de la chaîne du solvant est plus courte que celle du *n*-C_{13} alors qu'elle augmente lorsque les chaînes du solvant sont plus longues que celle du *n*-C_{13}. Toutefois, il n'existe aucune corrélation directe entre ces changements, induits par le solvant, dans les concentrations de conformères *gauche* et les quantités thermodynamiques de mélange qui ont été mesurées.

Introduction

The conformation, flexibility, and constitution of liquid hydrocarbons in their pure state or in mixtures with each other play an important role in determining their macroscopic behaviour. There currently is considerable interest in understanding the molecular-level phenomena associated with the measured macroscopic thermodynamic properties of mixing hydrocarbons with each other (1). The measured thermodynamic functions such as excess enthalpy or volume are a manifestation of interactions at the molecular level. The ΔH of mixtures of alkanes might be expected to be particularly simple since methyl and methylene groups in normal or branched alkanes may be taken as similar. Thus, the components of the mixture will be of the same chemical nature. Furthermore, differences in free volume between the alkane components of a mixture produce only small negative contributions to ΔH. More significant contributions to ΔH can arise from order effects, which may be of two kinds, one *intramolecular* involving *gauche–trans* isomerism and the other *intermolecular* involving orientational order of the alkane molecules. However, the time-averaged thermodynamic measurements are unable to resolve the relative significance of intramolecular isomerism and intermolecular short-range order in the total contribution to the observed excess thermodynamic quantities. The changes in packing (orientational order) must have an effect on the ability of these chain molecules to adopt different conformations. Thus, the two effects (inter- and intramolecular) cannot be easily separated. Spectroscopic methods are appropriate to attempt measurements of one or the other of these effects (or both together). For example, light scattering experiments have been used to measure changes in short-range intermolecular order (1, 2); on the other hand, Raman spectra indicated that within experimental error the total *gauche* concentration of liquid *n*-$C_{16}H_{34}$ is the same in the pure state and in CCl_4 solutions (2). The spectra of pure liquid hydrocarbons and their mixtures with each other are practically identical and the determination of their individual *gauche* concentrations is therefore a challenging problem. Isotopic labelling can be used to address this problem.

The results reported here represent an attempt to determine the average *gauche* concentration of one hydrocarbon in solution with other hydrocarbons. The method used for these measurements is based on the unique sensitivity of the infrared-active CD_2 rocking vibrations of specifically labelled *n*-hydrocarbons. This method was first introduced by Snyder to study the conformation of solid polyethylene (3). It was later used to study solid-state hydrocarbons (4) and also to measure *gauche* defect concentration in solid fatty acids (5). The spectra of specifically labelled *n*-hydrocarbons in the liquid state have also been analysed in detail and the necessary background for quantitative studies of chain conformation in hydrocarbon mixtures is available (6).

Experimental

n-Tridecane-7,7-d_2 (*n*-C_{13}-7,7-d_2) was purchased from Merck, Sharp & Dohme (Montreal, Canada). Its chemical purity was determined to be 99.2% from gas–liquid chromatography. Its isotopic purity was 98% atom D. The solvents used, cyclohexane, 2,2,4-trimethyl-pentane, *n*-heptane, *n*-octane, *n*-hexadecane, 2-methylpentane, 2,2-dimethylpentane, 3-methylpentane, 2,2-dimethylbutane, 2,3-dimethylbutane, and 3,3-dimethylpentane were from Aldrich (gold label) and were used as received.

Series of infrared spectra were recorded between 10 and 50°C using a Digilab FTS-11 Fourier transform infrared spectrometer equipped with a wide-range (~450 cm^{-1} cut off) HgCdTe detector. The samples consisted of neat liquid *n*-C_{13}-7,7-d_2 and its mixtures (always 50% by volume) with the above-mentioned solvents. Spectra were measured from solutions contained in cells of 50 μm path length with KBr windows. The resolution was 2 cm^{-1} and 200 interferograms were accumulated for each spectrum. The temperature was measured by a copper–constantan thermocouple in contact with the cell windows. The integrated band intensities due to the different conformers were measured by calculating the area of the observed bands from

band-fitted spectra. An iterative band-fitting program was used and spectra were processed after baseline correction due to the overlapping signals from the non-deuterated moieties of *n*-C_{13}-7,7-d_2 and solvents.

Results and discussion

The infrared bands due to the rocking vibrations of isolated CD_2 groups in a polymethylene chain occur between 600 and 680 cm^{-1}. For quantitative measurements of these bands, the solvents selected for study must not give rise to bands in this region which could interfere with the CD_2 rocking bands. The solvents used in this study were selected on that basis and the results presented here are from mixtures where the solvent bands do not overlap with the conformationally-sensitive CD_2 rocking signals from *n*-C_{13}-7,7-d_2.

The CD_2 rocking vibrations are almost completely decoupled from other vibrational modes of the unlabelled chain. The frequencies of the CD_2 rocking modes are uniquely sensitive to the conformation of the neighbouring C—C bonds as well as to the position of the CD_2 group in the chain. In Table 1 we summarize the observed frequencies for a CD_2 group in an otherwise non-labelled hydrocarbon chain. The values of the frequencies listed in Table 1 are for a CD_2 group in the interior of a chain and are from ref. 6.

In the spectra of long *n*-hydrocarbons ($n \geq 11$) the two bands at 646 and 652 cm^{-1}, due to tgg and tgt conformers respectively, overlap to such an extent that their separation is not possible. Therefore, we have meausred the combined area under the band at ~650 cm^{-1} (see Fig. 1) and refer to this quantity as I_{650}. Thus I_{650} represents the total intensity due to *tg* conformers (from tgg and tgt bond pairs). The area under the ttt band at ~622 cm^{-1} is termed I_{622} and represents the intensity due to the all-*trans* conformers. From these values, and following the derivations of ref. 6, the relative *gauche* concentration at the middle of the *n*-C_{13} chain is:

$$[1] \quad r_g(C_6—C_7) \equiv \frac{1}{2}[r_g(C_6) + r_g(C_7)] \cong \frac{n_{gt}}{n_{tt}} = \frac{1}{2}\frac{I_{650}}{I_{622}} \times A_r$$

where $r_g(C_6—C_7)$ is the ratio of the numbers of *trans–gauche* pairs to the numbers of *trans–trans* pairs and A_r is the relative absorptivity of the *tg* (~650 cm^{-1}) and *tt* (~622 cm^{-1}) bands. A_r has been determined to be 1.00 ± 0.07 for the rocking bands of CD_2 groups in the interior of chains (6); we shall use 1.0 as the value. From eq. [1], the average *gauche* fraction can be expressed as (6):

$$[2] \quad f_g(C_6—C_7) = \left[\frac{1}{r_g(C_6—C_7)} + 1\right]^{-1} \cong \frac{I_{650}}{I_{650} + 2I_{622}}$$

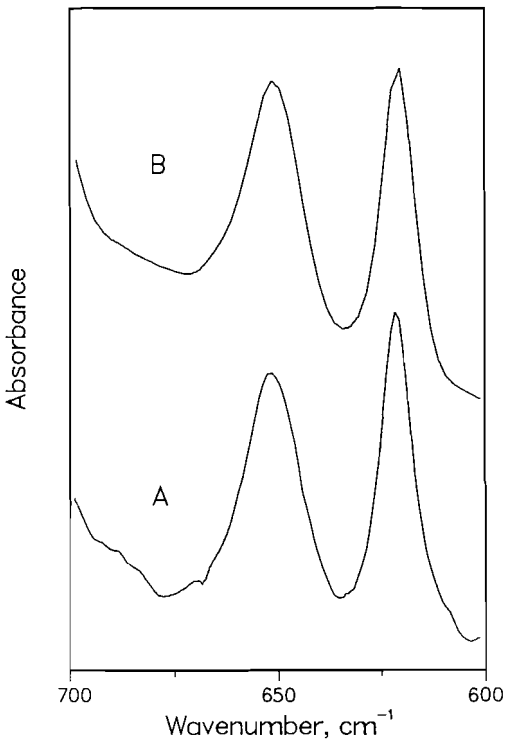

FIG. 1. Infrared spectrum (600–700 cm^{-1}) of *n*-C_{13}-7,7-d_2 pure (A) and as a 50% vol/vol solution in *n*-heptane (B).

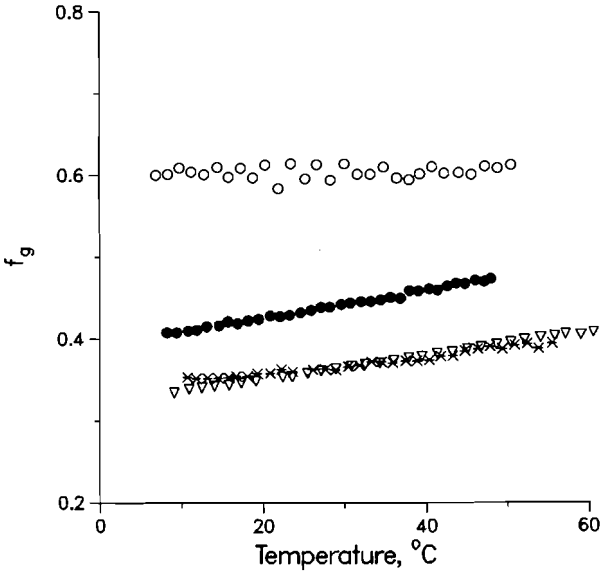

FIG. 2. Temperature dependence of the average *gauche* fraction (f_g) in *n*-C_{13}-7,7-d_2; neat liquid (●), and 50% vol/vol solutions of *n*-C_{13}-7,7-d_2 in: *n*-heptane (▽); *n*-octane (*); and *n*-hexadecane (○).

This is the quantity that we have calculated from the spectra of *n*-C_{13}-7,7-d_2.

Effect of solvent chain length on f_g

The temperature dependence of f_g for neat *n*-C_{13}-7,7-d_2 is compared in Fig. 2 with that for *n*-C_{13}-7,7-d_2 mixed with *n*-heptane, *n*-octane, and *n*-hexadecane. The values of f_g for *n*-C_{13} mixed with *n*-heptane and *n*-octane are practically identical. They are smaller than those for pure *n*-C_{13}. For example, at 25°C, $f_g = 0.43$ in pure *n*-C_{13} whereas $f_g = 0.36$ in *n*-C_{13} dissolved in either *n*-heptane or *n*-octane. Thus, when

n-C_{13} is mixed with these two solvents the concentration of *gauche* conformers at the middle of the n-C_{13} chain is less than in the pure state.

The case of n-C_{13}-7,7-d_2 mixed with n-hexadecane is the opposite, see Fig. 2. In this case the concentration of *gauche* conformers is much larger in solution than in the pure state f_g = 0.60 for the n-hexadecane solution compared to f_g = 0.43 for neat n-C_{13} at 25°C. The effect of n-C_{16} is to disorder (from the point of view of the *gauche* concentration) the n-C_{13} chains.

Taken together, the results of Fig. 2 can be summarized as indicating that when a normal hydrocarbon is mixed with another normal hydrocarbon of different chain length the concentration of *gauche* conformers in the middle of the longer hydrocarbon *decreases* (compare pure n-C_{13} with the solution of n-C_{13} in n-C_7 and n-C_8). On the other hand, the hydrocarbon with the shorter chain is disordered (i.e. the *gauche* concentration *increases*) when dissolved in a longer homologue. (Compare pure n-C_{13} with the solution in n-C_{16}.)

The observed heats of mixing of n-hydrocarbons with each other are invariably positive at ordinary temperatures (7) which is indicative at either inter- or intramolecular disorder being introduced upon mixing. An increase in f_g for an n-alkane could be accompanied by a positive enthalpy change. On mixing two n-alkanes of different chain length the longer alkane could contribute negatively and the shorter positively to the total ΔH. However, the total contribution of the intramolecular conformational part of the disorder to the observed heats of mixing cannot be derived from the present experiments since in each measurement the behaviour of only one of the components in the mixture is monitored.

Effect of branching of the solvent molecules

The effect of branching of the solvent hydrocarbon was studied by comparing the values of f_g (in n-C_{13}) when n-C_{13} was mixed with n-heptane and with two of its branched isomers, 2,2-dimethylpentane and 3,3-dimethylpentane; the corresponding results are shown in Fig. 3*A*. A comparison between n-octane and its branched isomer 2,2,4-trimethylpentane is shown in Fig. 3*B*.

The data of Fig. 3*A* show that the effect of n-heptane, 2,2-dimethylpentane, and 3,3-dimethylpentane on the values of f_g in n-C_{13} is similar. In all cases f_g is smaller in solution than in the pure state. Moreover, at 25°C the values of f_g are practically the same (~0.36) for all three mixtures.

In the presence of n-heptane and of its two branched isomers, the n-C_{13} chain contain less *gauche* conformers than in the pure state; thus, these three solvents create order in the n-C_{13} chains. However, the measured heats of mixing of n-hexadecane with n-heptane, 2,2-dimethylpentane, and 3,3-dimethylpentane are positive (102, 237, and 138 J/mol (8) respectively), indicating that order is destroyed on mixing a long n-alkane with these heptanes. The disorder introduced at the *intermolecular* (short range orientational) level must therefore compensate for the order created in n-C_{13} at the *intramolecular* level. In principle, intramolecular disorder could also be introduced in the solvent molecules while n-C_{13} is ordered. This is expected to be the case for n-heptane as solvent, following the data for different chain length presented above. However, in the case of 3,3-dimethylpentane the molecular shape does not allow for the introduction of *gauche* conformers due to steric crowding of the methyl groups and a similar situation occurs in 2,2-dimethylpentane. Therefore, since a large compensation of the intramolecular order created in n-C_{13} is not expected to come from 2,2-dimethylpentane and 3,3-dimethylpentane, intermolecular effects could be invoked. That is, when *order* is created at the intramolecular level in n-C_{13} the *disorder* introduced at the intermolecular level overcompensates to yield positive heats of mixing.

