Received May 8, 1985

ALBERT STOESSL and J. B. STOTHERS. Can. J. Chem. **64**, 1 (1986).

Attempts to clarify the biosynthetic origin of the eggplant stress metabolite aubergenone (**1**) by incorporation of label from sodium [2-$^2H_3$,1-^{13}C]acetate were frustrated by low yields and enrichment levels. However, the presence of deuterium in the biosynthetically significant 5-position was demonstrated by ^{2}Hmr for the closely related auberganol (**5**) and α- and β-eudesmol (**10** and **11**), suggesting that these compounds, and hence also **1**, are normal eudesmanes and not the products of a possible double rearrangement. Deuterium was also incorporated into the expected positions of 9-oxonerolidol (**12**), 9-oxynerolidol (**13**), and lubimin (**4**). Incorporation of label from [1,2-$^{13}C_2$]acetate could be determined satisfactorily only for **13** and its allylic isomer **14**, corresponding with expectations. This is the first report of **5** as a natural product and of **10**, **11**, and the 10-epimer of **4** as eggplant stress metabolites.

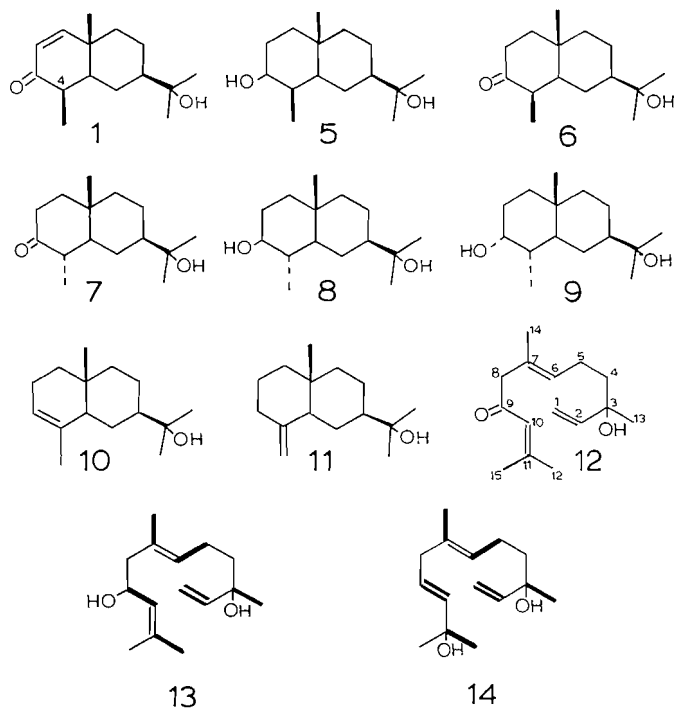
ALBERT STOESSL et J. B. STOTHERS. Can. J. Chem. **64**, 1 (1986).

Dans le but de déterminer l'origine biosynthétique de l'auberginone (**1**), un métabolite de stress de l'aubergine, on a effectué des essais d'incorporation de l'acétate-[$^2H_3$-2,^{13}C-1] de sodium qui n'ont pas réussi à cause des faibles rendements et des faibles niveaux d'enrichissement. Toutefois, on a pu démontrer la présence de deutérium dans la position 5, qui est significative d'un point de vue biosynthétique, en faisant appel à la rmn du ^{2}H de l'auberganol (**5**) et des α- et β-eudesmol (**10** et **11**) qui lui sont très apparentés; ces résultats suggèrent que ces composés et, par conséquent, le composé **1** sont des eudesmanes normaux et non pas des produits provenant d'une double transposition. Il y a aussi incorporation de deutérium dans les positions prévues du oxo-9 nérolidol (**12**), du oxo-9 nérolidol (**13**) et de la lubimine (**4**). Ce n'est qu'avec le composé **13** et son isomère allylique **14** que l'on a pu déterminer d'une façon satisfaisante l'incorporation d'un marqueur de l'acétate-[$^{13}C_2$-1,2] qui corresponde aux expectatives. Les résultats obtenus dans ce travail correspondent à une première concernant l'existence du composé **5** comme produit naturel et des produits **10**, **11** et de l'épimère en position 10 du composé **4** comme métabolites de stress de l'aubergine.

[Traduit par le journal]

Aubergenone (**1**), a metabolite of *Solanum melongena*, has until now been unique among the carbocyclic stress metabolites of the Solanaceae in that its structure is that of a normal eudesmane whereas the many other compounds of the group are derived from hypothetical eudesmane precursors by carbon and hydrogen migrations (1, 2). However, it has been shown recently (3) that the biosynthesis of rishitin (**2**), a member of the group, involves a remarkable second rearrangement of the vetispirane, hydroxylubimin (**3**) (Scheme 1). The possibility therefore arises that **1** may also be formed through a similar sequence. In principle, this question might be answered through the biosynthesis of **1** with [2-$^2H_3$,1-^{13}C]acetate incorporation. If a vetispirane is an intermediate, its formation may be accompanied by hydrogen (deuterium) migration from C-5 to C-4, as has been unambiguously demonstrated for **2**, **3**, and lubimin (**4**) (4). In the present case this could give rise to an observable signal in an uncluttered region of the ^{2}Hmr spectrum provided, of course, that the incorporation level is sufficiently high and that the C-4 hydrogen (deuterium) does not itself participate in the hypothetical second rearrangement. On the other hand, if **1** arises from an acyclic precursor without carbon–carbon rearrangement, the salient deuterium atom will remain bonded to C-5 and, therefore, be observable either directly or through the β-isotope shift in the C-6 absorption pattern.

To test these notions, eggplant fruit was treated with a suspension of *Monolinia fructicola*, as stress compound inducer, and, after 18 h, with [2-$^2H_3$,1-^{13}C]acetate (1.86×10^{-3} *M* effective concentration). A small amount of **1** was isolated after 2 days but the incorporation level was so low that only the deuterium signals for the methyl groups were observed in the ^{2}Hmr spectrum. The ^{13}C spectrum was similarly uninformative, revealing neither signal enhancements nor β-shifts for C-2, -4, -6, -8, -10, or -11. Fortunately, the situation was saved in part by the isolation of a new compound that was identified as a tetrahydroaubergenone, auberganol (**5**), by its ^{1}H, ^{13}Cmr, and mass spectra. Although this compound was not previously



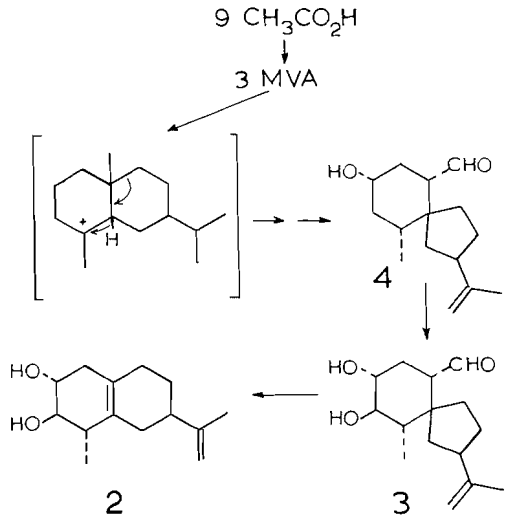
[1]Part 121 of ^{13}Cmr studies; for Part 120 see ref. 12.

[2]Communication No. 1010 from the Research Centre; Part 47 of "Postinfectional inhibitors from plants"; for Part 46 see ref. 13; for Part 45 see ref. 14; for Part 44 see ref. 15.

known from eggplant or other natural sources, it has been described as one of the intermediates in the laboratory synthesis of **1** from α-cyperone (5). The ^{1}Hmr and ms data for the eggplant metabolite are in excellent agreement with the literature values and the mp is satisfactorily close. To confirm the identity of **5**, however, the compound was oxidized to **6**, which was completely transformed to **7** on refluxing with ethanolic potassium hydroxide. Ketol **7** was obtained earlier as an intermediate in the synthesis of 4-*epi*-aubergenone (6). A sample of the latter compound[3] was hydrogenated to furnish authentic **7**, which was found to be identical to that obtained from **5**. As an aid for the assignment of the ^{13}Cmr spectrum of **5**, a portion of ketol **7** was reduced with sodium borohydride to furnish a mixture of two diols **8** and **9**. The major product **8** was isolated by fractional crystallization and exhibited the properties reported earlier for **8** as a precursor of **7** in the aforementioned synthesis of 4-*epi*-aubergenone (6). The minor diol **9** was therefore the 3α isomer. The ^{13}C data for **5**–**9** are collected in Table 1.

As in the case of **1**, the incorporation levels in **5** were too low to be detected by ^{13}Cmr. On the other hand, however, the ^{2}Hmr spectrum clearly showed the presence of deuterium in the methyl groups, with well-defined signals at δ 0.84, 0.86, and 1.18 for the 4-, 10-, and 11-methyl groups, respectively (^{2}H enrichment ca. 0.5%), and for some of the skeletal positions (broad absorptions ca. δ 1.05, 1.25, 1.4, 1.6). Most significantly, a sharp signal at δ 3.70 established the presence of deuterium at C-3 (enrichment ca. 0.15%) and the absence of absorption near δ 1.88 showed there was little or no deuterium at C-4. The absorption positions for the 3- and 4-deuterons were known from analysis of the proton spectrum in which irradiation at δ 1.88 collapsed the 4-methyl doublet, δ 0.84, to a singlet and eliminated a 5.5-Hz coupling in the carbinyl pattern at δ 3.70, thereby reducing the latter to a doublet of doublets, J = 5.5, 10.5 Hz. Some alteration in the spectrum near δ 1.25 indicated this to be the position of the 5-proton, thereby tentatively identifying an additional ^{2}H signal. From these observations it can be concluded that **5** was probably formed without deuterium migration from C-5 to C-4.[4] A definitive conclusion follows from the presence of deuterium at C-3, since this establishes that **5** is not formed by reduction of **1** but, rather, is either in a precursor or shunt relationship to **1**.

Another crystalline substance, m.p. 81–83°C, was isolated from the product and from its ^{13}C spectrum, found to be a 2:3 mixture of α- and β-eudesmols, **10** and **11**, respectively. These could not be separated by either column or preparative thin-layer chromatography but corresponded in all respects to the like mixture of the two compounds obtained by Cordano *et al.* (7) from *Balanites roxburghii*. The ^{13}Cmr spectrum of our product once again showed no discernible enrichment or β-shifts; the data are listed in Table 1. The ^{2}Hmr spectrum contained distinctive methyl signals at δ 0.71, 0.75, and 1.18 arising from the 4-, 10-, and 11-methyl groups, respectively, with broadened skeletal deuterium signals centred at δ 1.36, 1.44, 1.50, 1.60, and 2.30. The δ 2.30 signal corresponded to a multiplet in the proton spectrum containing one large coupling, ~12 Hz, which could be attributed to the 5-proton.



SCHEME 1

To evaluate the situation more fully, the major eggplant phytoalexins lubimin (**4**), 9-oxonerolidol (**12**), and 9-oxynerolidol (**13**) were also isolated for examination of their spectra. The ^{1}Hmr spectrum of the lubimin sample revealed the presence of ca. 10% of the 10-*epi* isomer which had been found previously in potato (8) but not eggplant. The ^{2}H spectrum of this sample was essentially the same as that recorded earlier for **4** isolated in the course of analogous incorporation experiments with potatoes (4), exhibiting readily assigned signals for deuterium at the aldehydic (δ 9.78), *exo*-methylene (δ 4.65), allylic (δ 1.60), and secondary methyl (δ 0.93) positions. In addition, broad signals centred at δ 1.0, 1.4, 1.8, and 2.3 arising from skeletal deuterons were evident, that at 1.4 corresponding to 1-^{2}H and (or) 4-^{2}H. The ^{2}Hmr spectrum of **12** contained prominent signals for each of the four methyl groups, δ 1.20, 1.50, 1.80, and 2.05, with that at δ 1.50 superimposed on absorption for skeletal methylene deuterons. In addition, a signal at δ 3.00 arising from the 8-methylene deuterons and weaker signals at δ 5.25, 5.95, and 6.10 confirmed the presence of deuterium at C-2, -6, and -10. These assignments followed from the proton spectra obtained in an earlier study (9) and reported previously by Hiroi and Takaoka (10). The major metabolite isolated in the experiment was 9-oxynerolidol (13) for which the ^{2}H spectrum readily revealed incorporation at the four methyl sites, δ 1.20 and 1.54, the latter signal arising from the three unresolved allylic methyl groups and more than three times as intense as the δ 1.20 signal. In addition, methylene absorption at δ 2.05 and olefinic signals at δ 5.95 and 5.22 were apparent. The lack of absorption in the range δ 2.1–5.1 confirmed the absence of incorporation at C-9. The ^{13}C spectrum of **13** revealed the presence of two diastereomers, as found previously (9, 10) in a ratio of ca. 2:1. In contrast to our earlier report, slightly different shieldings were found for 12 of the 15 carbons owing to the increased shift dispersion produced by the 3-fold increase of the observing frequency (300 vs. 100 MHz). The data are listed in Table 1. It may be noted that the original assignments for C-6 and -10 have been reversed (see below). The effects of deuterium incorporation were just apparent in the patterns observed for each of the enriched centres, C-1, -3, -5, -7, -9, and -11, with distinctive β-isotope shifts for C-1 (Δ =

[3]Professor R. B. Kelly kindly provided a generous sample of 4-*epi*-aubergenone.

[4]An unambiguous conclusion on this point is elusive because of the possibility of two consecutive deuterium migrations, i.e. an eudesmane → a vetispirane → an eudesmane with C-5 → C-4 → C-5 deuterium migration, although it is known that the second migration does not occur in the rearrangement of **3** → **2** (4). It would appear that the only approach to a solution of this question would involve testing of suitable vetispiranes for incorporation into **1**, experiments which are beyond the scope of the present study.

137 ppb), C-5 (110 ppb), C-7 (55 ppb), and C-9 (64 ppb) while the C-3 and -11 signals were broadened.

In a preliminary experiment, similarly inoculated aubergines were treated with sodium [1,2-$^{13}C_2$]acetate. Although aubergenone (**1**) was present in trace amounts, insufficient material could be isolated for spectroscopic examination. However, **13** and its allylic isomer **14** were isolated from tissue extracts by chromatography and their ^{13}C spectra recorded to determine the pattern of intact acetate units in each compound as indicated by the bold linkages in **13** and **14**. For each unit, the ^{13}C–^{13}C coupling constants could be measured and these data are included in Table 1. The relative intensities of the ^{13}C satellites and the central signal for the coupled carbons indicated that the ^{13}C enrichments were low, 0.25 and 0.15 ± 0.05% for **13** and **14**, respectively. The very low incorporation levels and the minimal yield of **1** dictated a change in tactics, leading to the experiment with [2-$^{2}H_3$,1-^{13}C]acetate described above.

Auberganol (**5**) and the eudesmols **8** and **9** were not present in readily detectable amounts in extracts from uninoculated aubergines. The experiments described above suggest that these, together with aubergenone (**1**), are normal, i.e. non-rearranged eudesmanoids. No eudesmanes have as yet been reported as stress metabolites of other species of the Solanaceae. It is at present unknown whether auberganol is antifungally active but at least one report describes (+)-β-eudesmol, isolated from *Hymenoclea monogyra*, as active against *Alternaria* spp. (11).

Experimental

General experimental procedures and instrumentation utilized were as described in earlier papers (8, 9) unless otherwise indicated. The ^{13}C and ^{2}Hmr spectra were recorded with a Varian XL-300 system using $CDCl_3$ (^{13}C) and $CHCl_3$ (^{2}H) solutions in 5-mm tubes.

Aubergines (imported from Florida) were purchased in the local market in November and were of unknown storage age and variety. The fruits (25) were cut longitudinally into equal halves, seeds and pith were scooped out, and the resulting shells were charged with a suspension of *Monilinia fructicola* (2×10^5 spores/mL, 40 mL/shell) and, after 22 h, with sodium [2-$^{2}H_3$,1-^{13}C]acetate (Merck Isotopes Inc., 98% ^{2}H, 90% ^{13}C, 8 mg (0.093 mmol in 10 mL of H_2O/shell). Two days after inoculation, the liquid diffusate was collected, combined with water rinsings, and extracted with ether. Necrotic tissue was scraped from the shells and extracted by steeping overnight in MeOH/EtOAc (1:1), concentrating the filtered extract until mainly aqueous, and reextracting with ether. On column chromatography over SiO_2 (Camag DFO; 300 g) in *sec*-BuOH/EtOAc (5:95), the diffusate extract afforded fractions (20 mL each) that consisted predominantly of 9-oxonerolidol (**12**) together with **10** and **11** (fractions 26–28, 53 mg), 9-oxynerolidol (**13**) and its allyl isomer **14** (fractions 29–34, 140 mg), a mixture of **4** and **1** (fractions 38–44, 41 mg), and crude crystalline **5** (fractions 50–61; 14.9 mg).

Rechromatography of fractions 26–28 gave 9-oxonerolidol (**12**) (18 mg, no discernible enhancement or shifts in the ^{13}C spectrum) and compounds **10** and **11** as a crystalline mixture (13.5 mg); mp 81–83°C after two recrystallizations (light petrol, −10°C); ^{1}Hmr ($CDCl_3$) δ (**10**): 0.75 (s, 3H, 10-Me), 1.18 (s, 6H, isopropyl Me's), 1.60 (bs, 3H, 4-Me), 5.30 (m, 1H, H-3); δ (**11**): 0.66 (s, 3H, 10-Me), 1.18 (s, 6H, isopropyl Me's), 4.42 (m, 1H), and 4.70 (m, 1H) *exo*-methylene protons; ^{13}Cmr (see Table 1); ^{2}Hmr indicated low enrichment of ca. 0.016 atoms D/molecule; *m/e*: 222, 204, 189, 164, 161, 149, 93, and 59 (100%). *Exact Mass* calcd. for $C_{15}H_{26}O$: 222.19835; found: 222.19805.

9-Oxynerolidol (**13**) was obtained nearly pure (97 mg) by rechromatography of fractions 29–34 ($MeOH/CHCl_3$ 5:95). The small amount of its allylic isomer that was also obtained was not further examined.

Aubergenone (**1**) (5 mg) was obtained from fractions 38–44 by column chromatography ($MeOH/CHCl_3$ 1:99) followed by multiple

[a]In ppm from internal TMS for $CDCl_3$ solutions.
[b]Upper data set for the major diastereomer (see text).
[c]One-bond ^{13}C–^{13}C coupling constants in Hz listed in square brackets; samples obtained from [1,2-$^{13}C_2$]acetate experiment.

preparative tlc (high performance precoated plates, Whatman Multi-K type CS5KC$_{18}$F/K5F; EtOAc/toluene/HOAc 30:60:1) and was combined for spectroscopy with another 3.2 mg similarly obtained from the tissue extract.

Lubimin (15 mg) was obtained in the above purification of **1**. It consisted of **4** accompanied by a small amount of its 10-epimer as judged from the ^{1}Hmr spectrum.

Auberganol (**5**) was purified by recrystallization from EtOAc (5 mg), mp 155–158°C; after a further recrystallization (EtOAc/hexane) it had mp 173.0–173.5°C (lit. (5) mp 166–166.5°C); ir ($CHCl_3$): 3605 (s), 3460 (br), 2935, 2870, 2855, 1450 (d), 1382, 1370, 1130, 1080, 1008, 903 cm^{-1}; too little sample was available for determination of the small rotation (lit. (5), $[\alpha]_D$ −2.7°); ^{1}Hmr ($CDCl_3$) δ: 0.86 (s, 3H, 10-Me), 0.84 (d, 3H, J = 7.4 Hz, 4-Me), 1.18 (s, 6H, isopropyl Me's), 1.92 (m, 1H, H-4), 3.71 (dt, J = 10.4 and 5.5 Hz, 1H, H-3); ^{13}Cmr (see Table 1). *Exact Mass* calcd for $C_{15}H_{28}O$: 240.20891; found: 240.20879.

The very complex tissue extract was used only for the isolation of **1** by similar chromatographic techniques.

In another experiment, similarly inoculated aubergines (20) were treated with sodium [1,2-$^{13}C_2$]acetate (1.68 mg) in 1 mL of H_2O added to 10 mL of spore suspension/shell. Aubergenone (**1**) was present only in trace amounts and could not be studied. 9-Oxynerolidol (**13**) (15 mg) and its isomer **14** (16 mg) were isolated from the tissue extract by chromatography over SiO_2 in EtOAc/CH_2Cl_2 1:4.

Reduction–epimerization of **5**

Auberganol (2.5 mg) in acetone (1 mL) at 0°C was treated at increasingly long intervals with small drops of the Jones' reagent (59 mg CrO_3, 2 mL H_2SO_4, H_2O to 15 mL) until a yellow colour persisted for 30 min. Excess reagent was destroyed with MeOH (few drops) and the solution extracted with Et_2O (2 × 10 mL); the extract was washed with 5% Na_2CO_3 (2 mL) and water (2 × 4 mL) and evaporated to give **6** (1.9 mg), homogeneous by tlc and ^{1}H and ^{13}Cmr spectra. This product was refluxed in 0.1 *M* KOH in EtOH (2 mL) at 74°C for 1 h, poured into H_2O (10 mL), acidified (2 *M* HCl, 0.11 mL), and extracted into $CHCl_3$ (2 × 5 mL) to give **7** as a syrup (~1 mg) identical (except for the presence of trace amounts of different impurities) with the sample prepared from synthetic 4-*epi*-aubergenone by tlc, ir, ^{1}H, and ^{13}Cmr spectra.

Reduction of 4-epi-*aubergenone*

The synthetic ketol (**6**) (15 mg) was hydrogenated over 5% Pd/C (25 mg, prereduced) in EtOH (15 mL) for 6 h. Essentially pure *trans*-dihydrocarissone (**7**) was obtained as a syrup on evaporation of the filtered solution.

4-epi-*Auberganols*

Synthetic **7** (12 mg) in MeOH (2 mL) was reduced with $NaBH_4$ (few grains) at 0°C. Extraction ($CHCl_3$) from ice-water gave a mixture of diols **8** and **9** (^{13}Cmr, see Table 1) as a syrup (11.5 mg). Crystallization from CH_2Cl_2 at −10°C gave **8** (3.2 mg), mp 136–140°C, raised to 138–140°C by a further crystallization; ^{1}Hmr ($CDCl_3$) δ: 0.83 (s, 3H, 10-Me), 0.97 (d, 3H, J = 6.8 Hz, 4-Me), 1.19 (s, 6H, $(CH_3)_2C(OH)$—), 3.14 (ddd, 1H, J = 5.0, 9.8, 11.0 Hz, H-3).

Acknowledgements

Thanks are due to G. Rock for general experimental assistance, S. Wilson and D. Hairsine for recording ^{1}Hmr and mass spectra, respectively; and to the Natural Sciences and Engineering Research Council of Canada for financial support. We thank Professor R. B. Kelly for the sample of 4-*epi*-aubergenone.

Influence de nitrates métalliques sur l'équilibre de dissociation ionique: $N_2O_4 \rightleftarrows NO^+ + NO_3^-$ dans le sulfolane

ABDELLATIF BOUGHRIET, MICHEL WARTEL[1] ET JEAN-CLAUDE FISCHER

Laboratoire de chimie analytique et marine, bâtiment C8, Université de Lille, 59655 Villeneuve D'Ascq Cédex, France

Reçu le 1er avril 1985

ABDELLATIF BOUGHRIET, MICHEL WARTEL et JEAN-CLAUDE FISCHER. Can. J. Chem. **64**, 5 (1986).

Au cours de la nitration des noyaux aromatiques par le N_2O_4 en milieu aprotonique, la présence d'un nitrate métallique tel que $Zn(NO_3)_2$, $Cu(NO_3)_2$ ou $UO_2(NO_3)_2$, génère l'espèce catalytique NO^+ selon la réaction $N_2O_4 + M(NO_3)_2 \rightleftarrows NO^+ + M(NO_3)_3^-$ [1]. L'étude voltampérométrique de la réduction de N_2O_4 en présence de nitrates métalliques $M(NO_3)_2$ sur électrode de platine a permis d'atteindre la valeur de la constante de l'équilibre [1] et celle de la constante de stabilité du complexe trinitrato formé selon $M(NO_3)_2 + NO_3^- \rightleftarrows M(NO_3)_3^-$ [2] dans le sulfolane (M = Zn, Cu, UO_2). La forte stabilité des complexes trinitrato $M(NO_3)_3^-$ est due aux propriétés peu solvatantes du solvant. Les comportements des ligands Cl^- et NO_3^- étant très voisins, cette hypothèse est vérifiée par l'étude de la stabilité des complexes chlorozincates[II] ($ZnCl_i^{2-i}$ (i = 1, 2, 3, 4)) dans le sulfolane, par voltampérométrie à courant nul sur électrode d'argent.

ABDELLATIF BOUGHRIET, MICHEL WARTEL, and JEAN-CLAUDE FISCHER. Can. J. Chem. **64**, 5 (1986).

The addition of a metallic nitrate such as $Zn(NO_3)_2$, $Cu(NO_3)_2$, or $UO_2(NO_3)_2$ to N_2O_4 solutions in aprotic media leads to the reclaiming of the NO^+ species (which is considered as a catalyst for the nitration of aromatics by N_2O_4) as follows: $N_2O_4 + M(NO_3)_2 \rightleftarrows NO^+ + M(NO_3)_3^-$ [1]. Using linear voltammetry, the study of the N_2O_4 reduction in the presence of metallic nitrates with a platinum electrode has allowed us to derive the equilibrium constant for reaction [1] and that corresponding to the formation of the trinitrato complexes in sulfolane according to: $M(NO_3)_2 + NO_3^- \rightleftarrows M(NO_3)_3^-$ [2] (M = Zn, Cu, UO_2). The strong stability of the $M(NO_3)_3^-$ complexes is due to the weak solvating character of the sulfolane. This hypothesis is also confirmed by the stability constants of zinc[II] chloride complexes: $ZnCl_i^{2-i} \rightleftarrows ZnCl_{i-1}^{3-i} + Cl^-$ (i = 1, 2, 3, 4) in sulfolane from a potentiometric study by means of a silver chloride – silver electrode.

Introduction

La nitration du naphtalène par N_2O_4 en milieu aprotonique a lieu selon un mécanisme faisant intervenir l'espèce catalytique NO^+ (1) provenant de la dissociation ionique de N_2O_4 selon $N_2O_4 \rightleftarrows NO^+ + NO_3^-$. Cependant, la constante de dissociation de N_2O_4 dans différents solvants aprotoniques est faible ($K^i_{N_2O_4} = 7{,}1 \times 10^{-8}$ mol dm^{-3} à 303 K dans le sulfolane (2), et $K^i_{N_2O_4} = 6{,}3 \times 10^{-10}$ mol dm^{-3} à 298 K dans le nitrométhane (3*a*)). Des composés tels que les nitrates métalliques ($UO_2(NO_3)_2$, $Cu(NO_3)_2$ et $Zn(NO_3)_2$) dans des solvants peu solvatants (favorisant les homoconjugaisons ou hétéroconjugaisons) favorisent la dissociation ionique de N_2O_4 par formation de complexes nitrato $M(NO_3)_i^{2-i}$ (i = 1, 2, 3, 4 et M = UO_2, Cu et Zn). Afin de mieux connaître le phénomène d'interaction entre N_2O_4 et ces nitrates métalliques, nous avons étudié les constantes de stabilité de ces complexes nitrato-métalliques:

[1] $M(NO_3)_{i-1}^{3-i} + NO_3^- \rightleftarrows M(NO_3)_i^{2-i}$

N'ayant pu intégrer ces différentes entités chimiques dans un couple électrochimique, mais également en raison de la faible concentration des espèces $M(NO_3)^+$, M^{2+} et NO_3^- en solution, les constantes de stabilité des complexes $M(NO_3)_2$ et $M(NO_3)^+$ n'ont pas pu être déterminées. Néanmoins, une étude voltampérométrique sur électrode de platine poli des solutions des dérivés oxygénés de l'azote (3) a montré que le système NO^+/NO est rapide dans le sulfolane, ce qui nous a permis d'entreprendre l'étude de la réaction entre N_2O_4 et $M(NO_3)_2$ selon

[2] $N_2O_4 + M(NO_3)_2 \rightleftarrows NO^+ + M(NO_3)_3^-$

La formation de NO^+ au cours de cette réaction a été suivie par ampérométrie.

Il est à noter que si les nitrates de cuivre et d'uranyle conduisent à des complexes trinitrato ($M(NO_3)_3^-$) (4), Addison *et al.* (4) soulignent, dans le cas du zinc, l'existence d'un complexe tétranitrato ($(NO^+)_2Zn(NO_3)_4^{2-}$). Ce complexe, formé lors d'un mélange $Zn(NO_3)_2$ et N_2O_4 en excès, est peu stable et se décompose à température ordinaire. Peu d'informations n'ont pu être relevées dans la bibliographie quant à sa stabilité en solvant aprotonique dipolaire. Les ions nitrate et chlorure ayant des propriétés solvatantes très proches dans le sulfolane, la transposition de l'étude des complexes $ZnCl_i^{2-i}$ (i = 1, 2, 3, 4), par potentiométrie à courant nul sur électrode d'argent, au complexe $Zn(NO_3)_4^{2-}$ devrait permettre de justifier la non-stabilité du tétranitratozincate[II] de dinitrosyle dans notre solvant.

Partie expérimentale

Le sulfolane (Prolabo) est purifié selon la méthode déjà décrite (5). Les perchlorates d'argent (Fluka) et de tétraéthylammonium (Carlo Erba) sont séchés à 333 K sous pression réduite durant 1 mois. Les chlorures de tétraéthylammonium (Eastman Kodak) et de zinc (Merck) sont séchés respectivement à 353 et 423 K sous pression réduite durant 8 jours.

Le $UO_2(NO_3)_2$ anhydre est obtenu par déshydratation à 373 K de $UO_2(NO_3)_2,6H_2O$ (Merck) sous pression réduite. Une telle technique n'est pas applicable aux nitrates de zinc et de cuivre qui se décomposent en conditions de déshydratation. Les nitrates $Zn(NO_3)_2$ et $Cu(NO_3)_2$ rigoureusement exempts d'eau sont donc préparés "*in situ*" par réaction dans le sulfolane entre de la poudre de métal (Cu, Zn) et un excès de N_2O_4. Quand la réaction est terminée, le mélange réactionnel est placé sous pression réduite, ce qui permet l'élimination de N_2O_4 en excès et des oxydes d'azote NO et N_2O_3 formés au cours de la réaction.

Le perchlorate de nitrosyle est préparé dans le nitrométhane par addition d'un excès de N_2O_3 à une solution de $HClO_4,H_2O$. Le solide recueilli après filtration est lavé au tétrachlorure de carbone.

Un millivoltmètre Isis 20000 Tacussel est utilisé pour la potentiométrie. La stabilité des mesures est contrôlée sur un enregistreur Tacussel EPL 2, relié au millivoltmètre. Toutes les préparations de solutions sont effectuées en boîte à gants. Les manipulations sont réalisées à 303 ± 0,1 K. L'électrode d'argent est recouverte d'un dépôt de AgCl, avant chaque manipulation, selon la méthode déjà décrite (2).

[1]Auteur à qui adresser la correspondance.

Les courbes intensité–potentiel, en régime stationnaire, sont tracées à 303 ± 0,1 K à l'aide d'un ensemble voltampérométrique Tacussel. La vitesse de rotation de l'électrode indicatrice de platine (diamètre, 0,8 mm) est de 10 tours/s. La vitesse de balayage des potentiels est de 5 mV/s. La voltammétrie cyclique est réalisée soit à l'aide de la même électrode soit avec une électrode de diamètre ≃ 2 mm.

L'électrode de référence a déjà été décrite (2). Le potentiel de demi-vague du système ferrocène–ferricinium est pris comme origine de l'échelle de potentiel.

Le dosage de l'eau est effectué par la méthode de Karl–Fischer (réactif généré par coulométrie (6)).

Les spectres Raman de solutions équimoléculaires des mélanges de N_2O_4 et nitrate métallique dans le sulfolane ont été obtenus à l'aide d'un spectromètre Raman Dilor R.T. 30. Pour cela, nous avons utilisé des tubes scellés contenant des solutions de 0,2 mol dm^{-3} en nitrate métallique et 0,2 mol dm^{-3} en N_2O_4. La radiation excitatrice est la raie à 488,0 nm d'un laser à argon ionisé, avec une puissance de 150 mW.

Résultats et discussion

Les courbes voltampérométriques sur électrode de platine poli de solutions de nitrate métallique ($UO_2(NO_3)_2$, $Cu(NO_3)_2$ ou $Zn(NO_3)_2$), en présence de perchlorate de tétraéthylammonium comme électrolyte indifférent, ne révèlent pas dans le sulfolane la vague d'oxydation caractéristique de l'ion nitrate ($E_{\frac{1}{2}}$ = +1,57 V (3)). Ce résultat suggère donc que ces nitrates métalliques sont peu dissociés dans notre solvant. L'addition de N_2O_4 à ces solutions fait apparaître sur les courbes $i = f(E)$ une vague cathodique différente de celle correspondant à la réduction de N_2O_4, et qui croît avec le rapport de concentration $[N_2O_4]/[M(NO_3)_2]$. De même, si l'on ajoute une solution de nitrate métallique à une solution de N_2O_4, il apparaît une nouvelle vague dont le potentiel, $E_{\frac{1}{2}} \simeq +0{,}74$ V, correspond à celui du système $NO^+ + e^- \rightleftarrows NO$ en présence de N_2O_4 (3*b*) (fig. 1, cas du nitrate d'uranyle). La présence de l'entité NO^+ en solution est confirmée par l'étude en spectroscopie Raman des mélanges équimoléculaires N_2O_4–$Cu(NO_3)_2$, N_2O_4–$UO_2(NO_3)_2$ et N_2O_4–$Zn(NO_3)_2$ dans le sulfolane. En effet, les spectres présentent une bande intense à 2285 cm^{-1}, caractéristique de la vibration d'élongation ν_{NO} de NO^+ (fig. 2) (7). Nous représentons en figure 3 l'évolution du courant limite de diffusion de la vague cathodique attribuée à NO^+ lors de l'addition de nitrate métallique à une solution de N_2O_4. La hauteur de cette vague tend vers une limite, ce qui laisse supposer l'existence d'un équilibre partiellement déplacé. Addison (4) signale, pour le cuivre et l'uranium, la formation des complexes $Cu(NO_3)_3^-$ NO^+ et $UO_2(NO_3)_3^-$ NO^+, et pour le zinc, la formation des complexes $Zn(NO_3)_3^-$ NO^+ et $Zn(NO_3)_4^{2-}$ $2NO^+$, lors de l'addition de nitrate métallique à N_2O_4 liquide. La réaction peut donc s'écrire, dans le cas des ions cuivrique et uranyle,

$$[2] \quad M(NO_3)_2 + N_2O_4 \rightleftarrows M(NO_3)_3^- + NO^+$$

Cette réaction laisse présager que la dissociation de $M(NO_3)_3^-$ en $M(NO_3)_2$ et NO_3^- est plus faible que celle de N_2O_4 selon $N_2O_4 \rightleftarrows NO^+ + NO_3^-$. Il est à noter que le complexe $[Zn(NO_3)_4][NO]_2$ se décompose à température ambiante (4). Des travaux récents (8) confirment, dans le cas de l'uranium, que seul le complexe $[UO_2(NO_3)_3^-][NO^+]$ existe. Notre étude portera, dans une première étape, sur les sels de cuivre et d'uranyle.

I. *Constantes d'équilibre de la réaction de N_2O_4 avec les nitrates de cuivre et d'uranyle dans le sulfolane*

L'étude électrochimique des mélanges N_2O_4–$M(NO_3)_2$ (avec $M^{2+} = Cu^{2+}$ et UO_2^{2+} et $[M(NO_3)_2]/[N_2O_4] \simeq 1$) montre que: (*i*) en voltammétrie cyclique, l'intensité du courant du pic cathodique i_c^p est proportionnelle à la racine carrée de la vitesse de balayage de potentiel; (*ii*) par voltammétrie linéaire, le courant limite i_l est proportionnel à la racine carrée de la vitesse de rotation de l'électrode. Le processus électrochimique n'est donc pas contrôlé par la cinétique de la réaction chimique [2]. La réduction de N_2O_4 en présence de nitrate métallique peut s'interpréter selon le processus

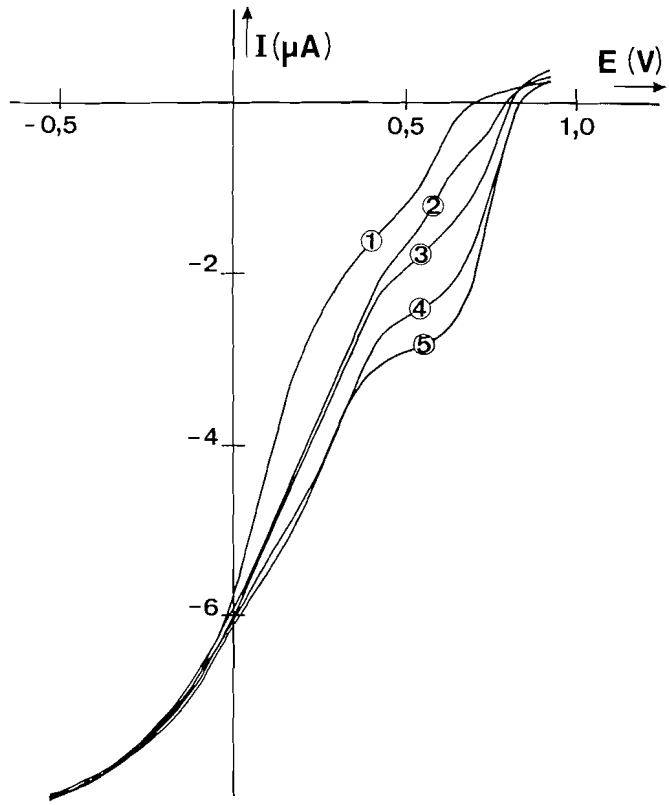

FIG. 1. Courbes intensité–potentiel obtenues dans le sulfolane à 303 K (électrode de platine poli) lors de l'addition de nitrate d'uranyle à une solution de N_2O_4. Électrolyte indifférent: $[(C_2H_5)_4NClO_4]$ = 0,1 mol dm^{-3}. $[N_2O_4]$ = 6,83 × 10^{-3} mol dm^{-3}; $[UO_2(NO_3)_2]$ = 0 (1), 1,01 × 10^{-3} (2), 2,47 × 10^{-3} (3), 4,90 × 10^{-3} (4), 6,87 × 10^{-3} mol dm^{-3} (5).

$$[2] \quad N_2O_4 + M(NO_3)_2 \rightleftarrows NO^+ + M(NO_3)_3^-$$

$$NO^+ + e^- \rightleftarrows NO$$

Le courant limite de diffusion étant proportionnel à la concentration de NO^+, soit $i_l(NO^+) = k_{NO^+}[NO^+]$, il est possible, connaissant le coefficient de proportionnalité $i_l(NO^+)/[NO^+]$ de la réduction de NO^+ (obtenue lors de l'étude d'une solution de $NOClO_4$) pour une même électrode tournante (surface: 0,50 mm^2) animée d'une vitesse de rotation identique (ω = 62,8 rad s^{-1}): k_{NO^+} = 770 ± 15 μA dm^3 mol^{-1}, d'atteindre la concentration en NO^+ libre. Nous pouvons ensuite déduire la constante d'équilibre $K_M^* = [NO^+][M(NO_3)_3^-]/[N_2O_4] \times [M(NO_3)_2]$, relative à la réaction [2]. À 303 K, les constantes K_M^* sont égales à 2,5 ± 0,4 et 1,7 ± 0,2, respectivement, pour $M^{2+} = Cu^{2+}$ et UO_2^{2+}. Ces constantes sont en accord avec une réaction [2] non totalement déplacée. En utilisant la valeur de la constante de formation de N_2O_4 selon $NO^+ + NO_3^- \rightleftarrows N_2O_4$, soit $K_{N_2O_4}^* = 1{,}6 \times 10^{+7}$ mol^{-1} dm^3 (2), nous pouvons atteindre les constantes de stabilité des complexes métalliques trinitrato à partir de la relation

$$K_3^*(M) = [M(NO_3)_3^-]/[M(NO_3)_2][NO_3^-] = K_M^* K_{N_2O_4}^*$$

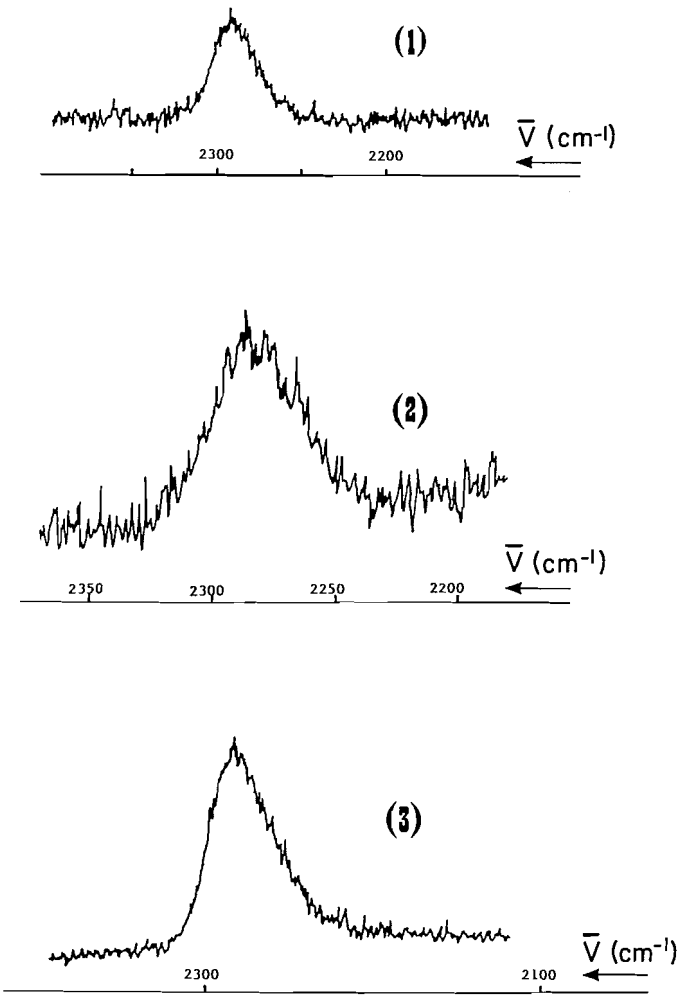

FIG. 2. Spectres Raman de mélanges N_2O_4 + $M(NO_3)_2$ dans le sulfolane. $[N_2O_4] = [M(NO_3)_2] = 0{,}2$ mol dm^{-3}. $\nu_0 = 488{,}0$ nm; puissance, 150 mW. N_2O_4 + $UO_2(NO_3)_2$ (1); N_2O_4 + $Zn(NO_3)_2$ (2); N_2O_4 + $Cu(NO_3)_2$ (3).

À 303 K, la constante $K_3^*(M)$ est égale à $4{,}0 \times 10^{+7}$ et $2{,}7 \times 10^{+7}$ mol^{-1} dm^3 respectivement pour le cuivre[II] et l'ion uranyle.

Les valeurs des constantes de dissociation des complexes trinitrato $M(NO_3)_3^-$ ($1/K_3^*(M)$) sont donc très proches de celle relative à la constante de dissociation ionique de N_2O_4 ($K^i_{N_2O_4} = 1/K^*_{N_2O_4}$), ce qui confirme la présence d'une réaction [2] équilibrée entre les nitrates métalliques et N_2O_4. Généralement les constantes de stabilité des complexes tétracoordonnés sont plus faibles que celles des complexes tricoordonnés; c'est le cas du cuivre[II] en présence du ligand Cl^- dans les solvants eau (9–11), acétonitrile (12), diméthylsulfoxyde (13, 14). Il était intéressant de confirmer cette hypothèse dans le cas du zinc[II] afin de montrer que le complexe $Zn(NO_3)_4(NO)_2$ n'existe pas dans le sulfolane. Ne pouvant déterminer la constante de stabilité du complexe $Zn(NO_3)_4^{2-}$, nous nous sommes intéressés à la complexation du zinc[II] avec le ligand Cl^- de comportement voisin de celui de l'ion NO_3^-.

II. *Constantes de stabilité des complexes chlorozincates[II] dans le sulfolane*

Il existe peu de travaux relatifs à la stabilité des complexes du zinc[II] en milieu aprotonique. Citons pour exemple ceux réalisés dans le solvant DMSO (16).

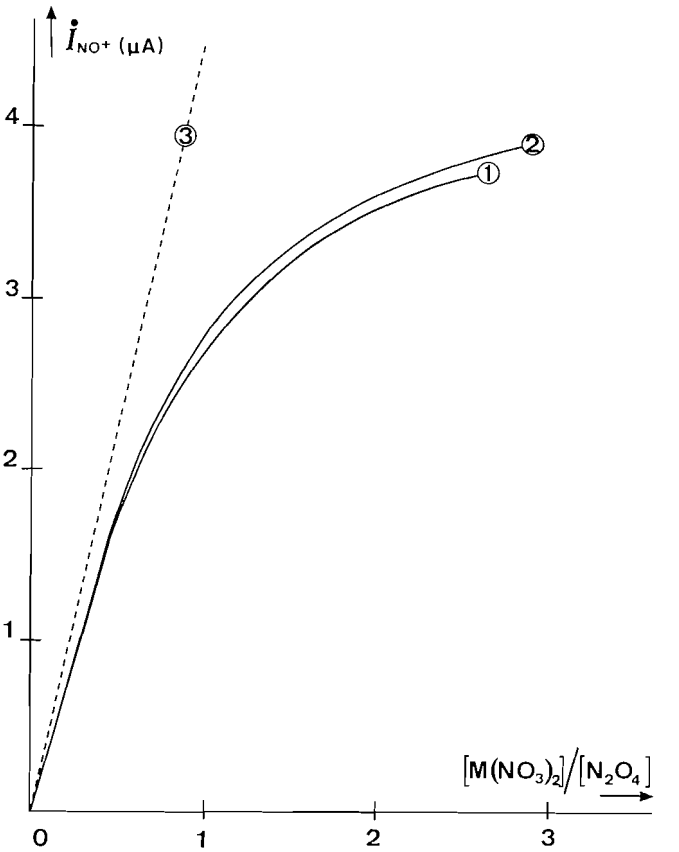

FIG. 3. Variation du courant limite ($i_l(NO^+)$) obtenu lors de l'addition de nitrate métallique à une solution $5{,}96 \times 10^{-3}$ mol dm^{-3} de N_2O_4 dans le sulfolane à 303 K (électrode de platine poli). Électrolyte indifférent: $[(C_2H_5)_4NClO_4] = 0{,}1$ mol dm^{-3}. $UO_2(NO_3)_2$ ou $Zn(NO_3)_2$ (1); $Cu(NO_3)_2$ (2); courant limite de diffusion pour une solution de NO^+ (3).

Afin d'accéder aux valeurs des constantes de stabilité K_i^* des complexes chlorozincates[II] relatives aux équilibres

[3] $\quad ZnCl_{i-1}^{3-i} + Cl^- \rightleftarrows ZnCl_i^{2-i}$

avec $i = 1, 2, 3, 4$

$$K_i^* = \frac{[ZnCl_i^{2-i}]}{[ZnCl_{i-1}^{3-i}][Cl^-]}$$

nous avons cherché à intégrer chacun de ces équilibres dans un couple électrochimique. Les complexes $ZnCl_4^{2-}$, $ZnCl_3^-$, $ZnCl_2$ et $ZnCl^+$ étant meilleurs donneurs de Cl^- que AgCl, nous avons pensé atteindre les constantes de stabilité de ces espèces grâce à l'utilisation de l'électrode d'argent recouverte de chlorure d'argent. En effet, cette électrode est indicatrice de la concentration de chlorure dans le sulfolane (2).

Nous avons suivi la neutralisation d'une solution de $ZnCl_4^{2-}$ (obtenue en mélangeant $ZnCl_2$ et $(C_2H_5)_4NCl$ dans un rapport de concentrations égal à 1/2) par une solution de perchlorate d'argent, par potentiométrie à courant nul. La courbe de titrage fait apparaître trois sauts de potentiel pour les rapports $[Ag^+]/[Cl^-]$: 0,25; 0,5; 1 (fig. 4). Ces sauts sont caractéristiques respectivement des réactions suivantes:

[4] $\quad ZnCl_4^{2-} + Ag^+ \rightarrow AgCl\downarrow + ZnCl_3^-$

[5] $\quad ZnCl_3^- + Ag^+ \rightarrow AgCl\downarrow + ZnCl_2$

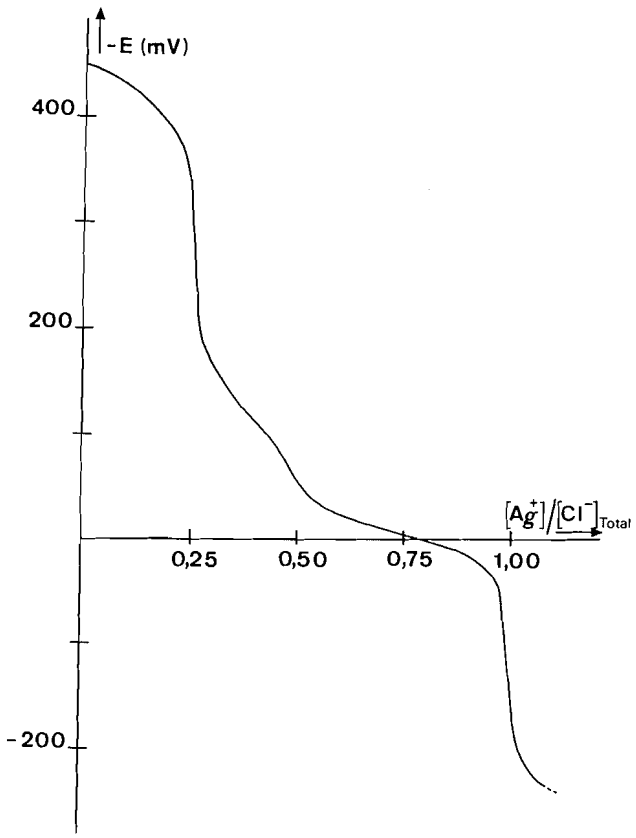

FIG. 4. Courbe potentiométrique (électrode Ag/AgCl) de dosage d'une solution de $ZnCl_4^{2-}$ ($0,5 \times 10^{-2}$ mol dm^{-3}) par une solution de $AgClO_4$ (0,2 mol dm^{-3}) dans le sulfolane. Électrolyte indifférent: $[(C_2H_5)_4NClO_4] = 0,1$ mol dm^{-3}.

et des deux réactions non discernables

[6] $ZnCl_2 + Ag^+ \rightarrow AgCl_\downarrow + ZnCl^+$

[7] $ZnCl^+ + Ag^+ \rightarrow AgCl_\downarrow + Zn^{2+}$

qui peuvent s'écrire globalement

$$ZnCl_2 + 2Ag^+ \rightarrow 2AgCl_\downarrow + Zn^{2+}$$

L'équation de Nernst appliquée au système électrochimique ([4]–[7])

[8] $ZnCl_i^{2-i} + Ag_\downarrow \rightleftarrows AgCl_\downarrow + ZnCl_{i-1}^{3-i} + e^-$

avec $i = 1, 2, 3, 4$, donne

$$E = E_0^i + 2{,}303 \frac{RT}{nF} \log \frac{[ZnCl_{i-1}^{3-i}]}{[ZnCl_i^{2-i}]}$$

L'analyse mathématique de la courbe de titrage montre que les réactions [4] et [5] sont rapides. Les coefficients de la loi de Nernst expérimentaux sont très proches de la valeur théorique (59 mV par unité logarithmique pour le couple [4] et 61 mV par unité logarithmique pour le couple [5]). Les potentiels normaux E_0^2 et E_0^3 ont été déterminés et ont pour valeurs respectives -420 mV et -124 mV (± 3 mV). Ces valeurs jointes aux valeurs du potentiel normal du système Ag^+/Ag (+373 mV (5)) et du produit de solubilité de AgCl ($3,7 \times 10^{-19}$ mol^2 dm^{-6} (5)), dans le sulfolane, permettent de calculer les constantes log K_4^* et log K_3^*, qui ont respectivement pour valeurs $+5,2 \pm 0,2$ et $+10,1 \pm 0,2$.

En ce qui concerne la variation de potentiel relative aux deux réactions simultanées [6] et [7], nous avons effectué un traitement mathématique des données par affinement selon la méthode des moindres carrés. Les résultats obtenus sont: coefficient expérimental de la loi de Nernst, $60 \pm 0,5$ mV; log $K_1^* = 12,1 \pm 0,2$; log $K_2^* = 13,4 \pm 0,2$; potentiels normaux $E_0^1 = +71 \pm 3$ mV et $E_0^2 = -7 \pm 2$ mV. Nous constatons que la constante K_2^* est supérieure à K_1^* comme le laissait présager la courbe potentiométrique où les neutralisations de $ZnCl_2$ et $ZnCl^+$ ne sont pas séparées. Ce phénomène a déjà été observé dans des solvants autres que le sulfolane: DMSO (16), méthanol (17), avec les ligands Cl^-, Br^-, I^- et SCN^-.

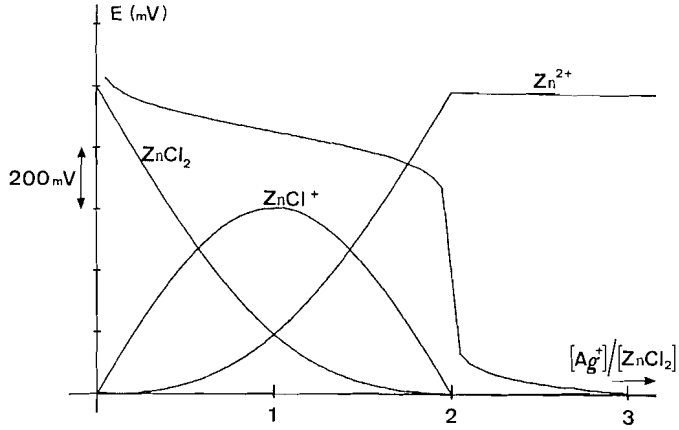

FIG. 5. Simulation de la neutralisation d'une solution de $ZnCl_2$ par $AgClO_4$. Évolution de la concentration des espèces $ZnCl_2$, $ZnCl^+$ et Zn^{2+} au cours du dosage.

À l'aide des valeurs des constantes K_1^* et K_2^*, nous avons effectué la simulation d'un dosage d'une solution de $ZnCl_2$ par $AgClO_4$ (fig. 5). Nous avons également reporté sur cette figure l'évolution de la concentration des différentes espèces au cours du dosage. Les deux réactions [6] et [7] donnent naissance a une seule vague, comme nous l'avons constaté expérimentalement.

Les complexes $ZnCl_4^{2-}$, $ZnCl_3^-$ sont plus stables dans le sulfolane et le diméthylsulfoxyde (16) (solvants aprotoniques) que dans le méthanol (17) et l'eau (18), en raison des propriétés peu solvatantes du sulfolane et du DMSO (tableau 1). Ces résultats sont en accord avec les hypothèses formulées par Ahrland (19), relatives à la solvatation des complexes métalliques en milieux protoniques et aprotoniques. En effet, les ligands susceptibles de former des liaisons hydrogènes sont fortement solvatés par les solvants protoniques, ce qui diminue la stabilité des complexes.

III. *Constante de stabilité du complexe trinitratozincate[II] dans le sulfolane*

Nous avons vu que la stabilité du complexe tétrachlorozincate[II] est plus faible que celle du trichlorozincate[II] (log $K_3^* = +10,1 \pm 0,2$ et log $K_4^* = 5,2 \pm 0,2$ à 303 K), ce qui est en accord avec les résultats relevés, dans le cas du cuivre, pour un solvant à propriété physique voisine du sulfolane (pouvoir donneur (DN) = 14,8), l'acétonitrile (DN = 14,1) (12). Cet écart de stabilité doit être retrouvé avec les complexes du nitrate tri- et tétra-coordonnés puisque les ligands Cl^- et NO_3^- ont, dans notre solvant, des solvatations très voisines: (*i*) les constantes d'acidité de HNO_3 et HCl sont proches, soit 16 (3*a*) et 14,5 (20), respectivement; (*ii*) les constantes d'homoconjugaison de HNO_3 et HCl ($AH + A^- \rightleftarrows A_2H^-$) sont toutes deux égales à 3,1 (2, 3*a*).

La réaction de N_2O_4 avec le complexe trinitrato selon

[9] $N_2O_4 + Zn(NO_3)_3^- \rightleftarrows NO^+ + Zn(NO_3)_4^{2-}$

doit être peu déplacée vers la formation du complexe nitrosyle,

TABLEAU 1. Constantes de stabilité des complexes chlorozincates[II]: $Zn(Cl)_i^{2-i}$ (i = 1, 2, 3, 4), en milieux protoniques et aprotoniques, relatives aux équilibres

$$Zn(Cl)_{i+1}^{3-i} + Cl^- \rightleftarrows Zn(Cl)_i^{2-i} \; (K_i^*)$$

Solvant (DN[a])	log K_1^*	log K_2^*	log K_3^*	log K_4^*	Réf.
Eau (DN = 18,0)	−0,19	−0,40	0,75	—	18
Méthanol	3,9	4,3	—	—	17
Diméthylsulfoxyde (DN = 29,8)	1,94	3,89	2,26	—	16
Sulfolane (DN = 14,8)	12,1±0,2	13,4±0,2	10,1±0,2	5,2±0,2	[b]

[a]Pouvoir donneur du solvant selon l'échelle de basicité de Gutmann et coll. (15).
[b]Nos valeurs.

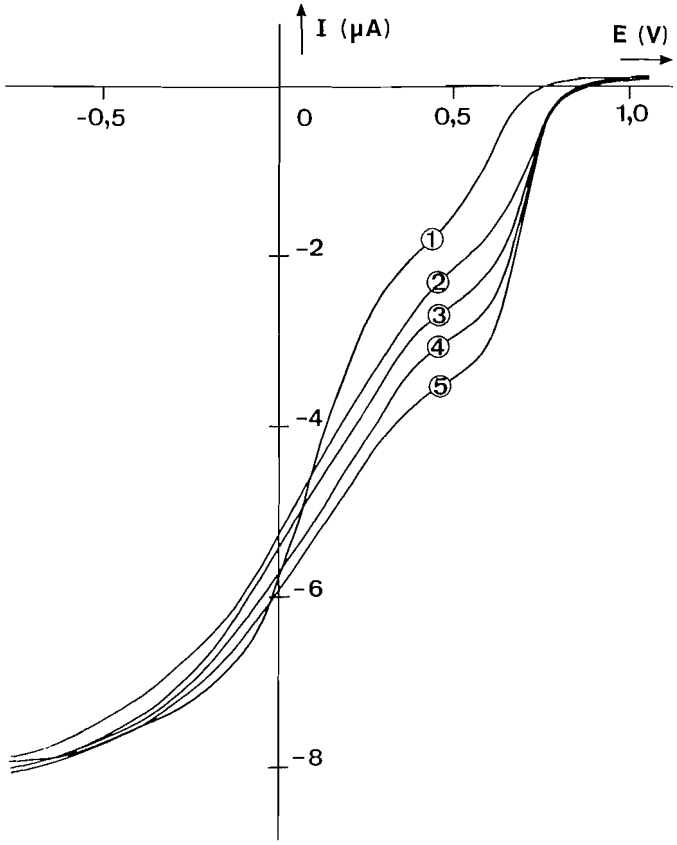

FIG. 6. Courbes intensité–potentiel obtenues dans le sulfolane à 303 K (électrode de platine poli) lors de l'addition de nitrate de zinc à une solution de N_2O_4. Électrolyte indifférent: $[(C_2H_5)_4NClO_4]$ = 0,1 mol dm^{-3}. $[N_2O_4] = 5{,}96 \times 10^{-3}$ mol dm^{-3}; $[Zn(NO_3)_2] = 0$ (1), $3{,}10 \times 10^{-3}$ (2), $5{,}30 \times 10^{-3}$ (3), $7{,}20 \times 10^{-3}$ (4), $11{,}40 \times 10^{-3}$ mol dm^{-3} (5).

et donc négligeable. Cette hypothèse est d'ailleurs confirmée par l'allure des courbes $i = f(E)$ obtenues au cours de l'addition de nitrate de zinc à une solution de N_2O_4 (fig. 6), allure très semblable à celle des courbes relatives aux mélanges N_2O_4 + $UO_2(NO_3)_2$ (fig. 1) donnant lieu uniquement à la formation d'un complexe $[(UO_2(NO_3)_3][NO]$.

De plus, la courbe représentant l'évolution du courant limite ($i_l(NO^+)$) de réduction de NO^+ (formé au cours de la réaction [2]) en fonction du rapport $[Zn(NO_3)_2]/[N_2O_4]$ (fig. 3), coïncide bien avec celle exprimant $i_l(NO^+)$ en fonction de $[UO_2(NO_3)_2]/[N_2O_4]$. Il est alors possible de déterminer la constante de la réaction

[10] $N_2O_4 + Zn(NO_3)_2 \rightleftarrows NO^+ + Zn(NO_3)_3^-$

par une étude similaire à celle réalisée avec les nitrates de cuivre et d'uranyle. La constante de la réaction [10] est égale à 1,8 ± 0,3, et la constante de stabilité du complexe trinitratozincate[II] est égale à $2{,}9 \times 10^{+7}$ mol^{-1} dm^3 à 303 K. Cette valeur, proche de celle de la constante de dissociation ionique de N_2O_4, empêche, dans le sulfolane, la formation par N_2O_4 de complexes plus coordonnés. La spectroscopie Raman apporte une preuve directe de la formation d'un sel de nitrosyle, lors de l'étude d'une solution équimoléculaire N_2O_4–$Zn(NO_3)_2$ (fig. 2), mais ne permet pas de conclure sur l'absence en solution du complexe $Zn(NO_3)_4^{2-}$; les bandes caractéristiques des vibrations de NO_3^- libre ou complexé sont masquées par les raies intenses et larges du sulfolane. Notons que la stabilité du complexe $Zn(NO_3)_3^-$ ($K_3^*(Zn) = 2{,}9 \times 10^{+7}$ dm^3 mol^{-1} à 303 K) est légèrement plus faible que celle du complexe $Cu(NO_3)_3^-$ ($K_3^*(Cu) = 4{,}0 \times 10^{+7}$ dm^3 mol^{-1} à 303 K), ce qui est en accord avec la classification des métaux en fonction de leur pouvoir complexant proposée par Irving et Williams (21).

En résumé, la présence de l'acide de Lewis $Zn(NO_3)_2$, dans une solution de N_2O_4, conduit dans le sulfolane à la formation de NO^+ et du complexe trinitratozincate[II]. Cette réaction est observée dans notre solvant grâce à une stabilité du complexe $Zn(NO_3)_3^-$ ($K_3^*(Zn) = 2{,}9 \times 10^{+7}$ dm^3 mol^{-1} à 303 K) voisine de celle de N_2O_4 selon $NO^+ + NO_3^- \rightleftarrows N_2O_4$ ($K_{N_2O_4}^* = +1{,}6 \times 10^{+7}$ dm^3 mol^{-1} à 303 K).

Conclusion

L'utilisation de la voltampérométrie a permis d'élucider le mécanisme de la réduction de N_2O_4 en présence des nitrates métalliques $Zn(NO_3)_2$, $Cu(NO_3)_2$ et $UO_2(NO_3)_2$ en milieu aprotonique:

[C] $N_2O_4 + M(NO_3)_2 \rightleftarrows NO^+ + M(NO_3)_3^-$

[E] $NO^+ + e^- \rightleftarrows NO$

Le processus électrochimique est contrôlé par le transfert monoélectronique réversible mis en jeu lors de la réduction de NO^+ en NO (système [E]). Ce résultat a rendu possible la détermination de la constante d'équilibre de la réaction [C], (K_M^*), et celle relative à la formation du complexe métallique trinitrato, $K_3^*(M)$, selon $M(NO_3)_2 + NO_3^- \rightleftarrows M(NO_3)_3^-$. À 303 K, les valeurs trouvées sont: $K_{Zn}^* = 1{,}8 \pm 0{,}3$; $K_{Cu}^* = 2{,}5 \pm 0{,}4$; $K_{UO_2}^* = 1{,}7 \pm 0{,}2$; $K_3^*(M) = 2{,}9 \times 10^{+7}$, $4{,}0 \times 10^{+7}$ et $2{,}7 \times 10^{+7}$ mol^{-1} dm^3, respectivement pour M = Zn, Cu et UO_2. Nous

avons négligé l'intervention des entités $M(NO_3)_4^{2-}$, $M(NO_3)^+$ et M^{2+}, dans les réactions précédentes, en raison de leur concentration trop faible dans la solution. Cette hypothèse a été confirmée par des travaux sur les mélanges N_2O_4–$M(NO_3)_2$ signalés dans la littérature, et par nos résultats obtenus dans la série des complexes chlorozincates[II] où la base Cl^- a un comportement vis-à-vis du métal Zn^{2+} très semblable à celui de NO_3^-.

L'addition de ces nitrates métalliques dans une solution de N_2O_4 permet donc, en milieu aprotonique, le déplacement de la base nitrate dans l'équilibre de dissociation ionique $N_2O_4 \rightleftarrows NO^+ + NO_3^-$, en libérant l'espèce NO^+. L'emploi facile de ces sels minéraux ainsi que leur grande solubilité dans le sulfolane, nous ont conduits à les utiliser comme agent catalytique dans les réactions de nitration par N_2O_4 des noyaux aromatiques (en générant en solution l'espèce catalytique NO^+) (1).

Remerciements

The electrochemical oxidation of 2,5-dihydroxybenzoic acid on a mercury electrode in aqueous solutions

D. SAZOU AND N. PAPADOPOULOS

Laboratory of Physical Chemistry, Department of Chemistry, University of Thessaloniki, Thessaloniki, Greece

Received August 29, 1984[1]

D. SAZOU and N. PAPADOPOULOS. Can. J. Chem. **64**, 11 (1986).

The electrochemical behaviour of 2,5-dihydroxybenzoic acid (2,5-DHBA) has been studied in the pH range 5.5–12.7 at a hanging mercury drop electrode (HMDE). Voltammograms show the existence of one reversible wave of 2,5-DHBA governed by diffusion conditions. In the oxidation process a two-electron transfer takes place, as shown by the controlled potential electrolysis. From the calculation of the voltammetric parameters (peak width $E_p - E_{p/2}$, peak current function $i_p/\sqrt{v}$) and from the other experimental data, a mechanism for the overall reaction in two different pH ranges, 5.5–9.5 and 9.5–12, is proposed.

D. SAZOU et N. PAPADOPOULOS. Can. J. Chem. **64**, 11 (1986).

Le comportement électrochimique de l'acide dihydroxy-2,5 benzoïque a été étudié à des pH allant de 5,5 à 12,7, à l'aide d'une électrode de mercure à goutte tombante. La vague réversible cyclovoltammétrique de l'acide dihydroxy-2,5 benzoïque est contrôlée par la diffusion. Le processus d'oxydation implique un transfert de deux électrons. Sur la base de calculs des paramètres voltammétriques (largeur du pic à mi-hauteur, $E_p - E_{p/2}$, et la fonction du courant du pic) ainsi que sur la base des autres données expérimentales, on propose un mécanisme concernant la réaction globale dans deux régions différentes de pH (5,5–9,5 et 9,5–12,0).

Introduction

Several studies have been carried out on the electrochemical behaviour of the hydroquinone–quinone system in aqueous as well as in nonaqueous solutions at different electrodes (1–9).

The oxidation–reduction potentials of a number of quinones have been studied to determine the aromatic character, particularly in the fused ring systems (10, 11). Ring substituents have a significant effect on these potentials, and the course of many reactions is regulated by them. Methyl substituted quinones have also been studied (12, 13).

The hydroxy-derivatives of salicylic acid, classical reagents in inorganic analytical chemistry, belong to the group of substituted hydroquinones. Very few papers have been reported on their complex formation and on the determination of their protonation constants (14–16). The monosubstituted hydroquinones with strong electron-withdrawing substituents such as —COOH, —CHO, and —NO_2 undergo anodic hydroxylation at low potentials in aqueous solutions. The evidence for this anodic hydroxylation has been provided by electrochemical techniques with carbon – Nujol paste electrodes for voltammetric studies and carbon cloth for preparative scale electrolysis (17, 18).

In this paper, we investigate the electrochemical behaviour of 2,5-dihydroxybenzoic acid (DHBA) in the pH range 5.5–12.7 phosphate buffer, at a hanging mercury drop electrode (HMDE). We attempted to investigate, under the same conditions, the electrochemical behaviour of 2,6- and 2,4-dihydroxybenzoic acids, but an oxidation wave was not obtained at the potential range available on mercury.

Experimental

2,5-Dihydroxybenzoic acid (2,5-DHBA), from Fluka A. G. "puriss p.a.", was purified by recrystallization from water and dried under vacuum.

As a supporting electrolyte solution, a solution buffered with phosphates was used. The ionic strength was 0.3 *M*. All reagents used were Fluka A. G. "puriss p.a.". The solutions of 2,5-DHBA were freshly prepared, after the deaeration of the supporting electrolyte. High purity argon was used for oxygen removal and all measurements were carried out in an argon atmosphere and at a temperature of 25 ± 0.1°C.

Cyclic voltammetric measurements were carried out on a HMDE (PAR 9323) of surface area 3.51×10^{-2} cm^2. A Pt sheet and a calomel electrode were used as counter and reference electrodes, respectively, and they were separated from the working electrode compartment by glassy diaphragms.

Electrolysis was carried out using a mercury pool working electrode.

The experimental setup included a G. Bank Electronic PCA-72L potentiostat, a G. Bank Electronic VSG-72L function generator, and a Hewlett Packard 7045A X–Y recorder.

Results

Cyclic voltammetric behaviour

The electrochemical behaviour of 2,5-DHBA was studied as a function of increasing pH. In acid solution, pH range 2–5, the 2,5-DHBA does not give any oxidation wave at a HMDE, in contrast to the hydroquinone, which under the same conditions gives a regular reversible wave from pH = 2.

At pH 5–6 one poorly-defined oxidation–reduction wave appears, while at pH 6 a well-defined wave is obtained. 2,5-DHBA oxidizes to the corresponding quinoid form, which, on the cathodic scan, reduces to the initial substance.

The peak separation, $E_{pa} - E_{pc}$, is equal to about 35 mV over the whole pH range studied.

In Fig. 1, the cyclic voltammogram of 2,5-DHBA in neutral solution at different sweep rates, v, is shown as an example. The peak current, i_p, at these scan rates is directly proportional to the 2,5-DHBA concentration, C, over the whole pH range, and, at the same sweep rates and pH values, the slope of the log i_p – log C line is equal to unity.

The peak potential, E_p, corresponding to the oxidation wave, does not vary with scan rate (Fig. 2). It can be seen that the plot is a straight line almost parallel to the x-axis over the whole scan rate range studied.

At pH about 9.5 the anodic wave of 2,5-DHBA appears to be distorted (split into two poorly-defined waves). This suggests that the depolarizer exists under two different forms. At this pH value the ionization of the first phenolic group begins, as the pK_2 of 2,5-DHBA has been found to be equal to about 10 (16).

[1]Revision received July 4, 1985.

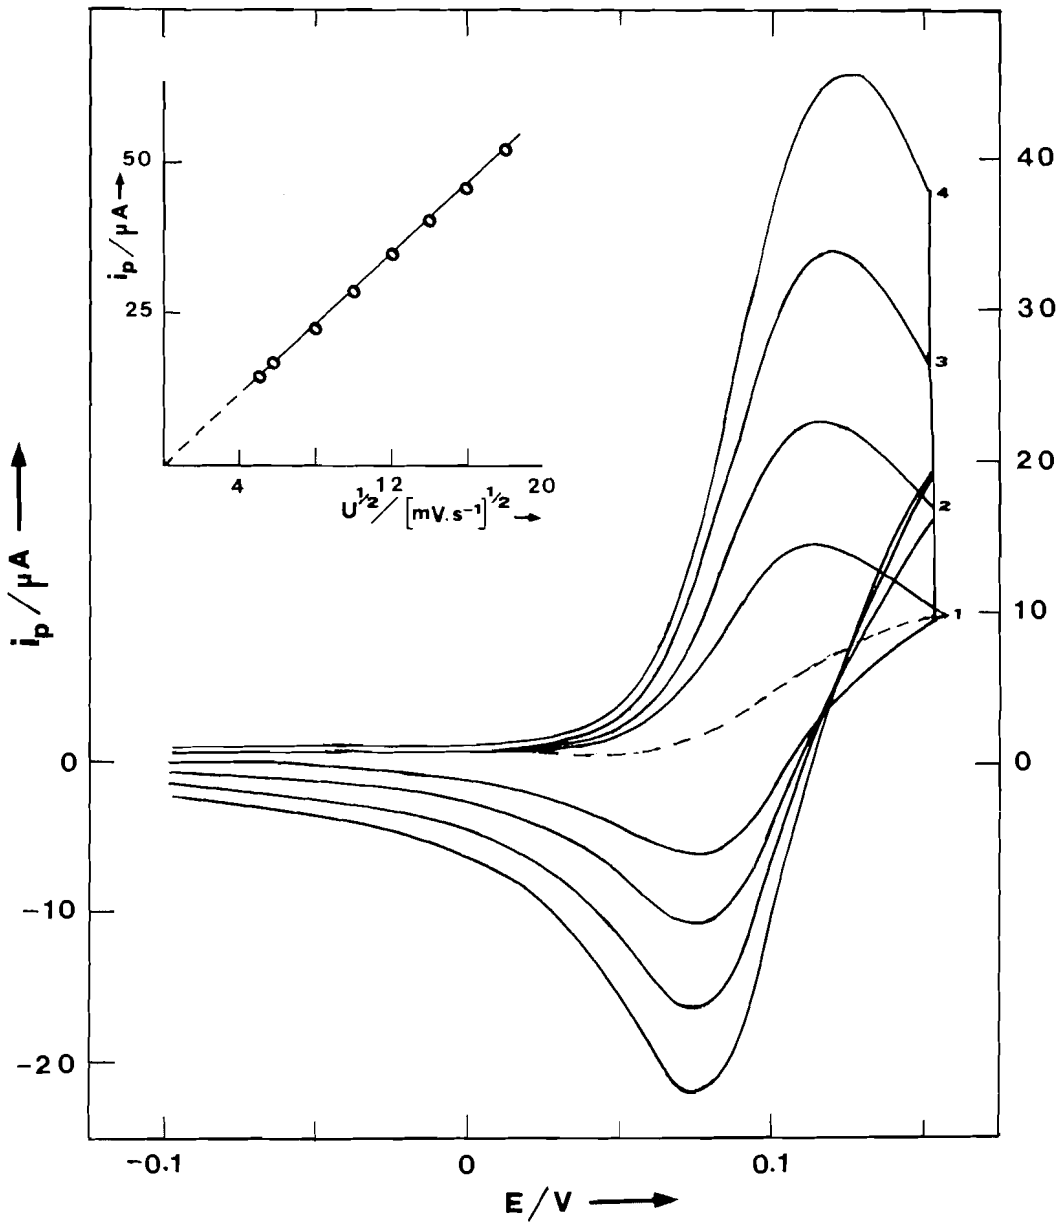

FIG. 1. Cyclic voltammogram of 2,5-DHBA ($C = 10^{-3}$ M) in phosphate buffer pH = 7.4 at different scan rates in mV s^{-1}: (1) 25, (2) 64, (3) 144, (4) 256. Inset: plot of i_p vs. $v^{1/2}$ for the anodic wave at different scan rates in mV s^{-1}: 25, 36, 64, 100, 144, 196, 256, 324.

In the pH range 5.5–9.5, the height of the anodic wave decreases with increasing pH and at pH 9.5 is split into two waves. Above this pH value only one wave appears, and its height decreases again as the pH increases. The peak potential shifts to more negative potentials with an increase in pH. The relationship between E_p and pH is shown in Fig. 3 where the values of the slopes of the linear segments are approximately −60 and −30 mV/pH unit.

At pH >12.7 the mechanism of the overall reaction changes. The cyclic voltammogram (Fig. 4), at this pH, illustrates an anodic wave and a corresponding reduction wave, owing to the oxidation product. At more negative potentials a second cathodic wave with a corresponding oxidation wave on a second scan appears. The first reduction wave, B, is not observed at low sweep rates, but as the scan rate increases, its height increases also. Moreover, when the mercury drop remains for several seconds at −0.15 V, both waves C and D increase. These results are explained by an ece (electrochemical chemical electrochemical) mechanism, in which the products of the chemical reaction are electroactive as well (19, 20). The oxidation product is probably a substituted quinone that, according to the bibliographic data for the behaviour of quinones in alkaline media, forms the intermediate substituted semiquinone resulting from one-electron reduction (17, 18, 21, 22). The radical anion may undergo radical dimerization or may disproportionate (waves C and D) (23).

A detailed study at pH >12.3 will be the subject of other work.

Protons involved in the overall process

As mentioned above, the variation of peak potential, E_p, of the anodic wave with pH is shown in Fig. 3.

The slope $(\partial E_p/\partial \text{pH})_C = (-0.059/n)\cdot p$ gives the number of protons, p, involved in the overall process.

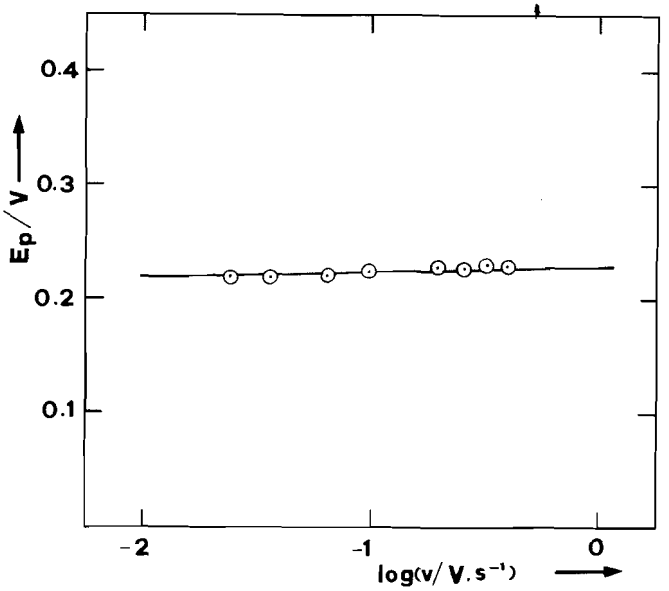

FIG. 2. Dependence of the peak potential, E_p, of the cyclic voltammogram of 2,5-DHBA ($C = 10^{-3}$ M) in phosphate buffer pH = 7.4 on the sweep rate, v.

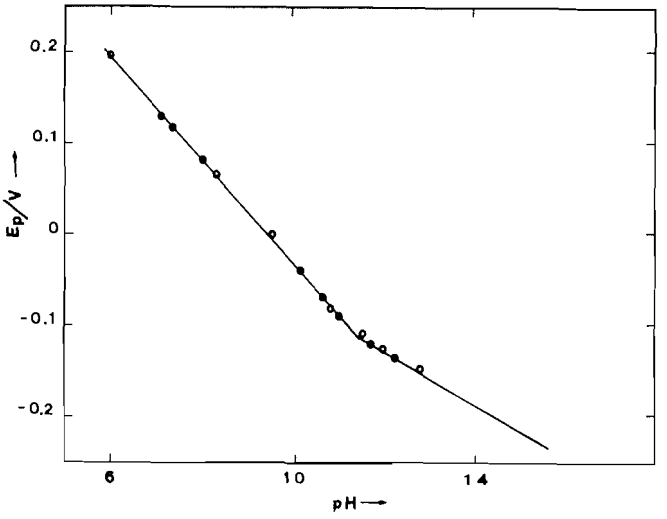

FIG. 3. Peak potential variation with pH for the anodic wave of 2,5-DHBA ($C = 10^{-3}$ M) at the scan rate of 100 mV s^{-1}.

Two linear segments with slopes −60 and −30 mV/pH unit are observed in the pH ranges 5–9.5 and 9.5–12, respectively. These slope values indicate that, in the overall reaction, two protons intervene in the pH range 5–9.5 and one proton intervenes in the pH range 9.5–12.

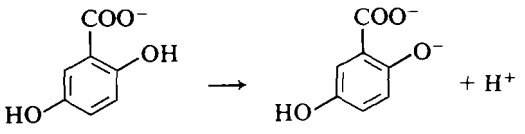
Discussion

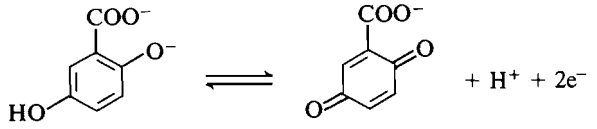
The data obtained indicate that the oxidation of 2,5-DHBA corresponds to a two-electron reversible diffusion controlled charge transfer process.

The slope values of the E_p vs. pH plot indicate that in the overall reaction two protons intervene in the pH range 5.0–9.5, because of the existence of both undissociated phenolic groups, and one proton in the pH range 9.5–12, where the first phenolic group is dissociated. The change in the slope of the plot E_p–pH, at pH about 9.5, is attributed to the second dissociation constant of the 2,5-DHBA ($pK_2 = 10$). These data, together with the pH dependence of the peak current, indicate the occurrence of a chemical reaction involving H^+ ions prior to the electron transfer taking place at the surface of the electrode.

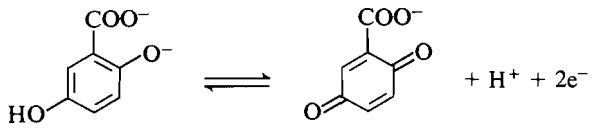
The overall reaction in the two pH ranges can be expressed as follows:

pH = 5.5–9.5





pH = 9.5–12



Finally, the oxidation of 2,5-DHBA seems to be a typical uncomplicated multistep reaction in which both charge transfers are reversible. Both, the initial form and the form that results after the transfer of the first electron, seem to be oxidized at the same potential and the wave observed has a peak height between a one-electron and two-electron reversible wave. These statements are supported by the following experimental results: The peak width, $E_p - E_{p/2}$, has an average value of 40 mV. This means that there is a small difference between the E_0 values for the two individual one-electron transfers (24, 25). The quantity $i_p/\sqrt{v}$ was constant over the wide range of scan rates used. The E_p was not shifted by increasing the scan rate. The ratio i_{pa}/i_{pc} was approximately unity when the base line was properly taken (24–26).

It has been reported by other authors (17, 18) that, in the case of 2-substituted hydroquinones, if the 2-substituent is electron withdrawing, such as —COOH, —CHO, —NO_2, hydroxylation occurs in an overall process, with a total of four electrons being found using controlled potential coulometry.

This hydroxylation was studied using carbon – Nujol paste electrodes and Pt electrodes modified by adsorbed metals and it was found that the M_{ads} promotes the reaction of hydroxylation (17, 18, 27).

However, in our case, in the pH range 5–12 on a mercury electrode, the reaction involves only a two-electron oxidation to the substituted benzoquinone. No evidence for anodic hydroxylation appeared under the voltammetric conditions used in this study.

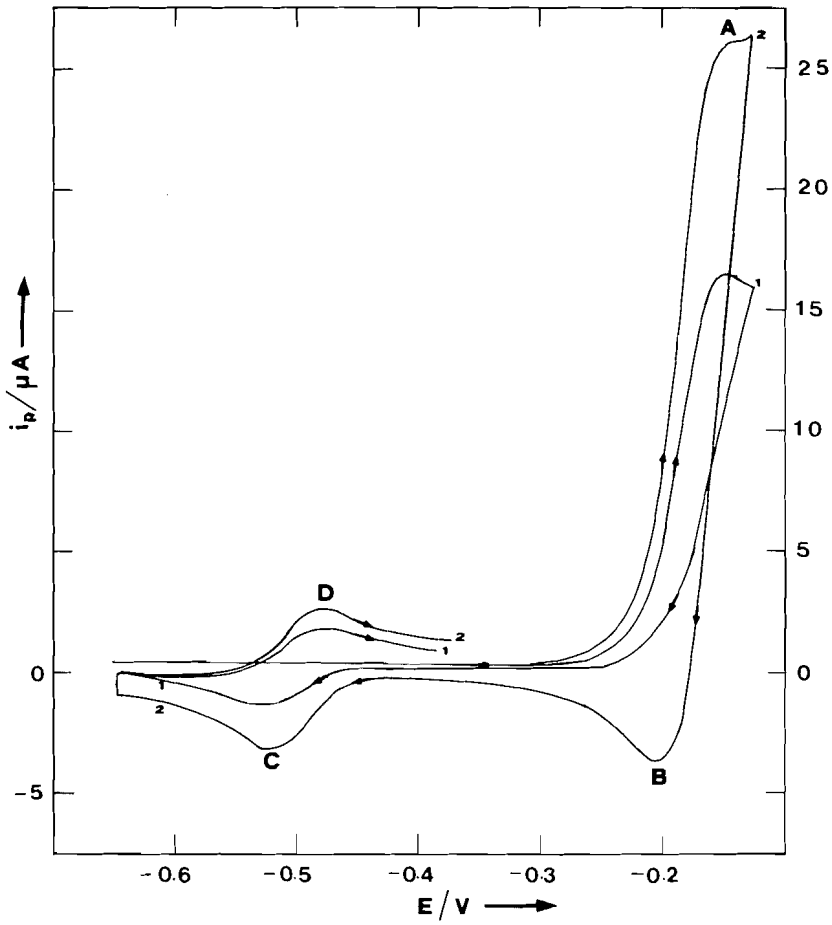


FIG. 4. Cyclic voltammogram of 2,5-DHBA ($C = 10^{-3} M$) at HMDE in phosphate buffer pH = 12.7 at two different scan rates: (1) 25 mV s^{-1}, (2) 100 mV s^{-1}.

Study of the main extracted species of cobalt(II) ion with dodecylthioglycolic acid as extractor

P. BENEITEZ,[1] S. J. ORTIZ, AND J. ORTEGA

Departamento de Electroquímica, Facultad de Ciencias, Universidad Autónoma, Cantoblanco, 28049 Madrid, España

Received November 6, 1984[2]

P. BENEITEZ, S. J. ORTIZ, and J. ORTEGA. Can. J. Chem. **64**, 15 (1986).

The distribution of cobalt(II) between water and an organic extractant (dodecylthioglycolic acid) dissolved in kerosene has been studied using a tracer of ^{60}Co. The aqueous media were always constituted by buffer solutions (acetic acid – sodium acetate) and the ionic strength was adjusted with sodium nitrate to 1 mol dm^{-3}. The main species of cobalt(II) originating in the organic phase has been isolated and characterized on the basis of elemental analysis, thermal gravimetric analysis, and ir spectra.

P. BENEITEZ, S. J. ORTIZ et J. ORTEGA. Can. J. Chem. **64**, 15 (1986).

Utilisant du ^{60}Co comme marqueur, on a étudié la distribution du cobalt(II) entre l'eau et l'acide dodécylthioglycolique, dissous dans du kérosène. Tous les milieux organiques étaient constitués de solutions tampons (acide acétique/acétate de sodium) et, dans chaque cas, on a ajusté la force ionique à 1 mol/dm^3, à l'aide de nitrate de sodium. On a isolé les principales espèces de cobalt(II) qui se retrouvent dans la phase organique et on les a caractérisées en se basant sur l'analyse élémentaire, l'analyse thermogravimétrique et sur les spectres ir.

[Traduit par le journal]

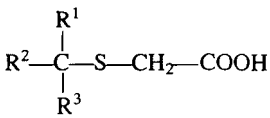
Introduction

Many papers have shown the utility of carboxylic acids in the extraction of metal ions but only some of them have involved a study of the stoichiometry of the extracted species (1–12). The cobalt extraction characteristic has attracted attention over a period of time. The early works of Jaycock and Jones, Schweitzer and Howe (13, 14) postulated that, for the extraction of that metal, the major species in the organic phase was CoR_2, but later works of Jaycock, Gindin, and co-workers (15–17) proposed that a dimeric species is present to a major extent in the organic phase. For the moment the situation concerning the structure of the extracted cobalt species does not appear to be resolved and the purpose of the present work is to report on some new studies. Thus the present paper is concerned with the extraction of cobalt(II) by dodecylthioglycolic acid in kerosene and the characterization of a solid compound isolated from the extract on the basis of elemental analysis, thermal gravimetric analysis, and ir spectra. A carboxylic acid containing a sulphide group in the β position with respect to the carboxylic group has been chosen, since the presence of the sulphur atom emphasizing the acid character of the compound enhances the cobalt ion extraction and allows their separation from stronger acid media.

Experimental

Reagents

The principal solution of ^{60}Co tracer was obtained from the Radiochemical Center of Amersham containing 10 μg Co/mL in the chloride state with an activity of 1 mCi/mL. HDTG acid (dodecylthioglycolic) was obtained from Phillips Petroleum Company with the general structure of:



where $R^1 + R^2 + R^3 = C_{11}H_{25}$, boiling point 220°C, and was used as received. Solutions of this organic acid were prepared in kerosene (S.S.T.) from Sociedad Petrolífera Española, Shell S.A., with dielectric constant 2.03. All the other reagents were of A.R. grade and were used without further purification. The solutions of these chemicals were freshly prepared just prior to use.

Extraction procedure

An aqueous solution (2 cm^3) containing ^{60}Co, buffer reagents (mixtures of acetic acid – sodium acetate 0.1 *M* with different pH), the metal salt (2×10^{-4} *M*), and with the ionic strength adjusted to unity with sodium nitrate was mixed in a glass tube with the same volume of organic solution containing the desired concentration of HDTG, and the tube was shaken for 50 min at constant temperature (25 ± 0.1°C). After equilibration, each sample was centrifuged, a 1-cm^3 portion of each phase was pipetted into a counting tube, and the γ-activity was measured in a well-type scintillation counter (Tracerlab Model 132 MA scaler). The remaining part of the aqueous phase was used for pH measurement with a pH meter (Metrohm Herisau E500) equipped with a glass combination electrode.

Preparation of the metal carboxylate

The metal carboxylate was prepared by extraction of cobalt(II) from an aqueous solution containing this metal (3×10^{-1} *M*) and the ionic strength adjusted to 1 *M* (sodium nitrate) with a solution of HDTG acid (1 *M*) in S.S.T. After equilibration the phases were separated and the organic phase was equilibrated once again with new aqueous solutions of metal. This organic phase, saturated with the metal carboxylate, was mixed with acetone (1:5) and a pink precipitate formed. It was removed, washed with two portions of acetone, recrystallized from ethanol, and dried at 90°C during 2 days.

Analyses

Elemental analysis was carried out by the Microanalytical Unit of the Consejo Superior de Investigaciones Cientificas (C.S.I.C.). The metal and sulphur contents were measured by standard methods (18, 19). The thermal gravimetric analysis was carried out by the Unit of the Instituto del Cemento (Eduardo Torroja).

Physical measurements

The ir spectra were measured between KBr discs and recorded in a Perkin–Elmer 557 spectrophotometer in the 200–4000 cm^{-1} region. The uv and vis spectra were obtained by a Beckman Acta 3-C spectrophotometer. The melting point was determined by a Yanagimoto MP-1 melting point apparatus. The water molecules in the cobalt species were determined by titration with Karl–Fischer reagent and free from a wet atmosphere. Molar conductance measurements were obtained with a Beckman type RC16B2 conductivity bridge using 5×10^{-4} *M* solution in chloroform at 25°C. Magnetic susceptibility measurement was carried out at room temperature by the Gouy method and was corrected for the diamagnetism of the component atoms using Pascal's constants (24).

Results and discussion

The plot of the experimental data, as log D against equilibrium pH, for the extraction of cobalt(II) from nitrate and buffer (HAc–NaAc) solutions with dodecylthioglycolic acid in kerosene leads to a similar curve in both cases, hence the nature of the extracted species is unaffected by acetate ions. Accordingly, and since the use of buffer solutions may contribute certain advantages to the extraction process, we have always used these buffer solutions in the extraction of Co(II).

The most general equilibrium for the extraction of cobalt(II) with a carboxylic acid can be written as follows (13).

$$[1]\quad j\mathrm{Co}^{2+} + 1/2(2j+x)\overline{(\mathrm{HDTG})_2} \rightleftarrows \overline{(\mathrm{Co(DTG)_2})_j(\mathrm{HDTG})_x} + 2j\mathrm{H}^+$$

for which

$$[2]\quad \log D = \log j + \log Kex + 1/2(2j+x)\log(\overline{C_{\mathrm{HDTG}}}) + (j-1)\log C_{\mathrm{Co}} - j\log\alpha_{\mathrm{Me}} + 2j\mathrm{pH} - 1/2(2j+x)\log 2$$

where α_{Me} denotes the side-reaction coefficient of the metal ion in the aqueous phase. Considering that under the experimental conditions of this work the hydrolysis of the metal ion may be assumed insignificant, then $\alpha_{Me} = 1$.

The data obtained in the extraction of cobalt(II) by dodecylthioglycolic acid in S.S.T. are shown in Fig. 1 as log D against equilibrium pH, and it can be seen that the slopes of the least-squares best-line fits range from about 2.6 to 3.4 and therefore j is not unity. The linearity of the plots falls off at high values of pH; it may suggest that at low hydrogen ion concentrations Co^{2+} exists as a mixture of hydrolysed forms. Using the data given in Fig. 1 the plot of log D − log C_{Co} against equilibrium pH leads to straight lines with slopes approximately 4.0 (Fig. 2); then, under the experimental conditions of this study the species of cobalt(II) extracted is dimeric ($j = 2$). From a plot of log D − log C_{Co} − 4 pH against log $(\overline{C_{\mathrm{HDTG}}})$ may be determined the number of acid molecules involving the extracted species. The plot for the experimental data (Fig. 3) leads to a straight line with slope = 2.5 and therefore $x = 1$. Thus, the graphical analysis of the data indicated a complex $(Co(DTG)_2)_2(HDTG)$ as the main extracted species and the extraction equilibrium [1] becomes:

$$[5]\quad 2\mathrm{Co}^{2+} + 5/2\overline{(\mathrm{HDTG})_2} \rightleftarrows \overline{(\mathrm{Co(DTG)_2})_2(\mathrm{HDTG})} + 4\mathrm{H}^+$$

The elemental analysis data of the isolated metal species (found: C 58.28, H 9.80, S 11.25, Co 10.05%) indicate the general formula $C_{28}H_{54}O_4S_2Co$ (*Anal.* calcd.: C 58.21, H 9.42, S 11.09, Co 10.20%). This species in the solid state is slightly soluble in the nonpolar solvents toluene, methanol, and diethyl ether; insoluble in solvents with high dipole moment, such as acetone, DMF, and DMS; and quite soluble in chloroform. The molar conductance in chloroform at 25°C was $\Lambda_m = 35.5\,\Omega^{-1}\,\mathrm{cm}^2\,\mathrm{mol}^{-1}$. It showed low melting point (192–195°C), and it decomposed at a temperature near the melting point showing colour change from pink to black.

The thermal gravimetric analysis study showed that the species was stable up to 200°C. At this temperature decomposition of the organic matter took place and the thermolysis curve showed a weight loss of about 80% of the whole weight (weight of sample 283.1 mg), all of which suggested that the isolated cobalt(II) species was not hydrated. The destruction of organic matter continued up to 310°C; at this point a perfectly horizontal stretch began, corresponding to the carbonate $CoCO_3$, and which continued up to 850°C. A new weight loss began at this temperature, to give finally a horizontal line due to the oxide Co_3O_4, which extended above 950°C. The titration with Karl–Fischer reagent for determination of water molecules likewise showed that the isolated cobalt species was anhydrous.

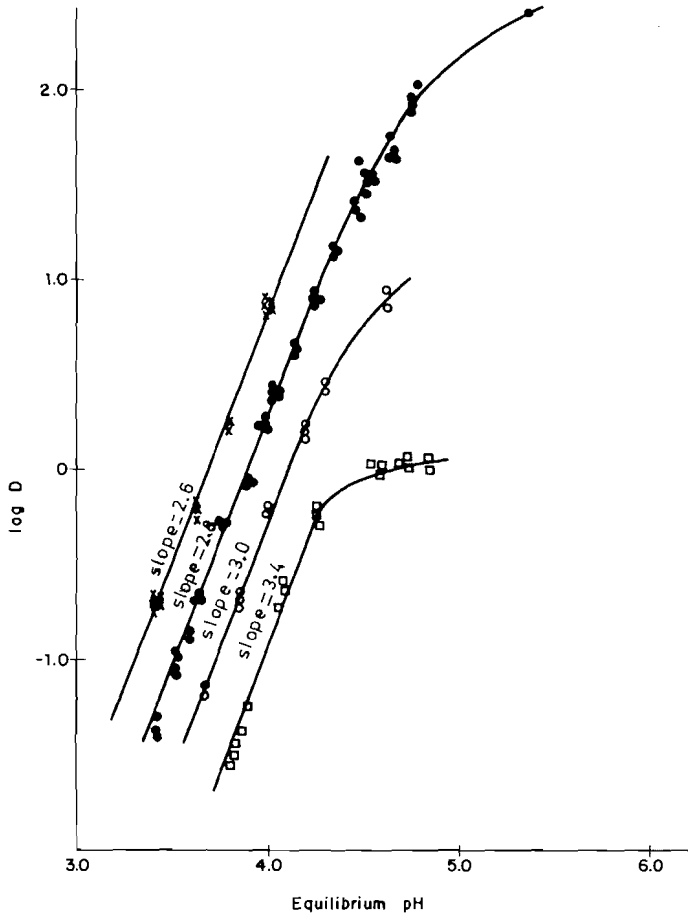

FIG. 1. Extraction of Co(II) with dodecylthioglycolic acid in kerosene. Acid concentration: ×, 1.0 *M*; ●, 0.5 *M*; ○, 0.25 *M*; □, 0.1 *M*.

The ir spectrum of the organic solution with the metallic species indicates the presence of the metal carboxylate; it shows two bands at 1590 cm^{-1} and 1385 cm^{-1}, which correspond to the antisymmetrical and symmetrical vibrations of the COO^- structure, respectively (21). Two strong bands at 1710 cm^{-1} and 1290 cm^{-1}, arising from the stretching vibration of the C=O and C—O in the COOH group, respectively, denote the presence of acid molecules in excess. One absorption band at 1645 cm^{-1} suggests an internal association (21), which is supported by the appearance of another band at 300 cm^{-1} attributed to ν(Me-S) (22). The ir spectrum of the pink precipitate formed exhibits almost the same pattern as that of the species in solution (bands at 1590 cm^{-1}, 1385 cm^{-1}, 1645 cm^{-1}, and 300 cm^{-1}). The absence of absorption bands at 1710 cm^{-1} and 1290 cm^{-1} suggests the absence of acid molecules in excess and therefore involving the complex. Likewise, the absence of a C=O stretching vibration band (1725–1690 cm^{-1}) shows the absence of an addition complex between the acetone and the extracted species, which was expected since the acetone rarely forms stable complexes. The magnetic moment of the compound is

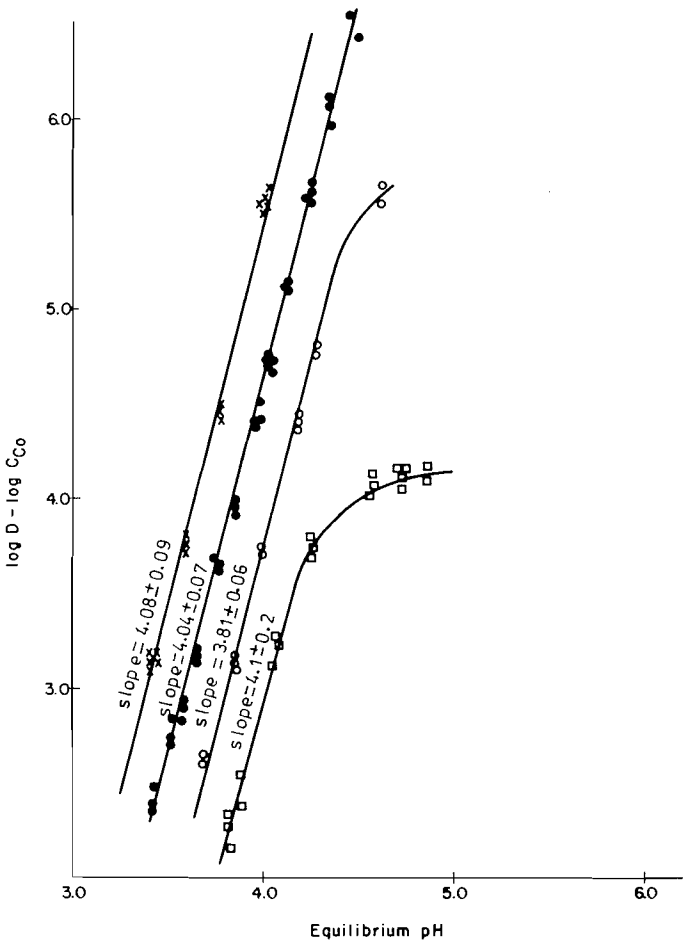

FIG. 2. Variation of log D − log C_{Co} against equilibrium pH in the extraction of cobalt(II) with dodecylthioglycolic acid in kerosene. Acid concentration: ×, 1.0 M; ●, 0.5 M; ○, 0.25 M; □, 0.1 M.

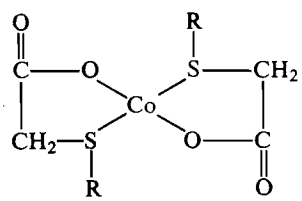
found to be 4.65 BM, which is acceptable for tetrahedral structure.

In summary, all these observations together with the elemental analysis indicate the species $Co(R—S—CH_2—COO)_2$ with a feasible tetrahedral structure (**1**):



1

Studies of mixed complex formation between metal carboxylates and amines, in the case of copper, have shown that an interaction takes place between the copper and free base amine. Ultraviolet spectra suggested that the amine interaction had destroyed the dimeric bridged structure of the copper carboxylate, as seen by the disappearance of a shoulder in the region 300–400 nm on addition of an amine to a copper carboxylate solution in chloroform (23). These studies, in the case of our cobalt carboxylate, have shown no band in that region and no effect on the uv spectrum of the metal carboxylate by the addition of trilaurylamine, all of which could suggest that the isolated cobalt species is not dimeric.

The kinetics of oxidation of glycolic, malic, tartaric, and citric acids by cerium(IV) ammonium nitrate were investigated in 0.006 mol dm^{-3} nitric acid. The reaction was catalysed by H^+ in the range 0.006–0.016 mol dm^{-3} at constant [NO_3^-] (0.02 mol dm^{-3}). The pseudo first-order rate constant k_{obs} was independent of [Ce^{III}] (0.0004–0.002 mol dm^{-3}). The proposed mechanism is based on the assumption that the formation of the precursor Ce(IV) – α-hydroxy acid complex precedes its rate controlling disproportionation, which is assisted by a proton, possibly due to the formation of the activated state [H^+—Ce^{IV} – HA]‡ (where Ce^{IV} is the reactive cerium(IV) species and HA is the α-hydroxy acid). The free radical $R^1R^2\dot{C}OH$ produced in the rate controlling step further reacts with a number of Ce(IV) molecules in the fast step to yield the final oxidation product. The activation parameters for the rate controlling step could be evaluated only in the oxidation of tartaric acid.

NARAIN DATT, RATAN R. NAGORI et RAJ N. MEHROTRA. Can. J. Chem. **64**, 19 (1986).

Opérant dans des solutions 0,006 mol/dm^3 en acide nitrique, on a étudié la cinétique des réactions d'oxydation des acides glycolique, malique, tartrique et citrique par le nitrate d'ammonium cérique(IV). À des concentrations en acide allant de 0,006 à 0,016 mol/dm^3 et à des [NO_3^-] constantes (0,02 mol/dm^3), la réaction est catalysée par les ions H^+. La constante de vitesse de pseudo-premier ordre, k_{obs}, est indépendante de la [Ce^{III}] (0,0004–0,002 mol/dm^3). Le mécanisme proposé repose sur l'hypothèse que la formation du complexe précurseur, Ce(IV) – acide α-hydroxylé, précède sa disproportionation dans l'étape qui détermine la vitesse et qui est assistée par un proton; cette assistance pourrait provenir de la formation de l'état activé [H^+—Ce^{IV} – HA]‡ (dans lequel Ce^{IV} est une espèce réactive du Ce(IV) et HA est un acide α-hydroxylé). Le radical libre $R^1R^2\dot{C}OH$, qui est formé dans l'étape qui détermine la vitesse, réagit ensuite avec un certain nombre de molécules de Ce(IV) dans l'étape rapide pour conduire au produit final d'oxydation. On n'a pu évaluer les paramètres d'activation de l'étape déterminante que dans le cas de l'oxydation de l'acide tartrique.

[Traduit par le journal]

Introduction

Since Krishna and Tewari (2) studied the kinetics of oxidation of α-hydroxy acids (lactic, malic, and mandelic acids) by cerium(IV) in aqueous sulphuric acid, there have been numerous investigations on the subject. These studies (3) dealt with one aspect or another, such as emphasizing a particular cerium(IV) species or suggesting a different one as the reactive species, supporting or contesting the formation of an intermediate cerium(IV) – α-hydroxy acid complex, reporting on the thermodynamic parameters, or investigating the effect of substituents on the benzene ring of mandelic acid, etc.

The oxidation in perchloric acid proceeded through an inner-sphere mechanism (4, 5). The complex $[CeA]^{3+}$, where A is the anion of the α-hydroxy acid HA, is thermodynamically more stable than its protonated form $[CeHA]^{4+}$ and is kinetically more reactive. One of these papers (5) also compared the results of the oxidation in sulphuric and perchloric acids.

However, the study of the reaction in nitric acid medium has not attracted much attention, the only report available being on the oxidation of substituted mandelic acids (6). This study drew our attention because the second-order rate constant (= k_{obs}/[mandelic acid]) was reported as 7.42×10^{-4} dm^3 mol^{-1} s^{-1} at 25°C and [HNO_3] = 1 mol dm^{-3}, in comparison to the value 3.39 dm^3 mol^{-1} s^{-1} at 20°C and [H_2SO_4] = 1 mol dm^{-3} (2). This seemed most unlikely in view of the various considerations related to the solution chemistry of cerium (IV) in nitric and sulphuric acid solutions.

Yet another reason for investigating this reaction was our interest in examining the dependence of the pseudo first-order rate constant k_{obs} on the initial [Ce^{IV}], for we had noted that k_{obs} decreased with increasing [Ce^{IV}] in the oxidation of diols (7) and carboxylic acids (8) in nitrate medium, though the disappearance of [Ce^{IV}] was always first order in any kinetic run corresponding to any initial [Ce^{IV}]. This phenomenon was ascribed to the reactivity of the dimeric cerium(IV) species, the existence of which has been demonstrated (9, 10) and questioned (11), in addition to monomeric species.

The preliminary investigations indicated that the rate of oxidation of mandelic acid was too fast to measure conveniently by the method adopted by us for following the kinetics. Strictly speaking, the rates are such that a clear picture of the study could be best provided by stopped flow technique, a facility presently not available to us.

Experimental

AnalaR (BDH) or Puriss (Fluka) grade α-hydroxy acids were used as received. The solutions were freshly prepared and standardized against a standard alkali. The solution of Ce(IV) ammonium nitrate (Loba, GR) was also freshly prepared and standardized against a standard Fe(II) solution. Ce(III) ammonium nitrate solution was prepared by the reduction of a standard cerium(IV) solution by hydrogen peroxide (Sarabhai-M.). The solution was heated, after the reduction of Ce(IV), to decompose the unreacted hydrogen peroxide. Sodium nitrate (E. Merck) solution of the desired strength was prepared by weighing of the sample. Nitric acid (BDH, AnalaR) solution was standardized against a standard alkali. The nitroferroin (G. F. Smith) solution was suitably diluted.

Stoichiometry

The stoichiometry in the oxidations of malic and tartaric acids was determined under conditions similar to those in the kinetic runs ([α-hydroxy acid] > 10 [Ce^{IV}]). The method adopted was the same as that described in the oxidation of malic acid in perchloric acid (4),

[5]Revision received July 12, 1985.

and involved the determination of formic acid by using mercury(II) chloride. The mercury(I) chloride was determined using an iodine–thiosulphate titration. Taking into account the blank corrections, it was found that $\Delta[HCO_2H]/\Delta[Ce^{IV}]$, from three determinations, was 0.097 ± 0.004 and 0.123 ± 0.008 respectively for malic and tartaric acids. Hence the stoichiometric equations for the oxidation of these acids are:

[1] $HO_2C.CH_2CHOH.CO_2H + 3H_2O + 10Ce^{IV} \rightarrow HCO_2H + 3CO_2 + 10Ce^{III} + 10H^+$

[2] $HO_2C.CHOHCHOH.CO_2H + 2H_2O + 8Ce^{IV} \rightarrow HCO_2H + 3CO_2 + 8Ce^{III} + 8H^+$

The oxidized reaction mixtures of glycolic, 2-methyl-2-hydroxypropanoic, and citric acids were treated with 2,4-dinitrophenylhydrazine. The precipitated hydrazones were purified and their melting points determined. The mps of the hydrazones from glycolic and 2-methyl-2-hydroxypropanoic acid were 165°C and 130°C, respectively, which correspond to the mps of the hydrazones of formaldehyde (lit. (12*a*) mp 163.5–164.5°C) and acetone (lit. (12*b*) mp 128°C). The hydrazone from citric acid decomposed on heating. Considering that citric acid and 2-methyl-2-hydroxypropanoic acid are structurally similar, it is concluded that citric acid is oxidized to acetone dicarboxylic acid. The stoichiometric equation in the oxidation of each of these acids is expressed as:

[3] $CH_2OH.CO_2H + 2Ce^{IV} \rightarrow HCHO + CO_2 + 2Ce^{III} + 2H^+$

[4] $HO_2C.CH_2.C(OH)CO_2H.CH_2CO_2H + 2Ce^{IV} \rightarrow HO_2C.CH_2.CO.CH_2CO_2H + 2Ce^{III} + CO_2 + 2H^+$

[5] $CH_3.C(OH)CO_2H.CH_3 + 2Ce^{IV} \rightarrow CH_3COCH_3 + CO_2 + 2Ce^{III} + 2H^+$

Test for free radicals

Reaction mixtures were degassed with nitrogen before the reaction was initiated. Acrylonitrile was added to partially oxidized reaction mixtures. The monomer was polymerized within a few minutes, indicating the presence of free radical in the reaction mixtures. The monomer was not polymerized when it was added separately to the solution of α-hydroxy acids and cerium(IV) ammonium nitrate.

Rate measurements

The kinetics were followed under pseudo first-order conditions, i.e. α-hydroxy acid was present in excess. The ionic strength of the reaction mixture was maintained with sodium nitrate. The pseudo first-order rate constant k_{obs} was calculated from the gradients of the linear plots between ln $(a - x)$ and time, where $(a - x)$ is the change in the titre value. Five milliliters of the reaction mixture was quenched in the same volume of Fe(II) solution, which was titrated against cerium(IV) sulphate solution of the same strength as that of the Fe(II) solution, using nitroferroin as the indicator. The microburette reading therefore directly gave the value of x. The microburette was graduated to 0.02 mL. Before adopting this method, it was ensured that the presence of α-hydroxy acid in concentrations present in the reaction mixtures did not alter the titre value of Fe(II) against cerium(IV) sulphate solution. This was achieved by using approximately 3 mol dm^{-3} sulphuric acid in the preparation of Fe(II) and Ce(IV) solutions. The reaction was invariably followed up to 80% completion, and the k_{obs} values were reproducible within ±5% from the replicate runs. The average values are reported in the tables.

Results

Dependence on [Ce^{IV}]

The first-order dependence on $[Ce^{IV}]$, indicated by the linearity of the plots between ln $(a - x)$ and time, was further confirmed by the fact that k_{obs} was independent of the initial $[Ce^{IV}]$ when varied in the range 0.002–0.012 mol dm^{-3} at constant $[NO_3^-]$, $[H^+]$, and [α-hydroxy acid].

0.032	—	—	—	0.78

*$I = 0.044$ mol dm^{-3} at 16°C.

Dependence on [Ce^{III}]

The effect of $[Ce^{III}]$ on the k_{obs} was investigated in the oxidation of malic acid only. The k_{obs} was independent of the initial $[Ce^{III}]$ over a tenfold variation (0.0002–0.002 mol dm^{-3}). It was found that $10^3 k_{obs} = 2.30 \pm 0.12$ s^{-1} at $[H^+] = 0.006$ mol dm^{-3}, [malic acid] = 0.02 mol dm^{-3}, $[Ce^{IV}] = 0.002$ mol dm^{-3} at 15°C.

Dependence on [α-hydroxy acid]

This was investigated for all the α-hydroxy acids. The results, Table 1, indicated an apparent zero-order dependence on [α-hydroxy acid]. However, a later analysis of the results indicated that these k_{obs} values were in fact the limiting values.

Dependence on [nitric acid]

These measurements were carried out at constant $[NO_3^-]$. The results in Table 2 indicated that k_{obs} increased with $[H^+]$. This observation is in disagreement with the one recorded in the oxidation of mandelic acid (6). This observation also distinguishes this study from the one in perchloric acid (5), in which k_{obs} decreased with increasing $[H^+]$.

The plot between k_{obs} and $[H^+]$ was linear and passed through the origin, indicating that the presence of H^+ is essential for the reaction, which is understandable because cerium(IV) salts hydrolyze in the absence of hydrogen ions. The representative plots for the oxidation of malic and citric acids are shown in Fig. 1.

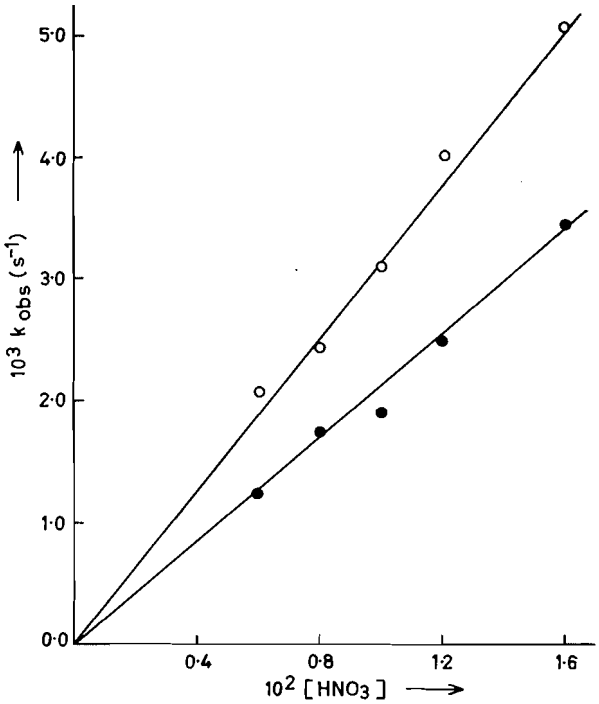

FIG. 1. Dependence of k_{obs} (s^{-1}) on [HNO_3] at constant ionic strength for the oxidation of malic (○) and citric (●) acids. Similar plots were also obtained in the oxidations of glycolic and tartaric acids. The experimental conditions are given in Table 2.

Dependence on [NO_3^-]

No systematic study was made to measure k_{obs} at different [NO_3^-] because of the well-known retarding effect of nitrate ions in oxidations in nitrate medium. However, a few experiments carried out at randomly varied [NO_3^-] confirmed that k_{obs} decreased with increasing [NO_3^-]. The reason for avoiding this study was that such measurements do not help in establishing the exact nature of the reactive cerium(IV) species, which could be any one of the various nitrate complexes of cerium(IV) (see reaction [8]).

Discussion

Cerium(IV) species

The chemistry of cerium(IV) in aqueous nitric acid is complicated. Several complexes represented by $[Ce(NO_3)_n]^{(4-n)}$, where n has an integral value between 1 and 6, are known (13). The mixed hydroxy–nitrate complexes represented by $[CeOH(NO_3)_n]^{(3-n)}$ (14–17), the hydroxy species $CeOH^{3+}$ (6, 18–21), and the equilibrium between monomeric and dimeric cerium(IV) (7–11), have all been postulated to explain the observed kinetics.

Since we used [HNO_3] < 0.06 mol dm^{-3}, both Ce^{4+} and $CeOH^{3+}$ could be present in the system (15). However, $CeOH^{3+}$ is not favoured as the reactive species because k_{obs} did not decrease with increasing [H^+], as expected in view of equilibrium [6]. A mixed hydroxy–nitrate complex, formed as a result of equilibrium [7], is also not favoured for the same reason. The possibility of the Ce^{4+} as oxidant is also excluded because of its extensive complexation with nitrate ions (22). This thus leaves the possibility that one of the several nitrate complexes may be reactive. The identification of a particular cerium(IV)–nitrate complex as the reactive one is not easy and this is perhaps one reason why several workers (23) have consistently avoided being specific about the reactive cerium(IV) species in nitrate medium.

$$[6]\quad Ce^{4+} + H_2O \overset{K_h}{\rightleftarrows} CeOH^{3+} + H^+$$

$$[7]\quad Ce(NO_3)_n^{(4-n)} + H_2O \overset{K_h'}{\rightleftarrows} [CeOH(NO_3)_n]^{(3-n)} + H^+$$

Mechanism

The formation of a Ce(IV) – α-hydroxy acid complex is evident from the deepening of the colour of Ce(IV) solution upon addition of α-hydroxy acids. Since the deepening of the colour is instantaneous, the formation of the precursor complex is considered to precede the slow rate controlling step. Measurements such as the wavelength of maximum absorbance, and determination of the formation constants of the precursor complexes, required the application of a high speed microprocessor controlled uv–visible recording spectrophotometer with a thermostatic compartment, a facility presently not available to us. The formation of the precursor complex is considered essential and is supported by the study in sulphuric (2) and perchloric acid (4, 5) solutions. The fact that k_{obs} was independent of [Ce^{III}] precluded the possibility of participation of Ce(III) in any step preceding the rate controlling step.

The consideration of the pK_a values of the α-hydroxy acids and the [H^+] used implied that both the dissociated and the undissociated forms of the α-hydroxy acid existed in the system. However, in view of the dependence of k_{obs} on [H^+], the possibility of A^-, the dissociated hydroxy acid, becoming the reactive entity is ruled out. Hence it is proposed that the undissociated hydroxy acid, HA, formed the precursor complex with the reactive cerium(IV) species.

The hydrolytic (22) and spectral studies (24, 25) have confirmed that cerium(IV) exists as a nitrate complex, and the X-ray crystallographic study (26) indicated that six bidentate nitrates are present around the cerium(IV) ion. Now, if it is assumed that a bidentate complex is formed between reactive cerium(IV) species and the α-hydroxy acid, then a nitrate ion will be lost in order to maintain the coordination number of 12. The situation is illustrated in equilibrium [8], which is consistent with the observed retarding effect of nitrate ions.

$$[8]\quad Ce(NO_3)_n^{(4-n)} + HA \overset{K}{\rightleftarrows} \left[\begin{array}{l} R^1\text{-}C(H)(O\text{-}Ce(NO_3)_{n-1})\text{-}R^2 \\ \quad\quad\quad\quad C(=O)\text{-}O\text{-}H \end{array}\right]^{(5-n)} + NO_3^-$$

[9]  $+ H^+ \xrightarrow{k} R^1R^2\dot{C}OH + Ce(III) + 2H^+$

[10] $(m-1)Ce^{IV} + R^1R^2\dot{C}OH \xrightarrow{\text{fast}}$  $+ (m-1)Ce^{III} + (m-1)H^+$

In equation [10], m is the number of Ce(IV) equivalents used in the oxidation of α-hydroxy acid according to the stoichiometric equations [1–5], and n has any integer value between 1 and 6. The rate of disappearance of $[Ce^{IV}]$ in terms of reactions [8]–[10] is given by eq. [11] where K_n is defined in the equilibrium [12].

$$[11]\quad \frac{-d[Ce^{IV}]}{dt} = \frac{mkK[Ce^{IV}][HA]\dfrac{K_n[NO_3^-]^n}{[NO_3^-]}[H^+]}{1 + K_n[NO_3^-] + \dfrac{KK_n[HA][NO_3^-]^n}{[NO_3^-]}}$$

$$[12]\quad Ce^{4+} + nNO_3^- \rightleftarrows [Ce(NO_3)_n]^{(4-n)}$$

The rate law deduced in eq. [11] is further simplified by dividing the numerator and denominator by $K_n[NO_3^-]^n/[NO_3^-]$, whence eq. [11] is reduced to eq. [13].

$$[13]\quad \frac{-d[Ce^{IV}]}{dt} = \frac{mkK[Ce^{IV}][HA][H^+]}{\dfrac{[NO_3^-]}{K_n[NO_3^-]^n} + [NO_3^-] + K[HA]}$$

Since $[NO_3^-] = 0.02$ mol dm^{-3} (the total ionic strength of the medium), it is easily seen that

$$K[HA] \gg \left(\frac{[NO_3^-]}{K_n[NO_3^-]^n} + [NO_3^-]\right)$$

Equation [13] is therefore further simplified to eq. [14], which is the observed rate law. Again, at constant $[H^+]$, $mk[H^+]$ can be replaced by the constant k_{lim} where k_{lim} is the limiting rate constant, and eq. [14] is reduced to eq. [15].

$$[14]\quad k_{obs} = mk[H^+]$$

$$[15]\quad k_{obs} = k_{lim}$$

The value of k ($= k_{lim}/8[H^+]$, $m = 8$ for tartaric acid) at different temperatures in the oxidation of tartaric acid is given in Table 3. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are also reported there. The corresponding values for the other hydroxy acids could not be obtained because the rate measurements in these systems were too fast.

The inclusion of a proton in the activated state, which could be visualized as $[H^+—Ce^{IV} - HA]^{\ddagger}$ formed in reaction [9], could help the delocalization of the electron and the formation of the free radical $R^1R^2\dot{C}OH$. The formation of the activated state $[H^+—Ce^{IV} - HA]^{\ddagger}$ as a result of reaction between a protonated Ce(IV) species and HA is not favoured because of the fact that the Ce(IV) species extracted by ether from a solution having 5.5 mol dm^{-3} nitric acid contained no ionizable proton (9*a*). The equilibrium between the monomeric and dimeric cerium(IV) species has no mechanistic significance in the present reaction because k_{obs} is independent of the initial $[Ce^{IV}]$. This will always be the case in all those reactions in which either the monomeric or dimeric species are singularly reactive.

The attempt to characterize the free radical by flow–esr technique proved unsuccessful (5). However, the formation of $R^1R^2\dot{C}OH$ (27) is favoured because its fast oxidation by a second Ce(IV) molecule explains the formation of HCHO in the oxidation of glycolic acid ($R^1 = R^2 = H$), and acetone dicarboxylic acid in the oxidation of citric acid ($R^1 = R^2 = CH_2CO_2H$), which is akin to the formation of acetone in the oxidation of 2-methyl-2-hydroxypropanoic acid ($R^1 = R^2 =$ Me).

The values of k decreased in the order: citric > glycolic > malic > tartaric acid, which is consistent with the reactivity: mandelic > 2-methyl-2-hydroxypropanoic > lactic > glycolic > malic acid in perchloric acid medium (4, 5). It is noted that the mechanism of the oxidation in nitric acid is different from that in perchloric acid because (*i*) k_{obs} decreased with increasing $[HClO_4]$ (4, 5), whereas it increased with increasing $[HNO_3]$, and (*ii*) k_{obs} was independent of $[NO_3^-]$ in perchloric acid (5), whereas nitrate ions retarded the k_{obs} in nitric acid. The latter needs an explanation. In perchloric acid, $CeOH^{3+}$(aq.) is the major reactive species because the contribution from Ce^{4+}(aq.) to k_{obs} is considered negligible (5). The k_{obs} will remain unaffected if $[CeOH^{3+}$(aq.)] is not adversely affected by the nitrate ions, and this is exactly the case because the hydrolytic studies in nitric acid (11) have suggested that the complexing of $CeOH^{3+}$(aq.) by NO_3^- is not appreciable in comparison to complexation of Ce^{4+}(aq.) by NO_3^-.

Although this study could not provide a value of k_{obs} for the oxidation of mandelic acid because the rate was too fast to handle with the method adopted, it has been established that the oxidation is not as slow as claimed by Banerji (6).

TABLE 3. The values of the rate limiting constant k in the oxidation of tartaric acid at different temperatures, and the values of $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$

T (°C)	12	15	20	25
10^3k (dm^3 mol^{-1} s^{-1})	1.57	2.68	4.50	8.32

$\Delta H^{\ddagger} = 90 \pm 2$ kJ mol^{-1}, $\Delta S^{\ddagger} = 17 \pm 3$ J K^{-1} mol^{-1}

Study of interaction of polymeric aluminium hydroxide with fluoride

N. PARTHASARATHY, J. BUFFLE,[1] AND W. HAERDI

Department of Inorganic, Analytical, and Applied Chemistry, University of Geneva, 1211 Geneva 4, Switzerland

Received January 10, 1985

N. PARTHASARATHY, J. BUFFLE, and W. HAERDI. Can. J. Chem. **64**, 24 (1986).

The interaction between polymeric aluminium hydroxide, Al_p, and fluoride has been investigated to optimize the conditions for removal of fluoride from waste waters of aluminium manufacturing plants using Al_p. The results of these studies have shown that the nature of products formed between Al_p and fluoride depends on the molar concentration ratio of fluoride to aluminium (r_F), pH, and initial fluoride concentration. In the absence of interfering ions, fluoride can be effectively precipitated as $Al_{13}(OH)_{29}F_{10}$ with Al_p, using $r_F \simeq 0.7$ and $4 < pH \leq 7$. At $r_F > 1$, Al_p dissociates and fluoride is precipitated as cryolite, and the residual fluoride concentration is controlled by its high solubility.

N. PARTHASARATHY, J. BUFFLE et W. HAERDI. Can. J. Chem. **64**, 24 (1986).

Dans le but d'optimiser les conditions permettant d'éliminer les ions fluorures des eaux usées des usines produisant de l'aluminium à partir de l'hydroxyde d'aluminium sous forme de polymère (Al_p), on a étudié l'interaction entre Al_p et les ions fluorures. Les résultats de ces études démontrent que la nature des produits formés entre Al_p et les ions fluorures dépend du pH, de la concentration initiale des fluorures et du rapport des concentrations molaires des ions fluorures/aluminium (r_F). Sous l'influence de Al_p et en l'absence d'ions pouvant créer des interférences, les ions fluorures peuvent être précipités d'une façon efficace sous forme de $Al_{13}(OH)_{29}F_{10}$, en utilisant un $r_F \simeq 0{,}7$ et $4 < pH \leq 7$. Lorsque $r_F > 1$, le Al_p se dissocie et les ions fluorures précipitent sous forme de cryolite; la concentration des ions fluorures résiduels est contrôlée par sa grande solubilité.

[Traduit par le journal]

Introduction

In the past few years there has been a growing interest in the small, highly charged cationic polymeric aluminium hydroxide, Al_p, because it seems to be a promising substitute for conventional aluminium salts as a coagulant in water treatment (1–3). The preparation and characteristics of Al_p have been reported in the literature (1, 3–15). We showed (15) that hydrolysed aluminium solutions having $r_{OH} = 2.5$ consist mainly (ca. 80%) of active polymeric aluminium hydroxide, Al_p. With increasing r_{OH} values, the proportion of Al_p formed decreases and increasing amounts of Al are found to be associated with the inert form of aluminium hydroxide. In addition, small amounts (5–10%) of monomeric aluminium are present in all the hydrolysed solutions. Al_p prepared by slow addition of base to aluminium nitrate solution to an OH/Al ratio of 2.5 showed (15) that its size is 10–20 Å, its average net positive charge is +7 (i.e. 0.5 per aluminium atom), and it consists probably of $Al_{13}O_4(OH)_{24}^{7+}$. Since Al_p is highly positively charged, it is expected to be very reactive towards dissolved species, particularly towards inorganic anions such as fluoride and phosphate, but the reactions between Al_p and dissolved inorganic pollutants have received very little attention (16, 17). In this paper the interaction of Al_p and fluoride has been investigated in order to get some insight into the reactivity of Al_p and to find optimal conditions for treatment of fluoride-containing waste waters, in particular those produced in the aluminium industry.

II. Experimental

II.1 *Reagents*

Reagent grade chemicals and demineralized water purified on Millipore – Milli Q systems were used throughout. All fluoride standards were prepared by serial dilution of stock 0.2 *M* sodium fluoride solution. Stock solutions of aluminium hydroxide were prepared as described in our previous paper (15) by hydrolysing aluminium nitrate solutions with a base (NaOH) to the desired hydrolysis ratio, r_{OH}, where $r_{OH} = [OH]_t/[Al]_t$; $[OH]_t$ is the total concentration of hydroxide ions, and $[Al]_t$ is the total aluminium ion concentration. r_{OH} was varied in the range 2.5–3.0. The total initial aluminium ion concentrations $[Al]_t$ were varied in the range $5 \times 10^{-3} - 2 \times 10^{-1}$ *M*, and the initial base concentrations were varied between 0.1 and 1 *M*. The hydrolysed solutions were characterized by ultrafiltration, aluminium-27 nmr, and Ferron methods as described elsewhere (15). The hydrolysed solutions were left to stand for 6 days before use, as the variations in pH of these solutions were found to be small (0.01 pH/day) after this period. Ionic strengths of the solutions were adjusted to the desired values with sodium nitrate solution.

II.2 *Apparatus*

Fluoride titrations were carried out using the titration assembly described in ref. 18. A fluoride ion selective electrode (ISE) coupled to a Metrohm (EA 441/5) Ag/AgCl reference electrode with saturated KCl salt bridge was used for making fluoride measurements. A Metrohm combination pH glass electrode (EA 120) was calibrated with pH 7 and 4 Merck standard buffers. Metrohm digital pH meters (E500) coupled to a Metrohm chart recorder (E478) were used for pH and potential measurements. A Tacussel PHIT NUM pH stat was used to maintain the pH constant.

The pH and emf were read to within ±0.01 pH unit and ± 0.1 mV, respectively, and the potentials were noted only after checking that the drift was less than 0.004 mV/min.

Unless otherwise stated, all measurements were made in polyethylene titration cells (or beakers) thermostated at 25 ± 0.1°C, with stirring and under an atmosphere of nitrogen.

II.3 *Methods*

II.3.1 *Analytical methods*

All analytical methods used were the same as those described elsewhere (18). However, the salient features are reiterated here. The free and the total fluoride concentrations in the samples were determined by means of a fluoride ISE. The total fluoride concentration was determined by using TISAB III containing CDTA as decomplexing agent for the aluminium fluoride complexes. The total aluminium concentrations in the samples were determined by flame atomic absorption spectrometry (faas) using a Pye Unicam SP1900 atomic absorption spectrometer. Size fractionation of the samples was performed by filtering samples successively through Schleicher and Schull filters of porosities: 8 μm, 0.45 μm, and 0.2 μm and Amicon membranes XM300, PM10, and UM 05 in an Amicon ultrafiltration (uf) cell (model 52). A 0.2-μm filter instead of the conventional 0.45-μm filter was chosen to distinguish between the particulate and dissolved components, because colloidal forms of aluminium have been found to pass through 0.45-μm filters (5) but to be retained by 0.2-μm filters (5, 15).

II.3.2 *Interaction of fluoride with Al_p*

For the sake of convenience the symbols r_F and r_F^b are designated for $[F]_t/[Al]_t$ and $[F]_b/[Al]_b$ respectively. r_F is a useful parameter for practical purposes, whereas r_F^b is indicative of the stoichiometry of the species formed. $[F]_b$ and $[Al]_b$ are the concentrations of fluoride bound to aluminium and aluminium initially bound to hydroxide as Al_p, respectively. Three forms of aluminium, denoted by Al_a, Al_p, and Al_c, have been shown to exist in partially hydrolysed aluminium solution (12, 13, 15). Al_a consists of monomeric species such as Al^{3+}, $AlOH^{2+}$, $Al(OH)_2^+$. Al_p is the polymeric aluminium hydroxide species. Al_c, the inert form of aluminium hydroxide, is composed of microcrystalline particles of solid aluminium hydroxide. For the sake of clarity the symbol r_{OH}^b will be used for the ratio $[OH]_b/[Al]_b$, where $[OH]_b$ is the concentration of hydroxide ions bound to aluminium as polymer.

II.3.2.1 *Potentiometric titration of Al_p with F*

Aliquots of a 0.1 *M* sodium fluoride solution were added to a solution of Al_p at the same pH (5.0) and ionic strength (0.1 *M*) as Al_p solution ($Al_t = 6 \times 10^{-3}$ *M*). The titrant was added at 30-min intervals and the pH was kept constant at 5.0 by means of a pH stat. The total concentration of fluoride was varied in the range $10^{-6} - 10^{-2}$ *M*. The potential, *E*, was measured with F^- ISE 10–15 min after each addition of the titrant and the corresponding free fluoride concentration was evaluated from the previously constructed calibration curve. As in the present system, the equilibrium was reached slowly. The attainment of equilibrium was checked by performing other titrations using longer equilibration times (24 h). The titrant in this case was added manually.

These experiments were run with solutions having various r_{OH} ratios ($2.5 \leqslant r_{OH} \leqslant 3$).

II.3.2.2 *Batch method*

To determine the nature of products formed during various stages of the titration, a batch technique was used. Aliquots of Al_p ($[Al]_t = 0.12\,M$; $r_{OH} = 2.5$; pH = 5.0) were added to known volumes of sodium fluoride solutions (pH = 5.0) contained in a series of polyethylene beakers under constant stirring. The ionic strengths of these solutions were adjusted to 0.1 *M* with sodium nitrate solution. The total aluminium concentration was kept constant ($[Al]_t = 6 \times 10^{-3}$ *M*) and $[F]_t$ was varied such that $0.1 \leqslant r_F \leqslant 3$ in one set of experiments. All solutions were kept at constant pH for 30 min, then filtered in cascade successively through membranes of porosity: 8 μm, 0.45 μm, 0.2 μm, XM300 (130 Å), PM10 (20 Å), and UM-05 (10 Å). $[Al]_t$, $[F]_t$, and the free fluoride concentrations, [F], were determined in each filtrate. The precipitate formed (if any) was washed with ethanol (70% v/v), dried over silica gel in a desiccator, and analysed by using chemical methods, ir, and photoelectron spectroscopy (ESCA).

II.3.3 *Effect of pH*

The Al_p–fluoride interaction was studied in two systems: (a) excess of aluminium and (b) excess of fluoride.

(a) $r_F \geqslant 3$ *(excess fluoride) (using a batch method)*

The batch method described above was used; r_F was kept constant and the pH was varied over the range $3 < pH \leqslant 7$. [F], $[F]_t$, and $[Al]_t$ in the 0.2-μm filtrates were determined.

(b) $r_F \geqslant 0.1$ *(using a titration procedure)*

Aliquots of fluoride solutions were added to hydrolysed aluminium solutions having varying r_{OH} immediately after performing the hydrolysis, and left to stand overnight under stirring conditions. These solutions were then back titrated with 0.1 *M* nitric acid, and the pH and [F] were measured after each addition. It must be pointed out that the titrant was added at intervals of 24 h in the pH range 4.5–5.5 as the attainment of equilibrium was slow under these conditions. These titrations were performed over the pH range $3 < pH \leqslant 8.5$. The aluminium concentrations studied were in the range $5.0 \times 10^{-3} - 10^{-4}$ *M* and the $[F]_t$ was 10^{-4} *M* in all cases except for $[Al]_t = 1.5 \times 10^{-4}$ *M*, where $[F]_t$ used was 10^{-5} *M*. The ionic strengths of these solutions were adjusted to 0.1 *M* with $NaNO_3$.

III. Results

III.1 *Fluoride bound and hydroxide released*

A typical plot of the potential, *E*, of F^- ISE against log $[F]_t$ for the titration of Al_p with fluoride is shown in Fig. 1. The solution appeared clear in zone 1, became turbid in zone 2, and finally a precipitate was observed (indicated by an arrow in Fig. 1). Hydroxide was released during the titration. The corresponding amounts of hydroxide released were calculated from the amount of acid required to maintain the pH constant.

The maximum amount of bound fluoride per aluminium(III) ion in the polymer is given by:

$$[1] \quad r_F^b = r_F^{eq}$$

and is found at the end point of the titration, i.e. when $[F]_t = [F]_{eq}$ (Fig. 1). Then:

$$[2] \quad r_F^{eq} = [F]_t^{eq}/[Al]_b = ([F]_t - [AlF] - [F])/[Al]_b$$

[AlF] is the concentration of the dissolved AlF^{2+} species. [AlF] was calculated by using the mass balance for monomeric aluminium species, Al_a, the free fluoride concentration obtained from F^- ISE measurement, and the stability constant of AlF,

$$[3] \quad \beta_1^F = [AlF]/[Al][F]$$

(Log $\beta_1^F = 6.03$ at $I = 0.1\,M$; ref. 19):

$$[4] \quad [Al]_a = [Al] + [AlF]$$

By combining eqs. [3] and [4] one obtains:

$$[5] \quad [AlF] = \frac{[Al]_a.\beta_1^F.[F]}{(1 + \beta_1^F.[F])}$$

r_F^{eq} in Fig. 1 was found to be 0.8. Similar titration curves were obtained for hydrolysed solutions having various r_{OH}. The corresponding r_F^{eq} are plotted against r_{OH}^b (Fig. 2). These results indicate that as r_{OH}^b increases, the amount of fluoride incorporated in the precipitate decreases.

The amount of OH^- released during the titration shown in Fig. 1 is replotted as a function of r_F (Fig. 3, curve (a)). Also shown are the results obtained from a batch method and by manual titration (curves (b) and (c)). This figure allows comparison of the results at three different time scales. For instance, at $r_F = 1$ the total equilibration time was 30 min for curve (c), 9 h for curve (a), and 240 h for curve (b). In all cases $[OH]_{rel}$ increases with r_F^b, but the comparison of these experiments shows that a relatively long time (hours) is required for the completion of reaction.

III.2 *Nature of the species formed in the Al_p–F system*

III.2.1 *$[Al]_t$ constant*

The size fractionation results for solutions with r_F ranging from 0.1 to 3.3 are summarized in Table 1. The percentages of Al and F in each fraction were calculated with respect to the total initial aluminium and fluoride concentrations, respectively. The proportion of aluminium and fluoride in the UM 05 filtrate is small regardless of the r_F value. Knowing that UM 05 filters retain Al_p and let through monomeric aluminium species Al^{3+} and AlF_n (15), the fraction of fluoride bound to aluminium as soluble Al_pF_n and AlF_n may be evaluated from the measured free and total fluoride concentrations in the UM 05 retentate and filtrates, respectively. For $r_F = 0.1$, the soluble fluoride was mainly present as Al_pF_n (found: 0.7% as F^-, 9.4% as AlF, 26% in Al_pF_n, and 64% in the solid with respect to $[F]_t$), whereas with r_F values greater than 0.5, the predominant form of soluble fluoride was AlF^+ (found: 0.7–2.3%, as F^-, 6.4–9.4% as AlF, 1.9–4.0% in Al_pF_n, and ≃70–90% in the solid).

The fluoride associated with the particulate form (0.2 μm)

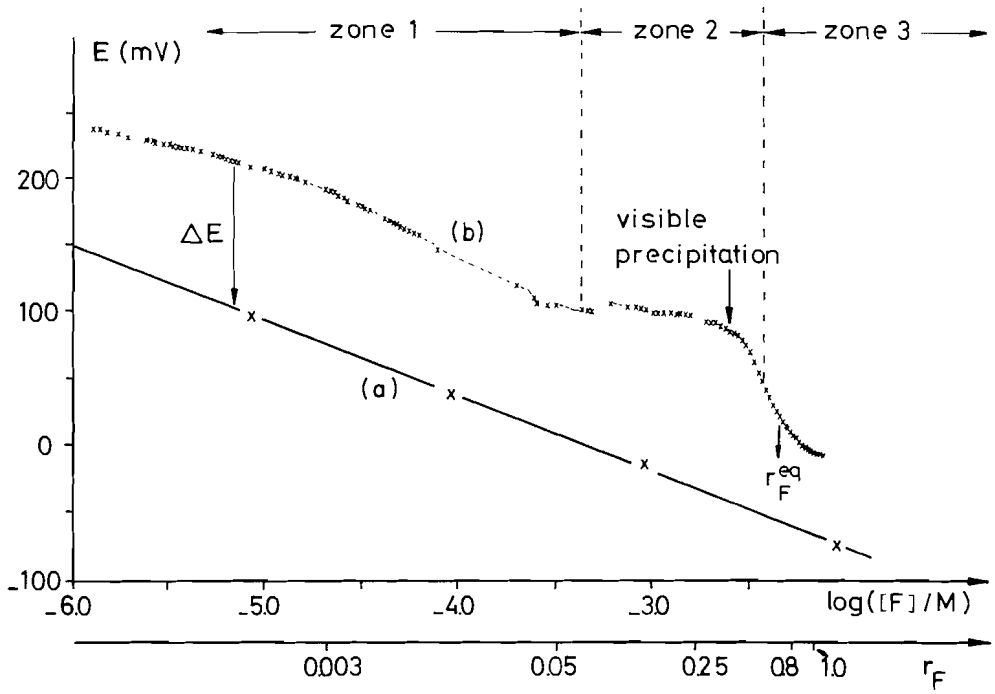

FIG. 1. A typical plot of E vs. log $[F]_t$ for the titration of Al_p with fluoride, monitored with fluoride ion selective electrode. Reference electrode used: Ag/AgCl/saturated KCl. Conditions used: curve (b), $[Al]_t = 6 \times 10^{-3}$ M; $r_{OH} = 2.5$; $I = 0.1$ M; pH = 5.0; $T = 25°C$. Curve (a), $[Al]_t = 0$; the other conditions were the same as for curve (b).

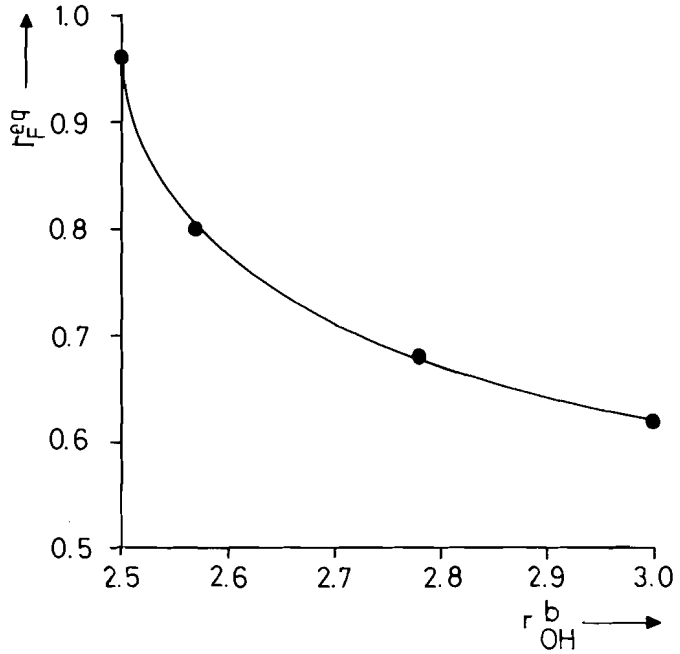

FIG. 2. A plot of r_F^{eq} vs. r_{OH}^b. Conditions used: $[Al]_t = 6 \times 10^{-3}$ M; $I = 0.1$ M $NaNO_3$.

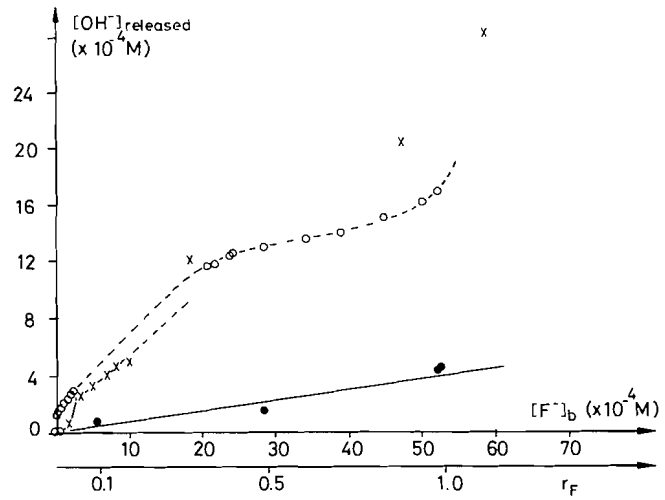

FIG. 3. Amount of hydroxide released ($[OH]_{rel}$) vs. fluoride bound to the polymer $Al_p([F]_b)$. Conditions used: $r_{OH} = 2.5$; $[Al]_t = 6 \times 10^{-3}$; $I = 0.1$ M $NaNO_3$. Curve (a) (○), automatic titration with the titrant added at 30-min intervals; curve (b) (×), manual titration, the interval between each addition being 24 h; curve (c) (●), batch method: each point in the curve was obtained after 30-min contact time.

increases with increase in the r_F ratio (64% of $[F]_t$ at $r_F = 0.1$; 90% at $r_F \geq 0.5$), which is consistent with the observation of turbidity followed by precipitation in zone 2 of the titration curve in Fig. 1. The ir, ESCA, and chemical analysis revealed that the nature of the solid formed depends on the r_F value. At r_F ratios of 0.1–1.0, the solid includes: 13% Al, 6.6% F, 20% OH, 0.1% Na, 59.6% H_2O, and the molar F/Al ratio = 0.69. This corresponds to a basic aluminium hydroxide of composition: $Al(OH)_{2.32}F_{0.68}Na_{0.01}$. With r_F ratio > 1, ESCA, chemical, and ir analysis of the solid yielded: 21% Al, 14.1% F, 6.7% Na, 43% H_2O, molar ratios of F/Al = 1.0 and Na/Al = 0.2, and characteristic ir bands for cryolite and alumina. These data correspond to a mixture of cryolite (Na_3AlF_6) and alumina (Al_2O_3) in a mole ratio of 1:3. These results suggest that Al_p decomposes into these products in the presence of excess of fluoride.

III.3 *Effect of pH on the nature of species formed*

III.3.1. *Excess of fluoride: zone 3 (Fig. 1)*

The distribution of various forms of fluoride are shown in Fig. 4 as a function of pH. These results were obtained with $[Al]_t =$

TABLE 1. Effect of r_F on the composition of Al_p–F system

Initial solution				0.2-μm Filtrate*				Filtrate of UM-05			
r_F	r_F^b	$[Al]_t$ (mM)	$[F]_t$ (mM)	$[Al]_f$ (mM)	$[Al]_f$ (%)	$[F]_f$ (mM)	$[F]_f$ (%)	$[Al]_f$ (mM)	$[Al]_f$ (%)	$[F]_f$ (mM)	$[F]_f$ (%)
0.1	0.11	5.8	0.57	5.3	91.4	0.21	36.2	0.67	11.6	0.06	9.8
0.5	0.56	5.8	2.9	0.43	7.4	0.35	12.1	0.57	9.9	0.23	7.9
1.0	1.13	5.9	5.9	0.63	10.7	0.71	12.0	0.60	10.1	0.53	9.0
3.16	3.58	6.0	19.0	0.13	2.2	2.3	12.1			1.91	10.1

*The results obtained with XM300 and PM10 filtrates were similar to those obtained with 0.2-μm filtrates. $I = 0.1\,M$ $NaNO_3$ M; pH = 5.5; $[X]_f$ = total concentration of X in a given filtrate.

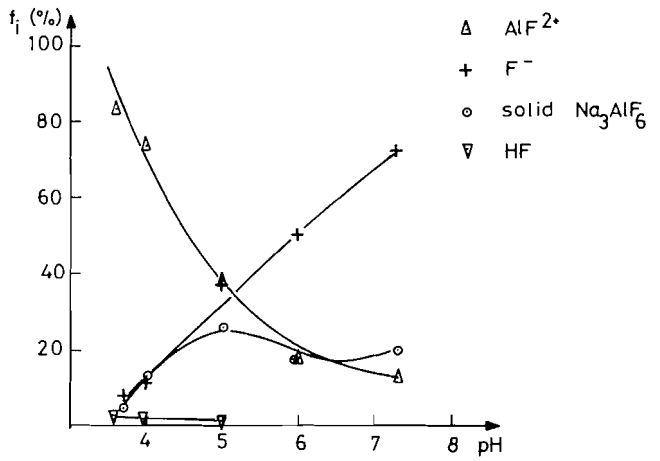

FIG. 4. Distribution of various forms of fluoride as a function of pH. f_i = fraction of each species with respect to total fluoride concentration. Conditions used: $[Al]_t = 1.7 \times 10^{-3}\,M$; $[F]_t = 5.1 \times 10^{-3}\,M$; $r_F = 3$, $r_{OH} = 2.5$.

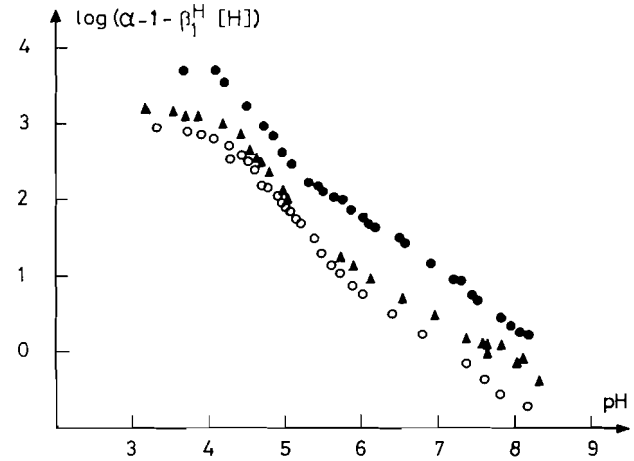

FIG. 5. Typical plots of log ($\alpha - 1 - \beta_1^H.[H]$) vs. pH. Conditions used: M; $[F]_t = 10^{-4}\,M$; $I = 0.1\,M$; $T = 25 \pm 0.1$°C; curve (●), $[Al]_t = 4.4 \times 10^{-3}\,M$; curve (▼), $[Al]_t = 2.2 \times 10^{-3}\,M$; curve (○), $[Al]_t = 7.7 \times 10^{-4}\,M$.

1.7×10^{-3} and $[F]_t = 5.1 \times 10^{-3}\,M$ using a batch method. The distribution of different forms of fluoride was computed from the measurements of the total and free fluoride concentrations in the 0.2-μm filtrates and retentates. It can be seen that the fraction of fluoride present as insoluble species is more or less independent of pH in the range 4.5–6.0, whereas the proportion of free and complexed fluoride varies with pH under the same conditions.

III.3.2. *Excess aluminium: zone 1 (Fig. 1)*

From the free fluoride concentrations measured at various pH during the back titration of Al_p plus F solutions with acid (sect. II.3.3 b), the degree of complexation of F, α, defined as (20):

[6] $\alpha = [F]_t/[F]$

was evaluated. For pH < 4.5, fluoride forms HF with hydrogen ions. Thus the mass balance equation for $[F]_t$ is:

[7] $[F]_t = [F] + [HF] + \Sigma\,[\text{All forms of F bound to Al}]$

Combining eqs. [6] and [7] with eq. [4] and the formation constants of HF, $\beta_1^H = [HF]/[H][F]$, and eq. [4] one obtains:

[8] $(\alpha - 1 - \beta_1^H.[H]) = \Sigma\,[\text{All forms of F bound to Al}]/[F]$

A value of $\beta_1^H = 3.01$ at $I = 0.1\,M$, independently evaluated, was used to compute the left hand side of eq. [8]. Typical plots of log ($\alpha - 1 - \beta_1^H[H]$) vs. pH for various $[Al]_t$ are shown in Fig. 5. The main feature of this titration curve is that it can be divided into three pH zones corresponding to the changes in its slopes:

(*i*) 5.5 < pH < 8. In this pH domain, the reactions proceed rapidly and the slopes of plots such as those shown in Fig. 5 can be evaluated for various aluminium concentrations. An average value of 0.65 ± 0.05 for the slope was obtained from titration curves performed at six different aluminium concentrations in the range $10^{-4} - 5 \times 10^{-3}\,M$.

(*ii*) 4.5 < pH < 5.5. In this pH range, the reactions were found to be very slow, taking up to 24 h to attain equilibrium. This may be due to depolymerization of polynuclear hydrolysed species. No attempt was made to interpret these results quantitatively as reactions were too sluggish.

(*iii*) pH < 4. The results in Fig. 5 show that log ($\alpha - 1 - \beta_1^H.[H]$) becomes independent of pH. The reactions in this case were found to be rapid.

IV. Discussion

In our previous paper (15) we showed that under mild hydrolysing conditions, hydrolysed aluminium solution is predominantly made up of polymeric aluminium hydroxide species which closely resembles $Al_{13}O_4(OH)_{24}^{7+}$. In particular, our results showed that the polydispersity of Al_p is small, more than 80% of the polymeric species being in the size range 10–20 Å. Consequently, in the subsequent discussions Al_p will be represented by $Al_{13}O_4(OH)_{24}^{7+}$ or $[Al(OH)_{2.48}]_n$ (n = 13), the two being stoichiometrically equivalent. It was also shown that the remainder of $[Al]_t$, which represents only ca. 10–20%, consists

of finely divided nonreactive aluminium oxi-hydroxide in equilibrium with traces of monomeric aluminium species.

IV.1. *Zone 1:*

IV.1.1. $r_F \leq 0.1$; *pH* < 4 *(Figs. 1 and 5)*

Hem and Roberson (5) showed that at pH < 4 aluminium exists mainly as monomeric species. Hence it may be assumed that for pH < 4, Al_p will dissociate completely into monomeric aluminium hydroxo species, provided equilibrium is attained. Since Al is present in excess, the predominant fluoro complex of aluminium would be AlF, whereas a major part of the total aluminium is present as Al^{3+} and $AlOH^{2+}$. Thus eq. [8] can be written as:

$$[8a] \quad (\alpha - 1 - \beta_1[H]) = [AlF]/[F] = \beta_1^F.[Al]$$

and the mass balance for the total aluminium concentration is given by:

$$[9] \quad [Al]_t = [Al] + [AlF] + [AlOH]$$

Since aluminium ions are present in excess, the approximation:

$$[10] \quad [Al]_t = [Al] + [AlOH]$$

holds. Combining eq. [10] with the formation constant given in eq. [11]:

$$[11] \quad \beta_1^{OH} = [AlOH]/[Al][OH]$$

one obtains:

$$[12] \quad [Al] = [Al]_t/(1 + \beta_1^{OH}.[OH])$$

β_1^F was evaluated from eqs. [8] and [12] using $\log \beta_1^{OH} = 9.0$ at 0.1 *M* ionic strength (19) and the experimental value of 3.01 for $\log \beta_1^H$. From all the titration data (Fig. 5), the mean value of $\log \beta_1^F$ was found to be 6.13 ± 0.04 (for 95% confidence limit). Considering the complexity of the system used, this value is in reasonable agreement with the value of 6.32 at 0.1 *M* ionic strength reported in the literature (19). Thus these results confirm that at pH values below 4.0, Al_p dissociates completely into monomeric aluminium species provided sufficient time is allowed to reach equilibrium (ca. 1 week).

IV.1.2. $r_F \leq 0.1$; $5 < pH < 8$

In this case a soluble complex is formed between the polymer and fluoride (Table 1, Fig. 1). As aluminium ions are present in excess, the fixation of one fluoride per molecule of polymer has been assumed for the reaction of Al_p with fluoride. This reaction may be written as:

$$[13] \quad Al_{13}O_4(OH)_{24} + F \rightleftharpoons Al_{13}O_4(OH)_{24-z}F + zOH$$

where z is the number of hydroxide ions released per fluoride bound. Let K_p be the ligand exchange constant:

$$[14] \quad K_p = \frac{[Al_{13}O_4(OH)_{24-z}F][OH]^z}{[Al_{13}O_4(OH)_{24}][F]}$$

The total fluoride concentration, $[F]_t$ is given by:

$$[15] \quad [F]_t = [F] + [Al_{13}O_4(OH)_{24-z}F]$$

or

$$[16] \quad \alpha = [F]_t/[F] = 1 + K_p[Al_{13}O_4(OH)_{24}]/[OH]^z$$

The concentrations of all forms of aluminium except Al_p are negligible compared to $[Al]_t$ under these conditions. As a first approximation, it is reasonable to assume:

$$[17] \quad [Al_{13}O_4(OH)_{24}] \simeq [Al]_t/13$$

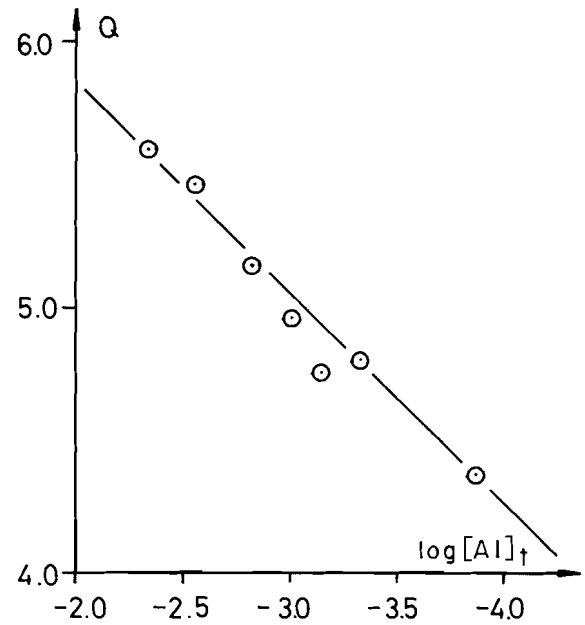

FIG. 6. A plot of Q vs. $[Al]_t$ (see eq. [19]).

Equation [16] can be written as:

$$[18] \quad (\alpha - 1) = \log (K_p/K_w^z.13) + \log [Al]_t + z\,pH$$

where K_w is the ionic product of water.

The value of z *was found* to be 0.65 ± 0.05 (for 95% confidence limits) (see sect. III.1.2). An average value of 0.6 OH released per fluoride fixed was also found experimentally for $r_F \leq 0.1$ (Fig. 3, curves (a) and (b)). Thus if sufficiently long equilibration times are used, then the observed stoichiometry for fluoride bound per hydroxide ion released is independent of the titration mode and is close to 0.6.

The value of K_p *can* be found from Fig. 5 and eq. [18]. Indeed the intercepts on the ordinate, Q, of the straight line plots (Fig. 5) in the pH region of interest should be dependent on $[Al]_t$:

$$[19] \quad Q = \log (K_p/K_w^z) + \log [Al]_t$$

The slope of such a plot (Fig. 6) was found to be 0.97, which is close to the theoretically predicted value of 1. K_p can be evaluated from the intercept of this plot and was found to be 1.03 ± 0.01, which is in agreement with a value of 1 expected for ligand exchange reaction between OH and F (5).

IV.2 *Zone 2:* $0.5 < r_F \leq 1$

Fluoride precipitates in this region. Under similar conditions Hsu (16) also observed the precipitation of phosphates and silicates with polymeric aluminium hydroxide species and has proposed a model for these precipitation reactions. According to this model, the phosphate and silicate ions reduce the charge of Al_p, inducing precipitation when its charge is completely neutralized. Analogous reaction schemes can be used for interpreting the fluoride–aluminium interactions. However, in this case, in addition to the neutralization of charge, the fluoride ions can replace some of the hydroxide ions incorporated in the polymer since it has a stronger affinity than phosphate for aluminium and is similar in size to hydroxide ions. This would then explain the release of hydroxide ions observed during the reaction between Al_p and fluoride. Since r_F^b represents the number of fluoride ions bound per aluminium, the reaction between Al_p and F can be represented in the general form:

[20] $1/n[Al(OH)_{2.46}]_n + r.F \rightleftharpoons 1/n[Al(OH)_{(2.46)}F_r]_n + mOH$

where $r = r_F^b$ in eq. [20].

In order to get an uncharged reaction product one must have:

[21] $0.54 + m = r_F^b$

By substituting the experimental value of r_F^b (= 0.8) in eq. [21], the value of m was found to be 0.26. The ratio $m/r_F^b = [OH]_{rel}/[F]_b$ is then found to be 0.32, which is in agreement with the experimental value of 0.35 obtained from Fig. 3, curves (a), (b), at $r_F = 0.8$.

The results of analysis of the solid phase also support the formation of mixed fluoro-aluminium compound. Thus all these results favour eq. [20], and by substituting $n = 13$ and $r_F^b = 0.8$, it becomes:

[22] $Al_{13}O_4(OH)_{24}^{7+} + 10\,F^- \rightleftharpoons Al_{13}O_4(OH)_{21}F_{10}(s) + 3\,OH^-$

As mentioned above, the formation of a mixed phosphato-aluminium complex in the reaction between phosphate and hydroxy aluminium species has also been reported (16, 17, 21). The H_2PO_4/Al mole ratio of the precipitate calculated from the results reported for $r_{OH} = 2.5$ and similar pH conditions yielded a value of 0.46, which would be comparable with the F/Al mole ratio (0.54) if no hydroxide ions were replaced by fluoride ions, as is the case for H_2PO_4. These findings therefore tend to suggest that the reaction mechanisms for the reaction of Al_p with both fluoride and phosphate follow similar pathways. It must be pointed out that the nature of the solid formed under these conditions is markedly different from the one formed where excess of fluoride is present (see sect. III.3.1).

IV.3. *Zone 3:* $r_F \geq 3$

In this case two observations were made: (a) formation of precipitate, and (b) existence of dissolved complexed fluoride (Fig. 1).

The results of analysis of the solid suggest that Al_pF_n depolymerizes into cryolite and alumina under these conditions. The formation of cryolite in the presence of excess of fluoride has also been reported by Hem and Roberson (5). A comparison of these results with those of Fig. 4 shows that the solubility of the fluoride is dependent on the total aluminium concentration and pH when $r_F > 3$. The solubility decreased with increased aluminium concentrations, whereas it increased with increased acidity below pH 4 and remains unaffected in the pH range 4.5–8.

The nature of the various forms of fluoride at $r_F \geq 3$ is shown in Fig. 4. It is apparent that the concentrations of free and bound fluoride are dependent on pH and the total aluminium concentration initially present.

Conclusions

The results of this study show that the interaction between fluoride and aluminium hydroxide polymer, Al_p, leads to the formation of several soluble and insoluble products depending on r_F, pH, and total applied fluoride and aluminium concentrations. The types of products formed as a function of r_F are summarized in Table 2. For $r_F \leq 0.1$, a significant portion of the total fluoride is present as soluble fluoride. At $r_F = 0.7$, $r_{OH} = 2.5$, and pH between 4 and 7, a major proportion of total fluoride is precipitated as $Al_{13}(OH)_{29}F_{10}$. Under these conditions about 7 mg/L of fluoride remains in the solution owing to the intrinsic solubility of this compound. At $r_F > 1$, Al_p dissociates and the reaction products under these conditions consist of a mixture of hydrated alumina and cryolite. The amount of dissolved fluoride present in these solutions was found to vary with the applied aluminium concentration and it is controlled by the high solubility of cryolite (0.042 g/L) (22).

TABLE 2. Summary of the main species formed between Al_p and F under the experimental conditions used in this work

	r_F		
pH	≤0.1	0.5–1.0	>1.0
4	HF, AlF	HF, AlF	HF, AlF
4–5.5	AlF		AlF
		Al_pF_{10} (s)	Na_3AlF_6
5.5–7	Al_pF_n	Al_pF_n	Al_2O_3, Na_3AlF_6
7–8		F adsorbed on Al $(OH)_3$	F

Thus if Al_p is used for precipitating fluoride, then the optimal conditions are as follows: $r_{OH} = 2.5$, $r_F = 0.7$, and $4 < pH < 7$, provided no interfering components are present. The removal of fluoride by Al_p from waste waters of aluminium manufacturing plants where interfering components are present is discussed elsewhere (23).

$HUO_2PO_4 \cdot 4H_2O$ (HUP) forms a laminar intercalate with butylamine, c = 29.30(5) Å, which accepts cationic metals in exchange for the n-butylammonium ions. Hydrated uranyl metal phosphates $M(UO_2PO_4)_2 \cdot nH_2O$ (M = Mn, Co, Ni, Cu, Zn, Cd) are obtained by ionic exchange and were studied by thermal analysis and X-ray diffraction. The tetragonal structures of all these product compounds are derived from HUP. The diffuse electronic reflectance spectra of every sample show characteristic UO_2^{2+} absorption bands. In the spectra of the Co, Ni, and Cu phosphates there are other bands in the 500–800 nm zone compatible with their observed aquocation transitions.

R. POZAS-TORMO, L. MORENO-REAL, M. MARTÍNEZ-LARA et S. BRUQUE-GAMEZ. Can. J. Chem. **64**, 30 (1986).

Le $HUO_2PO_4 \cdot 4H_2O$ (HUP) et la butylamine forment un composé laminaire intercalé (c = 29,30(5) Å) qui accepte des métaux cationiques en échange pour les ions n-butylammonium. On obtient les phosphates métalliques d'uranyle hydratés [$M(UO_2PO_4)_2 \cdot nH_2O$ dans lesquels M = Mn, Co, Ni, Cu, Zn et Cd] grâce à un échange ionique et on les a étudiés par analyse thermique et par diffraction des rayons-X. En se basant sur le HUP, on en déduit que tous ces composés existent dans des structures tétragonales. Les spectres de réflectance électronique diffuse de chacun de ces échantillons présentent des bandes d'absorption caractéristiques du UO_2^{2+}. Dans les spectres des phosphates de Co, Ni ou Cu, on trouve aussi d'autres bandes, dans la région de 500 à 800 nm, qui sont compatibles avec les transitions observées pour leurs aquocations.

[Traduit par le journal]

Introduction

The intercalation chemistry of the inorganic layered compounds is becoming increasingly important; in particular, the ionic exchange and adsorption characteristics and the host–guest relationships of the layered phosphates have been intensively studied in: $Zr(HPO_4)_2 \cdot H_2O$ (1); $Sn(HPO_4)_2 \cdot H_2O$ (2); $VOPO_4 \cdot 2H_2O$ (3), and $HUO_2PO_4 \cdot 4H_2O$ (HUP) (4, 5).

HUP belongs to the large family of uranium mica compounds with the general formula $M(UO_2PO_4)_2 \cdot nH_2O$ where M may be a mono or divalent cation. These compounds have a typical structure of negatively charged layers of $(UO_2PO_4)_n^{n-}$ separated by staggered layers of water molecules and compensating cations (6). In HUP, the latter are H^+, but these may be substituted by almost any other cations.

Pekarek and Vesely (7) have studied some thermodynamic phenomena of the ionic uptake by HUP/M (M^I to M^{IV}). Other authors investigated the proton conductivity of HUP and the HUAs (8, 9). The photoluminescent properties of these phosphates are reported in detail by Olken *et al.* (5).

A large number of synthetic compounds of the uranium mica type have been prepared. Uranyl phosphates of alkali metals, alkaline earth cations, and some transition metal ions were isolated by precipitating their respective ionic solutions (10–13) and also by ion exchange in HUP (5, 14).

The present work studies the uptake of divalent transition metal ions by the expanded intercalate $(C_4H_9NH_3)UO_2PO_4 \cdot 3H_2O$ and characterizes the final homoionic products, which all show good crystallinity and high degrees of hydration. The concept of using butylamine to facilitate exchange in layered hydrogen phosphates was first demonstrated by Clearfield and Tindwa (15), although Weiss *et al.* had prepared n-alkylammonium derivatives of hydrogen uranyl phosphate (16).

Experimental

Synthesis

The uranyl hydrogen phosphate tetrahydrate $HUO_2PO_4 \cdot 4H_2O$ (HUP) was prepared from uranyl nitrate and orthophosphoric acid in aqueous solution with the proportion U/P 1:1.1, according to the method of Schreyer and Baes (17). The resulting product was air dried and kept in a controlled humidity atmosphere (P_{H_2O} = 9.12 Torr; 1 Torr = 133.3 Pa). It was identified by chemical analysis, X-ray diffraction, and thermal analysis.

The intercalate $(C_4H_9NH_3)UO_2PO_4 \cdot 3H_2O$ (BAUP) was prepared by exposing HUP to a saturated atmosphere of n-butylamine vapour (NBA) for 2 days in a desiccator. The product was evacuated at room temperature and was left in a controlled humidity atmosphere (H_2SO_4 40% w/w). The composition of the intercalate, BAUP, was determined by spectrophotometry of P and U and Kjeldahl microanalysis of N; water content was measured by thermal analysis.

X-ray diffraction and infrared spectroscopy were used for structural arrangement determination.

Ionic uptake process

The $M^{2+}/C_4H_9NH_3^+$ uptake process was studied by bringing into contact aqueous suspensions of the BAUP intercalate with aqueous metal acetate solutions (up to final concentrations of 10^{-2} M) for 48 h at 25°C. Experiments were made with different equivalent amounts of metallic ions ranging from 0.4056 mequiv./g, or 20% of theoretical maximum uptake capacity (2.028 mequiv./g), to 4.056 mequiv./g, a 100% excess over capacity. The suspensions were then centrifuged and the solids washed until acetate removal was complete. These were then air dried and stored in an environment controlled at 50% humidity. The uptake of metallic ions in the exchange process was determined by analysis of the solid phase and its equilibrium solutions. Analytical data for the butylammonium and the various cation intercalates are available as supplementary material.[2]

[2]A table of analytical data (Table 1, supplementary material) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Instrumental

The instrumental techniques employed to characterize the new materials were infrared spectroscopy (Perkin Elmer 580), X-ray diffraction (Philips PW 1710), differential thermal and thermogravimetric analysis (Rigaku Thermoflex), diffuse reflectance and visible–ultraviolet spectroscopy (Kontron Uvikon 810), and atomic absorption spectroscopy (Varian AA 475 ABD).

Results and discussion

Characterization and structural determination of BAUP intercalate

The product powder X-ray diffraction pattern (Table 2) can be indexed on a tetragonal unit cell with $a = 6.968(7)$ and $c = 29.30(5)$ Å, though the basal spacing observed is 14.65 Å, which corresponds to the 002 reflection.[3] All the starting product *hk*0 lines were present in the intercalate with systematic absences when $h + k \neq 2n$. These data (Table 2)[3] show the persistence of the HUP framework *ab* plane and, in addition, clearly indicate that the tetragonal layer structure was preserved although the *c* axis was expanded. The most probable space group is $P4_2/n$.

Botto *et al.* (18) found 9.05 Å for the basal spacing (d_{002}) of the isostructural compound $NH_4UO_2PO_4 \cdot 3H_2O$. The perpendicular arrangement of an alkyl chain with four atoms of carbon between the layers would originate from 14.85 Å layer spacing, very close to that obtained here (14.65 Å). The existence of a monolayer in the *n*-butylamine intercalate (BAUP) contrasts with the bilayer found in the hydrogen phosphate of zirconium (19). This compound has an available layer surface area around the hydrogen atoms that is smaller than the HUP (24 $Å^2$ against 48.8 $Å^2$).

In the intercalate infrared spectrum, as well as the bands of the phosphate, water, and UO_2^{2+} vibrations, there are others which correspond to the following groups: $\nu_{CH_3\,sym.}$ (2970 cm^{-1}); $\nu_{CH_2\,sym.\,and\,asym.}$ (2940 cm^{-1}); $\nu_{CH_3\,sym.}$ (2880 cm^{-1}); $\delta_{NH_3^+\,asym.}$ (1620 cm^{-1}); $\delta_{NH_3^+\,sym.}$ (1530 cm^{-1} and 1510 cm^{-1}); δ_{CH_2,CH_3} (1470 cm^{-1}).

These data show that protonation of the guest amine has occurred to give rise to the butylammonium ions between the layers.

The thermogravimetric curve (Fig. 1) exhibits three stages of weight loss. The first corresponds to the initial dehydratation and is associated with two endothermic effects, which may be seen on the DTA curve, and are centred on 90 and 130°C. In the two following stages (150–200°C and 300–400°C), the organic cation is removed; this process occurs in two endothermic effects (at 240 and 315°C). The last of these immediately precedes a DTA exothermic effect (340°C), the result of the combustion of organic residues. These processes are comparable to the observed by Clearfield and Tindwa (19).

Ionic uptake

When the intercalate BAUP is placed in contact with metallic acetate solutions (M = Mn, Co, Ni, Cu, Zn, Cd), the following reaction takes place:

$$[1]\quad M^{2+}(aq) + 2(C_4H_9NH_3)UO_2PO_4 \cdot 3H_2O \rightarrow M(UO_2PO_4)_2 \cdot nH_2O + 2C_4H_9NH_3^+(aq)$$

[3]A table of crystal and X-ray powder diffraction data $(C_4H_9NH_3)UO_2PO_4 \cdot 3H_2O$ (Table 3, supplementary material) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

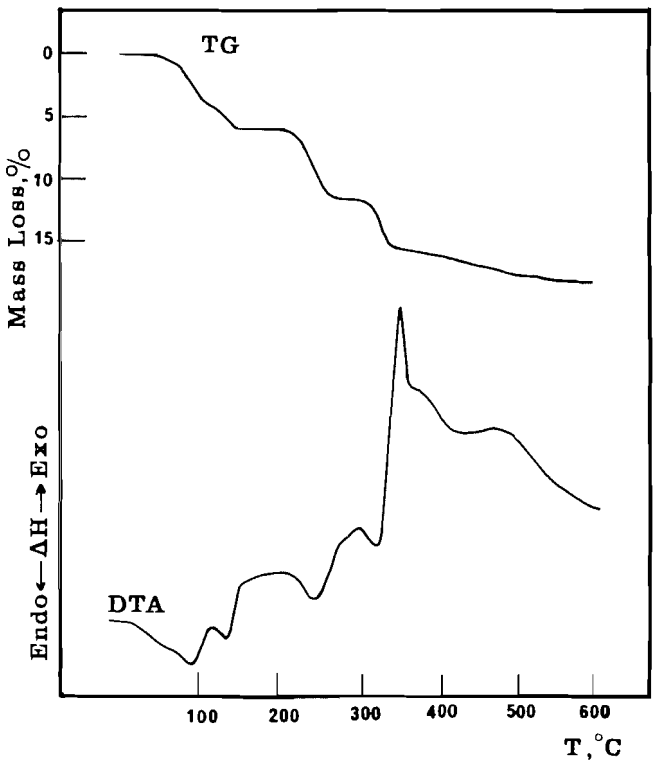

FIG. 1. TG and DTA curves of the $(C_4H_9NH_3)UO_2PO_4 \cdot 3H_2O$.

The ionic exchange reaction $M^{2+}/C_4H_9NH_3^+$ took place without hydrolysis of the ion-exchange solid. This was confirmed by determining P and U in the equilibrium solutions. In all cases the hydrolysis of P and U detected was below 0.6 and 1%, respectively. Greater percentages of hydrolysis were obtained when nitrate, chloride, or sulphate salts were involved in the ionic uptake reactions because of the higher acidity of these solutions.

The ionic exchange described in eq. [1] is quite fast and may be followed by measuring the equivalent values of the butylammonium liberated (Kjeldahl N analysis), and of the metallic ions that remain in the solution, to determine the quantity removed; both values coincide. The apparent velocity of the uptake process was studied for each metallic ion and, by way of example, we shall consider the exchange $Co^{2+}/C_4H_9NH_3^+$, taking place with an initial molar ratio of 0.65:1 (1.3 equivalents for each *n*-butylammonium equivalent at 25°C). Figure 2 shows that after an hour, 90% of the intercalated butylammonium ions have been substituted by cobalt. After 12 h, all the exchange positions are occupied. The exchange sites are now saturated by cobalt and the reaction is complete.

The curves obtained for the other ions are similar; their equilibrium times are between 10 and 12 h, and the molar ratios are 0.6–0.8 (M^{2+}): 1 (NBA).

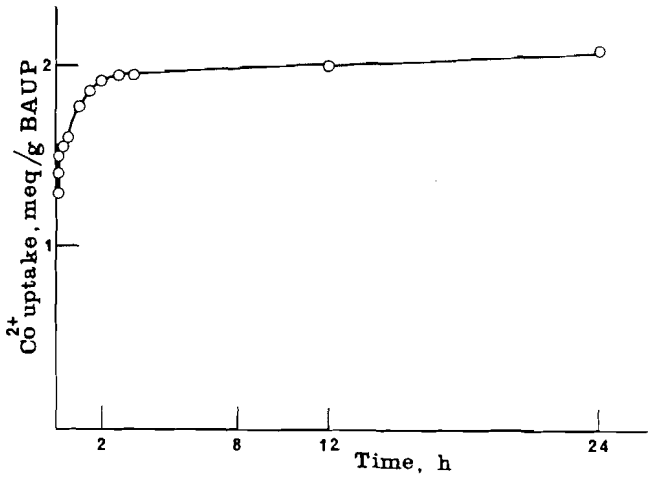

FIG. 2. Uptake of Co^{2+} by butylammonium uranylphosphate as function of time.

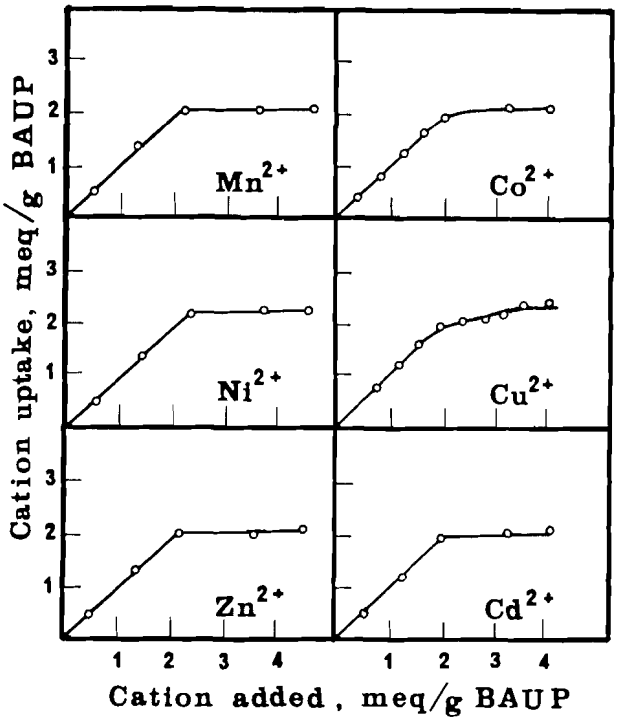

FIG. 3. Retention isotherms of cations by butylammonium uranylphosphate (BAUP).

In order to ensure equilibrium conditions, each isotherm point was obtained with 48 h contact time.

The exchange isotherms show that the BAUP ion exchanger has great affinity for metallic ions and that 1–1.6 equivalents of metallic ion for each equivalent of *n*-butylammonium are quite sufficient to give fully exchanged phases. All the isotherms (Fig. 3) show similar behaviour and may be fitted to a straight line using the equation of Langmuir's isotherm.

Following the exchange process, the product was examined by X-ray diffraction and, in comparison with starting product, the basal spacing was changed; in particular, there was a decrease in the *d*(001). As the exchange sites become saturated, the *hk*0 reflections persist; they are not affected by the ionic uptake. Figure 4 shows the changes in the X-ray diffraction patterns when the butylammonium is exchanged by Cu^{2+}. This indicates that the layered structure *ab* plane is unaltered.

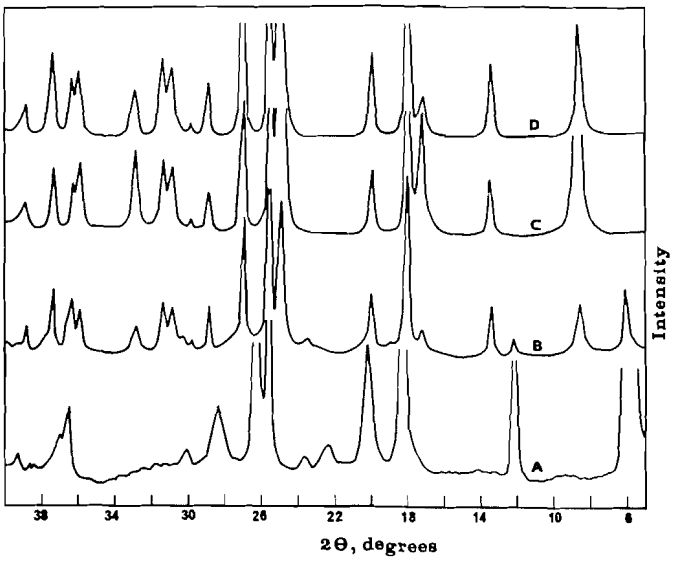

FIG. 4. X-ray diffraction patterns of Cu^{2+} exchanged $(C_4H_9NH_3)$-$UO_2PO_4 \cdot 3H_2O$ at various loadings: (A) BAUP; (B) BAUP + 0.6 symmetries of Cu^{2+}; (C) BAUP + 1.0 symmetries of Cu^{2+}; (D) BAUP + 1.6 symmetries of Cu^{2+}.

$Zn(UO_2PO_4)_2 \cdot 9.5H_2O$	3	56°C, 68°C	5.5	106°C	1	163, 300°C
$Cd(UO_2PO_4)_2 \cdot 8.5H_2O$*	3	50°C, 63°C	3.5	100°C	2	160, 193°C

*Two mixed phases.

Significant changes in the infrared spectra are produced by the substitution of *n*-butylamine by the metallic ions. In Fig. 5 a progressive decrease may be seen in the vibration bands corresponding to the CH_3, CH_2, and NH_3^+ groups as the uptake process of Co^{2+} ions proceeds. In the fully exchanged phases these bands have disappeared.

The P/U/M molar ratios of the solid compounds in which uptake is complete are 2:2:1; they correspond to hydrates with the general formula $M(UO_2PO_4)_2 \cdot nH_2O$, where $n = 8–10$.

Thermal analysis of the MUP hydrates shows that the water molecules are lost in a succession of endothermic effects (from 3 to 5) which occur between 50 and 300°C. In general, the successive stages of weight loss may be summarized by the following formulae:

$$M(UO_2PO_4)_2 \cdot nH_2O \xrightarrow[-xH_2O]{\text{I}} M(UO_2PO_4)_2 \cdot (n-x)H_2O$$

$$\xrightarrow[-yH_2O]{\text{II}} M(UO_2PO_4)_2 \cdot zH_2O \xrightarrow[-zH_2O]{\text{III}} M(UO_2PO_4)_2$$

Table 4 gives the values of x, y, and z and also the ranges of temperatures in which weight loss occurs. The DTA curves exhibit similar behaviour in all the solids studied. There are sharp, clear endothermic peaks associated with the initial effects of weight loss. The peaks of the third stages are more diffuse. In Fig. 6 may be seen the DTA and TG curves of NiUP.

The metal uranyl phosphates reported here correspond to fully hydrated phases that are structurally related to the naturally occurring minerals autunite and torbernite (13, 20, 21).

The diffractogram of hydrated UCdP shows a mixture of two phases: one, the fully hydrated compound with basal spacing of 11 Å, and the other, possibly a metaphase, whose basal spacing is close to 9 Å. When the cadmium compound was heated to 50°C, only one phase was seen; its composition was $Cd(UO_2PO_4)_2 \cdot 7H_2O$.

The crystalline compounds obtained by cation exchange showed very well-defined X-ray powder diffraction patterns that were indexed on the basis of a tetragonal unit cell.[4] Other authors (10, 11) obtained amorphous, or only slightly crystalline, phases when the transition metal uranyl phosphates are synthesized by precipitation from aqueous solutions of the appropriate ion.

Table 7 shows the lattice constants and X-ray powder pattern data obtained for the exchanged compounds. The a values compatible with the indexing of the recorded reflections are within limits of ± 0.008 Å of the a value obtained for the BAUP

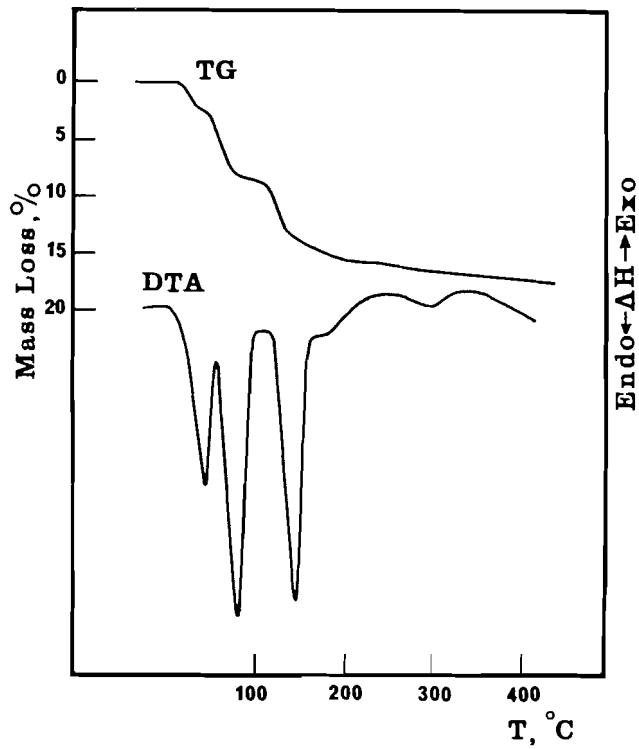

FIG. 6. TG and DTA curves of the $Ni(UO_2PO_4)_2 \cdot 9H_2O$.

intercalate. On the other hand, the c spacing values were double the values of the interlamellar spacings. This is in agreement with the literature (5, 14) for isostructural compounds.

Heated overnight at 50–60°C, the uranyl metal phosphates lose 1–3 water molecules and the basal spacing decreases to 8.5 or 9 Å. Some structural modification may be detected in the diffractograms, although their crystallinity persists and they may be indexed on a tetragonal system. Consequently $Cu(UO_2PO_4)_2 \cdot 10H_2O$, which is found naturally as the mineral torbernite, evolves into a very crystalline compound whose diffractogram and composition (7 hydrate) is identical to metatorbernite (21). In the case of $Mn(UO_2PO_4)_2 \cdot 9.5H_2O$, the partial dehydration leads to a non-tetragonal compound with lower symmetry. None of the 7-hydrate and 8-hydrate compounds subjected to heating will rehydrate in atmospheres of 50 to 60% relative humidity.

The uranyl metal phosphates (UMP) are yellow when the cation electron shell is complete or semi-complete (closed shell ions) (M = Zn, Cd, or Mn) and its electronic diffuse reflectance spectrum only shows the uranyl group vibronic transition bands in the region of 350–500 nm (22). The remaining UMP compounds (M = Co, Ni, and Cu) give a spectral pattern which contains

other bands in the 500–800 nm zone (Table 8) in addition to those mentioned previously. The values of λ_{max} of these 500–800 nm bands are compatible with the observed transitions in the respective aqueous cations with different degrees of distorted octahedral symmetry.

Concluding remarks

In this work we have shown that the layered intercalate BAUP, which was obtained from the HUP(s) + n-$BuNH_2$(v) reaction by ion exchange, gives very crystalline and highly hydrated uranyl metal phosphates. The layered material structures resulting from this process maintain the *ab* plane of the tetragonal lattice of the starting product; the basal spacing of each species is dependent on its degree of hydration. The water molecules serve an important structural function as they are found coordinated with the metallic cations in the form of labile octahedral aqueous complexes. Ongoing studies in these laboratories suggest that the intercalate ligand-substitution reactions might be occurring in the host compounds.

RAFAELA POZAS-TORMO, LAUREANO MORENO-REAL, MARÍA MARTÍNEZ-LARA, and ENRIQUE RODRÍGUEZ-CASTELLÓN. Can. J. Chem. **64**, 35 (1986).

The ion exchange reactions of *n*-butylamine intercalates of tin(IV) hydrogen phosphate and hydrogen uranyl phosphate towards carbonatotetraamminecobalt(III), chloropentaamminecobalt(III), and hexaamminecobalt(III) have been investigated. Independent of the complex cation charges, the amounts of Co(III) complex exchanged by the *n*-butylamine intercalate of tin(IV) hydrogen phosphate are practically the same. With the *n*-butylamine intercalate of hydrogen uranyl phosphate, the ionic exchange was completed and the composition was fixed by the exchanged Co(III) complex. The layer charge densities of these phosphates justify the different ionic exchange behaviour observed towards the large complex cations. All the products were characterized by chemical analysis, X-ray diffractometry, infrared spectroscopy, diffuse reflectance spectroscopy, and thermal analysis.

RAFAELA POZAS-TORMO, LAUREANO MORENO-REAL, MARÍA MARTÍNEZ-LARA et ENRIQUE RODRÍGUEZ-CASTELLÓN. Can. J. Chem. **64**, 35 (1986).

On a étudié les réactions d'échange d'ions des composés d'intercalation entre la butylamine et l'hydrogenophosphate d'étain(IV) et l'hydrogénophosphate d'uranyle avec le carbonatotétraamminecobalt(III), le chloropentaamminecobalt(III) et l'hexaamminecobalt(III). La charge des complexes cationiques n'influence pas le taux d'ions complexes de Co(III) échangés par les composés d'intercalation entre la butylamine et l'hydrogénophosphate d'étain. Dans le cas du composé d'interaction entre la butylamine et l'hydrogénophosphate d'uranyle, l'échange ionique est totale et le complexe d'ion Co(III) échangé en détermine la composition. Les densités de charge de la couche de ces phosphates justifient le comportement des différents échanges ioniques observés avec les grands complexes cationiques. On a caractérisé tous les produits obtenus par l'analyse chimique, la diffraction de rayons X, la spectroscopie infrarouge, la spectroscopie de reflexion diffuse et par l'analyse thermique.

[Traduit par le journal]

Introduction

Tin(IV) hydrogen phosphate monohydrate, $Sn(HPO_4)_2 \cdot H_2O$ (α-SnP), and hydrogen uranyl phosphate tetrahydrate, $HUO_2PO_4 \cdot 4H_2O$ (HUP), are layered inorganic ion exchangers (1, 2). α-SnP crystallizes in the monoclinic system; the interlayer distance is 7.8 Å. On the other hand, HUP crystallizes in the tetragonal system, with an interlayer distance of 8.8 Å. The ion exchange behaviour with alkali metals, alkaline earths, and first row transition metals of these phosphates was investigated (3–8). However, very little is known about ion exchange with large complexes on these exchangers. α-SnP is isostructural to α-zirconium hydrogen phosphate (α-ZrP) (1). Complex ions like $[Co(NH_3)_6]^{3+}$ and $[Cu(NH_3)_4]^{2+}$ were exchanged using the monohydrogen form, or the wider-spaced *n*-butylamine – α-ZrP intercalate (9, 10). Cr(III) Werner complexes have also been exchanged into HUP (11, 12).

The *n*-butylamine intercalated forms of α-SnP (BASnP) and HUP (BAUP) were chosen because of their large interlayer distances (19.5 and 14.4 Å, respectively), with wide passageways leading to the exchange site that would permit the interlayer penetration of large complexes. The characterization of the exchanged behaviour of BAUP will be reported.

Experimental

Preparation

All the chemicals were of reagent grade and were used without further purification. α-SnP and BASnP were prepared as described elsewhere (13, 14). HUP was prepared according to the method proposed by Schreyer and Baes (15). The BAUP was obtained by the same method used for BASnP. The complexes $[Co(NH_3)_4CO_3]NO_3$, $[Co(NH_3)_5Cl]Cl_2$, and $[Co(NH_3)_6]Cl_3$ were synthesized as reported in the literature (16).

Weighed amounts of $Sn(C_4H_{11}N)_2(HPO_4)_2 \cdot H_2O$ and $(C_4H_9NH_3)UO_2PO_4 \cdot 3H_2O$ were suspended for one day, at 25°C, in aqueous solutions of $[Co(NH_3)_4CO_3]NO_3$, $[Co(NH_3)_5Cl]Cl_2$, and $[Co(NH_3)_6]Cl_3$, which represented 300% of the exchange capacity. This operation was repeated once. The mixtures were filtered, and the solids were analyzed for their metal, water, and nitrogen contents.

Instrumentation

Metal content was determined using a Varian Techtron 475 ABD atomic spectrophotometer. The nitrogen content was determined by a micro-Kjeldahl method. X-ray films were obtained in Huber Debye–Scherrer cameras with diameters of 11.46 cm using a Siemens X-ray generator. A Siemens D-500 diffractometer was used for the X-ray diagrams. The radiation was nickel-filtered CuKα in each case. TG and DTA analyses were carried out using a Rigaku Thermoflex thermoanalyzer, at a heating rate of 10°C min^{-1}. Diffuse reflectance spectra were recorded on a Kontron–Uvikon 810 spectrophotometer with an integrating sphere attachment, which used $BaSO_4$ as the reference. Infrared studies were performed on a Beckman 4260 spectrophotometer by the KBr disc method.

TABLE 1. Composition and interlayer distances of the exchanged phases at 25°C

Composition	Interlayer distance (Å)
$Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.5H_2O$	11.90
$Sn[Co(NH_3)_5Cl]_{0.5}H(PO_4)_2 \cdot 1.51H_2O$	12.40
$Sn[Co(NH_3)_6]_{0.5}H_{0.5}(PO_4)_2 \cdot 3H_2O$	11.60
$[Co(NH_3)_4CO_3]UO_2PO_4 \cdot H_2O$	13.60
$[Co(NH_3)_5Cl]_{0.5}UO_2PO_4 \cdot 2.5H_2O$	9.64
$[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$	9.88

Results and discussion

Composition and X-ray data

Table 1 shows the composition and the interlayer distance of the exchanged phases at 25°C. The amount of cobalt(III) complex exchanged by BASnP is independent of the charge of the complex. Although the interlayer distances of these compounds are different, a reflection line at 9.1 Å was observed in the powder patterns of all the complex exchanged compounds. Because of the crystal distortion suffered in the intercalation process, the X-ray diffraction data of the BASnP derivatives show few reflection lines, and thus the calculation of unit cell constants based on the powder patterns is not possible.[2] The observed composition results from the "covering effect" of the guest molecule; that is to say, the complex ion bonded to phosphate groups impedes bonding at an adjacent site, as this site is now covered. A similar composition was seen when BAZrP was ion exchanged with tetraamminecopper(II) (9). With BAUP there was a complete ionic exchange with the complex cations. In this case, the composition is a function of the complex cation charge. This different behaviour between HUP and α-SnP is due to the different layer charge densities. HUP has a smaller layer density than α-SnP and consequently a bigger free area around the active site (48.8 $Å^2$ for HUP and 21.5 $Å^2$ for α-SnP (14)). Thus, total saturation with large complex cations can be attained. The hydration stoichiometry of these compounds shows a wide range.

Table 3 shows the X-ray crystallographic data for the HUP exchanged phases. All samples could be indexed to tetragonal unit cells. The reflection lines corresponding to the original *hk*0 planes were maintained.[3] The absence of *hk*0 lines when $h + k \neq 2n$ demonstrates the retention of the *n* glide plane of uranyl phosphate. The layer structure has been preserved, while the *c* axis has varied.

Infrared spectra

The ir spectra of the exchanged compounds of BASnP are shown in Fig. 1. The $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.51H_2O$ spectrum (curve A) shows bands, due to zeolitic water, occurring at 3570, 3490, and 1640 cm^{-1}; they can be superimposed upon those reported previously for α-SnP (17).

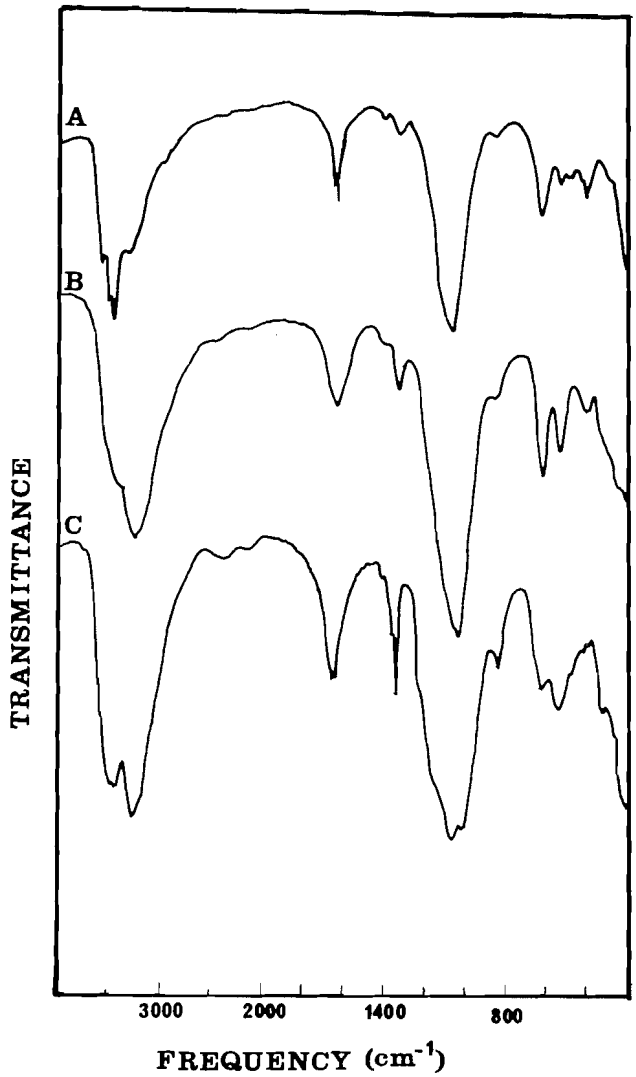

FIG. 1. Infrared spectra of (A), $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.5H_2O$; (B), $Sn[Co(NH_3)_5Cl]_{0.5}H(PO_4)_2 \cdot 1.5H_2O$; (C), $Sn[Co(NH_3)_6]_{0.5}H_{0.5}(PO_4)_2 \cdot 3H_2O$.

The water stretching in the $Sn[Co(NH_3)_5Cl]_{0.5}H(PO_4)_2 \cdot 1.5H_2O$ (curve B) and $Sn[Co(NH_3)_6]_{0.5}H_{0.5}(PO_4)_2 \cdot 3H_2O$ (curve C) are not so sharply defined and they are overlapped by the NH_3 stretching bands. Generally, the NH_3 stretching bands occur at higher frequencies (3300–3200 cm^{-1}) because these frequencies are sensitive to changes in the anion. (The anion of the complex salts (Cl^-) is substituted by the layer O_3PO^-.) The broadening of these bands is the result of hydrogen bonding as well as the overlapping of the individual N—H stretching bands of the complex (18). The NH_3 scissoring bands at 1330 cm^{-1} (curve B), and 1335 cm^{-1} (curve C), are sharp and practically superimposable on those of the original complexes (18). In all cases, the NH_3 rocking vibrations shift to higher frequencies and overlap the absorption bands of the phosphate group, as this rocking mode is very sensitive to the outer ions and the hydrogen bonding (19). The absence of characteristic bands in the region of 1500–1400 cm^{-1} and the higher frequency shift of the rocking mode indicate that the cobalt complex ion is now present as an amine complex and that the ammonia is hydrogen-bonded with the layer phosphate (20). The cobalt–nitrogen stretching bands are very weak and occur near 500 cm^{-1}.

[2]A table of X-ray powder diffraction data of $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.51H_2O$, $Sn[Co(NH_3)_5Cl]_{0.5}H(PO_4)_2 \cdot 1.51H_2O$, and $Sn[Co(NH_3)_6]_{0.5}H_{0.5}(PO_4)_2 \cdot 3H_2O$ (Table 2, supplementary material) may be purchased from the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]Tables of X-ray powder diffraction data of $[Co(NH_3)_4CO_3]UO_2PO_4 \cdot H_2O$, $[Co(NH_3)_5Cl]_{0.5}UO_2PO_4 \cdot 2.5H_2O$, and $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$ (Tables 4, 5, and 6, supplementary material) may be purchased from the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 3. X-ray crystallographic data of cobalt(III) complex uranyl phosphates (Cu $K_{\alpha_1\alpha_2}$; λ = 1.5418 Å, 20°C)

Compound*	Formula weight	a (Å)	c (Å)	Z	V (Å^3)	d_c	d_o
$[Co(NH_3)_4CO_3]UO_2PO_4 \cdot H_2O$	566.89	6.94(3)	27.42(42)	4	1321.41	2.85	2.83(1)
$[Co(NH_3)_5Cl]_{0.5}UO_2PO_4 \cdot 2.5H_2O$	499.79	6.94(2)	19.38(60)	4	932.33	3.56	3.55(1)
$[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$	446.32	6.98(3)	19.84(16)	4	967.72	3.06	3.09(1)

*All compounds belong to the tetragonal system.

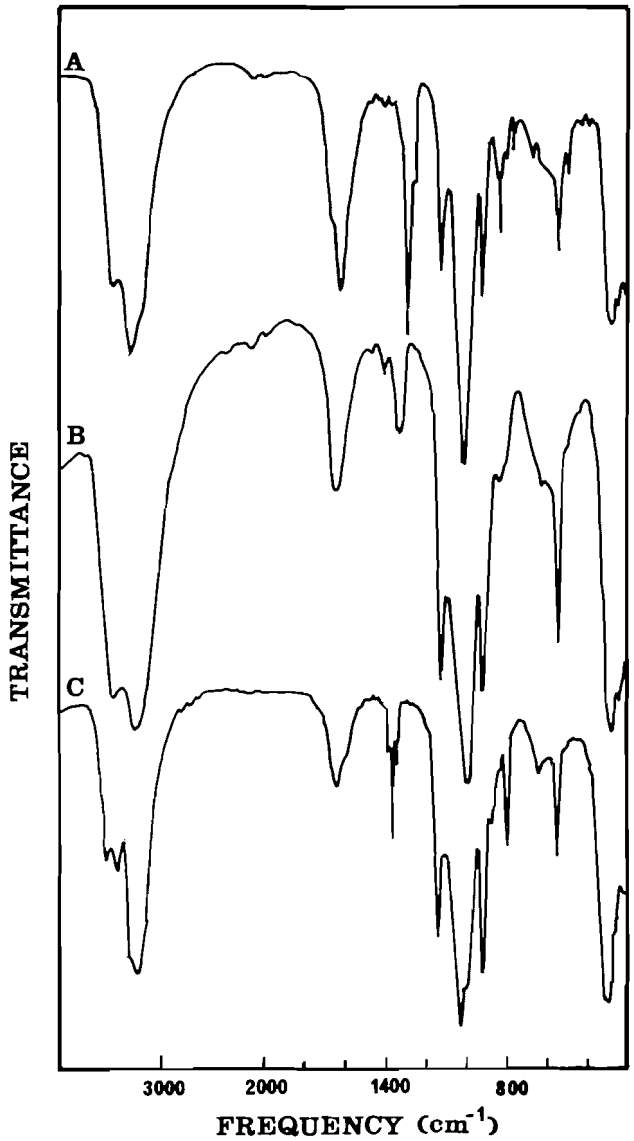

FIG. 2. Infrared spectra of (A), $[Co(NH_3)_4CO_3]UO_2PO_4 \cdot H_2O$; (B), $[Co(NH_3)_5Cl]_{0.5}UO_2PO_4 \cdot 2.5H_2O$; (C), $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$.

Phosphate vibration bands centered at 1000 cm^{-1} dominate all the spectra of Fig. 1.

Figure 2 shows the ir spectra of the exchanged phases of BAUP: $[Co(NH_3)_4CO_3]UO_2PO_4 \cdot H_2O$ (curve A), $[Co(NH_3)_5Cl]_{0.5}UO_2PO_4 \cdot 2.5H_2O$ (curve B), and $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$ (curve C). These spectra are well defined; there is a strong absorption band centered at 1000 cm^{-1} assigned to phosphate stretching (21), and a sharp band at 925 cm^{-1} assigned to the UO_2^{2+} asymmetric stretching vibration; the two dominate

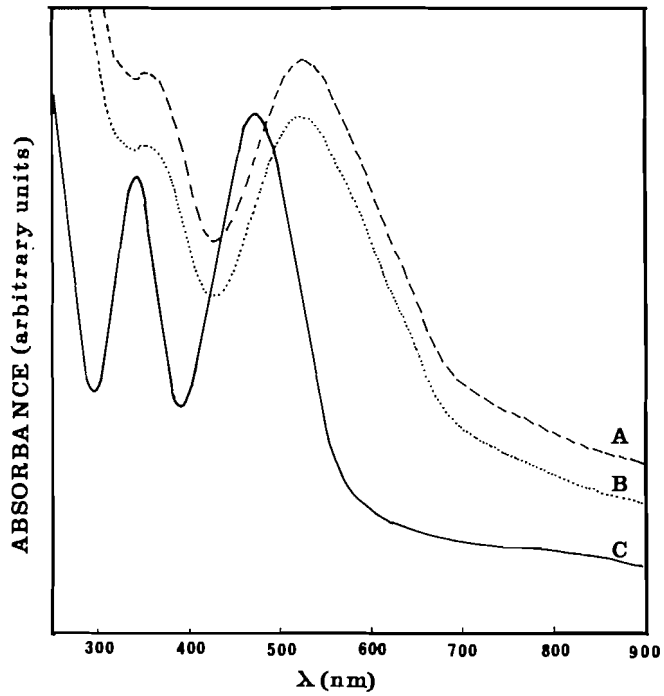

FIG. 3. Diffuse reflectance spectra of (A), $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.5H_2O$; (B), $Sn[Co(NH_3)_5Cl]_{0.5}H(PO_4)_2 \cdot 1.5H_2O$; (C), $Sn[Co(NH_3)_6]_{0.5}H_{0.5}(PO_4)_2 \cdot 3H_2O$.

all the spectra. Water bands occur at 3500 and 1630 cm^{-1}. The ammonia stretching vibration bands of these exchanged phases appear at 3300–3200 cm^{-1}. These values are near those previously observed in the α-SnP derivatives. This is to be expected, because the anions in the layered phosphate are similar. The NH_3 scissoring bands at 1270–1370 cm^{-1} are very sharp and similar to those of the cobalt(III) α-SnP complex. The metal–nitrogen stretching bands are better defined than those of α-SnP derivatives, and occur near 500 cm^{-1}. Sometimes these bands are overlapped by the phosphate group bending vibration band.

In a comparative study, the spectra of α-SnP and HUP derivatives are seen to be composites of those of the phosphate layer and the corresponding cobalt(III) ammonia complex ion. In both series the NH_3 stretching, bending, and rocking modes shift to higher frequencies due to hydrogen bonding phosphate. The NH_3 bending bands at 1620–1640 cm^{-1} overlap the water bending mode.

In all cases, the *n*-butylammonium ion absorption bands of the starting material disappeared.

Diffuse reflectance ultraviolet–visible spectra

The diffuse reflectance spectra of the α-SnP derivatives (Fig. 3) and the HUP derivatives (Fig. 4) are very different. In the

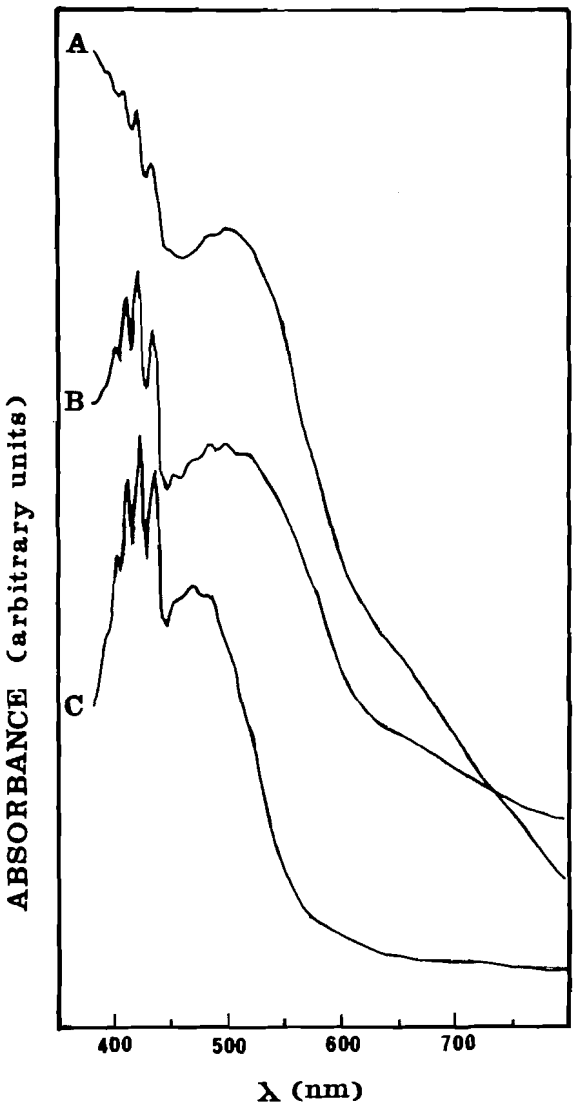

FIG. 4. Diffuse reflectance spectra of (A), $[Co(NH_3)_4CO_3]UO_2PO_4 \cdot H_2O$; (B), $[Co(NH_3)_5Cl]_{0.5}UO_2PO_4 \cdot 2.5H_2O$; (C), $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$.

former, the layered phosphate is inactive in the 300–900 nm region. However, the HUP diffuse reflectance spectrum shows many sharp peaks in the 340–500 nm region; these are derived from the spectrum of the uranyl moiety (22).

The spectra of the α-SnP derivatives correspond to the following ions exchanged: carbonatotetraamminecobalt(III), with maxima at 515 and 350 nm (curve A); chloropentaamminecobalt(III), with maxima at 520 and 350 nm (curve B); and hexaamminecobalt(III), with maxima at 470 and 340 nm (curve C). These spectra are practically superimposable on those of the salt complex employed (23, 24).

The spectra of the HUP derivatives (Fig. 4) are composed of those of HUP and the cobalt(III) complex ions. All the samples exhibit similar spectra in the 370–500 nm region. The absorption bands that correspond to the Co(III) complex ions overlap; it is only possible to distinguish them at 510 nm for $[Co(NH_3)_4CO_3]$-UP and $[Co(NH_3)_5Cl]$-UP, and at 470 nm for $[Co(NH_3)_6]$-UP. These values observed in the visible region coincide closely with those reported for the complex ions. However, the high absorption of the HUP layer in the ultraviolet

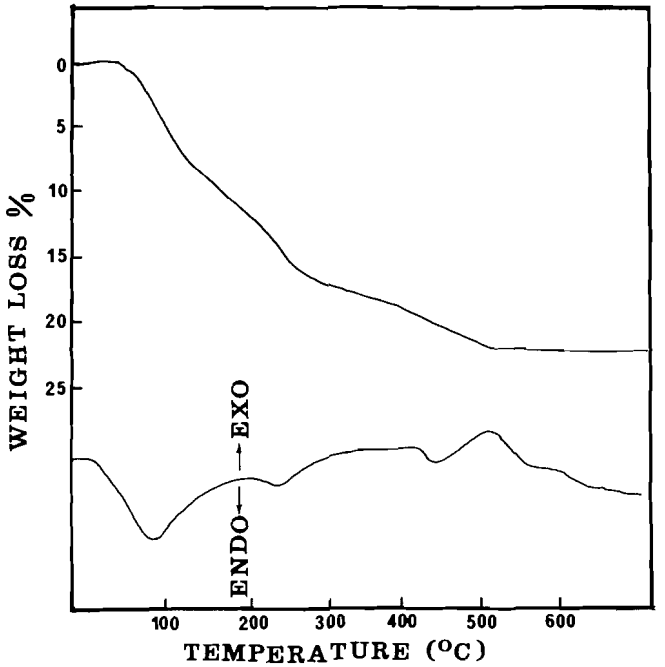

FIG. 5. DTA–TG curves of $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.5H_2O$.

region impedes the detection of the corresponding bands assigned to the $^1T_{2g} \leftarrow {}^1A_{1g}$ transition.

From these data we conclude that the Co(III) complex ions are present in the exchangers.

Thermal data

The thermal behaviour of the α-SnP derivatives and HUP derivatives was investigated. As representative examples, we show the decomposition processes of $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.5H_2O$ and $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$. In the DTA–TG curves of the former compound (Fig. 5), three different stages can be seen. The first (DTA peak at 84°C) corresponds to the removal of the water of crystallization. The second corresponds to the evolution of ammonia and carbon dioxide. Finally, the condensation of orthophosphate to pyrophosphate takes place between 400 and 500°C. In the X-ray powder diffraction patterns of the sample heated at 900°C, SnP_2O_7 could be identified[4] (25). This confirms the presence of the proton in the exchanged compound. However, the expected Co_3O_4 could not be detected. This spinel is the final product when $[Co(NH_3)_4CO_3]_2SO_4 \cdot 3H_2O$ is heated at 800°C (26).

The thermogravimetric curve of $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$ (Fig. 7) indicates that the decomposition of this compound occurs in three stages. The first corresponds to the removal of water. In the second, the ammonia and nitrogen liberation are almost overlapped; the cobalt(III) ion is reduced, as in the case of the hexaamminecobalt(III) halides (27). The third corresponds to the condensation of orthophosphate to pyrophosphate. The DTA curve supports this mode of decomposition. The experimental per cent weight loss on ignition agrees with the calculated value if the Co(III) reduction and the condensation to pyrophosphate are considered. A significant increment of the magnetic susceptibility was observed in the compound

[4]Figure 6, X-ray powder diffraction patterns of $Sn[Co(NH_3)_4CO_3]_{0.49}H_{1.51}(PO_4)_2 \cdot 1.5H_2O$ heated at 900°C, (Fig. 6, supplementary material) may be purchased from the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

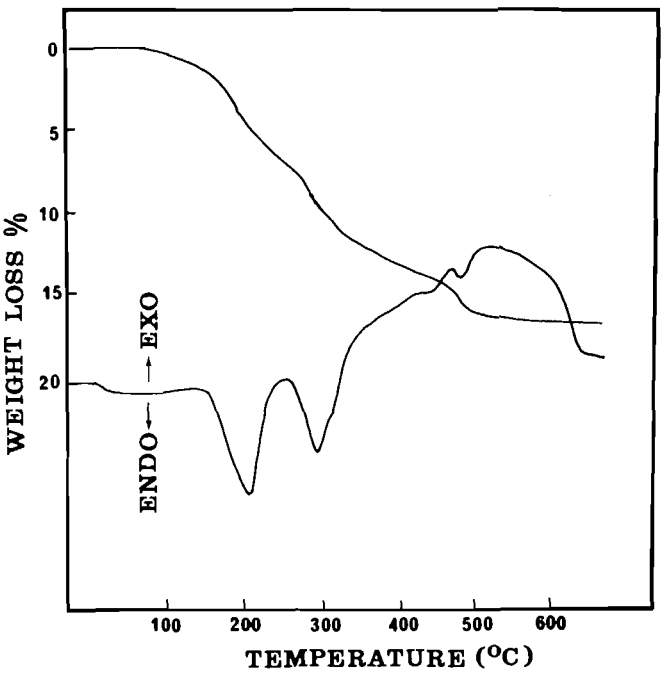

FIG. 7. DTA–TG curves of $[Co(NH_3)_6]_{0.33}UO_2PO_4 \cdot 2.21H_2O$.

heated at 600°C. This also supports the Co(III) reduction to Co(II).

Received May 2, 1985

H. C. ZEGERS, R. BOEGSCHOTEN, W. MELS, and G. SOMSEN. Can. J. Chem. **64**, 40 (1986).

A sampling device is described which enables the Picker flow heat capacity calorimeter to handle viscous liquids. The necessary constant liquid flow through the calorimetric cell is achieved by an overpressure on the entering liquids, and can be maintained by pressure control. In addition, the device permits automatic measurement of a number of samples. The approach is applied to densities and heat capacities of binary mixtures of dimethylformamide and the viscous liquids *N*-ethylacetamide, *N*-n-propylacetamide, and *N*-n-butylacetamide. The results appear to be accurate enough to establish excess molar heat capacities as well as apparent molar heat capacities.

H. C. ZEGERS, R. BOEGSCHOTEN, W. MELS et G. SOMSEN. Can. J. Chem. **64**, 40 (1986).

On décrit un dispositif déchantillonnage qui permet d'examiner des liquides visqueux à l'aide du calorimètre à écoulement de Picker. L'écoulement constant du liquide à travers la cellule calorimétrique, qui est nécessaire avec cette méthode, est réalisé en appliquant une surpression sur les liquides introduits et en maintenant un contrôle sur la pression. De plus, ce dispositif permet de réaliser une mesure automatique de plusieurs échantillons. On a appliqué cette approche à la détermination des densités et des capacités calorifiques de mélanges binaires de diméthylformamide avec des liquides visqueux comme les *N*-éthyl-, *N*-n-propyl- et *N*-n-butylacétamides. Les résultats semblent être assez fiables pour permettre de déterminer les capacités calorifiques molaires en excès ainsi que les capacités calorifiques molaires apparentes.

[Traduit par le journal]

Introduction

Heat capacities at constant pressure are useful quantities in the study of mixtures and solutions. They can be used to predict the temperature dependence of enthalpies of different processes in mixtures or solutions (dilution, reaction, etc.) and to relate adiabatic and isothermal compressibilities. Another use of heat capacities is to derive from them the apparent or partial molar heat capacities $C_{p,B,\phi}$ or $C_{p,B}$ of a component B, since these functions reflect the heat capacity of that component itself together with all changes in heat capacity caused by the different environments of a component particle in mixtures. Being related to the second derivative of the chemical potential with respect to the temperature, these functions are very sensitive to structural changes in the mixtures, especially in aqueous media. Although the importance of values of $C_{p,B,\phi}$ and $C_{p,B}$ to solution chemistry is obvious, their accurate experimental determination is difficult.

Since its introduction in 1971, the Picker flow microcalorimeter (1) has been used successfully to obtain volumetric heat capacities (C_p/V) of pure liquids, liquid mixtures, and solutions in such an accurate way that reliable apparent and partial molar heat capacities can be calculated. In essence, the microcalorimeter is a very sensitive heat balance that is able to detect differences in the volumetric heat capacities of two liquid samples down to $7 \times 10^{-5}\,J\,K^{-1}\,cm^{-3}$. To achieve this high accuracy, the flow rate of the liquid through the calorimetric cell must have a value of about $0.010\,cm^3\,s^{-1}$. In addition it must be very stable (±0.1%). Often this is hard to achieve, especially with organic liquids which may cause damage to pumps. In that case a popular alternative is to obtain the liquid flow supply by gravity. However, many organic liquids are too viscous to apply the gravity method and (or) may be so hygroscopic or sensitive to oxygen that contact with air should be avoided, making the flow-by-gravity method cumbersome. In order to overcome these problems we have developed a device that maintains a constant liquid flow through the calorimetric cell by a controlled overpressure on the entering liquids. Use of nitrogen as pressurizing gas at the same time provides protection of the liquid samples against contact with air. In addition, the device is able to handle a number of liquid samples automatically.

Experimental

Apparatus

A scheme of the sampling device is given in Fig. 1. The central unit is a programmable timer which activates simultaneously two nitrogen valves (a), an hplc valve (b), two sample changers (carrousels, (c)), and two pistons (d) to which a lid (e), a descending tube (f), and a nitrogen inlet (g) are attached. The device operates in the following way. Vials containing the liquid samples (h) and sealed by means of aluminum foil are installed in sample holders (i) mounted on a carrousel. Activated by the timer, a sample holder moves to a position below a piston. Subsequently the piston moves down, closing the sample holder by the lid (e). At the same time the descending tube pierces the aluminum foil and plunges into the liquid sample. After that, a slight overpressure of nitrogen gas is applied to the closed sample holder and the sample liquid starts to rinse the tubing between vial and valve (b). After some time valve (b) switches the liquid flow into the calorimeter. This situation is maintained until a measurement is finished. Then the same procedure is applied to a second sample by means of the other piston. The instrument is able to accommodate a total of 24 samples.

In this way the device can follow automatically a stepwise procedure as described by Grolier *et al.* (2) and Fortier and Benson (3), to measure the volumetric heat capacities of liquid mixtures with gradually changing compositions. Only the flow rate of the liquids through the calorimetric cell has to be watched, which can be performed by means of a flow meter or simple inspection of the electric output signal of the calorimeter. Changing viscosities of the mixtures may make it necessary to adjust the nitrogen overpressure in the sample holders, to maintain a constant flow of liquid. To achieve an optimal flow rate we never needed pressures higher than 1.7 bar (1 bar = 100 kPa).

Measurements

As a test, we carried out measurements with mixtures fed to the calorimeter both by our pressure device and by gravity. The results appeared to be identical, provided that the flow rates in both methods are comparable (4). This is due to the fact that heat loss to the environment of the calorimetric cell is dependent on the flow rate (see ref. 5).

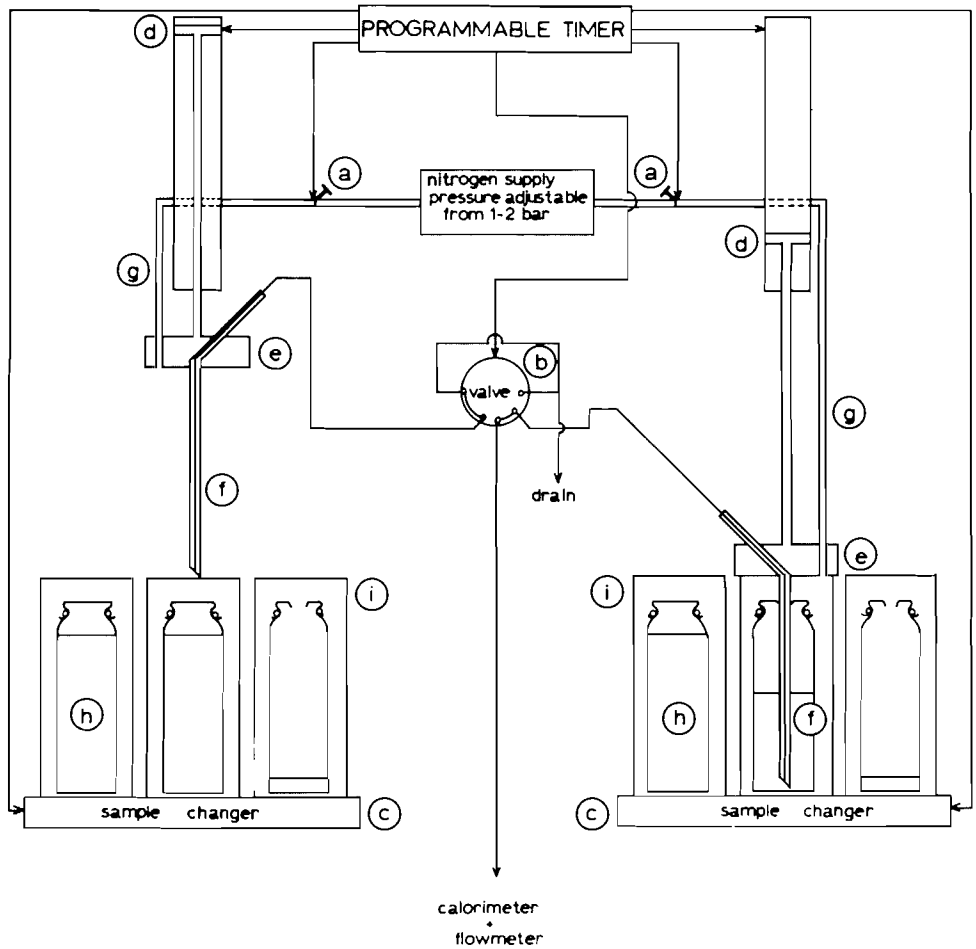

FIG. 1. Scheme of the sampling device for the Picker flow microcalorimeter; (a) nitrogen valve; (b) hplc valve; (c) sample changer (carrousel); (d) piston; (e) lid; (f) descending tube; (g) nitrogen inlet; (h) vial containing the liquid sample; and (i) sample holder.

In addition, a low flow rate must be avoided. In that case not only does the heat loss become very high but also the zones in which some mixing occurs between subsequent samples may become very large. Both influences reduce the reliability of the method. Our pressure device eliminates these undesirable effects and renders the calorimeter suitable for viscous liquids. We will illustrate this by presenting results of measurements on mixtures of *N*,*N*-dimethylformamide (DMF) with *N*-ethylacetamide (NEA), *N*-n-propylacetamide (NPrA), and *N*-n-butylacetamide (NBuA) over the complete mole fraction range. The latter three compounds constitute a series of liquids with increasing viscosity, 6.01, 10.7, and 14.0 cP, respectively (6).

Materials

DMF (Baker Analyzed Reagent) was stored over molecular sieves 4A for at least one week and used without further purification. NEA (Fluka, purum) was taken from stock. NPrA and NBuA were synthesized according to the reaction:

$$CH_3COOH + RNH_2 \rightarrow CH_3CONHR + H_2O$$

where R denotes an alkyl group (7, 8). This reaction was made quantitative by adding acetic anhydride to the reacting mixture. Acetic acid and acetic anhydride were removed by azeotropic distillation with methylcyclohexane (9). NEA, NPrA, and NBuA were purified by azeotropic distillation with benzene (to remove last traces of water and acetic acid) followed by fractional distillation under reduced pressure. The middle fraction was taken and stored over molecular sieves 4A.

The water contents of all compounds were determined by the modified Karl Fischer procedure of Verhoef and Barendrecht (10). In all cases the volume fraction of water was less than 0.0001. Gas–liquid chromatography showed a mole fraction purity of 0.995 or higher for each compound.

Procedure

Liquid mixtures of DMF with the various *N*-alkylacetamides were prepared by mass. Details of the procedure have been described before (11). The densities of the mixtures relative to the density of pure DMF were measured by a digital flow densimeter (Sodev, model 03D, Sherbrooke, Quebec). Heat capacities were obtained from volumetric heat capacities (C_p/V) measured with a Picker flow microcalorimeter (Setaram, model "chaleur specifique", Lyon, France), equipped with the automatic pressure device described above.

Results

Volumes

Densities d of the binary mixtures relative to the density of pure DMF (d_1^*) are presented in Table 1 as function of the mole fraction x_1 of DMF. The density of pure DMF measured with respect to that of pure water (12) is 0.943289 g cm^{-3} at 298.15 K, corresponding to a molar volume $V_1^* = 77.489$ cm^3 mol^{-1}. The molar volumes of the pure *N*-alkylacetamides NEA, NPrA, and NBuA are $V_2^* = 94.734$, 111.641, and 128.697 cm^3 mol^{-1} respectively, and compare very well with the values $V_2^* =$

94.66, 111.57, and 128.53 cm^3 mol^{-1} obtained by Vaughn and Sears (6).

Excess molar volumes of the mixtures were calculated from

$$[1] \quad V_m^E = V_m + x_1(V_2^* - V_1^*) - V_2^*$$

and are represented in Fig. 2. Apparent molar volumes $V_{i,\phi}$ of component i with mole fraction x_i are obtained from

$$[2] \quad V_{i,\phi} = V_i^* + V_m^E/x_i$$

with $i = 1, 2$. They are given graphically in Figs. 3 and 4.

Heat capacities

Volumetric heat capacities relative to DMF, $\Delta(C_p/V) = C_p/V - C_{p,1}^*/V_1^*$, were measured corresponding to a mean temperature of (298.15 ± 0.1) K. Using $C_{p,1}^*/V_1^* = 1.9146$ J K^{-1} cm^{-3} we obtained the molar heat capacities of the pure compounds NEA, NPrA, and NBuA. The values $C_{p,2}^* = 180.28$, 207.94, and 236.89 J K^{-1} mol^{-1}, respectively, agree very well with $C_{p,2} = 180$, 207, and 236 J K^{-1} mol^{-1} determined by Konicek, Suurkuusk, and Wadsö with a drop calorimeter (13, 14).

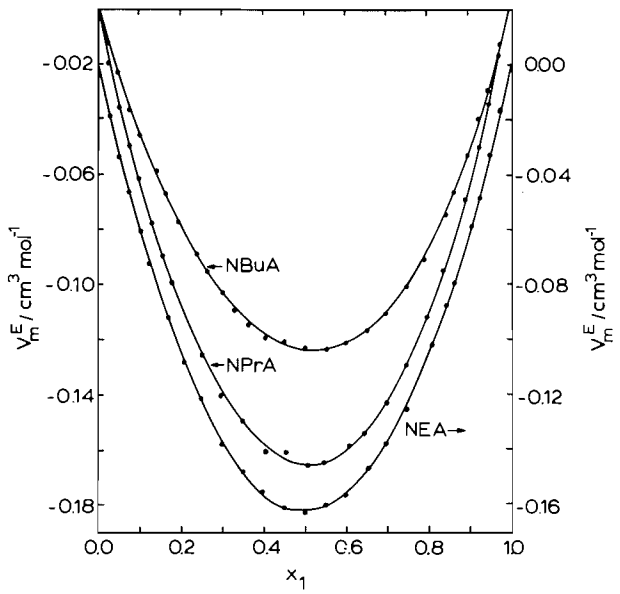

FIG. 2. Excess molar volumes for mixtures of dimethylformamide with some *N*-alkylacetamides.

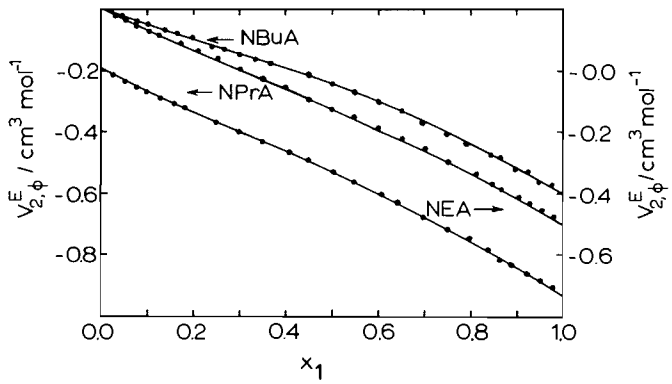

FIG. 3. Excess apparent molar volumes of *N*-alkylacetamides in mixtures with dimethylformamide.

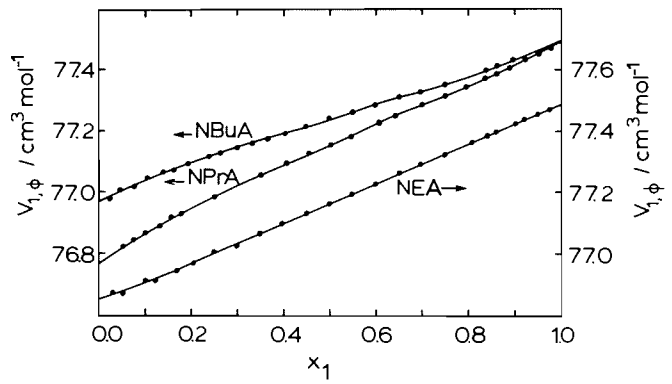

FIG. 4. Apparent molar volumes of dimethylformamide in mixtures with several *N*-alkylacetamides.

Excess molar heat capacities were calculated according to

[3] $$C^{E}_{p,m} = \{C^*_{p,1}/V^*_1 + \Delta(C_p/V)\}V_m - x_1C^*_{p,1} - x_2C^*_{p,2}$$

where the subscript 2 refers to NEA, NPrA, and NBuA. They are represented in Fig. 5. The apparent molar heat capacities $C_{p,i,\phi}$ of component i were calculated by

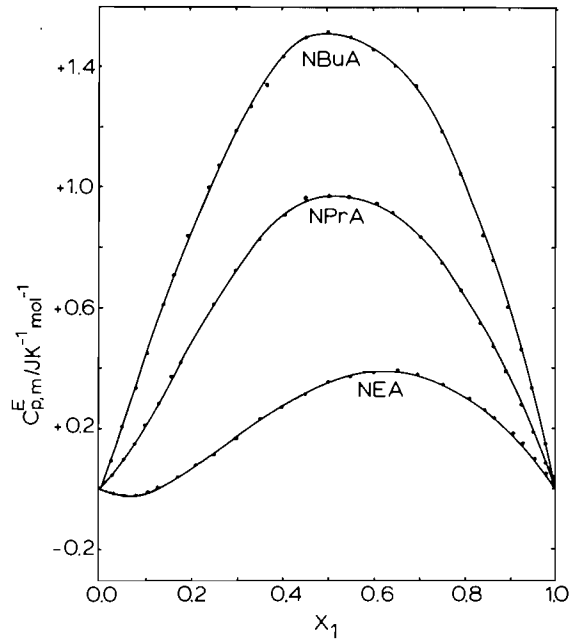

FIG. 5. Excess molar heat capacities for mixtures of dimethylformamide with several *N*-alkylacetamides.

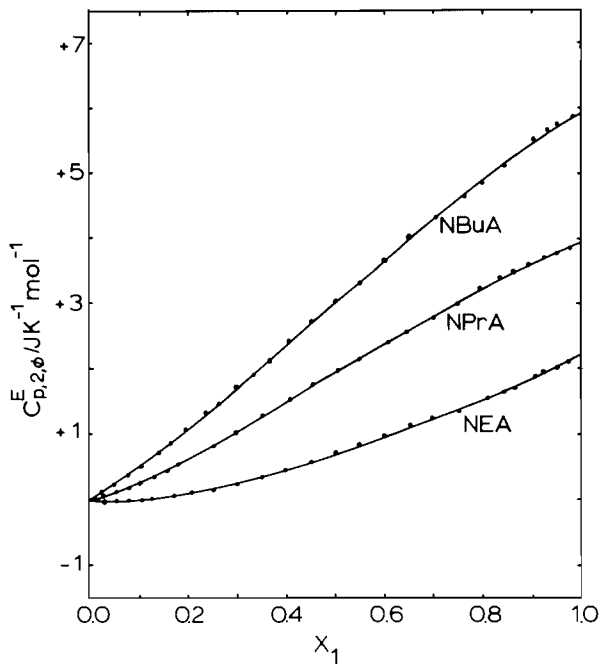

FIG. 6. Excess apparent molar heat capacities of *N*-alkylacetamides in mixtures with dimethylformamide.

[4] $$C_{p,i,\phi} = C^*_{p,i} + C^{E}_{p,m}/x_i$$

and are shown in Figs. 6 and 7.

Discussion

The molar excess volumes and heat capacities of the mixtures considered here can be described by the polynomial:

[5] $$Y^{E}_{m} = x_1x_2 \sum_{i=0}^{n-1} a_i(x_1 - x_2)^i$$

The coefficients a_i were obtained by a least-squares analysis and

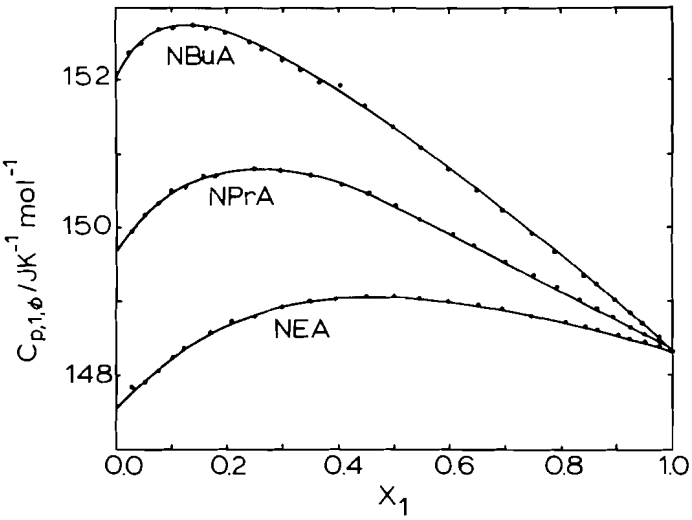

FIG. 7. Apparent molar heat capacities of dimethylformamide in mixtures with some *N*-alkylacetamides.

are presented in Table 2. Each experimental value was assigned unit weight. Table 2 gives also the standard deviation of the fit δ defined by

$$[6] \quad \delta^2 = \Sigma_N[Y_m^E(\text{exp}) - Y_m^E(\text{calc})]^2/(N - n)$$

where N and n denote the number of experimental points and coefficients, respectively.

As observed earlier (4), apparent molar quantities of compounds in binary mixtures of this type are largely determined by the molar quantities of the pure compounds and the apparent molar quantities of each compound at infinite dilution. Therefore a compilation of these data is presented in Table 3.

Apparent molar volumes

The functions $V_{2,\phi} - V_2^*$ $(= V_{2,\phi}^E)$ for the *N*-alkylacetamides are represented in Fig. 3. They are all negative and depend on x_1 almost linearly. Values of $V_{2,\phi}^E$ at infinite dilution, $V_{2,\phi}^{E,\infty}$, are −0.70, −0.73, and −0.60 $cm^3\,mol^{-1}$ for NEA, NPrA, and NBuA, respectively.

The apparent molar volumes of DMF in the mixtures (see Fig. 4) are smaller than its molar volume $V_1^* = 77.49\,cm^3\,mol^{-1}$. At infinite dilution in NEA, NPrA, and NBuA they amount to 76.85, 76.77, and 76.97 $cm^3\,mol^{-1}$, respectively.

According to the general equation

$$[7] \quad x_1(V_{1,\phi} - V_1^*) = x_2(V_{2,\phi} - V_2^*)$$

an observed linearity in the curves relating $(V_{2,\phi} - V_2^*)$ and x_1 means that also $V_{1,\phi}$ should depend on x_1 in a linear way. Hence, the approximately straight lines in Fig. 4 are in accordance with the almost linear relationships in Fig. 3.

The apparent molar volumes of DMF at infinite dilution, $V_{1,\phi}^{\infty}$, in the solvents NEA, NPrA, and NBuA do not show a systematic trend. In a series of dialkyl-substituted amidic solvents (CH_3CONR_2), we found earlier (4) that $V_{1,\phi}^{\infty}$ of DMF increases with the size of the alkyl group from R = ethyl. $V_{1,\phi}^{\infty}$ of DMF dissolved in dimethylacetamide does not fit the relation. This might indicate that in the present case the value of $V_{1,\phi}^{\infty}$ in NEA is the deviating one. Similar reasoning leads to the conclusion that the value of $V_{2,\phi}^{E,\infty}$ for NEA dissolved in DMF lies outside a general trend (see ref. 4).

Apparent molar heat capacities

Generally the values of $C_{p,2,\phi} - C_{p,2}^*$ $(= C_{p,2,\phi}^E)$ for NEA,

TABLE 3. Apparent molar volumes and heat capacities in the limiting regions of mixtures of DMF with several monosubstituted acetamides

Acetamide	$V^{\infty}_{1,\phi}$ ($cm^3\,mol^{-1}$)	$V^{*\,a}_{2}$ ($cm^3\,mol^{-1}$)	$V^{\infty}_{2,\phi}$ ($cm^3\,mol^{-1}$)	$C^{\infty}_{p,1,\phi}$ ($J\,K^{-1}\,mol^{-1}$)	$C^{*\,b}_{p,2}$ ($J\,K^{-1}\,mol^{-1}$)	$C^{\infty}_{p,2,\phi}$ ($J\,K^{-1}\,mol^{-1}$)
NEA	76.85	94.73	94.03	147.56	180.28	182.44
NPrA	76.77	111.64	110.91	149.69	207.94	211.85
NBuA	76.97	128.70	128.10	152.15	236.89	242.81

[a] $V^*_1 = 77.49\,cm^3\,mol^{-1}$.
[b] $C^*_{p,1} = 148.36\,J\,K^{-1}\,mol^{-1}$.

TABLE 4. Values of $C^{E,\infty}_{p,i,\phi}/V_i$ for mixtures of DMF with monosubstituted acetamides

Acetamide	$C^{E,\infty}_{p,1,\phi}/V_1$ ($J\,K^{-1}\,cm^{-3}$)	$C^{E,\infty}_{p,2,\phi}/V_2$ ($J\,K^{-1}\,cm^{-3}$)
NEA	−0.0103	0.0228
NPrA	0.0172	0.0350
NBuA	0.0489	0.0460

NPrA, and NBuA are positive over the complete mole fraction range. Only those for NEA at $0 < x_1 < 0.15$ are slightly negative. As Fig. 6 shows, there is a steady increase with the mole fraction of DMF towards a maximal value at infinite dilution. Here $C^{E,\infty}_{p,2,\phi}$ ranges from $2.2\,J\,K^{-1}\,mol^{-1}$ for NEA to $5.9\,J\,K^{-1}\,mol^{-1}$ for NBuA. The mean CH_2 increment in $C^{E,\infty}_{p,2,\phi}$ of $1.9\,J\,K^{-1}\,mol^{-1}$ is in good agreement with the same increment found for dialkylacetamides in DMF (4).

The apparent molar heat capacities $C_{p,1,\phi}$ of DMF in the three solvents NEA, NPrA, and NBuA (see Fig. 7) do not depend on x_1 in a monotonic way, but show maxima at $x_1 = 0.46$, $x_1 = 0.26$, and $x_1 = 0.13$, respectively. At infinite dilution, $C^{\infty}_{p,1,\phi}$ is 147.6, 149.7, and $152.2\,J\,K^{-1}\,mol^{-1}$, respectively. Only $C^{\infty}_{p,1,\phi}$ in NEA is smaller than the molar heat capacity of pure DMF. The mean CH_2 increment in the values is $+2.3\,J\,K^{-1}\,mol^{-1}$.

In previous work (4) we observed that heat capacities of binary mixtures of DMF and dialkylacetamides can be adequately described by equations of the type derived by Hildebrand and Wood (15), Scatchard (16), and Redlich *et al.* (17), like:

$$[8] \quad C^{E}_{p,m} = x_i(1 - \phi_i)V^*_i\sigma$$

$$[9] \quad C_{p,i,\phi} = C^*_{p,i} + (1 - \phi_i)V^*_i\sigma$$

$$[10] \quad C_{p,1} = C^*_{p,i} + (1 - \phi_i)^2V^*_i\sigma$$

where ϕ_i is the volume fraction of compound i in the mixture, $C_{p,i}$ is the partial molar heat capacity of compound i, and σ is an adjustable parameter. In order to describe the experimental data with the eqs. [8]–[10] it is necessary that

$$[11] \quad C^{E,\infty}_{p,1,\phi}/V^*_1 = C^{E,\infty}_{p,2,\phi}/V^*_2\ (= \sigma)$$

Within experimental error this is the case for mixtures of DMF and dialkylacetamides. Values of $C^{E,\infty}_{p,1,\phi}/V^*_1$ and $C^{E,\infty}_{p,2,\phi}/V^*_2$ for the compounds in this paper are presented in Table 4. They differ substantially. In our opinion this is due to a larger short range interaction in the present mixtures, caused by hydrogen bonding. Indeed a recent computer simulation study (18) indicates marked differences in short range ordering of the molecules between aprotic disubstituted amides and protic mono- or unsubstituted amides. Consequently, application of the eqs. [8]–[10] will be restricted to mixtures of related compounds where strong and directional short range interactions are absent.

Thermodynamics of solvent mixtures. I. Density and viscosity of binary mixtures of *N*-methylpyrrolidinone – tetrahydrofuran and propylene carbonate – acetonitrile

A. V. ANANTARAMAN
Defence Research Establishment Ottawa, Ottawa, Ont., Canada K1A 0Z4

Received April 25, 1985

A. V. ANANTARAMAN. Can. J. Chem. **64**, 46 (1986).

Excess volumes and viscosities of binary liquid mixtures of *N*-methylpyrrolidinone – tetrahydrofuran and propylene carbonate – acetonitrile are measured and examined in the light of empirical theories such as absolute rate, free volume, and regular solution theories. It is shown that non-ideality arises due to (a) shape factors, (b) molecular interaction, and that the two properties, excess volume and viscosity, illustrate these two aspects of non-ideality.

A. V. ANANTARAMAN. Can. J. Chem. **64**, 46 (1986).

On a mesuré les volumes en excès et les viscosités de mélanges liquides binaires de *N*-méthylpyrrolidinone – tétrahydrofuranne et de carbonate de propylène – acétonitrile et on les a étudiés en faisant appel à des théories empiriques comme celle de la vitesse absolue, et les théories du volume libre et de la solution régulière. On montre que le comportement non-idéal est dû aux facteurs de forme et à l'interaction moléculaire. On montre également que ces deux propriétés, à savoir le volume en excès et la viscosité, illustrent les deux aspects de ce comportement non-idéal.

[Traduit par le journal]

Introduction

During the past decade, significant advances have taken place in the commercial development of batteries using nonaqueous electrolytes. Such remarkable progress could not have been achieved without fundamental understanding of the thermodynamic and electrochemical behaviour of the active components in a battery. Mixed solvents of propylene carbonate (PC) with 1,2-dimethoxyethane (DME) or with tetrahydrofuran (THF) have been reported to give good cell performance (1, 2). Since organic mixed solvents offer a wide range of variations in electrolyte properties, their use in the development of high energy – density batteries is relevant and attractive.

The electrochemical behaviour of a nonaqueous battery can depend critically on the properties of the electrolyte. Among the properties of solvent mixtures, viscosity has an important role, because a low viscosity implies a low resistance to ionic transport within the medium. As part of a continuing investigation of the thermodynamic and other properties of solvent mixtures for nonaqueous battery systems, this paper reports the measurements of density and viscosity of mixtures of propylene carbonate – acetonitrile (AN) and *N*-methylpyrrolidinone (NMP) – tetrahydrofuran in the complete range of composition.

Experimental

Starting from high purity grade, the solvents were agitated with calcium hydride for 24 h in an argon atmosphere. Subsequently they were distilled under reduced pressure, and only the middle fractions were collected and stored in a dry argon atmosphere. The relevant properties of the pure solvents are listed in Table 1.

The solvent mixtures were prepared gravimetrically in an argon atmosphere and the measurements were done completely isolated from atmospheric contact.

The densities of pure solvents and their mixtures were measured at 5.0 ± 0.05°C, using a long-stem pyknometer which was calibrated with mercury. The experimental reproducibility, in general, is better than 1 part in 10^4.

Kinematic viscosities were measured in a specially designed capillary viscometer that allows measurements to be made without contact with air (3). A schematic diagram of the viscometer is shown in Fig. 1.

A gas-tight syringe of about 20-mL capacity is connected through a short silicon rubber tubing to the outlet at stopcock S_1. The ground glass stopcocks S_1 and S_2 are slightly greased and the clean dry viscometer is weighed. The apparatus is taken into an argon glove box and the required volume of high purity solvent is carefully introduced into the pear-shaped reservoir R. All the stopcocks and the rotoflo are tightly closed, and the unit is carefully taken out of the box and connected to a vacuum line at the ground joint G. The solvent in the reservoir is degassed by alternate freezing and thawing. The viscometer is set up in a suitable thermostat bath and, after attaining temperature equilibrium, the liquid is slowly drawn above the mark, M_1, by means of the syringe with the stopcocks S_1 open and S_2 closed. Any vapour drawn into the syringe is slowly pushed back into the viscometer with the pressure equalizer stopcock S_2 open. The stopcock S_1 is now closed and the time for flow between the two marks M_1 and M_2 is recorded. The procedure can be repeated for consistency.

The viscometer was calibrated using triple-distilled water and pure solvents. All measurements were done in a thermostat maintained at 5.0 ± 0.05°C. The accuracy of the measurement of viscosity is estimated to be better than 1%.

TABLE 1. Properties of pure components at 5.0°C.

Solvent	Density ρ (g cm^{-3})	Kinematic viscosity ν (CS)	Vapour pressure (Torr)[a]
N-methylpyrrolidinone	1.0447	2.168	≈0.2
Tetrahydrofuran	0.9035	0.635	62.7
Propylene carbonate	1.2203	3.128	0.5
Acetonitrile	0.7984	0.541	34.5

1 Torr = 133.3 Pa.

Results

The experimental values of densities and viscosities of the two binary systems are shown in Tables 2 and 3.

Excess volume

The excess volume V^E is calculated from densities, according to the relations

$$[1] \quad V^E = X_1 M_1 \left(\frac{1}{\rho} - \frac{1}{\rho_1}\right) + X_2 M_2 \left(\frac{1}{\rho} - \frac{1}{\rho_2}\right)$$

where X_i, M_i, and ρ_i are the mole fraction, molar mass, and density of component i and ρ denotes the density of the mixture. The results are shown in Figs. 2 and 3. The data can be fitted into

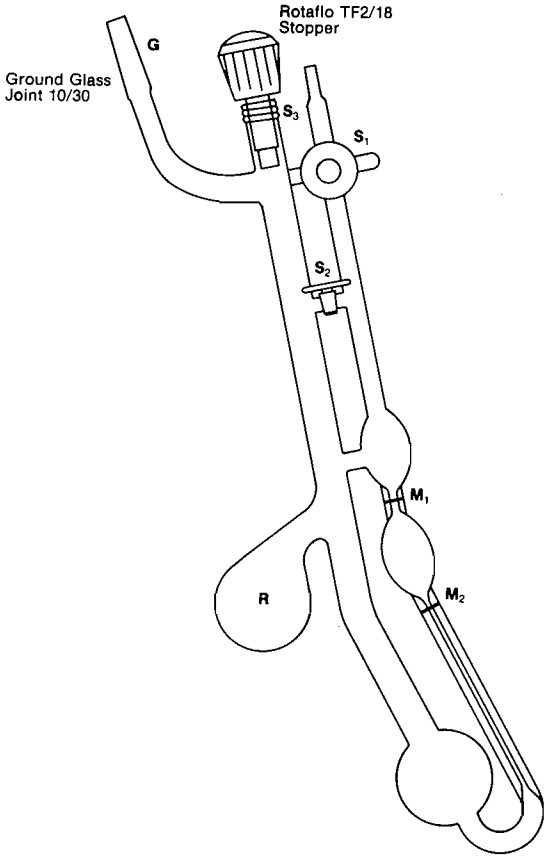

FIG. 1. Viscometer.

an equation of the form

$$[2] \quad V^E = X_1 X_2 \sum_{i=0}^{n} A_i (X_1 - X_2)^i$$

The optimum number of coefficients A_i is determined by the magnitude of the standard deviation σ. These coefficients are given in Table 4.

Viscosity

The dynamical viscosity η is calculated from the measured kinematic viscosity ν, and the corresponding density ρ, using the relation $\eta = \nu/\rho$. For ideal binary mixtures, viscosity is given by the Arrhenius equation,

where X_i and η_i are the mole fraction and viscosity of the pure components. Ideal viscosities calculated on the basis of eq. [3] for the two systems, along with the corresponding experimental data, are shown in Figs. 4 and 5.

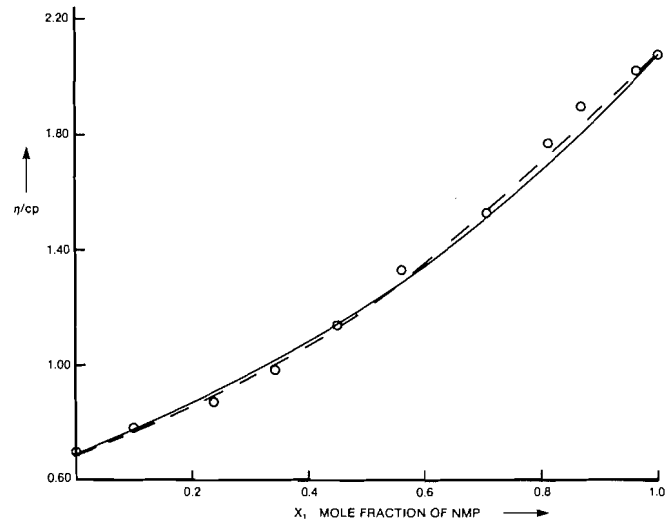

FIG. 4. Dynamic viscosity as a function of composition. System: NMP–THF. Temperature: 5.0 ± 0.05°C. --- Measured, — Ideal eq. [3].

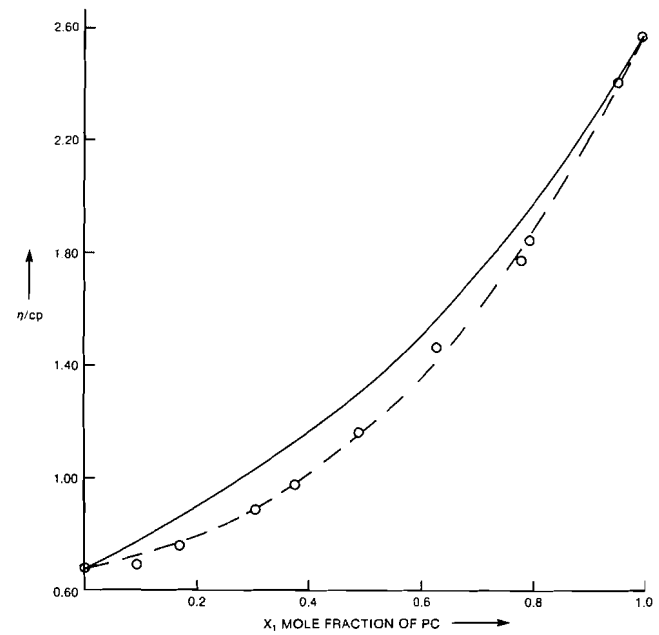

FIG. 5. Dynamic viscosity as a function of composition. System: PC–AN. Temperature: 5.0 ± 0.05°C. --- Measured, — Ideal eq. [3].

Discussion

The excess volumes for both the binary mixtures NMP–THF and PC–AN are negative over the entire range of composition. This implies that geometrical factors allowing the molecular species to form a more dense structure within the mixture may be important in both cases. The dense packing may be due to (a) different molecular sizes leading to interstitial accommodation in the mixture and (b) differences in free volume between the components.

On the basis of such geometrical arguments, the excess volume is expressed in terms of a reduced interaction energy parameter Λ_{ij}^* (4).

$$[4]\quad \frac{V^E}{V^*} = \frac{2.03}{Z}\left(\frac{kT}{\Lambda_{ij}^*} - X_i\frac{kT}{\Lambda_{ii}^*} - X_j\frac{kT}{\Lambda_{jj}^*}\right)$$

The reduced volume V^* is defined as $V^* = r^*/\gamma$, where γ is a numerical factor which depends on the geometrical arrangement of the molecules. r^* is the distance corresponding to the minimum of $\Lambda(r)$ and Z is the number of first neighbours in the quasi-lattice.

In this simple model, the solution behaves as a pure component characterized by the average value of the interaction parameter Λ_{ij}^*. The negative excess volumes of the two systems over the entire composition range suggest that the potential energy minimum of the unlike molecules is lower than the potential energy minima of either or both the like molecules.

Viscosity is a complex property and existing theories cannot adequately explain the viscosity behaviour of even simple fluid mixtures. Empirical theories such as the absolute rate theory and the free volume theory have been used in predicting the viscosity of liquid mixtures (5–7). Macedo and Litovitz (8) have combined the two theories so that the probability for viscous flow is taken as the product of probabilities for acquiring sufficient activation energy and the occurrence of an empty site. However, the validity and physical justification for the use of such theories in predicting viscosities of complex liquid mixtures is in doubt.

Based on the ideas of regular solution theory (9, 10), Grunberg and Nissan (11) have proposed an empirical expression for viscosities of real liquid mixtures,

$$[5]\quad \ln\eta = X_1\ln\eta_1 + X_2\ln\eta_2 + X_1X_2\epsilon$$

where ϵ denotes the extent of non-ideality of the system. The parameter ϵ is interpreted as a constant proportional to W/RT where W is the interchange energy arising from the increase in lattice energy due to juxtaposition of molecule 1 into the lattice of molecule 2. Grunberg (12) has derived an expression for the viscosity contribution to the interchange energy,

$$[6]\quad \ln\frac{\eta_{obs}}{\eta_{id}} = \frac{W}{RT}\alpha_1X_1X_2\left[X_2 + \frac{\alpha_2}{\alpha_1}X_1\right]$$

where η_{obs} represents the measured viscosity of the mixture; the constants α_1 and α_2 are calculated from the vapour pressures p_0 of pure components 1 and 2 according to

$$[7]\quad \frac{d(\ln\eta)}{d(\ln p_0)} = \alpha$$

Following Grunberg's procedure, we have calculated the interchange energy W as defined by eq. [6]. The results are shown in Tables 5 and 6 where the measured viscosities and the deviation, ϵ, are also included.

$$[8]\quad \epsilon = (\ln\eta_{obs} - \ln\eta_{id})/X_1X_2$$

It should be pointed out that the results shown in Tables 5 and 6 depend on the assumed parallelism between viscosity and vapour pressure, as given by eq. [7]. Also, accurate experimental data for viscosity and vapour pressure of pure components are required for evaluating reliable values of the constants α_1 and α_2. This is particularly so where the pure components have low vapour pressures, as in the case NMP and PC. The molar volumes of NMP and THF at 5.0°C are 94.86 cm^3 and 79.81 cm^3, respectively, and the viscosities of the two substances at 5.0°C are 2.075 cp and 0.703 cp, respectively. This suggests that the mixture NMP–THF would be expected to show considerable deviation from ideal behaviour. Furthermore, the constants α_1 and α_2 for NMP and THF, respectively, are significantly different, indicating that the two liquids are geometrically different.

Based on formal ideas of statistical mechanics, Bearman and

Jones (13) have derived an expression where the viscosity coefficient of a binary mixture is given as the sum of three integrals representing the interactions of like and unlike pairs of molecules. Using the simplifying assumptions of regular solution theory, the authors express the viscosity of a binary mixture in terms of the viscosities of pure components η_1 and η_2

$$[9] \quad \eta = X_1^2\eta_1 + 2X_1X_2\eta_{12} + X_2^2\eta_2$$

where η_{12} is a parameter attributed to unlike pair interactions. An identical equation was proposed earlier by Hind *et al.* (14) from purely empirical arguments.

Values of the parameter η_{12} calculated from experimental results for the two systems NMP–THF and PC–AN are shown in Tables 5 and 6. The interaction parameter η_{12} appears to give a constant value, particularly at low concentrations of the denser component in both systems. The arithmetic mean approximation, $\eta_{12} \sim (\eta_1 + \eta_2)/2$, and the geometric mean approximation, $\eta_{12} \simeq \sqrt{\eta_1\eta_2}$, are in poor agreement with the value of η_{12} calculated from eq. [9]. One of the major difficulties of fundamental theories such as that of Bearman and Jones is that η_{12} can only be obtained from experimental measurements and cannot be calculated a priori from η_1 and η_2.

Viscosity and excess volume are properties that exemplify different aspects of solution non-ideality. While excess volume reflects molecular dissimilarity among the components, viscosity, on the other hand, expresses the strength of intermolecular interaction. The system NMP–THF clearly illustrates this aspect. It shows a large excess volume of mixing, indicating the geometrical dissimilarity between NMP and THF. On the other hand, the viscosity of the system conforms closely to the Arrhenius expression for binary liquid mixtures, clearly pointing out the absence of specific intermolecular interactions between the components.

Our studies suggest that, contrary to the observations of Prolongo *et al.* (15), negative volume changes of mixing (denoting strong geometrical rearrangements between the components) do not result in a positive value for ϵ of eq. [5] and vice versa. General correlations between V^E and ϵ are difficult to make; the two properties are fundamentally different.

Jambon and Delmas (16) have measured the solution viscosities of binary systems involving globular molecules such as SnR_4 compounds (R = CH_3, C_2H_5, C_4H_9). Their analysis, based on free volume theories, suggests that no significant correlation exists between excess viscosity and free volume and that such empirical theories are fundamentally inadequate to explain the origin of excess viscosity.

Finally, our results show that viscosity behaviour of binary liquid mixtures cannot be explained in terms of interchange energy, as defined by eq. [6]. This equation is derived on the basis of the assumptions of regular solution theory, which ignores specific intermolecular interactions. It is believed that molecular shapes resulting from packing and intermolecular interaction energies are both important in accounting for viscosity behaviour.

The synthesis and X-ray structural characterization of bis[(2*S*,3*S*)-2,3-bis(diphenylphosphino)butane]rhodium(I) chloride and its reactivity towards small gas molecules

CHARLES G. YOUNG, STEVEN J. RETTIG,[1] AND BRIAN R. JAMES[2]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 9, 1985

CHARLES G. YOUNG, STEVEN J. RETTIG, and BRIAN R. JAMES. Can. J. Chem. **64**, 51 (1986).

The Rh(*S*,*S*-chiraphos)$_2^+$ cation, where chiraphos is 2,3-bis(diphenylphosphino)butane, has been synthesized and fully characterized by spectroscopy and single crystal data on the chloride salt (**1**). Crystals are monoclinic, a = 23.106(3), b = 12.4987(8), c = 21.455(3) Å, β = 128.539(5)°, Z = 4, space group $C2$. The structure was solved by conventional heavy atom methods and was refined by full-matrix least-squares procedures to R = 0.046 and R_w = 0.032 for 4509 reflections with $I > \sigma(I)$. The coordination about Rh is square planar distorted toward tetrahedral within the five-membered chelate rings, similar to that in Rh(dpe)$_2^+$, where dpe is 1,2-bis(diphenylphosphino)ethane, but the distortion toward tetrahedral is significantly greater in **1**; the methyl substituents further restrict rotational freedom about the P—Ph bonds, which leads to some blocking of the axial ligand sites by the four H atoms of the chelate-ring carbon atoms. In solution, **1** is unreactive towards O_2, CO, and H_2, but oxidatively adds HX (X = Cl, Br) to give *trans*-RhHX(*S*,*S*-chiraphos)$_2^+$ species.

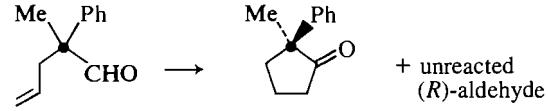
CHARLES G. YOUNG, STEVEN J. RETTIG et BRIAN R. JAMES. Can. J. Chem. **64**, 51 (1986).

On a synthétisé le cation Rh(*S*,*S*-chiraphos)$_2^+$, où le groupe chiraphos est le bis(diphénylphosphino)-2,3 butane, et on l'a caractérisé par la spectroscopie de rayons X sur un monocristal de son chlorure (**1**). Les cristaux appartiennent au groupe d'espace monoclinique C_2 avec a = 23,106(3), b = 12,4987(8), c = 21,455(3) Å, β = 128,539(5)°, Z = 4. On a résolu la structure par la méthode conventionnelle de l'atome lourd et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,046 et de R_w = 0,032 pour 4509 réflexions avec $I > \sigma(I)$. La coordination autour du Rh est un plan carré déformé de façon tétraédrique à l'intérieur du cycle à 5 chaînons du chélate, comme celle du Rh(dpe)$_2^+$, où le groupe dpe est le bis(diphénylphosphino)-1,2 éthane, mais la déformation tétraédrique est beaucoup plus accentuée dans le cas du composé **1**. De plus, les substituants méthyles restreignent la rotation libre autour des liaisons P—Ph, ce qui conduit à un certain blocage des sites axiaux du ligand par les 4 atomes d'hydrogène des atomes de carbone du cycle du chélate. Le composé **1**, en solution, ne réagit pas avec le O_2, le CO et le H_2 mais les halogénures HX (X = Cl, Br) s'additionnent de façon oxydante pour donner des espèces RhHX(*S*,*S*-chiraphos)$_2^+$ *trans*.

[Traduit par le journal]

Introduction

Earlier work from this laboratory has reported on the synthesis and characterization of Rh(P—P)$_2$X complexes, and their reactivity towards the small gas molecules H_2, O_2, CO, and HCl, with a view to exploring catalytic reactivity: X = Cl, BF_4, PF_6, SbF_6; P—P = dpm, dpe, dpp, dpb, and diop[3] (1, 2). The Rh(P—P)$_2^+$ cations, for example, were active for catalytic hydrogenation of olefins, including asymmetric hydrogenation with the chiral diop ligand system; even in cases where coordinatively saturated dihydrides, RhH$_2$(P—P)$_2^+$, are present, catalytic activity can result when one of the ditertiary phosphine ligands becomes monodentate (3). Reversible binding of CO by some of the Rh(P—P)$_2^+$ cations, particularly with P—P = dpp, led to studies revealing their efficiency for catalytic decarbonylation of aldehydes (4, 5), these systems being discovered independently by Pignolet and co-workers (6, 7). Attempts to then effect asymmetric decarbonylation of racemic aldehydes required the use of Rh(P—P$_2$)$^+$ complexes with P—P chiral; the known rigidity of the five-membered chiraphos ring (8, 9) prompted us to synthesize the Rh(chiraphos)$_2^+$ cation, and test its activity for decarbonylation, and for reactivity generally towards small gas molecules. We have reported on the attempted decarbonylation of racemic olefinic aldehydes, studies that led to a kinetic resolution of the aldehyde, one enantiomer preferentially undergoing intramolecular hydroacylation to a chiral disubstituted cyclopentanone, eq. [1].



[1]

(*R*,*S*)-aldehyde (*S*)-cyclopentanone

We report here the details and full characterization of the Rh(chiraphos)$_2^+$ Cl$^-$ complex (**1**) that catalyzes reaction [1] (10, 11) and also note its nonreactivity towards CO, O_2, and H_2; however, **1** oxidatively adds HCl to give *trans*-RhHCl(chiraphos)$_2^+$ Cl$^-$.

The well-known Rh(dpe)$_2^+$ cation, containing the corresponding unsubstituted, non-chiral, five-membered rings, was the earliest of the bis(ditertiaryphosphine)rhodium(I) cations to be studied regarding reactivity towards H_2 (12) amd O_2 (13). Since that time, as well as studies reported from this laboratory (1–5, 10, 11), several other groups have reported on Rh(P—P)$_2^+$ systems and their reactivity towards small gas molecules and related catalysis: hydrogenation, decarbonylation, hydroformylation, and hydroacylation (6, 7, 14–21).

[3]Abbreviations used: (+)-diop = 4*S*,5*S*-bis((diphenylphosphino)-methyl)-2,2-dimethyl-1,3-dioxolane; dpm = bis(diphenylphosphino)-methane; dpe = 1,2-bis(diphenylphosphino)ethane; dpp = 1,3-bis(diphenylphosphino)propane; dpb = 1,4-bis(diphenylphosphino)butane; (−)-chiraphos = 2*S*,3*S*-bis(diphenylphosphine)butane; *cis*(2=phos) = 1,2-bis(diphenylphosphino)ethylene.

Experimental

The cyclooctene dimer $[RhCl(C_8H_{14})_2]_2$ was prepared by a literature method (22). (2*S*,3*S*)-Chiraphos was purchased from Strem Chemicals Inc. and was used without further purification. Unless otherwise stated, all synthetic procedures were performed under argon using dry, deoxygenated solvents.

Conductivity measurements employed a Thomas Serfass bridge and cell using 10^{-3} *M* nitromethane solutions. Infrared spectra were recorded on a Perkin–Elmer 598 instrument as Nujol mulls. Ultraviolet–visible spectra were recorded on a Perkin–Elmer 552A spectrophotometer and optical rotation measurements employed a Perkin–Elmer 141 polarimeter. Proton (δ_{TMS} = 0 ppm) and ^{31}P-{^1H} nmr spectra were recorded on Bruker WH 400 MHz and Varian XL 100 (40.4 MHz for ^{31}P) spectrometers, respectively, at ambient temperatures. The ^{31}P nmr experiments employed an external PPh_3 reference but δ values are reported in ppm (upfield negative) from 85% H_3PO_4. Microanalyses were performed by Mr. P. Borda of this Department.

Rh(S,S-*chiraphos*)$_2^+$ *Cl*$^-$, **1**

A solution of *S*,*S*-chiraphos (0.94 g, 2.2 mmol) in benzene (10 mL) was added to a stirred solution of $[RhCl(C_8H_{14})_2]_2$ (0.36 g, 0.5 mmol) in benzene (20 mL); the resulting suspension was stirred for 1.5 h, whereupon the yellow solid was filtered, washed with warm benzene (30 mL), and vacuum-dried. The yield was 0.92 g (90%). At this stage the compound retains a half molecule of benzene of crystallization. *Anal.* calcd. for $C_{59}H_{59}ClP_4Rh$: C 68.80, H 5.77; found: C68.9, H 5.8. The unsolvated compound was obtained upon recrystallization (in air) from CH_2Cl_2/diethyl ether. *Anal.* calcd. for $C_{56}H_{56}ClP_4Rh$: C 67.88, H 5.70; found: C 67.8, H 5.7. Decomposition point in air = 275°C. Conductivity $\Lambda_M = 59\ \Omega^{-1}\,cm^2\,mol^{-1}$; $[\alpha]_D^{25°}$ +23.6° (*c* 2.5, ethanol); ir: strongest bands at 1420, 1090, 990, 735, 685, 520, 500, 470 cm^{-1}; uv–vis (CH_3OH): 410 (4130), 345 (sh. 4620), 313 (7040), 265 (29 400), 237 nm (ε 44 700 $M^{-1}\,cm^{-1}$); (CH_3NO_2): 410 nm (ε 4080); ^1H nmr ($CDCl_3$) δ: 0.53 (m, br, 12H, C*H*$_3$), 1.87 (m, br, 4H, C*H*), 7.0–7.5 (m, 40H, Ph); ^{31}P-{^1H} nmr (2:1 CH_2Cl_2/C_6D_6) δ: 60.6 (d, J_{Rh-P} = 130.8 Hz).

Yellow needles of **1** for a crystal structure analysis were grown in air by diffusing ether into a CH_2Cl_2 solution of the compound.

Rh(S,S-*chiraphos*)$_2^+$ *BF*$_4^-$, **2**

A solution of **1** (0.46 g, 0.46 mmol) in CH_2Cl_2 (10 mL) was treated with a solution of $AgBF_4$ (0.092 g, 0.47 mmol) in MeOH (10 mL). The resulting mixture was stirred for 1 h, then reduced to dryness under vacuum. The residue was extracted with CH_2Cl_2 (5–10 mL) and, after filtration, the compound was precipitated with diethyl ether. The yield was 0.43 g (90%). The compound was recrystallized in air from CH_2Cl_2/diethyl ether. *Anal.* calcd. for $C_{56}H_{56}BF_4P_4Rh$: C 64.54, H 5.42; found: C 64.2, H 5.5. Decomposition point in air = 305°C. Conductivity $\Lambda_M = 68\ \Omega^{-1}\,cm^2\,mol^{-1}$; ir: strongest bands at 1420, 1090–1010, 745, 690, 520, 500, 470 cm^{-1}; uv–vis and ^1H nmr as for **1**; ^{31}P-{^1H} nmr (2:1 CH_2Cl_2/C_6D_6) δ: 60.4 (d, J_{Rh-P} = 132.0 Hz). The PF_6^- and SbF_6^- salts are prepared similarly using the appropriate silver compound.

Reactivity of ***1*** *with gases*

The complex, either in the solid state or solution (MeOH or CH_2Cl_2), was completely unreactive toward CO, O_2, and H_2 at 1 atm (101.3 kPa) pressure and ambient temperatures. Hydrogen halides added oxidatively, however, to give the halogeno(hydrido)rhodium(III) derivative.

A solution of **1** (0.1 g, 0.1 mmol) in EtOH or CH_2Cl_2 (10 mL) was treated with HCl gas for ~10 min. The volume of the bleached solution was then reduced *in vacuo* to ca. 1 mL, when diethyl ether (20 mL) was added. Cooling produced white crystals that were filtered, washed with ether, and vacuum dried. The yield of *trans*-RhHCl(*S*,*S*-chiraphos)$_2^+$ Cl$^-$, **3**, was 0.09 g (90%). *Anal.* calcd. for $C_{56}H_{57}Cl_2P_4Rh$: C 65.48, H 5.50; found: C 62.5, H 6.0. Decomposition point in air = 90°C. Conductivity $\Lambda_M = 57\ \Omega^{-1}\,cm^2\,mol^{-1}$; $[\alpha]_D^{25°}$ +220.4° (*c* 2.6, ethanol); ir ν(Rh–H): 2130 cm^{-1}; uv–vis (CH_3OH): 288 (28 600), 275 (30 400), 268 (31 000), 265 nm (ε 30 700 $M^{-1}\,cm^{-1}$); ^1H nmr ($CDCl_3$) δ: −16.23 (9 lines, J_{Rh-H} = 16.0 Hz, $^2J_{H-P_A}$ = 16.0 Hz, $^2J_{H-P_B}$ = 8.0 Hz, 1H, Rh=*H*), 0.46 (virtual quartet, $^3J_{HH}$ = 7.5 Hz, $^{3,5}J_{HP}$ (apparent) = 7.5 Hz, 6H, 2 × C*H*$_3$), 0.96 (virtual quartet, $^3J_{HH}$ = 7.5 Hz, $^{3,5}J_{HP}$ (apparent) = 7.5 Hz, 6H, 2 × C*H*$_3$), 2.0 (m, 2H, 2 × C*H*), 3.4 (m, 2H, 2 × C*H*), 6.8–7.8 (m, 40H, Ph); ^{31}P-{^1H} nmr ($CDCl_3$) δ: 38.4 (dt, J_{P_A-Rh} = 94 Hz, J_{AB} = 27 Hz, 2P), 62.7 (dt, J_{P_B-Rh} = 94 Hz, J_{AB} = 27 Hz, 2P). The nmr spectra are essentially identical in acetone-d^6.

The complex *trans*-RhHBr(*S*,*S*-chiraphos)$_2^+$ Cl$^-$, **4**, was characterized by ^1H nmr after its formation *in situ* ($CDCl_3$) from the reaction of **1** and gaseous HBr; ^1H nmr ($CDCl_3$) δ: −15.12 (9 lines, J_{Rh-H} = 16.0 Hz, $^2J_{H-P_A}$ = 16.0 Hz, $^2J_{H-P_B}$ = 8.0 Hz, 1H, Rh—*H*), 0.53 and 1.00 (virtual quartets, as for **2**), 1.95 (m, 2H, 2 × C*H*), 3.72 (m, 2H, 2 × C*H*), 6.8–7.6 (m, 40H, Ph).

*X-ray crystallographic analysis of bis[2(*S*),3(*S*)-2,3-bis(diphenylphosphino)butane]rhodium(I) chloride*

A crystal bounded by the 8 faces (followed by their distances in mm from a common origin): {−1 1 1}, 0.07, {1 − 1 − 1}, 0.07, {1 0 − 1}, 0.08, {3 0 1}, 0.26 was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 30–38°) measured on a diffractometer with Mo-*K*α radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{56}H_{56}ClP_4Rh$ f.w. = 991.3

Monoclinic, a = 23.106(3), b = 12.4987(8), c = 21.455(3) Å, β = 128.539(5)°, V = 4847(1) Å^3, Z = 4, ρ_c = 1.359 g cm^{-3}, $F(000)$ = 2056, μ(Mo-*K*α) = 5.68 cm^{-1}. Absent reflections: *hkl*, $h + k$ odd, space group $C2$ (C_2^3, No. 5) required by molecular chirality.

Intensities were measured with graphite-monochromated Mo-*K*α radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 1.06–10.06° min^{-1} over a range of (0.70 + 0.35 tan θ) degree in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, showed only small random fluctuations. After data reduction,[4] an absorption correction was applied using the Gaussian integration method (23, 24). Transmission factors ranged from 0.915 to 0.933 for 100 integration points. Of the 5793 independent reflections measured, 4509 (77.8%) had intensities greater than or equal to $\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy-atom methods, the Rh and P coordinates being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters resulted in R = 0.054. In the final stages of refinement the hydrogen atoms were included as fixed contributors in idealized positions (methyl groups staggered in accordance with positions observed on a difference map, C(sp^2)—H = 0.97 and C(sp^3)—H = 0.98 Å, recalculated after each cycle). The absolute configuration is determined by that known for the chiral phosphine ligands. The scattering factors of ref. 25 were used for non-hydrogen atoms and those of ref. 26 for hydrogen atoms. Anomalous scattering factors from ref. 27 were used for the Rh, Cl, and P atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 559 variables. Reflections with $I < \sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.046 and R_w = 0.032 for 4509 reflections with $I \geq \sigma(I)$. For all 5793 reflections, R = 0.069. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.19σ, respectively. The mean error in an observation of unit weight was 1.676. A final difference map

showed maximum fluctuations of −0.63 to +0.55 e Å^3 near Rh and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 6,[5] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[5] Selected bond lengths, bond angles, and intra-annular torsion angles for the two chelate rings appear in Tables 2–4, respectively. Bond lengths and angles involving phenyl carbon atoms (Tables 2a and 3a), calculated hydrogen atom parameters (Table 5), and additional torsion angles (Table 7) are included as deposited material.

Discussion

Synthesis and characterization of the complexes

The yellow complex Rh(S,S-chiraphos)$_2^+$ Cl$^-$, **1**, is readily prepared from the rhodium(I) cyclooctene precursor as a benzene hemisolvate according to eq. [2]. The unsolvated complex is obtained by recrystallization from CH_2Cl_2/ether, or by sub-

[5]The structure factor table, Table 6 (anisotropic thermal parameters), and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[2] $RhCl(C_8H_{14})_2]_2 + 4$ chiraphos $\xrightarrow{C_6H_6}$ $2Rh(chiraphos)_2^+ Cl^- + 4C_8H_{14}$

jecting a finely ground sample of the hemisolvate to high vacuum. Treatment of **1** with Ag^+X^- ($X = BF_4$, PF_6, SbF_6) yields the corresponding X^- salt. The syntheses parallel those used earlier (1) for the analogous dpm, dpe, dpp, dpb, and diop complexes, although, in contrast to these (2), the chiraphos salts are completely air stable in the solid state and solution.

The conductivity data (28), identical uv–visible spectra of **1** and **2**, the absence of ν(Rh—Cl) bands in the 400–200 cm^{-1} region, and the crystallographic data for **1** are consistent with the presence of discrete cations and counter-anions in solution as well as the solid state. A solid state visible spectrum of **1** also shows an absorption maximum at 410 nm, the same as the solution value. The electronic absorption and emission spectral data for square planar $Rh(P—P)_2^+$ complexes have been analyzed in some detail (29–31). It should be noted that the $Rh(P—P)_2Cl$ complexes with P—P = dpm, dpb, and diop are five-coordinate in the solid state and in nonpolar solvents, while the dpe (diphos) and dpp analogues contain ionic chloride (1). Crystallographic data are now available for the ionic $Rh(dpe)_2^+ ClO_4^-$ (32), $Rh(dpp)_2^+ BF_4^-$ (33), $Rh(dpb)_2^+ BF_4^-$ (19), and $Rh(chiraphos)_2^+ Cl^-$ complexes (see below).

The ^{31}P-$\{^1H\}$ nmr spectrum of $Rh(chiraphos)_2^+$ at ambient temperatures displays a simple doublet produced by equivalent P atoms coupled to Rh; the large downfield shift, typical of five-membered ring systems, and coupling constant are very similar to the data for $Rh(dpe)_2^+$ (1). The ^1H nmr data are uninformative.

The nonreactivity of $Rh(chiraphos)_2^+$ towards H_2 or CO parallels that of $Rh(dpe)_2^+$ (2), while the inertness towards O_2 is surprising considering that the dpe analogue forms an isolable peroxorhodium(III) complex (2, 13, 34). In solution under Ar, however, the $Rh(dpe)_2O_2^+$ species readily loses O_2, and the process has been monitored spectrophotometrically to yield the following data at 30°C in methanol: $k_{on} \approx 0.25\ M^{-1}\ s^{-1}$, $k_{off} = 2.6 \times 10^{-3}\ s^{-1}$, and equilibrium constant K, measured by an independent static method, $= 60\ M^{-1}$, or $P_{1/2}$ (the pressure for 50% formation of the dioxygen complex) = 2.3 atm (2, 4). Steric factors within the chiraphos system must either decrease the k_{on}, or increase the k_{off} values, respectively, compared to the dpe system (see below).

Oxidative addition of HCl yields the *trans*-chlorohydrido derivative, **3**; the low carbon analysis is considered to result from contamination with lattice-held HCl, a feature observed with other $RhHCl(P—P)_2^+$ complexes (2) and the iridium analogues (35). The spectroscopy (ir and nmr) is consistent with the presence of a single metal complex. The high-field hydride resonance (Fig. 1) is an overlapping doublet of triplets of triplets (9 lines) produced by coupling to ^{103}Rh (16.0 Hz) and two sets of ^{31}P nuclei (16.0 and 8.0 Hz). A molecular two-fold symmetry in the $RhHCl(chiraphos)_2^+$ cation is indicated also by the pairs of well-separated resonances of two sets of $—CH_3$ (δ 0.46 and 0.96) and —CH groups (δ 2.0 and 3.4) in the ^1H nmr. Of interest, both $—CH_3$ resonances are quartets due to coupling to the neighbouring —CH proton and P nuclei, as well as virtual coupling to another P atom. This pattern implies strong $^2J_{PP}$ coupling, indicative of *trans*-P nuclei (36); decoupling of the —CH protons gives the expected virtual triplet due to coupling to two equivalent P nuclei (36).

The $^{31}P\{^1H\}$ nmr of **3** (Fig. 1) exhibits an A_2B_2X pattern, the two sets of P nuclei (δ 62.7, 38.4) being coupled to Rh and P.

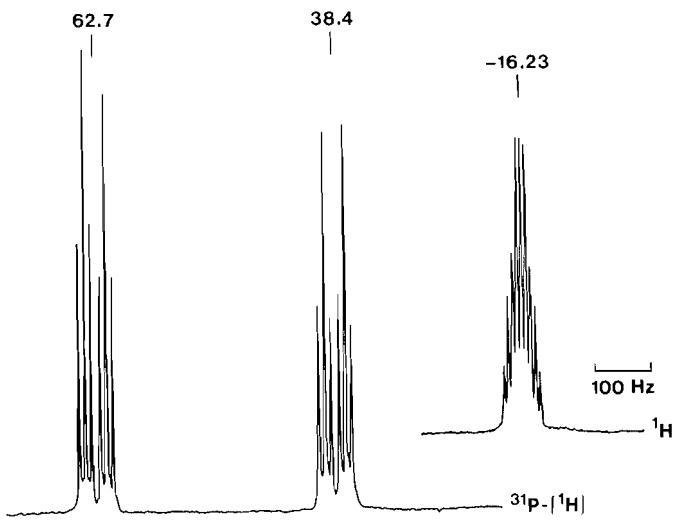

FIG. 1. The ^1H and $^{31}P\{^1H\}$ nmr spectra of *trans*-RhHBr(*S*,*S*-chiraphos)$_2^+$ Cl^- in $CDCl_3$ at ambient temperature.

Such A_2B_2 spectra have been used more commonly as diagnostic of *cis* geometry within $MHCl(P—P)_2$ complexes, with the required assumption of rapid exchange between H and Cl (17, 34, 37). However, distortion from C_{4v} (*trans*) symmetry, such that the pairs of P atoms become nonequivalent, can also give rise to A_2B_2 spectra; this is exemplified by the *trans*-$RuHCl((+)diop)_2$ complex, that distorts to minimize phenyl–phenyl interactions such that the P atom pairs subtend respective H—Ru—P angles of about 75° and 96°, a difference of >20° (37, 38). Such a structural feature in **3**, resulting from the preferred conformations of equatorial chiraphos ligands, would account for the two $^2J_{HP}$ values observed. The *trans* structure is strongly supported by: (a) the ^1H nmr virtual coupling data which require two sets of P nuclei, the members of which are mutually *trans*, i.e. near square-planar P donors; (b) the $^2J_{HP}$ couplings are typical of *cis*-disposed nuclei; the characteristically large *trans* J_{HP} values (39) are not observed; (c) the relatively high value of 2130 cm^{-1} for ν(Rh—H) is consistent with hydride *trans* to chloride (2, 39, 40); (d) the essential features of the metal–hydride resonance in the nmr are maintained at −60°C, which argues against a fluxional *cis*-HCl structure. Of other $RhHCl(P—P)_2^+$ cations (2), the only crystallographic data

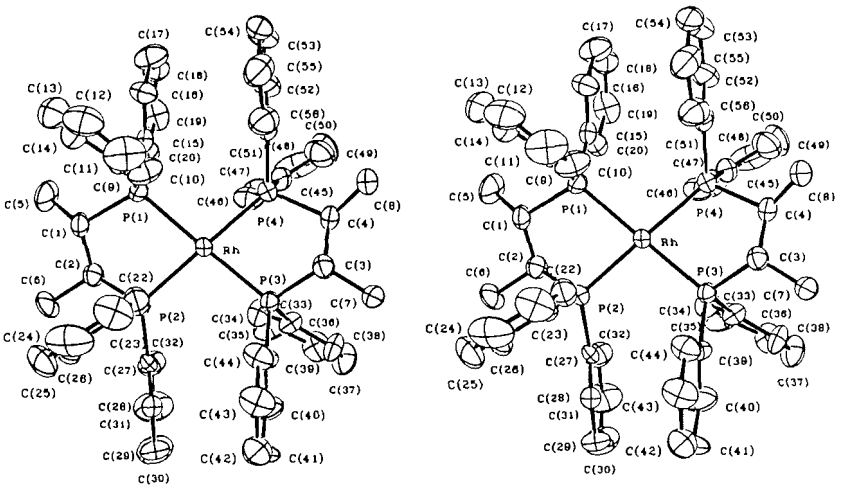

FIG. 2. A stereoscopic view of the Rh(S,S-chiraphos)$_2^+$ cation, and the numbering scheme used. Thermal ellipsoids enclose 50% probability levels. Hydrogen atoms have been deleted for clarity.

available are those for the P—P = dpm system, which has *trans* geometry (41).

The RhHBr(chiraphos)$_2^+$ complex was formed *in situ* from **1** using HBr; the nmr data correspond closely to those for **3**, and a *trans* geometry is again favoured. Unfortunately, **1** did not react with HF, which prevented a probing of the geometry via a $^2J_{HF}$ measurement.

*Structure description of Rh(*S,S*-chiraphos)$_2^+$ Cl$^-$*

The structure consists of discrete Rh(S,S-chiraphos)$_2^+$ cations and Cl$^-$ anions, the latter situated along the twofold axes $(0, y, 0)$ and $(\frac{1}{2}, y, \frac{1}{2})$. The nearest neighbours of each of the two crystallographically independent Cl$^-$ anions are six hydrogen atoms at distances of 2.79–2.90 Å. All cation–cation distances correspond to normal van der Waals interactions. Figure 2 shows a stereoscopic view of the rhodium cation, including the atom numbering scheme.

The Rh(S,S-chiraphos)$_2^+$ cation, as a whole, possesses approximate C_2 symmetry and, ignoring the carbon atoms of the chelate rings (and their methyl substituents), the symmetry is close to C_{2h}. The coordination about Rh is square planar, distorted toward tetrahedral. The Rh atom lies essentially in the P_4 mean plane (displacement −0.008(1) Å), while the phosphorus atoms lie alternately above and below the P_4 mean plane (displacements: −0.112(2), 0.120(2), −0.108(2), and 0.132(2) Å, respectively for P(1)–P(4)). The distortion of the coordination group in the closely related Rh(dpe)$_2^+$ cation is similar, but displacements of the P atoms from the coordination plane are significantly smaller (0.04 Å) (32).

The Rh—P distances in Rh(S,S-chiraphos)$_2^+$ (2.291(2)–2.308(2), mean 2.300 Å) are slightly longer than the values of 2.232(2)–2.289(2) Å reported for other square-planar S,S-chiraphos complexes of Rh(I) (9, 42) and similar to values of 2.289(6)–2.313(6), mean 2.306 Å, observed for Rh(dpe)$_2^+$ (32). The conformations of the two chelate rings are nearly identical (see Table 4) and are very similar to those observed in other complexes of S,S-chiraphos (9, 42, 43) and in the Rh(dpe)$_2^+$ cation (32).

One of the most unusual features of the Rh(S,S-chiraphos)$_2^+$ structure is the highly symmetric disposition of the phenyl rings. It is this feature that represents the major structural difference between this cation and the Rh(dpe)$_2^+$ cation, as well as nearly all structurally characterized complexes of bidentate bis(diphenylphosphine) ligands forming five-membered chelate rings. In addition to the steric interactions between the phenyl rings noted earlier for the Rh(dpe)$_2^+$ cation (32), the methyl substituents on the chelate rings further restrict rotational freedom about the P—Ph bonds. The C(5) and C(8) methyl groups make contact with carbon atoms of adjacent pseudoequatorial phenyl rings, while the C(6) and C(7) methyl groups are in contact with both adjacent phenyl rings (C(Me)···C(Ph) = 3.02(1)–3.37(9) Å, H(Me)···C(Ph) = 2.66–2.80 Å). As a result, the pseudoaxial phenyl rings are oriented more nearly perpendicular to the RhP_4 plane than in Rh(dpe)$_2^+$ and are oriented such that the hydrogen atoms attached to C(10), C(22), C(34), and C(46) effectively block any axial approach to the metal (Rh···H = 3.05, 2.87, 2.84, and 2.92 Å, respectively). These "blocking" hydrogen atoms, two from each ligand situated on opposite sides of the coordination plane, are in close contact with one another (H···H = 2.28, 2.36 Å) and with a phenyl hydrogen atom associated with a pseudoequatorial phenyl ring of the other ligand (H···H = 2.38–2.46 Å). This steric factor must certainly contribute to the lack of reactivity toward O_2 (compared with Rh(dpe)$_2^+$), even in solution.

Bond lengths and angles are generally as expected although some distances, particularly in the phenyl rings, are shortened as a result of relatively high thermal motion. The phenyl rings containing C(9), C(15), C(27), C(33), and C(39) are all significantly nonplanar (maximum deviation from the mean plane = 0.055(12) Å). This nonplanarity is most probably an artifact arising from the uncertainties in the positions of some of the peripheral ring atoms having higher thermal amplitudes, although some small deviations from planarity may arise from steric effects.

Received June 13, 1985

DONALD G. FLEMING, MASAYOSHI SENBA, DONALD J. ARSENEAU, IVAN D. REID, and DAVID M. GARNER. Can. J. Chem. **64**, 57 (1986).

Energetic positive muons thermalizing in alkane vapors are observed in either diamagnetic environments, with relative fraction f_D, or as the polarized muonium atom (Mu = μ^+e^-), with fraction f_{Mu}. The fraction f_D is found to vary from ~0.12 in CH_4 to ~0.24 in n-C_6H_{14} at pressures near 1 atm (300 K); some pressure dependence in yield is also observed, notably for the heavier alkanes. The diamagnetic fraction (yield) is interpreted as due to hot atom reactions (Mu*) in complete analogy with past studies in hot tritium (T*) chemistry. The data have been interpreted within the Wolfgang–Estrup formalism and compared with similar analyses of T* reactions for (unmoderated) alkane systems. It is concluded that the energy loss parameter (α) is determined largely by inelastic scattering effects. If these are assumed to be the same for both Mu* and T* moderation, then the resulting reactivity integrals (I) for the noncyclic alkanes are found to exhibit the same trend with mass as in hot tritium chemistry, giving, on average, ~6:1 for the ratio I(T*)/I(Mu*).

DONALD G. FLEMING, MASAYOSHI SENBA, DONALD J. ARSENEAU, IVAN D. REID et DAVID M. GARNER. Can. J. Chem. **64**, 57 (1986).

On a observé que des muons positifs, qui sont chargés d'énergie et qui se rechauffent dans des vapeurs d'alcane, existent soit dans un environnement diamagnétique avec une fraction relative f_D soit sous forme d'atome de muomum polarisé (Mu = μ^+e^-) avec une fraction f_{Mu}. À des pressions voisines de 1 atm (300 K), on a trouvé que la fraction f_D varie d'environ 0,12 dans le CH_4 à environ 0,24 dans le n-C_6H_{14}; on a aussi observé une relation entre la pression et le rendement, notamment dans le cas des alcanes plus lourds. On pense que la fraction diamagnétique (rendement) est due à des réactions d'atomes chauds (Mu*) et ceci est en accord complet avec les études antérieures réalisées dans la chimie du tritium chaud (T*). On a fait appel au formalisme de Wolfgang–Estrup pour interpréter les données et on les a comparées à des analyses identiques de réactions du T* dans des systèmes d'alcanes (non-modérés). On en conclut que le paramètre de perte d'énergie (α) est déterminé en grande partie par des effets de dispersion non élastiques. Si on admet que ces effets sont les mêmes pour les modérations tant du Mu* que du T*, on trouve alors que les intégrales résultantes d'activité (I) des alcanes non-cycliques exhibent la même tendance en ce qui a trait à la masse que dans la chimie du tritium chaud; on obtient ainsi un rapport moyen de I(T*)/I(Mu*) qui est d'environ 6:1.

1. Introduction

1.1 General remarks

The realm of studies in chemical reaction dynamics can be broadly divided into "hot" and "thermal" reactions, distinguished roughly by the translational energy of reacting species. In hot (atom or ion) reactions this energy is large compared to the value of k_BT characterizing thermal reactions, with the result that certain reaction channels which are energetically forbidden in the thermal energy regime become accessible at higher energies. The most direct knowledge about energetic reactions comes from atomic and molecular beam studies, where the capability of systematically varying the reaction energy (and angle) exists. The goal of such experiments is the measurement of true state-to-state cross sections, and while this goal is often not fully realized, molecular beam studies do provide the means by which theories of reaction dynamics can be most effectively tested on a microscopic level (1, 2). However, particularly in the case of *atom*–molecule reactions, these studies are limited to beam energies that are typically $\lesssim$1 eV so that the excitation function describing the energy dependence of the reactive cross section ($\sigma(E)$) cannot be extended to higher energies. The role of probing $\sigma(E)$ at energies $\gtrsim$1 eV has traditionally fallen to "hot atom" reactions, particularly recoil tritium experiments, in which the upper energy for significant reactivity is $\lesssim$30 eV (3–6). Although the excitation function in such studies emerges only indirectly as an integral result, defined by the hot atom "yield," these continue to be of interest (3). Photochemically generated hot H atoms (H*, D*, T*) have also been utilized and the much lower (few eV) incident energies characteristic of these atoms (7–9) provides some overlap with atomic beam work.

The importance of isotopic substitution, notably of the hydrogen atom, to the study of chemical reaction dynamics is well known, exemplified by the seminal work of Polanyi and co-workers on mass effects in chemical reactivity (10). In this respect there has recently been considerable interest in exploring the isotopic similarity between the muonium (Mu = μ^+e^-) and hydrogen (H) atoms, in both gases (11–14)[2] and liquids (15), motivated by the fact that the mass of the positive muon is only 1/9th the proton mass.

The effects of a change in isotopic mass on reaction dynamics can be quite different in hot versus thermal reactions. In the case of thermal reactions it is the threshold region of the excitation function that is of paramount importance, a region that is poorly explored by either hot atom or molecular beam studies. Both classical and quantum mechanical effects are important in thermal reactions (10), with marked changes seen upon the substitution of Mu for H (11–15); in particular, Mu is a very sensitive probe of quantum tunneling. In contrast, at the much higher energies characteristic of hot reactions, tunneling is relatively unimportant and mass effects on reaction dynamics should be almost entirely classical in nature (3, 4, 16–18). Indeed, atomic beam results at energies of ~1 eV are often very well described by classical calculations (1), even in the case of the H(D) + H_2 reaction (16, 19, 20).

Traditionally, recoil hot T chemistry has been the mainstay of

[1]1983–1984 John Simon Guggenheim Fellow. Author to whom correspondence may be addressed.

[2]Also, J. N. L. Connor and J. C. Whitehead, private communication.

studies in (light) hot atom chemistry (3–6), in which the incident triton is produced with kinetic energies ~ 100 keV, orders of magnitude larger than those of chemical interest. This is also the situation in Mu formation and hence the hot Mu (Mu*) chemistry in alkane vapors discussed here should be directly comparable with similar studies of T* reactivity (21–27).

The alkane vapors have been chosen for this comparison because the hot tritium yields seem to have been most reliably and systematically determined for these systems. From such a study one can hope to learn about the sensitivity of hot atom reaction dynamics to changes in isotopic mass, as in previous work on thermal reactions (11–14); indeed, a factor of *27* between the masses of Mu and T is the widest possible isotopic variation at the most sensitive end of the mass scale. The present paper is the first time that the subject of hot Mu reactivity has been addressed directly, although it has often been referred to (15, 28–30). It is hoped that comparison with the analogous hot tritium studies will help to sharpen the criteria for different theoretical models of hot atom reaction dynamics.

1.2. Muonium (tritium) formation and thermalization in gases

Positive muons (μ^+) enter the (gas) target of interest with kinetic energies $\gtrsim$ 3 MeV. The energy loss processes that the muon then undergoes can be divided into three stages (28–30), in analogy with related studies of proton charge exchange (31). Most of the incident energy is lost in the first stage, where Bethe–Bloch ionization dominates until a kinetic energy of ~30 keV is reached. At this energy, the muon velocity is comparable to that of electrons bound in atoms of the moderator and the μ^+ enters a regime of *cyclic* charge exchange, in which Mu is formed in one collision (with cross section σ_{10}) and lost in a subsequent collision (with cross section σ_{01}). There are ~100 of these charge exchange cycles, following which the muon emerges either in the Mu atom or as a bare μ^+ at a kinetic energy of ~30 eV.

In the third and final stage of thermalization a further factor of ~1000 loss in energy to k_BT occurs. It is during this third stage when hot atom (or ion) chemistry will be important, since reactive processes will compete with elastic and inelastic scattering in thermalizing the muon. In the present study of low ionization potential moderators (all lower than the 13.6-eV value of Mu itself), any muons that survive the charge exchange regime as bare muons are expected to rapidly produce Mu in subsequent collisions, since σ_{10} for exothermic charge exchange is large at such low energies (28, 31). Hence in hydrocarbon vapors charge exchange alone implies 100% Mu formation ($f_{Mu} = 1.0$), while observations of $f_{Mu} < 1.0$ are taken as evidence for the presence of Mu* reactions. In general these differences are small, manifest in the fraction of muons appearing in *diamagnetic* environments (f_D). In contrast to the present study of alkane vapors, it is noted that, in other gases, only in Kr and Xe is $f_{Mu} = 1.0$ observed (28), cases in which hot atom chemical reactions are not possible.

The concept that muonium is formed as a result of cyclic charge exchange is also believed to be the case in recoil tritium atom chemistry (3, 4, 6, 32). In the gas phase, tritons are produced from thermal neutrons via the ^{3}He(n, p)T reaction, endowing the recoil triton with 191 keV of kinetic energy. While this is much lower than the incident μ^+ energy of ~3 MeV, it is still much larger than chemical bond energies. The triton is likely also produced as an ion but, unlike the μ^+, at 191 keV its initial velocity is already comparable to those of the bound electrons in the moderator and hence it can be expected to undergo cyclic charge exchange as part of the initial thermalization stage. However, because of its mass, the triton (T atom) will emerge from the charge exchange regime at much higher energies than the muon, ~900 eV. At such energies, the electron loss cross section σ_{01} is appreciably larger than is the case for Mu at ~30 eV (31), and thus one might expect hot ion chemistry to be relatively more important in the case of the triton. The contribution of hot ions in determining measured yields in recoil tritium studies is, however, still thought to be small (3, 4, 32, 33).

2. The Wolfgang–Estrup theory of hot (T*) atom reactivity

In the Wolfgang–Estrup (WE) formalism (3–5), the fundamental expression for the total probability P of a hot (T*) atom reaction (often referred to as the "yield") is defined by

$$[1] \quad P = \sum_j \int_{E_1}^{E_2} f_j p_j(E) n(E) \mathrm{d}E$$

where $p_j(E)$ is the probability per collision for formation of product j at energy E, f_j is the relative chance of collision with component j, and $n(E)$ is the density of collisions between E and $E + \mathrm{d}E$. Collisions at energies above E_2 are too energetic to result in stable molecules, while E_1 is the minimum (threshold) energy for reaction. The central hypothesis of the WE theory is that the collisional density is given in terms of a *constant* fractional energy loss α, defined in the *absence* of reaction by

$$[2] \quad n(E)\mathrm{d}E = -\frac{1}{\alpha E}\mathrm{d}E$$

where, in the case of *elastic* scattering from *rigid spheres* (rs), α is given by

$$[3] \quad \alpha_{rs} = 1 - \frac{(M-m)^2}{2mM}\ln\frac{M+m}{M-m} \approx \frac{2m}{M}$$

with m and M being the masses of the incident hot atom and the moderator molecule, respectively. It is also assumed that the initial energy of the hot atom $E_0 \gg E_2$, ensuring a sufficient number of collisions so that a statistically well-defined energy distribution of hot atoms exists in the region $E_2 > E > E_1$. This assumption should be well justified for recoil T* ($E_0 \lesssim 900$ eV) and for the present Mu* study ($E_0 \lesssim 30$ eV), but may well be suspect for photochemically induced (epithermal) reactions (34). A further assumption is that $E_1 \gg k_BT$ so that any contribution from thermal reactions can be ignored (this is accomplished experimentally by the use of scavengers).

If $p_j(E)$ is finite at high energies, eq. [2] must be modified to take account of the fact that the hot atom may have already undergone reaction in the energy region of interest,

$$[4] \quad n(E)\mathrm{d}E = \frac{\mathrm{d}E}{\alpha E}\left[1 - \int_E^{E_2} fp(E')n(E')\mathrm{d}E'\right.$$

where here a single reactive component is assumed (hence the label "j" is no longer necessary). If $p(E)$ in this region is small, eq. [4] can be written as an exponential ($e^{-x} \sim 1 - x$) which, upon substitution into eq. [1] and re-expanding, yields the basic result of WE theory,

$$[5] \quad P = \frac{fI}{\alpha} - \frac{1}{2}\left(\frac{fI}{\alpha}\right)^2 + \frac{1}{6}\left(\frac{fI}{\alpha}\right)^3 + \ldots = 1 - \exp\left(\frac{-fI}{\alpha}\right)$$

Here I is the "reactivity integral," defined by

$$[6] \quad I = \int_{E_1}^{E_2}\frac{p(E)\mathrm{d}E}{E} = \frac{1}{\sigma_{max}}\int_{E_1}^{E_2}\frac{\sigma(E)\mathrm{d}E}{E}$$

where σ_{max} gives the total "geometrical" cross section. For a binary mixture of one reactant (R) and *inert* moderator (M), the collisional energy loss parameter can be written as $\alpha = f\alpha_R + (1 - f)\alpha_M$, which upon substitution into eq. [6] yields the result

$$[7] \quad \frac{-1}{\ln(1-P)} = \frac{\alpha_R}{I} + \frac{\alpha_M}{I}\frac{(1-f)}{f}$$

Hence, if the *total* reaction probability P can be found as a function of moderator mole fraction, then a kinetic plot of eq. [7] yields a straight line of slope α_M/I and intercept α_R/I. In practice, this may not be nearly so easy as it sounds. In hot tritium chemistry there can be several products formed from even a single reactant and the individual reaction probabilities P_i must be found for each product ($P = \Sigma_i P_i$).

Although the WE formalism has little *predictive* capability, since there is no a priori way to determine I and hence the cross section $\sigma(E)$, it has been very successful over the years in providing an easily understandable framework for the interpretation of experimental yields. From eq. [5] it can be seen that there are two competitive processes that determine these yields: the reactivity I and the collisional energy loss α; if I is large or α is small (or both), then the hot atom yield will be high. A large value for I clearly implies a large reaction cross section, while a small α means a large number of collisions during the slowing-down process, enhancing the probability for reaction. It is worth noting that the WE development can be "exact" only in the limit $p(E) \rightarrow 0$ (eq. [4]), a condition more likely to be met in Mu* than in T* chemistry.

Of the approximations noted above that form the basis of the WE theory, the most suspect is that of a constant fractional energy loss (α) with its implication of a time-independent (steady state) collision density $n(E)$. In recent years this assumption has been questioned, and alternative methods for the theoretical interpretation of hot atom reactions based on Monte Carlo methods (33, 35, 36) or on explicit time-dependent solutions of the Boltzmann equation (37–39) have been developed. See also refs. 16–18. These theoretical treatments demonstrate, however, that the WE formalism still provides a reasonable framework for the interpretation of experimental hot atom yields. In the discussion to follow we apply this formalism to a comparison of the yields of Mu* and T* reactions in alkane vapors.

3. Experimental technique and results

3.1 The μSR signals

The experiments were carried out at the TRIUMF cyclotron, a meson facility adjacent to the campus of the University of British Columbia. Surface (4.1 MeV) muons (40) were brought to rest in a gas target positioned between a pair of Helmholtz coils of 1.5-m diameter, which provided a magnetic field transverse to the muon spin in the range ~1 G to ~300 G. As a result of charge exchange and hot atom (or possibly hot ion) reactions, one can expect to observe thermalized muons in two environments: diamagnetic, with fraction f_D, and paramagnetic (Mu), with fraction f_{Mu}. A third possibility, the formation of muonium radicals (41), is regarded as extremely unlikely in the saturated bond systems under consideration and will not be discussed further here (see also ref. 30).

Regardless of its environment, the μ^+ ultimately decays in the parity violating process $\mu^+ \rightarrow e^+\bar{\nu}_\mu\nu_e$, emitting the positron preferentially along the muon spin axis. The decay positron is detected in coincidence with a data gate that is triggered by a stopped muon; the time difference between muon and positron is, on average, just the mean life of the muon, $\tau_\mu = 2.2\,\mu s$. This time-differential process is repeated many times until a histogram of ~10^6 events has been accumulated. In a transverse magnetic field, muons bound in the paramagnetic Mu atom and those in diamagnetic environments precess with distinctly different Larmor frequencies ($\nu_{Mu} = 103 \times \nu_D = 1.39\,MHz\,G^{-1}$), manifest as modulations of the decay histograms, and referred to as μSR (Muon Spin Rotation) "signals" $S(t)$. Examples are shown in Fig. 1 for room-temperature ethane gas at 1 atm pressure, at 7.6 G (top), and at 195 G (bottom). These can be thought of in analogy with free induction decay signals in magnetic resonance. The curves are χ^2 fits to the data, defined in the case of the top spectrum in Fig. 1 by

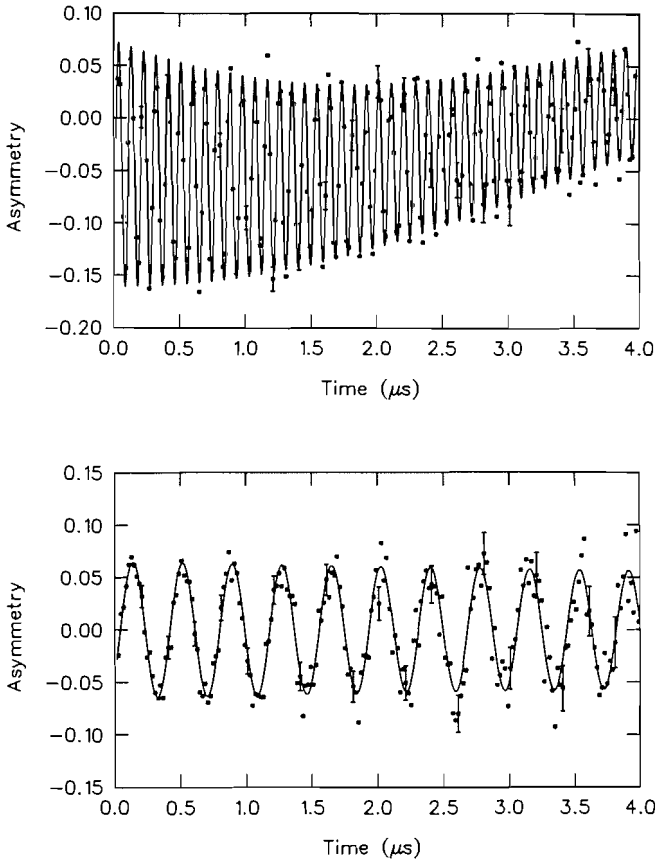

FIG. 1. μSR signals at room temperature in 1 atm ethane gas at 7.6 G (top) and 195 G (bottom). The solid line is a χ^2 fit to the data, as discussed in the text.

$$[8] \quad S(t) = A_{Mu}e^{-\lambda_{Mu}t}\cos(\omega_{Mu}t + \phi_{Mu}) + A_D e^{-\lambda_D t}\cos(\omega_D t - \phi_D)$$

where A_{Mu}, ω_{Mu}, ϕ_{Mu} and A_D, ω_D, ϕ_D are the initial amplitudes, precession frequencies, and phases for paramagnetic Mu and diamagnetic muons, respectively, while λ_M, λ_D are transverse relaxation times ($\lambda = 1/T_2$) accounting for the interaction of these species with their environments. In the weak (7.6 G) field of Fig. 1 (top), the signal is dominated by fast Mu precession; the signal from slowly precessing diamagnetic muons appearing only as an underlying curvature in the data. This is in contrast to the bottom spectrum at 195 G, where Mu precession is averaged out, both by the experimental time resolution (~3 ns) and by the coarse binning used, so that only the second term of eq. [8] is relevant. For further details of the technique, the reader is referred to refs. 28–30.

Of the parameters in eq. [8], we are concerned in this paper only with the amplitudes A_{Mu} and A_D of muons in paramagnetic muonium and in diamagnetic environments, since these indirectly reveal the hot process occurring during the muon's slowing down process. In particular, the polarizations (P_{Mu} and P_D) and relative fractions (f_{Mu} and f_D) are defined by

$$[9a] \quad P_{Mu} = 2A_{Mu}/A_{max} \qquad P_D = A_D/A_{max}$$

$$[9b] \quad f_{Mu} = P_{Mu}/(P_{Mu} + P_D), \qquad f_D = P_D/(P_{Mu} + P_D)$$

where A_{max} is the maximum possible amplitude for the experimental conditions (typically ~0.3); the factor of two accounts for the loss of observable Mu due to the μ^+–e^- hyperfine interaction (28–30, 42). The sum $P_D + P_{Mu}$ may be less than unity, the difference reflecting a "lost" or "missing" fraction of polarization, P_L.

Since we are interested in the signal amplitudes from muons stopping in the gas, any muons that actually stop in the walls of the target vessel must be corrected for. The source of this "wall effect" is the initial defining counter (3/8-mm thickness) and thin (1/8-mm) entrance window, which scatter some fractions of the more energetic muons into the Al walls, where they precess as diamagnetic muons (with amplitude A_W) and hence contribute to f_D. This can be corrected for experimentally, as discussed elsewhere (28–30) and can also be modeled from a Monte Carlo calculation of the muon stopping distribution. In the tables below (and in eqs. [9] above) A_D is defined by $A_D = A_D(obs) - A_W$, where $A_D(obs)$ is the experimentally observed total signal (e.g., Fig. 1, bottom).

3.2. *Procedure and results*

The alkanes employed as vapors in this study were all obtained commercially and were generally of high purity (total impurity content typically ≲0.5%, including other hydrocarbons). Two different gas target vessels were used. The gaseous alkanes (up to propane) were taken directly from the bottle without further purification and were used to fill a large vessel of ~180-L capacity. The heavier liquid alkanes (up to hexane, $n = 6$) were degassed by several freeze–pump–thaw cycles prior to usage in order to remove any dissolved oxygen. For these cases a different target design of smaller capacity (~30 L) was used (29, 30).

For each run the target vessel was filled with *neat* alkane vapor at a given pressure and μSR histogram spectra were recorded by detecting positron events in two independent "counter telescopes" at each of two different magnetic fields; ~200 G to measure A_D (Fig. 1, bottom) and ~8 G to measure A_{Mu} (Fig. 1, top). Usually at least two total pressures were employed in the range ~0.2 – ~1 atm, depending on the gas density. The polarizations P_D and P_{Mu} and the lost fraction P_L, as well as the relative fractions f_D and f_{Mu} (eqs. [9]), are recorded as a function of pressure in Table 1; the values given are weighted averages from the two independent histograms. Those for n-hexane and c-hexane are taken from ref. 30. The values for CH_4 are in good agreement with those previously reported (28).

It is noted, in agreement with previous studies (28–30, 42), that the lost fraction $P_L \rightarrow 0$ as the pressure increases to even moderate values (≲1 atm) at the relatively high densities of the present study. The missing fraction in gases is due to muon depolarization from the μ^+–e^- hyperfine interaction (ν_0 = 4463 MHz) *during* the charge exchange regime, an effect that is rapidly suppressed in the limit of "high" pressures when the time between collisions becomes short compared to $1/\nu_0$ (0.22 ns). This situation is in marked contrast to complementary studies of Mu formation in condensed media, where relatively large missing fractions (P_L ~ 20%) are routinely observed (15). In some cases the data in Table 1 also reveal a pressure dependence in the fraction f_D, notably in c-pentane (although curiously not in n-pentane), c-hexane, and n-hexane. Figure 2 presents a plot of f_D versus pressure for c-hexane; the solid curve shown is a fit to a simple three-body model which is discussed further in ref. 30.

4. Discussion

4.1 *Comparison of Mu* and T* yields in the alkanes*

In general, the extraction of reliable *absolute* total reaction yields from experimental data in hot tritium chemistry ($P = \Sigma_i P_i$) is not easily done since it is the *primary* reaction yield that is of interest, but the experimental (radiochromatographic) yields are obtained long after the reaction has ceased and complicated exchange processes may have occurred. Moreover, scavengers (e.g., Br_2, O_2) are invariably required in order to minimize the competition between hot and thermal tritons for specific reaction channels. As a result, often the yield of only one product (e.g. HT) is reliably determined and this is frequently given *relative* to some other yield, notably HT/RT yields in hydrocarbons. As a consequence, it is difficult to compare results from different laboratories and, in some cases, even to extract total yields from a given publication. Nevertheless, by examining a number of representative reports of both absolute yields and HT/RT ratios (21–27) one can hope to arrive at a reasonably reliable set of absolute T* yields with which the f_D values found in Mu* chemistry (Table 1) can be compared.

It is worth pointing out that two distinct advantages are

brought to the field of hot atom reactions by Mu chemistry: the μSR technique allows a *direct* interpretation of hot atom (ion) reactivity as manifest in the initial ($t = 0$) diamagnetic amplitudes A_D (and hence f_D, eq. [9]); and, moreover, truly thermal reactions can be distinguished from hot ones occurring at early times by the long (μs) time scale for *relaxation* of the μSR signal (eq. [8]), obviating the need for thermal scavengers. On the other hand, there is no possibility of clearly identifying individual diamagnetic product yields in muonium chemistry.

In analogy with hot tritium studies (7–9, 21–27), hot Mu atom reactivity with saturated hydrocarbon vapors (RH) can be described principally in terms of two reactions: abstraction ([10*a*]) and substitution (or displacement) ([10*b*])

$$\text{Mu}^* + \text{RH} \rightarrow \begin{cases} [10a] & (\text{MuH})^* + \text{R} \\ [10b] & (\text{MuR})^* + \text{H} \end{cases}$$

where the * indicates the possibility of forming translationally or rovibrationally excited product molecules, for which third-body collisions may be required to form a stable product. In hot tritium studies, the ratio of HT/RT yields exhibits a rather marked sensitivity to incident energy, pressure, moderator type, and to the nature of the hydrocarbon being attacked. Such a variation in reaction parameters can be expected to similarly affect the corresponding HMu/RMu yields.

There are two sources of moderator and (or) total pressure effects influencing the HT/RT yields in T* (Mu*) chemistry: translational excitation of (HT)* as a result of a high energy abstraction, and rovibrational excitation of (RT)* resulting from substitution reactions. In the case of translational excitation, light moderators (He) are very efficient at cooling, and hence result in a relative increase in HT yield, whereas heavy moderators (Xe) have the opposite effect, promoting dissociation of HT* and hence a reduction in yield (26, 35, 43). On the other hand, in those same studies it has been shown that for a range of moderators of mass comparable to that of the CH_3 group, such as Ne, there is little change in the HT/RT ratio; in addition, these ratios and the *total* yields are found to be essentially pressure independent for the alkanes up to $n = 4$ (21–26, 35). This is important for the present comparison of Mu* and T* reactivity in *pure* alkanes, since differences in measured yields can be construed as largely reflecting differences in hot atom reactivity rather than in moderation. Such a conclusion is consistent with recent studies of photochemically induced reactions in which only minor differences in the energy loss parameter α are found for different alkanes (7, 9). Moreover, these studies strongly indicate that *inelastic* effects dominate the energy loss process, as seen also in recoil tritium work in a variety of polyatomic moderators (26, 35, 43).

Although there is ample evidence that neither Mu* (Table 1 and refs. 28–30) nor T* (21–26, 44) yields are dramatically dependent on *total* pressure, in general some pressure dependence is expected, particularly for substitution reactions (eq. [10*b*]), depending on the level of residual excitation in the RT* (RMu*) product formed. In the hot tritium work there is a steady but modest increase in tritiated product yields related to (RT)* formation; typically ~30% increase for a factor of ~20 change in pressure up to ~3 atm (see, however, ref. 25). Analysis of these data in terms of RRK(M) theory indicates a broad distribution of excitation energies with a mean value of ~5 eV (23, 25, 26, 45, 46). A more dramatic change in yield with pressure is seen in the f_D values in Mu* chemistry in the heavier alkanes, which reach a constant yield asymptote at lower pressures (≲1 atm) than is typically seen in the T* data (Fig. 2 and ref. 30). This dependence suggests that the average excitation energy in the corresponding MuR* complex is lower (and also sharper) than in RT*, consistent with an expected reduced average energy for (substitution) reactions of hot muonium, since the initial (E_0) energy is so much less than in the case of hot tritium. The lack of any total pressure dependence in Mu* reactivity with the lighter alkanes (Table 1, ref. 30) suggests either relatively lower RMu* excitation energy, possibly due to their somewhat higher C—H bond energies (22, 47), or that H abstraction dominates for Mu*, unlike T* reactivity.

[a]Absolute reaction probability (total yield) of T* reactions, determined from several sources, as discussed in the text.

[b]Estimated errors ±10% (or more) for the noncyclic alkanes and ±20% (or more) for the cyclanes, as discussed in the text.

[c]Ratio of measured yield to that found for CH_4.

[d]The experimental hot atom Mu* yields, from Table 1 this paper and from refs. 28–30.

Table 2 compares our best estimates of absolute T* yields (i.e., total reaction probabilities, P) for *unmoderated* alkane (RH) vapors (21–27) with the corresponding f_D values seen in Mu* chemistry. The Mu values for N_2 and tetramethylsilane (TMS) are also included. In all cases, the values given are meant to be *pressure-independent* yields, taken from average values of "high" (~1 atm) pressure asymptotes from the original references and the present study. The hot atom yields in Table 2 likely represent upper bounds. In T* chemistry there could be contributions from thermal reactions, although the data were invariably obtained in the presence of scavengers. In addition, some of the earlier T* yields may have been obtained using slightly incorrect recoil tritium ranges, which could result in reported yields being about 10% too large (48). An indication of the absolute error expected in the T* data can be seen from the values for the cyclanes given in the lower half of Table 2; since P should be ≤1, ±20% is probably a conservative overall error, although ±10% is often quoted in some of the original papers. In the subsequent comparison with the WE formalism we consider only the noncyclic alkanes.

In both T* and Mu* chemistry, the role played by hot *ion* reactions is not clear; any such contributions would tend to raise the observed hot (atom) yield. In μSR studies, the importance of molecular ions is established to date only in the rare gases (49) and they can be expected to be of some importance in molecular

gases as well. However, it is unlikely that a significant number of molecular ions could be stably formed at energies much above a few eV (where hot atom reactivity dominates). Moreover, in the case of the alkanes, which all have ionization potentials lower than that of Mu (or T), molecular ion formation has to compete with exothermic Mu (or T) formation by low energy charge exchange. Hence, it is probably reasonable to ignore the role of hot ions in both the Mu* and T* yields of Table 2. This conjecture is supported by recent theoretical calculations on hot tritium ions in CH_4 (33), where it is concluded that their effect on both the collision density (eq. [4]) and on the integrated yield is relatively minor (except at very high energies), and also by earlier work in He-moderated hot tritium reactions in hydrocarbon vapors (21, 26, 48). See also discussion in refs. 3, 4, and 32.

The results for diamagnetic (hot atom) yields given in Table 2 for both Mu* and T* reactions should also be examined in light of results on the failure of the "additivity rule" in proton electron capture cross sections (σ_{10}) in the alkanes (50). At proton energies of ~800 keV (which would correspond to ~90 keV μ^+) significant loss of neutral atom formation in the larger alkanes is seen, due to a concomitant increase in the electron stripping cross section (σ_{01}) as the H (or Mu) atom traverses a large alkane molecule. By extrapolating the trend in ref. 50 to the data in Tables 1 and 2, however, one would expect about 50% less Mu formation in hexane than in methane, implying a corresponding increase of about a factor of five in the diamagnetic fraction, f_D. Although the present data do exhibit this trend, what is observed is not nearly so dramatic a change. Moreover, it must be remembered that the Mu (or T) atom actually *stops* in the gas and so the effects reported in ref. 50 need to be averaged over a wide energy interval, particularly down to energies near k_BT, where electron loss cross sections are much smaller than at higher energies. It can also be assumed that any loss of Mu in the larger alkanes will affect T in the same way and hence the ratios of T*/Mu* yields discussed below will not be affected.

Despite the above uncertainties, it appears that the following general conclusions can be drawn from the original references, the data in Table 1 and the comparisons in Table 2: (*1*) For the noncyclic alkanes the trends relative to CH_4 are essentially the same for both Mu* and T* reactions; in particular, both reactions exhibit an essentially constant yield beyond ethane. (*2*) Both Mu* and T* reactions exhibit pressure-dependent yields in many of the hydrocarbons, notably in the case of c-pentane, c-hexane, hexane (and TMS) in the case of Mu* (see also ref. 30) and in ethane (25), c-butane (23, 45), and ethyl fluoride (44) in T* chemistry. (*3*) In all cases, the absolute Mu* (f_D) yields are smaller than the corresponding yields for T* (*P*) reactions. In the case of the noncyclic alkanes in particular, the Mu* yields are lower on average than the corresponding T* yields by a factor of about 3.5.

We conclude then that Mu* and T* reactions behave rather similarly in the *gas phase*, although this situation is in contrast to that seen in the *liquid* phase. As noted, in hot tritium chemistry, the yields seen in liquids are usually the same as those found from high pressure (~3 atm) values in the corresponding gas phase studies (22–24), whereas in Mu chemistry, diamagnetic fractions seen in liquids are typically 3–5 times larger than in the gas phase (15). As we have remarked in earlier publications (29, 30), this dramatic difference is strongly supportive of the contention that radiation-induced "spur effects" dominate the determination of observed muon fractions in condensed media (15). However, it should be kept in mind tha many-body effects can also play an important role; indeed significant changes are known to occur in charge changing cros sections between the gas and condensed phases (51), effect which may be related to the loss of neutral atoms referred t above in the case of proton charge exchange in the larger alkane (50).

[a] α_M refers to the different (pure) moderators M in the table, for either T* or Mu*.
[b] Calculated from the rigid sphere approximation, eq. [3] in text.
[c] Calculated at 10 eV from intermolecular potentials using procedure of Estrup (52) and Belyaev *et al.* (53) as described in text.

4.2 *Reactivity integrals for Mu* and T* reactions in the alkanes*

In the WE theory of hot atom reactions the reactivity integral *I*, and the collisional energy loss parameter, α, are related to th measured hot atom yield by eq. [5]. For the comparison to b made here of Mu* and T* reactivity in *pure* alkanes, $f = 1$ (w also refer to these single component alkanes as "moderators") The experimental values for the reaction probabilities (yields are found in Table 2 for both T*(*P*) and Mu*(f_D) reactions. W now interpret these yields, for the noncyclic alkanes, in terms o the WE formalism.

Because the reaction yield in this formalism is given in term of the *ratio* I/α, some functional form of α must be assumed i order to arrive at a value for *I*, which is the more fundamenta quantity since it contains the reaction cross section of interes (eq. [6]). A common choice over the years has been to assum the rigid sphere values, α_{rs} (eq. [3]), for the energy los parameter. These values are given in Table 3 for both Mu* an T* colliding with the alkane moderators of Table 2; for refer ence, the corresponding values for Ne and Ar moderators ar also given. Table 3 also presents the value of α calculated fro "soft-sphere" intermolecular potentials (α_{ss}) at 10 eV from th calculations of Estrup (52) and Belyaev *et al.* (53) for moderator M = Ne, Ar, $H_2(D_2)$, and CH_4. For the other alkanes, the sam functional form as that used for CH_4 in ref. 52 is assumed. In th calculation of α (Table 3), the ss values depend on energy wit the rs (energy independent) limit being obtained at the lowes energies. However, at $\gtrsim$1 eV, the energy dependence in α_{ss} i relatively weak (52, 53), suggesting that photochemical an recoil T* studies and the present Mu* studies can be compare on the same basis.

From the α_M values (i.e., for moderator "M") given in Tabl 3, it is clear that considerable differences between different RH moderators should be expected. However, as previously referre to, this is decidedly not the case in hot tritium chemistry, where for example, beyond CH_4, the ratio α_M/α_{Ar} for M = C_2H_6 C_3H_8, and C_4H_{10} is essentially constant in both the ~1-e

TABLE 4. Calculated Mu* reactivity integrals in alkanes from the Wolfgang–Estrup formalism

[d]Calculated reactivity integrals for Mu* from eq. [5] using the α_M values from column 4 and the experimental yields of Table 2. Estimated errors are ±30%.
[e]Ratio of reactivity integrals for T* (column 2)/Mu* (column 5).
[f]Extrapolated from trends in the lower mass alkanes.

photochemical T* study of ref. 7 and in the recoil T* study of ref. 21. This large discrepancy between the experimentally determined values for α_M and those expected from elastic scattering models are strongly supportive of the earlier suggestion that *inelastic* cross sections play a dominant role in determining the energy loss process in T* chemistry and, by extension, in Mu* chemistry as well.

Indeed, if one assumes pure elastic scattering, then $\alpha(Mu^*)/\alpha(T^*) \simeq m_{Mu}/m_T$ for both rigid sphere and soft sphere moderation, which means that the factor of 3.5 in the ratio of T*/Mu* yields in the pure alkanes of Table 2 would translate into a factor of $\gtrsim$100 enhancement in the reactivity integrals $I(T^*)/I(Mu^*)$. This does not seem reasonable. Not only do we expect T* and Mu* to undergo appreciable hot atom reactivity in the same energy region ($\lesssim$20 eV), but extrapolation of isotope effects on reactive cross sections in the eV range from classical trajectory studies on a variety of molecules (12, 16, 17) indicates that a ratio $I(T^*)/I(Mu^*) \lesssim 10$ should be expected. In the absence of any detailed dynamical studies of hot atom Mu reactivity, we propose here to use the WE model to empirically determine $\alpha_M(T^*)$ in each *pure* alkane M from the experimental hot tritium yields (Table 2) and the published reactivity integrals $I(T^*)$ determined in different inert moderators. These $\alpha_M(T^*)$ values are then used to calculate $\alpha_M(Mu^*)$ for each M, recognizing the importance of inelastic contributions. Since the largest elastic contribution comes from the rigid sphere value, we adopt the definition

[11] $$\alpha = \alpha_{rs} + \alpha_{inel}$$

and determine α_{inel} from the T* data.

In general, $I(T^*)$ is obtained from kinetic plots of reaction yields vs. moderator mole fraction (eq. [7]) and thus its value depends on the choice of moderator. The most complete data have been obtained for CH_4, C_2H_6, C_3H_8, and C_4H_{10} (21) in different noble gas moderators, from which the extracted reactivity integrals for each alkane are found to differ by $\approx \pm 30\%$, on average. This can be taken as a measure of error in the procedure to extract $I(Mu^*)$ in comparison with the $I(T^*)$ values for each alkane. For the purposes of comparison, though, we adopt the value of $I(T^*)$ determined in a Neon moderator from ref. 21 since, as previously noted, the moderating efficiency of Ne is comparable to that of the CH_3 group in each alkane (26, 35, 43). The values for $I(T^*)$ are given in Table 4; those for pentane and hexane have not been reported, to our knowledge, so the values given are extrapolated from the lower mass alkanes. Using these values and those for the pure alkane yields from Table 2 in eq. [5] gives the results shown in the 3rd column of Table 4 for $\alpha_M(T^*)$. As expected, these show little variation with mass compared to the rigid sphere values (7, 9, 26, 35) and, moreover, exhibit the opposite trend; the value for CH_4 is also consistent with that determined by Seewald and Wolfgang in unmoderated methane (21). Correcting for $\alpha_{rs}(T^*)$ using the values in Table 3 in eq. [11] yields the corresponding values for $\alpha_{inel}(T^*)$.

A question now of considerable importance is: how different is α_{inel} likely to be for Mu* and T* slowing down in the alkane moderators? In general, one expects nonresonant vibrational relaxation of at least small molecules to be enhanced by light atoms (Mu), but relaxation of rotational levels to be enhanced for heavier atoms (T) (54); on the other hand, vibrational excitation due to strongly attractive potentials is expected to depend directly on the mass (1, 55). In addition, the transfer of incident translational energy to translational–rotational energy in the exit channel can depend both on the incident energy and the target molecule (10). We will simply assume here that α_{inel} is the *same* for both Mu* and T*, averaged over their respective energy intervals. In practice, then, from eq. [11], $\alpha_M(Mu^*) = \alpha_{inel}(T^*)$ for the RH moderators of Table 4 since $\alpha_{rs}(Mu^*)$ is too small (Table 3) in every case. The values for $\alpha_M(Mu^*)$ determined in this way for each of the alkane moderators M are given in column 4 of Table 4. These values are then used in conjunction with the experimental Mu* yields (Table 2) to find the corresponding reactivity integrals $I(Mu^*)$ from eq. [5], as given in column 5.

The reactivity integrals determined in this way for Mu* reactions mirror the trend seen to increasing reactivity with increasing numbers of C—H bonds in the corresponding $I(T^*)$ values, both exhibiting the saturation apparent in the yields themselves beyond ethane. It is apparent that beyond ethane (or even methane) the excitation functions for T*(Mu*) reactions in the alkanes do not display any pronounced intrinsic dependence on structure and (or) on the number of carbon atoms, consistent with model calculations (35, 46, 56) of hot tritium reactivity.

The last column in Table 4 gives the ratio of $I(T^*)/I(Mu^*)$, the overall average of which is ~6:1. If the reactive cross sections are assumed constant over a common energy interval, then $\sigma(T^*)$ would be larger than $\sigma(Mu^*)$ by this same factor (eq. [6], ref. 37). It should be kept in mind, however, that the data

have been viewed within the framework of the WE theory, a formalism that is constantly being called into question (37, 43). In addition, several simplifying assumptions have been made, the most suspect of which is likely the assumption that the dominant *inelastic* contributions to the slowing-down processes are the same for both hot muonium and hot tritium. The calculated ratios are certainly sensitive to this assumption, as can be seen by arbitrarily weighting the inelastic (or elastic) contribution differently for Mu* and T* moderation. For example, if we define $\alpha_{inel}(Mu^*) = 2\alpha_{inel}(T^*)$, then the ratio $I(T^*)/I(Mu^*)$ is simply reduced by approximately this same factor; conversely, if the opposite weighting is assumed, the ratio is correspondingly increased by a factor of two. Differences of a factor of five or so in the number of collisions required to moderate Mu* vs. T* atoms are probably reasonable. Clearly one cannot state with any confidence what the absolute reactivity integrals (or cross sections) are for hot muonium (or hot tritium) reactivity in the absence of more detailed theoretical guidance.

The present comparison of Mu* and T* reactivity in the alkanes represents, in fact, the first time that there has been a wide enough variation in isotopic mass to "test", in principle, dynamical models of hot atom reactivity. Unfortunately, the record to date on the success of direct theoretical calculations of $I(T^*)$ from specific excitation functions generated on a particular potential energy surface, in comparison with hot tritium results, is poor (18, 43). In Raff's calculation on methane (18), for example, the theoretical value for $I(T^*)$ is about a factor of 10 too low, although the ratio of HT/RT yields is well predicted. In general, this lack of success likely reflects a combination of poorly known potential surfaces at high energies and errors in the calculation of the collisional density $n(E)dE$, rather than in the dynamics themselves, which can presumably be accurately treated classically. It may be, moreover, that inaccuracies in the nature of the potential surface for a given reaction would cancel in the *ratio* of $I(T^*)/I(Mu^*)$, thus allowing a theoretical calculation of the corresponding collisional density and hence the reaction cross section. No calculation of this nature has yet been reported.

The only calculation to date of an excitation function comparing Mu* and T* over a wide enough energy range is the current work of Connor *et al.* on the $Mu^*(T^*) + F_2$ reaction (12), in which the same potential surface that was successfully utilized in calculations of *thermal* reaction rates (13) is employed. Although this surface is likely quite incorrect at high energies for the HF_2 system, and, moreover, cannot be expected to mirror the alkane systems of Table 4, it is interesting to note that an evaluation of eq. [6] with their excitation function gives ~2.5 for the ratio $I(T^*)/I(Mu^*)$, suggesting that the slowing down processes for Mu* are more efficient than for T*. It is hoped that the present results comparing hot Mu chemistry with hot tritium chemistry in the alkanes will stimulate further theoretical calculations.

5. Summary

In this paper we have compared the hot atom reactions of muonium (Mu*) on the alkane vapors, C_nH_{2n+2} (n = 1–6), with those determined elsewhere (7–9, 21–27) for hot tritium (T*) reactivity on these same alkanes. The corresponding experimental yields (Table 2) are found to be in the ratio $T^*(P)/Mu^*(f_D) \sim 3.5{:}1$, essentially independent of n; moreover, within experimental error (~±30%), they exhibit the same trend with increasing n, both showing a saturation effect in total yield beyond ethane. This kind of similarity and consistency in hot muonium and hot tritium yields in alkane vapors strongly supports our contention that the same reactions (eq. [10]), over comparable energy intervals are being seen by both Mu* and T*, and the factor of ~3.5 difference in their yields is a manifestation of dynamical mass effects on hot atom reactivity. Although it may seem surprising that the marked difference of a factor of 27 in isotopic mass between muonium and tritium should be reflected in only a factor of ~3.5 in total yields (indeed, differences in *thermal* rate constants between H and Mu are frequently much greater than this (11–15)), it must be remembered that the hot atom yield reflects a competition between moderating collisions, which are primarily nonreactive, and reactive (hot atom) collisions, during the slowing down process.

The measured yields of both Mu* and T* reactions in the alkanes have been interpreted within the framework of the Wolfgang–Estrup (WE) theory (3–5), in which the hot atom yield (P) of eq. [5] is defined in terms of two quantities: the reactivity integral "I" (eq. [6]) and the energy-loss parameter "α" (f = 1 in the present study of pure alkane moderators). Despite the continuing questions about the validity of this formalism (37, 43) recently brought into focus by current theories in which the explicit time dependence of the rate equations for the slowing down process is considered (37–39), the WE theory still remains the only easily tractable procedure for the interpretation of experimental hot atom yields, a role it has played for over 20 years now. In our analysis, we have observed that α is dominated by inelastic scattering effects, and moreover we have assumed that $\alpha_{inel}(Mu^*) = \alpha_{inel}(T^*)$, the latter determined from experimental hot tritium yields (eq. [11] and Table 4). With this assumption, the ratio of reactivity integrals $I(T^*)/I(Mu^*)$ is ~6:1 for the alkanes, from methane to n-hexane (Table 4). As emphasized in the text, the WE formalism makes no a priori prediction of either I (or equivalently, the excitation function, $\sigma(E)$) or of α, both being essentially model-dependent parameters in the theory; indeed, if we assume that inelastic moderation is more (or less) efficient for Mu* compared to T* (e.g., by a factor of 2), then the ratio $I(T^*)/I(Mu^*)$ changes accordingly.

Nevertheless, despite the uncertainties inherent in the WE formalism used and hence in our analyses of the T* and Mu* data carried out, the present study of these reactions represents the *first* time that the hot atom yields of two isotopes of such enormously differing masses have been carried out on the same (alkane) systems. It is hoped that the results will stimulate more detailed calculations of dynamical mass effects for hot atom reactivity, on the alkanes or on related systems (16–18). Some progress along these lines is currently underway (12).

Acknowledgements

One of us (D.G.F.) would like to thank Dr. Ian W. M. Smith and the Physical Chemistry Laboratory at Cambridge University for their hospitality during a three-month stay in 1984. D.G.F. would also like to thank the John Simon Guggenheim Foundation and the Scientific Council of NATO for their financial support during a sabbatical year abroad. The continuing research support of NSERC (Canada) is also gratefully acknowledged. Finally, we would like to thank Professors B. Shizgal, University of British Columbia, E. Mason, Brown University, and B. Rabinovitch, University of Washington, for their helpful comments concerning the theory of hot atom reactivity.

Received June 25, 1985

PARMINDER S. SURDHAR, DAVID A. ARMSTRONG, and VINCENT MASSEY. Can. J. Chem. **64**, 67 (1986).

The one- and two-electron reductions of 2-thioriboflavin with $\cdot CO_2^-$ and cyclic disulphide anion of dithiothreitol ($DS_2^-\cdot$) have been studied by the steady state γ and pulse radiolysis techniques. The $\cdot CO_2^-$ radical reacted with 2-thioriboflavin to give the neutral semiquinone ($\cdot$FlH) and the radical anion ($\cdot Fl^-$) at pH 5 and 10 respectively. The pK of the $\cdot$FlH radical was determined to be 7.4. In the case of the anion, the 2-thioriboflavin spectrum is similar in shape to that of FAD radical anion, but red shifted by 40–50 nm. Red shifts are also seen in the neutral $\cdot$FlH form for the 370-nm peak and 580-nm shoulder. However, in addition, there is strong enhancement of the absorbance at 500 nm. The spectrum of 2-thioriboflavin semiquinone produced in the presence of 2–5 mM dithiothreitol was perturbed, as was observed previously for unsubstituted flavin semiquinones in the presence of sulphydryls. The rate constants for the initial one-electron reduction step viz: [5] $Fl + \cdot CO_2^- \rightarrow \cdot Fl^- + CO_2$ were $4.0 \pm 0.5 \times 10^9\ M^{-1}\ s^{-1}$ and $1.3 \pm 0.2 \times 10^9\ M^{-1}\ s^{-1}$ at pH 7 and 10 respectively. The corresponding rate for the reaction of $DS_2^-\cdot$ with 2-thioriboflavin at pH 7 was determined to be $2.4 \pm 0.2 \times 10^9\ M^{-1}\ s^{-1}$. The continuous production of $DS_2^-\cdot$ radicals by γ radiolysis reduced 2-thioriboflavin to the dihydro form, and the flavin was regenerated on the addition of air. The $\cdot CO_2^-$ radical also effected a two-electron reduction. However, in this case, if the process was taken beyond the equivalence point, the dihydroflavin spectrum was bleached and the oxidized flavin could not be recovered.

PARMINDER S. SURDHAR, DAVID A. ARMSTRONG et VINCENT MASSEY. Can. J. Chem. **64**, 67 (1986).

Faisant appel aux techniques de la radiolyse γ de l'état stationnaire et de la radiolyse pulsée, on a étudié les réductions à 1 et à 2 électrons de la thio-2 riboflavine avec le $\cdot CO_2^-$ et l'anion cyclique disulfuré du dithiothréitol ($DS_2^-\cdot$). Le radical $\cdot CO_2^-$ réagit avec la thio-2 riboflavine pour donner la semiquinone neutre ($\cdot$FlH) et l'anion radicalaire ($\cdot Fl^-$) à des pH respectifs de 5 et de 10. Le pK du radical $\cdot$FlH est égal à 7,4. Dans le cas de l'anion, la forme du spectre de la thio-2 riboflavine est semblable à celle de l'anion radicalaire du FAD mais les bandes sont déplacées vers le rouge par environ 40–50 nm. Dans le cas de la forme neutre du $\cdot$FlH, on observe également un déplacement vers le rouge du pic à 370 et de l'épaulement à 580 nm. Mais, il y a de plus une forte augmentation de l'absorption à 500 nm. Le spectre de la semiquinone de la thio-2 riboflavine produite en présence de 2–5 mM dithiothréitol est perturbé par rapport à ce qui a été observé précédemment dans le cas des semiquinones de la flavine non substituée en présence de sulphydryles. Les constantes de vitesse de l'étape initiale de la réduction à l'électron [5] $Fl + \cdot CO_2^- \rightarrow \cdot Fl^- + CO_2$ sont respectivement de $4,0 \pm 0,5 \times 10^9\ M^{-1}\ s^{-1}$ et de $1,3 \pm 0,2 \times 10^9\ M^{-1}\ s^{-1}$ à des pH respectifs de 7 et de 10. La vitesse correspondante de la réaction $DS_2^-\cdot$ avec la thio-2 riboflavine à un pH de 7 est de $2,4 \pm 0,2 \times 10^9\ M^{-1}\ s^{-1}$. La production continue de radicaux $DS_2^-\cdot$ par radiolyse γ réduit la thio-2 riboflavine en la forme dihydro et l'addition d'air permet de regénérer la flavine. Le radical $\cdot CO_2^-$ permet également une réduction à 2 électrons. Mais dans ce cas, si on considère la réaction en déça du point d'équivalence, la coloration du spectre de la dihydroflavine disparaît et il n'est pas possible de récupérer la flavine oxydée.

[Traduit par le journal]

Introduction

Chemically modified flavins (Fl)[1] have been used successfully in recent years as probes of reaction mechanisms and of the protein environment around the bound flavin in a number of flavoproteins (1–4). In most cases the modified flavins have quite different absorption spectra, pKs, and redox potentials from their normal counterparts FAD or FMN. This also applies to the one-electron reduced semiquinone forms: $\cdot FlH/\cdot Fl^-$. Studies of the spectra of these semiquinone forms in the protein is an additional source of information on the immediate environment of the flavin and on the interactions with protein residues that may serve to stabilize it. For these reasons it is important to have as a reference the spectrum of the uncomplexed semiquinone forms of the modified flavins in aqueous solution.

This investigation is concerned with the formation and spectra of the semiquinone forms of 2-thioriboflavin, which has found use in several recent studies (1, 4). The experiments were performed by the pulse radiolysis technique (5), which was also utilized in earlier examinations of flavin semiquinones (6–9). The reducing radicals $\cdot CO_2^-$ and $DS_2^-\cdot$ (the radical of dithiothreitol, see reaction [4] below and footnote 1), were produced by the well-established sequence of reactions (5, 10):

[1] $4.2H_2O \rightsquigarrow 2.7e_{aq}^- + 0.6\cdot H + 2.8\cdot OH + 2.7H^+ + 0.5H_2 + 0.7H_2O_2$

[2] $e_{aq}^- + N_2O + H_2O \rightarrow OH^- + \cdot OH + N_2$

[3] $\cdot OH\ (\text{or}\ \cdot H) + HCO_2^- \rightarrow H_2O\ (\text{or}\ H_2) + \cdot CO_2^-$

[4] $\cdot OH\ (\text{or}\ \cdot H) + D(SH)_2 \rightarrow DS_2^-\cdot + H_2O\ (\text{or}\ H_2) + H^+$

Suitable concentrations of $D(SH)_2$ and formate were chosen so that the time scale of reactions [1]–[4] was much shorter ($\leqq 10^{-7}$ s) than that for the reaction of Fl with primary radicals e_{aq}^-, $\cdot H$, and $\cdot OH$. The Secondary radicals, $\cdot CO_2^-$ and $DS_2^-\cdot$,

[1]Abbreviations: Fl, flavin; $\cdot$FlH, flavin semiquinone; $\cdot Fl^-$, flavin semiquinone anion; FlH_2, dihydroflavin; FlH^-, dihydroflavin anion; LFl, lumiflavin; FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; $D(SH)_2$, reduced dithiothreitol; DS_2, oxidized dithiothreitol; $DS_2^-\cdot$, radical anion of dithiothreitol.

reacted with Fl on a ~10-μs time scale:

[5] $Fl + \cdot CO_2^- \rightarrow \cdot Fl^- + CO_2$

[6]/[−6] $\cdot FlH \rightleftarrows \cdot Fl^- + H^+$

[7] $Fl + DS_2^- \cdot \rightarrow \cdot Fl^- + DS_2$

Low dose rate "steady state" radiolysis experiments were also conducted with a Co^{60} γ source to establish that the final product formed by these reductions was the dihydroflavin FlH_2 (11).

Experimental

Materials

Dithiothreitol was from the Sigma Chemical Co. All other chemicals were the purest available grade and were used as supplied. The water for preparing solutions was redistilled, first from alkaline permanganate and then from acid dichromate (10).

Apparatus and procedures

All experiments were conducted at room temperature (24 ± 2°C) with solutions containing 10 m*M* phosphate buffer. In order to prevent its oxidation by air, solutions requiring dithiothreitol $D(SH)_2$ were prebubbled with nitrous oxide, which had been passed through a column of Ridox (Fisher Scientific Co.). The pH was finally adjusted by adding $HClO_4$ or NaOH.

The γ irradiations were performed in an A.E.C.L. ^{60}Co "gamma cell" with a steady dose rate of ~10 Gy/min. The precise dose rate was checked with a Fricke dosimeter (10) and corrections were made routinely for the natural decay of the isotope. The procedures were as described by Ahmad and Armstrong (11).

The pulse radiolysis experiments were performed by utilizing 2-μs pulses of electrons with a dose of 2–4 Gy/pulse from the 1.5-MeV Van de Graaff generator. Details of the generator and dosimetry have been described earlier (12).

Values of ΔA, the change in absorption per unit dose observed at a given time after the radiation pulse, were converted to [ε(Fl Radical) − ε(Fl)] at each wavelength by dividing ΔA by the concentration of radicals produced per kilogray. Values of ε(Fl Radical) at different pHs were then obtained by adding the appropriate values of ε(Fl). The values of ε(Fl, 490 nm) were taken to be 21 000 and 19 100 at pH 7 and 10 respectively (1).

Results and discussion

Pulse radiolysis

The changes in absorption produced by the reaction of $\cdot CO_2^-$ with 10–14 μ*M* 2-thioriboflavin at pH 5 at 80 μs after the irradiation pulse are plotted as a function of wavelength in Fig. 1. A typical oscilloscope trace illustrating the loss of absorbance at 490 nm with time can be seen in the top inset. The absolute spectra of the radicals at pH 5 and 10 were calculated from the changes in absorbance as described above. They have been presented in Figs. 2(a) and (b) (solid lines). Each spectrum has been based on at least two sets of experimental points.

The main features of the spectrum at pH 5 were a minimum at 420 nm, maxima at 360 and 500 nm, and a broad shoulder at about 620 nm. The spectrum at pH 10 showed a much stronger peak at 400 nm and a maximum at 510 nm. Above 540 nm the absorption tailed off and the shoulder at 620 nm was absent. The inset in Fig. 2(a) shows the absorbance coefficient of the radical at 580 nm as a function of pH. The curve through the points has been calculated for a p*K* of 7.4. This p*K* is attributed to the ionization of the radical in reaction [6], and may be compared to the p*K* of the radical of riboflavin, which is 8.3 (6). The lower value observed for 2-thioriboflavin is in accord with a similar lowering of the p*K* of the fully reduced form to 5.2,[2] which can be compared with the value of 6.5 for riboflavin (14).

The spectra of the neutral form of lumiflavin semiquinone and

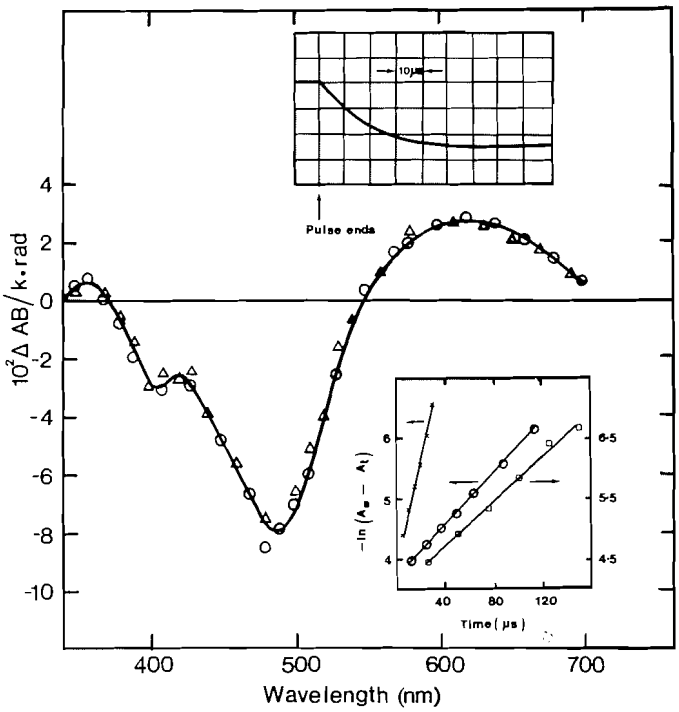

FIG. 1. Circles and triangles: change in absorbance (ΔAB) at pH 5 of 10–14 μ*M* 2-thioriboflavin in N_2O saturated 10 m*M* phosphate buffer containing 20 m*M* sodium formate. Dose 4 Gy/pulse. Top inset: oscilloscope trace illustrating the loss of absorbance with time at 490 nm. Bottom inset: plot of $-\ln(A_\infty - A_t)$ versus time for reaction of $\cdot CO_2^-$ with 15 μ*M* Fl (×), 7.7 μ*M* Fl (□) at pH 7, and 16.89 μ*M* Fl (○) at pH 10.

the FAD radical anion obtained under similar conditions (15, 16) are shown as dashed lines in Figs. 2(a) and (b). In the case of the anion the 2-thioriboflavin spectrum is similar in shape but red shifted by 40–50 nm. Red shifts are also seen in the neutral $\cdot FlH$ form for the 370-nm peak and 580-nm shoulder of lumiflavin. In addition there is strong enhancement of the absorbance at 500 nm.

The dash–dot lines in Figs. 2(a) and (b) are, respectively, the neutral semiquinone form of 2-thio-FMN flavodoxin and the anionic form of 2-thio-FMN lactate oxidase obtained by photoreduction (4). The anion spectrum in the flavoprotein is similar in shape to the free anion spectrum but the peaks are red shifted by 20–30 nm. In the flavodoxin, the 370-nm peak is similar in intensity and position. However, the 490-nm peak is drastically reduced and there is a much enhanced absorbance at 670 nm. These features must be attributed to interactions with amino acid residues in the flavin binding site.

The changes in absorbance during the period of reaction of Fl with $\cdot CO_2^-$ (top inset in Fig. 1) can be treated in terms of a pseudo first-order integrated rate equation. Plots of $\ln(A_\infty - A_t)$ versus time at two different flavin concentrations at pH 7 and a third plot at pH 10 have been presented in Fig. 1 (bottom inset). The pseudo first-order rate constants at pH 7 were plotted against [Fl] to obtain the value of k_5. This rate constant was $4.0 \pm 0.5 \times 10^9 M^{-1} s^{-1}$ in 20 m*M* formate and can be compared with $3.6 \pm 0.4 \times 10^9 M^{-1} s^{-1}$ for the corresponding reaction with riboflavin (6) and lumiflavin (15). As the pH increased above 8.5 the value of k_5 fell, reaching $1.3 \pm 0.2 \times 10^9 M^{-1} s^{-1}$ at pH 10. It may be noted that this corresponds to the pH region for ionization of thioriboflavin (p*K* = 9.8, Claiborne *et al.* (1)). Thus above pH 10 the dominant form of thioriboflavin, $Fl(-H)^-$, bears a negative charge, which would reduce the rate of reaction with $\cdot CO_2^-$. A similar reduction in

[2]Al. Claiborne and V. Massey, unpublished data.

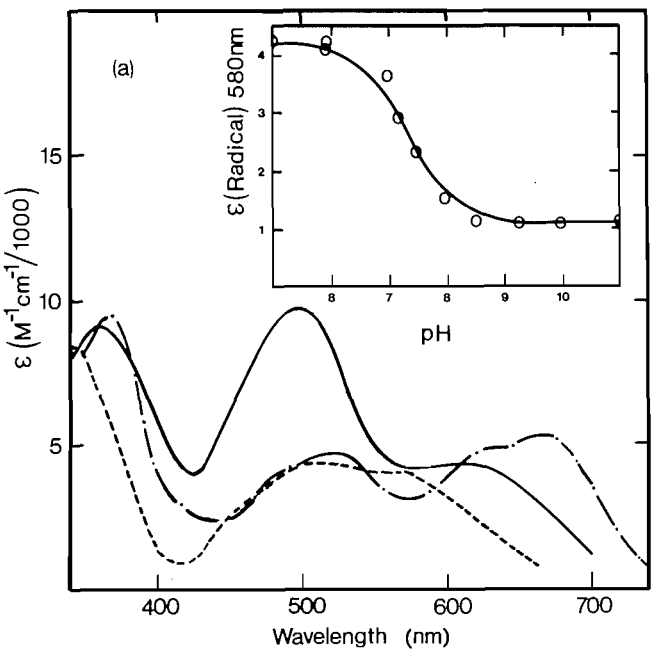

FIG. 2(a). Absorption spectra, at pH 5, of the neutral semiquinone produced from 10–14 μ*M* 2-thioriboflavin in N_2O-saturated 20 m*M* formate solutions by $\cdot CO_2$ (—). Absorption spectra, at pH 7, of lumiflavin radical produced under similar conditions (---). Absorption spectra of 2-thio-FMN flavodoxin radical produced by photoirradiation in 0.1 *M* potassium phosphate, pH 7.0, containing 30 m*M* EDTA and 1 μ*M* 5-deazaflavin (-·-). Inset: plot of ε(Radical) at 580 nm versus pH.

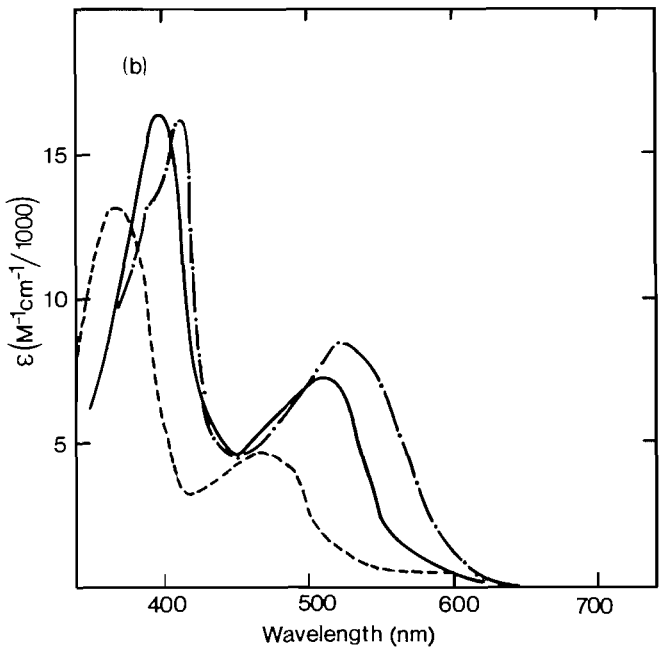

FIG. 2(b). Absorption spectra, at pH 10, of the radical anion produced from 16–18 μ*M* 2-thioriboflavin (—) and 10–40 μ*M* FAD (---) in N_2O-saturated 20 m*M* formate solutions at pH 10 by $\cdot CO_2^-$. Absorption spectra of 2-thio-FMN lactate oxidase at pH 7 produced under anaerobic conditions in the presence of 0.1 *M* glycine, 6 μ*M* 5-deazaflavin, and 0.01 *M* imidazole (-·-). Ordinate scale for (-·-) is in arbitrary units.

rate has been observed with unsubstituted flavins (6, 16). It may be noted that step [6] is too fast to be seen in our buffered solutions (17).

A number of pulse experiments were also performed in

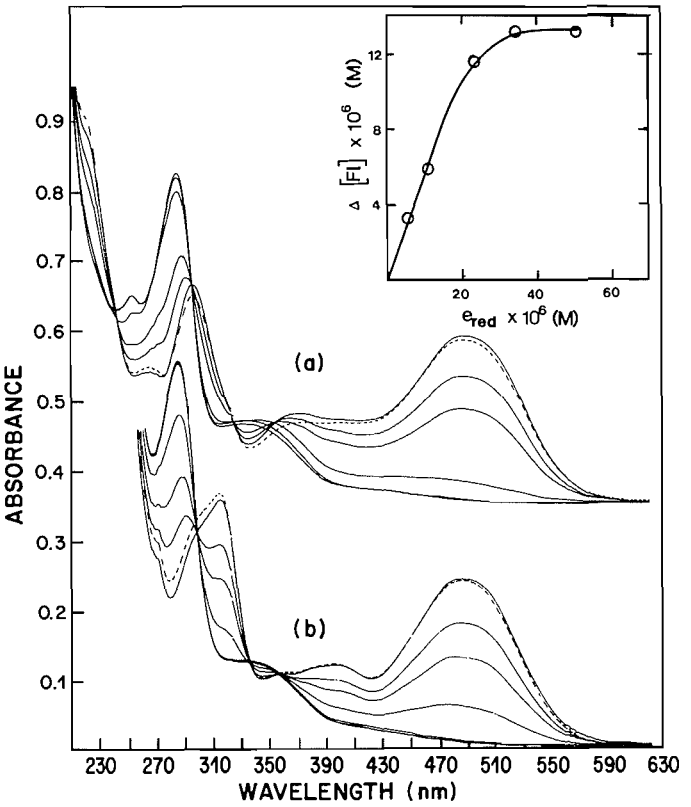

FIG. 3. (a) Spectra obtained from an N_2O-saturated solution of 13.43 μ*M* 2-thioriboflavin at pH 10 in 40 m*M* formate and 10 m*M* phosphate buffer before irradiation and after 1, 2, 4, 6, and 8 min of γ irradiation at 10 Gy min^{-1}. The absorbance scale has been displaced by 0.35 from zero for clarity. (b) Spectra obtained from an N_2O-saturated solution of 12.98 μ*M* 2-thioriboflavin at pH 9 in 2 m*M* dithiothreitol and 10 m*M* phosphate buffer before irradiation and after 1, 2, 4, 8, 12, and 15 min of γ irradiation at 10 Gy min^{-1}. The spectra after aeration of the irradiated solutions are shown by the dashed lines. Inset: change in [Fl], Δ[Fl], versus number of reducing equivalents of reducing species reacted for Fl + $\cdot CO_2^-$ at pH 10.

2–5 m*M* $D(SH)_2$ solutions at pH 7, using the $DS_2^- \cdot$ radical as the reducing species. As in the case of lumiflavin semiquinone, formed in sulphydryl-containing solutions (16, 18), the spectrum of the 2-thioriboflavin radical was somewhat perturbed, exhibiting increased absorption in the 400–500 nm region and lesser absorbance above 540 nm.

The slopes of pseudo first-order rate constants versus [Fl] for the reaction of $DS_2^- \cdot$ with 2-thioriboflavin at pH 7 gave $k_7 = 2.4 \pm 0.2 \times 10^9 M^{-1} s^{-1}$, which is a bit larger than $1.6 \pm 0.2 \times 10^9 M^{-1} s^{-1}$ for the corresponding reaction with lumiflavin (18).

Co^{60} γ-radiolysis

Spectral changes resulting from the reduction of 2-thioriboflavin with $\cdot CO_2^-$ and $DS_2^- \cdot$ radicals are shown in Figs. 3(a) and (b), respectively. In both cases the absorbance of Fl was suppressed by each successive dose of irradiation. For the $DS_2^- \cdot$ radicals there was no further change after 12 min of irradiation. Also, apart from the increase in absorbance below 310 nm due to the formation of DS_2 in reaction [7], the initial flavin absorption was completely restored on the addition of air. These observations are consistent with dihydroflavin as the only major product, formed via reactions [7], [6], and [8*a*–*c*] or [9].

[8*a*] $2FlH\cdot \rightarrow FlH_2 + Fl$

[8*b*] $\cdot Fl^- + FlH\cdot \rightarrow FlH^- + Fl$

[8c] $2\cdot FlH^- + H^+ \rightarrow FlH^- + Fl$

[9] $\cdot FlH + DS_2^-\cdot \rightarrow FlH^- + DS_2$

The flavin species present would vary with pH because of the ionizations of $\cdot FlH$ and FlH_2 (see above).

In the case of the $\cdot CO_2^-$ radicals, reference to the isobestic point at 354 in Fig. 3(a) and (b) shows that up to 2 min of radiation there was only one product formed. This is again attributed to dihydroflavin formation by the above reactions. Further treatment with $\cdot CO_2^-$ caused an apparent shift in the isobestic point and a continuing reduction in the absorption between 310 and 410 nm. On admission of air, the initial absorption of the flavin was completely restored only if the reduction was stopped at or before the equivalence point. If the reduction proceeded beyond this, the absorbance on reoxidation with air followed the pattern illustrated by the dashed line in Fig. 3(a). This type of behaviour has been seen in reactions of e_{aq}^-, and certain amine radicals with lumiflavin (15, 19). It is attributed to a further and irreversible reduction of FlH_2 by these species. It is interesting that in the case of 2-thioriboflavin it occurs with $\cdot CO_2^-$, which does not react with the dihydro forms of lumiflavin or FAD at this pH.

The spectra at the equivalence points for $\cdot CO_2^-$ reductions were taken to be those of 2-thiodihydroriboflavin. Values of $\epsilon(FlH_2)$ at 490 nm calculated from these agreed within ±2% for different flavin and formate concentrations at the pHs used. From these and the known value of ϵ(Fl) at 490 nm, the change in flavin concentration Δ[Fl] could be calculated. The inset in Fig. 3 is a plot of $\Delta[Fl] \times 10^6 M$ versus the equivalents of $\cdot CO_2^-$ radicals produced, $e_{red} \times 10^6 M$ (cf. Ahmad and Armstrong (15)). The values of η, the moles of reducing equivalents taken up per mole of flavin, were calculated from the initial slopes of such plots. As shown in Table 1, they lie in the range 1.8–2.2 with an average value of $1.9_3 \pm 0.1_1$, independent of $[HCO_2^-]$ and [Fl]. This indicates a two-electron reduction of the thioriboflavin in accord with eq. [10] at both pH 7 and 10.

[10] $2\cdot CO_2^- + Fl^- + 2H^+ \rightarrow FlH_2$ (or $FlH^- + H^+$)

Similar experiments were performed with $DS_2^-\cdot$ radicals from dithiothreitol except that in these cases a correction had to be made for the thermal reaction (13, 20):

[11] $D(SH)_2 + Fl \rightarrow DS_2 + FlH_2$ (or $FlH^- + H^+$)

At pH 10 the initial rate calculated from the slope of the absorbance versus time plot observed with an unirradiated 2 mM $D(SH)_2$ solution was $2.02 \times 10^{-7} M$ min^{-1}. Changes in flavin concentration calculated from this rate were subtracted from the initial changes observed in irradiated solutions to obtain the true change due to $DS_2^-\cdot$ radicals. A similar procedure was used at pH 9. However, below this pH the rate of the thermal reaction was negligible and no correction was necessary. The values of η for 10–20 μM Fl and 2 mM $D(SH)_2$ solutions were 2.24 ± 0.10, independent of pH in the range 5–10. This confirms the two-electron reduction of thioriboflavin by the $DS_2^-\cdot$ radicals.

TABLE 1. Summary of η for $\cdot CO_2^-$ radicals

[2-Thioriboflavin], μM	$[HCO_2^-]$, mM	pH	η
11.04	10	7	1.99
5.3	20	7	2.18
14.63	20	7	1.90
11.22	10	10	1.93
5.83	20	10	1.90
13.68	20	10	1.86
20.21	20	10	1.91
13.43	40	10	1.80

Summary

The present study has demonstrated that, as with unsubstituted flavins, the $\cdot CO_2^-$ and $DS_2^-\cdot$ anion radicals can effect the two-electron reduction of 2-thioriboflavin to the dihydroflavin. The rate constants for the initial one-electron step, reactions [5] and [7], are close to the "diffusion control limit" at pH 7 and are slightly reduced at pH 10 due to charge repulsion. These results are quite similar to those obtained with FAD, lumiflavin, and riboflavin. The spectrum of the radical anion of 2-thioriboflavin in free solution is similar to that of the normal flavin, but slightly red shifted. However, the spectrum of the neutral $\cdot FlH$ form is significantly different. This feature should certainly be taken into account in interpreting spectral data of the semiquinone spectrum in flavoproteins.

DANIEL COZAK, FRANÇOIS GAUVIN, and JACQUES DEMERS. Can. J. Chem. **64**, 71 (1986).

The paramagnetic ^1H nmr spectra for manganocene (**1**) and 1,1′-dimethylmanganocene (**2**), and the ^{13}C nmr spectra for 1,1′-diethylmanganocene (**3**) have been recorded in toluene solvent over a −90 to 90°C temperature range. **1** shows a low field and a high field ring proton resonance in its spectrum near −59°C. At higher temperatures the low field resonance is prevalent and becomes gradually averaged due to a fast spin exchange process that dominates the spectrum at 90°C. For the ring substituted derivatives **2** and **3**, resonances due to only one paramagnetic species were detected in the low temperature range. Above ambient temperature a new spectrum due to rapid spin exchange averaging is observed for these complexes. Results are readily interpreted in terms of ground state molecular cross-over exchanges between the $^2E_{2g}$, $^6A_{1g}$, and $^2A_{1g}$ spin states of the complexes.

DANIEL COZAK, FRANÇOIS GAUVIN et JACQUES DEMERS. Can. J. Chem. **64**, 71 (1986).

Nous avons enregistré les spectres de la rmn ^1H du manganocène (**1**), du diméthyl-1,1′ manganocène (**2**) ainsi que les spectres de résonance du ^{13}C pour le diéthyl-1,1′ manganocène à différentes températures entre −90 et 90°C. Le spectre du composé **1**, déterminé à −59°C, présente deux résonances paramagnétiques dues aux protons annulaires. La résonance se trouvant à champs faible domine les spectres déterminés à plus hautes températures. À 90°C, ce signal est dû à un spectre moyen causé par un échange rapide entre plusieurs états paramagnétiques de la molécule. Les spectres des composés **2** et **3**, déterminés à basse température, présentent un seul état paramagnétique. Aux températures supérieures à celles de la pièce, un nouveau spectre, dû aussi à un échange rapide entre plusieurs états paramagnétiques, remplace graduellement le premier. Les résultats expérimentaux sont interprétés en fonction de la dynamique des états électroniques fondamentaux $^2E_{2g}$, $^6A_{1g}$ et $^2A_{1g}$ connus pour ces molécules.

Introduction

Several paramagnetic transition metal compounds are known to exist in an equilibrium ground state between their low spin (ls) and high spin (hs) electronic configurations (1). However, the d^5 manganocene compounds are the only sandwich complexes known to have such an equilibrium (2). Also, magnetic susceptibility, epr (electron paramagnetic resonance), and photoelectronic studies have shown that both the electronic ls $a_{1g}^2 e_{2g}^3$ configuration, or $^2E_{2g}$ state, and the hs $a_{1g}^1 e_{2g}^2 e_{1g}^2$ configuration, or $^6A_{1g}$ state, are possible structures for the molecular ground states of $(\eta^5\text{-}C_5H_5)_2Mn$ (**1**) and its 1,1′-dimethyl substituted derivative $(\eta^5\text{-}C_5H_4CH_3)_2Mn$ (**2**) (3–5). Moreover, the electronic state associated with the other possible ls configuration, $e_{2g}^4 a_{1g}^1$, or $^2A_{1g}$ state, is generally considered too far above the ground state energy level to be significantly populated or involved in a multiple ground state cross-over exchange process (6). However, the $^2A_{1g}$ doublet state has been used to interpret the gas phase photoelectronic spectrum (7) of **1** and it has been suggested as a contributing factor to the larger isotropic paramagnetic nmr proton shifts (6) observed at room temperature for **2** compared to **1**. Thus, spectroscopic data point to the possible existence of these three ground states for manganocene compounds but direct spectroscopic detection and characterization of only the ls $^2E_{2g}$ and the hs $^6A_{1g}$ states have so far been reported (2, 6, 8).[3]

We wish to report here the paramagnetic ^1H nmr behavior for the unsubstituted manganocene complex **1** and its methylcyclopentadienyl derivative **2**, together with ^{13}C nmr data for the ethyl analogue, $(\eta^5\text{-}C_5H_4C_2H_5)_2Mn$ (**3**).

Experimental

Chemical reactions and manipulation of the compounds were carried out under a blanket of purified nitrogen in Schlenk-type vessels. Oxygen and water impurities from the nitrogen gas were controlled by passing the gas first over supported copper catalyst (BASF-R3-11) heated at 200°C, which was purchased from Badische Anilin and Soda-Fabrik AG, W. Germany, followed by 4A molecular sieve beds. The solvents used were refluxed for 1 h in a nitrogen atmosphere and passed over a drying agent before being distilled and stored.

Melting points were measured, in a nitrogen atmosphere, in sealed glass capillaries on a Thomas Hoover oil immersion type apparatus and are reported uncorrected. Mass spectra (ms) of the complexes studied were recorded on a Hewlett Packard 5995A mass spectrometer. Samples were placed in capillary glass tubes and introduced into the apparatus by means of a steel rod; they were then heated at a temperature rate of 64°C/min to 200°C under 10^{-6} Torr pressure (1 Torr = 133.3 Pa). Background subtracted spectra were regularly recorded for 15 min. A Varian EM 360A and a Bruker HX90 CW instrument were used to record the proton nuclear magnetic resonance (nmr) spectra of the diamagnetic compounds. The nmr spectra for the manganocenes were recorded on a Bruker WH-400 instrument from toluene-d_8 saturated solutions in 5-mm nmr tubes filled with nitrogen gas. For the liquid complex **3**, 1:10 (^1H) or 2:5 (^{13}C) (v/v) complex – toluene-d_8 mixtures were used to run the spectra. The temperature range from −90 to 90°C was covered in this study. The experimental chemical shifts were measured against the internal methyl carbon or proton resonance of the non-perdeuterated toluene solvent (<1%) and are reported in the text in δ units with positive values increasing downfield from TMS. Internal reference chemical shift values used: $\delta(C^1HD_2C_6D_5)$, 2.3 ppm and $\delta(^{13}CD_3C_6D_5)$, 21.3 ppm. Band widths at half-height, $H_{1/2}$, are given in parentheses following each chemical paramagnetic shift value in the text. Elemental C, H, and N analyses were done in duplicate by Schwarzkopf Microanalytical Laboratory, New York.

Anhydrous manganese bromide, $MnBr_2$, and sodium hydride, NaH,

[1]Taken in part from the M.Sc. Thesis of F.G., Laval University, Québec (Qué.), Canada, 1985.

[2]Author to whom correspondence may be addressed.

[3]Some controversy seems to exist on the necessity of involving the $^2A_{1g}$ ground state to explain the photoelectronic spectra of gaseous complex **1**, see refs. 4 and 7. Subsequently it was shown by epr that the ground states for **1** and **2** depend on the molecular environment. The epr spectroscopic data are available at low temperature. However, the main drawback of this spectroscopic method in the study of the dynamic spin process is the line broadening caused by rapid electron relaxation, which makes observation of the hyperfine structure impossible above −229°C; see refs. 2 and 8 for more details.

were purchased from Aldrich Chemical Co. Ethyl bromide was used as received from Fisher Scientific Co.

Synthesis

The sodium cyclopentadienides used in the preparations given here were prepared by deprotonating the corresponding dienes with sodium hydride (10).

Manganocene (1) and 1,1'-dimethylmanganocene (2)

Complexes **1** and **2** were prepared following the procedure described in the literature (11, 12). The following analytical data were obtained for the synthesized products. **1**: yield 46%; mp 167–169°C (lit. (11) mp 172–173°C). *Anal.* calcd. for $C_{10}H_{10}Mn$: C 64.88, H 5.45%; *Mol. Wt.*: 185.13 g; found: C 64.36, H 5.34%; *Mol. Wt.* (ms): 185. **2**: yield 57%; mp 60–62°C (lit. (12) mp 61–63°C). *Anal.* calcd. for $C_{12}H_{14}Mn$: C 67.61, H 6.62%; *Mol. Wt.*: 213.18 g; found: C 67.29, H 6.15%; *Mol. Wt.* (ms): 213.

1,1'-Diethylmanganocene (3)

First, ethylcyclopentadiene ligand was prepared in the following manner. Ethyl bromide, 32.9 g (302 mmol), diluted in an equal volume of tetrahydrofuran (THF) was added dropwise from a dropping funnel over a period of 1 hour to a 200-mL solution of sodium cyclopentadienide 1.50 *M* (300 mmol) in THF maintained at −10°C. The mixture was magnetically stirred for the next 15 h. The solution temperature was then raised to room temperature and the solution filtered on a glass frit to remove a white solid (NaBr). The filtrate was then extracted with 100 mL distilled water and the aqueous fraction further washed with 3 × 100 mL pentane. The THF and pentane fractions were then combined and dried over magnesium sulfate. The bulk of the pale yellow organic solution was then fraction distilled under normal pressure. Following the distillation of the pentane (35–36°C) and THF (66–67°C) fractions, a colorless liquid (11.4 g, 40%) passing at 53°C was collected by increasing the heating rate of the distillation. The expected mixture of structural isomers for the monomeric ethylcyclopentadiene gave the following proton chemical shifts and peak intensities: ^{1}H nmr ($CDCl_3$) δ: 1.14 (t, 9H), 2.38 (m, 6H), 2.90 (m, 4H), 6.23 (m, 6H) ppm. The product was then stored in a Schlenk tube over Dry Ice.

The sodium ethylcyclopentadienide salt was prepared by adding, dropwise, ethylcyclopentadiene, 13.4 g (142 mmol), to 3.50 g (146 mmol) sodium hydride in suspension in ca. 200 mL THF. The reaction mixture was left under magnetic agitation overnight, then filtered over a glass frit to remove any unreacted hydride. The reaction yield was determined by volumetric titration (0.471 *M*, 66%) of the organic sodium. This value was then used to determine the quantity of reactants used in the following step. Proton nmr spectra of the reaction product were recorded after evaporating the THF solvent under vacuum from an aliquot placed in an nmr tube, and replacing it by a deuterated solvent: ^{1}H nmr (toluene-d_8) δ: 1.02 (t, 3H), 2.33 (q, 2H), 5.38 (s, 4H) ppm.

In a typical experiment 11.30 g (52.6 mmol) manganese bromide was suspended in 10 mL THF in a 500-mL Schlenk flask and 200 mL sodium ethylcyclopentadienide (110 mmol) solution, 0.55 *M* in THF, was slowly added at 0°C while stirring. Once the addition was completed, the mixture was magnetically stirred at room temperature for 15 h. The insoluble NaBr formed during the reaction was removed from the solution by filtration and the solvent was pulled off on a vacuum line. This left an oily brown residue, which was washed with 3 × 200 mL hexane, leaving behind an insoluble solid. The hexane was then vacuum distilled until a thick red-brown oil (ca. 5 g) was left in the flask. The residue was then distilled under 13 Torr pressure. The middle distillate (107°C) gave 1.92 g (15%) of a highly air-sensitive red liquid corresponding to the pure product. *Anal.* calcd. for $C_{14}H_{18}Mn$: C 69.69, H 7.54, Mn 22.78%. *Mol. Results

Selected variable temperature proton nmr spectra showing the ring proton isotropic shifts for **1** over the full temperature range examined are shown in Fig. 1. These spectra can be regrouped in three temperature regions each having their spectral features. Starting at high temperatures (90°C), a single resonance at δ 27.9 ppm (800 Hz), due to the ring protons, is present at low field from the usual proton resonance region where π-bonded cyclopentadienyl rings are generally observed. This resonance showed two distinct temperature dependences. For the first, between 90 and 41°C, the ring protons moved upfield as the temperature was lowered. For the second, below 41°C, the same resonance shifted downfield, as predicted by the Curie Law, until the temperature reached −76°C. A third temperature region appeared at low temperatures, near −59°C, where a new resonance grew in at high field with concomitant decrease in intensity of the other low-field resonance, see Fig. 1. For example, at −59°C, the new signal is present at δ −25.8 ppm (1800 Hz) while the former is now at δ 28.3 ppm (4300 Hz). As the temperature is further lowered to −90°C the new signal moved upfield, following once more the Curie Law normally observed for the temperature-dependent isotropic shifts for most paramagnetic metallocene complexes (13, 14). The total shift variation observed is quite small for a given series of related spectra (ca. 2 ppm), considering the resonance band widths (probable error). Nevertheless, the spectra are quite reproducible and therefore the observed experimental errors fall well within the shift variations discussed or graphically represented below.

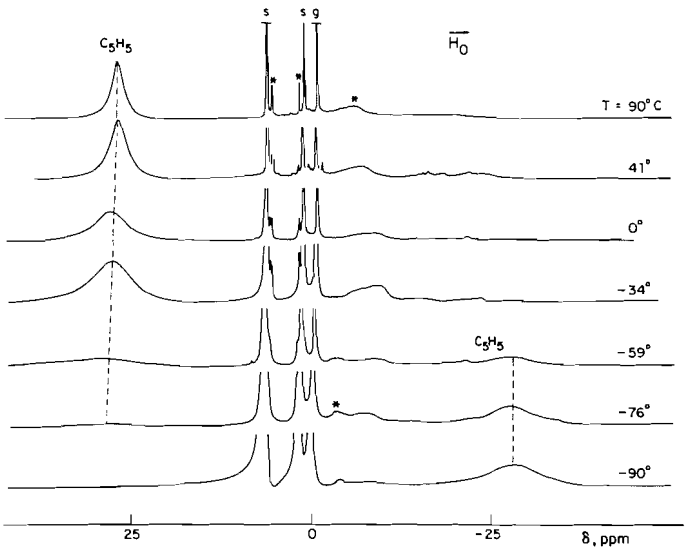

FIG. 1. Proton nmr spectra of **1** in toluene-d_8 at various temperatures. The C_5H_5 resonance at low temperatures is more evident at stronger recording amplitudes. The spectra *Y* scale is not constant in the figure: s, solvent; g, silicon grease; *, impurities.

The variable temperature proton nmr spectra for substituted complexes **2** and **3** were also recorded. In both cases two main temperature-dependent spectra were observed, one at high temperatures and the other at low temperatures. The high temperature limit spectrum, taken at 90°C, for the 1,1'-dimethyl substituted complex **2** is given in Fig. 2A and shows two broad resonances and a narrow signal at low field from the nmr region where the complexed diamagnetic ligand resonances are usually found. The low-field δ 131.8 (7700 Hz) and 78.3 ppm (3800 Hz) resonances observed at this temperature are assigned to the resolved ring protons and the δ 12.9 ppm (920 Hz) signal to the remaining methyl protons of **2**. At 41°C extensive line broadening in the spectrum made detection of paramagnetic nmr resonances impossible. Further lowering of the temperature yielded an exchange broadened spectrum discernible at 2°C and fully

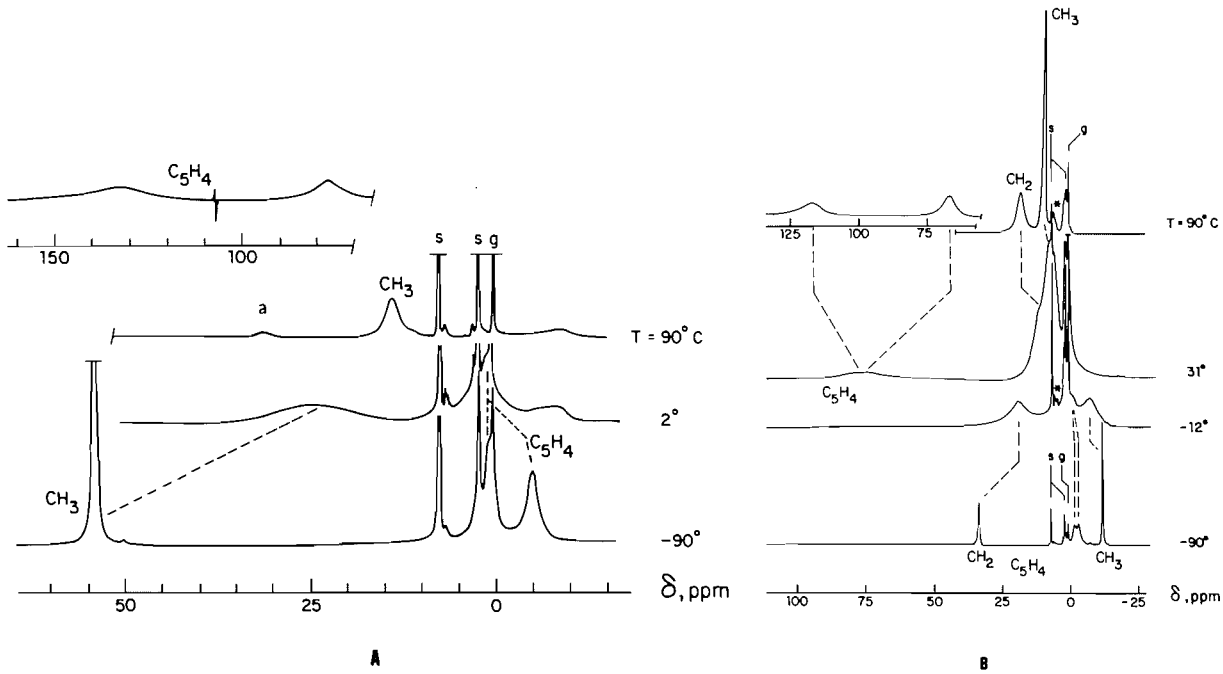

FIG. 2. Proton nmr spectra of **2** (A) and **3** (B) in toluene-d_8 at various temperatures. Only the "limit" spectra are shown: a, complex **1** as impurity; s, solvent; g, silicon grease; *, impurities.

grown-in at −90°C, as shown in Fig. 2A. The higher-field signals in the −90°C spectrum are assigned to the nonequivalent cyclopentadienyl protons δ 0.5 (540 Hz) and −4.5 ppm (650 Hz), and the low-field resonance at δ 50.6 ppm (270 Hz) is attributed to the methyl protons.

Similarly, the variable temperature proton nmr spectra for the 1,1′-diethyl substituted complex **3** are analogous to the dimethyl derivative discussed above and mutually confirm the chemical assignments made here for the resonances. The main temperature-dependent spectra are depicted in Fig. 2B. Hence at 90°C the spectrum showed two broad ring resonances present at δ 114.5 (3500 Hz) and 64.2 ppm (2300 Hz), together with two narrow signals at δ 18.5 (1200 Hz) and 10.3 ppm (340 Hz) assigned to the CH_2 and CH_3 protons, respectively. The isotropic chemical shifts observed did not follow the Curie Law. All four isotropic shifts moved upfield instead of downfield as the temperature was lowered from 90°C to approximately 31°C. Moreover, at 31°C the former two low-field ring resonances were fully collapsed into one signal at δ 77.8 ppm (8000 Hz) and the latter CH_2 and CH_3 signals were overlapping at δ 11.7 (ca. 2300 Hz) and 8.1 ppm (ca. 2000 Hz), respectively (see Fig. 2B). This spectrum gradually disappeared as the temperature was lowered and a new set of resonances was present at −12°C. This new spectrum evolved as the temperature was further lowered and was fully resolved at −90°C, with relatively narrow peaks at δ 33.6 (230 Hz) and −11.5 (110 Hz) ppm, due to CH_2 and CH_3 respectively, and a doublet resonance at δ −1.4 (570 Hz) and −2.8 ppm (570 Hz), due to nonequivalent ring protons.

Because of their poor solubility in toluene we were unable to record the corresponding ^{13}C nmr spectra for **1** and **2**. In THF-d_8 both ^1H and ^{13}C nmr results indicated a strong paramagnetic exchange interaction between the complexes and the solvent. Moreover, the proton spectra bear no resemblance to those taken in toluene. This result is not unexpected since THF and other Lewis bases are known to associate with manganocene to form addition compounds (15, 16). More details on this will be given elsewhere. However, **3** is miscible in toluene and its variable temperature ^{13}C nmr spectra were recorded. The spectra recorded above 44°C show non-Curie Law temperature-dependent isotropic carbon shifts as for the proton spectra. Though no other manganocene spectrum in toluene is available for comparison, we tentatively assign the two paramagnetic resonances in the spectrum, δ 471.1 ppm (480 Hz) and −126.0 ppm (210 Hz), to the ethyl CH_2 and CH_3 groups, respectively. The ring carbon resonance was not observed. At −9°C, no paramagnetic signals were detected in the spectrum due to line broadening caused by spin exchange. Below this temperature, near −43°C, a new spectrum appeared with a broad low-field peak at δ 271.8 ppm (650 Hz), followed by a doublet at δ 57.7 (270 Hz) and 43.7 ppm (220 Hz) located in the middle-field range, and at higher field a sharp signal was present at δ −104.0 ppm (220 Hz). At −28°C a single resonance at δ 52.4 ppm (480 Hz) is observed due to the collapsed middle-field signals, which are assigned to the nonequivalent ring carbons. The remaining low- and high-field resonances are due to the CH_2 and CH_3 carbons, respectively.

Figure 3 shows the dependence upon temperature of the observed proton chemical shifts (δ versus T^{-1}) for **1** and **3**. Once more, the plots represented in this graph underline the distinct magnetic behavior of these compounds. Hence at low temperatures ($T^{-1} \geq$ ca. 0.004 K^{-1}) the resonances have a linear Curie-type dependence on temperature and the extrapolation of this portion of the plots intercepts the ordinate axis within a reasonable value for the diamagnetic ligand chemical shifts. The other distinct region of these curves is at high temperature where the isotropic chemical shift variations do not obey the Curie Law. This is depicted in Fig. 3 by the departure from linearity in the curves, and increased paramagnetism is observed as the temperature increases ($T^{-1} <$ ca. 0.004 K^{-1}). A similar type of isotropic shift behavior has also been reported to be caused by metal-ring non-rigidity in cobaltocene derivatives (17). According to the Curie Law, the paramagnetic isotropic shift is inversely proportional to the temperature. Hence, at infinite temperature or $T^{-1} = 0\ K^{-1}$ the paramagnetic isotropic

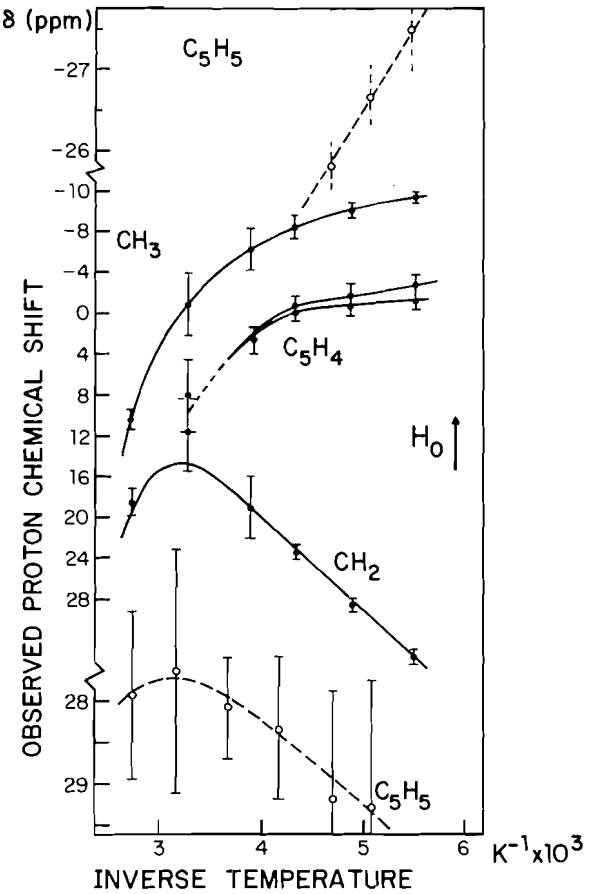

FIG. 3. The observed chemical shifts versus the inverse temperature plots for **1** (---○---) between −90 and 90°C and for **3** (—●—) between −90 and 30°C. The vertical bars on the curves are the probable errors for the observed chemical shifts, based on the band width at half-height, and are equal to $0.287 \times H_{1/2}$.

shifts should ideally be nil and the observed nmr chemical shifts would then be those of the diamagnetic ligand. In practice, extrapolation of the observed chemical shifts often falls in the δ 0–10 ppm region because of some error in the measured frequencies reported; $H_{1/2} = 10^2$–10^3 Hz.

The room temperature isotropic proton resonance for the solid complex **1** was first reported to be far upfield of the diamagnetic nmr region (−120 ppm from H_2O) (18). Our room temperature solution results coincide more closely with those of a subsequent communication where, in benzene solution, the ring protons for **1** are reported at δ 25.8 ppm and, for **2**, an unresolved doublet centered at δ 141 ppm is assigned to the ring protons with the methyl resonance reported to be at δ 81 ppm (117 and 70 ppm, respectively, in cyclohexane-d_{12}).[4] The differences in the shift positions quoted here and our results are due to the strong temperature and solvent dependence observed for the paramagnetism in these manganocenes.

Discussion

The low- and high-field proton resonances detected in the spectra of **1** can be interpreted as being due to two slow or non-exchanging molecular states of the manganocene molecule (exchange rate $< 10^3\ s^{-1}$). Slow exchange on the epr time scale between hs and ls configurations of **1** in host lattices has been observed previously (8). Departure of the chemical shifts from the Curie Law, evident in Fig. 3 by the inflection in the curve at high temperature ($T^{-1} < 0.004\ K^{-1}$), suggests that above ca. 40°C the resonances are time averaged by rapid spin exchange over two or more paramagnetic molecules, of which at least one has a strongly deshielding effect on the ring.

The nmr properties for **2** and **3** in toluene solution are better related to each other than with **1**. For the former complexes the resonances are at much lower fields at a given temperature (especially above room temperature) and there is a total absence of Curie Law behavior at elevated temperatures (low-field ring proton resonances). The linear relationship for the low temperature resonances (see Fig. 3 for **3**, for example) is indicative that spin exchange is not significant below ca. −46°C for the substituted manganocene complexes in solution. This contrasts with the two resonances observed for **1** in the same temperature range (see Fig. 3). Above this temperature there is, for both substituted complexes, an inflection in the curves towards low magnetic fields as the temperature is increased. Data for the high temperature region (30–90°C) are not shown on Fig. 3 for scaling reasons, i.e. $T^{-1} < 0.003\ K^{-1}$, but it can be seen that there is reversal of the slope below this point. Hence, the observed resonances for **2** and **3** can not be accounted for by the Curie Law in this temperature range and must be due to a rapid spin exchange similar to that mentioned for **1**.

The large low-field proton shift observed at 37°C for **2** relative to **1** has been interpreted by Switzer *et al.* as due to the presence of a rapid equilibrium involving a doublet $^2A_{1g}$ ground state (6). Moreover, variable temperature epr studies have shown that **1** and **2** have thermally populated $^2E_{2g}$ and $^6A_{1g}$ ground states exchanging in hydrocarbon solutions (2, 8). Based on the known electronic equilibria mentioned above, our variable temperature solution nmr results for the complexes studied can be interpreted in the following manner. For **1** at low temperatures in toluene, the ls $^2E_{2g}$ molecular ground state gives way to a hs $^6A_{1g}$ spin state as the temperature is raised. At higher temperatures a second spin exchange process is observed, presumably due to the rapid equilibrium between mainly $^6A_{1g}/^2A_{1g}$ spin states of the molecule. Similarly, at low temperatures, the substituted manganocenes show spectra for one main populated electronic state, which can be either the $^2E_{2g}$ or the $^6A_{1g}$ state, or possibly the time-averaged spectra of these rapidly exchanging states. At higher temperatures a rapid three-way $^2E_{2g}/^6A_{1g}/^2A_{1g}$ or a two-way $^6A_{1g}/^2A_{1g}$ spin exchange sets in, depending respectively on the preceding attribution.

R. J. WALTMAN and J. BARGON. Can. J. Chem. **64**, 76 (1986).

The electrochemical oxidation of aromatic heterocyclic compounds thiophene, pyrrole, and indole and benzenoid and nonbenzenoid polycyclic hydrocarbons azulene, fluorene, and pyrene yield electrically conducting polymers with conductivities of 10^{-5}–10 S/cm. The presence of substituents affects the electrical conductivity of these films and also their electroactive properties. Furthermore, substituents determine whether electropolymerization of these compounds can occur or whether soluble products are formed. The relative importance of these pathways is dependent on the stability of the intermediate radical cation. These effects are investigated by INDO molecular orbital calculations.

R. J. WALTMAN et J. BARGON. Can. J. Chem. **64**, 76 (1986).

L'oxydation électrochimique de composés hétérocycliques aromatiques comme le thiophène, le pyrrole et l'indole et des hydrocarbures polycycliques de type benzénique et nonbenzénique comme l'azulène, le fluorène et le pyrène donne des polymères conducteurs d'électricité avec des conductivités de 10^{-5} à 10 S/cm. La présence de substituants affecte la conductivité électrique de ces films ainsi que leur activité électrique. De plus, selon les substituants, on obtient soit une électropolymérisation de ces composés, soit la formation de produits solubles. L'importance relative de ces mécanismes dépend de la stabilité du cation radicalaire intermédiaire. On étudie ces effets à l'aide de calculs INDO d'orbitales moléculaires.

I. Introduction

The electrochemical oxidation of aromatic heterocyclic, benzenoid, or nonbenzenoid molecules frequently leads to the formation of an electrically conducting organic polymer film at the electrode surface (1–5). These films typically have good adhesion and electrical contact to the electrode surface. Thin films, when supported by an electrode surface, can be electrochemically cycled between the oxidized, conducting state, and the neutral, insulating state. Thicker films can be produced in the oxidized, conducting state and can be peeled off from the electrode surface to yield free-standing, electrically conducting films. Because these films are in the oxidized state, they represent polymeric cations, whereby their overall charge balance is achieved by the incorporation of counteranions which stem from the electrolyte of the "electroplating" solution.

According to this approach, conducting films have now been prepared from a wide variety of organic molecules. These include heterocyclic compounds such as pyrrole (1), thiophene (2), furan (3), indole (4), thianaphthene (4), and carbazole (5). Conducting polymeric films have also been prepared from polycyclic benzenoid and nonbenzenoid hydrocarbons such as azulene (5), fluorene (6), fluoranthene (6), triphenylene (6), and pyrene (6). Thus, the set of organic molecules which undergo electrochemical stoichiometry of the film-forming reactions; (*b*) opportunity to investigate the generality of the electropolymerization reaction. This can be achieved by studying: (*a*) the electrochemical stoichiometry of the film-forming reactions; (*b*) the parameters which determine the aptitude of a molecule to electropolymerize; and (*c*) how the aptitude for electropolymerization, i.e., reactivity, responds to the presence of substituents. The substituent effects can be further categorized into: (*i*) *electronic* effects, i.e., by its effect on the distribution of electrons at the reactive site; and (*ii*) *steric* effects, i.e., by its effect due to crowding at or near the reactive site. These considerations should provide a qualitative picture of the electropolymerization reaction.

Additional parameters, such as the properties of the resulting polymer films, are important in that the eventual technological application of these polymer films will require some versatility of their properties. This will most likely include the ability to vary the electrical conductivity of the films and the ability to improve the mechanical properties thereof. These goals can be met by chemical modification of: (*a*) the polymer film; (*b*) the electroplating solution; and (*c*) the structure of the starting molecule. This latter category falls into the domain of substituent effects and will be considered in some detail below. With respect to chemical modification of the polymer film itself (7) or of the electroplating solution (8), these topics have been the subject of recent reviews (7, 8). Recently also, the electrochemical preparation of conductive composites (such as from polyvinylchloride and polypyrrole) have provided polymer composite films which have the advantageous mechanical properties of the host polymer, yet retain the high electrical conductivity of the conductive polymer (9). In this report, we will describe the effect of substituents on the electropolymerization reaction and how substituents affect polymer film properties, i.e., their electrical conductivity. These aspects will be considered utilizing the following molecules as illustrative examples: pyrrole, thiophene, indole, azulene, fluorene, and pyrene. Finally, we will summarize some technological applications for which the high electrical conductivity and stability of these electrically conducting polymers have been exploited.

II. The electropolymerization reaction

Electrochemical stoichiometry

One of the important features found with the electropolymerization reaction is that it proceeds with electrochemical stoichi-

TABLE 1. Electrochemical data, elemental composition, and electrical conductivity of some electrically conducting polymers

Compound	E_{pa} monomer (V)	Voltammogram n value	Elemental composition of polymer	σ ($ohm^{-1}\,cm^{-1}$)	Reference
Pyrrole (C_4H_5N)	1.2	2.2–2.4	$C_{4.0}H_{3.5}N_{0.9}\,(BF_4)_{0.19}$	100	2, 11
Thiophene (C_4H_4S)	2.06	2.7	$C_{4.0}H_{3.3}S_{0.9}\,(BF_4)_{0.07}$	0.02	12, 13
2,2′-Bithiophene (C_8H_6S)	1.32	—	$C_{4.0}H_{2.1}S_{1.0}(HSO_4)_{0.17}$	0.1	12, 13
Indole (C_8H_7N)	1.26	2.1	$C_{8.0}H_{6.1}N_{1.0}(ClO_4)_{0.34}$	0.02	4
Thianaphthene (C_8H_6S)	1.75	2.4	$C_{8.0}S_{5.4}S_{1.0}(ClO_4)_{0.16}$	0.008	4
Carbazole ($C_{12}H_9N$)	1.30	2.5	$C_{12}H_{13}N(ClO_4)_{0.45}$	10^{-3}	5, 14
Azulene ($C_{10}H_8$)	0.96	2.1	$C_{10}H_{6.5}(ClO_4)_{0.25}$	10^{-2}–1	5
Fluorene ($C_{13}H_{10}$)	1.82	2.5	$C_{13.0}H_{9.5}(BF_4)_{0.23}$	10^{-4}	6
Fluoranthene ($C_{16}H_{10}$)	1.68	2.0	$C_{16.0}H_{9.6}(BF_4)_{0.18}$	10^{-5}–10^{-3}	6
Triphenylene ($C_{18}H_{12}$)	1.83	2.7	$C_{18.0}H_{11.4}(BF_4)_{0.20}$	10^{-4}	6
Pyrene ($C_{16}H_{10}$)	1.33	1.7	$C_{16.0}H_{12.0}(ClO_4)_{0.31}$	10^{-1}–1	6

ometry (2). This allows characterization of the film-forming reactions, which typically proceed with n values which are slightly in excess of 2.0 (2, 4–6). The n values can be measured in several ways. One of the most convenient is from voltammograms, utilizing the Nicholson and Shain (10) treatment for a totally irreversible reaction. For most of the film-forming reactions discussed here, the n values are usually in the range between 2.0 and 2.7 (Table 1), whereby 2 electrons/molecule are involved in the film-forming reaction, and the charge in excess of 2.0 is consumed in the concomitant electrooxidation of the polymer film. However, the n values derived from voltammograms really represent the total reaction at the electrode surface and can include secondary chemical reactions that accompany the electropolymerization reaction, such as dimerization reactions to form soluble products. This has been observed in the electropolymerization reaction of pyrene (6), and will be discussed below (Sect. III*f*) in more detail. For the moment, these data at least establish the fact that the electropolymerization reaction does involve approximately 2 electrons/molecule (Table 1).

A more quantitative estimate of the degree of oxidation in the polymer films comes from their elemental composition data (Table 1). These data reveal that all of the polymers of Table 1 are oxidized to the extent of 0.07 to 0.45. These data are, in general, consistent with the n values obtained from voltammetry.

Electrochemical aspects

Cyclic voltammetric studies of the molecules listed in Table 1 reveal that they all electrooxidize irreversibly. These data suggest that the intermediate radical cations are unstable and rather reactive. As an illustrative example, a typical cyclic voltammogram using pyrene is shown in Fig. 1. The first oxidation wave of pyrene occurs at an anodic potential of +1.33 V. Upon reversing the direction of sweep from the first oxidation wave, a corresponding cathodic wave owing to the reduction of the oxidized polymer film is observed in the region from ≃+1.0 to +0.6 V. Subsequent anodic sweeps reveal the growth of the polymer film at a lower oxidation potential, where the peak potential (E_{pa}) occurs at ca. +1.1 V. Thus, the cyclic voltammogram of pyrene has all the characteristics of an ECE reaction (15, 16), i.e., a sequence of steps whereby an electron transfer event (E) is followed by a chemical reaction (C) and a subsequent electron transfer reaction (E). Since the film-forming reaction can be described as a cascade of ECE reactions, the general term $E(CE)_n$ has been recently forwarded to describe the film-forming reactions (5).

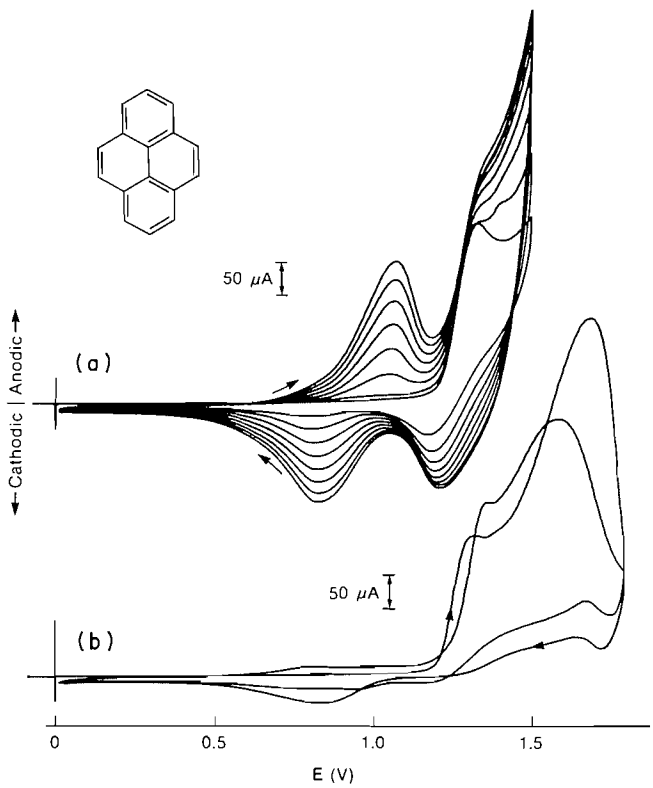

FIG. 1. Cyclic voltammogram of ≃5 μmol/cm³ pyrene in 0.1 *M* TEAFB/CH_3CN; (*a*) successive sweeps (200 mV/s) revealing growth of polymer and (*b*) two consecutive sweeps of pyrene from 0 to +1.80 V. The trace marked by the arrows is the first sweep. TEAFB is tetraethylammonium fluoroborate, an electrolyte.

Radical-cation coupling

When a molecule (R) is electrooxidized to its radical cation ($R^{+\bullet}$) at the electrode surface, the electron transfer reaction is much faster than the diffusion of R from the bulk solution to the electrode surface. Accordingly, at the applied voltage, molecules close to the electrode surface region will occur only in their oxidized state $R^{+\bullet}$. This insures a high concentration of $R^{+\bullet}$ at the electrode surface, which is continuously maintained by the steady state diffusion of R from the bulk. These monomeric radical cations can undergo a variety of follow-up reactions depending upon their intrinsic stability (4). When $R^{+\bullet}$ is relatively stable, it can diffuse away from the electrode surface and undergo reactions to form low molecular weight soluble products. If $R^{+\bullet}$ is very unstable, it can rapidly undergo indis-

criminate reactions with either the solvent or anions to form low molecular weight, and thus soluble, products equally well. Between these two stability ranges (which vary depending on the nature of $R^{+\bullet}$), $R^{+\bullet}$ can undergo dimerization reactions or "electropolymerization." These reactions are thought to proceed by the coupling of two radical cations. The concept of radical-cation coupling as a consequence of electrooxidation is not new, and has been applied before to explain the ECE reactions of many irreversible systems in which a monomer dimerizes to form a coupled product (14, 16). We wish to point out that electropolymerization reactions can be regarded as an extension of the dimerization reaction, i.e., they represent a sequence of dimerization reactions involving radical-cation coupling of $R^{+\bullet}$ with its oligomeric radical cations. Evidence for such a reaction pathway, in which chain propagation is dependent on the presence of $R^{+\bullet}$ (as opposed to R), is reflected in the following: (*a*) the cyclic voltammograms reveal an $E(CE)_n$ process, consistent with radical-cation coupling reactions; (*b*) the finding that in order to sustain film growth at the electrode surface the electrode potential (voltage) has to be maintained at the electrochemical oxidation potential of R, where R is not limited to a monomer, as evidenced by the facile electropolymerization of 2,2′-bithiophene) (17); (*c*) the film-forming reaction is surface localized, and no evidence of polymerization in the bulk of the solution has yet been observed (where for the concentrations the relation $[R] \ggg [R^{+\bullet}]$ holds); and (*d*) chronoabsorptometric studies (for R = pyrrole) reveal that polypyrrole films grow linearly with time t, and not $\sqrt{t}$. This latter finding implies that the rate-limiting step during film growth is the radical coupling process itself, and not the diffusion of monomer to the electrode surface (18). Thus, the evidence favoring the radical-cation coupling reaction is strong. In general then, the electropolymerization reaction for a molecule can be summarized by eqs. [1]–[4]. Equations [1]–[3] describe the step by step electropolymerization reaction of a monomer RH_2, while eq. [4] represents the overall electropolymerization reaction. Note that the electropolymerization reaction proceeds via an intermediate dihydro-oligomer dication, which then loses two protons to form the neutral oligomer.

$$[1]\quad RH_2 \xrightarrow[E_{pa}]{-e^-} RH_2^{+\bullet}$$

$$[2]\quad 2RH_2^{+\bullet} \rightarrow [H_2R{-}RH_2]^{2+} \xrightarrow{-2H^+} HR{-}RH$$

$$[3]\quad HR{-}RH \xrightarrow[E_{pa}]{-e^-} [HR{-}RH]^{+\bullet}$$

$$\xrightarrow{RH_2^{+\bullet}} [HR{-}RH{-}RH_2]^{2+} \xrightarrow{-2H^+} HR{-}R{-}RH$$

$$[4]\quad (X+2)RH_2 \xrightarrow[E_{pa}]{} HR{-}(R)_X{-}RH + (2X+2)H^+ + (2X+2)e^-$$

Street *et al.* (21) have observed that during the electropolymerization reaction, the pH of the solution becomes increasingly acidic, consistent with the elimination of protons during electropolymerization. The actual value of X is unknown, although recent tritium labelling studies (19) of poly-3,4-dimethylpyrrole-ClO_4 indicate that $X \simeq 750$, which corresponds to a molecular weight of $\simeq$100 000. However, Street *et al.* (19) have concluded that polypyrrole has a wide range of chain lengths, including some short-chained oligomers; therefore, such conversions may not be applicable in the usual way.

Structure–reactivity correlation

Due to the insolubility and the poorly crystalline nature of conducting polymers, characterization of their structure and physical properties has represented a considerable challenge. For example, solid state CMAS (^{13}C magic angle spinning) nmr studies of polyazulene-BF_4 films give rise to a single, broad-line resonance in the aromatic region, which only provides evidence for its ring integrity but no evidence for the linkage pattern of the monomer units in the polymer film (20). Much progress in the structural characterization of polypyrroles has been made, but the body of evidence comes primarily from a variety of indirect measurements, again due to its poorly crystalline structure (21). However, since vastly different aromatic molecules (Table 1) representing different classes of compounds have been found to electropolymerize and, moreover, since their anodic oxidation pathways are remarkably consistent, it would not be surprising if the polymer films were formed by a universal polymerization mechanism. Knowledge of this mechanism would decidedly assist characterization efforts, since a hypothetical polymer structure could be predicted. Accordingly, we have studied (13, 23) the electropolymerization reaction pathway by investigating: (*a*) the electronic structures of radical cations; and (*b*) the effect of substituents on the electropolymerization reaction. For this purpose, we will take advantage of a known (16) correlation between reactivity and the unpaired electron density of $R^{+\bullet}$, in particular with its degree of localization at a specific site. The electropolymerization reaction of pyrrole will be used as an illustrative example; however, all of the molecules listed in Table 1 follow an analogous reaction pathway.

The electrooxidation of pyrrole gives rise to polypyrrole in which the monomer units are linked primarily via their α,α′-positions (2). This hypothesis has been supported primarily by the failure of 2-substituted pyrroles to electropolymerize (2). Furthermore, oxidative degradation studies of chemically synthesized polypyrrole (25) yielded primarily 2,5-disubstituted products. Nuclear magnetic resonance studies (26) also suggest primarily α,α′-linked polypyrrole, although more recent XPS (X-ray photoemission spectroscopy) studies (27) show that as many as one out of three pyrrole rings is affected by structural disorder, part of which may be attributed to non-α,α′-linkages. Nevertheless, for a "simple" structure such as pyrrole, the gross structural features of its polymer can be predicted from the symmetry and reactivity of the pyrrole monomer. In fact, it has been suggested that the susceptibility of a given molecule towards electrophilic substitution is a valid reactivity index in determining the overall polymer linkage sites (22). Thus, polypyrrole can be expected to be (ideally) α,α′ linked, based upon the high selectivity of pyrrole to undergo electrophilic substitution at the α-positions. However, because electropolymerization proceeds via radical-cation coupling reactions, $R^{+\bullet}$ is the key intermediate species and, accordingly, its reactivity parameters are the pertinent ones. Moreover, as the electropolymerization reaction proceeds, *oligomeric* radical cations, which undergo radical coupling with other $R^{+\bullet}$ molecules, are produced at the electrode surface. As the oligomeric radical cations become larger in chain length, they become easier to electrooxidize (16, 17), and they become less reactive (23). However, electropolymerization is sustained because reactive monomer radical cations, which react with the oligomeric radical cations, are continuously produced. The site of radical coupling of $R^{+\bullet}$ to the oligomeric radical cation will depend upon the unpaired electron distribution in the oligomeric radical cation, which could be different from that of the monomeric $R^{+\bullet}$. Depending upon the unpaired electron distribution, nonregular linkages may occur. Thus, consideration of only the

TABLE 2. The π-electron density and the unpaired electron density of neutral and radical cation monomers, respectively, and their idealized polymer structures

Compound	π-Electron Density	Primary Electrophilic Reactive Site(s)	Unpaired Electron Density of Radical Cation	Ideal Polymer Structure

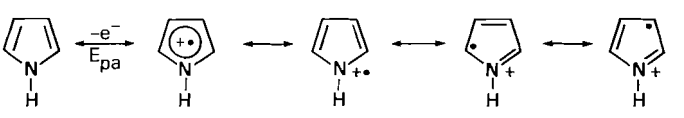
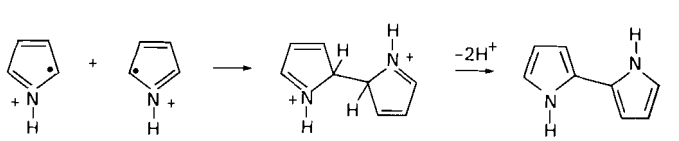
unpaired electron distribution of monomeric $R^{+\bullet}$ would allow, at best, extrapolation to a polymer structure whose linkage sites are the same as the reactive sites of the monomer radical cation $R^{+\bullet}$, i.e., an *idealized* polymer structure. These considerations are summarized in Table 2. Again, focussing on pyrrole as the illustrative example, it can be seen from Table 2 that the α-positions of the neutral monomer have the highest π-electron density, and accordingly, would be reactive in these positions. Thus, the primary electrophilic reactive sites are the α-positions (30). Consideration of the pyrrole radical cation also reveals that the positions of highest unpaired electron distribution are the very same α-positions, and thus, point to α,α′-linked polypyrrole. The other molecules shown in Table 2 reveal similar behavior. Thus, in general, the ideal polymer structure can be gleaned from either of the above considerations. However, because chain propagation does in fact depend upon $R^{+\bullet}$ and its oligomeric radical cations, departure from such an ideal structure based on the reactivity pattern of the monomer would not be unexpected. Thus, again utilizing the electropolymerization reaction of pyrrole as an illustrative example, we have applied INDO (intermediate neglect of differential overlap) (24) molecular orbital calculations to its various oligomeric radical cations, which occur intermediately in the electropolymerization reaction of pyrrole, to determine the trends in their reactivities and any differences which may occur in the reactivity pattern of oligomeric radical cations from their monomer radical cations. Therefore, we may determine the most probable linkage sites of the monomer units in the polymer.

The electrooxidation of monomeric pyrrole at an electrode surface gives rise to a delocalized radical cation. Our (23) INDO molecular orbital calculations reveal that, as expected, the delocalized pyrrole monomer radical cation **1** has the highest unpaired electron density at its equivalent α-positions (Fig. 2). Thus, among the resonance forms **2**–**4** shown, **3** is the most



1 **2** **3** **4**

important. Accordingly, when two monomeric pyrrole radical cations dimerize, radical coupling can be expected to occur at the α-positions. Indeed, dimerization to the dihydrodimer dication **5** proceeds with great facility, followed by loss of two protons to yield the neutral 2,2′ dimer **6**. The driving force for deprotonation among other things is stabilization by return to aromaticity.



5 **6**

The $E(CE)_n$ reaction at the anode surface continues with the electrooxidation of the dimer **6** to its radical cation **7**. Since the

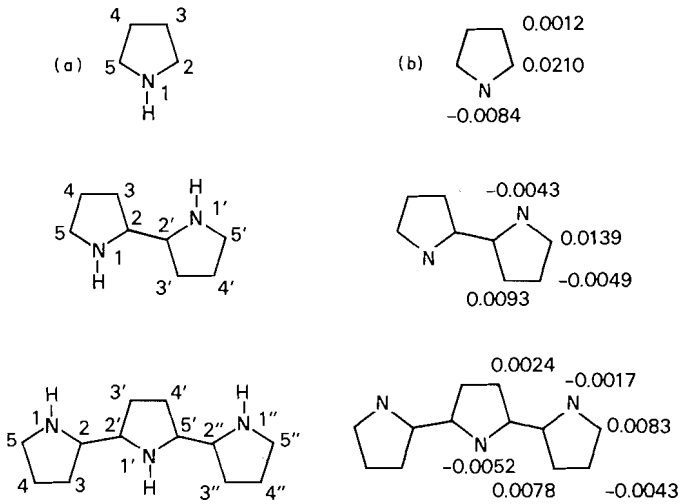


FIG. 2. (*a*) The numbering scheme for pyrrole oligomers and (*b*) open shell INDO molecular orbital calculations of the unpaired electron distribution of pyrrole, coplanar *anti* 2,2′-bipyrrole, and 2,2′:5′,2″-terpyrrole radical cations.

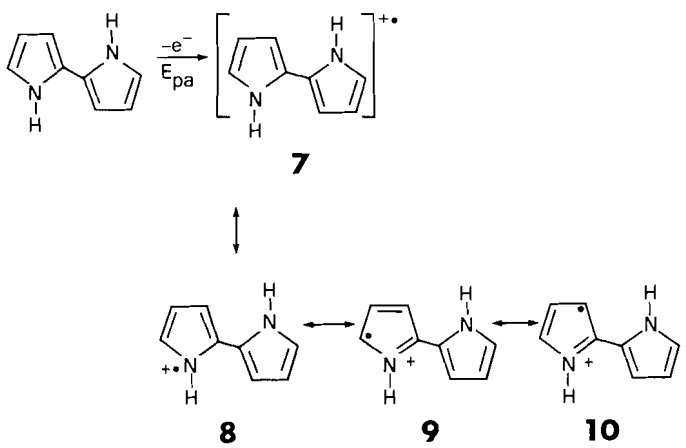
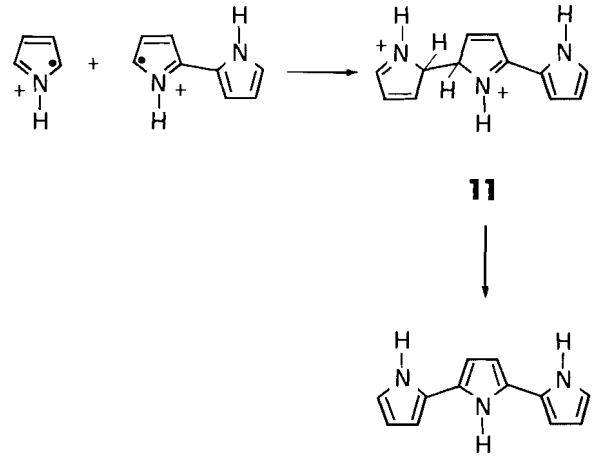
loss of an electron is now accommodated by two monomer units, the oxidation potential of **6** is lower than that of the monomer and should therefore be readily electrooxidized at the applied voltage (i.e., the voltage needed to electrooxidize the monomer), provided that it is not severely twisted (16). An example is given in Fig. 1. The unpaired electron distribution of the coplanar *anti* form **7** is given in Fig. 2. As was the case with the monomer radical cation, the highest unpaired electron density remains at the α-positions, namely the 5,5′-positions. However, because the unpaired electron is now distributed over two monomer units, delocalization dilutes the unpaired electron density (i.e., reactivity) of the α-positions in the dimer. Conversely, the β-positions have acquired more unpaired electron density, indicative of a different type of spin distribution in the dimer radical cation. A resulting consequence is stabilization and thus decreased reactivity of **7** in comparison with **1**. This may well account for the difficulty found in producing thick, continuous, free-standing polypyrrole films from the electrooxidation of either 2,2′-bipyrrole or 2,2′:5′,2″-terpyrrole (17), although it is reported to be possible (21).

Among the resonance forms shown for the dimer radical cation, INDO calculations (Fig. 2) predict **9** to be the predominant structure. The dimer radical cation can, therefore, be expected to continue to react primarily via the α-positions.



7 ↔ **8** ↔ **9** ↔ **10**

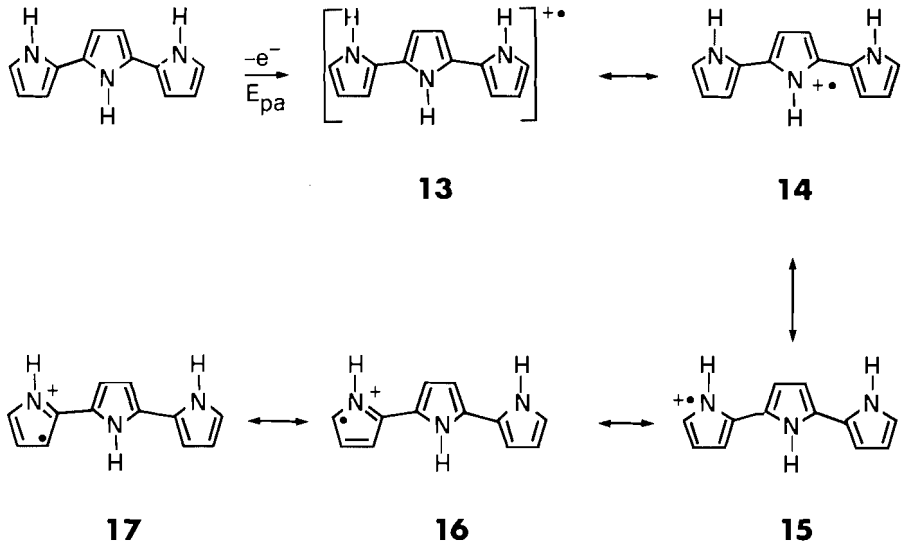
Thus, at this stage of the electropolymerization reaction, the surplus of monomer radical cations **3** at the electrode surface assures further predominance of α,α′-coupling, to yield the dihydrotrimer dication **11** that, upon deprotonation, forms the neutral trimer, i.e., 2,2′:5′,2″-terpyrrole **12**. Subsequent electrooxidation yields the radical cation **13**, for which the unpaired



11

12

electron distribution predicted by the INDO calculations is given in Fig. 2. The radical cation **13** in its coplanar *anti* configuration is predicted to be well delocalized, with much of the unpaired electron density residing at the 2′,5′-,5,5″-, and 3,3″-positions. It is interesting to note that here the α-positions, namely the 5,5″-positions, are no longer the positions with the highest unpaired electron density. They are comparable in the magnitude of their unpaired electron densities to those predicted for the 2′,5′- and 3,3″-positions. The 2′,5′-positions should be sterically inaccessible to monomer radical-cation attack. Conversely, the 5,5″-positions can be easily attacked by the monomer radical cations, thereby propagating α,α′ linkages still further. The 3- or 3″-positions, i.e., the β-positions, are somewhat sterically hindered and, therefore, a monomer radical cation would have to couple with the trimer radical cation in a nonplanar configuration. Thus, our INDO calculations predict that monomer radical cations could in principle undergo radical coupling reactions at either the 5,5″-positions (i.e., α-positions) or the 3,3″-positions (i.e., β-positions) of these oligomeric radical cations. The above conclusion is valid only if the criterion for reaction is the unpaired electron density. However, because the β-position is somewhat sterically inaccessible, α coupling should continue to predominate. Nevertheless, the INDO calculations reveal an important trend, namely, that as oligomerization proceeds from monomer to dimer to trimer radical cations, the unpaired electron distribution pattern does indeed differ from that of the monomer radical cation. Extrapolation of this trend suggests that as the oligomer progressively increases in chain length, the extensive π delocalization which sets in will delocalize the unpaired electron over the entire oligomer, such that further radical coupling would not be overwhelmingly favored at any single position. If the INDO results are taken literally, nonregular linkages would be much more prevalent in polypyrrole than previously appreciated, and the simple picture of a regularly α,α′-bonded polypyrrole would thus be grossly incomplete. Indeed, XPS studies of polypyrrole by Street *et al.* (27) reveal that as many as one in three pyrrole rings is affected by some kind of structural



13 14

17 16 15

disorder. This may include nonregular linkages. For example, the poor crystallinity of polypyrrole (27) could in part be explained in terms of β linkages. Thus, β,β′-dimethylpyrrole, which has both β-positions blocked with methyl groups, should contain none or few β linkages, and indeed yields a much more crystalline polymer (27).

If this concept is extrapolated to a more "complex" monomer such as pyrene (see below), which has potentially many more reactive positions, then nonregular bonding can be expected to occur more frequently.

III. Substituent effects

The stoichiometric electropolymerization reaction described above is not limited to the unsubstituted parent molecules (R). Rather, some substituted forms thereof undergo electropolymerization, provided that the substituent does not dramatically affect the reactivity of the molecule. As stated previously in the introduction, substituents can influence the electropolymerization reaction by either a *steric effect* or an *electronic effect*. They can also cause changes in the overall properties of the polymer film. These aspects will now be considered for a group of monomers that electropolymerize, and which exhibit such a substituent effect.

a. Polythiophene

1. Electrochemical data

Cyclic voltammetric data for thiophene and some 3-substituted thiophenes are summarized in Table 3. In general, the reactions which produce polymer films have n values between 2 and 2.7. These include thiophene, 3-methyl-, 3-bromo-, 3-iodothiophene, and thiophene-3-acetonitrile (Table 3). Among these, the best polymer films are prepared from thiophene, 2,2′-bithiophene, and 3-methylthiophene. These thin films, when supported by an electrode surface, display electroactive and electrochromic properties (12, 13). The peak oxidation potential (E_{pa}) of polythiophene-BF_4 occurs at +1.0 V. The cyclic voltammogram of a 1-μm thick film has a peak width at half height (PWHH) of ≃300–350 mV. Polythiophene films derived from 2,2-bithiophene also have an E_{pa} of +1.0 V, as may be expected. However, its cyclic voltammogram reveals a much sharper oxidation peak with a PWHH of ≃90 mV for a 1-μm thick film. This is most probably due to the more regularly α,α′-linked monomer units in the dimer derived polymer film, and the much lower degree of hydrogen saturation of the dimer derived film (Table 4), which may preserve the regularity of the polymer film to a higher degree than the monomer derived film. This hypothesis is consistent with a more homogeneous, i.e., more regularly α,α′-linked polymer film. A more uniform distribution of polymer chains can be expected to yield a much sharper peak.