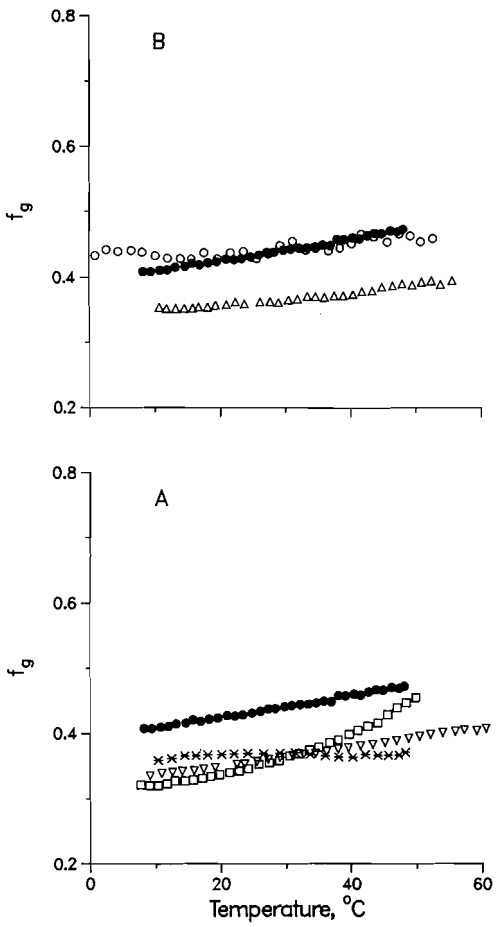

FIG. 3. *A*: Temperature dependence of f_g in n-C_{13}-7,7-d_2; pure liquid (●), and as 50% vol/vol solutions of n-C_{13}-7,7-d_2 in: n-heptane (▽), 2,2-dimethylpentane (*), and 3,3-dimethylpentane (□). *B*: Temperature dependence of f_g in n-C_{13}-7,7-d_2: pure liquid (●), and as 50% vol/vol solutions of n-C_{13}-7,7-d_2 in 2,2,4-trimethylpentane (○) and n-octane (△).

A comparison of the f_g values in n-C_{13} dissolved in n-octane and iso-octane is shown in Fig. 3*B*. In this case the branched isomer, iso-octane, produces no effect on the *gauche* bond concentration in the middle of the n-C_{13} chain. The same values of f_g are found for neat n-C_{13} and n-C_{13} mixed with iso-octane. This is in contrast to the situation with the linear hydrocarbon n-octane as solvent where the f_g value (i.e. the concentration of *gauche* conformers) is markedly smaller in solution than in neat n-C_{13}.

We have also measured the spectra of n-C_{13}-7,7-d_2 dissolved in cyclohexane and in four isomers of n-C_6: 2-methylpentane, 3-methylpentane, 2,2-dimethylbutane, and 2,3-dimethylbutane. The values of f_g derived from these spectra at 25°C are given in Table 2. The values of f_g for n-C_{13} mixed with the branched isomers of n-C_6 are smaller than f_g for neat n-C_{13} (see Table 2). Thus, these branched hydrocarbons induce a smaller concentration of *gauche* conformers at the centre of the n-C_{13} chain. As the value of f_g was not measured for n-C_{13} mixed with n-hexane the effect of these branched isomers of n-C_6 can not be

TABLE 2. Average *gauche* fraction (f_g) at the centre of the n-C_{13} chain measured from spectra of n-C_{13}-7,7-d_2 mixed with different solvents at 25°C

Solvent	f_g
None	0.43
Cyclohexane	0.46
2-Methylpentane	0.37
3-Methylpentane	0.38
2,2-Dimethylbutane	0.35
2,3-Dimethylbutane	0.38

compared directly with that of n-C_6. However, the close similarity of f_g in n-C_{13}-7,7-d_2 mixed with n-C_7 or n-C_8 (Fig. 2) allows us to speculate that f_g for n-C_{13} mixed with n-C_6 should be almost the same (i.e. ≈ 0.36). On that basis there are no large differences between f_g measured in the branched C_6 solvents and the linear C_6, a similar situation to that found for n-C_{13} mixed with n-C_7 and its branched isomers (Fig. 3*A*).

The value of f_g for n-C_{13} dissolved in cyclohexane is larger than that for pure n-C_{13} indicating (see Table 2) that the concentration of *gauche* conformers at the centre of the n-C_{13} chain is larger than in neat n-C_{13}. Cyclohexane is generally referred to as a globular solvent and from the intermolecular point of view it is an "order breaking" solvent when mixed with n-hydrocarbons (9). The effect of cyclohexane on the concentration of *gauche* conformers in the n-C_{13} chains is not very pronounced, i.e. there is only a slight increase in f_g between n-C_{13} in the pure state and that in cyclohexane solution. This would indicate that the large values of the enthalpy of mixing found for solutions of cyclohexane and hydrocarbons would probably be best explained by intermolecular contributions to the mixing phenomena.

Concluding remarks

The data presented herein demonstrate that the concentration of *gauche* conformers in n-hydrocarbons in mixtures is a function of the solvent. The *gauche* concentration in n-tridecane has been measured by utilizing the CD_2 rocking vibrations of a CD_2 group in position 7 of the n-tridecane chain. Thus, the present measurements only apply to the centre of the chain and no information is available regarding conformation at chain positions close to the terminal methyl groups. Positional dependence of the *gauche* concentration is known to occur in the case of solid n-hydrocarbons (4).

The magnitude of the changes observed in the values of f_g cannot be related directly to the differences in the energy difference between *gauche* and *trans* conformers (ΔE_{gt}). This is because our observable "I_{650}" is the combined intensity of bands due to tgt and tgg conformers. Thus, I_{650} contains contributions from conformers with one and two *gauche* bonds and their separation is not possible.

Although the present changes in the f_g values cannot be readily and easily correlated with thermodynamic measurements on the enthalpy of mixing they suggest that changes in the concentration of *gauche* conformers do not play the most important role in determining the macroscopic observables. For example, dissolving n-C_{13} in a branched alkane induces a decrease in the concentration of *gauche* conformers leading to a prediction of negative ΔH. However, the enthalpy of mixing of such a system is positive (9).

In the case of mixtures of n-hydrocarbons differing only in chain length a trend emerges in the dependence of the *gauche* concentration with chain length. In a given mixture, the concentration of *gauche* conformers *decreases* for the longer n-hydrocarbon and the opposite occur for the shorter n-hydrocarbon. In order to determine whether the two effects compensate each other, or whether more disorder is introduced in one component compared to the order created in the other component, it would be necessary to utilize two specifically-deuterated hydrocarbons that differ considerably in chain length.

Finally, while the present results are limited to a few solvents, it is demonstrated that this approach represents a direct method of determining the *gauche* concentration of n-hydrocarbons and should be useful to study other solvent systems.

Many solutes, added to water in amounts of a few mol%, cause an increase in the yield of solvated electrons (e_s^-) measured by pulse radiolysis. A pulse radiolysis study of *tert*-butanol (*t*BuOH) in D_2O has been carried out to investigate this phenomenon. Detailed measurements of the yield, measured as $G\epsilon_{max}(e_s^-)$, and the decay of solvated electrons were made at 6, 25, and 46°C over the range 0–5 mol% *t*BuOH. The maximum $G\epsilon_{max}(e_s^-)$ occurs at about 1 mol% *t*BuOH, but the exact concentration depends on the temperature of the sample and the time after the pulse at which the measurement is made. Three factors are examined as contributing to the increased $G\epsilon_{max}(e_s^-)$ in the presence of *t*BuOH and certain other solutes. They are (*i*) the change in viscosity produced by the added solute, (*ii*) the scavenging of OH radicals by the solute, thereby reducing the reaction of OH with e_s^-, and (*iii*) the possibility that the addition of the solute leads to an increase in the thermalization distance of the secondary electrons. It is concluded that effects (*i*) and (*ii*) are sufficient to explain the existing experimental data.

Lorsqu'on ajoute de faibles quantités (quelques mol%) de plusieurs solutés dans de l'eau, la radiolyse pulsée permet de mesurer une augmentation du rendement d'électrons solvatés (e_s^-). Dans le but d'évaluer ce phénomène, on a effectué une étude de la radiolyse pulsée du *tert*-butanol (*t*-BuOH) dans le D_2O. Opérant à 6, 25 et 46°C et à des concentrations de *t*-BuOH allant de 0 à 5 mol%, on a effectué des mesures détaillés des rendements, mesurés sous la forme de $G\epsilon_{max}(e_s^-)$, et des vitesses de déclin des électrons solvatés. La valeur maximale pour $G\epsilon_{max}(e_s^-)$ est observée autour de 1 mol% de *t*-BuOH; toutefois, la concentration exacte dépend de la température de l'échantillon et du temps qui s'est écoulé entre la pulsation et le moment où la mesure est faite. On a examiné trois facteurs qui pourraient contribuer à une augmentation de la valeur de $G\epsilon_{max}(e_s^-)$ en présence de *t*-BuOH et de certains autres solutés. Il s'agit (*i*) du changement de viscosité provoqué par l'addition du soluté, (*ii*) d'un piégeage des radicaux OH par le soluté qui réduit la réaction des OH avec les e_s^- et (*iii*) de la possibilité que l'addition du soluté conduise à une augmentation de la distance de thermalisation des électrons secondaires. On en conclut que les effets (*i*) et (*ii*) sont suffisants pour expliquer les données expérimentales existantes.

Introduction

A recent series of papers by Leu, Jha, Freeman, and Cygler (1–3) on alcohol–water solutions describes in considerable detail the effect of solution composition on the yield of solvated electrons (e_s^-) at 1 μs and on properties of e_s^- such as the width of its absorption band at half height and the wavelength of maximum absorption. Pulse radiolysis studies of alcohol–water solutions revealed that the maximum $G\epsilon_{max}(e_s^-)$ occurs at a few mol% alcohol, where the spectrum of e_s^- is not noticeably different from that in water (2, 3). A similar effect was observed by Tran-Thi, Koulkes-Pujo, Sutton, and Anitoff (4) for the addition of less than 2 mol% of several amides and dimethyl sulfoxide to water. Leu, Jha, and Freeman (2) concluded that the increased $G\epsilon_{max}(e_s^-)$ results from an increase in the thermalization distance of the secondary electrons brought about by a stiffening of the solvent structure by the added alcohol. Tran-Thi *et al.* (4) explained the increase in $G\epsilon_{max}(e_s^-)$ by the more conventional argument that scavenging of OH radicals by the solute reduces the extent to which OH radicals react with e_s^-.

It seemed worthwhile to study another system in detail to test these models further. We chose *tert*-butanol–water solutions because *tert*-butanol (*t*BuOH) represents the extremes of two properties which are important for these models, namely the effect of the solute on the structure of the solution and the reaction of the solute with OH radicals. Compared to most monohydric, aliphatic alcohols, *t*BuOH reacts rather slowly with OH (5) but, at the same time, *t*BuOH has an unusually strong effect on the structure of the solution (refs. 6–15, and references therein).

We carried out pulse radiolysis measurements of $G\epsilon_{max}(e_s^-)$ and the decay kineties of e_s^- using *t*BuOH/D_2O solutions at 6, 25, and 46°C. Under most conditions, we observed a maximum $G\epsilon_{max}(e_s^-)$ at about 1 mol% *t*BuOH. We conclude that the increase in $G\epsilon_{max}(e_s^-)$ caused by the addition of small amounts of alcohol to water, as reported here and elsewhere, is most reasonably explained by the increase in viscosity, and the scavenging of OH, by the added alcohol.

Experimental

tert-Butanol (Fisher Certified) was purified by repeated recrystallization (16) and its absorption spectrum was found to be structureless at wavelengths down to 220 nm. Its water content, as measured by the Karl Fisher method, was 4.94 mg cm^{-3}. D_2O (99.8 atom% D) was used as received from Merck, Sharp and Dohme. Solutions of *t*BuOH in D_2O were prepared by weight. The densities of the solutions were measured at 25°C. The density variation over the temperature range 6–46°C was assumed to be the same for all solutions in the range 0–5 mol% *t*BuOH (17).

Samples were deaerated by bubbling with argon (Airco, Superpurified) for 60 min and were sealed off in Suprasil cells of 5 mm optical pathlength. The cells were supported in the open air for measurements at "room temperature", and in a quartz Dewar with Suprasil windows for measurements at 6, 25, and 46°C. The temperature in the Dewar was maintained with a flow of nitrogen gas, regulated to ±1°C, and was measured with an HP model 2802A digital thermometer with the platinum resistance probe in contact with the metal cell holder.

Irradiations were carried out using single 40 ns pulses of 35 MeV electrons from a linear accelerator. Aluminum plates of 6–10 mm thickness were used to attenuate and spread the electron beam. The dose to the sample was always close to 1.4 krad per pulse, except for the measurements shown in Fig. 1, where a dose of about 6 krad per pulse was used. Dosimetry was carried out using O_2-saturated 5×10^{-3} *M* KSCN, taking $G\epsilon_{475}(SCN)_2^- = 2.2 \times 10^4$ *M* cm^{-1} (100 eV)$^{-1}$ at mid-pulse. Account was taken of the electron densities of the various

solutions at each temperature. Pulse-to-pulse variations in the dose were monitored with a secondary emission monitor (SEM).

The equipment and techniques used to measure optical absorption have been described previously (18–20). Measurements between 500 and 900 nm were made using an EG&G SHS-100 silicon photoiodide and a 50Ω load resistor, the system having a response time of 10 ns. Above 900 nm, a Barnes A-100 detector with a response time of 50 ns was used.

Apart from the data shown in Fig. 1, the present results were compiled from measurements made on one set of samples covering the range 0–5 mol% tBuOH/D_2O. These measurements are in good agreement with measurements made on another set of samples covering the same concentration and temperature range. Each value reported for $G\epsilon_{max}(e_s^-)$ at 100 ns is the average of six measurements. The measurements reported were made on solutions which had already received at least 10 krad. The present study required that the averaged values of $G\epsilon_{max}(e_s^-)$ for a given sample on a given day be reproducible to ±1%. This was achieved by careful attention to all details. Poorer reproducibility was found for solutions which had received an accumulated dose of less than 10 krad. A very important procedure was the careful "lining up" of the electron beam to avoid, as much as possible, instabilities in the beam during the day. If a dose variation greater than ±10% occurred, as evidenced by the SEM readings, a recalibration of the SEM against the dosimetry solution was carried out. The SEM signal was found not to be exactly proportional to the optical density of the dosimetry solution. Therefore, a calibration curve of optical density vs. SEM signal was prepared each day.