With the introduction of a β-methyl substituent, the polymer film is much more easily oxidized. A cyclic voltammogram of poly-3-methylthiophene shows similar features (Fig. 3): The presence of β-methyl substituent shifts the E_{pa} by ca. 300 mV cathodic of the E_{pa} of the unsubstituted polymer film, and is therefore electroactive in a region considerably less anodic than polythiophene. Also, the PWHH for a 1-μm thick film of poly-3-methylthiophene is ≃200 mV, considerably sharper than the parent polythiophene, although still not as sharp as the film derived from the 2,2′ dimer. Thus, we find that polythiophene films, when appropriately substituted, are electroactive in different regions of the electrochemical voltage scale.

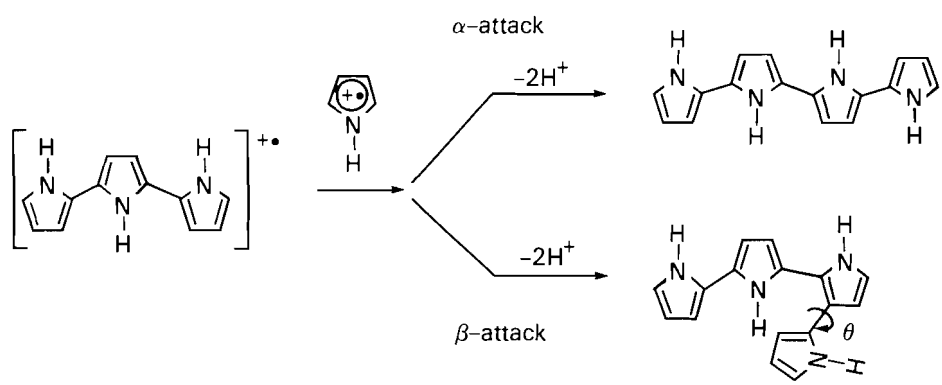


TABLE 3. Cyclic voltammetric data for thiophenes: monomer concentration 8.9–23.0 μmol cm^{-3} in 0.1 *M* TEAFB/CH_3CN with sweep rate 40 mV s^{-1} (ref. 13)

The electropolymerization of 3-thiopheneacetonitrile, and of 3-bromo- and 3,4-dibromothiophene is accompanied by much discoloration of the acetonitrile solution. This suggests that significant amounts of soluble products are produced simultaneously with the film-forming reaction. Polymer films are not obtained from 3-thiophene carboxylic acid and 3-cyano- and 3-nitrothiophenes. Thus, not all of the thiophene monomers electrooxidize to produce films. However, for those that do, a plot of the E_{pa} monomer versus E_{pa} polymer yields a structure–property correlation between thiophene monomers and their respective polymers (12). In particular, a linear correlation is obtained (Fig. 4), suggesting that the β-substituted monomers and their respective polymers are made up of a related system of π electrons, consistent with the fact that polythiophenes ought to consist primarily of α,α′-linked monomer units.

2. Hammett correlation and electropolymerization

In Fig. 5, the E_{pa} of some 3-substituted thiophenes are plotted against their respective Hammett substituent constants (σ^{+i}, according to Brown and Okamoto, see ref. 42). While E^0 should be used for this treatment, only the E_{pa} values are available for these irreversible reactions. However, we have shown (43) recently that the E_{pa} values are close to the E^0 values within a regular series of substituted fluorenes which electropolymerize. Thus, by analogy, the E_{pa} values of irreversible systems such as thiophenes must be close to, or linearly related to E^0 within a regular series. Accordingly, the shift in the E_{pa} values of the series of β-substituted thiophenes is dependent on three parameters, namely their polar, steric, and mesomeric effects (44). This behavior can be described by the usual Hammett–Taft equation:

$$[5] \quad E = \rho_\pi \sigma^{+i} + S$$

where $\rho_\pi \sigma^{+i}$ describes the polar-mesomeric effects, and S accounts for the steric factor (44). From these considerations, Fig. 5 allows three conclusions to be drawn. First of all, the straight line fit with a slope of $m = 0.80$ indicates that all of the monomers electrooxidize by the removal of a π electron from the thiophene ring. Secondly, the positive sign for the substituent constant ρ_π reveals that as the substituents take on more electrophilic character, the oxidation of the corresponding thiophene monomers proceeds with more difficulty. Finally, the steric term S appears to be minimal for the electrooxidation reaction of the thiophene monomers. Therefore, the primary effect exerted by the β-substituents is *electronic* and described by the $\rho_\pi \sigma^{+i}$ term. Thus, it appears that there is an optimum reactivity of the radical-cation intermediate which favors radical-cation coupling in the follow-up reaction to yield polymeric films. In this case, polymer films are obtained from thiophene, 3-methyl-, 3-bromo-, and 3-iodothiophenes. However, thick, free-standing conducting films are obtained only from the parent and methyl-substituted thiophene monomers (13). 3-Bromo- and 3-iodothiophene yield poorly conducting thin films. 3-Thiophenecarboxylic acid and 3-cyano- and 3-nitrothiophene yield no polymer films. Several reasons may be attributed to this

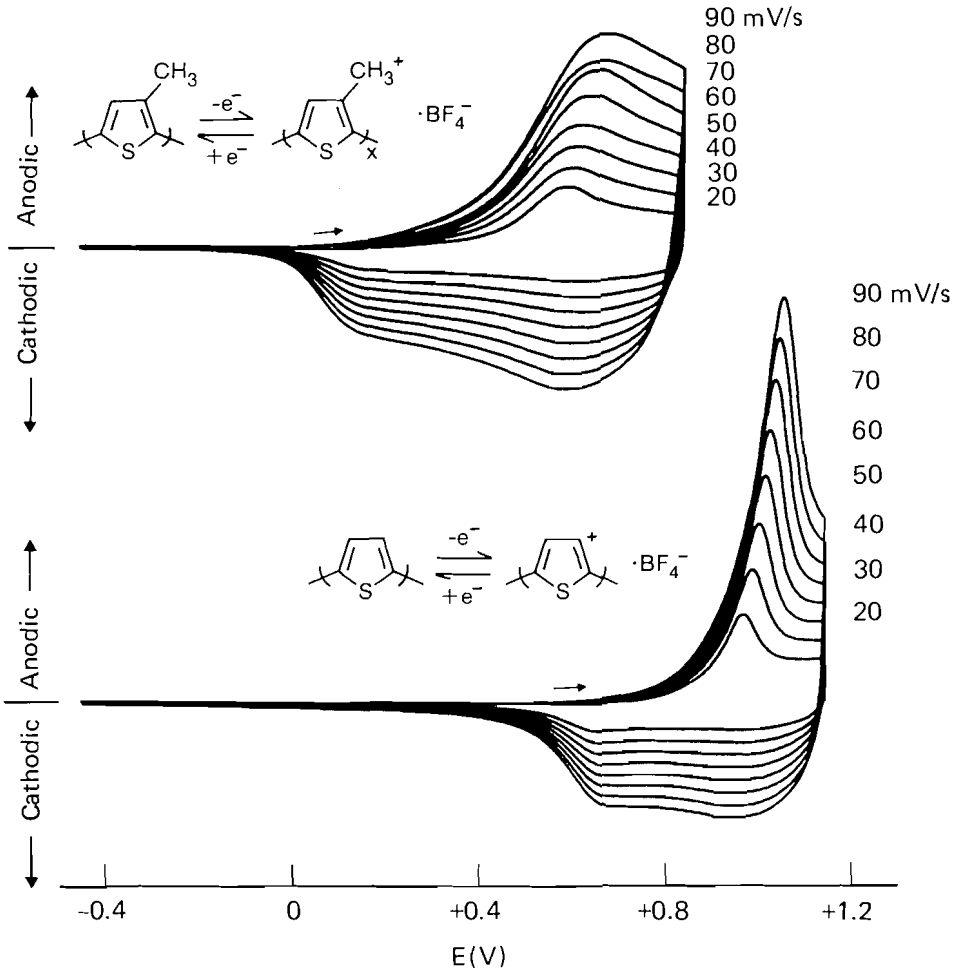

FIG. 3. Cyclic voltammograms of poly-1-methylthiophene-BF_4 (top figure) and polythiophene-BF_4 (bottom figure), in 0.1 *M* TEAFB/CH_3CN containing no other electroactive species.

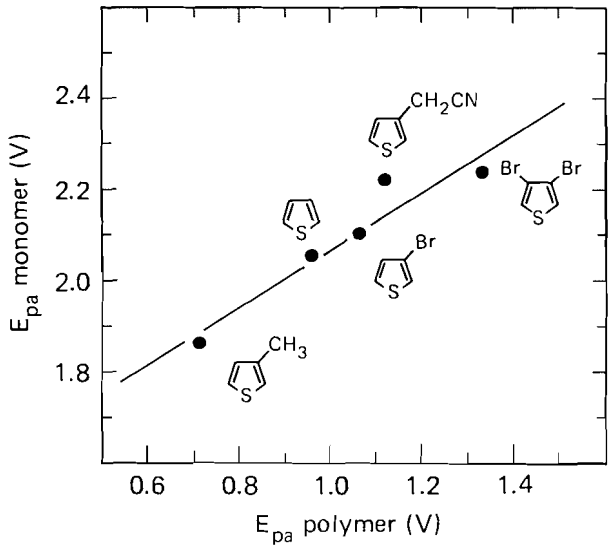

FIG. 4. Peak oxidation potential of thiophene monomers versus their respective polymers in 0.1 *M* TEAFB/CH_3CN.

finding. One interpretation postulates that the stability (or reactivity) of these monomers is affected by the β-substituents. As the reactivity of the radical cation increases, as reflected in their increasing oxidation potentials (Fig. 5), the more reactive they become. Thus, strongly electron-withdrawing groups destabilize the radical-cation intermediate such that its decreased lifetime favors rapid reaction with solvent or anions to form soluble products, rather than to electropolymerize.

While steric effects do not appear to play any significant role in the electrooxidation of the monomer, their subsequent follow-up reactions (such as electropolymerization) may be more susceptible to steric effects that, therefore, may well play a role in deciding whether the electropolymerization reaction can compete favorably with other accessible follow-up reactions, such as dimerization or capture by solvent. This may explain the overall inferior quality of the polymer films derived from 3-bromo- and 3-iodothiophenes, since their oxidation potential is not much different from the parent, and since halogens do not usually exert a strong electronic substituent effect. It is, however, interesting to note that while a 3-methyl substituent allows facile electropolymerization, a less bulky 3-cyano substituent altogether suppresses electropolymerization. Again, this is consistent with the interpretation of electronically induced substituent effects.

Thiophenes in which the 2-position is substituted do not electropolymerize, presumably due to blockage of the reactive α-position.

3. Polymer composition and electrical conductivity

The electrical conductivities of variously substituted polythiophene films are summarized in Table 4. Their elemental analyses reveal that the basic monomer units are preserved in the polymer films, and that their level of oxidation varies from ≈0.05 to 0.30. In general, polythiophenes have electrical

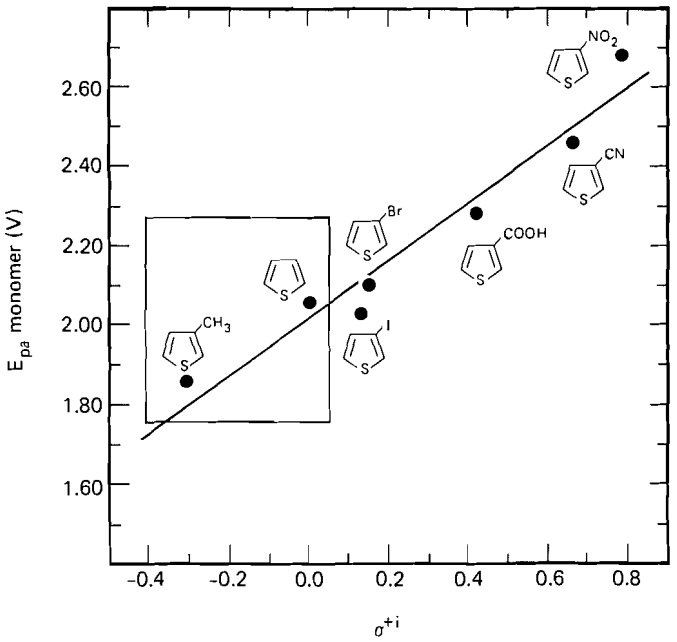

FIG. 5. Electrochemical peak oxidation potential of thiophene monomers versus their respective Hammett substituent constants. The monomers enclosed within the square electropolymerize.

conductivities between 10^{-2} and 20 S/cm, depending on the growth conditions (Table 4) and the counteranion that is incorporated into the polymer film. These values strongly depend on the exact nature of the polymerization conditions, which explains the variances that are observed in the electrical conductivity and film quality of polythiophene films (Table 4). Despite these shortcomings, the agreement is generally good. Comparisons with derivatized polythiophene films reveal that, in general, the addition of a 3-methyl substituent enhances the electrical conductivity of polythiophene by a factor of ≈10–1000 (Table 4). Thus, we see a case in which the electrical conductivity of a parent polymer is actually improved by the addition of a substituent. For polymer films derived from 3,4-dimethylthiophene (27, 45), the results are less definitive. In one case, pressed films of poly-3,4-dimethylthiophene-CF_3SO_3 exhibit conductivities as high as 50 S/cm (45). On the other hand, free-standing films derived from perchlorate anions (27) exhibit conductivities of 10^{-3} S/cm.

Hotta *et al.* (46) have shown that the preparation temperature of polythiophene films has a significant effect on the polymer film properties. In particular, films that were prepared at lower temperatures were consistently higher in their electrical conductivity than those prepared at room temperature. This was especially prominent for polythiophene-SO_4 films, whose electrical conductivity was higher by a factor of $\sim 10^3$ when prepared at 5°C compared with room temperature (46). Films prepared at the lower temperatures were also found to be more dense and tougher than their room temperature counterparts (46).

b. Poly-1-substituted pyrroles

*1. Poly-*n*-alkylpyrroles*

Another example in which substituents give rise to modifications in polymer film properties comes from 1-alkyl-substituted pyrroles (48). These data are summarized in Table 5. In particular, the electrical conductivity of the 1-alkyl-substituted pyrroles decreases with increasing size of the alkyl substituent (48). Thus, while polypyrrole films have an electrical conductivity of 100 S/cm, poly-1-methylpyrrole has a conductivity of 10^{-3} S/cm, and poly-1-isobutylpyrrole 10^{-5} S/cm. Also, the level of oxidation in the polymer films shows a decreasing trend with increasing size of the substituent (Table 5). The quality and yield of the polymer films also become poor with the larger alkyl substituents. From these results, it was concluded that the alkyl substituents alter the polymer film properties solely via a steric effect (48).

TABLE 5. The oxidation potential, oxidation level, and electrical conductivity of *N*-alkyl substituted pyrroles and polypyrroles. Data taken from Diaz *et al.* (48)

N-alkyl Group	E_{pa} (monomer) (V)	Oxidation level of polymer	σ (S/cm)
H	1.20	0.25–0.30	100
CH_3	1.12	0.23–0.29	10^{-3}
CH_2CH_3	1.22	0.20	10^{-3}
$CH_2CH_2CH_3$	1.26	0.20	10^{-3}
$CH_2CH_2CH_2CH_3$	1.22	0.11	10^{-4}
$CH_2CH(CH_3)_2$	1.24	0.08	10^{-5}

*2. Poly-*p*-substituted* n*-phenylpyrrole*

The substituent effects exerted by *p*-substituted *n*-phenylpyrroles are much more subtle than 1-substituted pyrroles since the electronic substituent effect is first transmitted through a phenyl ring before the pyrrole structure is affected. Furthermore, if the phenyl ring is twisted relative to the pyrrole moiety, the substituent effect is further diluted. Thus, the substituent effect is expected to be rather modest, and this is indeed the case (49). Salmon *et al.* (49) have plotted the E_{pa} of a variety of *p*-substituted *n*-phenylpyrroles versus their respective substituent constants, and obtained a straight line of slope $m = 0.16$, much less than that obtained for the 3-substituted thiophenes ($m = 0.80$) discussed previously. They have also obtained a straight line plot ($m = 0.18$) from a plot of the E_{pa} of poly-*p*-substituted *n*-phenylpyrroles as a function of σ^{+i}. From these data, they have concluded that substituents affect the *p*-substituted *n*-phenylpyrroles and their respective polymers similarly (49).

The assertion may be further verified if a plot of the E_{pa} values of the monomers against their respective polymers yields a linear correlation. Such a plot has been constructed in Fig. 6, utilizing the data of Salmon *et al.* (49). A least-squares fit yields approximately a straight-line fit, albeit a correlation coefficient of only 0.77. However, this serves to substantiate the structure–property correlation between monomers and their respective polymers, as discussed previously with poly-3-substituted thiophenes.

c. Polyindole

1. Electrochemical data

Cyclic voltammetric data for indole and some 5-substituted indoles are summarized in Table 6 (4). In general, the film-forming reactions have *n* values of approximately 2, as do the thiophenes (Sect. III*a*). These values are consistent with the *n* values obtained from elemental analysis (see below) and constant potential electrolysis. The constant potential electrooxidation of indole itself produces a light-green colored solution, and a green-black polymer film is deposited at the electrode surface. Among the substituted indoles that electropolymerize (Table 6), 5-cyanoindole and indole-5-carboxylic acid produce the best

films. The relative yields are 0.6, 0.5, and 0.4 mol/F (F = faraday) for indole-5-carboxylic acid, 5-cyanoindole, and indole, respectively.

From the electrooxidation of a wide variety of substituted indoles, it was found (4) that polymers can be obtained when substituents are present on the benzene ring, but not when they are present on the five-membered ring of indole. These included bulky substituents, such as with 5-chloro- or 5-bromoindole. Thus, these data suggested that the linkage sites of the monomer units in polyindole occur away from the benzene ring, namely at the five-membered ring of indole. Therefore, substituents on the benzene ring should have only an electronic but not a steric influence on the reactive radical cation.

2. Hammett correlation and electropolymerization

In Fig. 7, the E_{pa} of some 5-substituted indoles plotted against their respective Hammett substituent constants are shown. As observed previously for the thiophenes (Sect. III*a*), a linear correlation is obtained. Thus, electrooxidation of 5-substituted indoles results in a π-delocalized radical cation. The linear correlation also suggests that steric effects (see eq. [5]) are not important in the electrooxidation step. The slope obtained for the indole series is $m = 0.56$, smaller than that found previously for the thiophene series ($m = 0.80$). This indicates a less-pronounced substituent effect for the indole series, which can be accounted for in terms of its much larger π-structure, as well as to the fact that the substituents are further removed from the reactive sites, i.e., on an adjacent benzene ring.

Among the 5-substituted indoles, electropolymerization is observed when they are substituted with electron-withdrawing groups, and not with electron-donating groups (Fig. 7). The exceptions are the strongly destabilizing nitro substituent, and the weakly donating fluorene substituent. Since the 5-substituents exert only an electronic effect, inspection of Fig. 7 suggests that there is an optimum region in which the reactivity of the indole radical cation is well suited for the radical-cation coupling reaction, i.e., electropolymerization. Appropriate substituents can push indole in or out of this optimum region. Thus, with the more strongly electron-donating substituents such as a methyl or methoxy, the indole radical-cation intermediate becomes sufficiently stabilized to diffuse away from the electrode surface during its increased lifetime. The previously postulated tendency of the radical cations to undergo coupling reactions (Sect. II) would thus become reduced in favor of reactions in which the radical-cation intermediates would be captured by nucleophiles or solvent outside of the electrode surface region. Conversely, electron-withdrawing substituents up to the cyano group do not push the indole radical cation out of its optimum reactivity range (with respect to radical-cation coupling), and

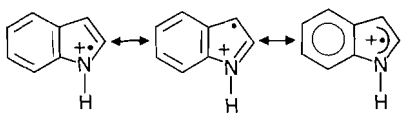
[a] 
thus electropolymerization is still possible. This behavior is opposite to that observed with the thiophenes (Sect. III*a*), whereby electropolymerization is suppressed by electron-withdrawing substituents, but not with a donating methyl group. This comparison serves to illustrate that, because the intrinsic stability of radical cations varies according to their structure, substituent effects need not follow the same pattern.

3. *Electronic structure of 5-substituted indoles: an INDO study*

In order to qualitatively investigate the "push–pull" effect of substituents on the indole moiety, open-shell INDO (24) calculations were performed. These results are summarized in Table 7. The indole radical cation is characterized by high unpaired electron densities at the 1- and 3-positions of the five-membered ring. The unpaired electron densities in the adjacent benzene ring are comparatively low. Thus, delocalization into the benzo-moiety of indole does not seem to be attractive, possibly because such resonance structures would require a loss of aromaticity of the six-membered ring. The indole radical cation can accordingly be represented via the resonance structures as shown below. The high unpaired electron density at the 1- and 3-positions identify these as the reactive sites, and also suggest that the monomer linkages in the polymer do occur in these same



positions, at least in an idealized structure for polyindole (Sect. II, Table 2).

Since the INDO calculations (Table 7) reveal that the unpaired electron density in indole is primarily localized in the five-membered ring, the electronic push–pull effects exerted by the 5-substituents can be expected to be mild. This appears to be the case indeed. The electronic structure of indole with a strongly destabilizing group such as cyano is similar to the parent. 5-Cyanoindole would therefore be expected to electropolymerize, and does so (4). The exception is 5-nitroindole, which does not electropolymerize even though its unpaired electron distribution is not too different from indole itself. It is important to emphasize here that the value of the INDO calculations comes from evaluating the *trends* which result from substitution, rather than from evaluating the data in any quantitative manner. In this way, some insights into the aptitude of any given molecule to electropolymerize, and its reactive sites, may be ascertained.

The *trend*, which is observed in the indole radical cation when substituted with increasingly electron-donating substituents, is one of decreasing unpaired electron density in the five-membered ring, concomitant with an increase in the unpaired electron density in the benzene ring. With 5-aminoindole, most of the unpaired electron is localized on the substituent nitrogen atom. Because of the decreasing reactivity at the 1- and 3-positions, radical-cation coupling becomes less likely as the substituent becomes more electron donating. This is indeed observed experimentally, where 5-methyl-, 5-methoxy-, 5-hydroxy-, and 5-aminoindole are found not to electropolymerize (Fig. 7). These findings establish two very important results: First, $R^{+\bullet}$ can undergo a variety of reaction pathways, depending upon its intrinsic stability. When $R^{+\bullet}$ is relatively stable, it can diffuse away from the electrode surface and undergo reactions to form soluble products. If $R^{+\bullet}$ is a highly unstable radical-cationic species, it can rapidly undergo indiscriminate reactions with either the solvent or anions to yield soluble products. In between these two stability extremes, $R^{+\bullet}$ can undergo electropolymerization. These findings also imply the possibility of electropolymerization of a substituted monomer that would otherwise not have electropolymerized in its unsubstituted form. Secondly, these data indicate that substituents, even when removed from the reactive position such that *steric effects* are unimportant, nevertheless can suppress the electropolymerization reaction by *electronic effects*.

4. Polymer composition and electrical composition

The elemental analyses and electrical conductivities of some substituted polyindoles are summarized in Table 8. Their elemental analysis reveals that the basic monomer unit and substituent are preserved in the polymer films. Their level of oxidation varies from 0.23 to 0.34. Polyindoles are poorly electrically conducting, as seen in Table 8. Their conductivities are between 10^{-5} and 10^{-4} S/cm. These data establish that a high uptake of counteranions does not necessarily give rise to highly conducting polymers (Table 1).

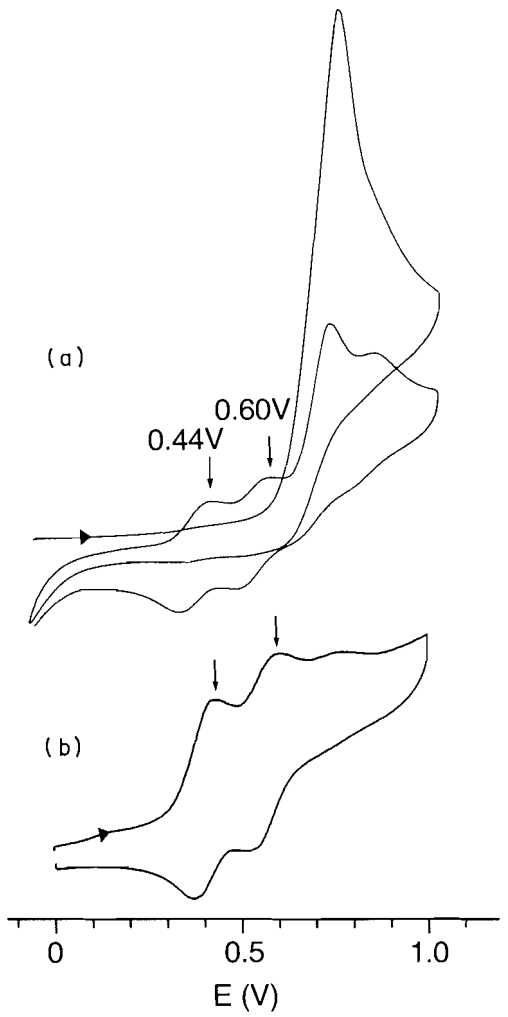

FIG. 8. Cyclic voltammogram in 0.1 *M* TEAFB/CH_3CN of: (*a*) guaiazulene, showing formation of the 3,3′ dimer on the second sweep (500 mV/s), and (*b*) the authentic 3,3′-biguaiazulene dimer.

d. Polyazulene

1. Electrochemical data

Cyclic voltammetric data for azulene and some 1-substituted azulenes are summarized in Table 9. All of the monomers electrooxidize irreversibly, except for 1,3-di-*tert*-butylazulene, which exhibits a reversible redox reaction. Among the monomers shown in Table 9, electropolymerization is observed only for azulene and 4,6,8-trimethylazulene. 1-Substituted azulenes do not electropolymerize, but instead form soluble products. These reactions are characterized by n values of $\simeq 1$, which is indicative of the formation of dimeric products (50). The formation of these dimers can be observed via cyclic voltammetry utilizing rapid sweep rates. For example, successive sweeps in the cyclic voltammogram of monomeric guaiazulene (Fig. 8) reveal the formation of 3,3′-biguaiazulene, which exhibits a two-wave reversible redox couple. These new peaks are in good agreement with the cyclic voltammogram of authentic 3,3′-biguaiazulene (Fig. 8). These data suggest that the equivalent 1- and 3-positions of azulene are important for electropolymerization. When the 1-position of azulene is blocked with a substituent, only dimerization occurs upon electrooxidation. This finding is consistent with the electronic structure of the azulene radical cation (40), which reveals that the positions of highest unpaired electron density occur at the equivalent 1- and 3-positions. These data identify them as the reactive positions, and also suggest that, in the idealized structure of polyazulene (Table 2), the monomer linkages in the polymer do occur in these same positions (Fig. 9). Thus, 1-substituents on azulene sterically hinder the electropolymerization reaction, much as 2-substituents block the electropolymerization reaction of pyrrole (2) or thiophene (12).

e. Polyfluorene

1. Electrochemical data

Cyclic voltammetric data for fluorene and some 1-substituted fluorenes are summarized in Table 10. As shown, the monomers that electropolymerize have n values in excess of 2.0. These include fluorene, and 1-methyl- and 1-methoxyfluorene.

2. Hammett correlation and electropolymerization

The E_{pa} values of some 1-substituted fluorenes plotted against their respective Hammett substituent constants are shown in Fig. 10. As seen previously with the thiophene series (Sect. III*a*) and the indole series (Sect. III*c*), a linear correlation is obtained (Fig. 10). Thus, the electrooxidation of 1-substituted fluorenes produces a delocalized radical cation whose substituents exert an electronic push–pull effect in a predictable manner. The slope of the line is $m = 0.18$, which does not indicate a pronounced substituent effect, at least when compared with the thiophenes series ($m = 0.80$) or the indole series ($m =$

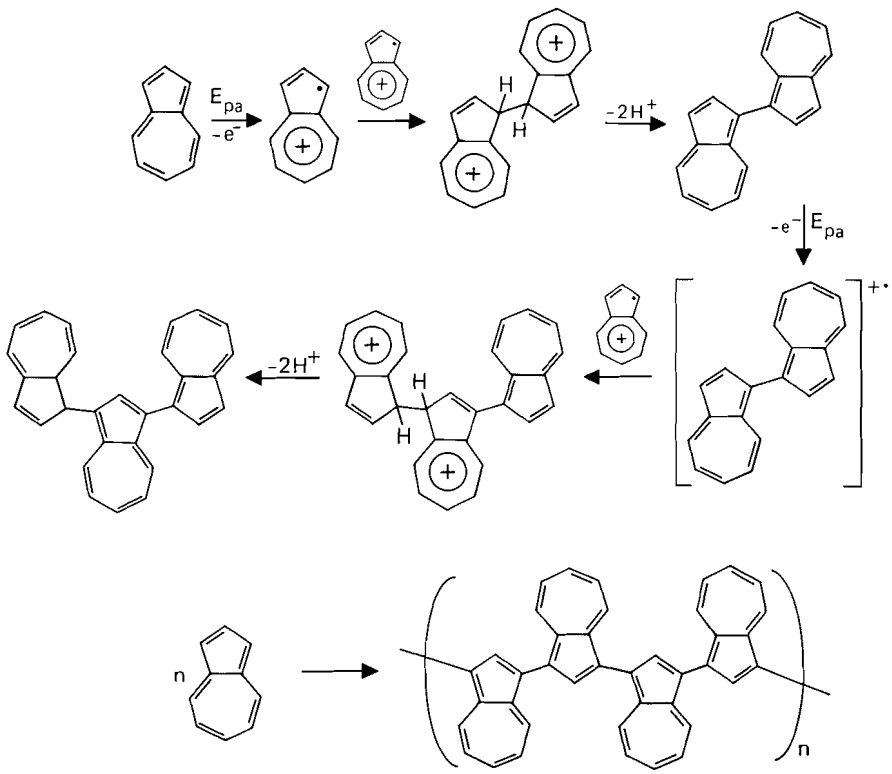

FIG. 9. A possible electropolymerization pathway for azulene.

TABLE 10. Cyclic voltammetric data for 2–5 μmol/cm^3 of fluorene and 1-substituted fluorenes in 0.1 *M* TEAFB/CH_3CN

Compound	E_{pa} (monomer) (V)	$i/AC\nu^{1/2}$ (A cm s$^{1/2}$ mol^{-1} V$^{-1/2}$)	n	Polymer film
Fluorene	1.86	3683	2.5	+
1-Hydroxyfluorene	1.63	1931	1.6	−
1-Methoxyfluorene	1.66	3791	2.5	+
1-Methylfluorene	1.78	3925	2.6	+
Fluorene-1-carboxylic acid	1.87	—	—	−

0.56). This may be attributed to the larger π structure of fluorene over thiophene or indole, which dilutes the substituent effect to a greater degree.

Among the 1-substituted fluorenes, electropolymerization is observed with the fluorenes that are substituted with electron-donating groups. These include the 1-methoxy- and 1-methylfluorenes. No electropolymerization is observed with the more strongly electron-donating hydroxy substituent, which stabilizes the delocalized fluorene radical cation such that electropolymerization is no longer a favorable follow-up reaction. Instead, its increased lifetime allows it to diffuse away from the electrode, and react to form soluble products. With the electron-withdrawing carboxylic acid group, the failure to electropolymerize indicates that the fluorene radical cation is sufficiently destabilized, and therefore very reactive. The unstable intermediate is rapidly captured by solvent or anion to produce soluble products.

3. Electronic structure of fluorene: an INDO study

INDO (24) molecular orbital calculations of the fluorene radical cation (51, 52) indicate that the positions of highest unpaired electron density occur at the equivalent 2- and 7-positions (Fig. 11). Thus, in the idealized structure of polyfluorene, the monomer units can be expected to be primarily 2,7 linked. The addition of substituents at the 1-position alters the distribution of the unpaired electron density and the stability of the fluorene radical cation, which in turn affects its aptitude to electropolymerize. With increasingly electron-donating substituents (methyl, methoxy, hydroxy), the unpaired electron-density distribution is increasingly localized within the substituted benzene ring, and the reactive 7-position becomes increasingly unreactive. As shown in Fig. 10, the electropolymerization cut-off point is reached at the methoxy substituent, and no electropolymerization is observed with fluorene substituted with a more electron-donating substituent such as a hydroxy.

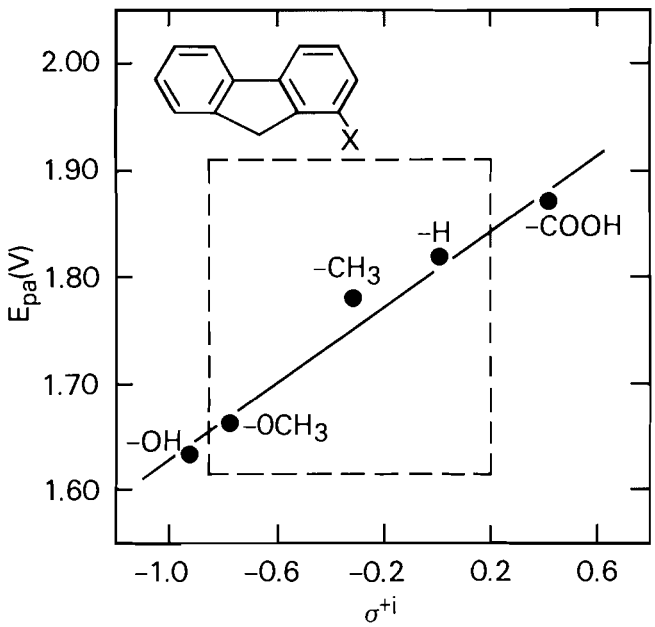

FIG. 10. Electrochemical peak oxidation potential of fluorene monomers versus their respective Hammett substituent constants. The 1-substituted fluorenes enclosed within the square electropolymerize.

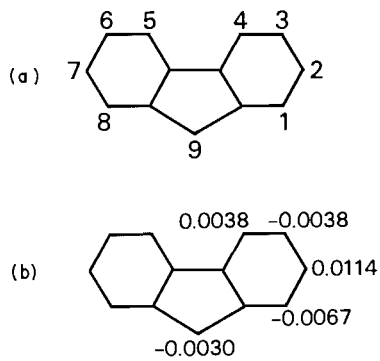

FIG. 11. (*a*) The numbering scheme for fluorene, and (*b*) open shell INDO molecular orbital calculation of the unpaired electron density of the fluorene radical cation.

TABLE 11. Elemental composition and electrical conductivity of some polyfluorenes (pressed polymers)

Compound	Elemental composition	σ (S/cm)
Fluorene ($C_{13}H_{10}$)	$C_{13.0}H_{9.5}(BF_4)_{0.23}$	10^{-4}
1-Methylfluorene ($C_{14}H_{12}$)	$C_{14.0}H_{10.9}(BF_4)_{0.12}$	10^{-5}
1-Methoxyfluorene ($C_{14}H_{12}O$)	$C_{14.0}H_{12.4}O_{1.9}(BF_4)_{0.16}$	10^{-5}

This result stems from the decreased unpaired electron density at the 7-position, which prevents a 2,7 linkage of the monomer units to form a polymer.

4. Polymer composition and electrical conductivity

The elemental analyses and electrical conductivities of some 1-substituted polyfluorenes are summarized in Table 11. Elemental analysis data indicate that the basic monomer units and

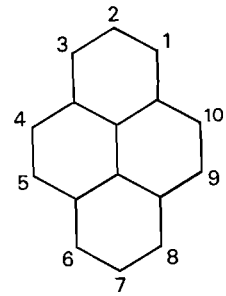

FIG. 12. The numbering scheme for pyrene.

substituents are preserved in the polymers and that the polymers are oxidized to the extent of 0.12 to 0.23 per monomer unit. The electrical conductivity of polyfluorenes is between 10^{-5} and 10^{-4} S/cm.

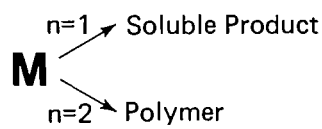
f. Polypyrene

1. Electrochemical data

Cyclic voltammetric data for pyrene (Fig. 12) and some of its 1-substituted derivatives are summarized in Table 12. As mentioned previously in Sect. II, the electrochemically estimated n value for pyrene (n = 1.7) is lower than would ordinarily be expected for these film-forming reactions, i.e., less than 2.0. This may result from the presence of competitive reaction pathways which have different electrochemical stoichiometries and different products, e.g., polymer versus soluble products (6). Thus, the n value of 1.7 is an apparent n value (n_{app}) for the *total* reaction. The n value for the film-forming reaction (n_p) is provided by the elemental composition of the polymer. Since n_{app} and n_p are both known (Table 1), the fraction of pyrene monomer which leads to polymer can be estimated. This assumes that the competing reaction is a dimerization reaction with n = 1, and that it is the only competing reaction (6). Thus, if f is the fraction of monomer which electropolymerizes, then $(1 - f)$ is the fraction that forms soluble species. From eq. [6],

$$[6] \quad n_{app} = n_p f + n_s(1 + f)$$

where n_p is 2.31 and is the n value of polypyrene determined from elemental analysis, and n_s is 1.0 and is the n value for dimerization. Thus, the fraction of pyrene monomers that gives rise to polymers is 0.54; i.e., approximately half of the monomers are used in the film-forming reaction.



2. Hammett correlation and electropolymerization

The E_{pa} values of pyrene and some 1-substituted derivatives plotted against their respective substituent constants are shown in Fig. 13. As previously observed with the thiophenes (Sect. III*a*), indoles (Sect. III*c*), and fluorenes (Sect. III*e*), a linear correlation is obtained. Thus, the electrooxidation of pyrene results in the removal of a π electron, yielding a delocalized radical cation. The slope of the line is m = 0.26, which, like 1-substituted fluorenes (m = 0.18), indicates a mild substituent effect. Of the monomers shown in Fig. 13, all give rise to

TABLE 12. Cyclic voltammetric data for 2–4 μmol/cm^3 of pyrenes in 0.1 *M* TEAFB/CH_3CN

Compound	E_{pa} (monomer) (V)	$i/AC\nu^{1/2}$ (A cm s$^{1/2}$ mol^{-1} V$^{-1/2}$)	n	Polymer formation
Pyrene	1.33	2033	1.7	+
1-Chloropyrene	1.42	1900	1.6	+
1-Bromopyrene	1.41	1973	1.6	+
1-Methylpyrene	1.27	1528	1.4	+
Pyrene-1-carboxylic acid	1.45	1790	1.5	+
Pyrene-1-sulfonic acid	1.82	—	—	−

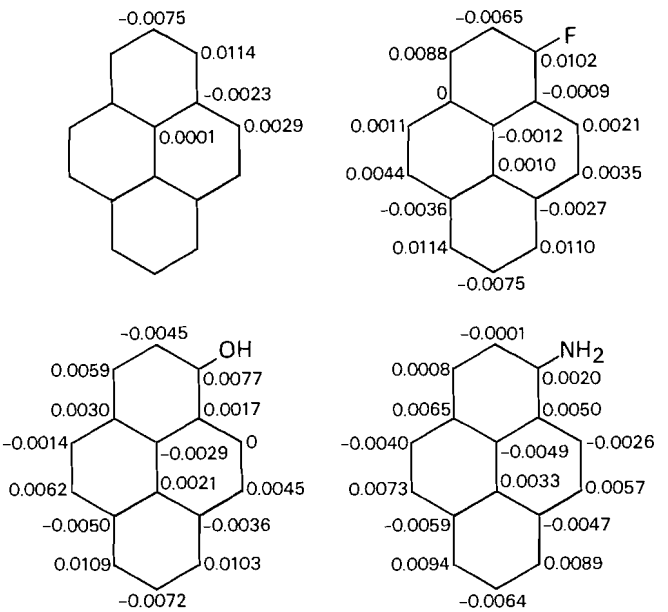

FIG. 14. Open shell INDO molecular orbital calculations of the unpaired electron density of some pyrene radical cations.

conducting polymer films. This includes the range from the electron-donating methyl group to the electron-withdrawing carboxylic acid group. Substituents outside of this range, i.e., those substituents which are either more electron donating than methyl, or more electron withdrawing than carboxylic acid, were not tested.

3. Electronic structure of pyrenes: an INDO study

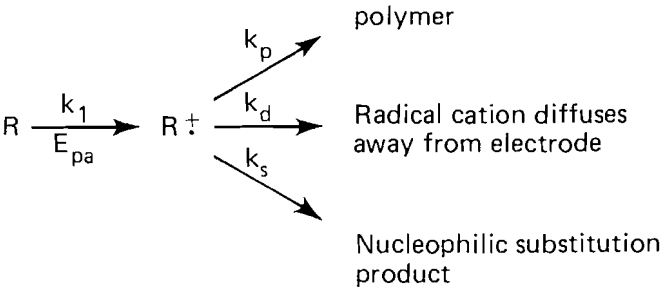
The electronic structure of the pyrene radical cation (53) is summarized in Fig. 14. An INDO (24) molecular orbital calculation reveals that the positions of highest unpaired electron density occur at the equivalent 1-, 3-, 6-, and 8-positions. The high unpaired electron densities also identify these positions as the reactive sites, suggesting that the monomer linkages in an idealized polymer structure do occur in these same positions. Thus, the first step in the electropolymerization reaction sequence (Sect. II), i.e., dimerization, produces 1,1′-bipyrene (Fig. 15). As with the monomer pyrene radical cation, the positions of highest unpaired electron density in the 1,1′-dimer occur at the 1-, 3-, 6-, and 8-positions, according to esr data (54, 55) for the 1,1′-bipyrene radical cation (Fig. 16). Thus, when 1,1′-bipyrene is electrooxidized to its radical cation, a monomer radical cation will attack the 1,1′-dimer radical cation at its unblocked 3-, 6-, or 8-positions, to produce a 1,1′:8′,1″-, 1,1′:6′,1″- and (or) 1,1′:3′,1″-trimer (Fig. 15). Extrapolation of the reactivity pattern suggests a polymer that is linked primarily via these positions, or some combination thereof.

4. Polymer composition and electrical conductivity

The elemental compositions and electrical conductivities of polypyrene and some 1-substituted polypyrenes are summarized in Table 13. These data reveal that the polymers are oxidized to the extent of 0.06–0.31 per monomer unit. Their electrical conductivities are in the range of 10^{-2}–1 S/cm, similar to the polyazulenes and polythiophenes.

IV. Substituent effects on the electropolymerization reaction: competitive kinetics

As outlined in the previous section, substituents decidedly influence the follow-up reaction, and therefore, the aptitude for the electropolymerization reaction of a molecule upon electrooxidation. They occur via a steric effect, or an electronic effect. In the latter case, the stability of the radical-cation intermediate is affected, and as shown in the scheme below, the fate of $R^{+\bullet}$ at



steady state is either to react with the polymer electrode, i.e., electropolymerization (k_p), to diffuse away from the electrode

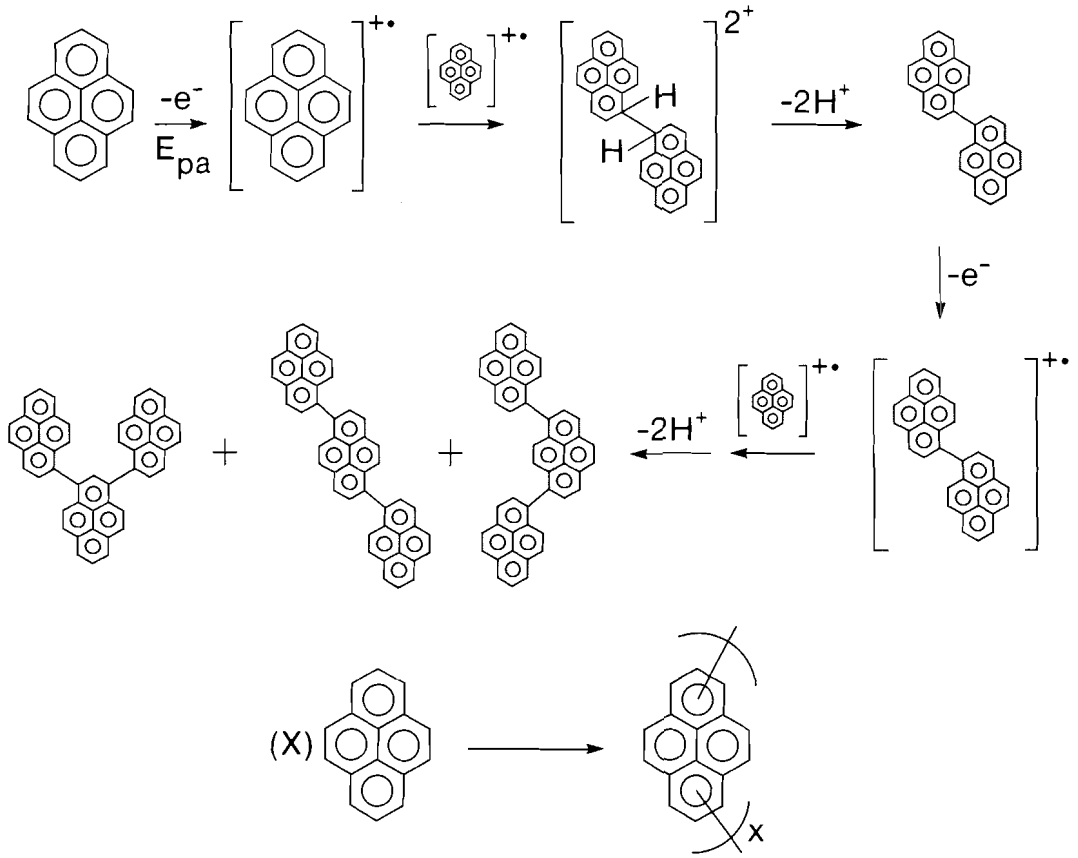


FIG. 15. A possible electropolymerization pathway for pyrene.

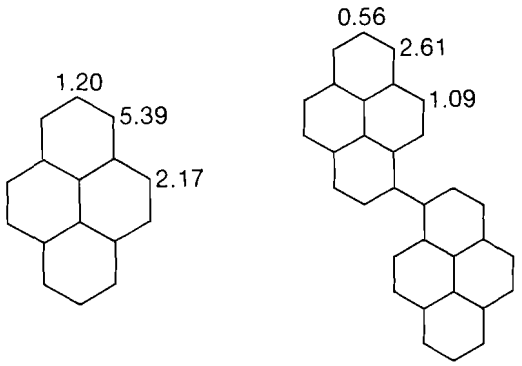

FIG. 16. Hyperfine splitting constants of pyrene and 1,1′-bipyrene radical cations according to the data of Cooper and Forbes (54).

(k_d), or to react with solvent (S) or anions (X^-) in the vicinity of the electrode surface (k_s) (4). Therefore, the fraction f_p of $R^{+\bullet}$ which undergoes electropolymerization is given by

$$[7] \quad f_p = \frac{k_p}{k_p + k_d + k_s([s] + [X^-])}$$

From eq. [7], we see that electropolymerization will occur when the stability of $R^{+\bullet}$ is such that $k_p \gg k_d + k_s([S] + [X^-])$. When the stability of $R^{+\bullet}$ is enhanced, for example by a substituent, then k_d becomes greater than $k_p + k_s([S] + [X^-])$. Under these conditions, $R^{+\bullet}$ will diffuse away from the electrode to produce soluble products. The proclivity of $R^{+\bullet}$ to undergo the electropolymerization reaction becomes reduced in favor of capture by nucleophiles or solvent. When $R^{+\bullet}$ becomes sufficiently unstable, it reacts indiscriminately with either solvent or anions and electropolymerization is suppressed. In this case, $k_s([S] + [X^-]) \gg (k_p + k_d)$. These considerations were vividly illustrated by the E_{pa}–Hammett plots of the various compounds discussed above.

TABLE 13. Elemental composition and electrical conductivity of some polypyrenes (pressed polymers)

V. Technological applications

a. Polymer electrodes

In the oxidized state, conducting polymer films such as polypyrrole (56), when supported by a Pt anode, are electrically conducting and therefore may be used as an anode to drive oxidation reactions. In particular, polypyrrole films coated onto Pt anodes, i.e., [Pt] polypyrrole electrodes, were used to investigate the redox reactions of various electroactive species dissolved in aprotic electrolyte solutions (7). Diaz *et al.* (7) found that the electrochemical data obtained from [Pt] polypyrrole electrodes compared favorably with bare Pt electrodes: the redox reactions occurred only at the electrode surface, electron transfer was rapid, and no absorption, adsorption, or reaction of the polymer electrode with the dissolved species occurred. Furthermore, modification of the polymer electrode surface by

TABLE 14. Some typical electrochromic data for a variety of polyheterocycles. Data taken from Garnier *et al.* (47)

Polymer	Anion	Oxidized form λ (nm)	Reduced form λ (nm)	Frequency response time (ms)

[b]Reference 61*c*.
[c]Reference 61*a*.

the attachment of electroactive species is facile. For example, polypyrrole films can be easily nitrated, then electrochemically reduced, followed by acylation to attach a desired group (57).

b. Electro-optical display devices

The color changes that accompany the electrochemical switching reaction, i.e., the reversible cycling between the oxidized conducting state and the neutral insulating state, suggest the applicability of electroactive polymers in passive display devices (58). In this regard, Garnier *et al.* (47, 59) have investigated the electrochromic behavior of a variety of polythiophene thin films supported by a Pt anode. Their data (59) are summarized in Table 14. The colors that are obtained depend upon both the chemical structure of the polymer and the counteranion that is incorporated into the film. The switching response times are typically 10–50 ms and are dependent on film thickness. They have concluded that a 0.1-μm film would represent the minimum thickness required to yield a sufficient color contrast on a Pt surface (59). Druy and Seymour (60) have also investigated the electrochromic behavior of polythiophene electropolymerized from the 2,2′ dimer. They report a switching response time of ~500 ms for a 0.42-μm thick film.

c. Battery applications

To our knowledge, *electrochemically* produced conducting polymers as battery electrodes have not yet been exploited to the same degree as has the chemically synthesized conducting polymer polyacetylene (61). However, polyacetylene batteries remain the prototype among batteries that are constructed using electrically conducting polymers, so the interested reader is referred to the pertinent references (61). As for electrochemically produced polymers, a preliminary account (13) utilizing polyazulene and polythiophene films, supported by a Pt surface as electrode, will be dilineated briefly and compared to the polyacetylene standard.

A simple "all-polymer" battery cell design consists of a neutral and an oxidized film of polyazulene (or of polythiophene) supported by a Pt surface, in an electrolytic solution (13). Such a cell in a closed circuit loop yields a maximum open-circuit voltage of ~2.3 V, and a maximum initial short-circuit current of ~4 mA. These data are summarized and compared with an all-polymer polyacetylene battery (61*c*) in Table 15. A typical voltage change during a constant current discharge of a polyazulene battery is shown in Fig. 17. The polyazulene batteries tested could be recharged to yield similar values in the regenerated cells, at least in the short term (13).

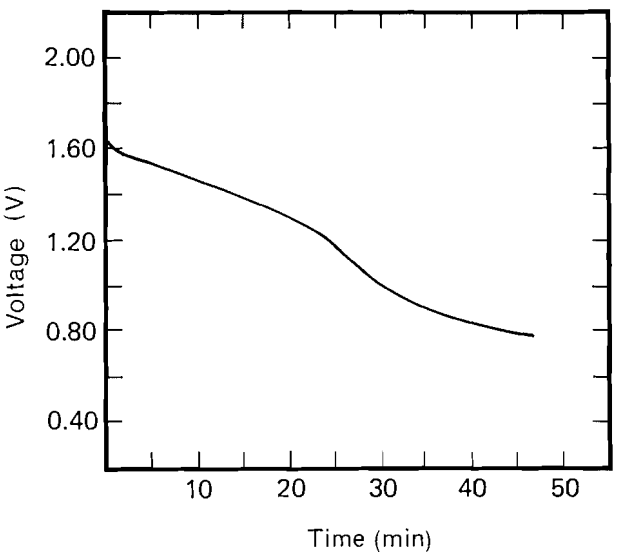

FIG. 17. A typical voltage change during 0.15-mA constant current discharge of a polyazulene battery cell.

d. Protection of semiconductor photoanodes

The proclivity of small-band-gap semiconductor photoanodes to photocorrosion in aqueous media has thwarted the development of inexpensive yet efficient photoelectrochemical cells for the conversion and storage of solar energy. Various approaches have now been undertaken in an effort to stabilize the semiconductor–electrolyte interface. They include, for example, (*a*) coating the semiconductor with thin metal films (62) or with semiconductors (63); (*b*) using nonaqueous electrolytes (64); (*c*) derivatizing the semiconductor surface itself with electroactive species (65); and (*d*) coating the semiconductor surface

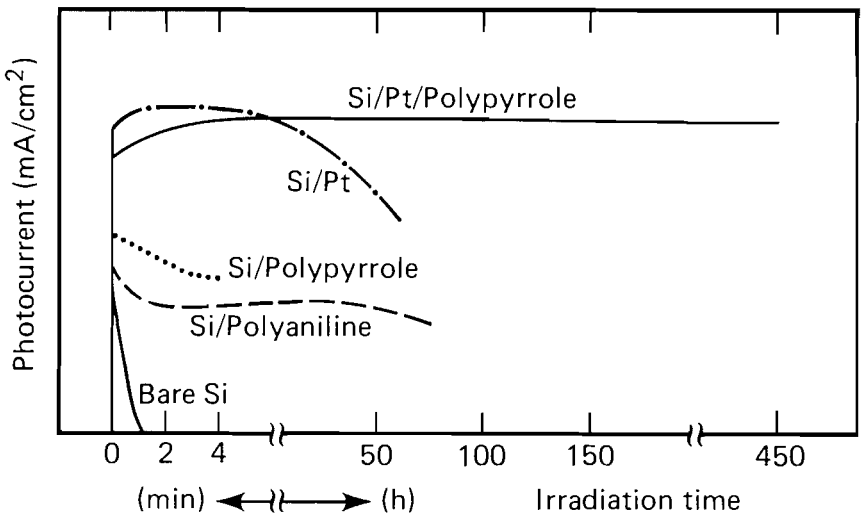

FIG. 18. A comparison of the relative stability of variously coated photoanodes. The bare Si, Si/Pt, and Si/Pt/polypyrrole photoanodes are in I^-/I_3^- electrolyte; taken from Skotheim *et al.* (66*b*). The Si/polyaniline photoanode is in a pH = 1 solution of 0.15 *M* $Fe^{2+/3+}$ and 0.1 *M* Na_2SO_4 in H_2SO_4; taken from Noufi *et al.* (68).

with electrically conducting polymers (66–71). The salient features of the latter will be summarized briefly.

The driving force for utilizing electrically conducting polymers as protective thin-film coatings on photoanodes stems from their high electrical conductivity and chemical stability (58). Thin films also have good adhesion to the Pt surface (72), although peeling off of the polymer films from the photoanodes continues to be a problem. More recently, poly-3-methylthiophene has been shown to yield improved adhesion to semiconductor photoanodes (71). Nevertheless, an electrically conducting polymer film acts as a barrier to ion/solvent transport to the photoanode surface and effectively minimizes photocorrosion for up to approximately several hundred hours, depending upon the system (66–71). Accordingly, redox reactions may be utilized to yield optimum open-circuit voltages with improved stability of the photoelectrochemical cell (68). Thus far, polypyrrole has been the film of choice primarily because of its high electrical conductivity, and because other electrochemically generated conducting polymers have not been available until more recently (Table 1). The stabilization to corrosion imparted by a polypyrrole (PP) film on n-Si is shown as an illustrative example in Fig. 18, taken from the data of Skotheim *et al.* (66*b*), and from Noufi *et al.* (68). The lifetime and photocurrent output of a Si/PP photoelectrode is improved over a bare Si photoelectrode; however, a Si/Pt/PP photoelectrode shows the greatest longevity with a lifetime of ~450 h and with no loss in photocurrent output. A thin metal-coated photoelectrode (Si/Pt) and a polyaniline-coated Si photoelectrode (68) are also shown for comparison (Fig. 18). It is also noteworthy that the performance characteristics of the polymer-coated photoanodes are comparable to those of the bare photoelectrodes (66–71).

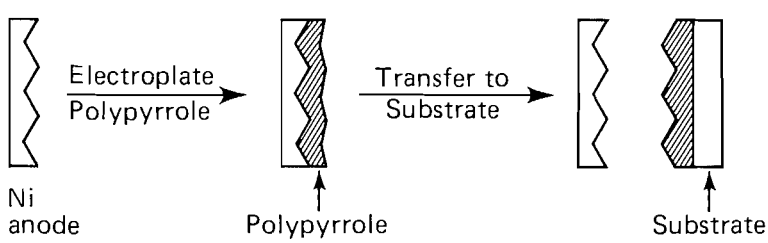
e. Information storage

In a novel application exploiting the high electrical conductivity of polypyrrole, Meyer *et al.* (73) have explored the possibility of its use for high-density information storage (74). As shown in the scheme below, adapted from Meyer *et al.* (73), polypyrrole is electrochemically grown onto an anode with a surface relief pattern. Polypyrrole is then peeled off and made to adhere to a solid substrate, leaving exposed the inverse surface relief pattern of the anode. The high electrical conductivity of polypyrrole may then be utilized for information storage as long as the information is stored as a relief pattern on the polymer film surface. The information is accessed by reading it capacitively with an electrode (73). Subsequent testing of this material in a video disk machine, as a disk of 210-mm diameter and supported by a substrate, revealed a virtually defect-free material of constant signal-to-noise ratio over the entire information containing disk; i.e., a high degree of surface relief replication with no distortion of information was achieved. Furthermore, because the decrease in conductivity of polypyrrole occurs over long periods (i.e., years), Meyer *et al.* (73) anticipate no problems associated with the readability of the information even after years of storage.

f. Other applications

The increasing usage of home-electronics products, coupled with an increasing density of electronic circuitry on chips, has presented problems with electromagnetic interference (EMI) previously unforeseen (75). In this regard, conductive plastics (9) may find use as shielding materials to prevent the passing of electromagnetic signals into the airwaves (75).

When polypyrrole is exposed to ammonia, its resistivity



increases. Lundström and co-workers (76) have prepared polypyrrole–paper composites, which can be used as sensitive ammonia detectors. When exposed to ammonia, the change in electrical conductivity of polypyrrole is related to the concentration of ammonia in air.

The search for electrode materials that extract metallic cations from solutions and interfaces has prompted Le Berre *et al.* (77, 78) to electrochemically synthesize electrically conducting polymers from macrocyclic ligands such as crown ethers. For example, thin films of poly(dibenzo-24-crown-8)-BF_4 supported by a Pt anode can be cycled reversibly from its oxidized, conducting state to its neutral, insulating state with no apparent loss of electroactivity, as long as the polymer is not electrochemically driven beyond its first oxidation state. The dicationic state is reported to be rather sensitive to the presence of nucleophiles, such that electroactivity becomes lost (77).

Intrinsic selectivity and its geometric significance in S_N2 reactions

SASON S. SHAIK
Department of Chemistry, Ben Gurion University, Beer Sheva 84105, Israel
Received July 8, 1985

SASON S. SHAIK. Can. J. Chem. **64**, 96 (1986).

An intrinsic selectivity is defined for identity S_N2 reactions ($X^- + RX \rightarrow XR + X^-$). This selectivity parameter is shown to yield information about: (*a*) the average looseness of the TS geometry in a reaction series; and (*b*) the sensitivity of the reaction series to geometric loosening.

SASON S. SHAIK. Can. J. Chem. **64**, 96 (1986).

On définit une sélectivité intrinsèque pour les réactions S_N2 d'identité ($X^- + RX \rightarrow XR + X^-$). On démontre que ce paramètre de sélectivité fournit de l'information concernant: (*a*) l'état de relachement de la géométrie de l'ET dans une série de réactions; et (*b*) la sensibilité des séries de réactions à des relachements géométriques.

[Traduit par le journal]

Ever since Leffler's proposal (1) that the Brønsted parameter can serve as a measure of transition state (TS) structure, there has existed an ongoing debate regarding the significance of selectivity parameters (2). The key question is, what kind of TS information is provided by selectivity measurements? To begin answering that, one must start with the fundamental reaction, *the identity exchange*. This work defines the *intrinsic selectivity* of identity S_N2 reactions (eq. [1]) and shows that such selectivity experiments may lead to geometric information about the *looseness* of the TS and the "flexibility" of its C···X bonds.

[1] $X:^- + R—X \rightarrow X—R + :X^-$

The reaction profile for an identity S_N2 reaction (3) is shown in Fig. 1. The reaction barrier follows eq. [2] where f is a

[2] $\Delta E^{\ddagger} = f(I_{X:} - A_{RX}) - B$

steepness variable that derives from the curvature of the intersecting curves. Whenever the curves descend steeply from the upper states towards the crossing point, the f-factor will be *small*, and vice versa when the descent is shallow (3, 4). The $I_{X:} - A_{RX}$ term is the vertical electron transfer energy from $X:^-$ to RX under the reaction conditions (gas phase (3*a*,*c*) or solution (3*b*)). The B factor is the crossing avoidance interaction which appears to be approximately constant for various X's (3*b*,*c*, 5).

Figure 2 shows a structure–reactivity plot using eq. [2]. The ensemble of reactions is predicted to fall into families such that the members ($X:^-/RX$) of each family share a common f-factor (6). In each family line the barriers increase in proportion to $I_{X:} - A_{RX}$ and the line slope is the characteristic f of the reaction family. The f-factor defines then the intrinsic selectivity (IS) of a reaction family as specified in eq. [3]:

[3] $$\text{IS} = f = \frac{\partial(\Delta E^{\ddagger})}{\partial(I_{X:} - A_{RX})}$$

The physical property that determines f has been shown (3*a*,*b*, 4) to derive from the delocalization properties of the substrate's radical anion $(R\text{—}\dot{X})^-$, which is described in eq. [4] in valence bond terms:

[4] $(R\text{—}\dot{X})^- = W_{X:}(R\cdot\ :X^-) + W_{R:}(R:^-\ \cdot X);\ W_{R:} + W_{X:} = 1$

Whenever the weight ($W_{R:}$) of $R:^-\cdot X$ is large, the odd electron of $(R\text{—}\dot{X})^-$ is delocalized away from the R union center. In such a case, the bond coupling interaction between X· and $(R\text{—}\dot{X})^-$ will become weak and the $X\cdot/(R\text{—}\dot{X})^-$ ⇝ $(X\text{—}R)/:X^-$ correlation lines will possess a shallow descent towards the crossing point in Fig. 1 (4). This will result in a large f, in eqs. [2] and [3], and hence also in a large intrinsic selectivity (IS). The IS of an identity-reaction family can then be reexpressed as in eq. [5] in terms of the $W_{R:}$ property.

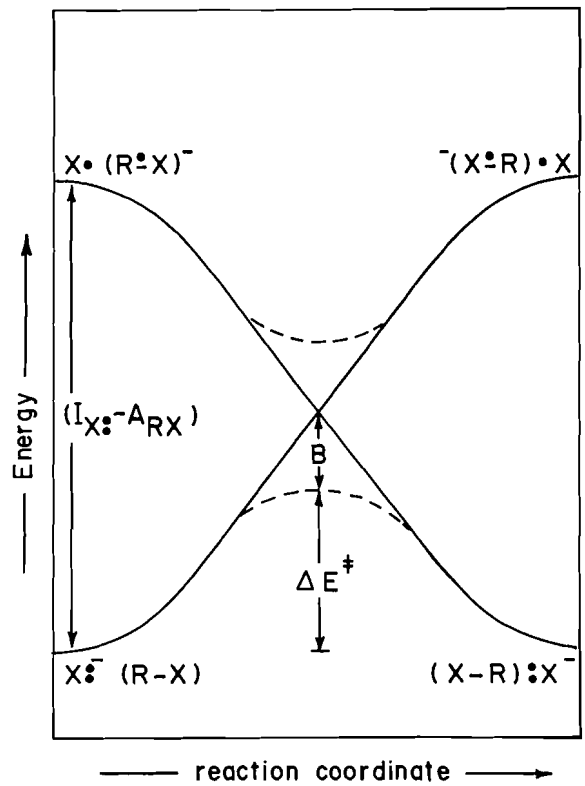

FIG. 1. State correlation diagram for identity S_N2 reactions. The two ends of the reaction coordinate represent the geometries of the encounter ion–molecule complexes. In reactions in solutions all the states are solvated (ref. 3*b*). The avoided crossing is shown by dashes near the intersection point. $\Delta E^{\ddagger}$ is the resulting reaction barrier.

[5] $$\text{IS} = f = \frac{\partial(\Delta E^{\ddagger})}{\partial(I_{X:} - A_{RX})} \propto W_{R:}$$

Collected in Table 1 are $W_{R:}$ indices and barriers for a few identity reactions that have been investigated experimentally and computationally (7, 8). As may be seen, the halide exchange reactions in entries 1–4 have smaller $W_{R:}$ values than

TABLE 1. $W_{R:}$ indices and barriers ($\Delta E^{\ddagger}$) for identity reactions $X^- + CH_3X \rightarrow XCH_3 + X^-$ in the gas phase and in solutions

		$W_{R:}$[a,b]			$\Delta E^{\ddagger}$ (kcal/mol)

[a] $W_{R:}$ is defined in eq. [4].
[b] The values are taken from ref. 3*b*. Note that in ref. 3*b* the symbol (b^2) is used for the $W_{R:}$ index.
[c] Calculated as described in refs. 3*b*,*c*, 4, 6*b*.
[d] Data from ref. 8.
[e] $\Delta G^{\ddagger}$ data from ref. 7*a*.
[f] $\Delta G^{\ddagger}$ datum from ref. 7*b*.
[g] $\Delta G^{\ddagger}$ datum from ref. 7*c* for ethanol as a solvent.

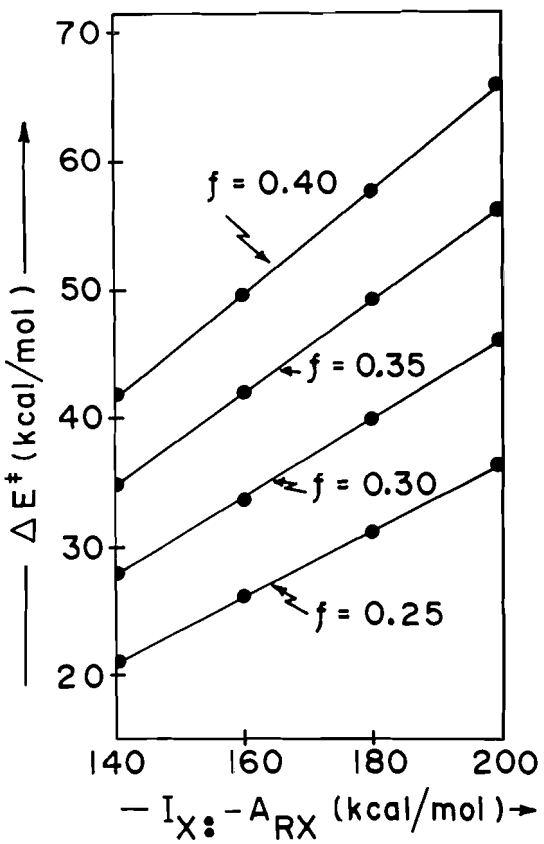

FIG. 2. Structure–reactivity plots of barriers ($\Delta E^{\ddagger}$) vs. vertical electron transfer energies ($I_{X:} - A_{RX}$) using eq. [2] (B = 14 kcal/mol, see ref. 3). Note that the slopes of the family lines are equal to the corresponding *f*-factors.

the exchange reactions of PhS^-, HS^-, HO^-, and NC^-. In accord with eq. [5], the halide exchange series is predicted to possess *a lower intrinsic selectivity* than the exchange series of PhS^-, HS^-, HO^-, and NC^-, in either the gas phase or in solution. Figure 3 is a plot of the experimental $\Delta G^{\ddagger}$ values (7) against the corresponding vertical electron transfer energies (3*b*) for the aqueous solution identity reactions that are collected in Table 1. The experimental data set is seen to obey the above prediction and to behave as the theoretical plots in Fig. 2. While it is clear from Fig. 3 that the two families exhibit different intrinsic selectivities, the question remains whether one can associate any property of the TS with such experimental IS parameters?

Consider then the geometric looseness (L) of the TS as defined (5), in eq. [6], by the fraction of C—X bond stretching

$$[6] \quad \Delta d^{\ddagger}/d^0 = L = (d^{\ddagger}_{CX} - d^0_{CX})/d^0_{CX}$$

in the TS relative to the bond length in the R—X molecule (d^0_{CX}). In previous publications (5, 6*b*) it was demonstrated that TS looseness correlates with the height of the barrier since both properties derive primarily from the C—X stretching deformation (5) that is required to achieve the crossing in Fig. 1.[1] Thus, looseness in a series of identity reactions is a result of the extent of C—X stretching that overcomes the $I_{X:} - A_{RX}$ energy gap and achieves a transition state at the crossing point of $X:^-/(R—X)$ and $X\cdot/(R\cdot\!\!-X)^-$ in Fig. 1. Large $I_{X:} - A_{RX}$ gaps and delocalization indices ($W_{R:}$) will require a greater C—X deformation and will thereby lead to looser transition state geometries (5). Since barriers and transition state geometries behave alike, it follows then that the intrinsic selectivity that derives from plots of barriers $\Delta E^{\ddagger}$ vs. ($I_{X:} - A_{RX}$) may serve as an indicator of transition state geometry.

Reliable geometric data for the identity reactions of X^- = NC^-, HO^-, HS^-, F^-, Cl^- is available from the *ab initio* studies of Wolfe *et al.* (8). These data are plotted in Fig. 4 against the natural logarithm of the gas phase electron transfer energies, $I_{X:} - A_{RX}$ (3*b*).[2] The looseness of the transition state is seen to

[1] This means that high barriers are associated with a high R—X stretching deformation and, hence, also loose TS geometries. See ref. 5 for a detailed treatment of this correlation. Such a correlation exists because the energy requried to dissociate the TS into three fragments ($X:^- + \dot{C}H_3 + X$) is given by $\Delta E_{dis} = D_{C—X} - \Delta E^{\ddagger}$ where D is the C—X bond energy (ref. 6*b*). Thus, the larger the $\Delta E^{\ddagger}$, the closer the TS to its dissociation limit.

[2] A line for the halide exchange transition states of X^- = F^-, Cl^-, and Br^- can be generated from MNDO geometries (ref. 9). The looseness varies in the order $F^- > Cl^- > Br^-$. The slope of the line, $\Delta d^{\ddagger}/d^0$ vs. ($I_{X:} - A_{RX}$), is 0.127 with 0.995 correlation coefficient. The looseness varies in proportion to the calculated barrier heights.

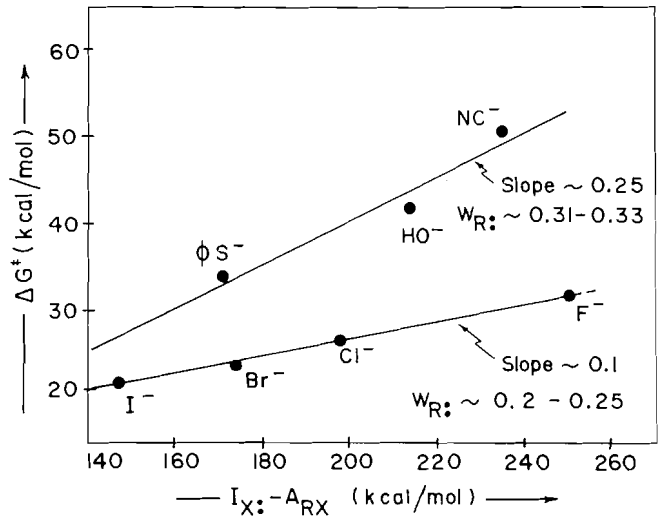

FIG. 3. Plots of experimental free energies of activation (ref. 7) against vertical electron transfer energies (ref. 3*b*) for aqueous solution identity reactions $X^- + CH_3X \rightarrow XCH_3 + X^-$. The X's are indicated alongside the family lines.

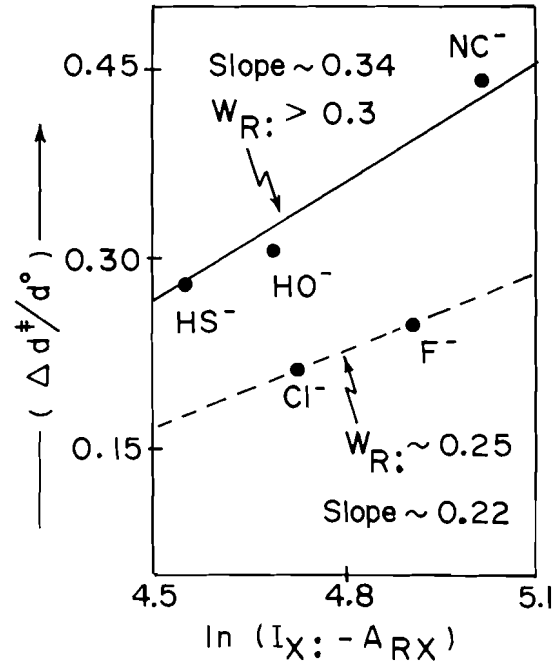

FIG. 4. Plots of the computed $\Delta d^{\ddagger}/d^0$ indices (ref. 5) against the vertical electron transfer energies (ref. 3*b*) for gas phase identity reactions $X^- + CH_3X \rightarrow XCH_3 + X^-$. The d^0 value refers to the C—X bond length of CH_3X in the ion–dipole encounter complex. The correlation coefficient for the upper solid line is 0.992. The lower dashed line is a two-point straight line that is used to indicate the separation of the two families (see, however, footnote 2).

increase in the following order of $X^- = NC^- > HO^- > HS^- > F^- > Cl^-$.[2] This is also the order of the corresponding barriers in the gas phase (or in solution), so that the loosest transition state, $(CN\cdots CH_3\cdots CN)^-$, belongs to the reaction with the highest barrier (see Table 1).[2] This correlation (5, 6*b*, 10) provides a basis for attaching a geometric significance to the intrinsic selectivity parameter (IS) that derives from plots of barriers $\Delta E^{\ddagger}$ vs. $(I_{X:} - A_{RX})$. Such a significance is projected in Fig. 4, which shows that the identity reactions fall into two families that differ in their $W_{R:}$ indices. The larger the $W_{R:}$ index of the reaction series, the looser the *average* transition state of the series. Thus, the exchange reactions of HS^-, HO^-, and NC^-, which are characterized by a large $W_{R:}$ index, possess on the average looser transition state geometries than the halide exchange reactions, which are characterized by a smaller $W_{R:}$ index. Since the IS parameter varies in proportion to $W_{R:}$ (eq. [5], Fig. 3), the intrinsic selectivity of a reaction series is associated then with the average transition state looseness in the series: *the higher the IS parameter, the looser, on the average, the transition states in the reaction series.*

A solvent is expected to effect only small changes in the looseness of transition states (6*b*, 10, 11) of the type $(X\cdots CH_3\cdots X)^-$.[3] Therefore the foregoing conclusion will carry over to the corresponding reactions in solutions. In general then, the curve-crossing model predicts that *an identity reaction series that possesses high intrinsic selectivity, IS, will exhibit, on the average, high intrinsic barriers and loose transition state geometries.* It follows that, both in the gas phase and in solution (Fig. 3), the *less* selective series of the halide exchange reactions will possess, on the average, *tighter* transition states than the more selective series of $X^- = NC^-$, HO^-, PhS^- (and (or) HS^-). Furthermore, both the intrinsic selectivity and the average transition state looseness will correlate with the average height of the intrinsic barriers in the corresponding series. These conclusions regarding the looseness of the transition states and the correlation of barriers and looseness in the two reaction series are in disagreement with previous conclusions of Albery and Kreevoy (7*a*).[4]

The geometric significance of the intrinsic selectivity (IS) parameter may be somewhat refined by inspecting Fig. 4. Having different slopes, the two lines[2] in the figure will theoretically intersect at $I_{X:} - A_{RX} \approx 41$ kcal/mol. This means that, *theoretically*, two reactions that belong to families having different IS parameters *may* possess the same degree of transition state looseness. This is the reason why the IS parameter can be strictly associated *only* with the *average* degree of looseness in a reaction series. There may then exist a more basic transition state property that is probed by the IS parameter. As shown in the following discussion, this property is the sensitivity of the reaction series to bond loosening in the transition state, $(X\cdots CH_3\cdots X)^-$, as a result of varying X.

The looseness of the transition state is a result of the C—X

[3]An extreme hydration (solvation by H_2O) is a complete proton transfer by the solvent (stabilization relative to the unprotonated TS by >100 kcal/mol). But even such extreme "solvation" does not seem to change the looseness of the TS significantly. Thus, $(H_2N\cdots CH_3\cdots NH_2)^-$ (supplementary material of ref. 8) differs by 4.5% in looseness in comparison with the doubly protonated TS $(H_3N\cdots CH_3\cdots NH_3)^+$ (ref. 12). The same difference is observed for the free molecules $CH_3—NH_2$ vs. $CH_3—NH_3^+$ (refs. 8, 12). Similar data exist for $(HO\cdots CH_3\cdots OH)^-$ vs. $(H_2O\cdots CH_3\cdots OH_2)^+$ (ref. 8 vs. ref. 13) and $CH_3—OH$ vs. $CH_3—OH_2^+$ (ref. 8 vs. ref. 14). Thus the $(X\cdots CH_3\cdots X)^-$ transition states appear to possess strong covalent bonds much like $CH_3—X$ molecules. The solvent will not change significantly the looseness of such transition states. For detailed thermochemical arguments, see refs. 6*b* and 10, while for isotope effect evidence see ref. 11.

[4]See refs. 5 and 6*b* for comparisons with the conclusions of the three-dimensional potential energy surface diagram model.

stretching deformation that is required to achieve a transition state (5) at the crossing point of Fig. 1. In accord, the looseness has been shown (10) to fit the approximate expression in eq. [7] where G is a constant, in energy units, for a reaction series (X^-/RX) that is typified by a constant $W_{R:}$. This equation is

$$[7] \quad (\Delta d^{\ddagger}/d^0) = L \approx {}_{/R:} \ln\left(\frac{I_{X:} - A_{RX}}{G}\right)$$

seen to mimic the trends in Fig. 4 such that in each series the looseness of the transition state increases as the electron transfer energy gap $I_{X:} - A_{RX}$ increases.[2] The change in TS looseness, which is brought about by varying X in the series, is proportional then to $W_{R:}$ as expressed in eq. [8].

$$[8] \quad \frac{\partial L}{\partial[\ln (I_{X:} - A_{RX})]} \approx W_{R:}$$

Thus a reaction series that possesses large $W_{R:}$ will experience great TS loosening or tightening effects as X is varied. In accord, the exchange series of $X^- = NC^-, HO^-, HS^-$ (and (or) PhS^-) is expected to exhibit a greater rate of variation in transition state looseness in comparison with the exchange series of $X^- = F^-, Cl^-, Br^-$, and I^-.

As can be seen from eqs. [5] and [8], both the barriers and the looseness of the transition state vary in proportion to $W_{R:}$ and, therefore, a somewhat stricter definition of IS can be formulated. Thus, intrinsic selectivity parameters, which derive from plots of $\Delta E^{\ddagger}$ vs. $(I_{X:} - A_{RX})$, measure not only the average looseness of the transition state, but also the sensitivity of the reaction series to geometric loosening as X is varied. It follows that a series of identity reactions that possesses a high IS parameter will then be characterized, *on the average*, by high intrinsic barriers and loose transition states. The looseness in such a series will be more sensitive to changes of X than a series that is characterized by low IS. This correlation of transition state properties derives from the notion (5, 6*b*, 10) that both barriers and transition state geometries result from the C—X stretching deformation required to overcome the $I_{X:} - A_{RX}$ gap and to achieve a transition state, $(X\cdots CH_3\cdots X)^-$, at the crossing point of Fig. 1.

Other identity reaction series can be generated by varying X. Intrinsic selectivity parameters can then be measured and coupled with isotope effect[5] measurements to test the predictions of this work. Once the physical significance of the intrinsic selectivity is unravelled, there may then exist a basis from which to understand the physical nature of selectivity parameters in nonidentity reactions.

[5]Some caution is warranted regarding isotope effect mesurements, since ion–dipole complexes $X^-\cdots CH_3X$ may exist in aprotic solvents (ref. 15). The observed isotope effect will consist then of an equilibrium isotope effect for complex formation and a kinetic contribution (ref. 15). See also concentration dependence of isotope effects in ref. 16.

The effect of substituents on the electrochemical oxidation potentials of 1,1,2,2-tetraphenylcyclopropane and 1,1,3,3-tetraphenylpropenyl radical

DANIAL D. M. WAYNER[1] AND DONALD R. ARNOLD[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 11, 1985[3]

DANIAL D. M. WAYNER and DONALD R. ARNOLD. Can. J. Chem. **64**, 100 (1986).

The effects of multiple substitution by methoxy and cyano in the 4-position(s) of 1,1,2,2-tetraphenylcyclopropane (**1**) and 1,1,3,3-tetraphenylpropenyl radical (**2**$^{\bullet}$) on the oxidation potentials have been measured. The results indicate that the oxidation process for the cyclopropanes (**1***a–m*) is irreversible. Nevertheless, the substituent effect on the potential is essentially additive and correlates reasonably well with $\Sigma\sigma^+$. A slow electron transfer process (an overall conversion of **1** to $\mathbf{2}^+$), with a transition state resembling the ring-opened radical cation, is consistent with these observations. The oxidation of the radical **2**$^{\bullet}$ is quasi-reversible in dichloromethane. In this case also, the substituent effect on the oxidation potential is additive and correlates with $\Sigma\sigma^+$. Any deviation from planarity of **2**$^{\bullet}$ is not sufficient to prevent substituents from exerting normal (additive) behaviour.

DANIAL D. M. WAYNER et DONALD R. ARNOLD. Can. J. Chem. **64**, 100 (1986).

On a mesuré les variations des potentiels d'oxydation du tétraphényl-1,1,2,2 cyclopropane (**1**) et du radical tétraphényl-1,1,3,3 propényle (**2**$^{\bullet}$) portant des substituants méthoxy et cyano en position 4. Les résultats indiquent que l'oxydation est irréversible dans le cas des cyclopropanes (**1***a–m*). Cependant, l'effet du substituant sur l'oxydation est essentiellement additif et cet effet est en bonne corrélation avec la valeur de $\Sigma\sigma^+$. Ces observations suggèrent un processus de transfert d'électron (une transformation globale de **1** en $\mathbf{2}^+$), qui est lent et qui implique un état de transition s'apparentant au cation radicalaire à chaîne ouverte. Dans le cas du radical **2**$^{\bullet}$, l'oxydation est quasi réversible dans le dichlorométhane. Dans ce cas, également, le substituant a un effet additif sur l'oxydation et cet effet est en accord avec la valeur de $\Sigma\sigma^+$. Les déviations de la planéité du composé **2**$^{\bullet}$ ne suffisent pas à contrecarrer l'effet normal (additif) des substituants.

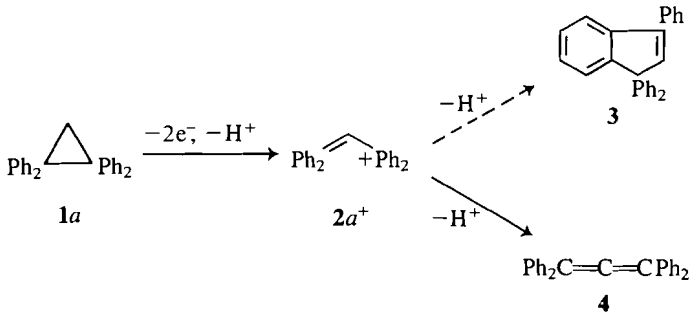
Introduction

The electrochemical oxidation of 1,1,2,2-tetraphenylcyclopropane (**1***a*) has been shown to lead to the formation of the 1,1,3,3-tetraphenylpropenyl cation ($\mathbf{2}a^+$) in acetonitrile and dichloromethane (1). This carbocation subsequently cyclizes to form 1,3,3-triphenylindene (**3**) or deprotonates to give tetraphenylallene (**4**), depending on the basicity of the medium (Scheme 1). The photosensitized (electron transfer) reactions of **1***a* involve the same intermediate ($\mathbf{2}a^+$). In this case, the ratio of **3** to **4** depends on the choice of sensitizer for the reaction (2).

Both of these reactions undoubtedly involve the 1,3-radical cation as the first intermediate. 1,3-Radical cations have not been well characterized. Because of the stabilizing effect of the tetraphenyl substitution, we had hoped to obtain some direct evidence for the involvement of this species during the electrochemical oxidation of **1***a*. Radical cations are generally more stable in dichloromethane than in acetonitrile (3), but even in this solvent, at sweep rates as high as 20 V s^{-1}, no evidence for a single one-electron transfer was obtained (2).

The homologous 1,2-radical cations are more easily studied. The effect of substitution on the electrochemical oxidation of tetraphenylethylene (**5**) is particularly interesting in this regard. It has been observed, by Bard and Phelps, that tetrakis(4-*N*,*N*-dimethylaminophenyl)ethylene undergoes a two-electron reversible oxidation while tetraanisylethylene is oxidized in two closely spaced one-electron steps (4). Furthermore, the anodic oxidation of the unsubstituted tetraphenylethylene occurs in two one-electron steps that are even further apart (5). Presumably, electron-donating substituents on the tetraphenylethylene decrease the potential of the second electron transfer step so that only one two-electron wave is observed in these cases. By analogy, it was anticipated that substitution with electron-withdrawing substituents on **1** would separate the two one-electron transfer steps. It was found, in fact, that the cyclic voltammogram of 1,1,2,2-tetra(4-cyanophenyl)cyclopropane (**1***i*) does exhibit two closely spaced waves of approximately equal peak currents (1).



SCHEME 1

The purpose of this paper is to report the details of the effect of substitution on the electrochemical oxidation potential of **1**. Combinations of cyano and methoxy substitutions were used in order to study the additivity of the substituent effects in these species. The preparation (and thermal isomerization) of these compounds has already been described (6).

The consequent formation of the allylic cation $\mathbf{2}^+$ from the oxidation of **1** provides a convenient opportunity to study the substituent effects on the reduction potentials of these intermediates. This potential, of course, corresponds to the oxida-

tion potential of the radical **2**·. Possible mechanistic implications also are considered.

Results

The oxidation potentials of **1***a–m* are listed in Table 1. All of the oxidations are irreversible with $E_p - E_{p/2}$ ranging from 130 to 230 mV. A plot of E_p versus $\Sigma\sigma^+$ gives a linear correlation with a slope of 217 ± 17 mV, an intercept of 1.38 ± 0.02 V, and a correlation coefficient of 0.956 (Fig. 1).

[a]Measured by cyclic voltammetry at a sweep rate of 400 mV s^{-1}.
[b]The stereochemical designation represents that of the tetraphenylcyclopropane precursor.
[c]Versus SCE.
[d]$E_{1/2} \approx E^0$ (ref. 14).

The reduction potentials of **2***a–m*$^+$ are given in Table 2. All of these reductions are quasi-reversible with a separation of $E_{p_a} - E_{p_c}$ between 70 and 90 mV. The plot of $E_{1/2}$ versus $\Sigma\sigma^+$ has a slope of 193 ± 12 mV and an intercept of 0.37 ± 0.01 V with a correlation coefficient of 0.982 (Fig. 2).

Discussion

The Hammett equation for electrochemical reactions (ref. 7, eq. [1]) is often used to describe the effect of varying electron

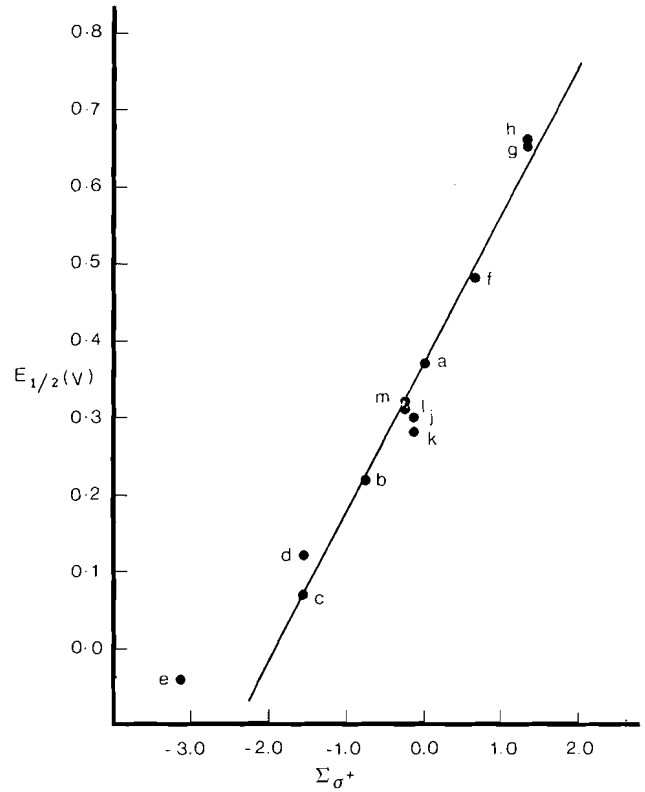

FIG. 2. The oxidation potentials ($E_{1/2}$) of the 1,1,3,3-tetraphenylpropenyl radicals (**2***a–m*$^{\bullet}$) versus $\Sigma\sigma^+$. (σ^+: OCH_3, −0.78; CN, 0.66).

demand at the reactive centre on the equilibrium constants (E^0) for a series of structurally related compounds. In general, these plots have slopes in the range 0.1–0.8 V (8). While this relationship is thermodynamically significant for reversible electrode processes, for irreversible processes the analysis is not straightforward.

[1] $E_{1/2} = (RT/nF)\rho\sigma$

Analysis of the oxidation of **1***a–m* by the Hammett approach gives a best-fit line with a slope of 217 mV and with a correlation coefficient of 0.956 (Fig. 1). The oxidation potential of **1***e*, which falls well off the line, was not included in this correlation. Including this point has a significant effect on the correlation coefficient (0.927 in this case) and the slope of the best-fit line decreases markedly, to 185 mV. The reason why the oxidation potential of this derivative falls off the line is not obvious but it may represent a saturation in terms of the substituent effect on the oxidation of **1**, or a change in the mechanism for the anodic process. In all cases only one anodic wave is observed.

There has been some controversy over the ability of a cyclopropyl ring to transmit electronic effects (9). It is in fact surprising to find that the oxidation potentials of **1***a–m* correlate as well as they do with $\Sigma\sigma^+$. If the electron is removed from a molecular orbital that is essentially localized on an aromatic ring, then substitution at another ring should not have a large effect on the oxidation potential, and certainly not an additive effect. The oxidation of **1***c*, however, is the same as that of **1***d*; similarly, the oxidation potentials of **1***h* and **1***g* are close. It is interesting that the oxidation potential of **1***j* is close to that of **1***k*. However, **1***m* is significantly easier to oxidize than **1***l*. In the latter case, the difference may be attributed to merostabilization in the radical ion. This effect has been used to explain the observed variation in reduction potentials of 4,4′-disubstituted benzophenones (10) and the oxidation (and reduction) potentials of tetraarylethylenes (11). However, the effect of merostabilization in the 4-methoxy, 4′-cyano substituted diphenylmethyl moiety is not large (only 3 kcal mol^{-1}). Furthermore, the observed oxidation potential of **1***j* (and **2***j*$^+$ and **2***m*$^+$, Table 2) is not anomalous.

The cyclopropane ring will be distorted in the 1,3-radical cation. Theoretical estimates of the length of the 1,2-bond in the radical cation of 1,2-divinylcyclopropane give a value of more than 1.9 Å (12). Thermochemical estimates of the strength of the one-electron, two-centre bond in **1***a*$^{\bullet+}$ give a value of only 5–8 kcal mol^{-1} (2). For the oxidation of **1**, the additivity of the substituent effect is undoubtedly derived from the interaction of all of the aryl rings in this ring-opened species, which interact through the vacant and half-filled *p*-orbitals. The idea of this product-like transition state is compatible with a slow electron transfer step (i.e. the electrochemical irreversibility).

Shono and Matsumura have measured the half-wave oxidation potentials of some 4-substituted arylcyclopropanes (13). In their work, a slope of 730 mV was obtained from the Hammett plot of $E_{1/2}$ versus σ^+. The slope of the best-fit line from the Hammett plot for **1***a–m* would be expected to be about one-fourth of the slope obtained for these monoarylcyclopropanes if the transition states (i.e. α) are similar. One-fourth of the slope reported by Shono and Matsumura is 183 mV. The observed slope of 217 mV obtained from **1***a–m* is close to this value. However, the limited number of substituents used in both studies makes further comparison difficult.

There are some interesting comparisons to be made with the oxidation potentials reported for the homologous tetraarylethylenes (**5**) (11). In this previous report the variation in the oxidation potential of several 4-methyl, 4-cyano, and 4-methoxy derivatives of **5** were correlated with $\Sigma\sigma^+$. The deviation of 1,2-di(4-methoxyphenyl)-1,2-di(4-cyanophenyl)-ethylene (**5***m*) from the best-fit line was attributed to merostabilization of the intermediate radical cation. We notice now, however, that there are some inconsistencies with this interpretation. For the oxidation (and reduction) of **5**, those compounds that show reversible electrochemical behavior form one line while those that show irreversible behavior fall on another line; all of the irreversible potentials show a positive deviation from the line formed by plotting the reversible potentials. This is to be expected since the deviation represents an increasing activation energy or, in electrochemical terminology, an increasing overpotential for oxidation. (Similarly, a negative deviation is observed for the reduction potential, indicating that there is an overpotential associated with the irreversible reduction.) The correlation of the overpotentials with $\Sigma\sigma^+$ is not a surprise since the overpotentials are related to the activation energy for the heterogeneous electron transfer. The oxidation (and reduction) of **5***m* is reversible. This point, in fact, lies on the line defined by the reversible oxidation potentials. These electrode processes probably involve the transfer of two electrons; thus, the effect of merostabilization *should not be observed* since the radical cation will not exist as a discrete intermediate.

It is interesting that the slope of the best-fit line for the irreversible oxidation potentials of **5** is 190 mV, which compares well with the 217 mV found for the oxidation potentials of **1**. (The slope of the line through those points corresponding to the reversible oxidation of **5** is 110 mV.) In the case of **1***m* the deviation *may* be attributed to merostabilization since the irreversible oxidation represents the barrier to the transfer of the first electron. However, the scatter of the points near $\Sigma\sigma^+ = 0$ as

well as the absence of the effect on the oxidation of $\mathbf{2}^{\bullet}$ preclude definitive conclusions from being drawn.

The electrochemical oxidation of **1***a* leads to the formation of $\mathbf{2}a^{+}$ (1, 2). A quasi-reversible wave in dichloromethane for the reduction of $\mathbf{2}a$–m^{+} is observed from the cathodic sweep in the cyclic voltammogram. In all cases, the reduction of $\mathbf{2}a^{+}$ is chemically reversible. Therefore, although the system is not electrochemically reversible, the value of E^{0} must lie between E_{p_a} −30 mV and E_{p_c} +30 mV (14). Analysis of the reduction potentials of $\mathbf{2}a$–m^{+} by the Hammett approach gives a slope of 193 mV with a correlation coefficient of 0.982 (Fig. 2). As was the case with **1***e*, the reduction potential of $\mathbf{2}e^{+}$ does not fall on the line. If this point is included in the correlation, the slope of the Hammett plot decreases to 163 mV, and the correlation coefficient decreases significantly (r = 0.966). The esr spectrum of $\mathbf{2}a^{\bullet}$ has been observed; it is a well-resolved spectrum of over 200 lines (15). In this study the radical (as well as the corresponding anion) was assumed to have a conformation in which two of the phenyl rings were in the plane of the propenyl π-system and the other two phenyl rings were parallel to each other but perpendicular to the propenyl π-system. If this were the case, additivity of the substituent effects would be unlikely since the heterogenous electron transfer process is fast and therefore cannot be preceded by, or concurrent with, aryl ring rotation. The additivity of substituent effects in, for example, the reduction of $\mathbf{2}c^{+}$ and $\mathbf{2}d^{+}$, $\mathbf{2}g^{+}$ and $\mathbf{2}h^{+}$, and the other pairs that have the same number and type of substituents indicates that a more reasonable conformation is one in which all of the rings are twisted in a propeller-like conformation. Otherwise, the effect of preferential rotation of, for example, the 4-cyanophenyl rings in $\mathbf{2}g^{+}$ out of the plane should be observed. A similar propeller-like conformation was reported for the tetraanisylethylene radical cation ($5e^{\bullet+}$) in which the rings were estimated to be twisted by about 30° (16).

It is interesting that the slope of the Hammett plot of the oxidation potentials of $\mathbf{2}a$–$m^{\bullet}$ is about the same as the slope from the plot of the oxidation potentials of **1***a*–*m*. In fact, a plot of E_p of **1** versus $E_{1/2}$ of **2** gives a slope of 1.09 ± 0.15, an intercept of 0.98 ± 0.06 V, and a correlation coefficient of 0.967. This, again, supports the suggestion that at the transition state for oxidation of **1**, all four aryl rings can interact with the developing charge.

Experimental

The synthesis and spectral characterization of **1***a*–*m* have been described previously (6, 17). Tetrabutylammonium perchlorate (TBAP) was obtained from Fisher Scientific Company, recrystallized three times from 95% ethanol, and dried in a vacuum oven (12 h at 80°C, 10 Torr (1 Torr = 133.3 Pa)). Dichloromethane (Fisher) was distilled from P_2O_5 and stored over 4A molecular sieves. The electrochemical cell and apparatus have been described previously (2). Typically, concentrations of 0.001 *M* (**1**) were used in a total cell volume of 10 mL. A sweep rate of 400 mV s^{-1} was used for all measurements.

A systematic study of reductions of unsymmetrically substituted maleic anhydrides by a variety of metal hydride reagents indicates that the high regioselectivity observed in these reactions is controlled chiefly by electronic factors.

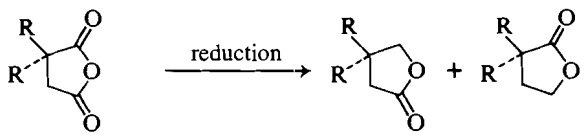
MARGARET M. KAYSER, LIVAIN BREAU, SONIA ELIEV, PETER MORAND et H. S. IP. Can. J. Chem. **64**, 104 (1986).

Une étude systématique de la réduction d'anhydrides maléiques substitués d'une façon non symétrique, par divers hydrures métalliques, indique que la régiosélectivité observée au cours de ces réactions est contrôlée principalement par des facteurs électroniques.

[Traduit par le journal]

There is continuing interest in reductions of unsymmetrical cyclic anhydrides to the corresponding lactones (1), and much effort has gone into the study of the mechanism of these reactions and into the development of methods permitting the selective reduction of one or the other carbonyl group to obtain the desired lactone (2).

The reductions of unsymmetrically substituted succinic anhydride **1** by simple metal hydrides ($NaBH_4$ and $LiAlH_4$) yield as the principal product lactone **2**, resulting from reduction of the more hindered carbonyl function (1). However, when selectrides (Aldrich Catalog No. 19, 987-7, 21-340-3, 22-076-0) are used as reducing agents, the major product of the reaction is lactone **3** (3).



1 **2** **3**

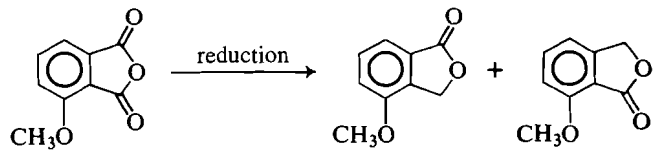
R = CH_3 or C_6H_5

These results have been rationalized in terms of steric effects in the following manner (4). The interaction between the substituent R, protruding above the plane of the carbonyl function, and the highly hindered selectride reagent is strong enough to offset other effects usually implicated in the regioselectivity control (5).

In the case of planar, unsymmetrical anhydrides such as phthalic **4** or maleic anhydride **7**, the substituent is located in the plane of the carbonyl function; thus, the steric interaction between the incoming reagent and the substituent should be minimal.

However, a recent study (6) on reductions of 3-methoxyphthalic anhydride **4** has shown that, while $NaBH_4$ reduction yields a mixture of two lactones in approximately 1:1 ratio, the selectride reduction produces mostly lactone **6**.

Knight and Pattenden (7) examined the regioselectivity of reductions of 2-methoxy-3-methyl and 2-methoxy-3-phenyl maleic anhydrides, *7a* and *7b*, by $LiAlH_4$ and lithium tri-*tert*-butoxyaluminum hydride (LITBAL). The only products obtained in these reductions resulted from hydride attack at the carbonyl function adjacent to the methoxy group (**8** and **9**).



4 **5** **6**

On the basis of (*i*) *ab initio* calculations for the complexation of methoxymaleic anhydride *7c* with a counterion (5), and (*ii*) the fact that the activation of a carbonyl function by a cation appears necessary for the reaction to occur (8), we have concluded that the regioselectivity observed in reductions of methoxymaleic anhydrides is due principally to the chelation of the methoxy group and the adjacent carbonyl function by the counterion (5).

In view of the above results, the methoxy substituent appears to be a key element in directing reduction to the adjacent carbonyl function in methoxymaleic anhydrides, but sterically prevents reduction of the neighbouring carbonyl function in 3-methoxyphthalic anhydride **4**. Such puzzling results and conflicting interpretations have prompted us to undertake a systematic study of the relative importance of chelating versus steric effects in reductions of planar cyclic anhydrides. The substituted methoxymaleic anhydrides were chosen as suitable models for this investigation, since chelating and electronic

effects of the methoxy substituent in position 2 could be consistently confronted with the steric effect of the substituent in position 3 of methoxymaleic anhydride molecule **7**. At the same time an insight into the steric influence of methyl (and phenyl) substituent(s) could be gained from a parallel study of reductions of methyl (and phenyl) maleic anhydrides.

Results

All model compounds were prepared via short synthetic routes. 2-Methoxy-3-phenylmaleic anhydride *7a* was synthesized by condensation of phenylacetonitrile with diethyloxalate, followed by methylation and acid hydrolysis (7). 2-Methoxy-3-methylmaleic anhydride *7b* was prepared by a slightly modified synthetic sequence first reported by Schreiber (9). The condensation between ethylpropionate and diethyloxalate in the presence of sodium ethoxide, generated *in situ*, gave ethyl β-methyloxalacetate, which was subsequently methylated with dimethylsulfate–K_2CO_3 to the diester **11**. Basic hydrolysis of **11** gave 2-methoxy-3-methylmaleic anhydride *7b* (eq. [1]).

Methyoxymaleic anhydride *7c* was prepared from tartaric acid **12** in a three-step synthetic sequence. In the first step tartaric acid **12**, on treatment with acetic anhydride and sulfuric acid, was converted to diacetyltartaric anhydride **13** (10). The anhydride **13** reacted with pyridine and glacial acetic acid to give the pyridinium salt of hydroxymaleic anhydride **14** (11), which was subsequently methylated with diazomethane to methoxymaleic anhydride *7c* (eq. [2]). This sequence gives an excellent overall yield of methoxymaleic anhydride.

The three substrates *7a*, *7b*, and *7c* were reduced with simple metal hydrides ($LiAlH_4$) and ($NaBH_4$) and with bulky selectride reagents (L-, Na-, and K-selectrides). The crude products were analyzed by proton nmr and gc/ms before purification. The results are listed in Table 1.

TABLE 1. Metal hydride reductions of methoxymaleic anhydrides

Compound	Reducing agent	Product ratio* 8 : 9
7a	$NaBH_4$	83 17
	LAH	25 75
	L-sel	17 83
	K-sel	30 70
7b	$NaBH_4$	80 20
	LAH	30 70
	L-sel	10 90
	K-sel	10 90
7c	$NaBH_4$	100
	LAH	100
	L-sel	100
	K-sel	100

*Product ratios were obtained from the analysis of nmr spectra of crude reaction products.

In all reactions, regardless of counterion present (Li^+, Na^+, K^+) or the nature of the nucleophile (compact or bulky), the products obtained were the result of hydride transfer to the carbonyl function adjacent to the methoxy substituent. We could not detect the isomeric lactone **10**, or the corresponding lactol, in either crude or purified products.

Citraconic (methylmaleic) anhydride **20** was reduced with several reducing agents under various conditions of concentration and temperature. The results are shown in Table 2. Several attempts to reduce phenylmaleic anhydride with selectride reagents gave no indication as to selectivity of this compound since the first step in the reduction appears to be hydride transfer

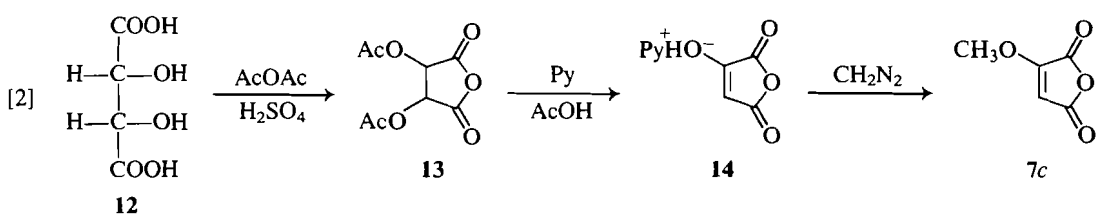

TABLE 2. Reductions of methylmaleic anyhydride **20**

*Reduction 100% means that no starting anhydride or diacid could be detected in the nmr spectrum of the crude product.

†Lactonic ratio α:β was established from the nmr spectra of the crude reduction products by comparing the signals for hydrogen attached to a double bond, δ 5.85 (α) vs. 7.15 (β), and methyl groups CH_3, δ 2.10 (α) vs. 1.95 (β).

‡Diacid recovered.

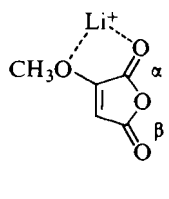
to a carbon–carbon double bond. The subsequent reduction of phenyl succinic anhydride gives a mixture of two phenyl butyrolactones.

Discussion

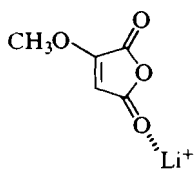
The role of a methoxy substituent in controlling regioselectivity of hydride transfer can be double in nature: (*1*) the formation of chelate (5), which activates the implicated carbonyl group α toward hydride transfer; (*2*) the promotion of enolization, which deactivates the carbonyl group β (13). Since both effects were discussed elsewhere (5, 13), we shall present here only a brief resumé.

The *ab initio* calculations for methoxymaleic anhydride – Li^+ complex have shown that the preferred binding site for the cation is the "bridged position", **15**, corresponding to the strong overlap between the cation and the lone pairs on the two oxygen atoms (5).

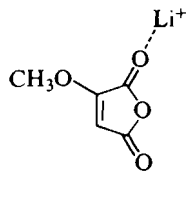
Chelate **15** is energetically favoured over the alternate structure **16** by 6 kcal mol^{-1} and over **17** by 10 kcal mol^{-1}.



15



16

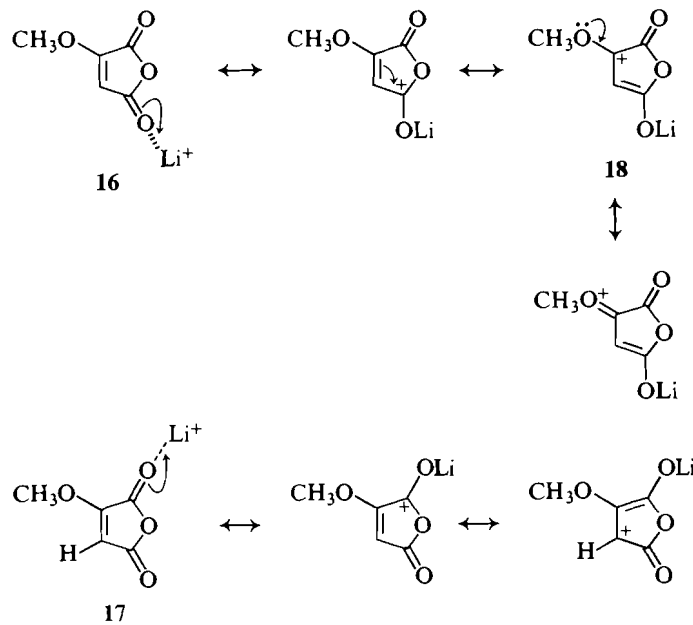


17

E (kcal mol^{-1}) −10 −4 0

Since association with a cation activates carbonyl function toward nucleophilic addition, the preferentially formed complex **15** is reduced selectively at the α-carbonyl group. Of the two remaining isomeric complexes, **16** is more stable than **17** by 4 kcal mol^{-1}. From the energy viewpoint **16** is the more likely candidate for reduction. However, the same effect that stabilizes complex **16** also diminishes reactivity of the carbonyl function β.

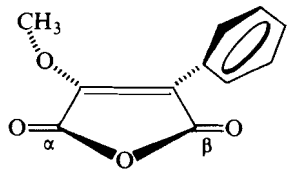
It is apparent from examination of the canonical forms of the complexes **16** and **17** that the stabilization of **16** is due to the π-electron donating capacity of the methoxy substituent **18**. For the same reason, **16** possesses a higher degree of enolate



16 **18** **17**

character and, since enolized carbonyl groups resist reduction by metal hydrides (14), the complex **15** is reduced in preference to **16**. The observed selectivity is a net result of these two effects.

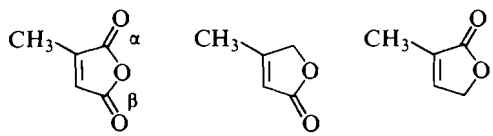
Steric effects, if any, are clearly less important. Evidently, the results of reductions of **7***a* and **7***b* could be interpreted in terms of steric control in the follow manner. The methyl substituent occupies "more space" in the immediate vicinity of the carbonyl function (β) than the methoxy group occupies in the immediate vicinity of the carbonyl function (α). Similarly, the phenyl group, which may assume a position perpendicular to the plane of the anhydride ring as shown in **19**, is more sterically important than the methoxy substituent. Thus, both the methyl and phenyl groups could, in theory, hinder the approach of a nucleophile, particularly a bulky selectride, toward the neighbouring carbonyl function more effectively than the methoxy group. However, if steric effects alone were involved, we would expect reversed regioselectivity in reductions of the unsubstituted methoxymaleic anhydride **7***c*, where steric com-



19

petition is between the methoxy group and the hydrogen atom. This, of course, is not the case; the regioselectivity in the reduction of **7***c* follows the pattern observed in reductions of other methoxymaleic anhydrides. In all the reductions studied only the lactone **9***c* was obtained and we were unable to detect any evidence of the isomeric lactone **10***c* in the crude reaction product.

The results obtained from reductions of methylmaleic anhydride suggest that the steric effect of a methyl substituent situated in the plane of the anhydride ring is only marginal (see Table 2). In a preliminary communication (4) on selectride reductions we have reported that, while $NaBH_4$ reduction of methylmaleic anhydride **20** gave mostly lactone **21**, the reduction with K-selectride yielded lactone **22** as the principal product. Systematic study of methylmaleic anhydride reductions with a variety of metal hydrides, under different reaction conditions (Table 2), has shown that the preliminary results were incorrect. The error was most likely due to the selective loss of the lactone **21** during work-up and distillation. In the present study we have examined, by proton nmr and gc/ms, the crude reaction products before attempting isolation and purification of the lactones. The results show that in all cases preferential reduction occurs at the carbonyl function next to the methyl group. The highest proportion (25–30%) of the alternate lactone **22** was obtained in the reduction of **20** by L-selectride, carried out at room temperature.

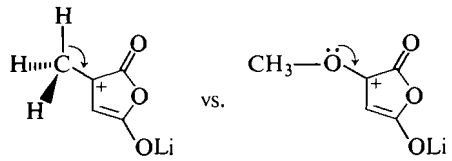


20 **21** **22**

Under the usual reaction conditions (temperature $-78°C \rightarrow -30°C$) the product distribution ratio is only marginally affected by the size of the nucleophile, which suggests that the steric effect is feeble.

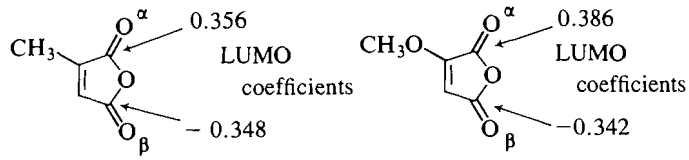
What does affect regioselectivity of these reductions, if the steric effect is ruled out, chelation is not applicable, and the stabilization of the enolate **23** is weak in comparison to the stabilization of enol **18**?

The *ab initio* calculations performed for the "naked" methylmaleic anhydride (**24**) show a small difference in the magnitude of the LUMO coefficients on the carbon atoms of the two carbonyl groups. We should point out that this difference is



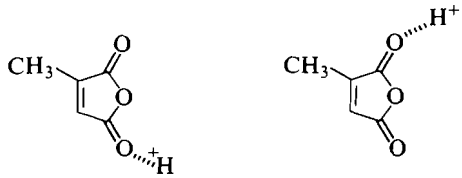
23 **18**

considerably larger in methoxymaleic anhydride, **25**. Since the size of the LUMO coefficient correlates well with the reactivity of a carbonyl function toward a nucleophile, these results indicate that the carbonyl group adjacent to the methyl substituent is intrinsically more reactive than the β-carbonyl group and is attacked preferentially even by a sterically demanding selectride reagent. These considerations are supported by the *ab initio* calculations (Gaussian 70 program with a minimal STO-3G basis set) (16). The study of protonation of methylmaleic anhydride[4] indicates that the association of H^+ with the β



24 **25**

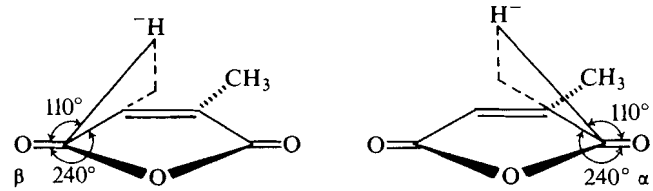
carbonyl group is favoured by 3.0 kcal mol^{-1} (**26**, **27**) which confirms the slight stabilizing effect of methyl substituent as illustrated in **23**. The calculations also show that the H^- attack should occur preferentially at the α-carbonyl group, **28** and **29**.



26 **27**

E (kcal mol^{-1}) −3 0

For both structures **28** and **29**, the optimal position for hydride attack, at the distance of 2 Å, was found to be above the double bond and at the angle of 110° to the plane of the carbonyl group. We did not optimize the position of H^- attacking the carbonyl group – H^+ complex. The calculations carried out for perpendicular attack showed slight, but consistent, preference



28 **29**

E (kcal mol^{-1}) 0 −7.5

for the α-attack. Hence, the intuitive interpretation of the experimental results in terms of electronic effects is supported by *ab initio* calculation.

Conclusion

The present studies indicate that the regioselectivity of metal hydride reductions of substituted maleic anhydrides is only marginally affected by steric congestion. The principal factors controlling regioselectivity of these reactions appear to be electronic in nature. These effects seem to be the following: (*1*) intrinsic reactivity of the carbonyl group adjacent to phenyl, methyl, or methoxy substituent; (*2*) activation of the carbonyl function next to the methoxy substituent by chelation with a counterion; (*3*) deactivation of the carbonyl function capable of forming (by electron-releasing substituent) stabilized enolate.

[4]The geometry for the parent maleic anhydride was obtained from the crystallographic data (17*a*). For the methyl substituted maleic anhydride, standard bond lengths and bond angles were used (17*b*).

Experimental

Proton and ^{13}C nmr spectra were recorded on a Varian HA-100 spectrometer in $CDCl_3$ or $(CD_3)_2CO$ as solvent and TMS as internal standard. The gc/ms spectra were obtained on a VG mass spectrometer with a DANI 7070 gas chromatograph, and infrared spectra on a Beckman TR-20 instrument.

The general procedure for the reactions with $LiAlH_4$ and $NaBH_4$ is described in ref. 15. The selectride reductions were carried out as follows: an anhydride (0.003 mol) was dissolved in dry, freshly distilled THF (100 mL). The mixture, flushed with a constant slow stream of dry N_2, was cooled in a Dry Ice – acetone bath. Li-, Na- or K-selectride (1 *M* in THF, 10 mL) was injected slowly into the reaction flask. The reaction was stirred for 2 h while the temperature was allowed to rise slowly to −30 or −20°C. At that time NaOH (4 *N*, 2 mL) and 30% H_2O_2 (3 mL) were added and stirring was continued overnight. The reaction mixture was acidified with 6 *N* HCl, reduced on a rotatory evaporator, and extracted several times with chloroform and diethyl ether. The combined organic layers were evaporated to dryness.

2-Methoxy-3-phenylmaleic anhydride, 7a

Condensation of phenylacetonitrile with diethyloxalate in the presence of sodium hydride (50% oil dispersion) gave ethyl (3-cyano-3-phenyl) pyruvate: mp 129–130°C (18); proton nmr δ ($CDCl_3$): 1.40 (t, 3H), 4.40 (q, 2H), 7.25–7.50 (m, 3H), 7.60–7.80 (m, 2H). Methylation of the pyruvate with dimethyl sulfate – K_2CO_3 gave ethyl (3-cyano-2-methoxy) cinnamate; proton nmr δ ($CDCl_3$): 1.40 (t, 3H), 3.8 (s, 3H), 4.43 (q, 2H), 7.30–7.50 (m, 3H), 7.60–7.80 (m, 2H). The hydrolysis in concentrated HCl/glacial acetic acid gave anhydride **7***a* as pale needles (yield 80%); ν_{max} (KBr): 1835, 1765, and 1635 cm^{-1}; proton nmr δ ($CDCl_3$): 4.30 (s, 3H), 7.35–7.50 (m, 3H), 7.85–8.00 (m, 2H). These results are in agreement with the data reported in the literature (7).

Reductions of 2-methoxy-3-phenylmaleic anhydride, 7a

Reductions carried out according to the general procedures gave 80–90% isolated yields of reduced products (**8***a* and **9***a*). Crude products were analyzed by proton nmr. Separation by chromatography in hexane–ether (1:4) gave 4-hydroxy-3-methoxy-2-phenylbut-2-enolide **8***a*: mp 132–134°C; ν_{mas} (KBr): 3280, 1715, and 1650 cm^{-1}; proton nmr δ ($(CD_3)_2CO$): 4.16 (s, 3H), 6.35 (s, 1H), 7.20–7.55 (m, 3H), 7.80–8.05 (m, 2H); and 3-methoxy-2-phenylbut-2-enolide **9***a*: mp 123–124°C; ν_{max} (KBr): 1745, 1645 cm^{-1}; proton nmr δ ($(CD_3)_2CO$): 4.15 (s, 3H), 5.15 (s, 2H), 7.26–7.45 (m, 3H), 7.85–8.12 (m, 2H).

2-Methoxy-3-methylmaleic anhydride, 7b

Under the continuous flow of N_2, sodium hydride (60% suspension in oil, 61.0 g) was washed with two portions of hexane and one of dry diethyl ether. After decanting solvents, a fresh diethyl ether (800 mL) was added. Absolute ethanol was added dropwise until evolution of H_2 ceased. The reaction mixture was cooled on an ice bath. Diethyl oxalate (209.0 g) followed by ethyl propionate (130.0 g) wre added to the stirred mixture. The reaction mixture was refluxed for 2 h 45 min, then cooled, diluted with ice water, and acidified with 6 *N* HCl to pH 2. The mixture was extracted with three 500-mL portions of ether. The combined organic layers were dried over $CaCl_2$ and reduced on a rotatory evaporator. Vacuum distillation of the residue gave β-methyl-oxalacetic ester (1.0 Torr (133.3 Pa), 85–95°C, 157 g, 63% yield). The ester was methylated with dimethyl sulfate – K_2CO_3 according to the procedure described by Knight and Pattenden (7). The resulting diethyl ether **11** (20.0 g) was refluxed for 2 h with 4 *N* KOH (100 mL). After cooling, the mixture was acidified with 6 *N* HCl and extracted with five 100-mL portions of ether. Ethereal extracts were dried over anhydrous $MgSO_4$ and the solvent was removed. The product obtained gave ir and nmr spectra identical to those described in the literature (8): mp 40–42°C; ν_{max} ($CHCl_3$): 1875, 1775, and 1675 cm^{-1}; proton nmr δ ($CDCl_3$): 4.25 (OCH_3), 2.10 (CH_3). The yield was 71%.

Reduction of 2-methoxy-3-methylmaleic anhydride, 7b

The reductions of **7***b* according to the general procedures gave 75–80% yields of isolated reduced products. Crude products were analyzed by proton nmr. Separation on thick-layer chromatography gave 5-hydroxy-4-methoxy-3-methyl-furan-2(5*H*)-one, **8***b*: mp 93°C (crystallized from benzene); ν_{max}: 3315, 1750, 1733, 1686 cm^{-1}; proton nmr δ ($CDCl_3$): 1.79 (s, 3H), 4.07 (s, 3H), 5.96 (C*H*OH), 6.2 (OH); and 4-methoxy-3-methyl-furan-2(5*H*)-one, **9***a*: ν_{max} (KBr): 1740 and 1665 cm^{-1}; proton nmr δ ($CDCl_3$): 1.75 (m, 3H), 3.97 (s, 3H), 4.67 (m, CH_2). The spectral data are identical with those described in the literature (19).

Methoxymaleic anhydride, 7c

Tartaric acid (103 g) was placed in a round-bottom flask, to which freshly distilled acetic anhydride (220 mL) and concentrated H_2SO_4 (6 mL) were added slowly. The mixture was stirred until all solid was dissolved. The solution was warmed and refluxed briefly (20 min). White crystalline diacetyltartaric anhydride precipitated on cooling. It was filtered, washed with cold dry ether, and dried. The yield of pure product was 118 g. Diacetyltartaric anhydride (26.0 g) was placed in a flask containing dry acetone (40 mL) and heated gently until dissolved. The solution was cooled in an ice bath to 10°C and dry pyridine (18 mL) was added with stirring. After a few minutes the colour of the reaction mixure changed from colourless to yellow-green. Glacial acetic acid (14 mL) was added in one portion with vigorous stirring to the mixture cooled below 10°C. The mixture was left overnight in a refrigerator. Pyridinium salt crystallized as fine, brown needles. It was filtered and washed with ice-cold *dry* diethylether (yield 15.2 g). The alcohol-free diazomethane (2.0 mg in 150 mL of dry ether) was added to a dry THF (200 mL) solution of the pyridinium salt (3.69 g). The solution was allowed to react for 30 min at 0°C. Then $AlCl_3$ (0.95 g) dissolved in dry ether (30 mL) was added. The reaction mixture was stirred for 1 h at room temperature. The white, flaky precipitate was removed by filtration. The organic solvents were removed and the product distilled at reduced pressure (0.5 Torr, 111°C) (ref. 12). The yield of **7***c* was 2.45 g, 100%; ν_{max} ($CHCl_3$): 1860, 1775, and 1645 cm^{-1}; proton nmr δ ($CDCl_3$): 4.05 (s, 3H), 5.75 (s, H); ms: M^+ 128, $M^+ - 44$, 84.

Reductions of methoxymaleic anhydride, 7c

Reductions carried out according to the general procedures gave only the lactonic product **9***c*. The isolated yields varied between 60 and 94%. In general the best yields were obtained with $LiAlH_4$, the poorest with $NaBH_4$. The selectride reductions produced **9***c* in 70–85% yields; **9***c*: ν_{max} ($CHCl_3$): 1785, 1745, and 1640 cm^{-1}; proton nmr δ ($CDCl_3$): 3.92 (s, 3H), 4.55 (s, 2H), 5.05 (s, 1H), ms: M^+ 114, 85, 69, 56.

Reductions of methylmaleic anhydride, 15

Reductions were carried out according to the general procedures. The variations in time and temperature as well as the yields and ratios of lactonic products obtained are shown in Table 2. Lactone **15***a*: proton nmr δ ($CDCl_3$): 2.14 (CH_3), 4.73 (d, CH_2—O), 5.87 (m, 1H); ms: M^+ 98. Lactone **15***b*: proton nmr δ ($CDCl_3$): 1.95 (CH_3), 4.77 (1, CH_2O), 7.15 (q, 1H); ms: M^+ 98.

B. Belleau, U. Gulini, R. Camicioli, B. J. Gour-Salin, and G. Sauvé. Can. J. Chem. **64**, 110 (1986).

The total synthesis of the position-17 sulfur analogs of the perchlorate salts of the morphinans, (±)-levorphanol and (±)-isolevorphanol via 4a-(2-aminoethyl)-1,2,3,4,4a,9-hexahydro-6-methoxyphenanthrene, a key intermediate in the synthesis of butorphanol (**4**), is described. 2D-Correlation and heterocorrelation nuclear magnetic resonance spectroscopy confirmed the configurational relationship of the isosteres.

B. Belleau, U. Gulini, R. Camicioli, B. J. Gour-Salin et G. Sauvé. Can. J. Chem. **64**, 110 (1986).

On décrit la synthèse totale des analogues portant un atome de soufre en position 17 des perchlorates des morphinanes, (±)-lévorphanol et (±)-isolévorphanol; ces synthèses se font par l'intermédiaire du (amino-2 éthyl)-4a hexahydro-1,2,3,4,4a,9 méthoxy-6 phénanthrène, un intermédiaire clé dans la synthèse du butorphanol (**4**). La rmn, corrélation 2D et hétérocorrélation, a permis de confirmer les relations configurationnelles des isostères.

[Traduit par le journal]

Introduction

In a previous publication (1) a rationale was presented that ascribes a fundamental role to the directionality of the nitrogen lone pair of morphinan-like structures in a stereocontrolled proton transfer process at the opiate receptor level. Structure–activity relationship studies (2) led to the conclusion that sulfonium salt analogs of well-known opiates like levorphanol and isolevorphanol **1***a,b* would help clarify the separate roles of ion pairing and hydrogen bond complex formation (as in a proton transfer complex) at the key counter anionic site level of the receptor. The key structural feature deserving exploitation here centers on the fact that the sulfonium ion cannot carry a proton-like tertiary amine, so that its incorporation as a substitute for the basic nitrogen of an opiate such as levorphanol should yield useful information about the role of the nitrogen lone pair (and its attached proton) in productive interactions with the receptors. In order that an unambiguous answer to this question may be secured, it is essential that the receptor probe engages in a unique mode of binding, as is the case for morphinan-like structures whose enantiomers are discriminated against in an absolute manner by the receptor binding sites, hence our choice of the levorphanol and isolevorphanol geometries as the patterns for the generation of sulfonium isosteres. In a preceding article (1), we described the synthesis of the sulfonium analog of isolevorphanol (isosulforphanol **3***a*) using a strategy patterned after that of Grewe and Mondon for the generation of morphinans (3). As it turned out, this strategy as applied to analogous sulphur-containing, non-nitrogenous intermediates led exclusively to the isomorphinan geometry (*trans* B/C fusion **3***a*) rather than the morphinan stereochemistry **2***a*, the usual well-known outcome of the Grewe process. The structure of the isosulforphanol **3***a* thus obtained (as well as that of an unexpected by-product) was established by single crystal X-ray analysis (1). It became obvious then that a different synthetic strategy had to be conceived in order to generate the isomeric sulforphanol analog **2***a* (*cis* B/C fusion). It is the purpose of this communication to describe such a selective but bifurcate strategy, allowing as well for an alternative and efficient synthesis of the already described isosulforphanol analog **3***a*.

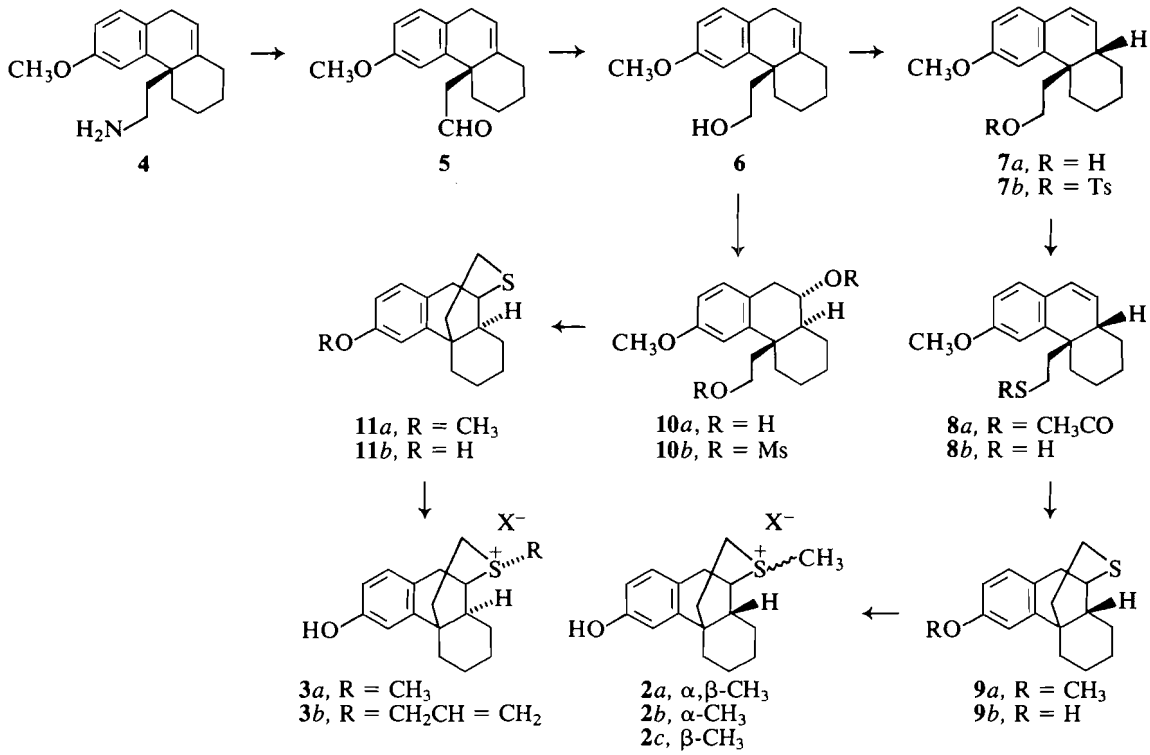
1*b*

The synthetic strategies leading to **2** and **3** are outlined in Scheme 1. The starting material **4** is the key intermediate in the commercial synthesis of butorphanol (4), and we endeavored to replace its amine function by a hydroxyl group that could then be transformed into a thiol group. In principle, a more direct approach to this transformation would involve reaction with a pyridinium intermediate with a suitable thiolate anion, a sequence based on Katritzky's method (5). Although the requisite 2,4,6-triphenylpyridinium intermediate could be easily obtained from **4**, all attempts at reacting it with a variety of relevant nucleophiles (thioacetate, thioxanthate, thiourea, acetate, iodide) failed to give any of the desired products (aromatization of ring B being the major event). In a parallel fashion all attempts at diazotization of **4** and its *N*-acetyl or 3,5-dinitrodibenzoyl derivatives (6) failed to yield any of the corresponding alcohol **6** or its esters. We thus turned our attention to a transamination process, with the hope of generating aldehyde intermediate **5**. Attempts to extrapolate the recently developed method of Buckley and Rapoport (7) to amine **4** using a 4-formyl-1-methyl pyridinium salt led to disappointing results, only very small yields of aldehyde **5** being formed. However, the use of excess ninhydrin under controlled conditions led to the desired aldehyde **5** in acceptable yields. Its structure was readily confirmed by spectroscopic methods and by borohydride reduction in high yield to the corresponding alcohol intermediate **6**. Access to this key intermediate provided an opportunity to develop an im-



SCHEME 1

proved process for the production of the isosulforphanol **3** previously synthesized (1). Thus hydroboration of **6** in the expected *anti*-Markovnikov fashion (8), followed by peroxide oxidation, produced diol **10***a* exclusively, as judged by nmr spectroscopy. The corresponding bis-mesylate **10***b* was readily obtained; this, upon treatment with sodium sulfide, led in good yield to the isosulforphan derivative **11***a*, which was identical in every respect with an authentic specimen. It was transformed into the isosulforphanol **3***a* as previously reported (1), and into **3***b* by reaction with allyl bromide (the structure of **3***a* having been established by single crystal X-ray analysis). Attention was then turned to the generation of the sulforphanol stereochemistry as in **9** (*cis* B/C fusion). We have previously shown (9) that angularly substituted hexahydrophenanthrenes analogous to **6** can be isomerized stereospecifically to conjugated forms like **7** to yield exclusively the product of β-face protonation at the B/C ring junction, thus allowing for the smooth generation of the desired *cis* fusion of the two rings. Intermediate **6** was therefore treated with potassium *tert*-butoxide in DMSO (9), whereupon **7***a* was obtained in good yield as judged on the basis of its nmr characteristics (distinct olefinic protons and expected coupling constant for a bridgehead proton). It was converted to the tosylate, which upon treatment with potassium thioacetate yielded thioacetate **8***a* readily and then thiol **8***b* after base-catalyzed deacetylation. After extensive experimentation, this air-sensitive thiol could be induced to undergo photochemical cyclization in 25–35% yields to the sulforphan derivative **9***a*. Conclusive evidence that **9***a* is the B/C-*cis* isomer of the established structure **11***a* was adduced by correlated homo- and heteronuclear nmr spectroscopy (Figs. 1–4) (10). The ^1H and ^{13}C nmr chemical shifts are given in Tables 1 and 2 respectively. The structure of **3***a*, as noted previously, was established from an analysis of its X-ray crystal structure.

Because the X-ray crystal structure of **2** is not yet available, evidence for its morphinan-like structure rests in part on the obvious presence in **9***a* of the benzylic $CH_{10A,B}$—CH_9—CH_{14} system, which in the nmr spectrum displays absorption characteristics closely similar to those of **11***a* (**9***a*, 3.15 (H_{10A}, ArCH), 3.47 (H_{10B}, ArCH) (AB portion of ABX pattern, $J_{H_{10A},H_{10B}} = 16$ Hz, $J_{H_{10A},H_9} = 6$ Hz); **11***a*, 3.24 (H_{10A}, ArCH), 3.56 (H_{10B}, ArCH) (AB portion of ABX pattern, $J_{H_{10A},H_{10B}} = 16$ Hz, $J_{H_{10A},H_9} = 6$ Hz). The configurational relationship between **2** and **3***a* was deduced from an analysis of the variations in ^1H and ^{13}C nmr chemical shifts in compounds **11***a* and **9***a*.

The H-15_{ax} appears at 2.53 ppm in **11***a* and at 1.84 ppm in **9***a*. The downfield shift experienced by this axial hydrogen in **11***a* is similar to that of the hydrogen of an axial methyl group on a cyclohexane ring (11). In the case of **9***a*, this interaction is removed and, as a consequence, the signal representing H-15_{ax} has shifted upfield by 0.69 ppm. The most dramatic change was observed with H-8_{ax}. This proton experiences two steric interactions, downfield shifting, paramagnetic in nature, with C-15_{ax} and S-17. When rings B and C are *cis* fused as in **9***a*, these two interactions are removed and the observed shift difference of −0.99 ppm (an average of 1.3 δ was used for H-$8_{ax,eq}$ in **9***a*) may be viewed as a reflection of this change. It is also interesting to note that the H-6_{ax} and H-6_{eq} protons in **11***a* appear at the same place (1.66 ppm) in spite of the anticipated shift difference between them (0.55 ppm: cyclohexane (12)). This is obviously due to its proximity to the H-15_{ax}, which imparts a downfield shifting effect on H-6_{ax}, thus offsetting the expected shift difference between H-6_{ax} and H-6_{eq} protons.

The diastereomeric relationship between **11***a* and **9***a* is also evident from their relative C-13 nmr chemical shifts. The most characteristic change is seen at C-15. This carbon has two γ-*gauche* interactions with C-6 and C-8 in **11***a* and therefore is expected to be shifted upfield. In **9***a*, the C-15 carbon has an *anti*-relationship with these two carbons and hence should be shifted downfield, as compared to **11***a*. The observed 12.89-ppm downfield shift of C-15 from **11***a* to **9***a* confirms this change in geometric relationship. Also consistent is the upfield

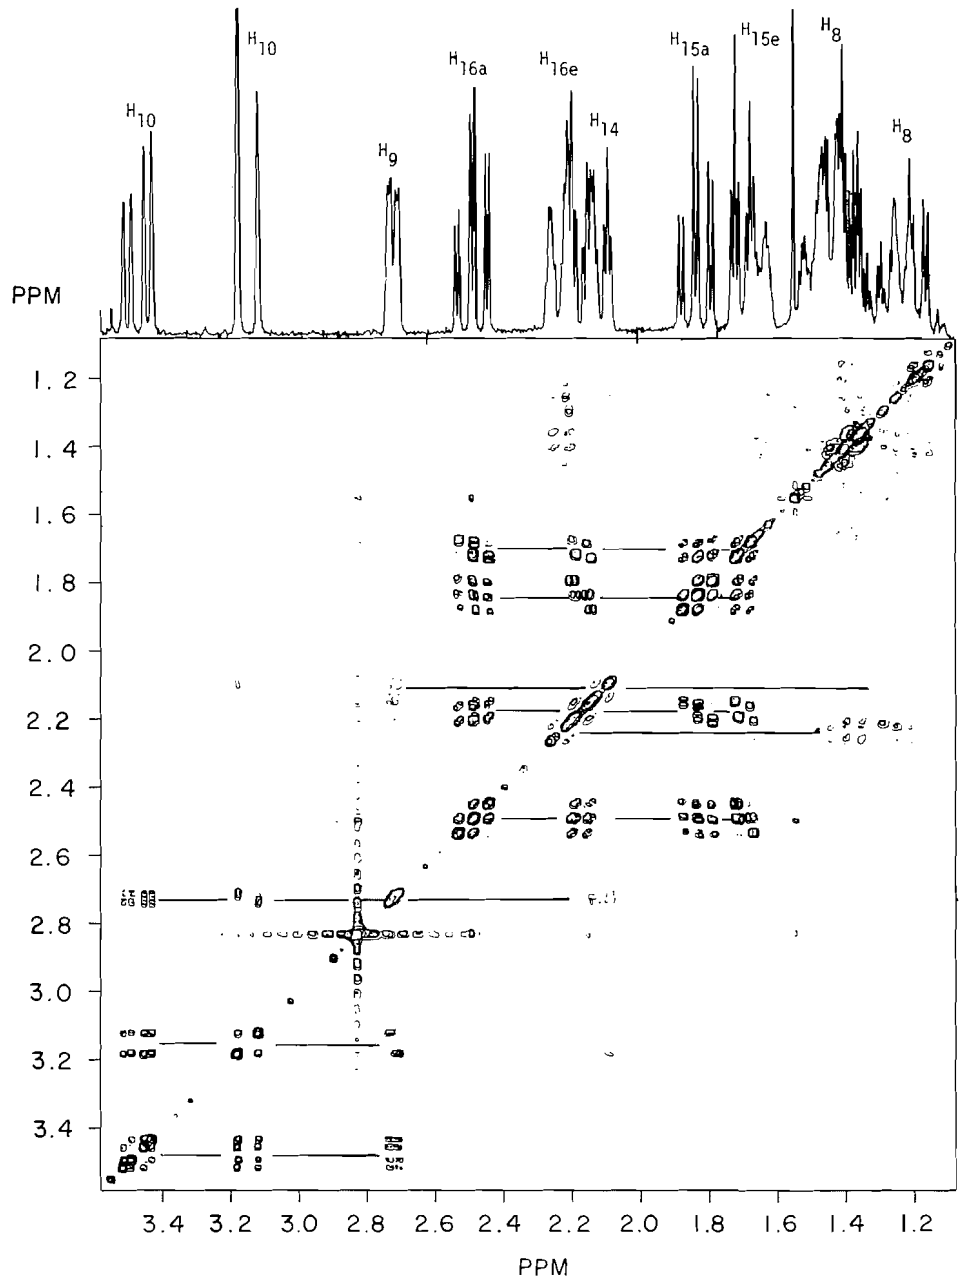


FIG. 1. Contour plot of the COSY 45 map of the aliphatic region of 3-methoxy-17-deaza-17-thiamorphinan (**9***a*); 256 were recorded (4 scans/spectrum). The matrix was 1024 × 1024 data points. The data were processed with a sine bell function.

shift (−5.07 ppm) of the C-12 carbon. In **11***a* this carbon is *anti* to both C-6 and C-8, whereas in **9***a* these are *gauche* to it. The reduced upfield shift, as compared to C-15, may be due to the absence of attached protons on the C-12 atom. The upfield shift (−5.2 ppm) experienced by C-10 in **9***a* is also in accordance with the geometric changes required when **11***a* is formally converted into **9***a*, namely an additional γ-*gauche* interaction with the C-8 atom. The downfield shift (5.02 ppm) of C-14 (from **11***a* to **9***a*) may have its origin in the reversal of the relative orientations of the C-15 and C-12 atoms which are β to the C-14 atom.

The ^{1}H and ^{13}C nmr shift differences therefore corroborate each other and support the geometric changes required in the formal conversion of **11***a* into **9***a*, thus establishing the diastereomeric relationship between **11***a* and **9***a*.

Sulforphan intermediate **9***a* was *O*-demethylated using boron tribromide to give **9***b*, which was *S*-methylated with methyl iodide to yield a mixture of the two possible methyl sulfonium iodide salts **2***a* (ratio of 55:45 as estimated by nmr). This result is in marked contrast to that observed with isosulforphan **11***b*, which gives a single sulfonium salt, that in which the *S*-methyl assumes the equatorial configuration (1). This different behaviour of **9***b* can only be ascribed to the absence of steric interference by ring C to an axial approach of the methylating reagent. However, the *trans*-B/C geometry of the isosulforphan isomer **11***b* effectively prevents such an axial approach. Separation of the two geometrical isomers **2***a* by chromatographic methods could not be achieved in a practical manner. Fractional crystallization of the iodide, perchlorate, or hexafluorophosphate salts was also unproductive. However, separation into the α-(equatorial) and β-(axial) (**2***b* and **2***c*) isomers could be achieved using the picrate salts.

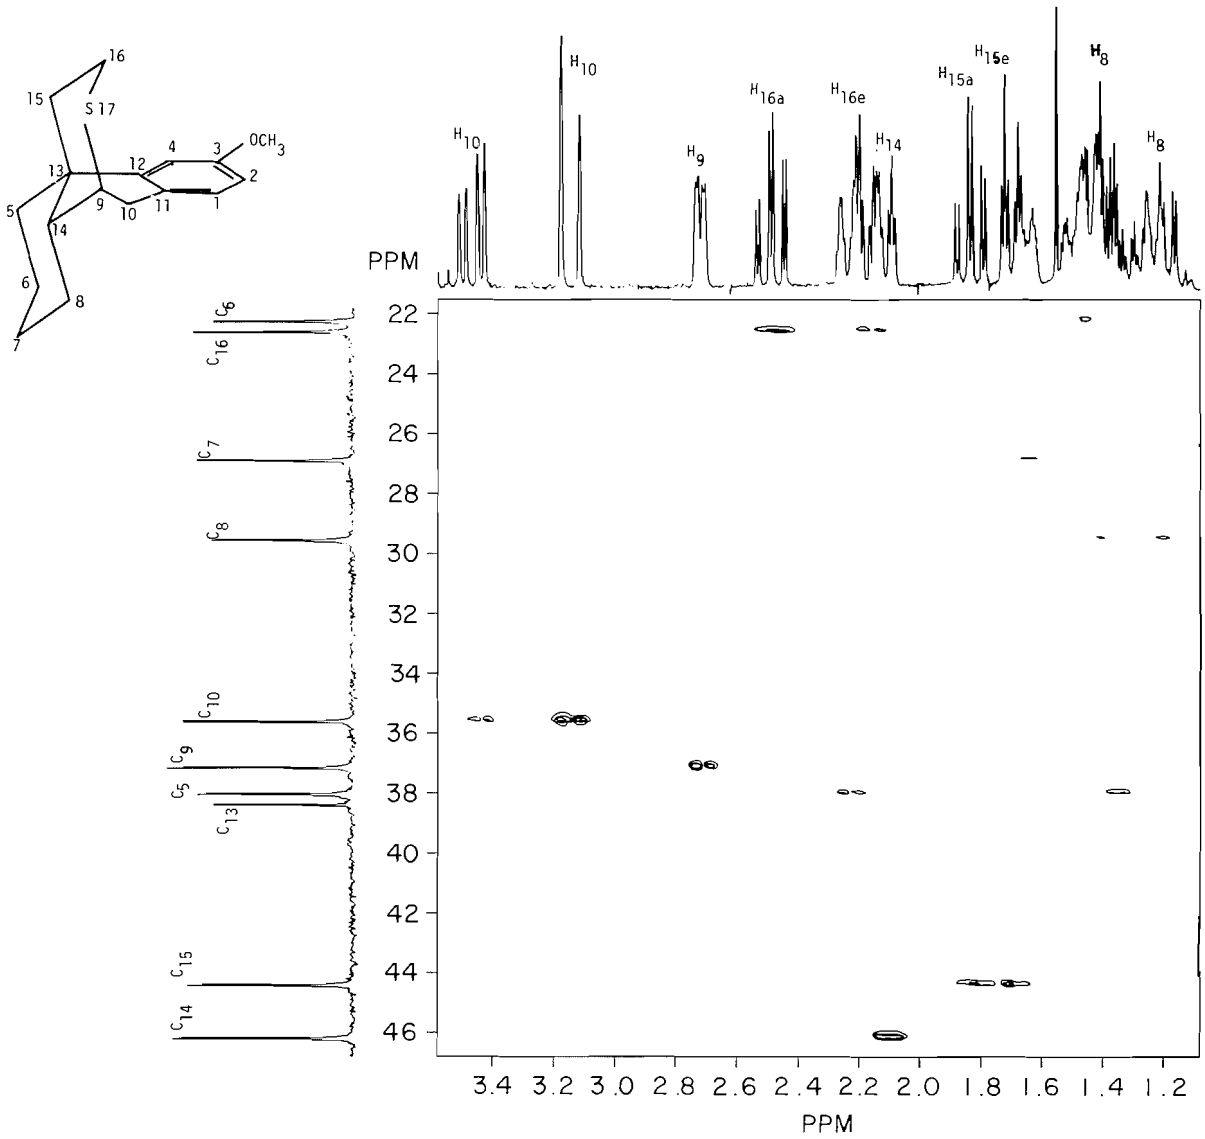

FIG. 2. Contour plot of the 2D heterocorrelation map of the aliphatic region of 3-methoxy-17-deaza-17-thiamorphinan (**9***a*) in $CDCl_3$; 256 spectra were recorded (16 scans/spectrum). The matrix was 1024 × 512 data points. The data were processed with line broadening in the detection domain and with a pseudo echo shape function in the evolution domain.

The configuration of the *S*-methyl groups of the two sulfonium salts was assigned unambiguously by ^{13}C nmr spectroscopy as based on well-known precedents (13). The relevant chemical shift assignments were made by 2D-homocorrelation and 2D-heterocorrelation nmr and the results compared with those previously reported for the case of 2*H*-tetrahydrothiapyran and the corresponding isomeric *S*-methyl salts (13). An axial *S*-methyl induces a smaller downfield shift (β-interaction) at the β-carbons than an equatorial *S*-methyl. The relevant ^1H and ^{13}C nmr data for epimers **2***b* and **2***c* are assembled in Tables 1 and 2, from which it can be deduced that the former has its *S*-methyl equatorially oriented and the latter has the same group axially oriented. Noteworthy are the C-14, C-15, and C-18 of **2***c*, which resonate upfield relative to those of **2***b*, whereas C-10 of the latter appears upfield relative to the same atom in **2***c*. These differences originate from γ-*gauche* interactions as well as a β-interaction with C-16 of the *S*-methyl group, as quantitatively specified in Table 2.

Supporting evidence for the assignment of configurations **2***b* and **2***c* was obtained from the geminal $^2J(H,H)$ values for the H-$16_{ax,eq}$ protons. These amounted to 12.2 and 14.0 Hz for **2***b* and **2***c*, respectively, in agreement with the experimental evidence of Fava and co-workers for relevant *S*-methylthionium cations (14).

The question of the relative thermodynamic stabilities of the equatorial (**2***b*) and the axial (**2***c*) epimers was answered by submitting each isomer to conditions of equilibration in acetonitrile-d_3 at 110°C for 1 week according to a previously established protocol (13). The ratio of epimers was monitored by nmr, using the relative peak intensities of the *S*-methyl groups at 2.86 (axial) and 2.76 ppm (equatorial) as the reference peaks. At equilibrium, both epimers yielded an identical K_{eq} value of 2.33, which translates in a ΔG°_{383} value of −0.66 kcal/mol in favor of the axial configuration. An examination of CPK models revealed that in the equatorial orientation (**2***b*), the *S*-methyl is in very close contact with C-10 (hindering free rotation of the methyl) whereas in **2***c*, the axial methyl does not suffer serious repulsions or rotational restrictions. This reversed

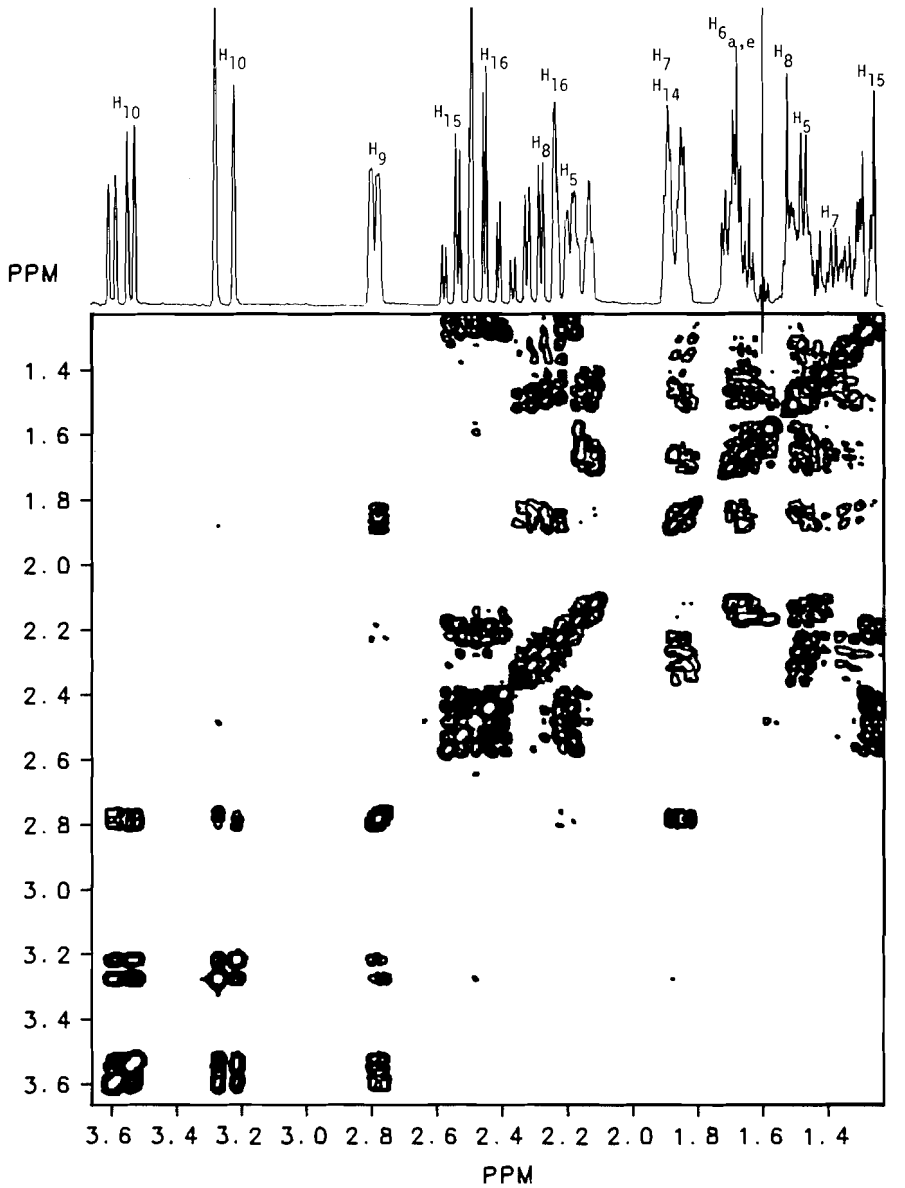

FIG. 3. Contour plot of the COSY 45 map of the aliphatic region of 3-methoxy-17-deaza-17-isothiamorphinan (**11***a*); 256 were recorded (4 scans/spectrum). The matrix was 1024 × 1024 data points. The data were processed with a sine bell function.

order of configurational stabilities for a methyl substituent relative to cyclohexane models has its origin in the relief of 1,3-diaxial compressions associated with the longer C—S bonds (≥1.8 Å). This result parallels those of Eliel and Willer (13) who also observed substantial destabilizing *gauche* interactions (ΔG^0_{373} = 1.2 kcal/mol) for an equatorial *S*-methyl in the *cis*-1-thiadecalin series. With **2***b*, the analogous destabilizing interaction is estimated to approach a similar value.

Preliminary pharmacological testing, using the experimental protocol already defined (1), indicated that the isomer mixture **2***a* is significantly more active than isosulforphanol **3***a*.

Experimental

General

Melting points and distillation temperatures are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 297 spectrometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were measured using a Varian XL-200 spectrometer. The 2D nuclear magnetic resonance experiments were carried out using a Varian XL-300 spectrometer. Tetramethylsilane was employed as the internal standard for all compounds. Mass spectrometric measurements were recorded on a Dupont 21-492B or LKB 9000 mass spectrometer.

1,2,3,4,4a,9-Hexahydro-6-methoxy-4a-phenanthrylacetaldehyde **5**

The hydrochloride salt of 4a-(2′-aminoethyl)-1,2,3,4,4a,9-hexahydro-6-methoxyphenanthrene **4** (2.5 g, 8.5 mmol) was dissolved in saturated aqueous $NaHCO_3$ solution (50 mL) and extracted with chloroform (3 × 50 mL). The organic extracts were dried and the solvent removed *in vacuo*. To the residue was added ethanol/water (1:1 v/v) (100 mL), followed by ninhydrin (6.0 g, 33.7 mmol) also dissolved in ethanol/water (1:1 v/v) (100 mL). If the reaction mixture became gummy an additional 100 mL of ethanol was added. The reaction flask was wrapped in aluminum foil and stirred under nitrogen for 30 min, after which time solid $NaHCO_3$ (7.5 g, 0.09 mol) was added. Stirring under nitrogen was continued for an additional 14 h and the ethanol evaporated *in vacuo*. The aqueous layer was extracted several times with ethyl acetate and the combined extracts washed with water, dried, and the solvent evaporated. The blue residue was purified by flash chromatography (8 in. × 1 in. silica gel 60 (230–400 mesh)), using hexane/ethyl acetate (9:1 v/v) as the eluent, to give a colourless oil that crystallized from hexane to yield 1.36 g (5.3 mmol, 62% yield) of white crystals; mp 72–74°C; ir ($CHCl_3$): 2815, 2715, 1712, 1610,

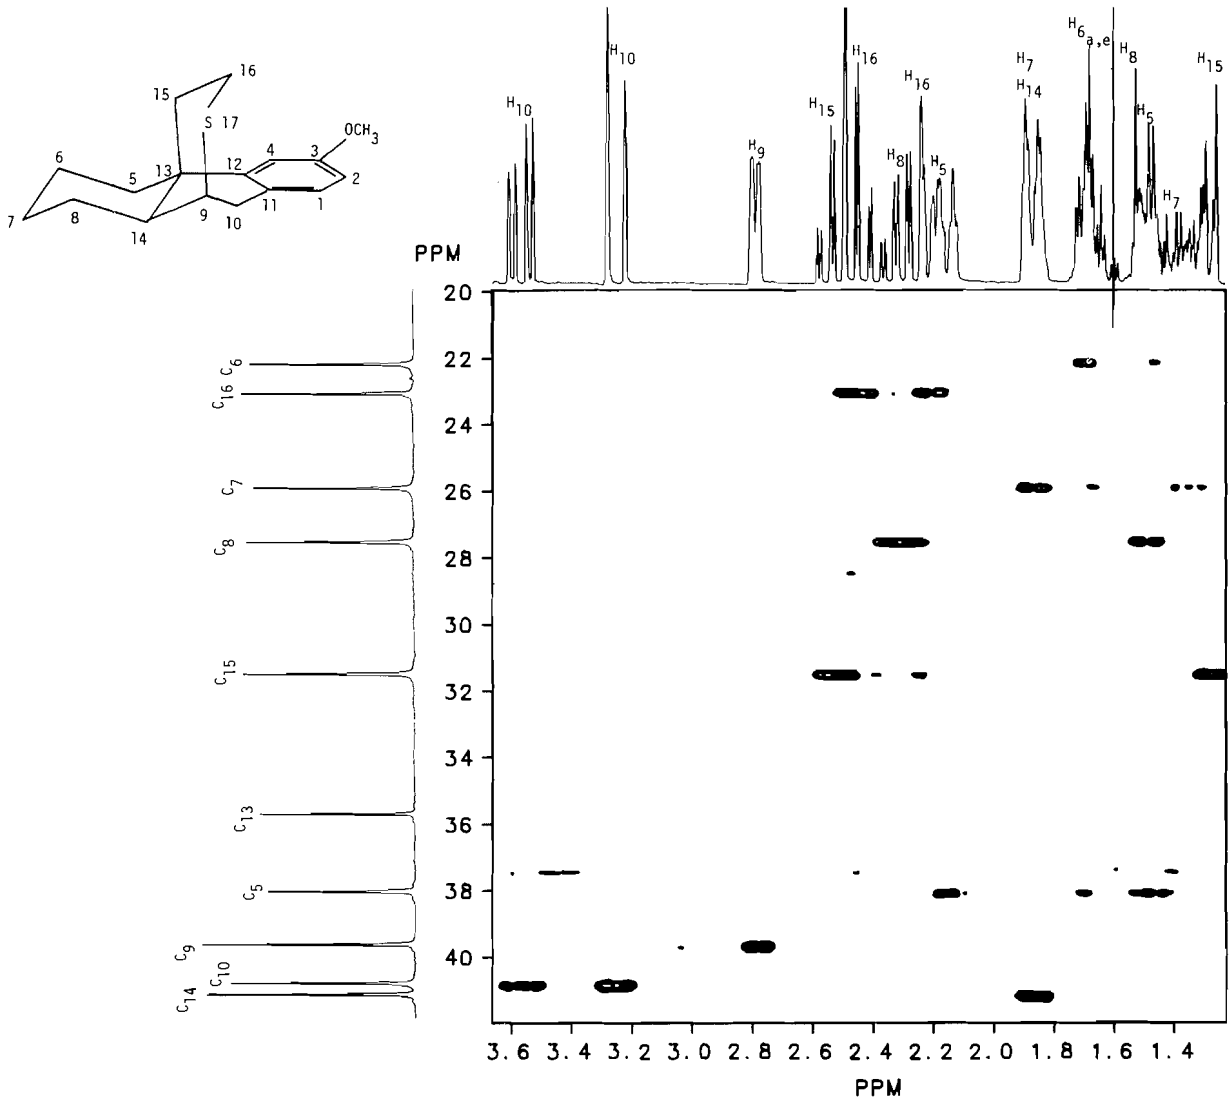

FIG. 4. Contour plot of the 2D heterocorrelation map of the aliphatic region of 3-methoxy-17-deaza-17-isothiamorphinan (**11***a*) in $CDCl_3$; 256 spectra were recorded (16 scans/spectrum). The matrix was 1024 × 512 data points. The data were processed with line broadening in the detection domain and with a pseudo echo shape function in the evolution domain.

[a]Solvent for nmr, $CDCl_3$.
[b]Negative and positive values represent upfield and downfield shifts respectively.
[c]Change from **11***a* to **9***a*.
[d]Solvent for nmr, CD_3CN.
[e]Change from **9***a* to **2***b*.
[f]Change from **9***a* to **2***c*.
[g]γ-*gauche* interactions; based on ref. 13, the expected value is −10.
[h]γ-*anti* interactions; expected value (13) is −4.
[i]β-interactions; expected value (13) is 11 (an axial *S*-methyl may accordingly be expected to be deshielded more weakly by about 6 ppm; however, the trend is in the correct direction).

1574, 1500, 1460, 1444 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.2–2.5 (m, 8H), 2.55, 3.12 (d of ABq, $CH_2C(O)$, J = 4 Hz, J = 16 Hz), 3.25–3.4 (m, CH_2Ar), 3.8 (s, OCH_3), 5.75 (s, $CH{=}C(R_2)$), 6.7–7.1 (m, 3H, ArH), and 9.25 (m, C(O)H); *m/e*: 212 ($M^{+\cdot}$ − $CH_3C(O)H$), base peak). *Anal.* calcd. for $C_{17}H_{20}O_2$: C 79.65, H 7.86; found: C 79.64, H 7.88.

4a-(2'-Hydroxyethyl)-1,2,3,4,4a,9-hexahydro-6-methoxy-phenanthrene **6**a

The preceding aldehyde **5** (0.50 g, 1.95 mmol) was dissolved in chloroform (20 mL) under nitrogen and the solution cooled to 0°C. A slurry of sodium borohydride (0.08 g, 2 mmol) in dry ethanol was added and the mixture stirred at 0°C for 30 min, followed by the addition of enough 10% aqueous HCl to produce a clear solution (10 mL). The aqueous layer was extracted with $CHCl_3$ (4 × 50 mL) and the combined extracts washed with saturated aqueous NaCl, dried, and the solvent evaporated *in vacuo*, leaving a pale yellow oil that crystallized from hexane to yield 0.47 g (1.82 mmol, 93.4% yield) of the alcohol **6** as white crystals; mp 78–79°C; ir (neat, oil): 3385, 1607, 1571, 1495, 1458, 1440 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.02–2.6 (m, 12H), 3.2–3.5 (m, 3H, CH_2OH), 3.77 (s, 3H, OCH_3), 5.63 (br s, 1H, $R_2C{=}C(H)$), 6.52–7.05 (m, 3H, ArH); *m/e*: 258 ($M^{+\cdot}$), 213 (base peak).

4a-(2'-Hydroxyethyl)-1,2,3,4,4a,10a-hexahydro-6-methoxy-phenanthrene 7a

The preceding alcohol **6** (1.0 g, 3.87 mmol) was dissolved in dry DMSO (20 mL) under nitrogen, the solution cooled to 5°C, and potassium *tert*-butoxide (1.0 g, 9.0 mmol) added. After stirring at room temperature for 48 h the mixture was cooled again, an additional quantity of potassium *tert*-butoxide (1.0 g, 9.0 mmol) added, and stirring continued for an additional 48 h. The mixture was poured onto water (50 mL), extracted with methylene chloride (3 × 50 mL), and the combined extracts washed several times with water (in order to remove all of the DMSO), then dried and decolourized with charcoal. Evaporation of the solvent left 0.9 g (3.49 mmol, 90.1% yield) of a colourless oil, which formed white crystals from hexane; mp 73.5–75°C; ir (neat, oil): 3380, 1602, 1563, 1487, 1470, 1430, 1420 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.9–2.6 (m, 12H), 3.2–3.6 (m, 3H, CH_2OH) 3.8 (s, 3H, OCH_3), 5.8 (H_{10_A}), 6.25 (H_{10_B}) (AB portion of ABX pattern, $J_{H_9H_{10A}}$ = 8 Hz, $J_{H_{10A}H_{10B}}$ = 16 Hz), 7.6–8.1 (m, 3H, ArH); *m/e*: 258 ($M^{+\cdot}$), 213 (base peak).

4a-(2'-Tosyloxyethyl)-1,2,3,4,4a,10a-hexahydro-6-methoxy-phenanthrene 7b

The above alcohol **7***a* (2.93 g, 11.34 mmol) was treated at 0°C in dry pyridine (18 mL) with a solution of *p*-toluenesulfonyl chloride (2.59 g, 13.58 mmol) in dry pyridine (5 mL). After stirring at 0°C for 20 h, the mixture was gradually diluted with cold water, causing separation of a light yellow solid, which was collected, washed with water, and dried *in vacuo* to yield 4.305 g (10.44 mmol, 92.0% yield) of the tosylate **7***b*; mp 86–88°C. It was used as such in the next step. An analytical sample was prepared by recrystallization from ether–hexane to give white crystals; mp 90.5–92°C; ir (neat, oil): 1170, 1355 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.7–2.5 (m, 10H), 3.7–4.05 (m, CH_2O), 3.8 (s, OCH_3), 5.75 (H_{10_A}), 6.25 (H_{10_B}) (AB portion of ABX pattern, $J_{H_9H_{10A}}$ = 8 Hz, $J_{H_{10A}H_{10B}}$ = 16 Hz)), 6.6–7.0 (m, 3H, ArH), 7.3, 7.6 (AB q, 4H, J_{AB} = 4 Hz, ArTs); *m/e*: 257 ($M^{+\cdot}$ − Ts), 91 (base peak). *Anal.* calcd. for $C_{24}H_{28}O_4S$: C 69.87, H 6.84; found: C 69.64, H 6.60.

4a-(2'-Acetylthioethyl)-1,2,3,4,4a,10a-hexahydro-6-methoxy-phenanthrene 8a

The preceding tosylate **7***b* (1.38 g, 3.33 mmol) was treated under N_2 with potassium thioacetate (0.42 g, 3.7 mmol) in refluxing dry THF (50 mL) for 12 h. The solvent was removed *in vacuo*, the residue taken up in $CHCl_3$ (74 mL), the solution washed with H_2O (4 × 50 mL), and the organic layer dried and evaporated *in vacuo*, leaving a yellowish oil. This oil was purified by flash chromatography (8 in. × 1 in. silica gel 60 (230–400 mesh)) using hexane/ethyl acetate (9:1 v/v) as the

eluent to give 0.7 g (2.2 mmol, 66.5% yield) of a colourless oil (homogeneous by tlc); ir (neat): 1688 cm^{-1}; nmr ($CDCl_3$) δ: 0.9–2.9 (m, 12H), 2.2 (s, 3H, C(O)CH_3), 3.8 (s, 3H, OCH_3), 5.8 (H_{10_A}), 6.25 (H_{10_B}), (AB portion of ABX pattern, $J_{H_9H_{10A}}$ = 6 Hz, $J_{H_{10A}H_{10B}}$ = 16 Hz)); *m/e*: 316 ($M^{+\cdot}$), 213 (base peak).

3-Methoxy-17-deaza-17-thiamorphinan **9**a

The above thioacetate **8***a* (9.08 g, 28.7 mmol) was treated under N_2 in dry deoxygenated THF (100 mL) with a solution of sodium methoxide (1.86 g, 34.42 mmol) in deoxygenated methanol. The mixture was stirred for 3 h, the pH adjusted to 4 with 5% deoxygenated aqueous citric acid, and the aqueous layer extracted with deoxygenated chloroform. The combined extracts were dried, the solvent removed *in vacuo* under N_2, and the resulting air-sensitive thiol **8***b* (colourless oil) irradiated under nitrogen in deaerated benzene (air cooling) with two GE sunlamps 136 (275 W, 110–125 VAC, 60 cyc) for 54 h. The solvent was removed *in vacuo* and the residue purified by flash chromatography (12 in. × 3 in. silica gel 60 (230–400 mesh)) using hexanes/toluene (3:1, v/v) as the eluent to yield a light yellow solid that was crystallized from hexane to give **9***a* as white crystals (1.93 g, 25.2% yield); mp 106.5–108°C; ir **9***a* (CH_2Cl_2): 2925, 1610, 1490, 1230 cm^{-1}; ^1H nmr **9***a* ($CDCl_3$) δ: 1–2.7 (m, 14H), 3.15 (H_{10A}, ArCH), 3.47 (H_{10B}, ArCH) (AB portion of ABX pattern, $J_{H_9H_{10B}}$ = 6 Hz, $J_{H_{10A}H_{10B}}$ = 16 Hz)), 3.8 (s, 3H, OCH_3), 6.6–7.1 (m, 3H, ArH); *m/e* (15): 274 ($M^{+\cdot}$), 213 (base peak). *Anal.* calcd. for $C_{17}H_{22}OS$: C 74.40, H 8.08; found: C 74.22, H 7.96; ^1H nmr **8***b* ($CDCl_3$) δ: 1.07–2.7 (m, 14H), 3.8 (s, 3H, OCH_3), 5.8 (H_{10_A}), 6.25 (H_{10_B}) (AB portion of ABX pattern $J_{H_9H_{10A}}$ = 6 Hz, $J_{H_{10A}H_{10B}}$ = 16 Hz)), 6.6–7.1 (m, 3H, ArH).

3-Hydroxy-17-deaza-17-thiamorphinan **9**b

The preceding 3-methoxy-17-deaza-17-thiamorphinan **9***a* (0.5 g, 1.82 mmol) was dissolved under N_2 in dry methylene chloride (10 mL) at −78°C followed by the addition of a solution (5 mL) of BBr_3 in CH_2Cl_2 (0.5 *M*) at −78°C. The reaction mixture was allowed to warm slowly to room temperature and, after 18 h, it was poured onto H_2O and the aqueous layer washed with CH_2Cl_2 (4 × 20 mL). The combined extracts were dried, the solvent removed *in vacuo*, and the residue purified by flash chromatography (6 in. × 1 in. silica gel 60 (230–400 mesh)) using $CHCl_3$ as the eluent to give a colourless oil that was crystallized from methylene chloride to yield 0.317 g (1.3 mmol, 67% yield) of white crystals; mp 134–136°C; ir (KBr disc): 3300, 2920, 2840, 1615, 1490, 1450, 1290, 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.9–2.8 (m, 14H), 3.1 (H_{10A}), 3.5 (H_{10B}) (AB portion of ABX pattern $J_{H_9H_{10B}}$ = 6 Hz, $J_{H_{10A}H_{10B}}$ = 16 Hz)), 4.75 (br s, 1H, OH), 6.7–7.1 (m, 3H, ArH); *m/e*: 260 ($M^{+\cdot}$), 199 (base peak).

α *and* β *sulforphanol isomers* **2**a

The above 3-hydroxy-17-deaza-17-thiamorphinan **9***b* (0.60 g, 2.32 mmol) was treated with CH_3I (4 mL) in CH_3CN (22 mL) and, after standing for 14 h, dry ether was added to the solution, whereupon white crystals separated. These were washed with dry ether and dried *in vacuo* to yield 0.90 g (2.24 mmol, 96.4% yield) of white crystals; no definite mp; ^1H nmr ($CDCl_3$ + CF_3COOD) δ: 1.2–4.0 (complex m, 20H), 2.98 (s, SCH_3), 3.1 (s, SCH_3), 6.8–7.3 (ArH); *m/e*: 260 ($M^{+\cdot}$ − CH_3I), 199 (base peak). *Anal.* calcd. for $C_{17}H_{23}IOS$: C 50.75, H 5.76; found: C 50.53, H 5.62.

The iodide salt (761 mg, 1.89 mmol) was dissolved without delay in methanol and the solution passed through an anion exchange column in the perchlorate form prepared as described previously (1) to yield a methanol solution of the perchlorate salt of sulforphanol **2***a*; the salt was obtained as a white solid after evaporation of the solvent. It was recrystallized from CH_3CN/hexane to give 671 mg (1.79 mmol, 94.6% yield) of long white needles incorporating the two *S*-methyl stereoisomers, as judged by nmr analysis; ^1H nmr ($CDCl_3/CF_3COOD$) δ: 1.1–3.8 (m, 20H), 2.8 (s, 3H, SCH_3), 3.0 (s, 3H, SCH_3), 6.7–7.2 (m, 3H, ArH); *m/e*: 260 ($M^{+\cdot}$ − CH_3ClO_4), 199. *Anal.* calcd. for $C_{17}H_{23}ClO_5S$: C 54.47, H 6.18; found: C 54.49, H 6.33.

The α-(equatorial CH_3) and β-(axial CH_3) isomers (**2***b* and **2***c*) could not be separated efficiently by hplc or as their perchlorate or hexafluorophosphate salts, but could be separated as their picrate salts. Thus treatment of the perchlorate or iodide salts mixture with sodium picrate in aqueous ethanol gave crude yellow crystals that, after three recrystallizations from warm ethanol, yielded **2***c* picrate as yellow needles; mp 176–178°C. The mother liquor, upon concentration followed by several recrystallizations of the solid from CH_3CN/Et_2O, yielded pure **2***b* picrate as yellow needles; mp 120–122°C. The two isomers were converted into their corresponding perchlorate salts by the anion exchange method previously described (1) to give, after recrystallization from CH_3CN/hexane, white crystals of pure α-sulforphanol perchlorate (**2***b*, mp 200°C (dec.)) and its isomer **2***c* (mp 208°C (dec.)).

4a-(2'-Hydroxyethyl)-10-hydroxy-1,2,3,4,4a,9,10,10a-octahydro-6-methoxyphenanthrene **10**a

The alcohol **6** (0.224 g, 0.95 mmol) was dissolved in CH_2Cl_2 (10 mL) under nitrogen and 10 *M* borane–dimethylsulfide (1 mL) was added. After 1 hour, 15% aqueous sodium hydroxide (20 mL) was added, followed by 30% aqueous hydrogen peroxide (20 mL), and the mixture was allowed to stand an additional 24 h. The solution was extracted with ether, which was washed with 15% aqueous sodium tartrate (3 × 40 mL) and H_2O (2 × 50 mL). The organic phase was dried and the solvent removed *in vacuo* to yield 0.26 g (0.95 mmol, 100% yield) of the crude diol. The diol was purified by flash chromatography (4 in. × 1 in. silica gel 60 (230–400 mesh)) using hexane/ethyl acetate (1:2 v/v) as an eluent to give 0.22 g (0.81 mmol, 85% yield) of white crystals; mp 138–139°C; ir (Kbr disc): 3300, 1600, 1570, 1490, 1400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.1–4.3 (m, 18H), 3.78 (s, 3H, OCH_3), 6.57–7.13 (m, 3H, ArH); *m/e*: 258 ($M^{+\cdot}$ − H_2O), 83 (base peak). *Anal.* calcd. for $C_{17}H_{24}O_2$: C 73.88, H 8.75; found: C 73.86, H 8.76.

4a-(2'-Mesyloxyethyl)-10-mesyloxy-1,2,3,4,4a,9,10,10a-octahydro-6-methoxyphenanthrene **10**b

The preceding diol **10***a* (1.97 g, 7.1 mmol) was dissolved in dry pyridine (100 mL) at 0°C, methane sulfonylchloride (3 mL) added, and, after 24 h at 0°C, the mixture was poured onto water (400 mL) and extracted with CH_2Cl_2 (3 × 50 mL). The combined extracts were washed several times with 10% aqueous HCl (5 × 50 mL), once with H_2O (50 mL), dried, and evaporated *in vacuo* to yield 2.77 g (6.42 mmol, 90.4% yield) of a yellow oil. This was purified by flash chromatography using ethyl acetate/hexane (2:1) as the eluent to yield 2.60 g (6.02 mmol, 84.8% yield) of a white solid, which was recrystallized from absolute ethanol to give 2.55 g (5.90 mmol, 83.1% yield) of white crystals; mp 115–116°C; ir (CH_2Cl_2): 1350, 1330, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.7–2.6 (m, 13H), 2.83 (s, 3H, CH_3SO_2), 3.00 (s, 3H, CH_3SO_2), 3.72 (s, 3H, OCH_3), 3.82–4.3 (m, 2H, CH_2OSO_2R), 4.63–5.18 (m, 1H, $CHOSO_2R$), 6.53–7.17 (m, 3H, ArH); *m/e*: 337 ($M^{+\cdot}$ − CH_3SO_3H, 213 (base peak). *Anal.* calcd. for $C_{19}H_{28}O_7S_2$: C 52.75, H 6.52; S 14.67; found: C 52.68, H 6.63, S 14.56.

3-Methoxy-17-deaza-17-isothiamorphinan **11**a

The above dimesylate **10***b* (2.4 g, 5.5 mmol) was treated in absolute ethanol (300 mL) with sodium sulfide nonanhydrate (14.5 g, 60.4 mmol) under N_2 and the mixture heated under reflux for 20 h. After cooling, the solvent was removed *in vacuo*, methylene chloride added to the residue, the suspended sulfur filtered off, the filtrate dried, and the solvent removed *in vacuo* to leave a yellow oil. This was purified by flash chromatography (6 in. × 1 in. silica gel 60 (230–400 mesh)) using hexane/ethyl acetate (25:1 v/v) as the eluent to give 1.02 g (3.72 mmol, 66.9% yield) of white crystals; mp 73–74°C; ir (neat, oil): 3300, 1600, 1570, 1490, 1400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.1–2.8 (m, 14H), 3.24 (H_{10_A}, ArCH), 3.61 (H_{10_B}, ArCH), (AB portion of ABX pattern, $J_{H_{10A},H_{10B}}$ = 16 Hz, $J_{H_9,H_{10A}}$ = 6 Hz)), 3.8 (s, 3H, OCH_3), 6.7–7.0 (m, 4H, ArH); *m/e*: 274 ($M^{+\cdot}$), 213 (base peak). *Anal.* calcd. for $C_{17}H_{22}OS$: C 74.40, H 8.08; found: C 74.61, H 8.17.

3-Hydroxy-17-deaza-17-allylthionium-17-isothiamorphinan bromide **3**b

3-Hydroxy-17-deaza-17-isothiamorphinan (0.222 g, 0.853 mmol)

was prepared by *O*-demethylation of **11***a* as previously described (1) and treated in dry acetonitrile (3 mL) with allylbromide (4.1 mL) under N_2. After 42 h, the solution was poured onto dry ether and the solid collected, washed with dry ether, and recrystallized from acetonitrile/ether to yield 273 mg (0.72 mmol, 84.0% yield) of white crystals; mp 131–133°C (dec.). *Anal.* calcd. for $C_{19}H_{25}BrOS$: C 59.84, H 6.61; found: C 59.93, H 6.55.

Characterization and elimination of cationic interferences on platinum

M. A. MOSTAFA AND M. A. KABIL
Chemistry Department, Faculty of Science, Mansoura University, Mansoura, A.R. Egypt

Received April 9, 1984[1]

M. A. MOSTAFA and M. A. KABIL. Can. J. Chem. **64**, 119 (1986).

Interfering effects of different cations on the atomic absorption signal of platinum can be completely eliminated by adding *n*-butylamine. The releasing action of *n*-butylamine comes through the formation of a volatile, platinum–amine complex, so the platinum species reaching the flame will normally be independent of the original composition of the solution. The inhibition release titration method has been used in studying the interfering effects to achieve a determinate characterization of compound formation.

M. A. MOSTAFA et M. A. KABIL. Can. J. Chem. **64**, 119 (1986).

Les interférences de divers cations sur l'absorption atomique des signaux du platine peuvent être complètement éliminés par l'addition de *n*-butylamine. L'effet de relargage de la *n*-butylamine provient de la formation d'un complexe volatil platine–amine qui fait que les espèces platiniques qui atteignent la flamme seront normalement indépendantes de la composition originale de la solution. On a fait appel à la méthode de titration avec élimination de l'inhibition pour étudier les effets d'interférence et obtenir une caractérisation déterminée de la formation du composé.

[Traduit par le journal]

Introduction

The determination of platinum by atomic absorption spectroscopy (AAS) has been reported in the literature (1–3). Lockyer and Hames (4) observed serious interferences from several metal ions. Addition of copper sulphate with a concentration above 20 000 μg/mL overcame the interferences encountered from noble metals and sodium. Although copper sulphate was added in a large excess, the interferences were not completely eliminated. Another study (5) showed that the serious depressive inter-element interferences of Ag, Al, Au, Bi, Ca, Co, Cr, Fe, Hg, K, Mg, Mn, Mo, and Ni were removed by buffering the solution with a mixture of cadmium and copper sulphates, each at 0.5%.

The disadvantage of the above method is the limitation of the buffer capacity in controlling interferences when some of the offending ions are present in concentration levels exceeding 200 μg/mL. Extraction procedures (6) have been presented to avoid interferences from a variety of matrices. The standard releasing agent for platinum is 1% lanthanum chloride (7). However, such methods hinder a better understanding of the phenomena during aspiration and atomization of the sample in the flame.

Experimental

Solutions

All solutions were prepared from B.D.H. chemicals and Analar grades. Stock solutions of the metals were prepared as chlorides; aliquots were suitably diluted to give the desired metal ion concentration used for the experiments. The stock solution of platinum (7×10^{-3} *M* chloroplatinic acid) was standardized using thiophenol (8).

Equipment

The atomic absorption spectrophotometer, Unicam SP 90A series 2, was fitted with a new HTA phototube, No. R 270 from EMI. Air was supplied through a PU 9003 air compressor. Acetylene was obtained from cylinders after passing through concentrated sulphuric acid and glass wool for purification. A continuous titration device (9) was attached to the instrument and the results were analyzed on a CASIO FX-502P type programmable pocket calculator. Absorbance values were recorded with a Philips PM 8251 single-pen recorder at chart speed of 30 cm min^{-1}.

The instrumental parameters were: lamp current, 12 mA; wavelength, 265.9 nm; slit width, 0.15 mm; obervation height, 1.0 cm; air flow rate, 5.0 L min^{-1}; fuel flow rate, 1.0 L min^{-1}.

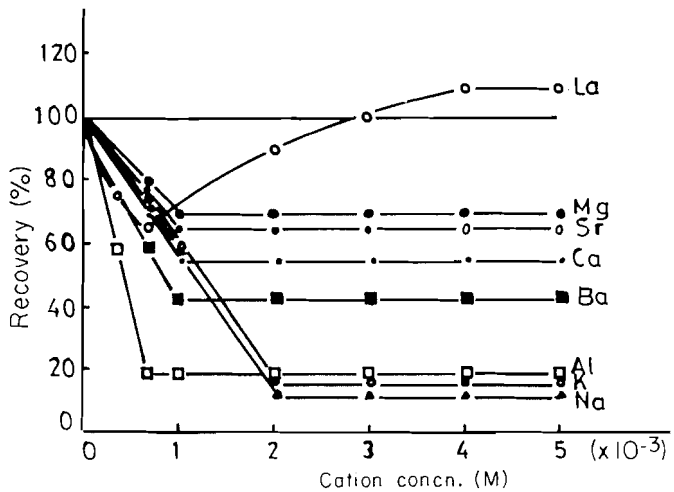

FIG. 1. Effect of some cations on the recovery of 1.025×10^{-3} *M* chloroplatinic acid.

Results and discussion

Interference of cations

Metal–metal interactions in a flame present a very complicated problem. Analysts can be puzzled from data reported by many workers in which no general observation can be concluded because any proposed mechanism for an inter-element interaction cannot be applied in general for others.

The initial study concerning the effect of different cations (as chlorides) on the absorbance of the standard platinum solution in an air–acetylene flame are represented in Figs. 1 and 2. It is evident that the absorbance is changed considerably by the foreign cations and that at a definite concentration of the interferent a pronounced inflection is observed. The graphs obtained when the time axis of the titration plot was converted to molar ratio between the interfering ion and platinum showed that the distinct breakpoints corresponded to $[M^+]/[Pt]$ at a ratio of 1:2, $[M^{2+}]/[Pt]$ at a ratio of 1:1, and $[M^{3+}]/[Pt]$ at a ratio of 2:3 (where M^+, M^{2+}, and M^{3+} are the mono, bi, and trivalent cations). The ratios are directly related to the formation of

[1]Revision received September 2, 1985.

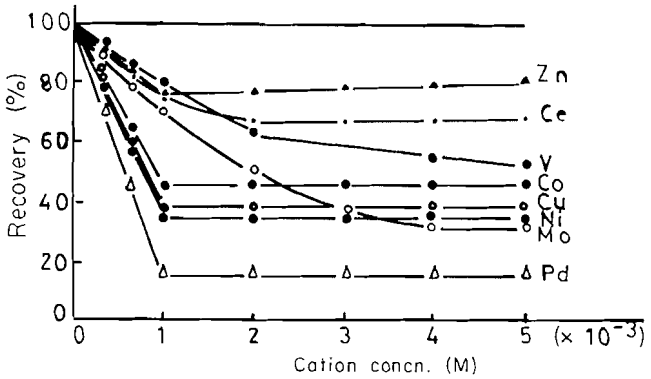

FIG. 2. Effect of some other cations on the recovery of 1.025×10^{-3} *M* chloroplatinic acid.

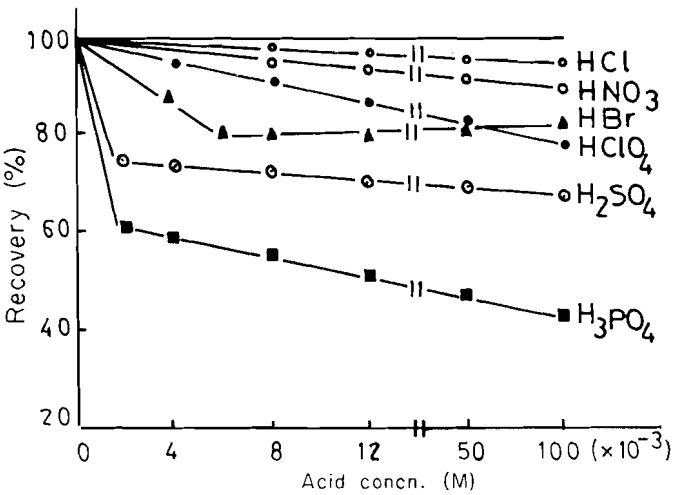

FIG. 3. Changes in the absorption signal of 200 μg/mL (1.025×10^{-3} *M*) platinum in the presence of inorganic acids.

$M_{2/n}[PtCl_6]$ and $M_2[PtCl_6]_3$, according to the following equations:

$$[1] \quad \frac{2}{n} M^{n+} + H_2[PtCl_6] \rightleftharpoons M_{2/n}[PtCl_6] + 2H^+, \qquad (n = 1 \text{ or } 2)$$

and

$$[2] \quad 2M^{3+} + 3H_2[PtCl_6] \rightleftharpoons M_2[PtCl_6]_3 + 6H^+$$

Thus the data suggests a condensed phase chemical interference in which a less volatile platinum salt is formed (10). The general trend of the graphs indicates that the absorbance decreases at the first stage of the titration, and after the stoichiometry is attained the graphs plateau, except for lanthanum. In the case of La the absorbance of platinum was restored to about 110 recovery percentage at a concentration of 4×10^{-3} *M* of lanthanum.

Effect of anions

It is difficult to independently investigate the influence of anions on the absorption signal of platinum because essentially all cations cause serious interferences on platinum. Inorganic acids are used for the decomposition of most samples, and the hydrogen ion has little effect on the dissociation of chloroplatinic acid. Thus anion interferences are best investigated using inorganic acids. The data in Fig. 3 show that the absorption signal of platinum is affected by the nature of the acid added. Hydrochloric and nitric acids have little influence. The decrease in the absorption signal was pronounced for other acids when the acid concentration became greater than 0.2 *M*. These acids decrease the signal even at low concentration. This may be due to some condensed phase interferences, i.e., crystallization of mixed salts with different thermal stabilities during evaporation and disintegration of aerosol. Evaporation of chloroplatinic acid solutions in the presence of sulphuric acid gives platinum sulphate (11). Curves 3, 5, and 6 of Fig. 3 indicate distinct breakpoints corresponding to $[PO_4^{3-}]/[Pt]$ and $[SO_4^{2-}]/[Pt]$ at ratios of 2:1 and $[Br^-]/[Pt]$ at a ratio of 6:1. Such ratios are directly related to the formation of $H_2[Pt(SO_4)_2(OH)_2]$, PtP_2O_7, and $H_2[PtBr_6]$ which are known as less volatile compounds in the flame (11).

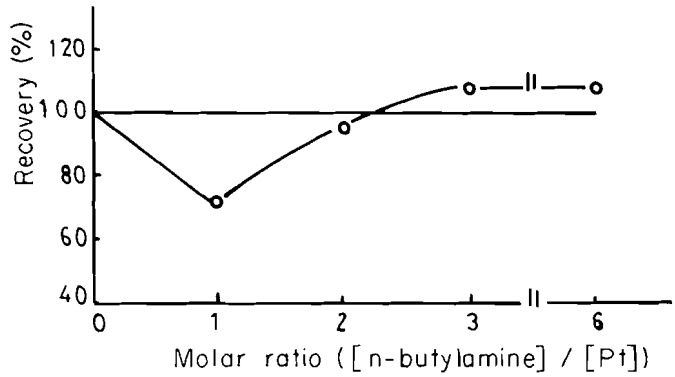

FIG. 4. Changes of the absorption signal of platinum as a function of the *n*-butylamine/Pt ratio.

Elimination of interferences

Platinum is known to form stable complexes with different amine compounds (12). A continuous AAS titration method was used to study the effect of *n*-butylamine on the chemical interferences affecting the Pt absorbance signal. Changes in the absorption signal of Pt were monitored continuously and recorded as a function of amine concentration and the data are shown in Fig. 4. A feature of the data shown in Fig. 4 is that the absorbance decreases and reaches a minimum at an [*n*-butylamine]/[platinum] ratio of 1:1. After reaching this ratio an enhancement occurs, reaching a maximum at about 108 recovery percentage. The behaviour of *n*-butylamine can be discussed according to three main steps which take place during the process of atomization. (*i*) Vaporization of the solid Pt–amine complex, followed by its decomposition in the flame produces platinum atoms, which instantaneously react with the oxidizing species already present in the flame. Such reaction yields PtO leading to the deficiency of platinum atoms, followed by a depression in the absorption signal. (*ii*) After a particular stoichiometric ratio was attained at 1:1 for Pt/*n*-butylamine, the decomposition of the complex may form a reducing species in the flame, such as, CN, NH, or CH, which may react with PtO according to the following equations:

$$[3] \quad PtO + NH \rightleftharpoons Pt + N + OH$$

$$[4] \quad PtO + CN \rightleftharpoons Pt + N + CO$$

(*iii*) The excess of *n*-butylamine leads to the formation of more reducing radicals in the flame which balance the excess of oxidizing species and restores the absorption signal to its normal value.

In support for the previous mechanism, Fig. 5 shows the relatively steady decrease in the emission intensity of the OH radical with the continuous increase in NH emission intensity as

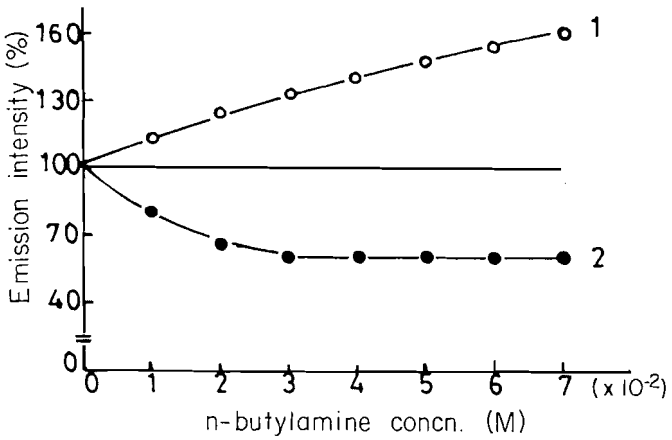

FIG. 5. Effet of *n*-butylamine on preclusion of the formation of oxidizing species OH and facility of the formation of reducing species NH. Emission intensity of NH or OH already present in the flame is assumed to be 100. All other results are normalized against this value. (○) NH emission intensity at 337 nm; (●) OH emission intensity at 281.1 nm.

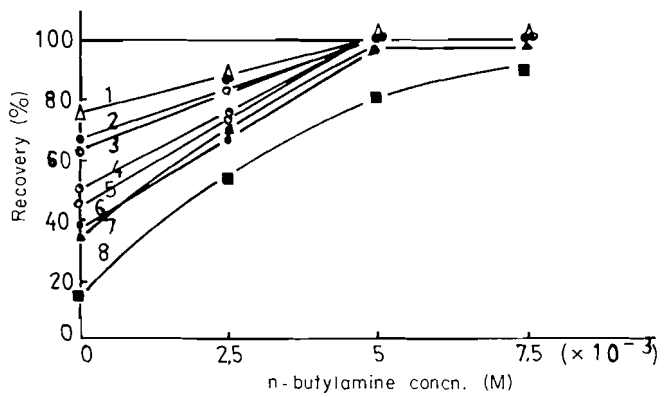

FIG. 6. Use of *n*-butylamine in eliminating interferences on 1.025×10^{-3} *M* Pt encountered from 2×10^{-3} *M* of some cations. Curves: 1, Zn; 2, Ce; 3, V; 4, Mo; 5, Co; 6, Cu; 7, Ni; 8, Pd.

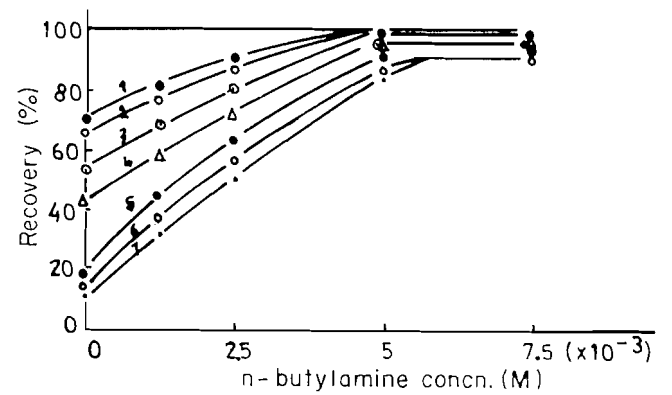

FIG. 7. Use of *n*-butylamine in eliminating interferences on 1.025×10^{-3} *M* platinum encountered from 2×10^{-3} *M* of some other cations. Curves: 1, Mg; 2, Sr; 3, Ca; 4, Ba; 5, Al; 6, K; 7, Na.

the *n*-butylamine solution is added. In such a case the decomposition of *n*-butylamine gives reducing fragments (CN and NH). Accordingly an enhancement in NH band emission intensity has occurred (Fig. 5, graph 1). Also, such fgragments scavenge OH radicals in the flame giving a suppression in OH band emission intensity (Fig. 5, graph 2). Such foundations can

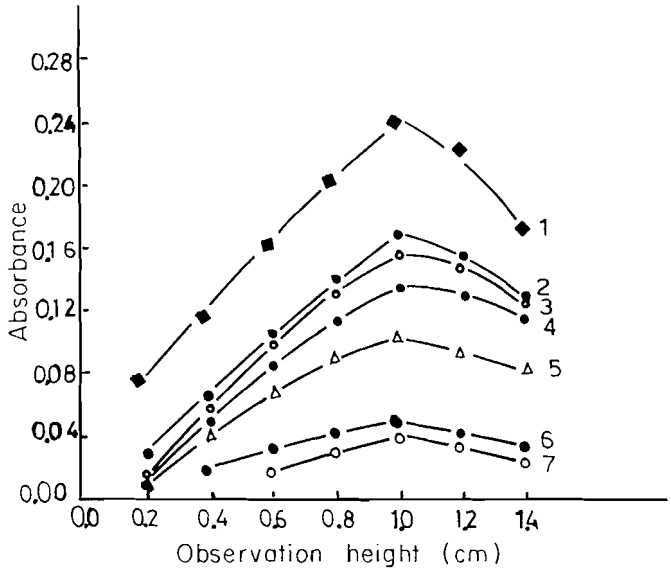

FIG. 8. Distribution of platinum atoms (1.025×10^{-3} *M*) as a function of observation height for different interferents, each in 2×10^{-3} *M*: 1, Pt only, the others having Pt and 2, Mg; 3, Sr; 4, Ca; 5, Ba; 6, Al; and 7, K.

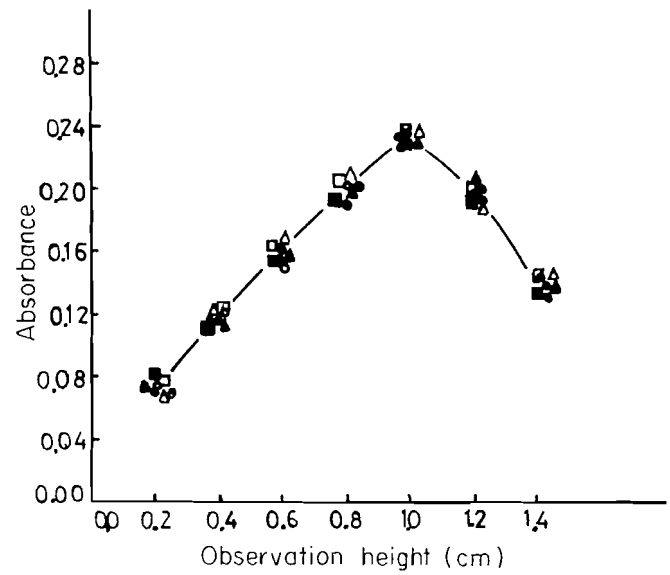

FIG. 9. Distribution of platinum atoms (1.025×10^{-3} *M*) as a function of observation height in 5×10^{-3} *M* of *n*-butylamine for different interferents, each in 2×10^{-3} *M* (○) Pt only, the others having Pt, *n*-butylamine, and (▲) Mg, (●) Sr, (⊙) Ca, (□) Ba, (△) Al, and (■) K.

be represented by the following equations:

[5] $CN + NH \rightleftharpoons N_2 + CH$

[6] $CN + OH \rightleftharpoons CO + NH$

When *n*-butylamine is added in sufficient concentration to samples containing interfering cations, the suppression is gradually eliminated (Figs. 6 and 7). The data are encouraging, except for Na, K, and Pd, where the recovery percentages are 84, 87, and 80.

The data in Fig. 8 illustrate the distribution of platinum atoms in the presence of different cations as a function of observation height. The effect of different concomitants were examined as a

function of observation height in the presence of 5×10^{-3} *M* *n*-butylamine. The data were completely coincident (Fig. 9) indicating that the formation of platinum–amine complex is attained in solution, protecting platinum from offending species. These data clearly illustrate the possibility of applying *n*-butylamine as a good masking agent for AAS determination of platinum.

M. C. CHALANDRE, J. BRUNETON, P. CABALION et H. GUINAUDEAU. Can. J. Chem. **64**, 123 (1986).

En plus d'une aporphine, les écorces de *Hernandia peltata* Meissner (Hernandiacées) ont fourni deux nouvelles bisréticulines et 10 dimères aporphine–benzylisoquinoléine. Quatre d'entre eux sont nouveaux: la (+) northalicarpine-6 **6**, la (+) *N*-oxythalicarpine-2′ **10**, la (+) hébridamine **11** et la (+) vilaportine **12**. L'hébridamine est le premier exemple de benzylisoquinoléine–phénanthrène et la vilaportine est un dimère comportant une moitié zwitterionique. La déhydrothalmélatine-6a,7 **9** est isolée ici pour la première fois à l'état naturel. La possibilité d'une relation biogénétique entre la (+) vanuatine et la (+) thalicarpine est envisagée.

M. C. CHALANDRE, J. BRUNETON, P. CABALION, and H. GUINAUDEAU. Can. J. Chem. **64**, 123 (1986).

The bark of *Hernandia peltata* Meissner (Hernandiaceae) has yielded four new dimeric alkaloids, namely (+)-6-northalicarpine **6**, (+)-thalicarpine 2′-*N*-oxide **10**, (+)-hebridamine **11**, and (+)-vilaportine **12**. Hebridamine is the first example of a benzylisoquinoline–phenanthrene dimer and (+)-vilaportine is a dimer with an oxoaporphinium zwitterionic moiety. The 6a,7-dehydrothalmelatine **9**, previously known as a synthetic compound, has been isolated from a natural source for the first time. The possibility of a biogenetic relationship between (+)-vanuatine and (+)-thalicarpine **7** is considered.

Il est connu que la (+) réticuline conduit, via un couplage oxydatif intramoléculaire, à de nombreuses structures monomériques (2, 3). Or récemment nous avons pu isoler de *Hernandia peltata* Meissner trois alcaloïdes dimères qui constituent le premier exemple connu d'un couplage oxydatif intermoléculaire de deux unités dérivées de la (+) réticuline (4). L'un d'entre eux, la (+) vanuatine **1** pourrait s'inscrire dans un schéma biogénétique conduisant à la (+) thalicarpine **7**, alcaloïde aporphine–benzylisoquinoléine dimère cytostatique présent en particulier chez *Hernandia ovigera* (**5**) et dont la présente note rapporte l'isolement en quantité notable dans *H. peltata*. Avant d'envisager une étude spécifique de cette biosynthèse, il importait d'approfondir la connaissance de la composition en alcaloïdes dimères de cette espèce. Nous rapportons ici l'isolement et l'identification de 13 alcaloïdes, 1 aporphine et 12 dimères, obtenus lors d'une étude sur un nouvel échantillon de cette plante. Six des molécules isolées sont originales: deux bisbenzylisoquinoléines de type bisréticuline et quatre dimères aporphine–benzylisoquinoléine.

L'extraction est conduite selon le procédé déjà décrit (4): une séparation préliminaire des monomères et des dimères est réalisée par filtration moléculaire sur gel de Sephadex LH 20; la fraction des alcaloïdes dimères est scindée en bases phénoliques et non phénoliques par partage entre une solution aqueuse d'hydroxyde de sodium diluée et du chlorure de méthylène.

Le fractionnement des bases phénoliques conduit à l'isolement de la (+) malékulatine **2** (0,2%) (4) et de deux nouveaux alcaloïdes bisbenzylisoquinoléiques de type bisréticuline, la (+) ambrimine **3** et la (+) éfatine **4**; la structure de ces deux dimères diphénoliques monopontés "tête à queue" a fait l'objet d'une autre note (1). Une suite de chromatographies sur colonnes de silice et de chromatographies sur couche mince préparatives a permis d'isoler neuf alcaloïdes à partir du mélange de bases non phénoliques. Un seul monomère, la (−) laetine a été isolé (6*c*); les autres alcaloïdes obtenus sont des dimères: la (+) thalicarpine **7** qui représente l'acaloïde majoritaire de cette fraction (0,1%), accompagnée de (+) vanuatine **1** (4), de (+) northalicarpine-2′ **5** et de (+) thalmélatine **8**.[3] Le cinquième alcaloïde isolé est la (+) déhydrothalmélatine-6a,7 **9** qui n'était jusqu'alors connue qu'à l'état de produit synthétique (5, 7).

La (+) northalicarpine **6**, $C_{40}H_{46}N_2O_8$, est un isomère structural de la (+) northalicarpine-2′ **5** (5). Le spectre de masse de **6** est très proche de celui de **5**, mais il présente un pic de base à m/z 206 au lieu de 192 comme dans le spectre de **5**. Le spectre de rmn du proton de **6** présentant un seul singulet dû à un *N*-méthyle est également très proche de celui de **5**, avec cependant deux différences sensibles; le singulet dû au méthoxyle en 7′ apparaît à δ 3,54 ppm comme dans le cas de la (+) thalicarpine (3,58 ppm) ou de la (+) pennsylvanine (3,56 ppm) (15), au lieu de 3,72 ppm comme dans le spectre de **5**, ce qui permet de dire que l'azote 2′ de **6** est engagé dans une amine tertiaire. La substitution de N-2′ par un méthyle est confirmée par la deuxième particularité du spectre de rmn de **6**, c'est-à-dire par la position relativement blindée du singulet dû au proton 8′ à 6,14 ppm. De même, le pic de base présenté par le spectre de masse de **6** à m/z 206, résultant de la coupure de la liaison

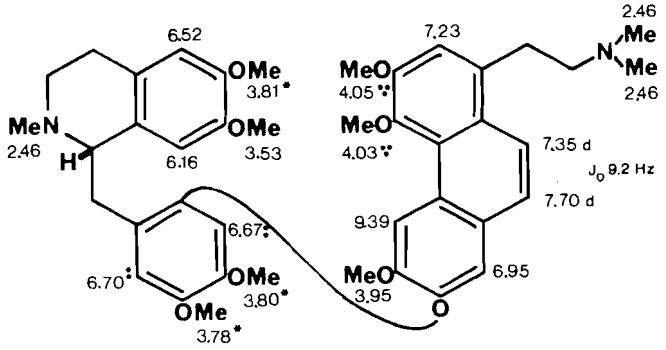
10

benzylique 1′-α, est en faveur d'une amine tertiaire en 2′ et d'une amine secondaire en 6, c'est-à-dire du côté aporphinique de la molécule. La (+) northalicarpine-6 est le premier exemple connu d'aporphine–benzylisoquinoléine déméthylée sur l'azote aporphinique, les seuls dimères"nor" connus dans cette série portant l'amine secondaire du côté de la partie benzylisoquinoléine ((+) northalicarpine-2′ et (+) noradiantifoline-2′) (5).

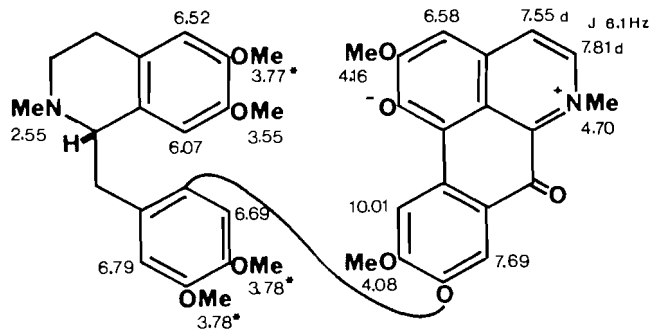
La (+) thalicarpine *N*′-oxide **10**, $C_{41}H_{48}N_2O_9$, présente dans son spectre de masse un très faible pic moléculaire à *m/z* 712 (0,1), traduisant l'incorporation d'un oxygène supplémentaire par rapport à la (+) thalicarpine **7** (5). Les spectres de rmn du proton de **7** et de **10** sont voisins bien que un des singulets dû à un *N*-méthyle de **10** soit déplacé vers les champs faibles à δ 3,39 ppm au lieu de 2,50 ppm, ainsi que le signal donné par le proton 1′ (4,87 au lieu de vers 3,80 ppm). L'ensemble de ces données et le fait que la réduction de **10** par le zinc chlorhydrique conduit à la (+) thalicarpine **7**, indiquent que **10** est la *N*-oxythalicarpine-2′.

Les positions respectives des signaux du proton 1′ et du *N*-méthyle-2′ (δ 4,81 et 3,39 ppm, respectivement) laissent penser qu'ils sont en position *trans* l'un par rapport à l'autre et donc que **10** serait la (+) β-*N*-oxythalicarpine-2′; cependant, une étude plus approfondie serait nécessaire pour confirmer la configuration de la fonction *N*-oxyde (8).

Peu de dimères porteurs d'une fonction *N*-oxyde ont été décrits jusqu'alors; 11 bisbenzylisoquinoléines de ce type ont



11



12

été rapportées (8), mais il semble que la (+) *N*-oxythalicarpine-2′ soit la première aporphine–benzylisoquinoléine *N*-oxyde à être isolée.

La (+) hébridamine **11**, $C_{42}H_{50}N_2O_8$, est un dimère dont le spectre de masse présente un pic moléculaire à m/z 710 (0,1%). Son spectre de masse présente les caractéristiques d'un groupement phénanthrène, en particulier un pic de forte intensité à m/z 58. Le pic de base à m/z 206 et le pic moléculaire très faible à m/z 710 indiquent que **11** est un dimère avec une moitié benzylisoquinoléique.

Le spectre de rmn du proton de **11** est également en faveur d'une structure de ce type présentant, à 2,46 ppm, un singulet de 9 protons résultant de la superposition d'un signal dû à un *N*-méthyle et d'un signal dû à un groupement diméthylamino d'un phénanthrène. Le système AB de deux protons à 7,35 (d) et 7,70 (d) ppm (J = 9,2 Hz), dû aux protons 6a et 7, ainsi que la présence d'un singulet fortement déblindé à 9,39 ppm, dû au proton en 11, sont des indications caractéristiques dans la série des phénanthrènes dérivés d'une moitié aporphinique (6). Les autres signaux présentés par le spectre de rmn sont identiques à ceux observés pour la (+) thalicarpine **7**, permettant donc d'attribuer à la (+) hébridamine la structure **11**.

Le dernier alcaloïde, la (+) vilaportine **12**, $C_{40}H_{44}N_2O_9$, est fortement coloré en vert. Son spectre uv (EtOH, λ_{max}: 227, 257, 320 et 392) est proche de celui des oxoaporphines et pratiquement superposable à celui des zwitterions type bétaïne des oxoaporphiniums comme l'alcaloïde PO-3, la corunnine, la nandazurine ou l'arosinine (6); pour ces derniers comme pour **12**, le spectre uv est fortement modifié en milieu acide (pour **12**; λ_{max}: 227, 255, 187 et 379), ce qui résulte de la tautomérie possible pour ces molécules (9). Le spectre de masse de la (+) vilaportine **12** indique qu'il s'agit d'une molécule dimère, présentant un pic moléculaire à m/z 692 (10%) et un pic de base à m/z 206, caractéristique d'une moitié benzylisoquinoléine. Le spectre de rmn du proton, résumé autour de la formule **12**, est en accord avec cette hypothèse; il est à noter tout particulièrement la position, dans les champs faibles à 4,70 ppm, du singulet de trois protons donnés par le *N*-méthyle de la moitié oxoaporphinium ainsi que la présence de six singulets dus à des méthoxyles; la présence de neuf oxygènes dans la molécule et de seulement six méthoxyles montre l'existence d'une fonction phénolique, ce qui confirme le type bétaïne de la (+) vilaportine et non d'un sel d'ammonium quaternaire comme dans la thaïlandine ou l'uthongine (6). La coloration verte et la position normale du signal correspondant au proton en 3 impliquent que l'hydroxyle soit en 1 (10). La comparaison des spectres de rmn de la (+) thalicarpine **7**, de la (+) thalmélatine **8** et de la (+) vilaportine **12** montre que la substitution sur la moitié benzylisoquinoléine reste la même.

Il n'existe qu'une seule structure dimère possédant une moitié oxoaporphinium vrai, le beccapolinium, un bisaporphinoïde isolé de l'Annonacée *Polyalthia cauliflora* (5). La (+) vilaportine constitue donc le premier exemple de dimère possèdant une structure benzylisoquinoléine–oxoaporphine.

Au terme de cette étude, il convient de procéder à un certain nombre de remarques. La première concerne la différence de composition alcaloïdique observée entre notre première étude réalisée sur un lot récolté en juillet et cette présente analyse effectuée sur un échantillon récolté en novembre. Il apparaît alors que si la (+) malékulatine **2** est présente dans les deux échantillons, la vanuatine **1**, qui représentait environ 2,5% des alcaloïdes de l'échantillon précédent, n'est présente ici qu'à l'état de traces; au contraire, la (+) thalicarpine **7** que nous n'avions pas pu mettre en évidence lors de la première étude, représente ici 4% des alcaloïdes totaux. En première approximation, tout semble se passer comme si une "balance biogénétique" existait entre la (+) thalicarpine **7** et la (+) vanuatine **1**. Une telle affirmation, cependant, doit être vérifiée par l'étude des variations saisonnières et par élimination, à la suite de prélèvements multiples, des possibilités de variations liées à des conditions édaphiques, écologiques ou climatiques. De plus, si une telle balance existe, on peut s'interroger sur la disparition, dans le lot de novembre, de la (+) vatéamine sans qu'apparaissent pour autant des dimères du type (+) foetidine. Il conviendrait enfin d'étudier les variations éventuelles de la composition en monomères; *H. peltata* est en effet riche en aporphines monomères (11) et donc rien n'exclut l'hypothèse que la (+) thalicarpine soit formée par couplage de la (+) réticuline avec une aporphine-1,2,9,10 tétrasubstituée (12).