The day-to-day variation in $G\epsilon_{max}(e_s^-)$ was greater than the variation during a single day. $G\epsilon_{max}(e_s^-)$ measured using a given sample varied by ±2% from one day to another. The average $G\epsilon_{max}(e_s^-)$ for a given solution at a given temperature was determined relative to $G\epsilon_{max}(e_{aq}^-)$ in neat D_2O at the same temperature on the same day. This value of $G\epsilon_{max}(e_{aq}^-)$ was, in turn, normalized to $G\epsilon_{max}(e_{aq}^-)$ in neat D_2O determined at 6, 25, and 46°C on a day when the utmost care was taken to ensure reproducibility. In this way, we arrived at an internally consistent set of results.

Results

D_2O was used instead of H_2O because of a concurrent study (21) which required D_2O. The use of D_2O has not caused any serious problems for our effort to understand the variation of $G\epsilon_{max}(e_s^-)$ with tBuOH concentration in aqueous solutions.

$G\epsilon_{max}(e_s^-)$ was measured at room temperature (about 21°C) for tBuOH/D_2O solutions covering the range 0–95 mol% tBuOH. The values of $G\epsilon_{max}(e_s^-)$ at 100 ns after the start of the pulse are shown in Fig. 1. The measurements at each concentration included a determination of $\lambda_{max}(e_s^-)$ which agreed with the published values (1). From 0–10 mol% tBuOH, $\lambda_{max}(e_s^-)$ remained constant at 720 (±10) nm. At higher tBuOH concentrations, λ_{max} moved to longer wavelengths. In tBuOH/D_2O solutions, there is an increase in $G\epsilon_{max}(e_s^-)$ on going from 0 to about 1 mol% tBuOH, followed by a decrease on going to higher tBuOH concentrations. The overall appearance of Fig. 1 is similar to that found by Leu *et al.* (2) for several alcohol–water systems. Included in Fig. 1 is a data point for $G\epsilon_{max}(e_s^-)$ at 100 ns in pure tBuOH at 27°C estimated from the experimental data used in ref. 16.

Having ascertained that the variation of $G\epsilon_{max}(e_s^-)$ with tBuOH concentration in water-rich solutions is similar to that in other alcohol–water solutions, we made a more detailed study of $G\epsilon_{max}(e_s^-)$ for solutions covering the concentration range 0–5 mol% tBuOH at 6, 25, and 46°C. The results are shown in Figs. 2, 3, and 4 for 50, 100, 500, 1000, and 5000 ns after the start of the pulse. No significant changes were found in the shape or the λ_{max} of the e_s^- spectrum over the range 0–5 mol% tBuOH at a given temperature, in agreement with the results of Leu, Jha, and Freeman (1). We adopted values of 697, 720, and 747 nm for λ_{max} at 6, 25, and 46°C, respectively. This variation in λ_{max} with temperature was calculated from the temperature

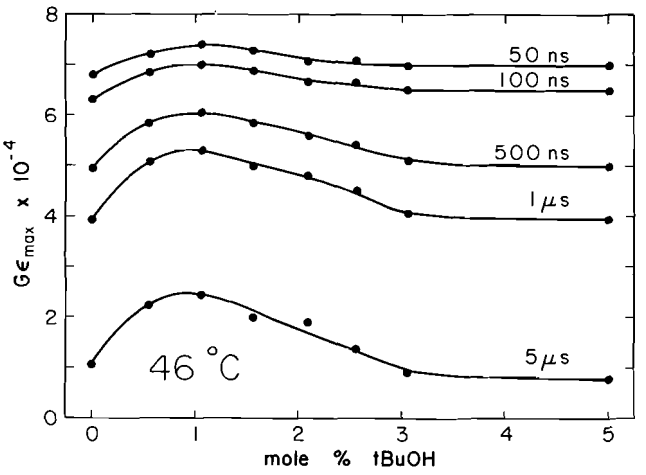

FIG. 4. $G\epsilon_{max}(e_s^-)$ versus mol% *t*BuOH for *t*BuOH/D_2O solutions at 46°C. The times after the start of the 40 ns pulse are indicated.

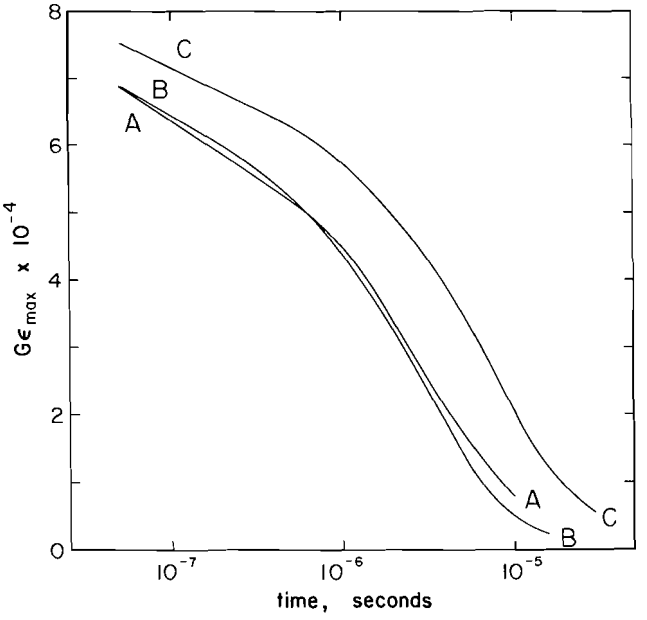

FIG. 5. $G\epsilon_{max}(e_s^-)$, for *t*BuOH solutions at 25°C, versus time. A, B, and C correspond to 0, 5.0, and 1.04 mol% *t*BuOH, respectively.

variation of e_{aq}^- in H_2O found by Michael, Hart, and Schmidt (22). Our less complete examination of λ_{max} agreed with these values. Any measurements made slightly off λ_{max} were corrected by use of the spectral shape of e_{aq}^- (23).

We measured $G\epsilon_{max}(e_{aq}^-)$ to be 6.32×10^4 at 720 nm in pure D_2O at 25°C, 100 ns. For e_{aq}^- in H_2O at 27°C, λ_{max} = 720 nm and $\epsilon_{max} = 1.9 \times 10^4$ (23). However, ϵ_{max} would have been 2.0×10^4 if the authors had used the same value of $G\epsilon_{475}(SCN)_2^-$ as we did for dosimetry. Assuming that the spectral shape of e_{aq}^- in ref. 23 also applies to e_{aq}^- in D_2O, and combining it with $\epsilon_{700}(e_{aq}^-)$ in $D_2O = 2.02 \times 10^4$ (24), we arrive at $\epsilon_{max}(e_{aq}^-) = 2.04 \times 10^4$ in D_2O at room temperature. Hence, our value $G\epsilon_{max}(e_{aq}^-) = 6.32 \times 10^4$ in D_2O at 25°C, 100 ns, leads to $G(e_{aq}^-) = 3.1$. In H_2O, Buxton determined $G(e_{aq}^-) = 2.8$ at 120 ns after a 5 ns pulse (25). Combined with an 11% higher yield of e_{aq}^- in D_2O than in H_2O (24), this predicts $G(e_{aq}^-) = 3.1$ in D_2O at 120 ns after a 5 ns pulse. Asmus and Fendler (26) reported $G(e_{aq}^-) = 3.06 \pm 0.05$ in D_2O, based on scavenging with millimolar SF_6.

The decay of e_s^- measured for D_2O, 1.04 mol% *t*BuOH and 5.0 mol% *t*BuOH at 25°C is shown in Fig. 5. The 24% decay of e_s^- between 50 and 500 ns for our 1.4 krad pulse in D_2O (curve A, Fig. 5) agrees with similar measurements in H_2O (27). The reactions from 1 μs onwards presumably follow homogeneous kinetics and can be modeled using MACKSIM, a computer program used to simulate water radiolysis (28, 29). The decay of e_{aq}^- in D_2O (curve A, Fig. 5) was successfully simulated using MACKSIM and a set of rate constants for D_2O (5, 24, 30, 31). A simulation assuming no D_2O_2 present before the pulse showed insufficient decay of e_{aq}^- from 10^{-6}–10^{-5} s indicating that accumulated D_2O_2 plays a role. Because of the decomposition of accumulated D_2O_2 by the room light and the analyzing light, its concentration preceding a pulse is unknown. Curve A (Fig. 5) was well simulated with an initial concentration of D_2O_2 of 3.5×10^{-6} *M*, i.e., twice the concentration produced by a single pulse, but not with initial D_2O_2 concentrations of 0 or 11×10^{-6} *M*.

Discussion

Spur and non-spur electrons and the free-ion yield

In the present study of *t*BuOH/D_2O solutions, in the study of Leu, Jha, and Freeman of other alcohols and water (2), and in the study of Tran-Thi, Koulkes-Pujo, Sutton, and Anitoff of amides etc. in water (4), it was found that the addition of solute, up to a few mol%, to water at room temperature caused an increase in $G\epsilon_{max}(e_s^-)$ over the time scale of the pulse radiolysis measurements. At yet higher solute concentrations, $G\epsilon_{max}(e_s^-)$ decreased. Leu *et al.* (2) attributed the increase in $G\epsilon_{max}(e_s^-)$ to an increase in the free-ion yield brought about by an increase in the thermalization distance of the secondary electrons, whereas Tran-Thi *et al.* (4) attributed it to OH scavenging by the solute.

Those solvated electrons which react with radiation-produced species in the spur, and whose decay obeys non-homogeneous kinetics, will be called spur electrons, $(e_s^-)_{sp}$. The remainder of the solvated electrons, those whose reactions obey homogeneous kinetics, will be called non-spur electrons, $(e_s^-)_{nsp}$. We assume that the free-ion yield, G_{fi}, as used by Leu *et al.*, corresponds to $G(e_s^-)_{nsp}$. The free-ion yield is the yield of electrons which escape eventual recombination with their geminate cations. Although G_{fi} is a very useful concept for the reactions of electrons in low dielectric media such as hydrocarbons, where most e_s^- reacts with cations, it is less useful in the case of water where much e_s^- reacts with a neutral species, the OH radical.[2] The G_{fi} concept is particularly inappropriate to apply to the changes caused by adding alcohol to water if the decay rate of e_s^- is affected significantly by the scavenging of OH. The addition of alcohol to water causes an increase in viscosity. This affects the spur reaction of e_s^- with OH through the reaction rate constant and the diffusion coefficients. By contrast, G_{fi} depends on the dielectric constant and might be affected quite differently. For these reasons we prefer to discuss e_s^- in alcohol–water solutions in terms of $G(e_s^-)_{sp}$ and $G(e_s^-)_{nsp}$. Johnson and Salmon (33) have addressed the inadequacy of G_{fi} to describe the reactions of e_s^- in methanol.

Scavenging experiments are often used to determine $G(e_s^-)_{nsp}$, using the fact that a reagent added at millimolar concentrations cannot compete effectively for e_s^- within the spur where

[2]W. G. Burns communicated to the authors that a computer simulation of reactions in water irradiated at low dose rates indicated that 57% of the decay of e_s^- at times earlier than 10 ns is due to reaction with the hydroxyl radical.

reactive species are present in high concentration, but can compete effectively outside the spur where the concentration of radiation-produced species is very low. In experiments in which only e_s^- is followed, $(e_s^-)_{nsp}$ can be separated from $(e_s^-)_{sp}$ by using the fact that spur decay is faster than non-spur decay. This method was used by Leu *et al.* (2) who applied eq. [1] of ref. 2 to $G(e_s^-)$, measured at times when spur decay was essentially complete, to calculate the maximum $G(e_s^-)_{nsp}$. We agree with their conclusion that the increased $G\epsilon_{max}(e_s^-)$ they observed on adding alcohol to water was caused by an increased $G(e_s^-)_{nsp}$ (which they call G_{fi}). It remains to be decided what caused the increased $G(e_s^-)_{nsp}$.

tBuOH–water

We find a maximum in $G\epsilon_{max}(e_s^-)$ versus *t*BuOH concentration at about 1 mol% *t*BuOH in D_2O at 25°C. For methanol, ethanol, and 1-propanol solutions in H_2O, the maxima are reported to occur at 2 mol% alcohol, but the few concentrations used in the 1–3 mol% range makes the maximum values of $G\epsilon_{max}(e_s^-)$ and the concentrations at which they occur somewhat uncertain. For 2-propanol/H_2O the maximum is reported to occur at 3 mol% alcohol (3). These maximum values of $G\epsilon_{max}(e_s^-)$ are greater than in the absence of alcohol by 12% for methanol, 15% for ethanol, 23% for 1-propanol, 16% for 2-propanol, and 11% for *t*BuOH/D_2O, the latter being the value at 50 ns, 25°C in Fig. 3. The general trend is for a greater maximum value the greater the value of the product k(OH + alcohol) × (concentration of alcohol at maximum $G\epsilon$). This trend implicates OH scavenging as a factor contributing to the change in $G\epsilon_{max}(e_s^-)$. Figures 2, 3, and 4 show that the ratio of the value of $G\epsilon_{max}(e_s^-)$ for 1 mol% *t*BuOH to the value for water increases with time. This is expected if OH is scavenged by *t*BuOH to produce a hydroxyalkyl radical which is less reactive towards e_s^- than is OH. We believe that this is a major reason for the increase in $G\epsilon_{max}(e_s^-)$ with added *t*BuOH (up to 1 mol% *t*BuOH).

At 6°C, 50 ns, unlike the situation at 25 and 46°C, 50 ns, the value of $G\epsilon_{max}(e_s^-)$ for 1 mol% *t*BuOH is about the same as the value in D_2O. If the greater $G(e_s^-)_{nsp}$ in 1 mol% *t*BuOH than in D_2O found at 50 ns at both 25 and 46°C were due to an increased thermalization distance in 1 mol% *t*BuOH, then the same effect should occur at 6°C but it does not. Several authors (15, 34–36) have concluded that the increased order brought about by adding small amounts of alcohol to water is a larger effect at lower temperatures. Therefore, if an increased thermalization distance were the cause of the maximum in $G\epsilon_{max}(e_s^-)$ versus *t*BuOH concentration we would expect this effect to be more pronounced at 6°C than at 25°C. This is not the case. Therefore, an increased thermalization distance is eliminated as the cause of the maxima observed. On the other hand, if the phenomenon is due to OH scavenging it should develop more rapidly at higher temperatures, just as we have observed. The fact that the rate constant k(OH + *t*BuOH) is much smaller than the diffusion controlled limit (5) makes it plausible that the activation energy for this reaction is sufficiently large to significantly slow down the OH scavenging at 6°C. The familiar maximum in $G\epsilon_{max}(e_s^-)$ versus mol% *t*BuOH, which appears only at longer times at 6°C, is attributed to an increase in the lifetime of $(e_s^-)_{nsp}$ caused by the eventual scavenging of OH by *t*BuOH.