Une autre remarque souligne l'homogénéité des structures décrites ici, toutes dimères de la (+) réticuline, ne variant que par leur état d'oxydation. Bien que les quantités isolées soient souvent faibles (quelques milligrammes ou dizaines de milligrammes par kilogramme de plante sèche), l'absence de stockage ainsi que les conditions de dessiccation et d'extraction permettent d'exclure l'hypothèse que ces composés soient des artéfacts. De plus, des dérivés oxydés comme la (+) oxothalicarpine et la (+) déhydrothalicarpine-6a,7 (5) ont déjà été mis en évidence dans des *Hernandia*. Enfin, il est intéressant de remarquer que *Hernandia peltata* livre presque tous les intermédiaires postulés pour le passage des aporphines aux oxoaporphines (13).

Partie expérimentale

Les pouvoirs rotatoires sont mesurés dans le $CHCl_3$ à l'aide d'un polarimètre Schmidt Haensch; les spectres uv sont enregistrés sur un appareil Beckman 530 et les spectres ir sur Perkin Elmer 580. Les spectres de rmn ont été réalisés sur des appareils Varian EM 360 et

Bruker WB 360 ($CDCl_3$, TMS = 0 ppm); les spectres de masse, sur AEI-MS 902.

Extraction des alcaloïdes totaux, purification

L'échantillon étudié (3,5 kg) a été récolté en novembre 1982 (réf PCNH-1079) et l'extraction est conduite selon le procédé déjà décrit (4). Les alcaloïdes totaux (105 g) sont filtrés sur Sephadex LH-20 ($CHCl_3$–MeOH, 30:70) ce qui conduit à recueillir une fraction enrichie en dimères de 31 g. La fraction d'alcaloïdes dimères est dissoute dans $CHCl_3$–Et_2O et la solution organique extraite par une solution diluée de NaOH (5%) pour séparer les bases phénoliques (17 g) et non phénoliques (11 g).

Fractionnement des alcaloïdes

Les bases phénoliques sont chromatographiées sur alumine désactivée par addition de 6% d'eau. L'élution par des solvants de polarité croissante permet d'isoler la (+) malékulatine **2** (3,2 g) (éluée par $CHCl_3$–C_6H_6, 50:50) et un mélange de **2**, **3**, **4** et de produits polaires (élué par $CHCl_3$–MeOH, 95:1, 95:5, 90:10); 1,8 g du mélange est rechromatographié sur colonne de gel de silice pour ccm (chromatographie en conche mince) ($CHCl_3$–MeOH, 88:12) et fournit **2** (306 mg) ainsi que la (+) ambrimine **3** (172 g) et la (+) éfatine **4** (298 mg).

Les bases non phénoliques sont séparées par chromatographie sur silice. L'élution est conduite avec un gradient de MeOH (de 0,5 à 20%) dans $CHCl_3$. Sont successivement isolés: 780 mg d'épimagnoline, lignane déjà décrit chez *H. peltata* (14), 3,5 g de (+) thalicarpine **7**, 1,3 g d'un mélange complexe, 1,1 g de **2** et 0,78 g de produits non identifiés. Le mélange élué après **7** est purifié par passage sur colonne de silice pour ccm ($CHCl_3$–MeOH, 95:5) et séparé en quatre groupes. Les groupes 1 (350 mg), 2 (165 mg) et 3 (105 mg) sont rechromatographiés sur colonne de silice pour ccm (pour 1, $CHCl_3$–C_6H_{12}–DEA, 40:55:5; pour 2 et 3, $CHCl_3$–AcOEt–MeOH–NH_4OH, 79:10:10:1). Le groupe 4 est traité en ccm préparative (CH_3CN–C_6H_6–EtOAc–MeOH–NH_4OH, 40:30:20:5:5). Le groupe 1 fournit la (+) hébridamine **11** (7 mg), les northalicarpine **5** (1,4 mg) et **6** (6,5 mg) ainsi que la (+) thalmélatine **8** (17 mg) et son dérivé déhydro-6a,7 **9** (2,2 mg). Le groupe 2 livre la laetine (1,1 mg), la (+) vanuatine **1** (3,2 mg) et la (+) vilaportine **12** (6 mg). Du groupe 3 sont isolés des produits en cours d'étude et le groupe 4 fournit 4,4 mg de (+) *N*-oxythalicarpine **10**.

Les produits **1**, **2** (4), **3**, **4** (1), **5**, **7**, **8**, **9** (5) ayant déjà été décrits, leurs constantes ne seront pas reprises ici. Pour **1**, **2** et **7**, ils sont identiques à des échantillons authentiques (f, ir, rmn, R_f en ccm); pour **5** et **9**, les constantes et données spectrales sont en bon accord avec les valeurs publiées.

(+) *Northalicarpine-6* ***6***: rmn (240 MHz (FT), $CDCl_3$): 2,45 (2′-NMe), 3,55 (7-OMe), 3,71 (1-OMe), 3,77 (6′-OMe), 3,78 et 3,83 (12′-OMe et 13′-OMe), 3,90 (2-OMe), 3,92 (10-OMe), 6,16 (H-8′), 6,47, 6,55, 6,58, 6,60, 6,62 (H-5′, H-3, H-11′, H-14′ et H-8), 8,21 (H-11); *m/z*: 680 (1), 490 (8), 324 (20), 322 (27), 206 (49), 192 (100).

The influence of pH in the tautomerism of 9,10-anthracenediols and 1,3-diketones

JOHN C. ANDERSON AND A. DOUGLAS BROADBENT[1]

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received July 2, 1985

JOHN C. ANDERSON and A. DOUGLAS BROADBENT. Can. J. Chem. **64**, 127 (1986).

Equations have been derived to describe how the ratio of the total concentration of all keto forms to that of all enolic forms (K') varies with changing pH, for a tautomeric system in which the enol and ketone are polyprotic acids. The influence of pH on the tautomerism of 2-amino-9,10-anthracenediol, 2,9,10-anthracenetriol, 2,4-pentanedione, and 1-(3-pyridyl)-1,3-butanedione was examined. The equilibrium constants for all the acid–base equilibria involved were calculated from the dependence of K' on pH.

JOHN C. ANDERSON et A. DOUGLAS BROADBENT. Can. J. Chem. **64**, 127 (1986).

On a dérivé des équations qui décrivent les variations du rapport (K') de la concentration totale de toutes les formes cétoniques sur celle de toutes les formes énoliques en fonction du pH d'un système tautomère dans lequel l'énol et la cétone sont des acides polyprotiques. On a étudié l'influence du pH sur la tautomérie de l'amino-2 anthracènediol-9,10, de l'anthracènetriol-2,9,10, de la pentanedione-2,4 et de la (pyridyl-3)-1 butanedione-1,3. À partir de l'effet du pH sur K', on a calculé les constantes d'équilibre de tous les équilibres acide–base impliqués dans cette étude.

[Traduit par le journal]

Introduction

A simple prototropic tautomerism, of the keto–enol type, consists of four coupled acid–base equilibria, as shown in Scheme 1. This represents the accepted pathways for interconversion of an enol (EH) and a ketone (KH). A clear distinction between the acidic dissociation reactions and the overall tautomerism is essential (1, 2). The tautomerism equilibrium constant, K_T, is a function of the acidic dissociation constants and is independent of pH (3).

$$EH \underset{}{\overset{K_1}{\rightleftharpoons}} E^- + H^+ \overset{K_2}{\rightleftharpoons} KH$$

$$H^+ + EH \underset{K_3}{\rightleftharpoons} HKH^+ \underset{K_4}{\rightleftharpoons} KH + H^+$$

$$K_T = [KH]/[EH] = K_1/K_2 = K_4/K_3$$

SCHEME 1

The influence of pH on the coupled acid–base reactions, constituting a tautomeric equilibrium, has not been widely studied, despite the significance of keto–enol and nitrogen heterocycle tautomerism in organic chemistry. The paucity of data on this aspect of tautomerism is not surprising on consideration of the criteria for optimum analysis of this problem. Firstly, the solution must have measurable amounts of the tautomeric species, and the analytical technique used must determine the concentrations of these without disturbing the equilibrium. Since the influence of pH is being considered, an aqueous or semi-aqueous solution is needed. This should not introduce any competing reactions, such as hydration, or result in inadequate solubility. Finally, the effect of the acid–base equilibra of the tautomers will be most obvious when at least one of them has an acidic dissociation constant in the normal aqueous pH range.

In this paper, the overall tautomerism equilibrium constant, K', is defined as the ratio of the total concentration of all ketonic to that of all enolic species. For Scheme 1,

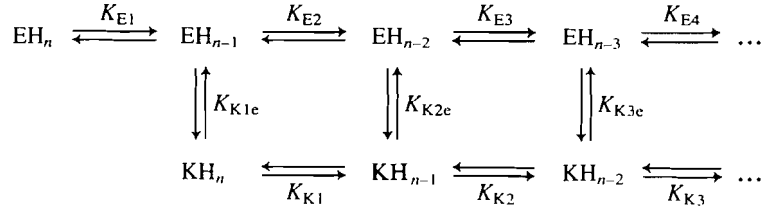
$$K' = ([HKH^+] + [KH])/([EH] + [E^-])$$

An equation for the dependence of K' on the concentration of hydrogen ion has been derived for a tautomeric system where both the ketone and enol are polyprotic acids. The tautomerism of 2-amino-9,10-anthracenediol, 2,9,10-anthracenetriol, 2,4-pentanedione, and 1-(3-pyridyl)-1,3-butanedione has been examined and the dependence of K' on pH has been used to determine the acidic dissociation constants of the various keto and enol forms and their influence on K_T.

Results and discussion

Reaction scheme

In a system where the enol and keto forms are polyfunctional acids and bases, Scheme 2 is applicable. Enolic species are represented by the symbol E and ketonic species by K.



SCHEME 2

Scheme 2 clearly illustrates that the overall tautomerism is a series of coupled acid–base equilibria. Hydrogen ions and ionic charges have been omitted from the scheme for clarity. The acidic dissociation constants are given for each step. These are apparent constants, which would be experimentally determined, so that no distinction between isomeric conjugate bases from ionization of a polyprotic acid is considered (4).

The overall tautomerism equilibrium constant, K', will have a form dependent upon the analytical technique that is used to measure the concentrations of the various species present in the

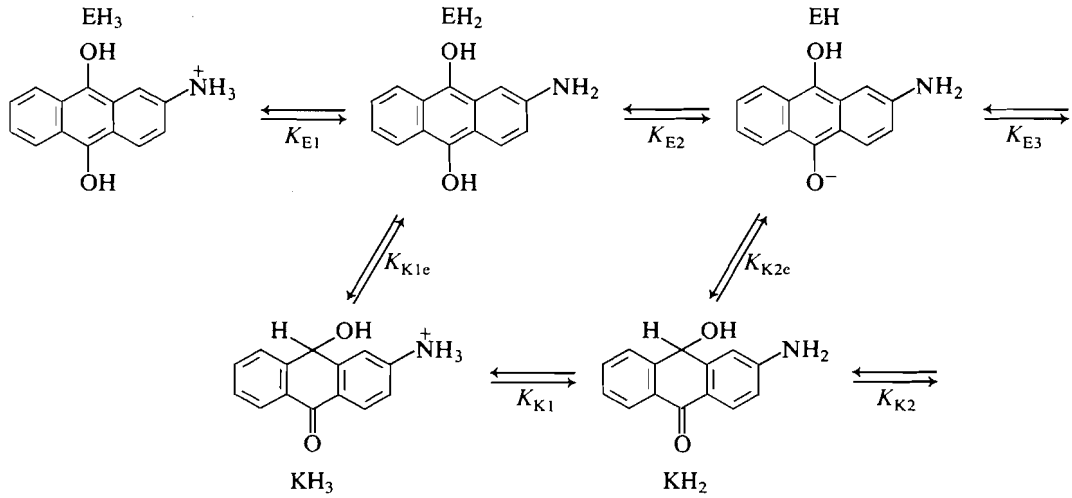

SCHEME 3

solution. If ideal solution behaviour is assumed, so that molarities are valid for activities, K' may be defined by

$$K' = \sum_0^n [KH_n] / \sum_0^n [EH_n]$$

Simple equilibrium considerations give

$$[1] \quad K' = \frac{K_{T1}\cdot(1 + K_{K1}/[H^+] + K_{K1}\cdot K_{K2}/[H^+]^2 + K_{K1}\cdot K_{K2}\cdot K_{K3}/[H^+]^3\cdots)}{(1 + K_{E1}/[H^+] + K_{E1}\cdot K_{E2}/[H^+]^2 + K_{E1}\cdot K_{E2}\cdot K_{E3}/[H^+]^3\cdots)}$$

$$[2] \quad = \frac{K_{T2}\cdot(1 + [H^+]/K_{K1} + K_{K2}/[H^+] + K_{K2}\cdot K_{K3}/[H^+]^2\cdots)}{(1 + [H^+]/K_{E1} + K_{E2}/[H^+] + K_{E2}\cdot K_{E3}/[H^+]^2\cdots)}$$

$$[3] \quad K_{T1} = [KH_n]/[EH_n] = K_{E1}/K_{K1e}$$

$$[4] \quad K_{T2} = [KH_{n-1}]/[EH_{n-1}] = K_{E2}/K_{K2e}$$

Both K_{T1} and K_{T2} are independent of pH and are related by

$$[5] \quad K_{T1}/K_{T2} = K_{E1}/K_{K1}$$

The above equations represent a more general situation than has been considered previously (3, 5) and are applicable over any range of pH.

2-Amino-9,10-anthracenediol

Bredereck *et al.* have studied the tautomerism of 2-amino-9,10-anthracenediol (2-amino-HOAOH) in aqueous ethanol solutions of varying pH (6). Although the keto form can be isolated by precipitation from a solution of the two tautomers (6), we were unable to confirm the structure by FT ^{1}Hmr, because of the very low solubility of the compound in the usual solvents. By analogy with the corresponding hydroxy-substituted derivatives (7), the keto form is considered to be 3-amino-10-hydroxy-9(10*H*)anthracenone, in which conjugation of the carbonyl and amino groups results in a low frequency ir carbonyl absorption band (6).

An interpretation of Bredereck's data on the variation of K' with changing pH, in terms of eq. [2], would require that the decrease in K', with decrease in pH from 8 to 6, as illustrated in Fig. 1, be related to protonation of the amino group in 2-amino-HOAOH ($EH_2 \rightarrow EH_3$ in Scheme 3). The ammonium ion would, therefore, have to have a pK_a of about 7. This is less acidic than typical phenylammonium ions, e.g., the conjugate acid of 2-aminoanthracene has a pK_a of 3.40 in 50% aqueous ethanol at 25°C (8).

Because of this unusual discrepancy, we re-investigated the tautomerism of 2-amino-HOAOH in buffered, aqueous ethanol solutions, over a wide range of pH, using polarography as described earlier (6, 7). The value of K' was determined from the ratio of the limiting, diffusion-controlled, cathodic current for the reduction of the anthracenone to the anodic current for the oxidation of the 2-amino-HOAOH. It was assumed that all the species had identical diffusion coefficients and that the influence of the applied potential on the drop-time did not affect the ratio of the recorded currents. The sum of the limiting currents for the 2-amino-HOAOH and its keto form was always within ±5% of the initial limiting current for the parent quinone, from which the 2-amino-HOAOH was generated by reduction using sodium dithionite, in neutral and basic solutions, or hydrogen and colloidal palladium in acidic solutions. The data are shown in Fig. 1.

Above pH 9, equilibrium between the two tautomers was attained within 1–2 min. In this pH region, there is reasonable correspondence between the previous and present K'–pH data, considering that all our pH values were 0.3–0.5 units higher than reported in the former study (6, 9). Below pH 9, the rate of ketonization of the 2-amino-HOAOH decreased significantly with decreasing pH. This is a consequence of the general base-catalysed mechanism, typical of tautomerism of an enol via the enolate ion, which is formed in a rapid pre-equilibrium. At pH <7, equilibration required 2–3 days and it became apparent that the values of K', previously reported for the pH range 6–9, were too low and were not equilibrium values. In addition, because of the confusion between acid–base and tautomeric equilibria, the published linear free energy relationship (6, 10) does not describe the influence of substituents on the

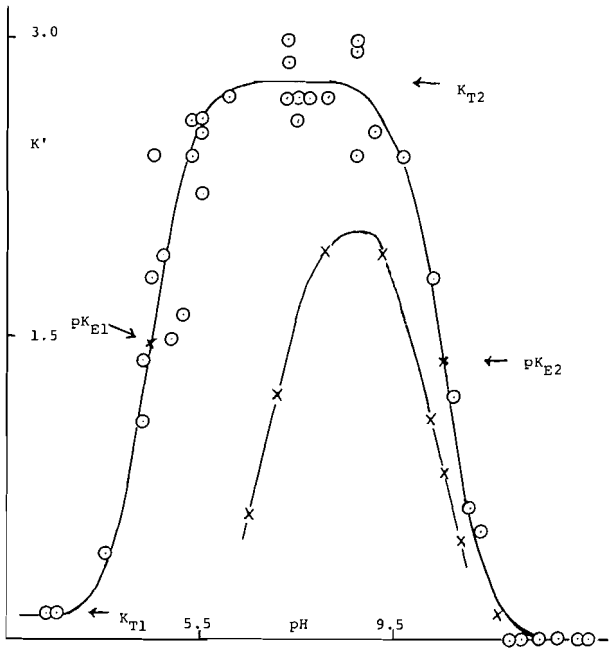

FIG. 1. The dependence of K' on pH for 50% aqueous ethanolic solutions of 2-amino-9,10-anthracenediol at 25°C. Circles represent experimental values and the line is based on the appropriate form of eq. [2], given below, using the values $K_{T1} = 0.08$, $K_{T2} = 2.71$, $pK_{E1} = 4.34$, and $pK_{E2} = 10.57$, which were derived from the K' data. Crosses represent previously published data (6).

$$K' = \frac{K_{T2} + K_{T1}\cdot[H^+]/K_{E1}}{1 + [H^+]/K_{E1} + K_{E2}/[H^+]}$$

equilibrium constant for tautomerism of anthracenediols, but rather their effect on the acidity of the C—H bond in the keto forms.

The redetermined values of K' are plotted as a function of pH in Fig. 1, which also shows the dependence based on the plateau values K_{T1} and K_{T2} and the two acidic dissociation constants, K_{E1} and K_{E2}, whose values were confirmed independently. The weighted least-squares estimates of these parameters were derived from the experimental data using a nonlinear regression procedure. Only these four constants are needed to define the curve, since the value of K_{E3} is so small that the term involving it in eq. [2] only becomes significant after K' is essentially zero. In addition, K_{K2} and K_{K3} are negligibly small and KH_3 and KH_2 (Scheme 3) are the only keto species present in the solution. Values of the constants are listed in Table 1.

The graph of $E_{1/2}$ versus pH, for the diffusion-controlled anodic wave for polarographic oxidation of the 2-amino-HOAOH, consisted of three linear sections with slopes close to −90, −60, and −30 mV/pH unit. These lines intersected at pH values of 3.9 ± 0.2 and 10.4 ± 0.1, which correspond to the values of pK_{E1} and pK_{E2} (11). The value of pK_{E3} was inaccessible since no evidence was found that $E_{1/2}$ became independent of pH in alkaline solution, as reported earlier (6).

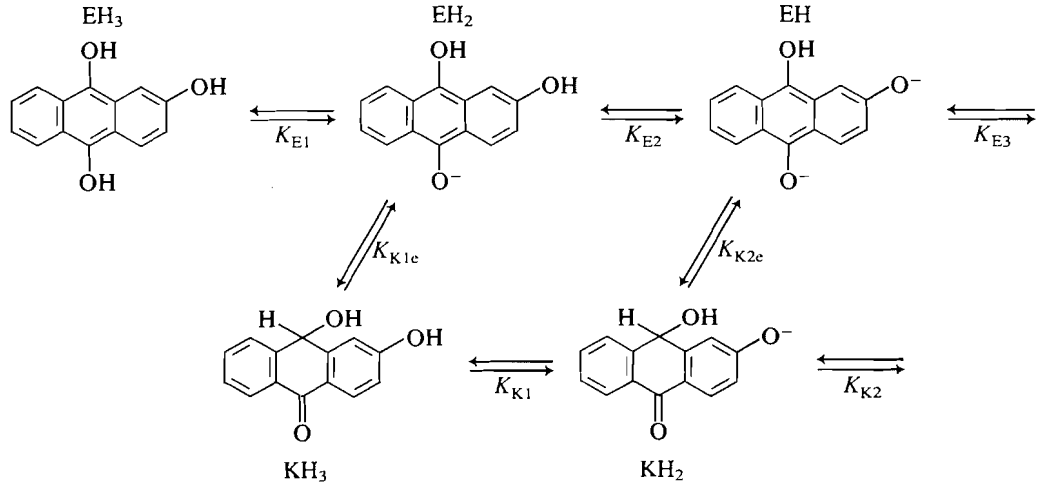
Freshly prepared solutions of 2-amino-HOAOH at pH 1 exhibited maximum absorbance at 381 nm in the uv spectrum, which decreased on increasing the pH of the solution. A graph of absorbance at 381 nm versus pH gave a typical neutralization curve, for which regression analysis of the usual plot of pH versus $\log (A_1 - A)/(A - A_2)$ gave an intercept of 4.15 ± 0.05, corresponding to pK_{E1}. In the acidic solutions examined, the 2-amino-HOAOH was generated by reduction of the parent quinone using hydrogen and colloidal palladium. The absorbance at 381 nm was determined as soon as reduction was complete, but it remained constant over 5–10 min since the rate of ketonization was too low to influence the reading.

The spectrophotometrically determined value of pK_{E1} of 4.15 is the most reliable. The determination of pK_a values from the dependence of $E_{1/2}$ on pH is inferior because the potentials cannot be measured with a precision better than ±5 mV and errors occur if the polarographic process is irreversible, or variations of diffusion coefficients occur over the pH range examined. Derivation of pK_a values from the dependence of K' on pH, in the case of 2-amino-HOAOH, was limited by the considerable scatter of the K' values. This was a consequence of the errors inherent in measuring limiting currents and the long equilibration time necessary for the volatile, air-sensitive, neutral and acidic solutions. Despite this, the constants K_{T1}, K_{T2}, pK_{E1}, and pK_{E2} uniquely describe the dependence of K' on pH and could be calculated from the experimental data. The other equilibrium constants in Scheme 3 were then calculated using eqs. [3], [4], and [5] (see Table 1).

2,9,10-Anthracenetriol

Equation [1] was applied to the published data on the tautomerism of 2,9,10-anthracenetriol in aqueous solution, where extensive ketonization occurs over only a narrow range of pH (7). The keto form KH_3 is considered to be 3,10-dihydroxy-9(10*H*)anthracenone, based on the structures of the 3,6,10- and 3,7,10-trihydroxy derivatives, which were established by ^{1}Hmr (7). The various species present are illustrated in Scheme 4.

Figure 2 shows how the polarographically determined values of K' for 2,9,10-anthracenetriol depend on pH and includes a matching plot of the appropriate form of eq. [1]. Only two keto



SCHEME 4

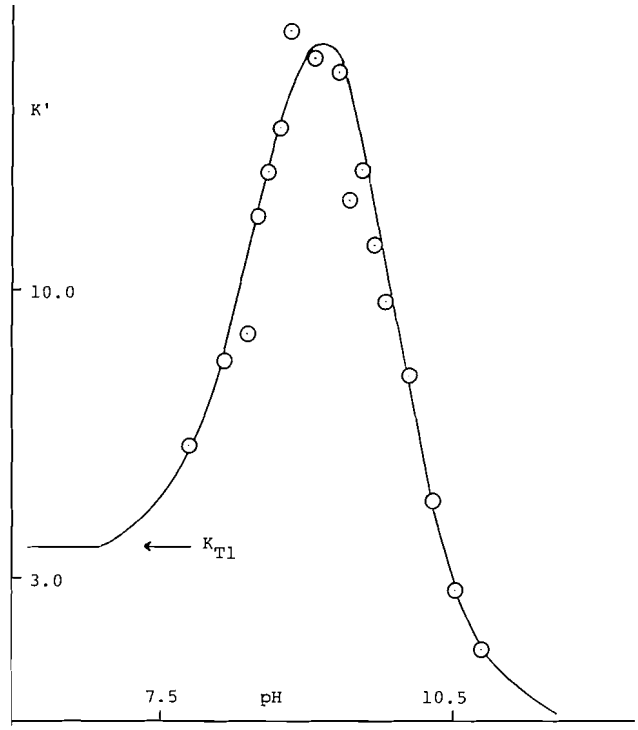


FIG. 2. The dependence of K' on pH for aqueous solutions of 2,9,10-anthracenetriol. Circles represent the published experimental data (7) and the line is the plot of the appropriate form of eq. [1], given below, using $K_{T1} = 3.9$, $pK_{E1} = 8.70$, $pK_{E2} = 9.67$, and $pK_{K1} = 7.90$.

$$K' = \frac{K_{T1}\cdot(1 + K_{K1}/[H^+])}{1 + K_{E1}/[H^+] + K_{E1}\cdot K_{E2}/[H^+]^2}$$

forms (KH_3 and KH_2) exist in the solution, because $K_{E2} > K_{E2e} > K_{K2}$, and K_{K3} is essentially zero, corresponding to the dissociation of an aromatic C—H bond. In addition, the value of K_{E3} is too small (2.5×10^{-13}) to be of influence (7).

The experimental data for K' did not show any plateau because of the proximity of the values of K_{E1} and K_{E2}. In this case, therefore, these acidity constants and K_{T2} cannot be derived from direct examination of Fig. 2. The values of K' above 10 could not be measured with great precision (±10%), so initially the analysis of the experimental data was achieved by adjustment of the values of K_{T1}, K_{E1}, K_{E2}, and K_{K1} to give the best visual fit to the K' – pH data points using the appropriate form of eq. [1]. Subsequently, better estimates of these equilibrium constants were derived by a nonlinear regression

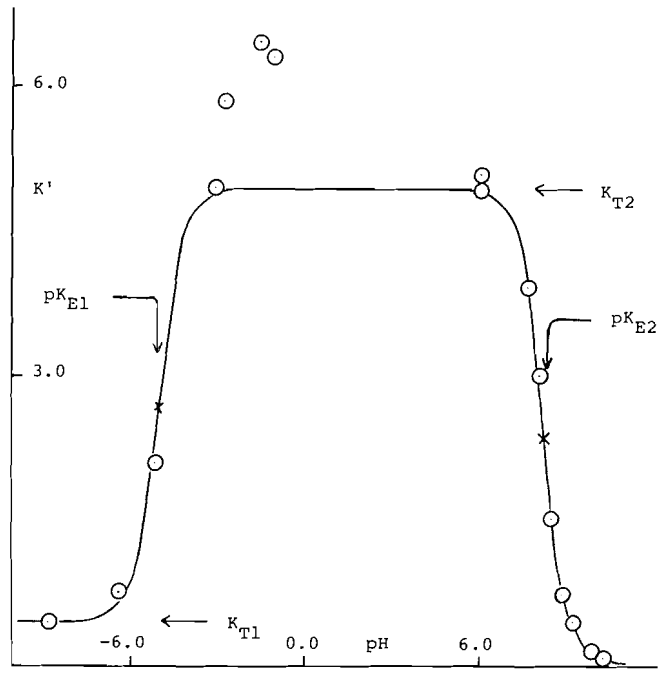

FIG. 3. The dependence of K' on pH for aqueous and sulfuric acid solutions of 2,4-pentanedione. The points represent published experimental data (5, 13) and the line is the plot of the appropriate form of eq. [2] with $K_{T2} = 5.03$, $pK_{E1} = -5.12$, $pK_{E2} = 8.19$, and $K_{T1} = 0.45$.

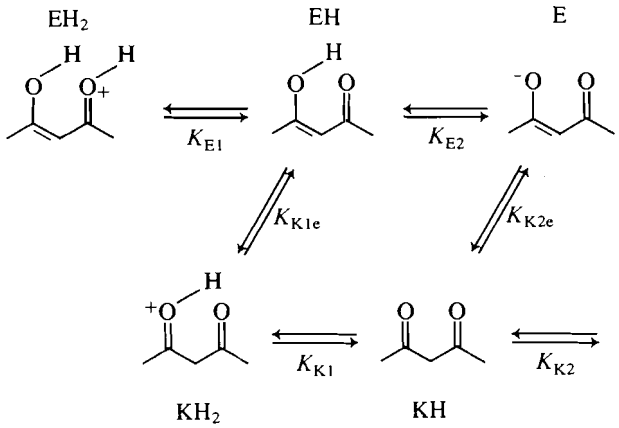
$$K' = \frac{K_{T2} + K_{T1}\cdot[H^+]/K_{E1}}{1 + [H^+]/K_{E1} + K_{E2}/[H^+]}$$

procedure. Their values are given in Table 1. This analysis demonstrated that the values of the four parameters uniquely define the dependence of K' on pH.

2,4-Pentanedione

There is little published data on the influence of pH in keto–enol systems. Zuman and co-workers (12) have studied the tautomerism of 1,3-dicarbonyl and related compounds, in the basic pH range, using spectrophotometric, polarographic, and bromine titration methods. Their results allowed the calculation of acidic dissociation constants for the enol and keto forms. Because of the limited pH range involved, the solutions contained only the enol and keto forms, and the enolate anion. A more detailed description is required when a wider pH range is considered.

The enol content of aqueous sulfuric acid and basic solutions



SCHEME 5

of 2,4-pentanedione has been determined (5, 13) and we chose to examine these data in relation to eq. [2] because of the range of acidity of the aqueous solutions studied. Values of K', calculated from the published data, are plotted as a function of pH in Fig. 3. The various species present are illustrated in Scheme 5.

The protonated enol EH_2 behaves as a diprotic acid (K_{E1}, K_{E2}), but for the keto form KH, K_{K2} is negligibly small since it corresponds to acidic dissociation of a C—H bond in a methyl group of the 2,4-pentanedione. This also applies to K_{E3}. The solution contains up to 5 species (Scheme 5) and there are 5 acidic dissociation constants neglecting K_{K2}. The appropriate form of eq. [2], given in Fig. 3, involves four constants, which can be read from the diagram. Nonlinear least-squares regression gave the values of the constants listed in Table 1, which differ slightly from those previously calculated (5, 13).

The K_{T2} plateau is not well defined, primarily because K' increases as the pH (Hammett acidity function) decreases from 0 to −3, prior to the large decrease in K' associated with the formation of the resonance-stabilized, protonated enol in strongly acidic solutions (pH < −3). This anomalous behaviour is a consequence of the large changes in sulfuric acid concentration resulting in variations of activity coefficient ratios (5).

To confirm the value of K' in weakly acidic aqueous solutions, we investigated the proton nmr spectrum of 2,4-pentanedione in such solutions. Integration of the ^{1}Hmr signals at 154 Hz (CH_3—CO group in enol and ketone) and 166 Hz (CH_3—C= group in enol) upfield from the water resonance of a 1.0 *M* aqueous 2,4-pentanedione solution, adjusted to pH 4.1 with dilute HCl, gave a value of $K_T = 4.68 \pm 0.16$ at 25°C. That this is lower than the anticipated plateau value is a consequence of the effect of the high concentration of the diketone decreasing K_T (14).

Various groups have established that the apparent acidic dissociation constant pK_{app} of 2,4-pentanedione in aqueous solution at 25°C is 9.05 ± 0.03 (15–17).

$$K_{app} = \frac{[H^+]\cdot[E^-]}{[K] + [E]} = \frac{K_{E2}}{1 + K_{T2}}$$

From the above equation, a value of $pK_{app} = 9.05$ and $K_{T2} = 5.0$ gives $pK_{E2} = 8.27$, which is in good agreement, considering differences in concentraton and ionic strength, with the value of 8.19 derived from the K' – pH data. The dependence of K' on pH thus provides a useful method for the determination of the acidic dissociation constants. In the case of K_{E1}, however, the value derived is not the true acidic dissociation constant because ketones follow a different acidity function than the amine indicators used to establish the Hammett acidity function used in Fig. 3 (18).

1-(3-Pyridyl)-1,3-butanedione

Scheme 6 describes the tautomerism of 1-(3-pyridyl)-1,3-butanedione. For this sytem, $n = 2$, but K_{K2} is negligibly small.

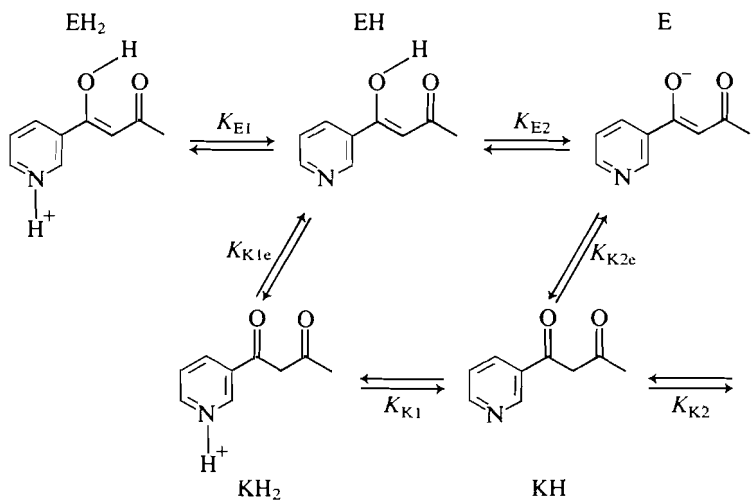
K' was determined by ^{1}Hmr spectroscopy in aqueous buffered dioxan solutions, by integration of the signal areas for the resolved methyl resonances of the enol and keto forms (enol CH_3, 2.04 ppm; keto CH_3, 2.20 ppm) and for the enol alkene and aromatic H-5 proton resonances (enol =C—H, 6.20 ppm; enol and keto aromatic H-5, 7.3 ppm).

$$K' = (\text{keto } CH_3)/(\text{enol } CH_3)$$

$$K' + 1 = (\text{aromatic H-5})/(\text{enol} =C—H)$$

Both methods gave consistent results but, in basic solutions of pH >8, the resolution of the enol and keto methyl resonances was unsatisfactory because of peak broadening, resulting from the enhanced rate of base-catalysed tautomer interconversion. In addition, because of the concentrated solutions required to obtain reliable signal integrations, and also because of the need to maintain a constant ionic strength, precise K' values could not be obtained at pH >8.7.

The experimental data are illustrated in Fig. 4, along with a plot of the appropriate form of eq. [2]. Approximate values for K_{T1}, K_{T2}, K_{E1}, and K_{E2} could be read from the points plotted in Fig. 4. Nonlinear least-squares regression gave the values in Table 1.



SCHEME 6

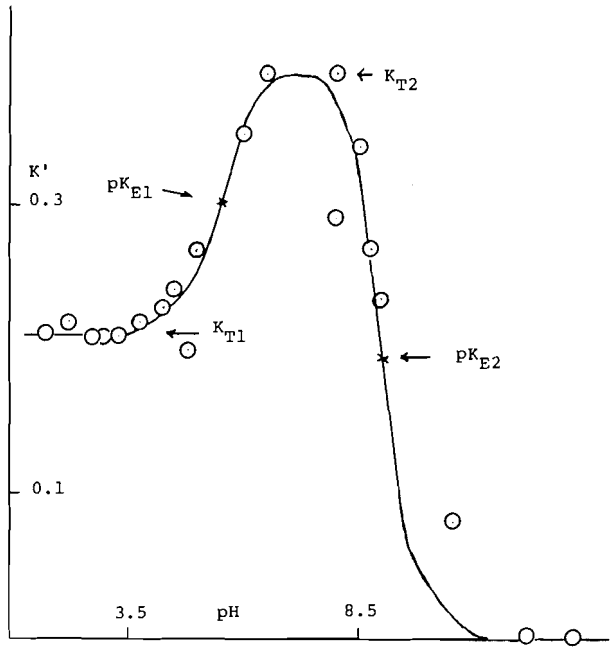


FIG. 4. The dependence of K' on pH for 30% v/v dioxan/water solutions of 1-(3-pyridyl)-1,3-butanedione at 35°C. The points represent experimental values and the line is the plot of the appropriate form of eq. [2] using $K_{T1} = 0.21$, $K_{T2} = 0.38$, $pK_{E1} = 5.51$, and $pK_{E2} = 9.18$.

$$K' = \frac{K_{T2} + K_{T1}\cdot[H^+]/K_{E1}}{1 + [H^+]/K_{E1} + K_{E2}/[H^+]}$$

Conclusion

The reaction scheme and equations used in this study describe the tautomeric and acid–base equilibria linking polyprotic enols and ketones. The experimental dependence of K' on pH provides sufficient data to calculate all the relevant acidic dissociation constants for both tautomers (see Table 1). In several cases, good estimates of both equilibrium and acidic dissociation constants could be read directly from the graph of K' vs. pH. The nonlinear regression provided the best values of the constants and also clearly established that the set of equilibrium and acidic dissociation constants uniquely describes the pH dependence of K'.

When the enol is the predominant tautomer, the acidic dissociation of the enol O—H bond, to give the enolate ion, is less favourable than that of the keto C—H bond, which gives the common conjugate base; i.e., $K_{En} < K_{Kne}$, a reversal of the usual order of O—H and C—H acidities.

Experimental

Materials

Commercial 2-amino-9,10-anthracenedione was purified by column chromatography ($SiO_2/HCCl_3$) and recrystallized from ethanol, mp 301°C.

1-(3-Pyridyl)-1,3-butanedione was synthesized from ethyl nicotinate by reported methods and recrystallized from ethanol/water, mp 81–82°C (19); ^{1}Hmr ($DCCl_3$) δ: 2.15 (s, 3H, enol CH_3), 6.15 (s, 1H, enol =C—H), 7.36 (m, $J_{4,5} = 8$ Hz, $J_{5,6} = 5$ Hz, $J_{2,5} = 1$ Hz, 1H, H-5), 8.14 (m, $J_{4,5} = 8$ Hz, $J_{4,6} = J_{2,4} = 2$ Hz, 1H, H-4), 8.72 (m, $J_{5,6} = 5$ Hz, $J_{4,6} = 2$ Hz, 1H, H-6), 9.05 (m, $J_{2,4} = 2$ Hz, $J_{2,5} = 1$ Hz, 1H, H-2), 16 (s, b, 1H, enol O—H).

Polarography

All polarographic measurements were performed using a Metrohm Polarecord E261. The polarographic cell has been described (20). The solutions of 2-amino-HOAOH were prepared by diluting 50.0 cm^3 of 8×10^{-4} M solution of 2-amino-9-10-anthracenedione in absolute ethanol with aqueous buffer solution and water to a final volume of 100 cm^3. Stoichiometric reduction of the quinone was achieved by amperometric titration with alkaline 0.05 M sodium dithionite solution under nitrogen, for solutions with pH >6.5, or by using hydrogen and colloidal palladium, and subsequent displacement of hydrogen by nitrogen, for acidic solutions. All solutions had an ionic strength of 0.1 M and were maintained at 25°C. The polarographic behaviour and the evaluation of K' (precision ±7%) have been described (9). For pH measurements with the Beckman Research pH Meter, the glass electrode was calibrated with aqueous standard solutions and the pH of the ethanolic solutions was recorded after adequate equilibration (~15 min).

Nuclear magnetic resonance

The ^{1}Hmr spectra of 1.0 M 1-(3-pyridyl)-1,3-butanedione solutions in 30% v/v dioxan/water were recorded using a Varian EM 360-L spectrometer at 35°C. Multiple integration of the appropriate signals gave K' with a precision of ±8%. The pH of the solutions was adjusted by including aqueous HCl, NaOH, or aqueous buffer solutions, so that the ionic strength was always 0.5 M. Two solutions with pH >9 had higher ionic strengths.

Nonlinear regression

Values of the equilibrium and acidic dissociation constants were derived from the K'–pH data using the weighted nonlinear least-squares regression procedure of the SAS Institute (SAS-ELIN).

The diazotization of 1-naphthylamine has been studied at acidities ranging from 10^{-2} to 1.5 *M*. At low acidities nitrosation takes place via the unprotonated form of the amine, and the rate-controlling step is either the interaction with the nitrosating agent or, if high concentrations of a nucleophile are present, the loss of a proton from the protonated nitrosamine (the nucleophiles studied were Cl^-, Br^-, SCN^-, and thiourea). At high acidities the protonated and free amines also react, the former of these reactions involving proton transfer to the solvent. In each case the proposed mechanism was supported by studying the reaction in D_2O, which also allowed the isotopic effect of the solvent on the formation equilibria of the various nitrosating agents to be obtained.

JULIO CASADO, ALBINO CASTRO, EMILIA IGLESIAS, M. ELENA PEÑA, et JOSÉ VÁZQUEZ TATO. Can. J. Chem. **64**, 133 (1986).

On a étudié la diazotation de la naphtylamine-1 dans un intervalle d'acidités allant de 10^{-2} à 1,5 *M*. À faible acidité, la nitrosation se produit via la forme non protonée de l'amine; l'étape déterminante de la réaction est soit l'interaction avec l'agent de nitrosation ou, s'il y a une forte concentration de nucléophiles, la perte d'un proton à partir de la forme protonée de la nitrosamine (les nucléophiles étudiés sont les ions Cl^-, Br^-, SCN^- et la thiourée). À des acidités élevées, les amines protonées et libres réagissent également. Dans le cas des amines protonées, la réaction implique un transfert de proton au solvant. Dans chaque cas, le mécanisme proposé repose sur une étude de la réaction dans le D_2O, qui permet également d'obtenir l'effet isotopique du solvant sur la formation à l'équilibre des divers agents de nitrosation.

[Traduit par le journal]

Introduction

The rate equations of diazotization reactions are heavily dependent on the experimental conditions, whose modification may change both the nitrosating agent (nitrosation being a preliminary step towards diazotization) and the slow step of the reaction, and at one time this behaviour gave rise to considerable controversy, the general validity of conflicting rate equations being claimed by their authors (1). Most research in this area has involved aromatic amines such as anilines and pyridines, whose diazonium ions are relatively stable and for which the effect of substitution has been analysed in some detail, but rather less is known about compounds with multiple rings. These considerations have led us to carry out a detailed study of the diazotization of 1-naphthylamine (1-NA) in water and in D_2O, at acidities ranging from 10^{-2} to 1.5 *M* and in the presence of various nucleophiles. 1-NA was chosen for its simplicity and the value of its pK_a, and because the only published study of its diazotization (2), in which ClNO was used as nitrosating agent, yielded a value of $1.9 \times 10^{10} M^{-1} s^{-1}$ for the attack constant at 0°C, which is surprisingly high compared with the values of $(1.0–5.9) \times 10^9 M^{-1} s^{-1}$ obtained at 25°C for anilines and their derivatives (3), and which are widely accepted as evidence of these reactions being diffusion controlled. It was expected that varying the experimental conditions might result in 1-NA exhibiting nucleophile catalysis, rate-limiting proton transfer to the solvent, and reactions via its free and protonate forms.

Experimental

All the reagents employed were Merck p.a. products and were used directly after drying. D_2O was supplied by the Spanish Nuclear Energy Board (Junta de Energía Nuclear) and contained 99.77% D. 1-NA and its solutions were protected from light to prevent their photodecomposition, but fresh solutions were in any case prepared at short intervals. The stability of the diazonium salt produced by the reaction and that of the 1-NA were verified experimentally under the various working conditions used. The decomposition of nitrite was also observed to be negligible during the course of the reaction, even under the most unfavourable conditions.

Kinetic measurements were carried out in a UVIKON 820 spectrophotometer, the temperature of the cell carrier being kept constant by a HETO 03T623 thermostat. A Radiometer 82 pH-meter with a GK 2401C combined electrode was used to measure pH.

The formation of the diazonium salt was monitored spectrophotometrically at 362 nm, a wavelength at which this salt is the only component of the reaction mixture to exhibit any appreciable absorption ($\epsilon = 6400\ M^{-1}\ cm^{-1}$). The integration method was used for kinetic analysis. When equal concentrations of nitrite and 1-NA were employed, the equation fitted to the experimental absorbance–time data was

$$[1] \qquad \frac{1}{A_\infty - A_t} = \frac{1}{A_\infty - A_0} - (k_2/\epsilon)t$$

A_t, A_∞, and A_0 being the absorbances at times t, infinity, and 0 respectively. When the reaction was slow enough for more than a 20-fold excess of amine to be used, the method of Davies, Swann, and Campey (4, 5) was used to fit the equation

$$[2] \qquad \ln (A_\infty - A_t) = \ln (A_\infty - A_0) - k_1 t$$

In either case the corresponding graphs (respectively $1/(A_\infty - A_t)$ against t and $\ln (A_\infty - A_t)$ against t) were linear for at least 85% of the reaction (Fig. 1) with standard deviations of less than 2%. When eq. [1] was used the values of A_∞ and A_0 were obtained experimentally. The values of k_1 and k_2 were reproducible to within ±3%. All experiments were carried out at 25°C.

Results and discussion

At acidities in the range 0.085–1.62 *M* $HClO_4$ the diazotization of 1-NA was found, using excess amine, to be of first order with respect to both reagents (Table 1). First-order behaviour with respect to HNO_2 was confirmed by the agreement between the experimental A_t–t data and eq. [2]. Thus,

$$[3] \qquad v = k_1[HNO_2] = k_2[1\text{-NA}]\,[HNO_2]$$

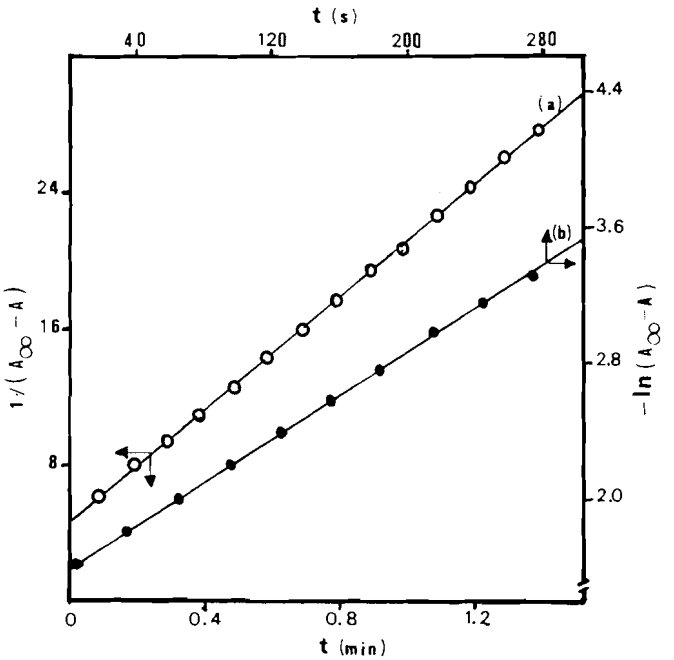

FIG. 1. (a) Typical pseudo-second-order plot of the diazotization of 1-NA at 25°C, $I = 0.35$ *M*, $[HNO_2] = [1\text{-NA}] = 3.27 \times 10^{-5}$ *M*, $[NaSCN] = 2 \times 10^{-3}$ *M*, $[H^+] = 0.1$ *M*. (b) Typical pseudo-first-order plot of the diazotization of 1-NA at 25°C, $I = 0.35$ *M*, $[1\text{-NA}] = 1.05 \times 10^{-3}$ *M*, $[HNO_2] = 3.27 \times 10^{-5}$ *M*, [NaCl] = 0.0266 *M*, $[H^+] = 0.1$ *M*.

Catalysis by nucleophiles

The influence of the nucleophiles Cl^-, Br^-, SCN^-, and $(NH_2)_2CS$ was studied at 25°C in 0.1 *M* $HClO_4$ using constant concentrations of nitrous acid and 1-NA ($I = 0.35$ *M*). Cl^-, Br^-, and SCN^- were used in the form of their sodium salts. The concentrations of NaCl and NaBr employed varied from 0.017 *M* to 0.25 *M*, those of NaSCN from 0.001 *M* to 0.015 *M*, and those of thiourea from 1.48×10^{-4} *M* to 2.23×10^{-4} *M*. The concentrations of HNO_2 and 1-NA were 3.3×10^{-5} *M* except in the experiments with Cl^-, which were slow enough to allow the use of excess amine (1.06×10^{-3} *M*).

Under the above conditions the halide ions and thiourea all catalysed the reaction. The graphs of k_2 against [Nucleophile] are curves in which k_2 tends with increasing [Nucleophile] to a limit that is the same for all nucleophiles employed (Fig. 2). This limiting value may be evaluated from the intercepts of the plots $1/k_2$ vs. $1/[X^-]$ (the average value is 4500 M^{-1} s^{-1} for all of them). This suggests the reaction mechanism to be of the kind put forward by Woppmann (2), in which the nitrosating agent is the nitrosyl salt of the nucleophile (Scheme 1). No evidence of nitrosation by any other agent ($NO^+(H_2NO_2^+)$ or N_2O_3) was observed.

Assuming the steady-state condition to be applicable to the intermediate I in Scheme 1,

$$[4] \qquad k_2 = \frac{k_2 K_{XNO} K_a [X^-]}{1 + (k_{-3}/k_4)[X^-]}$$

where $K_{XNO} = K_1 K_2$ is the equilibrium constant of the formation of the nitrosyl salt of the nucleophile, and K_a is the dissociation constant of the protonated amine (the value of 3.96 obtained spectrophotometrically by the present authors for the pK_a at 25°C and an ionic strength of 0.2 *M* agrees well with the value published by Hall and Sprinkle (6). Except for thiourea,[3] the values of k_2 were unchanged on working at pH 1.5.

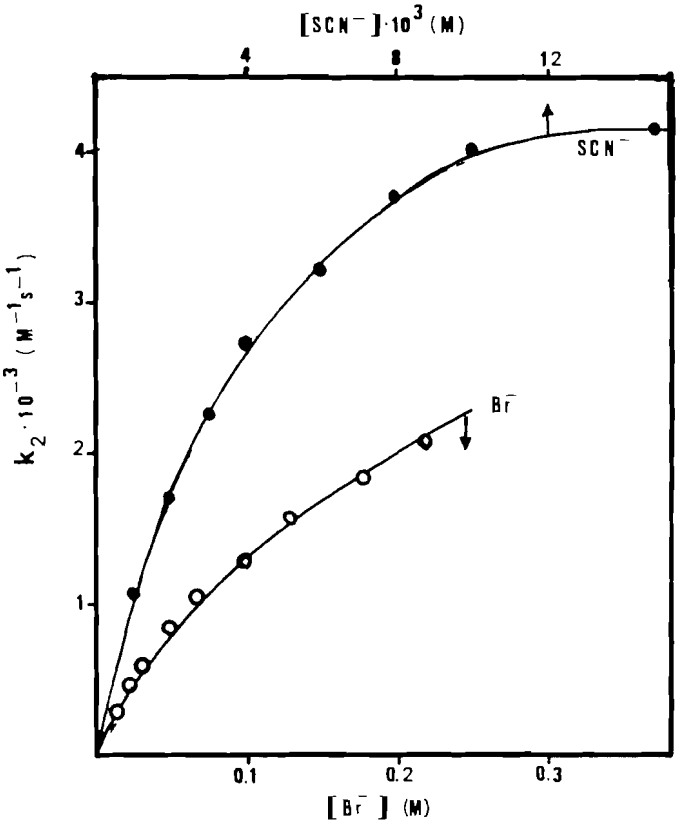

FIG. 2. Influence of the concentration of SCN^- (●) and Br^- (○) on the second-order rate coefficient, k_2 (eq. [4]) at 25°C, $I = 0.35$ *M*.

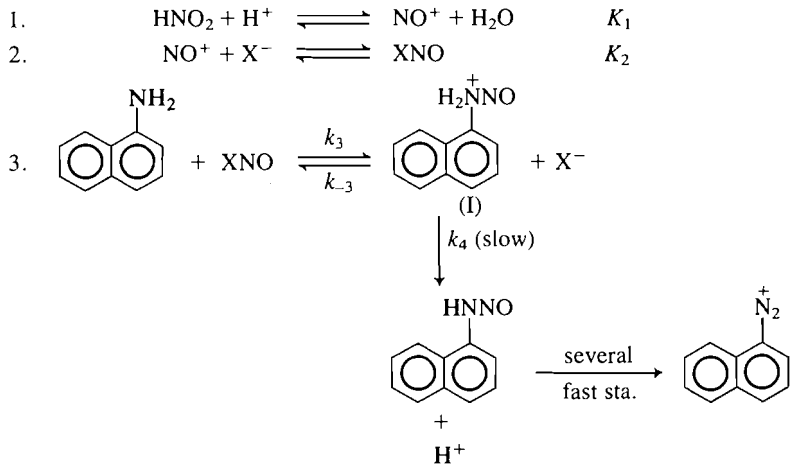
The values of k_3 and k_{-3}/k_4 obtained by plotting k_2^{-1} against $[\text{Nucleophile}]^{-1}$ are listed in Table 2. The values thus found for k_3(ClNO) and k_3(BrNO) indicate diffusion-controlled processes and are compatible with those reported by Williams and co-workers (3) and Schmid and Fouad (11) (Table 2). The much lower values of k_3 for SCNNO and nitrosothiourea are in keeping with the lower reactivity of these latter nitrosating agents, their greater catalytic effect being due to their large K_{XNO}. Figure 3 shows that the values of log (k_{-3}/k_4) are satisfactorily correlated with Pearson's nucleophilicity param-

[3]In this case it is necessary to take into account that the initial stoichiometric concentration of nitrous acid is equal to $[HNO_2]$ + [Nitrosothiourea]. Thus, $k_2 = k_3 K_{XNO} K_a [TU]/\{1 + (k_{-3}/k_4)[TU]\}(1 + K_{XNO}[H^+][TU])$.



(X^- = Cl^-, Br^-, SCN^-, thiourea)

eter, n (12), the value of 1.1 for the slope of the line being similar to those usually found for typical S_N2 substitutions on the carbon atom. The present results are thus in keeping with the usual order of nucleophilicity, $Cl^- < Br^- < SCN^- < (NH_2)_2CS$.

Support for the proposed k_4 step was sought by repeating the Br^- and SCN^- experiments in heavy water. The constants obtained in water and D_2O are shown in Table 3. If, as is reasonable, the isotopic effect on the k_3 process is assumed to be negligible, then a value of 3.11 may be calculated for the isotopic effect on the k_4 step. Since this value is that of a primary isotopic effect, the slow k_4 step must involve proton transfer.

The D_2O experiments also allow the isotopic effect on the K_1 equilibrium to be calculated from the values of $k_3K_{XNO}K_a$. If the effects on the K_2 equilibrium constant and the diffusion-controlled k_3 step are assumed negligible, then when the nucleophile employed is SCN^- or Br^- the values of pK_a obtained in water and D_2O and listed in Table 3 imply isotopic effects of 2.19 and 2.96, respectively, on the formation of NO^+. These values agree well with each other and with those reported by Challis *et al.* (13) for the nitrosation reaction

$$I^- + H_2NO_2^+ \rightarrow INO + H_2O$$

which supports the assumptions made in their derivation.

Experiments carried out to determine the influence of temperature on the diazotization of 1-NA by ClNO yielded the value of 79.67 kJ/mol for the Arrhenius activation energy and the values $\Delta H^{\ddagger} = 13.89$ kJ/mol and $\Delta S^{\ddagger} = -19.45$ J/(mol K) for the k_3 step.[4] The enthalpy of activation is within the accepted limits for a diffusion-controlled step (10–20 kJ/mol), and thus agrees with the value obtained for the constant k_3.

Catalysis by $HClO_4$ and $NaClO_4$

The influence of ionic strength on the diazotization of 1-NA was studied by varying the concentration of $NaClO_4$ in a series of experiments carried out at 25°C in 0.5 M $HClO_4$, using constant concentrations of nitrite and 1-NA of 2.75×10^{-5} M

[4]These quantities were calculated from the values at different temperatures of $k_3K_{ClNO}K_a$ (the slope of the graph of k_2^{-1} against $[Cl^-]^{-1}$) together with published values for K_{ClNO} at 0 and 25°C (7) and the values of K_a at 14 (5.55×10^{-5} M, $I = 0.2$ M) and 25°C (Table 3). The latter were obtained spectrophotometrically at 310 nm by the present authors because the values found in the literature for K_a at 15°C (14) and 25°C (6) afford a value of 136.6 kJ/mol for the enthalpy of ionization of the 1-naphthylammonium ion, which is enormously high compared with the values of 20–53 kJ/mol found for anilines (15) and would imply a negative enthalpy of activation.

TABLE 3. Values of the kinetic and thermodynamic parameters of eq. [4] in water and D_2O, $t = 25°C$

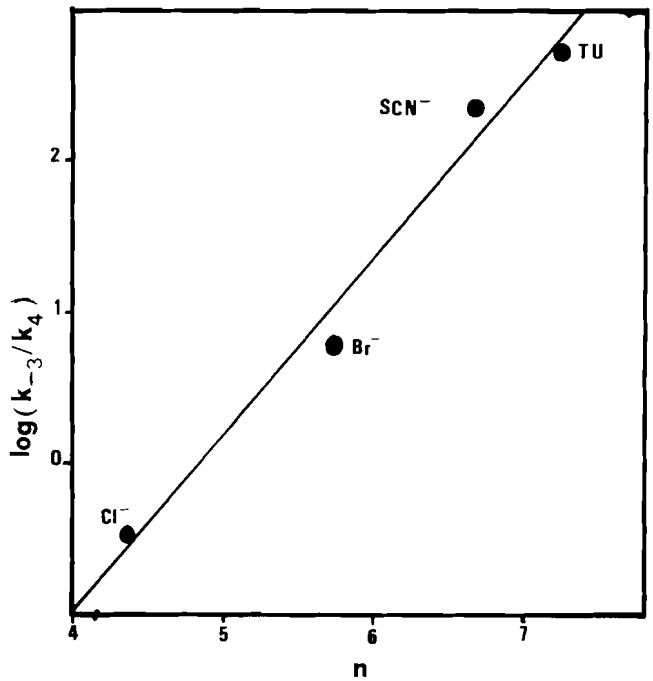

FIG. 3. Variation of log (k_{-3}/k_4) with Pearson nucleophilicity, n.

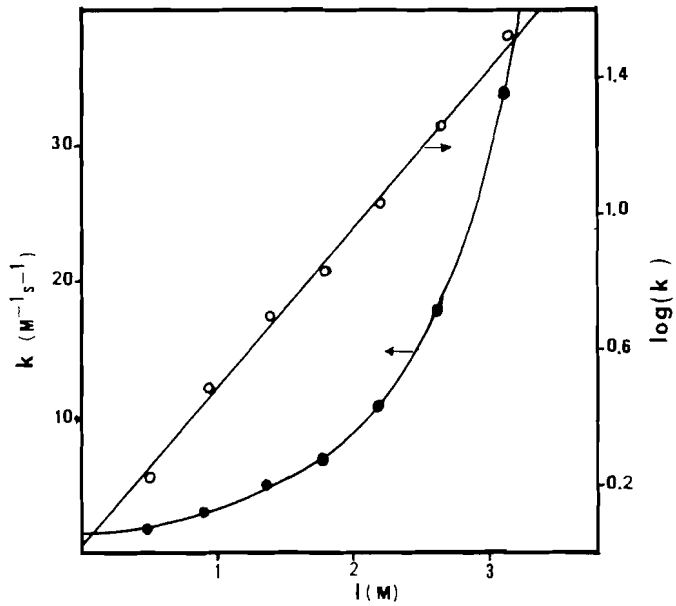

FIG. 4. Influence of the ionic strength on the second-order rate constant, k, at 25°C, $[HClO_4] = 0.5$ M, $[NaNO_2] = 2.75 \times 10^{-5}$ M, $[1\text{-NA}] = 1.32 \times 10^{-3}$ M.

and 1.32×10^{-3} M, respectively. The observed reaction rates reveal increasing catalysis as the concentration of salt rises, the dependence of the logarithm of the second-order experimental rate constant k on the ionic strength of the medium being linear, with a slope of 0.485 ± 0.017 (Fig. 4). These findings are similar to those obtained for other substrates (15), and may be considered as evidence of a secondary saline effect acting to increase the equilibrium concentration of the nitrosating agent (NO^+ or $H_2NO_2^+$).

The influence of acidity was studied by varying the concentration of $HClO_4$ from 0.15 to 1.5 M at 25°C and an ionic strength of 1.5 M controlled by $NaClO_4$, the concentrations of nitrous acid and 1-NA being those mentioned in the previous paragraph. In these conditions the rate equation is (16, 17)

$$[5] \qquad v = k[\text{Amine}][HNO_2]$$

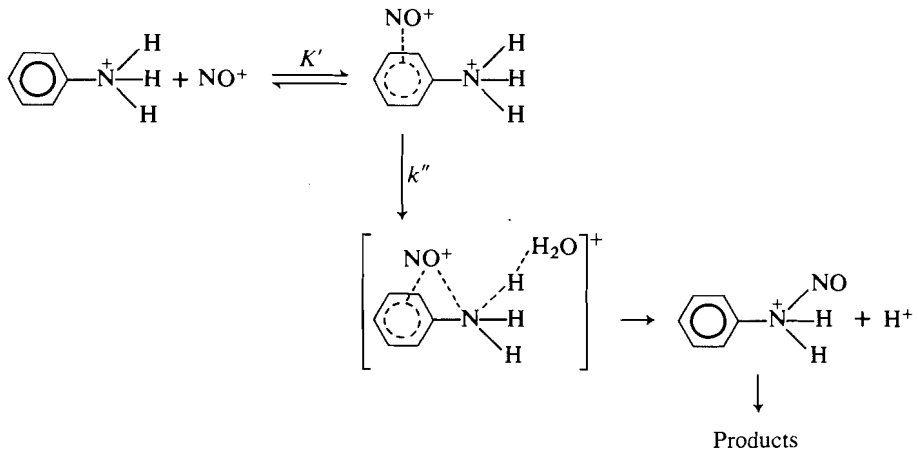
Figure 5 shows that the slope of the graph of log k against $-H_0$ varies with acidity, H_0 being the Hammett acidity function, whose values for concentrations of $HClO_4$ corrected for an ionic strength of 1.5 M were taken from ref. 17. The experimental constant k itself, however, is a linear function of h_0. These results are in keeping with there being interaction between the nitrosating agent (NO^+ or $H_2NO_2^+$) and the free and protonated forms of the amine, as in the diazotization of *o*-chloroaniline (17) and 2- and 4-aminopyridine-1-oxides (16*a*), for then

$$[6] \qquad v = k_5[\text{1-NA}][HNO_2]h_0 + k_6[\text{1-NAH}^+][HNO_2]h_0$$

which, since $[\text{1-NA}]h_0 = [\text{1-NAH}^+]K_a$, implies the linear relationship

$$[7] \qquad k = k_5K_a + k_6h_0$$

between k and h_0. If this hypothesis is accepted, comparison of eq. [7] with Fig. 5 implies values of 2.17 ± 0.09 and 2.44 ± 0.04 for k_5K_a and k_6, respectively, and the former of these in turn implies a value of 1.97×10^4 for $k_5 = k_{attack}K_{NO^+}$, (k_{attack} being the rate constant for the elementary process of reaction between NO^+ and the free amine), which is extremely high compared with the values of 2000–6000 found for the nitrosation of other amines by NO^+, and accepted as indicating a diffusion-controlled process (18). One reason for the high value of k_5 may lie in the exponential influence of ionic strength on the reaction (see above). If this effect is allowed for by using the data of Fig. 4 to obtain an equivalent value for zero ionic



SCHEME 2

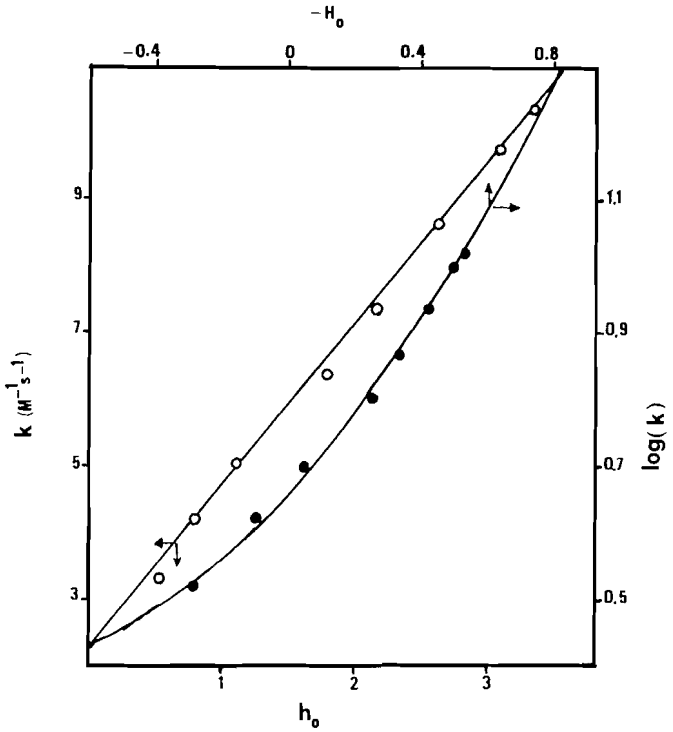


FIG. 5. Dependence of k (eq. [7]) on H_0 (●) and h_0 (○) at 25°C, $I = 1.5$ M, $[NaNO_2] = 2.75 \times 10^{-5}$ M, [1-NA] = 1.32×10^{-3} M.

strength according to the equation

$$[8] \qquad \log k_5 = \log k_5^0 + 0.485\, I$$

the result is a value of 3690 for k_5 that is fully compatible with published values for other substrates.

For the k_6 interaction between the nitrosating agent and the protonated form of the amine, a mechanism analogous to that shown in Scheme 2 for aniline is proposed, involving the association of the NO^+ ion and the aromatic ring in a complex that, upon losing a proton, rearranges to yield the nitroso compound. Naphthylamine's possession of two condensed rings increases the number of possible positions for NO^+ in the initial complex and hence the importance of nitrosation *via* the protonated form and, indeed, the value of k_6 for 1-NA is greater by a factor of 10 than for anilines and pyridines (16*c*), making this pathway significant at intermediate acidities.

Since the above scheme involves proton transfer to the solvent in the rate-controlling step of the reaction, a primary isotopic effect ought to be detectable. Measurements of k_6 in D_2O yielded the value of 1.59 for $(k_6)_{H_2O}/(k_6)_{D_2O}$ and, since $k_6 = k''K'K_{NO^+}$, the value of $(K_{NO^+})_{H_2O}/(K_{NO^+})_{D_2O}$ obtained earlier implies an isotopic effect of 3.50 for $K'k''$, which is indeed a primary isotopic effect and thus supports the validity of Scheme 2.

Replacement of a carboxyl function by fluorine, fluorodecarboxylation, is a new process that can be accomplished by the reaction of alkanoic acids with xenon difluoride. Primary, tertiary, and benzylic acids perform best in the reaction, which is conducted at room temperature in methylene chloride or chloroform solution. A reaction mechanism is proposed in which the acid is initially converted to a fluoroxenon ester, RCO_2XeF. The esters of the primary and secondary acids react by nucleophilic displacement by fluoride, as evidenced by incorporation of $^{18}F^-$ and no reactions common to free radicals or carbocations. The esters of the tertiary and benzylic acids react by converting to free radicals that can be further oxidized to carbocations. Thus incorporation of $^{18}F^-$ and racemization are observed with α-methoxy-α-trifluoromethylphenylacetic acid. Hydroxyl and amino functions inhibit the reaction. Aromatic and vinylic acids do not react.

TIMOTHY B. PATRICK, KAMALESH K. JOHRI, DAVID H. WHITE, WILLIAM S. BERTRAND, RODZIAH MOKHTAR, MICHAEL R. KILBOURN et MICHAEL J. WELCH. Can. J. Chem. **64**, 138 (1986).

Le remplacement d'une fonction carboxyle par un fluor, la fluorodécarboxylation, est une nouvelle réaction que l'on peut réaliser en faisant réagir les acides alcanoïques avec le diflorure de xénon. Les acides primaires, tertiaires et benzyliques sont les meilleurs acides pour cette réaction qui s'effectue à la température ambiante, dans du chlorure de méthylène ou du chloroforme. On propose un mécanisme réactionnel dans lequel l'acide conduit initialement à un ester fluoroxénonique RCO_2XeF. Les esters des acides primaires et secondaires réagissent par le biais d'un déplacement nucléophile par les ions fluorures tel que mis en évidence par l'incorporation du $^{18}F^-$, et non pas par les réactions mettant en jeu les radicaux libres ou les carbocations. Les esters des acides benzyliques et tertiaires réagissent en se transformant en radicaux libres qui peuvent être oxydés par la suite en carbocation. Ainsi, on observe l'incorporation de l'ion $^{18}F^-$ et la racémisation avec l'acide α-méthoxy α-trifluorométhylphényl acétique. Les fonctions hydroxy et amino inhibent la réaction. Les acides aromatiques et vinyliques ne réagissent pas.

The decarboxylation of carboxylic acids with replacement of halogen, halodecarboxylation, has proven both synthetically useful and mechanistically intriguing. The Hunsdiecker (1) or Kochi (2) reactions, which employ the use of silver, mercury, or lead salts, are the normal procedures for accomplishing halodecarboxylation. However, in current halodecarboxylation methodology the replacement halogen is restricted to chlorine, bromine, or iodine, and methodology for replacement by fluorine is unknown (3). In this paper we report our details on the reaction of xenon difluoride with alkanoic acids, the first general method for fluorodecarboxylation (4). In addition, the mechanistic aspects of the reaction are presented.

Results and discussion

Aliphatic carboxylic acids react with one equivalent of xenon difluoride (5) in methylene chloride or chloroform solution, according to eq. [1]. The reaction may be performed at room temperature and usually requires 8–16 h for completion. The yields of pure product reported in Table 1 are obtained simply by washing the reaction mixture with sodium carbonate solution followed by removal of the solvent.

[1] $RCOOH + XeF_2 \rightarrow R{-}F + Xe + HF + CO_2$

Alkanoic acids (entries 4, 5, 7, 9), arylalkanoic acids (entries 1–3, 6), and aryloxyacetic acids (entries 10,11) are examples of primary carboxylic acids that readily undergo fluorodecarboxylation. Although aromatic fluorination is known to occur with xenon difluoride (5), aromatic fluorination does not compete with the reaction at the carboxyl group by the xenon difluoride. Two dicarboxylic acids (entries 18, 19) are converted smoothly into the difluoro products with two equivalents of xenon difluoride. Also, the ketone function of levulinic acid (entry 8) is unaffected in the reaction and the carboxyl group is smoothly fluorodecarboxylated. Several secondary carboxylic acids tested for fluorodecarboxylation (entries 12, 13) give only small amounts of fluoro products, while norbornane-2-carboxylic and *trans*-2-phenylcyclopropanoic acids give no reaction.

Tertiary carboxylic acids, similar to the primary aids, are smoothly fluorodecarboxylated as seen in entries 15 and 16. However, the bicyclic acid, 3-phenylbicyclo[1.1.1]pentan-1-oic acid (entry 17)[5] displays decarboxylation with formation of its dimer; no fluoro product is obtained.

Carboxylic acids containing other protic functions, such as amino acids and cholic acid, give only unreacted starting material, as does cinnamic acid. Benzoic acid (entry 20) gives small amounts of benzoyl fluoride (6).

Our studies on fluorodecarboxylation show that both primary and tertiary acids react very well, but secondary acids react less readily. Mechanistic studies have allowed us to explain this behavior. Our mechanism, summarized in Scheme 1, begins with the formation of a xenon ester. We have not detected the ester, but its formation is based on experiments by DesMarteau and co-workers (7), who have shown that a xenon ester can be isolated from the reaction of trifluoroacetic acid with xenon difluoride at −24°C ($CF_3COOH + XeF_2 \rightarrow CF_3COOXeF +$

SCHEME 1

$(CF_3COO)_2$ Xe + HF). DesMarteau further showed that the xenon esters decarboxylated on warming to 23°C. Xenon esters have also been suggested as reaction intermediates in the works of Gregorcic and Zupan (8), Nikolenko and co-workers (6), and Musher (9). Thus our postulation of the formation of fluoroxenon ester A is strongly backed by literature precedent and supported by our observation of a required 1:1 acid–XeF_2 reaction stoichiometry.

For the case of primary and secondary carboxylic acids, the fluoro product is derived from nucleophilic displacement of CO_2 and Xe by F^-, mechanism (a). Evidence for this process comes from radiolabeling experiments performed with $(n\text{-}Bu)_4{}^+N\ {}^{18}F^-$. Thus when 3-phenylpropanoic acid is allowed to react with xenon difluoride in the presence of $^{18}F^-$ for 30 min at room temperature, a 40% radiochemical yield of 1-[^{18}F]-fluoro-2-phenylethane is obtained. Similarly, reaction of 4-bromobutanoic acid with $^{18}F^-/XeF_2$ leads to a 78% radiochemical yield of 1-[^{18}F]-fluoro-3-bromopropane. The ^{18}F could be incorporated into the products either as fluoride-18 ion or as a ^{18}F-exchanged xenon difluoride species such as $^{18}FXe^{19}F$. A complete exchange of $^{18}F^-$ with XeF_2 to produce $^{18}FXe^{19}F$ would permit statistically a maximum radiochemical yield of 50%, as only one of the two fluorine atoms of the $^{18}FXe^{19}F$ is radioactive. The 78% radiochemical yield of 1-[^{18}F]-fluoro-3-bromopropane could not be attained through involvement of an exchanged species. Furthermore, we have conducted an experiment in which $^{18}F^-$ and XeF_2 were allowed to react in methylene chloride solution under our radiochemical reaction conditions but in the absence of substrate acid. After evaporation of the methylene chloride with helium, the xenon difluoride was recovered quantitatively by vacuum sublimation at room temperature. The xenon difluoride recovered contained no radioactivity, and thus further shows that exchange of $^{18}F^-$ with XeF_2 did not occur. Literature precedent also exists to show that $^{18}F^-/XeF_2$ exchange would not occur under our reaction conditions (10). Thus in the major portion of the reaction the $^{18}F^-$ is incorporated into the product by the nucleophilic process shown in mechanism (a) in Scheme 1. Nucleophilic displacement also explains the higher reactivity of primary acids over secondary acids. Minor reaction processes may also be in operation, such as S_Ni substitution in ester A which has undergone exchange with radioactive fluoride.

$$PhCH_2CH_2COOH + XeF_2 + {}^{18}F^- \rightarrow PhCH_2CH_2{}^{18}F\ (40\%)$$

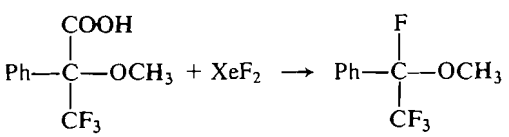
$$BrCH_2CH_2CH_2COOH + XeF_2 + {}^{18}F^- \rightarrow BrCH_2CH_2CH_2{-}{}^{18}F\ (78\%)$$

Several experiments showed that free radicals were not involved with primary acids. Thus 3-phenylpropanoic acid does not produce styrene by elimination nor does it react with benzene to produce bibenzyl. Also, 4-phenylbutanoic acid showed no internal cyclization similar to that observed when a primary radical is generated from lead tetraacetate reaction as described by Davies and Waring (11). In addition, rearrangement is not observed from reaction of 3,3-diphenylpropanoic acid (entry 6) with xenon difluoride. One would anticipate the formation of a 1,2-diphenylethane derivative if a primary radical were formed, because rearrangement is a well-known process in the 2-phenylethyl radical systems (12). In an interesting comparison with other halodecarboxylation methods, one observes that in the Hunsdiecker Cristol–Firth reactions of primary acids (1), a questionable free-radical process (13), rearrangement is rarely found. But in the Kochi lead tetraacetate – chloride chlorodecarboxylation, a known radical reaction (2), rearrangement and elimination both are common. Thus our experiments show that free radicals are not observed with primary acids, but that $^{18}F^-$ is incorporated in a nucleophilic process (mechanism (a)).

Evidence for mechanism (b) is obtained for systems which produce relatively stable free radicals and carbocations, the tertiary and benzylic systems. Thus when phenylacetic acid and xenon difluoride react in benzene solution, a mixture of diphenylmethane and benzyl fluoride is obtained. Control experiments show that the diphenylmethane did not arise from reaction of benzyl fluoride with benzene. The formation of diphenylmethane shows that a reactive intermediate is generated, and the absence of bibenzyl from radical coupling indicates that the intermediate is a carbocation.

$$PhCH_2COOH + XeF_2 + C_6H_6 \rightarrow PhCH_2Ph + PhCH_2F$$

The reaction of optically active α-trifluoromethyl-α-methoxyphenylacetic acid (**1**) gives α-fluoro-α-trifluoromethyl-α-methoxytoluene (**2**) in 95% yield with complete loss of optical activity, showing that a trivalent intermedite is involved in the mechanism. Furthermore, when the reaction is conducted in the presence of $(n\text{-}Bu)_4{}^+N\ {}^{18}F^-$ for 30 min at room temperature, the $^{18}F^-$ is incorporated into **2** in 65% radiochemical yield. The $^{18}F^-/XeF_2$ exchange experiments cited above and the 65% radiochemical yield show that a ^{18}F-exchanged species is not involved. Thus $^{18}F^-$ is incorporated as free fluoride ion in a reaction with a cationic intermediate. These results support mechanism (b) shown in Scheme 1 for tertiary and benzylic acids.



1 (optically active) **2** (racemic)

Finally, when 3-phenylbicyclo[1.1.1.]pentanoic-1-acid, a substrate which can produce a free radical but not a planar carbocation (13, 14), reacts with xenon difluoride, only radical dimerization is observed (entry 17). Thus each component of mechanism (b) has been observed experimentally.

In conclusion, we have shown that fluorodecarboxylation with xenon difluoride is an effective process for the conversion of carboxylic acids to alkyl fluorides. The mechanism of the

reaction involves nucleophilic displacement by fluoride for the primary and secondary acids, while free radicals and carbocations are involved for tertiary and benzylic systems. The reaction also holds promise as an important new method for the preparation of fluorine-18 labeled radiopharmaceuticals.

Experimental

Nuclear magnetic resonance spectra were obtained in deuteriochloroform solution on a JEOL FX-90 Q at 89.75 MHz for proton spectra with internal tetramethylsilane (δ 0.0) as a standard and at 84.26 MHz for fluorine spectra with external Freon-11 (fluorotrichloromethane, δ 0.0) as a standard. Mass spectra were obtained at 70 eV on a Varian MAT-111 direct inlet system or at the University of Illinois Mass Spectrometry Center. Xenon difluoride was purchased from PCR, Inc., Gainesville, Florida and used as obtained. Solvents CH_2Cl_2, $CHCl_3$, $CDCl_3$, and benzene were dried before use.

General procedure. 1-Fluoro-2-phenylethane (entry 2)

To a solution of 3-phenylpropanoic acid (150 mg, 1 mmol) in 15 mL of methylene chloride contained in a polyethylene bottle was added crystalline xenon difluoride (170 mg, 1 mmol).

The solution was stirred magnetically at 22°C for 10 h during which the colorless solution becomes slightly yellow. The resulting mixture was washed with 3% sodium bicarbonate (50 mL) solution. The organic solution was dried ($MgSO_4$) and concentated to yield analytically pure 1-fluoro-2-phenylethane (76% yield).

1-[^{18}F]-fluoro-2-phenylethane

A solution containing 2 mg 3-phenylpropanoic acid, 2 mmol of tetra-*n*-butylammonium fluoride, 2 mCi of $^{18}F^-$, and 0.3 mL of methylene chloride was treated with 2 mg of xenon difluoride. After standing for 30 min the solution was analyzed on a Waters high pressure liquid chromatograph equipped with a Magnum Parisil M9 10/50 silica gel column. Elution with CH_2Cl_2–CH_3CN (3:1) at a flow rate of 2.4 mL/min showed simultaneous ultraviolet detection (254 nm) and radioactive detection (NaI(Tl) detector) for the product at 16 min. Thin-layer chromatography on silica gel with 3:1 CH_2Cl_2–CH_3CN showed that 40% of the total radioactivity of the crude product was present as 1-[^{18}F]-fluoro-2-phenylethane. 1-[^{18}F]-fluoro-3-propane was prepared from 4-bromobutanoic acid in 78% radiochemical yield, and α-[^{18}F]-fluoro-α-trifluoromethyl-α-methoxytoluene **2** was prepared in 65% radiochemical yield from **1**. These reactions were conducted under identical conditions to those described for the preparation of 1-[^{18}F]-fluoro-2-phenylethane.

Preparation of tetrabutylammonium [^{18}F]fluoride: general procedure

Fluorine-18[6] was prepared from [^{18}O]H_2O by the $^{18}O(p, n)^{18}F$ reaction in a 2-mL metal cyclotron target (15). Approximately 3–5 mCi of the activity produced was mixed with 5 mmol of tetra-*n*-butylammonium fluoride (Aldrich) in a platinum crucible and taken to dryness at 100°C under a stream of nitrogen. The residue was further dried azeotropically by the addition and evaporation of two 0.1-mL portions of acetonitrile. The mixture was redissolved in 0.4 mL of methylene chloride to give approximately 1.5–3 mCi of radioactivity, which was added to the substrate contained in a small glass vial.

Bis(3-phenylbicyclo[1.1.1]-1-pentanyl)

3-Phenylbicyclo[1.1.1]pentan-1-oic acid (96 mg, 0.5 mmol) in 8 mL of $CDCl_3$ was treated with 90 mg (0.55 mmol) of xenon difluoride. After 8 h, gas evolution ceased and the yellow solution was analyzed by nmr. The analysis showed the complete absence of starting material and the complete absence of fluorinated products. Preparative hplc (Whatman Magnum Silica Gel, 50 mm × 10 mm, hexane–CH_2Cl_2, 9:1) gave pure product, 39 mg (35%).

α-Trifluoromethyl-α-methoxy-α-fluorotoluene

A solution containing 230 mg (1 mmol) of (+)-α-methoxy-+-trifluoromethyl-phenylacetic acid (α_D^{23} +69°, c = 1.6, CH_3OH) and 170 mg (1 mmol) of xenon difluoride in 15 mL of $CDCl_3$ was allowed to react until gas evolution ceased (4 h). Both nmr and hplc analyses showed the presence of only a single product, and the solution showed no optical activity at the sodium D line. Isolation by preparative hplc (Whatman Magnum Silica Gel, 50 mm + 10 mm, hexane–CH_2Cl_2, 3:1) gave 197 mg (95%) of pure product. The product showed no optical activity in either methanol or chloroform solvents.

[6]Fluorine-18 has a half-life of 110 min and its radioactivity may be counted conveniently in a gamma counter at 511 keV.

SUZANNE DEGUIRE, FRANÇOIS BRISSE, JACQUES OUELLET, and RODRIGUE SAVOIE. Can. J. Chem. **64**, 142 (1986).

A stoichiometric complex of formula $(COOH)_2 \cdot 2H_2O \cdot 18$-crown-6 has been obtained from oxalic acid and the macrocyclic polyether 18-crown-6. The crystals of the complex have a monoclinic unit cell and belong to the $P2_1/c$ space group. The components in the adduct are linked through hydrogen bonds in a polymer-like fashion: –crown–H_2O–HOOCCOOH–OH_2–crown–, where the oxalic acid molecules are present in two distinct disordered orientations. The infrared and Raman spectra of the complex are also reported and interpreted.

SUZANNE DEGUIRE, FRANÇOIS BRISSE, JACQUES OUELLET et RODRIGUE SAVOIE. Can. J. Chem. **64**, 142 (1986).

Un complexe de formule $(COOH)_2 \cdot 2H_2O \cdot 18$-couronne-6 a été obtenu à partir de l'acide oxalique et l'éther macrocyclique 18-couronne-6. Les cristaux du complexe ont une maille monoclinique et appartiennent au groupe d'espace $P2_1/c$. Le cristal est constitué d'un enchaînement –couronne–H_2O–HOOCCOH–OH_2–couronne–, où les différentes unités structurales sont reliées par ponts hydrogène. Les molécules d'acide oxalique sont alignées, de façon désordonnée, dans deux orientations différentes. Les spectres infrarouge et Raman du complexe sont rapportés et interprétés.

Introduction

Many neutral molecules with hydrogen bonding capacity form complexes with macrocyclic polyethers, such as 18-crown-6 (henceforth called 18C6), in which a water molecule serves as a linker between the proton donor and the crown (1). Carboxylic acids generally follow this trend, forming complexes with 18C6 of 2:2:1 or 1:1:1 (acid/water/18C6) stoichiometry, in which the acid is more or less firmly bound to water, depending on its acid strength, and the water molecules are themselves weakly hydrogen bonded to oxygen atoms of the crown (2). A particularly good example of this is found in the $CH_2(CN)COOH \cdot H_2O \cdot 18C6$ adduct, whose crystal and molecular structures have been determined by X-ray diffraction (3). Also of interest is the corresponding compound of 2:2:1 stoichiometry obtained from dichloropicric acid, in which proton transfer seems to occur from the acid to water, giving a charged-component complex involving the hydronium ion (4).

From the mode of complexation of carboxylic acids with the 18C6 crown, it was expected that dicarboxylic acids would simultaneously interact with two crown molecules in adducts of this type. This hypothesis has been verified by the synthesis of the $(COOH)_2 \cdot 2H_2O \cdot 18C6$ complex, whose crystal structure and vibrational spectra are reported in this paper.

Experimental

The complex (mp 90–94°C) was prepared by adding anhydrous oxalic acid (0.68 g) to a solution of 18C6 (2 g) in tetrahydrofuran (10 mL). Crystallization occurred at room temperature after addition of a small amount (0.3 mL) of water. The deuterated complex (~90% d_4) was obtained in a similar way, using a proportionally larger amount of D_2O. The stoichiometry of the complex was determined by elemental analysis, titration by NaOH, and from the integrated intensities of the peaks in the ^1H nmr spectrum ((CD_3COCD_3) δ:5.5 ($H_2C_2O_4$ and H_2O) and 3.6 (18C6)).

The infrared spectra, obtained from Nujol and hexachlorobutadiene mulls, were recorded on a Beckman IR4250 spectrophotometer and on a Bomem DA3.02 interferometer. The Raman spectra of solid samples sealed in capillary tubes were excited by the 514.5-nm line from a Spectra Physics Model 165 argon ion laser, and recorded on a microcomputer-controlled Spex Model 1400 spectrometer. The spectra were typically obtained at 400 mW laser power at the sample, 2 cm^{-1} spectral slit width, with an integration time of 2 s for each frequency increment of 1 cm^{-1}. The low-temperature measurements in both the infrared and the Raman spectra were made using conventional liquid nitrogen cryostats.

For this X-ray study, a well-developed single crystal of the complex, obtained by slow evaporation of a THF solution, was mounted on a Nonius-CAD4 diffractometer. The unit-cell dimensions and the orientation matrix have been obtained by a least-squares refinement of the angular settings of 25 well-centered reflections in the range $10 < 2\theta < 38°$. The diffracted intensities of 1747 reflections were measured within the sphere of reflection limited by $2\theta \leq 50°$ and $0 \leq h \leq 11$, $0 \leq k \leq 9$, $-17 \leq l \leq 17$, using the graphite monochromatized molybdenum radiation. The $\omega/2\theta$ scan technique was used with a scan width calculated by $\omega = (1.00 + 0.35 \tan\theta)°$. The intensities of three reference reflections, measured every hour, did not vary by more than 2% over the duration of the data collection. The centering of the crystal was verified every 100 measurements, and readjustment was made when needed. The diffracted intensities were corrected for Lorentz and polarization effects, but since the absorption coefficient for the Mo radiation was small, no absorption correction was applied.[2]

The 1206 reflections (69%) that satisfied the criterion $I \geq 1.96\sigma(I)$ were retained for the structure determination and refinement. $\sigma(I)$ was derived from the counting statistics. The scattering curves for O and C were taken from ref. 9 and those for H atoms from ref. 10. The $P2_1/c$ space group was assigned unambiguously from the systematic absence $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$. Since there are only two formulas per asymmetric unit, the center of the 18-crown-6 as well as that of the oxalic acid molecules must coincide with crystallographic centers of symmetry of the unit cell. The structure was solved using the multisolution program MULTAN. All the atoms constituting the 18C6

part were found on the first E-map. The others, including all the H atoms, were located on subsequent difference Fourier syntheses. The weighted least-squares refinement, minimizing $\Sigma w(|F_o| - |F_c|)^2$, was carried out with anisotropic temperature factors for O and C and isotropic temperature factors for H atoms. As the refinement proceeded, it was discovered that the oxalic acid, situated at $(0\,0\,\frac{1}{2})$, was present in two distinct orientations. A 50:50 distribution between the two orientations led to very different values of the corresponding isotropic thermal parameters. They were held at their averaged values and only the occupation factor of each atom was refined. For three of the atoms the occupation factors reached a value of 0.6, while at the same time they tended towards 0.4 for the other three atoms. This unequal convergence coincided for the three pairs of atoms, namely C(11), C(21); O(11), O(21); and O(12), O(22). Since the C—C distances of the two molecules of oxalic acid were unequal, the positions of these C atoms (C(11) and C(21)), were adjusted so that the two C—C distances remain equal to 1.540 Å. The least-squares process was resumed, but only the coordinates and thermal parameters of the oxygen and hydrogen atoms of both oxalic acids were refined. After convergence, R and wR had not changed while S was slightly lowered.[3] Since both refinements did converge in the same way whether the C coordinates were refined or set so that d(C—C) = 1.540 Å, the final coordinates and structure factor tables given here reflect the chemically more meaningful situation. The refinement was concluded when $R = 0.033$, $wR = 0.039$, and $S = 1.454$. At that time, the mean and highest values of the displacement-to-sigma ratio were 0.05 and 0.4, respectively. A final difference Fourier synthesis revealed only small fluctuations of the electron density, with extreme values of −0.13 and 0.11 e Å^{-3}.

Results and discussion

The unit-cell dimensions and other crystal data of interest determined from the X-ray diffraction study are given in Table 1. The atomic numbering is given on the diagram in Fig. 1. The bond distances and angles, calculated from the final atomic coordinates (Table 2),[4] are given in Table 3. The various structural units (18C6, oxalic acid, water) that are part of the complex are shown by the stereopair of Fig. 2. The structural units are H-bonded to one another to form a columnar arrangement in which the following sequence, crown ether–water–oxalic acid–water, repeats itself.

The 18-crown-6 molecule

The center of this molecule coincides with a crystallographic center of symmetry at $(\frac{1}{2}\,\frac{1}{2}\,0)$. The conformation of the ring is described by the $t\,t\,g$ sequence repeated six times (t = *trans*, g = *gauche*). The actual values of the ring torsion angles are given in Table 4. The C—O bond distances (average value 1.484 Å) are normal. However, the CH_2—CH_2 bond distances are all significantly shorter (average 1.484 Å) than the accepted distance of 1.535(5) Å for a C(sp^3)—C(sp^3) bond. Such a shortening of a CH_2—CH_2 bond in a —O—CH_2—CH_2—O— moiety has also been reported in noncyclic situations (11, 12) and does not depend upon the value of the —O—CH_2—CH_2—O torsion angle. Concurrently with a short C—C bond, it was noted that the O—C—C angles tended to be smaller than

109.5°. In the present case, where the —O—C—C—O sequence is included in a ring, the average of the six O—C—C angles is 109.5° while the average C—O—C angle is 112.4°.

The oxalic acid

As mentioned in the experimental section, the molecule of oxalic acid is present in the crystal form under two distinct orientations in a 40:60 ratio. However, when the C coordinates were refined, the C—C distances took the unusually different values of 1.569(4) and 1.504(6) Å. To remedy this anomaly, both C—C distances were kept at the fixed value of 1.540 Å. This choice took into account the C—C distance of oxalic acid in the gas phase, 1.548 Å (21), and 1.537 Å in both its α and β crystalline forms (22), as well as the value of 1.538 Å in the α-modification of the dihydrate (23).

The bond distances and angles (Table 3) of the two oxalic acid molecules agree very well. The two molecules are planar but for the H atoms, which deviate by 0.10(3) and 0.23(6) Å from their respective least-squares planes. These deviations favor the H bonds formed with the oxygen atom of the water molecule. The dihedral angle formed between the planes of the two molecules is close to 180°.

Hydrogen bonding

The water molecule, O(W), is the link between the crown ether and the oxalic acid. This disposition is identical to that observed with cyanoacetic acid (3). Since, however, oxalic acid is a diacid, instead of forming a complex of limited dimensions as in ref. 3, the structural units are arranged here in a polymer-like fashion.

O(W) forms two relatively long hydrogen bonds with the atoms O(2) and O(5) of the 18C6 molecule. At the same time, O(W) is an acceptor vis-à-vis the oxalic acid. The molecule of oxalic acid is present in two distinct orientations such that each hydrogen atom is H-bonded to O(W). These H bonds are significantly shorter than those between O(W) and the crown ether. The characteristics of these hydrogen bonds are presented in Table 5. All these H-bond distances compare well with those reported for the 18C·cyanoacetic acid·water complex of ref. 3.

TABLE 5. Characteristics of the hydrogen bonding in the $(COOH)_2 \cdot 2H_2O \cdot 18$-crown-6 complex

O(W)—H(W1)	0.88(2) Å	H(W1)···O(2)	1.98(2) Å	O(W)···O(2)	2.850(2) Å	O(W)—H(W1)···O(2)	169(2)°
O(W)—H(W2)	0.78(2)	H(W2)···O(5)	2.14(2)	O(W)···O(5)	2.877(2)	O(W)—H(W2)···O(5)	159(2)

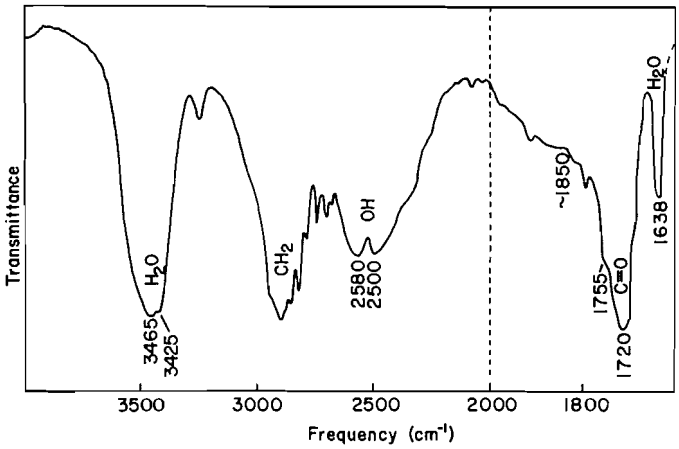

FIG. 3. Room temperature infrared spectrum of the $(COOH)_2 \cdot 2H_2O \cdot 18C6$ complex (hexachlorobutadiene mull) in the region 1500–4000 cm^{-1}.

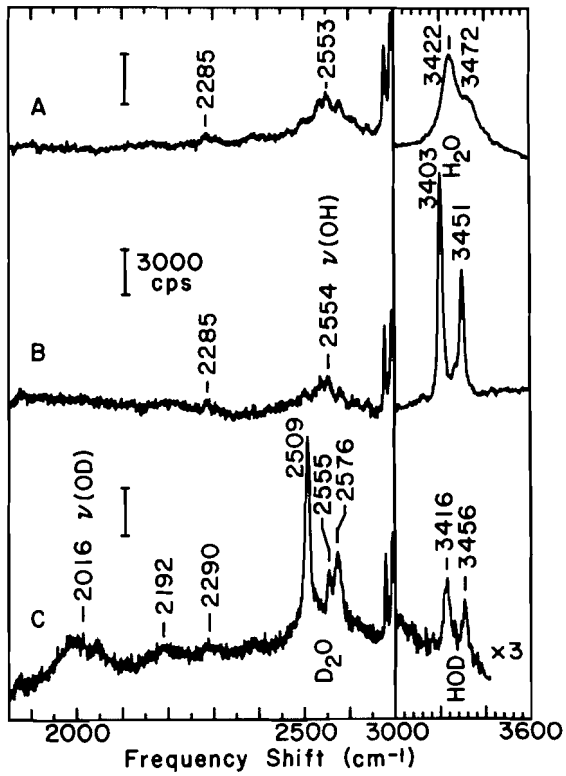

FIG. 4. High-frequency region of the Raman spectrum of the $(COOH)_2 \cdot 2H_2O \cdot 18C6$ complex at (A) 20°C and (B) −180°C. (C) Corresponding spectrum of a ~90% deuterated (acid and water) sample.

Vibrational spectra

The O—H stretching vibrations of the weakly bound water molecules give a strong doublet at 3425/3465 cm^{-1} in the infrared spectrum (Fig. 3). The two components are more easily seen in the Raman spectrum (3422/3472 cm^{-1}) (Fig. 4) even though their overall intensity is relatively much lower than in the infrared. At liquid nitrogen temperature, the doublet is completely resolved at 3403/3451 cm^{-1}. The observed splitting, 48 cm^{-1}, is very nearly equal to that expected for the ν_1 and ν_3 vibrations of intermolecularly uncoupled and symmetrically bound water molecules (13). However, as shown by X-ray diffraction, the two HOH···crown bonds in the complex are not exactly similar (O···O: 2.850 and 2.877 Å), and this is indicated in the spectrum of an incompletely deuterated sample by the appearance of a doublet, at 3431/3455 cm^{-1} (3417/3457 cm^{-1} at −180°C), due to the O—H stretching vibration of the HOD molecules (Fig. 4). The D_2O ν_1/ν_3 vibrations are shifted by a factor of 1.35 in the spectra of the deutero compound, where they give a doublet near 2550 cm^{-1}.

From the centrosymmetric structure of the oxalic acid molecules in the complex and the two different orientations that they can take, the O—H stretching modes of these units are expected to give doublets in both the infrared and Raman spectra. Furthermore, the two components of these doublets should have frequencies of ~2100 and 1900 cm^{-1} (14), based on the acid···water distances of 2.555 and 2.650 Å that characterize the two nonequivalent types of acid molecules in the crystal. However, both the infrared and Raman spectra (Figs. 3 and 4) fail to show any band of appreciable intensity in the 2100 cm^{-1} region. Neither can the absorption at ~1850 cm^{-1} in the infrared spectrum be attributed to a ν(OH) vibration, as this same band is present in the spectra of other similar complexes where the ν(OH) vibration is clearly identified at a much higher frequency (2). The 1850 cm^{-1} infrared band is most likely due to the overtone of the out-of-plane γ(OH) vibration of the acid, and to combination modes of the ether, such as those responsible for the very strong bands in the 800–1100 cm^{-1} region of the vibrational spectra.

The assignment of the acid ν(OH) vibrations in the spectra of the complex can be made in two different ways. Firstly, the two expected vibrations could be taken as having nearly equal frequencies, and thus explain the infrared doublet at 2500/2580 cm^{-1} and the scattering in the corresponding region of the Raman spectrum. This frequency range is characteristic of O···O distances of ~2.60 Å (14), which is the average of the water···crown distances (2.555 and 2.650 Å) determined above by X-ray diffraction. Alternatively, one of the expected vibrations could occur at ~2500 cm^{-1}, the second one being overshadowed by the CH stretching modes in the 2900 cm^{-1} region. This explanation is preferred, as the Raman spectrum of the deuterated complex shows two bands, at 2020 and 2195 cm^{-1}, with isotopic frequency shifts (1.26 and ~1.32 respectively) equal to those expected from the assumed frequencies of the corresponding ν(OH) vibrations (14). Note that both interpretations point to O···O distances that are not exactly equal to those determined by X-ray diffraction. The infrared spectrum of the deuterated complex (not shown) is similar to the Raman, with two absorption bands at 1985 and 2175 cm^{-1}, that at lower

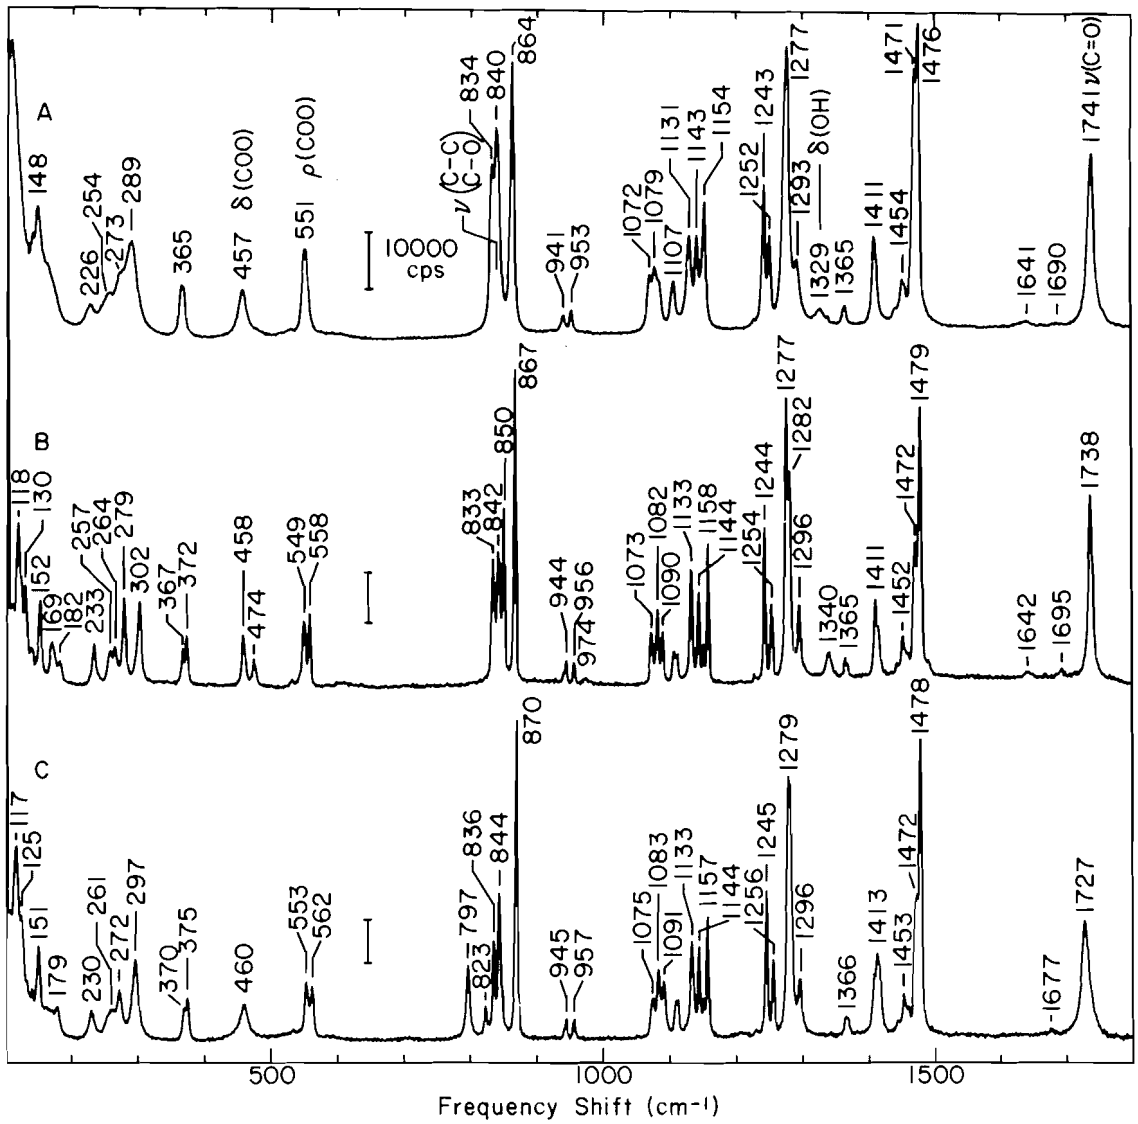

FIG. 5. Low-frequency region of the Raman spectrum of the $(COOH)_2 \cdot 2H_2O \cdot 18C6$ complex at (A) 20°C and (B) ~180°C. (C) Corresponding spectrum of a ~90% deuterated (acid and water) sample.

frequency being about twice as intense as the other one. If these two bands are assigned to the ν(OD) vibrations of the two types of acid molecules identified by X-ray diffraction, then their relative intensities should reflect the different occupational factors (0.6 and 0.4) associated with the two species.

The Raman spectrum of the crown moiety in the complex (Fig. 5) is almost identical to that obtained with metal complexes in which the crown adopts its highly symmetric D_{3d} conformation (15). This is in complete agreement with the X-ray results.

The bands attributable to the oxalic acid molecules can be readily identified in the Raman spectra, as this species has been thoroughly investigated by vibrational spectroscopy, in the gas phase (16), in rare gas matrices (17), and in both its α and β crystalline modifications (18–20). The room temperature Raman spectrum of the hydrogenated complex (Fig. 5A) is consistent with the centrosymmetric structure of these molecules, deduced from the X-ray measurements. This type of local symmetry results in a frequency non-coincidence of the infrared and Raman-active bands. For example, the C=O stretching modes give a symmetric vibration (A_g species in the C_{2h} space group), which is Raman active only, and an antisymmetric mode (B_u species), which is infrared active only. These two bands occur at 1738 cm^{-1} in the Raman and 1720 cm^{-1} in the infrared spectra. The shoulders at ~1755 and 1700 cm^{-1} alongside the main infrared band are probably due to combination modes, as they are also present in the infrared spectra of the uncomplexed acid (17, 19). The CO_2 rocking and bending modes at 551 and 457 cm^{-1} are also observed as singlets in the room temperature spectrum of the nondeuterated complex.

The structural parameters for the two types of acid molecules in the adduct (Fig. 2 and Table 3) are very similar. There is a general agreement between these findings and the Raman results, as many of the bands of the oxalic acid molecules are split in the low-temperature spectrum, which is consistent with a slight nonequivalence of the two types of acid molecules.

The C—C bond should give rise, for the mixed C—C/C—O stretching mode, to a band occurring near 840 cm^{-1}. Although there are several bands due to the ether in this region of the Raman spectrum (834, 840(?), and 864 cm^{-1}), the oxalic acid vibration appears to occur as a singlet, at 850 and 797 cm^{-1} in the spectra of the normal and deuterated complex respectively,

the weak band at 823 cm^{-1} in the spectrum of the deutero compound being attributable to the HOOCCOOD mixed isotopic species.

SERGE ALEX, RODRIGUE SAVOIE, MARIE-CLAUDE CORBEIL, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **64**, 148 (1986).

Two different crystalline complexes have been obtained from aqueous mixtures of glycylglycine (GlyGly) and methylmercury(II), and they were studied by vibrational spectroscopy and X-ray diffraction. In the first compound, a hydrogen atom of the protonated amino group of GlyGly is substituted by the CH_3Hg^+ cation, giving (CH$_3$Hg)GlyGly: orthorhombic, $Pna2_1$, a = 7.920(6) Å, b = 13.473(5) Å, c = 8.059(3) Å, and Z = 4. Further complexation on the carboxylate group yielded the complex [(CH$_3$Hg)$_2$GlyGly]ClO$_4$: monoclinic, $P2_1/c$, a = 6.407(4) Å, b = 24.439(6) Å, c = 8.461(2) Å, β = 93.82(4)°, and Z = 4. The sites of complexation and the conformations of these solid complexes are well reflected in their vibrational spectra. Raman spectra indicate that complexation in aqueous solutions is limited to substitution on the $-NH_3^+$ group of GlyGly.

SERGE ALEX, RODRIGUE SAVOIE, MARIE-CLAUDE CORBEIL et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **64**, 148 (1986).

Deux complexes cristallins différents ont été isolés à partir de solutions aqueuses de glycylglycine (GlyGly) et de méthylmercure(II), et ils ont été étudiés par spectroscopie de vibration et par diffraction des rayons X. Le premier composé a été obtenu par la substitution d'un hydrogène de la fonction amino protonée de la GlyGly par le cation CH_3Hg^+, pour donner la (CH$_3$Hg)GlyGly: orthorhombique, $Pna2_1$, a = 7,920(6) Å, b = 13,473(5) Å, c = 8,059(3) Å et Z = 4. Une complexation plus poussée, sur la fonction carboxylate, a permis d'obtenir le complexe [(CH$_3$Hg)$_2$GlyGly]ClO$_4$: monoclinique, $P2_1/c$, a = 6,407(4) Å, b = 24,439(6) Å, c = 8,461(2) Å, β = 93,82(4)° et Z = 4. Les spectres de vibration réflètent bien les sites de complexation de ces espèces, ainsi que leurs conformations propres. Les spectres Raman ont permis d'établir que la complexation en milieu aqueux était limitée à la substitution sur la fonction $-NH_3^+$ de la glycylglycine.

Introduction

The methylmercury cation CH_3Hg^+ has been used in our (1–4) and other laboratories (5) as a convenient probe for the coordination sites in nucleic acid constituents. This cation can also bind to proteins (6), and various organomercury compounds are currently used as heavy-atom labeling agents for structural studies by electron microscopy and X-ray diffraction (7).

Although the thiol groups appear to be the primary targets for mercury in proteins (6), coordination is likely to take place with other groups as well. The model complexes with monomeric amino acids considered so far involved mainly the sulfur-containing acids (8–13). Selenium analogs have also been examined (14). Relying mainly on ^{1}H nmr spectroscopy, Rabenstein *et al.* (15, 16) have investigated the equilibrium reactions between the CH_3Hg^+ cation and various amino acids in aqueous solutions. The only available crystal structure with a non-sulfur-containing amino acid is the tyrosine complex, in which one CH_3Hg^+ group is bonded to the NH_2 end of the molecule (17).

As part of our research program aimed at determining (via model systems) the mode of attachment of the CH_3Hg^+ cation to proteins and peptides, our initial effort is being directed to sulfur-free model ligands. Raman spectroscopy, applicable to both solids and aqueous solutions, is used to transfer the detailed structural information obtained by X-ray diffraction on solids to the species present in water. This technique also presents the advantage of providing an "instant" picture of the species in solution, since its time scale makes it less sensitive to exchange equilibria leading to signal averaging in ^{1}H nmr.

The present paper deals with glycylglycine (GlyGly), a dipeptide devoid of a side chain

$$^+H_3N—C(\alpha)H_2—CO—NH—C(\beta)H_2—COO^-$$

It can be regarded as a model for interactions of CH_3Hg^+ with the $-NH_3^+$ and $-COO^-$ ends of a protein chain.

Experimental

Reagents and techniques

Glycylglycine (BDH Chemicals) was used without further purification. The sources of CH_3Hg^+ ions were the hydroxide CH_3HgOH (1 *M* aqueous solution from Alfa Inorganics), the perchlorate CH_3HgClO_4, and the nitrate CH_3HgNO_3 (1 *M* aqueous solutions prepared as described earlier (2)). The CH_3Hg^+ ion was analysed potentiometrically by titration with KCl in ethanol (Ag/AgCl indicator electrode) (18). The various solutions studied by Raman spectroscopy were prepared at a concentration of 0.33 *M*, their pH being adjusted in each case with either NaOH or HNO_3 (4 *N*).

Raman spectroscopy

The Raman spectra, excited by the 514.5-nm line from a Spectra Physics Model 165 argon ion laser, were recorded on a Spex Model 1400 microcomputer-controlled spectrometer. The samples were contained in capillary tubes that, in the case of the highly light-sensitive solid complexes, were mounted on a motor shaft and rotated at high speed in the laser beam. Even so, the laser power at the sample had to be kept very low (~25 mW) in order to prevent sample decomposition. Solid glycylglycine and the various solutions, contained in cells mounted in a copper block maintained at 10°C, were studied at a laser power of 200 mW at the sample. The spectra were typically recorded at 5 cm^{-1} spectral slit width, with a 2-s integration time at each 2 cm^{-1} frequency increment.

Infrared spectroscopy

The ir spectra were recorded as KBr pellets with a Digilab FTS-15 C/D Fourier-transform spectrophotometer equipped with a Globar source and wide-band mercury cadmium telluride detector (Infrared

[1]Authors to whom correspondence may be addressed.

Associates, New Brunswick, NJ). Typically, 100 interferograms of 4096 points, recorded at an optical velocity of 1.2 cm/s and a maximal optical retardation of 0.5 cm, were co-added, apodized with a boxcar function, and Fourier transformed with 4 levels of zero filling, resulting in a spectral resolution of 2 cm^{-1}. The apparatus was purged with dry nitrogen during the experiments.

Nuclear magnetic resonance spectroscopy

The ^1H nmr spectra were obtained with a Bruker WH-90 spectrometer and they were referenced to TMS for DMSO-d_6 solutions or to DSS for D_2O solutions. The solvents were Silanor DMSO-d_6 (Merck, Sharp & Dohme Canada, 99.5% isotopic purity) and D_2O (Cambridge Isotope Lab., 99.8% isotopic purity).

Preparations

$(CH_3Hg)GlyGly$

One mmole (132 mg) of glycylglycine was dissolved in 1.0 mL of 1 *M* aqueous CH_3HgOH. On addition of absolute ethanol (10 mL), a colorless powder was immediately obtained. It was filtered off, washed with ethanol, and dried *in vacuo* for 24 h; yield 0.29 g, 82%; ^1H nmr (D_2O) δ: 3.97 (2H, s, α-CH_2), 3.81 (2H, s, β-CH_2), 0.90 (3H, s, CH_3Hg), $^2J(^1H-^{199}Hg)$ = 219 Hz. Crystals were grown by vapor diffusion of ethanol into a concentrated aqueous solution of the complex. The composition was confirmed by X-ray work (*vide infra*).

$[(CH_3Hg)_2GlyGly]ClO_4$

One mmole (132 mg) of glycylglycine was dissolved in a mixture of 1.0 mL of 1.0 *M* CH_3HgOH and 1.0 mL of CH_3HgClO_4. Ethanol was then added (~10 mL). After a few days at room temperature and in open air (hood), colorless rectangular platelets were obtained; yield: 0.21 g, 31%; ^1H nmr (D_2O) δ: 3.90 (2H, s, α-CH_2), 3.94 (2H, s, β-CH_2), 0.96 (6H, s, CH_3Hg), $^2J(^1H-^{199}Hg)$ = 228 Hz; (in DMSO-d_6) δ: 3.77 (2H, s, CH_2), 3.80 (2H, d, CH_2), 5.26 (2H, s, br, NH_2), 8.74 (1H, t, NH), 0.73 (6H, s, CH_3Hg), $^2J(^1H-^{199}Hg)$ = 220 Hz. The singlet at high field corresponds to both CH_3Hg groups in fast exchange. A crystal from the homogeneous samples was used for X-ray work.

The same compound was obtained by mixing $(CH_3Hg)GlyGly$ with an equal number of moles of CH_3HgClO_4 (from a 1.0 *M* aqueous solution), and adding ethanol. Precipitation occurred instantly, yielding very thin plates. The sample obtained this way had the same ir and ^1H nmr spectra as those prepared by the first method.

Crystal structure of $[(CH_3Hg)_2GlyGly]ClO_4$

$C_6H_{13}ClHg_2N_2O_7$ fw = 661.81

Monoclinic, $P2_1/c$, a = 6.407(4), b = 24.439(6), c = 8.461(2) Å, β = 93.82(4)°, V = 1321.9 $Å^3$, Z = 4, D_c = 3.324 g cm^{-3}, λ(MoKα̃) = 0.71069 Å (graphite monochromator), μ(MoKα) = 234.2 cm^{-1}, T = 293 K.

A crystal of dimensions (mm) 0.025 (between $0\bar{1}0$ and 010) × 0.115 ($001-00\bar{1}$) × 0.30 (irregular faces) was used for X-ray work. Initial cell parameters and monoclinic Laue symmetry were observed from precession and cone axis photographs. The systematic absences ($h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$), noted on the precession films and subsequently confirmed from the full data set, unambiguously defined the $P2_1/c$ space group. The cell parameters obtained from films were accurately determined by least-squares refinement on the setting angles of 25 randomly distributed reflections centered on an Enraf–Nonius CAD-4 diffractometer. The Niggli coefficients clearly indicated that no symmetry higher than monoclinic was present.

The intensity data were collected with the CAD-4 diffractometer as reported earlier (19). Three standard reflections monitored during the experiment indicated that the crystal slowly decomposed in the beam: their intensities had regularly decreased by 20% at the end of the data collection. This decay was taken into account at the data reduction stage. A total of 1763 independent $\bar{h}kl$ and hkl reflections ($2\theta < 45°$) were collected. After eliminating the systematically absent reflections, the data set consisted of 1705 unique reflections, of which 957 were retained as significantly above background ($I > 3\sigma(I)$) for structure determination. These data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 8 × 8 × 8, transmission range: 0.064–0.564).

The structure was solved by the heavy-atom method and refined on $|F_o|$ by standard least-squares procedures. Both Hg atoms were located from a Patterson synthesis and the remaining non-hydrogen atoms were located from a difference Fourier (ΔF) map phased on Hg. Isotropic refinement by full-matrix least squares converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.116$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.134$. The subsequent steps were carried out by block-diagonal least squares. The non-hydrogen atoms were refined anisotropically. The hydrogens whose positions were determined by those of the non-hydrogen atoms were fixed at idealized positions (C—H = 0.95 Å, N—H = 0.87 Å, B_{iso} = 5.0 $Å^2$). The methyl hydrogens were not visible in the ΔF map. The hydrogen parameters were not refined, but their coordinates were recalculated after each least-squares cycle. Anisotropic refinement of all non-hydrogen atoms converged to R = 0.043, R_w = 0.052, and a goodness-of-fit ratio of 1.78. The final ΔF map contained peaks in the range ±(1.2 − 2.2) e/$Å^3$ near Hg, and the general background was below ±0.9 e/$Å^3$ elsewhere.

Crystal structure of $(CH_3Hg)GlyGly$

$C_5H_{10}HgN_2O_3$ fw = 346.74

Orthorhombic, $Pna2_1$, a = 7.920(6), b = 13.473(5), c = 8.059(3) Å, V = 859.9 $Å^3$, Z = 4, D_c = 2.677 g cm^{-3}, λ(Mokα) = 0.71069 Å, μ(MoKα) = 178.5 cm^{-1}, T = 293 K.

The specimen used had the following distances (mm) between the indicated pairs of faces: 0.040 ($01\bar{1}-0\bar{1}1$) × 0.048 ($011-0\bar{1}\bar{1}$) × 0.490 ($100-\bar{1}00$). It was mounted on an Enraf–Nonius CAD-4 diffractometer and a set of 25 randomly distributed reflections were created by the search routine of the system. These reflections were centered and the indexing routine yielded a reduced cell of dimensions a = 7.920, b = 8.059, c = 13.473 Å with three 90° angles. This cell was checked with long-exposure oscillation photographs taken along the axes. These three films showed the expected layer line spacings and contained mirror planes consistent with the orthorhombic *mmm* Laue symmetry. The Niggli parameters unambiguously indicated that the lattice had no higher symmetry. Crystal density and fast scans on the $hk0$, $h0l$, and $0kl$ reflections pointed to $Pn2_1a$ (alternate orientation for $Pna2_1$) as the most likely space group. Prior to data collection, the b and c axes of the reduced cell were interchanged in order to define the cell in the standard $Pna2_1$ orientation.

The intensity data were collected as above. The three standards monitored during the experiment showed random fluctuation within ±3.4%. A set of 923 independent hkl reflections ($2\theta < 50°$) was collected. After removal of the systematic absences, a total of 819 unique reflections remained, of which 596 were retained ($I > 3\sigma(I)$) for structure determination. The data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 8 × 8 × 8, transmission range: 0.33–0.54).

The conditions of systematic absence ($0kl$, $k + l \neq 2n$; $h0l$, $h \neq 2n$) for space group $Pna2_1$ were confirmed by inspection of the full data set. These conditions were also consistent with the centric *Pnam* space group (alternate definition for *Pnma*), but this group was rejected at the end of the refinement. The structure was solved by the heavy-atom method and refined by full-matrix least-squares procedures. The x and y coordinates of Hg were determined from the Patterson synthesis. The z coordinate was arbitrarily set to 0.25 to define the origin along c. The ΔF map phased on Hg contained an artificial inversion center and two overlapping images as expected. However, all the non-hydrogen atoms belonging to one of the images could be assembled. Isotropic refinement converged to R = 0.094 and R_w = 0.101. The hydrogen atoms were treated as in the previous case. Anisotropic refinement converged to R = 0.023, R_w = 0.028, and a goodness-of-fit ratio of 1.08. The final ΔF map showed peaks of ±(0.7 − 1.0) e/$Å^3$ near Hg and a general background below ±0.54 e/$Å^3$ elsewhere. Refinement of the enantiomorphic structure led to R = 0.026 and R_w = 0.032. Therefore the results from the first refinement were retained. The absence of a mirror plane perpendicular to the c axis ruled out the possibility that the unit cell belongs to the *Pnam* space group.

The scattering curves were from standard sources (20). The f' and f'' contributions of Hg and Cl to anomalous dispersion were included in structure factor calculations (20). The programs used are listed elsewhere (21). The refined coordinates and equivalent isotropic temperature factors are listed in Table 1.[2]

Discussion

Description of the structures

The crystal of $(CH_3Hg)GlyGly$ contains discrete molecules (Fig. 1) in which one of the ammonium protons of the zwitterionic glycylglycine molecule has been substituted by a CH_3Hg^+ group. In view of the very soft character of mercury, preference for this nitrogen site over the harder carboxylate or amide oxygens was anticipated. In the $[(CH_3Hg)_2GlyGly]^+$ cation (Fig. 2) present in the perchlorate, one of the CH_3Hg^+ ions is similarly attached to the $-NH_2$ end, whereas a second CH_3Hg^+ ion is bonded to the carboxylate acting as a monodentate group.

The interatomic distances and bond angles are listed in Table 2. In all cases, the coordination of mercury is linear within 4(1)°. The Hg—N(1) distances found here (2.10(3) and 2.14(3) Å) are similar to those reported for complexes with simple amino acids (8, 17). Mercury binds less readily to harder oxygen sites, but the Hg—O(8) distance (2.07(2) Å) indicates a normal single bond (22) in the $[(CH_3Hg)_2GlyGly]^+$ ion. Linearly coordinated CH_3Hg^+ groups usually retain some electrophilic character in the equatorial region (assuming that the H_3C—Hg—N(O) direction is axial), where the metal is accessible. In the solid state this commonly leads to clustering around mercury of negatively charged groups, forming loose coordination bonds. In both of our compounds, one such secondary bond with Hg(1) is intramolecular and involves the amide oxygen O(4) at 2.82(2) Å in $[(CH_3Hg)_2GlyGly]^+$ and 2.71(1) Å in $(CH_3Hg)GlyGly$ (Table 3). Although weaker than the contact with a free carboxylate oxygen in the tyrosine complex (Hg···O = 2.62(2) Å) (17), this interaction is strong enough to control the conformation at this end of the complexes.

Light-atom positions cannot be determined with high accuracy in the presence of Hg (and Cl) atoms. Considering the large esd's, the bond lengths and angles of glycylglycine (23, 24) are not significantly affected by complexation. However, chain conformation is appreciably changed in the complexes. Glycylglycine should ideally contain two planar fragments: the carboxylate group (C(6), C(7), O(8), O(9)) and the amide group (C(2), C(3), O(4), N(5), C(6)). Therefore molecular conformation depends on the torsion angles about the C(2)—C(3), N(5)—C(6), and C(6)—C(7) bonds. In a strictly planar elongated chain, the angles about C(2)—C(3) and N(5)—C(6) should be 180°. For C(6)—C(7) the value would be 0° or 180°, depending on the carboxylate oxygen used to define it; the O(8) atom (leading to the torsion angle nearer 0°) is used here. In crystalline glycylglycine, departure from these ideal angles and

displacement of 0.15 Å of C(6) from the amide plane result in a dihedral angle of 24.9° between the carboxylate and the amide planes. In the $[(CH_3Hg)_2GlyGly]^+$ ion, the deviations are differently distributed and C(6) is not significantly displaced from the amide plane, so that the dihedral angle is only 8.6°. It is noteworthy that the O(8)-bonded CH_3Hg^+ group lies in the carboxylate plane, in spite of the absence of electronic constraint to force this orientation. Therefore, the roughly planar portion in the complex extends from the H_3C—Hg(8) group to the C(2) methylene group. In $(CH_3Hg)GlyGly$, the C(3)—N(5)—C(6)—C(7) angle differs by ~90° from those of glycylglycine and the 2:1 complex (Table 4). This is reflected by the bent conformation shown in Fig. 1. The conformation at the NH_2 end of the molecules is undoubtedly dictated by the Hg(1)···O(4) bonding contact mentioned earlier, which stabilizes the *cisoid* arrangement of N(1) and O(4).

The packing diagram of $[(CH_3Hg)_2GlyGly]ClO_4$ shows that the complex cations are organized in pairs in the unit cell (upper part of Fig. 3). The "dimer" consists of two centrosymmetrically-related $[(CH_3Hg)_2GlyGly]^+$ cations forming a pair of complementary N(1)—H(11)···O(9) hydrogen bonds of 3.05(3) Å. This N···O distance is typical of this type of hydrogen bonds (25). Two long complementary contacts of 3.02(2) Å are also found between Hg(8) and the amide oxygen O(4), but the binding effect is probably very small, because the O(8)—Hg(8) and C(3)=O(4) bonds are roughly parallel. In each molecule, the amide proton forms a N(5)—H(5)···O(14) hydrogen bond with a ClO_4^- oxygen (N(5)···O(14) = 3.06(4) Å). Besides these two moderately strong interactions, cohesion between the various structural subunits in the cell does not involve strong individual interactions. Dimers roughly oriented along the *c* axis are repeated along this direction, thereby defining infinite ribons at $y \sim 0$ and ~1/2. Successive dimers along *c* form two weak centrosymmetrically related hydrogen bonds, in which the remaining amino proton H(12) acts as a donor to the free oxygen O(9) of the next molecule. The N(1)···O(9) distance (3.22(3) Å) lies at the upper limit of the range proposed for such hydrogen bonds (25). As mentioned above, the ClO_4^- ion forms a strong hydrogen bond to the amide N—H proton. However, in contrast with most other CH_3Hg^+ comnplexes containing this anion (26), the Hg···O contacts are very long (Table 3). The shortest contact observed here is 3.26 Å for Hg···O(11), whereas distances just above 3.0 Å are common.

In the $(CH_3Hg)GlyGly$ neutral complex, the intermolecular interactions are on the average much stronger. They are shown in the packing diagram of Fig. 4. Besides the intramolecular

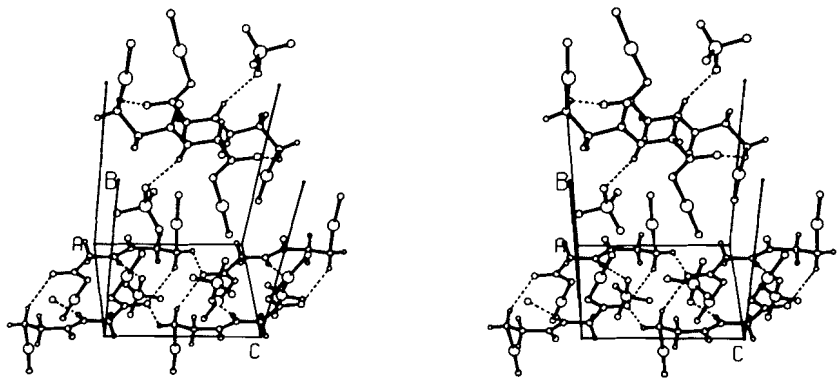

FIG. 3. Stereoview of the molecule packing for $[(CH_3Hg)_2GlyGly]ClO_4$. Dashed lines correspond to hydrogen bonding. The Hg···O contacts are shown as thin bonds. The atoms are represented by spheres of arbitrary size, with Hg and Cl being larger than the remaining non-hydrogen atoms. The atoms can be identified by comparison with Fig. 2. Only the O-1/2 portion of the *b* axis is shown.

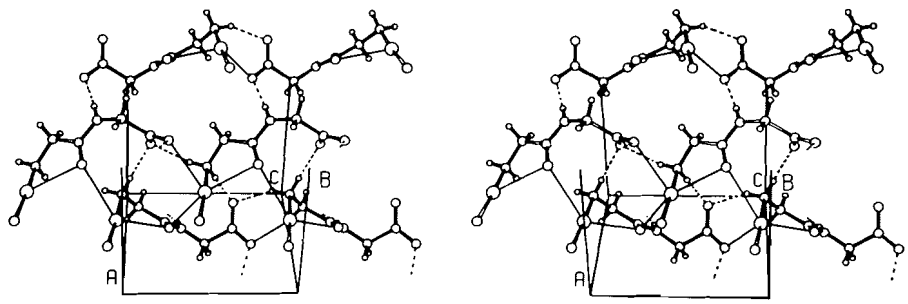

FIG. 4. Packing diagram for $(CH_3Hg)GlyGly$. Dashed lines represent hydrogen bonds. The Hg···O contacts are shown as thin bonds. The atoms can be identified by comparison with Fig. 1. Only the O-1/2 portion of the *b* axis is shown.

Hg···O(4) contact of 2.71(1) Å with the amide oxygen, any given Hg atom forms a strong intermolecular secondary bond with a carboxylate oxygen O(9) at 2.83(1) Å, and a weaker one with an amide oxygen at 3.04(1) Å. In addition, the $-NH_2$ groups establish moderately strong hydrogen bonds with O(8) oxygens belonging to two different molecules related by the *a* glide plane (N···O = 2.84 Å). These infinite chains extending along *a* are held to adjacent chains by strong interactions of 2.77(2) Å taking place at each monomer between the amide N(5)—H bond and carboxylate oxygen O(9).

Vibrational spectra

The Raman spectra of glycylglycine and of its two complexes with CH_3Hg(II) are shown in Figs. 5 and 6. The infrared spectra (Fig. 9, supplementary material) have also been obtained in the course of the present study. As they bring little information on these systems compared to the Raman data, they will not be discussed in detail.

The vibrational spectra of glycylglycine are well documented (27–31) and the interpretation of the spectra presented here is based on these earlier results.

CH_3Hg

The most characteristic spectral changes associated with the formation of the complexes are found in the 500 and 1200 cm^{-1} regions, where new strong bands due to methylmercury appear. A characteristic broad absorption is also observed in the infrared spectrum at ~810 cm^{-1}. The presence of methylmercury(II) in both the $[(CH_3Hg)_2GlyGly]ClO_4$ and $(CH_3Hg)GlyGly$ compounds can be clearly established from the very strong Raman bands at ~560 cm^{-1}, attributable to the Hg—CH_3 stretching vibration (ν(Hg—CH_3)) (refs. 32–34). The strong peak at 466 cm^{-1} in the spectrum of the *N*-substituted $CH_3HgGlyGly$ complex can also be unambiguously assigned to the Hg—N stretching vibration (ν(N—$HgCH_3$)), by comparison with other similar compounds, such as NH_2-substituted 9-methyladenine

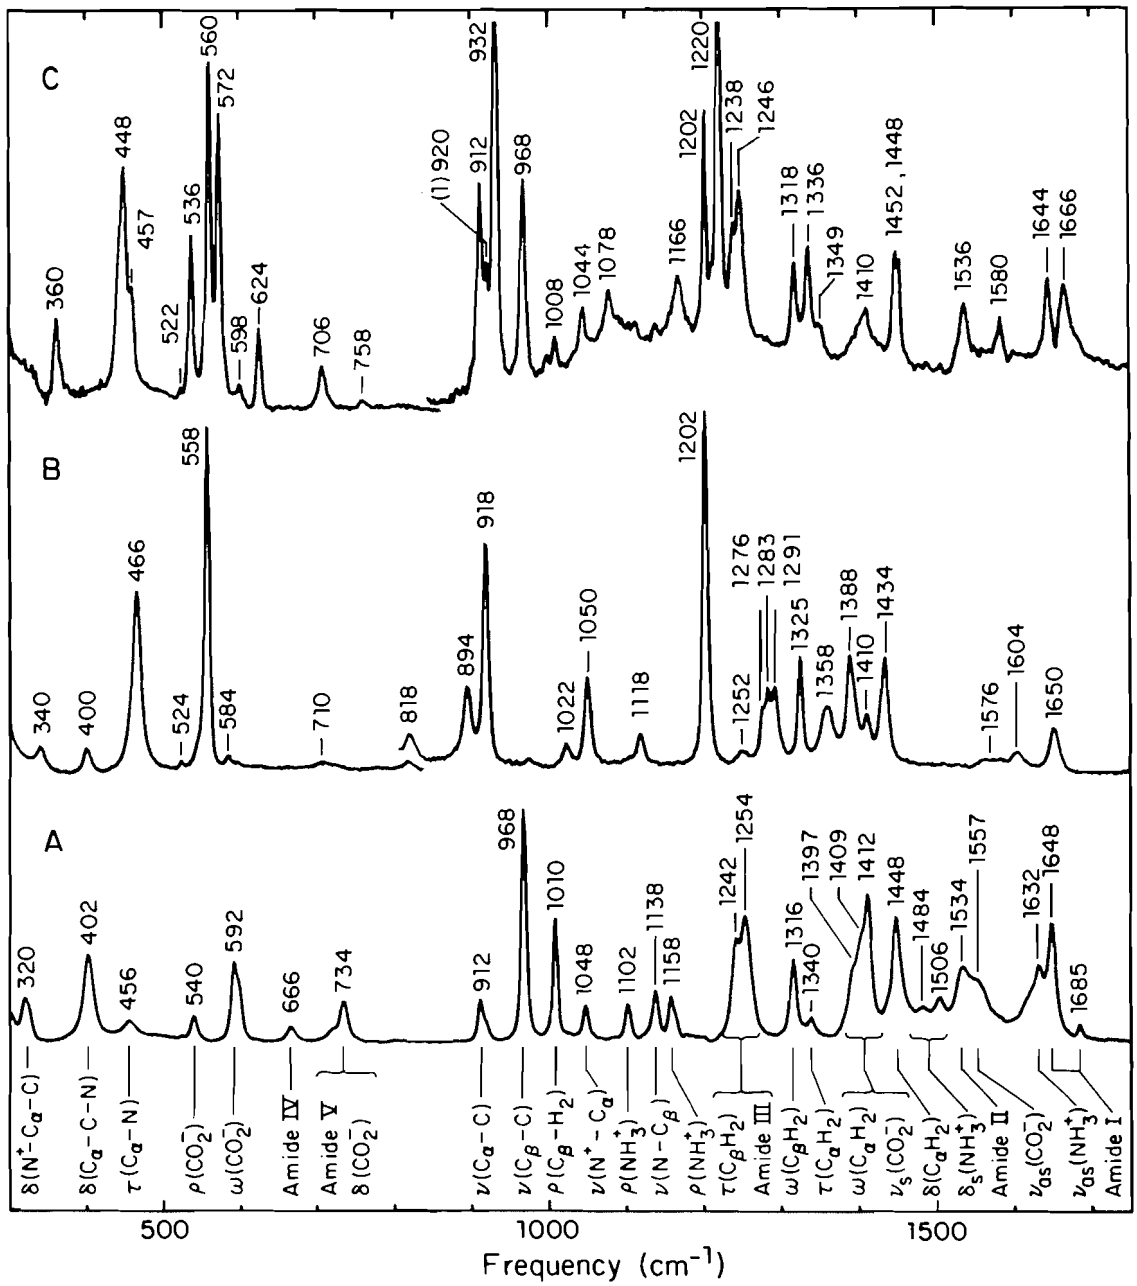

FIG. 5. Raman spectra of solid (A) glycylglycine (GlyGly), (B) $(CH_3Hg)GlyGly$, and (C) $[(CH_3Hg)_2GlyGly]ClO_4$ in the region 300–1750 cm^{-1}.

(482 cm^{-1}) (4) and adenine (470 cm^{-1}) (3), (methioninato)mercury(II) complex (481 and 518 cm^{-1}) (35), and the mercury–glycine complex (36).

In the $[(CH_3Hg)_2GlyGly]^+$ ion, the vibrations of the CH_3Hg group fixed on the NH_2-terminal section of the molecule have frequencies which are almost identical to those of (CH_3Hg)-GlyGly: the symmetric CH_3 bending mode ($\delta(CH_3)$) and $\nu(Hg—CH_3)$ vibrations occur at ~1200 and ~560 cm^{-1} respectively in both cases, whereas the $\nu(Hg—N)$ mode is shifted to ~450 cm^{-1} in the 2:1 compound, where it overlaps the ν_2 band of the perchlorate ion. This leaves the 536 cm^{-1}, 572 cm^{-1}, and 1220 cm^{-1} bands in the spectrum of the latter for the corresponding vibrations of the CH_3Hg unit linked to the carboxylate group. The assignment of the 536 cm^{-1} band to the Hg—O stretching mode is questionable, as this vibration has been given much lower frequencies in the compounds CH_3HgNO_3 (292 cm^{-1}) (32), and $CH_3HgSO_3CH_3$ (246 cm^{-1}) and $CH_3HgSO_4^-$ (273 cm^{-1}) (37). On the other hand, Green (33) has concluded from his extensive vibrational study of alkyl and aryl compounds of mercury(II) that absorptions due to Hg—O vibrations occur in the region 500–650 cm^{-1}. The antisymmetric $\nu_{as}(Hg—O)$ stretching mode of the $(CH_3Hg)_3O^+$ oxonium ion has also been given a relatively high frequency of 549 cm^{-1} (38). The $\nu(Hg—O)$ vibration of the methylmercury unit linked to the carboxylate group in $[(CH_3Hg)_2GlyGly]ClO_4$ should have a frequency somewhat lower than the corresponding $\nu(Hg—N)$ vibration of the *N*-substituted unit (466 cm^{-1} in $(CH_3Hg)GlyGly$), from the relative masses involved. However, the assignment of the 536 cm^{-1} peak to this vibration is consistent with the shorter Hg—O distance (2.09 Å vs. *r*(Hg—

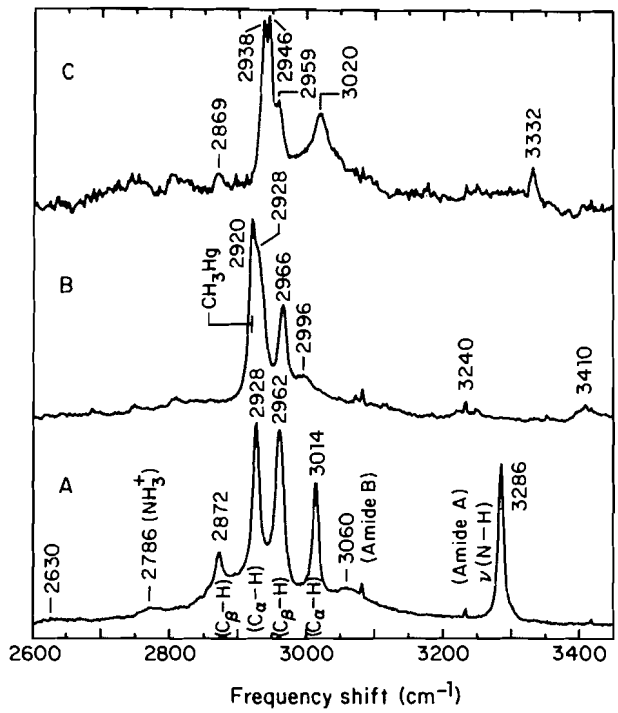

FIG. 6. High-frequency region of the Raman spectra of solid (A) glycylglycine (GlyGly), (B) (CH_3Hg)GlyGly, and (C) $[(CH_3Hg)_2$-GlyGly$]ClO_4$.

N): 2.14 Å) indicated from the X-ray study, although these values are highly uncertain. The local geometry could also be responsible for this increase of the ν(Hg—O) frequency: ∠ Hg—O—C: 121° vs. ∠ Hg—N—C: 114° and r(C—OHg): 1.31 Å vs. r(C—NHg): 1.51 Å.

—NH_3^+

The substitution of a proton of the NH_3^+ group by a CH_3Hg^+ ion in both complexes causes a disappearance of a number of bands attributable to vibrations of the protonated amino end of glycylglycine. These include the bands due to the symmetric and antisymmetric bending modes of this group near 1500 and 1630 cm^{-1} respectively, and those near 1100 and 1160 cm^{-1}, due to rocking modes. The absence of these bands in the spectra of the complexes is particularly meaningful, as they are not expected to be sensitive to other effects, such as conformational and environmental changes. The stretching modes of the NH_3^+ group are of little help in characterizing amino substitution, as they give weak and broad bands in the 3200–3250 cm^{-1} (ν_{as}) (27) and 2600–2800 cm^{-1} (ν_s) (39) regions of both the infrared and Raman spectra. Similarly, the vibrations of the NH_2 group resulting from the substitution of a proton by CH_3Hg^+ are weak, and they cannot be unambiguously identified in the spectra.

COO^-

The spectral changes associated with the neutralization of a carboxyl group and the formation of a Hg—O bond, such as in the $[(CH_3Hg)_2$GlyGly$]ClO_4$ complex, are not very characteristic when only the vibrational bands of the COO^- group are considered. The ν_{as} vibration at 1557 cm^{-1} in the Raman spectrum of GlyGly (1554/1576 cm^{-1} in the infrared) is shifted to 1580 cm^{-1} upon formation of the Hg—O bond, while the band at 1412 cm^{-1}, due to the corresponding symmetric stretching mode, loses most of its intensity. We have observed the same phenomenon with the $CH_3COOHgCH_3$ complex, where the band due to the $\nu_{as}(COO^-)$ mode of the CH_3COO^- ion shifted from 1564 to 1578 cm^{-1}, with a large intensity increase, and the band due to the $\nu_s(COO^-)$ mode at 1418 cm^{-1} showed a large decrease in intensity upon complex formation.[3] It has already been noted by Nakamoto *et al.* (41) that the shifts in frequency of the ν(CO) stretching vibrations of the COO^- group of carboxylic and amino acids are mostly confined to the asymmetric mode in such cases.

Conformation

The spectra of (CH_3Hg)GlyGly differ markedly from those of GlyGly, much more so than does that of the 2:1 complex. For example, the very strong infrared and Raman peak due to the amide N—H stretching vibration (amide A) at 3286 cm^{-1} in the spectra of GlyGly, and which is shifted to higher frequency (3332 cm^{-1}) with reduction in intensity in the Raman spectrum of the 2:1 complex, practically disappears in the spectra of (CH_3Hg)GlyGly. In fact, this band is shifted to 3240 cm^{-1} in the latter, with drastically reduced intensity. This behaviour is not directly related to the presence of CH_3Hg(II) in the complex and it must be interpreted in terms of the change in the backbone conformation of the dipeptide (see Table 4). Similar effects have been observed in the spectra of polypeptides (23, 42), a strong peak near 3290 cm^{-1} being characteristic of β-sheet structure, whereas a weak one near 3245 cm^{-1} is indicative of a non-ordered secondary structure. In the present case, both GlyGly and the 2:1 complex exist as extended molecular units, with crystal structures related to the β-sheet arrangement found in some polypeptides and proteins. On the other hand, the monosubstituted complex has a different conformation. The N(1)—C(2)—C(3)—N(5) and C(3)—N(5)—C(6)—C(7) torsion angles in this compound (−169° and −84° respectively) are better related to the ψ (= −145.3°) and φ (= −76.9°) angles measured in 3_1 helical polyglycine II (44).

A change of conformation of (CH_3Hg)GlyGly with respect to GlyGly is also indicated in other conformation-sensitive regions of the spectra (43). In the unsubstituted dipeptide, the amide III and amide I Raman bands are found at 1254 and 1665 cm^{-1} (average of the two factor-group components at 1644 and 1682 cm^{-1} (27)), whereas these vibrations occur at 1283/1291 and 1650 cm^{-1} in (CH_3Hg)GlyGly. The values for the complex are very similar to the frequencies of crystalline polyglycine II (1283 and 1654 cm^{-1}), which exists as a 3_1 helix (44). On the other hand, the frequencies of both GlyGly and the 2:1 complex are closer to those of polyglycine I (1255 and 1674 cm^{-1} (45)) which has an antiparallel rippled-sheet structure. Other conformation-related differences are evident when the Raman spectrum of (CH_3Hg)GlyGly is compared to that of GlyGly: (*i*) The very strong peak at 968 cm^{-1} in the Raman spectrum of GlyGly, assigned to the $\nu(C_\beta—C)$ stretching mode, is hardly detectable in the spectrum of (CH_3Hg)GlyGly. This region of the Raman spectrum is known to be conformation sensitive (46). (*ii*) The relative intensity of the C_α—N and C_β—N stretching modes at 1048 and 1138 cm^{-1} in the spectrum of GlyGly is strongly modified in that of (CH_3Hg)GlyGly, the peak at 1138 cm^{-1} being also shifted to 1118 cm^{-1}. (*iii*) The CH_2 bending mode at 1448 cm^{-1} in GlyGly is shifted to 1434 cm^{-1} in the *N*-substituted complex. This change parallels that observed in the spectrum of polyglycine II (3_1 helix), where this mode is shifted to a lower frequency by 12 cm^{-1}, from 1432 to 1420 cm^{-1}, with respect to polyglycine I (rippled-sheet structure) (30, 46). (*iv*) The C_β—H stretching more at 2872 cm^{-1} and the C_α—H vibration at 3014 cm^{-1} in the spectrum of

[3] S. Alex and R. Savoie, unpublished results.

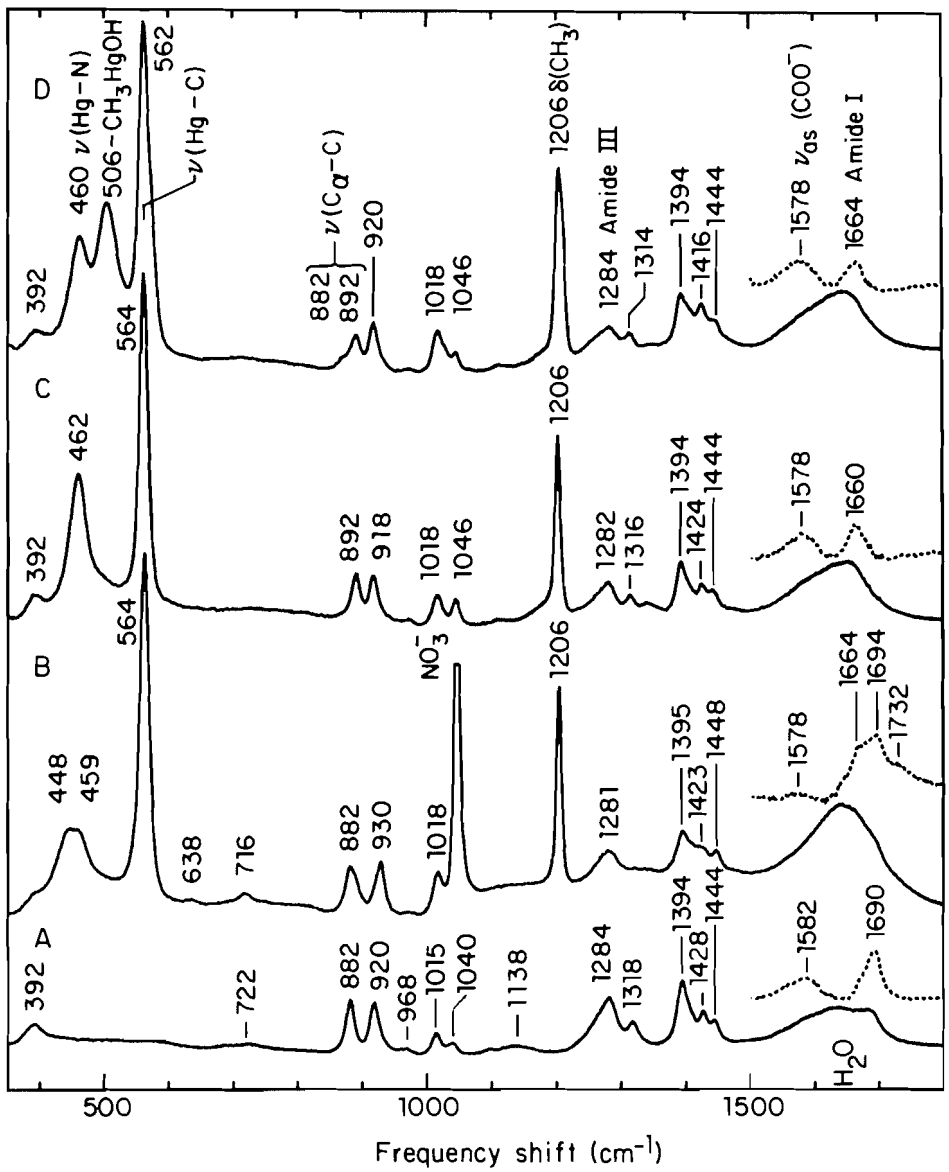

FIG. 7. Raman spectra of aqueous solutions of (A) glycylglycine (0.33 *M*) at pH = 7, and (B–D) equimolar mixtures (0.25 *M*) of glycylglycine and CH_3Hg(II) at (B) pH = 3, (C) pH = 7, and (D) pH = 9.

GlyGly merge into the central 2900–3000 cm^{-1} region of the spectrum of (CH_3Hg)GlyGly. It is noteworthy that these spectral changes, which are associated with a change in the conformation of the ligand, are more important than those expected on the basis of a mere substitution of a proton by a CH_3Hg^+ group.

Aqueous solutions

The Raman spectra of aqueous GlyGly in the presence of CH_3Hg(II) at various pH are shown in Fig. 7. The spectrum of the free species at pH 7 is also given for comparison. It shows that the dipeptide in aqueous solution has a structure that differs from that in the solid. In fact, the spectrum of aqueous GlyGly is quite similar to that of solid $CH_3HgGlyGly$, for which a bent rather than an extended structure is indicated from the spectra. The Raman spectrum of aqueous GlyGly varies little with the pH, the main changes being associated with the protonation of the carboxylic group (pK_a = 3.1) at low pH, which results in a decrease of the $\nu_{as}(COO^-)$ band at 1578 cm^{-1} and a corresponding increase in the band due to the C=O stretching mode of the COOH group at ~1730 cm^{-1}. Changes are also noted in the 900 cm^{-1} region at low pH, presumably for the same reason.

The disappearance of the 506 cm^{-1} band of CH_3HgOH from the spectrum of an equimolar aqueous mixture of GlyGly and CH_3Hg(II) at pH 7 shows that quantitative complexation of the methylmercury occurs. Furthermore, the 462 cm^{-1} band in the spectrum indicates that this occurs through substitution of a proton of the NH_3^+ group by a methylmercury ion. The presence of this sole type of complex is suggested by the sharpness of the peaks at 564 and 1206 cm^{-1}. At pH 9, the complex is partly dissociated, as evidenced by the band at 506 cm^{-1} and the shoulders present on the high-frequency side of the 562 and 1206 cm^{-1} bands. These secondary features, which are not present in the spectrum at pH 7, are attributable to CH_3HgOH (32). Note that the intensity of the 506 cm^{-1} band is misleading with regard to the actual amount of uncomplexed methylmercury in the solution, as this peak is basically much more intense than that at 462 cm^{-1}. (Full dissociation would

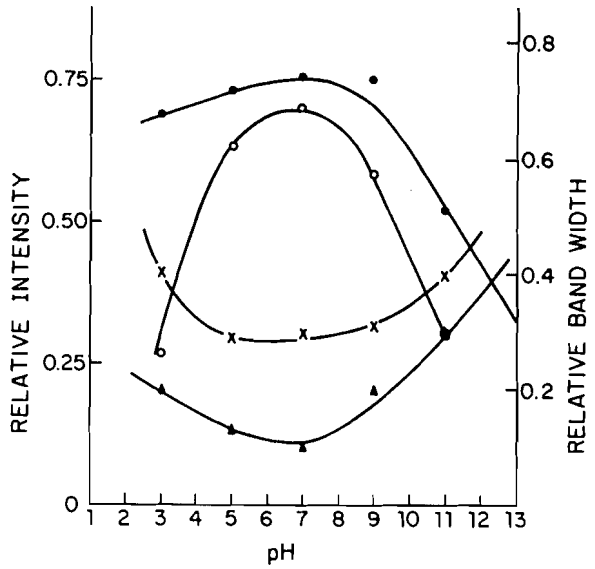

FIG. 8. Peak-height intensities of the (●) 564 (ν(Hg—C)) and (○) 462 cm^{-1} (ν(Hg—N)) Raman bands relative to the 1206 cm^{-1} ($\delta(CH_3)$) peak, and widths at half-intensity of the (×) 1206 ($\delta(CH_3)$) and (△) 564 cm^{-1} (ν(Hg—C)) bands, as a function of pH, in a 1:1 GlyGly/CH_3Hg(II) aqueous mixture.

cause the 506 cm^{-1} band to be twice as intense as that at 562 cm^{-1}, the latter being shifted to 572 cm^{-1}.)

The spectrum at pH 3 differs little from that at pH 7, except for the splitting of the 462 cm^{-1} band into an unresolved doublet at 448/459 cm^{-1}. The presence of the ~453 cm^{-1} component is quite significant, as it corresponds to the ν(Hg—O) vibration of the oxonium $CH_3HgOH_2^+$ ion (32), which also contributes to the 564 and 1206 cm^{-1} peaks.

Although it is not possible to determine accurately from the spectra the extent of complexation of GlyGly and CH_3Hg^+ in aqueous solutions at various pH, spectral changes in the bands associated with free and complexed CH_3Hg(II) clearly indicate that complexation is maximum near pH 7 (Fig. 8). The variation in intensity of the ν(N—$HgCH_3$) band at 462 cm^{-1} is particularly revealing in this respect, as it is not perturbed by other bands. The widths of the $\delta(CH_3)$ and ν(Hg—CH_3) bands are also indicative of the extent of the complexation, as these peaks become sharper when the concentration of the complexed species increases. This occurs because neighboring bands due to free methylmercury vanish upon complexation.

Methylmercury has been shown by ^1H nmr to react with the COO^- group of selected carboxylic and amino-carboxylic acids at low pH (15, 16, 40). In the present study, we have had no indication from the Raman spectra that this type of complexation occurs to any appreciable extent in aqueous solutions of GlyGly and CH_3Hg(II) at any pH between 1 and 6, even for a [CH_3Hg(II)]/[GlyGly] molar ratio of 2.

Subtraction of the spectrum of the solvent from those of the solutions permits the direct observation of the amide I band of the ligand in the 1650 cm^{-1} region (Fig. 7). This band surprisingly occurs at 1690 cm^{-1} in the spectrum of an aqueous solution of GlyGly at neutral pH, a value which is much higher than in solid GlyGly (1648/1682 cm^{-1}) and in crystalline (CH_3Hg)GlyGly (1650 cm^{-1}). This could mean that the conformation of GG changes upon dissolution in water. However, this hypothesis is not corroborated by the rest of the spectrum, particularly from the frequency of the amide III band, which remains unchanged at ~1280 cm^{-1}. More likely, the observed change in the amide I region is caused by a disruption of the hydrogen bonding network around the protonated amino group.

Substitution of a proton of the NH_3^+ group by a CH_3Hg^+ ion also shifts the amide I band from 1690 to 1660 cm^{-1}, the same effect being observed when the pH of an aqueous solution of free GlyGly is raised to high values (≧9), possibly as a result of the deprotonation of the NH_3^+ group. This emphasizes the fact that the spectral modifications associated with protonation, hydrogen bond formation, and conformational changes can be just as important as those resulting from the formation of a complex. However, the changes in the regions of the Raman spectra where vibrations involving the highly polarizable mercury atom occur are very characteristic, and they do reflect quite accurately the state, as well as the nature, of the sites involved in the complexation of peptides.

The ^{1}H nmr spectra of the benzene-1,2- and -1,3-dicarbaldehydes in carbon tetrachloride, benzene-d_6, and acetone-d_6 solutions at 300 K are analyzed. The stereospecific long-range couplings over five formal bonds between the sidechain and ring protons show that the 1,2 isomer exists as an 87:13 mixture of the *cis–trans* and *trans–trans* conformers in carbon tetrachloride. These populations are insensitive to solvent. Molecular orbital calculations utilizing extensive geometry optimization procedures imply that the *cis–cis* form, with proximate C=O bonds, is indeed of negligible significance as assumed in obtaining the populations of the other forms. Further calculations define a pathway of relatively low energy for interconversion of the two abundant forms, in agreement with dynamic nmr studies. For the 1,3 isomer the long-range couplings provide a check of the conformer populations deduced from dipole moment and ^{13}C nmr studies. For example, if the *cis–trans* form is 70% abundant, as deduced from the dipole moment in benzene solution, then the long-range couplings imply that the population of the *cis–cis* conformer is insignificant.

TED SCHAEFER, GLENN H. PENNER, RUDY SEBASTIAN et CRAIG S. TAKEUCHI. Can. J. Chem. **64**, 158 (1986).

On analyse les spectres rmn du ^{1}H des benzène dicarbaldehydes-1,2 et -1,3 qui ont été mesurés à 300 K et dans des solutions dans le tétrachlorure de carbone, le benzène-d_6 et l'acétone-d_6. Le couplage stéréospécifique à longue distance à travers cinq liaisons normales entre les protons du cycle et ceux de la chaîne latérale indique que dans le tétrachlorure de carbone l'isomère 1,2 existe sous la forme d'un mélange à 87:13 des conformères *cis–trans* et *trans–trans*. Le solvant n'a aucune influence sur cette répartition. Les calculs d'orbitales moléculaires, faisant appel à des procédés extensifs d'optimisation géométrique, suggèrent que la forme *cis–cis* ayant des liaisons s'approchant de C=O n'a pratiquement aucune importance dans la détermination des populations des autres formes. Des calculs plus poussés définissent un chemin réactionnel de faible énergie pour l'interconversion des deux formes abondantes et ceci est en accord avec les études de la rmn dynamique. Dans le cas de l'isomère-1,3, les couplages à longue distance constituent une vérification des populations des conformères qui ont été déduites à partir des études du moment dipolaire et de la rmn du ^{13}C. Par exemple, si la forme *cis–trans* est à 70%, tel que déduit à partir du moment dipolaire en solution dans le benzène, alors le couplage à longue distance implique que la population de la forme *cis–cis* n'est pas significative.

Introduction

The conformational preferences of the benzenedicarbaldehydes in solution have been investigated by a variety of techniques. The 1,2 isomer is often discussed in terms of three planar forms, for which the *ct* conformer has a statistical weight of two. Because the barrier to internal rotation in benzaldehyde is at least 19.5 kJ/mol in the gas phase (1–3) and about 30 kJ/mol in solution (4, 5), at ambient temperatures this approach seems reasonable, except perhaps for the *cc* form in which steric or electrostatic repulsions between the carbonyl bonds compete with the conjugation energy favoring planarity.

Indeed, based on extensive STO 3G MO computations that, however, did not utilize geometry optimization procedures, it was argued that the 1,2 isomer has three nonplanar stable conformers (6). The calculated populations gave a net dipole moment in good agreement with that measured in dioxane solution at 298 K (6). Alternatively, if only the planar *tt* and *ct* forms existed in dioxane, then the *ct* form was 60% abundant at this temperature (6). The same assumption, applied to the dipole moment in benzene solution, led to 64% as the abundance of the *ct* conformer (7). In the latter study, the dipole moment did not change significantly between 287 and 327 K.

The ^{13}C nmr spectrum of the 1,2 isomer in a 0.5 *M* Freon solution gave no indication of restricted rotation at the lowest attainable temperatures (8). Force field calculations suggested that the barrier to internal rotation in this isomer is rather lower than for the other two isomers, for which spectra arising from

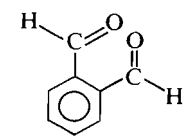
$\theta_1 = 0°, \theta_2 = 180°$



cc

$\theta_1 = 180°, \theta_2 = 0°$

the individual conformers could be observed (8). It also appeared that ^{1}H,^{13}C couplings could not be used as indicators of conformer populations (8).

Turning to the 1,3 isomer, dipole moments in benzene solution imply the presence of all three conformers (7), the double weighted *ct* form being 70% abundant near room temperature. In dioxane solution, the observed dipole moment was considered to be in reasonable agreement with a 0.18:0.56:0.26 ratio of *cc*/*ct*/*tt* forms, as was the Kerr constant (6). At 132 K in 0.5 *M* Freon solution, the ^{13}C nmr peak intensities yielded a ratio of 0.15:0.58:0.27 (8).

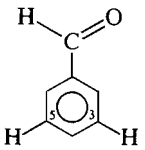
Now, it is known that $^5J(H, CHO) \equiv {}^5J$, in benzaldehyde and its derivatives, is stereospecific (9–12).

In **1**, ^5J(H-3, CHO) $\equiv {}^5J_t$ is 0.76 Hz and ^5J(H-5, CHO) $\equiv {}^5J_c$ is 0.00 Hz to within experimental error. That is, if the aldehyde group is held in one orientation, say by an intramolecular

[1]Undergraduate research participant, 1984–1985.



1

hydrogen bond, no ^5J_c is observable under conditions of very high resolution (13). The magnitude of ^5J_t changes slightly in the presence of an electronegative *ortho* substituent. This perturbation can be incorporated into conformational deductions.

For the 1,2 isomer, two ^5J values are in principle available from spectral analysis and can be used for conformational assessments. For the 1,3 isomer, only one ^5J is present, yet its value is useful as a check of possible conformer distributions. For example, the *tt* conformer has a large ^5J while the *cc* conformer should display no ^5J at all. The 1,4 isomer has degenerate chemical shifts for the ring protons and is not amenable to this approach. In any event, the ^{13}C nmr and dipole moment studies agree that it exists in equal proportions of the *ct* and *cc* conformers (6–8, 14).

Accordingly, the ^1H nmr spectra were analyzed for CCl_4, C_6D_6, and $(CD_3)_2C{=}O$ solutions of the 1,2 and 1,3 isomers. Furthermore, extensive geometry optimizations at the STO 3G level of molecular orbital theory were performed, particularly for the 1,2 isomer in which considerable bond angle deformations are likely to exist. This paper reports on the conformational deductions reached in this manner.

Experimental

The benzene-1,2- and -1,3-dicarbaldehydes (Aldrich) were prepared as 4.0 mol% solutions in CCl_4, C_6D_6, and $(CD_3)_2C{=}O$, which also contained a few drops of tetramethylsilane. The CCl_4 solutions had 10 mol% of C_6D_{12} as an internal lock material. These solutions were transferred to 5-mm od nmr sample tubes, were degassed by a number of freeze–pump–thaw cycles, and the tubes were then flame sealed.

The ^1H nmr spectra were accumulated on a Bruker AM 300 spectrometer at a probe temperature of 300 K. A wide sweepwidth survey spectrum was obtained in order to reference the spectrum with respect to TMS, and to locate the aromatic and sidechain regions. Each region was examined in detail, with sweepwidth and data size adjusted to give acquisition times of approximately 40 s. Four to sixteen scans were acquired. Zero filling to twice the original data size was done before transforming the FIDs using an exponential broadening of −0.1 and a gaussian multiplication of 0.6. Line widths at half height were approximately 0.05 Hz after this resolution enhancement (see Fig. 1).

The STO 3G MO (15) computations utilized the program Monstergauss (16). INDO MO (17) and INDO MO FPT (18, 19) calculations were also performed on an Amdahl 470/V8 system.

Results and discussion

Spectral analyses

These were done with the computer program NUMARIT (20), as modified in this laboratory. The ^1H nmr spectra of the 1,2 isomer arise from AA′BB′XX′ spin systems. Even though most calculated transitions were assigned and the root mean square deviations were ≤0.01 Hz, some significant correlations existed among the spectral parameters. These are given in Table 1.

Table 2 contains the ^1H nmr spectral parameters for the 1,3 isomer in three solvents. The spectra correspond to ABCC′XX′ spin systems, but in C_6D_6 solution the iterations diverged for such an approach. This occurred because of the particular magnitudes of the coupling constants and chemical shift differences. Therefore the spectrum was analyzed as if it arose from an ABC_2X_2 spin system. For the other two solutions, the spectra were analyzed in both ways. It turned out that the parameter of interest, $^5J(H,CHO)$, had the same value in both analyses for a given solution. $^4J_{46}$, the coupling between H-4 and H-6, could not be established.

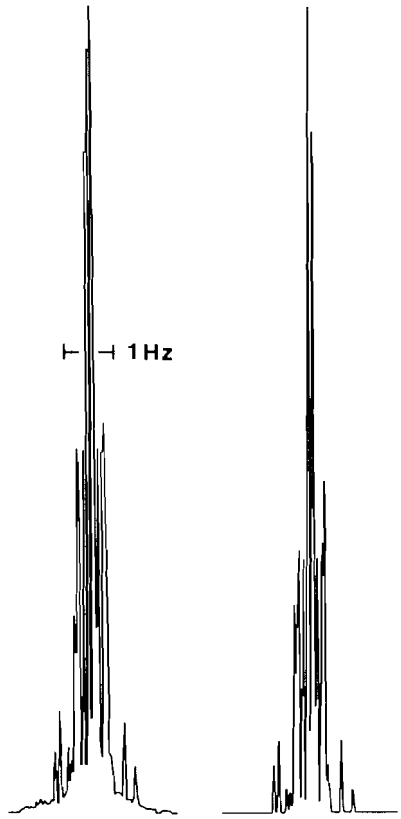


FIG. 1. The observed and calculated ^1H nmr spectra, at 300 MHz and 300 K, of the aldehyde protons in benzene-1,3-dicarbaldehyde as a 4.0 mol% solution in C_6D_6. The spectrum was accumulated as described in the text. The line width at half height is about 0.05 Hz. The computed spectrum assumed a lorentzian line shape and the plotter had some difficulty in reproducing the closely spaced peaks.

STO 3G MO computations

Previous computations of conformational energies (6, 7) did not use geometry optimization procedures, which should be particularly important for the 1,2 isomer. Because previous computations implied stable nonplanar conformers for the 1,2 isomer and because their abundant presence would complicate the conformational analysis, the present calculations used extensive geometry optimizations in an attempt at establishing the presence of nonplanar minima in the energy.

Calculations on benzaldehyde, in which the benzene moiety was held as a regular hexagon but all other bond angles and lengths were allowed to vary, gave eq. [1] as the potential function for rotation about the exocyclic C—C bond. Here $\theta = 0$ corresponds to the planar conformer and the fit uses seven angular values (15° intervals). At the 95% confidence level, the barrier is calculated as predominantly twofold with a small fourfold component. Full geometry optimization, allowing *all* angles and lengths to vary, yields an energy difference of 24.1 kJ/mol between the planar and perpendicular conformers. Microwave and far infrared spectra give an assumed twofold barrier of 19.5–20.5 kJ/mol (1, 3), so that the present calcula-

[a]Chemical shifts in Hz at 300.135 MHz to high frequency of internal TMS.
[b]4.0 mol% in CCl_4 containing 10 mol% C_6D_{12} and 0.5 mol% TMS.
[c]4.0 mol% in C_6D_6 containing 0.5 mol% TMS.
[d]4.0 mol% in $(CD_3)_2C{=}O$ containing 0.5 mol% TMS.
[e]Numbers in parentheses are the standard deviations in last significant figure, but see footnote [i].
[f]Analyzed as an ABCC′XX′ spin system. See text.
[g]Analyzed as an ABC_2X_2 spin system. See text.
[h]Parameters from an ABC_2X_2 analysis; iterations diverged for an ABCC′XX′ analysis.
[i]Due to the magnitudes of the couplings and the chemical shift differences, these parameters are not known; that is, the spectrum is insensitive to their values. ^6J(H-4, CHO) and $^4J_{46}$ are almost completely correlated, at 0.97.

TABLE 3. Relative energies of the conformers[a] of benzene-1,2-dicarbaldehyde calculated by geometry optimized STO 3G MO methods

θ_1 (deg)[b]	θ_2 (deg)	Energy (kJ/mol)	θ_1 (deg)	θ_2 (deg)	Energy (kJ/mol)
0	0	0.00[c]	0	30[d]	3.27
0	180	4.45[c]	0	60	11.95
180	0	20.32[c]	0	90	13.59
0	90	16.81	0	120	13.05
90	90	39.55	0	150	6.73
90	270	37.65	0	180	4.45

[a]The energies are given for structures in which the carbon framework of the benzene moiety is held as a regular hexagon but all other bond angles and lengths are optimized. The energy of the 0,0 conformer is −450.345 054 au.

[b]$\theta_1 = \theta_2 = 0$ defines the *cis–trans* or *ct* conformer, see structure in text.

[c]When *all* bond angles and lengths are optimized, the 0,0 conformer has an energy of −450.345 590 au and the 0,180 (*tt*) form is less stable by 4.50 kJ/mol while the 180,0 (*cc*) form is 18.81 kJ/mol less stable.

[d]The angles in this column identify one low-energy pathway of interconversion between the *ct* and *tt* conformers, the *cc* conformer having an insignificant population at 300 K.

tions somewhat overestimate the barrier. In the liquid or in solution, however, the internal barrier is nearer 30 kJ/mol.

[1] $V(\theta) = (24.26 + 0.05) \sin^2 \theta - (0.53 \pm 0.06) \sin^2 2\theta$

Perhaps, therefore, STO 3G MO computations on the 1,2 and 1,3 isomers will yield useful information on the stability of nonplanar conformers, in the sense that, although the calculations overestimate the energy necessary to break the π electron conjugation by a few kJ/mol in the gas phase, the presence of solvent will tend to compensate for the overestimation.

In fact, for the 1,3 isomer it is highly unlikely that nonplanar conformers are abundant at 300 K in solution, since the free energy of activation for interconversion of the planar conformers is 31.0 ± 0.5 kJ/mol at 163 K, the entropy of activation being small (8). Optimization of the geometry, with the constraint of a regular hexagon for the carbon network of the benzene entity, gave the *tt* form as 0.35 kJ/mol higher in energy than the *ct* form. The latter had an energy of −450.349907 au.

Some STO 3G MO results for the 1,2 isomer appear in Table 2. As expected, the *ct* form is most stable, followed by the *tt* form at 4.45 kJ/mol. The *cc* form is computed as 20.32 kJ/mol less stable than the *ct* form. This is up to 600 kJ/mol lower than that computed (6, 7) without bond angle and bond length relaxation. Nevertheless, the population of the *cc* form is expected to contribute negligibly to the conformational equilibrium at ambient temperatures, at least in the absence of substantial solvent perturbations of the conformer stabilities.

To test the possibility of relatively low rotational barriers in the 1,2 isomer, as indicated by the force field calculations and by the ^{13}C nmr data, one low-energy pathway between the *ct* and *tt* conformers is given in Table 3. The barrier to interconversion is only 13.6 kJ/mol. If 5 kJ/mol is added to this value to account for the overestimate expected on the basis of the computations for benzaldehyde above, but partially compensated by the solvent effect on the barrier of benzaldehyde, then the failure to observe ^{13}C nmr spectra of the *cc* and *tt* forms at the lowest temperatures attained (8) is rationalized. To trace out a complete rotational surface computationally would be very expensive.

To test, in a relatively inexpensive manner, whether the planar 1,2 conformers can lower their energy by out-of-plane rotations (6), *complete* optimizations were done in which the rotational angles θ_1 and θ_2 were also allowed to change and in which the benzene framework was allowed to distort from a hexagon. The conformers remained planar during these calculations, the energy of the *ct* form decreased to −450.345590 au, and the *tt* and *cc* forms lay 4.50 and 18.81 kJ/mol above *ct* in energy. Figure 2 displays the calculated geometry of the *cc* form, showing large angle distortions.

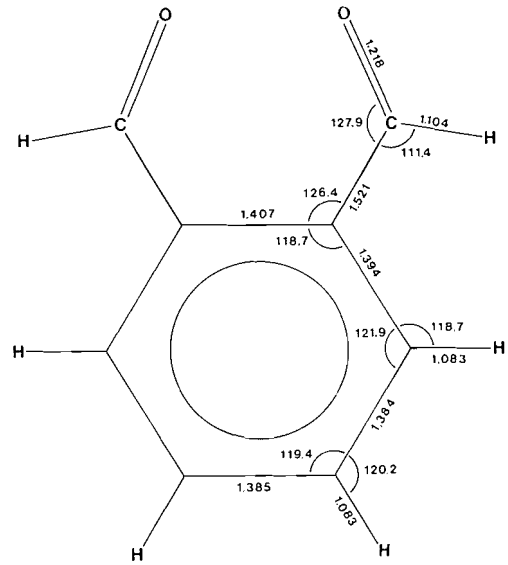

FIG. 2. The geometry of the planar *cis–cis* conformer of benzene-1,2-dicarbaldehyde as computed by STO 3G MO methods. Note the large deviations from a standard geometry, accounting for the fact that the relative energy of this structure is more than an order of magnitude lower than the computed energies in the literature (6, 7).

$^5J(H, CHO) \equiv {}^5J$ *and the conformational populations*

(i) The 1,2 isomer

According to the immediately preceding relative energies, the fractional populations in the gas phase are 0.92, 0.08, and 0.00 for the *ct*, *tt*, and *cc* forms, respectively, at 300 K.

In terms of the stereospecific properties of ^5J discussed in the introduction, namely that ^5J_t is large and ^5J_c vanishes, one has eqs. [2]–[4]. However, these equations are not linearly independent. If it is assumed that p_{cc} is zero, as seems likely form the computations above, then p_{ct} and p_{tt} follow from eqs. [2]–[4]. Note that $^5J_t = {}^5J_{26} + {}^5J_{24}$ is 0.778(2), 0.768(4), and 0.768(3) Hz in CCl_4, C_6D_6, and $(CD_3)_2C{=}O$ solutions, respectively. These numbers are very near the 0.76 Hz reported for benzaldehyde (21), implying a negligible intrinsic perturbation of ^5J by

the second substituent. The ratios of p_{ct}/p_{tt} follow as 0.87: 0.13, 0.86: 0.14, and 0.84:0.16 in CCl_4, C_6D_6, and $(CD_3)_2C{=}O$, respectively.

$$[2] \quad {}^5J_{24} = p_{ct}{}^5J_t/2 + p_{tt}{}^5J_t + 0p_{cc}$$

$$[3] \quad {}^5J_{26} = p_{ct}{}^5J_t/2 + 0p_{tt} + {}^5J_t p_{cc}$$

$$[4] \quad 1 = p_{ct} + p_{tt} + p_{cc}$$

These ratios are much larger than 0.64:0.36 in benzene and 0.60:0.40 in dioxane, as deduced from dipole moment measurements under the assumption that p_{cc} vanishes. Furthermore, on the basis of dipole moments computed by INDO MO methods, 1.44, 4.23, and 5.23 D for *tt*, *ct*, and *cc*, respectively, the simplest reaction field model (22) predicts an increase in this ratio on passing from CCl_4 to $(CD_3)_2C{=}O$ solutions. It may be noted, however, that for the pyridinecarbaldehydes (23) the conformer stabilities in solution depend significantly on the quadrupolar terms in this model (22). The measured moments are 4.42 D in benzene (7) and 4.27 D in dioxane (6). We see no reason to doubt the population ratios obtained from ^5J. Perhaps the additivity of group dipole moments assumed for the 1,2 isomer is somewhat less reliable than for the 1,3 isomer.

If some *cc* conformer is present, then the ratios above will change, of course. Suppose that p_{cc} is as large as 0.05. Then p_{ct}/p_{tt} becomes 0.76:0.19 in C_6D_6 solution, for example; the ratio decreases from 6.1 to 4.0. Naturally, this approach will not bring the ^5J results into agreement with the dipole results because the latter were interpreted on the basis of a vanishing p_{cc}.

Curiously, the gas phase populations based on STO 3G MO energies are in closer agreement with those deduced from ^5J in solution than the latter are with the populations deduced from dipole moments in solution. It is interesting that the populations appear to be insensitive to solvent polarity.

Substantial populations of nonplanar conformers would entail (24) a significant magnitude for $^6J(H,CHO)$. In benzaldehyde itself, ^6J is reported as 0.03 Hz (21) and, as a $\sigma{-}\pi$ coupling depending on $\sin^2\theta$, becomes -0.21 Hz in 2,6-dinitrobenzaldehyde (24). In the latter substantial out-of-plane conformations occur. In $(CD_3)_2C{=}O$ solution, ^6J for the 1,2 isomer is given as $-0.051(3)$ Hz by the iterative analysis. If this were a reliable number and the low-energy pathway computed above were correct also in solution, therefore implying significant out-of-plane torsional amplitudes, then one would conclude that both the *ct* and *tt* conformers represent only parts, albeit the major parts, of the conformational distribution. However, the -0.05 Hz was *not* observed as a splitting and in solution the potentials hindering torsions of aldehyde groups are usually larger than given by STO 3G MO methods, so that countable nonplanar forms cannot be substantiated in this manner.

Large populations of the *cc* conformer might well be reflected by an observable $^5J(CHO,CHO)$ because the INDO MO FPT computations yield 0.18 Hz for this conformer and only 0.06 Hz for the *ct* form, while the *tt* form is calculated to have a coupling of -0.05 Hz. The data in Table 1 imply a vanishing coupling in the three solutions.

It appears that the long-range coupling constants in the 1,2 isomer yield conformational information additional to that obtained from dipole moments and ^{13}C nmr spectra. For the 1,3 isomer these couplings are less informative.

(ii) The 1,3 isomer

The computed energies for optimized geometries yield gas phase fractional populations at 300 K of 0.57, 0.25, and 0.18 for the planar *ct*, *tt*, and *cc* conformers, respectively. In Freon solution, estimated to have a dielectric constant of about 10 at the temperature of measurement (8), the ^{13}C nmr spectra yield 0.56, 0.26, and 0.18 for these populations.

There is only one $^5J(H, CHO)$ value for the 1,3 isomer and eqs. [4] and [5] hold. Taking ^5J_c as zero as before and ^5J_t as 0.771 Hz (the mean of the values for the 1,2 isomer and very near the 0.76 Hz for benzaldehyde) yields eq. [6]. That the populations of *ct* and *tt* are somewhat solvent dependent can be seem from the data in Table 2, where ^5J is 0.482(1), 0.496(1), and 0.438(1) Hz in CCl_4, C_6D_6, and $(CD_3)_2C{=}O$ solutions, respectively.

$$[5] \quad {}^5J = p_{ct}{}^5J_t/2 + p_{tt}{}^5J_t + p_{cc}{}^5J_c$$

$$[6] \quad {}^5J = 0.38_6\, p_{ct} + 0.771\, p_{tt}$$

From the dipole moment in benzene solution it was concluded only that $p_{ct} = 0.70$. If this number is correct, then p_{tt} follows as 0.29 from eq. [6], leaving p_{cc} effectively zero at 300 K. In dioxane solution the dipole moment is apparently in reasonable agreement with the STO 3G MO energies above and with those computed in ref. 6. Such a distribution yields 0.413 Hz for ^5J, not in agreement with any of the numbers in Table 3 but closest to the value of 0.438 Hz in $(CD_3)_2C{=}O$ solution. The *cc* conformer of high dipole moment may be favored in this polar solvent, yet contributes nothing to ^5J. Its increased population in this solvent may well be the cause of the smaller ^5J observed.

Some limits on the populations of the various conformers can be established on the basis of ^5J. Thus, from eq. [6], one has ^5J as 0.386 Hz for $p_{ct} = 1$, 0.771 Hz for $p_{tt} = 1$, and 0.00 Hz for $p_{cc} = 1$. Reproduction of 0.482 Hz, as measured in CCl_4 solution at 300 K, is successful for $p_{ct}/p_{tt}/p_{cc}$ values of 0.75:0.25:0.00, 0.70:0.275:0.025, 0.60:0.33:0.07, 0.50:0.39: 0.11, 0.40:0.42:0.18, and so forth. In other words, p_{ct} cannot be more than 0.75 and then only if p_{cc} vanishes. Similarly, for the $(CD_3)_2C{=}O$ solution, p_{ct} can be as large as 0.86 if p_{cc} vanishes. However, this situation is unlikely and it is probable, as stated above, that p_{cc} increases in this solution.

The chemistry of peptides related to metabolites of *Trichoderma* spp. 2. An improved method of characterization of peptides of 2-methylalanine[1]

I. M. SHAW AND A. TAYLOR[2]

National Research Council of Canada, Atlantic Research Laboratory, Halifax, N.S., Canada B3H 3Z1

Received February 19, 1985[3]

I. M. SHAW and A. TAYLOR. Can. J. Chem. **64**, 164 (1986).

4-Chlorobenzoylazide reacts with amino acid and peptide esters to give the 4-chlorobenzoyl derivatives in 60–90% yield, at room temperature, without measurable racemization. The reaction also proceeds smoothly with hindered amines such as methyl 2-methylalaninate and with secondary amines, e.g. methyl L-prolyl-L-valinate. Ten examples of the reaction are reported with peptides, synthesized for the purpose, that might be accessible from hydrolysates of the numerous fungal metabolites now known, which contain a high proportion of 2-methylalanine. The derivatives of di-, tri-, tetra-, and pentapeptides were highly crystalline, with sharp melting points, and could be detected and integrated in the effluent from chromatography columns at about the 10-ng level. This simple method of derivatization might be usefully applied to the resolution of discrepancies in the physical properties of ostensibly the same 2-methylalanyl peptide prepared in different laboratories.

I. M. SHAW et A. TAYLOR. Can. J. Chem. **64**, 164 (1986).

L'azoture du chloro-4 benzoyle réagit avec les esters d'acides aminés et de peptides, à la température ambiante, pour conduire aux dérivés chloro-4 benzoylés avec des rendements de 60 à 90% et sans racémisation mesurable. La réaction se produit aussi facilement avec des amines encombrées, comme le méthyl-2 alaninate de méthyle, et avec des amines secondaires, comme le L-prolyl-L-valinate de méthyle. On rapporte dix exemples de la réaction avec des peptides, synthétisés à cette fin, qui peuvent se retrouver dans les hydrolysats de plusieurs métabolites de champignons qui sont maintenant connus pour contenir une grande proportion de méthyl-2 alanine. Les dérivés des di-, tri-, tétra- et pentapeptides sont très cristallins, ils ont des points de fusion bien définis et ils peuvent être détectés et intégrés en chromatographie à des niveaux de 10 ng. Cette simple méthode de préparer un dérivé peut être appliquée utilement à la résolution des différences dans les propriétés physiques de peptides de la méthyl-2 alanine qui semblent les mêmes, mais qui ont été préparés dans des laboratoires différents.

[Traduit par le journal]

In 1952 C. T. Calam and A. D. Ainley, working in the laboratories of the Dyestuffs Division of Imperial Chemical Industries, isolated a trypanocidal group of metabolites from a culture of a *Paecilomyces* sp.[4] The toxicity of the material led to its being abandoned as a therapeutic agent and further investigation of its chemistry was undertaken by Kenner and his colleagues. Kenner's work (2–4) on M13959 (= trypanocidin[4]) showed that its hydrolysis provided a number of unknown amino acids but that, among known compounds, there was a high proportion of 2-methylalanine. Since this work was published a large number of other fungal metabolites, which on acid hydrolysis provide 2-methylalanine in high yield, have been discovered. A list of these materials is given in Table 1 and it will be seen that a wide range of fungal genera are represented therein. In addition to the metabolites given in Table 1, stilbellin (8), elvapeptin (9), lilacinin (10), and CC1014 (1) may also belong to this group. The proportion of 2-methylalanine isolated from these materials is given in Table 2 and if (as is likely) the amino acid moieties are linked as peptides, then either the 2-methylalanine residues form an abnormal continuous segment or they are to be found in more or less alternate fashion. The resistance of these compounds to peptidases suggests that the latter supposition is true and this has found considerable support from fast atom bombardment (FAB) mass spectroscopy of some of the mixed natural products.

It has been shown that the zervamicins (Table 2 and ref. 11), the suzukacillins (6), and the alamethicins (12) are very complex mixtures and that the proportions of the individual components of the mixture depend on the conditions of growth of the producing fungus. These facts and the worldwide interest in the physiological properties of these materials have led to extraordinary synthetic efforts to obtain a single entity by synthesis (13–17). The results of these efforts in the alamethicin field have been symmarized by Schmidt and Jung (16), who show that the measurements of the physical properties of the synthetic products by the different groups fall outside normally accepted ranges of error. The structures of many of the intermediates in the syntheses have been established by detailed assignment of ^1H and ^{13}C nmr spectra (see e.g., ref. 18), by elemental analysis, and, in some cases, by X-ray crystallographic studies. However, the structures of several other intermediates are open to doubt. Seven examples are given in Table 3; these compounds have been synthesized by two or more groups of workers and there are few examples of duplicated experimental results lying within the normally accepted range of error (included in Table 3 are two examples where the results from different workers are in agreement). An explanation for the discrepancies in Table 3 may be the known abnormal behaviour of 2-methylalanyl peptides under various reaction conditions, including those commonly used in peptide synthesis (19–21). Whatever the explanation, it is clear that better methods of characterizing these peptides, either obtained by degradation of natural products or by synthesis, are required. We have attempted during the past decade to devise improvements in the characterization of these materials; some progress has been made and is reported in this and a following paper.

[3]Revision received August 26, 1985.

[4]We are indebted to Dr. W. B. Turner for a sample of M13959 and for the communication from our colleagues in the Laboratories of Imperial Chemical Industries of the decision to call this material "trypanocidin." In view of the fact (see Table 1) that two completely different groups of mould metabolites are now called "leucinostatin" it might be useful to reserve this term for the material described by Arai and his colleagues (48) and to call leucinostatin = M13959 = P168 = A20688 = 1907, metabolites of *Paecilomyces lilacinus*, trypanocidins. This would avoid confusion and would honour traditional prerogatives.

[a]An asterisk (*) indicates that X-ray crystallographic data can be obtained from the reference.
[b]The physical properties of efrapeptin(s) were kindly sent to us by Dr. R. L. Hamill, Lilly Research Laboratories, before publication.

In our hands peptides containing 2-methylalanine residues are easily and quantitatively esterified by treatment of the peptide, in solution in tetrahydrofuran (THF) containing 1% water, with ethereal diazomethane. We therefore sought an N-terminal group that, to serve our purpose, would have most of the following characteristics. It should enhance the ease of crystallization of the peptide and should confer absorption in the ultraviolet. Additionally, it should introduce an element not normally found in peptides, e.g. Cl, Br, or P, and which for mass spectroscopic reasons, discussed in a following paper, should exist as two or more stable isotopes whose natural abundance is known with high precision. Finally, the derivative should be formed under very mild conditions with minimum racemization of the terminal amino acid residue, but when formed should be sufficiently stable to withstand vigorous reaction conditions such as those encountered in the permethylation reaction (22).

It has been found that *N*-4-chlorobenzoyl derivatives satisfy many of the criteria given in the previous paragraph. Advocation of the use of this N-terminal group is not new (23), but we have found that such derivatives can be made at room temperature in THF by reaction of the peptide methyl esters with

Abbreviations used: Aib = 2-methylalanine; Iva = 2-amino-2-methylbutyric acid; Gly = glycine; Ala = alanine; Val = valine; Leu = leucine; Ileu = 2-amino-3-methylvaleric acid; Phe = phenylalanine; Pro = proline; 3-OHpro = 3-hydroxyproline; 3-Mepro = 3-methylproline; Glu = glutamic acid; Gln = glutamine. Unless stated otherwise all asymmetric centers are assumed to be L.

4-chlorobenzoylazide. As reported in the literature (24), this compound is a relatively stable crystalline solid and an improved preparation is given in the experimental section. It melts without decomposition at 42°C and shows no sign of decomposition at 80°C. We have kept 10-g samples at −15°C (it is volatile) for 2–3 years without measurable change in the melting point. The reaction of this reagent with a number of peptides is summarized in Table 4. The choice of peptides was dictated by their potential formation during degradation of the metabolites listed in Table 1. Thus proline is the N-terminus of most of these examples, because of the several methods available of preferential hydrolysis at proline peptide bonds (25–27). Details of the syntheses of the parent peptides are given in the experimental section; they usually followed the methods previously reported (28) and are summarized in Fig. 1. Whilst it is obvious that the compounds in Table 4 could be prepared by shorter and more simple routes than shown in Fig. 1, the object of the work was to use common preparative reactions in peptide chemistry to secure crystalline products and then to determine if analysis of the *N*-4-chlorobenzoyl derivatives would reveal the presence of unexpected impurities.

Figure 2 shows a chromatogram of the compounds in Table 4 on a commercially available reversed phase partition chromatography column; all components can be distinguished. The yields obtained in the chlorobenzoylation reaction are given in Table 4, and were calculated for analytically pure material without corrections for losses due to recrystallization, etc. Crude yields, i.e. material after removal of excess 4-chlorobenzoylazide and acidic and basic impurities, lay in the range of 65–90%. Mass spectroscopic evidence was obtained for the presence of hydrazine derivatives of the type $ClC_6H_4CO{\cdot}NH{\cdot}NR_2$ (where R_2 is the peptide chain) among the basic impurities, thus accounting, in part, for the low yields. A further possibility, that the low yields were due to reacemization of the N-terminal residue, was investigated by studying the reaction of the azide with the diastereoisomeric pair, methyl *N*-4-chlorobenzoyl-L(and D)-alanyl-2-methylalanyl-L-alaninates. The optical rotations of the intermediates made during the syntheses of these diastereoisomers are given in Table 5. Their separation by partition chromatography was difficult, but a partial separation (Fig. 3) was achieved and the conditions given in Fig. 3 were critical in the sense that very small changes led to apparently identical partition coefficients. About 40 ng of the D-alanine derivative was detected and integrated in the presence of about 0.4 μg of the L-alanine isomer. Similarly, about 70 ng of the latter was detected and integrated in the presence of 0.4 μg of the D-alanine isomer. Quantities in the range 10–15 ng were detected, but the peaks were not integrated, or the integration error was very great, due to incomplete separation. A linear least-mean-squares fit of all the data (weight of compound in ng vs. integrated area) gave a line of index of fit (= r^2) of 0.989 with a standard error of estimation of ±27 ng. Hence one can reliably estimate about 7% of one diastereoisomer in a mixture. When the analysis was carried out on the crude reaction products of 4-chlorobenzoylazide and methyl (L(or D)-alanyl-2-methylalanyl-

[a]R = 4-chlorobenzoyl, other abbreviations as in Table 2. Ciphers written below glutamic acid residues are γ-esters.
[b]Molecular weights calculated for the ^{35}Cl isotope.
[c]R_v = retention volume, i.e. time of elution × flow rate.

L-alaninate, only one isomer was detected (either L or D according to the starting material) and hence the extent of racemization was less than 7% in either case.

In agreement with other workers (29), we were unable to obtain satisfactory elemental analyses for crystalline methyl L-alanyl-2-methylalanyl-L-alaninate, possibly because of its deliquescent nature and (or) the presence of dioxopiperazines (19) formed during hydrogenolysis of its carbobenzyloxy derivative. However, methyl *N*-4-chlorobenzoyl-L-alanyl-2-methylalanyl-L-alaninate could be fully characterized (see experimental section and Fig. 2). In addition, the basic tripeptide methyl ester could be converted into the pentapeptide derivative (**1**), which also provided elemental analyses within acceptable error, though only one of the two proline conformers was detected in its ^{13}C nmr spectrum (30). An X-ray crystallographic structure determination (31) of this pentapeptide (**1**) established its structure and conformation and in particular the N-terminal acylproline residue.

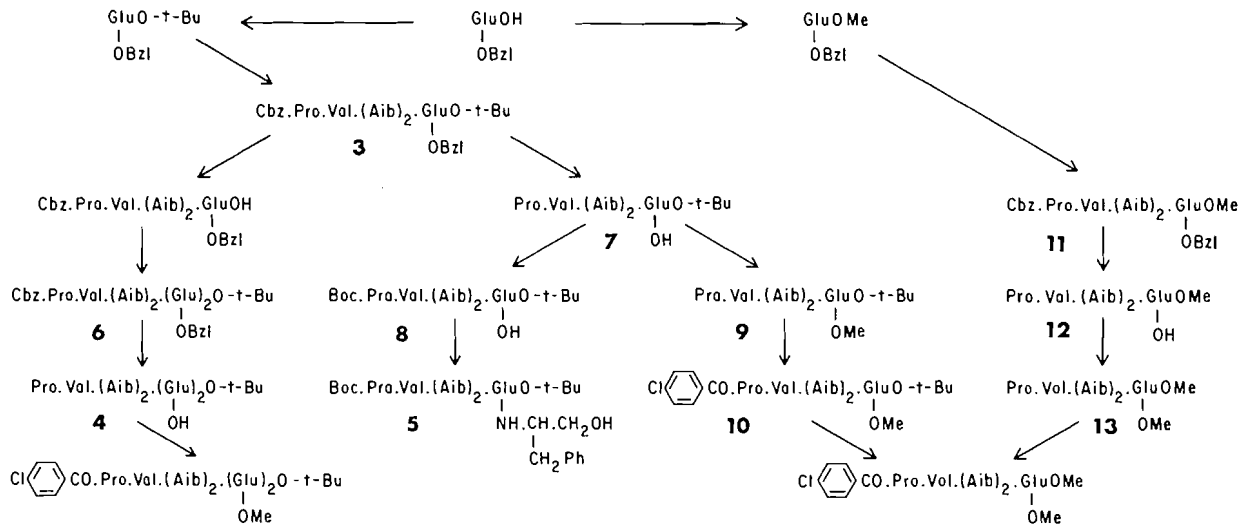

FIG. 1. Synthetic steps reported in the preparation of penta- and hexapeptides of 2-methylalanine. Abbreviations are the same as those defined in Tables 2, 4, and 5.

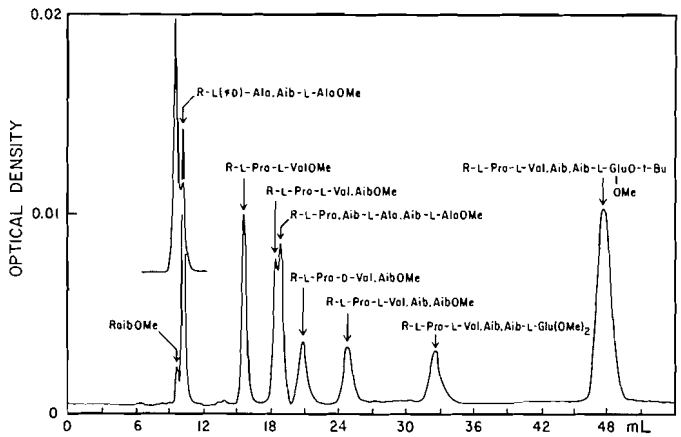

FIG. 2. Reversed phase partition chromatogram of the 4-chlorobenzoyl peptides found in Table 4. The column was a Dupont C_8 "Zorbax" 6 μm of dimensions 0.46 × 25 cm, of dead volume ca. 3 mL, and the solvent was 46% ammonium acetate buffer (0.01 *M*, pH 4.2) in methyl alcohol. The column was run at 22°C and the flow rate was 1.5 mL min^{-1}.

These encouraging results led us to investigate the elaboration of the tetrapeptide (**2**, R′ = H), the preparation of which on the 100-g scale has been reported (28), into the various structures postulated for the C-terminal moieties thought to be present in many of the natural products listed in Table 1. The reactions investigated are summarized in Fig. 1. Condensation of the tetrapeptide (**2**, R′ = H) with glutamyl diesters (α,γ-dimethyl; α-methyl-γ-benzyl; α-*tert*-butyl-γ-benzyl) gave reproducible yields on the 10-g scale in the range 50–60%, and conversion of these products to the *N*-4-chlorobenzoyl dimethyl ester derivative gave crystalline material in all cases. However, partition chromatography of the 3 products showed them to be mixtures of 4 components eluted at 29, 49, 61, and 72 mL. The 2 components of higher R_f were not detected after one recrystallization; the proportions of the 2 components of lower R_f depended on the nature of the glutamyl diester used in the condensation reaction and were (in the order given above) 100:100, 100:44, 100:10. It was possible in the 2 latter cases to purify the major component to the point where it represented

TABLE 5. Specific optical rotations of intermediates in the syntheses of methyl 4-chlorobenzoyl-L (and D)-alanyl-2-methylalanyl-L-alaninates

>99% of the mixture. The material from the 2 preparations shown in Fig. 1 had closely similar melting points, mass spectra, optical rotations, and ^1H and ^{13}C nmr spectra. However, the X-ray diffraction patterns of the crystals from different preparations were not always identical and the crystals were, physically, insufficiently stable for data collection. Like the 4-chlorobenzoylpentapeptide (**1**), only one acylproline conformer was detected in the ^{13}C nmr spectrum.

As shown in Fig. 1, the pentapeptide derivative (**3**) was converted into the crystalline *tert*-butyl ester (**4**). Correct elemental analytical data were obtained for this compound and many of the chemical shifts and C—H couplings in its ^{13}C nmr spectrum could be assigned (see experimental section). It was treated with diazomethane and the gummy product with 4-chlorobenzoylazide, but we were unable to induce the 4-chlorobenzoyl derivative to crystallize. It was obtained as a

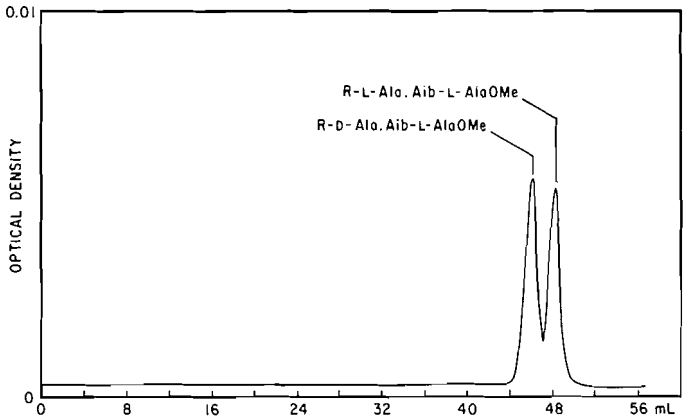

FIG. 3. Separation of methyl 4-chlorobenzoyl-L(and D)-alanyl-2-methylalanyl-L-alaninates. The column was the same as that used for the separations in Fig. 2, the solvent 62% ammonium acetate buffer (pH 4.2) in methyl alcohol, the flow rate 2 mL min^{-1}, and the separation was run at 22 ± 0.2°C. The peptides (0.2 μg of each) were applied to the column in 0.1 μL of methyl alcohol. The standard deviations of the retention volumes were 1.5 mL, $n = 11$, in the case of the L isomer and 1.4 mL, $n = 11$ for the D.

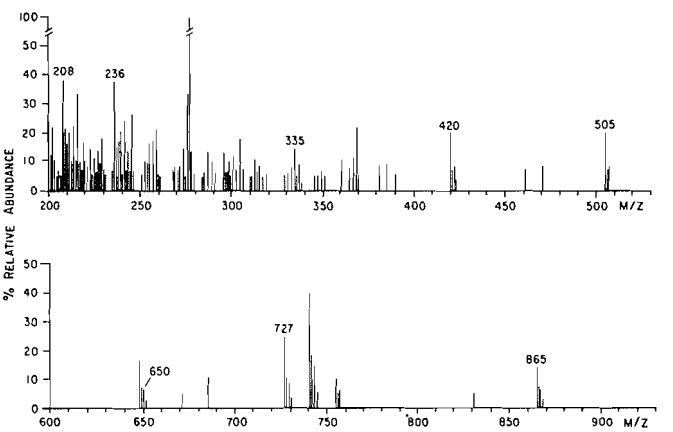

FIG. 4. Fast atom bombardment mass spectrum of ? di-γ-methyl α-*tert*-butyl *N*-4′-chlorobenzoyl-L-prolyl-L-valyl-2-methylalanyl-2-methylalanyl-L-glutamyl-L-glutamate.

colorless amorphous solid that, however, gave a FAB mass spectrum (Fig. 4) in complete accord with its supposed structure. The crystalline L-phenylalaninolhexapeptide (**5**) was also obtained, and much of its ^{13}C nmr spectrum assigned (see experimental section), but we were unable to convert it into a crystalline *N*-4-chlorobenzoyl derivative.

Experimental

Melting points are corrected, and infrared spectra were measured on a Perkin–Elmer 283 spectrometer. Ultraviolet spectra and optical rotations were determined on solutions of peptides in methyl alcohol on a Cary 14 spectrometer and a Rudolph polarimeter, respectively. The greatest error in optical rotation measurements was ±2%. The ^1H nmr spectra were obtained on a Varian 220-MHz instrument at the Canadian NMR Center at Toronto University Medical School; ^{13}C nmr data were collected on a Varian XL-100 instrument except those marked *, which were recorded on a Nicolet 360 NB spectrometer of the Atlantic Region Magnetic Resonance Center, Halifax, Nova Scotia. All nmr data are presented in the format used by Shaw and Taylor (28); all chemical shifts are reported in ppm downfield from the signal of Me_4Si. The equipment used for high pressure liquid chromatography has been described in detail (32); analytical chromatography was performed on Dupont C_8 "Zorbax" 6-μm columns of dimensions 0.46 × 25 cm; two Waters μBondapak C_{18} columns (0.78 × 30 cm) in series were used for preparative chromatography. The solvent used in all cases was methyl alcohol mixed with ammonium acetate buffer (0.01 *M*, pH 4.2, water of resistance >10 Mohms), the composition of the mixture being controlled by a solvent programming device (Waters Model No. 660). Mass spectra were measured on Kratos MS-50 and Dupont 21-110B instruments. Full experimental details of mass spectroscopic measurements are given in a following paper.

4-Chlorobenzoylazide

4-Chlorobenzoyl hydrazide (33) (10 g) was dissolved in acetic acid (150 mL) and the solution treated with hydrochloric acid (2 *N*, 250 mL). Light petroleum (bp 30–60°C, 400 mL) was added and the stirred mixture cooled to <5°C, when a solution (40 mL) of sodium nitrite (4.4 g) in water was added below the surface of the liquid. After 30 min at 5°C, the colorless precipitate had dissolved, the petroleum layer was separated, the aqueous raffinate extracted with light petroleum, and the dried (Na_2SO_4) combined extracts evaporated at 10°C/30 Torr (1 Torr = 133.3 Pa) to 100 mL. The mixture was kept at −15°C for 18 h, when the colorless crystals, mp 42°C, 8.3 g, 80%, were collected on a filter precooled to −15°C. This material was stored at −15°C in a screw-capped bottle kept inside a wide-mouth screw-capped jar that contained calcium chloride.

Methyl N-4-chlorobenzoyl-2-methylalaninate

Methyl 2-methylalaninate (0.5 g) (28) was dissolved in tetrahydrofuran (THF, 10 mL) and the solution treated with 4-chlorobenzoylazide (1 g). After 3 days at room temperature, the reaction solution was evaporated and the residue digested 3 times with light petroleum, the digest being decanted from the sticky residue each time. The final crystalline residue was collected (0.75 g, mp 115–125°C, 69%) and recrystallized from *n*-butyl acetate as plates, mp 134°C (subliming >115°C), 0.69 g, 63%. *Anal.* calcd. for $C_{12}H_{14}ClNO_3$: C 56.4, H 5.5, Cl 13.9, N 5.5%; found: C 56.3, H 5.5, Cl 14.1, N 4.6%.

N-Phenylmethoxycarbonyl-L-prolyl-2-methylalanine

N-Phenylmethoxycarbonyl-L-proline (34) (64.6 g), methyl 2-methylalaninate (30.5 g), and 1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 64 g) were dissolved in toluene (1.75 L) and the solution stirred at 55°C for 72 h. The toluene was evaporated, the residue dissolved in ethyl acetate (0.9 L), and the solution washed with dilute sodium bicarbonate (2%, 500 mL), dilute hydrochloric acid (2 *N*, 500 mL), and water. The dry (Na_2SO_4) solution was filtered and evaporated, the residue (100 g) dissolved in methyl alcohol (1 L), and the solution treated with sodium hydroxide (*N*, 416 mL) at 0°C. The reaction mixture was kept at room temperature and aliquots (5 mL) titrated with standard acid to determine when the reaction was complete. The solution was then evaporated to half volume, diluted with water (250 mL), extracted with ethyl acetate, and the raffinate acidified. The precipitated oil was taken up in ethyl acetate (500 mL), and the solution dried (Na_2SO_4), filtered, and evaporated. The residual oil usually crystallized spontaneously but crystallization can be induced by seeding. *N-Phenylmethoxycarbonyl-L-prolyl-2-methylalanine* (52 g, 60%) separated from tetrahydropyran as prisms, mp 137°C, $[\alpha]_D^{23}$ −65° (*c* 2, MeOH), δ_C ($C^2H_3O^2H$): 177.4; 174.0, 173.9; 156.5, 156.3; 137.8; 129.3; 128.9; 128.7; 68.0; 61.2; 61.0; 56.9; 48.3, 48.1; 32.1, 30.9; 25.6; 24.8; 25.1, 24.4. *Anal.* calcd. for $C_{17}H_{22}N_2O_5$: C 61.1, H 6.6, N 8.4, O 23.9%; found: C 61.2, H 6.7, N 8.4, O 24.1%.

Methyl 4-chlorobenzoyl-L-alanyl-2-methylalanyl-L-alaninate

N-Phenylmethoxycarbonyl-L-alanyl-2-methylalanine (77 g) (35) was suspended in toluene (500 mL), and freshly distilled methyl L-alaninate (26 g) and EEDQ (83 g) were added. The reaction mixture became a viscous paste and required a stirrer with adequate torque to keep it in suspension. The reaction mixture was heated to 45°C and was stirred for 42 h, after which the crystalline precipitate (83 g, 84%, mp 158–162°C) was collected. *Methyl N-phenylmethoxycarbonyl-L-alanyl-2-methylalanyl-L-alaninate* separated from tetrahydrofuran –

isopropyl ether (1:1) as needles, mp 164–165°C; $[\alpha]_D^{24}$ −35° (*c* 2, MeOH). *Anal.* calcd. for $C_{19}H_{27}N_3O_6$: C 58.0, H 6.9, N 10.7, O 24.4%; found: C 58.05, H 6.65, N 10.75, O 24.5%. The crude ester (77 g) was suspended in methyl alcohol (0.6 L), palladium on carbon (5%, 5 g) added, and the mixture agitated with hydrogen at 18°C and 70 atm (1 atm = 101.3 kPa). After 48 h, the reaction mixture was filtered through a bed of Celite, the filtrate evaporated at 40°C/12 Torr, and the residual oily solid stirred with ethyl acetate (0.5 L). The crystalline precipitate (44 g, 83%, mp 140–147°C, δ_C: 176.2; 174.8; 171.2; 57.7; 52.8 ($^1J_{CH_3}$ 147 Hz); 50.9 ($^1J_{CH}$ 145 Hz, $^2J_{CH_3}$ 4 Hz); 49.7 ($^1J_{CH}$ 139 Hz, $^2J_{CH_3}$ 5 Hz); 25.7 ($^1J_{CH_3}$ 129 Hz, $^3J_{CH_3}$ 4.5 Hz); 24.8 ($^1J_{CH_3}$ 127 Hz, $^3J_{CH_3}$ ~ 3 Hz); 17.8 ($^1J_{CH_3}$ 130 Hz, $^2J_{CH}$ ~ 1 Hz); 17.2 ($^1J_{CH_3}$ 130 Hz, $^2J_{CH}$ 5 Hz)) was collected. This ester was deliquescent and we were unable to obtain a satisfactory elemental analysis; it (0.5 g) was suspended in THF (15 mL) and the stirred suspension treated with 4-chlorobenzoylazide (0.37 g), when the precipitate gradually dissolved during 24 h. The reaction mixture was filtered through a bed of Celite 535 and the filtrate evaporated. The residue was digested with light petroleum, and the insoluble residue recrystallized from *n*-butyl acetate as needles, mp 190°C. *Anal.* calcd. for $C_{18}H_{24}ClN_3O_5$: C 54.3, H 6.1, Cl 8.9, N 10.6%; found: C 54.3, H 6.1, Cl 9.1, N 10.4%.

Methyl N-*4-chlorobenzoyl-*D*-alanyl-2-methylalanyl-*L*-alaninate*

Phenylmethoxycarbonyl-D-alanine (36) (5.6 g), methyl 2-methylalaninate (2.9 g), EEDQ (6.2 g), and toluene (100 mL) were stirred together at room temperature for 5 days. The reaction solution was evaporated, the residue dissolved in ethyl acetate (250 mL), and the solution washed successively with hydrochloric acid (*N*, ×2), water, sodium bicarbonate solution (2%, ×2), and finally water. The dry (Na_2SO_4) ethyl acetate solution was evaporated and the residual gum (7.3 g) dissolved in methyl alcohol (80 mL) and sodium hydroxide solution (10%, 20 mL). After 2 h at room temperature the solution was concentrated to 20 mL, acidified, and the precipitate collected (6.45 g, mp 168–170°C). N-*Phenylmethoxycarbonyl-*D*-alanyl-2-methylalanine* separated from ethyl acetate as prisms, mp 171–172°C, (*Anal.* calcd. for $C_{15}H_{20}N_2O_5$: C 58.4, H 6.5, N 9.1%; found: C 58.4, H 6.5, N 9.1%.) This acid (3.08 g) was suspended in toluene (70 mL), methyl L-alaninate (1.05 g) added, and then EEDQ (2.5 g). The mixture was stirred at 44°C for 72 h, when the solution was evaporated, the residue taken up in ethyl acetate (250 mL), and the acidic and basic by-products removed as usual. The dry (Na_2SO_4), filtered ethyl acetate solution was evaporated and the crystalline residue (mp 127°C, 3.32 g) collected. This protected tripeptide (3 g) in methyl alcohol (50 mL) was shaken with hydrogen (3.5 kg cm^{-2}) and palladium on carbon (5%, 0.2 g) for 18 h. The reaction mixture was filtered through a bed of Celite 535, the filtrate evaporated, the residue (1.8 g, mp 226–228°C) in THF (50 mL) treated with 4-chlorobenzoylazide (1.5 g), and the mixture stirred at room temperature for 48 h. The reaction mixture was filtered, the filtrate evaporated, and the residual gum taken up in ethyl acetate (25 mL). The solution was washed with dilute hydrochloric acid (*N*, 2 × 10 mL), water, sodium bicarbonate solution (2%, 2 × 10 mL), then dried, filtered, and evaporated. The resulting gum spontaneously crystallized after standing on the bench for 6 months (crystals are available for those in need). *Methyl* N-*4-chlorobenzoyl-*D*-alanyl-2-methylalanyl-*L*-alaninate* separated from *n*-butyl acetate as rectangular plates, mp 160°C, 2.1 g (*Anal.* found: C 54.5, H 6.1, Cl 8.45, N 10.7%).