$G(e_s^-)_{nsp}$ in alcohol–water solutions depends on the interplay of a number of factors. The dielectric constant is important in determining what fraction of electrons react with geminate ions. The fraction of electrons which react with OH in the spur will change with viscosity depending on how the diffusion coefficients change relative to the change in the reaction rate constant. Scavenging of OH radicals during and after the completion of spur reactions will change the decay rate of $(e_s^-)_{nsp}$. The concentration of alcohol at which the increase in $G\epsilon_{max}(e_s^-)$ changes to a decrease depends on these and other factors. The concentration of amides at which the maximum in $G\epsilon_{max}(e_s^-)$ occurs was suggested by Tran-Thi *et al.* (4) to depend also on the scavenging of presolvated electrons by the solute.

OH scavenging or increased thermalization distance?

The effect on $G\epsilon_{max}(e_s^-)$ of adding a few mol% *t*BuOH to D_2O is consistent with scavenging of OH by *t*BuOH to produce a hydroxyalkyl radical which is less reactive than OH towards e_s^-. The results are not consistent with the proposal of Leu, Jha, and Freeman (2) that such effects are mainly due to an increase in the thermalization distance of the electron. The strongest evidence in favour of the proposal by Leu *et al.* comes from their analysis of the measurements of Jonah, Matheson, Miller, and Hart (37) of e_s^- decay between 0.1 and 3.3 ns in water and 3 *M* EtOH. We now reexamine those results to see if an explanation other than that of Leu *et al.* is feasible.

Leu *et al.* dismissed OH scavenging as a factor for the 1.6-fold slower decay, between 0.1 and 3.3 ns, of e_s^- in 3 *M* ethanol (EtOH) than in water (37) because the factor 1.6 is so close to the 1.7-fold increase in viscosity on going from water to 3 *M* EtOH. The decay curve for e_s^- in 3 *M* EtOH superimposes the curve in water (37) if the times of the former are reduced 1.6-fold taking 0.1 ns as time zero. However, this treatment is rather insensitive to the shapes of the curves for 3 *M* EtOH and for water because both curves must coincide at the time taken as zero regardless of the reduction factor which is used to make them coincide at 3 ns. Given the rate constant of $1.3 \times 10^9\ M^{-1}\ s^{-1}$ for the reaction (OH + EtOH) in 3 *M* EtOH (the rate constant in water (5) corrected for the different viscosity of 3 *M* EtOH as indicated below), the OH radicals are half converted to the ethanol radical, ·EtOH,

$$OH + EtOH \rightarrow H_2 + \cdot EtOH$$

by about 0.18 ns, and entirely converted within a few ns. The analysis of Leu *et al.* implies that ·EtOH reacts as rapidly with e_s^- as does OH which seems unlikely because ·EtOH must have a smaller diffusion coefficient than OH. Another problem with the analysis of Leu *et al.* is that other studies indicate that the 1.7-fold increase in viscosity on going from water to 3 *M* EtOH leads to a reduction of (1.3–1.4)-fold in rate constants (38, 39). The complex dependence of e_s^- rate constants on viscosity when drastically changing the solution composition has been remarked upon (3).

We have analyzed the e_s^- decays from (0.1–3.3) ns, reported by Jonah *et al.* (37) in their Fig. 3, and conclude that they are satisfactorily explained by a combination of viscosity and scavenging effects. We assumed that $G(e_s^-)$ in both water and 3 *M* EtOH are the same at 1 ps. The decay of e_s^- in water between 1 ps and the earliest experimental point (Fig. 3, ref. 37) was determined from the solid curve in Fig. 20 of ref. 40 and the decay at longer times was taken from ref. 37. The decay of e_s^- in 3 *M* EtOH before the earliest experimental point was taken to be 1.4 times slower than in water (see preceding paragraph). The result is a higher value of $G(e_s^-)$ in 3 *M* EtOH than in water at the time of the earliest experimental point. The decay in water was superimposed on the decay in 3 *M* EtOH by multiplying the

time in water by a factor graduated from 1.4 at $\leq 10^{-10}$ s to 1.9 at 8×10^{-10} s to 2.0 at 1.2×10^{-9} s. Qualitatively, this sort of graduated factor is what one would expect if the OH radicals were being replaced by a less mobile ·EtOH radical over this time period. As described in the next paragraph, the factors seem reasonable. Hence, there appears to be no need to invoke an increased thermalization distance in 3 *M* EtOH to explain Fig. 3 of ref. 37.

The value of the rate constant of the reaction of e_s^- with ·EtOH has not been reported. A value of $8 \times 10^9\ M^{-1}\ s^{-1}$ has been reported for the reaction of e_s^- with the corresponding radical of methanol, $\cdot CH_2OH$, in methanol (32). The rate constant for the reaction of e_s^- with ·EtOH was estimated using the following assumptions; (*a*) the decay of e_s^- in 3 *M* EtOH is 2.0 times slower than in water at 1 ns, when all OH has been scavenged, (*b*) about 57% of the decay of e_s^- in the spur in water is due to reaction with OH (see footnote 2), and (*c*) all rate constants are 1.4 times smaller in 3 *M* EtOH than in water. On this basis we estimate that $k(e_s^- + \cdot EtOH) \simeq 1 \times 10^{10}\ M^{-1}\ s^{-1}$ in 3 *M* EtOH.

The chlorodienes (*E*)-4-chloro-3-methyl-1,3-hexadiene (**5***a*), (*E*)- and (*Z*)-4-chloro-2,3-dimethyl-1,3-hexadiene (**5***b*/**6***b*), (*E*,*E*)-5-chloro-4-methyl-2,4-heptadiene (**5***c*), (4*E*)- and (4*Z*)-5-chloro-3,4-dimethyl-2,4-heptadiene (**5***d*/**6***d*), chloroprene (**11***a*), and 2-chloro-3-methyl-1,3-butadiene (**11***b*) are selectively ozonized at the non-chlorinated double bonds to give the corresponding monoozonides **7**, **8**, and **12**. Further ozonolyses of the monoozonides of **5***b* and of **11***b* in methanol as well as epoxidation of the monoozonide of **5***b* and subsequent reaction of the resulting chloroepoxide with $AgBF_4$ are described.

KARL GRIESBAUM, ASHIS R. BANDYOPADHYAY et MARTIN MEISTER. Can. J. Chem. **64**, 1553 (1986).

Les chlorodiènes chloro-4 méthyl-3 hexadiène-1,3(*E*) (**5***a*), chloro-4 diméthyl-2,3 hexadiène-1,3(*E*) et (*Z*) (**5***b*/**6***b*), chloro-5 méthyl-4 heptadiène-2(*E*),4(*E*) (**5***c*), chloro-5 diméthyl-3,4 heptadiène-2,4(*E*) et -4(*Z*) (**5***d*/**6***d*), chloroprène (**11***a*) et chloro-2 méthyl-3 butadiène-1,3 (**11***b*) subissent des réactions sélectives d'ozonolyse au niveau des doubles liaisons qui ne sont pas chlorées pour conduire aux monoozonides correspondants **7**, **8** et **12**. On décrit aussi des ozonolyses subséquentes des monoozonides de **5***b* et de **11***b* qui ont été effectuées dans le méthanol ainsi que la réaction d'époxydation du monoozonide de **5***b* suivie d'une réaction subséquente avec du $AgBF_4$.

[Traduit par la revue]

Introduction

In recent years we prepared the α,β-unsaturated ozonides **1***a* (1), **1***b*–**1***f* (2), and **1***g* (3) by monoozonolyses of the corresponding conjugated dienes. The stability of these ozonides varied considerably, depending on the nature of the substituents R^1 and R^2. In an attempt at assessing the influence of chlorine substituents upon the formation and stability of α,β-unsaturated ozonides, we have now ozonided substrates **5***a*–**5***d*, **6***b*, and **6***d*, bearing the chlorine substituent in a terminal position of the conjugated diene system, as well as substrates **11***a* and **11***b* having 2-chloro-substituted conjugated diene systems.

Results and discussion

The hitherto unknown chlorodienes of structures **5** and **6** have been prepared by aldol condensations of 3-pentanone (**2**) with appropriately substituted components of structure **3**, followed by sequential reactions of the respective condensation products (**4**) with phosphorus pentachloride and potassium *tert*-butoxide. The configurations at the chlorinated double bonds of **5** and **6** have been assigned based on the experience (4) that the signal of the CH_3 group appears at lower field if the chlorine and the CH_3 substituents have a *cis* arrangement. The non-chlorinated double bond of **5***c* has been assigned an *E* configuration based on the large coupling constant (15.0 Hz) of the vinylic protons; the configurations of the non-chlorinated double bonds of **5***d* and **6***d* have not been determined. In a variation of a published procedure (5), diene **11***b* has been obtained from addition of HCl to 2-methyl-1-butene-3-yne.

Treatment of the dienes **5***a*–**5***d*, **6***b*, and **6***d* with ca. 0.8 molar equivalents of ozone in pentane at −78°C led to predominant attack at the non-chlorinated double bonds of the diene systems to yield mixtures of the corresponding monoozonide **7** or **8** and the corresponding carbonyl fragment **9** or **10**, respectively, whereas no ozonides derived from the chloro-substituted double bonds could be detected. Ozonides **7***a*, **7***b*, **7***c*, **7***d*, **8***b*, and **8***d* have been isolated in yields of 82, 30, 41, 40, 7, and 11%, respectively, based on the deficient amount of ozone applied. They are colorless liquids of considerable thermal stability, as evidenced by the fact that they gave rise to sharp peaks in gas chromatography (gc) and to molecular ions in gc–ms (mass spectral) analyses. Ozonides **7***c*, **7***d*, and **8***d* consisted of mixtures of the corresponding *cis*–*trans* isomers with respect to the positions of the substituents at the ozonide rings. In the case of **7***c*, the mixture has been separated and the isomers have been stereochemically assigned based on the assumption that the isomer having the longer gc retention time has *cis* configuration, as has been observed for other pairs of isomeric ozonides (6). Reductions with triphenyl phosphine gave **9***a* from **7***a* and **7***c*, **9***b* from **7***b* and **7***d*, and **10***b* from **8***b* and **8***d*.

Ozonolyses of dienes **11***a* and **11***b* under the aforementioned conditions resulted also in predominant attack at the non-chlorinated double bonds to give mixtures of the corresponding monoozonides (**12**) and carbonyl fragments (**13**); ozonides derived from the chloro-substituted double bonds again could not be detected. The liquid ozonides **12***a* and **12***b* have been isolated in 51 and 31%, respectively. It is known from other experiments[2] that the primary ozonide of **11***b* forms ca. 80% of **13***b*. Since ketone fragments usually do not undergo cycloadditions with carbonyl oxides to give ozonides (7), one would have expected a maximum yield of ca. 20% for ozonide **12***b*. The actual yield of 31% for **12***b* suggests, therefore, that at least part of the ozonide has been indeed formed by cycloaddition of **13***b* with the carbonyl oxide of formaldehyde. This leads to the conclusion that the α-chloro substituent activates the carbonyl group of **13***b*.

The α-chloro-substituted ozonides **12***a* and **12***b* are less stable than the β-chloro-substituted ozonides of structures **7**

and **8**, as evidenced by spontaneous decompositions during gc analyses and upon shock treatment. Treatment of the ozonides with dimethyl sulfide (DMS) gave a mixture of **13***a* and **14** starting from **12***a*, and **13***b* starting from **12***b*. The formation of **14** is rationalized by attack of the co-product DMSO (dimethylsulfoxide) at the allylic hydrogen of **12***a* and subsequent cleavage of the ozonide **12***a* in the same manner as had been experienced previously with other ozonides (2).

It appeared interesting to test the ozonolysis of representative examples of α- and β-chloro-substituted α,β-unsaturated ozonides, such as **7***b* and **12***b*, in methanol. For, based on previous experience with the direction of ozone cleavage of monochloro-substituted double bonds (8), such reactions should lead to **16** and **20**, respectively, as primary, and to **17** and **21**, respectively, as secondary products. To our knowledge, compounds of types **17** and **20** are unknown and though ozonides of type **21** are known, they have never been obtained via the corresponding acyl chloride precursors of type **20**.

Treatment of **7***b* with ozone in methanol/$CDCl_3$ at −78°C and subsequent warming of the mixture gave fragments **18** and **19** in a molar ratio of ca. 1:2, along with methyl formate and dimethoxymethane. Proton nmr analysis provided no evidence for the formation of **17** and showed, in fact, that the ozonide ring was no longer existent, as evidenced by the absence of the signals for the protons of the CH_2 group of the ozonide ring. It is concluded, therefore, that either **17** or its precursor **16** decomposes, possibly catalyzed by hydrogen chloride, to give two equivalents of **19** and products derived from the CH_2 moiety. Concurrently, **15** is solvolyzed by methanol to give **18**.

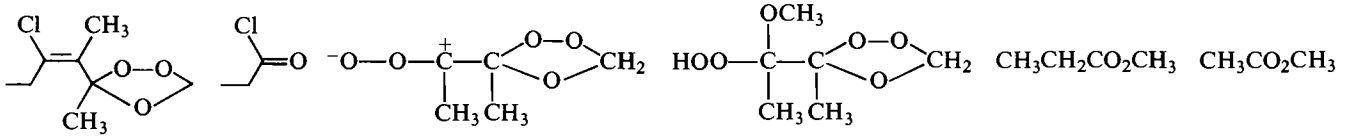
Ozonolysis of ozonide **12***b* in CH_3OD at −78°C afforded a mixture of **21** and **22** in nearly equimolar amounts, from which ozonide **21** has been isolated in 31% yield. Its structure was established by independent preparation via ozonolysis of methyl methacrylate (**23***a*) and by reduction with DMS to give **23***b*.