Methyl N-*(4-chlorobenzoyl)-*L*-prolyl-2-methylalanyl-*L*-alanyl-2-methylalanyl-*L*-alaninate*

N-Phenylmethoxycarbonyl-L-prolyl-2-methylalanine (15.7 g), methyl L-alanyl-2-methylalanyl-L-alaninate (12.95 g), and EEDQ (13 g) in tetrahydrofuran (THF, 0.5 L) were stirred together at 20°C for 72 h, when all the insoluble tripeptide had dissolved. The solution was evaporated and the residue dissolved in a mixture of ethyl acetate (0.7 L) and hydrochloric acid (*N*, 250 mL). The ethyl acetate phase was washed successively with hydrochloric acid (*N*, 250 mL), sodium bicarbonate solution (2%, 250 mL), and water (100 mL). The ethyl acetate solution was dried (Na_2SO_4), filtered, evaporated, and the crystalline residue (10.5 g, 39%, mp 178–179°C) taken up in hot *n*-butyl acetate (100 mL). The N-*phenylmethoxycarbonylpentapeptide* (**2**, R = C_7H_7O, R′ = Me) separated from *n*-butyl acetate as prisms, mp 180°C (blue in transmitted light just prior to melting); $[\alpha]_D^{22}$ −53° (*c* 1, MeOH). *Anal.* calcd. for $C_{28}H_{41}N_5O_8$: C 58.4, H 7.2, N 12.2, O 22.2%; found: C 58.3, H 7.3, N 12.2, O 22.3%. This ester (7.7 g) was dissolved in methyl alcohol (100 mL), palladium on carbon (5%, 0.5 g) added, and the mixture shaken with hydrogen at 3.5 kg cm^{-2} for 24 h, at which time the mixture was filtered through a pad of Celite and the filtrate evaporated. The residue was taken up in the minimum volume of hot THF, cooled, kept at 4°C for 18 h, and the crystalline precipitate (5.3 g, mp 157°C, 90%) collected. The *base* (pK_a 7.6) separated from tetrahydropyran as prisms, mp 157–159°C; $[\alpha]_D^{25}$ −81° (*c* 0.59, $CHCl_3$). *Anal.* calcd. for $C_{20}H_{35}N_5O_6$: C 54.4, H 7.9, N 15.9%; found: C 54.3, H 8.0, N 15.7%. This base (4.4 g) was stirred with THF (50 mL) and the mixture treated at 20°C with a solution of 4-chlorobenzoylazide (1.9 g) in THF (34 mL). The mixture was stirred for 24 h, when a clear solution was obtained, and after a further 24 h the solution was evaporated and the residue digested with petroleum ether (3 × 50 mL). The residue was taken up in ethyl acetate (250 mL) and the solution washed successively with hydrochloric acid (2*N*, 3 × 100 mL), water (100 mL), sodium bicarbonate solution (2%, 100 mL), and water (100 mL). The ethyl acetate solution was dried (Na_2SO_4), filtered, and evaporated and, to prepare a crystal for X-ray crystallography, the crystalline residue (3.7 g, 64%, mp 193–194°C) was taken up in hot *n*-butyl acetate (50 mL). The flask containing the hot (100°C) solution was placed in a water bath (capacity 12 L) at 55°C for 4 h, when the bath heater was switched off and it and the butyl acetate solution allowed to cool overnight. *Methyl* N-*(4′-chlorobenzoyl)-*L*-prolyl-2-methylalanyl-*L*-alanyl-2-methylalanyl-*L*-alaninate* (31) (**1**) separated from *n*-butyl acetate, mp 194°C; $[\alpha]_D^{24}$ −40° (*c* 1, $CHCl_3$); δ_C ($C^2H_3O^2H$): 177.0; 176.9; 174.7 (2C, resolved in $C_6{}^2H_6$–$C^2H_3O^2H$, 1:1), 174.25; 170.7; 137.75; 135.7; 130.1 (2C); 129.7 (2C); 62.8 (J_{CH} 146 Hz); 57.9; 57.6 (2C); 52.6 (J_{CH_3} 148 Hz); 51.8; 51.6 (J_{CH} 144 Hz, $^2J_{CH}$ 5 Hz); 49.7 (J_{CH} 142 Hz, $^2J_{CH}$ ~ 5 Hz); 30.5 (J_{CH_2} 135 Hz; 27.2; 26.55; 26.35; 24.5; 24.2; 17.4 (J_{CH_3} 129 Hz, $^2J_{CH}$ 5 Hz); 16.55 (J_{CH_3} 128 Hz, $^2J_{CH}$ 5 Hz). *Anal.* calcd. for $C_{27}H_{38}ClN_5O_7$: C 55.9, H 6.6, Cl 6.1, N 12.1, O 19.3%; found: C 56.1, H 6.6, Cl 6.0, N 12.0, O 19.4%.

*Methyl 4-chlorobenzoyl-*L*-prolyl-*L*-valinate*

L-Prolyl-L-valine (Sigma, 0.2 g) was suspended in THF (25 mL) and the stirred suspension treated with a solution (10 mL) of diazomethane (50 mg) in diethyl ether. After 18 h at room temperature a clear pale yellow solution was obtained. The solution was concentrated to 20 mL to remove ether and excess diazomethane and the concentrate was treated with 4-chlorobenzoylazide (0.18 g) in THF (10 mL). The solution was kept at room temperature for 24 h and was then filtered and evaporated. The residue was digested with light petroleum (bp 30–60°C, 3 × 20 mL) and the insoluble crystalline product recrystallized from cyclohexane as rosettes of very fine needles, mp 124–127°C. *Anal.* calcd. for $C_{18}H_{23}ClN_2O_4$: C 58.9, H 6.3, Cl 9.7, N 7.6%; found: C 58.6, H 6.4, Cl 9.8, N 7.6%.

Methyl N-*4-chlorobenzoyl-*L*-prolyl-*L*(and* D*)-valyl-2-methylalaninates*

These two compounds were prepared in exactly the same way and on the same scale as described for methyl *N*-4-chlorobenzoyl-L-prolyl-L-valinate, starting with L-prolyl-L(and D)-valyl-2-methylalanines (28). *Methyl* N-*4-chlorobenzoyl-*L*-prolyl-*L*-valyl-2-methylalaninate* separated from THF – isopropyl ether (1:1.5) as needles, mp 168°C. *Anal.* calcd. for $C_{22}H_{30}ClN_3O_5$: C 58.5, H 6.7, Cl 7.8, N 9.3%; found: C 58.4, H 6.7, Cl 7.8 N 9.3%. Its D-*valine isomer* separated from ethyl acetate as prisms, mp 171–172°C. *Anal.* found: C 58.5, H 6.5, Cl 7.9, N 9.6%.

*γ-Benzyl α-*tert*-butyl* N-*phenylmethoxycarbonyl-*L*-prolyl-*L*-valyl-2-methylalanyl-2-methylalanyl-*L*-glutamate*

γ-Benzyl L-glutamic acid (37) (30 g) suspended in dioxan (dried over Linde 4A molecular sieve, 60 mL) was cooled to −40°C, treated

with concentrated sulphuric acid (9 mL), and then with isobutylene (40 mL). The mixture was shaken in a glass pressure vessel at 20°C for 4 days, after which the pressure was released, ethyl acetate (200 mL) added, and the solution washed with sodium bicarbonate solution (5%, 3 × 100 mL). The bicarbonate washings were extracted with ethyl acetate (100 mL) and the combined organic phases washed with water, dried, and evaporated. The residue was taken up in ether and the theoretical quantity of hydrogen chloride in ether added at −10°C. The hydrochloride (23 g, mp 107–109°C; $[\alpha]_D^{22}$ +15° (*c* 2, MeOH)) was collected after storage at −15°C for 48 h. This hydrochloride (6.6 g) was suspended in toluene (200 mL), and the mixture treated with triethylamine (2.02 g) and shaken at 20°C for 15 min. *N*-Phenylmethoxycarbonyl-L-prolyl-L-valyl-2-methylalanyl-2-methylalanine (28) (**2**, R = C_7H_7O, R′ = H, 10.4 g) was added and, when it had dissolved, EEDQ (5.06 g). The mixture was stirred at 50°C for 72 h, when it was evaporated to ca. 50 mL, ethyl acetate (0.5 L) added, and the solution washed with citric acid (2*N*, 3 × 100 mL), brine (2%, 100 mL), sodium bicarbonate solution (2%, 2 × 150 mL), and finally water. The solution was dried (Na_2SO_4), filtered, and evaporated. The residue was taken up in THF (50 mL) and isopropyl ether (50 mL) added when the product (9.1 g, 57%, mp 160°C) separated. The N-*phenylmethoxycarbonylpentapeptide diester* (**3**) separated from ethyl acetate as needles, mp 165–166°C; $[\alpha]_D^{22}$ −58° (*c* 2, MeOH); δ_H (C^2HCl_3): 7.37 (5H), 7.34 (H, e), 7.34 (5H), 7.07 (H, e, J = 6 Hz), 6.83 (H, e), 6.75 (H, e), 5.31, 5.13 (2H, q, J = 13.3 Hz), 5.11 (2H), 4.41 (2H, m), 3.80 (H, t, J = 6 Hz), 3.54 (2H, t, J = 7 Hz), 2.57 (2H, m), 2.14 (5H, m), 1.93 (2H, m), 1.54 (3H), 1.48 (3H), 1.45 (15H), 0.88 (3H, d, J = 7 Hz), 0.83 (3H, d, J = 7 Hz); δ_C ($C^2H_3O^2H$): 177.2; 175.5 (bs); 175.2, 174.9, 174.4; 173.4; 172.4; 156.8, 156.2; 137.9 (bs); 137.5; 129.4; 129.0; 128.7; 82.4; 68.1; 67.0; 61.3; 60.3; 60.6; 57.7; 54.0; 48.4; 32.8; 31.5; 31.8; 31.0; 28.3; 27.7; 27.4; 26.7; 23.8; 19.6; 19.5; 19.2. *Anal.* calcd. for $C_{42}H_{59}N_5O_{10}$: C 63.5, H 7.5, N 8.8, O 20.2%; found: C 63.5, H 7.5, N 8.8, O 20.3%.

α-tert-*Butyl* L-*prolyl*-L-*valyl*-2-*methylalanyl*-2-*methylalanyl*-L-*glutamyl*-L-*glutamate*

The fully protected pentapeptide (**3**, 3 g) in deuteriochloroform (15 mL) was treated with a solution (30 mL) of trifluoroacetic acid (15 mL) in deuteriochloroform. The course of the reaction was determined by taking the ^1H nmr spectra of aliquots. After ca. 1.5 h there was no further decrease in intensity of the signal at δ_H 1.45. The reaction mixture was evaporated, the residue treated with diisopropyl ether, the amorphous solid collected, and the *acid* (2.7 g, $[\alpha]_D^{22}$ −58° (*c* 1.5, MeOH), δ_H (C^2HCl_3): 7.73 (H), 7.51 (H), 7.32 (5H), 7.30 (5H), 7.30 (H, e), 7.00 (H), 5.14 (2H), 5.08 (2H), 4.27 (2H, m), 3.81 (H, m), 3.55 (2H, m), 2.56 (2H, m), 2.00 (7H, bm), 1.46 (6H), 1.42 (6H), 0.82 (3H, d, $^3J_{HH}$ 6.5 Hz), 0.79 (3H, d, $^3J_{HH}$ 6.5 Hz). *Anal.* calcd. for $C_{38}H_{51}N_5O_{10}\cdot H_2O$: C 60.4, H 7.1, N 9.3 O 23.3%; found: C 60.4, H 7.1, N 9.3; O 23.1%, precipitated from dioxan solution (5 mL) with diisopropyl ether (50 mL). This acid (7 g), EEDQ (2.6 g), α-*tert*-butyl-γ-benzyl L-glutamate (from 3 g of hydrochloride, see above), and toluene (500 mL) were stirred together at room temperature for 72 h. The reaction mixture was evaporated, the residue taken up in ethyl acetate (500 mL), and acidic and basic by-products removed as described. The residue (= A, 35 mg) obtained after evaporation of the dry (Na_2SO_4) extract was purified by high pressure liquid chromatography, using methyl alcohol – ammonium acetate buffer (pH 4.2) 4:1. The main band eluting at ca. 48 mL was collected, the solution evaporated, and the residue taken up in *tert*-butyl alcohol. Lyophilization of the solution gave the N-*phenylmethoxycarbonylhexapeptide* (**6**) as a colorless solid, mp 50–55°C; $[\alpha]_D^{22}$ −43° (*c* 0.6, MeOH), δ_H (C^2HCl_3): 7.63 (H, e, d, $^3J_{HH}$ 8 Hz), 7.59 (H, e, d, $^3J_{HH}$ 8 Hz), 7.36 (5H), 7.34 (5H), 7.31 (5H), 7.05 (H, e), 6.95 (H, e), 6.46 (H, d, $^3J_{HH}$ 6 Hz), 5.24, 5.10 (2H, $^3J_{HH}$ 14.3 Hz), 5.09 (2H), 5.06 (2H), 4.40 (2H, m), 4.24 (H, m), 3.79 (H, t, $^3J_{HH}$ 7.5 Hz), 3.61 (2H, m), 2.50 (4H, m), 2.14 (9H), 1.55 (3H), 1.45 (12H), 1.38 (3H), 1.36 (3H), 0.75 (3H, d, $^3J_{HH}$ 7 Hz), 0.69 (3H, d, $^3J_{HH}$ 7 Hz). *Anal.* calcd. for $C_{54}H_{72}N_6O_{13}\cdot 0.5H_2O$: C 63.4, H 7.2, N 8.2, O 21.1%; found: C 63.2, H 6.95, N 8.1, O 21.2%. This triester (**9**, 10 g) in methyl alcohol (30 mL) was shaken with palladium on carbon (5%, 5 g) and hydrogen (3.5 kg cm^{-2}) at room temperature for 18 h. The reaction mixture was filtered through a bed of Celite (1 cm) and the filtrate evaporated. The residue (5.5 g) was taken up in hot methyl alcohol (15 mL) and the solution kept at 4°C for 48 h. The precipitated crystalline solid (3.85 g, mp 153–155°C) was collected. α-*tert-Butyl* L-*prolyl*-L-*valyl*-2-*methylalanyl*-2-*methylalanyl*-L-*glutamyl*-L-*glutamate* (**4**) separated from methyl alcohol as triclinic blades, mp 154–155°C; $[\alpha]_D^{21}$ −40.5° (*c* 0.8, MeOH); δ_C^* ($C^2H_3O^2H$): 179.4; 178.0; 177.1; 176.4; 174.5; 173.6; 172.2; 170.6; 82.7 (C, *t*-Bu); 60.94 ($^1J_{CH}$ 150.3 Hz); 60.0 ($^1J_{CH}$ 141 Hz); 58.1 (α-C aib); 58.0 (α-C aib); 55.0 ($^1J_{CH}$ 143 Hz); 54.25 ($^1J_{CH}$ 142 Hz); 47.5 ($^1J_{CH_2}$ 146 Hz); 34.2 ($^1J_{CH_2}$ 131 Hz); 32.7 ($^1J_{CH_2}$ ~ 125 Hz); 32.4 ($^1J_{CH}$ 129.7 Hz, β-val); 31.3 ($^1J_{CH_2}$ 136 Hz); 29.2 (?CH_2); 28.2 ($^1J_{CH_2}$ ~ 133 Hz); 28.3 (3C, $^1J_{CH_3}$ 127.9 Hz), 26.5 (?CH_3); 25.1 (3C, $^1J_{CH_3}$ 128 Hz); 19.9 ($^1J_{CH_3}$ 125 Hz); 18.5 ($^1J_{CH_3}$ ~ 123 Hz). *Anal.* calcd. for $C_{32}H_{54}N_6O_{11}$: C 55.0, H 7.8, N 12.0, O 25.2%; found: C 54.7, H 7.8, N 12.0, O 25.3%.

α-tert-*Butyl* L-*prolyl*-L-*valyl*-2-*methylalanyl*-2-*methylalanyl*-L-*glutamate*

The protected pentapeptide (**3**, 9 g) in methyl alcohol (120 mL) was shaken with palladium on carbon (5%, 0.6 g) and hydrogen (3.5 kg cm^{-2}) for 40 h at 20°C. The reaction mixture was filtered through a bed of Celite, the filtrate evaporated, and the crystalline residue (mp 115–117°C, 6.3 g) recrystallized from prop-2-ol-isopropyl ether (1:1) gave the α-*tert-butyl* L-*prolyl*-L-*valyl*-2-*methylalanyl*-2-*methylalanyl*-L-*glutamate* (**7**) as rosettes, mp 117–119°C; $[\alpha]_D^{22}$ −41° (*c* 0.87, MeOH); δ_C ($C^2H_3O^2H$): 180.2; 177.2; 175.5; 173.3; 172.9; 172.0; 82.2; 69.9; 60.6; 57.9; 57.7; 54.9; 47.6; 34.2; 31.7; 28.4; 27.5; 26.6; 25.8; 24.0; 23.1; 19.7; 19.1. *Anal.* calcd. for $C_{27}H_{47}N_5O_8$: C 56.9, H 8.3, N 12.3; O 22.5%; found: C 57.0, H 8.6, N 11.9, O 23.0%.

α-tert-*Butyl* tert-*butyloxycarbonyl*-L-*prolyl*-L-*valyl*-2-*methylalanyl*-2-*methylalanyl*-L-*glutamyl*(γ)-L-*phenylalaninol*

The *tert*-butyl ester described in the previous paragraph (**7**, 6 g) and magnesium oxide (0.9 g) were stirred with a solution (150 mL) of dioxan (75 mL) in water for 1 h at room temperature, when *tert*-butyloxycarbonylazide (3 g) was added and the mixture stirred at 35°C for 72 h. The reaction mixture was diluted with sodium bicarbonate solution (5%), cooled to 0°C, filtered, and extracted (pH 7.0) with ethyl acetate. The cold (0°C) raffinate was acidified to pH 3.0 with citric acid solution (2%), sodium chloride added to saturation, and the solution extracted (3 × 50 mL) with ethyl acetate. The extract was washed with water, dried (Na_2SO_4), filtered, and evaporated. The residue recrystallized from ethyl acetate – methyl alcohol (100:1) gave the N-*tert-butyloxycarbonyl derivative* (**8**) as prisms, mp 200–202°C; $[\alpha]_D^{22}$ −57° (*c* 1.15, MeOH). *Anal.* calcd. for $C_{32}H_{55}N_5O_{10}$: C 57.4, H 8.3, N 10.5%; found: C 57.2, H 8.3, N 10.4%. This product (**8**, 2.4 g), L-phenylalaninol (Aldrich, 0.54 g), and 2-isobutoxy-1-isobutyloxycarbonyl-1,2-dihydroquinoline (38) (1.2 g) were dissolved in ethyl alcohol (dried over Linde molecular sieve 3A and redistilled, 100 mL) and the reaction mixture was stirred at 35°C for 4 days. The resulting solution was evaporated, the residue (3.3 g) taken up in ethyl acetate (100 mL), and the solution washed successively with water (50 mL), sodium bicarbonate solution (2 × 50 mL), and water. The dry solution was evaporated, the residue dissolved in hot ethyl acetate (5 mL), and light petroleum added to turbidity. The mixture was kept at 4°C for 36 h, when the crystalline mass that had separated was collected. The *hexapeptide* (**5**) separated from ethyl acetate – light petroleum (bp 30–60°C, 1:1) as prisms, mp 110–112°C; $[\alpha]_D^{22}$ −83.6°; δ_C^* ($C^2H_3O^2H$): 177.2, 177.1; 176.1, 175.9; 175.6; 175.3; 174.9; 173.9, 173.8; 172.4, 172.3; 139.9 (quat. C); 130.5 (2C, $^1J_{CH}$ ~ 157 Hz); 129.4 (2C, $^1J_{CH}$ 158.8 Hz, $^2J_{CH}$ ~ 5 Hz); 127.2 ($^1J_{CH}$ 157.7 Hz, $^2J_{CH}$ ~ 8 Hz); 82.6 (quat. Bu ester); 81.25, 81.2 (quat. CH_3); 25.6 (? CH_2); 24.8 (? CH_2), 23.9 ($^1J_{CH_3}$ 128 Hz); 23.7 ($^1J_{CH_3}$ 128 Hz);

19.2, 19.3 ($^1J_{CH_3}$ 128 Hz, val). *Anal.* calcd. for $C_{41}H_{66}N_6O_{10}\cdot H_2O$: C 60.0, H 8.4, N 10.2, O 21.4%; found: C 60.3, H 8.4, N 10.2, O 21.2%.

Dimethyl N-*(4-chlorobenzoyl)-L-prolyl-L-valyl-2-methylalanyl-2-methylalanyl-L-glutamate*

(a) The α-*tert*-butyl ester (**7**, 1.7 g) was suspended in THF (100 mL) and the stirred mixture treated with diazomethane (70 mg) in ether (20 mL). After 0.5 h at 20°C the excess diazomethane was blown off with a stream of nitrogen, the solution evaporated, and the residue taken up in hot tetrahydropyran (15 mL). The solution was kept at 4°C for 18 h, when the crystals that separated were collected (1.7 g). The *α-tert-butyl-γ-methyl ester* (**9**) separated from tetrahydropyran as blades, mp 178–179°C; $[\alpha]_D^{24}$ −51° (*c* 1.38, $CHCl_3$). *Anal.* calcd. for $C_{28}H_{49}N_5O_8$: C 57.6, H 8.5, N 12.0%; found: C 57.4, H 8.4, N 12.0%. This diester (3 g) was dissolved in THF (150 mL) and the solution treated with *p*-chlorobenzoylazide (1.1 g) in THF (10 mL). The solution was stirred at 20°C for 72 h, then was evaporated and the residue digested with petroleum ether (bp 30–60°C, 3 × 50 mL). The crystalline residue was collected and the N-(*4-chlorobenzoyl*) derivative (**10**) separated from *n*-butyl acetate as prisms, mp 90–95°C, recrystallizing at 125–130°C and finally melting sharply at 178–179°C; $[\alpha]_D^{24}$ −86° (*c* 0.66, $CHCl_3$). *Anal.* calcd. for $C_{35}H_{52}ClN_5O_9$: C 58.2, H 7.2, Cl 4.9, N 9.7%; found: C 57.8, H 7.3, Cl 4.9, N 9.9%. This *tert*-butyl ester (**10**, 1 g) was dissolved in methyl alcohol (100 mL) and hydrogen chloride passed into the solution for 15 min. The temperature of the reaction mixture increased to 55°C, when it was cooled to 20°C and kept at this latter temperature for 72 h. The solution was evaporated, the residue taken up in ethyl acetate (100 mL), and the solution washed with sodium bicarbonate solution (2%, 3 × 50 mL), with ice-cold sodium carbonate solution (1%, 50 mL), and finally with water (2 × 50 mL). The dry (Na_2SO_4) ethyl acetate solution was filtered, evaporated, and the residue (0.72 g, 76%, mp 162°C; $[\alpha]_D^{24}$ −90°, containing 3.5% of a byproduct of lower R_f) was recrystallized by dissolving in *n*-butyl acetate (8 mL) and adding diethyl ether (12 mL). The precipitate was collected after storage at 4°C for 96 h. After 6 recrystallizations in this manner, *dimethyl* N-*(4'-chlorobenzoyl)-L-prolyl-L-valyl-2-methyalanyl-2-methylalanyl-L-glutamate* was obtained, containing 0.15% of the impurity, mp 168–169°C; $[\alpha]_D^{24}$ −99° (*c* 0.57, $CHCl_3$); crystal data: $P2_12_12_1$; orthorhombic; a = 16.60, b = 25.16, c = 10.23 Å; δ_H (C^2HCl_3): 7.48 (2H, J = 8.6 Hz), 7.42 (2H, J = 8.6 Hz), 7.39 (H, e, J = 6.2 Hz), 6.80 (H, e, aib NH), 6.55 (H, e, aib NH), 4.78 (H, $J_{H_\alpha H_\beta}$ = 7.8 Hz, $J_{H_\alpha H_{(N)}}$ = 6.2 Hz, val α-C*H*), 4.5 (H, m, glu α-CH), 3.76 (H, t, J = 6.1 Hz, pro α-CH), 3.70 (3H), 3.64 (3H), ~3.5 (H, m, val β-CH), ~2.5 (2H, m, pro δ-CH_2), 2.32 (H, m, pro β-CH_2), ~2.2 (2H, m, glu γ-CH_2), 2.1–2.3 (3H, m, pro), 1.91 (2H, glu β-CH_2), 2.04 (H, m, glu CH_2), 1.55 (3H, aib), 1.49 (3H, aib), 1.47 (3H, aib), 1.46 (3H, aib), 0.98 (3H, J = 6.3 Hz, val), 0.98 (3H, J = 6.3 Hz, val); δ_C^* ($C^2H_3O^2H$): 177.6; 175.7; 175.1; 174.5; 173.9; 173.8; 170.8; 137.5 (quat. arom.); 136.0 (quat. arom., $^2J_{CH}$ ~ 7 Hz); 130.0 (2C, $^1J_{CH}$ 164 Hz, $^2J_{CH}$ ~ 7 Hz); 129.7 (2C, $^1J_{CH}$ 167.5 Hz); 61.6 ($^1J_{CH}$ 148 Hz); 60.8 ($^1J_{CH}$ 141 Hz); 57.9 (aib α-C); 53.5 ($^1J_{CH}$ 138 Hz); 52.65 ($^1J_{CH_3}$ 147 Hz, ester Me); 52.0 ($^1J_{CH_3}$ 147 Hz, ester Me); 51.9 (aib α-C); 31.9 ($^1J_{CH}$ 138 Hz, β-val (39)); 31.3 ($^1J_{CH_2}$ ~ 130 Hz), 31.1 (? CH_2); 27.7 (? CH_3); 27.2 ($^1J_{CH_2}$ ~ 130 Hz); 26.9 ($^1J_{CH_3}$ 132 Hz); 26.6 ($^1J_{CH_2}$ 134 Hz); 23.7 ($^1J_{CH_3}$ 128 Hz); 23.6 ($^1J_{CH_3}$ 128 Hz); 19.6 ($^1J_{CH_3}$ 127 Hz); 19.3 ($^1J_{CH_3}$ 127 Hz). *Anal.* calcd. for $C_{32}H_{46}ClN_5O_9$: C 56.5, H 6.8, Cl 5.2, N 10.3, O 21.2%; found: C 56.4, H 6.9, Cl 5.2, N 10.1, O 21.1%.

(b) γ-Benzyl-L-glutamic acid (10.5 g) was suspended in THF (150 mL) and water (1.5 mL) was added. The mixture was stirred with a solution (100 mL) of diazomethane (2 g) in ether for 3 days at room temperature, after which the solution was evaporated, the residue taken up in ether (100 mL), the ether solution washed with sodium bicarbonate solution (2%, 100 mL), dried (Na_2SO_4), filtered, and the filtrate treated with hydrogen chloride. The precipitated hydrochloride (mp 133–134°C, 79%, 6 g), suspended in toluene (400 mL), was treated with triethylamine (2.04 g) and, after shaking the mixture for 5 min, with the *N*-phenylmethoxycarbonyl tetrapeptide (**2**, R = C_7H_7O, R′ = H, 10 g) (28) and EEDQ (5.2 g). The reaction mixture was treated as described for the analogous *tert*-butyl ester (**6**) and gave the *pentapeptide* (**11**) as prisms from *n*-butyl acetate, mp 144–146°C, 6 g, 41%; $[\alpha]_D^{24}$ −67° (*c* 4, MeOH). *Anal.* calcd. for $C_{39}H_{53}N_5O_{10}\cdot 0.25H_2O$: C 61.9, H 7.1, N 9.3, O 21.7%; found: C 61.9, H 7.2, N 9.5; O 21.2%. This ester (5 g) in methyl alcohol (120 mL) was shaken with hydrogen (4.2 kg cm^{-2}) and palladium on carbon (5%, 1 g). The reaction mixture was worked up as described for the ester (**10**) and gave the *pentapeptide methyl ester* (**12**) as prisms from methyl alcohol (70 mg mL^{-1}), mp 132–134°C. *Anal.* calcd. for $C_{24}H_{41}N_5O_8\cdot 1.5H_2O$: C 52.0, H 7.9, N 12.6, O 27.4%; found: C 51.9, H 8.0, N 12.5; O 27.0%. This iminoester (**12**, 1.5 g) was suspended in THF (75 mL) and a solution of diazomethane (0.12 g) in ether added. The peptide dissolved just as the color of the diazomethane disappeared. The *dimethyl ester* (**13**) separated from THF – isopropyl ether (1:3) as plates of characteristic trapezoid shape, mp 201–202°C, 1.5 g; δ_C: 177.5; 177.2; 175.3; 174.7; 173.7; 173.7; 61.4 ($^1J_{CH}$ 142 Hz); 60.1 ($^1J_{CH}$ 143 Hz); 57.7 ($^2J_{CH_3}$ 4.5 Hz); 57.7 (aib α-C); 53.3 ($^1J_{CH}$ ~ 145 Hz); 52.5 ($^1J_{CH_3}$ 147 Hz); 51.8 ($^1J_{CH_3}$ 147 Hz); 47.9 ($^1J_{CH_2}$ 144 Hz); 31.8 ($^1J_{CH_2}$ 134 Hz); 31.1 ($^1J_{CH}$ 131 Hz, val β-CH (39)); 27.1; 26.4 ($^1J_{CH_2}$ ~ 140 Hz); 27.8 ($^1J_{CH_3}$ 129 Hz, $^3J_{CH_3}$ 4 Hz); 26.8 ($^1J_{CH_3}$ 129 Hz, $^3J_{CH_3}$ 4 Hz); 23.5 (2C, $^1J_{CH_3}$ 129 Hz, $^3J_{CH_3}$ 4 Hz); 19.5 ($^1J_{CH_3}$ 130 Hz); 19.0 ($^1J_{CH_3}$ 130 Hz). *Anal.* calcd. for $C_{25}H_{43}N_5O_8$: C 55.5, H 7.9, N 12.9, O 23.7%; found: C 55.4, H 8.0, N 12.6; O 23.4%. This dimethyl ester (0.11 g) was suspended in THF (5 mL) and the mixture treated with 4-chlorobenzoylazide (40 mg). The reaction mixture was stirred at room temperature for 96 h, was evaporated, the residue titurated with light petroleum (3 × 20 mL), and the residue (0.12 g) then taken up in butyl acetate (3 mL) and diethyl ether (3 mL) added. The solution was kept for 18 h at 4°C, when the crystalline precipitate (0.1 g, mp 165–167°C; $[\alpha]_D^{24}$ −91° (*c* 1, $CHCl_3$)) was collected. The ^1H broadband-decoupled ^{13}C nmr spectrum of this material was identical to that of the material prepared by method (a); recrystallization as described in method (a) gave material with identical mp and specific optical rotation.

Acknowledgements

One of us (A.T.) thanks Dr. B. C. Das and Sir Ewart Jones F.R.S. in whose laboratories some of this work was done. Part of the work was carried out under the auspices of the joint France–Canada scientific agreement. We thank Dr. R. Greenhalgh for the FAB mass spectrum shown in Fig. 4, Dr. A. W. Hanson for crystallographic data, and Dr. A. W. McCulloch for helpful suggestions and comments on the typescript.

The reaction of phenol with the binuclear rhodium hydride $[\{(i\text{-Pr})_2PCH_2CH_2P(i\text{-Pr})_2\}Rh]_2(\mu\text{-H})_2$ generates $[\{(i\text{-Pr})_2PCH_2CH_2P(i\text{-Pr})_2\}Rh]_2(\mu\text{-H})(\mu\text{-OC}_6H_5)$, **2**, which was characterized by both solution spectroscopic techniques and a single crystal X-ray diffraction study. The structure was solved using Patterson and Fourier methods and refined to $R = 0.019$ ($R_w = 0.027$) for 6062 reflections; crystals of the compound are triclinic, space group $P\bar{1}$, with $a = 9.018(2)$, $b = 12.988(2)$, $c = 17.558(3)$ Å, $\alpha = 99.42(1)$, $\beta = 92.62(2)$, $\gamma = 91.85(2)°$, and $Z = 2$. Further reaction with excess phenol leads to the mononuclear complex $(\eta^5\text{-}C_6H_5O)Rh\{(i\text{-Pr})_2PCH_2CH_2P(i\text{-Pr})_2\}\cdot 2C_6H_5OH$, which contains two phenol units hydrogen bonded to the oxygen of the η^5-cyclohexyldienylone ligand. The presence of the bridging phenoxide ligand in **2** results in reduced reactivity as compared to the starting binuclear hydride dimer.

MICHAEL D. FRYZUK, MAY-LING JANG, TERRY JONES et FREDERICK W. B. EINSTEIN. Can. J. Chem. **64**, 174 (1986).

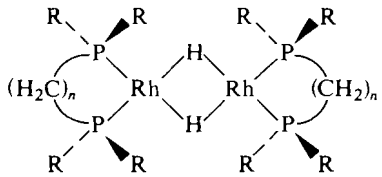
La réaction du phénol avec l'hydrure binucléaire du rhodium $[\{(i\text{-Pr})_2PCH_2CH_2P(i\text{-Pr})_2\}Rh]_2(\mu\text{-H})_2$ génère le composé **2**, $[\{(i\text{-Pr})_2PCH_2CH_2P(i\text{-Pr})_2\}Rh]_2(\mu\text{-H})(\mu\text{-OC}_6H_5)$, qui a été caractérisé à la fois par des techniques spectroscopiques et par une étude de diffraction des rayons-X sur un monocristal. On a résolu la structure par les méthodes de Patterson et de Fourier et on l'a affinée jusqu'à une valeur de $R = 0{,}019$ ($R_w = 0{,}027$) pour 6062 réflexions; les cristaux sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 9{,}018(2)$, $b = 12{,}988(2)$, $c = 17{,}558(3)$ Å, $\alpha = 99{,}42(1)$, $\beta = 92{,}62(2)$, $\gamma = 91{,}85(2)°$ et $Z = 2$. Une réaction subséquente avec un excès de phénol conduit à la formation d'un complexe mononucléaire, $(\eta^5\text{-}C_6H_5O)Rh\{(i\text{-Pr})_2PCH_2CH_2P(i\text{-Pr})_2\}\cdot 2C_6H_5OH$, qui contient deux unités de phénol qui sont liées par des ponts hydrogène à l'oxygène du ligand η-cyclohexyldiènylone. La présence du ligand phénolate comme pont dans le composé **2** réduit sa réactivité par comparaison avec celle de l'hydrure dimère binucléaire de départ.

[Traduit par le journal]

Introduction

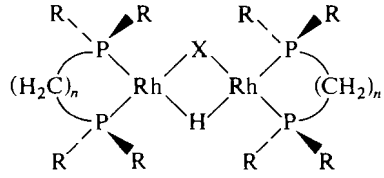
In attempts to design polynuclear metal complexes that are resistant to fragmentation, a variety of bridging ligands have been employed to secure two or more transition metals together. Some typical but not exhaustive examples of bridging ligands are phosphides (PR^{2-}, PR_2^-) (see ref. 1 for leading references), arsenides (AsR^{2-}, AsR_2^-) (see ref. 2 for leading references), sulfides (S^{2-}, SR^-) (see ref. 3 for leading references), and oxides (O^{2-}, OR^-) (see ref. 4 for leading references). Synthetic strategies in the construction of homonuclear and heteronuclear clusters with bridging ligands have been impressive; numerous methodologies now exist for the convergent synthesis of remarkably complex metal clusters (5). However, little mention has been given to the feasibility of these purported fragmentation-resistant clusters to act as catalysts (or even catalyst precursors) for a particular transformation. Indeed, many of these impressive syntheses lead to rather inert metal clusters, albeit with the bridging ligands appropriately in place (see ref. 6 for some exceptions).

For some time we have been investigating the synthesis and reactivity of coordinatively unsaturated rhodium-hydride clusters with chelating bidentate phosphine donors as the ancillary ligands (7–10). The binuclear members of this family of clusters **1** are especially active in the hydrogenation and isomerization of terminal olefins, apparently without fragmentation of the binuclear unit (8, 11, 12). Our strategy for the preparation of catalytically-active metal clusters that contain bridging ligands



1*a*, $n = 2$, R = *i*-Pr
1*b*, $n = 3$, R = *i*-Pr
1*c*, $n = 2$, R = *i*-OPr

involves modification of existing catalytically-active systems such as **1** to generate potentially fragmentation-resistant clusters of the type **2**. This approach is not only complementary to the strategies mentioned previously, but it also allows one to examine the effects, beneficial or otherwise, of the presence of a bridging ligand.



2, $n = 2$, $R = i$-Pr, X = OC_6H_5

In this paper we report some of our initial findings on the synthesis, structure and reactions of a complex of the type **2**, where the bridging ligand is a phenoxide (X = OC_6H_5).

Experimental section

General procedures and precautions were identical to those previously described (8, 13). The syntheses of $[(dippe)Rh]_2(\mu\text{-H})_2$ and

[1]Fellow of the Alfred P. Sloan Foundation (1984–1986).
[2]Recipient of an NSERC Summer Undergraduate Award (1983 and 1984).

(η^3-C_3H_5)Rh(dippe) (dippe = 1,2-bis(diisopropylphosphino)ethane) are described in ref. 9.

[(dippe)Rh]$_2$(μ-H)(μ-O—Ph)

To a solution of [(dippe)Rh]$_2$(μ-H)$_2$ (0.162 g, 0.22 mmol) in hexanes (4 mL) was added sublimed phenol (0.052 g, 0.55 mmol) in ~0.2 mL of toluene; the solution immediately turned from deep green to bright orange. The solution was allowed to sit undisturbed at room temperature for 12 h then at −30°C for 4 h to generate orange prisms. The solution was decanted away from the crystals, and the crystals washed with 3–4 mL of cold (−30°C) hexanes, and dried under vacuum. Yield: 0.151 g (83%), mp 182–184°C. ^{1}H nmr (C_6D_6, ppm): H_{ortho}, 7.38 (dd, $^3J_{meta}$ = 8.3 Hz, $^4J_{para}$ = 0.9 Hz); H_{meta}, 7.13 (dd, $^3J_{para}$ = 7.3 Hz); H_{para}, 6.73 (tt); PC*H*Me$_2$, 2.06, 1.76 (octets, ^2J_P = $^3J_{Me}$ = 7.1 Hz); PCH(C*H*$_3$)$_2$, 1.46, 1.17, 1.05, 0.94 (dd, ^3J_P = 15.3 Hz); PC*H*$_2$C*H*$_2$P, ~1.1 (complex multiplet obscured by PCH(C*H*$_3$)$_2$ resonances); Rh*H*Rh, −8.6 (ttt, $^2J_{Ptrans}$ = 61.5 Hz, $^2J_{Pcis}$ = 24.4 Hz, $^1J_{Rh}$ = 13.1). ^{1}P{^{1}H} nmr (C_6D_6, ppm relative to P(OMe)$_3$ at + 141.0): AA′MM′XX′ = P_A, 112.7 (m); P_B, 86.0 (m). IR (toluene, cm^{-1}): 1240 (C—O, s). *Anal.* calcd. for $C_{34}H_{70}OP_4Rh_2$: C 49.52; H 8.56; found: C 49.78; H 8.48.

[(dippe)Rh(η^5-C_6H_5O)]·2PhOH

Method 1: To a solution of [(dippe)Rh]$_2$(μ-H)$_2$ (0.162 g, 0.22 mmol) in toluene (5 mL) was added excess sublimed PhOH (~0.10 g, ~5 equiv.) in toluene (~0.5 mL) dropwise, then the resulting orange solution allowed to sit at room temperature for 18 h. The volatiles were removed under vacuum to give a red–orange solid. ^{1}H nmr analysis indicated a mixture of [(dippe)Rh]$_2$(μ-H)(μ-OPh) and [(dippe)Rh(η^5-C_6H_5O)]·2PhOH. Careful fractional crystallization from minimum toluene by the addition of hexanes yielded [(dippe)Rh(η^5-C_6H_5O)]·2PhOH as the more soluble component in approximately 50% yield.

Method 2: To a solution of (η^3-C_3H_5)Rh(dippe) (0.161 g, 0.40 mmol) in toluene (5 mL) was added sublimed PhOH (0.112 g, 1.19 mmol) in toluene (~0.5 mL) and the mixture allowed to stir for 24 h. The resulting deep orange solution was reduced in volume to ~0.5 mL and hexanes (1 mL) added. Cooling to −30°C gave orange crystals. Yield: 0.210 g (two fractions: 82%); mp 89–91°C. ^{1}H nmr (C_6D_6, ppm): PhO*H*...O, ~9–12 (br s); H_{ortho} (PhOH), 7.28 (dd, $^3J_{meta}$ = 8.0 Hz, $^5J_{para}$ = 0.9 Hz); H_{meta} (PhOH), 7.18 (dd, $^3J_{para}$ = 7.8 Hz); H_{para} (PhOH), 6.80 (tt); H_{ortho} (η^5-C_6H_5O), 6.25 (dd, $^3J_{meta}$ = 7.3 Hz; $^5J_{para}$ = 1.0 Hz); H_{meta} (η^5-C_6H_5O), 5.65 (dd, $^3J_{para}$ = 6.0 Hz); H_{para} (η^5-C_6H_5O), 4.70 (br t); PC*H*Me$_2$, 1.58 (br octet, ^2J_P = $^3J_{Me}$ = 7.0 Hz); PCH(C*H*$_3$)$_2$, 0.88 (dd, ^3J_P = 15.5 Hz); PC*H*$_2$C*H*$_2$P, 0.84 (m); PCH(C*H*$_3$)$_2$, 0.65 (dd, ^3J_P = 13.5 Hz). ^{31}P{^{1}H} nmr (C_6D_6, ppm relative to P(OMe)$_3$ at + 141.0); 105.5 (d, $^1J_{Rh}$ = 208 Hz). *Anal.* calcd. for $C_{32}H_{49}O_3P_2Rh$: C 59.44, H 7.64, found: C 59.66, H 7.57. IR (toluene, cm^{-1}): 2800 (OH, br); 1540 (C=O, s); 1271, 1246 (C—O, s).

Attempted preparation of (dippe)Rh(η^5-C_6H_5O)

To a solution of (η^3-C_3H_5)Rh(dippe) (0.032 g, 0.079 mmol) in toluene (2 mL) was added PhOH (0.79 mL of 0.1 *M* solution in toluene, 1 equiv.) and the mixture stirred at room temperature for 24 h. The volatiles were then removed and the mixture analyzed by ^{1}H nmr spectroscopy. Integration indicate that a ~2:1 mixture (η^3-C_3H_5)Rh-(dippe) and [(dippe)Rh(η^5-C_6H_5O)]·2PhOH was present.

Reactions of [(dippe)Rh]$_2$(μ-H)(μ-OPh)

Typically 10–20 mg of the complex was dissolved in C_6D_6 (0.4 mL) and placed in a 5 mm nmr tube sealed to a ground glass joint and fitted with a Teflon needle valve adapter. The nmr tube assembly was attached to the vacuum line and the solution degassed. Addition of the gaseous reactants (see below) was performed at −196°C and the tube sealed with a torch.

With H_2: by ^{1}H nmr, only the phenoxy-hydride dimer was detected even after long reaction times and heating to 75°C for 1 h.

With CH_2=CH_2: by ^{1}H nmr, only the phenoxy-hydride dimer was detected even after long reaction times.

With CO: As soon as the solution reached room temperature, an orange to yellow colour change was observed; by ^{1}H nmr, the solution contained PhOH and [(dippe)Rh(CO)]$_2$(μ-CO)$_2$ (12).

[a]Temperature 21 ± 1°C; Mo-K$_\alpha$ radiation, graphite monochromator, λ = 0.70930 Å (α$_1$), 0.71359 Å (α$_2$); function minimized was $\Sigma\omega(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega|F_o|^2)^{1/2}$, $\omega = 1/(\sigma^2(F) + 0.0006F^2)$.

Hydrogenation of 1-hexene

An identical procedure to that previously described (8) was utilized except that the catalyst precursor was [(dippe)Rh]$_2$(μ-H)(μ-OPh).

Deuterium labelling studies

[(dippe)Rh]$_2$(μ-D)$_2$ + PhOH. To a solution of [(dippe)Rh]$_2$(μ-D)$_2$ (0.039 g, 0.053 mmol) in C_6D_6 was added PhOH (0.009 g, 0.096 mmol) to generate an orange solution. Integration of the residual hydride resonance versus the proton resonances of the phenoxy ligand indicated an approx. 1:1 mixture of [(dippe)Rh]$_2$(μ-D)(μ-OPh) and [(dippe)Rh]$_2$(μ-H)(μ-OPh). The addition of excess PhOH does not change this ratio.

[(dippe)Rh]$_2$(μ-H) + d_5-PhOD. To a solution of [(dippe)Rh]$_2$-(μ-H)$_2$ (0.080 g, 0.107 mmol) in C_6D_6 (1 mL) was added C_6D_5OD (Aldrich; 0.012 g, 0.120 mmol); the resultant orange solution was analyzed by ^{1}H nmr. Integration of the hydride resonance indicated an approximately 50% (±5%) loss of the hydride intensity which corresponds to a ~1:1 mixture of [(dippe)Rh]$_2$(μ-H)(μ-OC$_6$D$_5$) and [(dippe)Rh]$_2$(μ-OC$_6$D$_5$) as found above.

Crystallographic analysis: Crystal data are given in Table 1. Precession and Weissenberg photographs (CuKα, λ = 1.5418 Å) were used to determine approximate cell dimensions and to assign the space group as *P*1 or $P\bar{1}$ (subsequent structure solution proved $P\bar{1}$ to be the correct space group). Accurate cell dimensions were determined by least squares refinement of 25 accurately centred reflections (2ρ = 15–20°) chosen from a variety of points in reciprocal space and measured with Mo-Kα radiation (λ = 0.71069 Å). Data were collected using an Enraf-Nonius CAD4-F diffractometer. Scan information is given in Table 1; background measurements were made by extending the scan range by 25% at each side of the scan. Measurement of 2 standard reflections every hour allowed monitoring of crystal decay and stability of the detection chain. Lorentz, polarization and absorption

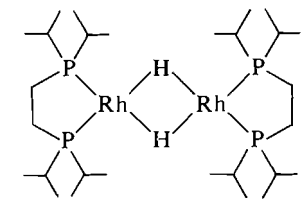
corrections have been made (see Table 1 for range of transmission coefficients).

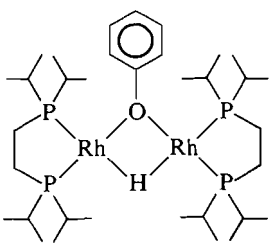
The structure was solved by conventional Patterson and Fourier methods. All atoms were located by successive difference-maps. The final cycles of full-matrix least-squares refinement were performed by varying the coordinates of all atoms, with anisotropic temperature factors for all non-hydrogen atoms and fixed isotropic temperature factors for hydrogen atoms (the U values used for hydrogen atoms were determined during earlier refinement when hydrogen coordinates were fixed). A weighting scheme was derived on the basis of trends in $w\Delta^2$ as a function of $|F_0|$ and sin ρ/λ (Table 1). An extinction correction (14) was also applied. The final difference map was essentially clean apart from a couple of weak peaks [0.24–0.30(5) e/Å^3] in the vicinity of Rh atoms. The maximum parameter shift during the last cycle of refinement was 0.1σ for a hydrogen atom and 0.03σ for a non-hydrogen atom. Atomic scattering factors including anomalous dispersion were taken from Tables for X-ray crystallography (15). Final positional and thermal parameters for non-hydrogen atoms were given in Table 2. Anisotropic thermal parameters, final positional, and thermal parameters for hydrogen atoms and structure factor listings are available as supplementary material (Tables 81–83).[3] The computer programs used here are those belonging to "The VAX 750/780 crystal structure system" (16).

Results and discussion

The reaction of deep green solutions of $[(dippe)Rh]_2(\mu\text{-}H)_2$ **1***a* (dippe = 1,2-bis)diisopropylphosphino)ethane) with phenol (C_6H_5OH) leads to an immediate colour change to orange and the formation of **2** in excellent yields. Monitoring the reaction shown in reaction [1] by $^{31}P\{^1H\}$ nmr spectroscopy indicates that one equivalent of phenol is enough to completely convert **1***a* to **2** in quantitative yield; in practice, between one and two



1*a*



2

equivalents are used. Addition of excess phenol does not affect the $^{31}P\{^1H\}$ nmr spectrum initially, however, a new species does begin to grow in with time (*vide infra*). The ^1H nmr spectrum of **2** is characterized by a symmetrical multiplet (triplet of triplet of triplets due to coupling with two ^{103}Rh, two *trans* ^{31}P and two *cis* ^{31}P nuclei) for the bridging hydride at −8.9 ppm and an AA′BB′C pattern for the protons on the bridging phenoxide; the dippe ligand resonances are appropriate for the symmetry of the complex. The $^{31}P\{^1H\}$ nmr spectrum consists of two sets of symmetrical resonances due to the AA′MM′XX′ spin system. The ir spectrum shows a strong C—O absorption at 1240 cm^{-1}.

The single crystal X-ray structure of **2** shown in Fig. 1 confirms the above basic structure (reaction [1]). The four phosphorus, two rhodium, the bridging hydrogen, and the bridging oxygen atoms are essentially coplanar. Selected bond distances and angles are contained in Table 3. The molecule is quite symmetrical with both Rh(1)—H(1) and Rh(2)—H(1) bond distances equal to 1.74(3) Å; similarly, the respective Rh(1)—O and Rh(2)—O bond distances of 2.117(1) and 2.114(2) Å are almost identical. The Rh—P bonds *trans* to the bridging hydride are approximately 0.05 Å longer than the Rh—P bonds *trans* to the bridging phenoxide group (compare Rh(1)—P)1) and Rh(2)—P(3) at 2.2209(7) Å to Rh(1)—P(2) at 2.1720(7) Å and Rh(2)—P(4) at 2.1657(7) Å). Although the Rh—P bond distances correlate with the stronger *trans* influence (17) of a hydride versus an oxygen donor, non-bonding

[3] Anisotropic thermal parameters, final positional and thermal parameters for hydrogen atoms and calculated structure amplitudes are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

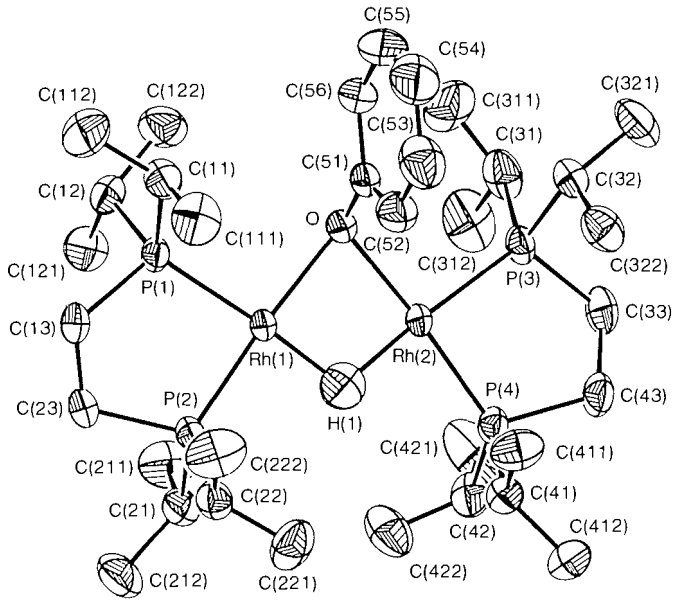


FIG. 1. ORTEP view and numbering and labelling scheme for $[(dippe)Rh]_2(\mu\text{-}H)(\mu\text{-}OC_6H_5)$. Thermal ellipsoids are drawn at the 50% probability level.

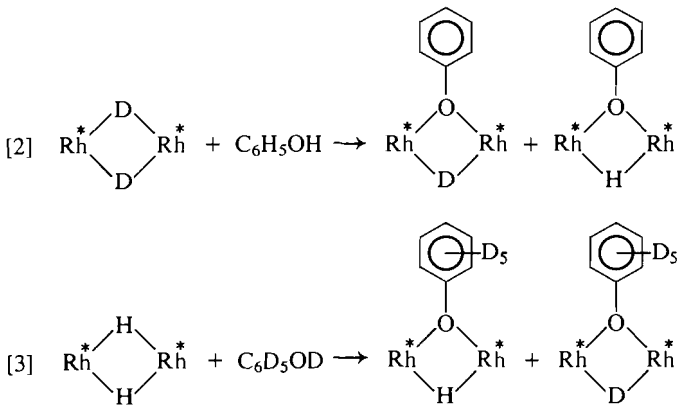
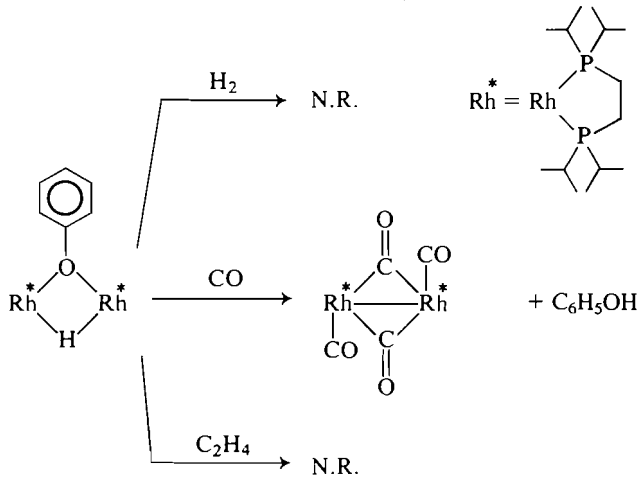
repulsions between the phenyl and the isopropyl groups may also be operative. The geometry around the oxygen atom is pyramidal with the following bond angles: Rh(1)—O—Rh(2), 88.22(5)°; Rh(1)—O—C(51), 119.6(2)°; Rh(2)—O—C(51), 117.2(2)°. The bite angles of the dippe ligands of 86.57(2)° and 86.77(3)° are only slightly larger than the previously observed angles of 85.89(4)° and 86.44(4)° in $[(dippe)Rh]_2(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}CH{=}CH_2)$ (19). The Rh—Rh distance of 2.7825(4) Å is similar to the observed distance of 2.8655(5) Å found in $[(dippe)Rh]_2(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}CH{=}CH_2)$.

The source of the bridging-hydride in the μ-phenoxide derivative **2** was investigated by analysis of the reaction of the dideuteride **1***a*′ with unlabelled phenol (reaction [2]) and the complementary reaction of the dihydride **1***a* with deuterated phenol reaction [3] (Rh* = Rh(dippe)).



In both reactions, ^1H nmr spectral analysis of the products showed that the phenoxy-deuteride and the phenoxy-hydride were formed in approximately equal amounts, regardless of the experimental conditions. These experiments establish that protonation by phenol, or more accurately oxidative adition of HX (X = OC_6H_5) proceeds through an intermediate which scrambles the hydrides and deuterides before the reductive elimination step.

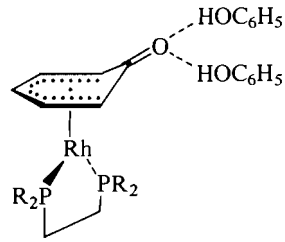
The phenoxy-hydride **2** is much less reactive than the starting binuclear dihydride **1***a*. For example, the addition of either H_2 (4 atm) or ethylene (1 atm) to **2** does not result in any observable change in the ^1H nmr spectrum. However, the addition of carbon monoxide to **2** results in an immediate colour change from orange to yellow; ^1H nmr spectral analysis indicates the presence of free phenol (equiv.) and the formation of $[(dippe)Rh(CO)]_2(\mu\text{-}CO)_2$ (12). Insertion of CO into the bridging-phenoxide was not observed (Scheme 1).



SCHEME 1

Under typical hydrogenation conditions, the phenoxy-hydride **2** does act as a catalyst precursor for the reduction (and isomerization) of 1-hexene; however, the rate is an order of magnitude slower than the starting dihydride **1***a* (see Experimental section (12)).

As mentioned above, when the formation of the phenoxy-hydride **2** from the binuclear dihydride **1***a* is monitored by $^{31}P\{^1H\}$ nmr spectroscopy, another product grows in with time in the presence of excess phenol, as evidenced by the appearance of a sharp doublet ($^1J_{Rh}$ = 208 Hz). This new material is formulated as the mononuclear complex $(dippe)Rh(\eta^5\text{-}C_6H_5O)\cdot 2C_6H_5OH$, **3**.



3, R = *i*-Pr

Characteristic of the cyclohexadienylone ligand is the upfield shift of the protons of the coordinated $\eta^5\text{-}C_6H_5O$ group in the ^1H nmr spectrum, and the presence of a strong band in the ir at 1545 cm^{-1} for the carbonyl stretch. The presence of the additional phenol units hydrogen-bonded to the carbonyl is apparent both from the broad singlet downfield (~9–11 ppm) in the ^1H nmr spectrum and the broad OH stretch in the ir; the analytical figures also support this formulation.

This type of structural unit contained in **3** is not unique. A number of ruthenium(II) derivatives of the general formula $(Ph_3P)_2HRu(\eta^5\text{-}C_6H_5O)\cdot S_X$ (where S = PhOH or MeOH), as well as the rhodium analogues of formula $(Ph_3P)_2Rh(\eta^5\text{-}C_6H_5O)\cdot(PhOH)_n$ (n = 2 or 3) have been isolated (18). The single crystal X-ray structure of $(Ph_3P)_2HRu(\eta^5\text{-}$

$C_6H_5O)\cdot 2PhOH$ is reported[4] to show the pentahapto mode of ligation of the cyclohexadienylone ligand and the presence of the two hydrogen-bonded phenol units. A more recent (19) crystal structure of $(Ph_3P)_2Rh(\eta^5\text{-ArO})$ (where ArO = 2,6-di-*tert*-butyl-4-methylphenoxy) also shows the interaction of just five carbons of the aromatic fragment with the rhodium centre.

The synthesis of **3** can also be achieved by the addition of excess phenol to the (dippe)rhodium allyl derivative **4** as shown in reaction [4].

Interestingly, attempts to generate **3** *without* the hydrogen-bonded phenol units by the direct addition of exactly *one equivalent* of phenol to the allyl complex **4** only resulted in the isolation of the starting allyl **4** and **3** in a 2:1 ratio, respectively: it would appear that in the presence of phenol the hydrogen-bonded adduct **3** is the preferred product. No further attempt

was made to generate the analogous cyclohexadienylone complex free of hydrogen-bonded phenol.

Conclusions

The results of this study show that the incorporation of a bridging ligand such as phenoxide to replace the bridging hydride diminishes the reactivity of the binuclear rhodium fragment; this is evidenced by both a complete lack of reactivity in stoichiometric reactions with dihydrogen and ethylene, as well as an order of magnitude reduced reactivity in the catalytic mode in the hydrogenation of 1-hexene, when compared to the very reactive $[(dippe)Rh]_2(\mu\text{-}H)_2$, **1***a*. Given that the typical bridging ligands are four- or six-electron donors (two electrons to each metal), coordinative saturation in polynuclear systems incorporating these bridging ligands is more easily achieved, ultimately generating less reactive or inert metal clusters.

Thermal rearrangement of functionalized 1,2-divinylcyclopropane systems. A convenient synthesis of substituted 4-cyclohepten-1-ones

EDWARD PIERS, MAX S. BURMEISTER, AND HANS-ULRICH REISSIG

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received July 12, 1985

EDWARD PIERS, MAX S. BURMEISTER, and HANS-ULRICH REISSIG. Can. J. Chem. **64**, 180 (1986).

Reaction of the acyl chlorides **14–21** with lithium (phenylthio)(*cis*-2-vinylcyclopropyl)cuprate (**2**) provided the ketones **22–29**. Compounds **22–25**, upon treatment with i-Pr_2NLi–Me_3SiCl, were converted cleanly into the enol silyl ethers **30–33**, which gave the 1,4-cycloheptadienes **34–37** upon thermolysis (100–110°C). Acid hydrolysis of the latter materials produced the corresponding 4-cyclohepten-1-ones **38–41**. However, subjection of the *cis*-2-vinylcyclopropyl ketones **26–29** to i-Pr_2NLi–*t*-$BuMe_2SiCl$ afforded, in each case, a mixture of isomeric enol ethers (**26** → **42** + **44** (1:1); **27** → **43** + **45** (1:9); **28** → **56** + **58** (1:1); **29** → **57** + **59** (4:1)). Thermolysis (150–175°C) of these mixtures, followed by acid hydrolysis of the resultant products, gave the 4-cyclohepten-1-ones **54**, **55**, **64**, and **65**, admixed with the corresponding 3-methylenecyclopentenes **52**, **53**, **62**, and **63**. On the other hand, treatment of the *trans*-2-vinylcyclopropyl ketones **70–74** with i-Pr_2NLi–*t*-$BuMe_2SiCl$ provided exclusively or predominantly the enol ethers **75–79**. Thermolysis (230°C) of the latter materials and subsequent acid hydrolysis of the resultant products **80**, **50**, **51**, **60**, and **61** afforded the 4-cyclopenten-1-ones **38**, **54**, **55**, **64**, and **65**.

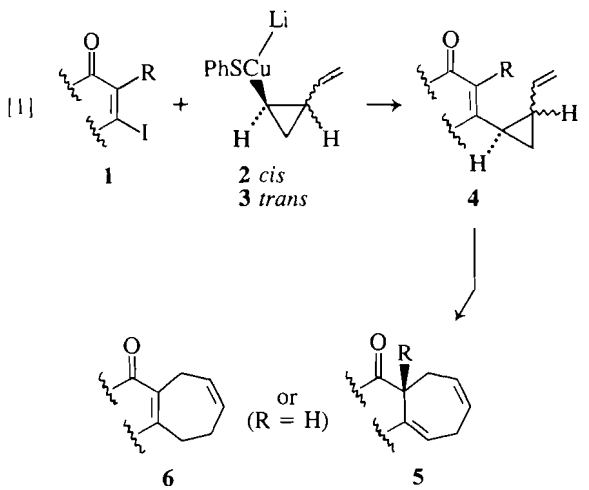
EDWARD PIERS, MAX S. BURMEISTER, et HANS-ULRICH REISSIG. Can. J. Chem. **64**, 180 (1986).

La réaction des chlorures d'acyle **14–21** avec le (phénylthio)(vinyl-2 cyclopropyle-*cis*) cuprate de lithium (**2**) conduit aux cétones **22–29**. Les composés **22–25**, traités par le i-Pr_2NLi–Me_3SiCl, se transforment proprement en éthers énoliques silylés **30–33** qui, par thermolyse (100–110°C), donnent les cycloheptadiènes-1,4 **34–37**. L'hydrolyse acide des composés **34–37** conduit aux cyclo-4 heptène-4 ones-1 **38–41**. Cependant, si on traite les vinyl-2 cyclopropylcétones-*cis* **26–29** avec le i-Pr_2NLi–*t*-$BuMe_2SiCl$ on obtient, dans chaque cas, un mélange d'éthers énoliques isomères (**26** → **42** + **44** (1:1); **27** → **43** + **45** (1:9); **98** → **56** + **58** (1:1); **29** → **57** (4:1)). La thermolyse (150–175°C) de ces mélanges, suivie d'une hydrolyse acide, donne les cycloheptène-4 ones-1 **54**, **55**, **64** et **65** mélangés avec les méthylènes-3 cyclopentènes correspondants **52**, **53**, **62** et **63**. Par ailleurs, si on traite les vinyl-2 cyclopropylcétones-*trans* **70–74** avec le i-Pr_2NLi–*t*-$BuMe_2SiCl$, on obtient exclusivement ou d'une façon majoritaire les éthers énoliques **75–79**. La thermolyse (230°C) de ces derniers, suivie d'une hydrolyse acide des produits résultants **80**, **50**, **51**, **60** et **61**, conduit aux cyclopentène-4 ones-1 **38**, **54**, **55**, **64** et **65**.

[Traduit par le journal]

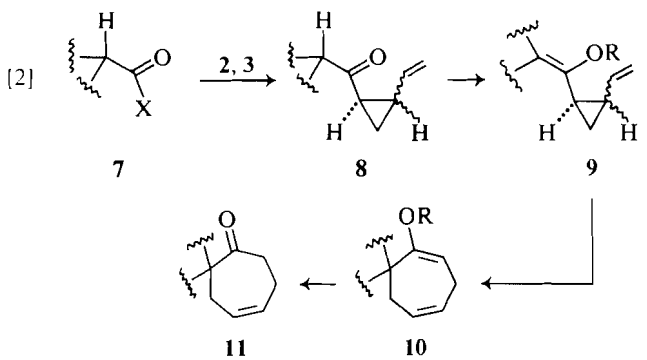
Introduction

Recent reports (1, 2) from this laboratory described, *inter alia*, the development and utilization of a new seven-membered ring annulation method which can be summarized in general terms by eq. [1]. Thus, reaction of cyclic β-iodo α,β-unsaturated ketones **1** (3) with a mixture of the lithium



(phenylthio)(2-vinylcyclopropyl)cuprates **2** and **3**, followed by thermal (Cope) rearrangement of the resultant mixture of β-(2-vinylcyclopropyl)enones **4**, provides the annulation products **5**, or, if R = H, **6**.

From a structural point of view, β-iodo enones **1** are vinylogous acyl iodides and, therefore, it is not surprising that these substances react smoothly and efficiently with cuprate reagents such as **2** and **3**. However, on the basis of this line of reasoning, it appeared appropriate to investigate whether or not this type of chemistry could be extended to include a new synthesis of 4-cyclohepten-1-ones **11** via a route outlined in eq. [2]. Explicitly, reaction of a suitable acyl derivative **7** with the cuprate reagents **2** and (or) **3** should provide the ketones **8**. Conversion of the latter materials into appropriate enol derivatives **9** and subsequent thermal rearrangement of the latter materials would, if successfully executed, lead to the cycloheptadienes **10**. Hydrolysis of the enol ether function of **10** would provide the substituted 4-cyclohepten-1-ones **11**. We report herein the results of our studies in this area.[1]



[1]For a preliminary report regarding some of the work outlined herein, see ref. 4. It should be noted that Wender and Filosa (5) have reported the preparation of 2,2,5-trimethyl-4-cyclohepten-1-one (karahanaenone) via a route similar to that outlined in eq. [2], although they did not prepare the requisite 2-vinylcyclopropyl ketone by reaction of an acyl derivative with an appropriate cuprate (cf. **7** + **2**, **3** → **8**).

Results and discussion

(a) *Preparation of the alkyl and cycloalkyl* cis-*2-vinylcyclopropylketones 22–29* (see Chart 1)

The thermal Cope rearrangement of compounds containing a *trans*-divinylcyclopropane system can normally be carried out efficiently by heating these substances at elevated temperatures (usually >160°C). However, it is well known (refs. 6, 7; see also citations given in ref. 1) that the corresponding rearrangement of *cis*-divinylcyclopropane substrates ordinarily occurs under much milder conditions, often at or slightly above ambient temperatures. Because of this fact, and because we wished to be able to characterize synthetic intermediates without resorting to tedious separations of isomeric substances, our initial work was carried out on isomerically pure alkyl and cycloalkyl *cis*-2-vinylcyclopropyl ketones.

CHART 1

The *cis* ketones **22–29** that were used in this work were prepared conveniently by reaction of the cuprate reagent **2** with the corresponding acyl chlorides **14–21**.[2] Thus, treatment of *cis*-1-bromo-2-vinylcyclopropane (**12**)[3] with 1.1–1.4 equivalents of *tert*-butyllithium in dry ether or tetrahydrofuran at −78°C, followed by reaction of the resultant cyclopropyllithium reagent **13** with phenylthiocopper (10) at −20°C, afforded a brown solution of the cuprate **2**. When the latter species was allowed to react (−78°C to room temperature) with each of the acyl chlorides **14–21**, the required ketones **22–29**, respectively, were formed smoothly and, in 7 out of the 8 cases, efficiently. Only the yield (41%) of the benzyl ketone **15** was below 80%. In each case, the ketone could be obtained in high purity (>95%) by simple distillation of the crude product.

(b) *Conversion of the ketones 22–29 into enol silyl ethers and thermal rearrangement of the latter substances* (see Chart 2)

Treatment of the ketone **22** with 1.2 equiv. of lithium diisopropylamide (tetrahydrofuran, −78°C), followed by trapping of the resultant enolate anion with Me_3SiCl, provided the crude enol ether **30**[4] in essentially quantitative yield. In similar fashion, the ketones **23–25** could be transformed smoothly into the ethers **31–33**, respectively. Enol trimethylsilyl ethers are not noted for their stability and, in addition, it was found that substances **30** and **31** rearranged slowly at or slightly above ambient temperatures. Therefore, compounds **30–33** were not purified but were subjected directly to thermolysis (neat, 100–110°C, 30 min). The resultant products **34–37**, respectively, were produced in excellent yields (>85%), could be purified by simple distillation, and were individually characterized. Acid hydrolysis of each of the Cope rearrangement products provided (>84%) the substituted 4-cyclohepten-1-ones **38–41**. Thus, at least with the substrates **22–25**, the initially proposed conversion (see **8** → **11**, eq. [2]) can be effected conveniently and efficiently.

Consecutive treatment of the cyclohexyl ketone **26** with i-Pr_2NLi and *t*-$BuMe_2SiCl$ under conditions similar to those outlined above did not produce cleanly the expected enol ether **42**. Instead, a mixture (~1:1) of **42** and the positional isomer **44**[5] was obtained. Thus, in contrast to the cyclobutyl (**24**) and cyclopentyl (**25**) ketones, kinetic deprotonation of **26** with lithium diisopropylamide resulted in competitive removal of protons H_A and H_B. This unusual result may be due at least partially to the fact that the (axial) proton H_A in **26** is sterically more hindered than the corresponding protons in **24** and **25**. Indeed, it appears that steric factors are of some importance in these reactions since deprotonation of **26** with lithium 2,2,6,6-tetramethylpiperidide (a more hindered base than i-Pr_2NLi) gave, after addition of *t*-$BuMe_2SiCl$, the enol ethers **42** and **44** in a ratio of ~3:7, respectively. Furthermore, when the 3,3-dimethylcyclohexyl ketone **27** (H_A hindered further by an axial methyl group) was subjected to the i-Pr_2NLi–*t*-$BuMe_2SiCl$ sequence, the products **43** and **45** were produced in a ratio of ~1:9, respectively.

It appears, however, that steric influences are not exclusively operative in these deprotonations, since subjection of cyclohexyl cyclopropyl ketone (**46**) to kinetic deprotonation (i-Pr_2NLi) and silylation gave exclusively (81% isolated yield) the enol ether **47**. Thus, the kinetic acidity of H_B in **26** is significantly greater than that of the corresponding proton H_C in **46**, even though the steric environments of these protons are similar. It is known (12) that the kinetic acidity of proton H_D in *cis*-1-acetyl-2-phenylcyclopropane (**48**) is 100 times that of H_E in the corresponding *trans* isomer **49**, a phenomenon which has been attributed to an electronic effect involving conjugation between the phenyl and acetyl groups in the *cis* isomer **48**. Perhaps the vinyl group in **26** exerts an electronic effect similar to that of the phenyl group in **48**, resulting in a relative increase in acidity of H_B (in **26**) compared to that of H_C in **46**.

Thermolysis (150°C, 1 h) of the mixture of **42** and **44** (~1:1) provided, in 81% yield, a mixture of substances consisting mainly of **50** (the product of Cope rearrangement of **42**) and **52** (the product of a "2-vinylmethylenecyclopropane rearrange-

[2]Other functional derivatives of carboxylic acids (e.g. RCOSPh, RCOSePh) can be employed in these reactions. However, in some of the cases in which comparisons were made, superior yields were obtained with acyl chlorides.

[3]Reduction of 1,1-dibromo-2-vinylcyclopropane (8) with tri-*n*-butylstannane (9) or with zinc metal in ether – acetic acid (1) provides mixtures of *cis*- and *trans*-1-bromo-2-vinylcyclopropane (ratios ~7:3 and 4–5:1, respectively). The monobromides can be separated by a combination of fractional distillation and column chromatography (180 g of silica gel/g of mixture, elution with pentane). See also ref. 5.

[4]This material was quite unstable and, therefore, its homogeneity and stereochemistry could not be established. However, it seems likely (ref. 11 and papers cited therein) that this enol ether consisted largely of the *Z* isomer, as shown in the structural formula.

[5]The presence of **44** in the isolated product mixture was indicated by an ir absorption at 1765 cm^{-1}, attributable to the stretching vibration of the exocyclic double bond in **44**, and by the subsequent acquisition of the rearrangement product **52**.

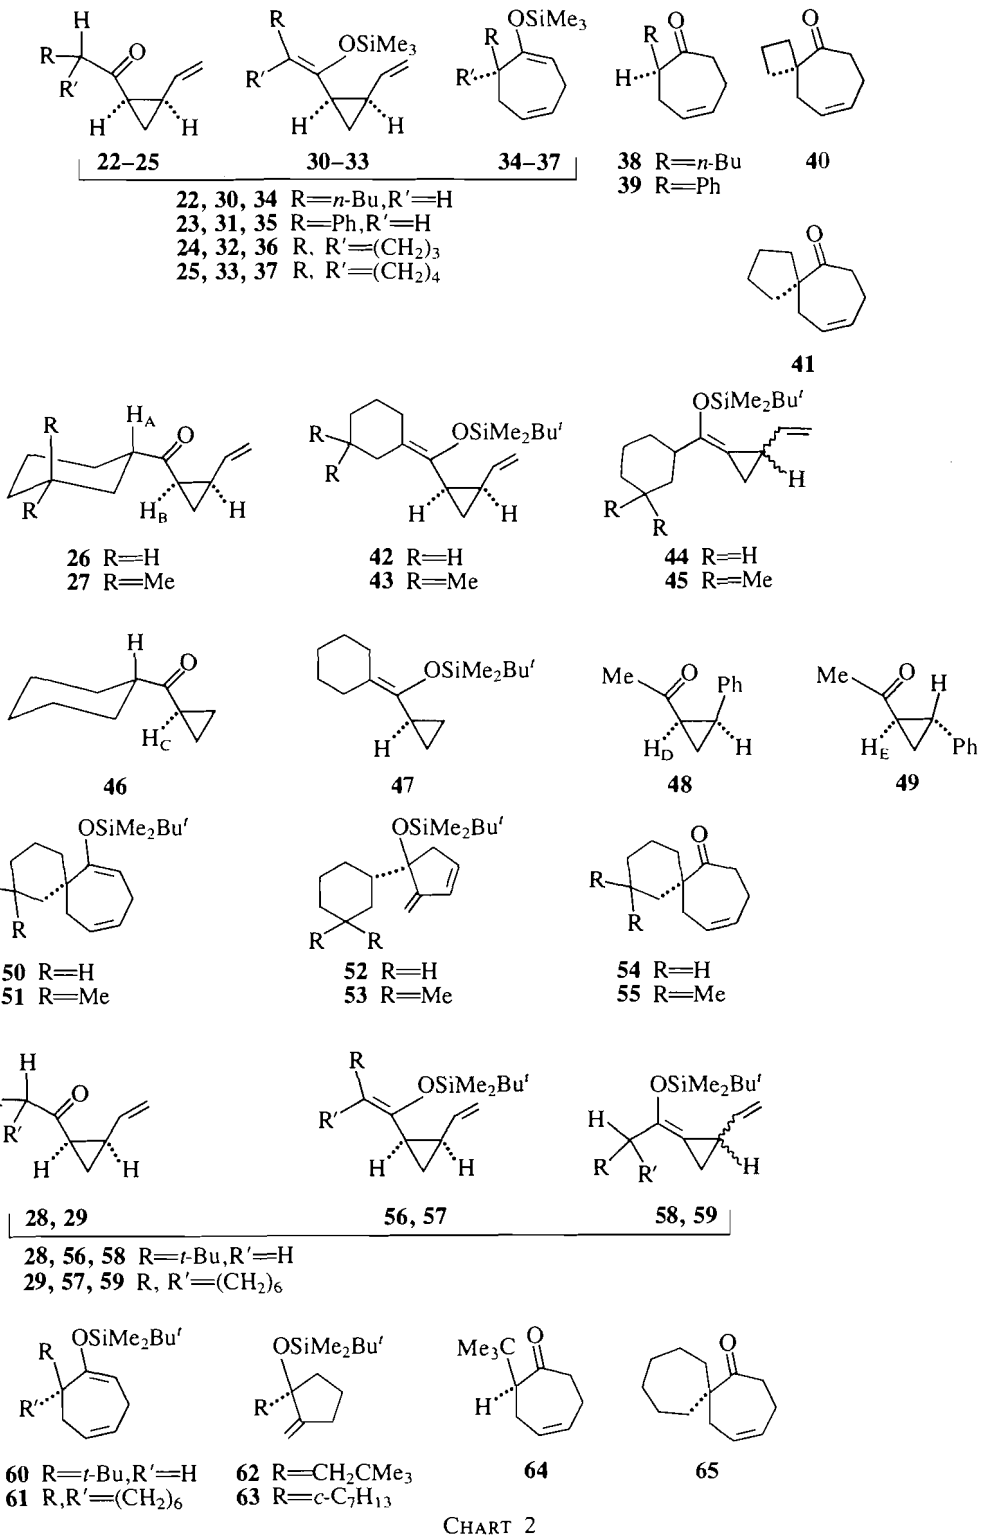

CHART 2

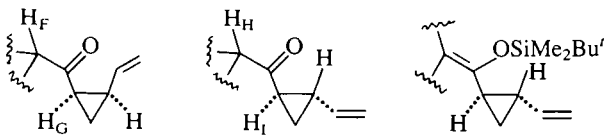
ment"[6] of **44**), in a ratio of about 1:1. When the thermolysis products were treated with 1 *N* hydrochloric acid in tetrahydrofuran, the enol ether **50** was hydrolyzed to the spiro ketone **54**, while **52** remained unchanged. Separation of **54** and **52** was achieved by chromatography and these materials were individually characterized. In similar fashion, thermolysis of the 1:9 mixture of **43** and **45**, followed by acid treatment of the resultant products **51** and **53**, gave a 1:9 mixture of compounds **55** and **53**, from which the latter substance could be isolated in pure form.

Use of the *cis* ketones **28** and **29** as substrates produced results similar to those obtained with **26** and **27**. Thus **28**, upon treatment with i-Pr_2NLi–*t*-$BuMe_2SiCl$, gave the positionally isomeric enol ethers **56** and **58** (ratio ~1:1), while **29** afforded a 4:1 mixture of **57** and **59**, respectively. Thermolysis of these mixtures and treatment of the resultant products (**60**, **62**; **61**, **63**) with aqueous acid produced, in each case, a mixture of the corresponding 4-cyclohepten-1-one (**64**, **65**) and the methyl-

[6]For examples and a discussion of this type of thermal rearrangement, see ref. 13 and papers cited therein.

enecyclopentene (**62**, **63**). The latter mixtures were separated and the substances were individually identified.

The results summarized above make it clear that some alkyl and cycloalkyl *cis*-2-vinylcyclopropyl ketones (e.g. **22–25**) serve as excellent substrates for the synthesis of functionalized 4-cyclohepten-1-ones (e.g. **38–41**) via the reaction sequence originally proposed (eq. [2]). However, other structurally similar ketones (e.g. **26–29**) did not give clean-cut results. Obviously, the difficulties associated with these substrates (general structure **66**) can be traced to the fact that when H_F is quite hindered, kinetically controlled deprotonation results in competitive removal of H_F and H_G. A possible solution to this problem would be to employ pure *trans* ketones (general structure **67**) in the place of the *cis* isomers **66**. In substrates **67**, the cyclopropyl proton H_I is sterically more hindered than H_G in **66** and, in addition, the (possible) acidity-enhancing electronic effect of the vinyl group (*vide supra*) on H_G in **66** would, presumably, be absent in **67**. Therefore, one might expect kinetic deprotonation of **67** to result in clean removal of H_H even in those cases in which this proton is quite hindered. Silylation of the enolate anion thus formed would give the enol ethers **68**.



66 **67** **68**

If the (high temperature) Cope rearrangement of the latter substances were to be clean and efficient, the problem of ultimately producing 4-cyclohepten-1-ones admixed with varying amounts of "unwanted" methylenecyclopentenes (e.g. **52**, **53**, **62**, **63**) will have been eliminated. The results of our experiments with *trans*-2-vinylcyclopropyl ketones are described below.

(c) *Preparation of the alkyl and cycloalkyl* trans*-2-vinylcyclopropyl ketones* ***70–74*** (see Chart 3)

The *trans* ketones **70**, **71**, and **74** were prepared efficiently by reaction of the corresponding acyl chlorides **14**, **18**, and **21** with the isomerically homogeneous cuprate reagent **3**. The latter

species was obtained from *trans*-1-bromo-2-vinylclopropane (**69**).[3] Alternatively, in order to avoid the rather tedious separation of the isomeric 1-bromo-2-vinylcyclopropanes **12** and **69**, the *trans* ketones could be derived by base-catalyzed equilibration of mixtures of *cis* and *trans* ketones. For example, reaction of the chlorides **19** and **20** with mixtures of the cuprate reagents **2** and **3**, followed by treatment of the resultant product mixtures (**27**, **72**; **28**, **73**) with potassium *tert*-butoxide in *tert*-butyl alcohol – tetrahydrofuran provided the *trans* ketones **72** and **73**, respectively. These materials were contaminated with small amounts (~6–7%) of the corresponding *cis* isomers but, from a preparative point of view, this lack of purity did not cause significant difficulties.

(d) *Conversion of the ketones* ***70–74*** *into enol silyl ethers and thermal rearrangement of the latter substances* (see Chart 4)

Treatment of the ketone **70** with i-Pr_2NLi–*t*-$BuMe_2SiCl$ produced, in high yield, the expected enol ether **75**. More importantly, similar reactions involving the substrates **71–74** gave, in each case, exclusively or predominantly the enol ether (**76–79**) resulting from initial removal of the proton H_J. Only in the case of the 3,3-dimethylcyclohexyl ketone **72**, in which removal of H_J is hindered by an axial methyl group, was any of the isomeric enol ether (**45**) formed (~12%).[7] Thus, use of the *trans* ketones as substrates did indeed eliminate largely or completely the problem of competitive deprotonation and the eventual production of mixtures of products.

CHART 4

As expected, Cope rearrangement of the *trans* divinylcyclopropanes **75–79** required temperatures (~230°C) considerably higher than those employed for the thermolysis of the *cis* compounds **30–33**, **42**, **43**, **56**, and **57**. However, in each case, it was gratifying to find that the corresponding cycloheptadiene

[7]Probably about one-half of this amount of **45** was formed from the *cis* ketone **27**, which was a contaminant (~7%) in the sample of **72** employed.

(**80**, **50**, **51**, **60**, **61**) was formed cleanly and efficiently. Acid hydrolysis of the enol ether function of each of these thermolysis products gave the 4-cyclohepten-1-ones **38**, **54**, **55**, **64**, and **65**, respectively.

Conclusion

The overall conversion of the acid chlorides **14–21** into the structurally diverse 4-cyclohepten-1-ones **38–41**, **54**, **55**, **64**, and **65**, respectively, reveals that the initially proposed scheme (eq. [2]) represents a viable method in organic synthesis. The study outlined above showed, however, that the method is more generally successful using alkyl and cycloalkyl *trans*-2-vinylcyclopropyl ketones (e.g. **70–74**) as intermediates rather than the corresponding *cis* ketones.

Experimental

General information

Melting points and distillation temperatures are uncorrected. Ultraviolet (uv) spectra were obtained on methanol solutions using a Cary 15 spectrophotometer. Infrared (ir) spectra were recorded on a Perkin–Elmer model 710B spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were measured on deuterochloroform solutions using a Bruker WP-80 spectrometer or Varian Associates HA-100 or XL-100 spectrometers. Signal positions are given in δ units, with tetramethylsilane as the internal standard. For compounds containing one or more *tert*-butyldimethylsilyl groups, the chemical shifts were measured relative to that of the chloroform proton (δ 7.25). High resolution mass spectra were measured with a Kratos MS-50 mass spectrometer. Gas–liquid chromatography (glc) was carried out with a Hewlett–Packard HP-5832 A gas chromatograph. Microanalyses were performed in the Microanalytical Laboratory at the University of British Columbia.

General procedure A. Preparation of the alkyl and cycloalkyl cis-*(22–29) and* trans-*2-vinylcyclopropyl ketones (70, 71, 74)*

To a cold (−78°C), stirred solution of *cis*- (**12**) or *trans*-1-bromo-2-vinylcyclopropane (**69**) in dry ether or dry tetrahydrofuran (3–4 mL/mmol of **12** or **69**), under an atmosphere of argon, was added, dropwise (syringe), a solution (~1.6 *M*) of *tert*-butyllithium (1.1–1.4 equiv.) in pentane, and the resulting solution was stirred at −78°C for 2 h. Solid phenylthiocopper (1 equiv.) was added, the resulting slurry was diluted with dry tetrahydrofuran (~5 mL/mmol of **12** or **69**), was allowed to warm to −20°C, was stirred at this temperature for 30 min, and was then recooled to −78°C. To the resulting clear, brown solution was added the appropriate acyl chloride (0.66 equiv.) and the reaction mixture was stirred at −78°C for 10 min, at −20°C for 1 h, and at room temperature for 1 h. The solution was treated with saturated aqueous ammonium chloride and ether (~0.25 mL and 10 mL/mmol of **12** or **69**, respectively). The mixture (a precipitate formed) was stirred for 20 min, was treated with anhydrous magnesium sulfate, and was then filtered through a column of Florisil (3 cm) layered over anhydrous magnesium sulfate (3 cm). The column was washed thoroughly with ether. Removal of the solvent from the combined filtrate gave an oil, which, upon distillation under reduced pressure, afforded the *cis*- or *trans*-2-vinylcyclopropyl ketone.

The following compounds were prepared by means of this procedure.

n-*Pentyl* cis-*2-vinylcyclopropyl ketone (22)*

From 73 mg (0.54 mmol) of hexanoyl chloride (**14**) there was obtained 78.5 mg (87%) of **22**; distillation temperaature 90–100°C/12 Torr (1 Torr = 133.3 Pa); ir(film): 3090, 3020, 1700, 1620 cm^{-1}; ^{1}H nmr δ: 0.75–2.4 (diffuse m, 13H), 2.50 (t, 2H, J = 7 Hz), 4.9–5.3 (8-line m, 2H), 5.48–5.9 (8-line m, 1H). *Anal.* calcd. for $C_{11}H_{18}O$: C 79.46, H 10.91; found: C 79.60, H 11.00.

Benzyl cis-*2-vinylcyclopropyl ketone (23)*

From 169 mg (1.09 mmol) of phenylethanoyl chloride (**15**) there was obtained 84 mg (41%) of **23**; distillation temperature 70–80°C/0.1 Torr; ir(film): 1695, 1640, 1605, 1500 cm^{-1}; ^{1}H nmr δ: 0.98–1.48 (m, 2H), 1.70–2.36 (m, 2H), 3.68 (s, 2H), 4.82–5.18 (6-line m, 2H), 5.4–5.8 (8-line m, 1H), 7.02–7.46 (m, 5H), *Anal.* calcd. for $C_{13}H_{14}O$: C 83.83, H 7.58; found: C 83.66, H 7.77.

Cyclobutyl cis-*2-vinylcyclopropyl ketone (24)*

From 155 mg (1.31 mmol) of the acyl chloride **16** there was obtained 182 mg (93%) of **24**; distillation temperature 100–110°C/12 Torr; ir(film): 3100, 1690, 1635 cm^{-1}; ^{1}H nmr δ: 0.8–1.5 (m, 2H), 1.55–2.4 (m, 8H), 3.12–3.5 (m, 1H), 4.82–5.26 (8-line m, 2H), 5.44–5.86 (8-line m, 1H). *Anal.* calcd. for $C_{10}H_{14}O$: C 80.01, H 9.40; found: C 79.70, H 9.33.

Cyclopentyl cis-*2-vinylcyclopropyl ketone (25)*

From 60 mg (0.45 mmol) of the acyl chloride **17** there was obtained 62.4 mg (85%) of **25**; distillation temperature 110–120°C/12 Torr; ir(film): 3100, 1695, 1635 cm^{-1}; ^{1}H nmr δ: 1.02–2.42 (m, 12H), 2.78–3.12 (m, 1H), 4.82–5.24 (8-line m, 2H), 5.40–5.82 (8-line m, 1H). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1204.

Cyclohexyl cis-*2-vinylcyclopropyl ketone (26)*

From 233 mg (1.59 mmol) of the acyl chloride **18** there was obtained 231 mg (82%) of **26**; distillation temperature 120–140°C/12 Torr; ir(film): 3090, 3020, 1690, 1640 cm^{-1}; ^{1}H nmr δ: 0.84–2.64 (m, 15H), 4.84–5.26 (8-line m, 2H), 5.42–5.84 (8-line m, 1H). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 80.76, H 10.19.

3,3-Dimethylcyclohexyl cis-*2-vinylcyclopropyl ketone (27)*

From 895 mg (5.51 mmol) of the acyl chloride **19** there was obtained 922 mg (87%) of **27**; distillation temperature 90–95°C/0.25 Torr; ir(film): 3060, 2990, 1690, 1630 cm^{-1}; ^{1}H nmr δ: 0.94 (s, 6H), 1.0–2.82 (m, 13H), 4.9–5.3 (m, 8 lines, 2H), 5.45–5.87 (m, 1H). *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1670; found: 206.1669.

Neopentyl cis-*2-vinylcyclopropyl ketone (28)*

From 179 mg (1.33 mmol) of 3,3-dimethylbutanoyl chloride (**20**) there was obtained 218 mg (88%) of **28**; distillation temperature 80–90°C/12 Torr; ir(film): 3075, 1695, 1640 cm^{-1}; ^{1}H nmr δ: 0.95–1.5 (m, 2H), 1.03 (s, 9H), 1.82–2.4 (m, 2H), 2.44 (s, 2H), 4.92–5.32 (8-line m, 2H), 5.56–5.96 (8-line m, 1H). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1357; found: 166.1359.

Cycloheptyl cis-*2-vinylcyclopropyl ketone (29)*

From 75 mg (0.47 mmol) of the acyl chloride **21** there was obtained 73 mg (81%) of **29**; distillation temperature 70–80°C/0.1 Torr; ir(film): 3075, 3005, 1695, 1635 cm^{-1}; ^{1}H nmr δ: 0.82–2.4 (m, 16H), 2.42–2.76 (broad unresolved m, 1H), 4.84–5.24 (8-line m, 2H), 5.44–5.86 (8-line m, 1H). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1515; found. 192.1518.

n-*Pentyl* trans-*2-vinylcyclopropyl ketone (70)*

From 99 mg (0.74 mmol) of hexanoyl chloride (**14**) there was obtained 105 mg (86%) of **70**; distillation temperature 100–110°C/12 Torr; ir(film): 3080, 3000, 1695, 1640 cm^{-1}; ^{1}H nmr δ: 0.8–2.1 (diffuse m, 13H), 2.55 (t, 2H, J = 7 Hz), 4.9–5.66 (m, 3H). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1357; found: 166.1355.

Cyclohexyl trans-*2-vinylcyclopropyl ketone (71)*

From 76 mg (0.52 mmol) of the acyl chloride **18** there was obtained 84 mg (91%) of **71**; distillation temperature 110–120°C/12 Torr; ir(film): 3080, 3000, 1695, 1640 cm^{-1}; ^{1}H nmr δ: 0.8–21. (diffuse m, 14H), 2.3–2.65 (m, 1H), 4.84–5.64 (m, 3H). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 80.99, H 10.24.

Cycloheptyl trans-*2-vinylcyclopropyl ketone (74)*

From 278 mg (1.74 mmol) of the acyl chloride **21** there was obtained 236 mg (71%) of **74**; distillation temperature 65–75°C/0.1 Torr; ir(film): 3080, 3000, 1690, 1640 cm^{-1}; ^{1}H nmr δ: 0.84–1.08 (m, 1H), 1.32–2.10 (m, 15H), 2.50–2.84 (m, 1H), 4.90–5.68 (m, 3H). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1515; found: 192.1520.

Preparation of 3,3-dimethylcyclohexyl (72) and neopentyl trans-*2-vinylcyclopropyl ketone (73)*

Reaction of the acyl chloride **19** (200 mg, 1.15 mmol) with 1.5 equiv. of a 1:1 mixture of the cuprate reagents **2** and **3**, via a procedure very similar to that described above, gave 174 mg (73%) of a mixture of the ketones **27** and **72** (~1:1). Similarly, treatment of 3,3-dimethyl-

butanoyl chloride (**20**) (430 mg, 3.19 mmol) with 1.5 equiv. of a mixture of **2** and **3** (~4.2:1, respectively) afforded 469 mg (90%) of a mixture of the ketones **28** and **73** (~3:1, respectively).

A solution of the 1:1 mixture of **27** and **72** (87 mg, 0.42 mmol) and potassium *tert*-butoxide (71 mg, 0.63 mmol) in 3 mL of dry tetrahydrofuran and 3 mL of dry *tert*-butyl alcohol was stirred at room temperature, under an atmosphere of argon, for 3 h. The reaction mixture was acidified by addition of dilute hydrochloric acid and the resultant mixture was extracted thoroughly with hexanes. The combined extract was washed with dilute aqueous sodium bicarbonate and brine, dried ($MgSO_4$), and concentrated. Distillation (90–100°C/0.25 Torr) of the residual oil gave 80 mg (92%) of a colorless oil that consisted of a mixture of the ketones **27** and **72** in a ratio of ~7:93, respectively. This material exhibited ir(film): 3060, 2990, 1690, 1630 cm^{-1}; ^1H nmr δ: 0.94 (s, 6H), 1.0–2.14 (complex m, 12H), 2.48–2.86 (m, 1H), 4.90–5.70 (m, 3H). *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1670; found: 206.1667.

A solution of the 3:1 mixture of **28** and **73** (380 mg, 2.32 mmol) and potassium *tert*-butoxide (104 mg, 0.93 mmol) in 3 mL of dry tetrahydrofuran and 0.5 mL of dry *tert*-butyl alcohol was stirred at room temperature, under an atmosphere of argon, for 23 h. Work-up as described above and distillation (80–90°C/12 Torr) of the crude product gave 197 mg (52%) of a colorless oil that consisted of a 6:94 mixture of the ketones **28** and **73**, respectively. This material exhibited ir(film): 3080, 1690, 1640 cm^{-1}; ^1H nmr δ: 0.9–1.55 (m, 2H), 1.05 (s, 9H), 1.86–2.12 (m, 2H), 2.48 (s, 2H), 4.90–5.68 (m, 3H). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1357; found: 166.1356.

General procedure B. Conversion of the cis*-2-vinylcyclopropyl ketones 22–25 into the cycloheptadienes 34–37*

To a cold (−78°C), stirred solution of lithium diisopropylamide (1.3–1.5 mmol/mmol of ketone) in dry tetrahydrofuran (3 mL/mmol of base), under an atmosphere of argon, was added slowly a solution of the ketone (**22–25**) in dry tetrahydrofuran (2 mL/mmol of ketone), and the resultant solution was stirred at −78°C for 1 h.

A quenching solution was prepared as follows. To a solution of trimethylsilyl chloride (~0.3 mL) in dry tetrahydrofuran (~1 mL) was added dry triethylamine (~0.2 mL). The mixture was stirred (argon atmosphere) for a few minutes and then was centrifuged. The solution above the solid material was used to trap the enolate anions.

Freshly prepared quenching solution (~1.2 mL/mmol of ketone) was added to the cold (−78°C) enolate anion solution and the mixture was stirred at −78°C for 15 min and then at room temperature for ~1 h. The mixture was partitioned between saturated aqueous sodium bicarbonate and pentane (~10 mL and 20 mL/mmol of ketone, respectively) and the aqueous phase was washed twice with pentane. The combined extract was washed with brine, dried (Na_2SO_4), and concentrated. The enol silyl ethers **30–33** thus obtained as yellow oils in essentially quantitative yields exhibited no ir carbonyl absorption and, since they were quite unstable, these substances were not purified further.

Thermolysis (neat, argon atmosphere, 100–110°C, 30 min) of the yellow oils, followed by bulb-to-bulb distillation of the resultant materials, provided the cycloheptadienes **34–37** as colorless oils.

*7-*n*-Butyl-1-trimethylsiloxy-1,4-cycloheptadiene (34)*

From 94 mg (0.57 mmol) of the ketone **22** there was obtained 119 mg (88%) of **34**; distillation temperature 120–130°C/12 Torr; ir(film): 1660, 1260, 840 cm^{-1}; ^1H nmr δ: 0.13 (s, 9H), 0.74–2.94 (diffuse multiplets, 14H), 4.81 (t, 1H, J = 5.5 Hz), 5.5–5.9 (m, 2H). *Exact Mass* calcd. for $C_{14}H_{26}OSi$: 238.1753; found: 238.1747.

7-Phenyl-1-trimethylsiloxy-1,4-cycloheptadiene (35)

From 92 mg (0.49 mmol) of the ketone **23** there was obtained 107 mg (85%) of **35**; distillation temperature 85–95°C/0.1 Torr; ir(film): 1655, 1600, 1495, 1250, 840 cm^{-1}; ^1H nmr δ: ~0 (s, 9H), 2.2–3.0 (m, 4H), 3.1–3.7 (m, 1H), 5.0 (t, 1H, J = 5.5 Hz), 5.3–6.2 (m, 2H), 7.1–7.5 (m, 5H). *Exact Mass* calcd. for $C_{16}H_{22}OSi$: 258.1440; found: 258.1448.

5-(Trimethylsiloxy)spiro[3.6]deca-5,8-diene (36)

From 120 mg (0.8 mmol) of the ketone **24** there was obtained 155 mg (87%) of **36**; distillation temperature 95–105°C/12 Torr; ir(film): 1660, 1645, 1250, 840 cm^{-1}; ^1H nmr δ: 0.19 (s, 9H), 1.54–2.74 (m, 10H), 4.82 (t, 1H, J = 6 Hz), 5.7–5.9 (m, 2H). *Exact Mass* calcd. for $C_{13}H_{22}OSi$: 222.1434; found: 222.1442.

6-(Trimethylsiloxy)spiro[4.6]undeca-6,9-diene (37)

From 68 mg (0.42 mmol) of the ketone **25** there was obtained 94 mg (96%) of **37**; distillation temperature 110–120°C/12 Torr; ir(film): 1650, 1250, 840 cm^{-1}; ^1H nmr δ: 0.17 (s, 6H), 1.1–2.1 (m, 8H), 2.22 (d, 2H, J = 6 Hz), 2.70 (t, 2H, J = 6 Hz), 4.84 (t, 1H, J = 6 Hz), 5.6–6.25 (m, 2H). *Exact Mass* calcd. for $C_{14}H_{24}OSi$: 236.1597; found: 236.1590.

General procedure C. Conversion of the trans*-2-vinylcyclopropyl ketones 70–74 into the cycloheptadienes 80, 50, 51, 60, 61*

To a cold (−78°C), stirred solution of lithium diisopropylamide (1.4–1.5 mmol/mmol of ketone) in dry tetrahydrofuran (4 mL/mmol of base), under an atmosphere of argon, was added slowly a solution of the ketone (**70–74**) in dry tetrahydrofuran (1 mL/mmol of ketone), and the resultant solution was stirred at −78°C for 45 min. A solution of freshly sublimed *tert*-butyldimethylsilyl chloride (1.6 mmol/mmol of ketone) in dry tetrahydrofuran (1 mL/mmol of chloride) was added, followed by dry hexamethylphosphoramide (0.5 mL/mmol of ketone). After the solution had been stirred at −78°C for 15 min and at room temperature for 2–3 h, it was partitioned between saturated aqueous sodium bicarbonate and pentane (~10 mL and 20 mL/mmol of ketone, respectively). The aqueous phase was washed twice with pentane. The combined extract was washed four times with saturated aqueous sodium bicarbonate, twice with brine, and dried ($MgSO_4$). Removal of the solvent, followed by bulb-to-bulb distillation of the remaining oil, gave the corresponding enol silyl ether (**75–79**)[8] as a colorless oil that exhibited no ir carbonyl stretching absorption.

Thermolysis of **75–79** was accomplished by heating (neat, argon atmosphere) these substances at 230°C (air-bath temperature) for 30–60 min. Direct distillation of the resultant materials provided the cycloheptadienes **80**, **50**, **51**, **60**, and **61**, respectively, as clear colorless oils.

*7-*n*-Butyl-1-*tert*-butyldimethylsiloxy-1,4-cycloheptadiene (80)*

From 197 mg (1.19 mmol) of the ketone **70** there was obtained 282 mg (85%) of **80**; distillation temperature 140–150°C/12 Torr; ir(film): 1660, 1260, 840 cm^{-1}; ^1H nmr δ: 0.09, (s, 6H), 0.88 (s, 9H), 0.70–2.95 (series of m, 14H), 4.80 (t, 1H, J = 5.5 Hz), 5.5–5.9 (m, 2H). *Exact Mass* calcd. for $C_{17}H_{32}OSi$: 280.2222; found: 280.2228.

7-(tert-Butyldimethylsiloxy)spiro[5.6]dodeca-7,10-diene (50)

From 176 mg (0.99 mmol) of the ketone **71** there was obtained 210 mg (74%) of **50**; distillation temperature 100–110°C/0.1 Torr; ir(film): 1640, 1250, 840 cm^{-1}; ^1H nmr δ: 0.12 (s, 6H) 0.94 (s, 9H), 1.15–1.95 (m, 10H), 2.30 (d, 2H, J = 6.5 Hz), 2.64 (t, 2H, J = 6.0 Hz), 4.76 (t, 1H, J = 6.0 Hz), 5.6–6.1 (m, 2H). *Anal.* calcd. for $C_{18}H_{32}OSi$: C 73.90, H 11.03; found: C 74.21, H 11.30. *Exact Mass* calcd.: 292.2222; found: 292.2226.

2,2-Dimethyl-7-(tert-butyldimethylsiloxy)spiro[5.6]dodeca-7,10-diene (51)

From 84 mg (0.41 mmol) of the ketone **72** (this material contained ~7% of the *cis* ketone **27**) there was obtained 78 mg (60%) of **51**, which contained ~12% of the methylenecyclopentene **53**; distillation temperature 110–120°C/0.35 Torr; ir(film): 1630, 1255, 850 cm^{-1}; ^1H nmr δ: 0.17, 0.19 (s, s), 0.75–1.00 (series of s), 1.01–2.75 (series of m), 4.72 (t, 1H), 5.60–5.86 (m, 2H).

*7-*tert*-Butyl-1-*tert*-butyldimethylsiloxy-1,4-cycloheptadiene (60)*

From 188 mg (1.15 mmol) of the ketone **73** (this material contained ~6% of the *cis* ketone **28**) there was obtained 267 mg (83%) of **60**; distillation temperature 140–150°C/12 Torr; ir(film): 1670, 1250, 840 cm^{-1}; ^1H nmr δ: 0.10, 0.12 (s, s, 3H each), 0.89, 0.99 (s, s, 9H each), 2.16–2.54 (m, 3H), 2.6–2.9 (m, 2H), 4.89 (t, 1H, J = 5.5 Hz), 5.36–5.82 (m, 2H). *Exact Mass* calcd. for $C_{17}H_{32}OSi$; 280.2222; found: 280.2226.

[8]The enol silyl ether **77** was accompanied by a small amount (~12%) of the isomeric enol ether **45**.

*1-(*tert*-Butyldimethylsiloxy)spiro[6.6]trideca-1,4-diene (**61**)*

From 186 mg (0.97 mmol) of the ketone **74** there was obtained 272 mg (91%) of **61**; distillation temperature 100–110°C/0.1 Torr; ir(film): 1665, 1260, 840 cm^{-1}; ^1H nmr δ: 0.10 (s, 6H), 0.90 (s, 9H), 1.22–2.08 (m, 12H), 2.29 (d, 2H, J = 6.5 Hz), 2.59 (t, 2H, J = 5.5 Hz), 4.62 (t, 1H, J = 5.5 Hz), 5.6–6.1 (m, 2H). *Exact Mass* calcd. for $C_{19}H_{34}OSi$: 306.2379; found: 306.2372.

*General procedure D. Hydrolysis of the enol silyl ethers **34** (**80**), **35–37**, **50**, **51**, **60**, **61** to the 4-cyclohepten-1-ones **38–41**, **54**, **55**, **64**, **65***

To a solution of the enol silyl ether in methanol or tetrahydrofuran (~10 mL/mmol of substrate) was added 1 *N* hydrochloric acid (~3 mL/mmol of substrate) and the resultant mixture was stirred, under an atmosphere of argon, at room temperature for 1–3 h. The reaction mixture was made basic by careful addition of cold saturated aqueous sodium bicarbonate and then was extracted thoroughly with pentane. The combined extract was washed with brine and dried ($MgSO_4$). Removal of the solvent, followed by bulb-to-bulb distillation of the residual material, provided the corresponding 4-cyclohepten-1-one as a colorless oil.

*2-*n*-Butyl-4-cyclohepten-1-one (**38**)*

From 97 mg (0.41 mmol) of the trimethylsilyl enol ether **34** there was obtained 58 mg (85%) of the ketone **38**. Alternatively, acid hydrolysis of the *tert*-butyldimethylsilyl enol ether **80** (87 mg, 0.31 mmol) gave 41 mg (80%) of **38**; distillation temperature 100–110°C/12 Torr; ir(film): 1705, 1660 cm^{-1}; ^1H nmr δ: 0.89 (br t, 3H, J = 6 Hz), 1.08–2.0 (m, 6H), 2.0–3.0 (m, 7H), 5.6–5.86 (m, 2H). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1366.

*2-Phenyl-4-cyclohepten-1-one (**39**)*

From 85 mg (0.33 mmol) of compound **35** there was obtained 51 mg (84%) of the ketone **39**; distillation temperature 95–105°C/0.1 Torr; ir(film): 1695, 1660, 1605, 1500 cm^{-1}; ^1H nmr δ: 2.2–3.1 (m, 6H, 4.00 (d of d, 1H, J =4.5, 10.5 Hz), 5.72–5.88 (m, 2H), 7.08–7.44 (m, 5H). *Anal.* calcd. for $C_{13}H_{14}O$: C 83.83, H 7.58; found: C 84.00, H 7.58.

*Spiro[3.6]dec-8-en-5-one (**40**)*

From 55 mg (0.25 mmol) of the enol ether **36** there was obtained 34 mg (91%) of the ketone **40**; distillation temperature 100–110°C/12 Torr; ir(film): 1700, 1660 cm^{-1}; ^1H nmr δ; 0.82–2.84 (series of m, 12H), 5.7–5.94 (m, 2H). *Anal.* calcd. for $C_{10}H_{14}O$: C 80.01, H 9.40; found: C 79.75, H 9.30.

*Spiro[4.6]undec-9-en-6-one (**41**)*

From 36 mg (0.15 mmol) of the trimethylsilyl enol ether **37** there was obtained 21 mg (85%) of the ketone **41**; distillation temperature 100–110°C/12 Torr; ir(film): 1695 cm^{-1}; ^1H nmr δ: 1.3–2.84 (series of m, 14H), 5.48–5.84 (m, 2H). *Anal.* calcd. for $C_{11}H_{16}O$: C 80.44, H 9.82; found: C 80.10, H 9.83.

*Spiro[5.6]dodec-10-en-7-one (**54**)*

From 92 mg (0.31 mmol) of the enol silyl ether **50** there was obtained 46 mg (84%) of the ketone **54**; distillation temperature 70–80°C/ 0.1 Torr; ir(film): 1700, 1650 cm^{-1}; ^1H nmr δ: 1.16–1.74 (series of m, 14H), 5.64–5.80 (m, 2H). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 81.10, H 10.30.

*2,2-Dimethylspiro[5.6]dodec-10-en-7-one (**55**)*

From 70 mg (0.22 mmol) of the enol silyl ether **51** (this material contained ~12% of **53**) there was obtained 33 mg (73%) of an oil (distillation temperature 95–105°C/0.25 Torr) that consisted of the ketone **55** and the methylenecyclopentene **53** (ratio ~87:13). A sample of **55**, obtained from this mixture by column chromatography on silica gel (elution with 1:7 ether – petroleum ether), exhibited ir(film): 1690, 1640 cm^{-1}; ^1H nmr δ: 0.76 (s, 3H), 0.91 (s, 3H), 0.9–2.45 (series of m, 13H), 2.78–2.88 (m, 1H), 5.72–5.84 (m, 1H), 5.86–5.97 (m, 1H). *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1670; found: 206.1683.

*2-*tert*-Butyl-4-cyclohepten-1-one (**64**)*

From 206 mg (0.74 mmol) of the *tert*-butyldimethylsilyl enol ether **60** there was obtained 108 mg (88%) of the ketone **64**; distillation temperature 110–120°C/12 Torr; ir(film): 1705, 1660 cm^{-1}; ^1H nmr δ: 0.94 (s, 9H), 2.1–3.14 (m, 7H), 5.4–5.86 (m, 2H). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1362.

*Spiro[6.6]tridec-4-en-1-one (**65**)*

From 75 mg (0.24 mmol) of compound **61** there was obtained 34 mg (73%) of the ketone **65**; distillation temperature 80–90°C/0.1 Torr; ir(film): 1700, 1650 cm^{-1}; ^1H nmr δ: 1.1–2.9 (series of m, 18H), 5.44–5.84 (m, 2H). *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1505.

Subjection of the cis*-2-vinylcyclopropyl ketones **26–29** to the sequence (a) LiN(i-Pr)$_2$–t-BuMe$_2$SiCl, (b) thermolysis, and (c) 1 N hydrochloric acid in tetrahydrofuran. Characterization of the dienes **52**, **53**, **62**, **63***

Deprotonation of each of the ketones **26–29** with lithium diisopropylamide, followed by reaction of the resultant mixtures of enolate anions with *tert*-butyldimethylsilyl chloride, was accomplished as described in general procedure C. From **26** there was obtained a mixture consisting mainly of the enol silyl ethers **42** and **44** (ratio ~1:1); **27** produced primarily compounds **43** and **45** (ratio ~1:9); **28** gave **56** and **58** (ratio ~1:1); **29** afforded **57** and **59** (ratio ~4:1). The yields were >85%. In each case, the product mixture exhibited an ir absorption at ~1765 cm^{-1}, attributable to the stretching vibration of the exocyclic double bond in compounds **44**, **45**, **58**, and **59**.

Thermolysis (**42**, **44**: neat, 150°C, 1 h; **43**, **45**: neat, 160°C, 45 min; **56**, **58**: neat, 175°C, 1 h; **57**, **59**: neat, 150°C, 1 h) of each of these mixtures, followed by bulb-to-bulb distillation of the resultant oils, provided (>80%) the corresponding rearrangement products **50**, **52**; **51**, **53**; **60**, **62**; **61**, **63**. In each case, the product ratio was close to that of the starting materials. Treatment of the mixtures of rearrangement products with 1 *N* hydrochloric acid in tetrahydrofuran as described in general prodedure D gave, in each case, a mixture of the corresponding 4-cyclohepten-1-one (**54**, **55**, **64**, **65**) and the unchanged methylenecyclopentene (**52**, **53**, **62**, **63**).

Compounds **54** (which showed spectra identical with those summarized previously) and **52** were separated by preparative tlc. The latter substance (distillation temperature 100–110°C/0.1 Torr) exhibited ir(film): 1635, 1250, 840 cm^{-1}; uv(MeOH): 231 nm (log ε 4.12); ^1H nmr δ: −0.05 (s, 6H), 0.84 (s, 9H), 0.9–2.15 (m, 11H), 2.36 (d of t, 1H, J = 18, 2 Hz), 2.65 (d of t, 1H, J = 18, 2 Hz), 4.90 (br s, 1H), 5.04 (s, 1H), 5.85–6.03 (m, 1H), 6.06–6.20 (m, 1H). *Exact Mass* calcd. for $C_{18}H_{32}OSi$: 292.2222; found: 292.2226.

Column chromatography (silica gel) of the 9:1 mixture of **53** and **55** gave a sample of the diene **53** (distillation temperature 95–105°C/0.1 Torr) which exhibited ir(film): 1630, 1250, 840 cm^{-1}; uv (MeOH): 232 nm (log ε 4.07); ^1H nmr δ: −0.07 (s, 6H), 0.80 (s, 3H), 0.82 (s, 9H), 0.88 (s, 3H), 1.05–2.75 (m, 11H), 4.88 (br s, 1H), 5.02 (s, 1H), 5.84–5.98 (m, 1H), 6.02–6.20 (m, 1H). *Exact Mass* calcd. for $C_{20}H_{36}OSi$: 320.2535; found: 320.2514.

Compounds **64** (spectral data identical with those given above) and **62** were separated by column chromatography on Florisil. The diene **62** (distillation temperature 120–130°C/12 Torr) exhibited ir(film): 1640, 1260, 840 cm^{-1}; uv (MeOH): 237 nm (log ε 4.05); ^1H nmr δ: −0.07, −0.05 (s, s, 3H each), 0.83, 1.01 (s, s, 9H each), 1.31 (d, 1H, J = 15 Hz), 1.75 (d, 1H, J = 15 Hz), 2.54 (d of t, 1H, J = 19, 2 Hz), 2.90 (d of t, J = 19, 2 Hz), 4.93 (br s, 1H), 4.99 (s, 1H), 5.84–6.02 (m, 1H), 6.06–6.22 (m, 1H). *Exact Mass* calcd. for $C_{17}H_{32}OSi$: 280.2222; found: 278.2225.

Compounds **65** (spectra identical with those given above) and **63** were separated by column chromatography on Florisil. The diene **63** (distillation temperature 100–110°C/0.1 Torr) exhibited ir(film): 1640, 1250, 830 cm^{-1}; uv (MeOH): 233 nm (log ε 3.95); ^1H nmr δ: −0.06 (s, 6H), 0.84 (s, 9H), 1.12–2.14 (m, 13H), 2.33 (d of t, 1H, J = 18, 2 Hz), 2.59 (d of t, 1H, J = 18, 2 Hz), 4.90 (br s, 1H), 5.03 (s, 1H), 5.88–6.06 (m, 1H), 6.08–6.26 (m, 1H). *Exact Mass* calcd. for $C_{19}H_{34}OSi$: 306.2378; found: 306.2382.

The zero-field ODMR of triplet state of chlorophyll *b* in n-octane has been carried out. The ODMR parameters measured at various fluorescence wavelengths suggest that Chl *b* is probably present in more than two ligated species in which water serves as the ligand.

S. HOTCHANDANI, R. H. CLARKE et R. M. LEBLANC. Can. J. Chem. **64**, 188 (1986).

Les études de ODMR au champ zéro d'état triplet de Chl *b* dans le n-octane ont été faites. Les paramètres ODMR mesurés à différentes longueurs d'ondes de fluorescence suggèrent que la Chl *b* existe sous la forme de plus de deux types de complexes où l'eau agit comme ligand.

Introduction

Recently, we reported the ligand effects on chlorophyll *a* (Chl *a*) in n-octane by zero-field optical detection of magnetic resonance (ODMR) of its triplet state (1). From the ODMR parameters, namely the zero-field splitting (ZFS) parameters and rate constants for the decay of first triplet to ground state measured at various fluorescence detection wavelengths (excited with 457.9 nm and 514.5 nm argon-ion laser lines), we showed that Chl *a* exists in two distinct monomeric species. These species were assigned to the mono- and biligated chlorophyll monomer in which water served as the ligand coordinated to the magnesium metal center. The molecule chlorophyll *b* (Chl *b*) also plays an important role in photosynthesis and possesses an aldehyde group instead of a methyl group in Chl *a* (2). The ligand effects on Chl *b* are thus worth examining.

The Chl *b* – ligand (water) interaction has been studied by Ballschmiter and Katz (3) and by Cotton *et al.* (4) by ir and electronic spectroscopic methods. Recently, Chapados and Leblanc (5) using ir technique have discussed the effect of water on Chl *a* and Chl *b* mono- and multilayer arrays. The presence of various ligated species was, however, not discussed in the above studies. Since the ZFS parameters of the triplet state are quite sensitive to the local interactions, the ODMR technique provides a suitable means for probing particularly the subtle ligand substitution differences in triplet state. Preliminary results on the zero-field ODMR of Chl *b* in n-octane have been reported by Clarke and Hofeldt (6); the ODMR experiments were carried out at only one wavelength (fluorescence maximum) and excited only with 457.9 nm argon-ion laser line. We present in this article the zero-field ODMR study of Chl *b* in n-octane at 2 K carried out at various fluorescence detection wavelengths and excited with 457.9 nm and 514.5 nm laser lines to examine the ligand effect on Chl *b* triplet state.

Materials and methods

Chlorophyll *b* was obtained from Sigma Chemical Co. and was used without further purification. The solvent n-octane (Gold Label, Aldrich Chemical Co.) was distilled once and did not show any emission in the region of Chl *b* fluorescence. The concentration of solutions used in these experiments were kept in the range of $\sim 10^{-6}$ *M*.

The zero-field ODMR experiments at 2 K were performed as described by Clarke and Hofeldt (6). The overall intersystem crossing rate constants (k_{dT}) for decay from the lowest triplet state to ground state were measured at 77 K by method of Avarmaa (7). The excitation of samples was achieved by irradiation with 457.9 or 514.5 nm lines of an argon-ion laser (Spectra Physics Model 164).

Results

(a) Fluorescence

When light from an argon-ion laser is used to excite a frozen solution of Chl *b* (not rigorously dried) in n-octane, fluorescence maximum is found to be dependent upon wavelength of excitation. For example, as shown in Fig. 1, the 514.5 nm excitation line produces fluorescence maximum at 659 nm whereas the 457.9 nm laser line produces maximum at 649 nm with a shoulder at 659 nm. The fluorescence maximum at 649 nm ($\lambda_{exc} = 457.9$ nm) is in agreement with the results of Clarke and Hofeldt (6) and is characteristic of Chl *b* monomers. All fluorescence spectra also show a band at ~710 nm, the origin of which is not yet well established but could be due to the water-linked Chl *b* dimer.

(b) ODMR frequencies

Figures 2 and 3 show the zero-field fluorescence detected ODMR spectra of Chl *b* in n-octane at 2 K recorded at various fluorescence detection wavelengths when excited with 457.9 and 514.5 nm laser lines.

It is seen from Fig. 2 ($\lambda_{exc} = 457.9$ nm) that at detection wavelengths 640 and 649 nm, two quite intense and well-resolved transitions, namely $|D| - |E|$ and $|D| + |E|$, both corresponding to microwave-induced decrease in fluorescence intensity, are clearly visible at 870 ± 10 and 1080 ± 10 MHz. These frequencies are consistent with the earlier results of Clarke and Hofeldt (6). As one moves to longer detection wavelengths, these ODMR transitions become less intense but appear at the same frequencies.

For excitation with 514.5 nm (Fig. 3), similar to $\lambda_{exc} =$ 457.9 nm, two transitions, leading to microwave-induced decrease in fluorescence intensity, at 870 and 1080 MHz are

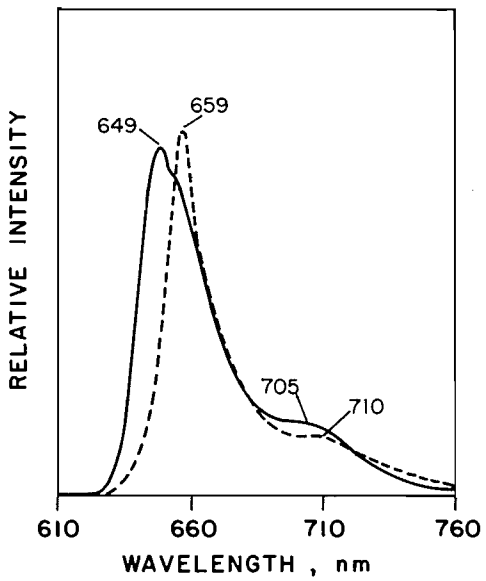

FIG. 1. The fluorescence spectra of Chl *b* in n-octane at 77 K. (—) λ_{exc} = 457.9 nm, (---) λ_{exc} = 514.5 nm.

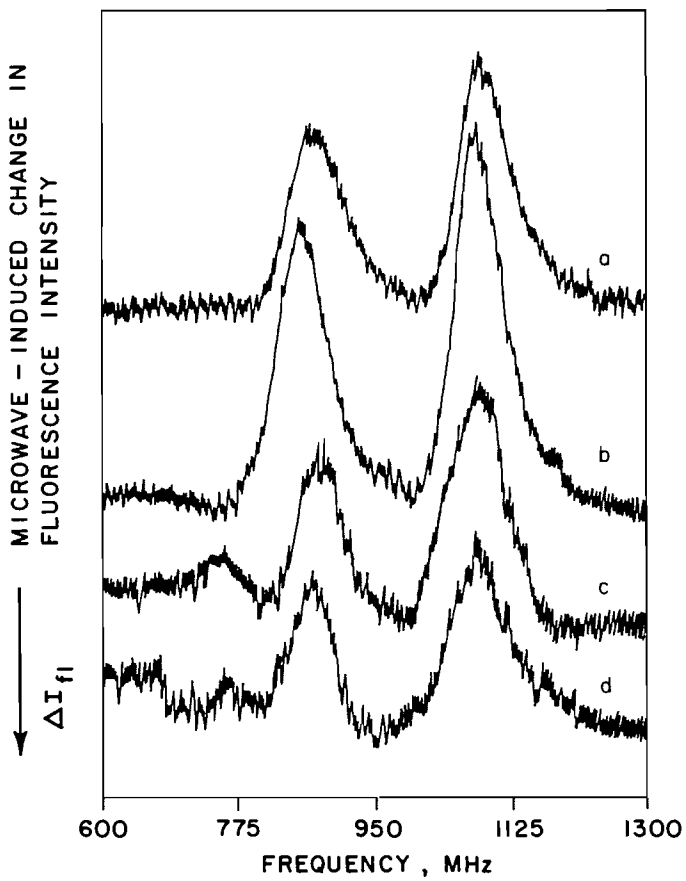

FIG. 2. Fluorescence detected zero-field ODMR spectra of Chl *b* in n-octane at 2 K. The sample is excited with a 457.9 nm line from argon-ion laser and spectra recorded at (*a*) 640 nm, (*b*) 649 nm, (*c*) 659 nm, and (*d*) 682 nm.

observed for 640 and 649 nm detection wavelengths although not as intense and not as well resolved. As one goes to longer wavelengths, one starts to notice the distortion of these (870 and 1080 MHz) transitions and growing in of the other transitions. At the detection wavelength of 659 nm the spectrum is already

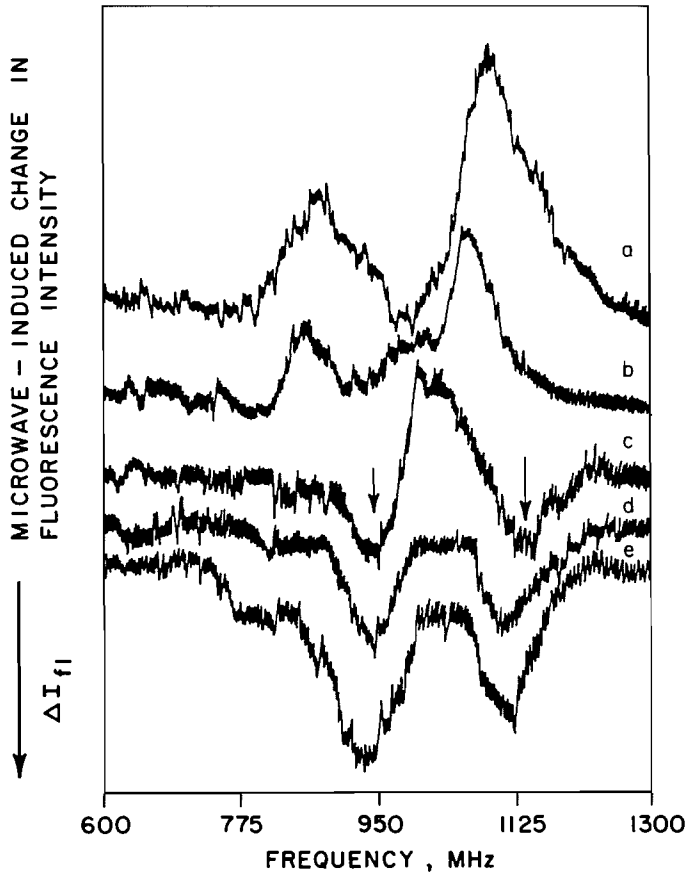

FIG. 3. Fluorescence detected zero-field ODMR spectra of Chl *b* in n-octane at 2 K; λ_{exc} = 514.5 nm laser line. The detection wavelengths are (*a*) 640 nm, (*b*) 649 nm, (*c*) 659 nm, (*d*) 672 nm, and (*e*) 682 nm.

complex. The transition at 870 MHz has completely disappeared and that at 1080 MHz has been replaced by transition at 1011 MHz. Furthermore, one can see feeble transitions (marked by arrows) at ~920 and 1120 MHz, both leading to microwave-induced increase in fluorescence intensity. At 672 nm a very interesting feature appears. There are now only two well-resolved and intense transitions at 923 and 1125 MHz leading to microwave-induced increase in fluorescence intensity. At 682 nm, the same transitions as observed at 672 nm are predominant.

It thus seems that excitation wavelength 457.9 nm predominantly excites the species with ODMR transitions at ~870 and 1080 MHz (leading to decrease in fluorescence intensity), while 514.5 nm is able to excite the species with ODMR transitions 920 and 1126 MHz (leading to an increase in fluorescence intensity) and also the species with ODMR transitions at ~870 and 1080 MHz (leading to decrease in fluorescence intensity). The complex shape of ODMR spectrum at 659 nm is probably due to simultaneous excitation of both species and thereby mixing the ODMR transitions. However, at wavelength 672 nm, far removed from 649 nm (fluorescence maximum due to one species) one can see only two well-resolved transitions at 920 and 1125 MHz due to another species. It should be mentioned that we have limited our ODMR discussion to Chl *b* monomers only (i.e. fluorescence wavelengths from 640 to 690 nm).

(c) Intersystem crossing rate constants (k_{dT})

The overall decay constants k_{dT} have been measured at various detection wavelengths (λ_{exc} = 457.9 nm and 514.5 nm)

TABLE 1. Triplet ODMR data of Chl *b* in n-octance

λ_{exc} (nm)	$\lambda_{fluorescence}$ (nm)	$\lambda_{detection}$ (nm)	Transition frequencies (MHz)	k_{dT}† (s^{-1})
457.9	649	640	866 (d)*, 1084 (d)	340
		649	857 (d), 1072 (d)	410
		659	750 (d), 885 (d), 1085 (d)	428
		682	878 (d), 1088 (d)	380
514.5	659	640	870 (d), 1087 (d)	160
		645	858 (d), 1062 (d)	175
		659	924 (i)*, 1011 (d), 1125 (i)	370
		672	923 (i), 1125 (i)	400
		682	739 (i), 919 (i), 1109 (i)	420

*(d) and (i) = microwave — induced decrease or increase in fluorescence intensity, respectively.
†k_{dT} = overall triplet decay constant.

and are presented in Table 1. A value of 380 ± 40 for k_{dT} is obtained when Chl *b* is excited with 457.9 nm. However, when excited with 514.5 nm laser line the rate constants seem to fall into two groups: (*1*) slower ($170 \pm 10\ s^{-1}$) rates for lower wavelengths 640–645 nm, and (*2*) faster (approximately double, $360 \pm 40\ s^{-1}$) rates for higher wavelengths 659, 672, etc.

Discussion

From fluorescence spectra it seems fairly reasonable to assign the two maxima at 649 and 659 nm to two distinct species, one being preferentially excited with 457.9 nm and the other by 514.5 nm laser line.

The two sets of ODMR frequencies, i.e., 870 and 1070 MHz, and 920 and 1125 MHz seem to support this assignment, and similar to the case of Chl *a* in n-octane, the higher frequencies can be assigned to monoligated and the lower frequencies to biligated species of Chl *b* (1). The analysis of rate constants, however, is not straightforward. These rate constants are known to be quite sensitive to local chlorophyll environment, particularly with respect to ligands attached to the central magnesium atom. Unless rigourously dried, water is always available for complexing with chlorophylls (via magnesium atom). Furthermore, there is also an aldehyde group available for binding with water in Chl *b*.

Comparing the results with Chl *a* in n-octane, where the assignment of rate constants to two species was a clear cut case, Chl *b* poses a problem. In Chl *a*, the rates for biligated species measured at its fluorescence maximum (excited with 457.9 nm) were found to be approximately double the rates for monoligated species detected at its fluorescence maximum (λ_{exc} = 514.5 nm). In Chl *b* too, we do see the slow ($160 \pm 10\ s^{-1}$) and fast ($340\ s^{-1}$, approximately double) rates, but the rates detected at 649 nm (fluorescence maximum of one species, λ_{exc} = 457.9 nm) and those at 659 nm (fluorescence maximum of other species, λ_{exc} = 514.5 nm) are almost the same $\sim 360 \pm 40\ s^{-1}$. This makes the assignment of fluorescence maxima as due to mono- and biligated species rather difficult. However, one can invoke the presence of the following species: (*1*) species excited preferentially with 457.9 nm laser line with fluorescence maximum at 649 nm, with ODMR frequencies at ~870 and 1080 MHz, and decay constants k_{dT} equal to $380 \pm 40\ s^{-1}$; (*2*) species preferentially excited with 514.5 nm and has fluorescence maximum at 659 nm, ODMR frequencies at 920 and 1125 MHz, and rates k_{dT} equal to $360 \pm 40\ s^{-1}$; and (*3*) species which emits fluorescence in short wavelength region 635–640 nm, (excited with 514.5 nm laser line) and has rates k_{dT} equal to $160 \pm 10\ s^{-1}$. Its ODMR transitions are probably very feeble, so much so that they are completely masked by 870 and 1080 MHz transitions belonging to the first species. The rate constants of first species ($380 \pm 40\ s^{-1}$) will, however, be dominated by the slower rates ($160 \pm 10\ s^{-1}$) of the third species.

It is at present difficult to pin point which one of the above three species is mono- or biligated (at the central magnesium atom), or ligated at aldehyde group, or ligated at ring V-keto group or ligated at all groups. However, following the arguments of Clarke and Frank (8) regarding the sensitivity of rate constants with respect to the ligand attachment; the first and the third species could be assigned, as in case of Chl *a*, to biligated and monoligated Chl *b* monomer, respectively, in which water is coordinated to magnesium metal center.

The assignment of the second species with fluorescence maximum at 659 nm, ODMR frequencies at 920 and 1125 MHz, and rate constants equal to $360 \pm 40\ s^{-1}$, is even harder. The higher ODMR frequencies suggest a monoligated (at Mg) species while higher rate constants suggest a biligated species. At present, we are unable to say much about its origin except to speculate that (in this species) the central magnesium atom is probably mono- or biligated with aldehyde or ring V-keto group or ligated with both the water on one side and the aldehyde or the ring V-keto group on the other side.

It should be pointed out that in all the species mentioned above, ring V-keto and aldehyde groups are probably always hydrogen bonded with water (if not ligated to magnesium atom). However, it is the ligation at the magnesium atom that produces the pronounced changes in the triplet state ODMR parameters (9) and other properties of chlorophylls (5, 10).

It thus seems that, substitution of an aldehyde group in Chl *b* for a methyl group in Chl *a* brings in quite dramatic changes: (*i*) contrary to Chl *a*, 457.9 nm laser line yields fluorescence of Chl *b* at shorter wavelength (i.e. 649 nm) relative to excitation with 514.5 nm (λ_{fl} = 659 nm); (*ii*) the detection and assignment of various species is much easier in Chl *a* than in Chl *b*; (*iii*) the rate constants k_{dT} for Chl *b* are approximately half those for Chl *a*. This can be explained due to more nonplanar structure of Chl *a* relative to Chl *b* (with —CHO group) leading to efficient spin–orbit coupling (6); (*iv*) the respective ODMR frequencies are higher in Chl *b* compared to those for Chl *a*, which is again due to the increased conjugation of π-electron network in Chl *b* due to —CHO group than in Chl *a* which has a methyl group.

In conclusion, the ODMR experiments suggest that Chl *b* in n-octane is probably present in more than two species though a definitive assignment of mono- or biligated species or species ligated at aldehyde group is not easy. The ligand is most probably water, however, the present results do not point out to the exact nature of the ligand, i.e., whether it is water or the aldehyde group.

Ion/molecule reactions in allene. III. Reactions of the parent ion with neutral alkanes

KENZO NAGASE[1] AND JAN A. HERMAN

Centre de Recherches sur les Atomes et les Molécules et le Département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received March 19, 1985

KENZO NAGASE and JAN A. HERMAN. Can. J. Chem. **64**, 192 (1986).

Ion/molecule reactions between the ion $C_3H_4^{+\cdot}$ ion, from allene and neutral alkanes were investigated by mass spectrometry. There are four $H^{\cdot}/CH_3^{\cdot}/H^-/H_2^-$ transfer reactions and relative rate constants were calculated. The overall rates increased in the order $CH_4 < C_2H_6 < C_3H_8 <$ i-$C_4H_{10} <$ n-C_4H_{10}. There is also a stabilization process by alkanes of $C_6H_8^{+\cdot}$ ion species, but its importance is lower than the above transfer processes.

KENZO NAGASE et JAN A. HERMAN. Can. J. Chem. **64**, 192 (1986).

Faisant appel à la spectrométrie de masse, on a étudié les réactions ion/molécule entre l'ion radical $C_3H_4^{+\cdot}$, obtenu à partir de l'allène, et des alcanes neutres. Il se produit quatre réactions de transfert $H^{\cdot}/CH_3^{\cdot}/H^-/H_2^-$ et on en a calculé les constantes relatives de vitesse. Les vitesses globales augmentent suivant l'ordre suivant: $CH_4 < C_2H_6 < C_3H_6 <$ i-$C_4H_{10} <$ n-C_4H_{10}. Il existe aussi un processus de stabilisation par les alcanes des espèces ioniques $C_6H_8^{+\cdot}$; toutefois, son importance est plus faible que celle provenant des processus de transferts mentionnés plus haut.

Introduction

In allene–alkane systems (alkanes: CH_4, C_2H_6, C_3H_8, n-C_4H_{10}, and iso-C_4H_{10}) photoionized at 10.0–10.6 eV (krypton resonance lines) only allene parent ions are formed. It was verified experimentally that the $\lambda = 116.5$ nm resonance line of krypton (10.6 eV) does not ionize to a measurable extent the n-butane and the methylpropane molecules, the ionization potentials (IP) of these compounds being near this threshold (10.55 and 10.57 eV, respectively). At 10 eV the parent ion, $C_3H_4^{+\cdot}$ (IP 9.6 eV), has some internal energy (<0.5 eV) but not enough to lead to fragmentation. It reacts with neutral allene in some characteristic ion/molecule reactions, which have been extensively studied (1–9). However, there is no report on the reactions of allene ions with neutral alkanes.

In the $C_3H_4 + RH_2$ systems where R is C_nH_{2n} one should expect the $H^-/H_2^-/H^{\cdot}$ transfers to be important ion/molecule processes (10, 11). The H^- transfer occurs efficiently in those cases where production of RH_2 represents a reasonable exothermic reaction channel for the ground state reactants. Transfer of H_2^- is always favoured thermodynamically in any $C_nH_{2n}^{+\cdot} + RH_2$ combination, which accounts for the observation that $k(H^-)/k(H_2^-) < 1.0$ even when hydride transfer is highly exothermic. It was also reported that thermoneutral or slightly endothermic H^-/H_2^- transfer processes with low cross-sections occur in the C_3H_6 + n-C_4D_{10} system and in this case it was assumed that a long-lived collision complex is formed favouring these reactions (12).

One can expect that since allene is a highly unsaturated hydrocarbon, its parent ions might form a long-lived collision complex with alkanes and undergo hydride and hydrogen atom transfer reactions, beside stabilization processes of excited ion species formed during ionization of allene. The present experiments describe the ion/molecule processes found in allene + alkane systems and an attempt is made to rationalize the results obtained.

Experimental

The experimental procedure and the high-pressure photoionization mass spectrometer have already been described (13). The measurements were made under field-free conditions inside the collision chamber with an electric field of low intensity (~5 V cm^{-1}) applied in the ionic optics. The distance between the plane of formation of the parent ions by photon impact and the exit slit was 2.2 mm. The experiments were done at room temperature, 25 ± 2°C, as indicated by a thermocouple connected to the collision chamber.

The allene from Matheson of 99.5% purity was used without further purification. Methane, ethane, propane, n-butane, and methylpropane, also from Matheson were of instrumental grade purity. Mixtures of known concentrations (usually around 10% of C_3H_4) were prepared in a conventional high vacuum manifold.

Results

The mass spectrum of the allene–methane mixture was, essentially, similar to that of the allene – rare gas system (9). On the other hand, the spectrum of the allene–ethane system was somewhat different, and those of propane, butane, and methylpropane systems were much different from that of allene – rare gas mixture. The pressure range employed in the present experiments is relatively high, favouring cluster formation of neutral allene. In all these $C_3H_4 + RH_2$ systems only neutral allene molecules form the solvation shell of the ion species. Therefore, the real abundance of each daughter-ion starting a family of solvated species can be represented by the total intensities of each family (e.g. $\Sigma I[C_6H_9^+(C_3H_4)_n]$ with $n = 0, 1, 2, \ldots$). The pressure dependence of the fractional intensities of the families of solvated ions species is shown in Figs. 1–5. In general there appear to be eight solvated ion families: $(C_6H_7^+)_f$, $(C_6H_8^{+\cdot})_f$, $(C_6H_9^+)_f$, $(C_6H_{11}^+)_f$, $(C_7H_7^+)_f$, $(C_7H_{11}^+)_f$, $(C_7H_{12}^{+\cdot})_f$, and $(C_7H_{13}^+)_f$, where the f subscript indicates the corresponding family of solvated ion species by neutral allene molecules. Their fractional intensities are pressure dependent and varied also with the nature of the alkane molecule.

In the case of allene–methane mixtures, four families of ion species were present: $(C_6H_7^+)_f$, $(C_6H_8^{+\cdot})_f$, $(C_6H_9^+)_f$, and $(C_7H_7^+)_f$. There was no evidence for ion/molecule reactions between the parent ion and methane.

On the other hand, the allene–ethane system showed an additional family of ions, $(C_7H_{11}^+)_f$. When perdeuterated ethane was used instead of C_2H_6, the intensity of the $(C_7H_{11}^+)_f$ family decreased and a mass peak corresponding to $C_7H_8D_3^+$ appeared, suggesting a neutral methyl group transfer. Furthermore, the fractional intensity of the $C_6H_9^+$ family increased, while in the case of allene + rare gas systems the abundance of

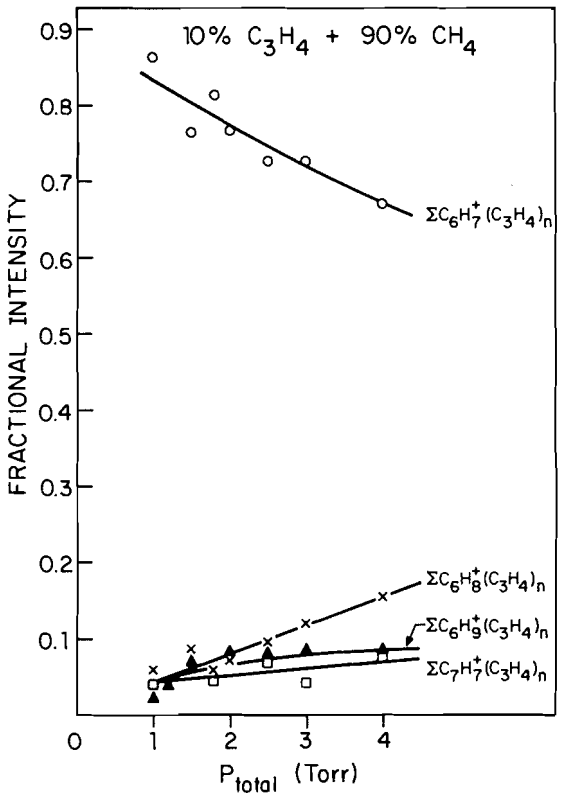

FIG. 1. Pressure dependence of the fractional intensities for the major ion families in the allene–methane mixture.

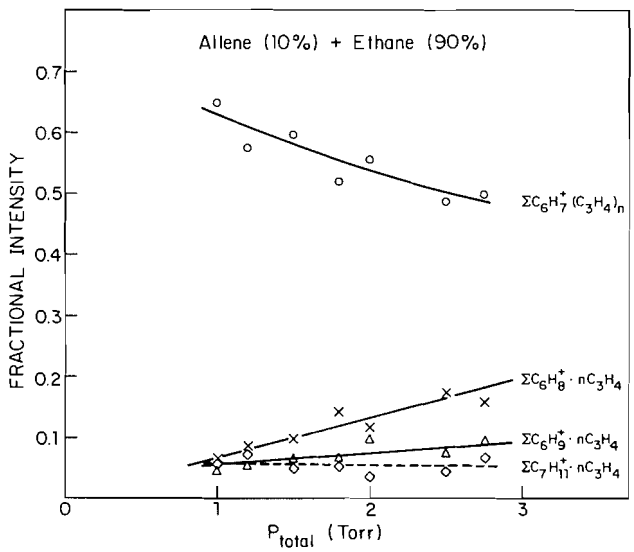

FIG. 2. Pressure dependence of the fractional intensities for the major ion families with allene–ethane mixture.

$(C_6H_9^+)_f$ was almost independent of the presence of the non-reacting gas (9).

In the case of allene + propane mixtures, a new family of ions appeared, $(C_6H_{11}^+)_f$, and the fractional intensities of the $(C_6H_{11}^+)_f$, $(C_6H_9^+)_f$, and $(C_7H_{11}^+)_f$ were strongly enhanced compared to allene + ethane system, indicating the occurrence of reactions between $C_3H_4^+$ and C_3H_8. A $H^\cdot$ transfer process explains the formation of the $C_6H_{11}^+$ species.

The butane + allene system gave two further additional families of ions species: $C_7H_{12}^{+\cdot}$ and $C_7H_{13}^+$. The ion species,

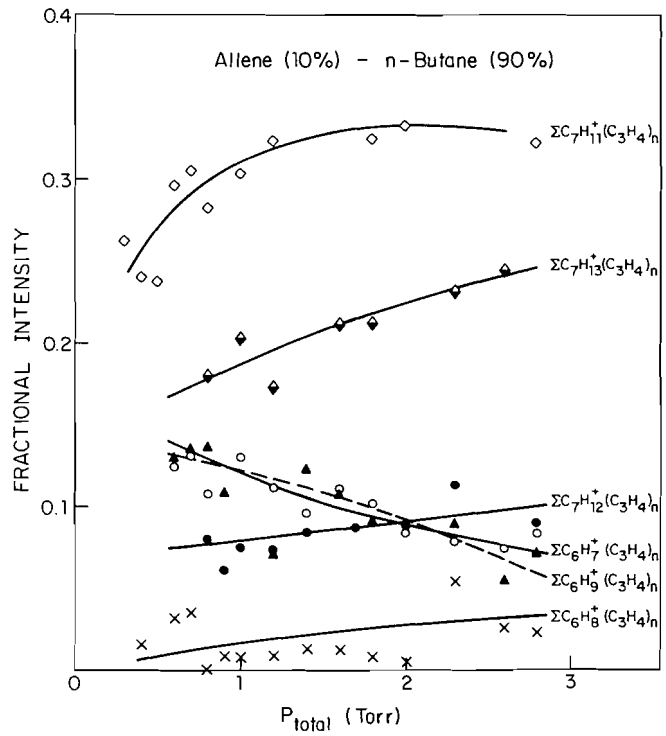

FIG. 4. Pressure dependence of the fractional intensities for the major ion families in the allene–n-butane mixture.

$C_7H_{13}^+$, is formed in a H^- transfer process, while the $C_7H_{12}^{+\cdot}$ results from a H_2^- transfer.

The families of ions formed in methylpropane + allene mixtures were the same as in the n-butane + allene mixtures, but important differences in fractional intensities were observed between the two isomers (Figs. 4, 5).

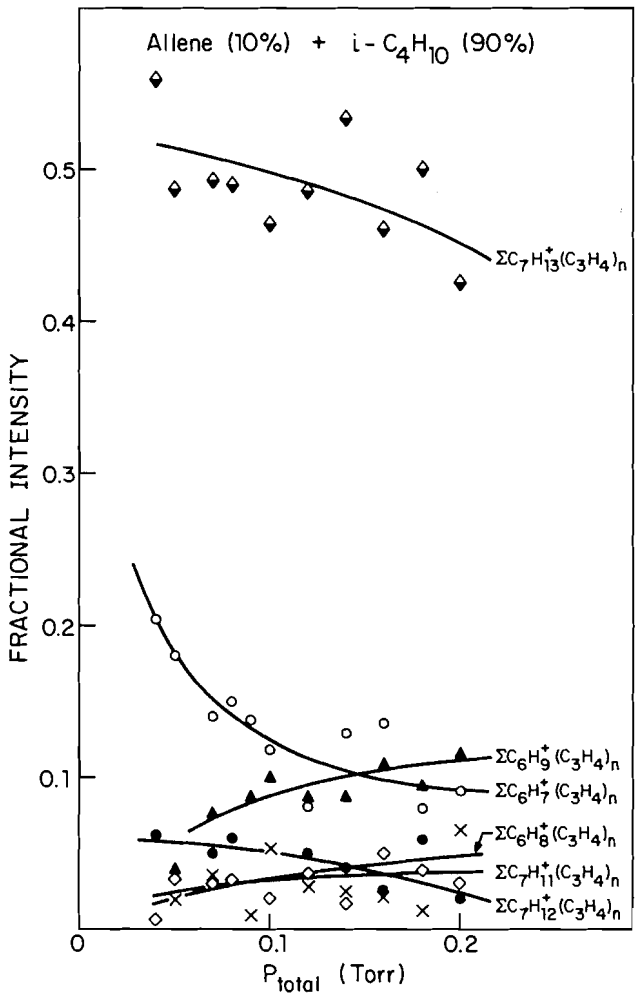

FIG. 5. Pressure dependence of the fractional intensities for the major ion families in the allene–i-butane mixture.

Discussion

In Part II we have proposed the following reaction scheme for allene-chemically "inert" gas systems in the relatively high pressure range ($0.2 < P(C_3H_4) < 1$ Torr) (9)

[1] $C_3H_4^+ + C_3H_4 \rightarrow (C_3H_4^{+\cdot}\cdot C_3H_4)^* \longrightarrow C_6H_7^+ + H^\cdot$

[2] $A^{+*} + C_3H_4 \longrightarrow C_6H_9^+ + C_3H_3^\cdot$

[3] $A^{+*} + C_3H_4 \xrightarrow[k_s(\text{or } k_s')]{} C_7H_7^+ + C_2H_5^\cdot$

[4] $A^{+*} + M\ (\text{or } C_3H_4) \longrightarrow C_6H_8 + M\ (\text{or } C_3H_4)$

where A^{+*} stands for the excited ion complex $(C_3H_4^{+\cdot}\cdot C_3H_4)^*$, M stands for a "chemically inert" third body molecule and k_s and k_s' are the collision stabilization or deactivation rate constants of the excited dimer-ion by M or neutral allene, respectively.

The $H^\cdot/CH_3^\cdot/H^-/H_2^-$ transfer processes might in principle take place either in reactive encounters between allene parent ions, $C_3H_4^{+\cdot}$, and the alkane neutrals, or between the complex dimer-ion, $(C_3H_4)_2^{+\cdot}$ and the alkane molecules. It is found experimentally that the formation of $C_6H_9^+$, $C_7H_{11}^+$, $(C_nH_{2n+1}\cdot C_3H_4)^+$, and $(C_nH_{2n}\cdot C_3H_4)^{+\cdot}$ species resulting from the above transfer processes, obeys a *second order* rate kinetics. This is easily explained assuming long-lived intermediate species, $(C_nH_{2n+2}\cdot C_3H_4)^{+\cdot *}$ and $(C_3H_4)_2^{+\cdot *}$, which on collision with neutrals can either dissociate in a backward reaction into reactants, or form the species under consideration.[2] In our experimental conditions the much higher concentration of alkane neutrals over the allene molecules suggests that the following reactions are favoured over the reaction involving the allene dimer-ion, $(C_3H_4)_2^{+*}$:

[5] $(C_3H_4^{+\cdot}\cdot C_nH_{2n+2})^* + C_3H_4 \rightarrow C_6H_9^+ + C_nH_{2n+1}^\cdot$

[6] $+ C_3H_4 \rightarrow C_7H_{11}^+ + C_{n-1}H_{2n+1}^\cdot$

[7] $+ C_3H_4 \rightarrow (C_nH_{2n+1}\cdot C_3H_4)^+ + C_3H_5^\cdot$

[8] $+ C_3H_4 \rightarrow (C_nH_{2n}\cdot C_3H_4)^{+\cdot} + C_3H_6$

where the $(C_3H_4^{+\cdot}\cdot C_nH_{2n+2})^*$ stands for the excited ion complex between the parent ion and the neutral alkane undergoing a $H^\cdot$ transfer (reaction [5]), $CH_3^\cdot$ transfer (reaction [6]), H^- transfer (reaction [7]), and H_2^- transfer (reaction [8]).

Reactions [1]–[8] yield the following kinetic expressions:

[9] $d[C_6H_7^+] = k_1[A^{+*}]$

[10] $d[C_6H_8^{+\cdot}] = k_s'[A^{+*}][C_3H_4] + k_s[A^{+*}][C_nH_{2n+2}]$

[11] $d[C_6H_9^+] = k_2[A^{+*}][C_3H_4] + k_5[C_3H_4^{+\cdot}\cdot C_nH_{2n+2}][C_3H_4]$

[12] $d[C_7H_{11}^+] = k_6[C_3H_4^{+\cdot}\cdot C_nH_{2n+2}][C_3H_4]$

[13] $d[(C_nH_{2n+1}\cdot C_3H_4)^{+\cdot}] = k_7[C_3H_4^{+\cdot}\cdot C_nH_{2n+2}][C_3H_4]$

[14] $d[(C_nH_{2n}\cdot C_3H_4)^{+\cdot}] = k_8[C_3H_4^{+\cdot}\cdot C_nH_{2n+2}][C_3H_4]$

For the convenience of the kinetic analysis, relative rates can be introduced. They are defined by the ratio of the rate of formation of the ion under consideration to the rate of formation of $C_6H_7^+$ species:

[15] $d[C_6H_9^+]/d[C_6H_7^+] = R/(R+1)\{k_2/k_1 + k_5/R'k_1\}P_t$

[16] $d[C_7H_{11}^+]/d]C_6H_7^+] = \{k_6/k_1(R+1)\}P_t$

[17] $d[C_nH_{2n+1}\cdot C_3H_4)^{+\cdot}]/d[C_6H_7^+] = \{k_7/k_1(R+1)\}P_t$

[18] $d[C_nH_{2n}\cdot C_3H_4)^{+\cdot}]/d[C_6H_7^+] = \{k_8/k_1(R+1)\}P_t$

[19] $d[C_6H_8^{+\cdot}]/d[C_6H_7^+] = R/(R+1)\{k_s'/k_1 + k_s/R'k_1\}P_t$

where R stands for the experimental mixing ratio $[C_3H_4]/[C_nH_{2n+2}]$ and $P_t = P(C_3H_4) + P(C_nH_{2n+2})$. In all experiments $R = 0.11$.

We will assume that the ratio $R' = [C_3H_4^{+\cdot}\cdot C_3H_4]/[C_3H_4^{+\cdot}\cdot C_nH_{2n+2}]$ of the concentrations of the ion complexes is proportional to the concentrations of reactants from which they are formed and therefore is equal or very close to the experimental mixing ratio, R. This is justified, because the life-time of collisional complexes formed from similar species is not very sensitive to their nature.

The left-hand side terms of the eqs. [15]–[19] correspond to the experimental ratio of fractional intensities of corresponding families of ion species.

The plots of expressions [15]–[18] are presented in Figs. 6–10, and the ratios of rate constants obtained from the corresponding slopes are given in Table 1. Some additional information about each plot are given below.

(*i*) The plots for expression [15] gave almost straight lines for all alkanes, Figs. 6, 7. From the slopes the values k_5/k_1 can be obtained, since the ratio k_2/k_1 is already known to be constant and its mean value is 0.25 $Torr^{-1}$ (9). The value k_5/k_1 for ethane is very small, but $H^\cdot$ transfer is certainly occurring, since a clear difference is observed in the slopes of $(C_3H_4 + C_2H_6)$ and

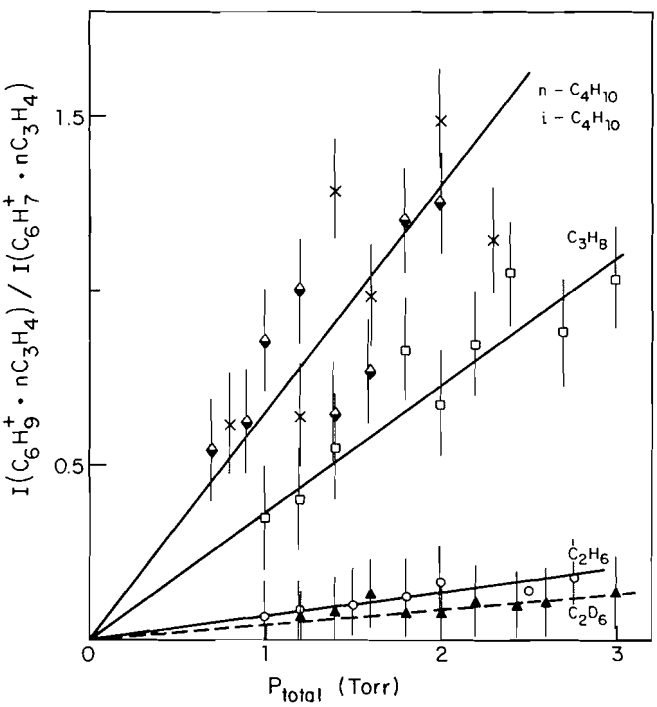

FIG. 7. Plot of expression [15] for the H• transfer process in the allene–alkane mixtures.

$(C_3H_4 + C_2D_6)$ systems and the difference could be accounted for by the formation of $C_6H_8D^+$.

(*ii*) The plots for expression [16] gave also straight lines for all alkanes, although the slope for n-butane changed and became small above 1 Torr, as shown in Fig. 8. The values k_6/k_1 obtained from the corresponding slopes which represent the relative CH_3• rate transfer are tabulated in the fourth column in Table 1.

(*iii*) In Fig. 9 are shown the plots for expression [17] for propane and butane isomers. In the case of ethane the fractional intensity was too weak to be plotted.

[a]n.m. = not measured.

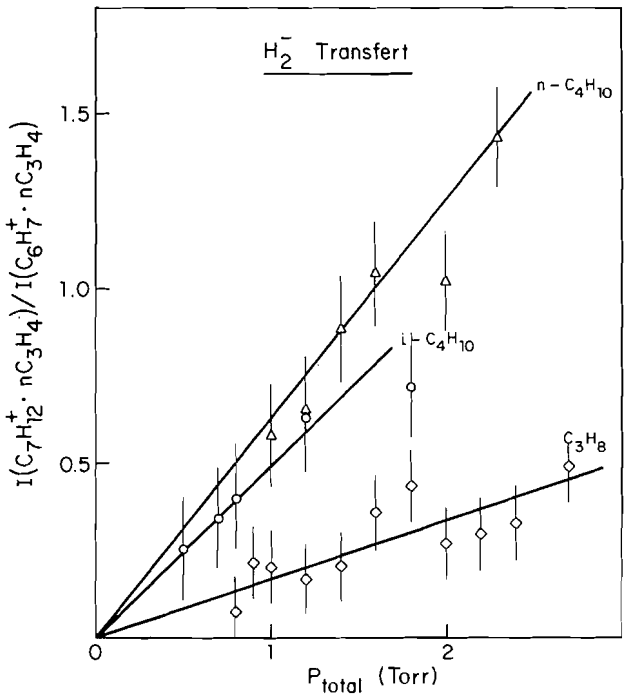

FIG. 10. Plot of expression [18] for the H_2^- transfer process in the allene–alkane mixtures.

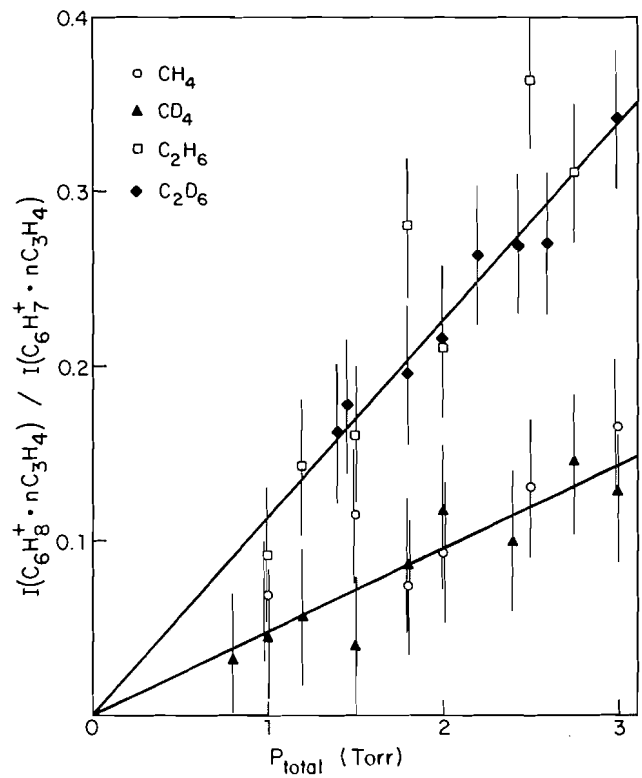

FIG. 11. Plot of expression [19] for the stabilization process of $C_6H_8^{+\cdot}$ in methane and ethane mixtures with allene.

(*v*) The energy transfer in stabilization processes from the parent ions to the alkanes acting as a bath gas was examined by plotting expression [19]. As shown in Fig. 11 methane and ethane gave straight lines and from the corresponding slopes the values of the ratio k_s/k_1 were calculated. They are 0.048 ± 0.02 for methane and 0.11 ± 0.03 $Torr^{-1}$ for ethane, when k_s'/k_1 is assumed to be 0.11 $Torr^{-1}$ (9). For the C_3–C_4 alkanes the fluctuations were too big to allow calculation of k_s/k_1 from the slopes and therefore their values are not given in Table 1.

Thus the kinetic treatment based on expressions [15] to [19] support the reaction scheme described by reactions [1] to [8]. The total relative reactivity for the four channels of ion/molecule reactions involving parent ions of allene, $C_3H_4^{+\cdot}$, and neutral alkanes is given by the sum of the relative rate constants for each channel and is presented in the first column of Table 1. It can be seen that the total relative reactivity increases with the size of the neutral alkane.

Although the reactivities might depend on the IP's other molecular factors will influence the specific reaction channels. In Table 2 are presented the heats of reactions of $CH_3^\cdot$/$H^\cdot$/H^-/H_2^- transfer processes for some systems involved in this study. The enthalpies of formation were taken from refs. 15 and 16.

In each case, with the exception of methane, the $CH_3^\cdot$ transfer is exothermic and, indeed, occurs in the $C_3H_4 + RH_2$ systems. It is also more favorable for propane and butane compared to $H^\cdot$ transfer (Table 2). One possible reason is that the C—C bond is weaker than the C—H bond by 35 kJ mol^{-1} in RH_2. On the other hand, in allene + methylpropane system the $H^\cdot$ transfer is more important compared to $CH_3^\cdot$ tansfer. This anomaly appears not to relate to thermochemistry (Table 2) and so presumably is kinetic in origin.

The differences in H^-/H_2^- transfer for the two butanes can be also accounted for on kinetic grounds. Although the H^- transfer is more favorable by ~8 and ~25 kJ mol^{-1} in butane and methylpropane, respectively, relative to H_2^- transfer, one also has to take into account the relative probability that the reaction complex does or does not fall apart after the transfer of the H^- entity. It was shown that the H_2^- transfer reaction proceeds through a two-steps stereospecific mechanism, refs. 14, 17–19. The reactive encounter between species initially involves the transfer of a singly H^- ion in the reaction complex in an exothermic process. This complex may then fall apart, resulting in a single particle transfer process, or a second H atom may be

TABLE 2. Enthalpies of some $H^{\cdot}/CH_3^{\cdot}/H^-/H_2^-$ transfer reactions for the $C_3H_4 + RH_2$ systems

Transfer process	Reaction	$\Delta H_r^{a,b}$ (kJ mol^{-1})

	$C_3H_4^{+\cdot}(i\text{-}C_4H_{10}, C_3H_5^{\cdot})tert\text{-}C_4H_9^+$	−123
H_2^-	$C_3H_4^{+\cdot}(n\text{-}C_4H_{10}, C_3H_6)$ 1-$C_4H_8^{+\cdot}$	−52
	$C_3H_4^{+\cdot}(i\text{-}C_4H_{10}, C_3H_6)$ i-$C_4H_8^{+\cdot}$	−98

[a]Heats of formation are taken from refs. 15 and 16.

[b]Due to the approximate value of the heat of formation of the allene ion (15), the estimated values of the heats of reactions are assumed to have an uncertainty of ±12 kJ.

transferred on an adjacent carbon atom while the reactants remain in the "loose" complex. Because the H_2^- transfer process is always in competition with H^- transfer reaction, both the total rate of reaction and the relative rates of the competing H^- and H_2^- reactions must be considered. It was already observed that the importance of H_2^- transfer relative to H^- transfer decreases with increasing branching (18). In methylpropane, the presence of a weakly bonded tertiary hydrogen atom in the reactant molecule apparently favors the occurrence of the H^- transfer reaction over the H_2^- transfer process as shown by the value of the ratio $k(1)/k(2) = 8.9$, compared to $k(1)/k(2) = 2$ for n-butane (Table 1). Here $k(1)$ and $k(2)$ stand for one- and two-particle transfer.

Limiting activity coefficients in dilute solutions of nonelectrolytes. II. Determination for polar–nonpolar and polar–polar binary mixtures, and the application of some solubility-parameter treatments

SHAPOUR AFRASHTEHFAR AND GENILLE C. B. CAVE
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received April 2, 1985

SHAPOUR AFRASHTEHFAR and GENILLE C. B. CAVE. Can. J. Chem. **64**, 198 (1986).

Activity coefficients were determined at 293.15 K for the more dilute component in 24 binary solutions of nonelectrolytes, by gas-chromatographic analysis of the equilibrium vapor phase. One component of the binary mixture was either nitromethane, nitroethane, 1-nitropropane, 2-nitropropane, ethanenitrile, propanenitrile, ethyl ethanoate, or butyl ethanoate; and the other component was either heptane, 1-heptene, or 1,6-heptadiene.

From the limiting activity coefficients of these components, some factors that affected their magnitude were identified. The values were also used to test the modifications of Prausnitz, Blanks, and Weimer, of Helpinstill and Van Winkle, and of Keller, Karger, and Snyder to the Scatchard–Hildebrand equation modified to accommodate polar components. In addition, the degree of constancy of the ratio of the dipole – induced dipole interaction parameter for a series of solutes in one solvent to that in another was considered.

SHAPOUR AFRASHTEHFAR et GENILLE C. B. CAVE. Can. J. Chem. **64**, 198 (1986).

Les coefficients d'activité ont été déterminés à 293.15 K pour la composante la plus diluée de 24 solutions binaires de non-électrolytes, par chromatographie en phase gazeuse de la phase vapeur à l'équilibre. L'une des composantes du mélange provenait de chacun des composés suivants: le nitromethane, le nitroéthane, le nitro-1 propane, le nitro-2 propane, l'éthanenitrile, le propanenitrile, l'éthanoate d'éthyle et l'éthanoate de butyle, tandis que l'autre composante provenait de chacun des composés suivants: l'heptane, l'heptène-1 et l'heptadiène-1,6.

L'utilisation des coefficients limites de l'activité de ces composantes ont permis l'identification de quelques facteurs qui affectent leur intensité. Ces valeurs ont également été utilisées pour vérifier la validité des modifications de Prausnitz, Blanks et Weimer, de Helpinstill et Van Winkle, et, de Keller, Karger et Snyder, à l'équation de Scatchard–Hildebrand, modifiée de façon à devenir applicable aux composantes polaires. De plus, le degré de constance du rapport du paramètre de l'interaction dipôle – dipôle induit pour une série de solutés dans un solvant, sur ce même paramètre évalué dans le cas d'un autre solvant, a été examiné.

Introduction

A previous study (1, 2*a*) described a static equilibration apparatus having a novel gas-chromatographic headspace sampler, which was used to evaluate the limiting activity coefficients of eight polar compounds in heptane and in benzene. In the present work, this study has been extended to include the same polar compounds in 1-heptene and 1,6-heptadiene as solvents, as well as heptane, 1-heptene, and 1,6-heptadiene as solutes in each of the eight polar compounds as solvents.

From the resulting limiting activity coefficients, some factors that affected their magnitude were identified, namely: (*i*) the chain length and the polarity of the solute, and (*ii*) the effect of one or more double bonds in the solvent, on the limiting activity coefficients of the polar compounds. The data may also be used for testing extended solubility-parameter models. In the present paper three such extended-solution treatments (3–8) are considered. In addition, the degree of constancy of the ratio of the dipole – induced dipole interaction parameters of a solute in two given solvents, first reported by Milanova and Cave (1), was tested.

Experimental

Static equilibration apparatus

The equilibration apparatus was the same one previously designed and used by Milanova (1, 2*a*). However, for the present work it was improved by enclosing the metal headspace sampler in an air thermostat, which led to better precision, and by adding a sidearm near the base of the cell to facilitate adding and removing the solutions. The improved version of the entire equilibration apparatus has been described in detail elsewhere (9).

The metal headspace sampler was housed in a double-walled air bath which fitted snugly over the sampler and its copper loops. Water at 295.15 K from a water thermostat was pumped continuously through the double-walled jacket of the air bath. A 2 K differential was thereby ensured between the sampling loops and the equilibration cell, in order to prevent any possibility of some condensation of equilibrated vapor in the loops.

When ethanenitrile was the solvent in the binary systems, somewhat high and non-reproducible results were obtained for the concentration of the hydrocarbon solute in the copper sampling loops. In this connection, Putnam *et al.* (10) have reported that liquid and solid ethanenitrile reacted with copper. Therefore, an all-glass headspace sampler was constructed and used for systems having ethanenitrile as solvent. It provided exactly the same function as the metal sampler of Milanova, and has been described in detail elsewhere (9*a*). It is illustrated in Fig. 1. This unit was custom-made including fabrication of the stopcock barrel and stopcock plug, from borosilicate thick-walled tubing to permit tapering. Briefly, a large six-way stopcock had a tapered hollow plug, inside which three hollow tubes had been blown (Fig. 1). These three tubes formed the actual sampling containers for the samples of equilibrium vapor. Six short hollow glass tubes were blown onto the stopcock barrel. Four of them ended in 10/19 outer joints, of which two (A and B, Fig. 1) were connected to the carrier-gas line, one (C) was connected to the vacuum, and one (D) was plugged. A fifth tube (E) ended in a 19/26 inner joint. Sixty-degree rotation of the stopcock brought each of the three sampling tubes in the plug in turn into juxtaposition with the barrel end of tube E; and the 19/26 joint could be connected directly to the equilibration cell so that the sampling tube in the stopcock became part of the cell space. The sixth tube (S_1) was to permit evacuation of the cell when necessary. The three sampling tubes were calibrated by filling them with water from a preweighed syringe which was then reweighed. Their volumes and standard deviations were found to be 2.9671 ± 0.00095 cm^3, 3.2811 ± 0.0121 cm^3, and 3.9285 ± 0.0108 cm^3 for 12 replicates.

Materials

The purification procedures are described in detail elsewhere (9*b*).

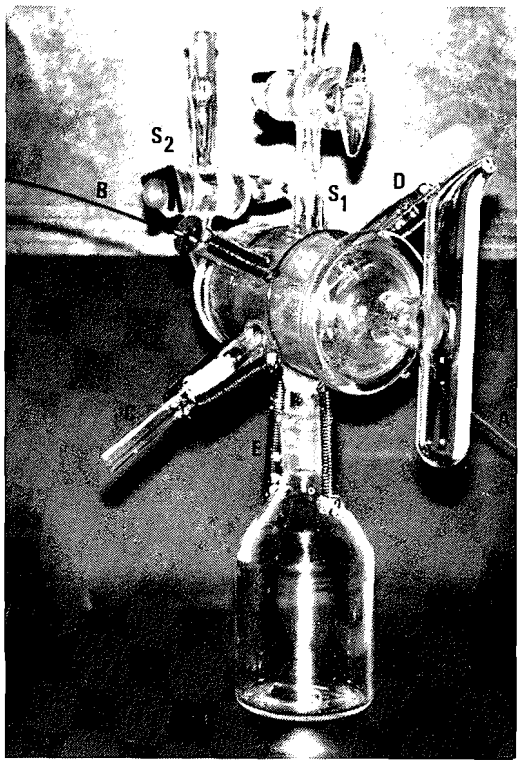

FIG. 1. Six-way all-glass headspace sampler attached to equilibration cell.

The final purities are in Table 1, together with the sources of the reagents, and the refractive indices and densities of the purified products. Final purities were determined by gas chromatographic analysis for impurities.

Except for a few variations noted below, the fractional distillations were carried out under reduced pressure after flushing the still with nitrogen, at an output rate of ca. 20 $cm^3 h^{-1}$ and a reflux ratio of ca. 50:1. The middle cuts were retained, stored in the dark over molecular sieves 3A, and used no later than a week after their purification.

The nitrocompounds were dried over P_2O_5, then fractionally distilled. The nitriles were fractionally distilled over molecular sieves 3A, at an output rate of 10 $cm^3 h^{-1}$. The esters were fractionally distilled without initial drying.

Heptane was purified by four fractional crystallizations followed by fractional distillation under nitrogen at atmospheric pressure.

1-Heptene was distilled from sodium in a spinning-band still and a nitrogen atmosphere, at a rate of 10 $cm^3 h^{-1}$ and a reflux ratio of 65:1.

1,6-Heptadiene was purified by preparative gas chromatography in a Varian Aerograph 705 in manual mode, on a column packed with 10% Carbowax 20M on 80/100 Chromosorb W at 255 K. The lots were processed 1 mL at a time.

Benzene was purified by six fractional crystallizations. Tetrachloromethane was fractionally distilled at atmospheric pressure. Cyclohexane was fractionally distilled over sodium at atmospheric pressure.

Procedure

The procedure used for equilibration and gas chromatographic analysis of the binary solutions and their vapors was essentially the one developed and used earlier by Milanova (2*b*), and reported in outline form in ref. 1. However, for the present work some precautionary refinements were added. The complete modified procedure is given elsewhere (9*c*). The refinements were (*i*) the equilibration apparatus was flushed with nitrogen before use; (*ii*) the solute and solvent were introduced into the equilibration cell via the sidearm that had been added to it, by two syringes weighed before and after dispensing the pure solute and solvent, respectively; (*iii*) the apparatus was degassed twice instead of once; (*iv*) not only was the equilibration cell immersed in a water thermostat set at 293.15 K as previously (2*b*), but also the metal headspace sampler was enclosed in the above-described air thermostat set at 295.15 K; (*v*) although liquid–vapor equilibrium was reached in 30 min; 2 h were allowed before the first sampling; (*vi*) after two to four vapor samples had been taken and analyzed, four samples of the liquid phase remaining in the cell were removed by syringe via the sidearm and analyzed by gas chromatography.

It was necessary to know the solubility parameter of 1,6-heptadiene, previously unreported. The value of $\Delta H^v_{298.15}$ was measured for us by Majer. He used our above-described product, with molecular sieves 3A added to prevent contamination by atmospheric humidity, and an adiabatic vaporization calorimeter described by Majer *et al.* (14). The mean of three runs was $\Delta H^v_{298.15} = 35.00$ kJ mol^{-1}. Then from their empirical relationship $\Delta H^v = K\,[(1 - T_r)e^{-T_r}]^{0.275}$, where T_r is the reduced temperature, 0.275 is a parameter from ΔH^v data on alkenes, K is obtained from the value of $\Delta H^v_{298.15}$, and using as the critical temperature 532.6 K, Majer calculated $\Delta H^v_{293.15} = 35.20$ kJ mol^{-1}, with an estimated uncertainty of 0.3%. We then calculated the

[a]Literature values of $^o\delta$ and $^{in}\delta$ are from ref. 7, converted to $MPa^{1/2}$ units. δ values were calculated from molal enthalpies of vaporization, reported in (1), except for 1-heptene which was from (11), and 1,6-heptadiene which was calculated from $\Delta 3H^v_{298.15}$, specially measured for the present study. Values of $^d\delta$, $^p\delta$, $^o\delta$, and $^{in}\delta$ have been rounded to three and two figures, as shown.

solubility parameter of 1,6-heptadiene to be 15.57 $MPa^{1/2}$ units at 293.15 K, using a molar volume of 135.6 $cm^3\ mol^{-1}$ (13).

Results

The method used to calculate limiting activity coefficients (γ_i^∞) from measured vapor concentrations of the solute is described in detail elsewhere (9*d*), and follows that used in an earlier study (1, 2). Briefly, an uncorrected activity coefficient (γ_i') was calculated for a solute in a given solvent at 293.15 K at each of its several concentrations, by assuming an ideal vapor and using the usual formula $\gamma_i' = C_i/C_i^0 x_i$. Here C_i is the molar concentration of solute in the equilibrium vapor over a solution of mole fraction x_i, and C_i^0 is the molar concentration of vapor over the pure liquid solute. The pure liquid at 293.15 K is taken as the standard state. The values obtained for γ_i' were then corrected for the non-ideality of the vapor by using second virial coefficients, to give the corrected values of γ_i. The values used for the pure (B_{ii}) and mixed (B_{ij}) virial coefficients were estimated by using the empirical method of Tsonopoulos (15).

For each binary system the vapor concentration of solute had been measured for 5 or 6 solutions over a range of mole fractions x_i of solute. The value of γ_i^∞ for the solute was then found by a linear least-squares fit of the (x_i, γ_i) data, i.e. $\gamma_i = \gamma_i^\infty + bx_i$. Application of the statistical F-test showed that at the 95% confidence level, terms higher than x_i were not significant in the concentration range used ($x_i < 0.01$).

The values for the limiting activity coefficients and their standard deviations are in Table 2, where subscript 1 refers to the C_7 component of the binary solution, and subscript 2 refers to the polar component listed in column 1.

The solubility parameter δ of each polar liquid was considered to consist as usual of a dispersion $^d\delta$ and a polar $^p\delta$ contribution, where $\delta^2 = {}^d\delta^2 + {}^p\delta^2$. These values for the eight polar compounds and the three hydrocarbons are in Table 3. For 1-heptene, δ was calculated from the molal heat of vaporization (11), and for 1,6-heptadiene from Majer's value of the molal heat of vaporization. The values of $^d\delta$ for 1-heptene and 1,6-heptadiene were calculated by the procedure already reported (1) for the eight polar compounds, namely, from a plot of $\bar{R}_0^{3/4} n^{1/4}/V^{1/4}$ vs. δ for the appropriate homologous series, where $\bar{R}_0$

[a]The values of ψ_{21} are for component 1 at infinite dilution, and those of ψ_{12} are for component 2 at infinite dilution.

TABLE 5. Ratios of ψ for a solute at infinite dilution in one solvent to its value in another solvent, for several polar–polar and polar–nonpolar binary mixtures at 293.15 K

System (solute in solvent)*	$\psi_{12}(A)/\psi_{12}(B)$†	s.d.
A: The 8 polar components in 1-C_7 B: The 8 polar components in n-C_7	1.23	0.040
A: The 8 polar components in 1,6-C_7 B: The 8 polar components in n-C_7	1.47	0.15
A: The 8 polar components in benzene B: The 8 polar components in n-C_7	1.34	0.061
System (solute in solvent)*	**$\psi_{21}(A)/\psi_{21}(B)$†**	**s.d.**
A: 1-C_7 in the 8 polar components B: n-C_7 in the 8 polar components	1.11	0.061
A: 1,6-C_7 in the 8 polar components B: n-C_7 in the 8 polar components	1.27	0.17
A: CCl_4 in the 8 polar components B: n-C_7 in the 8 polar components	1.16‡	0.097

*1-Heptene and 1,6-heptadiene are treated as polar in [1].

†$\psi_{12}(A)$ and $\psi_{12}(B)$ refer to ψ_{12}, and $\psi_{21}(A)$ and $\psi_{21}(B)$ refer to ψ_{21} from Table 4, for systems A and B respectively, named in column 1 of Table 5. The ratios in column 2 are in each case the means of eight systems; and s.d. is the standard deviation.

‡From ref. 1.

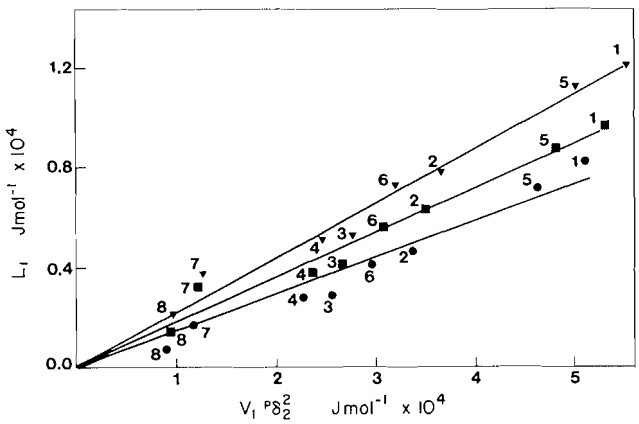

FIG. 2. Correlation between L_1 in [2] and $V_1{}^p\delta_2{}^2$ for hydrocarbons at infinite dilution in polar solvents. ▼, Heptane; ■, 1-heptene; ●, 1,6-heptadiene; *1*, nitromethane; *2*, nitroethane; *3*, 1-nitropropane; *4*, 2-nitropropane; *5*, ethanenitrile; *6*, propanenitrile; *7*, ethyl ethanoate; *8*, butyl ethanoate.

is the molar refractivity at zero frequency, n is the number of valence electrons in the constituent atoms, and V is the molar volume of the compound.

Discussion

Each value γ_2^∞ in Table 2 was used to compute a parameter ψ_{12} from

$$[1]\quad RT \ln \gamma_2^\infty = V_2[({}^d\delta_1 - {}^d\delta_2)^2 + {}^p\delta_1{}^2 + {}^p\delta_2{}^2 - 2\psi_{12}] + RT[1 - (V_2/V_1) + \ln (V_2/V_1)]$$

which is a combination of relationships proposed and used by Prausnitz and co-workers (3, 4). Similarly, each value of γ_1^∞ was used to compute a corresponding parameter ψ_{21} by using [1] with subscripts 1 and 2 replaced by 2 and 1, respectively. The second subscript in ψ_{ij} will henceforth denote the component which is at infinite dilution. The results are in Table 4. The values used for ${}^d\delta$ and ${}^p\delta$ were from Table 3, and those of molar volume V from ref. 11.

Milanova and Cave (1) evaluated ψ_{12} when each of the eight polar compounds in column 1 of Table 2 was the solute at infinite dilution in heptane and in benzene. The ratio of ψ_{12} when benzene was sovlent, to its value when heptane was solvent was nearly constant for the eight polar solutes, namely 1.34 ± 0.061. The values of ψ_{12} and ψ_{21} in Table 4 were used to test more extensively the degree of constancy of this ratio. The results are shown in Table 5.

The values in Tables 2 and 3 were also used to test the empirical correlation $\psi_{21} = k{}^p\delta_2{}^2$ of Weimer and Prausnitz (3), for binary mixtures of hydrocarbons (subscript 1) at infinite dilution in polar solvents (subscript 2). They evaluated k from plots of $V_1{}^p\delta_2{}^2$ vs. L_1, where

$$[2]\quad L_1 = RT \ln \gamma_1^\infty - V_1(\delta_1 - {}^d\delta_2)^2 - RT[1 - (V_1/V_2) + \ln (V_1/V_2)]$$

To be comparable, we also used this method. Figure 2 shows our linear plots forced through the origin for heptane, 1-heptene, and 1,6-heptadiene each infinitely dilute in our eight polar solvents. The resulting least-square values of k are given in Table 6. Thus, these systems obeyed the Weimer–Prausnitz

TABLE 6. Correlation constants in $\psi_{21} = k^{p}\delta_2^2$ and $\psi_{21} = k_1(^{p}\delta_1 - {}^{p}\delta_2)^2$ for hydrocarbons at infinite dilution in polar solvents

Class of hydrocarbon	k	k_1'	k_1''
Saturated (C_7)	0.390 ± 0.003	0.390 ± 0.003	0.399 ± 0.004
Saturated (C_5–C_{16})	0.396[a]	0.399[b]	
Mono-olefinic (1-C_7)	0.410 ± 0.003	0.388 ± 0.004	0.387 ± 0.005
Mono-olefinic (1-C_5)	0.415[a]	0.388[b]	
Di-olefinic (1,6-C_7)	0.426 ± 0.003	0.428 ± 0.004	0.383 ± 0.003

NOTE: The values of $^{d}\delta$ used for the calculation of k were from homomorph plots, to permit comparison with the k values of (3); k_1' refers to k_1 when $^{d}\delta$ values were found from homomorph plots, and k_1'' when $^{d}\delta$ values were found from refractivity data.

[a]Taken from ref. 3.

[b]Taken from ref. 4.

correaltion, even though only heptane was nonpolar. Moreover, as the number of double bonds was increased, so was k. However, this Weimer–Prausnitz correlation failed for those systems that consisted of the eight polar compounds at infinite dilution, in each of the three hydrocarbons. That is, linear plot through the origin, of L_2 vs. $V_2{}^{p}\delta_2{}^2$, were not reasonable ones (9*e*). Milanova and Cave (2) and Blanks and Prausnitz (4) reported the same failure.

Helpinstill and Van Winkle (5) carried out similar studies for saturated and unsaturated hydrocarbons at infinite dilution in polar solvents, but they took the small polarity of the olefins into account. Thus they wrote

$$[3]\quad RT \ln \gamma_1^{\infty} = V_1[(^{d}\delta_1 - {}^{d}\delta_2)^2 + (^{p}\delta_1 - {}^{p}\delta_2)^2 - 2\psi_{21}{}^*] + RT[1 - (V_1/V_2) + \ln (V_1/V_2)]$$

and they plotted $L_1{}^*$ vs. $V_1(^{p}\delta_1 - {}^{p}\delta_2)^2$, where

$$[4]\quad L_1{}^* = RT \ln \gamma_1^{\infty} - V_1(^{d}\delta_1 - {}^{d}\delta_2)^2 - RT[1 - (V_1/V_2) + \ln (V_1/V_2)]$$

and obtained a straight line through the origin, with $\psi_{21}{}^* = k_1(^{p}\delta_1 - {}^{p}\delta_2)^2$. From the data in Tables 2 and 3 for our hydrocarbons at infinite dilution in the eight polar solvents, values were found for k_1 and are given in Table 6. When the Helpinstill – Van Winkle correlation was tried by using the eight polar compounds at infinite dilution in each of the three hydrocarbons it failed. It is to be noted that in [3], dipole – induced dipole interactions are included in two terms, namely $(^{p}\delta_1 - {}^{p}\delta_2)^2$ and also $\psi_{21}{}^*$.

Keller *et al.* (6) proposed a solubility-parameter model for polar–polar and for polar–nonpolar binary systems, in which the solubility parameter δ of a non-hydrogen-bonding polar substance was derived to be

$$[5]\quad \delta^2 = {}^{d}\delta^2 + {}^{p}\delta^2 = {}^{d}\delta^2 + {}^{o}\delta^2 + 2^{in}\delta^{d}\delta$$

where $^{o}\delta$ is the contribution due to dipole–dipole interactions, and $2^{in}\delta^{d}\delta$ is that due to dipole – induced dipole interactions. Here, for a compound possessing a single polar substituent of dipole moment μ, $^{in}\delta = C\mu^2/V$ by definition, where C is a constant. Karger *et al.* (7, 8) applied the equations of Keller *et al.* (6) to evaluate $^{o}\delta$ and $^{in}\delta$ for many compounds.

In terms of relationships described by Keller *et al.* (6), the parameter ψ_{12} of [1] for a binary mixture would be given by

$$[6]\quad \psi_{12} = {}^{in}\delta_1{}^{d}\delta_2 + {}^{in}\delta_2{}^{d}\delta_1 + {}^{o}\delta_1{}^{o}\delta_2$$

for a polar–polar mixture. For a polar component 2 at infinite dilution in a nonpolar solvent 1, [6] becomes

$$[7]\quad {}^{in}\delta_2 = \psi_{12}/\delta_1$$

For each of the eight polar compounds in column 1 of Table 4, at infinite dilution in the solvent heptane, $^{in}\delta_2$ was calculated by using in [7] the data in column 3 of Table 4, and $\delta_1 = 15.32$. The resulting values of $^{in}\delta_2$ along with those of $^{o}\delta_2$ found from [5] are in Table 3. Values reported by Karger *et al.* (7) for some of these polar compounds are also in Table 3.

For heptane at infinite dilution in each of the eight polar compounds as solvents, inspection of columns 2 and 3 of Table 4 shows that a different set of $^{in}\delta_2$ values would be obtained. This suggests a limitation to the right-hand side of [6]; but the use of only the Flory–Huggins term for the entropy in [1] may also be a contributing factor. Hildebrand *et al.* (16) have already suggested that ψ_{12} would not expected to be the same as ψ_{21}.

It was noted above, and illustrated in Table 5, that for a given pair of hydrocarbon solvents, the ratio of ψ_{12} for a polar compound in one of these solvents, to its value ψ_{12}' in the other was reasonably constant for all eight polar compounds tested. Equation [6] may be used to describe this ratio. Thus, for polar–nonpolar mixtures

$$[8]\quad \frac{\psi_{12}}{\psi_{12}'} = \frac{^{in}\delta_2\delta_1}{^{in}\delta_2'\delta_1'}$$

where component 2 is the polar compound, and 1 the solvent.

Thus, ψ_{12}/ψ_{12}' becomes simply the ratio of the solubility parameters of the two solvents, which in the case of benzene and heptane reported by Milanova and Cave (2), is 1.23. Their experimental value was 1.34 ± 0.063.

For a polar–polar mixture, rearrangement of [6] gives

$$[9]\quad {}^{in}\delta_1 + \frac{^{o}\delta_2}{^{d}\delta_2}{}^{o}\delta_1 = \frac{\psi_{12} - {}^{d}\delta_1{}^{in}\delta_2}{^{d}\delta_2}$$

Therefore plots of the right hand side vs. $^{o}\delta_2/{}^{d}\delta_2$ for the polar solutes in 1-heptene and 1,6-heptadiene as solvents should be linear. By using [9], $^{in}\delta_1$ and $^{o}\delta_1$ for these solvents were calculated by least-squares fits of the relevant data in Table 3 and columns 5 and 7 of Table 4. The results with the standard deviations are in columns 5 and 7 of Table 3.

Finally, inspection of Table 4 shows that the values of ψ_{12} and ψ_{21} decrease when (*i*) the chain length in a homologous series of a component increases, in the case of each of the three C_7 hydrocarbon components in turn; (*ii*) the number of the double bonds in the C_7 component is decreased. The values of γ_1^{∞} and γ_2^{∞} in Table 3 obey trend (*i*) above. In that connection, Gerster *et al.* (17) found that γ_1^{∞} for pentane and 1-pentene decreased in several polar solvents as the chain length of those solvents increased.

These trends and values, and some others of $^{in}\delta$ in Table 3 are

useful as empirical guides when partial molal free energies alone are being considered. However, the values given for ψ have depended on the use of the Flory–Huggins entropy term in [1], and the use of that term alone for entropies of polar systems is suspect. Experimental values for the partial molal enthalpy would provide a better basis; and in conjunction with those of the partial molal free energy would provide values directly for the partial molal entropy. Such evaluations will be the subject of a subsequent report.

Acknowledgments

We are grateful to Dr. Vladimir Majer of the Institute of Chemical Technology in Prague for his generosity in measuring the enthalpy of vaporization of 1,6-heptadiene for us, and to Mr. George Kopp of McGill University for the fabrication of the six-way glass stopcock.

The reaction of 3-methyltricarballylic acid with acetic anhydride. Addendum: On Fittig's product from acylative decarboxylation of camphoronic acid

GEORGE M. STRUNZ AND PIERRE GIGUÈRE

Maritimes Forest Research Centre, Canadian Forestry Service, P.O. Box 4000, Fredericton, N.B., Canada E3B 5P7

Received September 6, 1985

GEORGE M. STRUNZ and PIERRE GIGUÈRE. Can. J. Chem. **64**, 204 (1986).

Two products, 2,7-dioxa-1,4,4,5-tetramethylbicyclo[3.2.1]octane-3,6-dione (**5**), and 2-acetonyl-2,3,3-trimethylsuccinic anhydride (**4**) were identified from the base-catalysed reaction of camphoronic acid, **2** (R′, R″ = CH_3), with acetic anhydride. The former (**5**) is believed to be identical with the product described by Fittig and assigned an isomeric formulation.

GEORGE M. STRUNZ et PIERRE GIGUÈRE. Can. J. Chem. **64**, 204 (1986).

On a identifié deux produits de la réaction de l'acide camphoronique avec l'anhydride acétique sous catalyse basique: le bicyclo[3.2.1] octane dioxa-2,7 dicéto-3,6 tetraméthyl-1,4,4,5 (**5**) et l'anhydride succinique acétonyl-2- triméthyl-2,3,3 (**4**). On croit que le premier composé (**5**) est le produit décrit par Fittig, qui lui a assigné une formulation isomerique.

In studying the mechanism by which bislactones of structure **1** are produced on reaction of the sodium salt of tricarballylic acid, **2** (R′, R″ = H), with carboxylic acid anhydrides, Fittig (1) extended his investigations to the more highly substituted homologue, camphoronic acid, **2** (R′, R″ = CH_3). The sodium salt of camphoronic acid, when heated with acetic anhydride, afforded some 3% of a crystalline product that Fittig considered to be the bislactone **3**. From this he concluded that formation of the bislactones **1** involves a mechanistic sequence other than the expected initial acylation at C-3 of tricarballylic acid with decarboxylation of the resulting β-ketoacid.

Our recent investigation of products derived from acylative decarboxylation of 3-methyltricarballylic acid, **2** (R′ = H, R″ = CH_3), led us to speculate that Fittig's product may in fact have been **4** or **5**, which can arise by a mechanism involving acylation at C-4 of a suitable derivative of camphoronic acid (2).

In this communication we report that acylative decarboxylation of camphoronic acid[1] through the agency of acetic anhydride in the presence of 4-dimethylaminopyridine affords the products **4** and **5** in yields of 24% and 37% respectively (crude crystalline products). These compounds were interconvertible through the ketodiacid, and their structures were readily assigned by comparison of their spectra with those of the analogous bisdemethyl products (2). The bislactone **5** is believed, by virtue of its melting point, to be identical with the product described by Fittig and assigned the isomeric structure **3** (1).

While the substituted succinic anhydride product predominated over the bislactone in the 3-methyltricarballylic acid experiment (2), the reverse is found here, presumably as a consequence of unfavorable steric interactions of the eclipsed groups in **4** (cf. Ref. 6).

Experimental

See ref. 2 for general description of instrumentation, etc.

Reaction of camphoronic acid with acetic anhydride

To freshly distilled acetic anhydride (10 mL) containing 4-dimethylaminopyridine (100 mg, 0.82 mmol) was added camphoronic acid (1.0 g, 4.58 mmol). The solution was heated under reflux for 32 h. During this period very slow evolution of carbon dioxide, indicative of the desired reaction, could be detected by the precipitation of carbonate from a solution of barium hydroxide. This had not completely ceased when the reaction was terminated by distillation of the volatile material under reduced pressure (water pump; bath temperature, ambient to 95°C). The dark brown residue was dissolved in ethyl acetate and treated with activated charcoal. After removal of the charcoal by filtration, the volume of the filtrate was reduced *in vacuo*, and the resulting solution deposited crystals of **5** (105 mg), mp 147–149°C, on standing in the refrigerator.

The mother liquor, after successive flash chromatography ($CHCl_3$–EtOAc, 99:1) and preparative layer chromatography ($CHCl_3$–EtOAc, 97:3), afforded additional crude crystalline **5** (234 mg; total yield 37%) as well as crude crystalline **4** (220 mg; 24%).

[1]The camphoronic acid used in this experiment was obtained by stepwise oxidation of (+) camphoric acid. The sequence, which involved oxidative decarboxylation (3) of the monomethyl ester of camphoric acid (4), and ozonolysis of the resulting methyl 3-dehydrocamphonanate, **6**, gave in our hands a more satisfactory yield (overall 36%) of camphoronic acid than the classical nitric acid oxidation of camphor (5).

Recrystallization of **5** from toluene gave fine colorless needles (289 mg), mp 146–149°C (lit. (1) mp 147.5–148°C); $[\alpha]_D^{27}$ +118° (*c* 0.525, $CHCl_3$); ir (KBr): 3000, 2955, 2890, 1803, 1747, 1467, 1454, 1397, 1379, 1373, 1344, 1298, 1264, 1247, 1195, 1173, 1135, 1108, 1073, 1033, 1013, 981, 939, 908, and 880 cm^{-1}; nmr ($CDCl_3$, 60 MHz) δ: 1.28 (3H, s), 1.34 (3H, s), 1.39 (3H, s), 1.77 (3H, s), 2.33 (2H, q, $|J_{AB}| \sim 12.5$ Hz; $\Delta\nu_{AB} \sim 20.5$ Hz); mass spectrum (*inter alia*) *m/z*: 199 $(MH)^+$, 198 $(M^{\ddagger})$, 141 $(M - C_3H_5O)^+$, 126 (M − CO and $CO_2)^{\ddagger}$, 111 $(C_6H_7O_2)^+$, 83 $(C_6H_{11})^+$, 43 $(CH_3\ CO)^+$ (base peak). *Anal.* calcd. for $C_{10}H_{14}O_4$: C 60.59, H 7.12; found: C 60.80, H 7.14.

Recrystallization of **4** (toluene–CCl_4) gave colorless needles (89 mg), mp 91–96°C; $[\alpha]_D^{27}$ +8.3° (*c* 0.53, $CHCl_3$); ir (KBr): 2990, 2955, 2915, 2890, 1845, 1772, 1708, 1485, 1470, 1455, 1406, 1385, 1372, 1364, 1283, 1255, 1196, 1166, 1122, 985, 958, and 935 cm^{-1}; nmr ($CDCl_3$, 200 MHz) δ: 1.22 (3H, s), 1.36 (3H, s), 1.40 (3H, s), 2.19 (3H, s), 2.94 (2H, q, $|J_{AB}|$ 18.7 Hz; $\Delta\nu_{AB}$ 27.6 Hz); mass spectrum (*inter alia*) *m/z*: 198 $(M^{\ddagger})$, 141 $(M - C_3H_5O)^+$, 126 (M − CO and $CO_2)^{\ddagger}$, 111 $(C_6H_7O_2)^+$, 83 $(C_6H_{11})^+$ (M − CO and CO_2 − $CH_3CO)^+$, 43 $(CH_3CO)^+$ (base peak).

An analytical sample, recrystallized from toluene–CCl_4, melted at 95–97°C. *Anal.* calcd. for $C_{10}H_{14}O_4$: C 60.59, H 7.12; found: C 60.60, H 7.13.

Differential heats of dilution of *tert*-butanol into water–*tert*-butanol mixtures at 26.90°C

YOSHIKATA KOGA
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6
Received August 27, 1985

YOSHIKATA KOGA. Can. J. Chem. **64**, 206 (1986).

The differential heats of dilution of *tert*-butanol into water–*tert*-butanol mixtures were measured at 26.90°C. The results in the range where the mole fraction of *tert*-butanol, x, is less than 0.05 indicate that the hydrophobic interaction is repulsive and of long range; the interaction appears to extend its tail as far as six molecular distances or longer. Above the threshold concentration $x \simeq 0.06$, the differential heats of dilution were close to zero and approximately independent of concentration and temperature.

YOSHIKATA KOGA. Can. J. Chem. **64**, 206 (1986).

On a mesuré à 26,90°C, les chaleurs différentielles de dilution du *tert*-butanol dans des mélanges *tert*-butanol–eau. Les résultats pour le *tert*-butanol dans la zone de fraction molaire $x < 0{,}05$ indiquent que l'interaction hydrophobe est répulsive et de grande portée; l'interaction semble prolonger son influence jusqu'à au moins six molécules de distance. Au-dessus de la concentration limite de $x \simeq 0{,}06$, les chaleurs différentielles de dilution se rapprochent de zéro et sont approximativement indépendantes de la concentration et de la température.

[Traduit par le journal]

The anomalous physical properties of *tert*-butanol (TBA) – H_2O mixtures at low concentrations of TBA have attracted much attention, and there are numerous thermodynamic data available in the literature (1–14). Of these, the quantities proportional to the second derivatives of the free energy with respect to appropriate variables appear to show more pronounced features. Examples include the concentration fluctuations (5–7), the compressibility (8, 9, 11), the expansibility (10, 12), the heat capacity (10, 12), and the partial molar volume (10, 13). While the integral heats of mixing have been determined and compiled (14), it is surprising that there appears to be no actual measurement of the differential heats of dilution in the literature.

In view of the fact that the differential heats of dilution could provide direct information about the energetics of the solute–solute interaction, or the hydrophobic interaction (2), such measurements were made in the present work at 26.90°C. The results suggest clearly that the solute–solute interaction is repulsive and of long range. It seems that this repulsive interaction is already operative at the mole ratio of TBA to H_2O of 1:1000. This is consistent with the concept of cooperative hydrogen bonding in H_2O (15); namely, the structure reinforcement of H_2O due to TBA molecules, or the hydrophobic hydration (1–4), extends a long distance via cooperative hydrogen bonding. Recent computer experiments (16, 17), while providing a deeper insight into the structure of the TBA–H_2O mixture, may be improved if the number of molecules is increased and the cooperativeness of the hydrogen bonds in H_2O is somehow included.

tert-Butanol was purified by refluxing for 24 h with CaH_2, followed by distillation. The normal boiling point was 82.42 ± 0.02°C. Freshly distilled water was used. The differential heats of dilution were measured by means of a LKB Bromma 8700 precision calorimetry system. A glass capsule containing about 0.7 g (≃0.01 mol) of TBA was broken in about 90 g of TBA–H_2O mixture. A small temperature change was followed by means of a thermister. The calibration of the system and the calculation of the differential heats of dilution, Δh, is standard (18). A small, almost negligible, correction was applied to the measured value of Δh to obtain the value at the unified temperature, 26.90 ± 0.02°C, the temperature of the bath, using $\Delta C_p (= \partial \Delta h / \partial T)$. The latter was obtained by performing the calibration runs before and after the capsule of TBA was broken (18). The error limit in Δh was estimated to be ±0.05 kJ mol^{-1}. The uncertainty in ΔC_p is inevitably large due to the fact that the method is not designed for measuring ΔC_p. It was estimated to be about ±100 J mol^{-1} K^{-1}, except for the range $0.07 < x < 0.13$, where it became enormous since the value of ΔC_p was calculated in effect as a quotient of zero over zero.

The results are plotted against the mole fraction of TBA, x, in Fig. 1 for Δh and in Fig. 2 for ΔC_p. In Fig. 2, the points in the range $0.07 < x < 0.13$ are omitted. The values at infinite dilution of TBA are those of Arnett, Kover, and Carter (19) and are shown by an arrow in each graph. Their value of Δh was corrected to that at 26.90°C. While they observed that Δh was constant for the range of x less than 2×10^{-4}, at the lowest mole fraction of the present measurement, $x \simeq 1 \times 10^{-3}$, the slope of the curve Δh vs. x already appears to be non-zero and positive. This means that at about this or a lower concentration, a solute molecule starts to feel the presence of the others in a repulsive manner. In other words, the structure reinforcement of H_2O due to TBA tails as far as $\sqrt[3]{(3/4\pi \times 1 \times 10^{-3})} \simeq 6$ molecular distance or longer. This repulsive interaction increases as the separation between solutes becomes shorter, as shown in Fig. 1 by the fact that the positive slope increases along with x for small x. When x reaches about 0.06, Δh becomes close to zero and approximately independent of x thereafter. This implies that in this region an additional TBA molecule feels as if it is within the bulk of pure TBA. The postulate that a clathrate of the type TBA $(H_2O)_n$, with $n \simeq 20$, forms at room temperature (6, 7) is not inconsistent. Thus, up to this threshold value of concentration, an additional TBA molecule has to force itself into an already somewhat reinforced network of H_2O and finds the least reinforced area, i.e. far enough from the existing TBA molecules to settle in. Then, it reorganizes the surrounding H_2O

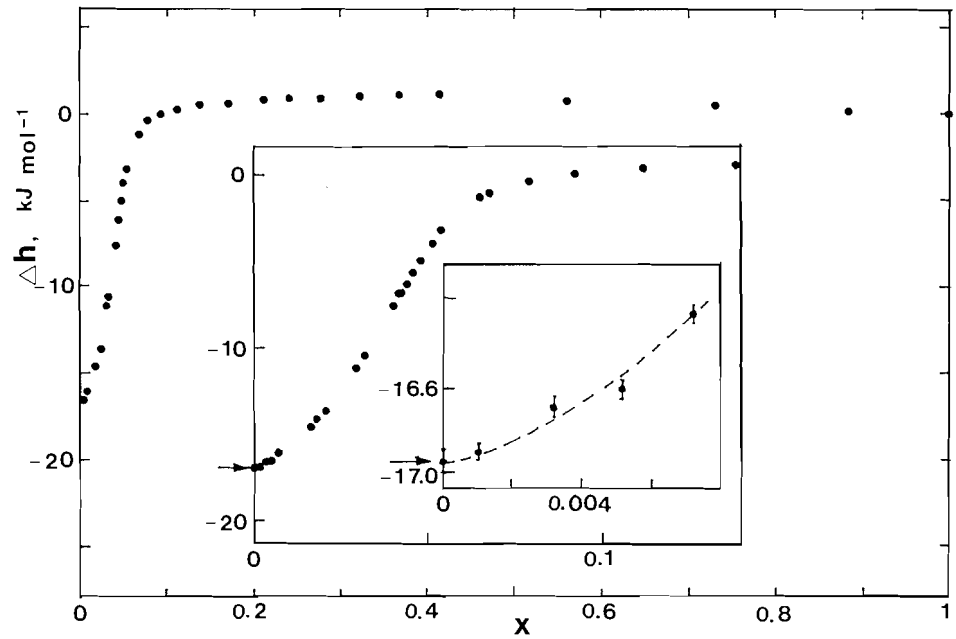

FIG. 1. The differential heats of dilution of *tert*-butanol into water–*tert*-butanol mixtures, Δh, against mole fraction, x, at 26.90°C.

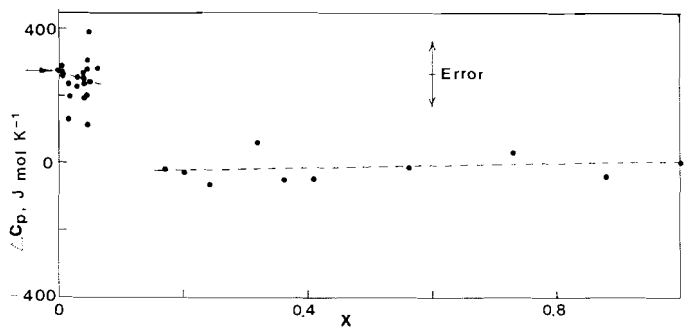

FIG. 2. The differential heat capacity changes, ΔC_p, against mole fraction, x, at 26.90°C.

molecules. As a result, the next TBA has more difficulty with a less exothermic differential heat of dilution. Beyond the threshold concentration, there is no more room for hydrophobic hydration, and the mixture consists of clathrates and TBA.

As shown in Fig. 2, ΔC_p is positive for x less than 0.06 and is small and negative, if not zero, for higher concentrations. It follows that the threshold occurs at a smaller value of x at higher temperature, which is consistent with the interpretation of the light scattering data (7).

Sterically hindered porphyrins having a fully hydrophobic cavity have been prepared. The cavity is capped with a 2,3,5,6-tetramethylbenzene moiety containing at the 1,4-positions methylene —$(CH_2)_n$— chains (n = 4, 5, 7) bonded at *trans* pyrrole rings of a porphyrin that is alkylated with methyl or ethyl groups at the other β-pyrrolic positions. The iron(III) chloride derivative of the 4,4-durene-capped base has been obtained as single crystals, and subjected to X-ray structural analysis. The typical high spin, square pyramidal geometry of five-coordinate hemin chlorides is maintained; the porphyrin core is strongly distorted and there is no interaction between the phenyl group of the strap and the iron.

SHANTHA DAVID, DAVID DOLPHIN, BRIAN R. JAMES, JOHN B. PAINE III, TILAK P. WIJESEKERA, FREDERICK W. B. EINSTEIN et TERRY JONES. Can. J. Chem. **64**, 208 (1986).

On a préparé des porphyrines stériquement empêchées et possédant une cavité hydrophobe complète. La cavité est cappée par un tétraméthyl-2,3,5,6 benzène portant, dans les positions 1 et 4, des chaines méthylènes (—$(CH_2)_n$— où n = 4, 5, 7) liés aux cycles pyrroliques *trans* d'une porphyrine qui est alkylée par des groupements méthyle ou éthyle dans les autres positions β du pyrrole. On a obtenu un cristal unique du dérivé du chlorure de fer(III) de la base cappée par le durène-4,4 et on l'a soumis à une analyse par diffraction des rayons-X. La géométrie de pyramide carrée et à spin élevée qui est typique des chlorures d'hémines pentacoordonnées est maintenue; le noyau de la porphyrine est fortement déformé et il n'y a acune interaction entre le groupement phényle et le fer.

[Traduit par le journal]

There have been numerous attempts to prepare simple iron(II) porphyrin complexes which will reversibly bind oxygen in a manner analogous to hemoglobin and myoglobin (1–3). A major problem with the "readily available" protein-free model systems is that, in the presence of oxygen, an irreversible oxidation to μ-oxo-iron(III) dimers occurs; this autooxidation proceeds via the formation of a monomeric iron-dioxygen adduct, which subsequently reacts with a second iron(II) porphyrin unit (4). The synthesis of porphyrins with protective structures covering one face of the macrocycle has proved to be an effective way of inhibiting this "dimerization." Several such porphyrins have been synthesized, the best-known systems being the "picket-fence" (5) and "pocket" (6) porphyrins of Collman *et al.*, the "capped" (7) porphyrins of Baldwin and co-workers, and the "cyclophane hemes" (8) of Traylor *et al.* In addition, model systems with steric hindrances on both faces of the porphyrin (the "basket-handle" porphyrins (9) of Momenteau *et al.*), as well as those with protective structures on one and appended imidazole ligand on the other side, have been prepared (10, 11).

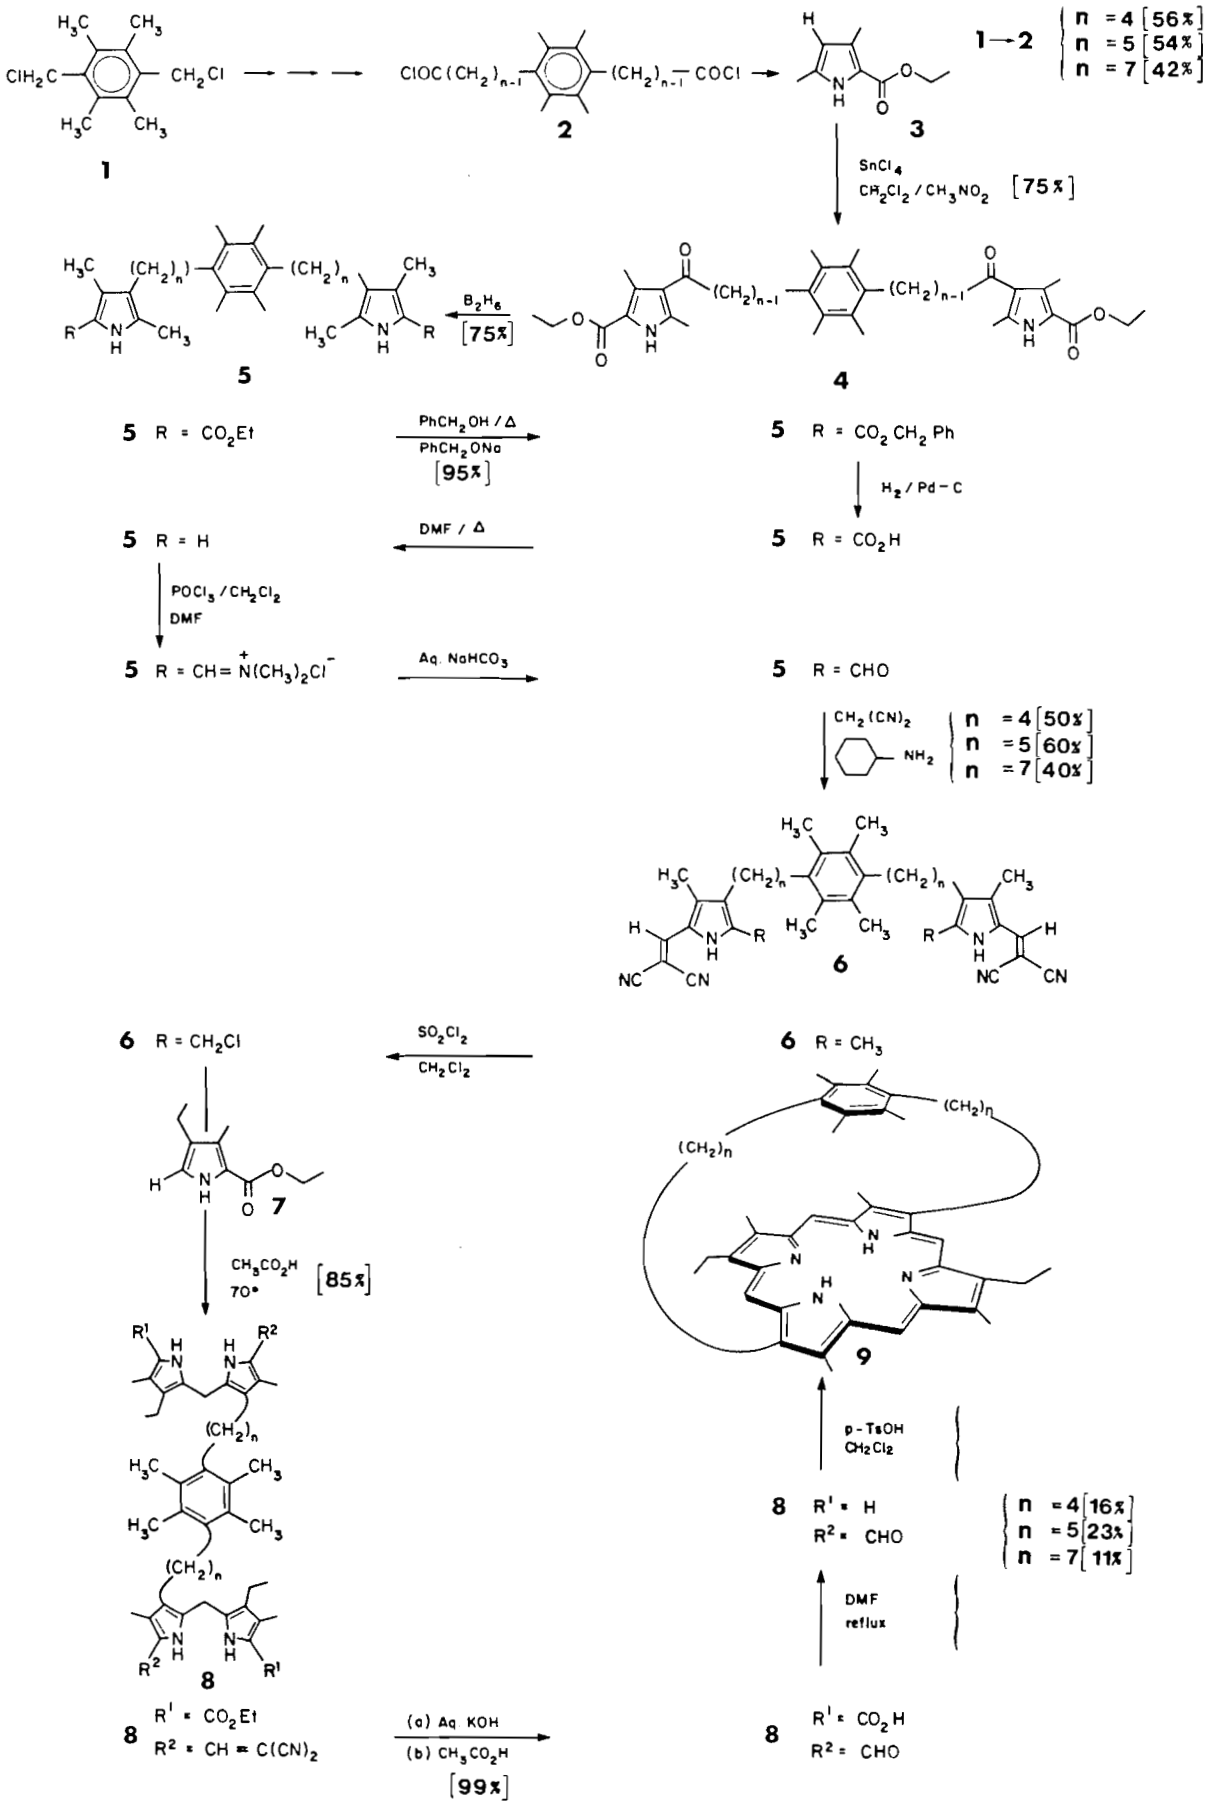
Two fundamentally different approaches have been adopted for the synthesis of hindered porphyrins. The first is an extension of single-step coupling of benzaldehyde and pyrrole to produce *meso*-tetraphenylporphyrin (12). Aromatic aldehydes with potential amino groups as *ortho*-substituents are condensed with pyrrole and the protective structures are linked to the amino groups via amide linkages using appropriate acyl chlorides (5, 6). In a modification of this method, the protective structures are linked to the aromatic aldehydes at their *ortho* positions via ester or ether functions, prior to the coupling with pyrrole (7, 9, 10). The most widely used approach to the synthesis of hindered porphyrins has been to condense, via ester or amide linkages, a diagonally β-substituted preformed porphyrin with a terminally bifunctional molecule carrying appropriate functional groups (8, 11, 13–15).