Recently, we had shown that α,β-unsaturated ozonides can be readily converted into the corresponding epoxides by treatment with peracid (1). It appeared, therefore, interesting to examine the epoxidation of representative examples of the chlorinated α,β-unsaturated ozonides obtained in the present study. Treatment of ozonide **7***b* with *m*-chloroperbenzoic acid yielded two stereoisomeric epoxyozonides of structure **24** and the α-chloro-β-ketoozonide **25**, the latter probably by post isomerization of **24**. The stereochemical identity of the epoxyozonides (**24**) has not been elucidated; they have been arbitrarily denoted as **24***A* and **24***B*. Reductions with triphenyl phosphine gave **26** from **24***A* and **24***B*, and **27** from **25**.

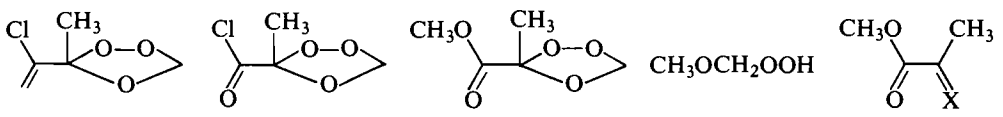
Epoxyozonide **24***A* gave a spontaneous reaction with $AgBF_4$ to yield the α,β-unsaturated ozonide **30** and two isomeric α-fluoro-β-ketoozonides, **31***A* and **31***B*, of unassigned stereochemistry. On the basis of previous results with substituted 2-chlorooxiranes (9), these products can be rationalized by dechlorination of **24** with silver ions, followed by ring opening of the ensuing carbenium ion **28** to give carbenium ion **29**. The latter, in turn, may undergo deprotonation to give **30** or reaction with the BF_4 anion to give **31**.

Treatment of ozonides **12***a* and **12***b* with *m*-chloroperbenzoic acid failed to yield the corresponding epoxyozonides and hence their reactions with $AgBF_4$ could not be examined.

The following conclusions are drawn from the foregoing results: (*1*) Both 1-chloro- and 2-chloro-substituted conjugated dienes can be converted into monoozonides by selective ozone attack at the respective non-chlorinated double bonds. However, monoozonides of 2-chloro-substituted dienes appear to be less stable than those of 1-chloro-substituted dienes. (*2*) Carbonyl oxides that are attached to an ozonide ring as in **16** could not be trapped with methanol to give stable α-hydroperoxyozonides of type **17**. Instead, the reaction led to abnormal products, resulting from cleavage of the carbon single bond that

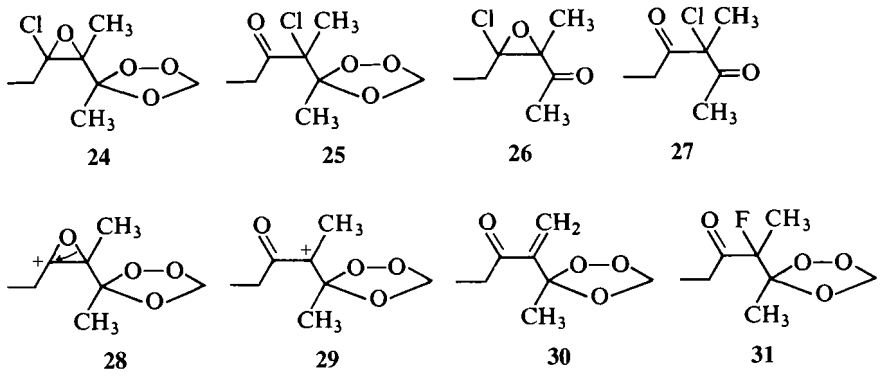


7*b* **15** **16** **17** **18** **19**



12*b* **20** **21** **22** **23**

a: X = CH_2; *b*: X = O



links the carbonyl oxide moiety with the ozonide moiety. This is reminiscent of the behavior of α-oxo-carbonyl oxides, which also preferentially evade trapping by methanol and lead to abnormal products via cleavage of the carbon single bond that links the oxo and the carbonyl oxide moiety (10). (*3*) α-Chlorooxo-ozonides like **20** can be trapped by methanol to give α-methyl carboxylated ozonides. This is noteworthy, for in view of the notorious instability of α-ketoozonides one would have expected that the electron-withdrawing effect of chlorine renders α-chlorooxo-ozonides even less stable. The fact that **20** could be trapped by methanol at low temperature does not exclude, however, that it is unstable at elevated temperatures. In fact, we suspect that it was the corresponding α-chlorooxo-ozonide that caused a violent explosion of the crude product from the diozonolysis of **11***a* in pentane after it had reached room temperature.

Materials and methods

Materials

Chemicals, solvents, and technical gases were of commercial grades.

Analytical methods

The ^{1}H nmr and ^{13}C nmr spectra were routinely recorded on Bruker instrument WP 60, and in special cases on Bruker instruments WH 250 and WM 300; ir spectra were recorded on a Beckman IR 4260 spectrometer and mass spectra on a Hewlett Packard instrument 5985 B. The gc analyses were carried out on a Shimadzu GC/6A and on a Varian 1400 instrument, using a temperature program of 60–160°C at 4°C/min and glass columns with the following sizes and packings: (A) 0.3 × 300 cm, 5% Carbowax 20 M on Chromosorb G; (B) 0.3 × 500 cm, 5% Carbowax 20 M on Chromosorb G; (C) 0.3 × 300 cm, 5% Nitrilesiliconoil XE 60 on Chromosorb G; (D) 0.3 × 50 cm, 5% Nitrilesiliconoil XE 60 on Chromosorb G. Temperature of injection port 200°C for conditions A, B, C and 70°C for condition D.

Preparation of **5**a

To a suspension of 639 g (3.07 mol) of phosphorus pentachloride and 3 L of ether, a solution of 229.2 g (2.05 mol) of 4-methyl-4-hexene-3-one (**4***a*) (11) in 1 L of ether was added dropwise at room temperature with vigorous stirring. Then the mixture was refluxed with stirring for 24 h, cooled to room temperature, and 1 L of an aqueous solution of 10% sodium carbonate was added dropwise. The organic phase was separated, the aqueous phase was extracted with ether, and the extracts were combined with the organic phase. The combined ether solutions were washed with aqueous sodium bicarbonate and dried over sodium sulfate. After removal of the ether in a rotary evaporator, there remained 284.5 g of a light brown liquid. A mixture of 76.0 g (0.68 mol) of potassium *tert*-butoxide in 200 mL of dry *tert*-butanol and 55.7 g of the above liquid was refluxed with stirring for 24 h. Then 200 mL of water was added at room temperature and the mixture was extracted twice with 500 mL, each time, of *n*-pentane. The combined extracts were washed twice with 500 mL of water and dried over sodium sulfate. After removal of *n*-pentane in a rotary evaporator there remained 19.0 g of a brown liquid. The latter was divided into two equal parts, which were separately processed by flash chromatography (12) (column 5 × 46 cm; 390 g of silica gel; *n*-pentane) to give a total of 7.4 g of **5***a* of approximately 86% purity. The latter product was again submitted to flash chromatography under the same conditions to give 3.2 g of **5***a* of 97% purity according to gc analysis (condition C).

*(E)-4-Chloro-3-methyl-1,3-hexadiene (***5**a*):* colorless liquid; ir (film): 1625 cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$, TMS), δ: 1.14 (t, J = 7.5 Hz, 3H), 1.95 (t, J = 0.8 Hz, 3H), 2.57 (q, J = 7.5 Hz, 2H), ABX system with δ_A 5.12 (1H), δ_B 5.25 (1H), δ_X 6.68 (1H), J_{AB} = 1.4 Hz, J_{AX} = 11.0 Hz, J_{BX} = 17.0 Hz; ms, *m/e* (relative intensity): 132, 130 (25, 75) M^+, 117, 115 (12, 38) $(M - CH_3)^+$, 95 (100) $(M - Cl)^+$; gc t_R (condition C) 8.3 min. The neat substance discolored at room temperature, therefore no elemental analysis was attempted. The stereochemical assignment of **5***a* is based on the fact that mono-ozonolysis followed by reduction gave **9***a*.

Preparation of **5**c was by the same procedure as described for the preparation of **5***a*: Reaction of 320.0 g (1.54 mol) of phosphorus pentachloride in 1 L of ether and 129.1 g (1.0 mol) of 4-methyl-4-heptene-3-one (**4***c*) (11) in 1 L of ether yielded 173.0 g of a light brown liquid. Reaction of 25.2 g (0.225 mol) of potassium *tert*-butoxide in 200 mL of *tert*-butanol and 27.0 g of the above brown liquid gave 16.3 g of crude **5***c*. This was divided into two equal parts, which were separately processed by flash chromatography as described for **5***a* to give a total of 6.2 g of a colorless liquid. From the latter, pure **5***c* was isolated by flash chromatography under the same conditions as above.

*(E,E)-5-Chloro-4-methyl-2,4-heptadiene (***5**c*):* colorless liquid; ir (film): 1605 cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.10 (t, J = 7.3 Hz, 3H), 1.92 (s, 3H), 2.52 (q, J = 7.3 Hz, 2H), ABX_3 system with δ_A 6.32 (1H), δ_B 5.63 (1H), δ_X 1.75 (3H), J_{AB} = 15.0 Hz, J_{BX} = 1.2 Hz, J_{AX} = 6.3 Hz; ms, *m/e* (relative intensity): 146, 144 (30, 88) M^+, 131, 129 (18, 52) $(M - CH_3)^+$, 109 (100) $(M - Cl)^+$; gc t_R (condition C) 13.3 min.

Preparation of **5**b *and of* **6**b

A solution of 258.0 g (3 mol) of 3-pentanone, 388.8 g (3.6 mol) of chlorotrimethylsilane, and 727.2 g (7.2 mol) of triethyl amine in 1.2 L of dimethyl formamide was refluxed with stirring for 24 h, cooled to room temperature, and extracted three times with *n*-pentane. The combined extracts were sequentially washed with 1 *N* aqueous hydrochloric acid, with a 5% aqueous solution of sodium bicarbonate and water, and subsequently dried over sodium sulfate. The *n*-pentane was distilled off through a 30-cm packed column and the residue was distilled at vacuum through the same column to give 369.6 g (78%) of 3-trimethylsiloxy-2-pentene having a bp of 76–77°C at 85 Torr (1 Torr = 133.3 Pa).

To a solution of 789.2 g (4.19 mol) of titanium tetrachloride in 250 mL of dichloromethane, 241.3 g (4.16 mol) of acetone and subsequently 671.2 g (4.25 mol) of 3-trimethylsiloxy-2-pentene were added dropwise with stirring at ca. 0°C, and the mixture was kept stirring at room temperature for 16 h. Then 1 L of a 10% aqueous solution of sodium bicarbonate was added, the organic layer was separated, the aqueous layer was extracted with dichloromethane, the extracts were combined with the organic layer, and dichloromethane

was removed in a rotary evaporator at room temperature and 15 Torr. To the liquid residue, 5 g of *p*-toluenesulfonic acid and 1 L of benzene were added and the benzene was distilled off through a 30-cm packed column. The liquid residue was added to 1 L of ether, sequentially washed with a 5% aqueous solution of sodium bicarbonate and water, dried over sodium sulfate, and filtered. From the filtrate the ether was removed at room temperature and 15 Torr and the residue was distilled through a 30-cm packed column. The fraction distilling at 67–73°C (30–23 Torr) comprised 263 g and contained 78% of 4,5-dimethyl-4-hexene-3-one (**4***b*); ^{1}H nmr ($CDCl_3$, TMS), δ: 1.08 (t, J = 7.5 Hz, 3H), 1.75 (s, 3H), 1.81 (s, 6H), 2.53 (q, 2H).

To a suspension of 416.0 g (2.0 mol) of phosphorus pentachloride in 1.8 L of ether, a solution of 126.0 g (1.0 mol) of the above crude **4***b* in 1 L of ether was added dropwise at room temperature with vigorous stirring, and the reaction product was worked up in the manner described above for the preparation of **5***a*. After removal of pentane there remained 118.6 g of a brown liquid, which was distilled through a 30-cm packed column to afford 69.4 g of a distillate with a bp of 83–87°C (110 Torr). Distillation of the latter through a 1-m spinning band column afforded 19.7 g of a fraction with a bp of 89°C (110 Torr) containing 88% of **5***b* and 10% of **6***b* as shown by gc analysis. From this distillate samples of pure **5***b* and **6***b* have been isolated by pgc (preparative gas chromatography) (glass column, 0.7 × 300 cm, 5% Carbowax 20 M on Chromosorb G; 60–160°C at 3°C/min).

*(E)-4-Chloro-2,3-dimethyl-1,3-hexadiene (**5**b)*: colorless liquid; ir (film): 1640 cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.21 (t, J = 7.2 Hz, 3H), 1.83 (m) and 1.90 (s, partly overlapping signals of 6H altogether), 2.45 (q, J = 7.2 Hz, 2H), 4.78 (m, 1H), 4.97 (m, 1H); ms, *m/e* (relative intensity): 146, 144 (26, 100) M^+, 131, 129 (7, 16) $(M - CH_3)^+$, 109 (90) $(M - Cl)^+$; gc t_R (condition A) 5.7 min. *Anal.* calcd. for $C_8H_{13}Cl$ (144.7): C 66.43, H 9.06, Cl 24.51; found: C 66.53, H 8.91, Cl 24.33.

*(Z)-4-Chloro-2,3-dimethyl-1,3-hexadiene (**6**b)*: colorless liquid; ir (film): 1640 cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.12 (t, J = 7.3 Hz, 3H), 1.80 (s) and 1.83 (m, overlapping signals of 6H altogether), 2.41 (q, J = 7.3 Hz, 2H), 4.83 (m, 1H), 5.05 (m, 1H); ms, *m/e* (relative intensity): 146, 144 (33, 100) M^+, 131, 129 (8, 25) $(M - CH_3)^+$, 109 (38) $(M - Cl)^+$; gc t_R (condition A) 6.3 min. *Anal.* calcd. for $C_8H_{13}Cl$ (144.7): C 66.43, H 9.06, Cl 24.51; found: C 66.25, H 8.82, Cl 24.40.