Porphyrins produced by such methods are limited, however, in the size of the cavity produced. In addition, truly hydrophobic cavities cannot be produced since the protective structures are linked to the porphyrin by polar amide, ester, or ether linkages. An early attempt at the preparation of such a hydrophobic system using rigid dipyrromethene precursors resulted in very low yields during the cyclization step (16).

The synthetic route originally developed in this department to construct permanently deformed porphyrins (17, 18) appeared to be ideally suited for the synthesis of a sterically hindered porphyrin having a fully hydrophobic cavity.

Commercially available 1,4-bis(chloromethyl)-2,3,5,6-tetramethylbenzene (**1**) was converted into the diacid chlorides (**2**) using standard malonate chemistry. The incorporation of the durene strap into the porphyrin[1] was initially carried out with the bis-pentanoic and heptanoic acid derivatives (**2**, n = 5 and 7), as outlined in the scheme. 2-Ethoxycarbonyl-3,5-dimethylpyrrole (**3**), prepared by the reductive condensation (19) of diethyloximinomalonate with 2,4-pentanedione, was condensed with **2** to give the diketo bispyrrole (**4**), using a method previously employed for the preparation of covalently linked porphyrins (20). Diborane reduction, in THF, of **4** gave the bispyrrole ethyl ester (**5**, R = CO_2Et), which was transbenzylated (21) in refluxing benzyl alcohol and catalytic sodium benzyloxide. The benzyl ester (**5**, R = CO_2CH_2Ph) was converted to the dicyanovinyl protected derivative (**6**, R = CH_3) using standard

[1]All new compounds were characterized by satisfactory elemental analysis, and mass and nmr spectroscopy.



SCHEME I

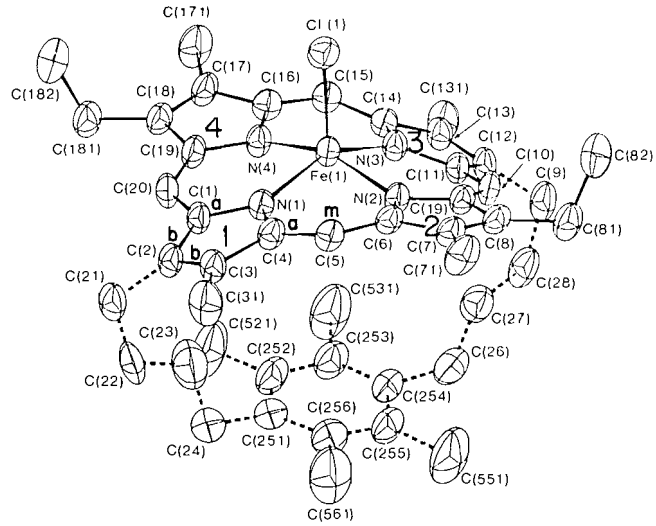


FIG. 1. A SNOOPI (32) diagram of the hemin **10** (50% probability contours for all atoms; hydrogen atoms have been omitted for clarity; the dashed bonds are used to distinguish between the "strap" and the porphyrin skeleton).

techniques (21–23). The intermediates in this sequence were unstable and neither isolated nor characterized. However, the dicyanovinyl group both protects the aldehyde function and provides a compound suitable for chromatographic purification.

The conversion of **6** (R = CH_3) to the chloromethyl derivative **6** (R = CH_2Cl) was carried out under conditions favourable for an electrophilic, rather than a radical, reaction to prevent competitive chlorination of the benzene substituents (24–28); chlorination in the dark using two equivalents of sulfuryl chloride in methylene dichloride at room temperature gave **6** (R = CH_2Cl), which was isolated and immediately condensed with the pyrrole **7** (17) to give **8** (R^1 = CO_2Et; R^2 = $CH{=}C(CN)_2$ in consistently greater than 90% yield, attesting to the high regioselectivity of the preceding chlorination step.

Deprotection of the formyl group and saponification of the esters was achieved using KOH in refluxing aqueous *n*-propanol. The reaction was followed by the disappearance and appearance of bands at 407 and 320 nm, respectively. Removal of the *n*-propanol followed by acidification gave the 5-carboxy-5′-formyldipyrromethane dimer **8** (R^1 = CO_2H; R^2 = CHO). Decarboxylation in refluxing DMF (followed by the disappearance of a 280-nm band) gave **8** (R^1 = H; R^2 = CHO), which was not isolated. Instead, most of the DMF was removed *in vacuo*, the residue dissolved in dichloromethane, and the remaining DMF removed by extraction with water. The dried dichloromethane containing the 5-unsubstituted-5′-formyldipyrromethane was added to a solution of *p*-toluenesulfonic acid in methanol/dichloromethane over a period of 5–6 days using a syringe pump.

The capped porphyrins **9** (*n* = 4 or 5 or 7) were the only porphyrins present in the reaction mixture and were readily isolated and purified by chromatography. The overall yields of the decarboxylation and cyclization steps were 11–16% (**9**, *n* = 4), 22–31% (**9**, *n* =5), and 9–13% (**9**, *n* = 7) and ~100 mg of porphyrin was readily available from one such reaction sequence.

The free base **9** (*n* = 4), in THF, was treated with an excess of $FeCl_2$, in methanol. The mixture was refluxed, under N_2, for 1 h. The solvent was removed and the residue washed with water and then chromatographed on alumina (activity V). Elution with CH_2Cl_2 gave the green μ-oxo dimer. Treatment of the eluate with 0.2 *M* HCl gave the hemin chloride **10**, which was recrystallized from CH_2Cl_2/hexane (85% yield). Crystals of the hemin **10** were prepared by the addition of methanol to a dichloromethane solution (~0.1 *M*) to a ratio of 3:7 (v/v). Standing at room temperature for ~5 days yielded single crystals for X-ray structural analysis.[2]

The molecular structure of the hemin **10** shown in Fig. 1 (32) indicates a very distorted porphyrin core, which results directly from the carbon "strap." Nevertheless, the square pyramidal coordination environment found about the Fe atom is typical of

[2]A crystal suitable for data collection was mounted in a thin-walled glass tube and centred on an Enraf–Nonius CAD4-F diffractometer. Accurate cell dimensions were determined by least-squares refinement of the setting angles of 25 accurately centred reflections (with $15° < 2\theta < 20°$) chosen from a variety of points in reciprocal space. The crystal system was found to be triclinic and consequently the space group was P1 or $P\bar{1}$ (subsequent structure solution uniquely defined the space group as $P\bar{1}$). A total of 5795 independent reflections were measured, of which 3271 were classed observed ($F/\sigma(F) > 5\sigma(F)$) and used in structure refinement. Lorentz and polarization corrections have been made. The Fe atom was located from the Patterson map, while all other non-hydrogen atoms were found from subsequent difference-Fourier maps. At this stage, the presence of a crystallization molecule of dichloromethane was detected in the unit cell, disordered in at least two different arrangements. The exact mode of this disorder is complicated and, although a number of chemically reasonable models were investigated, no satisfactory description of this volume could be made. We were able to minimize the electron density in this volume by fixing the "porphyrin" parameters and performing full-matrix least-squares refinement of the occupancies, coordinates, and temperature factors of two fractional dichloromethane molecules that overlapped at a common C site. Subsequent difference maps revealed clearly the positions of the hydrogen atoms of the porphyrin molecule (solvent hydrogens were not located). Refinement was continued by separation of the structure into three batches: batch 1 contained Fe(1), Cl(1), and the porphinato skeleton (248 variables); batch 2 consisted of the "strap" and peripheral methyl and ethyl groups (369 variables); and batch 3 was made up of the disordered solvent molecule (31 variables). A number of full-matrix least-squares cycles were performed on each batch alternately until the refinement had converged. During these cycles, hydrogen atoms were constrained with respect to their parent carbon atoms (C—H = 0.95(2) Å; H—C—H = 110(2)°; C—C—H = 110(2)°) and an overall isotropic temperature factor was refined for (*i*) methyl hydrogens, (*ii*) methylene hydrogens, and (*iii*) "C_m" hydrogens. The final cycle of refinement, with all hydrogen and solvent parameters fixed and the coordinates and anisotropic thermal parameters of the non-hydrogen atoms allowed to vary, produced essentially no shifts ($\Sigma(\text{shift/e.s.d.})^2 = 2.52$) and gave final agreement factors of $R = 0.038$ and $R_w = 0.048$ for 470 variables. The final difference map contained a number of residual peaks (0.18–0.40 A^{-3}) in the solvent region and two peaks (0.28 and 0.31 e A^{-3}) close to Fe(1). Weights were derived on the basis of trends in $w\Delta^2$ as a function of $\sin\theta/\lambda$ and F_0 (Table 1).[3] Atomic scattering factors including anomalous dispersion were taken from Tables for X-ray Crystallography (29). Final positional and U_{iso} temperature factors are given in Table 2.[3] Anisotropic, thermal parameters, hydrogen parameters, bond parameters, mean-planes data, and structure factor listings have also been deposited (Tables 3–7).[3] Data reduction and initial structure solution were performed using "The NRC VAX crystal structure system" (30), whereas the latter stages of structure solution and refinement were carried out using "CRYSTALS, Oxford University" (31). All calculations were performed using an "in-house" VAX750 computer.

other high spin Fe(III) porphyrins that do not contain a "strap" (33) (Table 8).[3] The Fe(1)—Cl(1) distance of 2.232(1) Å is close to the value of 2.218(6) Å found for [Fe(proto)(Cl)] (34) and the distance from Fe(1) to the centre of the phenyl ring of 5.613 Å indicates no interaction between the phenyl group of the "strap" and Fe(1).

The distortion of the porphinato skeleton found here is not as marked as found in the related deformed free-base porphyrin with short-strap bridging reported earlier (18, 35). The angle between the best planes of pyrrole rings 1 and 3 is 43.0° compared with 68.5° in the earlier example, while the corresponding angle between rings 2 and 4 is 17.2° compared to 13.5° in the more deformed case (18, 35). Atom pyramidalization (χ_{pyr}) and bond twist (τ_{twist}) parameters (36) for the porphinato skeleton (Table 9) suggest that strain induced by the strap is distributed throughout the entire molecule rather than being localized within the two "strapped" pyrrole rings. Mean-plane data determined for each pyrrole ring further support distribution of strain throughout the molecule, viz. the "strapped" C atoms C(2) and C(12) within rings 1 and 3, respectively, lie well out (0.06–0.10 Å) of the plane defined by the other atoms in their rings. Also, C_a atoms in pyrrole rings 2 and 4 lie out of plane with respect to the other ring members, in a direction towards the "strap."

Bond distances and angles around the porphinato skeleton are remarkably similar to those found in other "undistorted" nonstrapped XFe(III) porphyrins (Table 10) (37, 38). The bond parameters for the "strap" and alkyl substituents do not appear unusual. Transannular parameters indicate that the central porphyrin cavity has contracted as a result of binding to Fe(1), e.g. N(1)—N(3) and N(2)—N(4) are 3.965(5) and 4.016(5) Å, respectively, cf. 4.003(4) and 4.241(4) Å in a severely distorted porphyrin (35).

The aminolysis of aryl diphenylphosphinates, *p*-nitrophenyl diphenylphosphinothionate, -phosphinothioate, and -phosphinodithioate by *n*-butylamine, by the secondary amines piperidine, pyrrolidine, morpholine, and dipropylamine, as well as by a series of diamines, has been studied in acetonitrile. The general reactivity order is diamines > butylamine > *sec*-amines. Butylaminolysis follows a two-term rate law, one first order in amine and the other second order in amine. The second order in amine term predominates. *sec*-Amines and diamines follow a rate law which is first order in amine only. Leaving group effects, solvent effects, and activation parameters support a pathway which involves rate-determining collapse of a zwitterionic pentacoordinate intermediate. In the case of butylamine this collapse is general base catalyzed and for the diamines the reaction is intramolecularly general base catalyzed.

ROBERT D. COOK, WAFA A. DAOUK, ASAAD N. HAJJ, AHMAD KABBANI, ANWAR KURKU, MUNA SAMAHA, FUAD SHAYBAN et OHANNES V. TANIELIAN. Can. J. Chem. **64**, 213 (1986).

Opérant dans l'acétonitrile, on a étudié l'aminolyse des diphénylphosphinates d'aryles et des diphényl-phosphinothionate, -phosphinothioate et -phosphinodithioate de *p*-nitro-phényle par la *n*-butylamine, par les amines secondaires comme la pipéridine, la pyrrolidine, la morpholine et la dipropylamine ainsi que par une série de diamines. L'ordre de réactivité générale est le suivant: diamines, butylamine, amines secondaires. La butylaminolyse obéit à une équation de vitesse impliquant deux termes, un du premier ordre en amine et un autre du deuxième ordre en amine. Le terme du deuxième ordre en amine prédomine. Les réactions avec les amines secondaires et avec les diamines obéissent à une équation du premier ordre en amine seulement. Les effets de groupements nucléofuges et de solvants ainsi que les paramètres d'activation sont en accord avec un mécanisme réactionnel impliquant une étape déterminante au cours de laquelle il y a décomposition d'un intermédiaire zwitterionique pentacoordonné. Dans le cas de la butylamine, cette décomposition est soumise à une catalyse générale des bases et, pour les diamines, la réaction est soumise à une catalyse générale des bases qui est intramoléculaire.

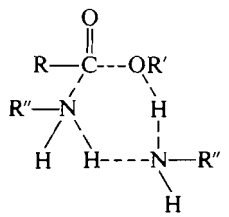
Introduction

Aminolysis reactions of carboxylic esters in aprotic solvents have been the subject of several reports starting with the work of Menger in 1966 (1). Menger found that the butylaminolysis of *p*-nitrophenyl acetate (*p*-NPA) in chlorobenzene is second order in amine and that tertiary amines only mildly catalyze the reaction. A mechanism involving concerted bifunctional catalysis was proposed, with a transition state similar to **1**.



1

Shawali and Biechler (2) reported that the butylaminolysis of both phenyl dichloroacetate and difluoroacetate in *p*-dioxane follows a mixed rate law (eq. [1]) and that tertiary amines do catalyze the reaction. On the other hand, for secondary amine aminolysis, only the term which is first order in amine appears. For butylaminolysis the authors suggest that the reaction proceeds via a neutral tetrahedral intermediate, with the second amine molecule catalyzing the breakdown of this intermediate by proton removal. The bifunctional cyclic mechanism was proposed by Satchell and Secemski (3) as the pathway of the aminolysis of *p*-NPA in diethyl ether. These authors also report that [2.2.2]diazobicyclooctane catalyzes the reaction; a pathway involving nucleophilic catalysis was proposed (4). Later papers by the groups of Menger (5) and Watson (6) clearly show the presence of catalysis by tertiary amines in several systems and concluded that a two-step general base mechanism is preferable over the concerted pathway. Menger and Smith (5*a*) also reported linear free energy relationship data that strongly support the collapse of the intermediate as the rate-determining step, with the second amine molecule catalyzing the reaction by removing a proton from the zwitterionic form of the intermediate (**2**).

[1] Rate = k_2[ester][amine] + k_3[ester][amine]^2

There have been several other reports on the aminolysis of carboxylic esters in aprotic media showing catalysis by proton

acceptors (7), ionophones (8), as well as intramolecular effects by groups in the acid part (9) and the phenol part (10) of the ester. Aminolysis reactions by imidazole (11) and by aminopyridines (12) as well as catalysis of the imidazole reaction by lithium perchlorate (13) have also been studied.

In this paper we report our results on the aminolysis of three phosphinate esters (**3**–**5**) as well as on *p*-nitrophenyl diphenylphosphinothionate (**6**), -phosphinothioate (**7**), and -phosphinodithioate (**8**). Compounds **4**–**8** were studied with butylamine

$(C_6H_5)_2P(O)OC_6H_4X$	**3**	X = *p*-NO_2
	4	X = *p*-CN
	5	X = *m*-NO_2
$(C_6H_5)_2P(S)OC_6H_4NO_2$-*p*	**6**	
$(C_6H_5)_2P(O)SC_6H_4NO_2$-*p*	**7**	
$(C_6H_5)_2P(S)SC_6H_4NO_2$-*p*	**8**	

only but ester **3** was studied with butylamine, a series of secondary amines, and diamines. There is one previous report on the aminolysis of a phosphinate ester and a comparison will be made with this work (14).

Results

Rate data

The observed rate constants as well as the calculated second-order rate constants ($k_2 = k_{obs}/[amine]$) for the butylaminolysis of **3**–**8** are given in Table 1. A plot of the k_2 for the butylaminolysis of **3** versus amine concentration is given in Fig. 1. The slope, k_3, is $5.31 \times 10^{-2}\ M^{-2}\ s^{-1}$ ($r = 0.987$) and the intercept, k_2, is $8.02 \times 10^{-4}\ M^{-1}\ s^{-1}$ or approximately 1.4% of the k_3. Therefore within the range of amine concentrations used in our experiments the butylaminolysis of **3** follows the rate law of eq. [1] with the third-order term predominating. The other esters in Table 1 give similar results and their k_2 and k_3 values are reported in Table 2.

The k_{obs} and k_2 values for the aminolysis of **3** with *sec*-amines and diamines are given in Tables 3 and 4, respectively. Figure 2 gives the plot of k_{obs} versus amine concentration for the piperidinolysis of **3**. Table 5 gives the data collected on the aminolysis reactions in chlorobenzene and Table 6 reports the results of the experiments carried out in the presence of tertiary amines.

Activation parameters

The activation parameters for the butylaminolysis of **3** and **8** as well as for the piperidinolysis, and the aminolysis with 1,3-diaminopropane of **3** are given in Table 7.

Limitations on the rate data

The reproducibility of the rate data for a given amine concentration was good. The major source of fluctuation was due to the difficulty of reproducing identical amine concentrations. The best results were obtained when the amine was delivered using a Gilmont microsyringe (for all primary amines and diamines). For the secondary amines, stock solutions were prepared and delivered by pipet. In the latter case the third figure in the observed rate constants is unlikely to be significant.

The values of k_2 and k_3 for most systems are determined graphically. The errors in this determination, especially when less than 5 data points are used, are going to be large (±10%). This will be particularly true for k_2, which is determined from the intercept. These errors in the rate constants will carry over to the calculations of the activation parameters. A reasonable error limit for the second-order reaction would be ±3 kcal/mol for the $E_a(\Delta H^{\neq})$ and ±10–15 eu for the $\Delta S^{\neq}$.

Discussion

Butylaminolysis

The butylaminolysis of all the esters studied follows the two-term rate law represented in eq. [1] with the exception of ester **6**, which has only a k_3 component. With all the esters k_3 is larger than k_2 (Table 2), and the k_3/k_2 ratio is larger; that is, catalysis is more important for the esters with the more basic leaving groups (**3**, **4**, **5**, and **6** versus **7** and **8**). The aminolysis of **3** is catalyzed by the tertiary amines imidazole, pyridine, and triethylamine (Table 6) and therefore a cyclic concerted mechanism is ruled out. There are two reasonable pathways: (*i*) a general base-catalyzed direct displacement and (*ii*) a rate-determining general base-catalyzed breakdown of a pentacoordinate zwitterionic intermediate (eq. [2]).

In the rate-determining step of both of these pathways, negative charge is generated on the leaving group in the transition state. Although only three compounds with *para* substituents have been studied (**3**–**5**), their rates of aminolysis (k_3) correlate with the σ^- values of the substituents and not with the σ values. The calculated ρ value using σ^- is 2.55 (r = 0.983). The significance of such a correlation with only three points is limited; however, what is clear is that the *p*-CN ester (**4**) is more reactive than the *m*-NO_2 ester (**5**), in line with the σ^- values and not with the σ values of the substituents. In support of rate-determining loss of the leaving group are the reactivity ratios for the phenol versus thiophenol leaving groups. The ratios of the k_3 values for **7**/**3** and **8**/**6** are 18.2 and 9.4, respectively. For the uncatalyzed reaction (k_2), where the basicity of the leaving group might be expected to be more important, the ratio for esters **7**/**3** is 143. The large drop in rate when the butylaminolysis of **3** is studied in chlorobenzene also supports a pathway with a highly charged transition state (Table 5). These data have led to the suggestion of a transition state with negative charge on the leaving group and, for the case of the pathway involving intermediate formation, rate-determining collapse of the intermediate will only be possible if the intermediate is the dipolar ion represented in structure **9** (5).

The question of whether or not there is an intermediate along the reaction path in displacement at phosphorus in acyclic phosphorus esters is the difficult one to answer. Kirby and Warren (15) and Emsley and Hall (16) have summarized the evidence and argue for a direct displacement in these acyclic systems. On the other hand, there is ample evidence for intermediates in the reactions of cyclic phosphorus esters (17) and in two acyclic systems involving the acid-catalyzed hydrolysis of a phosphinothionate (18*a*) and a phosphonate (18*b*). In our report on the alkaline hydrolysis of a series of alkyl dialkylphosphinates and their sulfur analogs we were unable to eliminate either possibility, i.e., direct displacement versus intermediate formation (19). However, in the hydrolysis of aryl esters, with one exception (20), the rates correlate with Hammett's σ values, and not with the σ^- values, supporting a mechanism where no charge is generated on the leaving group in the rate-determining step and therefore, by implication, supporting rate-determining formation of an intermediate (21). The ratio of reactivity under conditions of alkaline hydrolysis for aryl diphenylphosphinothioates and aryl diphenylphosphinates is only 4, which is considerably less than is observed in the aminolysis reactions and is in line with the above statements.

The atom doubly bonded to phosphorus influences the reactivity of the esters significantly. For example, the ratios of k_3's for **3**/**6** and **7**/**8** are 22.8 and 72, respectively. The greater reactivity of the P=O esters is generally rationalized in terms of the differences in polarizability and solvation of the two groups (22). In acetonitrile the latter may not be very important. A summary of P=O/P=S reactivity ratios is presented in ref. 19 for several different systems and it is suggested that the values of these ratios cannot lead to significant mechanistic conclusions.

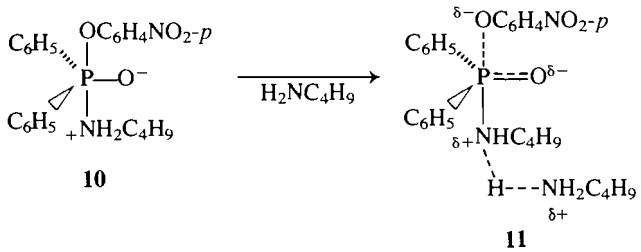
[2] $R_2P(O)OR' + R''NH_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\underset{+NH_2R''}{|}}{\overset{O^-}{\overset{|}{R_2P-O-R'}}} \xrightarrow[H_2NR'']{k_2} R_2P(O)NHR'' + R'OH$

9

The butylaminolysis reactions give highly negative entropies of activation (Table 7). The values obtained are quite small for both the k_2 and k_3 components (23) (the entropies of activation for the second-order reaction have larger errors incorporated into the calculation because of the fact that the values of k_2 are intercepts). Negative activation energies have been obtained for the third-order components, which, although unusual, have been observed in other systems and are suggested as being support for intermediate formation along the reaction pathway in contrast to a direct displacement (24). The transition from tetrahedral phosphorus to a charged pentacoordinate intermediate, coupled with the incorporation of a second amine molecule in the transition state, should lead to very negative entropies of activation. As well as being a termolecular reaction, there should also be considerable restriction of rotation in the transition state as well as some electrorestriction of solvent.

Therefore, for the mechanism, a process similar to eq. [2] is likely. The transition from intermediate (**10**) to transition state (**11**) can be pictured as in eq. [3], where a zwitterion is going

[3]



10 **11**

towards two separated ions; that is, there is greater charge separation in the transition state, which is reached late on the reaction coordinate, than there is in the intermediate. Under the reaction conditions it is the *p*-nitrophenoxide anion that is being observed at 423 nm (25). The slower reaction in the less polar chlorobenzene would be expected for this process.

The bimolecular reaction pathway can be thought of as the slow dissociation of the zwitterionic intermediate, with subsequent loss of a proton to a second amine molecule, or as slow simultaneous intramolecular proton transfer to O^- and loss of phenoxide followed by proton loss to a second amine molecule.

Bel'skii *et al.* (14) have reported their results on the aminolysis of the very reactive phosphinate *p*-nitrophenyl bis(chloromethyl)phosphinate by a series of primary and secondary amines in benzene. They have also suggested, in line with Menger's original suggestion for carboxylates, that a zwitterionic intermediate exists along the reaction pathway.

Secondary amine aminolysis

The aminolysis reactions of **3** with the secondary amines piperidine, morpholine, pyrrolidine, and di-*n*-propylamine all follow a rate law where only the k_2 term appears. This result is supported by the lack of significant catalysis with tertiary amines (Table 6). The observed rate of aminolysis by these amines is slower than that observed for butylamine and this rate order is the opposite of that observed for carboxylate esters (5). The overall slower rate is due to the absence of a general base-catalyzed pathway for the *sec*-amine aminolysis. Both for most carboxylic ester systems (5) and for the phosphinate studied by Bel'skii's group (14), a mixed rate law was obtained for the reactions with secondary amines. The reactivity order observed in the aminolysis reactions of *p*-nitrophenyl bis-(chloromethyl)phosphinate is piperidine > butylamine > diethylamine (14).

There is a good correlation between the rates of aminolysis of **3** and the pK_a of the amines as measured in acetonitrile (26) with the exception of morpholine, which is considerably more reactive than its basicity would predict. The entropy of activation of the piperidinolysis of **3** is −59 eu, which is very small for a bimolecular reaction and suggests a restricted transition state.

TABLE 8. Relative rates for the diaminolysis of **3** in acetonitrile at 30°C; $[H_2N(CH_2)_nNH_2]$ = 0.08 *M*

n	Relative rate	pK_a[a]	ΔpK_a[b]
2	1.75	18.46	5.45
3	4.66	18.70	4.72
4	5.42	20.12	4.78
5	2.58	19.14	2.17
6	1.00	—	—

[a] pK_a in acetonitrile; ref. 26.
[b] $\Delta pK_a = pK_a^2 - pK_a^1$; ref. 26.

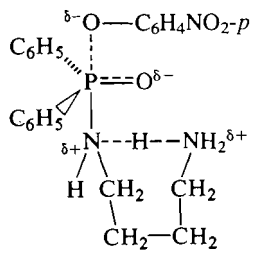
The reason for the lack of a third-order term is most likely steric in origin, inasmuch as the larger secondary amines prevent a second amine molecule from being involved in the rate-determining step. The observation of general base catalysis with Bel'skii's ester reflects the smaller size of the $ClCH_2$ substituent.

Once again this bimolecular pathway can be rationalized as either rate-determining dissociation of the zwitterionic intermediate, followed by loss of a proton, or as a rate-determining intramolecular proton transfer to the O^-, coinciding with loss of the leaving group.

Diaminolysis

The diaminolysis reactions of **3** follow a rate law which is first order in amine only; their reaction rates, however, are greater than those observed for either butylamine (7 times faster per amino group) or for the secondary amines. Anderson, Su, and Watson (6) observed a similar rate enhancement for 1,3-diaminopropane over butylamine in the aminolysis of *p*-NPA in chlorobenzene. A mechanism identical to the other systems but with intramolecular general base catalysis would appear to best fit these results. Of the unsubstituted diamines, the 1,4-diaminobutane is the most reactive (Table 8), in accord with its having the highest basicity of the diamines studied (26). Table 8 also gives the ΔpK_a ($pK_a^2 - pK_a^1$) values for the diamines, which show a break at the point at which intramolecular hydrogen bonding, and subsequently catalysis, becomes less important. The diamine that gives the maximum rate would go through a transition state (**13**) involving proton transfer in a seven-membered ring, one atom of which is the sterically small hydrogen.

The entropy of activation calculated for the 1,3-diaminopropane reaction is −92 eu. This is an extremely small value for



13

TABLE 9. Relative rates for the aminolysis of **3** by *N*-substituted diamines in acetonitrile at 30°C

Diamine	Relative rate
$H_2NCH_2CH_2NH_2$	1.08[a]
$CH_3NHCH_2CH_2NH_2$	2.28
$(CH_3)_2NCH_2CH_2NH_2$	1.00
$H_2N(CH_2)_3NH_2$	0.87[a]
$CH_3NH(CH_2)_3NH_2$	1.36
$(CH_3)_2N(CH_2)_3NH_2$	1.00
$CH_3NHCH_2CH_2NHCH_3$	1.84[a]
$CH_3NHCH_2CH_2CH_2CH_3$	1.00

[a]Rate/2 to account for two reactive sites.

a bimolecular reaction and reflects a large degree of freezing of rotation of the molecules in the transition state. This same system has also been studied in chlorobenzene, where the reaction followed a mixed rate law (eq. [1]) and the overall rate is considerably decreased ($k_2 = 6.12 \times 10^{-4} M^{-2} s^{-1}$). Such a solvent effect supports a highly charged transition state.

A most interesting observation is the inhibition of reaction observed when tertiary amines are present. Table 6 shows that the rate of aminolysis with 1,3-diaminopropane is retarded in the presence of imidazole, pyridine, and triethylamine. A possible explanation for this result would involve the inhibition of catalysis because of intermolecular hydrogen bonding between the "free" end of the diamine and the tertiary amine. There is no spectral evidence, in this case or in any other in this study, of imidazole acting as a nucleophile.

Table 9 summarizes the data for the *N*-substituted diamines. In the case of the monosubstituted diamines it is assumed that the reaction proceeds via nucleophilic attack of the primary amine and catalysis by the secondary amine, a conclusion reached because of the differences in reactivity between the two amine systems. The order of catalytic ability parallels the basicity of the amine end that is acting as a catalyst ($1° < 2° > 3°$) (26). Although a third-order term is not observed in the reactions with secondary amines, it appears that there is some intramolecular catalysis of a secondary amine reaction by another secondary amine in the case of *N*,*N*′-dimethylethylene diamine, where it is 4 times more reactive than methylbutylamine (2 times per amino group) (Table 9).

Experimental

Synthesis of the esters

The *p*-nitrophenyl diphenylphosphinate, **3**, *p*-cyanophenyl diphenylphosphinate, **4**, and *m*-nitrophenyl diphenylphosphinate, **5**, were prepared according to the method of Haake and Hurst (27). The *p*-nitrophenyl diphenylphosphinothioate, **7**, and diphenylphosphinodithioate, **8**, were prepared by the method of Spense, Swan, and Wright (28) while the *p*-nitrophenyl diphenylphosphinothionate, **6**, was synthesized by the procedure of Williams, Douglas, and Loran (29). Table 10 gives the physical constants for the esters, as well as their literature values. The highly reactive ester **7** could never be purified completely; small amounts of diphenylphosphinic acid always remained in the sample. The ester was used as is in the kinetic determinations and it was shown that adding diphenylphosphinic acid had no effect on the reaction.

Kinetics

The reaction rates were followed by measuring the increase in absorbance due to the production of phenol or thiophenol using Pye–Unicam model SP6-550, model SP8-250, and the Perkin–Elmer model 450 spectrophotometers. Reactions were carried out in thermostatted cells and the temperatures reported are within ±0.1°C. The kinetic wavelengths used for the different esters are reported in Table 10.

TABLE 10. Melting points and kinetic wavelengths for the esters **3**–**8**

	Melting point (°C)		Kinetic wavelength (nm)	
Ester	Observed	Literature	CH_3CN	C_6H_5Cl
3	149–150	149–150[a]	423	336
4	110–112[b]	—	290	—
5	120–123	124[c]	350	—
6	84–86	88–90[d]	423	—
7	121–123[e]	—	490	—
8	165–167	168–169[f]	490	—

[f]Reference 28.

Most reactions were initiated by adding the required amount of amine with a Gilmont microsyringe to a 25-mL volumetric flask containing $1.3 \times 10^{-5} M$ ester in acetonitrile or chlorobenzene. For the very fast reactions the amine was added directly to the thermostatted cuvette. In all runs the amine was in large excess over the ester so that pseudo-first-order conditions prevailed. Reactions were followed to completion, except for ester **8**, and all plots gave excellent straight lines to well over 95% reaction, with correlation coefficients of the least-squares analyses of the data greater than 0.99. The data reported in the tables are the average of 2–3 runs in each case; reproducibility of the kinetic determinations was excellent. For ester **8** the rates were determined from Guggenheim plots because the thiophenol product undergoes slow oxidation. This oxidation was not a problem in the aminolysis of **7** because of its much faster rate. Second-order rate constants were determined by dividing the k_{obs} by the amine concentration and third-order rate constants were obtained from the plot of k_{obs}/[amine] vs. [amine]. The reactions with 1,6-diaminohexane, a solid, as well as with some of the secondary amines, were carried out by making a stock solution of the amine in acetonitrile and adding an appropriate volume to a stock solution of ester. The amide product with 1,6-diaminohexane precipitated from solution; however, because of the relative slowness of the reaction the solution could be filtered before absorbance readings were taken.

The amides formed with three of the amines were isolated from the reaction mixtures and identified by comparison with authentic samples.

Polymérisation de l'acide molybdique induite par l'acide métatungstique

P. COURTIN ET J. LEFEBVRE[1]

Laboratoire de chimie des polymères inorganiques, Université Pierre et Marie Curie, 4, place Jussieu, 75230 Paris Cédex 05, France

Reçu le 17 janvier, 1985[2]

P. COURTIN et J. LEFEBVRE. Can. J. Chem. **64**, 220 (1986).

En solution aqueuse, l'acide métatungstique se décompose très lentement en oxyde tungstique, haut polymère insoluble, et la polymérisation de l'acide molybdique préparé par échange d'ions à partir du molybdate, Na_2MoO_4, est limitée ($n = 24$). L'addition d'acide métatungstique à l'acide molybdique entraîne la formation relativement rapide de hauts polymères solubles. Ce sont des acides mixtes molybdotungstiques dont la composition dépend de la fraction molaire $f = [Mo]/[Mo + W]$ du mélange. En particulier si $0{,}80 \leqslant f \leqslant 0{,}95$, la réaction des acides est totale; c'est une méthode pour obtenir des sols très riches en molybdène, puisque le rendement en haut polymère est égal à 80%. La formation de l'acide mixte peut résulter soit de l'interaction directe des deux acides, soit de la décomposition de l'acide métatungstique substitué par le molybdène, formé transitoirement. Durant la polymérisation suivie par ultracentrifugation et échange d'ions, la teneur en Mo et W des acides mixtes ne varie pas.

P. COURTIN and J. LEFEBVRE. Can. J. Chem. **64**, 220 (1986).

In acid media, metatungstic acid very slowly decomposes into tungstic oxide, an insoluble high polymer; under the same conditions, the polymerization of molybdic acid, prepared by ion exchange from the molybdate, Na_2MoO_4, is limited ($n = 24$). The addition of metatungstic acid to molybdic acid involves the relatively rapid formation of soluble high polymers. These are mixed molybdotungstic acids whose compositions vary according to the molar fraction, $f = [Mo]/[Mo + W]$, of the reaction mixture. When $0.80 \leqslant f \leqslant 0.95$, this reaction is complete: this is a method of obtaining colloids very rich in molybdenum since the yield in high polymer is equal to 80%. The formation of the mixed acid can be due either to the direct interaction of the two acids or to the decomposition of the metatungstic acid, substituted by the molybdenum, which would be formed transiently. As determined by ultracentrifugation and by ion exchanges, the relative proportions of Mo and W in the mixed acids do not vary during the course of the polymerization.

Introduction

Beaucoup d'oxydes de métaux de transition (WO_3, V_2O_5) peuvent être obtenus à l'état colloïdal ou de gel; ce sont alors des matériaux aux propriétés intéressantes, qui se prêtent à de nombreuses applications: réalisation de cellules électrochromiques ou de dispositif d'affichage, emploi comme semi-conducteur (1). Les gels tungstiques ou vanadiques sont facilement obtenus suivant une méthode développée au laboratoire (2): préparation d'un acide à partir d'un sel passé sur une résine échangeuse de protons, suivie de la polymérisation de cet acide par élimination de H_2O entre deux groupements M—OH voisins. Les gels molybdiques, par contre, ne sont pas obtenus par cette voie parce que la polymérisation de l'acide molybdique formé est limitée. Il est donc nécessaire d'utiliser la préparation de Graham–Murgier (3) qui part de solutions très concentrées.

Cependant, un autre moyen d'accéder aux gels molybdiques dans des conditions moins restrictives de concentration pourrait consister à incorporer à l'acide molybdique peu condensé un autre acide pouvant évoluer spontanément vers une forme hautement condensée, par exemple, l'acide tungstique, afin d'induire la formation d'un haut polymère mixte. En effet, des composés mixtes à base de tungstène et de molybdène sont aisément obtenus aussi bien dans le domaine des faibles condensations (hexa- et dodéca-métallates (4)) que dans celui des condensations élevées caractéristiques des gels (5). Le problème est donc de savoir si la texture hautement condensée de l'acide tungstique est susceptible de se maintenir dans le polymère mixte, même lorsqu'il y est présent en faible proportion.

Dans ce travail, le tungstène a été introduit dans la solution aqueuse molybdique sous forme d'hétéropolyacide possédant la structure de Keggin (6) de formule générale $H_{(8-n)}[X\,W_{12}O_{40}]$ où n est le degré d'oxydation de l'hétéro-élément X (X = Si, H_2). En effet, nous avons observé qu'en solution aqueuse pure, l'un de ces composés faiblement condensés, l'acide métatungstique ($X = H_2$), avait la propriété de se transformer très lentement en acide tungstique très condensé.[3] C'est donc sous cette forme que le tungstène a principalement été introduit dans la solution aqueuse molybdique, avec l'avantage de ne pas apporter d'autre élément étranger que le tungstène. D'autres hétéropolyacides du type précédent (X = Si) ou mixtes lui ont été ensuite comparés pour tenter de préciser le mécanisme de formation des acides mixtes molybdotungstiques polymérisés.

Partie expérimentale

1. *Réactifs*

1.1 *Acide molybdique*

Il est préparé par échange d'ions sur une résine cationique de type Dowex 50 W X-2, 100–200 mesh, sous forme H^+, à partir d'une solution de molybdate de sodium $Na_2MoO_4 \cdot 2H_2O$ à 20°C.

1.2 *Hétéropolyacides tungstiques*

Ils sont préparés suivant les méthodes classiques (8), par extraction ou par échange d'ions.

1.3 *Hétéropolyacides substitués molybdotungstiques*

Les sels sont d'abord préparés (4, 9), puis les acides, par échange d'ions.

Le système mixte à étudier est préparé soit par mélange des réactifs 1.1 et 1.2, soit par dissolution de 1.3. Il est défini par sa fraction molaire $f = [Mo]/[Mo + W]$. Les réactions sont lentes; elles sont suivies pour la plupart à température constante de 20°C.

2. *Techniques et méthodes analytiques*

2.1 *Ultracentrifugation préparative*

Réalisée dans un appareil Beckman Spinco, modèle E équipé d'un rotor à godets SW65E, à 36 000 r/min pendant 100 min, elle permet la séparation des hauts polymères qui sont rassemblés au fond du tube sous forme d'un gel. En surface, on dispose d'une solution pure de composés légers.

[1]Auteur à qui adresser la correspondance.

[2]Révision reçue le 19 septembre 1985.

[3]P. Courtin, résultats non publiés.

2.2 *Échange d'ions*

Par passage sur une résine Amberlite CG-400, 100–200 mesh, sous forme Cl^-, les ions polymolybdiques sont fixés. En utilisant 2 méquiv. de résine pour 0,10 méquiv. de molybdène, l'échange est complet quelle que soit la concentration.

2.3 *Hydrolyse rapide à pH contrôlé*

Réalisée sous azote, à pH constant égal à 8, par addition de soude pendant 1 min à l'aide d'un combititreur Methrohm E 415, elle permet la dégradation alcaline en ions MoO_4^{2-} et WO_4^{2-} des formes labiles du mélange exclusivement.

2.4 *Hydrolyse totale*

Réalisée par un excès de soude à l'ébullition, elle permet la décomposition totale du système à l'état d'ions MoO_4^{2-} et WO_4^{2-}.

2.5 *Analyse*

Les hétéropolyanions substitués $[XMoW_{11}O_{40}]^{(8-n)-}$ sont dosés par polarographie en milieu acide chlorhydrique $1{,}0 \times 10^{-1}$ *M* (X = H_2) et par spectrophotométrie d'absorption à 500 nm, après réduction, à pH 2, du molybdène par le chlorure stanneux en solution dans le glycérol (10) (X = Si). Les autres dosages sont effectués après hydrolyse des mélanges:

Hydrolyse rapide: la somme $[MoO_4^{2-} + WO_4^{2-}]$ labile est titrée par dosage protométrique avec l'acide chlorhydrique en présence de mannitol (11), et MoO_4^{2-} est déterminé, à 475 nm, par spectrophotométrie d'absorption du complexe coloré formé avec le pyrocatéchol en tampon phosphate (pH 7,50) (12); le métatungstate est dosé par polarographie en tampon phosphate de pH 7,50 (13).

Hydrolyse totale: MoO_4^{2-} et WO_4^{2-} sont dosés simultanément, à 475 et 350 nm, par spectrophotométrie d'absorption du complexe formé avec le pyrocatéchol en tampon phosphate de pH 7,50, ou par polarographie en milieu acide chlorhydrique 8 *M* (14).

3. *Masse molaire*

La condensation est mesurée par ultracentrifugation analytique à l'aide d'un appareil Beckman équipé de l'optique Schlieren.

3.1 *Les coefficients de sédimentation apparents*, $(s_p)_{app}$, sont déterminés en cellule de 12 mm d'épaisseur, à double secteur, à différentes vitesses de rotation ($14\,000 < v < 26\,000$ r/min), dans des solutions suffisamment diluées pour éliminer les effets dus aux interactions moléculaires ($1{,}0 \times 10^{-2}\ M < \text{Mo} < 5{,}0 \times 10^{-2}\ M$). Le solvant ajouté au moment de la mesure est constitué de chlorure de lithium à la concentration $5{,}0 \times 10^{-2}$ *M*. La distribution des coefficients $(s)_{app}$ est obtenue au moyen de la fonction de distribution normalisée $g(s) = 1/C(dC/ds)$ où *C* est la concentration du soluté (15).

3.2 *Les coefficients de diffusion*, D_w, sont obtenus par centrifugation à basse vitesse, $v = 10\,000$ r/min, en cellule à frontière synthétique à capillaire, selon la méthode de Fujita – Van Holde (16).

3.3 *La masse molaire* des composés lourds est calculée à l'aide de la relation de Svedberg (17); celle des composés légers est obtenue par construction du diagramme d'Archibald après centrifugation en transition vers l'équilibre de sédimentation (18), à différentes vitesses ($15\,000 < v < 42\,000$ r/min), avec cellule à double secteur, à remplissage homogène.

Résultats expérimentaux

I. *État du système à l'équilibre*

Il est déterminé lorsque les concentrations des constituants ne varient plus avec l'âge, c'est-à-dire au bout de 30 jours à 20°C. Le système est toujours homogène.

1. *Polymérisation du système*

Le coefficient de sédimentation apparent est supérieur à 50 svedbergs pour tous les mélanges dont la fraction molaire $f = [Mo]/[Mo + W]$ est comprise entre 0,08 et 0,94. Il se forme donc des hauts polymères dans un domaine étendu de compositions. Le système est assez polydispersé (fig. 1) mais ne renferme qu'une famille de composés lourds de coefficient de sédimentation moyen de l'ordre de 100 svedbergs quelle que soit la valeur de *f* entre 0 et 1, la concentration en molybdène

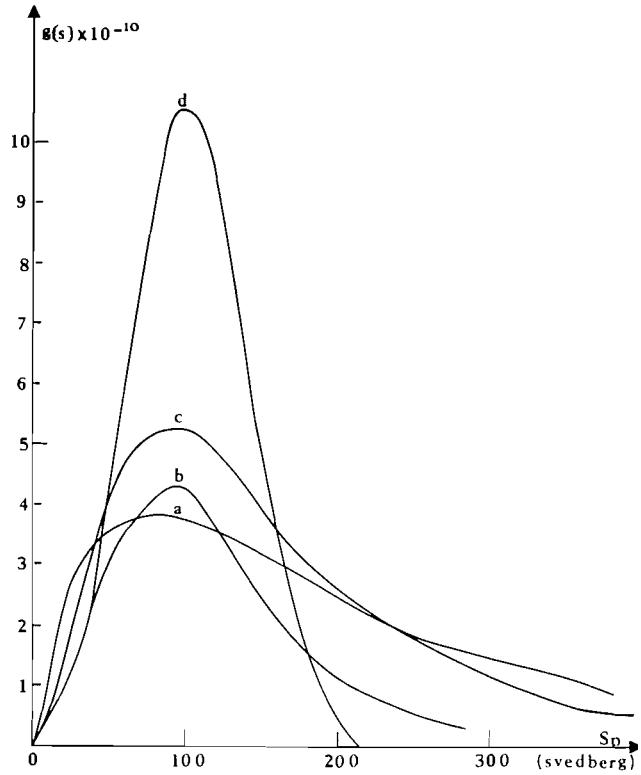

FIG. 1. Distribution du coefficient de sédimentation apparent $(s_p)_{app}$ mesuré dans les mélanges de fraction molaire $f = 0{,}50$ (a); 0,66 (b); 0,75 (c) et 0,80 (d).

dans le haut polymère étant voisine de $1{,}0 \times 10^{-2}\ M$. La distribution des coefficients de sédimentation tend à se resserrer lorsque *f* augmente.

2. *Composés lourds formés dans le système*

Ils sont recueillis après ultracentrifugation préparative, sous forme d'un gel amorphe aux rayons X. La proportion de molybdène et de tungstène polymérisé peut être importante—80% de ce qui a été introduit. Elle est atteinte dans un domaine de compositions qui est plus large pour le molybdène, $0{,}14 < f < 0{,}94$ (fig. 2, courbe a), que pour le tungstène, $0{,}80 < f < 0{,}94$ (fig. 2, courbe b), en raison de la persistance de la forme métatungstique dans les mélanges de $f < 0{,}80$ (fig. 2, courbe c). À partir des résultats de l'analyse élémentaire (tableau 1), on peut exprimer la composition des acides mixtes dans le haut polymère (H.P.), en fraction molaire $f_{H.P.} = [Mo]_{H.P.}/[Mo + W]_{H.P.}$. Elle dépend de la composition initiale du mélange (fig. 3): d'abord constante et égale à 0,50 pour les faibles valeurs de *f* ($0 < f < 0{,}30$), elle croît ensuite jusqu'en $f = 0{,}90$ de façon pratiquement linéaire. Au-delà de $f = 0{,}95$, la précision des analyses n'est plus suffisante pour préciser le mode de variation de $f_{H.P.}$, en particulier l'existence éventuelle d'une limite vers $f_{H.P.} = 0{,}95$.

La masse molaire des composés lourds calculée à partir des mesures de coefficients de sédimentation et de diffusion du gel remis en solution est de l'ordre de $1{,}0 \times 10^5$ pour une concentration moyenne de $(1{,}0\text{–}4{,}0) \times 10^{-2}\ M$ en molybdène (tableau 2).

II. *Évolution des mélanges avec l'âge*

1. *Masse molaire*

Durant les trois premiers jours d'évolution, la masse molaire apparente des mélanges reste égale à la masse moyenne des

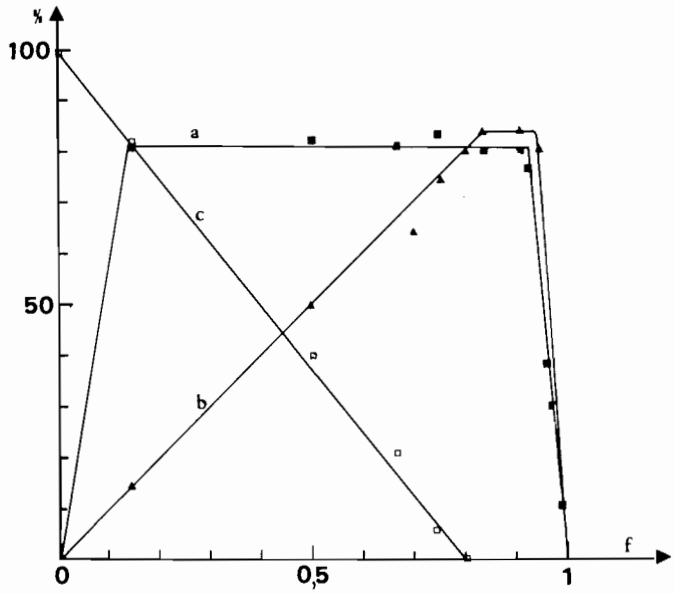

FIG. 2. Répartition du molybdène et du tungstène dans les mélanges à l'équilibre, en fonction de leur fraction molaire f: Mo (a) et W (b) dans le haut polymère; W(c) sous forme métatungstique.

TABLEAU 1. Analyse élémentaire des gels en fonction de la fraction molaire f du mélange

	%			
f	Mo	W	Mo/W	Charge par mole (Mo + W)
0,08	19,80	36,50	1	0,16
0,17	20,50	39,25	1	0,15
0,50	25,00	32,80	1,46	0,10
0,66	25,50	22,00	2,25	0,17
0,80	25,83	12,63	3,92	0,18

constituants ($M \simeq 3000$). Puis un composé lourd sédimente en ultracentrifugation. Au fur et à mesure que progresse la formation de ce composé lourd, on observe que son coefficient de sédimentation, mesuré dans le milieu même de formation, augmente (tableau 3). Ceci pourrait signifier que le composé lourd tend à se polymériser davantage, mais il est également possible que la variation du coefficient de sédimentation soit due simplement aux changements de concentration du milieu réactionnel. Pour le vérifier, le composé lourd a été isolé par ultracentrifugation, puis redissous dans du LiCl $5{,}0 \times 10^{-2}$ M: son coefficient de sédimentation prend alors une valeur approximativement constante (40–50 svedbergs), quels que soient son âge et le rapport f (tableau 4). Il ne semble donc se former qu'une seule famille de hauts polymères.

2. *Composition des acides mixtes légers*

Les mélanges en cours d'évolution sont constitués de formes labile et inerte. La forme inerte ne renferme que du métatungstate; la forme labile contient des acides mixtes, lourds et légers et éventuellement l'acide molybdique n'ayant pas réagi. Les composés légers peuvent être isolés durant les premiers jours d'évolution avant que le haut polymère ne se forme: les ions polymolybdiques sont d'abord éliminés par échange d'ions, puis le composé mixte est séparé du métatungstate par précipitation de son sel de césium à 25°C. Le rapport $[Mo/W]_{léger}$ des composés légers ainsi isolés (tableau 5) est égal à celui

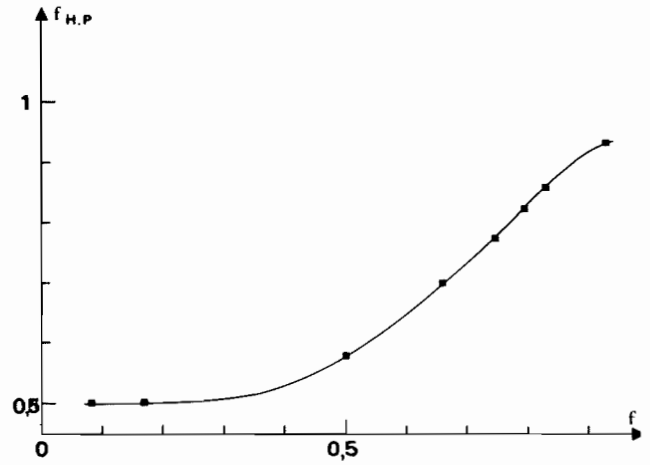

FIG. 3. Fraction molaire $f_{H.P.}$ du haut polymère en fonction de la fraction molaire f du mélange.

TABLEAU 2. Masse molaire des gels en fonction de la fraction molaire f du mélange

f	$[Mo]_{H.P.}$ $(10^{-2} M)$	$(s_p)_{app}$ (svedberg)	D_w (10^{-6})	$(M_{ww})_{app}$
0,08	0,50	52	0,95	$1{,}6 \times 10^5$
0,17	1	50	0,90	$1{,}7 \times 10^5$
0,50	3,75	48	1,02	$1{,}5 \times 10^5$
0,66	4	40	1,27	$1{,}0 \times 10^5$

déterminé dans les composés lourds à l'équilibre (tableau 1), la charge, par contre, est plus élevée. D'après la masse molaire mesurée ($M \simeq 3400$), le degré de condensation moyen des acides mixtes formés initialement est égal à 18. La polymérisation a donc lieu par simple diminution de la charge, sans modification de la composition en molybdène et tungstène. Ceci est vérifié par les dosages des constituants dans les composés lourds et légers, en cours d'évolution des mélanges. Ils indiquent en effet que le rapport [Mo/W] y est le même et que sa valeur demeure constante durant l'évolution (tableau 6). De plus, ils indiquent que l'acide molybdique finit par réagir totalement (fig. 4, courbe a), contrairement à l'acide métatungstique (fig. 2). La vitesse de réaction peut être mise sous la forme d'une loi du premier ordre par rapport à la concentration en acide molybdique, $v = k_1[Mo]$, avec $k_1 = 0{,}115$ d^{-1} à 20°C.

3. *Comparaison avec d'autres hétéropolyacides*

3.1 *Acide silico-12 tungstique (X = Si).* En fin d'évolution, après 20 jours à 40°C, un composé lourd sédimente en ultracentrifugation et tout l'acide molybdique a réagi. En cours d'évolution, les dosages par la soude, à pH 8, des acides débarassés des ions polymolybdiques par échange d'ions, indiquent que le molybdène se répartit sous une forme labile constituée d'un acide mixte molybdotungstique, de composition constante, en grande partie polymérisé, et sous une forme inerte, constituée de l'acide substitué $H_4[SiMoW_{11}O_{40}]$. Cette dernière réaction n'était pas observée avec l'acide métatungstique.

3.2 *Acides substitués* $H_{(8-n)}[XMoW_{11}O_{40}]$. Aucune évolution n'est observée par polarographie et ultracentrifugation dans la solution d'acide $H_4[SiMoW_{11}O_{40}]$, même en présence d'acide molybdique, au contraire de la solution d'acide $H_6[H_2MoW_{11}O_{40}]$. Dans celle-ci, le pourcentage d'acide

0,80	4,00	3,90	3,80	4,07

s'annule au bout de 30 jours à 20°C (fig. 4, courbe b): sa vitesse de réaction peut se mettre sous la forme $v = k_3$[acide substitué], avec $k_3 = 0,123\ d^{-1}$ à 20°C; elle ne dépend pas de la concentration en acide molybdique éventuellement présent. Au terme de l'évolution, le coefficient de sédimentation vaut 57 svedbergs et le molybdène est totalement dosé sous une forme labile à pH 8, tandis que le tungstène se répartit sous formes labile (en quantité égale au molybdène) et inerte (seul, à l'état de métatungstate). Les produits de la réaction sont donc l'acide métatungstique et un acide mixte, de rapport Mo/W = 1, qui se polymérise.

Discussion

1. Les résultats montrent qu'il est possible d'obtenir des acides mixtes hautement polymérisés en solution, par interaction des acides molybdique et métatungstique, dans un grand intervalle de fraction molaire $f = [Mo]/[Mo + W]$ des mélanges. En particulier si $0,80 < f < 0,95$, la réaction est totale; ce sont les conditions de préparation de sols riches en molybdène.

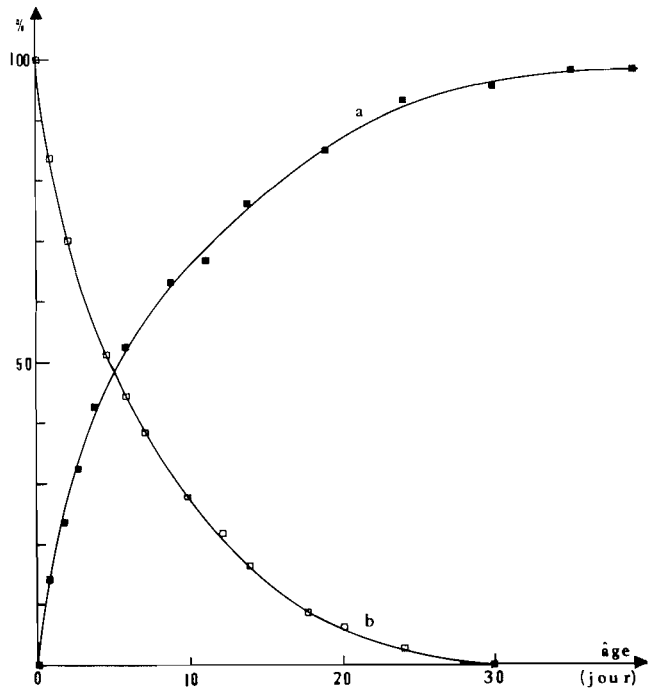

FIG. 4. Évolution du système avec l'âge: (a) solution d'acides métatungstique et molybdique de fraction molaire $f = 0,17$: pourcentage de Mo combiné; (b) solution d'acide métatungstique substitué par du molybdène ($H_6[H_2MoW_{11}O_{40}]$): pourcentage d'acide restant.

La fraction molaire du haut polymère $f_{H.P.}$ est alors égale à celle du mélange. Toutefois au-delà de $f = 0,90$, sa détermination précise devient vite difficile, en raison justement du pourcentage très élevé de Mo par rapport à celui de W. La fraction molaire $f_{H.P.}$ devrait tendre vers une limite correspondant à celle de l'espèce légère formée. Expérimentalement, elle se situe au-dessus de $f_{H.P.} = 0,94$, ce qui correspond à l'introduction d'un tungstène dans une molécule de 18 ou 24 centres métalliques ($f_{H.P.} = 0,944$ ou $0,958$).

Les sols sont constitués de deux familles de composés de même rapport Mo/W, mais de masses très différentes. La répartition entre les deux s'établit en général ainsi: 80% d'espèces lourdes et 20% de légères. Du point de vue polymérisation, le système étudié ici se comporte comme les autres systèmes mixtes, à base d'acide antimonique en particulier, étudiés au laboratoire. Tous ces systèmes sont constitués de plusieurs familles d'espèces de masse molaire différente en équilibre. Si les deux acides en présence peuvent évoluer spontanément vers une forme hautement condensée, les familles d'espèces en présence diffèrent à la fois par leur masse molaire et leur composition. Ceci a été vérifié sur le système acide antimonique – acide tungstique (19). Par contre, si l'un des éléments en présence n'évolue pas spontanément vers une forme hautement condensée, les familles d'espèces en présence ne diffèrent que par leur masse molaire. Cette conclusion valable dans le cas des composés de l'acide antimonique et des acides phosphorique, arsénique et arsénieux (20) est aussi

vérifiée dans le cas des composés molybdovanadiques (7) et dans le cas présent des composés molybdotungstiques.

2. La fraction molaire $f_{H.P.}$ ne varie pas de façon continue comme la fraction molaire f du mélange, puisqu'elle est constante dans l'intervalle $0 < f < 0{,}30$. Cette particularité est le signe d'un comportement différent des mélanges selon la valeur de leur fraction molaire. C'est probablement au niveau de la formation de l'espèce légère que se situe cette différence, puisque la polymérisation ne modifie pas la fraction molaire de l'espèce mixte.

À partir des résultats obtenus avec les deux hétéropolyacides tungstiques ($X = H_2$ et Si) d'une part, et avec les acides substitués correspondants d'autre part, nous proposons le schéma suivant pour rendre compte de la formation des acides mixtes.

(*i*) L'action de l'acide molybdique sur l'hétéropolyacide est double:

[1] formation d'espèce légère mixte

[2] formation d'espèce substituée $[XMoW_{11}O_{40}]^{8-n}$

(*ii*) Suivant la nature de X, une troisième réaction peut avoir lieu:

[3] formation d'espèce légère mixte à partir de l'espèce substituée.

L'influence de la valeur de la fraction molaire f du mélange intervient au niveau de la compétition entre les réactions 1 et 2: aux faibles valeurs de f, la réaction 1 est négligeable devant l'autre, dans le cas des mélanges avec l'acide métatungstique. Les réactions 1 et 2 sont bien mises en évidence dans le cas de l'acide silico-12 tungstique; elles sont simultanées, puisque la polymérisation ne se fait pas à partir de l'acide substitué, même en présence d'acide molybdique. Dans le cas de l'acide métatungstique, nous pouvons penser que la réaction se déroule suivant le même processus, bien qu'aucun résultat ne montre la présence de l'espèce substituée correspondante (en particulier, la présence de molybdène sous une forme inerte à pH 8). Pour que la réaction 2 ne soit pas observée expérimentalement, il suffit que sa vitesse soit égale à celle de la réaction 3 qui a lieu obligatoirement dans ce cas. C'est ce qui est vérifié expérimentalement: les deux constantes de vitesse k_1 et k_3 sont voisines et k_1 est bien la constante de vitesse de la réaction 2 si la réaction 1 est négligeable en $f = 0{,}17$. Dans ces conditions ($0 < f < 0{,}30$), l'acide mixte ne se forme que suivant [3] et sa composition est constante. Aux plus fortes valeurs de f, la réaction 1 n'est plus négligeble, et la composition varie.

FERNANDO P. COSSÍO, JESÚS M. AIZPURUA, and CLAUDIO PALOMO. Can. J. Chem. **64**, 225 (1986).

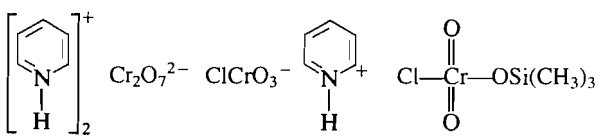
The synthetic utility of chromium(VI) reagents together with chlorotrimethylsilane, as new oxidizing systems, is described. Pyridinium dichromate (PDC) in combination with chlorotrimethylsilane oxidizes *tert*-butyldimethylsilyl ethers in good to excellent yields. Trimethylsilyl chlorochromate, a new chromium(VI) reagent, also was found efficient for this oxidative-deprotection method. These reagents were applied to the oxidation of some *N*-(2-phenyl-2-hydroxyethyl)azetidin-2-ones as well as *N*-(2-phenyl-2-trialkylsiloxy)azetidin-2-ones into their corresponding carbonyl compounds, key intermediates for *N*-unsubstituted β-lactams. Oxidation of hydroquinones and protected trialkylsilyl hydroquinones was also described. Protection of hydroquinones by means of the *tert*-butyldimethylsilyl group was achieved by using the readily available *tert*-butyldimethylchlorosilane (TBDMCS) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as base, which avoids the use of sophisticated and (or) sensitive reagents.

FERNANDO P. COSSÍO, JESÚS M. AIZPURUA et CLAUDIO PALOMO. Can. J. Chem. **64**, 225 (1986).

On décrit l'utilité en synthèse des réactifs du chrome(VI), utilisés de concert avec le chlorotriméthylsilane, comme nouveaux systèmes oxydants. Le dichromate de pyridinium (DCP), utilisé de concert avec le chlorotriméthylsilane, oxyde les éthers *tert*-butyldiméthylesilylés avec des rendements qui vont de bons à excellents. On a aussi trouvé que le chlorochromate de triméthylsilyle, un nouveau réactif du chrome(VI), est un réactif utile pour la méthode de déprotection oxydative. On a appliqué ces réactifs à l'oxydation, en dérivés carbonylés correspondants, de quelques *N*-(phényl-2 hydroxy-2 éthyl) azétidinones-2 ainsi que de *N*-(phényl-2 trialkylsiloxy-2) azétidinones-2, des intermédiaires clés dans la préparation de β-lactames qui ne sont pas substitués sur l'azote. On décrit aussi l'oxydation d'hydroquinones et d'hydroquinones protégées par des groupements trialkylsilyles. On a réalisé la protection des hydroquinones par le groupement *tert*-butyl-diméthylesilyle en les faisant réagir avec le *tert*-butyl-diméthylchlorosilane (TBDMCS), qui est facilement disponible, en présence du diaza-1,8 bicyclo[5.4.0] undécène-7 (DBU) comme base; cette méthode évite l'utilisation de réactifs sophistiqués ou sensibles.

[Traduit par le journal]

Oxidation is a fundamental process in organic synthesis and several reagents have been developed for a wide variety of transformations (1). Among the reagents available for the oxidation of organic compounds, the chromium(VI) derivatives have received growing attention in the past years (2). However, there is still considerable interest in the development of new methods for oxidation reactions. Since the appearance of pyridinium dichromate **1** (PDC) (3) and pyridinium chlorochromate **2** (PCC) (4), other similar oxidizing reagents have been developed by varying the amine ligand associated with the dichromate and chlorochromate anions. Recently, we have reported (5) a new class of chromium(VI) reagent, trimethylsilyl chlorochromate **3**, which was an efficient reagent in the



(PDC) **1** (PCC) **2** **3**

oxidation of alcohols into the corresponding aldehydes and ketones.

This communication reports new synthetic applications of this heretofore unknown reagent **3** and some quite fruitful investigations on a new oxidizing system involving pyridinium dichromate (PDC) in combination with trimethylchlorosilane.

Oxidation of alcohols and trialkylsilyl esters

In connection with our objectives in carbacephem antibiotics, we required an efficient synthesis of β-lactams of type **11** as model key intermediates. A synthetic route of this kind is based on the transformations outlined in Scheme 1, in which we need an effective mild oxidizing reagent.

The key to the first step of our approach is that protection of the hydroxyl group as its trialkylsilyl ether in the starting imine **6** seems to be critical in order to obtain the desired precursors **10**. Without protection of the hydroxyl group the product obtained was an oxazolidine **9** instead of the expected β-lactam **10**. Thus, treatment of an acetic acid **8** with an appropriate trimethylsilyl protected imine **7** (R^3: TMS) in equimolar amounts with phenyl dichlorophosphate in the presence of triethylamine gave, after work-up, the free hydroxy β-lactam **10** (R^3: H) (6).

However, we now have found that when the *tert*-butyldimethylsilyl group was used in place of the trimethylsilyl moiety for the protection of the hydroxyl group in the starting imine **6**, the *tert*-butyldimethylsiloxy β-lactam **10** (R^3: TBDMS) was obtained instead of the corresponding unprotected β-lactam **10** (R^3: H). An unexpected result was found on attempting to prepare the β-lactam **10***d* from phenoxyacetic acid and the trimethylsilyl protected imine **7***d* by means of our recently reported reagent, thionyl chloride/*N*,*N*-dimethylformamide (7). In such a case, the trimethylsiloxy β-lactam **10***e* was obtained instead of the expected unprotected β-lactam **10***d*.

The second step of the method involves the use of an efficient reagent for oxidation of protected as well as unprotected β-lactam **10**. Although the direct conversion of trimethylsilyl ethers of secondary alcohols to ketones has been reported (8), there is no report concerning the oxidation of TBDMS ethers of alcohols.[3] Among many oxidizing reagents available, the general utility of pyridinium dichromate (PDC) in nonaqueous media is well recognized; this reagent allows mild and large-

scale oxidation of a wide range of alcohols to carbonyl compounds in dichloromethane at room temperature. Unfortunately, in the case of free hydroxy β-lactam **10** (R^3: H) these conditions lead to a very long and incomplete reaction and in some cases undesired products are obtained. For instance, we have found that when β-lactam **10***d* was subjected to PDC oxidation in dichloromethane at room temperature for 30 h, the corresponding β-lactam **11***b* was isolated in 60% yield along with the starting material **10***d* (as directed by tlc analysis of the crude product). In this case, 4-methoxybenzaldehyde was also detected, probably by oxidative cleavage of the C-4 bond. When the method was tested with the β-lactam **10***g*, the corresponding oxidized β-lactam **11***c* was obtained in 66% yield, but the starting β-lactam **10***g* was also recovered. Attempts to apply this procedure for the oxidative deprotection of *tert*-butyldimethylsiloxy β-lactams **10** was unsuccessful: no oxidation takes place between PDC or PCC reagents and **10***c* or **10***f* in dichloromethane as solvent.

Our new finding is that reaction of protected as well as unprotected β-lactams **10** with PDC reagent in combination with trimethylchlorosilane leads to a rapid and mild efficient method for oxidation of these β-lactams to their corresponding carbonyl compounds **11**. Thus, treatment of β-lactam **10***f*, prepared from the β-lactam **10***d* by means of *tert*-butyldimethylchlorosilane (TBDMCS) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (9), with PDC reagent and trimethylchlorosilane (molar ratio, substrate/reagent/$ClSiMe_3$ 1:1.5:3.5) in dichloromethane as solvent, gave after 60 min of reaction at room temperature the corresponding oxidized β-lactam **11***b* in 95% isolated yield. The utility of this method is exemplified by the direct oxidative deprotection of *tert*-butyldimethylsiloxy β-lactam **10** prepared by reaction of phenoxyacetic acid **8** with the corresponding *tert*-butyldimethylsilylated Schiff bases **7** (R^3: TBDMS) promoted by phenyl dichlorophosphate reagent. In these cases, the oxidized β-lactams **11** were obtained in overall yields in the range of 40%. From the examples listed in Table 1, the reagent **3** as well as the PDC/$ClSiMe_3$ system is general in scope, since various hydroxy compounds, trimethylsilyl ethers, and *tert*-butyldimethylsilyl ethers are readily oxidized into their corresponding carbonyl compounds in good to excellent yields.

It is noteworthy that our procedure represents the first oxidative-deprotection method for *tert*-butyldimethylsilyl ether.[3] These compounds are stable towards Jones reagent (10) and towards PDC reagent, as we have demonstrated here; however, they are readily oxidized by reagent **3** or by the PDC/$ClSiMe_3$ system. A key feature of these β-lactams **11** is shown by their use as potential precursors of *N*-unsubstituted β-lactam antibiotics (Scheme 3). Thus, we have found that treatment of **11***b* with 4-*N*,*N*-dimethylaminopyridinium bromide perbromide ($DMAPHBr_3$) (11) affords the corresponding α-bromoketone **14**, which was easily converted into the *N*-unsubstituted β-lactam **15** by means of sodium hydrogen carbonate and water in acetone as solvent. Better results can be obtained following Barluenga's method (12) for the bromine substitution. Treat-

ment of the resulting amidocarbinol with triethylamine for a few hours gives the *N*-unsubstituted β-lactam **15** in moderate yield.

Oxidation of hydroquinones and trialkylsilyl protected hydroquinones

In view of the results obtained, we also extended our studies to the oxidation of the silyl ethers of hydroquinones. Although Miller and co-workers (13) have demonstrated the utility of silylation–oxidation as a method for the protection and deprotection of the hydroquinone function, in some cases the oxidative deprotection failed to provide the expected quinone. Now we have found that oxidation of trimethylsilyl hydroquinones and *tert*-butyldimethylsilyl hydroquinones by means of trimethylsilyl chlorochromate **3** or by the PDC/$ClSiMe_3$ system proceeds quickly at room temperature, giving the corresponding quinones in excellent yields.

The reaction was carried out in dichloromethane as solvent by addition of a dichloromethane solution of the silyl ether to a solution of the reagent **3** in the same solvent. The solution was initially homogeneous, but within a few minutes the reaction mixture darkened and a black residue appeared. The progress of the reaction can be followed by tlc analysis and the reaction was found complete in 10–15 min in all the cases tested. After work-up, the isolated crude products are almost pure as judged by their physical properties. As can be seen from the results listed in Table 4, the oxidation reaction is more rapid than the oxidation of unprotected hydroquinones (Table 2), but this is probably due to the low solubility of these last compounds in the reaction solvent. It is interesting to note that, whereas the PCC oxidation (13) was unsuccessful for compounds containing electron-withdrawing groups such as **16***d* in the aromatic ring, as well as the nonactivated bis(*tert*-butyldimethylsilyl) ether **16***a*, our procedure gives the corresponding quinones in good yields. Similarly, we have found that PDC reagent also was found unsuitable for carrying out this transformation. However, PDC reagent in combination with trimethylchlorosilane provides another efficient route to quinones from trialkylsilyl protected hydroquinones.

TABLE 2. Oxidation of hydroquinones **16** into quinones **17** by means of reagent **3**

16 (R^3: H)	Time (h)	Yield (%)[a]
a	1.5	90
b	0.5	97
d	0.5	95
e	1.0	90

[a]Isolated yield of **17** by column chromatography (silica gel 70–230 mesh. Eluent: ether/hexane 1:1).

On the other hand, the *tert*-butyldimethylsilyl ethers were prepared by treatment of hydroquinones **16** with *tert*-butyldimethylchlorosilane (TBDMCS) and 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) as base in dichloromethane. The reaction was slightly exothermic and, after 5–10 min of stirring at room temperature, a single spot was detected by tlc analysis (silica gel plates, eluent: EtOAc/hexane 1:3), which indicated a complete transformation. These compounds were isolated by vacuum distillation and used in the next step without further purification. In comparison, the TBDMCS/pyridine system was unsuccessful for *tert*-butyldimethylsilylation of hydroquinones, and the

SCHEME 4

use of triethylamine instead of DBU provided the expected silyl hydroquinones, but in lower yields and with longer reaction times. Particularly, in the case of 1,4-bis(*tert*-butyldimethylsiloxy)-2,5-di-(*tert*-butyl)benzene, reaction of TBDMCS and 2,5-di-(*tert*-butyl)-1,4-hydroquinone in the presence of triethylamine does not take place and the starting hydroquinone was recovered unchanged. Our procedure would appear to be an attractive alternative to the perchlorate (14*a*) or *tert*-butyldimethylsilyltriflate (13) methods, and avoids the use of other sophisticated or sensitive reagents such as allyl-*tert*-butyldimethylsilane (14*b*), *tert*-butyldimethylsilyl enol ethers of 2,4-pentanedione (14*c*,*d*), *tert*-butyldimethyliodosilane (14*e*), and *N*-*tert*-butyldimethylsilylamides (10).

Although the causes of differences in reactivity of PDC and $PDC/ClSiMe_3$ towards TBDMS ethers are not clear at present, the easy preparation and the synthetic versatility of the reagents reported, as good oxidizing agents, is obviously, as demonstrated by these limited number of examples, and may be readily extended to further applications.

Experimental

Melting points were determined on a Büchi SMP-20 melting point apparatus and are uncorrected. Proton nmr spectra were measured on a Varian EM-360 Espectrometer and are reported in parts per million downfield from internal tetramethylsilane. All the starting materials used in this work were either commercially available in generally 98% or higher purity, and used without further purification, or prepared by standard literature procedures.

Preparation of trimethylsilyl chlorochromate ***3***

Finely powdered chromium trioxide (1.0 g, 10 mmol) was exposed to atmospheric moisture for 5–10 min and then chlorotrimethylsilane (1.30 mL, 10 mmol) was added. The mixture was stirred at 30–35°C until the formation of an homogeneous orange-red solution (5–10 min), which was diluted with 20 mL of the appropriate solvent (CH_2Cl_2, CCl_4, or $ClCH_2CH_2Cl$). Finally, dry nitrogen was bubbled through the solution to eliminate the traces of hydrogen chloride formed.

General procedure for the preparation of Schiff bases ***6***

All the Schiff bases were prepared in a similar manner and used without purification. The following are representative of general procedures.

Method A

The liquid aldehyde (10 mmol) was added to the finely powdered 2-amino-1-phenylethanolamine (1.4 g, 10 mmol) and the mixture was heated until total solution was obtained and was then allowed to stand at room temperature. The precipitated product was dissolved in dichloromethane and dried with magnesium sulphate. Filtration and evaporation of the solvent gave the imine in sufficient purity for use in the next step.

Method B

A mixture of the aldehyde (10 mmol), 2-amino-1-phenylethanolamine (10 mmol), and magnesium sulphate in dichloromethane (30 mL) was stirred at room temperature for 2 h. The work-up, as described in method A, gave the corresponding Schiff base **6**.

Preparation of trialkylsilyl ethers of Schiff bases ***6***

General procedure for trimethylsilylation of Schiff bases ***6***

To a solution of an imine **6** (10 mmol) and triethylamine (1.4 mL, 10 mmol) in dry dichloromethane (25 mL) cooled at 0°C was added trimethylchlorosilane (1.2 mL, 10 mmol). The resulting mixture was stirred at room temperature for 60 min, and the resulting solution of the Schiff base **7** (R^3: TMS) was used as such for the next step.

General procedure for tert*-butyldimethylsilylation of Schiff bases* ***6***

To a suspension of the Schiff base **6** (2.5 mmol) in dichloromethane (10 mL), DBU (0.52 mL, 3.5 mmol) was added. When the imine was dissolved, *tert*-butyldimethylchlorosilane (0.53 g, 3.5 mmol) was added and the mixture was stirred at room temperature for a certain time (30–60 min, the reaction can be monitored by tlc analysis; eluent: EtOAc/hexane 1:1). The *tert*-butyldimethylsilyl ether of the Schiff base **7** (R^3: TBDMS) was used as such for the next step.

Preparation of β-lactams ***10*** *(R^3: H). General procedure from phenyl dichlorophosphate reagent* ***(6)***

To a solution of an imine **6** (10 mmol) and triethylamine (1.4 mL, 10 mmol) in dry dichloromethane (25 mL) cooled at 0°C, trimethylchlorosilane (1.2 mL, 10 mmol) was added. The resulting mixture was stirred at room temperature for 60 min. A substituted acetic acid **8** (10 mmol), triethylamine (4.2 mL, 30 mmol), and phenyl dichlorophosphate (1.5 mL, 10 mmol) were consecutively added at 0°C. The resulting mixture was stirred for 24 h at room temperature. Water (20 mL) was added and stirring was continued for a further 15 min. This washing was repeated and finally the organic layer was separated and dried (Na_2SO_4). Evaporation of the solvent gave a waxy residue that was treated with ethanol–water to give the β-lactams **10** (R^3: H): **10***a*, mp 185–190°C; **10***d*, mp 175–177°C; **10***g*, mp 175–178°C (lit. (6) mps 185–190, 175–177, 175–178°C, respectively).

Preparation of tert*-butyldimethylsilyl ethers of β-lactams* ***10*** *(R^3: TBDMS). General procedure*

To a suspension of the β-lactam **10** (R^3: H) in benzene (10 mL), and DBU (0.48 mL, 3.2 mmol), was added *tert*-butyldimethylchlorosilane (0.45 mL, 3 mmol) at room temperature and the reaction mixture was refluxed for 5 h (the reaction can be monitored by tlc; silica gel plates, eluent: AcOEt/hexane 1:1); then, the resulting suspension was diluted with dichloromethane and washed with water (10 mL) and 0.2 *N* hydrochloric acid (10 mL). The organic layer was dried (Na_2SO_4) and the solvent evaporated under reduced pressure to give the nearly pure β-lactam **10** (R^3: TBDMS), which was recrystallized from hexane or ethanol/hexane to give a fairly pure product in 90–95% yield.

cis*-3-Phenoxy-4-phenyl-1-(2′-phenyl-2′-*tert*-butyldimethylsiloxyethyl)azetidin-2-one* ***10***c

cis*-3-Phenoxy-4-phenyl-4-(4′-methoxyphenyl)-1-(2′-phenyl-2′-*tert*-butyldimethylsiloxyethyl)azetidin-2-one* ***10***f

From β-lactam **10***d* (0.39 g, 1 mmol), yield: 92%, mp 131–134°C; ir ($CHCl_3$) ν (cm^{-1}): 1770 (C=O); nmr ($CDCl_3$) δ (ppm): 7.3–6.4 (m, 14H, arom.), 5.0 (d, J = 5 Hz, 1H, CH), 4.7 (t, J = 6 Hz, 1H, CH—OSi), 4.2 (d, J = 5 Hz, 1H, CH), 3.9 (d, d, J = 6 Hz, J' = −14 Hz, 1H, N—CH—COSi), 3.6 (s, 3H, OCH_3), 2.8 (d, d, J = 6 Hz, J' = −14 Hz, 1H, N—CH—COSi), 0.8 (s, 9H, C—CH_3), 0.0 (s, 3H, $SiCH_3$), −0.2 (s, 3H, $SiCH_3$). *Anal.* calcd. for $C_{30}H_{37}NO_4Si$: C 71.52, N 2.78, H 7.42; found: C 71.43, N 2.97, H 7.52.

cis*-4-(4′-Methoxyphenyl)-3-phenoxy-1-(2′-phenyl-2′-trimethylsiloxyethyl)azetidin-2-one* ***10***e*. Typical procedure from thionyl chloride – dimethylformamide reagent*

In a 25-mL dropping funnel, benzene (5 mL), *N,N*-dimethylformamide (1 mL, 10.2 mmol), and thionyl chloride (0.8 mL, 11 mmol) were added consecutively. After 3–5 min, two phases were separated and the reagent (lower layer) was added to a suspension of phenoxyacetic acid (1.52 g, 10 mmol) in dichloromethane (10 mL) at 0°C. After stirring at 5–10°C for 10 min, the resulting solution was added dropwise to a solution of the Schiff base **7***d* (2.55 g, 10 mmol) and triethylamine (4.7 mL, 33.6 mmol) in dichloromethane (25 mL) at 0–5°C. The resulting mixture was stirred overnight at room temperature, and washed with water (25 mL) and saturated sodium hydrogen carbonate solution (25 mL). The organic layer was dried (Na_2SO_4) and the solvent evaporated under reduced pressure. The resulting oil was crystallized from ethanol–water to give **10***e* (1.4 g, 30%), mp 135–136°C; ir ($CHCl_3$) ν (cm^{-1}): 1790 (C=O); nmr ($CDCl_3$) δ (ppm): 6.4–7.4 (m, 14H, arom.), 5.3 (d, J = 5 Hz, 1H, CH), 5.0 (t, J = 6 Hz, 1H, CH), 4.5 (d, J = 5 Hz, 1H, CH), 4.1 (d, d, J = 6 Hz, J' = −14 Hz, 1H, N—CH—COSi), 3.9 (s, 3H, OCH_3), 3.0 (d, d, J = 6 Hz, J' = −14 Hz, N—CH—COSi), 0.2 (bs, 9H, CH_3). *Anal.* calcd. for $C_{27}H_{31}NO_4Si$: C 70.25, N 3.03, H 6.77; found: C 70.11, N 3.06, H 6.74.

Oxidation of β-lactams ***10***

cis*-3-Phenoxy-4-phenyl-1-(2′-phenyl-2′-oxoethyl)azetidin-2-one* ***11***a

Method A: To a suspension of PDC (1.13 g, 3 mmol) in dichloromethane (20 mL), trimethylchlorosilane (0.9 mL, 7.09 mmol) was added and the dark red-brown mixture was stirred for 3 min. Then *cis*-3-phenoxy-4-phenyl-1-(2′-phenyl-2′-hydroxyethyl)azetidin-2-one **10***a* (0.72 g, 2 mmol) was added and the mixture was stirred for 30 min. Next, moist silica gel was added and the suspension was filtered off through a pad of silica gel to give a dark solution, which was concentrated under reduced pressure. The product was isolated by column chromatography (silica gel 70–230 mesh, eluent: AcOEt/hexane 1:1) to give **11***a* (0.60 g, 85%), mp 175–176°C; ir ($CHCl_3$) ν (cm^{-1}): 1760, 1690 (C=O); nmr ($CDCl_3$) δ (ppm): 7.7–6.4 (m, 15H, arom.), 5.5 (d, J = 5 Hz, 1H, CH), 5.2 (t, J = 5 Hz, 1H, —CH—), 5.0 (d, J = −18 Hz, 1H, N—CH—CO), 4.0 (d, J = −18 Hz, 1H, N—CH—CO). *Anal.* calcd. for $C_{23}H_{19}NO_3$: C 77.28, H 5.37, N 3.92; found: C 77.83, H 5.11, N 3.70.

Method B: To a solution of *N*-(2′-phenyl-2′-*tert*-butyldimethylsiloxyethyl)-2-phenylimine **7***c* prepared as above in dichloro-

methane (20 mL) was consecutively added, at 0°C, phenoxyacetic acid (1.52 g, 10 mmol), triethylamine (4.2 mL, 30 mmol), and phenyl dichlorophosphate (1.5 mL, 10 mmol) and the mixture was stirred at room temperature for 20 h. After this time, the reaction product was worked up by washing with water (20 mL), 0.1 *N* hydrochloric acid (15 mL × 2), and water (20 mL) again, and by drying over sodium sulphate to give a solution of the crude *cis*-1-(2′-phenyl-2′-*tert*-butyldimethylsiloxyethyl)-3-phenoxy-4-phenyl-azetidin-2-one, which was added dropwise to a solution of the trimethylsilyl chlorochromate **3** (20 mmol) prepared as above. The resulting dark suspension was stirred at 0°C for 35 min. When the reaction was complete, moist silica gel was added to hydrolyze the remaining oxidizing agent. Filtration of the mixture through a pad of silica gel and evaporation of the solvents yielded a crude solid that was heated under vacuum (60°C/1 Torr; 1 Torr = 133.3 Pa) to eliminate siloxane by-products, affording *cis*-3-phenoxy-4-phenyl-1-(2′-phenyl-2′-oxoethyl)azetidin-2-one **11***a* (1.42 g, 40% overall yield), mp 175–176°C, from ethanol.

cis-*4-(4′-Methoxyphenyl)-3-phenoxy-1-(2′-phenyl-2′-oxoethyl)-azetidin-2-one* ***11***b

To a suspension of PDC (0.82 g, 2.18 mmol) in dichloromethane (20 mL), trimethylchlorosilane (0.96 mL, 7.56 mmol) was added at 0°C. After 3 min, *cis*-4-(4′-methoxyphenyl)-3-phenoxy-1-(2′-phenyl-2′-*tert*-butyldimethylsiloxyethyl)azetidin-2-one **10***f* (0.48 g, 0.96 mmol) was added and the dark-brown reaction mixture was stirred at room temperature for 60 min. Moist silica gel was then added and the resulting suspension was filtered off through a pad of silica gel, the solvent being evaporated under reduced pressure. The product was purified by column chromatography (silica gel 70–230 mesh; eluent: AcOEt/hexane 1:1) to give **11***b* (0.34 g, 95%), mp 97–99°C; ir ($CHCl_3$) ν (cm^{-1}): 1790, 1730 (C=O); nmr ($CDCl_3$) δ (ppm): 7.7–6.1 (m, 14H, arom.), 5.4 (d, J = 5 Hz, 1H, —CH—), 5.1 (d, J = 5 Hz, 1H, —CH—), 4.9 (d, J = −18 Hz, 1H, N—CH—CO), 3.9 (d, J = −18 Hz, 1H, N—CH—CO), 3.5 (s, 3H, OCH_3). *Anal.* calcd. for $C_{24}H_{21}NO_4$: C 74.39, H 5.47, N 3.62; found: C 75.03, H 5.91, N 4.10.

cis-*4-(4′-Nitrophenyl)-3-phenoxy-1-(2′-phenyl-2′-oxoethyl)-azetidin-2-one* ***11***c

To a suspension of the crude *N*-(2′-phenyl-2′-*tert*-butyldimethylsiloxyethyl)-1-(4′-nitrophenyl)imine **7***h* (10 mmol) prepared from 4-nitrobenzaldehyde (1.51 g, 10 mmol) and 2-amino-1-phenylethanolamine (1.4 g, 10 mmol), followed by *tert*-butyldimethylsilylation as described above, was added consecutively, at 0°C, phenoxyacetic acid (1.52 g, 10 mmol), triethylamine (4.2 mL, 30 mmol), and phenyldichlorophosphate (1.5 mL, 10 mmol) and the mixture was stirred at room temperature for 20 h. After general work-up, the crude β-lactam **10***h* was dissolved in dichloromethane (30 mL) and PDC (11.3 g, 10 mmol) was added. Then, trimethylchlorosilane (9 mL, 70 mmol) was added dropwise at 0–5°C and the resulting mixture was stirred at room temperature for 4 h. After general work-up, the pure product was isolated by column chromatography (eluent: AcOEt/hexane 1:3) to give *cis*-4-(4′-nitrophenyl)-3-phenoxy-1-(2′-phenyl-2′-oxoethyl)azetidin-2-one **11***c* (1.6 g, 40%), mp 160–165°C (from ethanol); ir ($CHCl_3$) ν (cm^{-1}): 1800, 1720 (C=O); nmr ($CDCl_3$) δ (ppm): 8.1–6.5 (m, 14H, arom.), 5.6 (d, J = 5 Hz, 1H, CH), 5.3 (d, J = 5 Hz, 1H, CH), 5.1 (d, J = −18 Hz, 1H, N—CH—CO), 4.1 (d, J = −18 Hz, 1H, N—CH—CO). *Anal.* calcd. for $C_{23}H_{18}N_2O_5$: C 68.64, H 4.52, N 6.96; found: C 69.15, H 4.07, N 7.32.

cis-*4-(4′-Methoxyphenyl)-3-phenoxy-1-(1′-bromo-2′-phenyl-2′-oxoethyl)azetidin-2-one* ***14***

cis-4-(4′-Methoxyphenyl)-3-phenoxy-1-(2′-phenyl-2′-oxoethyl)-azetidin-2-one (0.97 g, 2.5 mmol) was dissolved in acetic acid (10 mL), 4-*N*,*N*-dimethylaminopyridinium bromide perbromide (0.91 g, 2.5 mmol) was added, and the mixture stirred for 15 min. The precipitate was then filtered off and washed with water and ethanol, giving the product **14** (1.0 g, 86%), mp 110–112°C (dec.); ir ($CHCl_3$) ν (cm^{-1}): 1780, 1700 (C=O); nmr ($DCCl_3$) *erythro* and *threo* compound δ (ppm): 3.2 and 3.3 (s, 3H, OCH_3), 4.8 (d, J = 5 Hz, 1H, CH), 4.9 and 5.0 (d, J = 2 Hz, 1H, Br—CH—CO), 5.3 (d, J = 5 Hz, 1H, CH), 6.0–7.5 (m, 14H, arom.). *Mol. wt.* calcd. for $C_{24}H_{20}BrNO_4$: 466.36; found: M^+, 466.

cis-*4-(4′-Methoxyphenyl)-3-phenoxyazetidin-2-one* ***15***

Method A: cis-4-(4′-Methoxyphenyl)-3-phenoxy-1-(1′-bromo-2′-phenyl-2′-oxoethyl)azetidin-2-one **14** (1.4 g, 3 mmol) was dissolved in acetone (30 mL) and water (10 mL). Sodium hydrogen carbonate (0.51 g, 6 mmol) was then added and the mixture was stirred at room temperature for 15 h. After this time, the solid was filtered off and washed with water and ethanol and the product was recrystallized from ethanol to give the title product **15** (0.61 g, 20%), mp 166–170°C (lit. (15) mp 166–167°C).

Method B: To s stirred solution of HgO (0.28 g, 1.25 mmol) and 35% aqueous tetrafluoroboric acid (0.62 g, 2.5 mmol) in tetrahydrofuran (5 mL) was added *cis*-4-(4′-methoxyphenyl)-3-phenoxy-1-(1′-bromo-2′-phenyl-2′-oxoethyl)azetidin-2-one **14** (1.16 g, 2.5 mmol). The mixture was stirred at room temperature for 2 h and then treated successively with saturated sodium hydrogen carbonate solution and 2 *N* sodium hydroxide until basic. The precipitated HgO was filtered off (0.23 g, 80%) and the filtrate was extracted with dichloromethane (20 mL × 2). The organic extracts were dried and the solvent evaporated under reduced pressure giving an oil, which was dissolved in dichloromethane (5 mL); then triethylamine (0.28 mL, 2 mmol) was added and the mixture was stirred for 3 h. Next, the mixture was washed successively with 2 *N* hydrochloric acid (5 mL) and water (5 mL). The organic layer was separated and dried over sodium sulfate and the solvent evaporated under reduced pressure to give **15**, which was crystallized from ethanol (0.24 g, 35%), mp 167–170°C (lit. (16) mp 167–170°C; lit. (15) mp 166–167°C).

General procedure for the oxidation of hydroquinones ***16***

A solution of reagent **3** (30 mmol) prepared as above was added dropwise to a suspension of the hydroquinone **16** (10 mmol) in the same solvent (10 mmol). The resulting dark-brown mixture was stirred at room temperature for the time indicated in Table 2. The progress of the reaction was monitored by tlc analysis at regular intervals. Soon after completion of the reaction moist silica gel was added and the mixture was filtered off through a pad of silica gel to give a yellow solution that was concentrated under reduced pressure to afford crude product. Isolation by column chromatography (silica gel; eluent: diethyl ether/hexane 1:1) gave a pure 1,4-benzoquinne **17**.

*Preparation of 1,4-bis(*tert*-butyldimethylsiloxy)benzenes*

A solution of *tert*-butyldimethylchlorosilane (0.660 g, 4.4 mmol), in CH_2Cl_2, the hydroquinone **16** (2.0 mmol), and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (0.760 g, 5.0 mmol), was stirred at room temperature for 30 min. The mixture was washed with water (5 mL), 0.1 *N* hydrochloric acid (10 mL), and saturated $NaHCO_3$ solution (5 mL), then dried (Na_2SO_4) and evaporated to yield crude 1,4-bis-(*tert*-butyldimethylsiloxy)benzenes, which were purified by reduced pressure distillation.

For 1,4-bis(trimethylsiloxy)benzenes, the same procedure was followed, using trimethylchlorosilane instead of *tert*-butyldimethylchlorosilane.

General procedure for the oxidation of 1,4-bis(trimethylsiloxy)-benzenes

Method A

To a stirred ice-cold solution of trimethylsilyl chlorochromate **3** (6.0 mmol) prepared as above in dichloromethane (10 mmol), a solution of the corresponding 1,4-bis(trimethylsiloxy)benzene (2.0 mmol) in the same solvent (5 mL) was added dropwise over a 5-min period, and stirred for 30 min. The reaction was monitored by tlc analysis (silica gel plates; eluent: AcOEt/hexane 1:2). On completion, moist silica gel (5.0 g) was added and the mixture was shaken for 5 min, decolorized, and filtered off through a pad of silica gel to give a solution that was concentrated and purified by reduced pressure distillation to afford a fairly pure quinone **17**.

Method B

To a suspension of PDC (5.64 g, 15 mmol) in dichloromethane (15 mL), trimethylchlorosilane (4.5 mL, 35.4 mmol) was added at 0°C and then the corresponding 1,4-bis(trimethylsiloxy)benzene (5 mmol) was added to the resulting red-brown mixture. The reaction was stirred at room temperature for 15 min, then filtered off through a pad of silica gel (230–400 mesh) and washed with dichloromethane. The resulting yellow solution was treated with water (15 mL × 2). The organic layer was dried (Na_2SO_4) and the solvent evaporated under reduced pressure to give the corresponding quinone **17**.

*General procedure for the oxidation of 1,4-bis(*tert*-butyldimethylsiloxy)benzene*

Method A

To a cooled (0°) solutions of trimethylsilyl chlorochromate **3** (15 mmol), prepared as above in dichloromethane (15 mmol) was added and the reaction mixture was stirred at the same temperature for 20–30 min. On completion, wet silica gel (10 g) was added to hydrolyze the remaining oxidizing species and the mixture was filtered through a pad of silica gel. The organic solution was dried and the crude quinone purified by column chromatography (silica gel; eluent: hexane/ether 1:1).

Method B

To a suspension of PDC (1.97 g, 5.23 mmol) in dichloromethane (10 mL), trimethylchlorosilane (1.59 mL, 12.52 mmol) was added at 0°C and the corresponding 1,4-bis(*tert*-butyldimethylsiloxy)benzene (5.0 mmol) was then added to the resulting red-brown mixture. The reaction was stirred for 15 min, then filtered off through a pad of silica gel (230–400 mesh) and washed with dichloromethane. The resulting yelow solution was treated with water (15 mL × 2) and the organic layer was dried (Na_2SO_4). The solvent was evaporated under reduced pressure and the resulting product was purified (elution of silanol) by column chromatography (silica gel; eluent: diethyl ether/hexane 1:1) to give the corresponding pure benzoquinone **17**.

STEPHEN G. WITHERS, IAN P. STREET, and STEVEN J. RETTIG. Can. J. Chem. **64**, 232 (1986).

The preferred conformation of 2-fluoro-2-deoxy β-D-mannopyranosyl fluoride has been determined in the solid state by X-ray crystallography and in aqueous solution by 2-dimensional *J*-resolved proton nuclear magnetic resonance. Crystals of 2-fluoro-2-deoxy β-D-mannopyranosyl fluoride are monoclinic, *a* 4 10.9150(8), *b* 4 4.9079(4), *c* 4 6.9902(6) Å, β = 105.158(4)°, $Z = 2$, space group $P2_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.028$ and $R_w = 0.031$ for 797 reflections with $I \geq 3\sigma(I)$. The sugar ring was present in an essentially undistorted $^4C_1$ chair conformation. Weak, but significant interactions, presumably hydrogen bonding of the type OH ... F and CH ... F, are observed within the crystal lattice. Coupling constants observed in the proton nmr were consistent only with a $^4C_1$ chair conformation in solution. These observations are briefly discussed in terms of recent findings concerning the interaction of fluorodeoxy sugars with enzymic binding sites.

STEPHEN G. WITHERS, IAN P. STREET et STEVEN J. RETTIG. Can. J. Chem. **64**, 232 (1986).

On a déterminé la conformation privilégiée du fluorure du fluoro-2 déoxy-2 β-D-mannopyrannosyle tant à l'état solide en faisant appel à diffraction des rayons-X qu'en solution aqueuse en faisant appel à la rmn du ^1H bidimensionnelle résolue pour *J*. Les cristaux du fluorure du fluoro-2 déoxy-2 β-D-mannopyrannosyle sont monocliniques avec $a=10,9150(8)$, $b=4,9079(4)$, $c=6,9902(6)$ Å, β=105,158(4)°, $Z=2$ et groupe d'espace $P2_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R=0,028$ et $R_w = 0,031$ pour 797 réflexions avec $I \geq 3\sigma(I)$. Le cycle du sucre existe essentiellement dans une conformation chaise $^4C_1$ qui n'est pas déformée. Dans la maille du cristal, on observe des interactions faibles, mais significatives, qui sont probablement dues à des liaisons hydrogènes du type OH . . . F et CH . . . F. Les constantes de couplage observées dans le spectre rmn du ^1H en solution ne peuvent être expliquées que par une conformation chaise $^4C_1$. On discute brièvement de ces résultats par rapport aux résultats obtenus récemment concernant l'interaction des sucres fluoro-déoxy avec les sites de liaison enzymatique.

[Traduit par le journal]

Introduction

The mode of interaction of carbohydrates and proteins has been attracting considerable interest of late, particularly since the antigenic determinants of red blood cells are oligosaccharides and it is their interaction with receptor proteins that is central to blood type recognition (1). In order to probe the intermolecular forces dominating such interactions, deoxy- and fluorodeoxy-saccharide analogues have been employed in several specificity studies (2–5). Such analogues are useful since the hydroxyl moiety is replaced by a smaller, and therefore sterically compatible, substituent, but one of different electronic properties. Systematic studies of mono-substituted derivatives can therefore provide information on the factors contributing to binding at each position. The enzyme glycogen phosphorylase provides a useful model system for a study of carbohydrate/protein interactions since the three-dimensional structure of the glycogen phosphorylase/glucose complex has been determined by X-ray crystallography (4). Studies currently in progress involve a systematic study of the specificity of this enzyme for glucose as an inhibitor and for its substrate glucose-1-phosphate, using a series of deoxy and fluorodeoxy analogues. However, since the enzyme is known to bind glucose in its $^4C_1$ conformation (4, 6) it was considered important to establish that substitution of one or more fluorine atoms into the ring did not distort the sugar away from this preferred $^4C_1$ conformation. Such concerns were based upon the previous observation (7) that 2,3,4-tri-*O*-acetyl β-D-xylopyranosyl fluoride adopts the $^1C_4$ conformation in solution, as a result of interactions between the dipole associated with the C—F bond and that associated with the ring oxygen atom. This provided a convincing demonstration of the strength of the anomeric effect associated with a fluorine substituent at the anomeric centre, since in its preferred conformation the acetoxy substituents at C(2), C(3), and C(4) are forced into unfavourable axial orientations. In the case under consideration a complete inversion to a $^1C_4$ conformation is considerably less likely, primarily as a result of the requirement for the bulky hydroxymethyl group at C(5) to then adopt an axial configuration with consequent repulsive interaction. However, since any significant distortion in the molecule could affect its ability to bind to the enzyme, it was deemed important to investigate this possibility.

2-Fluoro-2-deoxy-β-D-mannopyranosyl fluoride was selected as the most likely compound, in the series being texted, to be distorted, on the basis of dipolar repulsions between the two fluorine substituents and the ring oxygen atom, in the $^4C_1$ conformation. Its solid state structure was thus determined by X-ray crystallography and its conformation in solution ascertained by proton nmr. The X-ray crystal structure has also provided some insight into the involvement of the fluorine atom in hydrogen bonding within the crystal lattice.

Experimental

2-Fluoro-2-deoxy β-D-mannopyranosyl fluoride was obtained by Zemplen deacetylation (8) of its tri-*O*-acetate. The protected sugar, obtained by the addition of trifluoromethyl hypofluorite to D-glucal tri-*O*-acetate (9), was kindly provided by Dr. D. Dolphin.

The ^1H nmr spectra were determined in D_2O at ambient temperature on a Bruker WH-400 spectrometer. The ^1H nmr chemical shifts are referenced to external DSS at 0 ppm. The ^{19}F nmr chemical shifts are referenced to external trifluoroacetic acid in D_2O at 0 ppm. The

homonuclear 2-dimensional *J*-resolved spectrum was obtained using the standard pulse sequence shown below, at 256 different values of t_1. 256 spectra of 1K data points requiring 48 acquisitions each were thus obtained and the resultant matrix then transformed in the t_1 and t_2 dimensions.

Single crystals of 2-fluoro-2-deoxy β-D-mannopyranosyl fluoride were obtained by vapour diffusion of petroleum ether into a solution of the title compound in diethyl ether/methanol.

X-ray crystallographic analysis

A crystal bounded by the 10 faces (followed by their distances in mm from a common origin): ±(1 0 0), 0.12, ±(1 0 −1), 0.09, ±(1 0 1), 0.14, ±(1 1 −2), 0.19, ±(−1 1 2), 0.23 was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 35–42°) measured on a diffractometer with Mo-*K*α radiation (λ(*K*α$_1$) = 0.70930 Å, λ(*K*α$_2$) = 0.71359 Å). Crystal data at 22°C are:

$C_6H_{10}F_2O_4$ fw = 184.14

Monoclinic, a = 10.9150(8), b = 4.9079(4), c = 6.9902(6) Å, β = 105.158(4)°, V = 361.43(5) Å^3, Z = 2, ρ_c = 1.692 Mg m^{-3}, $F(000)$ = 192, μ(Mo-*K*α) = 1.62 cm^{-1}. Absent reflections: 0*k* 0, *k* odd, space group $P2_1$ (C_2^2, No. 4).

Intensities were measured with graphite-monochromated Mo-*K*α radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 0.80–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured by 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, showed only small random variations. Of the 919 independent reflections measured and processed,[3] 797 (86.7%) had intensities greater than or equal to 3σ(I) above background, where $\sigma^2(I) = S + 2B + (0.04(S-B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an *E*-map and those of the hydrogen atoms from a subsequent difference map. Hydrogen atoms were refined with isotropic and non-hydrogen atoms with anisotropic thermal parameters. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.028 and R_w = 0.031 for 797 reflections with $I \geq 3\sigma(I)$. For all 919 reflections, R = 0.041. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma \| F_o| - |F_c\| / \Sigma |F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.001 and 0.014σ respectively. The mean error in an observation of unit weight was 1.648. A final difference map showed no unusual features, maximum fluctuations being −0.26 and +0.18 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1 and the packing diagram in Fig. 2. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (12). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0007 Å^2. Analysis of the six-membered ring gave rms ΔU_{ij} = 0.0009 Å^2 and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (12, 13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformation of the six-membered ring are listed in Table 4, and hydrogen bond and weak C—H . . . (F/O) interaction data in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 7–9) are included as supplementary material.

resonances and couplings in this spectrum as a means of determining its solution conformation were unsuccessful. Rather than embark on a lengthy series of decoupling experiments to permit assignment, a homonuclear (^{1}H) two-dimensional *J*-resolved spectrum was obtained and is presented as a contour plot in Fig. 3(b). In such a presentation the coupling constant axis contains ^{1}H–^{1}H coupling constant information only, while the projection onto the chemical shift axis produces the proton-decoupled, but still fully fluorine-coupled ^{1}H spectrum, thus enormously simplifying assignment. The assignment achieved is presented in Table 10. The coupling constants observed are consistent only with a $^4C_1$ conformation for the sugar, as follows. Large coupling constants (approximately 10 Hz) between H(5) and H(4) and between H(4) and H(3) are uniquely consistent with a *trans*-diaxial arrangement of these protons, while large vicinal proton–fluorine coupling constants of 30 Hz and 17.8 Hz between H(3) and F(2) and between H(1) and F(2) respectively are indicative of a *trans*-diaxial arrangement of these substitutents (14, 15). In fact, all the *trans*-diaxial coupling constants are slightly larger than those determined for the fully acetylated sugar (15). This could be due to differences in electronegativity of acetate (16) versus hydroxyl substituents or to a solvent effect, but is more likely due to the deprotected sugar adopting a more rigid $^4C_1$ conformation in D_2O than the protected sugar adopts in $CDCl_3$. The possibility of some degree of distortion of the protected sugar (based upon nmr data) was discussed in this earlier paper (15). The value of 2-dimensional nmr in such a spectral

*Superscripts refer to symmetry operations: $x, y, 1+z$; x, y, z; $1-x, y-1/2, 2-z$; $1-x, y-1/2, 1-z$; $-x, 1/2+y, 1-z$; and $-x, 1/2+y, 2-z$, respectively.

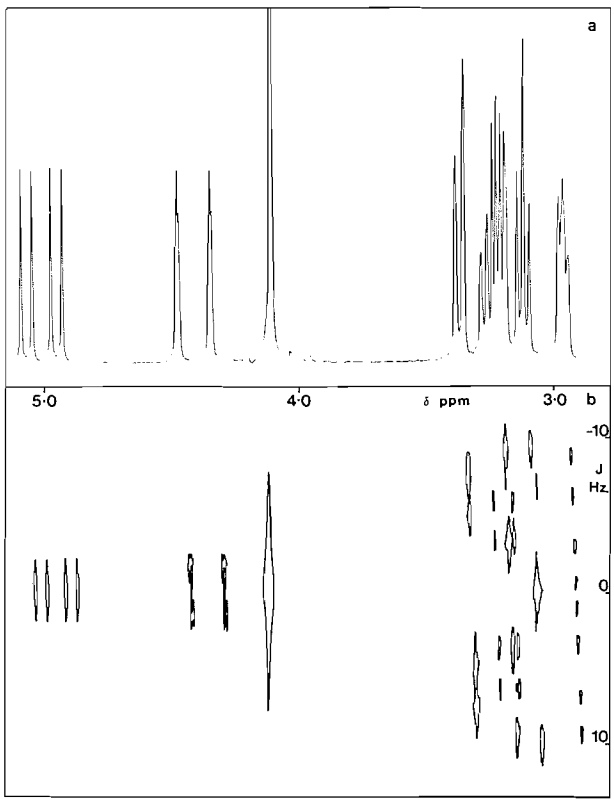

FIG. 3. The ^1H nmr spectra of 2-fluoro-2-deoxy β-D-manno-pryanosyl fluoride in D_2O at 400 MHz and ambient temperature. (a) 1-Dimensional spectrum; (b) 2-dimensional *J*-resolved spectrum.

assignment is best illustrated by a couple of examples from Fig. 3. The multiplet due to H(5) ($\delta = 2.95$ ppm) is well resolved in the two-dimensional nmr, and all couplings are seen to be proton–proton couplings, with no proton–fluorine coupling. The multiplets between $\delta = 3.14$ ppm and $\delta = 3.30$ ppm are well resolved in the two-dimensional nmr as resonances from two protons, one of which (H(6′), $\delta = 3.21$ ppm) is a proton coupled double doublet ($J(6–6') = 12.4$ Hz, $J(6' -5) = 5.9$ Hz) with a small long-range fluorine coupling that manifests itself as a broadened contour. The other resonance (H(3), $\delta = 3.23$ ppm) contains both fluorine–proton and proton–proton coupling and thus appears as two double doublets separated along the chemical shift axis by the fluorine coupling constant. Similarly the resonance due to H(1) is seen to contain only fluorine–proton couplings and no proton–proton coupling, and thus appears as a multiplet along the chemical shift axis. A $^4C_1$ conformation is therefore unequivocally assigned for this compound under these conditions.

The bond lengths and bond angles for the title compound, as determined by X-ray crystallography, are presented in Tables 2 and 3. The three-dimensional structure with carbon, oxygen, and fluorine atoms represented as thermal ellipsoids is presented in stereo format in Fig. 1. The compound is clearly in the normal $^4C_1$ conformation with one axial fluorine (F(2) and one equatorial fluorine (F(1). The distance C(2)—F(2) is very similar to the average C—F value of 1.40 Å observed for several other deoxyfluoro sugar derivatives (17–21), but slightly greater than the average value for the paraffinic C—F bond (22) (1.38 Å), whereas the C(1)—F(1) bond is slightly shorter (1.368 Å). This shorter C(1)—F(1) bond length is interesting, as similar observations have been made previously on the relative shortening of the C(1)—O(1)H bond length in many structure determinations of pyranose sugars (23). The pyranose ring is essentially unstrained since very little distortion is observed based upon the intra-annular torsion angles (23) (Table 4) and upon the calculated puckering parameters as defined by Cremer and Pople (24). Comparison of the intra-annular torsion angles with a set of average torsion angles for mannose calculated previously (23), based upon 12 mannose structures, reveals that some small differences (5° or less) in angle, centred around C(5) and O(5), are observed. The puckering parameters reveal the same minor distortions. Parameters calculated are $Q = 0.582$ Å, $\theta = 4.2°$, $q_2 = 0.043$ Å, $q_3 = 0.580$ Å. Comparable values for mannose calculated from the average mannose coordinates (25) are $Q = 0.5505$ Å, $\theta = 2.56°$, $q_2 = 0.0245$ Å, $q_3 = 0.5499$ Å. The deviation from an ideal chair conformation ($\theta = 0°$) is proportional to θ and is small, although slightly greater than that of the average mannose structure. The above average total puckering amplitude, Q, arises from larger than normal (by about 0.03 Å) displacements of atom O(5) and C(5) from the mean plane of the ring. As a consequence, the intracyclic bond angles at O(5) and C(5) are smaller than the average values of 113.4° and 110.2°, respectively (25).

There is a considerable amount of hydrogen bonding in the crystal, both between adjacent molecules and also within the molecule (Fig. 2). All the hydroxyls are involved in hydrogen bonding both as donors and as acceptors, and are often multiply involved. The ring oxygen also acts as a hydrogen bond acceptor. Several weak interactions involving the fluorine atoms are observed. F(2) is involved in a weak intramolecular interaction with OH(3), as evidenced by the relatively short

TABLE 10. ^1H nuclear magnetic resonance assignment

Chemical Shift δ (ppm)	^1H–^1H coupling constants (Hz)	^{19}F–^1H coupling constants (Hz)

H(6) = 3.36	H(5)–H(6′) = 5.9	F–H(4) ≈ 1
H(6′) = 3.21	H(6)–H(6′) = 12.4	F–H(69) ≈ 1
F(1) = 31.37 (Φ* = 147.53)		F(1)–F(2) = 12.7
F(2) = − 43.50 (Φ* = 222.40)		

F...H distance. This results in OH(3) being rotated slightly away from its other stronger hydrogen bonding partner, OH(6) of an adjacent molecule. F(1) is involved in a weak interaction with the CH proton of C(2), which is presumably activated towards such interaction by virtue of its two electronegative substituents. Such involvement of fluorine atoms in hydrogen bonding interactions is relatively unusual but not unprecedented, and Glusker and co-workers (26) have recently summarized their status. A more recent structure (27) in which a short intermolecular C—F---H—O bond is observed has also been published and an earlier study (28) has established the existence of weak C—H---F hydrogen bonds. While such interactions are weak, they are doubtless significant, as evidenced in this case by the high density and low temperature factors observed despite the removal of two hydroxyl groups.

Direct observation of such interactions is important in the light of the many recent studies regarding interaction of fluorinated substrate analogues with biological systems (2–5, 29, 30), and particularly with regard to studies of fluorocarbohydrate/protein interactions where such hydrogen bonding has been invoked (4, 30) to explain the high affinity for the protein of fluorodeoxy derivatives as compared to deoxy derivatives.

CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN, and SEAMUS FRANCIS O'SHEA. Can. J. Chem. **64**, 237 (1986).

The direct irradiation of 7-cyanobenzocyclooctatetraene (**5**) led to 6- and 7-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**7** and **8**; $\Phi_7 = \Phi_8 < 0.0001$). On direct irradiation, **7** gave 1-cyanobenzosemibullvalene (**6**; $\Phi = 0.19$), **5** ($\Phi = 0.022$), and 2-cyanonaphthalene ($\Phi = 0.04$), whereas **8** gave 7-cyanobenzosemibullvalene (**16**; $\Phi = 0.03$), **5** ($\Phi = 0.22$), naphthalene ($\Phi = 0.12$), and 4-cyano-7,8-benzotetracyclo[3.3.0.$0^{2,4}$.$0^{3,6}$]oct-7-ene (**17**, $\Phi = 0.03$). Upon sensitized irradiation, **7** gave **6** ($\Phi = 0.68$) and 2-cyanonaphthalene ($\Phi = 0.007$), while **8** gave **16** ($\Phi = 0.01$) and naphthalene ($\Phi = 0.52$). Deuterium labelling studies suggest that **6** and **16** derive from Zimmerman di-π-methane rearrangements.

CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN et SEAMUS FRANCIS O'SHEA. Can. J. Chem. **64**, 237 (1986).

La photolyse directe du cyano-7 benzocyclooctatetraène (**5**) conduit aux cyano-6 et -7 benzo-2,3 bicyclo[4.2.0]octatriènes-2,4,7 (**7** et **8**; $\Phi_7 = \Phi_8 < 0{,}0001$). Par irradiation directe, **7** conduit au cyano-1 benzo semi-bullvalène (**6**; $\Phi = 0{,}19$), à **5** ($\Phi = 0{,}022$) et au cyano-2 naphtalène ($\Phi = 0{,}04$), tandis que **8** conduit au cyano-7 benzo semi-bullvalène (**16**; $\Phi = 0{,}03$), à **5** ($\Phi = 0{,}22$), au naphtalène ($\Phi = 0{,}12$), et au cyano-4 benzo-7,8 tetracyclo[3.3.0.$0^{2,4}$$0^{3,6}$]octène-7 (**17**; $\Phi = 0{,}03$). Par irradiation sensibilisée, **7** conduit à **6** ($\Phi = 0{,}68$) et au cyano-2 naphtalène ($\Phi = 0{,}007$), alors que **8** conduit à **16** ($\Phi = 0{,}01$) et au naphtalène ($\Phi = 0{,}52$). Des études de marquages au deuterium suggèrent que **6** et **16** dérivent des transpositions di-π-méthanes de Zimmerman.

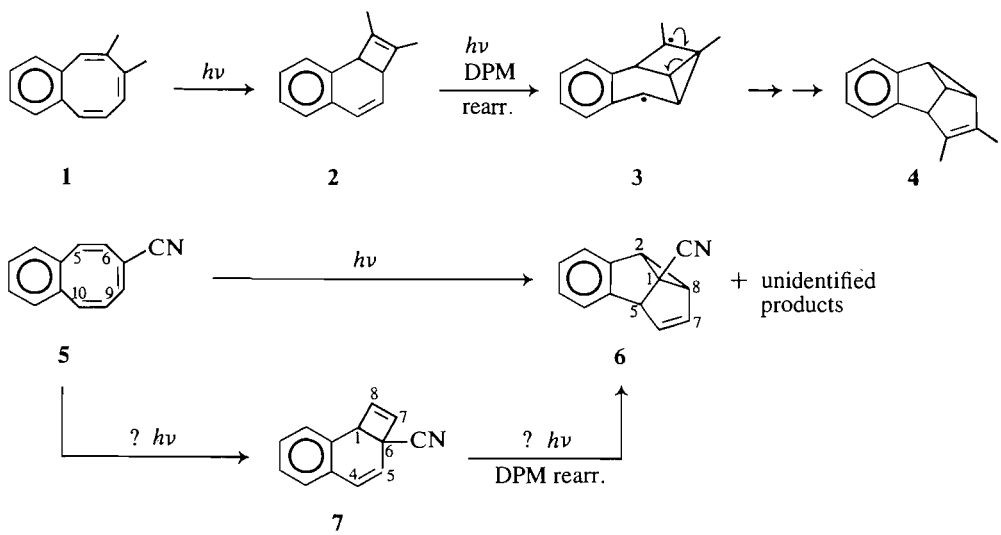
Introduction

On the basis of deuterium labelling studies we reported that the photoformation of 6,7-dimethylbenzosemibullvalene (i.e., 6,7-Me_2-BSB (**4**)) from 6,7-dimethylbenzocyclooctatetraene (i.e., 6,7-Me_2-BCOT (**1**)) can be accounted for in terms of a Zimmerman di-π-methane (DPM) rearrangement of the initially formed diene **2** (1). In the light of this observation we suggested that the known (2) conversion of 7-CN-BCOT (**5**) to 1-CN-BSB (**6**) on direct irradiation might follow a similar reaction sequence, and hence involve the intermediate formation of 6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (i.e., diene **7**). We now present evidence to support this view, and other results which demonstrate that the extent of DPM rearrangement in such dienes is strongly dependent on substituent location.

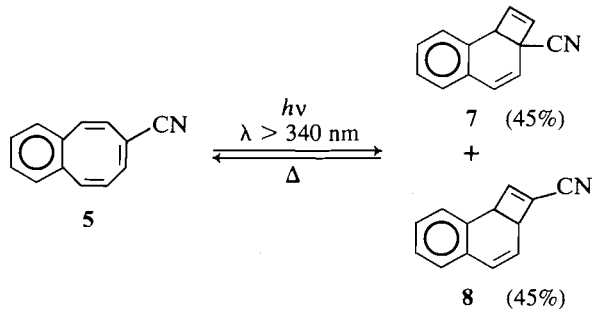
Results

The direct irradiation of COT **5** at wavelengths > 340 nm led cleanly not only to the anticipated diene **7** but also to the alternate $2\pi + 2\pi$ ring closure product **8**. The two products were formed in equal amounts, in high chemical yield, but in very low quantum efficiency ($\Phi_7 = \Phi_8 < 0.0001$).

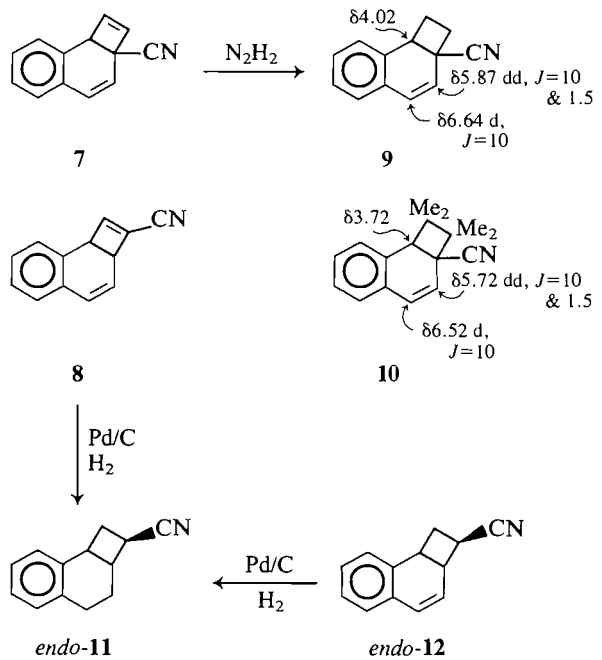
The structures of **7** and **8** were deduced from nmr data (see Experimental) and chemical evidence. Thus, treatment of **7** with diimide led to the selective reduction of the nonconjugated (cyclobutene) double bond to give 7,8-dihydro-6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene (**9**). The nmr data for **9** agree well with those reported for the corresponding protons of **10** (3) (see Scheme 3). In the case of diene **8**, reduction with diimide was ineffective. However, catalytic hydrogenation with 10% Pd on C gave **11**, a tetrahydro derivative of **8**. The same



SCHEME 1



SCHEME 2



SCHEME 3

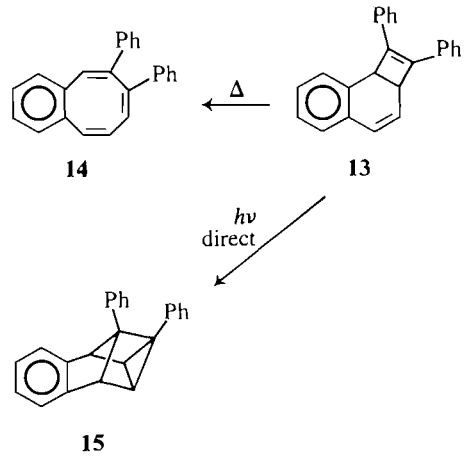
material was the only significant product from the hydrogenation of the known compound **12** (4).[1]

Further support for structures **7** and **8** derives from their facile thermal conversion to COT **5** (cf. the thermolysis of **13** to **14**, Scheme 4 (5)). The rearrangements were detectable on the gc at column temperatures >100°C for **7**, and >135°C for **8**, and are essentially quantitative upon flash gas phase thermolysis at 350°C.

Photochemically, dienes **7** and **8** are also labile. The product formations from the direct and sensitized irradiations are depicted in Scheme 5; the yields given are based on consumed starting materials.

The formation of 4-cyano-7,8-benzotetracyclo-[3.3.0.$0^{2,4}$.$0^{3,6}$]oct-7-ene (**17**) in the direct irradiation of **8** is analogous to the photoisomerization of **13** to **15** reported by Collin and Sasse (5). The structure of **17** was assigned on spectroscopic grounds alone. The mass spectrum shows a strong molecular peak at *m/e* 179 and, like **15**, contains a major fragmentation peak at *m/e* 128, corresponding to naphthalene ion. The C_2 symmetry of **17** is reflected by the ^{1}H nmr spectrum, which shows only five sets of resonance signals: three in the aliphatic region centred at δ 4.36 (H-1, 6), δ 3.28 (H-5), and at δ 2.96 (H-2, 3) (cf. δ 4.24 (H-1, 6), and δ 2.52 (H-2, 3) for **15**

[1]We thank Professor McCullough of McMaster University for a comparison sample of authentic **12**.



SCHEME 4

(6)), and two in the aromatic region. The aliphatic signals approximate an AA'MXX' spin system, with H-5 appearing as a quintet ($J_{5,1(6)} = J_{5,2(3)} = 4.5$ Hz), as does the corresponding proton in the related derivative **18** ($J_{5,1(6)} = 4.5$ Hz and $J_{5,2(3)} = 5$ Hz (7)).[2]

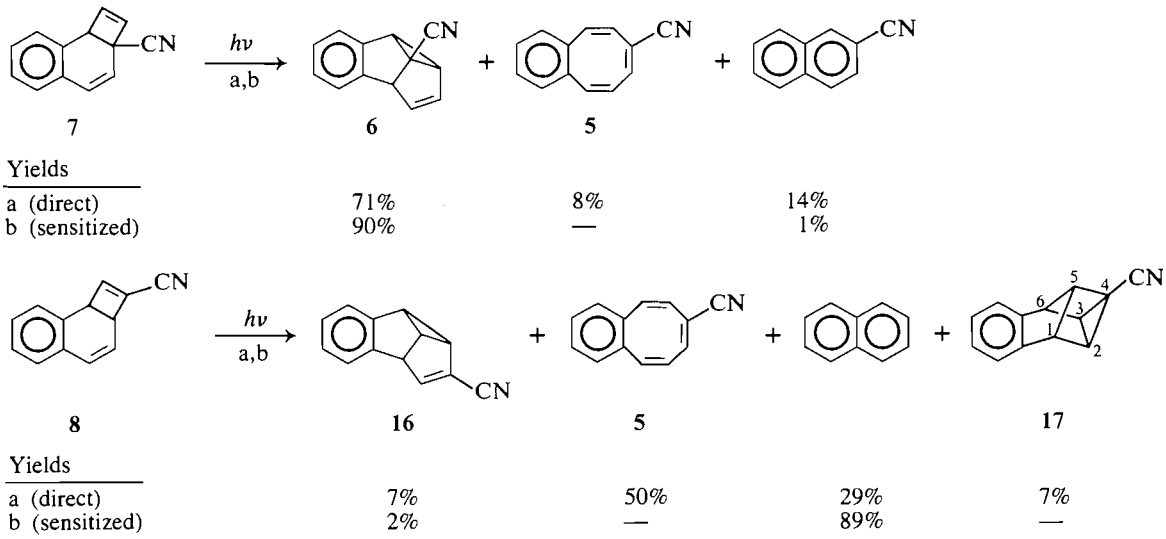
Structural assignment in the case of photoproduct **16** was less straightforward since the compound undergoes rapid polymerization upon solvent removal, thus limiting the physical characterization. Nevertheless, the mass spectrum, nmr data, and hydrogenation results provide strong support for the proposed benzosemibullvalene structure.

The mass spectrum (via gc/ms) established the molecular weight as 179 and the ^{1}H nmr spectrum revealed the uniquely characteristic coupling constants of the rigid benzosemibullvalene framework. The nmr data for **16** are compared with those of **6** and parent benzosemibullvalene **19** (8) in Table 1. Note that the protons of **16** appear within the expected chemical shift regions; the 0.7-ppm downfield shift of H-6 relative to H-6 in **19** agrees well with the reported chemical shift substituent constant of 0.8 ppm for the *cis* proton of acrylonitrile (9). Chemical evidence in favour of the structure was obtained from the brief exposure of **16** to catalytic hydrogenation (10% Pd on C; 3 min). Two major components were formed, but only one (**20**, 31%) was isolated. 7-Cyano-2,3-benzobicyclo[3.3.0]octa-2,6-diene (**20**) is a stable crystalline dihydro derivative of **16** and can be viewed as a product of 1,4-addition of hydrogen to C-2 and C-6 of **16**. Other 1,4-addition reactions of semibullvalenes are well known (7, 10).

In addition to aromatic signals, the nmr spectrum of **20** shows one vinylic proton at δ 6.52 and six distinctly separated one-proton multiplets, corresponding to four allylic or benzylic methylene protons between δ 2.76 and δ 3.27, and two benzylic or allylic bridgehead methine protons at δ 3.75 (H-5) and δ 3.98 (H-1), which are strongly coupled ($J_{1,5} = 8.5$ Hz). This large coupling between the methine protons is incompatible with bicyclo[3.2.1]octadiene structures that could conceivably arise from alternative cyclopropyl ring cleavages of **16**. Furthermore, the high-field methine at δ 3.75 is coupled to the vinylic proton ($J = 2.5$ Hz), and this observation, along with other features of the nmr, permits us to exclude **21** as a contending structure.

Lastly, in connection with the photoproducts **16** and **17**, control experiments were carried out to examine if either

[2]We are grateful to Professor Klumpp of Vrije Universiteit, The Netherlands, for communicating to us nmr spin decoupling results for **18**.



SCHEME 5

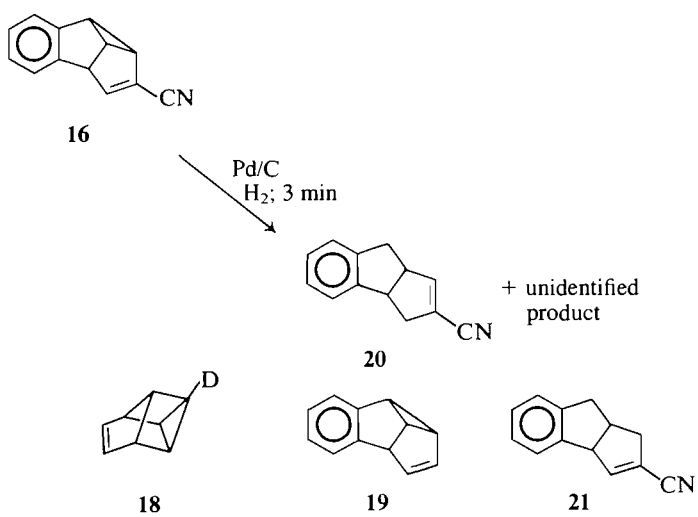
H-6	6.24 d	5.47 dd	5.70 dd
H-7	—	5.08 dd	5.20 dd
H-8	2.90 t	2.60 dt	3.33 dd

[a]Run in $CDCl_3$ (**6**) or CCl_4 (**16** and **19**) solvent with TMS as internal standard.
[b]Corresponding coupling constants, where applicable, are within 0.5 Hz; typically, $J_{1,2} = J_{1,5} = J_{2,8} = 6.5$, $J_{5,6} = J_{7,8} = 2.5$, and $J_{6,7} = 5.0$ Hz.

converted to the other under the conditions used for the photolyses of diene **8**. Tetracyclic **17** was found to be stable to direct (Pyrex filter) and sensitized (benzophenone) photolyses, but SB **16** slowly disappeared under both irradiation conditions to give polymeric mterial. Thus **16** is not a secondary photoproduct arising from **17**, and vice versa.



SCHEME 6

Mechanistic considerations

Whereas the formation of SB **6** from diene **7** can be most reasonably accounted for in terms of a single mechanism, a DPM rearrangement involving initial bridging between C-5 and C-7 (Scheme 7, route *i*), there are at least two plausible pathways that can rationalize the formation of SB **16** from diene **8**, i.e., route *ii* (Scheme 7), a DPM rearrangement which commences with C-5–C-7 bridging, and route *iii*, which involves initial C-4–C-8 bridging. Routes *ii* and *iii* are skeletally nonequivalent and deuterium labelling studies were therefore undertaken to determine which operates.

The labelled dienes **7***a* and **8***a* were conveniently obtained from the photolysis of the known (2) deuterated COT **5***a* (ca. 86%-d_1 at C-9). The observation that SB **16***a* is produced on either direct or sensitized photolysis of **8***a*, as determined by ^{1}H nmr analysis, can be seen to be in accord with the DPM mechanism depicted as route *ii*.

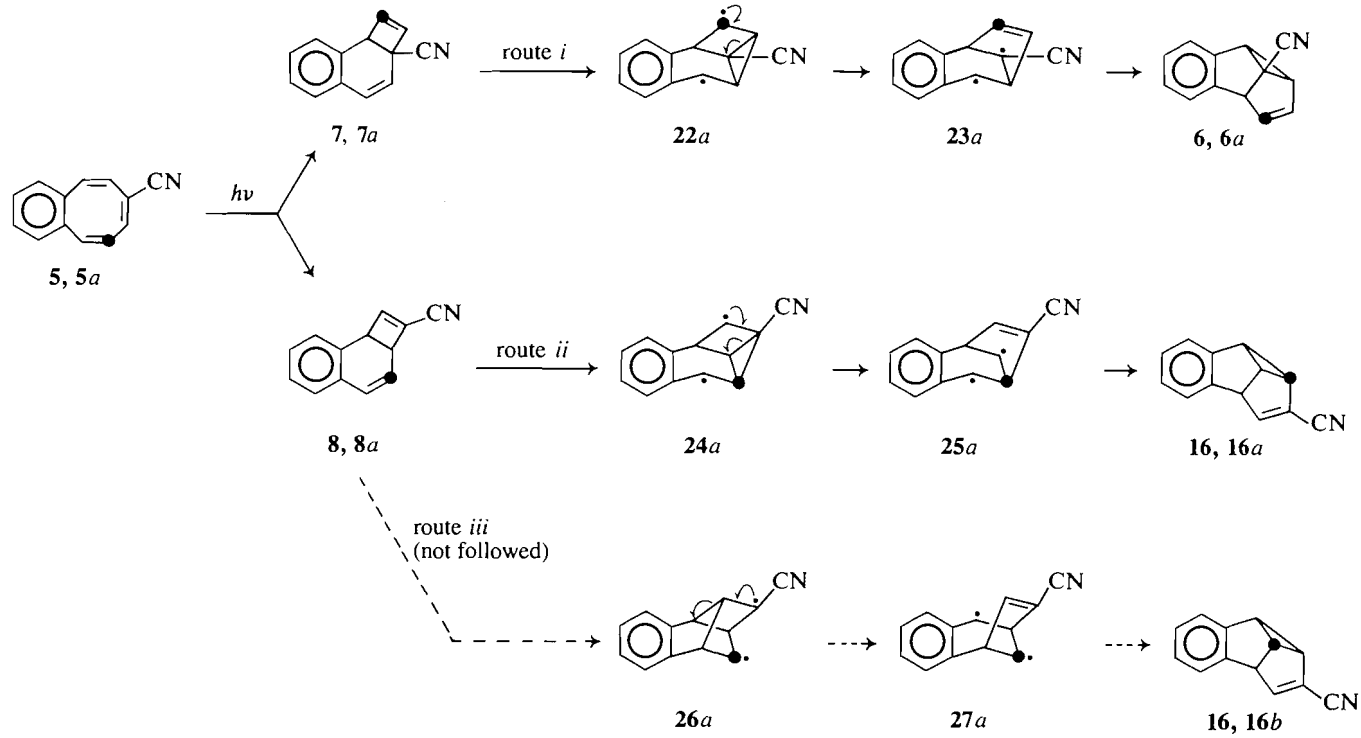
In the case of diene **7***a*, the direct and sensitized irradiations led to SB product containing the deuterium label at C-6, as required by the DPM rearrangement shown (Scheme 7, route *i*). The results complement those obtained from a previous labelling study of the conversion of COT **5** to SB **6** on direct irradiation, where COT **5** was deuterated at C-6 and C-10 (1, 2).

Singlet and triplet energies of 7 and 8 and quantum yields

Diene **7** showed strong fluorescence in cyclohexane at room temperature, and a singlet energy of 95 kcal/mol was assigned from intersection of the absorption and fluorescence spectra. No fluorescence could be detected for diene **8**, but a value of $92 \leq E_s \leq 95$ kcal/mol was estimated from the uv long-wavelength band.

"Effective" triplet energies of ca. 59 kcal/mol for both **7** and **8** (cf. E_T 61 kcal/mol for styrene, and $61 \leq E_T \leq 59$ kcal/mol for Me_2-diene **2** (1)) were obtained from triplet sensitization experiments. Thus the diene triplet reactions were efficiently sensitized by benzophenone (E_T 69 kcal/mol) and Michler's ketone (E_T 62 kcal/mol), modestly by 2-acetonaphthone (E_T 59 kcal/mol), but not effectively by 1-acetonaphthone (E_T 56 kcal/mol). These data are included with other quantum yield information in Table 2.

A remaining aspect is the sensitized photolysis of COT **5**. Attempts to sensitize **5** with thioxanthone or with *p*-dimethylaminobenzophenone, using filters transmitting light between



SCHEME 7

[a]Ferrioxalate actinometry; runs for **7** and **8** were done in cyclohexane, and those for **5** were done in both cyclohexane and benzene. Φ's given are extrapolated to zero conversion; product analyses (internal hydrocarbon standard) by gc (and nmr for **7**) at several conversions <10%. Experimental error of Φ's is ±10%. For sensitized runs, sensitizers absorb <95% of incident light.

[b]Nap = naphthalene.

wavelengths 315 and 383 nm (the absorption tail of **5** at $3 \times 10^{-3} M$ extends beyond 440 nm, hence the need for a window, rather than a cut-off filter), led to no observable formation of **7** or **8** (i.e., Φ_7, $\Phi_8 < 0.0001$) or any other product. Here the triplet energy of COT **5** (**5** is not phosphorescent) is assumed to be close to that of COT **1** ($E_T \leq 56$ kcal/mol (1)), and it is assumed that energy transfer from thioxanthone (E_T 65.5 kcal/mol) at $1.4 \times 10^{-3} M$ (11) and *p*-dimethylaminobenzophenone (E_T 62 kcal/mol) at $3.1 \times 10^{-3} M$ is efficient. These sensitization results, coupled with only "upper-limit" quantum yields for the formation of dienes **7** and **8** upon direct irradiation, caution us about speculating as to the excited state(s) involved in the photochemistry of COT **5**.

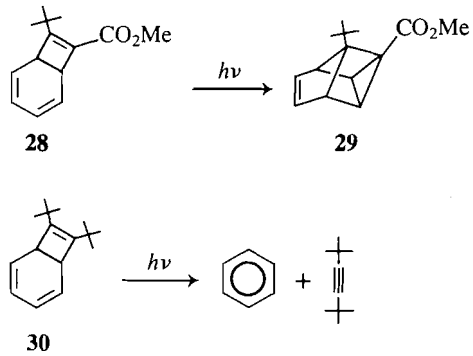
Discussion

Excited state multiplicities

Sensitization of **7** and **8** led to naphthalene and semibullvalene products (i.e., SB **6** plus 2-cyanonaphthalene from **7**, and SB **16** plus naphthalene from **8**) and are attributed to triplet (T_1) processes. For the direct irradiations, multiplicity assignments cannot be made for all the photoproducts. Clearly, however, COT **5** is a singlet product of both **7** and **8**, and tetracyclic **17** is a singlet product of **8**, since they are not formed in sensitized runs. For the remaining products from direct irradiations, straightforward application of the Zimmerman "ratio bracketing rule" (12) suggests that 2-cyanonaphthalene (from **7**) and SB **16** (from **8**) are mainly (>90%) singlet derived, but SB **6** (from **7**) and naphthalene (from **8**) may arise from singlet or triplet states (via intersystem crossing from S_1), or some composite of the two. The singlet (mostly) origin of SB **16** is noteworthy, since DPM rearrangements in rigid systems are generally triplet initiated (13).

Product dependency on substituent location

The singlet products of **7** and **8** are similar to those reported for the benzobicyclo[4.2.0]octa-2,4,7-trienes **2** (1) and **13** (5),



SCHEME 8

and here we comment only on the failure of **7** to give a tetracyclic isomer of the type observed for **8** (→ **17**) and **13** (→ **15**). That **7** does not undergo the cycloaddition (nor does diene **2** (1)) is attributed to the lack of sufficient donor–acceptor interactions between the potential $2\pi + 2\pi$ partners (14, 15). This situation resembles that found for the dienes **28** (16) and **30** (17), where only polar substituted **28** undergoes the ring closure process (→ **29**, Scheme 8).

For the diene triplets, a striking divergence of behaviour has been encountered. As was found for diene **2**, the triplet reactivities of **7** and **8** involve competition between two reaction types: a DPM rearrangement to a semibullvalene, and a cyclobutene ring cleavage to a naphthalene (and presumably an acetylene). Extremes of the competition are observed for the cyano derivatives, where the DPM rearrangement is of synthetic proportions in **7**, but is almost totally suppressed in the case of **8**.

The meager production of SB **16** may reflect a general reluctance of di-π-methanes to rearrange via initial bridging to the α-carbon of an acrylonitrile moiety. Note the avoidance of such a liaison in the sensitized rearrangements of the related compounds, 2-cyanobenzobarrelene (2), 5,6-dihydro-2-cyanobenzobarrelene (18), and 2-cyanobenzonorbornadiene (19), where bridging to the β-carbon of the acrylonitrile moiety occurs. Contrastingly, the high efficiency of the DPM rearrangement in bridgehead[3] substituted **7** accords with the enhanced DPM reactivity noted by Zimmerman for systems in which the methane carbon is substituted by delocalizing groups (20).

However, the importance of the above correlations on the triplet product bifurcation is difficult to assess since factors promoting the cleavage process may also be significant and working in tandem with those favoring SB formation. One observation to be made in this regard is that the proportion of naphthalene product increases as the stability (in terms of π-bond energy) of the acetylene unit expelled increases, i.e., the SB/naphthalene product ratios are 99:1 for **7**, 37:63 for **2** (1), and 2:98 for **8**, and the order of acetylene stability is HC≡CCN > MeC≡CMe > HC≡CH.

Finally, CNDO/S-Cl calculations of changes of atom–atom interaction energies in excited states of **2**, **7**, and **8** were carried out to examine for possible correlations between initial distributions of electronic excitation and the observed triplet product competitions.[4] Selected atom–atom energies for the dienes are given in Table 3 (see Experimental). Inspection of the data

TABLE 3. Changes[a] in atom–atom interaction energies (eV) resulting from electronic excitation to the lowest triplet (T_1) state of dienes **2**, **7**, and **8**

	Change in interaction energy (eV)		
Atom–atom	**2**	**7**	**8**
1–2	−0.55	−0.64	1.34
2–3	3.61	3.64	−0.01
3–4	−3.76	−3.85	0.17
4–5	6.82	6.93	−0.06
5–6	−1.06	−0.97	0.56
1–6	−0.27	−0.30	0.39
6–7	1.11	1.08	−1.03
7–8	−0.18	−0.45	9.77
1–8	0.74	0.88	−1.85
2–8	−0.04	−0.07	−0.35
4–8	−0.02	−0.02	0.02
5–7	−0.08	0.04	−0.08

[a]Calculated by the CNDO/S-CI method using the theoretical parameterization (26). Negative values are interpreted as "forces" tending to bring atoms together, while positive values cause the atoms to move further apart. Calculations on the full molecules were performed; only selected values are given here.

reveals no convincing correspondence to the product preferences. In part this is due to the near-degeneracy of the T_1 and T_2 states of **2**, and the sensitivity of the T_1 and T_2 states of **8** to the different parameterization forms employed (see Experimental). Further studies aimed at delineating the product-controlling feature(s) in 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes are in progress.

Experimental

The nmr spectra were recorded on either Bruker 400-MHz, Varian 200-MHz or 60-MHz instruments, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants (J) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. The ir spectra were recorded on a Perkin–Elmer 337 spectrometer and are given in cm^{-1}. The uv spectra (run in cyclohexane solvent) were measured on a Cary 15 spectrometer; maxima are given in nm, with ϵ_{max} values in parentheses; sh = shoulder. The gc/ms was recorded on an HP 5985 B instrument fitted with an SPB-1 glass capillary column, 30 m × 0.32 mm. All other mass spectra were recorded on an MS 9 (A.E.I.) instrument. Melting points are uncorrected. Elemental analyses were performed by Galbraith Labs, Inc., Knoxville, TN. Fluorescence and phosphorescence studies were carried out on an Aminco–Bowman spectrometer. Column chromatography was performed with Silica Gel 60 (230–400 mesh; Merck) mixed with Sylvania 2282 phosphor and slurry packed into quartz columns permitting monitoring by a hand uv lamp. The gc analyses were made on a Varian 3700 instrument (FID), coupled to a Varian CDS 111 computing integrator, and fitted with an SE-30 glass capillary column, 30 m × 0.32 mm. Cyclohexane solvent for photolyses was prepared by scrubbing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Sensitizers were distilled or recrystallized prior to use.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium pressure mercury arc surrounded by a water-cooled quartz immersion well. For direct irradiations, the light was filtered through a cylindrical Pyrex sleeve, unless otherwise stated. For irradiations at wavelengths > 340 nm the light was passed through an aqueous filter (Pyrex) jacket (10-mm path length) containing a solution prepared from 750 g NaBr and 8 g $Pb(NO_3)_2$ in 1 L of water. Three types of sample cell were used.

[3]For a discussion of the influence of bridgehead substituents in DPM photochemistry, note the recent publications of Paquette *et al.* (21).

[4]This approach is similar to the "ΔP" method originally suggested by Zimmerman (22, and references cited therein).

Cell A (200-mL sample volume) consisted of a cylindrical collar (Pyrex), which surrounded the aqueous filter jacket. The cell was fitted with gas inlet and exit ports, and sample solutions were purged with argon prior to, and during irradiations. Cells B (35 mL volume) and C (3.5 mL volume) were test-tube-like vessels (quartz) and sample solutions contained therein were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

Direct irradiation of COT 5

A solution of 228.5 mg (1.28 mmol) of **5** (2) in 200 mL of benzene was photolyzed at >340 nm for 55 h in cell A. The photolysate composition analysed for 113.9 mg (50%) of COT **5**, 51.0 mg (22%) of **7**, and 51.2 mg (22%) of **8**, as determined by a combination of gc and nmr analyses, after the addition of a known amount of standardized tetradecane. (Note: due to the facile thermal conversion of **7** (but not **8**) to COT **5** on the column (at 120°C), gc analysis alone is inadequate.) The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (2 cm × 60 cm) with 2% ether–cyclohexane solvent. The first band contained a mixture of **5** and **8**, and the second band gave 48.5 mg (21%) of **7**, mp 57–59°C (from hexane); ir (Nujol): 2230, C≡N; uv: 258 sh (5 800), 266 (7 700), 276 (7 500), 285 sh (4 700), 287 sh (3 600), and 293 sh (1 000): nmr (400 MHz; $CDCl_3$): 7.19–7.28 (m, 2H, aromatics), 7.11–7.17 (m, 2H, aromatics), 6.46 (d, 1H, H-4, $J_{4,5} = 10$), 6.19 (dd, 1H, H-7, $J_{7,8} = 2.8$, $J_{7,1} = 1$), 6.07 (dd, 1H, H-8, $J_{8,7} = 2.8$, $J_{8,1} = 1$), 5.85 (d, 1H, H-5, $J_{5,4} = 10$), and 4.46 (br s, 1H, H-1); spin decoupling experiments: irradiation of H-4 collapsed H-5 to an s; irradiation of H-1 collapsed H-7 and H-8 to doublets ($J_{7,8} = 2.8$). Mass spectrum showed molecular ion at *m/e* = 179.0724 (100%); $C_{13}H_9N$ requires 179.0734. *Anal.* calcd. for $C_{13}H_9N$: C 87.12, H 5.06, N 7.82; found: C 86.86, H 5.21, N 7.75.

The first band from chromatography was concentrated and the residue dissolved in 4 mL of hexane. Storage of the solution at 2°C led to crystallization of COT **5**. Filtration gave 72.1 mg (32%) of recovered COT **5**; the filtrate (90.6 mg) contained 54% **8** and 46% **5** by gc analysis. The filtrate was rechromatographed as above; early fractions contained mixtures of **8** and **5**, and later fractions gave 30.2 mg (13%) of pure **8** (from hexane), mp 68–70°C; ir (Nujol): 2220, C≡N; uv: 262 sh (6 600), 268 (7 600), 278 sh (6 600), 291 sh (3 200), and 302 sh (650); nmr (400 MHz; $CDCl_3$): 7.16–7.22 (m, 2H, aromatics, 7.06–7.13 (m, 2H, aromatics), 6.71 (d, 1H, H-8, $J_{8,1} = 1$), 6.42 (d, 1H, H-4, $J_{4,5} = 10$), 5.93 (dd, 1H, H-5, $J_{5,4} = 10$, $J_{5,6} = 4.5$), 4.22 (br d, 1H, H-1, $J_{1,6} = 4.5$), and 4.00 (t, 1H, H-6, $J_{6,1} = J_{6,5} = 4.5$); spin decoupling experiments: irradiation of H-8 sharpened the H-1 d ($J_{1,6} = 4.5$); irradiation of H-5 collapsed H-6 to a d ($J_{6,1} = 4.5$) and H-4 to an s: irradiation of H-1 collapsed H-8 to an s and H-6 to a d ($J_{6,5} = 4.5$); irradiation of H-6 collapsed H-1 to a br s and H-5 to a d ($J_{5,4} = 10$). Mass spectrum showed molecular ion at *m/e* = 179.0734 (33%), 128 (base peak). *Anal.* found: C 87.32, H 5.08, N 7.78.

Diimide reduction of diene 7

To a stirred mixture of 50.6 mg (0.28 mmol) of **7** and 1.0 g (5.2 mmol) of potassium azodicarboxylate in 25 mL of dioxane at room temperature, a total of 2 mL of acetic acid was added during a 5-h period. The mixture was stirred overnight, then treated with a second portion of 1.0 g (5.2 mmol) of potassium azodicarboxylate and 2 mL of acetic acid. The resulting mixture was then added to 100 mL of toluene, and washed with 10% sodium carbonate solution (100 mL), followed by water (2 × 50 mL). The toluene solution was dried ($MgSO_4$), concentrated, and the residue was passed through Silica Gel 60 (0.7 cm × 12 cm) with 4% ether–cyclohexane solvent, to give 33.6 mg (66%) of colourless **9**, mp 46–48°C, after two recrystallizations from hexane; ir (Nujol): 2200, C≡N; uv: 257 sh (6 380), 265 (7 900), 269 sh (7 500), 273 sh (7 400), 281 sh (4 900), and 286 sh (3 570); nmr (400 MHz; $CDCl_3$): 6.97–7.26 (m, 4H, aromatics), 6.64 (d, 1H, H-4, $J_{4,5} = 10$), 5.77 (dd, 1H, H-5, $J_{5,4} = 10$, $J_{5,1} = 1.5$), 4.02 (br, t, 1H, H-1, $J_{1,8} = J_{1,8'} = 9$, $J_{1,5} = 1.5$), 2.93 (m, 1H, H-7), and 2.36 (m, 3H remaining methylenes); spin decoupling experiments: irradiation of H-4 collapsed H-5 to a d ($J_{5,1} = 1.5$); irradiation of H-5 collapsed H-4 to an s and sharpened the H-1 t; irradiation of H-1 collapsed H-5 to a d ($J_{5,4} = 10$) and modified to δ 2.36 m; irradiation of the δ 2.36 m collapsed H-1 and H-7 to singlets. Mass spectrum showed molecular ion at *m/e* = 181.0889 (10%), 153 (base peak); $C_{13}H_{11}N$ requires 181.0892. *Anal.* calcd. for $C_{13}H_{11}N$; C 86.15, H 6.12, N 7.73; found: C 86.21, H 6.21, N 7.73.

Catalytic reduction of endo*-7-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene (12)*

A stirred mixture of 110.0 mg (0.61 mmol) of **12** (4) and 23 mg of 10% Pd on C in 10 mL of ethyl acetate was hydrogenated at room temperature and pressure during 10 min. The catalyst was removed (centrifuge) and the solution concentrated. The residue was chromatographed on Silica Gel 60 (1 cm × 55 cm) with 5% ether–cyclohexane. Short-path distillation (75°C/0.1 Torr; 1 Torr = 133.3 Pa) of the main band gave 102 mg (92%) of *endo*-7-cyano-2,3-benzobicyclo[4.2.0]-oct-2-ene (**11**) (gc purity >99%) as a colourless oil; ir (neat liquid): 2230, C≡N; uv: 247 sh (105), 253 sh (190), 260 sh (290), 265 sh (360), 266 (380), and 272 (385); nmr (400 MHz; $CDCl_3$): 7.14–7.20 (m, 3H, aromatics), 6.98–7.03 (m, 1H, aromatic), 3.63 (q, 1H, H-1, $J_{1,6} = J_{1,8} = J_{1,8'} = 9$), 3.40 (br q, 1H, H-7, $J_{7,6} \simeq J_{7,8} \simeq J_{7,8'} \simeq 9$), 2.83–3.05 (m, 3H, H-4, H-6, H-8), 2.78 (ddd, 1H, H-4′, $J_{4',4} = 15.5$, $J_{4',5(5')} = 9$, $J_{4',5'(5)} = 4$), 2.34 (m, 1H, H-8′, $J_{8',7} \simeq J_{8',1} \simeq 9$, $J_{8',8} = 11$, $J_{8',x} \simeq 1.0$), 2.10–2.20 and 1.99–2.08 (m, 2H, C-5 methylenes) spin decoupling experiments: irradiation of H-1 modified H-8′ (incomplete decoupling) and the 2.83–3.05 m; irradiation of H-8′ collapsed H-1 and H-7 to br triplets ($J = 9$). Mass spectrum showed molecular ion at *m/e* = 183.1048 (23%), 130 (base peak); $C_{13}H_{13}N$ requires 183.1048. *Anal.* calcd. for $C_{13}H_{13}N$: C 85.21, H 7.15, N 7.64; found: C 85.47, H 7.09, N 7.62.

Catalytic reduction of diene 8

A stirred mixture of 14.5 mg (0.08 mmol) of **8** and 9.0 mg of 10% Pd on C in 10 mL of ethyl acetate was hydrogenated at room temperature and pressure during 15 min. The reaction mixture was worked up as in the hydrogenation of **12** (above) to give 12.9 mg (87%) of colourless oil identical (gc, ir, nmr) to **11**.

Gas phase thermolysis of diene 7

Over a 30-min period, 18.0 mg (0.10 mmol) of **7** was distilled into a Pyrex tube (2 cm × 30 cm) packed with glass beads (0.5-cm diameter) maintained at 350°C. The pressure in the system was kept at 8 Torr by the passage of nitrogen. The thermolysis product (no 2-cyanonaphthalene by gc), collected in a cooled U-trap (ice-water), was chromatographed on Silica Gel 60 (1 cm × 40 cm) with 2% ether–cyclohexane. Crystallization of the main band from hexane gave 16.5 mg (92%) of COT **5**, mp 101–103°C (lit. (2) mp 102–103°C).

Gas phase thermolysis of diene 8

The above apparatus and same conditions were used to convert 12.1 mg (0.07 mmol) of diene **8** to 11.6 mg (96%) of COT **5**, mp 101–103°C. No naphthalene was detected (gc) in the thermolysis product.

Direct irradiation of diene 7

A solution of 88.6 mg (0.50 mmol) of **7** in 30 mL of cyclohexane was photolyzed (Pyrex filter) for 3.5 h in cell B. The photolysate composition analysed for 7.5 mg (10%) 2-cyanonaphthalene, 44.3 mg (50%) SB **6**, 26.2 mg (30%) diene **7**, and 5.1 mg (6%) COT **5**, as determined by gc and nmr after addition of a known amount of standardized tetradecane. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (1.5 cm × 55 cm) with 2% ether–cyclohexane solvent. The first band gave 4.9 mg (6%) of COT **5**, mp 101–103°C (from hexane). The second band gave 6.2 mg (8%) of 2-cyanonaphthalene, mp 62–64°C (from hexane). The third band gave 23.4 mg (26%) of unreacted diene **7**. The fourth band gave 41.7 mg (47%) of material, mp 94–96°C (from hexane), identical (mixture mp, nmr, gc) to the known (2) 1-cyanobenzotricyclo-[3.3.0.$0^{2,8}$]octa-3,6-diene (**6**).

Direct irradiation of diene 8

A solution of 92.6 mg (0.52 mmol) of **8** in 30 mL of cyclohexane was photolyzed (Pyrex filter) for 4.5 h in cell B. The photolysate composi-

tion analysed for 15.9 mg (24%) naphthalene, 38.1 mg (41%) COT **5**, 16.6 mg (18%) diene **8**, 5.3 mg (6%) tetracyclic **17**, and 5.1 mg (6%) SB **16**, as determined by gc and nmr after the addition of a known amount of standardized tetradecane. The photolysate was concentrated to 10 mL and chromatographed in Silica Gel 60 (1.5 cm × 45 cm) with 3% ether–cyclohexane. The first band gave 9.3 mg (14%) of naphthalene, mp 78–80°C (from ethanol). The second band gave 40.8 mg of a mixture of COT **5** and diene **8**; crystallization of the mixture from hexane gave 17.2 mg (19%) of COT **5**, mp 101–103°C (from hexane), and the filtrate when rechromatographed gave 7.5 mg (8%) of recovered **8** and 15.6 mg of a mixture of COT **5** and diene **8**. The third band, containing SB **16**, was concentrated to ca. 5 mL (note: SB **16** rapidly polymerizes when solvent free), then diluted with 30 mL of CCl_4, and concentrated to ca. 5 mL. Subsequent repetitions of the CCl_4 addition (30 mL each) and concentration cycle led to essentially complete removal of the original ether–cyclohexane solvent system to give a solution of **16** (gc purity >99%) in CCl_4: nmr (200 MHz; CCl_4), see Table 1; nmr (400 MHz; 1:1 ratio of $CCl_4/CDCl_3$): 7.36–7.42 (m, 1H, aromatic), 7.03–7.23 (m, 3H, aromatics), 6.30 (d, 1H, H-6, $J_{6,5} = 2.5$), 4.05 (dd, 1H, H-5, $J_{5,1} = 6.5$, $J_{5,6} = 2.5$), 3.38 (q, 1H, H-1, $J_{1,5} = J_{1,2} = J_{1,8} = 6.5$), 3.20 (t, 1H, H-2, $J_{2,1} = J_{2,8} = 6.5$), and 2.95 (t, 1H, H-8, $J_{8,1} = J_{8,2} = 6.5$); spin decoupling experiments: irradiation of H-6 collapsed H-5 to a d ($J_{5,1} = 6.5$): iradiation of H-5 collapsed H-6 to an s, and H-1 to a t ($J_{1,8} = J_{1,2} = 6.5$); irradiation of H-1 collapsed H-5 to a d ($J_{5,6} = 2.5$), H-2 to a d ($J_{2,8} = 6.5$), and H-8 to a d ($J_{8,2} = 6.5$); irradiation of H-2 collapsed H-1 to a t ($J_{1,8} = J_{1,5} = 6.5$) and H-8 to a d ($J_{8,2} = 6.5$); irradiation of H-8 collapsed H-1 to a t ($J_{1,2} = J_{1,5} = 6.5$) and H-2 to a d ($J_{2,1} = 6.5$); gc/ms showed molecular ion at *m/e* = 179 (67%), 178 (base peak).

The fourth and last band gave 4.1 mg (4%) of **17**, mp 130–132°C (from hexane); ir (Nujol): 2225, C≡N; uv: 249 sh (120), 254 sh (200), 260 (320), 265 sh (440), 266 (480), and 273 (560); nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 2H, aromatics), 7.16–7.22 (m, 2H, aromatics), 4.33–4.38 (m, 2H, H-1 and H-6), 3.28 (quintet, 1H, H-5, $J_{5,1(6)} = J_{5,2(3)} = 4.5$), and 2.91–2.98 (m, 2H, H-2 and H-3); spin decoupling experiments: irradiation of H-1,6 collapsed H-5 to a t ($J_{5,2} = J_{5,3} = 4.5$) and H-2,3 to a d ($J_{2(3),5} = 4.5$); irradiation of H-5 modified both H-1,6 and H-2,3; irradiation of H-2,3 collapsed H-5 to a t ($J_{5,1} = J_{5,6} = 4.5$) and H-1,6 to a d ($J_{1(6),5} = 4.5$). Mass spectrum showed molecular ion at *m/e* = 179.0723 (72%), 178 (base peak), 128 (51%).

Sensitized irradiation of diene 7

A solution of 34.8 mg (0.19 mmol) of **7** and 4.7 mg (0.02 mmol) of Michler's ketone in 35 mL of cyclohexane was photolyzed at >340 nm for 1 h in cell B (100% conversion by gc). The photolysate composition analysed for 31.2 mg (90%) SB **6** and 0.3 mg (1%) 2-cyanonaphthalene, as determined by gc after the addition of a known amount of standardized tetradecane. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (1.5 cm × 25 cm) with 2% ether–cyclohexane solvent. The first band gave a trace of 2-cyanonaphthalene (identified by tlc and gc comparisons with authentic sample), and the second band gave 30.4 mg (87%) of SB **6**, mp 94–96°C (from hexane).

Sensitized irradiation of diene 8

A solution of 46.0 mg (0.26 mmol) of **8** and 4.7 mg (0.02 mmol) of Michler's ketone in 35 mL of cyclohexane was photolyzed at >340 nm for 1 h in cell B (100% conversion by gc). The photolysate composition analysed for 29.3 mg (89%) naphthalene and 1.1 mg (2%) SB **16**, as determined by gc after the addition of a known amount of standardized tetradecane. The photolysate was concentrated (to 10 mL), and chromatographed on Silica Gel 60 (1.5 cm × 30 cm) with 3% ether–cyclohexane. The first band gave 16.8 mg (51%) naphthalene, mp 78–80°C (from ethanol). The second band was concentrated to ca. 5 mL and the solvent was exchanged for CCl_4. The nmr spectrum of the resulting solution was identical to that of SB **16**.

Catalytic reduction of SB 16

A stirred mixture of ca. 28 mg (ca. 0.16 mmol) of **16** and 6.4 mg of 10% Pd on C in 5 mL of ethyl acetate was hydrogenated at room temperature and pressure during 3 min. The catalyst was removed (centrifuge) and the resulting solution, when analysed by gc, showed three major peaks of relative area 1 (**16**): 2 (**20**): 3 (unknown). The solution was diluted with 30 mL of cyclohexane and concentrated to 5 mL. Repetition of the cyclohexane addition (30 mL) and concentration to 5 mL was followed by chromatography on Silica Gel 60 (1.5 cm × 60 cm) with 3% ether–cyclohexane solvent; 10-mL fractions were collected. Fractions 1–47 contained nothing. Fractions 48–51 gave 8.7 mg (31%) of colourless **20**, mp 99–101°C (from hexane); ir (Nujol): 2225, C≡N; uv: 248 sh (20), 253 sh (340), 259 (600), 263 sh (740), 266 (980), and 272 (1 200); nmr (400 MHz; $CDCl_3$): 7.20–7.32 (m, 4H, aromatics), 6.52 (dt, 1H, H-6, $J_{6,5} = J_{6,8} = 2.5$, $J_{6,8'} = 1.5$), 3.98 (br t, 1H, H-1, $J_{1,5} = J_{1,8} = 8.5$, $J_{1,8'} \simeq 1.0$), 3.75 (m, 1H, H-5), 3.27 (dd, 1H, H-4, $J_{4,5} = 9$, $J_{4,4'} = 16.5$), 3.16 (m, 1H, H-8, $J_{8,8'} = 16$, $J_{8,1} = 8.5$, $J_{8,6} = 2.5$, and $J_{8,5} = 2.7$ (homo-allylic coupling)), 2.96 (dd, 1H, H-4′, $J_{4',4} = 16.5$, $J_{4',5} = 2$), 2.76 (dm, 1H, H-8′, $J_{8',8} = 16$, $J_{8',1} \sim 1.0$, $J_{8',5} = 2$, $J_{6',8} = 1.5$); spin decoupling experiments: irradiation of H-6 modified H-5 and collapsed H-8 to a ddd ($J_{8,8'} = 16$, $J_{8,1} = 8.5$, $J_{8,5} = 2.7$), and H-8′ to a ddd ($J_{8',8} = 16$, $J_{8',1} = 1$, $J_{8',5} = 2$); irradiation of H-1 collapsed H-5 to a dm ($J_{5,4} = 9$), H-8 to a dt ($J_{8,8'} = 16$, $J_{8,5} = 2.7$, $J_{8,6} = 2.5$), and modified H-8′; irradiation of H-5 modified H-6 to a br s, and collapsed H-1 to a br d ($J_{1,8} = 8.5$), H-4 to a d ($J_{4,4'} = 16.5$), H-8 to a ddd ($J_{8,8'} = 16$, $J_{8,1} = 8.5$, $J_{8,6} = 2.5$), H-4′ to a d ($J_{4,4'} = 16.5$), and H-8′ to a br d ($J_{8',8} = 16$); irradiation of H-4 modified H-5 and H-4′ (incomplete decoupling) irradiation of H-8 modified H-5 and H-1 (incomplete decoupling),and collapsed H-6 to a br s and H-8′ to a single m; irradiation of H-4′ modified H-5 and collapsed H-4 to a d ($J_{4,5} = 9$); irradiation of H-8′ modified H-5 and H-8, and collapsed H-6 to a t ($J_{6,5} = J_{6,8} = 2.5$) and H-1 to a sharp t ($J_{1,5} = J_{1,8} = 8.5$). Mass spectrum showed molecular ion at *m/e* = 181.0894 (100%); $C_{13}H_{11}N$ requires 181.0892.

Fractions 52–59 contained 4.2 mg (15%) of recovered **16** as determined by gc after the addition of a known amount of standardized tetradecane. Fractions 60–120 contained essentially nothing. Further elution with 0.5 L of 5% ether–cyclohexane also gave no product material. Thus the major reduction product (unknown) adheres strongly to the silica gel.

*Labelled COT 5*a

Deuterated COT **5***a* (86%-d_1 at C-9) was prepared as previously described (2); nmr (400 MHz; $CDCl_3$): 7.21–7.31 (m, 2.88H, 2 aromatics + residual C*H*Cl_3), 6.95–7.05 (m, 2.00H, 2 aromatics), 6.75 and 6.73 (d and s, 1.95H, H-5 and H-10, $J_{5,6} = 11.5$), 6.67 (s, 0.95H, H-8), 6.07 (dd, 0.14H, H-9, $J_{9,10} = 11.5$, $J_{9,8} = 4$), and 5.95 (d, 0.96H, H-6, $J_{6,5} = 11.5$); errors from nmr signal integrations are within ±0.05H for **5***a*, and for all subsequent integrations of deuterated compounds.

*Labelled dienes 7*a *and 8*a *from COT 5*a

A solution of 219.3 mg (1.22 mmol) of COT **5***a* (86%–d_1 at C-9) (2) in 200 mL of benzene was photolyzed at >340 nm for 40 h in cell A. The photolysate was worked up as in the case of the direct irradiation of COT **5** to give 38.7 mg (18%) of **7***a* and 23.3 mg (11%) of **8***a*. For **7***a*, nmr (400 MHz; $CDCl_3$): 7.19–7.28 (m, 3.17H, 2 aromatics + residual C*H*Cl_3), 7.11–7.17 (m, 2.00H, 2 aromatics), 6.46 (d, 0.98H, H-4, $J_{4,5} = 10$), 6.19 (s, 0.96H, H-7), 6.07 (dd, 0.12H, H-8, $J_{8,7} = 2.8$, $J_{8,1} = 1$), 5.85 (d, 1.00H, H-5, $J_{5,4} = 10$), and 4.46 (s, 0.95H, H-1). For **8***a*, nmr (400 MHz; $CDCl_3$): 7.16–7.22 (m, 1.97H, 2 aromatics), 7.06–7.13 (m, 2.00H, 2 aromatics), 6.71 (d, 0.97H, H-8, $J_{8,1} = 1$), 6.42 (s, 0.98H, H-4), 5.93 (dd, 0.14H, H-5, $J_{5,4} = 10$, $J_{5,6} = 4.5$), 4.22 (br d, 1.03H, H-1, $J_{1,6} = 4.5$), and 4.00 (d, 1.00H, H-6, $J_{6,1} = 4.5$).

*Direct irradiation of labelled diene 7*a

A solution of 21.6 mg (0.12 mmol) of **7***a* in 30 mL of cyclohexane was photolyzed (Pyrex filter) for 6 h in cell B. The photolysate, when worked up as in the case of the direct irradiation of unlabelled **7**, gave 11.6 mg (54%) of SB **6***a*; nmr (60 MHz; CCl_4): 6.90–7.40 (m, 4.00H, aromatics), 5.60 (dd, 0.14H, H-6, $J_{6,5} = 2.5$, $J_{6,7} = 5$), 5.12 (d, 0.94H, H-7, $J_{7,8} = 2.5$), 4.12 (s, 1.01H, H-5), 3.60 (d, 1.02H, H-2, $J_{2,8} = 7$), and 3.27 (dd, 0.99H, H-8, $J_{8,2} = 7$, $J_{8,7} = 2.5$).

*Sensitized irradiation of labelled diene 7*a

A solution of 16.1 mg (0.09 mmol) of **7***a* and 4.7 mg (0.02 mmol) of Michler's ketone in 35 mL of cyclohexane was photolyzed at >340 nm for 20 min in cell B. The photolysate, when worked up as in the case of the sensitized irradiation of unlabelled **7**, gave 13.5 mg (84%) of SB **6***a*; nmr (60 MHz; CCl_4): 6.90–7.40 (m, 4.00H, aromatics), 5.60 (dd, 0.14H, H-6, $J_{6,5} = 2.5$, $J_{6,7} = 5$), 5.12 (d, 0.95H, H-7, $J_{7,8} = 2.5$), 4.12 (s, 0.94H, H-5), 3.60 (d, 0.95H, H-2, $J_{2,8} = 7$), and 3.27 (dd, 0.95H, H-8, $J_{8,2} = 7$, $J_{8,7} = 2.5$).

*Direct irradiation of labelled diene 8*a

A solution of 39.9 mg (0.22 mmol) of **8***a* in 35 mL of cyclohexane was photolyzed (Pyrex filter) for 9 h in cell B. The photolysate, when worked up as in the case of the direct irradiation of unlabelled **8**, gave ca. 1.7 mg (4%) of SB **16***a*; nmr (400 MHz: 1:1 ratio of $CCl_4/CDCl_3$): 7.36–7.42 (m, 1.00H, 1 aromatic), 7.03–7.23 (m, 3.12H, 3 aromatics), 6.30 (d, 0.99H, H-6, $J_{6,5} = 2.5$), 4.05 (dd, 1.00H, H-5, $J_{5,1} = 6.5$, $J_{5,6} = 2.5$), 3.38 (t, 0.97H, H-1, $J_{1,2} = J_{1,5} = 6.5$), 3.20 (d, 0.96H, H-2, $J_{2,1} = 6.5$), and 2.95 (t, 0.14H, H-8, $J_{8,1} = J_{8,2} = 6.5$).

*Sensitized irradiation of labelled diene 8*a

A solution of 35.9 mg (0.20 mmol) of **8***a* and 4.7 mg (0.02 mmol) of Michler's ketone in 35 mL of cyclohexane was photolyzed at >340 nm for 38 min in cell B. The photolysate, when worked up as in the case of the sensitized irradiation of unlabelled **8**, gave ca. 0.5 mg (ca. 1%) of SB **16***a*; nmr (400 MHz; 1:1 ratio of $CCl_4/CDCl_3$): 7.36–7.42 (m, 1.00H, 1 aromatic), 7.03–7.23 (m, 3.06H, 3 aromatics), 6.30 (d, 1.01H, H-6), 4.05 (dd, 0.97H, H-5), 3.38 (t, 0.98H, H-1), 3.20 (d, 1.00H, H-2), and 2.95 (t, 0.13H, H-8).

Phosphorescence and fluorescence of COT 5 and dienes 7 and 8

Compounds **5**, **7**, and **8** showed no phosphorescence spectra at 77 K in 1:1 isopentane/methylcyclohexane glass, and only **7** showed fluorescence in cyclohexane at room temperature (maxima at 330 nm). Intersection of emission and absorption spectra for **7** occurred at 300 nm, corresponding to a singlet energy of 95 kcal/mol. The singlet energy of **8** was estimated to be $92 \leq E_s \leq 95$ kcal/mol from the uv spectrum, which showed onset of absorption at ca. 310 nm and the lowest energy peak (a shoulder) at 302 nm.

Quantum yield determinations

Quantum yields were performed on an apparatus previously described (23), which includes an optical bench arranged for beam splitting into a ferrioxalate actinometer (24). Sample solutions (3 mL) of reactants (ca. $3–10 \times 10^{-3}$ *M*) and sensitizer, if any (benzophenone, 2×10^{-2} *M*; Michler's ketone, 0.57×10^{-3} *M*; 1- and 2-acetonaphthone, 3×10^{-2} *M*), were dexoygented prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. For Φ's and further experimental details, see Table 2. Note that Φ's for sensitized irradiations of COT **5** with thioxanthone (E_T 65.5 kcal/mol; 1.4×10^{-3} *M*) or with *p*-dimethylaminobenzophenone (E_T 62 kcal/mol (25); 3.1×10^{-3} *M*) in benzene solvent are not included in Table 2 since we were unable to show that photoproduct(s) formed in these runs (see below). However, actinometer experiments carried out on the optical bench, with 366 nm light, permit us to place an upper value of $\Phi < 0.0001$ for the formation of **7** or **8**, if either were a photoproduct; gc together with nmr analyses would have detected >1% presence of the dienes, if formed.

Sensitized irradiations of COT 5

(a) With thioxanthone

A solution of 1.8 mg (0.01 mmol) of COT **5** and 1.0 mg (0.005 mmol) of thioxanthone in 3 mL of benzene was irradiated for 24 h in cell C with 315–385 nm light (obtained from a cylindrical uranium glass (Ace) sleeve (2 mm) and a UG-11 (Schott) glass filter (3 mm); transmission maximum was 42% at 357 nm; transmittance at 366 nm was 35%). The photolysate composition showed no loss of starting material or sensitizer, as indicated by a combination of gc and nmr analyses after the addition of a known amount of standardized tetradecane. No photoproducts were observed. Note that with the same apparatus and filter system, a solution of 1.6 mg (0.009 mmol) of diene **7** and 1.0 mg (0.005 mmol) of thioxanthone in 3 mL of benzene was 30% converted to SB **6** within 2 min.

(b) With p*-dimethylaminobenzophenone*

A solution of 5.7 mg (0.03 mmol) of COT **5** and 6.3 mg (0.03 mmol) of *p*-dimethylaminobenzophenone in 90 mL of benzene was divided into three equal portions. Each portion was separately irradiated for 12 h in cell C with 315–385 nm light. The three photolysates were combined and chromatographed on Silica Gel 60 (0.9 cm × 15 cm). Elution with 2% ether–cyclohexane gave 5.0 mg (88%) of recovered COT **5**, mp 101–103°C (from hexane); further elution with 6% ether–cyclohexane gave 6.4 mg (102%) of recovered sensitizer, mp 83–87°C.

Calculations

All calculations were made within the general framework of the CNDO semi-empircal molecular orbital method as previously described (2, 18). With the exception of the bridgehead C5—C6—C7 angle (23), the ground state geometries were determined using the CNDO-2 parameterization (26). By repeating the calculations for a range of values (105–120°), the bridgehead angles were shown to have negligible effects on the results; the values given in Table 3 were obtained for a fixed angle of 115°.

The vertical excitation energies were determined by configuration interaction with the CNDO/S parameterization (27), using a modified version of the program QCPE #315, originally written by Del Bene and Jaffé (28). The number of configurations included was found not to importantly influence the results, and the values given in Table 3 were obtained from 90 states. The CI expansion coefficients were employed to partition the excitation energy into single atom and atom–atom interaction energies (2).

Previously, we had interpreted the changes in atom–atom energies to indicate the initial nuclear motions resulting from excitation, and the approach proved useful for rationalizing product distributions in the DPM rearrangements of several benzobarrelene derivatives (2, 18). In the present examples this approach clearly does not work, e.g., note the entries for C5–C7; the changes in atom–atom energies are not only small, but in the case of **7**, where SB formation is the observed major product, predict repulsion between the initial bridging atoms of the DPM rearrangement.

Additionally, it should be pointed out that even the competition between localization of the excitation in the cyclobutenyl (C7—C8) versus the styrenyl (C4—C5) vinyl moieties is not clear-cut, since for **2**, T_1 and T_2 are near-degenerate ($T_1 - T_2 \simeq 0.1$ eV), with T_2 being more heavily weighted with excitation energy in the cyclobutenyl vinyl. Also, changing from the theoretical to the Pariser form of the repulsion integrals, usully held to be better for calculating triplet excitation energies, leads to a reversal in the order of the two lowest triplets for **8**, and results in a heavier weighting of excitation energy in the styrenyl vinyl of T_1. This combination of circumstances leads us to conclude that the calculations are unreliable in product prediction in the systems at hand.

Reactions of 1-hydroxy-1,3-dihydrobenzo[*c*]thiophen-2,2-dioxides. Preparation of benz-fused δ-sultines

TONY DURST, JAMES L. CHARLTON, AND DAVID B. MOUNT

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received April 29, 1985

TONY DURST, JAMES L. CHARLTON, and DAVID B. MOUNT. Can. J. Chem. **64**, 246 (1986).

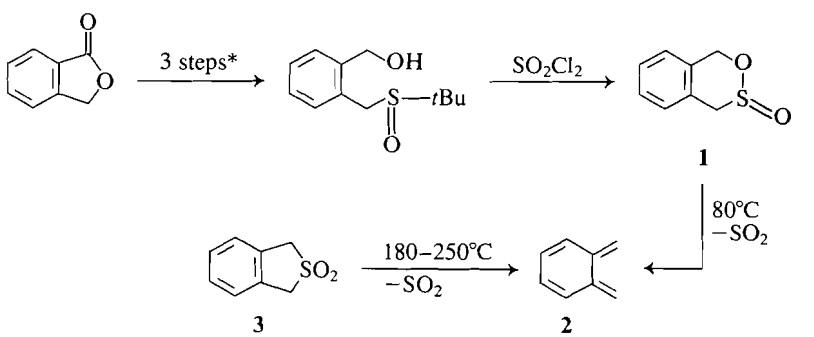
4,5-Benzo-3,6-dihydro-1,2-oxathiin-2-oxides (benz-fused δ-sultines) **1**, were prepared by reaction of 1-hydroxy-1,3-dihydrobenzo[*c*]thiophen-2,2-dioxides **6** with $NaBH_4$. Derivatives of **1** bearing alkyl substituents at position 6 are accessible from **1** upon reaction of **6** with 2RLi. 3-Aryl substituted derivatives were prepared by converting 2-benzylbenzylalcohols into their O, C dianion followed by quenching with SO_2 and acidification. Benz-fused δ-sultines such as **15–17** were also prepared via the dianion route.

TONY DURST, JAMES L. CHARLTON et DAVID B. MOUNT. Can. J. Chem. **64**, 246 (1986).

On a préparé les benzo-4,5 dihydro-3,6 oxathiine-1,2 oxydes-2 (δ-sultines fusionnées avec des benzènes (**1**) en faisant réagir les hydroxy-1 dihydro-1,3 benzo[*c*]thiophène-dioxydes-2,2 (**6**) avec le $NaBH_4$. On peut obtenir les dérivés de **1** portant des substituants alkyles en position 6 en faisant réagir les composés **6** avec 2 RLi. On a préparé les dérivés portant des groupements aryles en position 3 en transformant les benzyl-2 benzylalcools en leurs dianions O et C qui sont ensuite piégés par le SO_2 avant d'être acidifiés. On a aussi préparé les δ-sultines **15–17** par le biais de la voie impliquant les dianions.

[Traduit par le journal]

A number of years ago we developed a route to cyclic sulfinate esters that we applied to the synthesis of several benz-fused sultines such as **1** (1). These 6-membered ring sultines showed considerable promise as sources of *o*-quinodimethanes since they readily lost SO_2 at about 80°C (1), or approximately 100–150° lower than the corresponding 1,3-dihydrobenzo[*c*]thiophene-1,1-dioxide, **3** (2).[1,2] The ortho-quinodimethane **2**, generated from **1**, was trapped efficiently with dienophiles such as dimethyl fumarate and maleic anhydride (1). When less reactive trapping agents were used the diene was recaptured by sulfur dioxide to afford the sulfone **3** (1, 2).



*Reagents: *t*BuSK, Δ; $LiAlH_4$; MCPBA, −20°C, EtOAc

SCHEME 1

Because of problems associated with the preparation of the derivatives of **1** via the route shown in Scheme 1, the full potential of these compounds as precursors of **2** has not been realized.

Very recently we showed that **1** and a number of derivatives are easily synthesized via a two or three-step sequence commencing with the readily available *ortho*-substituted benzaldehydes, **4***a*, *b*, or the related ketons such as **4***c* (3).

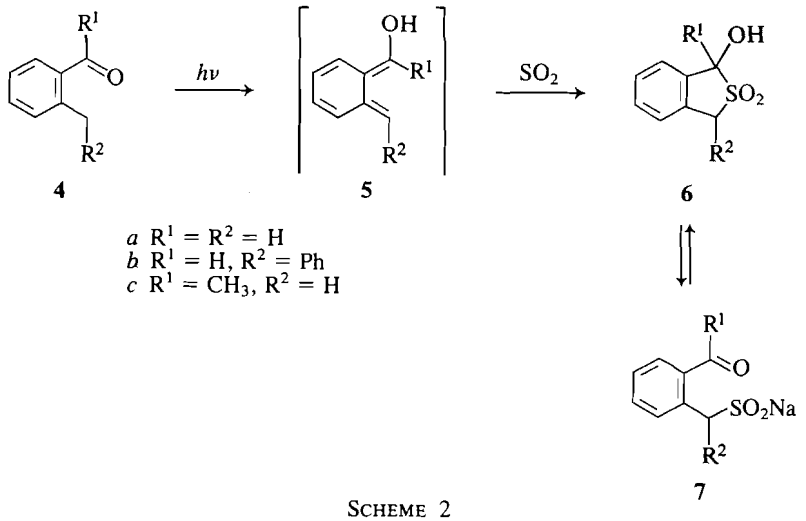
Thus photolysis of **4** in benzene, containing sulfur dioxide, generated the dienols **5**, which were trapped by the SO_2 to afford the α-hydroxysulfones **6** in acceptable yields (4, 5). The photolysis reaction can be carried out on multigram quantities. The desired compounds were easily separated from neutral organic by-products, based on their reversible conversion to the aldehyde sulfinates **7** (Scheme 2).

The hydroxy sulfones **6** can be converted to a variety of substituted δ-sultines in several ways. Reaction of **6***a* with sodium borohydride in methanol followed by acidification afforded the sultine **1** in 70% yield. The sequence obviously involves the reduction of the *in situ* generated **7***a* to the benzylic alcohol **8**. Two possible mechanisms could account for the formation of sultine **1** (Scheme 3). The function of the acid could be to protonate either the sulfinic acid function of **8**, to generate **8***a*, or the benzylic alcohol, giving **8***b*. Cyclization occurs in the case of **8***a* by a displacement at sulfinyl sulfur, while loss of H_2O from **8***b* could generate a benzylic cation that is trapped by the sulfinate oxygen rather than at sulfur to form **1**.

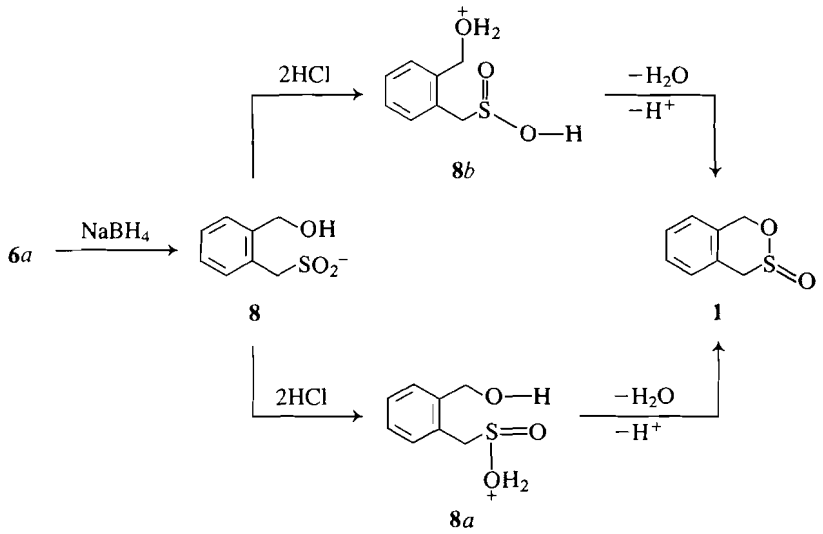
We had initially suggested the mechanism passing through **8***b*, since the benzylic cation generated from **8***b* by loss of H_2O should represent a hard electrophilic centre and Meeks and

[1]In our earlier publications (3, 5) this compound was inadvertently named as the [*b*] isomer.

[2]For a review on the generation of *o*-quinodimethanes from a variety of sources including 1,3-dihydrobenzothiophene-2,2-dioxides see ref. 2*a*.



SCHEME 2



SCHEME 3

Fowler (6) had shown that sulfinates are alkylated preferentially at oxygen with hard, very reactive, alkylating agents and at sulfur by soft reagents. The alternative route involving displacement of H_2O from the protonated sulfinic acid **8***a* is now considered more reasonable, since Bunton and Hendy (7) have shown via ^{18}O labelling that methyl *p*-toluenesulfinate undergoes hydrolysis in acidic media with S—O bond cleavage.[3]

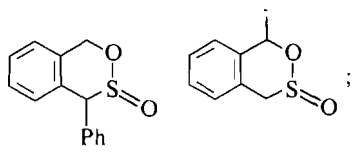
$$C_7H_7—\overset{\overset{O}{\|}}{S}—OCH_3 + H_2O^{18} \xrightarrow{H^+} C_7H_7—\overset{\overset{^{18}O}{\|}}{S}OH + CH_3OH$$

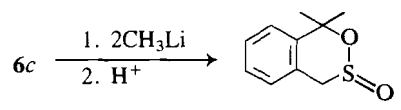
None of the isomeric sulfone **3** was detectable in the nmr spectrum of the crude product, an observation which gives additional support to the latter mechanism.

Similar treatment of the hydroxysulfones **6***b* and **6***c* gave **9** (79%) and **10** (55%), respectively. In these cases isomeric mixtures were obtained. The structures were assigned on the basis of the nmr and infrared spectra, and analytical data (see experimental section). All sultines showed the expected S=O stretching frequency in the 1100–1140 cm^{-1} range. The δ-sultines reported herein failed to show the molecular ion peaks in their mass spectra, with the base peaks generally occurring at $M^{+\cdot} - 64$.

Non-hydrogen substituents can be introduced α to the sultine oxygen by reaction of **6** with alkyllithiums, such as methyllithium: i.e., **6***c* → **11**. Functionalized lithocarbanions should react likewise, thus suggesting the possibility of preparing a wide variety of sultines by this route. Grignard reagents, unfortunately, do not react cleanly with the hydroxy sulfones **6** and we have as yet been unable to isolate and identify products from these attempts.

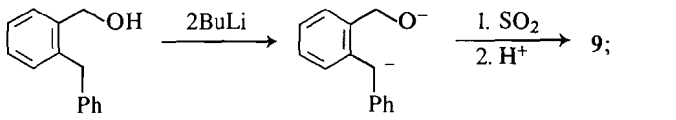
The fact that the hydroxy sulfinate **8** is an intermediate in the conversion of **6***a* to **1** suggested that other routes to **8** should be investigated. An obvious method was the generation of the dilithio species **12** followed by treatment with sulfur dioxide. Thus, raction of *ortho*-benzylbenzyl alcohol with 2 equivalents



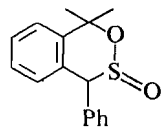


[3]We are indebted to a referee for pointing out this reference.

of *n*Buli in THF at 20°C for 1 h gave a dark-colored solution containing **12**, which was quenched with excess SO_2. The solvent was evaporated and the residue warmed with concentrated HCl. The nmr yield of sultine **9** was 50–70% (several experiments), with the remainder being recovered starting material. Similar treatment of *ortho*-benzyl-α,α′-dimethylbenzyl alcohol afforded the sultine **13**, mp 104°C, in 38% isolated yield. An attempted conversion of *ortho*-methylbenzyl alcohol into sultine **1** was unsuccessful, presumably due to the difficulty of forming the required dianion. The dianion route to these interesting δ-sultines is apparently restricted to cases in which the intermediate is accessible, as in the case for **12**.

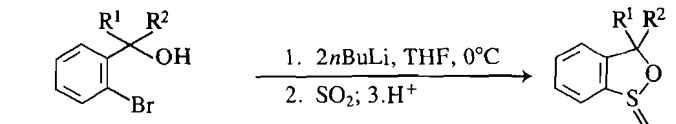


12



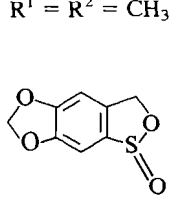
13

The dianion route is also applicable to the formation of 5-membered benz-fused sultines. Thus the dianions of **14***a–c*, generated from the appropriate bromoalcohols by treatment with 2 equivalents of *n*Buli in THF at 0°C, reacted with sulfur dioxide at −78°C to form the intermediate sulfinates, which on acidification gave the expected sultines **15***a–c* in 60–70% isolated yield. Similar metallation of 6-bromo-3,4-methylenedioxybenzyl alcohol followed by SO_2 treatment gave a variable ratio of the sultines **16** and **17** in up to 70% yield. The mixture resulted from the isomerization of the initially formed 6-lithio derivative to the more stable 2-lithio anion. A similar isomeriza-

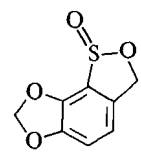


14*a* $R^1 = R^2 = H$
14*b* $R^1 = H, R^2 = CH_3$
14*c* $R^1 = R^2 = CH_3$

15*a–c*



16



17

tion has been observed during the halogen–metal exchange of the cyclohexylimine of 6-bromopiperonal (9). Pure **17** was produced upon treatment of 3,4-methylenedioxybenzyl alcohol with 2*n*Buli, SO_2, and acidification as above. These sultine-forming reactions mirror the formation of γ-lactones via the reaction of the same dianion intermediates with carbon dioxide and suggest that, in general, this parallel should continue to be expected (10).

We are currently studying the preparation of δ-sultines fused to heterocyclic systems such as the furan, thiophene, and indole rings and the use of such compounds for the generation of the corresponding orthoquinodimethanes. The latter have received considerable attention in the indole series as key intermediates in the synthesis of some indole alkaloids (11).

Experimental

"Work-up" indicates that the reaction mixture was poured into a saturated NH_4Cl solution and extracted with CH_2Cl. The organic extracts were dried over anhydrous $MgSO_4$ and the solvent evaporated to yield the crude product. The nmr spectra were taken on a Varian XL-300 or Varian T-60 instrument in $CDCl_3$ solution.

*Conversion of the hydroxy sulfones **6** to sultines. General procedure using $NaBH_4$*

The hydroxy sulfone (**6***a*, *b*, or *c*), 100 mg, was dissolved in 5 mL of methanol at 0°C. $NaBH_4$ (70 mg) was added, the reaction was stirred for 30 min, and then the solvent was evaporated. To the crude product was added 5 mL of concentrated HCl, the mixture was stirred at 50°C for 3 min, cooled, diluted with H_2O, and extracted with CH_2Cl_2. Further work-up afforded the crude sultines, which were purified by silica gel chromatography.

*Sultine **1***

Yield 70%; ir: 1130 cm^{-1}; ^1H nmr: 3.55 (d, J = 15.5 Hz, 1H), 4.42 (d, J = 15.5 Hz, 1H), 4.96 (d, J = 13.7 Hz, 1H), 5.30 (d, J = 13.7 Hz, 1H), 7.2–7.4 (m. 4H); ms *m/e* (rel. %): 168 (0.2), 105 (10), 104 (100), 103 (42). *Anal.* calcd. for $C_8H_8O_2S$: C 68.82, H 4.95, S 13.13; found: C 68.70, H 4.67, S 12.94.

Yield 79%; ir: 1130 cm^{-1}; ^1H nmr: 4.71 (s, 1H), 5.06 (d, J = 14.4 Hz, 1H), 5.43 (d, J = 14.4 Hz, 1H), 7.06 (d, J = 6 Hz, 1H), 7.2–7.7 (m, 8H): ms *m/e* (rel. %): 181 (14), 180 (93), 179 (100), 178 (46). *Anal.* calcd. for $C_{14}H_{12}SO_2$: C 68.82, H 4.95, S 13.13; found: C 68.70, H 4.67, S 12.94.

*Sultine **10***

Yield 55%, 1:1 mixture of diastereomers, separable on silica gel chromatography using ethyl acetate – hexane 1:3. The less polar isomer had ir: 1110, 1140 cm^{-1}; ^1H nmr: 1.82 (d, J = 6.6 Hz, 3H), 3.51 (d, J = 15.2 Hz, 1H), 4.57 (d, J = 15.2 Hz, 1H), 5.40 (q, J = 7.6 Hz, 1H), 7.25–7.5 (m, 4H); ms *m/e* (rel. %): 119 (10), 118 (100), 117 (85), 116 (16), 91 (22). *Anal.* calcd. for $C_9H_{10}O_2S$: C 59.31, H 5.53, S 17.60; found: C 59.63, H 5.20, S 17.20.

The less polar isomer had ir: 1110, 1140 cm^{-1}; ^1H nmr: 1.85 (d, J = 6.6 Hz, 3H), 3.82 (d, J = 14.2 Hz, 1H), 4.01 (d, J = 14.2 Hz, 1H), 5.06 (q, 1H, J = 6.6 Hz), 7.3–7.5 (m); ms *m/e* (rel. %): 119 (10), 118 (100), 117 (87), 115 (21) 91 (25). *Anal.* calcd. for $C_2H_{10}SO_2$: C 59.31, H 5.53, S 17.60; found: C 59.55, H 5.23, S 17.86.

*Sultine **11***

Sulfone **6***c* (50 mg) was dissolved 15 mL of dry THF under N_2 at 20°C and treated with 3.0 mL of 1.6 *M* CH_3Li (large excess). After 1 h the reaction mixture was quenched with 2 mL of methanol. The solvents were evaporated, and the residue was warmed to 40°C with 5 mL concentrated HCl for 5 min, cooled, and diluted with 20 mL of H_2O. Extraction with CH_2Cl_2 afforded 39 mg (80%) of **11**; ir: 1120 cm^{-1}; ^1H nmr: 1.60 (s, 3H), 1.83 (s, 3H), 3.79 (d, J = 15 Hz, 1H), 4.03 (d, J = 15 Hz, 1H), 7.2–7.6 (m, 4H): *Anal.* calcd. for $C_{10}H_{12}O_2S$: C 61.19, H 6.16, S 16.34; found: C 60.92, H 6.02, S 16.55.

*Sultine **9** via the dianion route*

o-Benzylbenzyl alcohol (1.0 g) was dissolved in 25 mL of THF containing 0.4 mL of tetramethylethylenediamine. The solution was cooled to −78°C and *n*Buli (2.2 *M* in hexane) was added slowly. The solution was warmed to 20°C and left for 1 h. Sulfur dioxide was introduced until the deep red colour was quenched. The reaction mixture was evaporated and the residue stirred with 10 mL of concentrated HCl for 15 min. The reaction was worked up by diluting with 40 mL of H_2O, extracting with CH_2Cl_2, and washing the extracts with 5% $NaHCO_3$ solution. The yield of crude product was 1.19 g, which appeared to be a 70:30 mixture of **9** and starting alcohol by nmr. Recrystallization from ethanol afforded 494 mg (40%) of **9** with properties identical to those described above.

Sultine ***13***

ortho-Benzyl-α,α′-dimethylbenzyl alcohol (470 mg) and 0.2 mL of tetramethylpiperidine were dissolved in 25 mL of THF at 0°C under N_2. *n*Buli (2.3 mL of 2.5 *M*, 2.2 equiv.) was added dropwise via syringe and the solution was stored for 3 h at 20°C during which time a deep red colour developed. The flask was recooled to 0°C and SO_2 was introduced until the colour changed to yellow. The solvent was evaporated and the residue treated with concentration HCl as above. Work-up gave 465 mg of an orange oil, which contained 65% of the sultine **13** in addition to the starting alcohol. Chromatography on silica using 9:1 hexane – ethyl acetate afforded 206 mg (38%) of **13**, mp 104°C; ^{1}H nmr: 1.67 (s, 3H), 1.90 (s, 3H), 5.04 (s, 1H), 7.1–7.5 (m, 9H); ms *m/e* (rel. %): 209 (37), 193 (100), 178 (56), 165 (17). *Anal.* calcd. for $C_{16}H_{16}O_2S$: C 70.55, H 5.92, S 11.77; found: C 70.28, H 6.09, S 11.97.

Preparation of sultines ***15*** *and* ***16****. General procedure*

The appropriate *o*-bromobenzyl alcohol, ~1 g, was dissolved in THF at −78°C, reacted with 2.2 equiv. of *n*Buli for 15 min, warmed to 0°C for 15 min, and then recooled to −78°C. Excess SO_2 was introduced. The THF was evaporated and the residue stirred with 1 mL H_2O and 5 mL of concentrated HCl for 10 min. Extraction with CH_2Cl_2, followed by washing with saturated $NaHCO_3$ solution, furnished a crude product that was purified by silica gel chromatography.

Sultine ***15***a: isolated yield (61%) (8).

Sultine ***15***b: isolated yield 78% (mixture of diastereomers) (8).

Sultine ***15***c: isolated yield (56%) (8).

Sultine ***16***

Isolated yield 70%, mp 130–132°C; ^{1}H nmr: 5.43 (d, J = 13.3 Hz, 1H), 5.87 (d, J = 13.3 Hz, 1H), 6.10 (d, J = 1.2 Hz, 1H), 6.12 (d, J = 1.2 Hz, 1H), 6.82 (s, 1H), 7.10 (s, 1H); ms *m/e* (rel. %): 198 (75), 181 (10), 150 (100), 134 (28), 121 (21), 104 (16), 76 (31). *Exact Mass* calcd. for $C_8H_6O_4S$: 197.9985; found: 197.9978.

Sultine ***17***

To 1.00 g of 3,4-methylenedioxybenzyl alcohol, disolved in 15 mL of dry THF at 0°C, was added 5.8 ml of 2.5 *M* *n*Buli (2.2 equiv.). The solution was stirred for 2 h during which time a red colour developed. Sulfur dioxide was introduced until the red colour disappeared. Work-up, identical to that described for **15**, yielded 925 mg of crude product, which was judged to be 70% product **17** by nmr. Silica gel chromatography using hexane – ethyl acetate (4:1) afforded 56% of **17**, mp 120–121°C; ^{1}H nmr: 5.48 (d, J = 13.0 Hz, 1H), 5.91 (d, J = 13.0 Hz, 1H), 6.13 (d, J = 1.4 Hz, 1H), 6.15 (d, J = 1.4 Hz, 1H), 6.87 (d, J = 7.8 Hz, 1H), 6.99 (d, J = 7.8 Hz, 1H); ms *m/e* (rel. %): 198 (100), 150 (20), 134 (94), 121 (11), 105 (12), 104 (10), 92 (12), 78 (22). *Exact Mass* calcd. for $C_8H_6O_4S$: 197.9985; found: 197.9997.

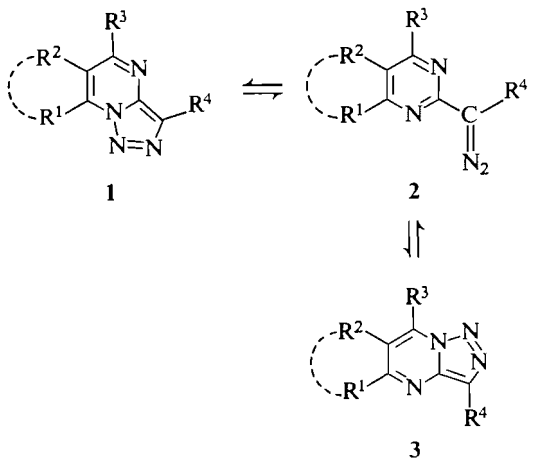
Received July 5, 1985

DONALD L. HOOPER, HARTFORD W. MANNING, RONALD J. LAFRANCE, and KEITH VAUGHAN. Can. J. Chem. **64**, 250 (1986).
Alumina-catalysed cyclization of a series of 1-(2′-acylphenyl)-3-cyanomethyltriazenes (**5**) affords good yields of the previously unreported 5-alkyl- and 5-aryl-1,2,3-triazolo[1,5-*a*]quinazolines (**8**). The parent heterocycle, 1,2,3-triazolo[1,5-*a*]quinazoline, has been observed for the first time as the product of cyclization of 1-(2′-formylphenyl)-3-cyanomethyltriazene.

DONALD L. HOOPER, HARTFORD W. MANNING, RONALD J. LAFRANCE et KEITH VAUGHAN. Can. J. Chem. **64**, 250 (1986).
La cyclisation, catalysée par l'alumine, d'une série de (acyl-2 phényl)-1 cyanométhyl-3 triazènes (**5**) conduit, avec de bons rendements, aux alkyl-5 et aryl-5 triazolo-1,2,3[1,2-*a*]quinazolines (**8**) qui n'avaient pas été décrites antérieurement. L'hétérocycle de base, la triazolo-1,2,3[1,5-*a*]quinazoline a été observée pour la première fois comme produit de la cyclisation du (formyl-2 phényl)-1 cyanométhyl-3 triazène.

[Traduit par le journal]

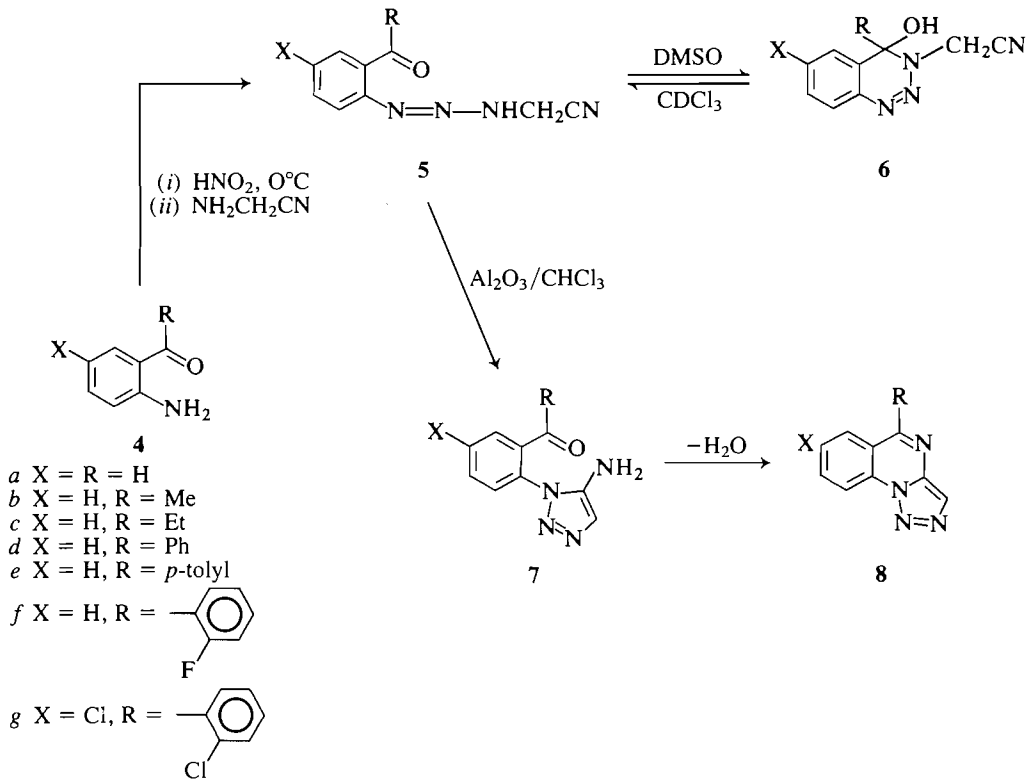
1,2,3-Triazolo[1,5-*a*] pyrimidines undergo thermal equilibrium between two isomeric structures **1** and **3** via the intermediacy of an open-chain diazo compound **2** (1). The diazo form (**2**) can become the predominant isomer of the equilibrium mixture when the pyrimidine ring is fused at R^1 and R^2 to a π-deficient aromatic heterocycle, such as a *v*-triazole (2). On the other hand, ring fusion at R^1/R^2 with a π-excessive thiophene ring (3) results in preference for the tricyclic angular structure (**1**), as is also the case for benzene ring fusion in the 1,2,3-triazolo[1,5-*a*]quinazolines. The first examples of this comparatively rare heterocycle were reported as products of the base-catalysed condensation of reactive methylene compounds with *o*-azidobenzoic acids (4), which affords 1,2,3-triazolo[1,5-*a*]quinazolines invariably substituted with 5-oxo or 5-amino groups and with a substituent at position C-3. In this communication, we report that alumina-catalysed cyclization of a series of 1-(2′-acylphenyl)-3-cyanomethyltriazenes (**5**) provides a convenient synthesis of the previously unreported 1,2,3-triazolo[1,5-*a*]quinazoline **8***a* and of its 5-alkyl[3] and 5-aryl derivatives **8***b*–*g*.



Diazotization of the arylamine **4** and coupling with α-aminoacetonitrile, followed by neutralization with aqueous sodium carbonate to pH 8, affords the triazene **5**, which exists in the solid state and in DMSO solution as the cyclic isomer, the 1,2,3-benzotriazinol (**6**). In chloroform solution, the equilibrium **5** ⇌ **6** lies in favour of the open-chain triazene form, so that when a chloroform solution of a triazinol ⇌ triazine is treated with solid, neutral alumina over a 24- to 48-h period, cyclization of the triazene occurs readily. The intermediate 1-aryl-5-amino-1,2,3-triazole (1) is not isolated, and further cyclization, with dehydration, affords the novel 1,2,3-triazolo[1,5-*a*]quinazoline **8**. Presumably the initial cyclization step **5** → **7** is the rate-determining step in the overall process; the subsequent cyclization of **7**, by nucleophilic attack of the 5-amino group of the intermediate triazole at the 2′-acyl carbonyl group, must be relatively fast.

Yields and physical data of the intermediate 3-cyanomethyl-1,2,3-benzotriazin-4-ols (**6***a*–*g*) are given in Table 1. The ir spectrum in Nujol of, typically, **6***b* shows the absence of carbonyl and the presence of a broad hydroxyl band at 3170 cm^{-1} anticipated for the cyclic structure (5). The ^1H nmr spectra of the triazinols in DMSO-d_6 (Table 2) demonstrate clearly the exclusive adoption of the cyclic form (**6**) with no trace of the ring-open form (**5**) in this medium; all the spectra show a characteristic AB quartet, J_{AB} ~ 17.8 Hz, as expected for the diastereotopic N—CH_2—CN protons adjacent to the chiral centre at C-4 of the triazine. The spectrum of **6***c* also shows multiplicity of the diastereotopic methylene protons of the ethyl substituent at C-4. All compounds in this series exhibit a low-field singlet at ca. δ 8 arising from the hydroxylic proton at C-4. The aromatic patterns all show a characteristic high-field signal, corresponding to a proton on the α-carbon of the benzene

[1]For Part VIII, see ref. 6.
[2]Author to whom all correspondence should be addressed.
[3]A preliminary account of the synthesis of **8***b* has been described in a recent article, which describes the general cyclization of 1-(2′-acetylphenyl)3-alkyltriazenes (6).



ring (adjacent to the CR(OH)N moiety); this signal is an 8-Hz doublet with fine structure arising from long-range coupling, except in the case of **6***g*, in which only the long-range coupling is observed.

The ring-open forms of these triazinols, the triazenes (**5**), are clearly evident in nmr and ir spectra run in chloroform solution. For example, the ir spectrum of the phenyl derivative (**5***d*) in $CHCl_3$ shows a strong carbonyl band at 1710 cm^{-1} and a weak, broad NH absorption band at 3250 cm^{-1}; the strong OH absorption band observed at 3150 cm^{-1} in the Nujol mull spectrum is absent in the chloroform solution spectrum. The ^1H nmr spectrum of **5***d* in $CDCl_3$ shows a strong two-proton singlet for the methylene protons at δ 4.7 ppm; only a trace of the AB system of **6***d* is evident in the $CDCl_3$ spectrum. The ^{13}C nmr spectrum of this solution (Table 3) confirms the dominance of the open-chain form (**5***d*), as indicated by the low-field carbonyl signal at δ 198.7 and a single observable N—CH_2 signal at δ 47.4. The ^{13}C nmr spectrum of the ethyl analogue (**5***c*) in deuteriochloroform also shows a carbonyl signal at δ 204.0, the N—CH_2 signal at δ 47.4, and C-ethyl group signals at δ 32.8 (CH_2) and 8.3 (CH_3).

The conversion of the triazene (**5**) in chloroform to the triazoloquinazoline (**8**) over alumina is a general high-yield reaction for all of the *o*-acylarylamines that we have investigated (see Table 4 for physical data). The ^1H nmr spectra of the triazoloquinazolines are listed in Table 5 and are totally consistent with the assigned structures. The common characteristic of these spectra is the one-proton singlet at ca. δ 8.2–8.3, arising from the isolated proton at C-3 of the triazoloquinazoline. Other features of the spectra are readily assigned to the 5-alkyl and 5-aryl group protons or to the protons of the pyrimidine-fused benzene ring. The parent heterocycle, 1,2,3-triazolo[1,5-*a*]quinazoline (**8***a*), has the additional feature in the ^1H nmr spectrum of a one-proton singlet at δ 9.00, assigned

lized to afford the triazinol (**6**). Yields, and physical and spectroscopic data of these products are given in Tables 1 and 2. Table 3 gives the nmr characteristics of two of these products in deuteriochloroform, in which the triazinols revert to the open-chain triazene form (**5**).

1,2,3-triazolo[1,5-a]quinazolines (8). General procedure

The appropriate triazinol (0.40 g) was dissolved in chloroform (25 mL) and the solution poured over anhydrous neutral alumina (14 g). The mixture was stirred at room temperature and the progress of reaction followed by tlc until complete disappearance of the reactant had taken place (usually within 24 h, but sometimes requiring 48 h). The mixture was filtered and the alumina washed with several aliquots of chloroform. The combined chloroform solutions were evaporated and the residual product recrystallized from a suitable solvent to afford the 1,2,3-triazolo[1,5-*a*]quinazoline (**8**). Yields, and physical and spectroscopic characteristics of these products are given in Tables 4, 5, and 6. The proton spectra measured for compounds **8***a* and **8***b* were iteratively fitted using the ITRCAL program supplied by Nicolet Instrument Corporation as part of the software package for the NIC-360 NB spectrometer.