Preparation of **5**d *and* **6**d was by the same procedure as described above for the preparation of **5***b* and **6***b*: Reaction of 361.3 g (1.91 mol) of titanium tetrachloride in 1.4 L of dichloromethane with 137.4 g (1.91 mol) of 2-butanone and 301.0 g (1.91 mol) of 3-trimethylsiloxy-2-pentene gave 102.0 g of a colorless distillate, bp 94–99°C (50 Torr). Reaction of 302.8 g (1.46 mol) of phosphorus pentachloride in 1.5 L of ether with 102.0 g of the above distillate and subsequent distillation of the crude product through a 30-cm packed column gave 47.0 g of a slightly brown liquid, bp 83–87°C (42 Torr). Reaction of 2.77 g (24.7 mmol) of potassium *tert*-butoxide in 30 mL of *tert*-butanol with 3.9 g of the above liquid gave 2.03 g of crude product, from which 0.66 g of **5***d* and 0.43 g of **6***d* were isolated by flash chromatography (column 5 × 45 cm, 166 g of silica gel; *n*-pentane).

*(4E)-5-Chloro-3,4-dimethyl-2,4-heptadiene (**5**d)*: colorless liquid; ir ($CDCl_3$): 1640 cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$, TMS), δ: 1.07 (t, J = 7.3 Hz, 3H), 1.84 (t, J = 0.9 Hz, 3H), 2.36 (qq, J = 7.3 and 0.9 Hz, 2H), A_3B_3X system with δ_A 1.62 (3H), δ_B 1.68 (3H), δ_X 5.23 (1H), J_{AB} = 1.1 Hz, J_{AX} = 6.7 Hz, J_{BX} = 1.5 Hz; ^{13}C nmr ($CDCl_3$, TMS, broad band decoupled), δ: 13.37, 13.45, 15.30, 19.55, 29.41, 121.73, 132.17, 135.81, 136.44; ms, *m/e* (relative intensity): 160, 158 (9, 23) M^+, 123 (18) $(M - Cl)^+$; gc t_R (condition B) 15.2 min. *Anal.* calcd. for $C_9H_{15}Cl$ (158.7): C 68.12, H 9.53, Cl 22.34; found: C 68.18, H 9.37, Cl 22.24.

*(4Z)-5-Chloro-3,4-dimethyl-2,4-heptadiene (**6**d)*: colorless liquid; ir ($CDCl_3$): 1635 cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$, TMS), δ: 1.11 (t, J = 7.3 Hz, 3H), 1.78 (t, J = 0.6 Hz, 3H), 2.38 (qq, J = 7.3 and 0.6 Hz, 2H), A_3B_3X system with δ_A 1.64 (3H), δ_B 1.70 (3H), δ_X 5.25 (1H), J_{AB} = 1.1 Hz, J_{AX} = 6.8 Hz, J_{BX} = 1.5 Hz; ^{13}C nmr ($CDCl_3$, TMS, broad band decoupled), δ: 12.51, 13.36, 14.71, 19.15, 28.94, 121.69, 129.20, 134.94, 137.46; ms, *m/e* (relative intensity): 160, 158 (9, 18) M^+, 123 (16) $(M - Cl)^+$; gc t_R (condition B) 16.2 min. *Anal.* calcd. for $C_9H_{19}Cl$ (158.7): C 68.12, H 9.53, Cl 22.34; found: C 68.01, H 9.32, Cl 22.43.

*Chloroprene (**11**a)* was available as a 50% solution in toluene. It was isolated by distillation through a 80-cm packed column at 200 Torr into a receiver cooled to −20°C and then stored at −20°C in the presence of added hydroquinone. Before each ozonolysis reaction, an adequate amount was redistilled through a 20-cm packed column under the above conditions; gc t_R (condition B) 5.3 min; 99% purity.

*Preparation of 2-chloro-3-methyl-1,3-butadiene (**11**b)*

A mixture of 30.0 g copper-I chloride, 12.0 g ammonium chloride, and 56.0 g (0.84 mol) 2-methyl-1-butene-3-yne (13) in 210 mL of concentrated hydrochloric acid was shaken for 4 h at room temperature in a 400-mL sealed glass ampoule. The dark product was submitted to steam distillation, the aqueous phase of the distillate was neutralized with potassium carbonate, extracted with dichloromethane, and the extracts combined with the organic phase of the distillate, dried over potassium carbonate, and distilled through a 30-cm packed column in the presence of hydroquinone. The fraction boiling at 47–49°C (158 Torr) was redistilled through a 1-m spinning band column at 158 Torr to give pure **11***b*. It was stored at −20°C in the presence of hydroquinone and redistilled at 158 Torr through a 20-cm packed column immediately before its use.

*2-Chloro-3-methyl-1,3-butadiene (**11**b)*: colorless liquid; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.98 (m, 3H), 5.17 (m, 1H), 5.43 (s, 2H), 5.59 (m, 1H).

General procedure for the ozonolysis reactions

Solutions of the substrates in *n*-pentane were ozonized at −78°C. The product mixtures were warmed up to room temperature, the solvent was removed in a rotary evaporator at 15 Torr and room temperature, and the peroxidic liquid residues were separated by flash chromatography (pentane:ether 30:1, column 4 × 46 cm, 270 g of silica gel for the isolation of **7***b* and **8***b*; column 2 × 65 cm, 110 g of silica gel for the isolation of the remaining ozonides).

Ozonolysis of **5**a

A solution of 0.65 g (5 mmol) of **5***a* in 10 mL of pentane was treated with 3.8 mmol of ozone to give 0.86 g of liquid residue, from which 0.58 g (82%) of **7***a* and 0.01 g (2%) of **9***a* were isolated.

*3-[(E)-2-Chloro-1-methyl-1-butenyl]-1,2,4-trioxolane (**7**a)*: colorless liquid; ir (film): 1645 cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.16 (t, J = 7.3 Hz, 3H), 1.83 (s, 3H), 2.52 (q, J = 7.3 Hz, 2H), 5.12 (s, 1H), 5.35 (s, 1H), 5.84 (s, 1H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 13.36 (q, J = 128.8 Hz), 13.66 (q, J = 129.2 Hz), 28.85 (t, J = 127.3 Hz), 95.08 (dd, J = 173.8 and 166.4 Hz), 100.21 (d, J = 178.6 Hz), 123.70 (s), 143.32 (s); ms, *m/e* (relative intensity): 180, 178 (2, 7) M^+, 150, 148 (6, 19) $(M - CH_2O)^+$, 134, 132 (34, 100) $(M - CH_2O_2)^+$; gc t_R (condition D) 10.5 min. *Anal.* calcd. for $C_7H_{11}ClO_3$ (178.6): C 47.07, H 6.20, Cl 19.85; found: C 46.94, H 6.20, Cl 19.76.

*(E)-3-Chloro-2-methyl-2-pentenal (**9**a)*: colorless liquid; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.29 (t, J = 7.2 Hz, 3H), 1.91 (s, 3H), 2.92 (q, J = 7.3 Hz, 2H), 10.03 (s, 1H); ms, *m/e* (relative intensity): 134, 132 (34, 100) M^+, 119, 117 (3, 13) $(M - CH_3)^+$, 97 (31) $(M - Cl)^+$; gc t_R (condition B) 15.4 min.

Ozonolysis of a mixture of **5**b *and* **6**b

A solution of 2.88 g (20 mmol) of **5***b* and **6***b* in a ratio of 9:1 in 30 mL of pentane was treated with 16 mmol of ozone to give 2.72 g of liquid residue, from which 930 mg (30%) of **7***b*, 210 mg (7%) of **8***b*, 265 mg (11%) of **9***b*, and 75 mg (3%) of **10***b* have been isolated.

*3-[(E)-2-Chloro-1-methyl-1-butenyl]-3-methyl-1,2,4-trioxolane (**7**b)*: colorless liquid; ir (film): 1645 cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$, TMS) ABM_3X_3 system with δ_A 2.44 (1H), δ_B 2.73 (1H), δ_M 1.88 (3H), δ_X 1.15 (3H), J_{AB} = 13.0 Hz, J_{AM} = 0.8 Hz, J_{AX} = J_{BX} = 7.3 Hz, δ: 1.59 (s, 3H), 5.07 (s, 1H), 5.16 (s, 1H); ^{13}C nmr ($CDCl_3$, TMS), δ: 12.99 (q, J = 129.4 Hz), 17.04 (q, J = 126.7 Hz), 22.46 (q, J = 127.6 Hz), 30.4 (t, J = 125.3 Hz), 94.1 (dd, J = 149.1 and

167.0 Hz), 109.31 (s), 137.00 (s), 137.55 (s); ms, *m/e* (relative intensity): 194, 192 (15, 41) M^+, 148, 146 (68, 85) $(M - CH_2O_2)^+$, 133, 131 (30, 82) $(M - C_2H_5O_2)^+$, 67 (77) $(C_5H_7)^+$, 43 (100) $(CH_3CO)^+$; gc t_R (condition D) 9.2 min. *Anal.* calcd. for $C_8H_{13}ClO_3$ (192.6): C 49.88, H 6.80, Cl 18.41; found: C 49.92, H 6.79, Cl 18.54.

*3-[(Z)-2-Chloro-1-methyl-1-butenyl]-3-methyl-1,2,4-trioxolane (**8**b)*: colorless liquid; ir ($CDCl_3$): 1640 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$, TMS) $A_2M_3X_3$ system with δ_A 2.42 (2H), δ_M 1.80 (3H), δ_X 1.12 (3H), $J_{AM} = 0.6$ Hz, $J_{AX} = 7.4$ Hz, $J_{MX} = 0$ Hz, δ: 1.69 (s, 3H), 5.06 (s, 1H), 5.18 (s, 1H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 12.23 (q, $J = 129.6$ Hz), 15.34 (q, $J = 129.6$ Hz), 20.55 (q, $J = 129.6$ Hz), 30.78 (t, $J = 129.6$ Hz), 93.76 (dd, $J = 166.8$ and 171.6 Hz), 108.94 (s), 131.35 (s), 132.83 (s); ms, *m/e* (relative intensity): 194, 192 (10, 29) M^+, 148, 146 (48, 78) $(M - CH_2O_2)^+$, 133, 131 (29, 72) $(M - C_2H_5O_2)^+$, 67 (78) $(C_5H_7)^+$, 43 (100) $(CH_3CO)^+$; gc t_R (condition D) 10.8 min. *Anal.* calcd. for $C_8H_{13}ClO_3$ (192.6): C 49.88, H 6.80, Cl 18.41; found: C 50.05, H 6.83, Cl 18.31.

*(E)-4-Chloro-3-methyl-3-hexene-2-one (**9**b)*: colorless liquid; ir (film): 1690, 1600 cm^{-1}; ^1H nmr ($CDCl_3$, TMS), δ: 1.16 (t, $J = 6.9$ Hz, 3H), 2.03 (t, $J = 0.9$ Hz, 3H), 2.28 (s, 3H), 2.53 (q, $J = 6.9$ Hz, 2H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 12.99 (q, $J = 128.2$ Hz), 17.41 (q, $J = 129.2$ Hz), 29.76 (q, $J = 128.2$ Hz), 30.65 (t, $J = 128.2$ Hz), 132.85 (s), 145.09 (s), 201.27 (s); ms, *m/e* (relative intensity): 148, 146 (19, 61) M^+, 133, 131 (18, 49) $(M - CH_3)^+$, 67 (51) $(C_5H_7)^+$, 43 (100) $(CH_3CO)^+$; gc t_R (condition C) 15.6 min. *Anal.* calcd. for $C_7H_{11}ClO$ (146.6): C 57.34, H 7.56, Cl 24.18; found: C 57.43, H 7.57, Cl 24.12.

*(Z)-4-Chloro-3-methyl-3-hexene-2-one (**10**b)*: colorless liquid; ir (film): 1700 cm^{-1}; ^1H nmr ($CDCl_3$, TMS), δ: 1.16 (t, $J = 7.3$ Hz, 3H), 1.86 (s, 3H), 2.39 (s, 3H), 2.45 (q, $J = 7.3$ Hz, 2H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 11.84 (q, $J = 127.9$ Hz), 15.82 (q, $J = 128.9$ Hz), 29.19 (t, $J = 128.9$ Hz), 29.87 (q, $J = 127.9$ Hz), 133.34 (s), 134.22 (s), 204.11 (s); ms, *m/e* (relative intensity): 148, 146 (33, 100) M^+, 133, 131 (31, 95) $(M - CH_3)^+$, 67 (60) $(C_5H_7)^+$, 43 (46) $(CH_3CO)^+$; gc t_R (condition C) 18.5 min. *Anal.* calcd. for $C_7H_{11}ClO$ (146.6): C 57.34, H 7.56; found: C 57.47, H 7.70.