High resolution ^1H and ^{13}C nmr spectroscopy at 500 MHz and 125 MHz was used for the structural analysis of the *O*-antigen of *Salmonella landau*, which belongs to the Kauffmann–White serogroup N. This bacterial lipopolysaccharide was extracted from whole cells and hydrolyzed by mild acid to give lipid-free *O*-polysaccharide. Conventional one-dimensional ^1H and ^{13}C nmr data showed the polysaccharide to contain four monosaccharides in each repeating unit and, in addition, to carry an average of one *O*-acetyl group for every two repeating units. Two-dimensional nmr experiments aided the unambiguous assignment of the ^1H and ^{13}C resonances and thereby permitted the structural analysis of this polysaccharide by nmr techniques alone. The structure of the de-*O*-acetylated repeating unit was established as→2)-α-D-PerNAc*p*-(1 → 3)-α-L-Fuc*p*-(1 → 4)-β-D-Glc*p*-(1 →3)-α-D-GalNAc*p*(1→$_n$ through the use of methods which included homonuclear shift correlated (COSY and NOESY) experiments. The interpretation of this data was supported and simplified by consideration of firmly established ^{13}C chemical shift assignments obtained from a heteronuclear $^1H/^{13}C$ shift correlated experiment. A three-dimensional model of the *O*-antigen obtained by semi-empirical calculations is shown to be consistent with interatomic distance constraints imposed by data from 2-D NOESY and one-dimensional nOe difference spectroscopy.

DAVID R. BUNDLE, MANFRED GERKEN et MALCOLM B. PERRY. Can. J. Chem. **64**, 255 (1986).

On a utilisé le rmn du ^1H et du ^{13}C à 500 et à 125 MHz pour déterminer la structure du *O*-antigène de la *Salmonella landau* qui appartient au groupe sérique N de Kauffmann et White. On a extrait ce lipopolysaccharide bactérien des cellules complètes et on l'a hydrolysé en milieu légèrement acide pour obtenir le *O*-polysaccharide sans lipides. Les données conventionnelles en une dimension de la rmn du ^1H et du ^{13}C montrent que le polysaccharide contient quatre monosaccharides dans chaque unité de base et que, de plus, il porte une moyenne d'un groupement *O*-acétyle par deux unités de base. Sur la base d'expériences de rmn en deux dimensions on a pu faire des attributions non-ambiguës des résonances ^1H et ^{13}C qui ont ainsi permis de faire une analyse structurale de ce polysaccharide uniquement par des techniques de rmn. On a établi que la structure de l'unité de base déacétylée est→2)-α-D-PerNAc*p*-(1 → 3)-α-L-Fuc*p*-(1 → 4)-β-D-Glc*p*-(1 → 3)-α-D-GalNAc*p*(1→$_n$ en faisant appel à des méthodes qui incluent des expériences de corrélations de déplacements homonucléaires (COSY et NOESY). L'interprétation de ces données est en accord avec et a été simplifiée par la considération d'attributions de déplacements chimiques de ^{13}C qui sont bien établies et qui ont été obtenues à partir d'une expérience de corrélation hétéronucléaire de déplacements $^1H/^{13}C$. On démontre qu'un modèle tridimensionnel du *O*-antigène, obtenu par des calculs semi-empiriques, est en accord avec les contraintes de distances interatomiques imposées par les données de NOESY en 2-D et par la spectroscopie différentielle unidimensionnelle de l'effet Overhauser nucléaire.

Introduction

The lipopolysaccharides (LPS) of gram-negative bacteria assigned in the Kauffmann–White scheme (1) to serogroup N, have been shown to be serologically cross-reactive with *Yersinia enterocolitica* 0:9, *Brucella abortus*, and *E. coli* 0:157 (2–4). This observation gained structural significance when the O-antigens of the first two bacteria were shown to be homopolymers of 1,2-linked 4,6-dideoxy-4-formamido-α-D-mannopyranosyl (perosamine) units (5, 6). Compositional analysis showed that the O-antigens of *S. landau* and *E. coli* 0:157 also contained the sugar, perosamine (7), and structural analysis of these O-antigens became necessary in order to further understanding of these important cross-serological relationships.

Bacterial LPS contains three structurally distinct portions, each covalently linked to the other in a contiguous structure. The polymeric O-chain is linked to the core oligosaccharide, which in turn is linked via the acid-labile, 3-deoxyoctulosonic acid (KDO), ketosidic bond to lipid A, the hydrophobic anchor that secures the whole "molecule" in the outer membrane of the gram-negative cell wall (11). Mild acid hydrolysis severs the KDO – lipid A linkage, liberating the O-chain still linked to core oligosaccharide and chloroform-soluble lipid A.

The success of two-dimensional nmr experiments at 500 MHz, when applied to low molecular weight proteins (8, 9), indicated that such techniques should be particularly useful for the analysis of O-antigen structure. Since these polymers, unlike much larger capsular polysaccharides, have an average molecular weight around 10 000 daltons, the limitations to the successful execution of certain two-dimensional experiments, such as $^1H/^{13}C$ shift correlation, imposed by short transverse relaxation times (T_2) (10), should not apply. This communication reports the application of homo- and heteronuclear shift correlated spectroscopy to the delineation of a complex heteroglycan structure, without recourse to other structural methods except for the initial identification of the component monosaccharides.

Results and discussion

In order to perform a complete structural analysis of a polysaccharide, the following questions must be answered unambiguously: (*1*) the identity of the component monosaccharides present and their absolute configuration; (*2*) the ring size and anomeric configuration of each monosaccharide; (*3*) the position of linkages between sugar units; (*4*) sequence and arrangement of sugar residues in linear or branched structures; (*5*) the nature, position, and quantity of non-carbohydrate substituents. With the exception of absolute configuration, nmr methods can in principle satisfy all aspects of these requirements. Indeed, an unstated objective, the elucidation of

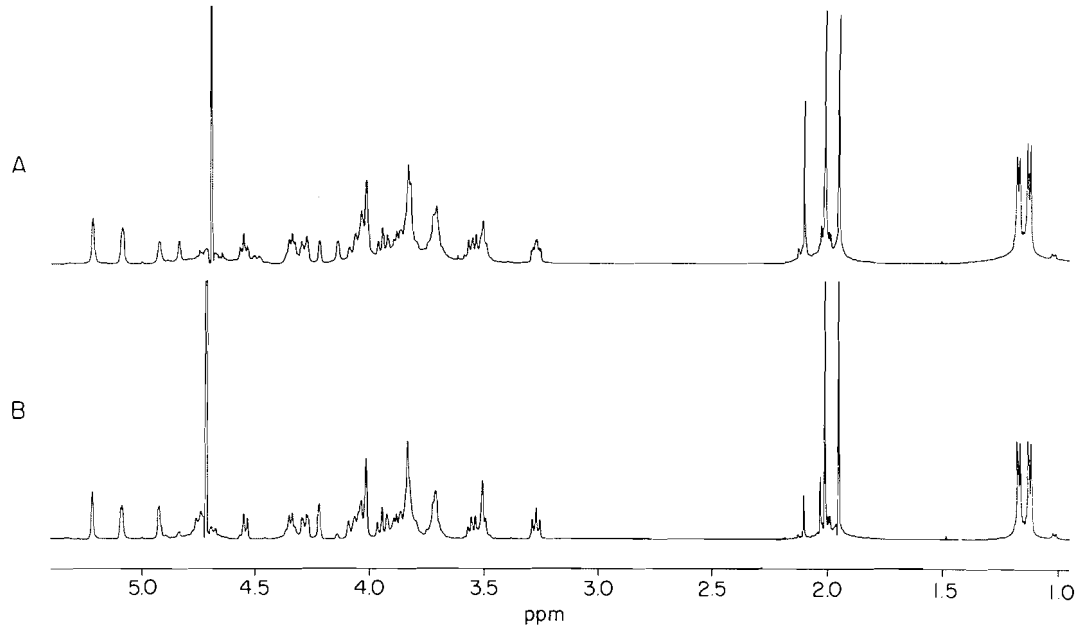

FIG. 1. Resolution enhanced ^{1}H nmr spectra of: A, the native *O*-polysaccharide liberated from LPS by mild acid hydrolysis and recorded at 303 K; B, the *O*-deacetylated polysaccharide recorded at 300 K.

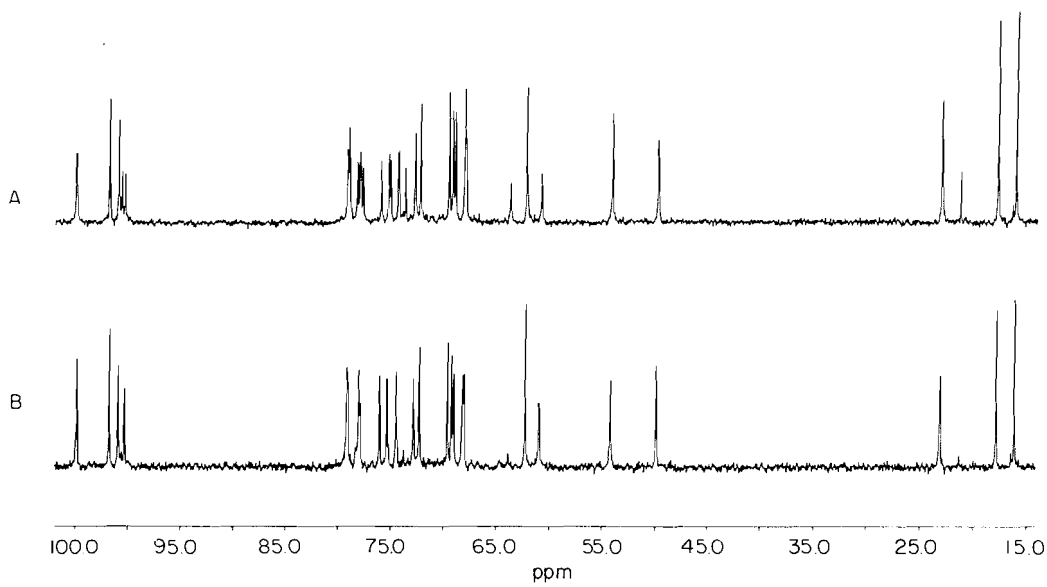

FIG. 2. The ^{13}C nmr spectra of A, native, and B, *O*-deacetylated polysaccharides recorded at 310 K. Simplification of the spectrum follows the removal of the *O*-acetyl residue.

three-dimensional structure, may also be approached by the nmr technique.

The lipid-free O-polysaccharide was prepared from the LPS of *S. landau* by conventional methods, which involved mild acid hydrolysis and gel filtration on Sephadex G-50 to obtain polymeric material. This O-polysaccharide was subjected to total acid hydrolysis, reduction, acetylation, and gc – mass spectrometry of alditol acetates. In this way the component sugars were identified and the absolute configuration was determined after conversion of the monosaccharides to the corresponding (−)-2-butyl glycosides (12). The component sugars were shown to be 2-amino-2-deoxy-D-galactose, D-glucose, L-fucose, and 4-amino-4,6-dideoxy-D-mannose (perosamine, PerN), present in equimolar proportions. Examination of the ^{1}H nmr spectrum of the O-polysaccharide (Fig. 1) also showed the presence of ester-linked acetate, 0.5 mol relative to the two *N*-acetyl groups, which indicated that both amino sugars were present as their acetamido derivatives. Complex spectral patterns were simplified by saponification of ester-bound acetate (Figs. 1 and 2), and the resultant spectra were consistent with a repeating unit structure containing four sugars and one *O*-acetyl group for every two repeating units. The limited complexity of the ^{13}C spectrum of the native polysaccharide (Fig. 2A) suggested that *O*-acetylation occurred at only one site in the tetrasaccharide repeat. Analysis of typical ^{1}H and ^{13}C features supports the analytical data for sugar composition, in that two amino sugars, present as acetamido derivatives, and two 6-deoxy sugars are component monosaccharides. Proton

and ^{13}C chemical shift and heteronuclear coupling constant data (13) (Tables 1 and 2) also indicated the presence of three α- and one β-linked monosaccharide in each repeating unit.

Considerable information was obtained even from such cursory examination of the one-dimensional spectra. However, to deduce the sequence and position of interglycosidic linkages by nmr methods, to a degree of certainty comparable with that reached by classical methylation analysis and chemical degradation, requires unambiguous assignment of all the ^1H and ^{13}C resonances. When this is done for proton signals, nOe (nuclear Overhauser effect) difference spectra (14) provide a reliable method for determination of both the sequence and linkage between contiguous residues (15–17), provided serious overlap of the resonances of interest do not occur. Conclusions from proton nOe measurements may be supported by ^{13}C data for the aglyconic carbon atoms, which are known to experience considerable deshielding (18). The approach adopted here was to make as complete an assignment as possible of the proton resonances via COSY experiments and, since the quantities of polysaccharide permitted it, to support this analysis by assigning the ^{13}C spectrum through a $^1H/^{13}C$ shift correlated experiment. Following these, proton nOe experiments to establish the sequence and postion of glycosidic linkages were envisioned.

Homonuclear shift correlated spectra were recorded with and without suppression of the HOD signal. At one temperature, 300 K, this signal could be positioned between the two highest field anomeric resonances, a position in which no resonances were obscured by solvent peaks. Two windows, the anomeric and 6-deoxy resonances, are available as starting points for the analysis of the COSY spectra (Fig. 3). The first of these signals led to the identification (via cross-peaks) of H-2 ring protons, whilst the H-5 signals of the deoxy residues are located from cross-peaks to the methyl resonances at ca. 1.20 ppm. The anomeric resonances in order of decreasing chemical shift were arbitrarily assigned the notation H-1a, H-1b, H-1c, and H-1d; then, following the cross-peaks, resonances H-1b to H-4b and H-1d to H-4d were assigned. In the case of residue, d, coincident resonances occurred, H-3d/H-4d, with an apparent absence of cross-peaks. This introduced a degree of uncertainty into the assignments, which were, nevertheless, substantiated via a $^1H/^{13}C$ shift correlation map. Overlapping signals due to

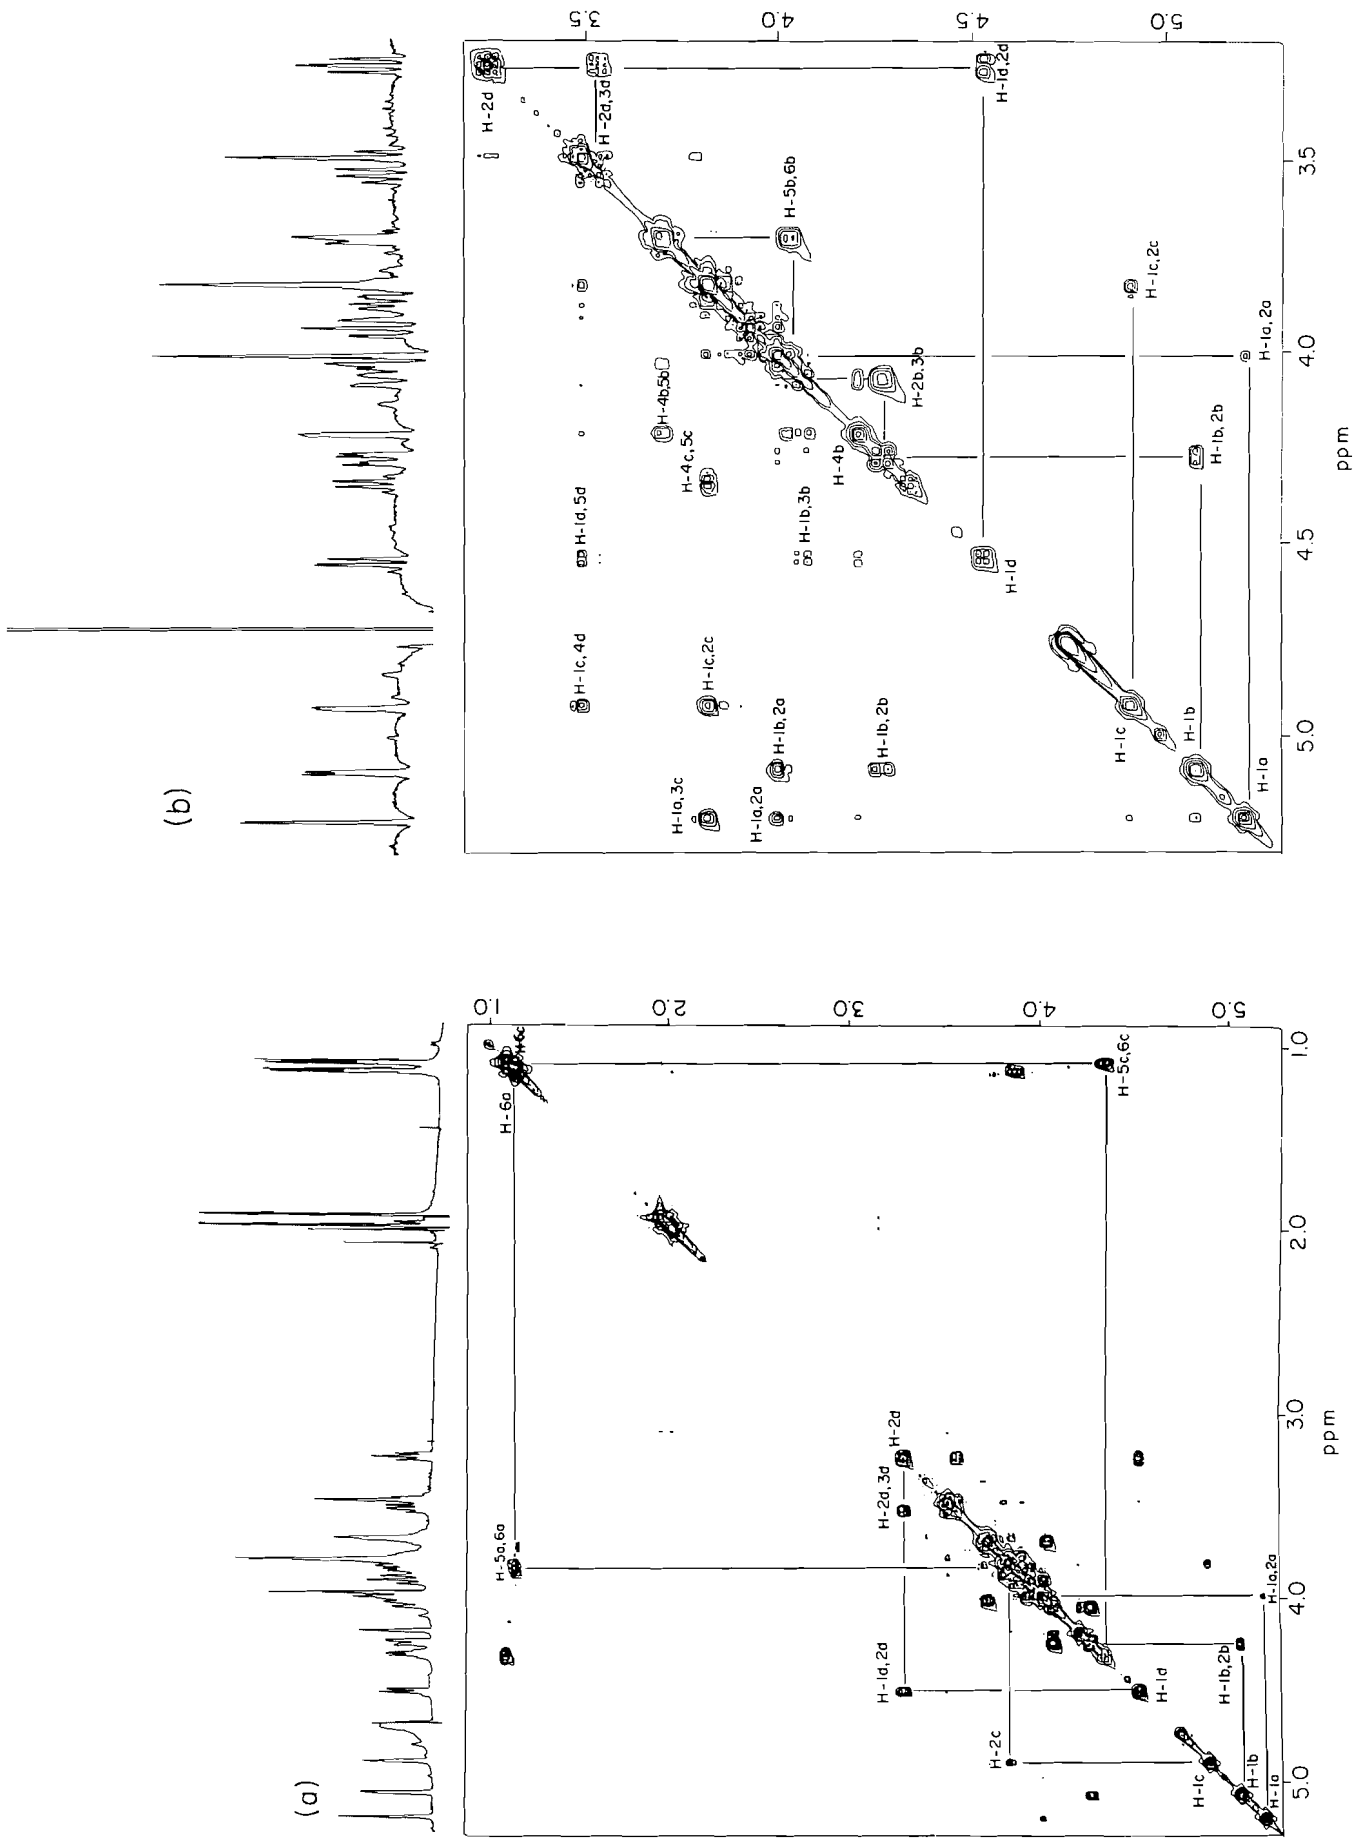

FIG. 3. (a) COSY contour plot of the full spectrum of the de-*O*-acetylated polysaccharide 5.30–1.00 ppm recorded at 300 K. (b) COSY (lower half) and NOESY (upper half) contour plots of the ^{1}H spectral region 5.30–3.20 ppm. The NOESY experiment was conducted with a 200-ms mixing time. Some spin diffusion is apparent. The one-dimensional projection is depicted along the F_2 axis.

H-2a and H-3a prevented the unambiguous location of H-4a, which may be assigned via H-6a and H-5a. The identity of the 6-deoxy signals as originating from either unit a or c was clearly evident since H-5a, a pseudo quartet in the one-dimensional spectrum, is typical of a pyranoside possessing the *galacto* configuration with small $J_{4,5} \sim 1$ Hz and $J_{5,6} \approx 6$ Hz. Although a low-intensity cross-peak identifies H-4c via H-5c (Fig. 3(a)), proximity or overlap of H-2c, H-3c, and H-4c prevents the unambiguous assignment of the former two resonances. Thus via the COSY experiment, 70% of the ring proton resonances were identified without assumptions of the identity or configuration of the component saccharides. Based on the monosaccharide composition and the partial ^{1}H assignments, residues a and c were identified as the 6-deoxy sugars. Comparison of chemical shift data (Table 1) with that compiled from the literature (18) enabled residue d to be identified as a β-D-glucopyranosyl unit and residue b as a 2-acetamido-2-deoxy-α-D-galactopyranosyl unit. Residue c, on the basis of the chemical shift and $J_{1,2}$ value (2.4 Hz), was assigned as an α-L-fucopyranosyl unit, which required residue a to be a 4-acetamido-4,6-dideoxy-α-D-mannopyranosyl unit.

Numerous variants of the COSY experiment continue to be introduced and a relayed COSY (19) could in principle be used to identify the missing assignments H-3a, H-5b, H-6b, H-3c, H-4d, H-5d, and H-6d, although in this modification attention to J tuning becomes important (20). Since the quantity of polysaccharide available allowed it, an alternate approach was adopted, the construction of a ^{1}H/^{13}C correlation map (Fig. 5). This identified the ^{1}H chemical shifts of the H-6b and H-6d protons via their respective C-6 resonances, in agreement with partially relaxed ^{1}H spectra (18). The assignment of H-6 resonances led directly to the assignment of H-5b and H-5d, leaving only H-3a, H-3c, and H-4d as the ambiguous ^{1}H signals. It should be recalled that in each of these cases the evidence from the COSY experiment suggested that coincident signals were responsible for the absent cross-peaks, H-3a with H-2a, H-3c with H-2c, and H-4d with H-3d. Correlation of most ^{1}H signals with the corresponding ^{13}C resonances via the ^{1}H/^{13}C shift correlated experiment was straightforward, although for certain ring protons coincident resonances in F_1 complicated assignment of the ^{13}C spectrum. This problem was partially resolved by examination of F_1 cross sections through each ^{13}C signal, as the ^{13}C resonances were well resolved. However, since resolution in F_1 permitted only those proton multiplets with large ^3J values to be observed, this approach was limited to the identification of H-4d, H-3c, and H-3a.

Examination of ^{13}C chemical shifts (Table 2) and a comparison of these with literature values (21, 22) indicated which pyranose ring atoms were involved in glycosidic linkages. Thus those ^{13}C atoms that experienced significant deshielding, C-2a, C-3b, C-3c, and C-4d, were the putative linkage sites. Although ^{13}C chemical shifts are strongly indicative of the position of glycosidic linkages, the sequence of monosaccharides in the polymer chain together with the position of the linkages were most readily determined by measurement of inter-residue nOe's. This may be accomplished by one-dimensional nOe difference spectra (Fig. 4) (15, 17) or via the two-dimensional nmr equivalent, a NOESY experiment (Fig. 3(b)) (16, 23). Interpretation of the sequence via such dipolar coupling is strongly dependent upon conformation; however, substantial experimental evidence supports the *exo*-anomeric effect (24), which requires anomeric and aglyconic protons to be in virtual van der Waals contact (25), thereby forming the basis of this

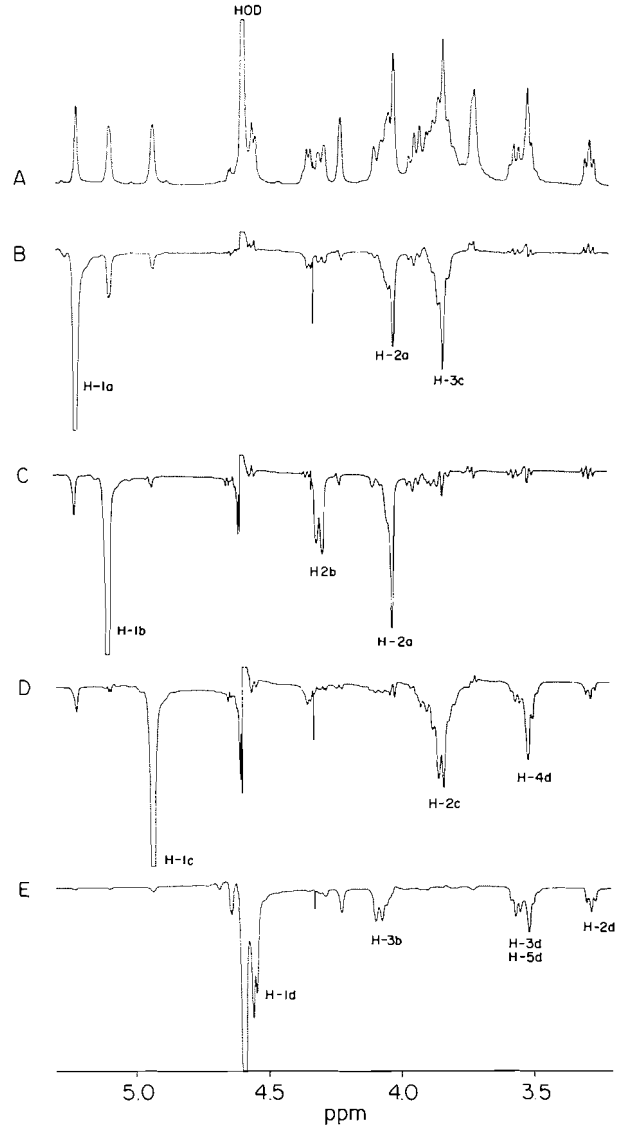

FIG. 4. One-dimensional nOe difference spectra for irradiation of the respective anomeric protons H-1a – H-1d, measured at 310 K. A, off-resonance control spectrum. B, difference spectrum obtained by irradiation of H-1a. C, difference spectrum obtained by irradiation of H-1b. D, difference spectrum obtained by irradiation of H-1c. E, difference spectrum obtained by irradiation of H-1d.

method of sequence and linkage determination. Thus nOe difference spectra permitted the proton attached to the aglyconic carbon atom to be identified, and in the NOESY contour plot the same resonance is correlated via a cross-peak to the anomeric proton involved in each glycosidic linkage. The results of the nOe difference and NOESY experiments (Figs. 4 and 3(b)) require that residue a (α-D-PerNAc) is linked α-1,3 to α-L-Fuc (residue c), since irradiation of H-1a resulted in nOe's for H-2a and, in addition, for a proton which may only be one of H-2c, H-3c, or H-4c. Thus residue a must be glycosidically linked to residue c and the ^{13}C data (Table 2) require that the position of this linkage be C-3c. The α-L-Fuc unit is linked to the 4 position of the β-D-Glc residue since the dipolar coupling across the glycosidic bond is to either H-3d or H-4d, and ^{13}C data (Table 2) indicated that the aglyconic carbon atom was C-4d. The β-D-glucopyranosyl unit exhibited significant intra-ring nOe's between H-1d, H-3d, and H-5d, which was consistent with the

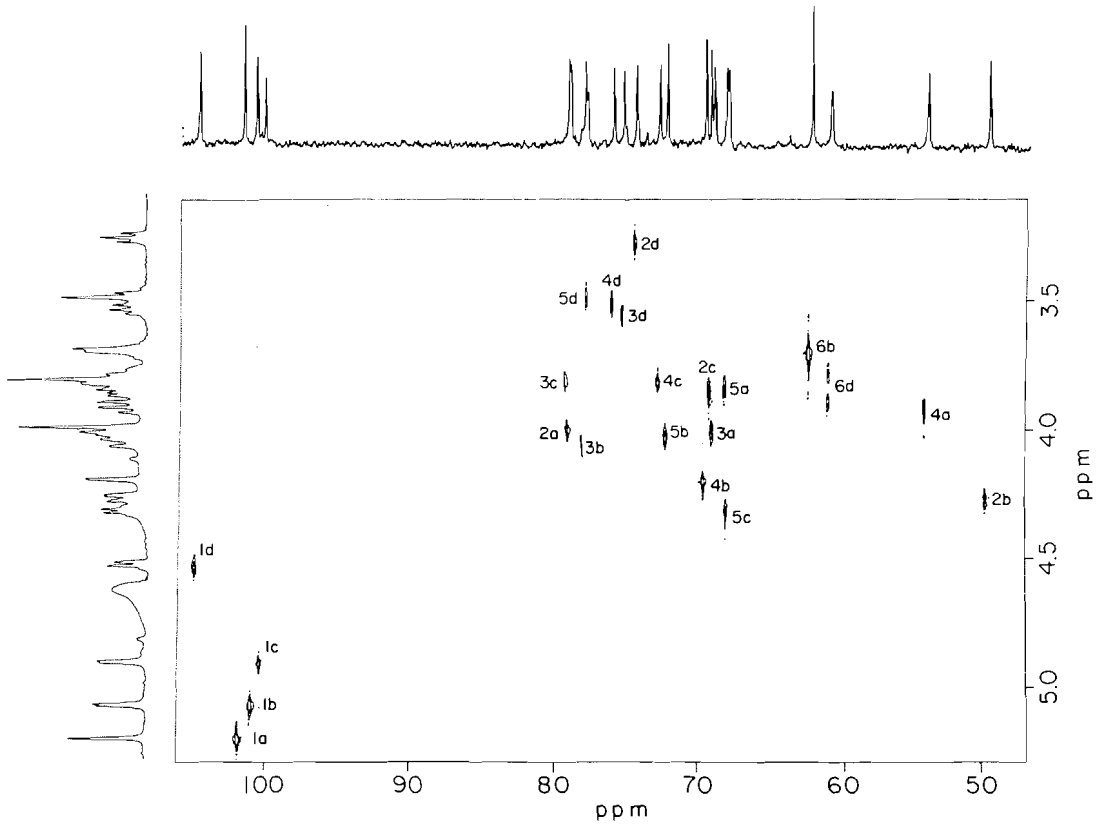

FIG. 5. Heteronuclear $^1H/^{13}C$ shift correlation map for the spectral regions of F_2, δ 106.0–47.0 ppm and F_1, δ 5.30–3.10 ppm. The sample, 60 mg of de-*O*-acetylated polysaccharide dissolved in 500 μL of D_2O, gave acceptable S/N after 800 scans, permitting data to be acquired at 310 K during 62.5 h of instrument time. The respective ^{13}C and ^1H one-dimensional projections are displayed along the F_2 and F_1 axes.

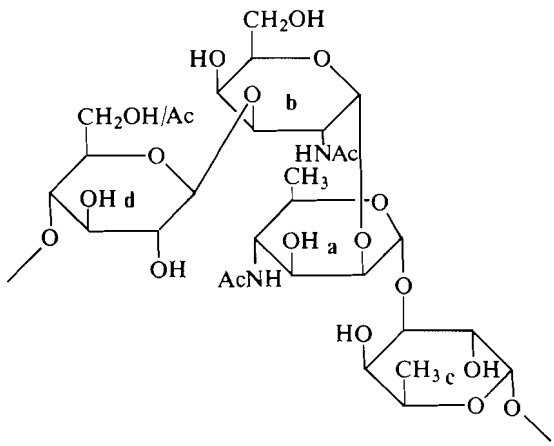
1,3 diaxial orientation of the protons of this pyranosyl moiety. The largest inter-ring nOe was observed between H-1d and H-3b, in agreement with the downfield shifted C-3b resonance. Thus the β-D-Glc, residue d, was linked 1,3 to α-D-GalNAc, unit b. Lastly, nOe's observed from H-1b to H-2b and either H-2a or H-3a established the sequence b–a, but again overlap of crucial proton resonances failed to distinguish between the two possible sites of the inter-ring linkage. However, the one-dimensional nOe difference spectrum showed a narrow multiplet at δ 4.02 suggesting a 1,2 linkage, which was supported by the ^{13}C shift of C-2a. Although overlap of proton resonances H-2a/H-3a, H-2c, H-3c/H-4c, and H-3d/H-4d complicated identification of linkage position in three out of four cases, the proton nOe experiments did permit the repeating unit sequence a–c–d–b to be established. In combination with the $^1H/^{13}C$ correlation map, linkage positions were clearly and unambiguously determined. In this connection the assignment of ^{13}C resonances made possible by the extensive homo- and heteronuclear shift correlations was an essential element of this approach.

The chemical repeating unit of the *Salmonella landau* O-antigen determined by nmr methods was



→4)-β-D-Glc*p*-(1→3)-α-D-GalNAc*p*-(1→2)-α-D-PerNAc*p*-(1→3)-α-L-Fuc*p*-(1—

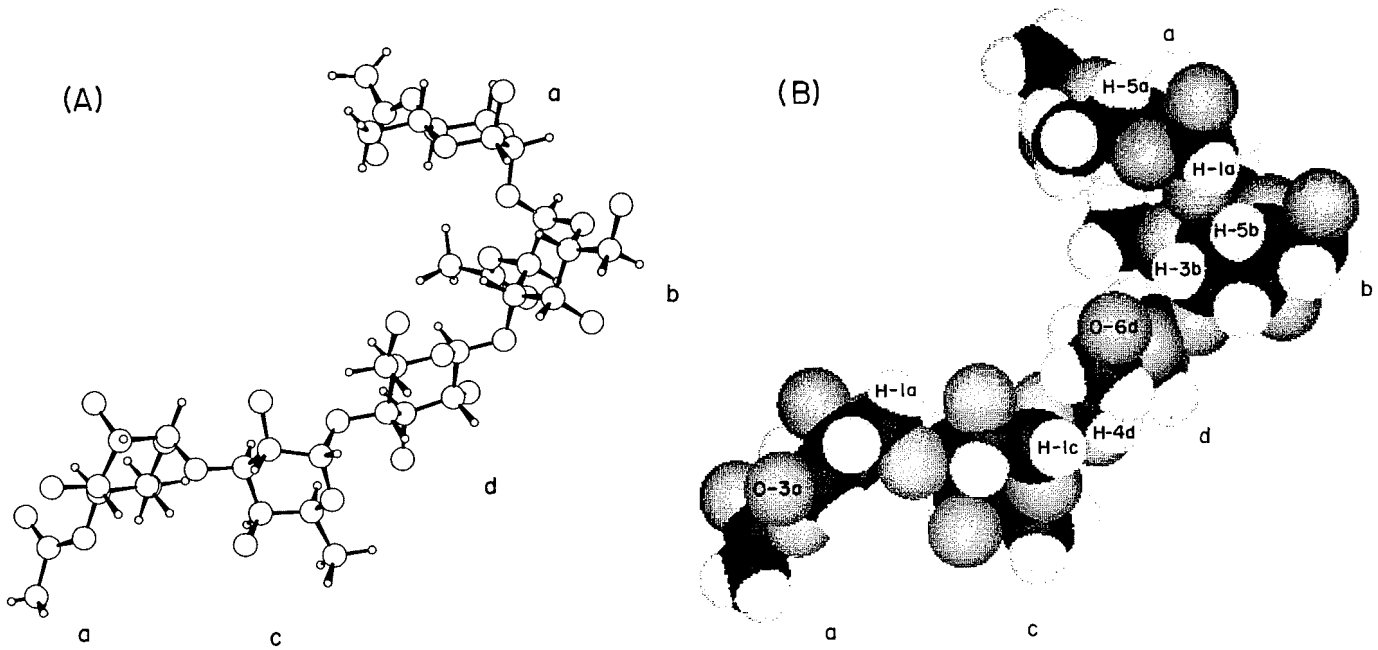


FIG. 6. Ball and stick (A) and CPK (B) models of a hypothetical minimum energy conformation of the pentasaccharide of *S. landau* *O*-antigen, unit sequence PerNAc→Fuc→Glc→GalNac→PerNAc (designated a→c→d→b→a). The ϕ/ψ values for each of the consecutive glycosidic linkages are presented in Table 3. The torsional angles H-5—C-5—C-6—O-6 depicted for the Glc and GalNAc residues are −60° and −60°. Hydrogen atoms of hydroxyl groups are omitted from the calculation and the model plots.

As previously mentioned, the native polysaccharide carried one *O*-acetyl group for every two repeating units and the location of this group remained the outstanding feature to be determined. The chemical shifts of the ^{13}C resonances affected by the occurrence of an ester-linked acetate are recorded in Table 2. Proton and ^{13}C data indicated that one in two repeating units carried an *O*-acetate group, which complicated assignment since resonances due to acetylated and non-acetylated structural elements exhibited similar intensities. It was immediately obvious from a ^{13}C DEPT experiment (26), which distinguishes methine and methylene carbons, that the C-6d resonance at 60.74 ppm was reduced in intensity and a new signal, downfield shifted by 2.39 ppm and also due to C-6d, had appeared in this spectrum of the native polysaccharide. Similarly, new resonances occurred corresponding to other carbon atoms in immediate proximity to the site of acetylation; thus the C-5d resonance was upfield shifted by 4.30 ppm, whilst C-4d exhibited a downfield shift of 1.76 ppm, a pattern of shift changes consistent with C-6d as the site of acetylation, and with literature values for the sign and magnitude of these shifts (27). In agreement with this, C-1c experienced a small but significant 0.3-ppm shift, which could be expected since the α-L-Fuc, unit c, was linked 1,4 to the β-D-Glc residue. The H-1c signal was shielded by ca. 0.1 ppm (Fig. 1) and both these effects could be anticipated, since a 1,4 linkage places the anomeric centre of residue c in close proximity to the hydroxymethyl group of unit d (Fig. 6) (28). Examination of a resolution enhanced proton spectrum of the native polysaccharide revealed that the multiplets due to the acetylated H-6d resonances were located at ca. 4.30 and 4.55 ppm. Minor shift differences throughout the ring protons of residue d were observed but, with the exception of the H-1c signal, barely perceptible shifts were seen for other ring protons. Finally, nOe difference spectra performed by irradiation of each H-1c signal, due to acetylated and non-acetylated components, showed that an nOe to a multiplet centred at 4.30 ppm, a downfield shifted H-6d resonance, could be detected only for irradiation of the shifted H-1c resonance. The native *Salmonella* serogroup N O-chain, therefore, possesses the tetrasaccharide sequence shown above, which may be acetylated at O-6d and, in the case of *Salmonella landau*, carries one such *O*-acetyl per two repeating units.

Finally, drawing on the network of inter-ring nOe's in combination with semi-empirical calculations, it was possible to propose a three-dimensional model of the O-antigenic polysaccharide. The minimum energy molecule calculated by the HSEA method (24, 29) and by application of the related but more sophisticated GESA programme (30) gave ϕ and ψ values for each glycosidic linkage that differed in each ϕ,ψ pair (calculated by either method) by less than 5 degrees (Table 3). The distance matrix for this molecule without the *O*-acetyl group at O-6d was consistent with the nOe data from the one-dimensional experiments and the semi-quantitative data obtained from NOESY experiments carried out with different mixing times. In addition to the short interproton distances corroborated by the pattern of observed nOe's, specific deshielding effects may be correlated with short, ca. 2.5 Å, oxygen-to-proton distances (Table 3). One such case is the H-5c resonance that, compared to the chemical shift observed in the corresponding glycoside (18), is deshielded by 0.4 ppm. This correlates with a H-5c to O-3d separation of 2.5 Å in the minimum energy conformation. These results are in agreement with similar observations made for other O-antigens, in that the HSEA-calculated conformation for the repeating unit also satisfies the observable nmr parameters for the polymeric structure (31, 32). Ball and stick and CPK projections of the repeating unit without the *O*-acetyl group are presented (Figs. 6A and 6B).

In this study we have used the COSY, NOESY, and heteronuclear shift correlated experiments for the structural analysis of a polysaccharide. The most powerful of the three is the COSY

TABLE 3. Glycosidic torsion angles and selected interatomic distances for the *S. landau* repeating unit in the minimum energy conformation

Parameter	Glycosidic torsional angles			
	α-D-PerNac-(1 → 3)-α-L-Fuc-(1 → 4)-β-D-Glc-(1 → 3)-α-D-GalNac-(1 → 2)-α-D-PerNac			
ϕ^H/ψ^H	−50.0°/−11.5°	43.0°/7.0°	53.5°/15.0°	−42.5°/−23.0°
Selected inter-atomic distances (in Å) across glycosidic bonds	H-1a, H-3c 2.47; H-5a, H-4c 2.31; O-5a, H-3c 2.64;	H-1c, H-4d 2.33; H-5c, O-3d 2.62; O-5c, H-4d 2.79;	H-1d, H-3b 2.49; O-5d, H-3b 2.50;	H-1b, H-2a 2.44 O-5b, H-2a 2.70 H-5b, H-1a 2.39

experiment, which through the rigorous assignment of the proton spectrum provides the key to the assignment of the ^{13}C spectrum and, finally, the interpretation of the nOe's in terms of linkage and sequence. Although the quantity of polysaccharide or spectrometer time available does not always allow the $^{13}C/^{1}H$ shift correlation experiment to be performed, it is clear that the assignment of linkage position can often only be unambiguously decided by reference to the chemical shifts of the aglyconic carbon atoms, which are most readily obtained from this experiment. Less time demanding experiments (33, 34) to identify the aglyconic carbon atoms are available but the unambiguous identification of these is then dependent upon correct assignment of the remaining ring carbon atoms. Although these may often be assigned by inspection or comparison with extensive literature data (21, 22), a rigorous treatment requires a $^{1}H/^{13}C$ correlation map. Elaborate nmr experiments to establish polysaccharide structure, although possible, are not necessarily the most practical approach to structural analysis. Recent publications from this laboratory illustrate the effective combination of classical methods with high resolution nmr at high field strength for the analysis of complex bacterial polysaccharides (35, 36). Conventional methylation analysis can most effectively establish linkage positions, leaving the nOe experiment to determine the sequence of saccharide units either in the polymer itself or within fragments readily obtained by particular degradation techniques suited to the structure under study. Such an approach combats the problem encountered even at 500 MHz (37), overlapping and poorly separated ring proton multiplets.

Experimental

Bacterial strain and growth

Salmonella landau (LCDC S-1358; NRCC 4124) a Kauffman–White serogroup N organism, was obtained from Dr. H. Lior, Laboratory for Disease Control, National Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario. Bacteria were grown in a 28-L fermentor on brain heart infusion media in submerged culture for 18 h (7) and cells were killed by addition of phenol to 0.75% (w/v) final concentration. After 2 h at 6°C, cells were collected by centrifugation in a Sharples continuous centrifuge, and the twice-saline-washed cells were digested with lysozyme, ribonuclease, deoxyribonuclease, and trypsin (38), followed by phenol–water extraction (39). Purified LPS (250 mg) from the phenol phase was heated in 1.5% acetic acid (200 mL) for 2 h at 100°C. Precipitated "lipid A" was removed by centrifugation and the supernatant was lyophilized and chromatographed on a Sephadex G-50 column (2.5 × 60 cm) eluted with 0.05% pyridinium acetate pH 4.7 buffer. The column effluent was monitored for refractive index changes and the peak eluting at the void volume was collected and lyophilized (100 mg), once from water and twice from deuterium oxide.

Gas chromatographic analysis

Glycoses were determined by glc of their alditol acetates (40) using inositol as an internal standard. Polysaccharide samples (0.5 mg) were hydrolyzed in sealed glass tubes with 1 *M* sulphuric acid (500 μL) for 15 h at 100°C followed by barium carbonate neutralization. Aminoglycose estimation was performed following hydrolysis with anhydrous hydrofluoric acid (500 μL) for 4 h at 20°C, HF was evaporated by a stream of dry nitrogen, and the amino-hexose was converted to either an alditol acetate or TMS derivative. The configuration of the individual hexoses was determined by glc analysis of their trimethylsilylated (−)-2-butyl glycosides (12).

Alditol acetates were separated on a column of 3% (w/w) SP2340 on 80–100 mesh Supelcoport, and trimethylsilylated derivatives were separated on a column of 10% neopentylglycol sebacate polyester on 80–100 mesh Chromosorb W, both as previously described (7).

Gas–liquid chromatography – mass spectra were done using a Hewlett–Packard 5985B glc–ms system employing the 3% (w/v) SP2340 column above and an ionization potential of 70 eV. Identification of each hexose was based upon comparison of retention time and mass spectrum with those of authentic laboratory reference specimens.

Nuclear magnetic resonance measurements

Two solutions of the polysaccharide in deuterium oxide (5 mg/400 μL and 80 mg/mL) were prepared for ^{1}H and ^{13}C measurements respectively. All spectra were recorded in the pulsed Fourier transform mode, with quadrature detection on a Bruker AM-500 spectrometer using either selective or dual $^{1}H/^{13}C$ 5-mm probeheads and a 10-mm broadband probehead.

Proton spectra, 500 MHz, were recorded at 300 and 310 K using spectral widths of 2.5 kHz, a $\pi/2$ pulse (9 μs for selective and 28 μs for the dual probehead), a 16 K data set for a digital resolution of 0.3 Hz/point, an acquisition time of 3.2 s, and a relaxation delay of 3.0 s during which an r.f. field, 22 dB below 0.2 W, was applied at the resonance frequency of the HOD signal. Resolution enhancement prior to Fourier transformation was achieved in one of two ways; either the Lorentz-to-Gauss line shape transformation (41) was used with typical values for line broadening of −1.0 Hz and a Gaussian broadening factor of 0.4, or a non-shifted sine bell filtering function was used for maximum resolution enhancement with good S/N (signal-to-noise). Chemical shifts are expressed relative to internal acetone (1%) (δ = 2.225 ppm). In order to optimize delay periods for 2-D experiments, proton T_1 values were determined by the nonselective inversion recovery method (42) and were ca. 1.5 s for the hexose ring protons. Heteronuclear $^{1}J_{C,H}$ coupling constants for the anomeric positions were measured by gated decoupling (18).

Carbon-13 spectra, 125 MHz, were recorded at 310 K for a 25-kHz spectral width using a $\pi/2$ pulse (8.5 μs for the 5-mm and 22 μs for the 10-mm probeheads) and a 32 K data set. In order to minimize heating effects, gated broadband decoupling of 1 W was used to establish nOe buildup during a delay period of 0.7 s, followed by ca. 1-W composite pulse decoupling (WALTZ) (43) during a 0.65 s acquisition time. Coupled and decoupled DEPT experiments (26) were performed for a 12.5-kHz spectral width, using a $3\pi/2$ proton pulse to distinguish CH and CH_2 resonance and for enhanced S/N during measurement of the anomeric $^{1}J_{C,H}$ coupling constants. The delay between pulses $(2J)^{-1}$ was set at 3.4 ms. Chemical shifts are expressed relative to internal 1,4-dioxane (1% v/v) (δ = 67.4 ppm).

Two-dimensional nmr experiments were recorded by means of the

Bruker DISNMRP software. Homonuclear shift correlated COSY (44) and NOESY (45) experiments were performed with and without suppression of the HOD resonance. Selective and continuous irradiation at the frequency of the HOD signal using decoupler power 40 dB below 0.2 W, except during acquisition, provided optimal suppression of this solvent peak. The COSY and NOESY data were obtained using a matrix ($t_1 \times t_2$) of 256 × 1024 points that was zero filled to either 512 × 1024 or 1024 × 2048 points and, following resolution enhancement in both dimensions by a non-shifted sine-bell window function, the doubly-transformed data were processed to give magnitude spectra. The spectral width of the matrix was 2500 Hz in both dimensions (a digital resolution of either 4.88 Hz/pt or 2.44 Hz/pt depending on the level of zero filling employed). The $\pi/2$ pulse was 9.0 μs and a minimum delay of 1.5 s was used between transients for each value of the incrementable delay t_1. The number of transients per FID was 64 for the COSY and 128 for the NOESY experiments.

Heteronuclear shift correlated spectra (46) were recorded on a 500-μL sample (containing 60 mg of polysaccharide) in a 5-mm tube using a spectral width in F_2 of 7800 Hz (62 ppm) covering the anomeric and ring carbon atoms, and 1140 Hz (2.24 ppm) in F_1 for the corresponding protons. The data were obtained using a matrix ($t_1 \times t_2$) of 256 × 2048 points that were zero filled to 1024 × 4096 points and doubly transformed to give a power spectrum. The $\pi/2$ pulse widths were 8.5 μs for ^{13}C and 30.0 μs for ^1H, while the fixed delays τ_1 and τ_2 were selected for all multiplicities ($\tau_1 = (2J)^{-1}$ 3.4 ms, $\tau_2 = (4J)^{-1}$ 1.7 ms). Digital resolution in F_2 was 3.8 Hz/pt and in F_1, 1.1 Hz/pt. A recycle delay of ca. one proton T_1 was employed, and 800 transients/FID were collected and composite decoupling of ca. 1 W was applied during acquisition in order to minimize heating effects. Gaussian window functions were used in both dimensions, a line broadening of 5 Hz was employed for the F_2 domain, whilst the F_1 domain was optimized by the Lorentz-to-Gauss transformation employing a line broadening of −4.0 Hz and a Gaussian broadening factor of 0.3. The total acquisition time was 62.5 h.

Semi-empirical calculations

Semi-empirical potential energy calculations, HSEA method (29, 30), were used to compute the minimum energy for a pentasaccharide corresponding to the repeating unit of *S. landau* O-polysaccharide. Calculations were performed in 5-degree steps of the φ and ψ angles, for each disaccharide segment of the polysaccharide, and the glycosidic valence angle was set at 117°. The same structure was also modelled using the GESA (29) programme, which uses an algorithm that allows all the glycosidic torsion angles to be simultaneously relaxed together with the H5—C5—C6—O6 torsion angles. The atomic coordinates for heavy atoms of α-L-fucopyranose (47), β-D-glucopyranose (48), and 2-acetamido-2-deoxy-α-D-galactopyranose (49) were taken from X-ray data and the coordinates of the hydrogen atoms were generated as previously described (30) using a C—H bond length of 11.0 nm. Coordinates for 4-acetamido-4,6-dideoxy-α-D-mannopyranose were generated by bond modification of α-D-mannopyranose neutron diffraction data (50). The *N*-acetyl group was positioned such that the carbonyl bond eclipsed the C-4 to H-4 bond. An *O*-acetyl group was also positioned on the O-6d atom of β-D-Glc and the minimum energy recalculated for incorporation of this feature.

The ball and stick drawings and shaded CPK plots were produced by the PLUTO and VERSFAN (51) programmes. All programmes were run on the NRC IBM 3080 computer.

Ternary charge transfer complexes. II.[1] Complexes with Group III and IV elements in the anion[2]

SYDNEY BROWNSTEIN,[3] ANNE MORRISON, AND LIANG K. TAN
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9
Received August 15, 1985

SYDNEY BROWNSTEIN, ANNE MORRISON, and LIANG K. TAN. Can. J. Chem. **64**, 265 (1986).

Intensely colored charge transfer complexes are formed from $NOMX_4$ (M = B,Al,Ga,Tl; X = Cl,F) and benzene or methyl substituted benzenes. $(NO)_2MX_6$ (M = Si,Ge,Sn,Ti; X = Cl,F) also form complexes with methyl substituted benzenes. Magnetic resonance and optical spectroscopic parameters are presented. $NOMX_4$ forms stronger complexes than $(NO)_2MX_6$ and complexes containing fluorine are stronger than those with chlorine.

SYDNEY BROWNSTEIN, ANNE MORRISON et LIANG K. TAN. Can. J. Chem. **64**, 265 (1986).

Il se forme des complexes de transfert de charge très colorés lors des réactions du benzène ou de benzènes substitués par des groupements méthyles avec des dérivés $NOMX_4$, dans lesquels M = B, Al, Ga et Tl alors que X = Cl et F. Les dérivés $(NO)_2MX_6$, dans lesquels M = Si, Ge, Sn et Ti alors que X = Cl et F, forment aussi des complexes avec les benzènes substitués par des groupements méthyles. On rapporte les paramètres de rmn et de spectroscopie optique des complexes. Les $NOMX_4$ forment des complexes qui sont plus forts que ceux provenant des $(NO)_2MX_6$ et les complexes contenant du fluor sont plus forts que ceux contenant du chlore.

[Traduit par le journal]

Introduction

The preparation of stable charge transfer complexes of NOCl, MCl_n, and an aromatic hydrocarbon has been reported (1). In this article the properties of such complexes will be discussed as a function of the aromatic compound and the counterion to the NO group, where the central element of the counterion is from Group III or IV of the periodic table and the halogen is chlorine or fluorine.

Following is a brief description of the nitrosyl salts that were used in this study. A reproducible synthesis of $NOBCl_4$ has been reported (2). From an analysis of its Raman spectrum (3) and the temperature dependence of its dissociation it is concluded that the compound should be formulated as $NO^+BCl_4^-$ (4). $NOBF_4$ is also a well-known ionic solid (5). Both Raman (6) and X-ray (7) studies of $NOAlCl_4$ support its formulation as an ionic solid. There is no definitive evidence for $NOAlF_4$ nor $(NO)_3AlF_6$. $NOGaCl_4$ may be readily synthesized from excess NOCl and the metal (8). An apparently definitive study has been made on the synthesis of $NOTlCl_4$ (9). $(NO)_2SiF_6$ (10), $(NO)_2GeF_6$ (11), $(NO)_2SnF_6$ (10), and $(NO)_2TiF_6$ (10) are known, but the mixed chloride fluoride has only been reported with tin as central atom (12). There is no report of $(NO)_2MCl_6$; M = Si, Ge. The compound $(NO)_2SnCl_6$ is an ionic compound insoluble in liquid nitrosyl chloride (13). Both it and $(NO)_2TiCl_6$ can be readily prepared by reaction of NOCl with the metal chloride dissolved in CCl_4 (14)

The existence of charge transfer complexes was first established with iodine/aromatic complexes, where equilibrium constants of 1 and 6 were found for their formation with benzene and mesitylene (15). The appearance of a new, intense ultraviolet absorption maximum, which is definitive for these complexes, was explained as arising from the partial transfer of a Π electron from the donor to the acceptor species (16). Strong complexes were found with tetracyanoethylene as acceptor, giving equilibrium constants of 2 and 17 for benzene and mesitylene (17).

Complexation of the nitrosyl cation with aromatic compounds was first reported in 1963 (18), and has been studied in solution and in the gas phase by optical and ion cyclotron resonance spectroscopy (19, 20). Solid charge transfer complexes between the nitrosyl cation and aromatic compounds were only recently reported and have much greater stability towards dissociation than those with iodine and tetracyanoethylene (1). Complexes of similar stoichiometry but with NO^+ replaced by Ga^+ have been reported (21, 22). They are not charge transfer complexes since they are colorless and dissociate very readily.

Experimental

Magnetic resonance spectra were obtained on a Varian Associates XL-100 spectrometer equipped with a Nicolet Fourier transform attachment operating at 100 MHz for protons, or on a Bruker AM-400 operating at 400 MHz for protons. All chemical shifts, except for ^{19}F, are reported with respect to tetramethylsilane, although neopentane was used as an internal reference since it is inert under these conditions. A correction of 0.92 ppm was applied for protons and 31.4 ppm for ^{13}C. Fluorine chemical shifts are reported with respect to internal $CFCl_3$ as zero. Visible spectra were obtained on a Cary 210 spectrometer in CH_2Cl_2 as solvent.

Chemicals

Nitrosyl chloride, nitrosyl fluoride, boron trichloride, boron trifluoride, aluminum trifluoride, silicon tetrafluoride, germanium tetrafluoride, stannic fluoride, and bromine trifluoride were used without further purification. Benzene, toluene, *p*-xylene, mesitylene, sulfur dioxide, neopentane, and methylene chloride were purified and used as previously described (23, 24).

Aluminum chloride, purified by repeated vacuum sublimation, was transferred in a dry box under dried nitrogen, via a sidearm, to a glass tube closed by a stainless steel valve. The sidearm was then sealed under vacuum. An excess of nitrosyl chloride was condensed into the reactor and the reaction was allowed to proceed to completion in excess NOCl as solvent. All volatile materials were removed by pumping under vacuum to give $NOAlCl_4$, which was stored under vacuum. $NOGaCl_4$ was prepared in a similar manner except that the pure metal, rather than the chloride, was used as starting material. $NOTlCl_4$ was prepared directly in the spectral cell by reaction of NOCl with the appropriate amount of anhydrous thallic chloride. Both $SnCl_4$ and $TiCl_4$ were vacuum distilled into containers closed with Teflon high

vacuum stopcocks. $(NO)_2MCl_6$; M = Sn, Ti, were prepared in the reaction vessels by vacuum transfer of weighed quantities of NOCl and MCl_4. A similar procedure was followed with $(NO)_2GeF_4Cl_2$. An excess of NOF was added to $SnCl_4$ or $TiCl_4$ dissolved in SO_2 and all volatile materials were removed under vacuum to give white, solid $(NO)_2MCl_4F_2$; M = Sn,Ti, in good yield. Some attack of the NOF upon the glass reaction vessel was observed. $(NO)_2MF_6$; M = Sn,Ti, were prepared by reaction of MF_4 with neat BrF_3 and NOCl, followed by evaporation of the volatile species under vacuum. Attack on the reaction vessel was observed. $(NO)_2MF_6$; M = Si, Ge was prepared directly from NOF and MF_4 in SO_2 solution.

Sample preparation

An appropriate weighed quantity of $NOMCl_4$ was transferred in a dry box into either an nmr tube equipped with a straight-line, high vacuum Teflon stopcock or a similarly equipped sidearm to a quartz curette containing a magnetically controlled spacer to vary the optical path length. The other reagents were then transferred as vapors, via a vacuum line system, to the container. The quantity of solvent was weighed in a precalibrated container before transfer to the spectral cell so that accurate equilibrium constants or extinction coefficients could be calculated. Aromatic compounds of low volatility were weighed and added, in the dry box, to $NOMCl_4$ before addition of the volatile species. Similar procedures were followed with $(NO)_2MCl_6$ except that its transfer, as such, was unnecessary.

Results and discussion

The reaction of NOCl and BCl_3 in anhydrous methylene chloride as solvent does not immediately lead to the formation of solid insoluble $NO^+BCl_4^-$. From the boron chemical shift values listed in Table 1 for freshly prepared samples containing NOCl and BCl_3 it appears that there is immediate complex formation and rapid exchange between complexed BCl_3 and an excess of free BCl_3. After several hours there is extensive precipitation and the samples set to a semi-solid mass. The boron chemical shifts agree with those observed for the dimethyl sulfide complex (25). Although the characteristic deep color of a ternary charge transfer complex was observed for solutions containing toluene, *p*-xylene, and hexamethylbenzene, the erratic onset of precipitation of $NOBCl_4$ prevented a detailed study of these systems.

The reaction of NOF and BF_3 in sulfur dioxide as solvent immediately produces white, solid, insoluble $NOBF_4$. A pale yellow solution with an excess of benzene, and orange with an excess of toluene, are formed in SO_2 with negligible solubilization of the $NOBF_4$. Most of the $NOBF_4$ is brought into solution with an excess of *p*-xylene to give an intense red color. From the boron and fluorine chemical shifts, listed in Table 1 for the complexes with *p*-xylene, mesitylene, and hexamethylbenzene, one can conclude that in these soluble complexes the ion BF_4^- is in a similar environment to that of tetramethylammonium fluoroborate dissolved in SO_2. The proton resonance and uv spectra of the $NOBF_4$·hexamethylbenzene complex are listed in Table 2.

$NOAlCl_4$ is quite soluble in liquid sulfur dioxide. There is rapid exchange between the complexed $AlCl_3$ and an excess of free $AlCl_3$, but little change in chemical shift of ^{27}Al from that of $NOAlCl_4$ upon formation of a ternary charge transfer complex. The chemical shift values for some representative samples are listed in Table 1. The chemical shift values are consistent with those observed for the $AlCl_3$·dimethyl ether complex (25). The dependence of the proton and carbon chemical shifts of benzene upon the relative concentrations of the free and complexed species is shown in Table 3. It is assumed that all the benzene is complexed in the presence of excess $NOAlCl_4$. From the chemical shifts thus obtained for pure complex and that of benzene alone, it is possible to calculate the equilibrium constant for complex formation from the chemical shifts observed with an excess of benzene. The large values found in this way confirm the assumption of complete complex formation with excess $NOAlCl_4$. The accuracy of the calculations is quite poor since it depends upon a small difference between two large numbers. The calculated values are listed in Table 3.

Proton and carbon chemical shifts in SO_2 solution and uv–visible spectral data in CH_2Cl_2 solution for many complexes with $NOAlCl_4$ are listed in Table 2. For comparison, the uv parameters are listed for the uncomplexed hydrocarbons and for the tetracyanoethylene (TCNE) complexes.

The reaction of AlF_3 with NOF in SO_2 as solvent requires a few minutes at room temperature. Under these conditions the Pyrex glass also reacts, so that upon addition of the aromatic hydrocarbon one gets a mixture of the charge transfer complexes with $NOBF_4$, $(NO)_2SiF_6$, and nitrosyl aluminum fluoride. The relative proportions can be inferred from the intensities of the fluorine resonance signals, which confirms the reaction between NOF and AlF_3. Proton chemical shifts and visible absorption parameters will be average values and not definitive but the ^{19}F and ^{27}Al chemical shifts of some complexes are listed

[a] Data from ref. 17.

in Table 1. These were confirmed for the hexamethylbenzene complex by a synthesis using BrF_3 and NOCl (26).

Evidence from uv, and from proton, fluorine, and carbon resonance spectroscopy shows that $(NO)_2SiF_6$ is brought into solution and forms charge transfer complexes with mesitylene and hexamethylbenzene but not with less highly methyl substituted benzenes. The data are presented in Table 2. Similar reactivity was observed with $(NO)_2GeF_6$. The fluorine chemical shifts for these species are listed in Table 4. The mixed chlorofluoride $(NO)_2GeF_4Cl_2$ also forms a complex with hexamethylbenzene and spectral parameters are listed in Tables 2 and 4.

$(NO)_2SnCl_6$ forms complexes of reasonable stability with hexamethylbenzene and mesitylene. The mixed chloride fluoride $(NO)_2SnCl_4F_2$ is brought into SO_2 solution and forms complexes with *p*-xylene, toluene, and benzene as well. Spectral data are listed in Tables 2 and 4. Where complex formation is not essentially complete, proton and carbon chemical shifts are not listed since these would be average values for the mixture of free and complexed hydrocarbon. Neither SnF_2 nor SnF_4 react with NOF or NOCl in SO_2 suspension. $(NO)_2SnF_6$, prepared from SnF_4, BrF_3, and NOCl (26), appears to react, at least partially, with benzene and the other aromatic hydrocarbons. Spectral data are listed in Tables 2 and 4. Reactions with TiX_4 are essentially similar to those with SnX_4 and their spectral parameters are also listed in Tables 2 and 4.

Complexes with fluorine in the anions appear to form more

$(NO)_2TiF_6$·hexamethylbenzene	47.0

readily than those which only contain chlorine ligands. Thus $NOBF_4$ is brought into solution by *p*-xylene, mesitylene, and hexamethylbenzene to form a complex, but $NOBCl_4$ is not. Reasonably complete complex formation is observed with $(NO)_2SnCl_4F_2$ and toluene, but with $(NO)_2SnCl_6$ mesitylene is required for a complex of similar strength.

It is reasonable to assume that the displacement to lower field of the chemical shift for the ring protons and carbon atoms in the charge transfer complexes, compared to the uncomplexed hydrocarbon, is probably larger when there is greater electron transfer. This displacement increases from 0.62 for the aromatic protons of benzene to 0.72 for toluene, 0.70 for *p*-xylene, and 0.77 for mesitylene. A similar trend is found in the 7.9-ppm displacement of the aromatic carbons in $NOAlCl_4$·benzene to 18.9 ppm for $NOAlCl_4$·hexamethylbenzene. For a given hydrocarbon the extent of the shift of λ_{max} to longer wavelength is taken as an indication of the strength of complex formation within this series. Although the equilibrium constant for complex formation of an aromatic hydrocarbon is much greater with $NOMCl_4$ than with tetracyanoethylene, the long wavelength shift of the absorption maximum is greater with the tetracyanoethylene complexes. The difference in the maxima between free and complexed hydrocarbon decreases for the $NOMCl_4$ complexes from benzene at 670 Å to hexamethylbenzene at 560 Å, while for the tetracyanoethylene complexes it increases from 1.160 Å for benzene to 2.670 Å for hexamethylbenzene. These results suggest a slightly different origin for the charge transfer band in the two series of complexes.

From these considerations one may conclude that within Group III the order of complex formation is $NOAlCl_4$>$NOGaCl_4$>$NOTlCl_4$>$NOBF_4$. It appears that the species $NOMCl_4$; M = Al,Ga,Tl, form stronger complexes than $(NO)_2MX_6$; M = Si, Ge, Sn, Ti, X = Cl,F, since only the former have strong complexes with benzene. Within Group IV, titanium and tin complexes are of approximately equal strength, with those of germanium being weaker, and those of silicon still weaker. There is therefore a very significant effect of the anion upon the extent of charge transfer complexation in solution for this type of compound.

There is a slight decrease in nuclear magnetic resonance frequency on going from MCl_3 to MCl_4^- where M is boron or gallium, and a slight increase for aluminum. Similar shifts are observed upon reaction of BCl_3 or $AlCl_3$ with NOCl, but there is a very large gallium resonance change from $GaCl_3$ to $NOGaCl_4$ and its complex with benzene. There is no obvious explanation for the different behaviour of the gallium resonance since the proton and carbon resonances and uv spectra of its benzene complex are similar to those with aluminum and thallium.

The moisture sensitivity of all of these complexes was such that meaningful infrared spectra could not be obtained. We were also unable to grow adequate quality crystals of these compounds for single crystal X-ray structure determinations. No

ternary complexes were observed with hexamethylbenzene, $TiCl_4$ and NO, NO_2, $SOCl_2$, $POCl_3$, ICl_3, and SCl_4.

Received June 27, 1985

A. Martin de P. Nicholas and Donald R. Arnold. Can. J. Chem. **64**, 270 (1986).

Electron spin resonance (esr) hfc values of π-radicals are found to be linearly related to the stabilization energy due to spin delocalization. Application of this relationship to benzyl radicals permits the representation of $\sigma^{\cdot}_{\alpha}$ values on an energy scale. Mulliken charges in the α- and β-spin systems are found to provide valuable information about factors governing the effects of substituents on spin delocalization in benzyl radicals. These effects can be rationalized by considering four types of spin–spin interactions involving σ- and π-electrons in the α- and β-spin systems. The Mulliken analysis shows that all substituents are stronger π α-acceptors (or weaker π α-donors) at the *para* position relative to the *meta* position. Similarly, in the β system the *meta* derivatives are the better acceptors. This may be understood in terms of the excess of π α-spin at the *para*-carbon and the excess of π β-spin at the *meta*-carbon. Similar effects are observed in the σ framework.

A. Martin de P. Nicholas et Donald R. Arnold. Can. J. Chem. **64**, 270 (1986).

On a trouvé que les valeurs de chf de la rpe des radicaux π sont reliés d'une façon linéaire avec l'énergie de stabilisation due à la délocalisation du spin. L'application de cette relation aux radicaux benzyles permet de représenter les valeurs $\sigma^{\cdot}_{\alpha}$ sur une échelle d'énergie. On à trouvé que les charges de Mulliken des systèmes de spin α et β fournissent des informations utiles concernant les facteurs gouvernant les effets des substituants sur la délocalisation des spin dans les radicaux benzyles. On peut rationaliser ces effets en considérant quatre types d'interactions spin–spin impliquant des électrons σ et π dans les systèmes de spin α et β. L'analyse de Mulliken montre que, par rapport aux substituants en position *méta*, tous ceux qui sont en position *para* sont des accepteurs -απ plus forts (ou des donneurs -απ plus faibles). De la même manière, dans les systèmes substitués en β, les dérivés substitués en *méta* sont de meilleurs accepteurs. On peut comprendre ceci en fonction d'un excès de spin-α π sur le carbone en *para* et d'un excès de spin-β π sur le carbone *méta*. On observe des effets similaires dans le cadre des électrons σ.

[Traduit par le journal]

Introduction

The dominant interaction of the unpaired electron in a π-radical is with the electrons paired in the π-bonds. Such interactions are characterized by the delocalization of the spin throughout the π system. The resulting spin density distribution is apparent from the electron spin resonance (esr) spectrum of these species. The esr hyperfine coupling constants (hfc's) reflect this delocalization of the unpaired electron and, intuitively, should be related to the stabilization energy of these radicals. Thus, we proposed the $\sigma^{\cdot}_{\alpha}$ scale, based on esr hfc's of the benzylic hydrogens, which should indicate the effect of ring substituents on the delocalization, and therefore the stabilization, of benzyl radicals (1, 2). This substituent parameter scale is defined by eq. [1].

$$[1] \quad (\sigma^{\cdot}_{\alpha})_X = 1 - (\alpha\text{-hfc}_X) / (\alpha\text{-hfc}_H)$$

where α-hfc is the hfc due to the hydrogens at the benzylic position and the subscript indicates the substituent.

Values of $\sigma^{\cdot}_{\alpha}$ can be used in Hammett type linear free-energy relationships to assess the relative importance of variation in spin density on reaction rates and equilibrium. Although correlation of the rate of reaction, for example, with $\sigma^{\cdot}_{\alpha}$ indicates benzyl radicals are involved, and the magnitude of the reaction constant, $\rho^{\cdot}$, assesses the relative importance of the variation in benzyl radical stabilization on the rate of reaction, it has not been possible, up to now, to quantitatively evaluate $\rho^{\cdot}$ values on an absolute energy scale (1).

In this paper, we describe how esr hfc's and experimentally determined rotational barriers (V_2) can be used to quantitatively assess the effects of substituents on the π-stabilization of benzyl radicals due to spin delocalization (SE(R$^{\cdot}$)). Accordingly, we will not include contributions from other stabilizing interactions in our assessment of radical stability. Hence, these SE(R$^{\cdot}$) values will differ significantly from other SE values based on the total stabilization of the open-shell species, R$^{\cdot}$. For example, in polyenyl radicals SE(R$^{\cdot}$) will be, by our definition, the *additional* stabilization conferred on the radical on account of spin delocalization.

In closed-shell species, a Mulliken population analysis (3, 4) permits an understanding of the charge interactions present in the molecule. We have found such an analysis to be useful in rationalizing interaction energies in benzenoid systems (5). Here, we apply such an approach to substituted benzyl radicals. Mulliken charges in the α- and β-spin systems are used to make a semiquantitative analysis of the interactions governing the stability of a radical.

Details of calculations

Standard single determinant MO theory was used. The *ab initio* MO calculations described were obtained by the use of the GAUSSIAN 76 program (6) on a Control Data CYBER 170-730 system. The open-shell, spin-unrestricted (UHF) procedure was employed (7) to compute the energies of the benzyl radicals with the benzyl group coplanar with the phenyl ring. The minimal STO-3G basis set (8) was used. Partial geometry optimizations, subject to imposed symmetry constraints, were performed. A standard phenyl ring (optimized values for benzene) with hexagonal symmetry was assumed in every case (9). The parameters used for the STO-3G calculation were r_{CC} = 1.38669 Å and r_{CH} = 1.08258 Å (9).

Geometry optimizations were carried out at the STO-3G level (10). The r_{CH} of the CH_2 group for X=H was assumed for all the substituted radicals because the optimization of this parameter for the substituents, X = H, *meta*-F, *para*-F, *meta*-CN,

and *para*-CN, in the coplanar form of $XC_6H_4CH_2$ affected the total energy by less than 0.03 kJ mol^{-1}. Model CH_3 groups (r_{CH} = 1.09 Å and <HCH = 109.47°) were used for the methyl and methoxy substituents. For the methoxy radicals, the orientation of the OMe group with the C—O bond perpendicular to the ring was found to be more stable than when it was coplanar with the ring.

Except in the cases mentioned above, all other geometrical parameters of the substituent and the CH_2 group were optimized. The STO-3G total energies are listed in Table 1.

Results and discussion

Relationship between π-stabilization energy and esr hfc's of π-radicals

The π-stabilization energy of a π-radical, SE(R$^\cdot$), is given by eq. [2]:

$$[2] \quad SE(R^\cdot) = V_2(CH_2) - V_2^* \qquad \text{(1)}$$

where $V_2(CH_2)$ and V_2^* are the rotational barriers of the $CH_2^\cdot$ group of the radical $R^\cdot = ZCH_2^\cdot$, in the presence and absence of spin delocalization, respectively (11, 12). In this section, we investigate the relationship between SE(R$^\cdot$) and the α-hfc of the methylene hydrogens for a series of π-radicals. The relevant data are listed in Table 2; the radicals are arranged in the order of decreasing α-hfc's.

The first radical considered is a hypothetical π-radical with a SE(R$^\cdot$) of zero. The α-hfc of this species is equal to the Q value given by the McConnell relationship (13).

$$[3] \quad \alpha\text{-hfc} = Q\rho \qquad \text{(2)}$$

where ρ is the π spin density, unity in this case. This Q value is obtained conveniently as the algebraic sum of the hyperfine coupling constants of the allyl radical (13*b*). It is interesting to note that the Q value derived in this way is in excellent agreement with the α-hfc of the methyl radical, in a planar conformation, corrected for vibrational effects (14).

The α-hfc and SE(R$^\cdot$) values for the acetylmethyl (15) and allyl (11) radicals were available in the literature. The SE(R$^\cdot$) for the benzyl radical was assumed to be equal to that of the phenethyl radical (16). Such an assumption is reasonable because the hfc for the benzylic (α) and *para*-hydrogens are approximately the same in the two radicals (17).

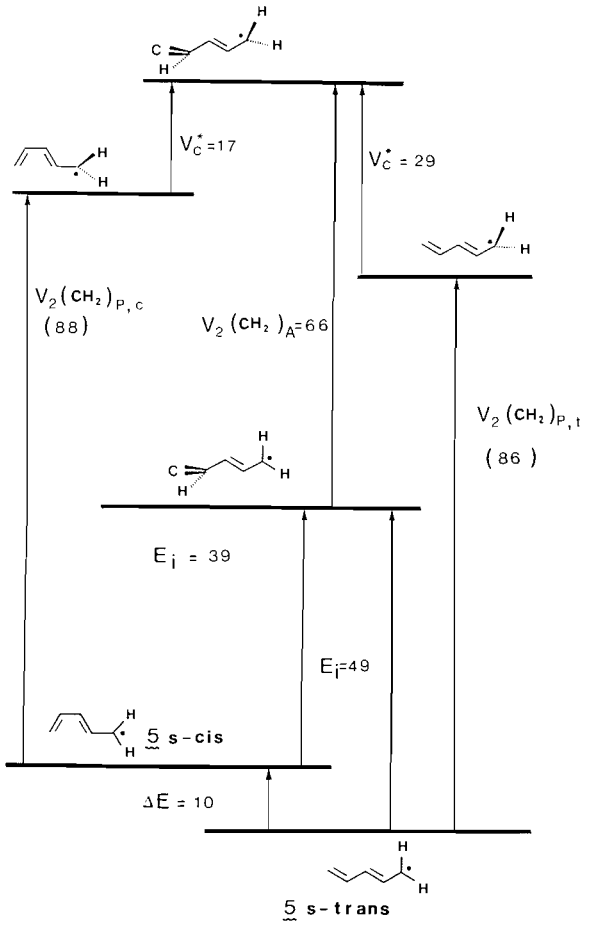

FIG. 1. A schematic representation of the relationship between the π-stabilization energy due to spin delocalization (SE(R$^\cdot$)) and the activation barrier for the terminal s-*cis* s-*trans* isomerization in the pentadienyl radical. Values are given in units of kJ mol^{-1}.

In the pentadienyl and heptatrienyl radicals a direct determination of SE(R$^\cdot$) from eq. [2] is at present not feasible. Here we will show how these SE values may be estimated using the thermochemical cycle illustrated in Fig. 1 for the pentadienyl radical.

From Fig. 1 we get:

$$[4a] \quad V_2(CH_2^\cdot)_{P(t)} = E_i(t \rightarrow c)_P + V_2(CH_2^\cdot)_A - V_c^*(t \rightarrow c)_P \qquad \text{(3)}$$

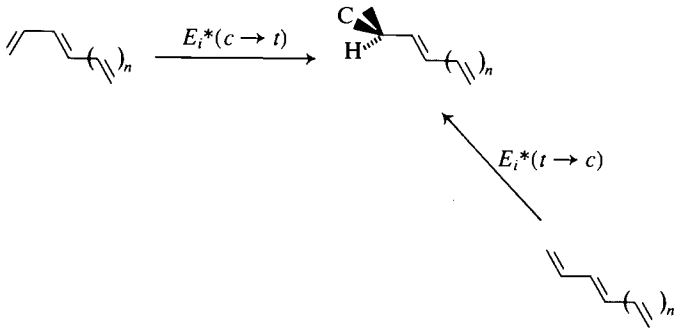
$$[4b] \quad V_2(CH_2^\cdot)_{P(c)} = E_i(c \rightarrow t)_P + V_2(CH_2^\cdot)_A - V_c^*(c \rightarrow t)_P \qquad \text{(4)}$$

Substitution of eq. [2] in eq. [4] gives:

$$[5a] \quad SE(R^\cdot)_{P(t)} = E_i(t \rightarrow c)_P + SE(R^\cdot)_A - V_c^*(t \rightarrow c)_P \qquad \text{(5)}$$

$$[5b] \quad SE(R^\cdot)_{P(c)} = E_i(c \rightarrow t)_P + SE(R^\cdot)_A - V_c^*(c \rightarrow t)_P \qquad \text{(6)}$$

where the subscripts P and A denote the pentadienyl and allyl radicals, respectively, and *c* and *t* correspond to the s-*cis* and s-*trans* forms of the pentadienyl radical, respectively. Values of E_1, the barrier to rotation of the terminal double bond about the C_2—C_3 bond, have been determined by esr spectroscopy (12). V_c^* corresponds to the E_i value in the perpendicular form of the radical. Since the $CH_2^\cdot$ group is orthogonal to the π system in this conformation, the V_c^* barrier is analogous to the E_i^* barrier in the following isomerization of closed-shell polyenes.



Hence,

[6a] $E_i^*(c \rightarrow t)_n = V_c^*(c \rightarrow t)_n$

[6b] $E_i^*(t \rightarrow c)_n = V_c^*(t \rightarrow c)_n$

where the pentadienyl and heptatrienyl radicals correspond to $n = 0$ and 1, respectively. For $n = 0,1$ and 2, values of $E_i^*(c \rightarrow t)$ and $E_i^*(t \rightarrow c)$ of 17 and 29 kJ mol^{-1} have been reported (18).

From eqs. [5] and [6], we get values of 82 and 84 kJ mol^{-1} for the $SE(R^{\cdot})_{P(t)}$ and $SE(R^{\cdot})_{P(c)}$, respectively. The difference of 10 kJ mol^{-1} in the heat of formation for the two forms of this radical is approximately equal to the corresponding difference of 12 kJ mol^{-1} in the closed-shell polyenes. That is, while the π-stabilization due to spin delocalization is the same for the two forms of the pentadienyl radical, the ΔH^0_f values differ on account of greater steric interaction in the *cis* form. Accordingly, we may assume that in general, for a polyenyl radical (X),

[7] $SE(R^{\cdot})_{X(c)} = SE(R^{\cdot})_{X(t)} = SE(R^{\cdot})_X$

In the heptatrienyl radical, using arguments discussed above, we can write equations similar to eqs. [5*a*] and [5*b*]:

[8] $SE(R^{\cdot})_{H(t)} = E_i(t \rightarrow c)_H + SE(R^{\cdot})_{P(t)} - V_c^*(t \rightarrow c)_H$

[9] $SE(R^{\cdot})_{H(c)} = E_i(t \rightarrow c)_H + SE(R^{\cdot})_{P(c)} - V_c^*(c \rightarrow t)_H$

where the subscript H denotes the heptatrienyl radical. An upper limit of 35 kJ mol^{-1} has been evaluated for $E_i(c \rightarrow t)_H$ using the esr method and, since $SE(R^{\cdot})_{P(c)}$ and $V_c^*(c \rightarrow t)_H$ are known, a $SE(R\cdot)_H$ value of 102 kJ mol^{-1} is obtained from eqs. [7] and [9].

The *linear* relationship between the α-hfc of the methylene hydrogen and the π-stabilization energy, plotted in Fig. 2, is represented well ($r = 0.997$) by:

[10] $SE(R^{\cdot})$ (kJ mol^{-1}) $= 145 \pm 3 - (5.75 \pm 0.20)$ α-hfc (G)

It is interesting to note that the magnitude of the intercept in Fig. 2 is equal to half the π-bond energy in ethylene. We can rationalize this observation in the following way: spin delocalization is in essence the interaction of α-spin with β-spin. This interaction is at a maximum for the formation of the π-bond of ethylene from two $CH_2^{\cdot}$ moieties, with unit spin density on each of the carbons. The intrinsic energy of this π-bond is equal to twice the stabilization resulting from the complete "delocalization" (that is, bonding, in this case) of an unpaired electron in a π framework. Consequently, such "delocalization" results in zero residual spin on the carbons. Hence the $SE(R^{\cdot})$ value of a hypothetical π-radical with a zero α-hfc should be equal to half the intrinsic energy of the π-bond in ethylene, as is observed.

Green and Walton have alternatively suggested that $SE(R^{\cdot})$ is dependent upon the *logarithm* of α-hfc (12). We favour the inverse linear relationship for several reasons. The correlation coefficient for the linear plot in Fig. 2 is excellent ($r = 0.997$), significantly better than for the alternative logarithmic relationship ($r = 0.97$). Furthermore, there is a fundamental inconsistency in the SE values derived by Green and Walton that causes us to question the validity of their analysis. For the pentadienyl and heptatrienyl radicals they have derived a total π-stabilization energy, SE(total), that includes contributions from factors other than spin delocalization. Consequently, this leads to an artificial increase in the SE values in these two species relative to the other radicals. For example, the SE(total) for the benzyl radical corresponds to the sum of $SE(R^{\cdot})$ and the intrinsic aromatic stabilization present in the benzyl radical with the $CH_2^{\cdot}$ group perpendicular to the ring. While such SE(total) values may be of

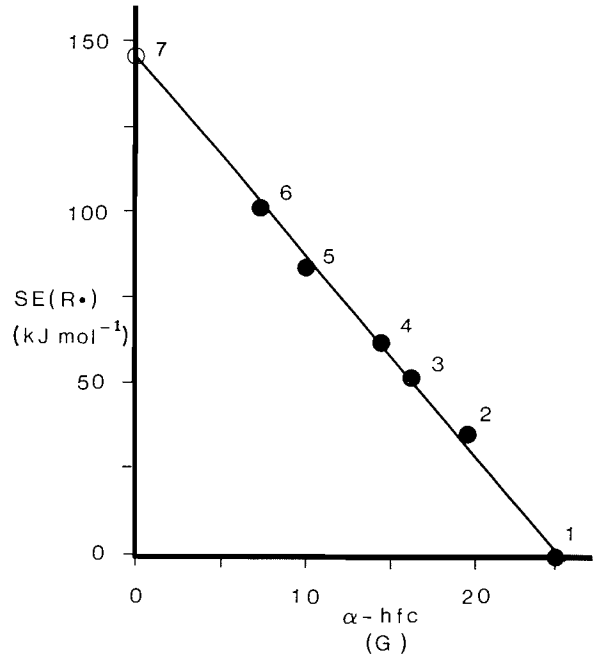


FIG. 2. A plot of the π-stabilization energy ($SE(R^{\cdot})$) versus the esr hfc of α-H of the CH_2 group (α-hfc) in π-radicals of the form $ZCH_2^{\cdot}$. Points are numbered according to Table 2. The correlation coefficient for the line, including points 1–6, is $r = 0.997$.

interest, we believe that attempting to relate these energy quantities to hfc's is unwarranted, and can lead to erroneous conclusions. This is so because SE(total) values include stabilizing interactions not dependent on the unpaired spin distribution, which can vary significantly from one system to another without a concomitant change in the hfc.

It is also significant that the result for the acetylmethyl radical is in agreement. The apparent discrepancy between the SE value for this radical (15) and the bond dissociation enthalpy value (DH^0) for acetone (19) is not surprising, since the stability of the radical is only one factor affecting DH^0 (20).

Application to benzyl radicals

Applications of eqs. [1] and [10] to benzyl radicals gives:

$$[11]\quad \delta SE(R^\cdot) = K\,\sigma^\cdot_\alpha$$

where δSE(R˙) is the substituent effect, relative to hydrogen, on the π-stabilization energy of a benzyl radical, and K is a constant. This definition of benzyl radical stability, eq. [11], focuses only on substituent effects involved directly with variations in spin density at the benzylic position. This approach has been adopted because we are primarily interested in correlating relative stability to reactivity involving the benzylic radical, and in assessing ρ˙ values on an energy scale.

A reduction of the α-hfc of a benzyl radical by 1.0 G corresponds to an increase in stabilization of ca. 6 kJ mol^{-1}, or, one $\sigma^\cdot_\alpha$ unit is equivalent to 93 kJ mol^{-1}. The range of known $\sigma^\cdot_\alpha$ values (1), from *para*-thiomethyl (0.063) to *meta*-cyano (−0.026) represents a variation in benzyl radical stability of 8 kJ mol^{-1}.

This analysis now allows a more quantitative evaluation of the significance of ρ˙ values. For example, the ρ˙ for the thermal isomerization of 2-aryl-3,3-dimethylmethylenecyclopropane (1,21) indicates that this rearrangement is only about half as sensitive to substituent effects as is the benzyl radical. This, of course, assumes that the entropy of the reaction is unaffected by substitution.

Relationship between Mulliken charges and $\sigma^\cdot_\alpha$ values

Table 3 lists σ and π charges donated (or withdrawn) by the substituent and the CH_3 group of monosubstituted toluenes. Table 4 lists σ and π charges donated (or withdrawn) by the substituent and the CH_2 group of the analogous benzyl radicals in the coplanar conformation. These calculated charge effects reflect interactions resulting only from charge redistribution (5); spin redistribution is not taken into account. For example, the group charges for the benzyl radicals (Table 4) are smaller than those observed for he corresponding toluenes (Table 3), but the isodesmic interaction energies are generally larger in the benzyl radicals (Table 5). This is because spin related effects are not included in the charge analysis in Table 4.

Table 4 shows that the net charge effect on the radical is similar to that in closed-shell systems, for all substituents. For example, the net charge effect of both *meta*- and *para*-cyano

TABLE 5. Substituent effects on isodesmic interaction energies (ΔE) in benzyl radicals and toluenes

substituents is strong π and σ withdrawal. However, the ability of these substituents to delocalize spin from the benzylic position is very different in nature (1). It is useful, therefore, to examine whether a better understanding of the effects of spin delocalization in benzyl radicals can be obtained by separating the total charge effect into the individual contributions from the α- and β-spin systems.

Table 6 shows the effects of substituents on interactions involving Mulliken α-charges. These charges are essentially estimates of α-spin donation (or withdrawal) by a group attached to the phenyl ring. The benzylic group is shown to be a strong π α-spin donor and σ α-spin acceptor. Thus, substituents that are strong π α-spin acceptors and σ α-spin donors favourably interact with the benzyl group and stabilize the radical.

Table 7 shows the effects of substituents on interactions involving Mulliken β-charges. The benzylic group is shown to be a strong π β-spin acceptor and σ β-spin donor. Consequently, substituents that are strong π β-spin donors and σ β-spin acceptors should favourably interact with the benzyl group and stabilize the radical.

Next, we compare this Mulliken population analysis of the α- and β-spin systems with the relevant $\sigma^{\cdot}_{\alpha}$ values for several substituents.

Cyano substituent

The $\sigma^{\cdot}_{\alpha}$ values indicate that this substituent very effectively delocalizes spin when in the *para* position and localizes spin (relative to hydrogen) when in the *meta* position (1). This behaviour is described well by the Mulliken analysis; while *para*-cyano shows stabilizng interactions, *meta*-cyano displays destabilizing interactions with the benzylic groups in both spin systems.

Depending on the electron demand of the benzylic group, the nature of the substituent can vary significantly from that observed in closed-shell systems. Thus, while the cyano substituent is usually considered a strong π acceptor, reflected by a large positive σ-value, in a benzyl radical this group acts as a π α-donor in the *meta* position and a π β-donor in the *para* position. Furthermore, the calculated dipole moments of the cyano substituted benzyl radical and toluene, listed in Table 8, also indicate that the nature of the cyano substituent is very different in the two systems.

Methoxy substituent

This group strongly delocalizes spin in the *para* position (1). From Tables 6 and 7 it is apparent that *para*-methoxy has a positive $\sigma^{\cdot}_{\alpha}$ value because of stabilizing interactions in the β-spin system. This substituent has similar types of interactions at the *meta* position, but, now the destabilizing interactions in the α-spin system dominate to make this radical slightly destabilized relative to the unsubstituted benzyl radical (1). All π effects involving the lone pair of electrons require rehybridization of the electronegative oxygen atom and consequently will be susceptible to effects caused by σ interactions. In fact, in comparison to the cyano substituent, the methoxy derivatives show larger σ effects. The calculations show that the most stable orientation of the methoxy group is with the C—O bond perpendicular to the phenyl ring. Thus, C—O type hyperconjugative spin delocalization is possible. It is clear that the effect of this substituent, although usually regarded simply as a two-centre–three-electron interaction, is actually the net result of both σ and π effects in the α- and β-spin systems.

Fluoro substituent

Fluoro is one of the few substituents with a destabilizing interaction at all positions (Table 9). The population analysis

suggests that this is due to the destabilizing interaction in the α-spin system, which more than compensates for the stabilizing effects in the β-spin system. Although both fluoro and methoxyl act as β donors in closed-shell species, their behaviour in the benzylic radical is very different. This results from weaker π and stronger σ effects in the fluoro substituted radicals.

The charge/spin analysis predicts that the behaviour of this substituent should be similar at the *para* and *ortho* positions, as observed in their esr spectra.

Methyl substituent

The $\sigma^{\cdot}_\alpha$ value is positive for this group at both the *para* and *meta* positions, although, at the *meta* position the stabilizing effect is very small (0.002 ± 0.003). The Mulliken analysis correctly predicts that the methyl group will delocalize spin strongly at the *para* position, but the *meta*-methyl group is shown as destabilizing in both spin systems. However, *meta*-methyl is a weaker σ β-donor than *meta*-hydrogen. Thus, the σ β-interaction in *meta*-methyl will be stabilizing relative to the unsubstituted benzyl radical; this may account for the mild stabilizing power of this substituent. The magnitude of the π-charge effects of this substituent are relatively small, and hence may change in sign on small perturbations. Furthermore, the assumption of equal partitioning, intrinsic to the Mulliken scheme, may cause incorrect assignments of charges to be made in this case.

The chemistry of peptides related to metabolites of *Trichoderma* Spp. 3. An unusual dehydration reaction of 2-methylalanine peptides after electron impact ionization[1]

W. D. JAMIESON AND A. TAYLOR[2]

National Research Council of Canada, Atlantic Research Laboratory, Halifax, N.S., Canada B3H 3Z1

Received June 27, 1985

W. D. JAMIESON and A. TAYLOR. Can. J. Chem. **64**, 277 (1986).

Peptides of 2-methylalanine, where this residue is not the C-terminus, give molecular ions of low abundance on electron impact ionization, but abundant ions are formed by loss of the elements of water from the molecular ion. The dehydration reaction does not occur in permethylated derivatives, nor under the milder ionization conditions in the chemical ionization source. The reaction does not appear to be time or temperature dependent, but depends on the steric hindrance of the NH group of the 2-methylalanine residue. The reaction occurs at sites where 2-methylalanine is not the C-terminal amino acid. In the cases of two pentapeptides where the dehydration reaction was of high probability, the correct sequence was found by semi-quantitative measurements of reaction rates in the first field-free region of a double focussing mass spectrometer.

W. D. JAMIESON et A. TAYLOR. Can. J. Chem. **64**, 277 (1986).

Lors de la spectrométrie de masse par ionisation sous impact électronique, les peptides de la méthyl-2 alanine, dans lesquels ce résidu n'est pas C-terminal, donnent des ions moléculaires dont l'abondance relative est faible; toutefois, il se forme des ions abondants par la perte des éléments de l'eau à partir de l'ion moléculaire. La réaction de déshydratation ne se produit pas ni avec les dérivés perméthylés ni avec les conditions d'ionisation plus douces prévalentes lors d'ionisations chimiques. Il ne semble pas que la réaction dépende du temps ou de la température; toutefois, elle dépend de l'empêchement stérique du groupement NH du résidu de la méthyl-2 alanine. La réaction se produit à des sites où la méthyl-2 alanine n'est pas l'acide aminé C-terminal. Dans les cas de deux pentapeptides pour lesquels la réaction de déshydratation était très probable, on a pu établir la séquence correcte en effectuant des mesures semi-quantitatives de vitesses de réactions dans la première région sans champ d'un spectromètre de masse à double focalisation.

[Traduit par le journal]

Some aspects of the chemistry of the complex fungal metabolites containing 2-methylalanine moieties have been reviewed in a recent paper (1). Although these metabolites are resistant to catalytic hydrolysis by peptidases (2), there is a considerable body of evidence which can best be interpreted by assuming that they are polypeptides (3). Foremost among this evidence are mass spectroscopic studies on degradation products obtained by acid hydrolysis of metabolites (4). More recently, use of fast atom bombardment (FAB) sources has provided impressive mass spectroscopic data, which has thrown light on the structure of several of the natural products (5). By contrast, mass spectroscopy of some *N*-acyl derivatives of synthetic peptides of 2-methylalanine gave anomalous results in the sense that molecular ions were not observed (6). For example, methyl L-prolyl-L-valyl-2-methylalanyl-2-methylalaninate (6), examined directly or as its *N*-chloroacetyl, *N*-trifluoroacetyl, *N*-deuterioacetyl, or phenylmethoxycarbonyl derivative, did not provide a detectable molecular ion, nor fragment ions of high molecular weight that could be attributed to well-known ion reactions, e.g. $(R.COX.R')^+ \rightarrow R.CO^+$ or R^+ (X=O, NH). Examination of these spectra suggested that ionization preferentially occurred at the N-terminal acyl group and resulted in loss of the marker group, thus making the spectra complex. A further disadvantage of these N-terminal groups emerged when it was found that they were either unstable under permethylation conditions (7), or underwent *C*-methylation.

In an attempt to overcome these problems we investigated the mass spectroscopy of *N*-4-bromobenzoyl and *N*-4-chlorobenzoyl derivatives of the tetrapeptide mentioned in the previous paragraph. These groups were chosen because the natural abundances of the bromine and chlorine isotopes are well established (8), thus making them eminently suitable as markers. In addition, it seemed likely that they would survive permethylation without elaboration or degradation. Part of the electron impact mass spectrum of the tetrapeptide (**4**, R = 4-Br.C_6H_4CO) is shown in Fig. 1A. If one disregards the presence of protonated species, there are only 5 pairs of isotopic pairs, each of the 5 pairs being separated by 28 (31) mass units. Going down the mass scale, they represent the sequential loss of $NH.CMe_2CO_2Me$; $NH.CMe_2CO$; $NH.CH(C_3H_7).CO$; and $N(C_4H_7)CO$. The ions of m/z 538, 540 probably arise by loss of the valine side chain by the mechanism previously proposed (9); clearly this reaction is of low probability in this case. Omitted from Fig. 1A are prominent doublet metastable ions corresponding to the fragmentations (only ^{79}Br species given): $581^+ \rightarrow 549^+ + 31$; $549^+ \rightarrow 464^+ + 85$; $464^+ \rightarrow 436^+ + 28$; $436^+ \rightarrow 379^+ + 57$; $379^+ \rightarrow 280^+ + 99$; $280^+ \rightarrow 252^+ + 28$; and $252^+ \rightarrow 183^+ + 79$. However, as can be seen in Fig. 1A, the spectrum is complicated by the presence of protonated species of all the major ions, leading to uncertainty as to the molecular weight and difficulty in interpretation of ion reactions in the first field-free region of the mass spectrometer (see below). Though such protonated ions are present in published spectra of many aromatic bromo compounds (10), they (as far as we know) have excited little comment, despite the presence in our MS-50 spectra of prominent metastable species indicating the reactions: $(R+H)^+ \rightarrow R^+ + H$.

The mass spectrum of the tetrapeptide (**4**, R = 4-Cl.C_6H_4.CO) is shown in Fig. 1B for comparison. The spectrum is clearly very similar, but it is complicated by the presence of protonated species only in the cases of the M^+ and $(M-31)^+$ ions, where they are of relatively low abundance. This result, together with the known (11) greater stability of aromatic chloro groups in the electron impact ionization source, led us to restrict our studies to this marker group.

The pentapeptide **9** (6) has an abnormal ^{13}C nmr spectrum, because ^{13}C signals due to only one conformer of the proline ring are observed. We thought, based on the promising results

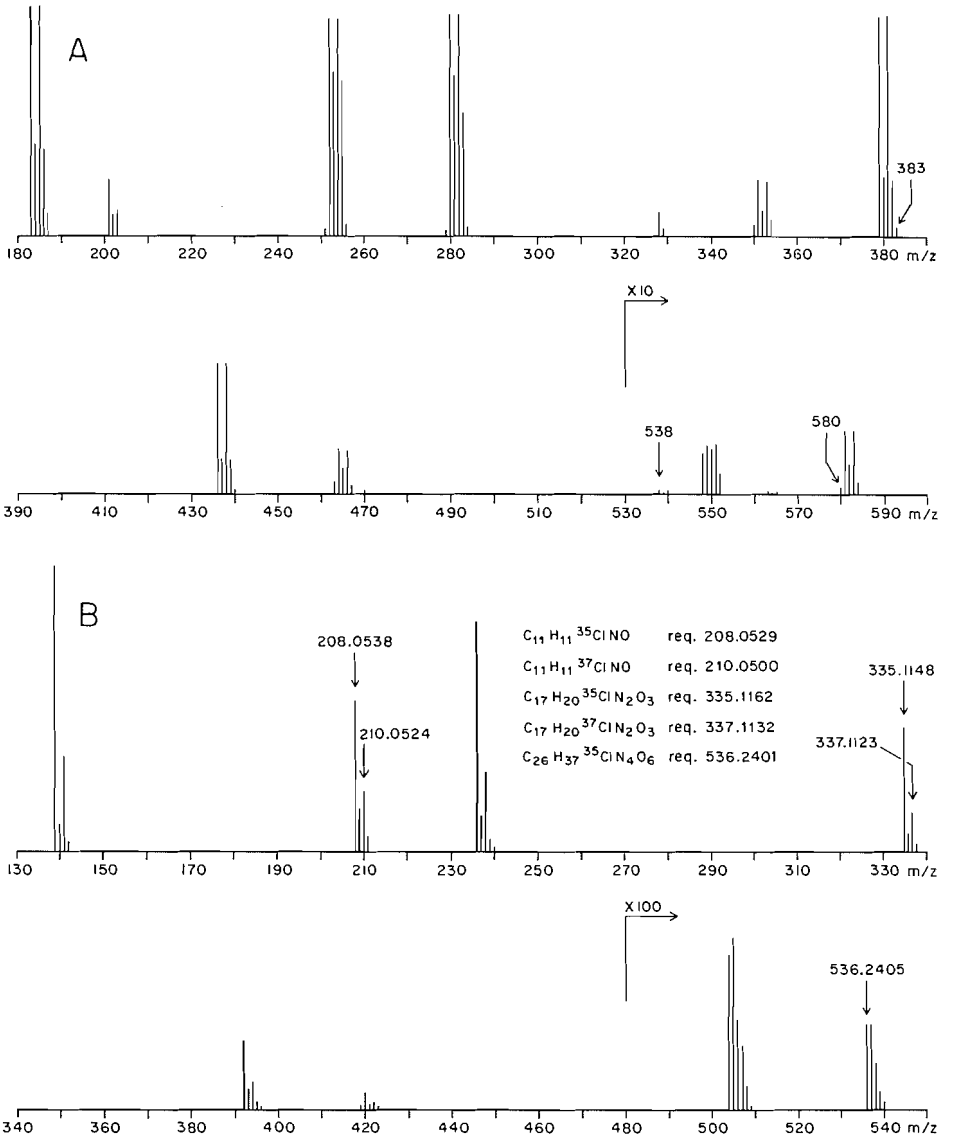

FIG. 1. Electron impact ionization mass spectrum of methyl *N*-4-bromobenzoyl-L-prolyl-L-valyl-2-methylalanyl-2-methylalaninate. Ions of lower abundance than those at m/z 538 and all metastable ions have been omitted. B. Mass spectrum of methyl *N*-4-chlorobenzoyl-L-prolyl-L-valyl-2-methylalanyl-2-methylalaninate (**4**, R = ClC_6H_4CO).

described in the previous paragraph, that this structural uncertainty might be resolved by an examination of its mass spectrum. To our surprise, the mass spectrum shown in Fig. 2A was obtained. The abundances of the group of ions at m/z 561, 562, 563, 564, and 565 were consistent with the view that m/z 561 was a molecular ion instead of that expected at m/z 579^+. No ion reaction $579^+ \rightarrow 561^+ + 18$ could be demonstrated in the first field-free region of the mass spectrometer, and although an ion of m/z 579 could be detected at high gain its intensity was, on average, only about 2% of the ion at m/z 561. Further, the ratio of abundances of ions at m/z 579 and 581 did not correspond to that expected for ions of the elemental compositions $C_{27}H_{38}{}^{35}ClN_5O_7$ and $C_{27}H_{38}{}^{37}ClN_5O_7$. Permethylation of this compound gave a single product as determined by chromatography, but the expected ions at m/z 635, 637 were not observed (Fig. 2B). The question of the structure of the peptide **9** was unequivocally solved by X-ray crystallographic analysis (12), thus demonstrating that the mass spectrum of **9** (Fig. 2A) was anomalous.

Mass measurement of the ions at m/z 561, 563 revealed that they differed from that expected for the peptide **9** in elemental composition by the elements of water. Dehydration of peptides containing serine, threonine, asparagine, and (or) glutamine residues in the electron impact ionization source of the mass spectrometer is common (13), but we know of no precedent for the experimental results given in Fig. 2A.

It was decided, therefore, to investigate the question of whether this dehydration reaction was an anomaly characteristic only of **9** or whether it was an example of a more general phenomenon.

To this end a number of compounds have been synthesized; the syntheses have either been reported or are to be found in the experimental section. All of the compounds were crystalline, had sharp melting points, and on elemental analysis gave results within experimental error. All were homogeneous on reverse phase partition chromatography and the retention volumes measured are given in Table 1. The protected glutaminyl di- and tripeptides (e.g. **7**) were appreciably soluble in water and the

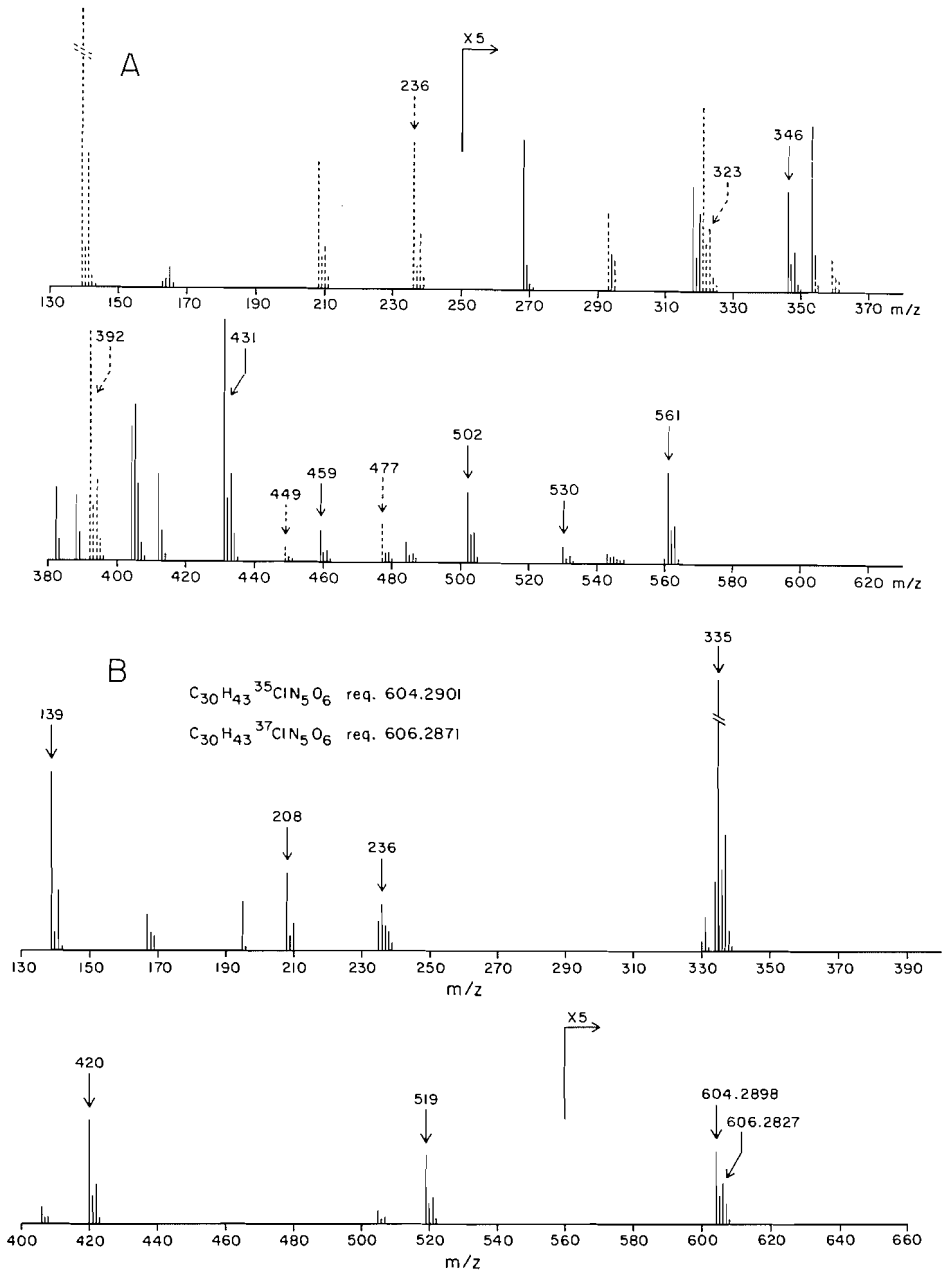

FIG. 2. A. Electron impact ionization mass spectrum of methyl *N*-4-chlorobenzoyl-L-prolyl-2-methylalanyl-L-alanyl-2-methylalanyl-L-alaninate (**9**, R = ClC_6H_4CO). Ions represented by dotted lines are expected fragments from normal C=O fissions in peptide chains; solid lines represent fragments derived from $(M - 18)^+$ or $(M - 36)^+$. B. Mass spectrum of methyl *N*-4-chlorobenzoyl-L-prolyl-*N*-2-dimethylalanyl-L-*N*-methylalanyl-*N*-2-dimethylalanyl-L-*N*-methylalaninate. Ions of <1% of the ion at *m/z* 604 have been omitted.

crystalline peptides were hydrated, the water of hydration being tenaciously held. This unexpected phenomenon was reported recently for an analogous compound (14).

The following conclusions may be drawn from the data given in Tables 1 and 2. The dehydration reaction does not occur when the C-terminal amino acid is 2-methylalanine but does occur when the C-terminal sequence is *N*-2-methylalanylglycine, *N*-2-methylalanylalanine, *N*-2-methylalanylvaline, or *N*-2-methylalanylglutamic acid. The abundances of some of the fragment ions seen in the spectra are given in Table 2. In those cases where the dehydration reaction was probable, the reaction which resulted in fission of the ester alkoxy group was always attended by the corresponding dehydrated ion. When the C-terminal group was a glutamyl diester (e.g. **6**, **7**), dehydrated ions were observed corresponding to the sequential loss of alkoxyl, carbonyl, and the two methylene moieties of the side chain.

Several of the peptides were permethylated; these are indicated in Table 1 by an entry indicating their retention volumes on partition chromatography. None of the permethylated compounds underwent the dehydration reaction and this is illustrated by a comparison of Figs. 2A and 2B. It follows that at least one of the hydrogen atoms eliminated as water in the dehydration reaction is a nitrogen substituent. The data in Tables 1 and 2 suggest that the nature of the side chain of the amino acid that *N*-acylated the 2-methylalanine residue is important in the dehydration reaction. Thus the abundance ratio $(M-18)^+/M^+$ in the case of α-methyl-γ-benzyl *N*-

10	73	45	205	1.5*
7	56	27*	630	(?)190*
5	390	55	950	4*
9	24	111	395	325
6	13	22	395	8*

Compound numerals refer to Table 1; * indicates relative intensities of the $^{35}Cl/^{37}Cl$ pairs, not natural abundance.

4-chlorobenzoylglycyl-2-methylalanylglutamate (**8**) is 23, but for the pentapeptide with the C-terminus 2-methylalanyl-2-methylalanylglutamate (**6**), the ratio is 3. The NH group between two 2-methylalanine residues is not readily exchanged (14), and in our hands cannot be methylated except under forcing conditions when C-methylation also occurs. The data in Table 1 therefore support the hypothesis that the probability of dehydration depends on the steric hindrance of the 2-methylalanyl NH group. Thus all the 6 peptide-chain atoms $^1NH.^2C(ME)_2.^3CO.^4NH.^5CH(R).^6CO$ are involved in the dehydration process.

Reference to Fig. 2A shows that the same functionality can be involved in a dehydration reaction when it is embedded in a peptide chain; for this peptide, chlorine-containing ions that have lost 2 mols of water (Fig. 2A, m/z 543) are observed, and also ions that have lost the terminal $CO.NH.CH(Me).CO_2Me$ (m/z 431) group and yet are still 18 mass units less than expected (Fig. 2A, m/z 449).

The dehydration reaction was not observed in the chemical ionization source when methane was used as the reagent gas, and the $(M-1)^+$, $(M+1)^+$, $(M+29)^+$, and $(M+41)^+$ abundance ratios ($(M+1)^+ = 100$) for a representative group of compounds are give in Table 3. Except for the glutamic acid derivative (**8**), these ratios are those expected for ionization at an ester functionality (15), but ions providing sequence information were scarce and loss of chlorine was an important competing reaction.

Thus there are difficulties in unambiguously determining the molecular weights and the sequence of amino acid residues in peptides of unknown structure containing 2-methylalanine. A possible method of surmounting these difficulties lies in using the ion fragmentation reactions that occur in the first field-free region of the CEC 21-110B mass spectrometer. In Figs. 3A and 3B are shown the results of such parent ion fragmentation experiments for the daughter ions m/z 236, 238 and m/z 280, 282, recorded in the spectra reproduced in Figs. 1B and 1A respectively.

When the curves representing the ^{35}Cl and ^{37}Cl species and

Compound numerals refer to Table 1.

the ^{79}Br and ^{81}Br analogues are compared, it is apparent that the areas under the peaks (in Figs. 3A and 3B) are in the same ratio as the ratio of the natural abundances of the isotopes. In the case of the Cl species, similar experiments (see below) to determine the parents of other prominent pairs of daughter ions in Fig. 1A also revealed that the ratio of the areas under the peaks was the same as the ratio of the natural abundance of the isotopes. In all, 10 determinations of the ratios of the areas were made and the mean value found was 2.81 ± 0.30, which compares well with the generally accepted value of 3.08 (8). Thus an estimate of the precision of the measurements can be made.

Figure 3 shows that the analogous pairs of daughter ions m/z 236, 238 and m/z 280, 282 are formed by decomposition of pairs of parent ions and that both pairs of 4 reactions are: $R.NH.CH(C_3H_7).CO^+ \rightarrow R^+ + NH.CH(C_3H_7).CO$ and $R.NH.CH(C_3H_7)^+ \rightarrow R^+ + NH.CH(C_3H_7)$. Similar unimolecular decomposition reactions were observed when the peptide **9** (R = ClC_6H_4CO) was examined. Thus the ions at 139, 141 were the daughters of parents of m/z 208, 210 and 236, 238, and the latter, in turn, were the daughters of parents $R.NH.CMe_2CO^+$ (m/z 321, 323) and $R.NH.CMe_2^+$ (m/z 293, 295). The experiments were continued, using the parents as daughter ions until no further parents could be found. In all cases it was found that the daughter ions arose preeminently from only two parent ions. The pair m/z 579, 581 had no detectable parents. The experiments, therefore, provided unambiguous sequence information.

An estimate of the probability of the reactions with respect to one another may be made by normalizing the signals of the daughter ions (e.g. see Fig. 3A) to their relative abundances in the mass spectrum (Fig. 2A). These calculations give the relative rates, in arbitary units, of the various reactions and these are summarized for the sequence $579^+ \rightarrow 548^+ \rightarrow 477^+ \rightarrow 392^+ \rightarrow 321^+ \rightarrow 236^+$ in Table 4. Also in Table 4 is given the reaction rate for the fragmentation $346^+ \rightarrow 236^+ + 110$ and it is clear that the probability of this reaction is much lower than that of the alternative: $321^+ \rightarrow 236^+ + 85$. A similar analysis applied to the pentapeptide **6** also gave the correct sequence of amino acids and demonstrated that the ions of m/z 505, 507 (= $Cl.C_6H_5CO—N(C_4H_7)CO—NH.CH(CHMe_2).CO.NH.C(Me_2).CO.NH.C(Me_2).CO^+$) were not daughters of parents of m/z 630, 632, or 661, but were derived from m/z 648, 650 and 679, 681. The method, which requires about 50 μg of sample, therefore has some promise but requires automation and application to many other examples.

N-4-Chlorobenzoylation of peptides of 2-methylalanine is a useful procedure for their characterization, since these derivatives are easy to crystallize, can be detected in the effluent from chromatograms in quantities of a few ng, and can be prepared without detectable racemization at the N-terminal amino acid residue (1). The mass spectroscopic results reported here add to the value of these derivatives, for although the spectra are complicated by dehydration reactions and by protonation, reliable sequence information can be obtained.

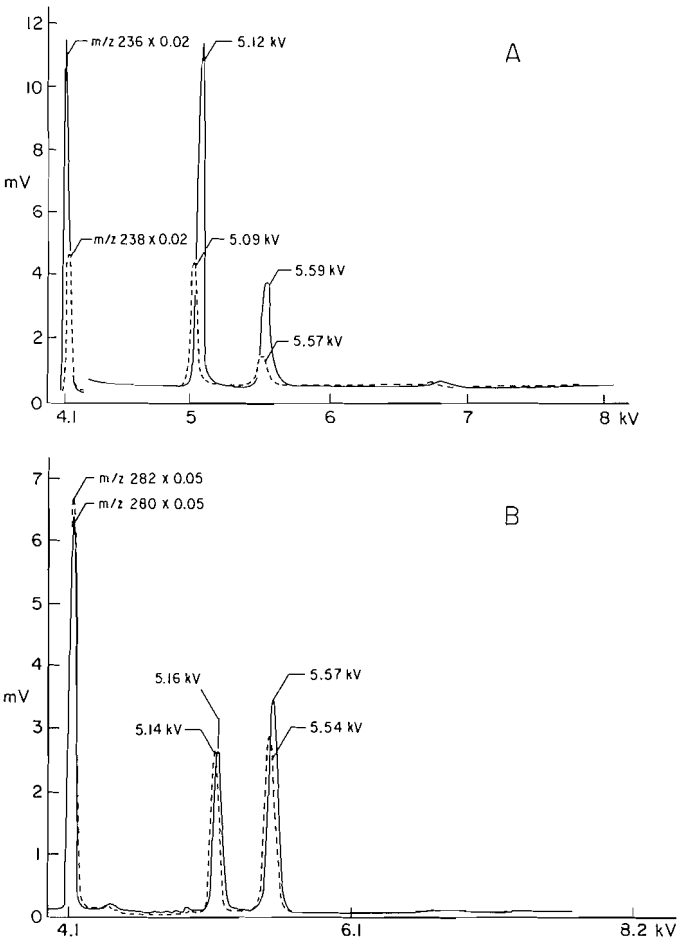

FIG. 3. A. Unimolecular ion decomposition of $Cl.C_6H_4.CO.N(C_4H_7).CO.NH.CH(C_3H_7)CO^+$ (5.59 kV) and $Cl.C_6H_4.CO.N(C_4H_7).CO.NH.CH(C_3H_7)^+$ (5.12 kV); solid line represents ^{35}Cl species and the dotted line ^{37}Cl. B. Ion decompositions of $Br.C_6H_4.CO.N(C_4H_7).CO.NH.CH(C_3H_7).CO^+$ (5.57 kV) and $Br.C_6H_4.CO.N(C_4H_7.CO.NH.CH(C_3H_7)^+$ (5.16 kV); solid line ^{79}Br, dotted line ^{81}Br. In all cases the abscissa are the accelerating voltages and the mass of the parent ions can be calculated from the formula: m/z daughter ion × p/q, where p is the acceleration voltage (kV) at which the parent ions appear and q is the voltage at which the daughter ion is observed.

Experimental

Melting points are not corrected. Infrared spectra were measured on a Perkin Elmer 238B spectrometer; samples were dispersed in potassium bromide discs. The ^1H and ^{13}C nmr spectra were measured on solutions in $C^2H_3O^2H$ using a Varian XL-100 spectrometer and the facilities at the Atlantic Region Magnetic Resonance Center, Halifax, N.S. Ultraviolet spectra were determined on solutions in methyl alcohol using a Cary 14 spectrometer. The purity of all peptides was assessed by high pressure reversed phase partition chromatography on a Dupont "Zorbax" C_8 column of dimensions 0.46 × 25 cm. All other instrumentation used for chromatography has been described in detail (16). Electron impact mass spectra were recorded on Kratos MS-50 and C.E.C. 21-110B instruments. The sensitivity of the latter instrument was enhanced[3] by using an Hamamatsu (Model R595)

[3]We are indebted to Dr. S. E. Scheppele for details of these modifications before publication.

TABLE 4. Relative rates, in arbitrary units, of ion reactions that indicate the sequence of amino acid residues in the pentapeptide **9** (R = 4-chlorobenzoyl)

Ion reaction	Relative rate
$\rightarrow 579^+$	ND
$579^+ \rightarrow 548^+ + 31$	150
$548^+ \rightarrow 477^+ + 71$	470
$477^+ \rightarrow 392^+ + 85$	1200
$392^+ \rightarrow 321^+ + 71$	8600
$321^+ \rightarrow 236^+ + 85$	3100
$(346^+ \rightarrow 236^+ + 110)$	4

electron multiplier (20 stage, modified to have 300 kΩ stage resistors), the output of which was amplified by a Keithley (Model 427) current amplifier. Samples were introduced directly into the source of both instruments, in the case of the C.E.C. mass spectrometer by means of a temperature-controlled quartz probe.[4] All mass measurements were made by the peak matching method using an ion in the spectrum of perfluorokerosene as a standard. The relative rates of ion decomposition reactions in the first field-free zone of the ionic flight path of the CEC instrument were measured by tuning the magnetic field to detect a particular daughter ion when the accelerating voltage was 4 kV (defining the average kinetic energy of the ion beam). The accelerating voltage was then scanned to higher values, keeping the setting of the magnetic field and the electric sector voltage constant. Ionic decompositions were detected and recorded by using the ion current as the *y*-axis signal on an *x*/*y* recorder and the accelerating voltage (suitably attenuated) as the *x*-axis signal. The intensities of the peaks obtained (see Fig. 3) were measured by making several Xerox copies of the graphs, excising the peaks, and weighing the excised paper. Chemical ionization mass spectra were obtained using a Finnigan 4000 quadrupole mass spectrometer equipped with a modified (17) INCOS data system and using methane or deuteriomethane as the reagent gas. Some CI spectra were measured on a modified (18) MS-9 instrument using the same ionization gases. Peptides were permethylated by the method described in an earlier paper (7).

N-*4-Chlorobenzoylglycyl-2-methylalanine*

Ethyl 4-chlorobenzoylglycinate (19) (18 g) was dissolved in methyl alcohol (250 mL) and a solution (50 mL) of sodium hydroxide (5 g) in water added. After 2 h, titration of an aliquot showed that the ester had been completely hydrolysed and the remainder of the reaction mixture was concentrated to 40 mL, cooled to 0°C, and acidified. The precipitate (mp 133–137°C (sublimes above 120°C), 15.5 g, 97%) was taken up in boiling water (700 mL), the mixture filtered, the filtrate kept at 4°C for 18 h, and the crystalline precipitate (14.7 g, lit. (20) mp 143–145°C) collected. This acid (6.4 g) was suspended in toluene (300 mL) and the stirred mixture treated with a solution (100 mL) of 1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ, 7.5 g). The mixture was stirred at room temperature for 10 min, when methyl 2-methylalaninate (6) (4.5 g) was added. The reaction mixture was heated to 50°C and maintained at this temperature for 60 h, when it was cooled and evaporated. The residue was taken up in ethyl acetate (300 mL), acidic and basic impurities removed in the usual way (6), and the dried (Na_2SO_4), filtered solution evaporated. The colorless solid residue (7 g) was taken up in hot toluene (50 mL), and the filtered solution kept at room temperature for 50 h, at which time the crystals that had separated were collected. *Methyl 4-chlorobenzoylglycyl-2-methylalanine* (**2**) separated from toluene as needles, mp 150–151°C; λ_{max}: 236 nm (ϵ = 17 400). *Anal.* calcd. for $C_{14}H_{17}ClN_2O_4$: C 53.8, H 5.4, Cl 11.4, N 8.95%; found; C 53.7, H 5.5, Cl 11.3, N, 8.5%. This ester (5 g) was dissolved in methyl alcohol (50 mL) at 55°C and the warm solution treated with a solution (25 mL) of sodium hydroxide (1.2 g) in water. The reaction mixture was immediately cooled to room temperature and aliquots of the solution titrated to follow the extent of the hydrolysis. When the hydrolysis was complete (ca. 1 h) the solution was evaporated to 20 mL, then diluted with water (50 mL) and acidified. N-*4-Chlorobenzoylglycyl-2-methylalanine* separated from ethyl alcohol as needles mp 247–249°C; 4.3 g, 90%. *Anal.* calcd. for $C_{13}H_{15}ClN_2O_4 \cdot 0.5H_2O$: C 50.7, H 5.2, N 9.1%; found: C 50.5, H 4.7, N 9.6%.

Ethyl N-*4-chlorobenzoylglycyl-2-methylalanyglycinate* (***11***)

Ethyl glycinate hydrochloride (Mann Laboratories, 0.7 g) was suspended in toluene (40 mL) and the mixture treated with triethylamine (0.51 g). The mixture was shaken for 10 min, when *N*-4-chlorobenzoylglycyl-2-methylalanine (1.5 g) and EEDQ (1.25 g) were added. The mixture was heated to 50°C and was stirred at that temperature for 60 h, at which time it was evaporated, the residue taken up in ethyl acetate (150 mL), and acidic and basic impurities removed as usual (6). The dry (Na_2SO_4) ethyl acetate solution was filtered and the filtrate evaporated to give a colorless gum (2.1 g). This gum crystallized spontaneously after standing on the bench for several days; the crystals were readily recrystallized from either toluene or *n*-butyl acetate. *Ethyl* N-*chlorobenzoylglycyl-2-methylalanylglycinate* (***11***) separated from *n*-butyl acetate as needles, mp 125–126°C; λ_{max}: 236 nm (ϵ 16 800). *Anal.* calcd. for $C_{17}H_{22}ClN_3O_5$: C 53.2, H 5.7, Cl 9.3, N 10.95, O 20.9%; found C 53.1, H 6.0, Cl 9.3, N 10.8, O 21.0%.

α-*Methyl* γ-*benzyl* N-*4-chlorobenzoylglycyl-2-methylalanyl-*L-*glutamate*

α-Methyl γ-benzyl L-glutamate hydrochloride (21) (1.43 g) was suspended in toluene (100 mL) and the mixture shaken with triethylamine (0.55 g) for 10 min. *N*-4-chlorobenzoylglycyl-2-methylalanine (1.5 g) and EEDQ (1.25 g) were added to the stirred mixture, which was kept at 45–50°C for 7 days, when it was evaporated and the residue dispersed in ethyl acetate (200 mL). The precipitate (0.32 g) dissolved when the mixture was shaken with sodium bicarbonate solution (5%, 100 mL). The ethyl acetate phase was washed successively with ice-cold hydrochloric acid (2 *N*, 4 × 100 mL), water, sodium bicarbonate solution (5%, 2 × 50 mL), and water. The dry (Na_2SO_4), filtered ethyl acetate solution was evaporated and the crystalline residue collected. The *tripeptide diester* (**8**) separated from *n*-butyl acetate (2 g in 15 mL) as long fine needles, mp 144°C; $[\alpha]_D^{24}$ −13.7° (*c* 0.84, MeOH); λ_{max}: 236 nm (ϵ 15 400). *Anal.* calcd. for $C_{26}H_{30}ClN_3O_7$: C 58.7, H 5.6, Cl 6.7, N 7.9%; found: C 58.6, H 5.6, Cl 6.8, N 8.1%.

Ethyl N-*4-chlorobenzoyl-*L-*prolyl-*L-*valyl-2-methylalanylglycinate*

Ethyl glycinate hydrochloride (2.8 g) was suspended in toluene (20 mL), triethylamine (2 g) added, and the mixture shaken for 10 min at room temperature. The stirred reaction mixture was treated with a solution of *N*-phenylmethoxycarbonyl-L-prolyl-L-valyl-2-methylalanine (6) (8.7 g) and EEDQ (5 g) in toluene (200 mL). After 70 h at 45°C the reaction mixture was evaporated, the residue taken up in ethyl acetate (300 mL), and acidic and basic by-products removed in the usual way. The dry (Na_2SO_4) ethyl acetate solution was filtered and the filtrate evaporated to provide a gum (9 g), which has resisted all attempts at crystallization. This gum (8 g) in methyl alcohol (100 mL) was shaken with palladium on carbon (5%, 0.25 g) and hydrogen (3.5 kg cm^{-2}) for 24 h when the reaction mixture was filtered through a bed of Celite 545 (0.5 cm) and the filtrate evaporated. When the gummy residue was titurated with THF or tetrahydropyran, crystals were obtained that could be recrystallized as hexagonal plates, mp 89–91°C, from either solvent. However, on standing at room temperature they changed to a clear resin, which readily crystallized when treated with one of these solvents. The crystalline material (1 g) in THF (15 mL) was treated with 4-chlorobenzoylazide (1) (0.5 g) and the colorless solution kept for 3 days at room temperature. The reaction mixture was evaporated and the residue digested several times with petroleum ether (bp 30–60°C, 3 × 50 ml), when the residual gum was taken up in ethyl acetate (50 mL), and the solution washed with ice-cold hydrochloric acid (2 *N*, 4 × 10 mL) and water (2 × 50 mL). The dry (Na_2SO_4), filtered solution was evaporated to give a gum (0.32 g,

[4]Available from Masspec Inc., P.O. Box 9314, College Station, Texas 77840, U.S.A.

24%). This gum, which appeared to be homogeneous chromatographically, was found to contain a few crystals after standing for several months. It was found that treatment of the mixture of gum and crystals with a few drops of *n*-butyl acetate (but not with any of some 20 other solvents tried) resulted in very slow crystallization and a crop of needles (0.18 g, mp 112–118°C) could be collected after 2–3 weeks. These needles exhibited the same characteristics as the gum, i.e. they could be taken up in about 5 mL of *n*-butyl acetate at 100°C, and the solution over a period of 3–4 weeks, in a sealed container, deposited fine needles of **5** (*R* = *4-chlorobenzoyl*), mp 113–116°C; $[\alpha]_D^{24}$ −93 (*c* 0.46, MeOH); λ_{max}: 225 nm (ε 12 900). *Exact Mass* (ms), *m/z*: 524.2284 ($C_{25}H_{35}{}^{37}ClN_4O_6$ requires 524.2215), 522 (Table 1), 506.2124 ($C_{25}H_{33}{}^{37}ClN_2O_5$ requires 506.2110), 504.2103 ($C_{25}H_{33}{}^{35}ClN_2O_5$ requires 504.2139). *Anal.* calcd. for $C_{25}H_{35}ClN_4O_6$: C 57.4, H 6.7, Cl 6.8, N, 10.7%; found: C 57.3, H 6.7, Cl 7.1, N 10.7%.

Methyl N-*4-chlorobenzoyl-*L*-glutaminyl-2-methylalanine-*L*-valinate*

N-Phenylmethoxycarbonyl-L-glutamine (22) (15 g) and EEDQ (14.5 g) were dissolved in THF (200 mL). After 5 min methyl 2-methylalaninate (6.2 g) was added to the solution and a voluminous precipitate was obtained. The reaction mixture needed a stirrer of adequate torque to keep the precipitate in suspension while it slowly went into solution over a period of 18 h. After 44 h at 35°C, the solution was evaporated, the residue dissolved in ethyl acetate (100 mL), and acidic and basic by-products removed. The ethyl acetate solution was evaporated and the residue (19.9 g) taken up in methyl alcohol (200 mL). The solution was treated with sodium hydroxide (*N*, 70 mL), the reaction mixture kept for 2 h at room temperature, then concentrated at 40°C under reduced pressure to 50 mL, diluted with brine (10%, 50 mL), and extracted with ethyl acetate (2 × 50 mL). The raffinate was acidified and extracted with ethyl acetate (3 × 100 mL). The combined acid extracts were washed with brine (10%, 2 × 50 mL) and with ice-cold water (10 mL). The dry (Na_2SO_4) solution was filtered and evaporated to give a gum (11.9 g), which solidified on trituration with petroleum ether (bp 30–60°C) N-*Phenylmethoxycarbonyl-*L*-glutaminyl-2-methylalanine* separated from ethyl acetate as very fine needles, mp 142°C; $[\alpha]_D^{22}$ −24.1° (*c* 1.4, MeOH), δ_H (THF($^2H_8$)): 7.73 (H, e), 7.30 (5H), 6.90 (H, e), 6.76 (H, e), 6.61 (H, e), 5.05 (2H), 4.17 (H, m), 2.23 (2H, m), 1.97 (2H, m), 1.47 (3H), 1.46 (3H). *Anal.* calcd. for $C_{17}H_{22}N_3O_6$: C 56.0, H 6.1, N 11.5%); found: C 55.8, H 6.3, N 11.2%. This acid (7.3 g) was suspended in toluene (200 mL) and EEDQ (5 g) added. The stirred mixture was treated with methyl valinate (2.6 g; methyl valinate hydrochloride (23) (10 g) was dissolved in chloroform (700 mL) and the solution cooled to 5°C when it was saturated with ammonia. The precipitated ammonium chloride was collected by filtration and the filtrate evaporated at −5°C, 15 Torr (1 Torr = 133.3 Pa), to about 50 mL. The residue was fractionally distilled through a Fenski column (15 × 1 cm), the ester (8.5 g) collected at 35°C, 20 Torr, and the mixture stirred at 45°C for 60 h. The crystalline precipitate (7.5 g) was collected and was recrystallized from ethyl acetate as fine needles of *methyl* N-*phenylmethoxycarbonyl-*L*-glutaminyl-2-methylalanyl-*L*-valinate* (**7**, R = C_7H_7OCO), mp 138–140°C; $[\alpha]_D^{24}$ −28° (*c*, 0.311, MeOH), δ_H ($C^2H_3O^2H$): 7.33 (5H, m), 5.08 (2H), 4.24 (H, *J* = 6.9 Hz), 4.05 (H, m), 3.69 (3H), 2.32 (2H, m), ca. 2.0 (3H, m), 1.49 (3H), 1.44 (3H), 0.90 (3H, *J* = 6.9 Hz), 0.87 (3H, *J* = 6.9 Hz). *Anal.* calcd. for $C_{23}H_{34}N_4O_7 \cdot 0.25H_2O$: C 57.2, H 7.2%; found: C 57.1, H 6.8%. The *ethyl ester* was similarly prepared and was recrystallized as needles from water, mp 87–91°C. *Anal.* calcd. for $C_{24}H_{36}N_4O_7 \cdot H_2O$: C 56.5, H 7.5, N 11.0%; found: C 56.4, H 7.5, N 10.9%. The urethane methyl ester (2 g) in methyl alcohol (100 mL) was treated with dilute hydrochloric acid (0.2 *N*, 20 mL) and palladium on carbon (0.25 g, 5%). The mixture was shaken with hydrogen (1.76 kg cm^{-2}) for 48 h. The colorless precipitate that separated was dissolved by adding water (30 mL). The catalyst was filtered, and most of the methyl alcohol evaporated from the filtrate. The residual aqueous solution was lyophilized, the residue suspended in chloroform, and the stirred suspension saturated with ammonia. The precipitated ammonium chloride was collected by filtration, the filtrate evaporated, the residue taken up in THF (75 mL), and the solution treated with 4-chlorobenzoylazide (0.9 g). After 3 days at room temperature the reaction was evaporated, the residue stirred with petroleum ether (100 mL) for 6 h, and the amorphous solid (1.8 g) thoroughly washed with petroleum ether. The product was taken up in hot water (125 mL), a small quantity of insoluble material removed by filtration, and the filtrate kept at 4°C for 18 h. *Methyl 4-chlorobenzoyl-*L*-glutaminyl-2-methylalanyl-*L*-valinate* (**7**, R = ClC_6H_4CO) separated from water as needles, mp 91–92°C; $[\alpha]_D^{24}$ +1 ± 5° (*c*, 0.4 MeOH); λ_{max}(MeOH); 238 nm (ε 15 100); δ_H: 7.87 (2H), 7.46 (2H, *J* = 8.5 Hz), 4.41 (gluαCH, *J* = 7 Hz), 4.22 (valαCH, *J* = 6.5 Hz), 3.7 (3H), ca. 2.4 (gluαCH_2, m), ca. 2.1 (gluβCH_2, valβCH, m, assigned by double resonance experiments), 1.52 (3H), 1.46 (3H), 0.85 (valMe, *J* = 6.8 Hz), 0.77 (valMe, *J* = 6.8 Hz); δ_C: 177.8; 176.7; 173.6 (2, C=O); 168.9, 139.0; 133.4; 130.3; (2C, $^1J_{CH}$ = 164 Hz); 129.6 (2C, $^1J_{CH}$ = 167 Hz); 58.1; 55.7 ($^1J_{CH}$ = 143.5 Hz); 52.39 ($^1J_{CH_3}$ = 148.5 Hz); 32.49 ($^1J_{CH_2}$ = 127.5 Hz); 31.63 ($^1J_{CH}$ = 134.5 Hz); 27.95 ($^1J_{CH_2}$ = 131 Hz); 26.68 ($^1J_{CH_3}$ = 129.7 Hz); 24.38 ($^1J_{CH_3}$ = 128.6 Hz); 19.49 ($^1J_{CH_3}$ = 127 Hz); 19.03 ($^1J_{CH_3}$ = 125 Hz). *Anal.* calcd. for $C_{22}H_{31}ClN_4O_6 \cdot H_2O$: C 52.75, H 6.6, Cl 7.2, N 11.2%; found: C 52.4, H 6.7, Cl 7.2, N 11.5%. The ether ester was prepared in the same way and separated from water as needles, mp 85°C.

Methyl N-*4-bromobenzoyl-*L*-prolyl-*L*-valyl-2-methylalanyl-2-methylalaninate*

A solution (50 mL) of methyl L-prolyl-L-valyl-2-methylalanyl-2-methylalaninate (6) (**4**, R = H, 1 g) in THF (75 mL) was treated with 4-bromobenzoylazide (24) (mp 46°C, prepared from 4-bromobenzoylhydrazide (24) in the same way as has been described (1) for 4-chlorobenzoylazide, 0.7 g) and the reaction mixture stirred at room temperature for 3 days. The reaction mixture was filtered, the filtrate evaporated, and the residue digested with cold toluene (3 × 20 mL). The residual 4-bromobenzoyltetrapeptide (**4**, R = 4-bromobenzoyl) separated from THF–diisopropyl ether (1:2) as prisms, mp 144–146°C; $[\alpha]_D^{23}$ −85° (*c* 0.37, MeOH); λ_{max}: 229 nm (ε 13 000). *Anal.* calcd. for $C_{26}H_{37}BrN_4O_6$: C 53.7, H 6.4, Br 13.8, N 9.6%; found: C 53.65, H 6.4, Br 13.6, N 9.7%.

The Raman spectrum of kaolinite #9 at 21°C

K. H. MICHAELIAN

Energy, Mines & Resources Canada, CANMET, Edmonton Coal Research Laboratory, P.O. Bag 1280, Devon, Alta., Canada T0C 1E0

Received August 8, 1985

K. H. MICHAELIAN. Can. J. Chem. **64**, 285 (1986).

The Raman spectrum of kaolinite #9, a layer silicate of composition $Al_2Si_2O_5(OH)_4$ from Mesa Alta, New Mexico, USA, is reported and compared to previously published Raman and infrared spectra, as well as calculated lattice vibration frequencies, of other kaolinite samples. In the OH stretching region, a Raman band is observed at 3684 cm^{-1}, a frequency which is generally unknown in infrared spectra of kaolinite. The two most likely origins of this band are (*a*) uncoupled inner-surface hydroxyl stretching, and (*b*) transverse/longitudinal splitting involving the 3695 cm^{-1} band, which occurs in both Raman and infrared spectra of kaolinite. The existing data do not conclusively show which of these explanations is correct. In the lattice vibration region, most of the observed Raman bands of kaolinite #9 have been tentatively assigned by comparison with published frequency calculations and existing assignments of infrared spectra of various kaolinites. The descriptions of many of the vibrational modes are approximate, partly because extensive mixing of vibrations makes a simple description of them impossible.

K. H. MICHAELIAN. Can. J. Chem. **64**, 285 (1986).

On rapporte les spectres Raman de la kaolinite #9, une couche de silicate de composition $Al_2Si_2O_5(OH)_4$ provenant de Mesa Alta, New Mexico, USA, et on les compare aux spectres Raman et infrarouges rapportés antérieurement ainsi qu'aux fréquences de vibration calculées pous des réseaux d'autres échantillons de kaolinite. Dans la région d'élongation OH, on observe une bande de vibration à 3684 cm^{-1}, une fréquence qui est généralement inconnue dans les spectres infrarouges de la kaolinite. Les deux origines le plus probables pour cette bands sont (*a*) une élongation qui n'est pas couplée d'un hydroxyle de la surface interne, ou (*b*) un déboublement transversal/longitudinal impliquant la bande à 3695 cm^{-1} qui se retrouve tant dans les spectres Raman qu'infrarouges de la kaolinite. Les données existentes ne démontrent pas d'une façon concluante laquelle de ces explications serait correcte. Dans la région de vibration du réseau, on a attribué la plupart des bandes Raman observées pour la kaolinite #9 en faisant une comparaison avec les fréquences calculées qui ont été publiées et avec les attributions existantes des spectres infrarouges de diverses kaolinites. Les descriptions de plusieurs modes vibrationnels ne sont qu'approximatifs; ceci est dû au fait que des recouvrements importants de vibrations font qu'il est impossible de les décrire simplement.

[Traduit par le journal]

Introduction

The scarcity of Raman spectra of clay minerals in the literature means that important structural information is lacking in many cases. For example, interpretation of the OH stretching vibrations of the layer silicates in terms of known structures has, in most cases, been based only on infrared absorption spectra. This situation is largely caused by two factors: first, infrared spectrometers tend to be more readily available and simpler to operate than Raman instrumentation; secondly, clays such as layer silicates yield weak Raman spectra, making it difficult to obtain research-quality results.

Several years ago, Wiewiora, Wieckowski, and Sokolowska (1) published what is believed to be the first successful Raman study of kaolinite sub-group minerals, which are made up of layers consisting of a single silica tetrahedral sheet and a single alumina octahedral sheet, and have the formula $Al_2Si_2O_5(OH)_4$. For Keokuk kaolinite the authors observed, but did not assign, a a number of bands between 100 and 1100 cm^{-1}; in the OH stretching region, they found bands at 3620, 3650, 3667, 3682, and 3692 cm^{-1}. The known (2) infrared-active OH stretching vibrations of kaolinite occur at 3620, 3652, 3669, and 3697 cm^{-1}; hence 3682 cm^{-1} can be regarded as a new OH stretching frequency.

The assignment of the OH stretching bands of kaolinite to particular types of hydroxyl groups has been a subject of interest for many years, and the observation of another OH vibrational frequency has important implications regarding previous spectra–structure correlations for kaolinite. Wiewiora *et al.* (1) attributed the 3682 cm^{-1} band to a "coupling vibration in phase" involving inner-surface hydroxyl groups. As is discussed below, assignment of this band to an uncoupled inner-surface hydroxyl vibration and, alternatively, to longitudinal/transverse splitting has also been considered in the present investigation. The available evidence suggests that the 3682 cm^{-1} band arises from uncoupled inner-surface hydroxyl stretching.

The present study of the Raman spectrum of kaolinite #9 was undertaken with the following goals: (*1*) comparison with previously published Raman spectra of kaolinite, to determine whether differences due to particle size, origin of the kaolinite, or other factors, are observed; (*2*) assignment of the Raman spectrum of kaolinite in terms of hydroxyl group vibrations, the vibrations of the silica layer, and those of the alumina layer; (*3*) comparison with infrared specta of kaolinite; (*4*) establishment of priorities for further Raman investigations of kaolinite.

Experimental

Kaolinite #9, from Mesa Alta, New Mexico, USA, was obtained from Ward's Natural Science Establishment, Inc. Its purity was checked using X-ray diffraction and an inductively coupled argon plasma spectrometer. The only impurity detectable in the X-ray analysis was a small amount of quartz. The ICAP showed trace quantities of Ca, Fe, Mg, and Na, in decreasing order of abundance. Potassium was not included in this analysis.

Raman spectra were excited using the 476.5-, 488.0-, and 514.5-nm lines of a Coherent Radiation CR6 argon ion laser; power levels at the sample were between 40 and 300 mW. A small monochromator eliminated argon plasma lines from the laser beam before it was allowed to strike the sample. All of the bands reported in this paper were observed using at least two different excitation lines.

Scattered light was analysed with a 0.85-m Spex model 1403 double monochromator equipped with 1800 groove/mm holographic gratings,

and detected with a thermoelectrically cooled RCA C31034 photomultiplier tube and photon counting electronics. The monochromator and the electronics were controlled by a Spex Datamate. The strongest Raman bands gave intensities of about 3.5×10^4 counts/s at a laser power of 40 mW and a spectral slit width of 5 cm^{-1}. Spectra were calibrated using neon emission lines; accuracies of the band positions are about ± 1 cm^{-1} for the stronger bands, decreasing to about ± 3 cm^{-1} for weaker bands. No correction was made for the slight frequency dependence of the sensitivity of the optical system.

The best spectra were obtained for large (~25 mm) lumps of kaolinite, the form in which it was supplied. Powdered samples and films on microscope slides were also briefly examined. In all three cases, the spectra showed the same Raman bands. However, the scattering from finely ground kaolinite is very weak, giving Raman spectra with poor signal/noise ratios. Because of this, spectra of lumps of kaolinite #9 are the only ones presented in this paper.

Results and discussion

Each of the laser lines used to excite the Raman spectra of kaolinite caused fluorescence that subsides with time, reaching a minimum in about 1–2 h. Further irradiation does not totally eliminate the fluorescence, however, and Raman spectra of kaolinite #9 contain a broad fluorescence band that extends from about $\Delta\nu = 200$ to 6000 cm^{-1} with respect to the 488.0-nm laser line. A similar background is visible in the spectra of Wiewiora *et al.* (1) and in Raman spectra of other layer silicates (3). Ideally, the effect of this fluorescenee could be eliminated by utilizing the difference in the times required for the fluorescence and scattering processes. For simplicity, in the present work the fluorescence background was reduced in the 300–1000 cm^{-1} and 3600–3720 cm^{-1} regions with a baseline linearization program.

The vibrations of layer silicates are conveniently discussed in terms of their constituent units. Hence, for kaolinite, Raman and infrared spectra can be interpreted by considering vibrations of the hydroxyl groups, the silica tetrahedra, and the alumina octahedra. With regard to the latter two structures, Ishii *et al.* (4,5) have published results of detailed calculations of lattice vibration frequencies of a series of layer silicates, which facilitates assignment of some of the Raman bands of kaolinite. Therefore the Raman spectrum of kaolinite is discussed below in terms of hydroxyl vibrations and lattice vibrations. The different regions of the spectrum are shown in Figs. 1–4; band positions and relative intensities are given in Table 1.

1. *Hydroxyl vibrations*

1.1 *Kaolinite #9*

The OH stretching region of the Raman spectrum of kaolinite #9 is shown in Fig. 1. Five bands are identifiable, the two at highest frequency being incompletely resolved. Four of the bands (3695, 3669, 3651, and 3620 cm^{-1}) occur at the same frequencies as the well-known infrared absorption bands designated (6) A, B, C, D, respectively. The fifth band, at 3684 cm^{-1}, is not found in published infrared spectra of kaolinite; this band will be denoted A′ in this paper. As indicated in the Introduction, all five bands were observed in the Raman spectrum of Keokuk kaolinite by Wiewiora *et al.* (1); however, band A′ is more prominent in their spectra than is the case in Fig. 1.

Figure 2 shows resolution enhancement of the inner-surface hydroxyl stretching region of the Raman spectrum of kaolinite #9. The sharpened spectrum was obtained using the frequency domain deconvolution method of Jones and Shimokoshi (7). In this example, a Lorentzian band shape and a half width of 10 cm^{-1} were used; the effective range of the triangle-squared apodization function was 0.2 cm. Improved resolution of bands A and A′ permits determination of their frequencies as 3695 ± 1 cm^{-1} and 3684 ± 1 cm^{-1}, respectively. The use of other apodization functions is not expected to affect these conclusions significantly.

In addition to the OH stretching vibrations, the in-plane bending of inner hydroxyls and of surface hydroxyls (both of which include some motion of aluminum ions (8)) also yields

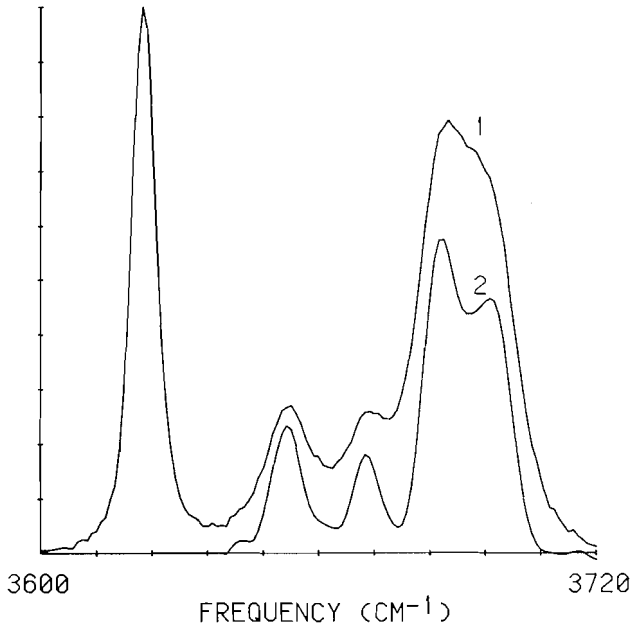

FIG. 2. Curve 1: observed spectrum, OH stretching region; Curve 2: deconvolution of inner surface hydroxyl stretching bands. Bands at 3695 and 3684 cm^{-1} are designated A and A′, respectively (see text).

Raman bands. The inner hydroxyls give rise to the band at 915 cm^{-1} (Fig. 4), while the surface hydroxyls cause the shoulder at ~938 cm^{-1} (9).

1.2 *Assignment of OH stretching vibrations*

Although A′ was regarded as a newly-found OH stretching band by Wiewiora *et al.* (1), it should be noted that several authors have proposed the existence of a second band within the envelope of band A, which is asymmetric in infrared spectra of kaolinite. Serratosa, Hidalgo, and Vinas (10) suggested that band A originates from two types of hydroxyls with a slight difference in energy. The comparatively high frequency of this band implies that the OH groups involved do not participate in hydrogen bonding, whereas the band width indicates the opposite. These conflicting viewpoints can be rationalized by postulating that the observed envelope contains two bands (10,11). More recently, Rouxhet, Samudacheata, Jacobs, and Anton (12) studied infrared spectra of synthetic kaolinites with varying degrees of deuteration, which permitted conclusions regarding coupling of OH or OD stretching vibrations. They found that band fitting of the OH stretching region assuming the presence of four bands was unsuccessful, and concluded that "five components are necessary to account for the spectrum of a kaolinite in which both coupled and uncoupled OH or OD groups are present." Hence even before Raman spectra were available, five OH stretching bands were expected for kaolinite.[1]

Before discussing the assignment of these OH stretching bands, it should be recalled that there are three types of hydroxyl groups in kaolinite (13): (*a*) "outer hydroxyls" at the surface of microcrystals, including both hydroxyls at broken edges and hydroxyls of the octahedral sheet at the upper surface; (*b*) "inner-surface" hydroxyls at the surface of the octahedral sheet opposite tetrahedral oxygens of the next layer; and (*c*) "inner hydroxyls" which are common to the octahedral and tetrahedral sheets. Assignments of the infrared OH stretching bands of kaolinite, which have been reviewed by Farmer (14), generally invoke only the latter two types of hydroxyl groups. Intercalation studies (15,16) show that bands A, B, and C arise from inner-surface hydroxyls, while D is due to inner hydroxyls. Some authors associate each of A, B, and C with particular hydroxyls in the kaolinite structure, while others attribute these bands to coupling of the inner-surface hydroxyl stretching vibrations. Possible confusion may arise from the fact that the relative intensities of the bands are somewhat dependent on the source of the kaolinite (2,17); e.g., band B is observable only in the spectra of well-crystallized samples (18).

The assignment by Rouxhet *et al.* (12) combines features of both of the just-mentioned interpretations regarding coupling of inner-surface stretches. These authors attributed bands A and B to, respectively, in-phase and out-of-phase stretching of the two inner-surface hydroxyls perpendicular to the kaolinite layers; band C was assigned to the third inner-surface hydroxyl, which, on the basis of electrostatic energy calculations (19) and transition moments of A, B, and C (11,12), was believed to be nearly parallel to the layers. A recent infrared study of kaolinite crystallinity (20) concluded that this assignment was consistent with the calculated (19) structure. However, this attribution of band C may now have to be revised, since very recent theoretical (21) and crystal structure (22, 23) investigations of kaolinite have shown that the third inner-surface hydroxyl group has a more vertical orientation than was previously thought to be the case.

Infrared spectra obtained by Rouxhet *et al.* (12) show that weakly deuterated kaolinite (in which the OD oscillators are uncoupled) has an OD stretching band at 2714 cm^{-1} that is replaced by bands at 2723 and 2708 cm^{-1} in spectra of fully deuterated samples. The isotope shifts of the latter two bands with respect to bands A and B of undeuterated kaolinite are 1.357 and 1.355, respectively. Using an average isotope shift of 1.356[2] and 2714 cm^{-1} as the frequency of an uncoupled OD stretching vibration leads to a calculation of $1.356 \times 2714\ cm^{-1} = 3680\ cm^{-1}$ for the frequency of an uncoupled inner-surface hydroxyl vibration. This prediction is supported by the observed shift of band A to lower frequency, caused by growing-in of the ~3680 cm^{-1} band at a high degree of deuteration, when the OH oscillators are not coupled. Moreover, it is consistent with the conclusion that a fifth band, at about 3680 cm^{-1}, is necessary to fit the observed infrared spectrum of kaolinite. In fact, a frequency of about 3680 cm^{-1} for uncoupled inner-surface hydroxyl stretching has been proposed previously by other authors (24, 25). In contrast, the stretching frequency of "free" OH groups (24) is about 3750 cm^{-1}, as has been observed for kaolinite by reflection spectroscopy (26).

Wiewiora *et al.* (1) rejected the conclusion that A′ arises from uncoupled OH groups, largely because the kaolinite that they examined was well crystallized. These authors emphasized the general tendency of symmetrical vibrations to yield strong Raman bands, and therefore attributed A′ to the "the coupling vibrations in phase" of the OH groups that give rise to bands B and C. However, the appearance of a strong OH stretching band in the Raman spectrum does not necessarily indicate that it arises from in-phase coupling; as Wiewiora *et al.* (1) noted, the symmetrical OH stretching vibrations of dickite, which involves three hydroxyl groups, does not yield a strong Raman band.

[1]We have observed an intensity differential at the frequency of band A′ when subtracting diffuse reflectance FTIR spectra of kaolinite #9, and a shoulder on band A near 3684 cm^{-1} in photoacoustic FTIR spectra of other kaolinites.

[2]This value is erroneously given as 1.366 in ref. 12.

Moreover, Raman spectra of two different kaolinite samples that have been examined in the present investigation show band A′ with relative intensity significantly less than observed by Wiewiora *et al.* (1), bringing further uncertainty to an interpretation based on the high intensity of A′ in their spectra.

An alternative assignment of band A′ can be suggested using the reasoning of Farmer and Russell (27), who showed that transverse and longitudinal frequencies need to be considered when analysing spectra of layer silicates. Vibrations perpendicular to the layers occur at the longitudinal frequency ν_l, while those parallel to the layers occur at the transverse frequency ν_t. Hence a particular vibration can give rise to two bands: the characteristic splitting of the ~1100 cm^{-1} infrared absorption band of kaolinite (2), which is observed only for larger particle sizes (18), is due to this effect. Similar reasoning suggests that band A′ could be the transverse mode equivalent to band A, which falls near the longitudinal frequency. If this explanation is correct, A′ would appear with reduced intensity in the Raman spectrum of kaolinite in which the particle size is smaller than that of kaolinite #9. This was investigated by recording the OH region of the Raman spectrum of international kaolinite,[3] which was shown to have an average particle size significantly less than that of kaolinite #9 by comparing FTIR spectra of the two samples. Raman spectra of international kaolinite showed an A′/A intensity ratio which is equal, within experimental uncertainty, to that of kaolinite #9. These results suggest that transverse/longitudinal splitting is not responsible for the occurrence of band A′ in the Raman spectrum of kaolinite.

The interpretations of band A′ that have been outlined show that the data presently available do not permit a definite conclusion with regard to its assignment. If one considers coupling of OH vibrations to be the likely origin of A′, then the assignment of Wiewiora *et al.* (1) seems less satisfactory than that of Rouxhet *et al.* (12), since a qualitative observation regarding Raman intensities is not as definitive as the results of deuteration experiments, which are a common means for analysing coupling of OH vibrations. Furthermore, the present investigation has shown that band A′ is probably not due to transverse/longitudinal splitting, but further Raman studies of other kaolinite samples having a range of particle sizes are required before this explanation can be fully evaluated.

2. *Lattice vibrations*

2.1 *The 100 – 300 cm^{-1} region*

The 100 – 300 cm^{-1} region of the Raman spectrum of kaolinite #9 is shown in Fig. 3. Bands are identifiable at 143, 197, 245, and 270 cm^{-1}; a shoulder occurs on the low frequency side of the 143 cm^{-1} band at about 130 cm^{-1}. Because the low frequency vibrations of kaolinite have not been studied very thoroughly, the assignments of these bands, which are presented below, must be regarded as tentative.

Ishii *et al.* (4,5) calculated vibrational frequencis of 127, 130 and 285 cm^{-1} for the ideal hexagonal C_{6v} Si_2O_5 lattice; for the less symmetrical C_{3v} lattice, the predicted frequencies were 113, 209, and ~290 cm^{-1}. The symmetry of the Si_2O_5 lattice is certainly less than C_{6v} in kaolinite; however, if the effect of deviation from C_{6v} symmetry on the vibrational modes is not very great, the calculated 127 and 130 cm^{-1} bands could still be invoked to account for the 130 and 143 cm^{-1} Raman bands, respectively. The corresponding frequencies reported for Keokuk kaolinite[4] (1) are 120 and 132 cm^{-1}; a very recent spectrum of Georgia kaolinite (28) shows a single band at 141 cm^{-1}. Far infrared diffuse reflectance spectra of kaolinite obtained in our laboratory (29) show, among others, bands at 120, 132, and 141 cm^{-1}, which may be analogous to the observed Raman bands.

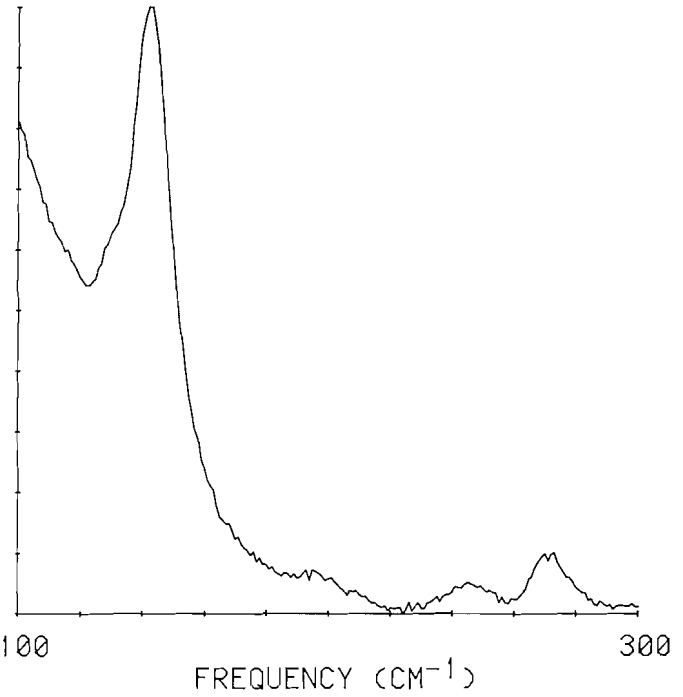

FIG. 3. Raman spectrum of kaolinite #9: 100 – 300 cm^{-1} region.

The 197 cm^{-1} Raman band, whose infrared counterpart is at 196 cm^{-1} (29), can be attributed to vibrations (probably translations) of hydroxyl ions (4). An alternative assignment is to the 209 cm^{-1} mode calculated for the C_{3v} Si_2O_5 lattice. The 245 cm^{-1} Raman band, which corresponds to a shoulder in the infrared spectrum (29) at 248 cm^{-1}, is assigned to a mixture of silicon–oxygen deformation and hydroxyl libration (4). The final Raman band in this region, at 270 cm^{-1}, is observed in infrared spectra at 273 cm^{-1} in transmission (18) and at 279 cm^{-1} by diffuse reflectance (29); this band is assigned (18) to mixed silicon–oxygen deformations and octahedral sheet vibrations.

2.2 *The 300 – 900 cm^{-1} region*

The remainder of the lattice vibration region is shown in Fig. 4. The Raman spectrum of kaolinite #9 between 300 and 900 cm^{-1} contains bands at 336, 394, 418, 431, 463, 516, 638, 710, 751, and 790 cm^{-1}. Comparison of these frequencies with those in infrared spectra of kaolinite shows that several Raman bands occur at lower frequencies than their nearest infrared counterparts: recent ir data for kaolinite (18) include bands at 348, 432, 472, 542, 650, 755, and 797 cm^{-1}. The only infrared frequencies near 394 and 418 cm^{-1} are shoulders at 383, 411, and 421 cm^{-1} recently observed (29) using diffuse reflectance. The 710 cm^{-1} Raman band does not have an obvious infrared analogue. The origin of the differences between Raman and infrared frequencies may be transverse/longitudinal splitting, or simply

[3]The author is grateful to Dr. V. C. Farmer for providing this sample.

[4]Identical frequencies of 120 and 132 cm^{-1} are given in Table 1 of ref. 1 for kaolinite, dickite, and nacrite, although the spectra in that paper suggest that the frequencies are not the same for each mineral.

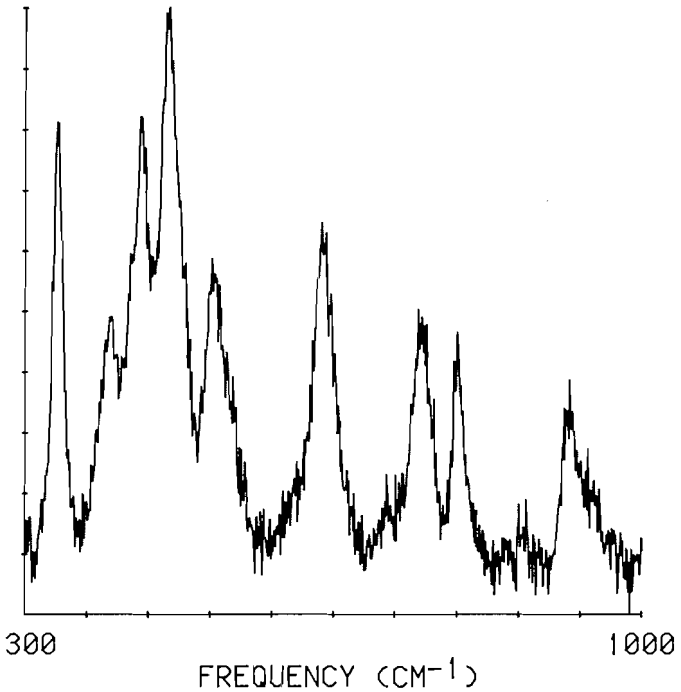

FIG. 4. Raman spectrum of kaolinite #9: 300 – 1000 cm^{-1} region.

that different vibrations are active in the Raman and infrared spectra; further work is required before the comparison of infrared and Raman spectra of kaolinite can be more thoroughly understood. This will permit more detailed conclusions regarding the structure of this mineral.

The Raman frequencies (except 394 and 710 cm^{-1}) can be assigned in a straightforward manner if it is assumed that the respective Raman and infrared frequencies have common origins. Bands at 336, 418, 431, 463, 516, and 638 cm^{-1} are attributed to mixed SiO deformations and octahedral sheet vibrations (18); the 516 cm^{-1} vibration involves an Si—O—Al linkage (8). The 751 cm^{-1} band is due to vibrations of SiOAl groups (8) and surface hydroxyls (14). SiOAl vibrations also give rise to the 790 cm^{-1} band (8).

The bands at 516 and 638 cm^{-1}, which are prominent in the Raman spectrum of kaolinite #9 (Fig. 4), are also present in the spectrum of Georgia kaolinite recently published by Johnston *et al.* (28); however, these bands were not observed for Keokuk kaolinite (1). Several attempts to observe these two bands in the spectrum of international kaolinite were inconclusive because of the extremely weak scattering in the lattice vibration region for this finely ground sample. Thus the data available so far suggest that the 516 and 638 cm^{-1} bands are sample dependent, although investigation of the Raman spectra of other kaolinite samples is required before these results can be fully explained.

Conclusions

The above discussion has shown that a significant amount of work must be carried out before the Raman spectrum of kaolinite is fully understood. The following experiments are proposed in order to elucidate some of the ambiguous points which have already been mentioned.

(*a*) Raman spectra of a number of different kaolinite samples should be obtained in order to determine whether differences in relative intensities of band A′ (3684 cm^{-1}) are attributable to sample origin.

(*b*) Raman spectra of a particular kaolinite sample ground to different particle sizes are required to establish whether transverse/longitudinal splitting accounts for the appearance of band A′.

(*c*) The samples mentioned in (*a*) should be examined with respect to possible occurrence of Raman bands at 516 and 638 cm^{-1}.

(*d*) As a final point, the experiment mentioned under (*a*) could be repeated at low temperature, where reduced band widths might facilitate the characterization of the OH stretching bands.

Received June 25, 1985

PETER TAYLOR and VINCENT J. LOPATA. Can. J. Chem. **64**, 290 (1986).

Equilibrium iodide activities have been measured as a function of pH for the phase assemblages α-Bi_2O_3 + Bi_5O_7I + aqueous solution and Bi_5O_7I + BiOI + aqueous solution, yielding the following Gibbs energies of formation for the bismuth oxyiodides: $\Delta_fG^0(Bi_5O_7I, s, 298\ K) = -1266.1 \pm 5.8\ kJ\ mol^{-1}$; and $\Delta_fG^0(BiOI, s, 298\ K) = -247.8 \pm 2.8\ kJ\ mol^{-1}$. Using published data for the assemblage BiOI + BiI_3 + aqueous solution, we estimate that $\Delta_fG^0(BiI_3, s, 298\ K) = -160.0 \pm 16.2\ kJ\ mol^{-1}$ and $\log K_{sp}(BiI_3) = -15.3 \pm 3.4$.

PETER TAYLOR et VINCENT J. LOPATA. Can. J. Chem. **64**, 290 (1986).

On a mesuré les activités des iodures à l'équilibre en fonction du pH des assemblages de phase α-Bi_2O_3 + Bi_5O_7I + solution aqueuse et Bi_5O_7I + BiOI + solution aqueuse et l'on en a déduit les énergies de Gibbs suivantes pour la formation des oxyiodures: $\Delta_fG^0(Bi_5O_7I, s, 298\ K) = -1266{,}1 \pm 5{,}8\ kJ\ mol^{-1}$; et $\Delta_fG^0(BiOI, s, 298\ K) = -247{,}8 \pm 2{,}8\ kJ\ mol^{-1}$. En se basant sur des données connues relatives à l'assemblage de phase BiOI + BiI_3 + solution aqueuse, nous avons évalué les paramètres suivants: $\Delta_fG^0(BiI_3, s, 298\ K) = -160{,}0 \pm 16{,}2\ kJ\ mol^{-1}$ et $\log K_{sp}(BiI_3) = -15{,}3 \pm 3{,}4$.

[Traduit par le journal]

Introduction

Many metal halides undergo hydrolysis to one or more basic halides, and ultimately to the metal oxide or hydroxide. In 1934, Montignie (1) reported the sequential hydrolysis of BiI_3 by KOH to BiOI and Bi_5O_7I. Dyrssen and Yen (2) have described equilibria between BiI_3 and BiOI in acidic iodide solutions. Rulmont (3) and Ketterer and Krämer (4) have recently described the preparation and characterization of Bi_5O_7I, while Klimakov *et al.* (5) have determined phase relationships involving BiOI, $Bi_7O_9I_3$, and Bi_5O_7I in the condensed anhydrous system BiI_3–Bi_2O_3.

Here we report the stability limits of Bi_5O_7I with respect to interconversion with BiOI and α-Bi_2O_3 in aqueous solutions at 25°C, and estimate the Gibbs energies of formation of solid Bi_5O_7I, BiOI, and BiI_3. This work was prompted by the possibility of using Bi_5O_7I to immobilize radioactive isotopes of iodine. In this regard, Kharbanda *et al.* (6), Ramani *et al.* (7), and Mel'nikov *et al.* (8) have described the sorption of ^{131}I on "bismuth hydroxide." Basic iodides have received little attention as hosts for ^{129}I, according to recent reviews by Vance *et al.* (9) and Burger *et al.* (10).

Experimental methods

Starting materials were reagent-grade $Bi(NO_3)_3 \cdot 5H_2O$, α-Bi_2O_3, KI, and carbonate-free aqueous solutions of NaOH and KOH. Solutions of desired iodide and hydroxide molarities were prepared using deionized water. The pH was adjusted and measured using automatic titration equipment (Metrohm E526 titrator and E535 dosimat, or Mettler DV/DK modular system). This system was calibrated with standard buffer solutions at pH = 7.00 and 9.18. This provided an adequate basis for measurements of pH up to about 11.5, above which the electrode showed discernible deviation from Nernstian response, as discussed below. Iodide activities were measured using an Orion Model 94-53 specific ion electrode and a Model 90-02 double-junction reference electrode, calibrated using standard solutions with iodide activities ranging from 10^{-2} to 10^{-7} mol dm^{-3}. Nernstian response was sustained over this range so long as solutions were carefully purged with nitrogen.

Solution compositions were computed on a molar activity basis. Since the equilibrium constants determined from this work (K_9 and K_{10}) are dimensionless, it is not necessary to distinguish between molarity and molality in subsequent calculations. In any case, most of the solutions used in the final equilibrium determinations were too dilute for this distinction to be significant.

Solids were identified by X-ray powder diffraction (XRD), using CuKα radiation and a Philips PW-1150 diffractometer with a diffracted-beam monochromator. Solid iodides were also characterized by thermogravimetric analysis, done manually on 1-g samples because of damage by evolved iodine to components of a recording microbalance in preliminary experiments with lead and bismuth iodides. Samples were heated in fireclay boats in a horizontal tube furnace, for periods of ~0.5 h at increasing temperatures (~25 K intervals), until constant weight indicated complete conversion to Bi_2O_3.

Preparation and characterization of bismuth oxyiodides

(a) BiOI

About 10 g of BiOI was prepared by mixing solutions of $Bi(NO_3)_3 \cdot 5H_2O$ and a small excess of KI over that required by eq. [1].

$$[1] \quad Bi(NO_3)_3 + H_2O + I^- \rightarrow BiOI + 2H^+ + 3NO_3^-$$

A deep orange-red precipitate of BiOI formed rapidly, together with some dark gray material, probably BiI_3 formed by reaction [2].

$$[2] \quad BiOI + 2H^+ + 2I^- \rightarrow BiI_3 + H_2O$$

The solids were isolated by filtration, and the BiI_3 was rapidly hydrolyzed back to BiOI upon washing with water (reverse of reaction [2]). The solid was identified as pure BiOI by XRD, based on the published diffraction pattern (11). Thermal decomposition of the BiOI in air occurred in two stages. In the first stage, between 250 and 480°C, the observed weight loss of 26.4% agreed well with the value of 27.03%, calculated for the formation of Bi_5O_7I, according to eq. [3].

$$[3] \quad 5BiOI + O_2 \rightarrow Bi_5O_7I + 2I_2$$

In the second stage, between 600 and 700°C, the remaining

[1]Issued as AECL No. 8736.

iodine was removed, in accordance with eq. [4].

[4] $4Bi_5O_7I + O_2 \rightarrow 10Bi_2O_3 + 2I_2$

The overall weight loss of 33.9% agreed well with the calculated value of 33.79%, based on eq. [5].

[5] $4BiOI + O_2 \rightarrow 2Bi_2O_3 + 2I_2$

This decomposition behaviour is similar to that reported by Rulmont (3). Krämer (12) determined a different route for the decomposition of BiOI in a nitrogen atmosphere, with successive losses of BiI_3 to form progressively more oxygen-rich phases: $Bi_4O_5I_2$, $Bi_7O_9I_3$, Bi_5O_7I, and finally, Bi_2O_3.

(b) Bi_5O_7I

This iodide was prepared in 10-g quantities, both by hydrolysis of BiOI with excess aqueous KOH, and by the reaction of α-Bi_2O_3 powder with excess aqueous KI, in accordance with eqs. [6] and [7], respectively.

[6] $5BiOI + 4OH^- \rightarrow Bi_5O_7I + 4I^- + 2H_2O$

[7] $5Bi_2O_3 + 2I^- + H_2O \rightarrow 2Bi_5O_7I + 2OH^-$

Each reaction proceeded to completion overnight in a stirred reaction vessel at room temperature. The XRD patterns of the filtered, washed solids were identical with each other and with the pattern obtained from the intermediate product of thermal decomposition of BiOI, described above (eq. [3]). These patterns are similar to those previously reported for Bi_5O_7I (3–5), except for additional weak features, as shown in Table 1. These features are reproducible, and the entire pattern can be indexed on the basis of the orthorhombic unit cell reported by Ketterer and Krämer (4), as shown in Table 1. The tetragonal and orthorhombic unit cells proposed by Rulmont (3) cannot account for all the lines. All the diffraction peaks we observed can be assigned Miller indices, *hkl*, with *l* even, suggesting a cell with *c* equal to one half of the value reported by Ketterer and Krämer (4). We presume that they observed some weak features in their single-crystal diffraction data that necessitated the larger cell. The general agreement between our intensity data and theirs is poor, perhaps because our 00*l* intensities are increased by preferred orientation. There was no indication that our solids contained any structurally essential water or other components, and thermogravimetric data agreed well with eq. [4]. All the samples decomposed between 500 and 700°C, with total weight losses of 9.35, 9.7, and 9.0%, respectively, from solids prepared from Bi_2O_3 and iodide, BiOI and hydroxide, and partial thermal decomposition of BiOI. The calculated weight loss for eq. [4] is 9.26%.

The crystal structure of a second form of Bi_5O_7I, designated β-Bi_5O_7I, was recently reported by Ketterer *et al.* (14); we have not observed this solid in any of our experiments.

Determination of stability limits

The stability limits of bismuth oxide – iodide solids in contact with aqueous solutions can be expressed by equilibria [8]–[10].

[8] $\frac{1}{2}BiI_3(s) + OH^-(aq) \overset{K_8}{\rightleftharpoons} \frac{1}{2}BiOI(s) + I^-(aq) + \frac{1}{2}H_2O(l)$

[9] $\frac{5}{4}BiOI(s) + OH^-(aq) \overset{K_9}{\rightleftharpoons} \frac{1}{4}Bi_5O_7I(s) + I^-(aq) + \frac{1}{2}H_2O(l)$

[10] $Bi_5O_7I(s) + OH^-(aq) \overset{K_{10}}{\rightleftharpoons} \frac{5}{2}Bi_2O_3(s) + I^-(aq) + \frac{1}{2}H_2O(l)$

These are variants of eqs. [2], [6], and [7], respectively, chosen

[1]Orthorhombic unit cell, a = 16.267(4) Å (1 Å = 0.1 nm), b = 5.356(2) Å, c = 11.503(2) Å, obtained by least-squares refinement of the cell reported by Ketterer and Krämer (4), but with the value of c halved. The 18 uniquely indexed lines were used in the refinement. For the 30 lines listed, the maximum difference between observed and calculated 2θ is 0.031°, and only three values exceed 0.02°. Observed d spacings were calibrated using a BaF_2 internal standard (a = 6.1971 Å, according to the unpublished data of D. A. Hewitt (13)). Computations were done using a program written by D. E. Appleman and H. T. Evans, Jr., U.S. Geological Survey, Geological Division, Washington, DC, U.S.A. 20244. The large number of near coincidences of d_{calc} values arise because $a \simeq \sqrt{2}c$, hence $d(hkl) \simeq d(h'kl')$ when $h^2 + 2l^2 = h'^2 + 2l'^2$. Asterisks indicate the *hkl* values favoured in ref. 4.

because each equilibrium constant, in a dilute aqueous system, is simply expressed as the quotient of iodide and hydroxide activities.

[11] $K_{eq} = \{I^-\}/\{OH^-\}$

whence

[12] $-\log K_{eq} = \log K_w + pH + pI$

where $pI = -\log \{I^-\}$. In other words, each pair of adjacent solids in the sequence $BiI_3 \rightarrow BiOI \rightarrow Bi_5O_7I \rightarrow Bi_2O_3$ should buffer the iodide activity at a particular value at a given pH. Dyrssen and Yen (2) observed such behaviour with BiI_3 + BiOI in acidic solutions with an ionic strength of 3.0 mol dm^{-3}. Their data correspond to a value of about 10.0 for log K_8, as discussed below. We have measured equilibrium iodide activities as a function of pH for each of the solid pairs, BiOI + Bi_5O_7I and Bi_5O_7I + α-Bi_2O_3 and hence estimated K_9 and K_{10}, respectively.

A third bismuth(III) oxyiodide, $Bi_7O_9I_3$, was reported by Klimakov *et al.* (5) as an equilibrium phase in the system BiI_3–Bi_2O_3. We have not positively identified it in this study, but have evidence that it occurred in some experiments at 100°C. This suggests that it is metastable with respect to the disproportionation reaction [13] near ambient temperature.

[13] $Bi_7O_9I_3 \rightleftharpoons Bi_5O_7I + 2BiOI$

However, it is more likely that it is a stable solid, but is difficult to nucleate in ambient-temperature aqueous solutions.

Equilibrium between α-Bi_2O_3, Bi_5O_7I and solution

Preliminary attempts to determine the equilibrium constant K_{10}, by allowing mixtures of α-Bi_2O_3 and Bi_5O_7I powders to equilibrate with various solutions of KOH and (or) KI, met with limited success because of slow kinetics. However, one series of experiments, in which 0.3 g of each solid was shaken for a week in 20 cm^3 of KI solution (0.001 to 1.0 mol dm^{-3}) in stoppered Teflon bottles, gave results consistent with the expected equilibrium behaviour, with log $K_{10} \simeq -3$. Similar results were obtained when successive aliquots of KOH and (or) KI were added to stirred suspensions of the mixed solids, while the pH and pI were monitored. A deviation towards less negative values of log K_{10} occurred at pI values above about 6; this deviation was reduced by continuously purging the reaction vessel with nitrogen. Dissolved oxygen is known to interfere with iodide-selective electrodes at such low iodide activities (15); displacement of iodide from the solid phase by traces of carbonate may also have contributed to the deviation.

Some preliminary kinetic experiments showed that the rate of uptake of iodide by Bi_2O_3 powder is enhanced by pretreating the oxide with aqueous iodide, presumably because a layer of Bi_5O_7I is formed on the oxide surface. We therefore ran a series of equilibration experiments with iodide-treated Bi_2O_3. About 5 g of α-Bi_2O_3 was stirred overnight with sufficient aqueous KI to achieve about 20% conversion to Bi_5O_7I (eq. [7]). Measurements of iodide activity and pH confirmed that iodide uptake was almost quantitative. The solution was filtered, and the solid was washed repeatedly with water and immediately resuspended in 40 cm^3 of deionized water purged with nitrogen. The solution chemistry stabilized at pH $\simeq$ 9.5 and pI $\simeq$ 8. Aliquots of KOH or KI were then added, and the pH and pI were monitored continuously. After addition of each aliquot, equilibrium was re-established at successively higher pH and lower pI values, with pH + pI remaining constant at about 17.6, which corresponds to log $K_{10} \simeq -3.6$, at ambient temperature (23 ± 2°C). Although equilibrium could be approached from either direction, it was attained more quickly after addition of KI than KOH (ca. 10 min, rather than ca. 100 min). Therefore, in the definitive series of equilibrium measurements, aliquots of KI only were added to the solution, to minimize the total duration of the experiments.

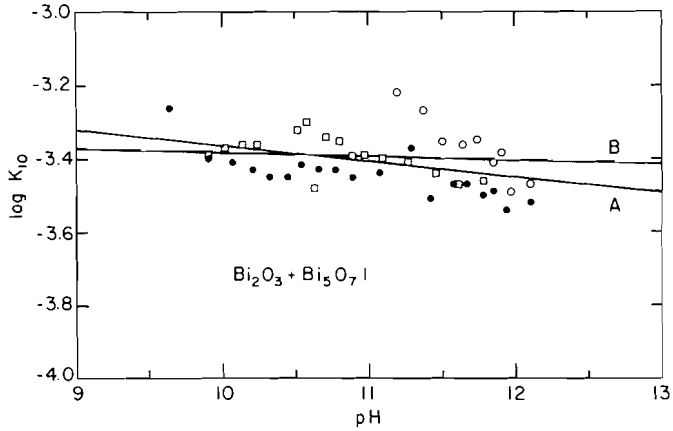

FIG. 1. Measurements of log K_{10} (14.00 − pH − pI) as a function of pH, from three series of experiments with α-Bi_2O_3 + Bi_5O_7I at 25°C. Lines A and B represent linear regressions of all data and data at pH < 11.5, respectively.

In this final series of experiments, the above procedure was repeated in a vessel thermostatted at 25°C, at least 30 min being allowed for equilibration between addition of aliquots of iodide. No significant changes were observed on standing for a further 16 h. Results are presented in Fig. 1.

Linear regression analysis of all 44 data yielded line A, with a slope, $d(\log K_{10})/d(pH) = -0.042$. The main cause for this nonzero slope appeared to be a small deviation of the pH-sensing electrode from linear behaviour at pH > 11.5. The existence of such a deviation was confirmed by pH measurements on freshly diluted standard hydroxide solutions, but no correction was attempted. When the analysis was limited to the 30 data at pH ≤ 11.5, the slope was reduced to −0.011 (line B). Based on these data, we obtained log $K_{10} = -3.39 \pm 0.13$ (2σ). However, some systematic differences are apparent between the three experiments, probably because of minor calibration errors. A value of log $K_{10} = -3.39 \pm 0.20$ probably represents the total experimental uncertainty more accurately.

Equilibria between Bi_5O_7I, BiOI, and solution

Although Bi_5O_7I was converted to BiOI by acidic iodide solutions, and BiOI was hydrolyzed to Bi_5O_7I by basic solutions, our intitial attempts to measure equilibrium behaviour between these two solids in near-neutral solutions (eq. [10]) were unsuccessful, because of the very slow interconversion kinetics. However, our success in obtaining equilibrium data from iodide-treated Bi_2O_3, as opposed to simple mixtures of Bi_2O_3 and Bi_5O_7I (preceding section), prompted us to attempt equilibrium measurements on partially hydrolyzed BiOI, rather than on a mixture of BiOI and Bi_5O_7I.

About 5 g of BiOI was stirred overnight with sufficient aqueous KOH to achieve about 20% conversion to Bi_5O_7I. The solid was isolated by filtration, washed, and then submitted to an experimental procedure similar to that for the Bi_2O_3–Bi_5O_7I equilibrium measurements, described above. In these experiments, equilibrium was usually re-attained within a few seconds

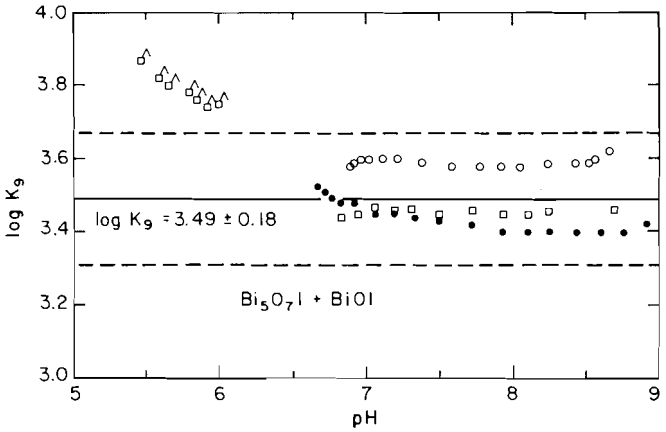

FIG. 2. Measurements of log K_9 (14.00 − pH − pI) as a function of pH, from three series of experiments with Bi_5O_7I + BiOI at 25°C. Flagged squares are measurements recorded while the pH was slowly drifting up and represent upper limits of log K_9 (see text).

of addition of aliquots of hydroxide, but only after several hours following addition of iodide. Most equilibrium measurements were therefore made by successive additions of hydroxide.

Results of three series of experiments with BiOI and Bi_5O_7I in a solution thermostatted at 25°C are shown in Fig. 2. The data at pH < 7 represent upper limits of K_9, since both pH and pI continued to drift for several hours, perhaps because of slow equilibration of the polymeric species that dominate the solution chemistry of bismuth in this pH range (16). Both pH and pI remained stable in experiments at pH values between 7 and 9; they were normally recorded about 15 min after addition of hydroxide. Analysis of the data obtained at 7 < pH < 9 in these three runs yielded values for log K_9 of 3.42 ± 0.04 (2σ), 3.59 ± 0.02, and 3.46 ± 0.01. Clearly, systematic errors between the series outweigh the random errors within each series. Based on these three separate measurements, we estimate that log K_9 = 3.49 ± 0.18.

Gibbs energies of formation of Bi_5O_7I, BiOI, and BiI_3

The Gibbs energies of formation of the bismuth iodides can be calculated from those of α-Bi_2O_3(s), $H_2O(l)$, OH^-(aq), and I^-(aq), together with K_8, K_9, and K_{10}, using eqs. [14]–[16]:

$$[14]\quad \Delta_fG^0(Bi_5O_7I, s) = \tfrac{5}{2}\Delta_fG^0(\alpha\text{-}Bi_2O_3, s) + \Delta_fG^0(I^-, aq) + \tfrac{1}{2}\Delta_fG^0(H_2O, l) - \Delta_fG^0(OH^-, aq) + RT \ln K_{10}$$

$$[15]\quad \Delta_fG^0(BiOI, s) = \tfrac{4}{5}\{\tfrac{1}{4}\Delta_fG^0(Bi_5O_7I, s) + \Delta_fG^0(I^-, aq) + \tfrac{1}{2}\Delta_fG^0(H_2O, l) - \Delta_fG^0(OH^-, aq) + RT \ln K_9\}$$

$$= \tfrac{1}{2}\Delta_fG^0(\alpha\text{-}Bi_2O_3, s) + \Delta_fG^0(I^-, aq) + \tfrac{1}{2}\Delta_fG^0(H_2O, l) - \Delta_fG^0(OH^-, aq) + RT(0.2 \ln K_{10} + 0.8 \ln K_9)$$

$$[16]\quad \Delta_fG^0(BiI_3, s) = 2\{\tfrac{1}{2}\Delta_fG^0(BiOI, s) + \Delta_fG^0(I^-, aq) + \tfrac{1}{2}\Delta_fG^0(H_2O, l) - \Delta_fG^0(OH^-, aq) + RT \ln K_8\}$$

$$= \tfrac{1}{2}\Delta_fG^0(\alpha\text{-}Bi_2O_3, s) + 3\Delta_fG^0(I^-, aq) + \tfrac{3}{2}\Delta_fG^0(H_2O, l) - 3\Delta_fG^0(OH^-, aq) + RT(0.2 \ln K_{10} + 0.8 \ln K_9 + 2 \ln K_8)$$

Robie *et al.* (17) list the following Gibbs energies of formation at 298.15 K and 100 kPa, with aqueous species referring to a standard state of 1 mol kg^{-1}: Bi_2O_3(s), −493.453 ± 1.464 (2σ) kJ mol^{-1}; $H_2O(l)$, −237.141 ± 0.084 kJ mol^{-1}; OH^-(aq), −157.328 ± 0.090 kJ mol^{-1}; I^-(aq), −51.915 ± 0.860 kJ mol^{-1}. (These error limits are stated in ref. 17 as twice the estimated standard deviations.) Substituting in eqs. [14]–[16], we obtain expressions [17]–[19].

$$[17]\quad \Delta_fG^0(Bi_5O_7I, s, 298\ K) = [(-1246.79 \pm 4.65) + RT \ln K_{10}]\ kJ\ mol^{-1}$$

$$[18]\quad \Delta_fG^0(BiOI, s, 298\ K) = [(-259.88 \pm 1.72) + RT(0.2 \ln K_{10} + 0.8 \ln K_9]\ kJ\ mol^{-1}$$

$$[19]\quad \Delta_fG^0(BiI_3, s, 298\ K) = [(-286.20 \pm 3.70) + RT(0.2 \ln K_{10} + 0.8 \ln K_9 + 2 \ln K_8)]\ kJ\ mol^{-1}$$

Using the values for K_9 and K_{10} derived here, we obtain

$$\Delta_fG^0(Bi_5O_7I, s, 298\ K) = -1266.1 \pm 5.8\ kJ\ mol^{-1}$$

$$\Delta_fG^0(BiOI, s, 298\ K) = -247.8 \pm 2.8\ kJ\ mol^{-1}$$

Dyrssen and Yen (2) obtained log K_{20} (= 2 log [H^+] + 2 log [I^-] (their log K_s)) = −8.50 for equilibrium [20] in 3 mol dm^{-3} aqueous sodium perchlorate solution.

$$[20]\quad BiI_3(s) + H_2O \rightleftharpoons BiOI(s) + 2H^+ + 2I^-$$

Equilibrium constants K_{20} and K_8 are related by eq. [21].

$$[21]\quad \log K_{20} = 2 \log K_8 + 2 \log K_w$$

Using the value log K_w = −14.22 ± 0.02 in 3 mol dm^{-3} aqueous sodium perchlorate, as reported by Ingri *et al.* (18), but without attempting to correct K_{20} for ionic strength effects, we estimate log K_8 = 10.0 ± 1.0. Application of this value to eq. [19] yields $\Delta_fG^0(BiI_3, s, 298\ K)$ = −160.0 ± 16.2 kJ mol^{-1}. Combining this value with data for Bi^{3+}(aq) and I^-(aq) from ref. 17 (Δ_fG^0 = 82.80 ± 0.85 and −51.915 ± 0.860 kJ mol^{-1}, respectively), we calculated the solubility product of BiI_3: log $K_{sp}(BiI_3, 298\ K)$ = −15.3 ± 3.4.

This solubility product is in better agreement with the value of −15.6 reported by Dyrssen and Yen (2) than −18.1, as reported by Ahrland and Grenthe (19), although both literature values lie within our estimated error limits. A value near −15 also appears to be more consistent with observations on BiI_3 precipitation, as summarized by Eve and Hume (20). However, since the Dyrssen–Yen data again refer to 3 mol dm^{-3} perchlorate media, direct comparisons are not strictly valid.

Conclusions

From the viewpoint of radioactive iodine immobilization, the most important conclusion is that Bi_5O_7I is seven orders of magnitude more stable than BiOI, and about fourteen orders of magnitude more stable than BiI_3, towards hydrolysis, if "stability" is expressed as the minimum iodide activity at a given pH, at which the solid can exist at equilibrium. Expressed another way, the lowest controlled iodide activities that can be achieved in this system are those buffered by the solid phase assemblage, Bi_2O_3 + Bi_5O_7I, and are expressed by the relationship, pH + pI = 17.39 ± 0.20 at 25°C. However, considerable care is necessary in the pretreatment of solids in order to achieve this equilibrium in a reasonably short time. A full understanding of the behaviour of a bismuth oxyiodide waste form for radioactive iodine also requires some knowledge of redox chemistry, iodine speciation, and interactions with other anions. We have previously reported data on the stability

of basic bismuth carbonates (21), and are presently investigating reactions of Bi_2O_3 with other common anions in aqueous systems. The Gibbs energy data presented here permit calculation of stability at 25°C with respect to redox reactions involving any other species for which Gibbs energies of formation are known.

Reçu le 29 mai 1985

DANIÈLE DRUET, LOUIS COMEAU et JEAN-PIERRE ZAHRA.Can. J. Chem. **64**, 295 (1986).

La structure de l'opigénine, une aglycone issue de la fraction glycosidique d'*Opilia celtidifolia*, a été établie grâce aux données spectroscopiques (ir, rmn du ^1H et du ^{13}C, masse) de l'opigénine et des ses dérivés. Il s'agit d'un triterpène nouveau, de structure voisine de celle du 3β-hydroxy lupane, mais avec un isopropyle en position 20 et un pont oxyméthylène en position 20–28.

DANIÈLE DRUET, LOUIS COMEAU, and JEAN-PIERRE ZAHRA. Can. J. Chem. **64**, 295 (1986).

The structure of opigenin, an aglycone from the glycosidic fraction of *Opilia celtidifolia*, has been established by study of the genin and its derivatives by means of ir, mass spectroscopy, and ^1H and ^{13}C nmr spectroscopy. This is a new triterpene whose skeleton resembles that of 3β-hydroxy lupane but with an isopropyl group in position 20 and an oxymethylene bridge in position 20–28.

[Traduit par le journal]

Introduction

Dans le cadre d'une étude sur les plantes médicinales d'Afrique de l'Ouest, une Opiliacée de Côte d'Ivoire, *Opilia celtidifolia*, a retenu notre intérêt. Il s'agit d'une liane que l'on trouve le plus souvent dans la zone des savanes et dont la pharmacopée locale fait de multiples usages (1–3).

Dans un premier temps, l'étude structurale des aglycones issues de la fraction glycosidique de la plante nous a permis, d'identifier les composés majeurs (4). Il s'agit de l'acide oléanolique de son acétate et de l'hédéragénine, des triterpènes pentacycliques.

Dans un second temps, l'étude des composés mineurs a permis la mise en évidence de plusieurs substances comprenant, entre autres, un alcool terpénique présent en très faible quantité (moins de 0,7%, en poids, de la totalité des aglycones), dont nous avons tenté d'établir la structure. Une étude analytique préliminaire n'a pas permis d'identifier ce composé à un triterpène de structure connue. Il nous a donc fallu, afin de compléter l'étude structurale, préparer quelques uns de ses dérivés. Les résultats obtenus lors de l'étude de ces dérivés ont révélé un squelette hydrocarboné assez inhabituel dans la série des triterpènes pentacycliques. Nous avons donc dénommé cette aglycone "opigénine". Une étude ultérieure, conduite sur les autres composés mineurs, devrait nous permettre d'établir les relations existant entre l'opigénine et les autres triterpènes présents dans la plante. S'il s'avère que cette aglycone ne résulte pas d'un réarrangement subi par une aglycone de structure classique, il sera alors nécessaire d'établir le processus biosynthétique qui est à l'origine de sa formation.

Résultats et discussion

L'opigénine a été isolée plusieurs fois à partir d'extraits provenant de lots différents d'*Opilia celtidifolia*, selon les conditions décrites dans la partie expérimentale. Obtenue par chromatographie sur colonne à partir du mélange des aglycones acétylées, sa pureté est contrôlée par ccm (chromatographie sur couche mince) et clhp (chromatographie liquide à haute pression). Les traces d'acide oléanolique résiduel sont éliminées par cristallisation du chlorure de méthylène. Les cristaux obtenus (F = 275–280°C) présentent une structure en feuillet qui ne convient pas pour la diffraction des rayons X. Ils répondent positivement au test de Liebermann–Burchard et négativement à celui du tétranitrométhane.

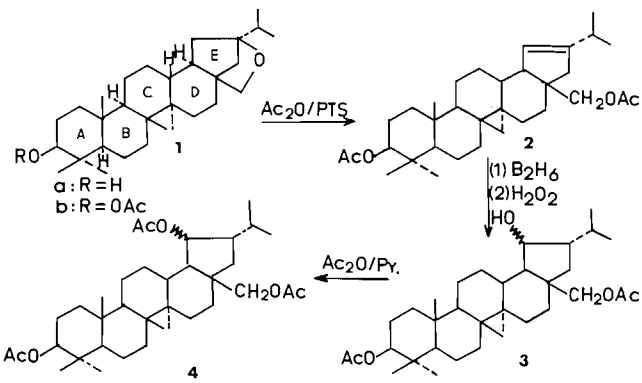

FIG. 1. Structure de l'opigénine et de ses dérivés.

Une partie des cristaux est désacétylée par hydrolyse en milieu basique afin d'établir les constantes physico-chimiques de l'opigénine **1***a*, Recristallisée du dichlorométhane, l'opigénine présente un point de fusion de 265–267°C. Le résultat de l'analyse centésimale et la présence en spectrométrie de masse d'un pic d'ion moléculaire à m/z = 442 conduisent à la formule brute $C_{30}H_{50}O_2$. La spectrométrie infrarouge montre qu'il s'agit d'un alcool (νOH à 3500 cm^{-1}) *gem*-diméthylé (νCH à 1360 et 1380 cm^{-1}). L'absence d'absorption dans le domaine 850–870 cm^{-1} laisse supposer que l'opigénine ne présente pas de liaison éthylénique, ce qui confirme le test au tétranitrométhane. En spectrométrie de masse, l'opigénine donne la fragmentation caractéristique des triterpènes pentacycliques hydroxylés en 3: on remarque, en effet, à m/z = 189, 203 et 207, les pics résultant d'une scission au niveau du cycle C, déjà décrite par ailleurs (5–8). Deux autres fragments permettent de préciser la structure de l'aglycone: l'un, à m/z = 411, doit résulter de la perte de CH_2O et H• et suggère la présence d'un

NOTA: Les valeurs des déplacements chimiques sont données en parties par million avec le TMS comme référence (d = doublet, dd = doublet dédoublé, t = triplet, q = quadruplet, m = multiplet).

pont oxyméthylène; l'autre, à m/z = 381, provient de la perte d'une molécule d'eau et d'un groupement isopropyle. La présence de ce groupement sur la molécule est confirmée par le pic de base à m/z = 43 (5). La rmn du ^1H à 200 MHz est effectuée, pour des raisons de commodité, sur l'opigénine acétylée **1***b*. Les signaux obtenus pour les groupements méthyles (tableau 1) correspondent à la présence de cinq groupements angulaires et d'un groupement isopropyle. À δ = 2,04 ppm, un singulet (3H dû au méthyle d'un groupement acétyle montre que l'opigénine ne possède qu'un hydroxyle acétylable. La position de ce groupement est donnée à δ = 4,5 ppm (^3J = 10 Hz, ^3J = 6 Hz) par le quadruplet caractéristique, dans les systèmes triterpéniques pentacycliques, du couplage $^3J_{aa}$ et $^3J_{ae}$ du proton en 3 axial, lorsque celui-ci se trouve en α d'un acétyle (10). On en déduit que l'hydroxyle acétylable occupe la position 3 équatoriale. Les doublets dédoublés observés à δ = 3,35 et 4,16 ppm ($^2J_{AB}$ = −7 Hz, $^4J_{AA'}$ = 2 Hz, $^4J_{BB'}$ = 1,5 Hz) correspondent à deux hydrogènes situés sur un carbone porteur d'une fonction éther-oxyde, en l'occurrence un groupement oxyméthylène. On peut considérer qu'ils constituent les deux parties A et B d'un système AB dont chaque branche est dédoublée par la présence d'un couplage à longue distance du type ^4J. Il s'avère, d'après les observations effectuées par certains auteurs (9) sur des dérivés de triterpènes possédant un pont oxyméthylène, que de tels couplages ne sont possibles que si les têtes de pont sont des carbones quaternaires (fig. 2). La valeur relativement faible trouvée pour la constante de couplage J_{AB} des protons du groupement oxyméthylène indique que ce pont se trouve inclus dans un cycle tendu à quatre ou cinq atomes. On note en effet, dans la littérature, des valeurs de J_{AB} de cet ordre pour des composés dont le groupement —CH_2O— appartient à un cycle à cinq atomes: 6 et 7 Hz pour des dérivés du 3β-hydroxy 13β,28β-époxy oléan-11,12-ène (11), 7 et 7,5 Hz pour des dérivés du 3β-acétoxy 19β,28β-époxy lupane (12). Cette constante est comprise entre 10 et 12 Hz lorsque le groupement —CH_2O— fait partie d'un cycle à six atomes: 11 Hz pour le 3β-acétoxy 20β,28β-époxy lupane (13). Le spectre de rmn du ^{13}C, enregistré sur l'acétate **1***b* en utilisant toutes les techniques appropriées à la détermination de la nature des différents types de carbones présents dans la molécule (APT, INEPT, ADEPT), fait apparaître: 8 carbones primaires (CH_3—) à δ = 27,9; 24,8; 21,3; 20,1; 16,4; 16,4; 15,8; 14,2 ppm; 11 carbones secondaires (—CH_2—) à δ = 69,0; 38,5; 34,9; 33,8; 29,8; 27,9; 26,5; 25,4; 23,7; 22,7; 18,1 ppm; 6 carbones tertiaires (—CH—) à δ 80,9; 55,5; 50,7; 47,1; 42,4; 39,7 ppm; 7 carbones quaternaires (—C—) dont aucun n'est éthylénique à δ = 170,9; 72,2; 41,5; 40,7; 37,8; 37,1; 31,7 ppm.

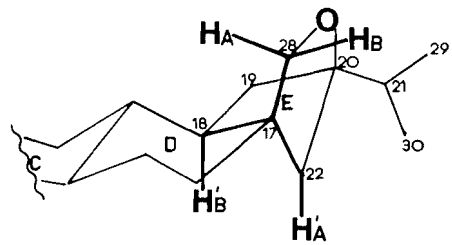

FIG. 2. Structure du cycle D de l'opigénine.

L'attribution de ces différents glissements chimiques figure dans le tableau 2 établi après détermination de la structure de l'opigénine.

Le test de Liebermann–Burchard, la fragmentation caractéristique en spectrométrie de masse et la présence de méthyles angulaires en rmn du ^1H suggèrent un squelette hydrocarboné de type triterpène pentacyclique.

La présence d'un groupement isopropyle, caractérisé aussi bien en spectrométrie de masse qu'en rmn du ^1H, nous a amené à effectuer une étude comparative des constantes de rmn du ^1H et du ^{13}C obtenues pour l'acétate d'opigénine **1***b*, avec celles données par la littérature (9, 12–20). En rmn du ^1H, on constate que l'opigénine présente une certaine similitude avec les dérivés du lupane et du hopane et plus particulièrement avec ceux du 3β-acétoxy lupène (tableau 1). On note l'absence de signal pour le méthyle en 17, ce qui peut être l'indice d'une "fonctionnalisation" du carbone en 28. En rmn du ^{13}C, on constate une identité presque parfaite entre les glissements chimiques des carbones des cycles A, B, C et d'une partie du cycle D ($C_{(1)}$–$C_{(16)}$ et $C_{(23)}$) de l'acétate d'opigénine et du 3β-acétoxy lupane (tableau 2), les différences constatées au niveau des cycles D et E étant vraisemblablement dues à la présence du pont oxyméthylène et du groupement isopropyle sur ces cycles. L'ouverture du pont oxyméthylène est effectuée par action de l'acide paratoluène sulfonique dans l'anhydride acétique sur l'acétate d'opigénine

TABLEAU 2. En rmn du ^{13}C, glissements chimiques comparés du 3β-acétoxy lupane et de l'opigénine et de ses dérivés

C	3β-Acétoxy lupane	**1***b*	**2**	**4**	C	3β-Acétoxy lupane	**1***b*	**2**	**4**
1	38,3	38,5	38,6	38,0	16	35,5	34,9	35,3	32,1

11	20,9	22,7	22,8	21,3	26	15,9	15,8	16,1	16,0
12	25,0	26,5	26,8	25,7	27	14,4	14,2	14,9	14,7
13	37,9	39,7	38,4	37,5	28	18,0	69,0	61,0	61,9
14	42,7	41,5	42,2	44,0	29	15,1	20,1	21,1	20,8
15	27,4	27,9	27,6	28,8	30	23,0	24,8	22,9	21,2

NOTA: Les valeurs de δ sont données en parties par million avec le TMS comme référence. Pour **1***b*: δ(*C*=O) = 170,9 ppm et δ(CO*C*H$_3$) = 21,3 ppm. Pour **2**: δ(*C*=O) = 171,0 ppm et 171,5 ppm et δ(CO*C*H$_3$) = 21,3 et 21,5 ppm. Pour **4**: δ(*C*=O) = 177,8; 171,8; 170,3 ppm et δ(CO*C*H$_3$) = 21,1; 21,3; 21,5 ppm.

1*b* (21). On obtient ainsi le composé **2** qui présente, en spectrographie infrarouge, l'absorption caractéristique des liaisons éthyléniques à 800 cm^{-1}. En spectrométrie de masse, le pic de l'ion moléculaire situé à m/z = 526 permet, avec l'analyse centésimale, de déterminer la formule brute: $C_{34}H_{54}O_4$. À côté des fragments 189 et 203 caractéristiques des triterpènes, on remarque trois fragments intéressants: Le premier à m/z = 423 ($M^{+\cdot}$ − CH_3CO_2H−$CH(CH_3)_2$) confirme la présence d'un groupement isopropyle. Le second à m/z = 406 ($M^{+\cdot}$ − 2 CH_3CO_2H) montre que la molécule est diacétylée et le troisième nous apprend que l'un des acétyles est porté par un carbone primaire: m/z = 453 ($M^{+\cdot}$ − CH_2OCOCH_3). La rmn du ^1H apporte quelques précisions sur la conformation de la molécule (tableau 1). Ainsi pour les méthyles de l'isopropyle on observe deux doublets. L'un est centré sur δ = 0,86 ppm (^3J = 6,5 Hz), et ses composantes sortent dans les signaux des méthyles du cycle A à δ =0,84 et 0,88 ppm; l'autre doublet, centré sur δ = 1,00 ppm, (^3J = 6,5 Hz) apparaît nettement. La courbe d'intégration est en accord avec cette analyse. La présence de ces deux doublets traduit la nonéquivalence des méthyles du groupement isopropyle (22). Deux singulets, à δ = 2,04 et 2,08 ppm (2 × 3H), dus aux méthyles de deux acétyles confirment la diacétylation. La présence d'une fonction alcool primaire est marquée par deux doublets centrés respectivement sur δ = 3,83 et 4,30 ppm (2 × 1H, $^2J_{AB}$ = −11 Hz) et attribuables aux protons non équivalents d'un groupement —CH_2OAc porté par un carbone quaternaire. Enfin, centré sur δ = 5,23 ppm, un doublet (1H, ^3J = 7 Hz) indique la présence d'une liaison éthylénique trisubstituée dont le proton n'est couplé qu'avec un seul proton vicinal, donc en α d'un carbone tertiaire: $(R)_2$—CH—CH=C—$(R)_2$. La rmn du ^{13}C confirme cette disposition avec deux pics dus respectivement à un carbone éthylénique quaternaire à δ = 140,1 ppm et à un carbone éthylénique tertiaire à = 117,9 ppm.

Le composé **2** se présente donc comme un diol triterpénique pentacyclique insaturé. L'ouverture du pont oxyméthylène a conduit à l'apparition d'une fonction alcool primaire et d'une liaison éthylénique trisubstituée. L'absence du méthyle angulaire sur le carbone 17 et les valeurs des glissements chimiques des protons du groupement —CH_2OAc, très voisines de celles données dans la littérature (12) pour le 3β,28β-diacétoxy lupa-20,30-ène, nous amènent à positionner ce groupement sur le carbone en 17. L'emplacement de la double liaison, vraisemblablement sur les cycles D ou E, ne peut être déterminé avec précision que si l'on additionne sur celle-ci un groupement chimique convenable. L'hydroboration oxydative de **2** conduit, après purification, au composé d'addition hydroxylé **3**. En rmn du ^1H, on constate que les doublets attribués aux protons non équivalents du —CH_2OAc ont subi un déplacement (δ = 3,79 et 4,42 pm, 2 × 1H, $^2J_{AB}$ = −11 Hz) par rapport au composé **2**, ce qui indique un changement dans l'environnement chimique de ces protons. On remarque également deux quadruplets (1H au total), situés à δ = 5,29 et 5,45 ppm, et présentant des constantes de couplage voisines et égales respectivement à ^3J = 12 Hz, ^3J = 6 Hz et ^3J = 10 Hz, ^3J = 6 Hz. Ces deux quadruplets sont dans le rapport de 1:4, si l'on compare les intégrations respectives. Comme cela a déjà été signalé par ailleurs (23), la réaction d'hydroboration a conduit aux deux stéréoisomères α et β. La présence, dans le spectre, de deux singulets situés à δ = 8,55 et 9,15 ppm (1H au total), et disparaissant par échange avec D_2O, donc attribuables aux protons des OH, confirme l'isomérie. Les valeurs relativement importantes des glissements chimiques observées ici, et que l'on peut attribuer en première approximation aux protons situés en α des groupements hydroxyles apparus après hydroboration oxydative, montrent que ceux-ci sont situés dans le cône de blindage d'un groupement chimique voisin. En fait, si l'on considère les étapes qui ont conduit au composé **3**, il ne peut s'agir que du groupement —CH_2OAc. L'acétylation de **3** donne le triacétate **4** que l'on recristallise facilement dans l'hexane. La masse de l'ion moléculaire, 586, obtenue en spectrométrie de masse, jointe à l'analyse centésimale, conduit à la formule $C_{36}H_{58}O_6$. On retrouve à nouveau les fragments 203 et 189 caractéristiques des triterpènes pentacycliqus et quelques fragments qui montrent que la molécule est triacétylée (m/z = 526, 466 et 406), que l'une des fonctions alcools acétylées est primaire (m/z = 453, $M^{+\cdot}$—CH_3CO_2H – CH_2OCOCH_3; m/z = 393. $M^{+\cdot}$ −(2 × CH_3CO_2H) − CH_2OCOCH_3) et qu'il existe un groupement isopropyle (m/z = 483, $M^{+\cdot}$ − CH_3CO_2H − $CH(CH_3)_2$). La rmn du ^1H confirme la présence des trois

groupements acétyles (trois singulets 3 × 1H à δ = 2,02; 2,05; 2,13 ppm) et montre que les protons non équivalents du —CH_2OAc en 17 ont subi à nouveau une variation de glissement chimique (δ = 3,98 et 4,28 ppm, $^2J_{AB} = -11$ Hz). Ceci est en faveur de l'hypothèse que nous avons faite concernant la présence, dans l'environnement immédiat de ce groupement, d'un autre groupement, en l'occurrence l'hydroxyle acétylé provenant de l'hydroboration oxydative. La rmn du ^{13}C permet, au moyen de l'APT d'attribuer tous les glissements chimiques observés aux différents carbones de la molécule (tableau 1). On note que le carbone porteur de l'hydroxyle provenant de l'hydroboration oxydative est un carbone secondaire.

En résumé, l'étude du dérivé résultant de l'ouverture du pont oxyméthylène nous a permis de fixer la position de ce groupement entre le carbone en 17 et un autre carbone tétrasubstitué en tête de pont. En tenant compte du fait qu'il existe un groupement isopropyle, vraisemblablement situé sur le cycle E, et que l'hétérocycle formé par le pont oxyméthylène ne comporte pas plus de cinq atomes, il est alors possible de proposer la structure **1***a* pour l'opigénine.

Deux faits expérimentaux justifient le choix de cette structure. En premier lieu, l'examen du modèle moléculaire correspondant à la structure **1***a* montre qu'après ouverture du pont oxyméthylène, le proton de la liaison éthylénique présente un angle dièdre d'environ 100° avec le proton en 18α. Cet angle correspond à une constante de couplage en rmn du ^1H d'environ 7 Hz. C'est bien ce que l'on observe expérimentalement. En second lieu, si notre hypothèse structurale est exacte, le composé résultant de l'hydroboration oxydative doit présenter un proton en position 19, qui par couplage avec les protons 18α et 20β donnera un quadruplet en rmn du ^1H. Nous observons en effet une telle figure de couplage avec, toutefois, la particularité d'un dédoublement dû à l'isomérie α–β du proton en 19.

La structure **1***a* est donc cohérente avec les résultats expérimentaux obtenus et peut donc être raisonnablement proposée pour l'opigénine.