*Ozonolysis of **5**c*

A solution of 0.72 g (5 mmol) of **5***c* in 10 mL of pentane was treated with 4 mmol of ozone to give 0.95 g of liquid residue, from which 157 mg (20%) of *cis*-**7***c*, 163 mg (21%) of *trans*-**7***c*, and 68 mg (13%) of **9***a* have been isolated.

cis-*3-[(E)-2-Chloro-1-methyl-1-butenyl]-5-methyl-1,2,4-trioxolane (*cis-**7**c)*: colorless liquid; ir (film): 1650 cm^{-1}; ^1H nmr ($CDCl_3$, TMS), δ: 1.16 (t, $J = 7.3$ Hz, 3H), 1.47 (d, $J = 5.0$ Hz, 3H), 1.85 (s, 3H), 2.52 (q, $J = 7.3$ Hz, 2H), 5.46 (q, $J = 5.0$ Hz, 1H), 5.93 (s, 1H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 13.37 (q, $J = 127.0$ Hz), 13.71 (q, $J = 132.1$ Hz), 17.84 (q, $J = 128.0$ Hz), 28.82 (t, $J = 127.0$ Hz), 100.60 (d, $J = 178.9$ Hz), 101.99 (d, $J = 172.8$ Hz), 125.16 (s), 142.20 (s); ms, *m/e* (relative intensity): 194, 192 (7, 22) M^+, 150, 148 (8, 21) $(M - CH_3CHO)^+$, 134, 132 (23, 68) $(M - CH_3CHO_2)^+$, 125 (100) $(M - ClO_2)^+$, 67 (65) $(C_5H_7)^+$; gc t_R (condition D) 12.4 min. *Anal.* calcd. for $C_8H_{13}ClO_3$ (192.6): C 49.88, H 6.80, Cl 18.41; found: C 49.74, H 6.76, Cl 18.63.

trans-*3-[(E)-2-Chloro-1-methyl-1-butenyl]-5-methyl-1,2,4-trioxolane (*trans-**7**c)*: colorless liquid; ir (film): 1640 cm^{-1}; ^1H nmr ($CDCl_3$, TMS), δ: 1.16 (t, $J = 7.3$ Hz, 3H), 1.47 (d, $J = 4.9$ Hz, 3H), 1.84 (s, 3H), 2.48 (q, $J = 7.3$ Hz, 2H), 5.39 (q, $J = 4.9$ Hz, 1H), 5.90 (s, 1H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 13.38 (q, $J = 128.8$ Hz), 13.79 (q, $J = 128.8$ Hz), 16.07 (q, $J = 128.0$ Hz), 28.85 (t, $J = 128.8$ Hz), 100.85 (d, $J = 178.6$ Hz), 102.57 (d, $J = 170.5$ Hz), 123.82 (s), 143.28 (s); ms, *m/e* (relative intensity): 194, 192 (9, 27) M^+, 150, 148 (8, 24) $(M - CH_3CHO)^+$, 134, 132 (21, 62) $(M - CH_3CHO_2)^+$, 125 (100) $(M - ClO_2)^+$, 67 (50) $(C_5H_7)^+$; gc t_R (condition D) 11.3 min.

*Ozonolysis of **5**d*

A solution of 627 mg (4 mmol) of **5***d* in 10 mL of pentane was treated with 152 mg (3.2 mmol) of ozone to give 713 mg of liquid residue, from which 264 mg (40%) of **7***d* and 96 mg (21%) of **9***b* have been isolated.

*3-[(E)-2-Chloro-1-methyl-1-butenyl]-3-methyl-1,2,4-trioxolane (**7**d)*: colorless liquid consisting of two stereoisomers of **7***d* in a ratio of ca. 3:1, as evidenced by the intensities of the $CH_3(CH)$ signals that appeared in different chemical shift positions; ir (film): 1640 cm^{-1}; ^1H nmr ($CDCl_3$, TMS), major isomer, δ: 1.14 (t, $J = 7.3$ Hz), 1.42 (d, $J = 4.9$ Hz), 1.57 (s), 1.88 (s), 2.55 (q, $J = 7.3$ Hz), 5.31 (q, $J = 4.9$ Hz); minor isomer, δ: 1.14 (t, $J = 7.3$ Hz), 1.38 (d, $J = 4.9$ Hz), 1.55 (s), 1.88 (s), 2.55 (q, $J = 7.3$ Hz), 5.31 (q, $J = 4.9$ Hz); ms, *m/e* (relative intensity): 208, 206 (13, 39) M^+, 193, 191 (4, 13) $(M - CH_3)^+$, 148, 146 (16, 31) $(M - CH_3CHO_2)^+$, 139 (94) $(M - ClO_2)^+$, 127 (50) $(M - CH_3CHOCl)^+$, 111 (30) $(M - CH_3CHOOCl)^+$, 67 (69) $(C_5H_7)^+$, 43 (100) $(CH_3CO)^+$; gc t_R (condition D) 10.3 min. *Anal.* calcd. for $C_9H_{15}ClO_3$ (206.7): C 52.30, H 7.31, Cl 17.16; found: C 52.31, H 7.24, Cl 17.00.

*Ozonolysis of **6**d*

A solution of 427 mg (2.7 mmol) of **6***d* in 10 mL of pentane was treated with 100 mg (2.1 mmol) of ozone to give 408 mg of liquid residue, from which 48 mg (11%) of **8***d* and 190 mg (60%) of **10***b* have been isolated.

*3-[(Z)-2-Chloro-1-methyl-1-butenyl]-3-methyl-1,2,4-trioxolane (**8**d)*: colorless liquid consisting of two stereoisomers of **8***d* in a ratio of 5:1 based on the intensities of the $CH_3(CH)$ signals that appeared in different chemical shift positions; ir (film): 1640 cm^{-1}; ^1H nmr ($CDCl_3$, TMS), major isomer, δ: 1.11 (t, $J = 7.4$ Hz), 1.42 (d, $J = 4.9$ Hz), 1.68 (s), 1.80 (s), 2.38 (q, $J = 7.4$ Hz), 5.32 (q, $J = 4.9$ Hz); minor isomer, δ: 1.11 (t, $J = 7.4$ Hz), 1.36 (d, $J = 4.9$ Hz), 1.65 (s), 1.80 (s), 2.38 (q, $J = 7.4$ Hz), 5.32 (q, $J = 4.9$ Hz).

*Reductions of ozonides **7**a–**7**d and **8**d*

A solution of the respective ozonide in $CDCl_3$ was admixed with 40 mg of triphenylphosphine in an nmr tube and the tube was repeatedly shaken; ^1H nmr and gc analyses showed the formation of **9***a* from **7***a* and **7***c*, of **9***b* from **7***b* and **7***d*, and of **10***b* from **8***b* and **8***d*.

*Ozonolysis of **11**a*[3]

A solution of 2.445 g (27.6 mmol) of **11***a* in 33 mL of *n*-pentane was treated with 21.4 mmol of ozone at −78°C. Then 1 mL of methanol, 1 g of sodium bicarbonate, and 1 g of sodium sulfate were added, the mixture was kept stirring at −10°C until it became neutral, then was filtered and the solids washed with dichloromethane. The filtrate was distilled at room temperature and 0.2 Torr into a series of three traps kept at 0°C, −25°C, and −78°C. The fraction collected at −78°C (20 mL) contained pentane and dichloromethane, along with trace amounts of **13***a*. The fraction collected at −25°C (0.2 g) contained **12***a* and **13***a* in a ratio of 93:7. The fraction collected at 0°C consisted of 1.40 g (51%) of ozonide **12***a*, according to ^1H nmr analysis. For analytical purposes a sample of it was further purified by preparative thick layer chromatography (20 × 20 cm silica gel plate, trichloromethane:hexane 1:1) and subsequently distilled at room temperature and 0.1 Torr.

*3-(1-Chloroethenyl)-1,2,4-trioxolane (**12**a)*: colorless, shock sensitive liquid; ir (film): 1638 (C=C) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$, TMS), δ: 5.19 (s, 1H), 5.32 (s, 1H), 5.62 (m, 1H), 5.63 (d, $J = 1.9$ Hz, 1H), 5.79 (dd, $J = 1.9$ and 0.7 Hz, 1H); ^{13}C nmr ($CDCl_3$, TMS), δ: 94.64 (td, $J = 171$ and ca. 2 Hz), 100.45 (dm, $J = 176$ Hz), 118.49 (dd, $J = 164$ and 163 Hz), 134.58 (m); ms, *m/e* (relative intensity): 138, 136 (7, 22) M^+, 106, 104 (24, 47) $(M - O_2)^+$, 75 (44) $(M - C_2H_2Cl)^+$, 63, 61 (44, 100) $(C_2H_2Cl)^+$. *Anal.* calcd. for $C_4H_5ClO_3$ (136.5): C 35.19, H 3.69, Cl 25.97; found: C 35.27, H 3.62, Cl 25.88.

*2-Chloropropenal (**13**a)* has been identified by gc and ^1H nmr analysis with the help of an authentic sample, which was obtained by

[3] **Caution!** Application of more than one equivalent of ozone in pentane should be avoided, since treatment of chloroprene (**11***a*) with excess ozone in pentane at −78°C and subsequent warm-up of the mixture led to a violent explosion soon after the product had reached room temperature.

the following procedure: A mixture of 84.0 g (1.5 mol) of propenal and 200 mL of water was saturated with chlorine at ca. 0°C, a trace of *tert*-butyl-1,2-dihydroxybenzene was added, and the product was submitted to steam distillation. The organic phase of the distillate was dried over sodium sulfate, filtered, and distilled through a 20-cm packed column; bp 46°C (40 Torr); ^{1}H nmr ($CDCl_3$, TMS) AB-system with δ_A 6.44 (1H), δ_B 6.60 (1H), J_{AB} = 2.0 Hz, δ: 9.47 (s, 1H); ms, *m/e* (relative intensity): 92, 90 (36, 100) M^+, 63, 61 (12, 33) $(M - CHO)^+$; gc t_R (condition B) 14.1 min.

Treatment of ***12***a *with DMS*

To a mixture of 307.0 mg (4.9 mmol) of dimethyl sulfide and 1.5 mL of $CDCl_3$ a solution of 219.0 mg (1.6 mmol) of ***12a*** in 1.5 mL of $CDCl_3$ was added dropwise and kept stirring for 2 h at 0°C. Then 0.11 mL of methanol was added and stirring was continued for 21 h at room temperature; ^{1}H nmr analysis showed the presence of ***13a*** and of ***14*** (δ 6.03, d and 6.56, d, J = 1.5 Hz) in a ratio of 83:17, along with DMS (δ 2.12), DMSO (δ 2.62), and methoxymethanol (δ 3.44 and 4.74, s, each) (1).

Ozonolysis of ***11***b

A solution of 1.991 g (19.4 mmol) of ***11b*** in 30 mL of pentane was treated with 15 mmol of ozone at −78°C and worked up as described in the ozonolysis of ***11a***. The filtrate was concentrated by evaporation of solvent in a rotary evaporator at room temperature and reduced pressure. From the liquid concentrate (5 mL), 710 mg (31%) of ***12b*** and 100 mg (6%) of ***13b*** were isolated by flash chromatography (column 2.2 × 160 cm, 250 g silica gel, dichloromethane). Ozonide ***12b*** was subsequently distilled at room temperature and 10^{-2} Torr.

*3-(1-Chloroethyl)-3-methyl-1,2,4-trioxolane (****12****b)*: colorless, shock sensitive liquid; ir ($CDCl_3$): 1632 (C=C) cm^-; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.71 (s, 3H), 5.11 (s, 1H), 5.34 (s, 1H), AB system with δ_A 5.45 (1H), δ_B 5.75 (1H), J_{AB} = 1.5 Hz; ^{13}C nmr ($CDCl_3$, TMS), δ: 20.14 (q, J = 130 Hz), 94.79 (dd, J = 174 and 167 Hz), 106.66 (s), 115.00 (t, J = 164 Hz), 139.37 (s); ms, *m/e* (relative intensity): 152, 150 (0.3, 0.8) M^+, 89 (16) $(M - C_2H_2Cl)^+$, 63, 61 (8, 23) $(C_2H_2Cl)^+$, 43 (100) $(CH_3CO)^+$. *Anal.* calcd. for $C_5H_7ClO_3$ (150.6): C 39.89, H 4.68, Cl 23.54; found: C 39.88, H 4.52, Cl. 23.35.

*2-Chloro-1-butene-3-one (****13****b)* has been identified by gc, ms, and ^{1}H nmr analysis with the help of an authentic sample that was obtained by the following procedure: A solution of 70.0 g (1.0 mol) of 1-butene-3-one in 150 mL of dichloromethane was saturated with chlorine at ca. 0°C, neutralized with sodium bicarbonate, dried over magnesium sulfate, filtered, and concentrated in a rotary evaporator at room temperature and 25 Torr. The liquid residue (153.0 g) was added dropwise to a stirred mixture of 130 mL (1.1 mol) of quinoline and a trace amount of *tert*-butyl-1,2-dihydroxybenzene at 115°C and 160 Torr, after which the resulting ***13b*** was distilled off through a 15-cm packed column. The distillate (35 g) was immediately redistilled through a 20-cm packed column in the presence of trace amounts of *tert*-butyl-1,2-dihydroxybenzene to give 10.5 g (10%) of ***13b*** as a colorless liquid; ^{1}H nmr ($CDCl_3$, TMS), δ: 2.46 (s, 3H), AB system with δ_A 6.08 (1H), δ_B 6.39 (1H), J_{AB} = 2.0 Hz; ms, *m/e* (relative intensity): 106, 104 (26, 76) M^+, 63, 61 (13, 39) $(M - CH_3CO)^+$, 43 (100) $(CH_3CO)^+$; gc t_R (condition B) 14.4 min. The material undergoes polymerization.

Reduction of ***12***b *with DMS*

To a mixture of 44.6 mg (0.72 mmol) of DMS in 0.4 mL of $CDCl_3$ was added a solution of 40.6 mg (0.27 mmol) of ***12b*** in 0.4 mL of $CDCl_3$ at room temperature; ^{1}H nmr analysis after 24 h showed the presence of ***13b*** and of DMSO (δ 2.63, s) in a ratio of 1:1.

Ozonolysis of ***7***b *in* $CH_3OH/CDCl_3$

A solution of 101 mg (0.522 mmol) of ***7b*** and 67 mg (2.1 mmol) of methanol in 2 mL of $CDCl_3$ was treated with ozone at −60°C until it turned blue, was then flushed with nitrogen, warmed up to room temperature, and admixed with 70 mg (0.417 mmol) of 1,1,2,2-tetrachloroethane as a standard; ^{1}H nmr analysis ($CDCl_3$, TMS) showed the presence of ***18*** (δ 1.15, t, J = 7.2 Hz, $CH_3(CH_2)$; 2.33, q, CH_2) and of ***19*** (δ 2.06, s, CH_3CO) in a molar ratio of 1:2, as well as methyl formate (δ 3.77, d, J = 0.8 Hz, CH_3O; 8.05, m, CH) and dimethoxymethane (δ 4.59, s, CH_2); gc analysis (condition B) with the help of authentic samples confirmed the presence of ***18*** (t_R = 6.6 min) and ***19*** (t_R = 5.1 min).

Ozonolysis of ***12***b *in* CH_3OD

A solution of 190 mg (1.3 mmol) of ***12b*** in 1.8 mL of CH_3OD was ozonized at −78°C until it turned blue, was flushed with nitrogen, admixed with 500 mg each of sodium bicarbonate and sodium sulfate, warmed up to 0°C, and diluted with 15 mL of dichloromethane. The salts were filtered off and the filtrate was concentrated at room temperature and 12 Torr; ^{1}H nmr analysis ($CDCl_3$, TMS) of the liquid residue (2 mL) showed the presence of ***21*** and ***22*** (δ 4.98, s, CH_2) (14) in a ratio of 1:0.9. By flash chromatography (column 2 × 30 cm, 50 g silica gel, dichloromethane), 60 mg (31%) of ***21*** was isolated.

Preparation of ***21*** *by ozonolysis of* ***23***a

A solution of 1.034 g (10.3 mmol) of ***23a*** in 14 mL of pentane was ozonied at −78°C until it turned blue, was then flushed with nitrogen, warmed up to room temperature, and kept until the original precipitate had dissolved. The mixture was concentrated in a rotary evaporator at room temperature and 20 Torr. From the liquid residue 1.05 g (72%) of ***21*** was isolated by flash chromatography and subsequently distilled at room temperature and at a pressure below 10^{-4} Torr.

*3-Carbomethoxy-3-methyl-1,2,4-trioxolane (****21****)*: colorless, shock sensitive liquid; ir (CCl_4): 1768 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.71 (s, 3H), 3.82 (s, 3H), 5.09 (s, 1H), 5.40 (s, 1H); ^{13}C nmr ($CDCl_3$, TMS), δ: 18.50 (q, J = 131 Hz), 53.04 (q, J = 148 Hz), 95.16 (d, d, J = 175 and 167 Hz), 103.95 (s), 168.83 (s); ms, *m/e* (relative intensity): 149 (100) $(M + 1)^+$ by chemical ionization; 89 (31) $(M - CO_2CH_3)^+$, 59 (24) $(CO_2CH_3)^+$, 43 (100) $(CH_3CO)^+$ by electron impact ionization. *Anal.* calcd. for $C_5H_8O_5$ (148.1): C 40.54, H 5.44; found: C 40.45, H 5.48.

Reduction of ***21*** *with DMS*

A solution of 40.0 mg (0.64 mmol) of DMS in 0.4 mL of $CDCl_3$ was admixed with 27.5 mg (0.18 mmol) of ***21*** in 0.4 mL of $CDCl_3$; ^{1}H nmr analysis with the help of authentic samples showed the presence of ***23b*** (δ 2.49, s and 3.88, s) and of DMSO (δ 2.62, s) in a ratio of 1:1.

Epoxidation of ***7***b

A solution of 1.38 g (7.2 mmol) of ***7b*** and 1.49 g (8.6 mmol) of *m*-chloroperbenzoic acid in 30 mL in dichloromethane was refluxed for 32 h and decanted from a colorless precipitate, which appeared during cooling to room temperature. The precipitate was washed with pentane, the decanted pentane was admixed with the main solution, and the mixture was concentrated in a rotary evaporator at room temperature and 15 Torr. The liquid residue (1.78 g) was separated by flash chromatography (column 4 × 46 cm, 280 g of silica gel, pentane:ether 20:1) to give 190 mg (13%) of ***24A***, 60 mg (4%) of ***24B***, and 60 mg (4%) of ***25***.

*3-Methyl-3-(*cis*-3-chloro-3-ethyl-2-methyl-2-oxiranyl)-1,2,4-trioxolanes (****24****)*

Isomer ***24***A: colorless liquid; ir (film): no absorption in the regions of the C=C and C=O stretching bands; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.22 (t, J = 7.2 Hz, 3H), 1.57 (s, 3H), 1.64 (s, 3H), 2.26 (m, 2H), 5.04 (s, 1H), 5.16 (br s, 1H).

Isomer ***24***B: colorless liquid; ir (film): no absorption in the regions of the C=C and C=O stretching bands; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.22 (t, J = 6.9 Hz, 3H), 1.54 (s, 3H), 1.68 (s, 3H), 2.20 (m, 2H), 4.99 (s, 1H), 5.21 (s, 1H).

*3-Methyl-3-(2-chloro-3-oxo-2-pentyl)-1,2,4-trioxolane (****25****)*: colorless liquid; ir (film): 1770 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.07 (t, J = 7.2 Hz, 3H), 1.57 (s, 3H), 1.76 (s, 3H), 2.84 (m, 2H), 5.18 (m, 2H).

Reduction of ***24***A *and of* ***24***B *with triphenylphosphine*

Solutions of ***24A*** and of ***24B*** in $CDCl_3$ were admixed with 40 mg of triphenylphosphine, each in nmr tubes at room temperature. The

^{1}H nmr analyses after 5 min showed in each case the presence of **26**. In addition, a precipitate appeared, probably polymeric formaldehyde.

trans-*2-Acetyl-3-chloro-3-ethyl-2-methyloxirane (26)* has been identified by comparison of ^{1}H nmr data with those of authentic **26**, which was obtained by the following procedure: A solution of 1.52 g (10.4 mmol) of **9***b* and 2.02 g (11.7 mmol) of *m*-chloroperbenzoic acid in 20 mL of dichloromethane was refluxed for 48 h, decanted from a colorless precipitate, and concentrated at room temperature and 15 Torr. The residual liquid (2.1 g) was separated by flash chromatography (same conditions as for **24** above) to give 65 mg (4%) of **26** as a colorless liquid; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.13 (t, J = 7.0 Hz, 3H), 1.68 (s, 3H), 1.83 (center of m, overlapping with the singlet at 1.68), 2.22 (s, 3H).

Reduction of **25** was by the same procedure as that of **24**. The ^{1}H nmr analysis ($CDCl_3$, TMS) showed the presence of **27**; δ: 1.11 (t, J = 7.4 Hz, 3H), 1.75 (s, 3H), 2.32 (s, 3H), 2.72 (q, J = 7.4 Hz, 2H).

Reaction of **24**A *with* $AgBF_4$

To a solution of 630 mg (3.2 mmol) of $AgBF_4$ in 10 mL of ether, 560 mg (2.7 mmol) of **24***A* in 5 mL of ether was added dropwise with stirring at −10°C. The mixture was kept stirring at −10°C for 30 min and then separated by flash chromatography (column 5 × 40 cm, 318 g of silica gel, pentane:ether 10:1) to give 110 mg (24%) of **30**, 105 mg (20%) of **31***A*, and 30 mg (6%) of **31***B*.

3-Methyl-3-(oxo-1-pentene-2-yl)-1,2,4-trioxolane (30): colorless liquid; ir (film): 1685 (C=O), 1620 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.11 (t, J = 7.1 Hz, 3H), 1.75 (s, 3H), 2.67 (q, J = 7.1 Hz, 2H), 5.09 (s, 1H), 5.18 (s, 1H), 6.07 (s, 1H), 6.22 (s, 1H); ^{13}C nmr (300 MHz, $CDCl_3$, TMS), δ: 8.16 (q, J = 132.7 Hz), 22.48 (q, J = 132.7 Hz), 32.88 (t, J = 123.4 Hz), 94.31 (dd), 107.58 (s), 124.88 (dd), 147.58 (s), 201.13 (s).

3-Methyl-3-(2-fluoro-3-oxo-2-pentyl)-1,2,4-trioxolanes (31)

Isomer **31**A: colorless liquid; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.05 (t, 7.1 Hz, 3H), 1.49 (d, J_{FH} = 1.8 Hz, 3H), 1.54 (d, J_{FH} = 22.5 Hz, 3H), 2.71 (m, 2H), 5.13 (s, 1H), 5.18 (s, 1H).

Isomer **31**B: colorless liquid; ^{1}H nmr ($CDCl_3$, TMS), δ: 1.05 (t, J = 7.2 Hz, 3H), 1.49 (d, J_{FH} = 22.0 Hz, 3H), 1.53 (d, J_{FH} = 2.4 Hz, 3H), 2.71 (m, 2H), 4.93 (d, J_{FH} = 1.1 Hz, 1H), 5.07 (s, 1H).

Synthesis of 6-alkynylated uridines

HIROMICHI TANAKA, KAZUHIRO HARAGUCHI, YACHIYO KOIZUMI, MARIKO FUKUI, AND TADASHI MIYASAKA[1]

School of Pharmaceutical Sciences, Showa University, Hatanodai 1-5-8, Shinagawa-ku, Tokyo 142, Japan

Received November 22, 1985

This paper is dedicated to Professor Morio Ikehara on the occasion of his retirement from Osaka University in March 1986

HIROMICHI TANAKA, KAZUHIRO HARAGUCHI, YACHIYO KOIZUMI, MARIKO FUKUI, and TADASHI MIYASAKA. Can. J. Chem. **64**, 1560 (1986).

6-Alkynylated uridines, a hitherto unknown class of compounds, were synthesized by a coupling reaction of terminal alkynes with 6-iodo-2′,3′-*O*-isopropylidene-5′-*O*-methoxymethyluridine in the presence of bis(triphenylphosphine)palladium(II) chloride and copper(I) iodide. 6-Ethynyl-2′-deoxyuridine was also prepared by using 6-iodo-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)-2′-deoxyuridine as a starting material.

HIROMICHI TANAKA, KAZUHIRO HARAGUCHI, YACHIYO KOIZUMI, MARIKO FUKUI et TADASHI MIYASAKA. Can. J. Chem. **64**, 1560 (1986).

Faisant appel à une réaction de couplage des alcynes terminaux avec l'iodo-6 *O*-isopropylidène-2′,3′ *O*-méthoxyméthyl-5′ uridine, en présence de chlorure de bis(triphénylphosphine) palladium(II) et d'iodure de cuivre(I), on a synthétisé des uridines portant des groupements alcynes en position 6, une classe de composés qui étaient jusqu'à maintenant inconnue. On a aussi préparé de l'éthynyl-6 déoxy-2′ uridine en utilisant l'iodo-6 (tétraisopropyldisiloxane-1,3 diyl)-3′,5′ déoxy-2′ uridine comme produit de départ.

[Traduit par la revue]

Because of their significant biological activities, 5-alkynylated pyrimidine nucleosides in general and 5-alkynylated uracil nucleosides in particular have attracted considerable attention in the field of nucleoside chemistry.

The earlier method for the preparation of these compounds is based on the classical condensation method wherein protected sugar derivatives and appropriate bases were used (1–3). Later, on the basis of a modified procedure for the coupling reaction of terminal alkynes with aryl halides reported by Sonogashira *et al.* (4), Robins and co-workers described an elegant application of this method for the preparation of 5-alkynyluracil nucleosides (5–7).

While an alternative method for the coupling reaction is also available (8), Robins' approach, palladium–copper catalyzed coupling of terminal alkynes with 5-iodouracil nucleosides, seems to be most widely applicable to the modification of nucleosides, as has been shown in the synthesis of 6-, 8-, and 2-alkynylated purine nucleosides (9, 10).

On the other hand, although 6-ethynyluracil has been prepared and found to suppress the proliferation of leukemia L1210, B-16 melanoma, and Lewis lung carcinoma cells (11), pyrimidine nucleosides having an alkynyl group in the C-6 position have not yet appeared in the literature. This might be related to the fact that the classical condensation method with 6-substituted pyrimidines has almost always resulted in the predominant formation of N^3-glycosylated products (12–15).

We have recently published a series of papers on the lithiation of nucleosides, which furnished general access to the modification of their base moieties (16–20). 6-Substituted uridines, which have thus far been difficult to synthesize, are now easily accessible by our method (16), the lithiation of 2′,3′-*O*-isopropylidene-5′-*O*-methoxymethyluridine (**1**) with LDA (lithium diisopropylamide) and subsequent reactions of the lithiated species with electrophiles. An apparent candidate for synthesizing 6-alkynyluridines might be a 6-iodouridine derivative that can be prepared by using iodine as an electrophile in the above reaction (21, 22).

Thus 6-iodo-2′,3′-*O*-isopropylidene-5′-*O*-methoxymethyluridine (**2**), prepared in 76% yield from **1** according to the published procedure (22), was deprotected by treatment with 50% aqueous trifluoroacetic acid (TFA) to produce **3** as crystals (mp 130–132°C) in quantitative yield. However, the use of **3** as a starting material resulted in the formation of an intractable mixture of products under Robins' conditions with DMF as a cosolvent. Accordingly, we then examined the coupling reaction of **2** with terminal alkynes.

Treatment of **2** with phenylacetylene in triethylamine at 60°C for 2 h under positive pressure of dry argon in the presence of bis(triphenylphosphine)palladium(II) chloride and copper(I) iodide gave a 71% yield of the 6-[2-(phenyl)ethynyl]uridine derivative (**4**) after column chromatography on silica gel. The presence of an alkynyl group in **4** was clear from the ir spectrum (ν 2180 cm^{-1}); ^{1}Hmr ($CDCl_3$: δ 6.02, H-1′; δ 6.40, H-5; δ 7.26–7.56, phenyl) and ms (M^+ m/z: 428) spectra were in good agreement with its structure. Other terminal alkynes also work equally well, as shown in Table 1. It should be mentioned that protection of the hydroxyl group in propargyl alcohol was not necessary to effect smooth coupling with **2**. The 6-ethynyluridine derivative (**8**) was obtained from its trimethylsilyl precursor (**7**) upon treatment with methanolic ammonia. Since the use of silica gel decreased the isolated yield of **8** to a considerable extent, magnesium silicate was used as an adsorbent in its column chromatography.

A similar coupling reaction of the 5-bromo-6-iodouridine derivative **10**, accessible from **9** by LDA lithiation followed by iodination, with phenylacetylene was also carried out. It was found, however, that most of **10** was deiodinated during the reaction, leading to the isolation of **9** in 50% yield.

Concurrent deprotection of 2′,3′-*O*-isopropylidene and the 5′-*O*-methoxymethyl groups in the above products (**4–6** and **8**) was accomplished with 50% TFA at room temperature to furnish the corresponding 6-alkynyluridines (**11–14**) in good yields. The results are summarized in Table 2.

Finally, the C-6 ethynylation of 2′-deoxyuridine was examined by using 6-iodo-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)-2′-deoxyuridine (**15**) as a starting material (18).

Compound **15** was subjected to reaction with trimethylsilylacetylene under Robins' conditions for 1 h. As the resulting