Partie expérimentale

Les points de fusion ont été pris sur microscope à platine chauffante de Reichert. Les spectres ir ont été effectués sur un appareil Leitz. Les pouvoirs rotatoires ont été mesurés dans le chloroforme au moyen d'un micropolarimètre Perkin–Elmer. Les spectres de rmn du ^1H ont été enregistrés indifféremment sur Varian XL 100, Varian XL 200 et Brucker AM 200, en solution dans le deutérochloroforme avec le TMS comme référence interne. Les spectres de rmn du ^{13}C ont été déterminés sur Varian XL 200 et les spectres de masse, sur Thompson ou L. K. B.

1. *Isolement de l'acétate d'opigénine 1b*

L'opigénine est extraite à partir des aglycones brutes obtenues par hydrolyse acide de la fraction glycosidique d'*Opilia celtidifolia* (4). Celles-ci (79 g), placées dans un Soxhlet, sont lavées à l'oxyde d'éthyle durant 72 h. L'évaporation du solvant permet de récupérer 40 g de résidu que l'on acétyle à 25°C à l'aide de 80 mL d'anhydride acétique en présence de 400 mL de pyridine anhydre. La réaction dure 48 h. Après élimination des réactifs sous pression réduite la phase organique est reprise au dichlorométhane, lavée successivement au Na_2CO_3, à l'eau, à l'HCl 2 *N*, puis à nouveau à l'eau jusqu'à neutralité. Après séchage sur Na_2SO_4 et élimination du solvant, on obtient 41,2 g d'acétates d'aglycones.

Ces acétates sont ensuite fractionnés par chromotographie sur colonne de silice (50 g de silice par gramme d'aglycones), avec comme éluant le mélange hexane–oxyde d'éthyle (90:10 en volume). À partir de 5 g d'aglycones acétylées, on isole en moyenne 35 mg d'acétate d'opigénine **1***b*, soit 0,7% en poids des aglycones brutes. Après cristallisation du mélange dichlorométhane–hexane, l'acétate d'opigénine présente les caractéristiques suivantes: *F* 275–280°C; α_D^{45} +25,6°, (*c* 26,6×10^{-3}, $CHCl_3$); ir cm^{-1} (KBr); 1724, 1389, 1380, 1250, 1142, 1117, 869; rmn ^1H et ^{13}C ($CDCl_3$): tableaux 1 et 2; masse *m/z*: 484(49), 424(100), 409(38), 381(47), 355(35), 342(24), 219(19), 205(35), 203(37), 189(94). *Anal.* calc. pour $C_{32}H_{52}O_3$: C 79,33; H 10,74; O 9,92; tr.: C 79,17; H 11,09; O 9,74%.

2. *Obtention de l'opigénine*

On saponifie durant 3 h au reflux, 21 mg d'acétate d'opigénine **1***b* à l'aide de 8 mL de potasse 2 *N* méthanolique. Après dilution, la fraction hydro-alcoolique est extraite à l'oxyde de éthyle, l'extraite éthéré est lavé à l'eau, séché sur Na_2SO_4, et le solvant est éliminé. Le résidu (18 mg) est recristallisé dans le dichlorométhane et l'on observe les caracteristiques suivantes: *F* 265–267°C; ir cm^{-1}(KBr): 3500, 1380, 1360, 1142, 1117, 865; rmn ^1H et ^{13}C ($CDCl_3$): tableaux 1 et 2; masse *m/z*: 442(45), 424(20), 411(6), 409(8), 381(3), 207(33), 203(15), 189(45), 43(100). *Anal.* calc. pour $C_{30}H_{50}O_2$: C 81,45; H 11,31; O 7,24; tr.: C 81,16; H 11,44; O 7,40%.

3. *Ouverture du pont oxyméthylène*

On additionne 53 mg d'acide paratoluène sulfonique à 64 mg d'opigénine **1***a* dans 10 mL d'anhydride acétique et porte le tout à 117–120°C durant 30 min (21). Après ce temps, on dilue à l'eau et extrait au dichlorométhane. La solution organique est lavée au $NaHCO_3$ aqueux, puis à l'eau jusqu'à neutralité. Après séchage sur Na_2SO_4 et élimination du solvant, on récupère 74 mg de résidu. Le composé **2** est séparé des produits secondaires par chromatographie sur colonne de silice avec le mélange hexane – oxyde d'éthyle (90:10 en volume) comme éluant. On isole ainsi 14 mg de produit pur que l'on recristallise à partir du mélange hexane–dichlorométhane et qui présente les caractéristiques suivantes: *F* 237–240°C; α_D^{25} +13,6° (*c* 21×10^{-3}, $CHCl_3$); ir cm^{-1}(KBr): 1725, 1355, 1232, 1025, 975, 800; rmn ^1H et ^{13}C ($CDCl_3$): tableaux 1 et 2; masse *m/z*: 526(9), 466(42), 423(10), 406(16), 393(10), 363(5), 203(39), 189(72), 43(100). *Anal.* calc. pour $C_{34}H_{54}O_4$: C 77,56; H 10,26; O 12,17; tr.: C 77,43; H 10,34; O 12,23%.

4. *Hydroboration oxydative du composé 2*

Une solution de 20 mg de produit **2** dans 2 mL de THF anhydre est portée à 0°C, puis saturée successivement à l'aide d'azote désoxygéné et de diborane. On maintient la solution sous agitation à 20°C durant 3 h et alcalinise à l'aide de 3,2 mL de soude 3 *N*. On ajoute alors goutte à goutte, sous agitation, 3,2 mL de peroxyde d'hydrogène à 30%. Le mélange est abandonné 1 h à 20°C, puis la fraction organique est extraite à l'oxyde d'éthyle. Après lavage à l'eau jusqu'à neutralité et séchage sur Na_2SO_4, le solvant est éliminé. Le résidu pèse 19,3 mg. L'analyse par ccm montre que ce résidu est essentiellement constitué de deux produits pondéralement majoritaires, accompagnés de trois produits secondaires. L'un des produits majoritaires est identifié à **2**, l'autre est isolé en ccm préparative sur plaque Merck 60 GF_{254}. Après élution à l'aide du mélange hexane – oxyde d'éthyle (25:75 en volume), on obtient 9,2 mg de produit **3**.

L'acétylation de **3** est effectuée à 25°C durant 48 h à l'aide de 1 mL d'anhydride acétique et 2 mL de pyridine anhydre. L'acétate est récupéré de la manière habituelle et recristallisé à partir de l'hexane. On obtient 7 mg de composé **4** que l'on identifie par rmn du ^1H et du ^{13}C ainsi que par spectrométrie de masse, et qui présente les caractéristiques suivantes: *F* 240–245°C; ir cm^{-1}(CS_2): 2925, 1740, 1475, 1370, 1250; rmn du ^1H et du ^{13}C ($CDCl_3$): tableaux 1 et 2; masse *m/z*: 586(35), 526(20), 483(15), 466(45), 453(33), 406(10), 393(9), 203(20), 189(50), 43(100). *Anal.* calc. pour $C_{36}H_{58}O_6$: C 73,72; H 9,90; O 16,38; tr.: C 73,63; H 9,91; O 16,45%.

Rate constants (k_s) of alkaline fading of crystal violet (CV^+) have been determined at 25°C by spectrophotometric measurements in aqueous mixtures of some protic, aprotic, and dipolar aprotic cosolvents. Transfer free energies of the substrate (CV^+), $\Delta G_t^0(CV^+)$, were also determined in some of the solvent systems from solubility measurements of the chloride salt, and by subtracting $\Delta G_t^0(Cl^-)$ obtained earlier by use of the tetraphenylarsonium tetraphenylboron (TATB) extrathermodynamic assumption. This helped determine transfer free energies of the transition state ($X^{\neq}$), $\Delta G_t^0(X^{\neq})$, as ΔG_t^0 values of lyate ion (S^-) based on the TATB assumption are already known for all of these solvent systems. The observed log (k_s/k_w) – composition profiles reveal that the relative solvation of the reacting species rather than the dielectric constant of the solvents dictates the complex variation of the rates of the reaction in these solvent systems. Correlation of $-\Delta G_t^{\neq}(= RT \ln k_s/k_w)$ with $\Delta G_t^0(S^-)$ indicates that the reaction is largely controlled by the relative solvation of S^- in most of the cases. But analysis of $\Delta G_t^0(CV^+)$ and $\Delta G_t^0(X^{\neq})$ – composition profiles for some of the solvent systems reveals that the non-compensation of the ΔG_t^0 contributions of initial-state substrate and of the transition-state complex, which may be considered to be an outer-sphere complex $[CV^+](S^-)$, is also in accord with what is expected from the relative solvating characteristics of the cosolvents as guided by their respective physico-chemical properties.

URMILA MANDAL, SUMITA SEN, KAUSHIK DAS et KIRON KUMAR KUNDU. Can. J. Chem. **64**, 300 (1986).

On a déterminé les constantes de vitesse (k_s) de la décoloration alcaline du cristal violet (CV^+), opérant à 25°C, dans des mélanges aqueux de cosolvants protiques, aprotiques et aprotiques dipolaires et faisant appel à des mesures spectrophotométriques. On a aussi déterminé les énergies libres de transfert du substrat (CV^+), $\Delta G_t^0(CV^+)$, dans quelques systèmes de solvants en se basant sur des mesures de solubilité du chlorure et en soustrayant les valeurs de $\Delta G_t^0(Cl^-)$ qui ont été obtenues antérieurement en faisant l'hypothèse extrathermodynamique du tétraphénylbore tétraphénylarsinium (TBTA). On a ainsi pu déterminé les énergies libres de transfert de l'état de transition ($X^{\neq}$), $\Delta G_t^0(X^{\neq})$, sous la forme de valeurs de ΔG_t^0 de l'ion lyate (S^-) qui sont basées sur l'hypothèse du TBTA et qui sont déjà connues pour tous ces systèmes de solvants. Les profils composition – log (k_s/k_w) observés révèlent que c'est la solvatation relative des espèces plutôt que la constante diélectrique des solvants qui régit la variation complexe des vitesses de réaction dans ces systèmes. Une corrélation entre le $-\Delta G_t^{\neq}(=RT \ln k_s/k_w)$ et le $\Delta G_t^0(S^-)$ indique que, dans la plupart des cas, la réaction est principalement contrôlée par la solvatation relative de S^-. Une analyse des profils composition $-\Delta G_t^0(CV^+)$ et $\Delta G_t^0(X^{\neq})$ pour quelques solvants révèle que l'on peut considérer que le fait qu'il n'y a pas de compensation des contributions du substrat de l'état initial et du complexe de l'état de transition, qui peut être considéré comme un complexe périphérique $[CV^+](S^-)$, est aussi en accord avec ce que l'on peut attendre à partir de caractéristiques de solvatations relatives des cosolvants, tels que prescrites par leurs propriétés physico-chimiques.

Introduction

Kinetic solvent effects on reactions in different media are often rationalized in the light of general parameters such as "solvent polarity," which sum up all the specific and non-specific interactions of the media with initial and transition states (1). Unfortunately, a quantitative measure of this property is always empirical and the values obtained are of best use only for reactions having reactants similar in nature to those employed as model probes. Consequently a large number of solvent polarity scales are available (1). Moreover, such data for mixed solvents are scanty and are quite difficult to assess on the basis of the values for the pure components.

Since the pioneering work of Leffler and Grunwald (2), Arnett *et al.* (3), and Parker and co-workers (4), increasing efforts (5–11) to rationalize kinetic solvent effects on various reactions from a thermodynamic approach have recently been noted. These essentially entail determining the kinetic solvent effects by splitting the activation parameters into contributions from initial and transition states, and hence attempting to correlate (12) and to understand (8) their behaviour in light of the relevant physico-chemical properties of the solvents.

Recent evaluation of free energies of transfer, $\Delta G_t^0(i)$, of individual ions in various pure and mixed solvents provides a useful means to study the solvent effect on rates of reactions involving charged particles in solution from the viewpoint of short-range interactions between the ions and the solvent media. Thus the kinetic characteristics of a chemical reaction can be correlated with, or even predicted from, the thermodynamic properties of the reacting species. The present paper aims to study kinetic solvent effects for the alkaline decolorization reaction of the dye crystal violet (CV^+), which is actually the process of carbinol base formation as shown below (13). In fact, the contribution of (**2**) to the resonance hybrid suggests an electron deficiency at the *tert*-carbon position and hence lyate ion (S^-) is likely to attack this position to form the colorless carbinol base (13).

Notably, nucleophilic substitution reaction involving tertiary centres of CV^+ or malachite green (MG) as the substrates and various nucleophiles including OH^-, H_2O, etc. have been extensively studied (14). In fact, on the basis of these studies using water as the standard nucleophile and MG as the standard substrate, Ritchie (14) proposed his well-known linear free energy relation (LFER): $\log (k/k_0) = N^+$, where the terms have the usual significance. This relation accommodates the unusual and interesting situation that cation–anion combination reactions involving tertiary centres show no change in selectivity with change of substrate. Later Scott and co-workers (15) proposed a general form of the Ritchie equation, $\log (k/k_0) = S^+N^+$ (S^+ = constant), to accommodate further data of a similar nature.

Colored crystal violet cation

Colorless carbinol base

In the present study the rate of the reaction has been followed spectrophotometrically in aqueous mixtures of dimethyl sulphoxide (DMSO), *N,N*-dimethyl formamide (DMF), acetonitrile (ACN), tetrahydrofuran (THF), dioxane (D), 1,2-dimethoxyethane (DME), 2-methoxyethanol (ME), urea (UH), ethylene glycol (EG), and glycerol (GL). The solubilities of crystal violet chloride (CV^+Cl^-) in some of these mixed solvents (aqueous DMSO, UH, EG, and GL) have also been determined with a view to evaluating standard free energies of transfer of the initial-state substrate $\Delta G_t^0(CV^+)$ and hence that of the transition state $\Delta G_t^0(X^{\neq})$, as $\Delta G_t^0(S^-)$ values are obtainable from earlier work (16). Here S^- denotes the lyate ion, which is purely OH^- in the case of aqueous aprotic or dipolar aprotic solvents but comprises OH^- and possibly some conjugate base ion OR^- in amphiprotic cosolvants (ROH) like ME, EG, or GL. These are based on the widely used tetraphenylarsonium tetraphenylboron "reference electrolyte" extrathermodynamic assumption (17):

$$\Delta G_t^0(PH_4B^-) = \Delta G_t^0(Ph_4As^+) = \tfrac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$$

Experimental

The organic cosolvents were purified by following usual methods (16). Crystal violet chloride (CV^+Cl^-) (E. Merck) was used as received. The absorption maximum was found to be at 590 nm (13, 18), the molar extinction coefficient at this wavelength being 9.27×10^4 (18). All the experiments were carried out at 25°C. The mixed solvents were prepared by mass dilution.

The reaction under study can be considered to be pseudo-first order if the concentration of the lyate ion is maintained at a much higher level than that of crystal violet. This was precisely the experimental condition, the concentrations of S^- and crystal violet being ~ 1.5–5.0×10^{-3} *M* and 7.0–7.5×10^{-6} *M* respectively. Under these conditions

$$-\frac{d[dye]}{dt} = k'[dye]$$

where $k' = k[S^-]$. k' was obtained by following the reaction with the help of a Perkin Elmer D2000 spectrophotometer and k was calculated to eliminate the effect of differing concentrations of S^-. These rate constant k (L mol^{-1} min^{-1}) values have been presented in Table 1 along with $\Delta G_t^{\neq}$ values (see Discussion) obtained therefrom. $\Delta G_t^0(S^-)$ values are taken from the literature as cited in the footnotes to Table 1.

Table 2 gives the solubilities of crystal violet chloride. ΔG_t^0 values for the dye have been calculated by the usual relation (19) computing the required activity coefficient data by the extended Debye–Hückel equation, tentatively assuming the ion size parameters for crystal violet cation and the chloride ion to be 5 Å and 3 Å, respectively. $\Delta G_t^0(CV^+)$ has been obtained by subtracting the literature values (as cited in footnote to Table 2) of $\Delta G_t^0(Cl^-)$ from the total ΔG_t^0 for the dye.

Discussion

As indicated in the Introduction, the usual approach of correlating the kinetic solvent effects with some of the widely used solvent polarity scales (1), though feasible and useful for pure nonaqueous solvents, is difficult in most of the aquo-organic solvents because of scanty "solvent polarity" data. It was therefore considered useful to analyze the present data on the basis of solute–solvent interactions of the involved species and the relevant physico-chemical properties of the mixed solvents.

Thus turning to the results of the present study, it is found that in general the rate constant increases with addition of organic cosolvent to water, as shown by a plot of log (k_s/k_w) vs. mol% organic cosolvents (Fig. 1). This may be expected, as in most of the cases the mixed solvents have a lower dielectric constant than water and the reaction under study involves charge annihilation. Accordingly, in the only case where the dielectric constant progressively increases, i.e. UH–water mixtures (20), the rate constant has been found to decrease. However, that the dielectric constant is not the only parameter involved is clearly demonstrated by the log (k_s/k_w) – composition profiles in some other media, e.g., aqueous mixtures of GL, EG, ACN, and DMF. In the first case, the rate constant decreases in spite of decreasing dielectric constant while in the latter three cases the rate constant profiles pass through extrema, whereas the dielectric constants are known to decrease almost monotonically with cosolvent compositions (21–23). Furthermore, no reflection of the initial maxima in dielectric constant in aqueous DME (24) has been observed in the variation of rate constant in the mixtures.

A closer look at Fig. 1 reveals that the log (k_s/k_w) – composition profiles are similar in pattern for aqueous GL, EG, ME, and THF. It is interesting to note that the number of OH groups in the hydroxylic cosolvent molecules decreases in the order GL > EG > ME, and this is just the reverse of the order of the rate constant values. Apparently, this shows that the presence of hydroxylic cosolvents renders the nucleophile OH^-

TABLE 1. Kinetic and thermodynamic data for the reaction under study and the reacting species involved at 25°C

Organic cosolvent	Wt.%	Mol%	log k	log k_s/k_w	$\Delta G_t^{\ddagger}$ (kJ mol^{-1})	$\Delta G_t^0(S^-)$ (kJ mol^{-1})[a–f]

or OR^- less reactive than in the presence of aprotic cosolvents. On the other hand THF, being an aprotic solvent, makes OH^- increasingly desolvated (25, 26) and hence more and more active than for reactions in water, provided initial and transition states are more or less equally solvated in the respective solvent systems.

However, for other aqueous aprotic mixtures, e.g. aqueous DMSO, DMF, ACN, and DME, an initial minimum or such a trend can be observed in the respective log (k_s/k_w) – composition profiles. Clearly, something occurs at lower organic compositions in these mixtures which opposes the effect of the well-known "anion desolvating" affinity of these aprotic cosolvents (26–30). This might be the effect of initial- and transition-state solvation and (or) the effect of the release of water monomers by possible breakdown of three-dimensional (3D) hydrogen-bonded water structure on addition of these cosolvents (6*b*, 23, 28, 29, 31–34). This sometimes influences the relative solvation of certain ionic and non-ionic solutes (25–30, 34), especially large-sized hydrophobic ones, and is referred to as structural interactions (35). Once this compensating effect is overcome, the log (k_s/k_w) – composition profiles rise sharply at higher composition of these dipolar aprotic cosolvents.

In the case of aqueous UH, another factor may be operative to some extent. The zwitterionic forms of UH molecules may stabilize the positive charge of crystal violet cations on the peripheral N atoms of its quinonoid forms, thus hindering the formation of carbinol base. This would then contribute to the decrease of k_s values in aqueous UH, in addition to the effects of dielectric constant referred to earlier, and to the observed increased solvation of OH^- through positive charge centres of zwitterionic forms of UH (27).

The above discussion suggests that the change in rate of a reaction upon solvent transfer is primarily determined by the solvation of reacting species. To test the validity of this hypothesis, plots of $-\Delta G_t^{\ddagger}$, which is the negative of change in free energy of activation upon solvent transfer, and of $\Delta G_t^0(S^-)$ vs. mol% cosolvent have been shown in Fig. 2 for a few

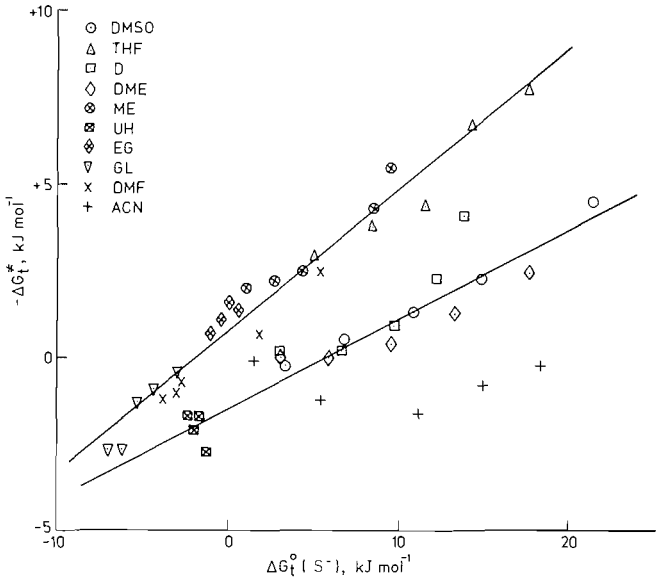

FIG. 3. Plots of $-\Delta G_t^{\ddagger}$ vs. $\Delta G_t^0(S^-)$ for alkaline decolorization of crystal violet in different aquo-organic solvent mixtures.

representative mixed solvents. $\Delta G_t^{\ddagger}$ can be obtained by applying Eyring's equation

$$k = (RT/Nh) \exp(-\Delta G^{\ddagger}/RT)$$

the symbols having their usual significance, and defining

$$\Delta G_t^{\ddagger} = \Delta G_s^{\ddagger} - \Delta G_w^{\ddagger} = 2.303\, RT \log(k_w/k_s)$$

In all the cases the two profiles are found to be qualitatively similar, which implies that the kinetics of the chosen reaction is seemingly largely controlled by the solvation of S^-. Inspired by this observation, a plot of $-\Delta G_t^{\ddagger}$ vs. $\Delta G_t^0(S^-)$ has been constructed for all the solvent systems studied (Fig. 3). Despite a small amount of scatter, the data are largely found to lie on two straight lines of differing slopes, one consisting of the results from aqueous mixtures of DMSO, D, DME, and UH and the other of results from aqueous THF, ME, DMF, EG, and GL. Data from ACN–water mixtures seem to fit neither line. However, the slopes of both lines are far from unity, which indicates that there is a large difference between the solvation of the initial state (substrate, CV^+) and its transition state.

Evidently, analysis of the relative contributions of initial and transition states should be rewarding. Four solvent mixtures, two from each group, viz., aqueous DMSO, UH, EG, and GL, have been therefore selected to study the effect of solvation of the substrate crystal violet cation (CV^+) and its transition state $X^{\ddagger}$. Figure 4 compares the values of $\Delta G_t^0(CV^+)$ and $\Delta G_t^0(X^{\ddagger})$ with solvent composition. $\Delta G_t^0(X^{\ddagger})$ has been obtained from the relation

$$\Delta G_t^{\ddagger} = \Delta G_t^0(X^{\ddagger}) - \Delta G_t^0(CV^+) - \Delta G_t^0(S^-)$$

From Fig. 4 it appears that CV^+ and its transition state $X^{\ddagger}$ are increasingly more solvated in aqueous mixtures of the cosolvents DMSO, EG, and GL, but less so in UH; their relative order is DMSO > EG > GL $\gg$ UH.

In view of the fact that CV^+ is a triphenyl methyl dye with three $(CH_3)_2N$-substituted phenyl groups attached to the positively charged *tert*-carbon atom at the centre and has quinonoid resonating forms, its solvation in aqueous mixtures of different

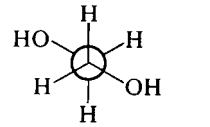
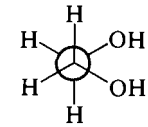
cosolvents with varying physico-chemical properties is likely to be an involved process. Firstly, because of its large size, Born-type (36) electrostatic interactions seem negligibly small. This is also borne out by the fact that, despite increased dielectric constant of aqueous urea solution, the $\Delta G_t^0(CV^+)$ – composition profile grazes the abscissa instead of becoming increasingly negative due to this effect, while the reverse would have been true in the other cases because of decreased dielectric constant. Evidently other factors are more important. Of the various other possible factors, such as ion–dipole, ion – induced dipole, ion–quadrupole, and dispersion interactions, which are likely to affect its solvation, the last factor is seemingly most effective. Just as the Born-type electrostatic interactions are negligibly small, because of low surface charge density around this large-sized ion, so are the other types of ion–dipole/quadrupole interactions. This is also borne out by the observation that CV^+ is much more strongly solvated in aqueous DMSO than in aqueous UH, which follows the order of polarizabilities and not the dipole moments (vide Table 3). Of course the effective polarizability, which contributes directly to the magnitude of the dispersion interaction, is rather difficult to assess in the mixed solvents. However, the extent of hydrogen-bonding interactions in aquo-organic mixtures is likely to determine the accessibility of the hydrophobic portion of the organic cosolvent molecule for dispersion interaction. Thus the presence of increased number of H-bonding centres is likely to decrease the hydrophobicity of an organic cosolvent molecule in aqueous mixtures and thus reduce the magnitude of dispersion interaction with an organic solute, as expected on the basis of polarizability of the pure cosolvents, alone. Thus for urea, though not most polar among these cosolvents (vide Table 3), its possible pronounced ion–dipole interaction effect is seemingly hindered by its capability of forming urea–water clusters (37) due to three possible H-bonding centres in its zwitterionic forms. Despite the possible formation of hydrates of DMSO (6*b*), the larger polarizability and unhindered hydrophobicity of two CH_3 groups of the DMSO molecule possibly cause larger dispersion interactions in DMSO–water mixtures than in urea–water mixtures. The observed larger solvation of Ph_4As^+/Ph_4B^- in DMSO – water mixtures as compared to that in urea–water mixtures (27) also substantiates this contention. Notably, that the possibility of increased stabilization of the quinonoid forms of CV^+ by the zwitterionic forms of UH might partly contribute to the decreased k_s values in UH–water mixtures, as referred to earlier, is not seemingly correct.

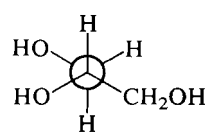
Again, the above consideration regarding the effect of H-bonding on hydrophobicity of the cosolvents and on dispersion interactions is also true for aqueous protic cosolvents and accounts for the observation that CV^+ is more strongly solvated in aqueous EG than in aqueous GL in spite of the higher polarizability of GL compared to that of EG (vide Table 3). Moreover, the dispersion interaction, being of short range, requires close proximity of the interaction centres. The approach of the large CV^+ towards the hydrophobic methylene chains in the cosolvents is sterically more hindered in aqueous GL than in aqueous EG owing to H-bonding interactions between H_2O and OH groups, and can be expected from the conformational structures of EG (**1***a* and **1***b*) and GL (**2***a* and



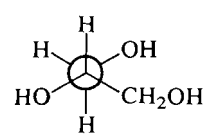
1*a*



1*b*



2*a*



2*b*

2*b*) molecules. The presence of three H-bond donating centres in GL, compared to two in EG, thus decreases the hydrophobicity of the former to a greater extent. ΔG_t^0 of another larger hydrophobic organic ion, viz. Ph_4As^+/Ph_4B^-, was found earlier to follow the same order as the number of H-bond donating centres in the organic cosolvent molecule, for aqueous mixtures of ethanol, EG, and GL (38). Evidently, despite the larger polarizability of the cosolvent GL compared to DMSO (Table 3), the larger H-bonding propensity of GL with water molecules through three OH groups of GL seemingly hinders the hydrophobic CH_2 chain from approaching CV^+ to impart a large dispersion interaction, as compared to that in DMSO–water mixtures.

The observed qualitative similarity between the composition profiles of $\Delta G_t^0(CV^+)$ and $\Delta G_t^0(X^+)$ indicates that the solvation of the transition state is dictated by the factor involved in solvation of the substrate, i.e. by dispersion interactions. Consequently, the $\Delta G_t^0(X^+)$ values are found to be nearly zero in UH–water mixtures, as are the $\Delta G_t^0(CV^+)$ values, whereas both these values are highly negative in DMSO–water mixtures. It is interesting to note that while in aqueous DMSO $\Delta G_t^0(X^+) > \Delta G_t^0(CV^+)$, the order is just the reverse in aqueous EG or GL. In other words, the transition state becomes less solvated in the presence of DMSO, an aprotic cosolvent, compared to the substrate, contrary to what is observed in mixtures of water with hydroxylic cosolvents EG or GL. This is compatible with the expectation that for effective solvation the transition state, which may be considered as a quasi-stable outer-sphere union of CV^+ and OH^- or OR^-, requires molecules having good hydrogen bond donating ability, besides being capable of undergoing dispersion interactions. So, relative to the substrate, the transition state is found to be solvated to a greater extent in GL, which contains three OH groups, than in EG, which has only two of them.

Thus it appears that in DMSO–water mixtures the effect of larger stabilization of CV^+ over its transition state opposes the effect of pronounced stabilization of OH^- (37) and results in a slight minimum in the log (k_s/k_w) – composition profile at the initial composition. The same may also be more or less true for other aqueous dipolar aprotic cosolvents. In urea–water mixtures, the opposing effects of initial- and transition-state solvation being relatively small, the observed decreased rates of the reaction are chiefly guided by the effect of increased stabilization of OH^- (27) as referred to earlier. On the other hand, in the cases of aqueous EG and GL mixtures, larger stabilization of the transition state over its initial state opposes the effect of increased stabilization OH^-/S^- (38, 39) in the respective cases. And while the former effect nearly nullifies the other in the case of EG, the retarding effect of the pronounced solvation of OH^-/S^- in GL–water mixtures (38) overcomes the accelerating effect of larger stabilization of the transition state over its initial state, thus imparting smaller k_s than k_w values.

Thus, the results of the present study clearly demonstrate that correlation of the relative solvation of the reactants and the transition state with the relative physico-chemical properties of the solvents offers better insight into the kinetic solvent effect. It is hoped that the same will be true for other reactions as well.

The metathesis of *N*-silylamines and benzeneselenenyl chloride. An efficient selenenamide synthesis

THOMAS G. BACK[1] AND RUSSELL G. KERR
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4
Received July 23, 1985

THOMAS G. BACK and RUSSELL G. KERR. Can. J. Chem. **64**, 308 (1986).

The metathesis reactions of *N*-(trimethylsilyl)dialkylamines with benzeneselenenyl chloride afford high yields of *N*,*N*-dialkylselenenamides **1***a*–**1***f*. Similarly, *N*-(trimethylsilyl)acetamide produces the unstable *N*-(phenylseleno)amide **2** *in situ* while *N*-(trimethylsilyl)imidazole and *N*-(trimethylsilyl)benzimidazole undergo selenenylation at the 4- and 2-position, respectively, to provide the selenides **3** and **4**. *N*-(Trimethylsilyl)phthalimide failed to react under these conditions.

THOMAS G. BACK et RUSSELL G. KERR. Can. J. Chem. **64**, 308 (1986).

Les réactions de métathèse des *N*-(triméthylsilyl)dialkyl-amines avec le chlorure de benzènesélénényle conduisent aux *N*,*N*-dialkyl-sélénénamides **1***a*–**1***f*. De la même manière, la *N*-triméthylsilyl)acétamide conduit, *in situ* à la *N*-(phénylséléno) amide **2** instable alors que le *N*-(triméthylsilyl)imidazole et le *N*-(triméthylsilyl)benzimidazole subissent respectivement des sélénénylations dans les positions 4 et 2 pour conduire aux sélénides **3** et **4**. La *N*-(triméthylsilyl)phtalimide ne réagit pas dans ces conditions.

Introduction

N,*N*-Dialkylbenzeneselenenamides (**1**) (1) comprise a relatively unexplored class of compounds that have recently been shown to possess some synthetically useful properties. They transform aldehydes to their α-selenenylated derivatives (1–3) and convert olefins such as cyclohexene to β-acetoxy selenides in the presence of acetic anyhydride (1). They are also sufficiently nucleophilic to perform Michael additions upon acceptors such as enones (1) and dimethyl acetylenedicarboxylate (4) to afford β-amino-α-phenylseleno carbonyl compounds after intramolecular selenenylation.

Unfortunately, the preparation of selenenamides **1** is hampered by their hydrolytic instability, and their direct synthesis via eq. [1] often provides but modest yields, particularly in the case of more hindered amines (1).

[1] $$PhSeX + 2R_2NH \rightarrow \underset{\mathbf{1}}{PhSeNR_2} + R_2NH_2^+X^-$$
X = Cl, Br, OH

Recently the metathesis reactions of benzeneselenenyl chloride with trimethylsilyl cyanide (5) (eq. [2]) and trimethylsilyl isothiocyanate (6) (eq. [3]) have proven convenient methods for the synthesis of phenyl selenocyanate and benzeneselenenyl thiocyanate, respectively. These reactions are rapid and quantitative and the volatile by-product chlorotrimethylsilane is easily removed with the solvent.

[2] $$PhSeCl + Me_3SiCN \rightarrow PhSeCN + Me_3SiCl$$

[3] $$PhSeCl + Me_3SiNCS \rightarrow PhSeSCN + Me_3SiCl$$

It therefore seemed a reasonable extension of these processes to prepare selenenamides by the similar metathesis of the selenenyl chloride with *N*-(trimethylsilyl)amines (eq. [4]). We now report that this approach provides an efficient and simple synthesis of both cyclic and acyclic selenenamides. The results are summarized in Table 1, which indicates the yields of distilled products. The crude products obtained after removal of volatile material, but prior to distillation, are formed essentially quantitatively and are of sufficient purity for most purposes, providing that strictly anhydrous conditions are maintained.[2]

[4] $$PhSeCl + Me_3SiNR_2 \rightarrow \underset{\mathbf{1}}{PhSeNR_2} + Me_3SiCl$$

TABLE 1. Preparation of selenenamides $PhSeNR_2$ (**1**)

Selenenamide	$-NR_2$	Isolated yield, %	bp, °C (Torr)[a]
1*a*	$-NMe_2$	83	40 (0.10)[b]
1*b*	$-NEt_2$	81	70 (0.10)
1*c*	$-N\text{-}iPr_2$	80	75 (0.10)
1*d*		82	75 (0.12)
1*e*		77	80 (0.10)
1*f*		79	80 (0.10)

[a]All products were distilled in a Kugelrohr apparatus.
[b]Literature (1) bp 39–40°C (0.1 Torr).

Several related systems were also investigated. *N*-(Trimethylsilyl)acetamide reacted rapidly with the selenenyl chloride in an nmr experiment to provide a new product with a methyl singlet at δ 1.98, attributed to the expected *N*-(phenylseleno)-acetamide (**2**) (eq. [5]). An impurity signal was also observed at δ 1.76. Attempts to purify the desired product resulted in decomposition.

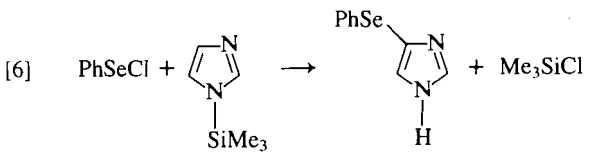
[5] $$PhSeCl + Me_3SiNHC(=O)Me \rightarrow \underset{\mathbf{2}}{PhSeNHC(=O)Me} + Me_3SiCl$$

N-(Trimethylsilyl)imidazole and *N*-(trimethylsilyl)benzimidazole underwent selenenylation at carbon instead of at nitrogen to afford the products **3** and **4** (eqs. [6] and [7]), respectively. It is not known whether *C*-selenenylation occurs directly in the first

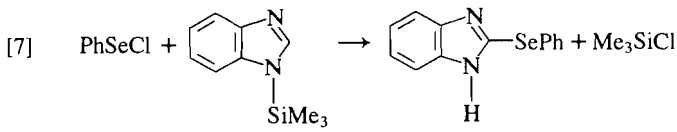
[1]Author to whom correspondence should be addressed.

[2]While this work was in progress, Tomoda *et al.* reported the generation of **1***b* *in situ* by a similar procedure and employed it to selenenylate butanal (7). The selenenamide was characterized by nmr spectroscopy but was not isolated.

step of these processes, or whether the *N*-phenylseleno derivatives are the initial products but rearrange rapidly to the more stable compounds **3** and **4**. By analogy, it has been suggested that anilines undergo similar initial *N*-selenenylation followed by rearrangement of the phenylseleno group to the aromatic ring (8).

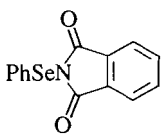


3



4

An attempt to prepare the useful reagent *N*-(phenylseleno)-phthalimide (**5**) (9) from *N*-(trimethylsilyl)phthalimide and the selenenyl chloride failed as no reaction occurred. It is interesting to note that, in contrast to the latter processs, *N*-(trimethylsilyl)amides, -azoles, and -imides are known to react with various sulfur chlorides to afford generally high yields of stable *N*-thioamides (10), *N*-thioazoles (11), and *N*-thioimides (12).



5

It is evident that the above method provides a convenient route to *N*,*N*-dialkylselenenamides. Similar methodology may furnish access to other selenium-nitrogen compounds in the future.

Experimental

The nmr spectra were recorded on a Hitachi Perkin Elmer R24B or on a Varian XL200 spectrometer in deuteriochloroform solution unless otherwise noted. Chemical shifts are reported in ppm downfield from tetramethylsilane. Infrared spectra were obtained on a Nicolet 5DX FTIR spectrometer and mass spectra were recorded on a Kratos MS80 instrument. Elemental analyses were performed by Dr. W. S. Lin at the University of Calgary.

All *N*-silylamines and *N*-silylazoles were obtained from commercial sources or were prepared by standard literature methods (13). All other reagents were commercially available.

A typical procedure for the preparation of selenenamide **1***a* follows. All other products in Table 1 were prepared in the same manner. Known compounds **1***a*–**1***c* (1) and **1***f* (3) were identified by their ir and nmr spectra, while complete spectral and analytical details are provided for new compounds **1***d*, **1***e*, **3**, and **4**.

N,N-*Dimethylbenzeneselenenamide (**1**a)*

Benzeneselenenyl chloride (960 mg, 5.00 mmol) in 8 mL of dichloromethane was added to a solution of *N*-(trimethylsilyl)dimethylamine (585 mg, 5.00 mmol) in 2 mL of the same solvent. The red colour of the selenenyl chloride was immediately discharged. The resulting pale yellow solution was concentrated under a stream of nitrogen and distilled in a Kugelrohr apparatus at ca. 40°C (0.10 Torr; 1 Torr = 133.3 Pa) to afford 831 mg (83%) of the title compound, with nmr spectrum as reported previously (1).

N-*(Phenylseleno)pyrrolidine (**1**d)*: ir (film): 1574, 1176, 1022, 937, 739, 693 cm^{-1}; nmr: 7.7–7.1 (complex, 5H), 3.1 (m, 4H), 1.8 (m, 4H); mass spectrum, *m/e* (relative intensity, %): 227 (M^+, ^{80}Se, 38), 225 (M^+, ^{78}Se, 24), 70 (M^+ − PhSe, 100). *Anal.* calcd. for $C_{10}H_{13}NSe$: C 53.09, H 5.80, N 6.19; found: C 52.88, H 5.91, N 6.50.

N-*(Phenylseleno) piperidine (**1**e)*: ir (film): 1578, 1211, 1022, 897. 735, 691 cm^{-1}; nmr: 7.7–7.1 (complex, 5H), 2.96 (m, 4H), 1.5 (complex, 6H); mass spectrum, *m/e* (relative intensity, %): 241 (M^+, ^{80}Se, 45), 239 (M^+, ^{78}Se, 23), 84 (M^+ − PhSe, 100). *Anal.* calcd. for $C_{11}H_{15}NSe$: C 54.99, H 6.31, N 5.83; found: C 54.89, H 6.08, N 6.12.

N-*(Phenyseleno)acetamide (**2**)*

The product **2** was prepared in $CDCl_3$ solution in the usual manner; nmr: 7.5–6.9 (complex, 5H, Ph), 1.98 (s, 3H, MeC=O of **2**), 0.37 (s, 9H, Me_3SiCl). An impurity was observed at 1.76 (s), integrating at 1.2H. Attempts to isolate the product resulted in decomposition.

*4-(Phenylseleno)imidazole (**3**)*[3]

Benzeneselenenyl chloride (192 mg, 1.00 mmol) in 2 mL of dichloromethane was added to *N*-(trimethylsilyl)imidazole (140 mg, 1.00 mmol) in 2 mL of the same solvent. After stirring for 5 min at ambient temperature, the colour of the reaction mixture changed from red to orange and a white precipitate formed. This was filtered and washed with 2 mL of dichloromethane to afford 205 mg (92%) of compound **3**, mp 191–195°C (from methanol–ether); ir (Nujol); 3390–2200 (very broad) 1654, 1567, 1542, 1055, 937, 734, 661 cm^{-1}; nmr ($CDCl_3$ – DMSO-d_6): 7.65 (s, 1H), 7.20 (shoulder) and 7.1 (br s, total 6H); ^{13}C nmr: 140.0, 131.8, 129.5, 129.3, 128.7, 126.0, 118.8; mass spectrum, *m/e* (relative intensity, %): 224 (M^+, ^{80}Se, 47), 222 (M^+, ^{78}Se, 28), 144 (M^+ − Se, 100). *Anal.* calcd. for $C_9H_8N_2Se$: C 48.44, H 3.62, N 12.56; found: C 48.52, H 3.60, N 12.74.

*2-(Phenylseleno)benzimidazole (**4**)*[4]

Benzeneselenenyl chloride (192 mg, 1.00 mmol) in 2 mL of dichloromethane was added to N-(trimethylsilyl)benzimidazole (190 mg, 1.00 mmol) in 2 mL of the same solvent. The colour of the reaction mixture immediately changed from red to yellow. Concentration *in vacuo* afforded product **4** as a solid foam (254 mg, 93%), mp 131–135°C (from dichloromethane–hexane); ir (Nujol): 3300–2100 (very broad), 1769, 1619, 1586, 1571, 1273, 1246, 752, 745, 735 cm^{-1}; nmr ($CDCl_3$ – DMSO-d_6): 8.74 (br s, 1H, exchanged with D_2O), 8.0–7.1 (complex, 9H); ^{13}C nmr: 141.2, 135.1, 131.2, 129.1, 127.7, 122.1, 121.7, 115.4; mass spectrum, *m/e* (relative intensity, %): 274 (M^+, ^{80}Se, 8), 272 (M^+, ^{78}Se, 5), 118 (M^+ − C_6H_4Se, 100). *Anal.* calcd. for $C_{13}H_{10}N_2Se$: C 57.15, H 3.70, N 10.26; found: C 57.28, H 3.43, N 10.04.

[3]The isomeric 2-(phenylseleno)imidazole structure can be ruled out on the basis of the ^1H and ^{13}C nmr spectra. The low field proton singlet at 7.65 ppm is consistent with a hydrogen atom at C-2. Furthermore, since 2-substituted imidazoles have tautomerically equivalent C-4 and C-5 positions, the appearance of three ^{13}C nmr signals at 140.0, 126.0, and 118.8 ppm from the imidazole moiety (the remaining signals are assigned to the PhSe group) confirms the 4-(phenylseleno) structure.

[4]In contrast to **3**, the lack of a low field proton signal from the hydrogen atom at C-2 (ca. 8.4 in benzimidazole) indicates that **4** is the 2-(phenylseleno) isomer. This is confirmed by the ^{13}C nmr spectrum, which contains only four benzimidazole signals in addition to the resonances from the PhSe group. This is consistent only with the symmetrical 2-substituted system where tautomerization renders C-4, C-7 and C-5, C-6 equivalent (14).

Kinetics and mechanism of the thermal decomposition of the thiosulphatopentaamminecobalt(III) ion in dilute aqueous acid

ANTHONY MARTIN NEWTON

Department of Chemistry, University of the West Indies, Cave Hill, St. Michael, Barbados

Received May 14, 1985

ANTHONY MARTIN NEWTON. Can. J. Chem. **64**, 311 (1986).

In acetic acid – sodium acetate buffer of pH 5.6 (25°C) the $Co(NH_3)_5S_2O_3^+$ ion undergoes redox decomposition rather than aquation. First-order kinetic are observed and the reaction products Co^{2+}, NH_3, and $S_4O_6^{2-}$ are due to internal reduction of Co(III) by coordinated $S_2O_3^{2-}$. In dilute perchloric acid of pH <4 the rate is retarded, first-order plots are not linear, and $S_4O_6^{2-}$ is not a major product of the reaction. It is proposed that, in dilute $HClO_4$, protonation of $Co(NH_3)_5S_2O_3^+$ depletes the concentration of the reactive complex and that decomposition of coordinated $HS_2O_3^-$ occurs. Conversion of O-bonded $S_2O_3^{2-}$ to S-bonded $S_2O_3^{2-}$ in the reactive complex is also considered.

ANTHONY MARTIN NEWTON. Can. J. Chem. **64**, 311 (1986).

Dans un tampon d'acide acétique – acétate de sodium, à pH 5,6 et à 25°C, l'ion $Co(NH_3)_5S_2O_3^+$ subit plutôt une réaction d'oxydo-réduction qu'une réaction d'aquation. On observe une cinétique du premier ordre et les produits de la réaction, soit le Co^{2+}, le NH_3 et le $S_4O_6^{2-}$, proviennent de la réduction interne du Co(III) par l'ion $S_2O_3^{2-}$ coordonné. L'acide perchlorique dilué, pH <4, retarde la vitesse alors que les courbes d'ordre un ne sont pas linéaires et que l'ion $S_4O_6^{2-}$ n'est pas un produit majoritaire de la réaction. On pense que, en présence de $HClO_4$ dilué, la protonation de l'ion $Co(NH_3)_5S_2O_3^+$ diminue la concentration du complexe réactif et que l'ion coordonée $HS_2O_3^-$ se décompose. On considère également la transformation de l'ion $S_2O_3^{2-}$ lié par l'oxygène en l'ion $S_2O_3^{2-}$ lié par le soufre dans le complexe réactif.

[Traduit par le journal]

Introduction

In dilute aqueous acid the majority of acidopentaammine complexes of cobalt(III) undergo the aquation reaction and pseudo-first-order kinetics are observed (1, 2). However, redox decomposition is reported to complicate the aquation of $Co(NH_3)_5I^{2+}$ (3) and of $Co(NH_3)_5NO_2^{2+}$ (4). The results reported here show that in dilute aqueous acid the $Co(NH_3)_5S_2O_3^+$ ion undergoes redox decomposition rather than aquation.

Experimental

Analytical grade reagents and deionized water were used throughout. Thiosulphatopentaamminecobalt(III) nitrate was prepared by Ray's method (5). It was analysed for content of ammonia and the relative formula mass was measured by ion exchange chromatography. (Calculated for $[Co(NH_3)_5S_2O_3]NO_3$: NH_3 = 26.8%; M_r = 318; found: NH_3 = 26.6%; M_r = 318.)

Sodium tetrathionate dihydrate was prepared by slowly adding, with shaking, a suspension of iodine in absolute ethanol to solid sodium thiosulphate pentahydrate until the iodine colour persisted in the reaction mixture. The crude product was rapidly filtered and washed with ethanol to remove excess iodine. It was then dissolved in the minimum volume of water, ethanol was added, and the mixture was cooled in an ice–salt bath overnight. The crystals which formed were filtered off, washed with ethanol, ether, and stored over calcium chloride. Analyses for tetrathionate ion (6), water of crystallization, and relative formula mass were done. (Calculated for $Na_2S_4O_6 \cdot 2H_2O$: $S_4O_6^{2-}$ = 73.2%; H_2O = 11.7%; M_r = 306; found: $S_4O_6^{2-}$ = 73.2%; H_2O = 11.7%; M_r = 308. The absorption spectrum in dilute $HClO_4$ showed a maximum at 216 nm with $\epsilon = 9.20 \times 10^3\ M^{-1}\ cm^{-1}$, while in acetic acid–sodium acetate buffer at pH 5.6 (25°C) the maximum was at 219 nm with $\epsilon = 8.53 \times 10^3\ M^{-1}\ cm^{-1}$.

Spectrophotometric measurements were carried out using a Zeiss PMQ-II and a Pye Unicam SP8-400 spectrophotometer. The absorption maximum of $Co(NH_3)_5S_2O_3^+$ at 290 nm ($\epsilon = 1.37 \times 10^4\ M^{-1}\ cm^{-1}$) was used to follow the kinetic runs and the concentration of $Co(NH_3)_5S_2O_3^+$ was about $4 \times 10^{-5}\ M$. In those cases where the appearance of Co^{2+} was followed, the Co^{2+} was measured by Kitsen's method (7) and the HCl method (8).

The reaction mixtures were protected from light. Kinetic studies in acetic acid–sodium acetate buffer at pH 5.6 (25°C) were done in the temperature range 45–60°C and at least 80% of each run was followed. Kinetic studies were also done in dilute $HClO_4$ ($10^{-3} - 10^{-1}\ M$) at 59°C.

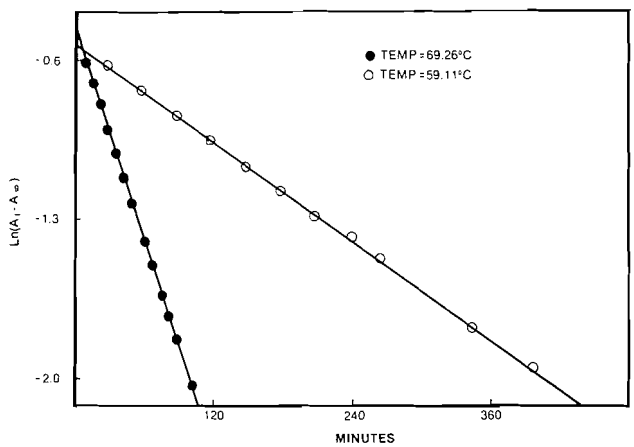

FIG. 1. Semilog plot for the decomposition of $Co(NH_3)_5S_2O_3^+$ in acetic acid – sodium acetate buffer of pH 5.6.

Results

Decomposition at pH 5.6

As shown in Fig. 1, the reaction at pH 5.6 is first order and the rate constants, k, were obtained from the equation

$$[1] \quad \ln [(A_0 - A_\infty) / (A_t - A_\infty)] = kt$$

and are summarized in Table 1. These rate constants fit an Arrhenius equation

$$[2] \quad k = 5.82 \times 10^{16} \exp(-E_a/RT)$$

k being in the units s^{-1} and E_a being 133 kJ mol^{-1}. The results from Table 2 show the stoichiometry of the reaction to be that given by eq. [3].

$$[3] \quad Co(NH_3)_5S_2O_3^+ \rightarrow Co^{2+} + 5NH_3 + \tfrac{1}{2}S_4O_6^{2-}$$

The addition of sodium thiosulphate to the reaction mixture

TABLE 1. First-order rate constants for the decomposition of $Co(NH_3)_5S_2O_3^+$ at pH 5.6

Temperature (°C)	10^5k (s^{-1})
69.26	28.6 ± 0.10
59.11	6.70 ± 0.06
	7.29 ± 0.06[a]
	7.34 ± 0.09[b]
44.58	0.82 ± 0.01

[a]$[Co(NH_3)_5S_2O_3]^+ = 4 \times 10^{-4} M$; measuring rate of appearance of Co^{2+}.
[b]$[Co(NH_3)_5S_2O_3]^+ = 4 \times 10^{-4} M$; measuring rate of disappearance of complex ion.

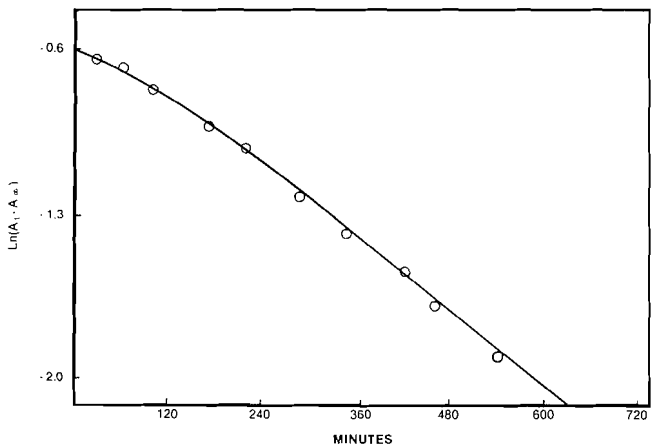

FIG. 2. Time dependence of the optical absorbance, A (290 nm), of a solution of $[Co(NH_3)_5S_2O_3]NO_3$ in 0.1 M $HClO_4$ at 59°C.

had no appreciable effect on the rate in the concentration range (1.0–5.0) × 10^{-3} M, and free $S_2O_3^{2-}$ is therefore not a reactant at any stage of the reaction.

Decomposition in dilute $HClO_4$

In dilute perchloric acid at pH 4 or lower, the kinetics of the redox decomposition of $Co(NH_3)_5S_2O_3^+$ are more complicated than at pH 5.6, and semilog lots are concave downwards with the latter part of these plots being almost linear (Fig. 2). There was no evidence from the spectra of partially reacted solutions or from ion exchange chromatography on such solutions of any cobalt-containing species other than the starting material and $Co(H_2O)_6^{2+}$. Analysis of the product solutions under these conditions showed a complete conversion of Co(III) to Co(II). The absorbance of the solutions at 216 nm (the wavelength of maximum absorbance of the tetrathionate ion in dilute perchloric acid) suggested a concentration of tetrathionate that was much higher than was possible from the mass of the starting material and assuming the stoichiometry to be that of eq. [3].

It seems clear therefore that in dilute perchloric acid (pH < 4) $Co(NH_3)_5S_2O_3^+$ either does not decompose according to eq. [3] or, if it does, the tetrathionate ion produced decomposes partially or completely, giving one or more products of molar absorbance index greater than that of $S_4O_6^{2-}$ and which may also have a catalytic effect on the redox process, thus causing curvature of the semilog plots.

To test the latter interpretation, the effect of added tetrathionate on the rate was studied at 59°C and $[S_4O_6^{2-}] = 1.9 \times 10^{-3}$ M. Under these conditions the semilog plots (Fig. 3) were similar to those for the reaction in dilute perchloric acid only.

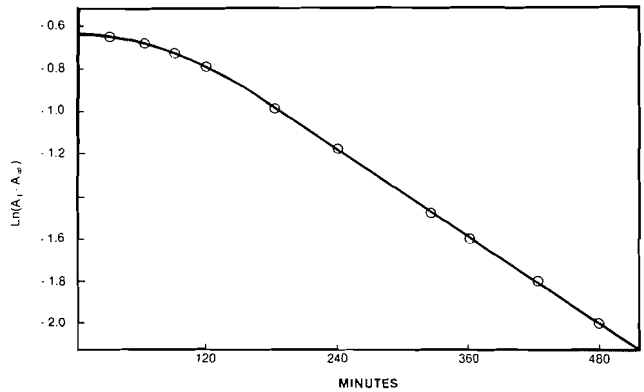

FIG. 3. Semilog plot for the decomposition of $Co(NH_3)_5S_2O_3^+$ in 0.1 M $HClO_4$ − 1.9 × 10^{-3} M $Na_2S_4O_6$ at 59°C.

TABLE 2. Analysis of the products of the decomposition of $Co(NH_3)_5S_2O_3^+$ at 59.11°C in acetic acid – sodium acetate buffer of pH 5.6.

10^4 [Complex] (M)	Product	Found	Expected by reaction [3]
1.00	$10^4[Co^{2+}]$ M	1.01[a]	1.00
1.03		1.01[a]	1.03
90.0		88.5[a]	90.0
0.448		0.430[b]	0.448
43.2	$10^3[NH_3]$ M	20.9[c]	21.6
35.0		17.1[c]	17.5
0.652	$10^5[S_4O_6^{2-}]$ M	3.57[d]	3.26
6.628		3.38[d]	3.14

[a]$[Co^{2+}]$ determined by Kitsen's method (7).
[b]Reaction in 0.1 M $HClO_4$ and $[Co^{2+}]$ determined by the HCl method (8).
[c]$[NH_3]$ determined by micro-Kjeldahl distillation.
[d]$[S_4O_6^{2-}]$ determined spectrophotometrically.

Furthermore, a 1.9 × 10^{-3} M solution of $Na_2S_4O_6$ in 0.1 M perchloric acid and at a temperature of 59°C showed no change in optical absorbance over a period of 72 h, and added Na_2SO_4 (1.9 × 10^{-3} M) and added $Na_2S_2O_8$ (1.9 × $10^{-3}M$) had the same effect on the rate as did the $Na_2S_4O_6$. It is therefore safe to conclude that the decomposition of $S_4O_6^{2-}$ is not important in the redox decomposition of $Co(NH_3)_5S_2O_3^+$ in dilute perchloric acid.

The product Co^{2+} is reported to catalyse the radiolytic decompositions of $Co(NH_3)_5H_2O^{3+}$ and $Co(NH_3)_6^{3+}$ (9). The effect of added $CoSO_4$ (1.9 × 10^{-3} M at 59°C) was therefore studied, but no change in the rate of the redox decomposition was detected. This observation therefore rules out the participation of $Co(H_2O)_6^{2+}$ in the reduction of the Co(III) centre by either an inner sphere or outer sphere mechanism.

Discussion

That the ammine ligand in $Co(NH_3)_5S_2O_3^+$ is involved in the redox process is unlikely, since coordination deactivates NH_3 towards oxidation (10). Furthermore, in the redox decomposition of $Co(NH_3)_5OH_2^{3+}$, a slow process at 59°C (k_{obs} at 70°C = 1 × 10^{-8} s^{-1}) (11), oxidation of an aquo ligand rather than an ammine ligand is the initial redox step (12).

Since $S_2O_3^{2-}$ is readily oxidized by a number of oxidising agents, including Fe^{3+}, it is almost certain that the redox decomposition of $Co(NH_3)_5S_2O_3^+$ involves a single electron transfer from the thiosulphato ligand to Co(III). The mechanism which seems to be operative when $Co(NH_3)_5S_2O_3^+$ decomposes at pH 5.6 is that given in eqs. [4] and [5].

[4] $Co(NH_3)_5S_2O_3^+ \rightarrow Co^{2+} + 5NH_3 + S_2O_3^-$

[5] $2S_2O_3^- \rightarrow S_4O_6^{2-}$

The existence of the $S_2O_3^-$ radical ion has been postulated for other systems (13,14) and an intramolecular electron transfer mechanism has been suggested for the redox decomposition of $Co(NH_3)_5NO_2^{2+}$ (4).

An alternative mechanism is one in which the $Co(NH_3)_5S_2O_3^+$ undergoes aquation, followed by a redox reaction between the products $Co(NH_3)_5OH_2^{3+}$ and $S_2O_3^{2-}$. This mechanism was, however, rejected for the following reasons:

1. The rate of disappearance of the complex was always the same as the rate of appearance of Co^{2+}, whereas the rate at which Co^{2+} is produced by the reaction of $Co(NH_3)_5H_2O^{3+}$ with $S_2O_3^{2-}$ is much too slow to account for the rate of production of Co^{2+} in the reaction of interest.

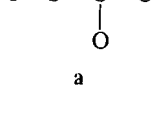
2. This alternative mechanism would require the rate of Co^{2+} production to be dependent on the concentration of added $S_2O_3^{2-}$, a requirement which has not been met.

An acid-catalysed pathway contributes to the aquation of $Co(NH_3)_5SO_4^+$ (15). Since the $S_2O_3^{2-}$ and SO_4^- ions are of similar basicity (pK_a for dilute $HS_2O_3^-$ and HSO_4^- being ~1.74 and 2.0, respectively, at 25°C (16)), protonation of the starting complex at pH 4 and lower seems a reasonable suggestion in the present case.

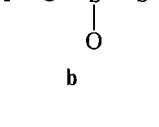
[6] $Co(NH_3)_5S_2O_3^+ + H^+ \rightleftharpoons Co(NH_3)_5S_2O_3H^{2+}$

The protonated species should be relatively inactive in internal redox since the electron transfer process should now be more difficult. Protonation of some of the $Co(NH_3)_5S_2O_3^+$ would deplete the concentration of reactive complex, resulting in a reduction in the rate of the redox process. This latter suggestion is supported by the fact that at 59°C, at pH 5.6, the rate is $6.7 \times 10^{-5}\ s^{-1}$, whereas at the same temperature but in $4.02 \times 10^{-3}\ M$ $HClO_4$ it is $5.4 \times 10^{-5}\ s^{-1}$ and in $1.05 \times 10^{-1}\ M$ $HClO_4$ it is $5.1 \times 10^{-5}\ s^{-1}$. The latter two rate constants were determined from the linear portions of the semilog plots. Since $S_2O_3^{2-}$ disproportionates in acid, it may be that a similar process occurs involving coordinated $HS_2O_3^-$ and this may account for the optical absorbance at 216 nm of the final product solutions of the redox decomposition of $Co(NH_3)_5S_2O_3^+$ at pH $\leq$ 4.

No reaction is known to occur between SO_4^{2-} and I_2, whereas iodine is readily reduced by $S_2O_3^{2-}$, which is structurally similar to SO_4^{2-}. On this basis it has been suggested that a species **a** rather than **b** is an intermediate in the $I_2/S_2O_3^{2-}$ reaction (17).



a



b

Similarly a species containing an I—S bond rather than an I—O bond has been suggested as an intermediate in the oxidation of the tetrathionate ion to SO_4^{2-} by iodine (18).

The available evidence shows the O-bonded isomer to comprise at least 90% of the $Co(NH_3)_5S_2O_3^+$ ion (19). Since an intermediate having an I—S bond is believed to be involved in the $I_2/S_2O_3^{2-}$ redox reaction, it therefore seems that the O-bonded $Co(NH_3)_5S_2O_3^+$ must convert to the S-bonded isomer before the redox reaction occurs. Rates of isomerization are known to be retarded by the presence of acid (20) and hence such a mechanism may be important in depleting the concentration of the reactive complex. Additionally, the relative rates of such an isomerization at pH $\leq$ 4, and the redox process, may be responsible for, or at least contribute to, the curvature of the first-order plots.

The radiolytic reduction of uranyl ions in degassed sulphuric acid solutions containing various organic solutes was studied. It was shown that while ĊOOH, CO_2^-, and α-hydroxy-alkyl radicals reduced uranyl ions, the β-hydroxy-alkyl radicals and those derived from gluconic acid could not affect the reduction. The oxidation of uranium(IV) by hydrogen peroxide at pH 0.7 involves hydroxyl radicals in a chain mechanism but at pH 2.0 the oxidation proceeds by a non-radical reaction pathway. From the enhancement of the rate of oxidation of uranium(IV) by oxygen in the presence of 2-propanol, a mechanism involving the perhydroxyl radical, which reconciles earlier published data on kinetics and oxygen tracer studies, is proposed for the oxygen–uranium(IV) reactions.

A. JOHN ELLIOT, SHAHSULTAN PADAMSHI et JANA PIKA. Can. J. Chem. **64**, 314 (1986).

On étudie la réduction radiolytique des ions uranyles dans des solutions dégazées d'acide sulfurique contenant divers solutés organiques. On montre que, contrairement aux radicaux ĊOOH, CO_2^- et α-hydroxy-alkyles qui réduisent les ions uranyles, les radicaux β-hydroxy-alkyles et ceux provenant de l'acide gluconique ne peuvent effectuer la réduction. L'oxydation de l'uranium(IV) par le peroxyde d'hydrogène à un pH de 0,7 fait intervenir des radicaux hydroxyles dans un mécanisme en chaîne; toutefois, à un pH de 2,0, la réaction d'oxydation s'effectue par une voie non-radicalaire. En se basant sur le fait que la vitesse d'oxydation de l'uranium(IV) par l'oxygène est plus grande en présence de propanol-2, on propose pour cette réaction un mécanisme qui implique le radical perhydroxyle. Ce mécanisme permet de concilier les données publiées antérieurement tant sur la cinétique que sur les études par marqueurs d'oxygène.

Introduction

Contamination of pipework with UO_2 will occur following the rupture of a nuclear fuel bundle either in test or in accident conditions. One strategy to decontaminate this pipework is to oxidize the insoluble UO_2 (a uranium(IV) compound) in the presence of suitable complexing agents and corrosion inhibitors to the more soluble uranyl ion (a uranium(VI) species). One mixture reported to be effective for this decontamination is a solution containing hydrogen peroxide, oxalic acid, gluconic acid, and 8-hydroxyquinoline (1). During the decontamination many free-radical reactions will be initiated both from the radiation fields and from the chemistry involved in the oxidation of uranium ions. However, in the open literature only limited information is available on free-radical reactions involving uranium. In this paper we report on the reduction of uranyl ions by organic radicals, and the oxidation of soluble uranium(IV) ions by both hydrogen peroxide and oxygen with and without organic solutes present.

Experimental

Materials

The chemicals used were purchased from the following companies: Fisher Scientific (uranyl sulphate, 2-propanol, sodium formate, sodium oxalate), Anachemia (sulphuric acid), Aldrich (sodium gluconate ($HOCH_2[CHOH]_4CO_2Na$)), J. T. Baker (hydrogen peroxide, 2-methyl-2-propanol (*tert*-butanol)). All were used as supplied except *tert*-butanol, which was multiply recrystallized. Triply distilled water was used for solution preparation. Uranium(IV) ions were prepared by electrolytically reducing uranyl ions at a platinum electrode under a nitrogen atmosphere.

Methods

Samples for steady-state radiolysis studies were degassed on a vacuum line (freeze–pump–thaw cycles) in a round-bottom flask and then poured under vacuum into a 10-cm pathlength Spectrosil optical cell. The above procedures were carried out in semi-darkness to prevent photolytic reduction of the uranyl ion. The samples were irradiated in an AECL Gammacell at a dose rate of about 1.7×10^{19} eV $L^{-1} s^{-1}$. In experiments where the sample was photolyzed, a high pressure xenon arc lamp was used. The uv–vis spectra of these solutions were recorded on a Cary 17 spectrophotometer.

A limited number of pulse radiolysis experiments were also performed and in these studies the solutions were degassed by the syringe-bubbler technique. The 2.25-MeV electron accelerator and detection system has been described elsewhere (2).

To study the reaction of uranium(IV) ions with hydrogen peroxide, the solution containing the uranium(IV) ions and the solution containing the hydrogen peroxide were deoxygenated separately by stripping with nitrogen gas, rapidly mixed, and then transferred to a 10-cm cell under a nitrogen atmosphere. For experiments where organic solutes were present, the solute was added to the uranium(IV) solution before deoxygenation. The change in concentration of uranium(IV) during the experiment was monitored by its absorption near 650 nm using either a Cary-17 or Cary-118 uv–vis spectrometer. Hydrogen peroxide was assayed by the tri-iodide method of Ghormley and co-workers (3).

For the autoxidation of uranium(IV), the reaction is slow enough for the solution to be saturated with oxygen. When this oxidation was carried out with an alcohol present, the alcohol was added after the solutions were oxygen saturated.

Results and discussion

Radiolysis of uranyl sulphate solutions

Experimental observations

The yields of uranium(IV) have been measured in γ-irradiated degassed sulphuric acid solutions containing 10^{-3} mol L^{-1} uranyl sulphate and one of the following organic solutes: 0.1 mol L^{-1} 2-propanol, 0.1 mol L^{-1} sodium formate, 0.1 mol L^{-1} sodium gluconate, 1.0 mol L^{-1} *tert*-butanol. The yield of uranium(IV) was monitored (see Fig. 1) by its absorption near 650–670 nm (the absorption maxima varied depending on the degree of complexation with the organic solute). In general, the procedure was to give the solution an irradiation dose of

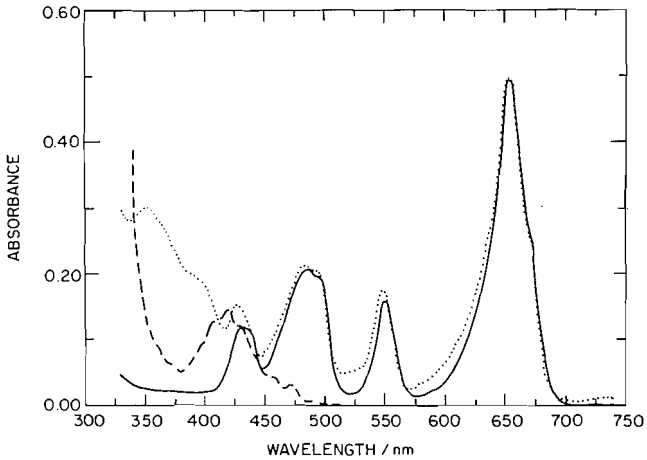

FIG. 1. Spectra of a degassed 10^{-3} mol L^{-1} UO_2SO_4 solution containing 0.1 mol L^{-1} 2-propanol at pH 1.1; before irradiation (---); after 22.5×10^{21} eV L^{-1} radiation, where complete conversion to U(IV) has occurred (—); after 30×10^{21} eV L^{-1} radiation where some U(III) has been formed (...).

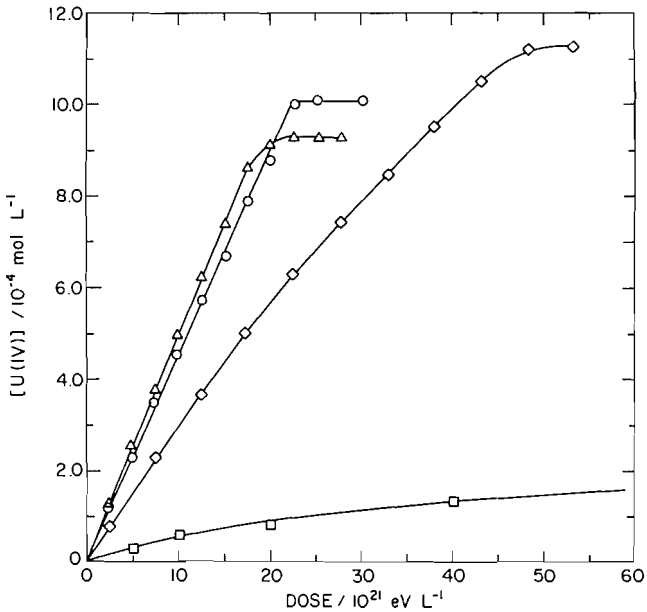

FIG. 2. Yield of uranium(IV) as a function of dose for degassed 10^{-3} mol L^{-1} uranyl sulphate solutions containing: 0.1 mol L^{-1} 2-propanol at pH 1.1 (○); 0.11 mol L^{-1} oxalate at pH 2.0 (△) and pH 5.0 (◇); 1.0 mol L^{-1} *tert*-butanol at pH 1.4 (□).

$2-5 \times 10^{21}$ eV L^{-1} and then record the spectrum; this cycle was repeated until such time as all the uranyl ions were converted to uranium(IV), as illustrated in Fig. 2. For solutions containing 2-propanol, formate, or oxalate, the yield of uranium(IV) was calculated assuming 100% conversion. As a check, the maximum yield of uranium(IV) was confirmed by photolytically reducing the uranyl ions. This was not possible when oxalate was present, as photolysis of these solutions forms CO and CO_2 but very little uranium(IV) (4). In the cases where *tert*-butanol or gluconate were present, complete reduction by radiolysis was not always possible; however, the extinction coefficient of uranium(IV) was determined by the complete photolytic reduction of uranyl ions in these solutions.

With the 2-propanol and formate solutions, after complete conversion of the uranyl ions to uranium(IV) (either radiolytically or photolytically), a small steady-state concentration of uranium(III) was formed (see Fig. 1) on continued radiation. Both from the published extinction coefficient at 350 nm (1200 L mol^{-1} cm^{-1} (5)) and from oxidizing the uranium(III) back to uranium(IV) (by air or the slower reaction with water), it is estimated that uranium(III) constituted less than 2% of the uranium ions under these conditions.

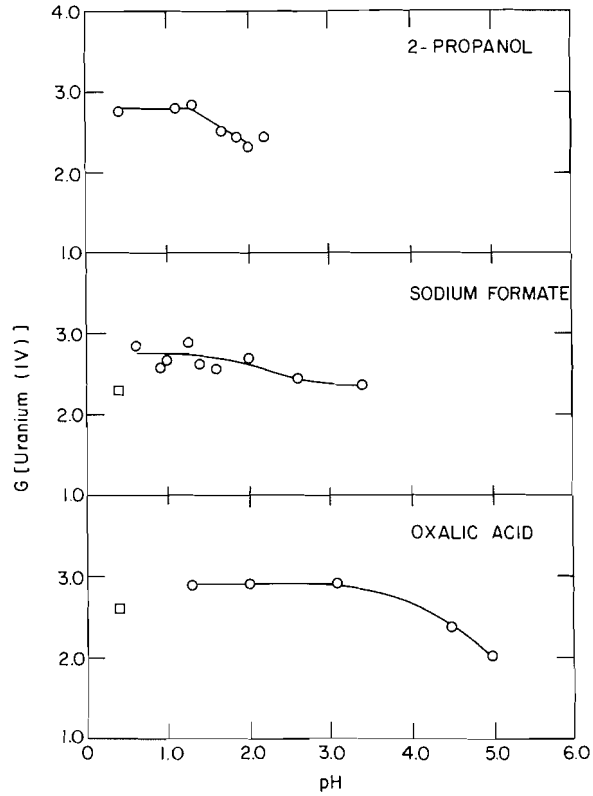

FIG. 3. The *G*-value for uranium(IV) as a function of pH from degassed 10^{-3} mol L^{-1} uranyl sulphate and 0.1 mol L^{-1} organic solute (○). The symbols (□) are the data reported by Hyder.

The dependence of the *G*-value (i.e. number formed per 100 eV of energy absorbed) of uranium(IV) on pH for solutions containing 2-propanol, sodium formate, and oxalic acid is shown in Fig. 3. The pH was adjusted using sulphuric acid. Also shown by the squares in Fig. 3 are the *G*-values reported by Hyder (6). For solutions containing 2-propanol and sodium formate, the uranium(IV) formed precipitated above pH 2.1 and 3.5, respectively. For solutions containing 0.1 mol L^{-1} sodium gluconate, at pH 4.4 the *G*-value for uranium(IV) was 1.4 as calculated from the initial slope of the yield versus dose plot, while at pH 2.0, the *G*-value was zero. The uranium(IV) ion can exist in this solution as it was formed by photolytic reduction. For 1.0 mol L^{-1} *tert*-butanol solutions, the initial *G*-value for uranium(IV) was 0.35 ± 0.10 for the pH range 0.7–2.0. An example of the data is shown in Fig. 2. The uranyl ion could be totally reduced to uranium(IV) photolytically in these solutions.

Some further radiolysis experiments were performed using deoxygenated 10^{-3} mol L^{-1} uranium(IV) sulphuric aid solutions containing 0.5 mol L^{-1} *tert*-butanol. The *G*-value for uranium-(IV) loss was less than 0.3 for pH 0.7–2.1. This small yield can be attributed to oxidation by radiolytic hydrogen peroxide (see later).

Proposed mechanism

For the solutions studied here, most of the ionizing radiation is absorbed by the water to form the species shown in reaction [1].

[1] $H_2O \rightarrow e^-_{aq}(2.7), OH(2.7), H(0.55), H_2(0.45), H_2O_2(0.7)$

The yields for dilute aqueous solutions are given in parentheses and are expressed in G-values. These values will be up to 10% higher for $G(e^-_{aq} + H)$ and $G(OH)$ at some of the solute concentrations used in these experiments (8).

Depending on the pH of the solution, the organic solute (S) present, and how far the reduction of the uranyl ions has proceeded, the solvated electrons will be scavenged either by the uranyl ions or the organic solute to form uranium(V) (reactions [2]–[4]),

[2] $UO_2^{2+} + e^-_{aq} \rightarrow U(V) \qquad k_2 = 1\text{–}3 \times 10^{10}\,L\,mol^{-1}\,s^{-1}$ (8)

[3] $S + e^-_{aq} \rightarrow S^- \qquad k_3 < 10^8\,L\,mol^{-1}\,s^{-1}$ (9)

[4] $S^- + UO_2^{2+} \rightarrow U(V)$

or will be scavenged by the protons to form hydrogen atoms (reaction [5]).

[5] $H^+ + e^-_{aq} \rightarrow H \qquad k_5 = 2 \times 10^{10}\,L\,mol^{-1}\,s^{-1}$ (9)

These hydrogen atoms formed through [1] and [5] will either reduce the uranyl ions,

[6] $UO_2^{2+} + H \rightarrow U(V) \qquad k_6 = 4.5 \times 10^7\,L\,mol^{-1}\,s^{-1}$ (10)

or react with the organic solute present. For all solutes except oxalic acid, the radical produced from the reaction of the hydrogen atom will be the same as that formed from the hydroxyl radical. With oxalic acid it is thought that the product from hydrogen atom reaction is similar to the electron adduct of oxalic acid (11).

In the discussion so far, all reactions involving uranyl ions (reactions [2], [3], and [6]) lead to the formation of uranium(V). Uranium(V) is not long lived in aqueous solution as it disproportionates as shown in reaction [7] (for solutions containing sulphate ions):

[7] $U(V) + U(V) \rightarrow UO_2^{2+} + U(IV) \qquad 2k_7 \sim 1.2 \times 10^4[H^+]\,L\,mol^{-1}\,s^{-1}$ (12, 13)

In general, where the degree of hydrolysis and complexation of the uranium ions is poorly defined, they will be referred to as U(IV), etc. However, in the present experiments the uranium-(VI) was always present as the uranyl ion UO_2^{2+} and will be referred to as such, although it will be complexed with anions in the solution, e.g. SO_4^{2-}.

Not all the radicals formed from the reaction of hydroxyl radicals and hydrogen atoms with the organic solute are capable of reducing uranyl ions. This is best illustrated with β-hydroxy-alkyl radical formed from *tert*-butanol.

[8] $(CH_3)_3COH + OH \rightarrow \dot{C}H_2\text{—}C(CH_3)_2OH + H_2O \qquad k_8 = 6.3 \times 10^8\,L\,mol^{-1}s^{-1}$ (14)

[9] $(CH_3)_3COH + H \rightarrow \dot{C}H_2\text{—}C(CH_3)_2OH + H_2 \qquad k_9 = 1.7 \times 10^5\,L\,mol^{-1}s^{-1}$ (15)

With *tert*-butanol present, the initial $G(U(IV))$ of 0.35 ± 0.10 (see Fig. 2) can be explained by the 25% of $G(e^-_{aq} + H)$ which are scavenged by the uranyl ions through reactions [5] and [6] followed by reaction [7]. This leads to a prediction of a G-value for uranium(IV) of ~0.4. It is obvious from these results that the β-hydroxy-alkyl radical does not reduce uranyl ions. Likewise the low G-value for uranyl ions (<0.3) when uranium(IV) solutions containing $0.5\,mol\,L^{-1}$ *tert*-butanol were irradiated indicates that this β-hydroxy-alkyl radical also cannot oxidize uranium(IV). The small G-value is consistent with the oxidation of uranium(IV) by radiolytically produced hydrogen peroxide and this reaction will be discussed later.

The radicals formed from gluconic acid by reaction with hydroxyl radicals and hydrogen atoms also cannot reduce uranyl ions to uranium(IV). At pH 4.4, where all the electrons were scavenged by the uranyl ion, $G(U(IV))$ was about half of $G(e^-_{aq})$, i.e. 1.5 (reactions [2] and [7]), while at pH 2, where $G(U(IV))$ was zero, greater than 90% of the solvated electrons were scavenged through reaction [5]. Assuming the rate constant for hydrogen atom reaction with gluconic acid is similar to that with glucose (i.e. $\sim 10^8\,L\,mol^{-1}\,s^{-1}$ (15)), all the hydrogen atoms were scavenged by the gluconic acid.

Over the pH range studied (pH 0.7–3.4) with formate added, the formate will exist essentially as formic acid ($pK = 3.75$). In these experiments all the radical species formed from water (reaction [1]) will lead to the reduction of uranyl ions. The hydrogen atoms and hydroxyl radicals that react with the formic acid will, depending on the pH, form either CO_2^- or COOH ($pK = 1.4$ (17)), both of which are strong one-electron reducing agents.

[10] $UO_2^{2+} + CO_2^-(COOH) \rightarrow U(V) + CO_2(+H^+)$

As can be seen in Fig. 3, the G-value for uranium(IV) drops as the pH increases, this in part can be attributed to the decrease in radical yield over this pH range (7). Also over this pH range, the mechanism for the reaction of the hydrogen peroxide (formed in [1]) with uranium(IV) changes, as will be described in detail in the next section. In summary, oxidation by hydrogen peroxide of uranium(IV) proceeds slowly at pH 0.7 and predominantly by a mechanism which produces hydroxyl radicals.

[11] $U(IV) + H_2O_2 \rightarrow U(V) + OH^- + OH$

In the presence of formic acid, the hydroxyl radicals are converted to COOH, which undergoes reaction [10], so that, overall, little uranium(IV) is lost. At pH 2, the oxidation of uranium(IV) is much faster and proceeds through a path that does not produce hydroxyl radicals. Under these conditions uranium(IV) will be oxidized directly to uranium(VI) by the radiolytically produced hydrogen peroxide. This is indicated in Fig. 3 by the decrease in the G-value of uranium(IV) with an increase of the pH from pH 0.7, where the G-value is given by [12],

[12] $G(U(IV)) \sim 0.5\,[G(e^-_{aq}) + G(H) + G(OH)]$

to a value approaching, at pH 3, that given by [13],

[13] $G(U(IV)) \sim 0.5\,[G(e^-_{aq}) + G(H) + G(OH)] - G(H_2O_2)$

The situation when 2-propanol was added is very similar to that of formate. In these experiments all the radicals formed in [1] and [5] react with 2-propanol.

[14] $(CH_3)_2CHOH + OH \rightarrow 0.86\,(CH_3)_2\dot{C}OH + 0.14\,\dot{C}H_2CH(CH_3)OH + H_2O \qquad k_{14} = 2.3 \times 10^9\,L\,mol^{-1}\,s^{-1}$ (14)

[15] $(CH_3)_2CHOH + H \rightarrow 0.86\,(CH_3)_2\dot{C}OH + 0.14\,\dot{C}H_2CH(CH_3)OH + H_2 \qquad k_{15} = 7.9 \times 10^7\,L\,mol^{-1}\,s^{-1}$ (15)

Of the radicals formed in reactions [14] and [15], only 86% of these are α-hydroxy-alkyl radicals (18) that are capable of reducing uranyl ions (reaction [16]). By analogy to the *tert*-butanol experiments described earlier, the 14% which are β-hydroxy-alkyl radicals will not reduce uranyl ions. The rate constant for reaction [16] was measured in pulse radiolysis experiments by following pseudo-first-order decay of the $(CH_3)_2\dot{C}OH$ radical at 340 nm in a pH 1 solution containing 2.7–5.2 × 10^{-3} mol L^{-1} uranyl sulphate and 1 mol L^{-1} 2-propanol. The value for k_{16} at 22°C was (4.1 ± 0.3) × 10^7 L mol^{-1} s^{-1}.

[16] $(CH_3)_2\dot{C}OH + UO_2^{2+} \rightarrow U(V) + (CH_3)_2CO$

$k_{16} = 4.1 \times 10^7$ L mol^{-1} s^{-1}

The situation when oxalate is the added solute is different in that oxalate complexes strongly with both the uranyl ion (19) and with uranium(IV). For the pH range 1.3–3.1 (Fig. 3), the *G*-value for uranium(IV) was constant at 2.9. This is consistent with the hydroxyl radical reacting with oxalate to form a radical that can reduce the uranyl ion.

[17] $\begin{matrix}COO^- \\ | \\ COOH\end{matrix} + OH \rightarrow \begin{matrix}CO\dot{O} \\ | \\ COOH\end{matrix}$ or $\dot{C}OOH + CO_2$

$k_{17} = 6 \times 10^7$ L mol^{-1} s^{-1} (16)

The drop in the *G*-value above pH 3 is probably a consequence of the competition for hydroxyl radicals between the oxalate and the radiolysis product uranium(IV) as the radiolysis proceeds. This is supported by the yield versus dose plot at pH, which is gently curved (Fig. 2).

[18] $\begin{matrix}COO^- \\ | \\ COO^-\end{matrix} + \dot{O}H \rightarrow \begin{matrix}CO\dot{O} \\ | \\ COO^-\end{matrix}$ (or $CO_2 + CO_2^-$)

$k_{18} = 1 \times 10^7$ L mol^{-1} s^{-1} (16)

[19] $U(IV) + OH \rightarrow U(V) + OH^-$ $k_{19} = 8 \times 10^8$ L mol^{-1} s^{-1} (10)

At pH 5, the oxalate exists essentially as the dianion, which has a lower rate constant (reaction [18]) than at lower pH's where the oxalic acid is in the mono-anion form (reaction [17]).

Reactions of uranium(IV) ions with hydrogen peroxide

Experimental observations

To understand the role of radiolytically produced hydrogen peroxide in the radiation chemistry of uranium ions, the reaction of uranium(IV) ions with hydrogen peroxide was studied in deoxygenated sulphuric acid solutions at pH 0.7, 1.5, and 2.0. These experiments were carried out with and without hydroxyl radical scavengers present. In the absence of scavengers, the uranium(IV) ions were oxidized to uranyl ions; the rate of this reaction increased with pH for a given uranium(IV) ion and hydrogen peroxide concentration, as shown in Figs. 4a and b. At pH 0.7 for 10^{-3} mol L^{-1} uranium(IV) ions, increasing the hydrogen peroxide concentration increased the reaction rate (compare open to filled circles in Fig. 4a). The addition of 0.12 mol L^{-1} 2-propanol to a solution containing 10^{-3} mol L^{-1} uranium(IV) and 10^{-3} mol L^{-1} hydrogen peroxide (Figs. 4a and b: triangles) inhibits the loss of uranium(IV) at pH 0.7, while at pH 2.0 the addition of 0.12 and 1.2 mol L^{-1} 2-propanol had only a minimal effect on uranium(IV) loss (Fig. 4: triangles and squares; note that 1.2 mol L^{-1} 2-propanol has a lower initial uranium(IV) concentration than the 0.12 mol L^{-1} 2-propanol solution). The effect of adding 0.08 mol L^{-1} formate to the reaction solution at pH 0.7 was similar to that of adding

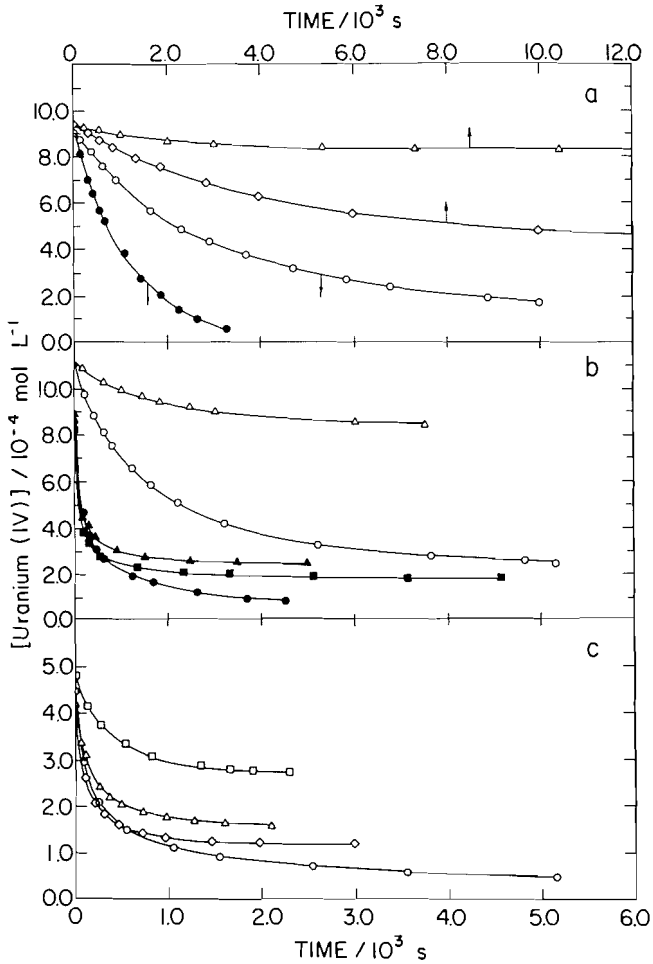

FIG. 4. The disappearance of uranium(IV) as a function of time. 0.12 mol L^{-1} 2-propanol. However, in contrast to 2-propanol, at pH 2 the addition of higher concentrations of formate (0.45 mol L^{-1}) did inhibit the uranium(IV) loss to a limited extent over the addition of 0.08 mol L^{-1} formate. This is shown in Fig. 4c, along with the results for 0.12 mol L^{-1} 2-propanol. In this figure, the initial concentrations of uranium(IV) and hydrogen peroxide were halved to slow the initial rate.

Figure 5 summarizes the stoichiometry of the reaction in the absence of hydroxyl radical scavengers for the three pH values

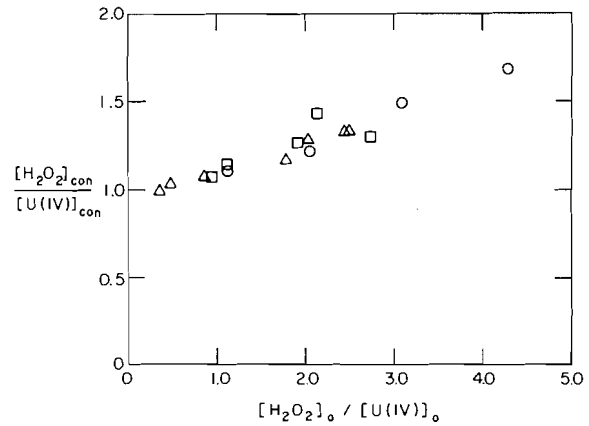

FIG. 5. A plot of the ratio of hydrogen peroxide consumed to uranium(IV) consumed as a function of the initial concentration ratio: pH 0.7 (○); pH 1.5 (△); and pH 2.0 (□).

where the ratio of hydrogen peroxide consumed to uranium(IV) consumed is plotted as a function of the initial concentration ratio. It should be noted that an earlier study by Baker and Newton (20) found that in deoxygenated 2 mol L^{-1} perchloric acid, the consumption ratio of $[H_2O_2]/[U(IV)]$ was constant at 1.024 ± 0.016 for the initial concentration ratio range of $[H_2O_2]/[U(IV)]$ of 0.54–18. This is quite different from our results in the less acidic sulphuric acid solutions studied here and may be associated with the ionic state of uranium(IV) ion. In 2 mol L^{-1} perchloric acid, the uranium(IV) will exist as U^{4+}.

[20] $U^{4+} + H_2O \rightleftharpoons UOH^{3+} + H^+ \qquad K_{20} = 0.1$ (21)

In the current experiments at pH 2, about 55% of the uranium(IV) will be UOH^{3+}, 5% as U^{4+}, and the remainder as the ion pair USO_4^{2+}.

[21] $U^{4+} + HSO_4^- \rightleftharpoons USO_4^{2+} + H^+ \qquad K_{21} = 3.3 \times 10^2$ (22)

At pH 1, the uranium(IV) will essentially all exist as the ion-pair USO_4^{2+}.

Proposed mechanism

Our results at pH 0.7 can be understood in terms of the free-radical chain sequence originally proposed by Baker and Newton (20) (reactions [11], [22], [19], [23], [7]) and the additional reactions [24]–[26]. In these reactions, U(VI) can either be the ion pair, USO_4^{2+}, or U^{4+} but not the hydrolysed form UOH^{3+}.

Initiation:

[11] $U(IV) + H_2O_2 \rightarrow U(V) + OH + OH^-$

Propagation:

[22] $U(V) + H_2O_2 \rightarrow UO_2^{2+} + OH + OH^-$

[19] $U(IV) + OH \rightarrow U(V) + OH^- \qquad k_{19} = 8 \times 10^8$ L mol^{-1} s^{-1} (10)

Termination:

[23] $U(V) + OH \rightarrow UO_2^{2+} + OH^-$

[7] $U(V) + U(V) \rightarrow U(IV) + UO_2^{2+}$

Side reactions:

[24] $OH + H_2O_2 \rightarrow OOH + H_2O \qquad k_{24} = 2.7 \times 10^7$ L mol^{-1} s^{-1} (23)

[25] $OOH + OOH \rightarrow H_2O_2 + O_2 \qquad 2k_{25} = 8.6 \times 10^5$ L mol^{-1} s^{-1} (24)

[26] $U(IV) + OOH \rightarrow UO_2^{2+} + OH$

Reactions [24]–[26] would explain the stoichiometry observed in Fig. 5. In these reactions, hydrogen peroxide (reaction [24]) competes with uranium(IV) (reaction [19]) for the hydroxyl radical. Provided reaction [25] can compete with [26], then more hydrogen peroxide will be consumed than uranium(IV). The reason for our choice of reaction [26] (25, 26) over reaction [27] (27) will be outlined in the next section.

[27] $U(IV) + OOH \rightarrow U(V) + H_2O_2$

The situation is even more complex than the above side reactions suggest. Studies on the disproportionation reaction [7] have indicated an effect of the product UO_2^{2+} on the rate due to a uranium(V)–uranyl complex (13). Other studies indicate that the uranyl ion will complex with both hydrogen peroxide (28) and the perhydroxyl radical, OOH (29). This also will affect the kinetics as the uranyl ion concentration builds up during the experiment.

The results for the addition of 2-propanol or formate at pH 0.7 basically conform with this mechanism, i.e. hydroxyl radicals formed in [11] and [22] are scavenged to form a reducing radical that can then reduce the uranyl ions back to a lower oxidation state by reactions [10] or [16] followed by [7]. Furthermore, the results when 0.46^{-1} mol L *tert*-butanol was added to 10^{-3} mol L^{-1} uranium(IV), 10^{-3} mol L^{-1} hydrogen peroxide solution at pH 0.7 are also consistent with the mechanisms [11], [22], [23], and [7]. In this case, approximately two molecules of peroxide were consumed for every uranium(IV) lost (Fig. 4a) since *tert*-butanol scavenges the hydroxyl radicals formed in reactions [11] and [22] but, as was seen in previous section, the β-hydroxy-radical formed (reaction [8]) cannot reduce the uranyl ion back to uranium(IV). These results indicate that in the presence of *tert*-butanol the reaction rate is controlled by reaction [11] because all the hydroxyl radicals formed in [11] and [22] are scavenged by the *tert*-butanol and cannot propagate the chain reaction. In the absence of *tert*-butanol, reactions [22] and [19] can propagate the chain reaction so that now reaction [22] is the rate-limiting step. Based on these last two statements and the data in Fig. 4a, estimates for k_{11} of 0.21 L mol^{-1} s^{-1} and for k_{22} or 55 L mol^{-1} s^{-1} have been made.

In pH 2 solutions in which the 0.12 and 1.2 mol L^{-1} 2-propanol added was more than sufficient to scavenge all the hydroxyl radicals generated (reaction [14]), the uranium(IV) was still consumed. This implies that hydroxyl radicals are not a major intermediate at this pH. An explanation is that the oxidation proceeds by two mechanisms: one involving U^{4+} and USO_4^{2+} in which hydroxyl radicals are formed as intermediates, and the other involving UOH^{3+} in which hydroxyl radicals are not generated. This second mechanism has a rate constant which is larger than that associated with the first mechanism. This would also explain the pH dependence of the rate. As mentioned earlier, at pH 1.0 the UOH^{3+} will constitute less than 5% of the uranium(IV) ions but that percentage rises to 55% at pH 2 for the solutions containing 2-propanol. The formic acid results are also consistent with the above proposal. The 0.08 mol L^{-1} formate solutions at pH 0.7 and 2.0 both behaved similarly to the 0.12 mol 2-propanol solutions. The probable reason that the 0.45 mol L^{-1} formate could inhibit the loss of uranium(IV) at pH 2 (Fig. 4c) was that the sulphate ion concentration was higher in this experimental solution because the pH of the sodium formate was adjusted by the addition of sulphuric acid. The higher sulphate concentration would decrease the UOH^{3+} concentration and raise the USO_4^{2+} concentration. It should be noted that no evidence exists for a complex between uranium(IV) ions and formate ions, as the wavelength of maximum absorption and the asociated extinction did not change in the presence of the 0.45 mol L^{-1} formic acid.

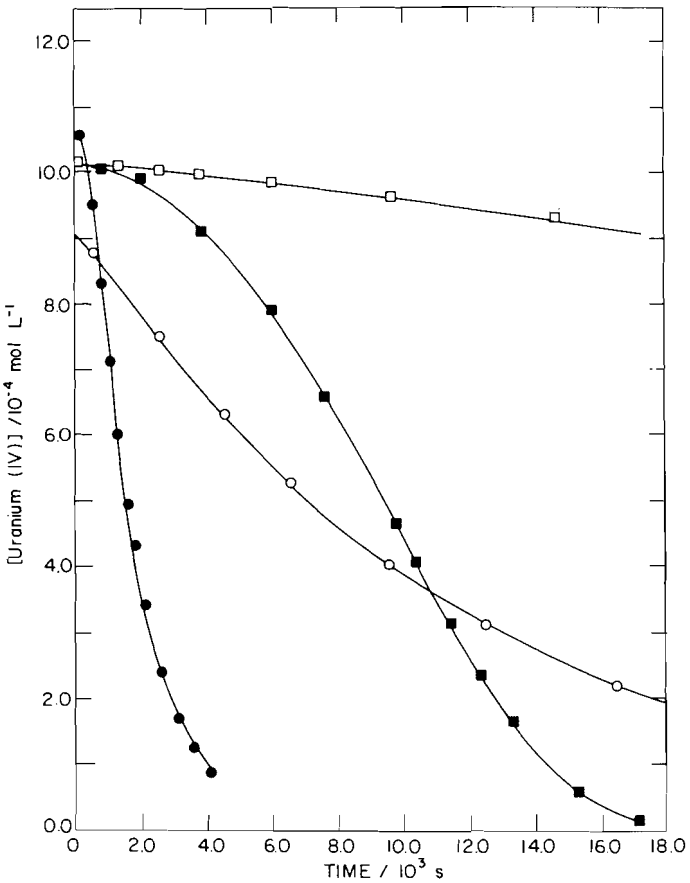

FIG. 6. The time dependence for the reaction of oxygen (initially 1.3 $\times$ 10^{-3} mol L^{-1}) with uranium(IV) without (○, □) and with 0.12 mol L^{-1} 2-propanol (●, ■) present. The circles are for pH = 2.0 and the squares are for pH = 0.8.

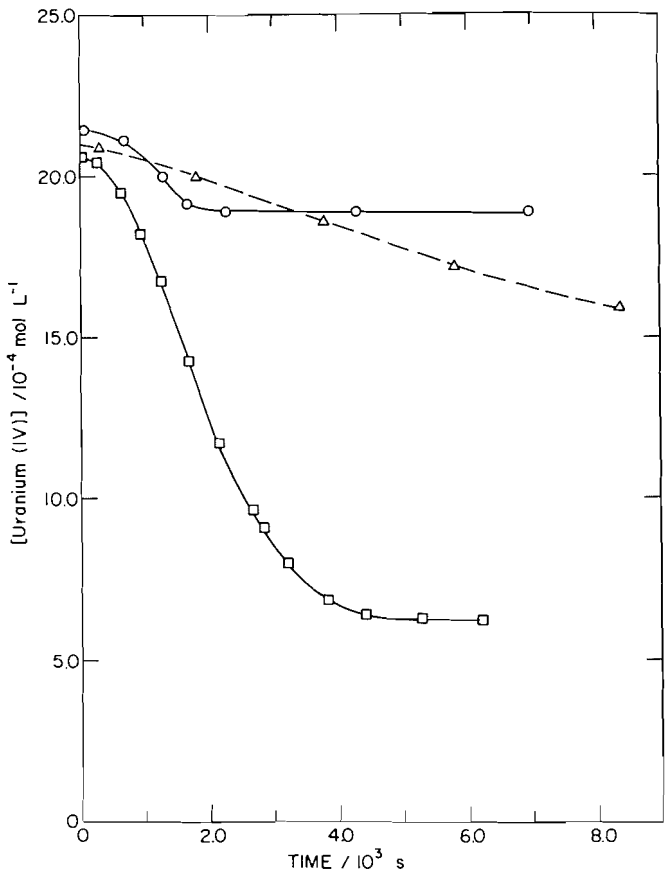

FIG. 7. The time dependence for the reaction of uranium(IV) (initially ~2.1 $\times$ 10^{-3} mol L^{-1}) with oxygen at pH 1.3: $[O_2]_0$ = 1.3 $\times$ 10^{-3} mol L^{-1} (△); $[O_2]_0$ = 1.3 $\times$ 10^{-3} mol L^{-1} oxygen and 0.12 mol L^{-1} 2-propanol (□); $[O_2]_0$ = 2.6 $\times$ 10^{-4} mol L^{-1} oxygen and 0.12 mol L^{-1} 2-propanol (○).

A possible mechanism for the reaction of UOH^{3+} with hydrogen peroxide could be the simpler bimolecular reaction [28].

[28] $UOH^{3+} + H_2O_2 \rightarrow UO_2^{2+} + H_2O$

However, this reaction does not explain the stoichiometry observed at this pH, as shown in Fig. 5. At the present we have been unable to propose a mechanism that satisfactorily explains these pH 2 results. The results obtained at pH 1.5 can be explained if both mechanisms are operating simultaneously.

The above results are consistent with the oxygen tracer experiments of Gordon and Taube (30) for the oxidation of uranium(IV) with hydrogen peroxide. They reported that as the pH rose from 0.35 to 1.5, the number of oxygen atoms transferred from the peroxide to the product uranyl ion increased from 1.0 to 1.18. This could be rationalized in terms of the mechanism change we observed in this study.

Reaction of uranium(IV) with molecular oxygen

Experimental observations

The effect of 2-propanol on the rate of oxidation of uranium(IV) by molecular oxygen was studied to determine if free radicals were involved. In general, the loss of uranium(IV) was followed (spectroscopically at 652 mn) in solutions that initially contained about 10^{-3} mol L^{-1} uranium(IV) ions and were oxygen saturated (1.3 $\times$ 10^{-3} mol L^{-1}). The pH (0.8–2.0) was adjusted with sulphuric acid. In agreement with earlier reports, the rate of uranium(IV) loss increases with pH (open symbols in Fig. 6); the effect of adding 0.12 mol L^{-1} 2-propanol was to increase the rate of oxidation (sigmoidal curves—solid points in Fig. 6). From Fig. 7 the overall stoichiometry of the reaction when 2-propanol was present shows that one oxygen molecule was consumed for every uranium(IV) ion oxidized. The increase in the rate of reaction on addition of 0.12 mol L^{-1} 2-propanol at all pH's studied implies that free radicals are involved and that at least some hydroxyl radicals are generated.

Proposed mechanism

Before speculating as to what these reactions are, it should be noted that little consensus exists in the literature as to the mechanism involved in the oxidation by molecular oxygen of uranium(IV) ions (27, 30, 31). A mechanism which accommodates the kinetic results of Halpern and Smith (27), the tracer study of Gordon and Taube (30), and the present results is given below. In these reactions the oxygen atoms derived from molecular oxygen are marked with an asterisk. The pH dependence of the reaction indicates that UOH^{3+} (equilibrium [20]) is the most reaction uranium(IV) ion.

Initiation:

[29] $UOH^{3+} + O^*O^* \rightarrow UO_2^{+} + O^*O^*H$

[30] $UO_2^{+} + O^*O^* + H^+ \rightarrow UO_2^{2+} + O^*O^*H$

Labelling propagation step:

[31] $UOH^{3+} + O^*O^*H \rightarrow UOO^{*2+} + O^*H + H^+$

[32] $UOH^{3+} + O^*H \rightarrow UOO^{*+} + 2H^+$

[33] $UOO^{*+} + O^*O^* + H^+ \rightarrow UOO^{*2+} + O^*O^*H$

The termination reactions are given by reactions [23] and [7]. Summing reactions [31]–[33], the overall equation [34] is arrived at,

[34] $2\,UOH^{3+} + O^*O^* \rightarrow 2\,UOO^{*2+} + 2H^+$

where both atoms in the molecular oxygen are incorporated into different uranyl ions. This satisfies the restrictions imposed by the tracer experiments (28). The pH dependence is satisfied by UOH^{3+} acting as the active species (equilibrium [20]). In fact, the reported (32) retardation of the reaction in sulphuric acid solutions (as compared to perchloric acid) could be the direct result of equilibrium [20] competing with equilibrium [21].

The effect of adding 2-propanol is to circumvent reaction [32] by scavenging the hydroxyl radical formed in reaction [31] through reaction [14]. The alkyl radicals (HR) formed in [14] react with oxygen to form a peroxy radical, which will dissociate to form the perhydroxyl radical (33).

[35] $H\dot{R} + O_2 \rightarrow HROO\dot{} \rightarrow R + HOO\dot{}$

The OOH radical recycles back to [31] so that the reactions [31], [14], and [35] become the propagating cycle. As the alcohol molecule is oxidized in this cycle also, this leads to the stoichiometry observed in our experiments where one uranium(IV) ion was oxidized per oxygen molecule consumed.

The choice for the mechanism of the reaction of OOH with uranium(IV) as being reaction [31] rather than reaction [27] was made for two reasons. Firstly, if hydrogen peroxide was the product (reaction [27]) then, at pH 2, based on the uranium(IV)/hydrogen peroxide/2-propanol results reported earlier, no hydroxyl radicals would be formed and hence 2-propanol should have had no effect on the reaction rate. Secondly, to meet the isotopic labelling requirements (30) over the pH range studied, reaction [31] has to be chosen rather than [30], followed by reactions [11], [22], [19], [23], [7].

Conclusion

In this study, some of the free-radical redox reactions involving uranium ions have been characterized. In particular, we have shown that for alkyl radicals derived from alcohols, only the α-hydroxy-alkyl radical can reduce uranyl ions and that the β-hydroxy-alkyl radicals can neither reduce uranyl ions nor oxidize uranium(IV) ions. The mechanism for the reaction of hydrogen peroxide with uranium(IV) was demonstrated to change from a free-radical chain reaction involving hydroxyl radicals (reactions [11], [22], [19], [23], [7]) at pH 0.7 to non-free-radical oxidation reaction at pH 2 (possibly reaction [27]). From studying the 2-propanol mediated oxidation of uranium(IV) by oxygen, the reaction of the perhydroxyl radical (OOH) with uranium(IV) has been shown to form hydroxyl radicals (reaction [26]) rather than hydrogen peroxide (reaction [27]). This has enabled us to propose a mechanism for the reaction of oxygen with uranium(IV) (reactions [29]–[33]) that satisfies both the kinetic (27) and tracer (30) experiments.

The reaction of the molybdenum tricarbonyl anion, $[MeGapz_3]Mo(CO)_3^-$, with the organotin chlorides, Ph_3SnCl, Me_3SnCl, and Me_2SnCl_2, has yielded a series of complexes in which direct Mo—Sn single bonds are featured. The $[MeGapz_3]Mo(CO)_3SnMe_2Cl$ complex shows an interesting solution behavior in which a transition from a 3:4, or piano stool structure, to a 3:3:1, or capped octahedral arrangement, is thought to occur. The 3:3:1 structure has been demonstrated in the solid state for the $[MeGapz_3]Mo(CO)_3SnPh_3$ compound by means of a crystal structure determination. Crystals of [methyltris(1-pyrazolyl)-gallato-*N*,*N*,*N*](triphenylstannyl)tricarbonylmolybdenum are monoclinic, a = 11.4439(8), b = 19.5116(8), c = 15.2686(12) Å β = 111.370(3)°, Z = 4, space group $P2_1/c$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.025 and R_w = 0.031 for 5259 reflections with $I \geq 3\sigma(I)$. Important bond lengths include: Mo—Sn = 2.8579(3), Mo—N = 2.239(2)–2.244(2), Mo—C = 1.967(3)–2.000(3), Sn—C = 2.151(3)–2.166(3), Ga—N = 1.920(3)–1.931(3), and Ga—C = 1.943(4)Å.

EMMANUEL C. ONYIRIUKA, STEVEN J. RETTIG et ALAN STORR. Can. J. Chem. **64**, 321 (1986).

L'anion molybdène tricarbonyle, $[MeGapz_3]Mo(CO)_3^-$, réagit avec les chlorures organo-stanniques, Ph_3SnCl, Me_3SnCl et Me_2SnCl_2, pour donner une série de complexes dans lesquels on remarque des liaisons simples directes Mo—Sn. Le complexe $[MeGapz_3]Mo(CO)_3SnMe_2Cl$ en solution présente un comportement intéressant; on croit qu'il se produit une transition d'une structure 3:4, arrangement en tabouret de piano, vers une structure 3:3:1, arrangement octaédrique cappé. En se basant sur une détermination de la structure cristalline, on démontre l'existence de la structure 3:3:1 dans le composé $[MeGapz_3]Mo(CO)_3SnPh_3$ à l'état solide. Les cristaux du [méthyltris(pyrazolyl-1)gallato-*N*,*N*,*N*](triphénylstannyl)tricarbonylmolybdène sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec a = 11,4439(8), b = 19,5116(8), c = 15,2686(12) Å, β = 111,370(3)°, Z = 4. On a résolu la structure par les méthodes conventionnelles de l'atome lourd et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,025 et de R_w = 0,031 pour 5259 réflexions avec $I \geq 3\sigma(I)$. Les longueurs importantes de liaison comprennent Mo—Sn = 2,8579(3), Mo—N = 2,239(2)–2,244(2), Mo—C = 1,967(3)–2,000(3), Sn—C = 2,151(3)–2,166(3), Ga—N = 1,920(3)–1,931(3) et Ga—C = 1,943(4) Å.

[Traduit par le journal]

Introduction

Some time ago Trofimenko (1) introduced the anionic symmetrical tridentate chelating tris(1-pyrazolyl)borate ligand systems, $[RBpz_3]^-$ (where R = H, alkyl, aryl, or pyrazolyl; pz = pyrazolyl, $N_2C_3H_3$). The analogous $[MeGapz_3]^-$ ligand was introduced later and its coordinating properties explored (2–5). Both the above ligand systems, being six-electron donors, have been likened to, and compared with, the cyclopentadienyl ion in many isoelectronic complexes (1–5). Recently we have exploited this similarity in investigations of the reactivity of the $[HBpz_3]Mo(CO)_3^-$ and $[MeGapz_3]Mo(CO)_3^-$ ions towards transition metal halide species to produce novel transition metal – transition metal bonded compounds (6). The present account details our findings on the reactivity of the $[MeGapz_3]Mo(CO)_3^-$ ion towards Ph_3SnCl, Me_3SnCl, and Me_2SnCl_2. Complexes containing direct Mo—Sn bonds have been isolated and the compound $[MeGapz_3]Mo(CO)_3SnPh_3$ has been characterized by an X-ray crystallographic analysis.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran (THF), CH_2Cl_2, benzene, and *n*-hexane were dried by refluxing over Na/benzophenone, CaH_2, potassium, and $CaSO_4$ respectively, followed by distillation. Me_3SnCl (Aldrich Chemicals), Ph_3SnCl (Alpha Chemicals), and Me_2SnCl_2 (PCA Chemicals) were used as supplied. The sodium salt of the methyltris(1-pyrazolyl)gallate ligand, $Na^+[MeGapz_3]^-$, was prepared as a THF solution as described previously (2). Tris-acetonitrile molybdenum tricarbonyl, $(MeCN)_3Mo(CO)_3$, was prepared as described in the literature (7).

Synthesis of $[MeGapz_3]Mo(CO)_3SnMe_3$

To a stirred THF solution of $(MeCN)_3Mo(CO)_3$ (0.107 g, 0.353 mmol) an equimolar amount of the $Na^+[MeGapz_3]^-$ ligand solution (0.353 mmol in 10 mL THF) was added. An almost immediate color change from yellow to amber was observed upon mixing the reactants. The reaction mixture was stirred at room temperature for ~2 days and the ir spectrum of the resulting solution was recorded to ensure the complete formation of $Na^+[MeGapz_3]Mo(CO)_3^-$. The resulting solution was then reacted directly with an equimolar amount of Me_3SnCl (0.070 g, 0.353 mmol) in the same solvent. The cloudy, dark orange, reaction mixture produced was stirred for another 2 days after which the solvent was removed *in vacuo* to afford a dark orange-brown oily residue. This residue was extracted with *n*-hexane and filtered. Upon slow evaporation of the solvent from the filtrate, dark orange crystals of the desired product were recovered in ~68% yield. The compound is stable under nitrogen but decomposes slowly on exposure to air. Analytical, ir, and nmr data for the complex are presented in Table 1 and its ^1H nmr spectrum is shown in Fig. 1. The mass spectrum of the compound displayed signals due to the $[P-3CO]^+$ ion at ~544, but signals due to the parent ion, P^+, were not observed.

Synthesis of $[MeGapz_3]Mo(CO)_3SnPh_3$

A solution of the Na^+ $[MeGapz_3]Mo(CO)_3^-$ salt in THF was prepared as described above. An equimolar amount of Ph_3SnCl (0.136 g, 0.353 mmol) in THF was added to the salt solution. The resulting cloudy reaction mixture was stirred for ~2 days after which the solvent was removed *in vacuo*. The dark yellow residue remaining was extracted with CH_2Cl_2 and filtered. An equal amount of hexane was added to the filtrate and the mixed solvents were allowed to evaporate slowly. A chocolate-brown sticky solid with some visible tinge of yellow was left

behind. This mixture was washed with CH_2Cl_2 and the liquid decanted off slowly to leave behind bright-yellow air-stable crystals of the desired product $[MeGapz_3]Mo(CO)_3SnPh_3$ in approximately 40% yield. Pertinent physical data for this complex are presented in Table 1. The mass spectrum of the complex displayed the parent ion signal, P^+, at ~816, together with prominent signals due to the ions $[P\text{-}CO]^+$, $[P\text{-}2CO]^+$, $[P\text{-}3CO]^+$, and $[P\text{-}3CO\text{-}Me]^+$.

Synthesis of $[MeGapz_3]Mo(CO)_3SnMe_2Cl$

A THF solution of the Na^+ $[MeGapz_3]Mo(CO)_3^-$ salt was prepared as described above and an equimolar amount of Me_2SnCl_2 (0.1933 g, 0.880 mmol), in the same solvent, was added slowly. The initial yellow color of the starting molybdenum tricarbonyl anion darkened slightly during the reaction. The reaction mixture was stirred for ~1 day after which the solvent was removed *in vacuo*. The resulting orange residue was extracted with benzene and filtered. Slow evaporation of the solvent from the filtrate yielded yellow crystals of the desired product from concentrated solutions in ~50% yield. Pertinent physical data for this complex are included in Table 1. The mass spectrum of the complex displayed a strong parent ion, P^+, signal at ~650. In addition signals due to the $[P\text{-}CO]^+$, $[P\text{-}2CO]^+$, $[P\text{-}3CO\text{-}Me]^+$, and $[P\text{-}3CO]^+$ ions were also observed, the latter being the strongest in the spectrum. The relative intensities of the lines in these signals agreed well with a computer-generated profile, taking into account the relative abundances of the naturally occurring isotopes of Mo, Ga, Sn, and Cl (see Fig. 2).

Physical measurements

The ir spectra were recorded on a Perkin–Elmer 598 spectrometer, ^{1}H nmr spectra were recorded on a Bruker WP-80 instrument, and mass spectra on a Kratos AES M50 spectrometer at ~100°C and 70 eV. Elemental analyses were performed by Mr. P. Borda of the U. B. C. microanalytical laboratory.

X-ray crystallographic analysis of [methyltris(1-pyrazolyl)gallato-N,N,N](triphenylstannyl)tricarbonylmolybdenum

A crystal bounded by the 7 faces (followed by their distances in mm from a common origin: {0 1 0}, 0.21, {1 0 0}, 0.13, (0 −1 1), 0.29, (0 1 1), 0.22, (0 1 −2), 0.28 was mounted in a general orientation. Unit-cell parameters were refined by least squares on $2\sin\theta/\lambda$ values for 25 reflections (2θ = 40–47°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, ($\lambda(K\alpha_2)$ = 0.71359 Å. Crystal data at 22°C are:

$C_{31}H_{27}GaMoN_6O_3Sn$ fw = 815.94

Monoclinic, a = 11.4439(8), β = 19.5116(8), c = 15.2686(12) Å, β = 111.370(3)°, V = 3174.9(4) Å^3, Z = 4, ρ_c = 1.707 Mg m^{-3}, $F(000)$ = 1608, μ(Mo-$K\alpha$) = 20.4 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 1.26–10.06° min^{-1} over a range of (0.70 + 0.35tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (8,9). Transmission factors ranged from 0.469 to 0.610 for 96 integration points. Of the 7254 independent reflections measured, 5259 (72.5%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S-B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy-atom methods, the coordinates of the Sn, Mo, and Ga atoms being determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C(sp^3)—H = 0.98, C(sp^2)—H = 0.97 Å, methyl groups staggered in accordance with observed peaks), recalculated after each cycle of refinement. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. Anomalous scattering factors from ref. 12 were used for the Sn, Mo, and Ga atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.025 and R_w = 0.031 for 5259 reflections with $I \geq 3\sigma(I)$. For all 7254 reflections R = 0.050. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, and $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.21σ respectively. The mean error in an observation of unit weight was 1.280. A final difference map showed maximum fluctuations of −1.3 to +0.61 e Å^{-3} within 1.0 Å of Mo and

Sn, respectively, and was essentially featureless away from the heavy atoms. The final positional and thermal parameters appear in Tables 2 and 6[3], respectively. Bond lengths and angles appear in Tables 3 and 4, respectively. Calculated hydrogen atom parameters (Table 5) and a complete listing of torsion angles (Table 7) are included as supplementary material.[3] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

Results and discussion

A number of complexes of the type $[MeGapz_3]M(CO)_2X$ (where M = Mo or W, X = η^3-allyl or NO) have been reported and the compound $[MeGapz_3]M(CO)_2(\eta^3-C_3H_5)$ has been structurally characterized (2). Recently the tricarbonyl anion $[MeGapz_3]Mo(CO)_3^-$ has yielded complexes with Mo—Rh and Mo—Cu bonds by reaction with Wilkinson's catalyst, $Rh(PPh_3)_3Cl$, and the tetrameric copper species $[Cu(PPh_3)Cl]_4$ (6). As part of an ongoing investigation into the reactivity of the $[MeGapz_3]Mo(CO)_3^-$ ion, its behavior towards a number of organotin chlorides has been studied. Thus, 1:1 reactions with Ph_3SnCl, Me_3SnCl, and Me_2SnCl_2 yielded yellow-orange crystalline products of Mo—Sn bonded species, e.g.

$$[MeGapz_3]Mo(CO)_3^- + Ph_3SnCl \rightarrow [MeGapz_3]Mo(CO)_3SnPh_3 + Cl^-$$

The complexes are moderately air-stable in the solid state but solutions deteriorate on exposure to air. It is interesting to compare the compounds with those reported some time ago by Patil and Graham in which the $MeGapz_3^-$ ligand is replaced by the Cp^- group (13). In both series of compounds only terminal CO bands are displayed in their ir spectra, indicative of direct Mo–Sn interaction without accompanying bridging CO ligands. In the case of the cyclopentadienyl complexes three strong terminal CO bands were observed in each case, whereas the three compounds reported here show different patterns. Thus, both the "$SnPh_3$" and "$SnMe_2Cl$" complexes give one weak and two strong ν_{CO} vibrations, whereas the "$SnMe_3$" complex

displays one strong and two weak ν_{CO} bands. Perhaps these variations reflect a difference in structure between the complexes (see below). The ^{1}H nmr data for the "$SnPh_3$" and "$SnMe_3$" complexes show all three pyrazolyl groupings to be equivalent in solution, indicating a symmetrical structure for the complexes. The spectrum for the $[MeGapz_3]Mo(CO)_3SnMe_3$ complex is shown in Fig. 1. The ^{1}H nmr spectrum of $[MeGapz_3]Mo(CO)_3SnMe_2Cl$ is interesting since it changes with time and solvent (Fig. 3 shows the change, with time, in the spectrum of the complex in toluene-d_8. A similar effect was observed using benzene-d_6 as solvent. Thus, initially the spectrum shows two "sets" of signals. The most intense set of signals is consistent with a symmetrical 3:3:1 or capped octahedral structure as shown in Fig. 4A, similar to that established for the "$SnPh_3$" derivative (see below). In this arrangement free rotation about the Mo—Sn bond in solution would give the observed pattern of equivalent pyrazolyl signals and a singlet for the "$SnMe_2$" grouping. In the second "set" of signals the two Sn—Me groups are nonequivalent and yet the pyrazolyl groups seemingly remain equivalent. This pattern is difficult to rationalize since even a static 3:4, or four-legged piano stool arrangement (Fig. 4B) would be expected to give inequivalent pyrazolyl groups as well as possibly distinguishing between the two Me groups on the Sn atom. A rotation of the $MeGapz_3$ moiety about the Ga···Mo axis might afford a rationale for the observed equivalence of the pyrazolyl groups in this second arrangement. A similar rotation of the $HBpz_3$ grouping in the complexes $[HBpz_3]Mo(CO)_2(\eta^3-C_3H_5)$ and $Cp_2MoH_2 \rightarrow Cu[HBpz_3]_2$ has been invoked to explain the equivalence of the pyrazolyl groups in the room temperature ^{1}H nmr spectra of these compounds (14). In any event, with time, the species responsible for the weaker set of signals gradually disappears and one is left with only one set of signals, explicable in terms of a 3:3:1 structure. Interestingly, Patil and Graham (13) report a singlet for the "$SnMe_2$" protons in their $CpMo(CO)_3SnMe_2Cl$ complex for which they speculate a 3:4 or piano stool structure similar to that demonstrated by Bennett and Mason (15) for the complex $(\eta\text{-}C_5H_5)Mo(CO)_3Et$.

The chemistry of M—M′ bonded derivatives (where M′ = Ge or Sn; M = Mo or W) has been studied quite extensively but, rather surprisingly, no X-ray structural data has been reported for complexes of the type $(\eta\text{-}C_5H_5)M(CO)_3M'R_3$ (where R = alkyl or aryl), the molecular arrangements proposed for these species being based primarily on ir and ^{1}H nmr data (16). The X-ray crystal structure of the complex $[MeGapz_3]Mo(CO)_3SnPh_3$ presented here represents what we believe to be the first reported structure of this type, in which the $[MeGapz_3]$ moiety replaces the $\eta\text{-}C_5H_5$ ligand in the general formulation given above. The

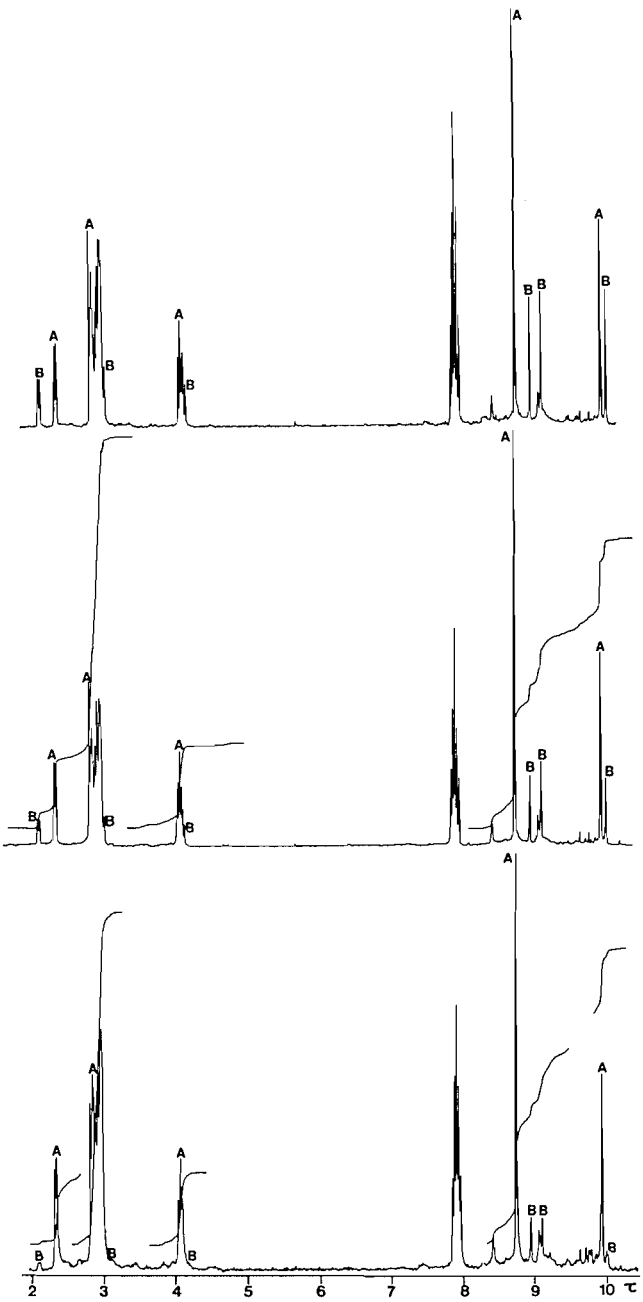

FIG. 3. Room temperature 80-MHz ^{1}H nmr spectra of [MeGapz$_3$]-Mo(CO)$_3$SnMe$_2$Cl in toluene-d_8, showing the change with time: initial spectrum (top), after 1 day (middle), and after 5 days (bottom). (A) 3:3:1 structure, (B) 3:4 structure.

X-ray structure analysis confirms the 3:3:1 arrangement predicted on the basis of the ^{1}H nmr and ir data. The molecule, which has approximate C_3 symmetry, is shown in Fig. 5. The structure is similar to that recently reported for the compound [MeGapz$_3$]Mo(CO)$_3$Cu(PPh$_3$) (6) but different from the 3:4 piano stool structures of the related molecules (η-C$_5$H$_5$)-Mo(CO)$_3$Sn(Cl)[η-C$_5$H$_5$)Fe(CO)$_2$]$_2$ (17), [HBpz$_3$]Mo(CO)$_3$Br (18), and (η-C$_5$H$_5$)Mo(CO)$_3$Et (15). The multi-metal species with η-C$_5$H$_5$ replacing MeGapz$_3$ on Mo and the [(η-C$_5$H$_5$)-Fe(CO)$_2$] groupings replacing the Me groups on Sn may well be incapable of adopting a 3:3:1 structure due to the bulky Fe-containing substituents. However, one of the interesting aspects that prompted Curtis and Shiu (18) to determine the structure of

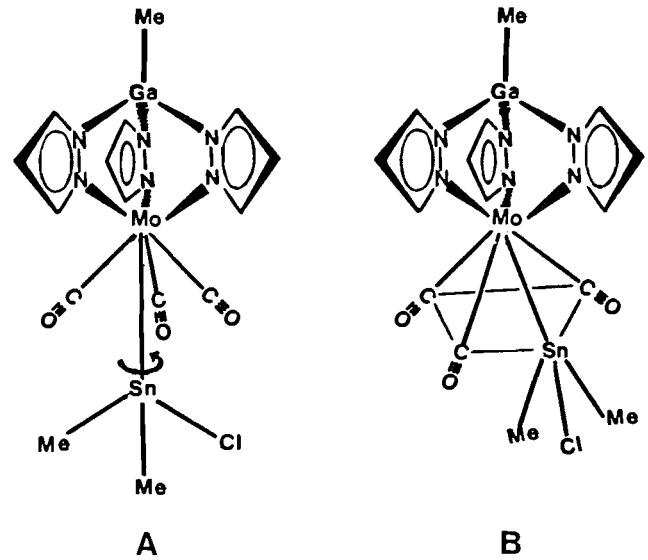

FIG 4. Possible molecular arrangements for the [MeGapz$_3$]Mo-(CO)$_3$SnMe$_2$Cl complex in solution: (A) 3:3:1 structure, (B) 3:4 structure.

the above bromo derivative was the possibility of observing a 3:3:1 capped octahedral structure. Thus calculations by Kubacek *et al.* (19) had shown that such an arrangement represents a minimum in the potential energy surface for (η-C$_5$H$_5$)ML$_4$ complexes where the global minimum (ground state) is always the 3:4 structure.

The structure of the [MeGapz$_3$]Mo(CO)$_3$SnPh$_3$ complex clearly shows the presence of three terminal carbonyl groups with bond angles of 169.7(3), 172.1(3), and 172.7(3)° for the Mo—C—O units, the slight deviations from linearity being directed away from the Sn centre and probably caused by the proximity of the phenyl groups on the Sn atom. The C—O bond distances of 1.154(4), 1.139(3), and 1.141(3) Å are also in the range expected for terminal carbonyl groups and the Mo—C distances of 1.967(3), 2.000(3), and 1.994(3) Å are consistent with a terminal CO bonding arrangement. The above parameters show that one of the carbonyl groups differs significantly from the other two. This represents the most significant departure from overall C_3 molecular symmetry and can be ascribed to a weak C—H···O hydrogen bond (C(10)—H(10)···O(1)(x, 1/2-y,z-1/2), H···O = 2.39, C···O = 2.326(4) Å, C—H···O = 162°, C—O···H = 156°) linking molecules in infinite chains extending along the b axis. All other intermolecular distances are greater than the sums of van der Waals radii.

The Ga···Mo—Sn unit with angle of 178.49(1)° is essentially linear and, as expected, the planar pyrazolyl groups (χ^2 = 0.2–6.9, maximum deviation from the mean plane 0.007(4) Å), whilst eclipsing the distant phenyl groups (planar to within 0.011(5) Å, χ^2 = 2.0–13.1) on Sn, are staggered with respect to the three CO ligands on the Mo centre. The Mo—Sn distance of 2.8579(3) Å observed for the present complex is considerably shorter than the expected distance of 3.00 Å based on the sum of covalent radii (1.39 + 1.61 Å) for the two atoms (15, 20–22). The distance is, however, comparable to the first Mo—Sn distance reported, 2.891(5) Å for the complex [(η-C$_5$H$_5$)Mo-(CO)$_3$]Sn(Cl)[(η-C$_5$H$_5$)Fe(CO)$_2$]$_2$ (17). As in the structure described herein, the Sn atom in this multi-metal complex is in a pseudotetrahedral environment. Cameron and Prout (23) have reported a Mo—Sn distance of 2.691(4) Å for the complex

TABLE 4. Bond angles (deg) with estimated standard deviations in parentheses

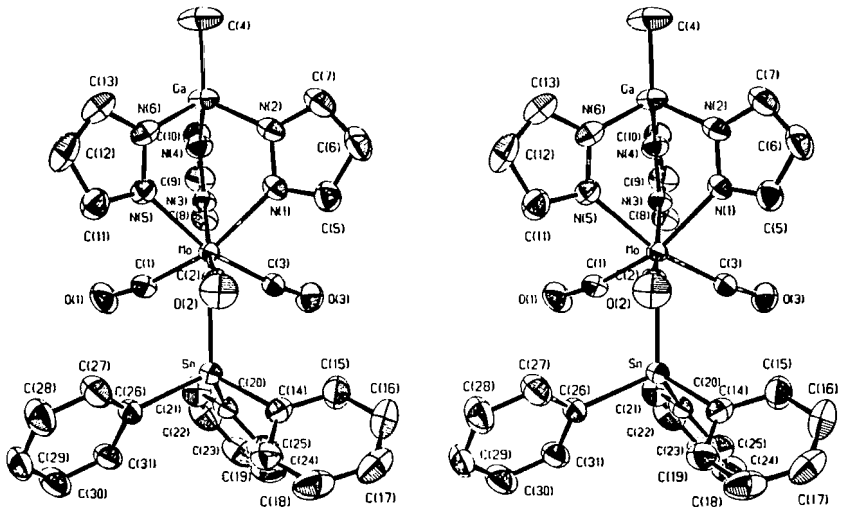

FIG. 5. Stereoscopic view of the $[MeGapz_3]Mo(CO)_3SnPh_3$ molecule; 50% probability thermal ellipsoids are shown.

$(\eta\text{-}C_5H_5)_2Mo(SnBr_3)Br$ in which the Sn atom is in a distorted trigonal bipyramidal environment with a fourth, long, Sn···Br interaction of 3.411 Å. A similar environment for the Sn atom has been reported for the complex (bipy)(Cl)$Mo(CO)_3$(SnMeCl_2), (bipy = 2,2′-bipyridyl), in which the Mo—Sn distance of 2.753(3) Å was interpreted as indicative of some multiple bond character (24). The same authors reported the structure of the tungsten–tin complex ($MeS(CH_2)_2SMe$)(Cl)$W(CO)_3$(SnMeCl_2) in which the W—Sn distance of 2.759(3) Å was argued to reflect the similarity of the W and Mo covalent radii (25). In both these structures there is a bridging Cl ligand between the metal centres, with a long Sn—Cl distance.

The present study has demonstrated the ability of the $[MeGapz_3]Mo(CO)_3^-$ anion to form complexes with organotin moieties in which the Mo and Sn metal centres are linked by a single covalent bond. We are presently extending our investigations into the reactivity of the $[MeGapz_3]Mo(CO)_3^-$ anion to include other main group compounds and will report on our findings in due course.

Adsorption isotherms for coadsorption studies from solution

PANAGHIOTIS NIKITAS AND ADRIANI PAPPA-LOUISI
Laboratory of Physical Chemistry, University of Thessaloniki, Thessaloniki, Greece
Received April 11, 1985

PANAGHIOTIS NIKITAS and ADRIANI PAPPA-LOUISI. Can. J. Chem. **64**, 328 (1986).

The mixed adsorption of k adsorbates from solution on energetically homogeneous surfaces is studied by means of lattice statistical thermodynamics. The adsorption layer is considered to behave as a non-electrolyte bulk solution composed from k adsorbates and solvent. On the basis of this assumption the adsorption isotherms and their state equations are determined by means of the lattice theory of strictly regular solutions and Flory–Huggins statistics. The thermodynamic restrictions imposed when these models have to be applied to real systems are also determined and discussed.

PANAGHIOTIS NIKITAS et ADRIANI PAPPA-LOUISI. Can. J. Chem. **64**, 328 (1986).

Faisant appel à la thermodynamique statistique des résaux, on a étudié l'adsorption mixte des adsorbates de type k en solution sur des surfaces homogènes actives. On considère que la couche d'adsorption se comporte comme une solution non électrolytique formée par les adsorbates de type k et par le solvant. Cette hypothèse permet de déterminer les isothermes d'adsorption et leurs équations d'état en faisant appel à la théorie de réseau des solutions strictement régulières et aux statistiques de Flory–Huggins. On détermine également et on discute des restrictions thermodynamiques qui s'imposent lorsqu'on applique ces modèles à des systèmes réels.

[Traduit par le journal]

I. Introduction

When a substance is adsorbed on a solid surface from solution, then the adsorption process takes place by the displacement of the preadsorbed solvent molecules by the adsorbate ones. This adsorption process may be also considered to take place on the coadsorption of k substances, $A_1, A_2, \ldots, A_k$ from a solution of a solvent S, provided that there are not significant differences in the adsorption free energies of A_i. That is, we can accept that the adsorption of A_i may be described by the following chemical equations:

$$[1] \quad A_i(b) + r_i S(ads) \rightleftarrows A_i(ads) + r_i S(b)$$

where r_i is the number of solvent molecules displaced from the surface solution by one A_i molecule and the symbols (b), (ads) denote the bulk solution and the adsorption layer, respectively.

The number of the equilibrium equations [1] is equal to k and therefore the relation between the concentrations of the adsorbed particles and those in the bulk solution, i.e. the adsorption isotherm, will be expressed by a system of k equations. In the case of dilute solutions the general expression of these equations is

$$[2] \quad F_i(\vartheta_1, \vartheta_2, \ldots, \vartheta_k) = \beta_i c_i$$

where ϑ_i is the fraction of the surface covered by A_i, c_i the concentration of A_i in the bulk solution, and β_i is an adsorption equilibrium constant.

According to current views (1–5) we can consider that the adsorption layer on an electrode surface behaves as a non-electrolyte bulk solution of $k+1$ components, i.e. of the k adsorbates $A_1, A_2, \ldots, A_k$ and of the solvent S. The non-electrolyte solution theories which have already been used for the study of the adsorption of a single solute from a solution onto an energetically homogeneous surface are (*i*) the lattice theory of the strictly regular solutions (SRS) (6–9) and (*ii*) Flory–Huggins statistics (FH) (6, 8, 10). The isotherms developed on the basis of these theories give a realistic description of the adsorption layer features (4, 5, 11–14). For this reason, in the present work we shall apply the above theories to the general problem of the coadsorption of k adsorbates from solution on energetically homogeneous surfaces.

II. Adsorption from $k+1$ component solution

1. Model of SRS theory

In this model we accept the following:

a. The adsorption layer is a three-dimensional phase and behaves as a non-electrolyte bulk solution composed of N_1 molecules of adsorbate A_1, N_2 molecules of A_2, ..., N_k molecules of A_k, and $N_{k+1} \equiv N_S$ molecules of the solvent S. The molecules are spherical or effectively spherical and they are approximately of the same size.

b. The $N = \sum_{i=1}^{k+1} N_i$ molecules of the adsorption layer occupy sites of a regular lattice. Each molecule occupies a single site and there are no vacant sites in the lattice. All sites are energetically equivalent.

c. The interactions between the adsorbed molecules are weak so that interactions between non-nearest-neighbouring molecules are considered negligible.

The adsorbed molecules may vibrate about their lattice sites. If the vibration modes and, more generally, the internal degrees of freedom of a molecule are independent of the presence of other molecules in neighbouring sites, then the canonical ensemble partition function, Q, for the surface solution will be

$$[3] \quad Q = \prod_{i=1}^{k+1} q_{\text{in},i}^{N_i} \sum e^{-E/kT}$$

where E is the total interaction potential energy and $q_{\text{in},i}$ is the internal partition function of the A_i component. The sum is over all the possible distributions of the adsorbed molecules on the lattice sites.

If N_{ij} is the number of the nearest-neighbouring pairs of sites occupied by an A_i and an A_j molecule, W_{ij} the interaction energy between the molecules A_i, A_j in the pair, and E_i the residual energies due to interactions of the adsorbed particle A_i with the adsorbing surface and surrounding particles in the bulk solution including the dipole-field interactions, then the total energy E may be expressed as

Printed in Canada / Imprimé au Canada

[4] $$E = \sum_{i=1}^{k+1} N_i E_i + \sum_{i \leq j}^{k+1} N_{ij} W_{ij}$$

However, in an arbitrary lattice we generally have

[5] $$N_{ii} = \tfrac{1}{2} c N_i - \tfrac{1}{2}\{N_{i1} + N_{i2} + \ldots + N_{i(i-1)} + N_{i(i+1)} + \ldots + N_{ik+1}\}$$

where c is the coordination number of the lattice. Therefore

[6] $$E = \sum_{i=1}^{k+1} (N_i E_i + U_i) + \sum_{i<j}^{k+1} N_{ij} W^{ij}$$

where

[7] $$U_i = c N_i W_{ij}/2$$

and

[8] $$W^{ij} = W_{ij} - (W_{ii} + W_{jj})/2$$

Now, introducing eq. [6] into eq. [3] and using the zeroth approximation (6) for the evaluation of the sum we get

[9] $$\ln Q = \sum_{i=1}^{k+1} \{N_i \ln q_{\mathrm{in},i} - N_i \ln N_i - (U_i + N_i E_i)/kT\} + N \ln N - \sum_{i<j} (N_i N_j c W^{ij}/NkT)$$

since for random mixing the mean value of N_{ij} is equal to cN_iN_j/N.

The chemical potentials of the adsorbed molecules, $\mu_i(\mathrm{ads})$, are

[10] $$\frac{\mu_l(\mathrm{ads})}{kT} = -\left(\frac{\partial \ln Q}{\partial N_l}\right)_{N_{i \neq l}, T} = -\ln q_{\mathrm{in},l} + (cW_{ll}/2 + E_l)/kT + \ln X_l + \sum_{i \neq l} X_i(1 - X_l)\mathrm{A}_{il} - \sum_{\substack{i<j \\ i,j \neq l}} X_i X_j \mathrm{A}_{ij}$$

where

[11] $$X_i = N_i/N$$

and

[12] $$\mathrm{A}_{ij} = cW^{ij}/kT$$

The chemical potentials in the bulk solution, $\mu_i(\mathrm{b})$, can be expressed in terms of mole fractions. If we also accept the unsymmetrical system as the reference system (15, 16) then at the region where Henry's law is valid we have

[13] $$\mu_i(\mathrm{b}) = \mu^0{}_i + kT \ln (c_i/c_s) \qquad i \neq k+1$$

and

[14] $$\mu_s(\mathrm{b}) = \mu^0{}_s$$

where $\mu_i{}^0$ is the chemical potential of the ith component in its standard state.

At equilibrium the chemical potentials will fulfill the equations:

[15] $$\mu_l(\mathrm{ads}) - r_l \mu_s(\mathrm{ads}) = \mu_l(\mathrm{b}) - r_l \mu_s(\mathrm{b}) \qquad l \neq k+1$$

since we accept that the adsorption process takes place on the basis of eq. [1]. Introducing eqs. [10], [13], and [14] into eq. [15] we obtain:

[16] $$\ln \frac{X_l}{X_s{}^{rl}} + \{X_s(1 - X_l) - r_l X_l(1 - X_s)\}A_{lk+1} + \sum_{i \neq l,k+1} X_i(1 - X_l + r_l X_l)A_{il} - \sum_{i \neq l,k+1} \{X_s X_i + r_l X_i(1 - X_s)\}A_{ik+1} + \sum_{i<j} X_i X_j (r_l - 1)A_{ij} = \ln \frac{c_l}{c_s} + \ln \beta_l$$

where

[17] $$\ln \beta_l = \{\ln (q_{\mathrm{in},l}/q_{\mathrm{in},s}^{rl}) + c(r_l W_{ss} - W_{ll})/2kT + (E_l + \mu_l{}^0 - r_l \mu_s{}^0)/kT\}$$

Equations [16] compose the system of isotherms which describes the coadsorption of the substances A_i ($i = 1, \ldots, k$) from a solution of a solvent S on an energetically homogeneous surface under the assumption that the adsorption layer behaves as a strictly regular bulk solution. So isotherms [16] are strictly valid for $r_i = 1$ or for values of r_i very close to unity. Isotherms [16] may be also used for values of r_i appreciably different from unity (9, 14). However, in this case, the interaction parameters A_{ij} are not any longer given by eq. [12], since the faults resulting from the entropic terms, $\ln (X_l/X_s{}^{rl})$, are expected to contribute erroneously to the values of A_{ij}.

For isotherms [16] to be used in the interpretation of adsorption experimental data, the mole fraction X_i have to be expressed as a function of the surface coverages ϑ_i. If Γ_i is the number of moles per unit area of the adsorbate A_i, then we have:

[18] $$X_l = \Gamma_l / \sum_{i=1}^{k+1} \Gamma_i$$

But $\Gamma_i = \vartheta_i \Gamma_{i,\max}$ and $\Gamma_{s,\max} = r_i \Gamma_{i,\max}$. Therefore we have

[19] $$X_l = \frac{\vartheta_l / r_l}{1 - \sum_{i=1}^{k} \frac{r_i - 1}{r_i} \vartheta_i}$$

and

[20] $$X_s = 1 - \sum_{x=1}^{k} X_i$$

2. Models of FH statistics

In this model, as in the case of SRS model, the adsorbed molecules are arranged in space following the geometry of a regular lattice. However, in this model, the adsorption layer is a two-dimensional phase and each adsorbed molecule can occupy more than one site in the lattice.

In order to analyze the properties of this model we first examine the case of a surface solution having zero energy of mixing. If M is the total number of lattice sites and n_i the number of sites occupied by a single A_i molecule, then we have

[21] $$M = \sum_{i=1}^{k+1} n_i N_i$$

and

[22] $$\vartheta_i = n_i N_i / M$$

The total differential of the free energy of the adsorbed phase

can be expressed in the form:

$$[23]\quad \frac{dA}{MkT} = \sum_{i=1}^{k} \frac{1}{n_s n_i} \ln (\lambda_i^{n_s}/\lambda_s^{n_i}) d\vartheta_i$$

where λ_i is the absolute activity of A_i. However, the ratio $\lambda_i^{n_s}/\lambda_s^{n_i}$ is directly proportional to the ratio of the probability that a group of $n_i n_s$ sites are occupied entirely by n_s particles of A_i, $P(n_s$ particles $A_i)$, to the probability that this group is occupied by n_i particles of the solvent S, $P(n_i$ particles $S)$. That is (6, 7, 10)

$$[24]\quad \frac{\lambda_i^{n_s}}{\lambda_s^{n_i}} = \kappa_i \frac{P(n_s \text{ particles } A_i)}{P(n_i \text{ particles } S)} = \kappa_i \alpha_i$$

where κ_i is a constant independent of the composition of the adsorption layer. Now, if we accept that the probability of occupation of a lattice site is independent of the presence of particles in neighbouring sites, then we have

$$[25]\quad \alpha_i = (\vartheta_i/\rho_i)^{n_s}/(\vartheta_s/\rho_s)^{n_i}$$

where ρ_i is the number of distinguishable ways in which a particle A_i as a whole can be placed in the lattice after one of its elements has been placed.

Introducing eqs. [24], [25] into eq. [23] and integrating, we obtain

$$[26]\quad \frac{A}{MkT} = \sum_{i=1}^{k} \{\vartheta_i[\ln (\kappa_i \rho_s^{n_i/n_s}/\rho_i) + \ln \vartheta_i - 1]/n_i\} + (\vartheta_s \ln \vartheta_s - \vartheta_s)/n_s + \text{const.}$$

while the free energy of mixing will be given by

$$[27]\quad \frac{\Delta A_m}{MkT} = \sum_{i=1}^{k+1} (\vartheta_i \ln \vartheta_i)/n_i$$

Now, the chemical potentials of the adsorbed particles can be easily obtained from

$$[28]\quad \frac{\mu_l(\text{ads}) - \mu_l^0(\text{ads})}{kT} = \left(\frac{\partial \Delta A_m/kT}{\partial N_l}\right) N_{i \neq l} = \ln \vartheta_l + 1 - n_l \sum_{i=1}^{k+1} \vartheta_i/n_i \qquad l = 1, \ldots, k+1$$

where $\mu_l^0(\text{ads})$ is the chemical potential of the pure A_l substance at the adsorption layer.

The above equations hold for the ideal case where the energy of mixing is zero. Yet the field effect is not taken into consideration. In order to overcome these weaknesses we can introduce into eq. [28] appropriate activity coefficients, f_i, and internal partition functions, q_i, in which we formally include both the internal degrees of freedom and the field effect. Thus we have

$$[29]\quad \frac{\mu_l(\text{ads})}{kT} = \ln \vartheta_l + 1 - n_l \sum_{i=1}^{k+1} \vartheta_i/n_i + \mu_l^0(\text{ads})/kT + \ln f_l - \ln q_l$$

If the process of adsorption is again assumed to be represented by eq. [1], then we have $r_i = n_i/n_s$ and, introducing eq. [29] into eq. [15], we obtain the isotherms:

$$[30]\quad \ln \frac{\vartheta_l}{e^{(r_l-1)} \cdot \left(1 - \sum_{i=1}^{k} \vartheta_i\right)^{r_l}} + \ln \frac{f_l}{f_s^{r_l}} = \ln \frac{c_l}{c_s} + \ln \beta_l$$

where we have

$$[31]\quad \ln \beta_l = (\mu_l^0 - r_l \mu_s^0 - \mu_l^0(\text{ads}) + r_l \mu_s^0(\text{ads}))/kT + \ln (q_l/q_s^{r_l})$$

Isotherms [30] can be used only when the relation between f_i and ϑ_i or X_i is known. To a molecular level and for the adsorption of a single adsorbate from solution, this relation has been determined by means of the Bragg–Williams and the quasi-chemical approximation (13). However, these two approximations lead to remarkable deviations from the experimental data (13, 14), so that it is useless to extend them to the case of the joint adsorption. On the contrary, the determination of the relation between $f_i/f_s^{r_i}$ and X_i to a macroscopic level has led to isotherms with high applicability (13). This treatment can be easily extended to the joint adsorption from solution. The excess free energy, g^e, with respect to the free energy of an athermal mixture due to the non-zero energy of mixing, is related to the activity coefficients by the known relation (17)

$$[32]\quad g^e/kT = \sum_{i=1}^{k+1} X_i \ln f_i$$

Then

$$[33]\quad \frac{\partial g^e/kT}{\partial X_l} = \ln f_l - \ln f_s$$

and therefore

$$[34]\quad \ln f_l = \frac{g^e}{kT} + \frac{\partial g^e/kT}{\partial X_l} + \sum_{i \neq k+1} X_i \frac{\partial g^e/kT}{\partial X_i}$$

$$[35]\quad \ln f_s = \frac{g^e}{kT} - \sum_{i \neq k+1} X_i \frac{\partial g^e/kT}{\partial X_i}$$

Now, if we expand the excess free energy g^e to a power series

$$[36]\quad g^e = kT \sum_{i<j}^{k+1} \sum_{m=0}^{n} A_m^{ij} X_i X_j (X_i - X_j)^m$$

we obtain

$$[37]\quad \ln f_l = \sum_{i<j} \sum_m A_m^{ij} \{(\lambda X_p - X_i X_j)(X_i - X_j)^m - m X_i X_j (X_i - X_j + (-1)^{\mu}\lambda)(X_i - X_j)^{m-1}\}$$

$$[38]\quad \ln f_s = \sum_{i<j} \sum_m A_m^{ij} \{(\sigma X_i - X_i X_j)(X_i - X_j)^m - m X_i X_j (X_i - X_j + \sigma)(X_i - X_j)^{m-1}\}$$

where $\lambda = 1$ when i or $j = l$, $\lambda = 0$ when i and $j \neq l$; μ is an even number when $l = j$ and odd number when $l = i$; $p \neq l$ and $p = i$ or j; finally, $\sigma = 1$ when $j = k$ and $\sigma = 0$ when $j \neq k$. Also, m may depend upon the values of i, j.

III. Thermodynamic restrictions and equations of state

Isotherms [16] and [30] are of the general form

$$[39]\quad F_i(X_1, X_2, \ldots, X_k) = \beta_i c_i$$

If Φ is the surface pressure of the adsorbed phase, then

$$[40]\quad d\Phi = \sum_{i=1}^{k} \frac{\partial \Phi}{\partial \ln c_i} d \ln c_i$$

However,

$$[41]\quad d \ln c_i = \sum_{l=1}^{k} \frac{\partial \ln F_i}{\partial X_l} dX_l$$

and, in dilute solutions, from the Gibbs adsorption theorem we get

$$[42]\quad \vartheta_i = a_i \frac{\partial \Phi}{\partial \ln c_i}$$

where

$$[43]\quad a_i = 1/RT \cdot \Gamma_{i,\max}$$

Therefore

$$[44]\quad d\Phi = \sum_j \left(\sum_i \frac{\vartheta_i}{a_i} \frac{\partial \ln F_i}{\partial X_j} \right) dX_j$$

$d\Phi$ is an exact differential. So we must have

$$[45]\quad \frac{\partial}{\partial X_n}\left\{\sum_i \frac{\vartheta_i}{a_i}\frac{\partial \ln F_i}{\partial X_l}\right\} = \frac{\partial}{\partial X_l}\left\{\sum_i \frac{\vartheta_i}{a_i}\frac{\partial \ln F_i}{\partial X_n}\right\} \qquad n \neq l$$

The system of isotherms [39] should fulfill these equations in order to be compatible with thermodynamics. Substituting F_i from eq. [16] or [30] into eq. [45], we obtain that the condition [45] is fulfilled if and only if

$$[46]\quad r_i/a_i = \text{constant}$$

Parameter r_i is taken equal to the ratio of the molecular volumes of the adsorbate A_i and the solvent S, (V_i/V_s), or equal to the ratio of the areas covered by these substances on the electrode surface. These two choices depend upon the choice of the dimensions of the adsorbed phase. If this is considered as a two-dimensional layer, as it is used in the case of Flory–Huggins isotherms, then $r_i = S_i/S_s$ and

$$[47]\quad r_i/a_i = RT \cdot 10^{14}/S_s L = \text{const.}\ (S_i,\ S_s \text{ in nm}^2/\text{molecule})$$

where L is Avogadro's constant; i.e., in this case no thermodynamic restriction is imposed. However, if we consider the adsorption layer as a three-dimensional phase, then the restriction r_i/a_i = const. is not always fulfilled. Usually in this case the restriction [46] presupposes that the adsorbed substances have the same height in the adsorption layer.

Integrating [45] and following lengthy algebra, or alternatively from eq. [9], taking into account the restriction [46], the equations of state of the coadsorption isotherms developed here may be calculated. They are the following:

a. *Model of SRS theory*

$$[48]\quad \frac{\Phi}{b} = -\ln X_s + \sum_{i<j\neq k+1} X_i X_j A_{ij} - \sum_{i\neq k+1} X_i(1-X_s)A_{ik+1}$$

where

$$[49]\quad b = r_i/a_i$$

b. *Model of FH statistics*

$$[50]\quad \frac{\Phi}{b} = -\ln \vartheta_S - 1 + \sum_{i=1}^{k+1} \frac{\vartheta_i}{r_i} + \sum_{i<j}\sum_m A_m{}^{ij}\{mX_iX_j(X_i - X_j + \sigma) - (\sigma X_i - X_iX_j) \times (X_i - X_j)\}(X_i - X_j)^{m-1}$$

IV. Adsorption from three-component solution

The general relationships developed above can be used in practice only for coadsorption of two substances from solution. In this case, for the use of isotherms [16], [30] ca. 10^2 measurements are required, while an increase in the number of adsorbates increases the number of measurements exponentially.

For adsorption from three-component solution the above equations may be rewritten in the following form:

a. *Model of SRS theory*

Adsorption isotherms

$$[51]\quad \ln(X_A/X_s{}^{r_A}) + X_B\{1 + (r_A - 1)X_A\}A_{AB} + \{X_s(1-X_A) - X_A(1-X_s)r_A\}A_{AS} - X_B\{r_A - (r_A-1)X_s\}A_{BS} = \ln(c_A/c_S) + \ln\beta_A$$

$$[52]\quad \ln(X_B/X_S{}^{r_B}) + X_A\{1 + (r_B - 1)X_B\}A_{AB} - X_A\{r_B - (r_B-1)X_S\}A_{AS} + \{X_S(1-X_B) - X_B(1-X_S)r_B\}A_{BS} = \ln(c_B/c_S) + \ln\beta_B$$

Equation of state

$$[53]\quad \frac{\Phi}{b} = -\ln X_S + X_AX_BA_{AB} - (X_A{}^2 + X_AX_B)A_{AS} - (X_B{}^2 + X_AX_B)A_{BS}$$

b. *Model of FH statistics*

Adsorption isotherms

$$[54]\quad \ln\frac{\vartheta_A}{e^{(r_A-1)}(1-\vartheta_A-\vartheta_B)^{r_A}} + \ln\frac{f_A}{f_S{}^{r_A}} = \ln\frac{c_A}{c_S} + \ln\beta_A$$

$$[55]\quad \ln\frac{\vartheta_B}{e^{(r_B-1)}(1-\vartheta_A-\vartheta_B)^{r_B}} + \ln\frac{f_A}{f_S{}^{r_B}} = \ln\frac{c_B}{c_S} + \ln\beta_B$$

where

$$[56]\quad \ln\frac{f_A}{f_S{}^{r_A}} = \sum_{i=0}^{n}\{[X_B(1-X_A) + r_AX_AX_B](X_A - X_B) + iX_AX_B[1 - X_A + X_B - r_A(X_B - X_A)]\}A_i(X_A - X_B)^{i-1} + \sum_{i=0}^{n}\{[X_S(1-X_A) - r_AX_A(X_A + X_B)](X_A - X_S) + iX_AX_S[1 - X_A + X_S + r_A(2X_A + X_B)]\}B_i(X_A - X_S)^{i-1} - \sum_{i=0}^{n}\{[X_BS_S + r_AX_B(X_A + X_B)](X_B - X_S) - iX_BX_S[1 - X_A - 2X_B + r_A(X_A + 2X_B)]\}C_i(X_B - X_S)^{i-1}$$

$$[57]\quad \ln\frac{f_B}{f_S{}^{r_B}} = \sum_{i=0}^{n}\{[X_A(1-X_B) + r_BX_AX_B](X_A - X_B) - iX_AX_B[1 + X_A - X_B + r_B(X_B - X_A)]\}A_i(X_A - X_B)^{i-1} - \sum_{i=0}^{n}\{[X_AX_S + r_BX_A(X_A + X_B)](X_A - X_S) - iX_AX_S[1 - 2X_A - X_B + r_B(2X_A + X_B)]\}B_i(X_A - X_S)^{i-1} + \sum_{i=0}^{n}\{[X_S(1-X_B) - r_BX_B(X_A + X_B)](X_B - X_S) + iX_BX_S[1 - X_B + X_S + r_B(X_A + 2X_B)]\}C_i(X_B - X_S)^{i-1}$$

However, this form of isotherms is not also appropriate for an easy application to experimental data. The study of the individual adsorption on the basis of isotherms of this model showed that a satisfactory description of the experimental data is possible, even if $n = 0$ (13). If $n_i = 0$ then eqs. [56], [57] are reduced to

$$[58]\quad \ln(f_A/f_S^{r_A}) = X_B[1 + (r_A - 1)X_A]A_0 + [X_S(1 - X_A) - r_A X_A(1 - X_S)]B_0 - X_B[r_A - (r_A - 1)X_S]C_0$$

$$[59]\quad \ln(f_B/f_S^{r_B}) = X_A[1 + (r_B - 1)X_B]A_0 - X_A[r_B - (r_B - 1)X_S]B_0 + [X_S(1 - X_B) - r_B X_B(1 - X_S)]C_0$$

Note that eqs. [58], [59] are identical to the energetic terms of isotherms [51], [52].

Equation of state

$$[60]\quad \frac{\Phi}{b} = \frac{1 - \vartheta_A - \vartheta_B}{1 - X_A - X_B} - \ln(1 - \vartheta_A - \vartheta_B) - 1 + A_0 X_A X_B - B_0(X_A^2 + X_A X_B) - C_0(X_B^2 + X_A X_B)$$

In the above equations the interaction parameters A_{AS}, A_{BS}, B_0, and C_0 may be obtained from the individual adsorption of the substances A and B under the assumption that the presence of an adsorbate (say A) at the interface does not change significantly the intermolecular interactions of the other adsorbate (B) with the solvent and within its molecules. On the contrary, the parameters A_{AB} and A_0 can be calculated only from the interpretation of the coadsorption experimental data.

When $r_A = r_B = 1$, isotherms [51], [52] or [54], [55] are reduced to

$$[61]\quad \ln\frac{\vartheta_A}{1 - \vartheta_A - \vartheta_B} + \vartheta_B A_{12} + \vartheta_A A_1 = \ln\frac{c_A}{c_S} + \ln\beta_A$$

$$[62]\quad \ln\frac{\vartheta_B}{1 - \vartheta_A - \vartheta_B} + \vartheta_A A_{12} + \vartheta_B A_2 = \ln\frac{c_B}{c_S} + \ln\beta_B$$

i.e., the known isotherms of Frumkin for adsorption of two substances are obtained with parameters:

$$[63]\quad A_{12} = A_{AB} - A_{AS} - A_{BS},\ A_1 = -2A_{AS} \text{ and } A_2 = -2A_{BS}$$

The equation of state of these isotherms is

$$[64]\quad \frac{\Phi}{b} = \frac{A_1}{2}\vartheta_A^2 + \frac{A_2}{2}\vartheta_B^2 + A_{12}\vartheta_A\vartheta_B - \ln(1 - \vartheta_A - \vartheta_B)$$

The Frumkin isotherms are also obtained if we accept that $r_A = r_B = 1$ and that the solvent behaves as a continuous medium. In this case we obtain the isotherms [61], [62] with parameters:

$$[65]\quad A_{12} = cW_{AB}/kT,\ A_1 = cW_{AA}/kT, \text{ and } A_2 = cW_{BB}/kT$$

Note that there is a characteristic difference in the physical meaning of the interaction parameters between the two models of the Frumkin isotherms. Thus in the case of the continuous solvent model, parameters A_1 and A_2 are identical to those of the single adsorption. On the contrary, in the case of the discrete solvent model there is no identity in the interaction parameters of the individual and the joint adsorption. So we have to use eq. [63] for the calculation of A_1, A_2. Obviously, the values of A_{12}, obtained in the two cases, will be different. Finally the restriction [46] leads to the identity $S_A = S_B$. Therefore in the Frumkin isotherms the identity of the dimensions of the adsorbed molecules is not imposed simply from the model of the isotherm but also from thermodynamic reasoning.

Coadsorption of triphenylphosphine – triphenylphosphine oxide, triphenylphosphine – dodecyldiphenylphosphine oxide, and dodecyldiphenylphosphine oxide – tri(*n*)octylphosphine oxide from methanolic solutions on a polarized mercury electrode

ADRIANI PAPPA-LOUISI AND PANAGHIOTIS NIKITAS
Laboratory of Physical Chemistry, University of Thessaloniki, Thessaloniki, Greece
Received August 11, 1985

ADRIANI PAPPA-LOUISI and PANAGHIOTIS NIKITAS. Can. J. Chem. **64**, 333 (1986).

The coadsorption of triphenylphosphine – triphenylphosphine oxide, triphenylphosphine – dodecyldiphenylphosphine oxide, and dodecyldiphenylphosphine oxide – tri(*n*)octylphosphine oxide on a polarized mercury electrode from methanolic solutions of LiCl is investigated by means of electrocapillary measurements. Results show that reorientation or other molecular modifications do not take place during the coadsorption process. The adsorbed molecules maintain their orientation with the phenyl and alkyl groups in contact with the electrode surface. Thus, the adsorption maxima of the substances in the mixed adsorption are located at the same polarization region as in the single adsorption, although their separation distance increases as the bulk concentration of adsorbates rises due to changes in the electrical characteristics of the interface. This shift is not observed when the two substances are adsorbed at the same, or nearly the same, potentials (charges). In all cases the adsorption of a substance leads to a decrease in the adsorption of the coadsorbate to an extent depending on the electric field. The influence of the field on the adsorption isotherms cannot be determined by means of the surface pressure method but by determining the type of adsorption isotherm. It was found that all the systems studied follow an isotherm based on the strictly regular solutions theory. The interaction parameters are independent of the field, while the standard free energy of adsorption of an adsorbate, within experimental error, is independent of the presence of the coadsorbate. This is due to the insignificant change in the bulk adsorbate solvent interactions caused by the presence of the coadsorbed substance in the solution.

ADRIANI PAPPA-LOUISI et PANAGHIOTIS NIKITAS. Can. J. Chem. **64**, 333 (1986).

On fait appel à des mesures électrocapillaires pour étudier la coadsorption des mélanges triphénylphosphine – oxyde de triphénylphosphine, triphénylphosphine – oxyde de dodécyldiphénylphosphine, oxyde de dodécylediphénylphosphine – oxyde de tri(*n*)octylphosphine, en solution de LiCl dans le méthanol, sur une électrode polarisée au mercure. Les résultats indiquent qu'il n'y a pas de réorientation ou d'autres modifications moléculaires lors de la coadsorption. Les molécules adsorbées maintiennent leur orientation avec les groupes phényles et alkyles, qui sont en contact avec la surface de l'électrode. Ainsi les maxima d'adsorption de ces substances dans l'adsorption mixte se situent dans la région de polarisation qui correspond à l'adsorption simple et ceci en dépit du fait que leur distance de séparation augmente avec l'augmentation de la concentration globale des adsorbates due aux variations des caractéristiques électriques de l'interface. On n'observe pas ce déplacement lorsque les deux substances sont adsorbées au même potentiel (charges) ou presque. Dans tous les cas, l'adsorption d'une substance provoque une diminution du taux d'adsorption de la molécule coadsorbée et cet effet dépend du champ électrique. On ne peut pas déterminer l'influence du champ sur les isothermes d'adsorption en faisant appel à la méthode de la pression de la surface; toutefois, il est possible de le faire en déterminant le type d'isotherme d'adsorption. On a trouvé que tous les systèmes étudiés obéissent à un isotherme basé sur la théorie des solutions rigoureusement régulières. Les paramètres d'interaction ne dépendent pas du champ alors que l'énergie libre normale d'adsorption d'une molécule adsorbée ne dépend pas, à l'intérieur des erreurs expérimentales, de la présence d'une molécule coadsorbée. Ceci est dû à des changements non significatifs dans les interactions entre la molécule adsorbée et le solvant que provoquent la présence de molécules coadsorbées en solution.

[Traduit par le journal]

I. Introduction

Although the investigation of the mixed adsorption of organic substances from solutions began in 1930, with the work of Ockrent and Butler (1–3), the literature on this subject is poor. The main reason must be attributed to the great number of measurements necessary for a detailed study of this phenomenon. If N, where $N > 10$, is the number of the necessary measurements for the study of the individual adsorption of a substance, then for the coadsorption of two substances ca. 10^2 measurements are required. Because of the experimental difficulties, but also due to the lack of a quantitative approach to the coadsorption phenomenon based on realistic models, a number of publications have a purely qualitative character (4–7). A strictly quantitative work is that of the Russian investigators, which exclusively involves the model of the three parallel condensers as a basis for the study of the mixed adsorption (8–13). However, this approach, being oriented towards a certain direction, leaves some aspects of the problem undefined.

In the present work we attempt a quantitative study of the coadsorption of organic compounds from solution without reference to a priori models, such as that of the three parallel capacitors. We check the possibility of extending the thermodynamic method, developed through the works of Parsons, Trasatti, and their co-workers (14–20) for the interpretation of adsorption data, to the mixed adsorption from solution as well as the applicability of the mixed adsorption isotherms developed in ref. 21. For this reason we studied the interfacial behaviour of the systems triphenylphosphine (TPP) – triphenylphosphine oxide (TPO), triphenylphosphine (TPP) – dodecyldiphenylphosphine oxide (DDPO), and dodecyldiphenylphosphine oxide (DDPO) – tri(*n*)octylphosphine oxide (TOPO) at the mercury – methanolic solution interface. The individual adsorption of these substances has already been studied in our laboratory (22–24). So by studying their mixed adsorption there is the possibility of a quantitative study of the adsorption characteristics of one substance in the presence of another at the interface.

II. Experimental

Description of the experimental apparatus and details on the origin and purity of the chemicals employed are given elsewhere (22–24). Measurements were carried out with a non-siliconized capillary. The

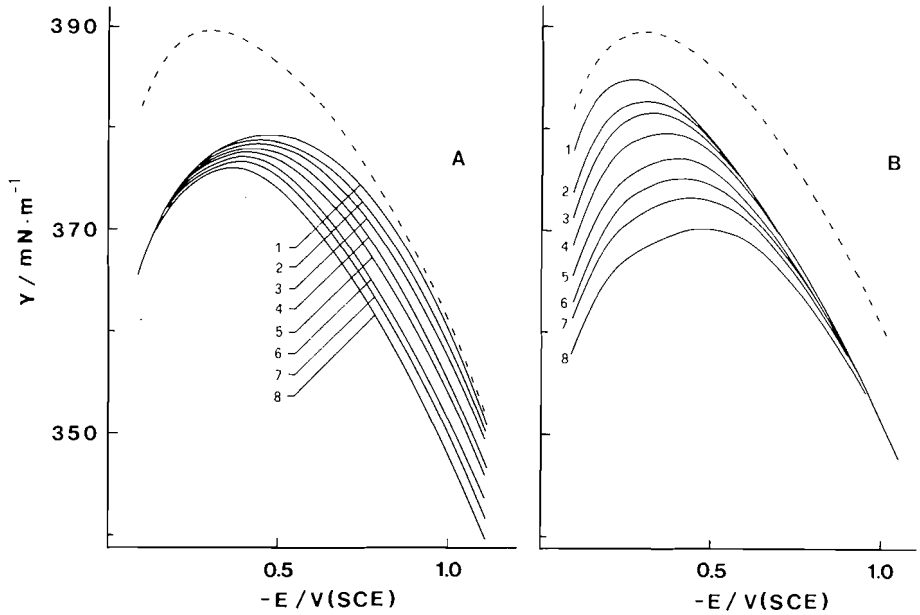

FIG. 1. Electrocapillary curves of Hg in methanolic 0.1 *M* LiCl + *xM* TPP + *yM* TPO solutions. (A) $x = 4 \times 10^{-3}$ and *y*: (1) 0, (2) 5×10^{-3}, (3) 1×10^{-2}, (4) 2×10^{-2}, (5) 3×10^{-2}, (6) 5×10^{-2}, (7) 7×10^{-2}, (8) 0.1. (B) $y = 5 \times 10^{-2}$ and *x*: (1) 0, (2) 4×10^{-4}, (3) 1×10^{-3}, (4) 2×10^{-3}, (5) 4×10^{-3}, (6) 7×10^{-3}, (7) 1×10^{-2}, (8) 2×10^{-2}. Broken line corresponds to the base electrolyte solution.

characteristics of the capillary, its calibration, and the procedure used for measuring the surface tension has also been described previously (25).

For the study of the coadsorption of the substances under investigation, the electrocapillary curves of Hg in the solutions 0.1 *M* LiCl + *xM* A + *yM* B/MeOH where A, B = TPP, TPO, DDPO, TOPO were determined. In the system TPP (A) – TPO (B) we used 12 values of *x* between 0 and 2×10^{-2} and 12 values of *y* in the range from 0 to 0.2. For every value of *x* (or *y*), *y* (or *x*) ranged through its values. In the system TPP (A) – DDPO (B) we used 12 values of *x* (or *y*) between 0 and 2×10^{-2} for *y* (or *x*) = 0 and *y* (or *x*) = 2×10^{-3}, while in the system TOPO (A) – DDPO (B) *x*, *y* took also 12 values, *x* between 0 and 2×10^{-2} for $y = 0$ and 1×10^{-3}, and *y* between 0 and 0.1 for $x = 0$, 1×10^{-3}. In addition, for a detailed study of the change in the adsorption maximum of a substance due to the presence of another adsorbate at the interface, we also took measurements, at an indicative level, in the systems TOPO–TPP and TOPO–TPO.

III. Results and discussion

1. Generalities

Figure 1 shows some of the electrocapillary curves of the system TPP–TPO. It is seen that the presence of a second adsorbate, in the bulk of the solution from which the adsorption of a substance takes place, causes depression of the surface tension (γ) values. This depression depends upon the electrical state of the electrode. In the system of constant TPP concentration (Fig. 1A), electrocapillary curves are strongly depressed in the negative region whereas they coincide with that of the base solution in the positive region. The opposite holds in a system of constant TPO concentration (Fig. 1B). Therefore TPP, in the presence of TPO, is not practically adsorbed on Hg at extreme negative potentials, whereas, on the contrary, the adsorption of TPP in the positive region prevails over TPO adsorption. An analogous behaviour is observed in the system TPP–DDPO (Fig. 2). On the contrary, in the system DDPO–TOPO (Fig. 3) a characteristic depression of the surface tension values over all the potential range examined is observed. Particularly for the system of constant TOPO concentration, the shape of the electrocapillary curves shows that, phenomenologically, the electric field of the interface does not affect the free energy of DDPO adsorption in the presence of TOPO.

The shift of the electrocapillary maximum (ecm) is positive as the concentration of phosphinoxides in the solution increases, and it is negative for the TPP adsorption. In all cases this is analogous to the shift of the ecm that is shown by the corresponding substances on their individual adsorption from the same base electrolyte solution (22–24). Therefore in the systems under investigation, the adsorption of a substance does not lead to reorientation of the coadsorbate, at least at the electrocapillary maximum region.

2. Potential and charge of maximum adsorption

According to the Gibbs adsorption theorem, the electrical coordinates of the maximum in adsorption of an adsorbate A_l in the presence of other adsorbates $A_{i \neq l}$, $i = 1, 2, \ldots k$ can be determined from the charge (σ^m) vs. potential (*E*) curves (18). As in the case of the individual adsorption of a substance from solution, of a given A_l concentration, c_{A_l}, the adsorption of A_l is at a maximum at the charge and potential of the intersection point of the relevant curve with that of the base solution.

The coordinates of the adsorption maximum can also be determined from the maximum in the curves of surface pressure (Φ) against potential (*E*) or charge (σ^m) at constant concentrations of $A_{i \neq l}$. However, we should note that in this case, the maximum in the Φ vs. *E* curve, which corresponds to the concentration c_{A_l}, is not always identified with the maximum adsorption of A_l at this concentration. In the limit of dilute solution, the Gibbs adsorption equation for constant potential and constant concentrations of all the substances in the solution, except from that of A_l, takes the form (26)

$$[1] \qquad -d\gamma = RT\Gamma^S_{A_l} d \ln c_{A_l}$$

where $\Gamma_{A_l}{}^S$ is the relative concentration of A_l. Intergrating eq. [1], we have

$$[2] \qquad \Phi = \gamma_0 - \gamma = RT \int_0^{c_{A_l}} \Gamma^S_{A_l} d \ln c_{A_l}$$

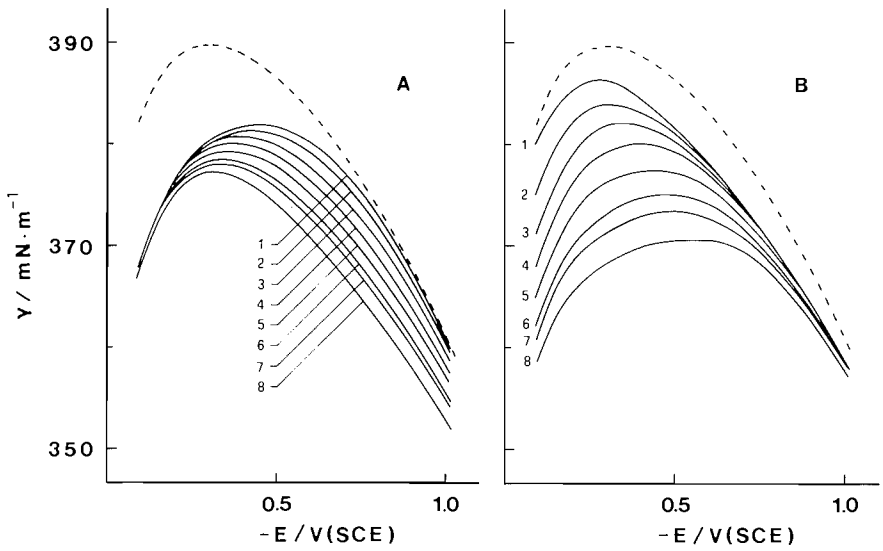

FIG. 2. Electrocapillary curves of Hg in methanolic 0.1 *M* LiCl + *xM* TPP + *yM* DDPO solutions. (A) $x = 2 \times 10^{-3}$ and *y*: (1) 0, (2) 4×10^{-4}, (3) 1×10^{-3}, (4) 2×10^{-3}, (5) 4×10^{-3}, (6) 7×10^{-3}, (7) 1×10^{-2}, (8) 2×10^{-2}. (B) $y = 2 \times 10^{-3}$ and *x* as the *y* values in (A). Broken line corresponds to the base electrolyte solution.

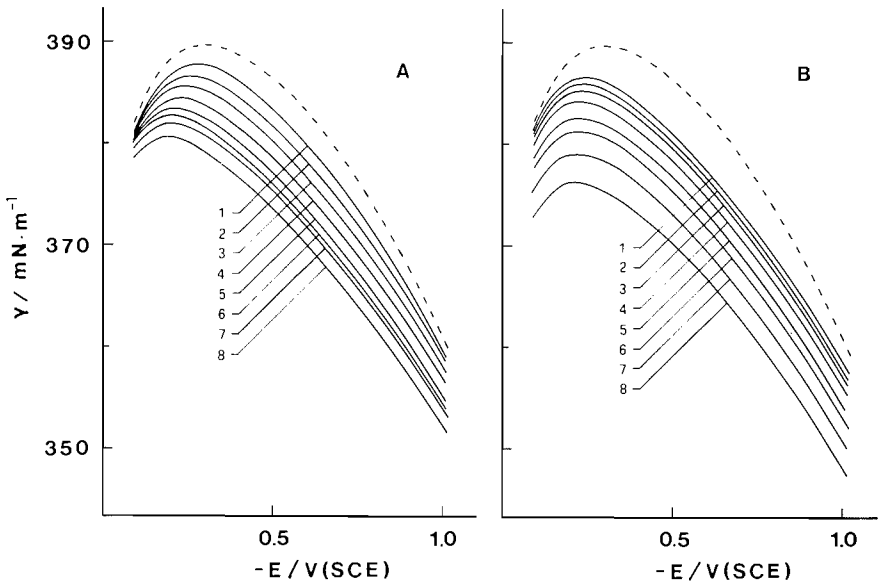

FIG. 3. Electrocapillary curves of Hg in methanolic 0.1 *M* LiCl + *xM* DDPO + *yM* TOPO. (A) $x = 1 \times 10^{-3}$, and *y*: (1) 0, (2) 4×10^{-4}, (3) 1×10^{-3}, (4) 2×10^{-3}, (5) 4×10^{-3}, (6) 7×10^{-3}, (7) 1×10^{-2}, (8) 2×10^{-2}. (B) $y = 1 \times 10^{-3}$ and *x*: (1) 0, (2) 1×10^{-3}, (3) 2×10^{-3}, (4) 4×10^{-3}, (5) 1×10^{-2}, (6) 2×10^{-2}, (7) 4×10^{-2}, (8) 0.1. Broken line corresponds to the base electrolyte solution.

where γ_0 is the surface tension of the base solution, that is, the electrolyte solution that contains the substances $A_{i \neq l}$ at constant concentrations. From eq. [2] and the first mean value theorem we obtain

$$[3] \quad \left(\frac{\partial \Phi}{\partial E}\right)_{c_{A_l}} = RT \int_0^{c_{A_l}} \left(\frac{\partial \Gamma^S_{A_l}}{\partial E}\right)_{c_{A_l}} \cdot \mathrm{d} \ln c_{A_l} = c_{A_l} \left(\frac{\partial \Gamma^S_{A_l}}{\partial E}\right)_{c'_{A_l} \leq c_{A_l}}$$

where c_{A_l}' denotes that the quantity $(\partial \Gamma^s_{A_l}/\partial E)$ refers to a concentration of A_l less than or equal to c_{A_l}. At the maximum of the Φ vs. *E* curve, which corresponds to c_{A_l}, we have

$$[4] \quad \left(\frac{\partial \Phi}{\partial E}\right)_{c_{A_l}} = 0 \quad \text{and} \quad \left(\frac{\partial^2 \Phi}{\partial E^2}\right)_{c_{A_l}} < 0$$

and therefore

$$[5] \quad \left(\frac{\partial \Gamma^S_{A_l}}{\partial E}\right)_{c'_{A_l}} = 0 \quad \text{and} \quad \left(\frac{\partial^2 \Gamma^S_{A_l}}{\partial E^2}\right)_{c'_{A_l}} < 0$$

That is, the maximum in the Φ vs. *E* curve at c_{A_l} corresponds to the adsorption maximum of A_l at a concentration c_{A_l}', which generally is smaller than c_{A_l}. The maximum in the Φ vs. *E* plots will give the adsorption maximum of A_l only when it is independent of the concentration of A_l.

If we now use Parson's function (27) $\xi (= \gamma + \sigma^m E)$, then at constant electrode charge, Gibbs eq. [1] takes the form

$$[6] \quad -\mathrm{d}\, \xi = RT \Gamma^S_{A_l} \mathrm{d} \ln c_{A_l}$$

and, therefore, whatever holds for Φ vs. *E* plots also holds for the plots of $\Phi (= \xi^0 - \xi)$ against σ^m.

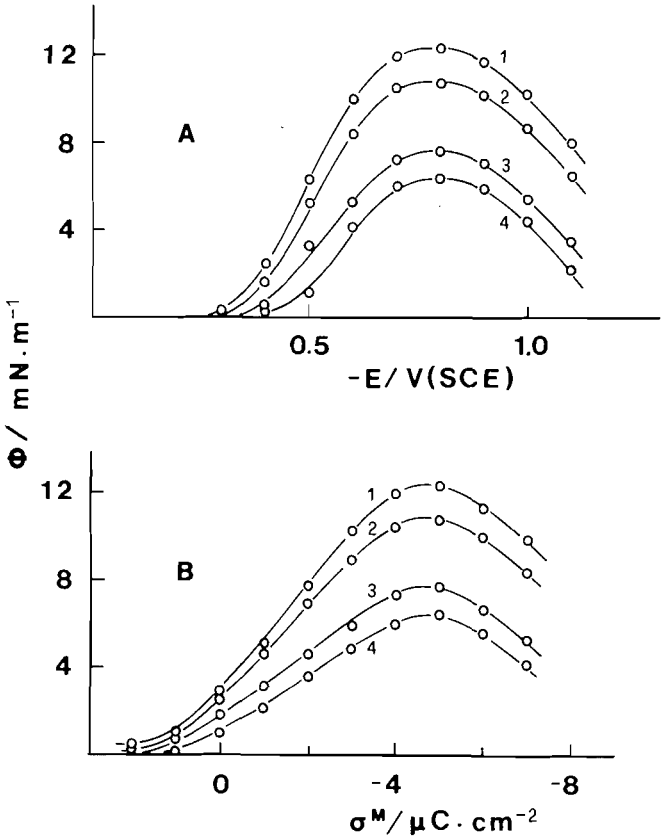

FIG. 4. Relative surface pressure curves as a function of potential (A), and charge (B), of methanolic 0.1 M LiCl + $1 \times 10^{-2} M$ TPP solutions in the presence of the following TOPO concentrations: (1) 6×10^{-2}, (2) 3×10^{-2}, (3) 1×10^{-2}, (4) 5×10^{-3} M.

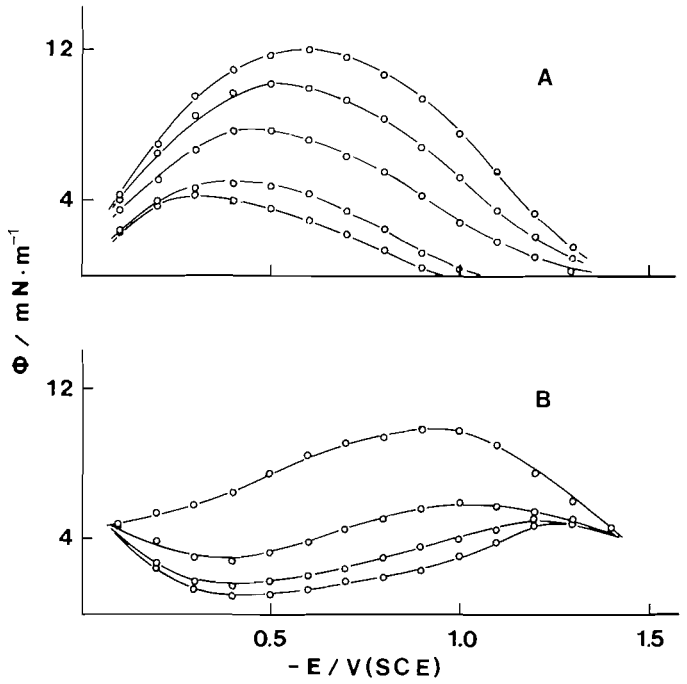

FIG. 5. Relative surface pressure curves as a function of potential (A) due to TOPO ($1 \times 10^{-2} M$) adsorption in methanolic 0.1 M LiCl + xM TPO solutions, where x: (1) 0, (2) 1×10^{-2}, (3) 2×10^{-2}, (4) 5×10^{-2}, (5) 0.1. and (B) due to TPO ($5 \times 10^{-2} M$) adsorption in methanolic 0.1 M LiCl + xM TOPO, where x: (1) 0, (2) 1×10^{-3}, (3) 5×10^{-3}, (4) 1×10^{-2}.

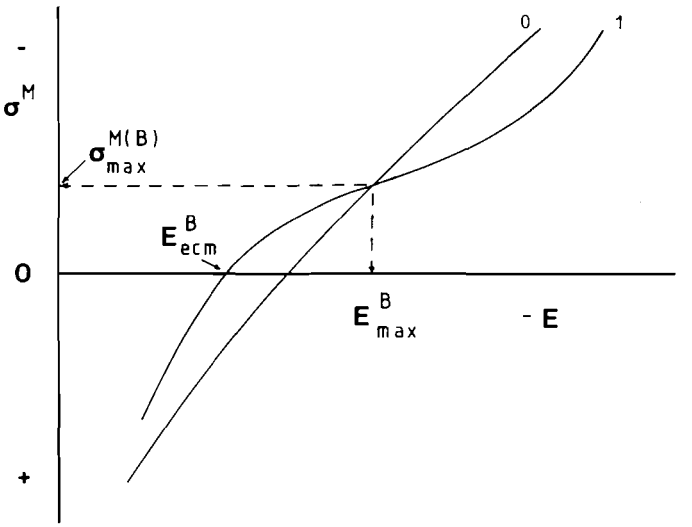

FIG. 6. Typical dependence of the electrode charge on potential in the absence (0) and in the presence (1) of a substance (B) adsorbed at the negative region.

In the systems studied the adsorption maxima were determined from the σ^m vs. E and Φ vs. E (or σ^m) plots, since in all cases they were concentration independent (Fig. 4). It was found that when two substances in their individual adsorption show adsorption maxima at different potentials and charges, then in their mixed adsorption, these maxima mutually separate further. This is shown in Fig. 5 where we give, as examples, some Φ vs. E plots of the system TPO–TOPO. The extent of the mutual separation depends on the position of the individual adsorption maxima and on the concentration of the adsorbates. The more remote the individual adsorption maxima of adsorbates, the weaker their mutual shift, while the bulk concentration of one absorbate affects only the adsorption maximum of the other adsorbate, shifting it with its increase. When the two substances are adsorbed at the same, or nearly the same, potentials (charges), as in the case of the system DDPO–TOPO, then there is no detectable shift in the adsorption maxima in the mixed adsorption of these substances.

Qualitatively, the interpretation of these experimental data can be achieved if we take into consideration the changes in the total dipole moment per unit area of the interface due to the adsorption process. Figure 6 displays typical σ^m vs. E curves for a substance (B) absorbed in the negative region. Note that at the adsorption maximum of B, the net dipole moment per unit area, introduced by the solvent, is equal to that introduced by the substance B. At potentials more negative than E^{B}_{max}, the solvent introduces greater dipole moment than B, due mainly to the reorientation process of its molecules (28–30), while at more positive potentials than E^{B}_{max}, the dipole moment introduced by the solvent is less than that of B. Now if we regard the system "solvent S + adsorbate B" as a new solvent S′, then the solvent S′ introduces into the interface smaller dipole moment (per unit area) than the solvent S at potentials more negative than E^{B}_{max}, but greater at the opposite potential region. So, if an adsorbate A has its adsorption maximum in S at a potential more negative than E^{B}_{max}, then, in the solvent S′, this maximum will be shifted to even more negative potentials until the dipole moment introduced by A into the interface becomes equal to that introduced by S′. The opposite will occur if A is adsorbed at more positive potentials than E^{B}_{max}.

This could also explain the shift of E_{max}, $\sigma^m{}_{max}$ of DDPO and TOPO to lower negative values with respect to that of TPO in their individual adsorption from methanolic solutions (23, 24).

The increase in the concentration of B causes the solvent S′ to be more differentiated than S. Consequently, the greater the surface concentration of B, the greater the effect on the adsorption maximum of A. An exception is the case of coadsorbed substances that have their adsorption maxima at about the same position. Then the dielectic characteristics of the new solvent S′ are differentiated only on both sides of their common maximum, and therefore there is no change in their adsorption maxima. Finally, the independence of the adsorption maximum of a substance A from its concentration, when it is coadsorbed with a substance B, can be explained if, at a certain potential, the ratio of the B molecules to those of S (which are displaced directly or indirectly from the surface solution by one A molecule) is independent of the concentration of A. This must hold, as the ratio of the displaced molecules of B and S depends mainly upon the bulk B–S interactions and the field -dipole interactions of the substances B and S.

The above interpretation of the shift of E_{max}, $\sigma^m{}_{max}$ holds in the case where the adsorbates A and B behave as simple dielectrics. If, during the coadsorption process, molecular modifications or reorientations of the adsorbed A and B molecules take place, then strong deviations from the expected behaviour are possible.

3. Experimental adsorption isotherms

The relative surface concentration of an adsorbed species A_l may be determined from eq. [1] and it is related to the real surface concentration Γ_{A_l} by means of

$$[7] \quad \Gamma^S_{A_l} = \frac{1}{RT}\left(\frac{\partial\gamma}{\partial \ln c_{A_l}}\right)_{c_{A_i\neq l}} = \Gamma_{A_l} - \frac{X^b_l}{X^b_S}\Gamma_s$$

where X_l^b, $X_s{}^b$ are the bulk mole fractions of the substance A_l and solvent S, respectively. When the adsorbed molecules are effectively spherical or cylindrical, we have:

$$[8] \quad 1 = \sum_{i=1}^{k} S_{A_i}\frac{\Gamma_{A_i}}{n_i}L\cdot 10^{-14} + S_s\frac{\Gamma_s}{n_s}L\cdot 10^{-14}$$

where n_i, n_s are the number of the adsorbed layers of the substance A_i and the solvent S; S_{A_i}, S_s are the areas covered by an adsorbed A_i and S molecule, respectively, at saturation, and L is the Avogadro constant. In eq. [8] Γ_{A_i}, Γ_s are expressed in mol/cm^2 and S_{A_i}, S_s in mm^2. Now, from eqs. [7] and [8] we obtain

$$[9] \quad \Gamma_{A_l} = \frac{\Gamma^S_{A_l}\dfrac{S_s}{n_s} + \left(\dfrac{10^{14}}{L} - \sum\limits_{i\neq l}^{k}\Gamma_{A_i}\dfrac{S_{A_i}}{n_i}\right)\dfrac{X^b_{A_l}}{X^b_s}}{\dfrac{S_s}{n_s} + \dfrac{S_{A_l}}{n_l}\dfrac{S^b_{A_l}}{X^b_s}}$$

The fraction of the electrode surface covered by the molecules of A_l may be calculated from

$$[10] \quad \vartheta_{A_l} = \Gamma_{A_l}/(\Gamma_{A_l})_{max} = \Gamma_{A_l}/(10^{14}/L\,S_{A_l})$$

Equation [10] was used for the calculation of the surface composition of the system TPP–TPO. In these calculations the following approximations were made: We assumed that the area covered by an adsorbed A (or B) molecule, S_A (or S_B) is independent of the presence of the other substance at the interface and equal to the corresponding value of S_A (or S_B) obtained from the individual adsorption of A (or B). This approximation is justified by the fact that the interpretation of the shifts of E_{ecm} and E_{max} shows that in the systems studied the presence of substance A (or B) in a solution of B (or A) does not cause, at the interface, reorientation or any other kind of molecular modification that would strongly affect the intermolecular interactions, and, consequently, the intermolecular distances of the adsorbed molecules. We also accepted that $n_A = n_B = 1$ and approximately $n_s = 2$.

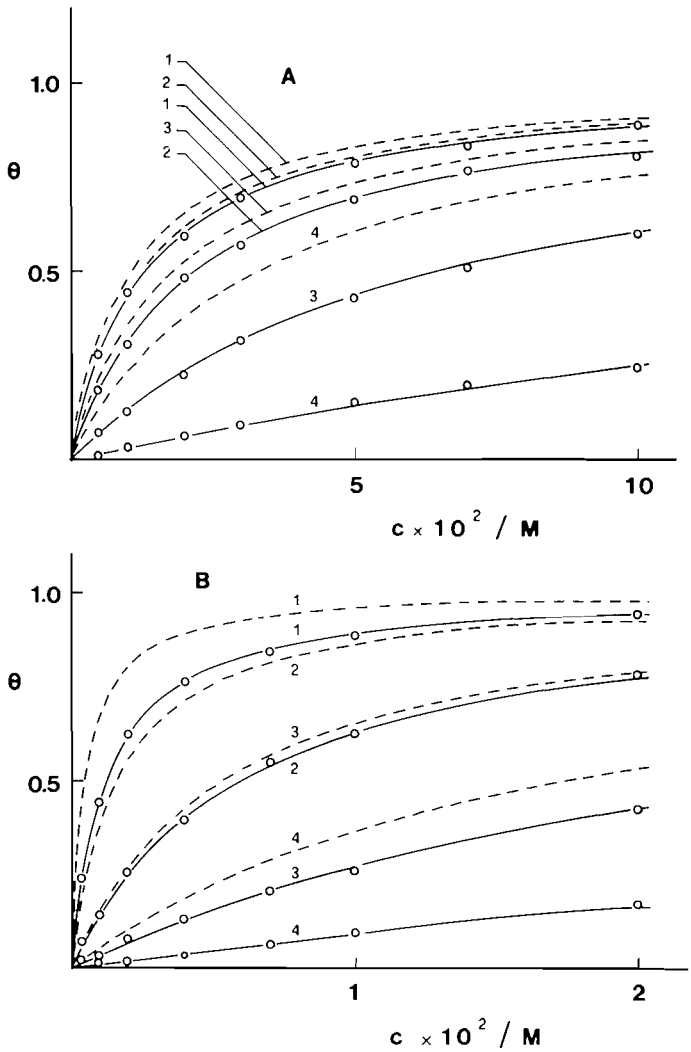

FIG. 7. Experimental adsorption isotherms (A) of TPO in methanolic 0.1 M LiCl + 4 × 10^{-3} M TPP solution at the following potentials: (1) −0.9, (2) −0.7, (3) −0.5, (4) −0.3 V (SCE) and (B) of TPP in methanolic 0.1 M LiCl + 5 × 10^{-2} M TPO at the following potentials: (1) −0.3, (2) −0.5, (3) −0.7, (4) −0.9 V (SCE). Broken lines are the corresponding individual experimental isotherms of (A) and (B).

In the systems TPP–DDPO and TOPO–DDPO there is no possibility of using eq. [10] because of the limited experimental data. However, the use of dilute solutions allows for calculations of the interfacial composition, with a good approximation, by means of

$$[11] \quad \vartheta_i = \vartheta_i^s = \Gamma_i^s/(\Gamma_i)_{max}, \qquad i = \text{A or B}$$

Some mixed–adsorption isotherms of TPP and TPO on Hg are provided in Fig. 7. In the same figure the isotherms of the individual adsorption of TPP, TPO are also provided for comparison purposes. As is expected, the amount adsorbed from each component in its mixed adsorption is lower than that

in its individual adsorption. Yet the adsorption of a component decreases to a greater extent at field values where the second component, which coexists at the interface, is more strongly adsorbed.

4. Influence of the electric field on the adsorption isotherms

In the individual adsorption of a substance from solution the field effect on the isotherms may be determined by means of the surface pressure method (14, 18). We shall show that this method does not provide information in the case of the mixed adsorption.

Let us consider two surface pressure curves, Φ^0 vs. ln c_A at constant c_B for two different potentials or, more correctly, for two different values of potential difference across the inner layer. Here Φ^0 is the surface pressure of A with respect to the solution of the base electrolyte. At not too high concentrations of A the slope of these curves is directly proportional to ϑ_A. The surface pressure Φ^0 may be generally expressed as

$$[12] \quad \Phi^0 = \Phi^0(\vartheta_A, \vartheta_B)$$

while from the adsorption isotherms we have

$$[13] \quad f(\vartheta_A, \vartheta_B) = \beta_B c_B$$

where β_B is the adsorption equilibrium constant of B. From eqs. [12] and [13], $\vartheta_A = g(\Phi^0, \beta_B)$; that is, the slope of Φ^0 vs. ln c_A at a constant value of Φ^0 depends on the electric field. Therefore, independent of whether or not the field changes the isotherm interaction parameters, the surface pressure curves (Φ^0 vs. ln c_A) are not superimposed by sliding parallel to the horizontal axis. The same is expected to hold for the relative surface pressure Φ, that is, the surface pressure with respect to the base electrolyte solution that also contains, in constant concentration, the substance B, because we have

$$[14] \quad \Phi = \Phi^0(\vartheta_A, \vartheta_B) - \Phi^0(\vartheta_A = 0, \vartheta_B{}^0)$$

$$[15] \quad f(\vartheta_A, \vartheta_B) = \beta_B c_B$$

$$[16] \quad f(\vartheta_A = 0, \vartheta_B{}^0) = \beta_B{}^0 c_B$$

which again lead to a field dependence relation for ϑ_A of the form: $\vartheta_A = g\,(\Phi, \beta_B, \beta_B{}^0)$.

In Figs. 8, 9, and 10 examples of surface pressure curves Φ^0, for the substances studied, are shown. Note that they cannot be superimposed.

On the contrary, in all systems studied and in the polarization range for which the individual adsorption isotherms are congruent with respect to potential (22–24), the relative surface pressure curves were superimposed, by sliding parallel to the horizontal axis, in opposition to the expected behaviour (Fig. 11). This disagreement will be analysed below.

The electric field of the interface affects the interaction parameters of the isotherm and its equilibrium constant, which is related to the free energy of adsorption.

The interaction parameters of the mixed-adsorption isotherms are determined from the A–B, A–A, B–B, A–S, and B–S interfacial interactions (21). If, in the coadsorption process, reorientation or any other molecular modification of the adsorbed molecules of A and B does not occur, then, with a good approximation, we can accept that the presence of a substance at the interface does not affect the interactions of the molecules of the other substance, between themselves and the solvent. Therefore the influence of the field on the isotherm interaction parameters, relate to the A–A, A–S, B–S interactions, may be calculated from the study of the individual adsorption of the substances A and B. For the isotherm

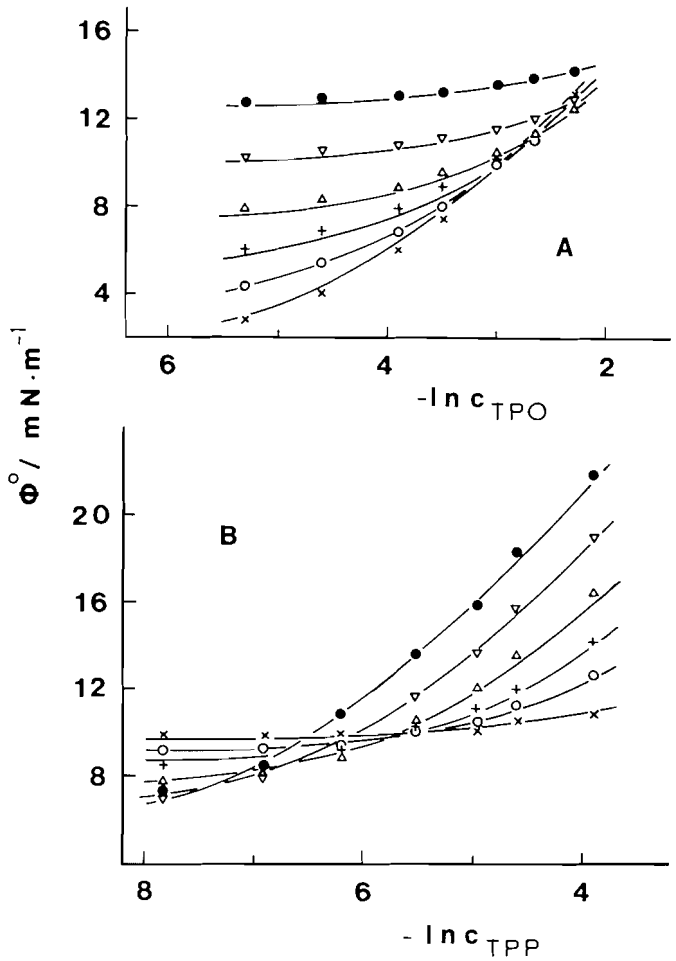

FIG. 8. Surface pressure curves (A) of TPO in methanolic 0.1 *M* LiCl + 4×10^{-3} *M* TPP solution and (B) of TPP in methanolic 0.1 *M* LiCl + 5×10^{-2} *M* TPO at the following potentials: (●) −0.3, (▽) −0.4, (△) −0.5, (+) −0.6, (○) −0.7, (×) −0.9 V (SCE). Solid lines are calculated according to SRS isotherms with parameters as indicated in Table 1.

parameter related to the A–B interactions, information may only be obtained from its determination at every potential (charge), as it is shown below.

In what concerns the free energy of adsorption ΔG_i^0, i = A or B, we can notice the following. The value of ΔG_i^0 is mainly determined from the bulk interactions of the species i with the solvent medium, its specific interactions with the electrode surface, and the electrostatic interactions of i with the electric field. Consequently, the change of ΔG_i^0 with the field is expected to be determined only from the electrostatic interactions of the molecules of species i with the electric field, provided again that there is no reorientation of the adsorbates A and B in the coadsorption process. Therefore, the change of ΔG_i^0 (say i = A), to a good approximation, is independent of the presence of the other substance (B) at the interface and may be determined from the study of the individual adsorption of the i component by the surface pressure method.

5. Isotherm parameters

The experimental data for the systems studied were analyzed by means of the isotherms of the SRS theory, of the Flory–Huggins statistics with $n_i = 0$, and the Frumkin isotherms, all in the form given in ref. 21. In order to test these isotherms, and for reasons mentioned above, we accepted that the parameters A_{AS}, A_{BS}, A_1, A_2 of the isotherms, related to the A–A, B–B, A–S,

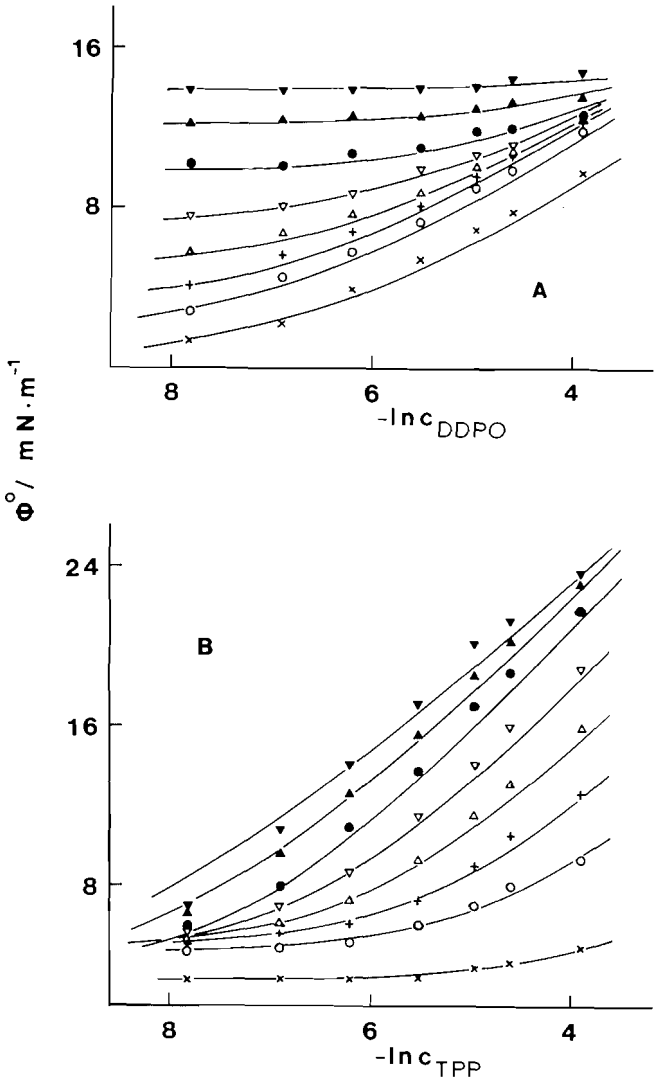

FIG. 9. Surface pressure curves (A) of DDPO in methanolic 0.1 *M* LiCl + 2×10^{-3} *M* TPP solution and (B) of TPP in methanolic 0.1 *M* LiCl + 2×10^{-3} *M* DDPO solution at various potentials. Symbols as in Fig. 8, plus (▼) for −0.1 and (▲) for −0.2 V (SCE). Solid lines are calculated according to SRS isotherms with parameters as indicated in Table 1.

and B–S interactions, may be calculated from the individual adsorption of the corresponding substance. In the present paper the values of these parameters were calculated from ϑ vs. c data by using the procedure described in ref. 31, with isotherms of individual adsorption obtained from eqs. [51], [54], and [61] of ref. 21. The surface pressure method was also used with state equations obtained from eqs. [53], [60], and [64] of ref. 21. The results obtained are provided in Table 1. These are in reasonable agreement with those obtained in refs. 22–24. Note that the isotherm of Flory–Huggins statistics does not describe the adsorption of DDPO and TOPO (32), and therefore the corresponding mixed-adsorption isotherms cannot be applied to the systems TPP–DDPO and TOPO–DDPO.

Now, before testing the mixed-adsorption isotherms in the systems studied, it is necessary to consider the thermodynamic restrictions imposed (21). As it has been shown (21), the Frumkin isotherms can be used when $S_A = S_B$, SRS isotherms when $b_A = b_B$ (where $b_i = r_i\ RT\ (\Gamma_i)_{max}$), while for the Flory–Huggins isotherms there is no restriction if we consider that the adsorption phase is a two-dimensional layer. Table 2

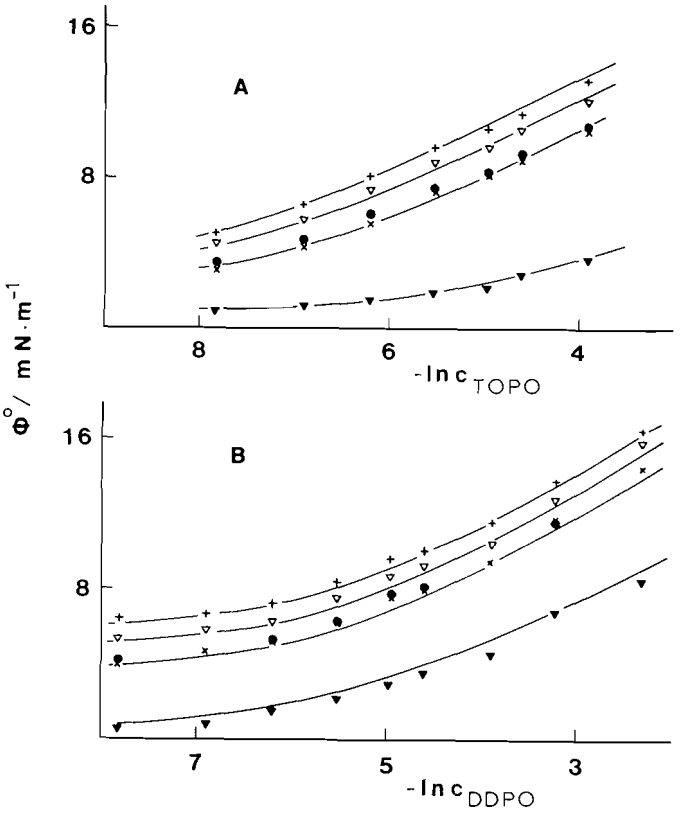

FIG. 10. Surface pressure curves (A) of TOPO in methanolic 0.1 *M* LiCl + 1×10^{-3} *M* DDPO solution and (B) of DDPO in methanolic 0.1 *M* LiCl + 1×10^{-3} *M* TOPO solutions at various potentials. Symbols as in Fig. 9. Solid lines are calculated according to SRS isotherms with parameters as indicated in Table 1.

TOPO	1.61	1.03	10.90	27.82	8.67

shows the values of the relevant parameters. Note that the Frumkin isotherms may be applied only to the TPP–TPO system, while the SRS isotherms, to a good approximation, may be applied to all systems we have studied, by using a mean value for $r_i\,RT\,(\Gamma_i)_{max}$.

The tests of the isotherms were carried out either by using ϑ vs. *c* data or the state equations of the isotherms from Φ vs. ln *c* data. In the first case the isotherms are rewritten in a linear form and the experimental data are plotted accordingly. For example, SRS isotherms may be expressed as

$$F = -A_{AB}\Theta_B + \ln \beta_A \quad [17]$$

$$G = -A_{AB}\Theta_A + \ln \beta_B \quad [18]$$

where

$$F = \ln (X_A/X_S^{r_A}) + [X_S(1 - X_A) - X_A(1 - X_S)r_A]A_A - X_B[r_A - (r_A - 1)X_S]A_{BS} - \ln (c_A/c_S) \quad [19]$$

$$G = \ln (X_B/X_S^{r_B}) - X_A[r_B - (r_B - 1)X_S]A_{AS} + [X_S(1 - X_B) - X_B(1 - X_S)r_B]A_{BS} - \ln (c_B/c_S) \quad [20]$$

$$\Theta_B = X_B[1 + (r_A - 1)X_A] \quad [21]$$

$$\Theta_A = X_A[1 + (r_B - 1)X_B] \quad [22]$$

$$X_i = (\vartheta_i/r_i) \Big/ \left(1 - \frac{r_A - 1}{r_A}\vartheta_A - \frac{r_B - 1}{r_B}\vartheta_B\right), \quad i = \text{A or B} \quad [23]$$

$$X_S = 1 - X_A - X_B \quad [24]$$

and the experimental data are plotted as *F* vs Θ_B at c_A = const. and *G* vs. Θ_A at c_B = const. Examples of some tests are given in Fig. 12.

The slopes of these plots yield the values of A_{AB} parameters and the intercepts of the graphs give the free energy of mixed adsorption of the substances studied. The values of the isotherm parameters calculated in this way were used as a first approximation for the calculation of the theoretical surface pressure curves from the corresponding equation. The calculated curves were compared with experimental points in plots of Φ against ln *c*. Usually, small changes in A_{AB}, β_A, β_B parameters were found to be necessary in order for the calculated curves to be fitted to the experimental points. Figures 8–11 show some of the tests of the isotherms under investigation on the basis of the state equations. The calculated values of the interaction parameters are provided in Table 1, while Fig. 13 shows the change in free energy of mixed adsorption of the substances studied, which is calculated from the SRS isotherms, as a function of potential.

In all cases we have studied, the free energy of mixed adsorption of a substance coincides with the corresponding value of the individual adsorption of this substance. On the basis of models, ΔG_i^0 (i = A or B) is given by eq. [17] or [31] of ref. 21. Note that the main influence of a substance B on the free energy of adsorption of A comes from the change in the chemical potential μ_A^0 caused by the presence of B in the bulk solution. μ_A^0 is the chemical potential of A in a hypothetical ideal solution of A, B, and S having $X_A^b = 1$ (33–35). Therefore μ_A^0 depends upon the solvent system and changes when B is added to the solution. However, in our systems, the bulk concentration of B is quite low, thus resulting in negligible influence of B on μ_A^0 and, consequently, on ΔG_A^0.

Having calculated the isotherm parameters, we can now check the superimposability of the relative surface pressure curves (Fig. 11). In the negative region, the coadsorption of TPP and TPO is described by the Langmuir isotherms. In this ideal case, we have

$$\Phi = -RT(\Gamma_A)_{max} \ln \frac{1 - \vartheta_A - \vartheta_B}{1 - \vartheta_B^0}$$

TABLE 3. Values of relative surface pressure due to the coadsorption of TPP–DDPO and DDPO–TOPO calculated according to the SRS isotherms

Adsorbate system	TPP–DDPO					
Constant molar concentration, c/M	2×10^{-3} TPP			2×10^{-3} DDPO		
	DDPO			TPP		
ϑ	0.3	0.5	0.8	0.3	0.5	0.8
Φ, mN m^{-1} ($E = -0.3$ V)	1.30	2.95	8.79	1.89	3.58	8.36
($E = -1.0$ V)	1.29	2.66	6.31	1.92	3.64	8.13
Adsorbate system	DDPO–TOPO					
Constant molar concentration, c/M	1×10^{-3} DDPO			1×10^{-3} TOPO		
	TOPO			DDPO		
ϑ	0.3	0.5	0.8	0.3	0.5	0.8
Φ, mN m^{-1} ($E = -0.3$ V)	0.98	1.95	3.95	1.13	2.18	4.89
($E = -1.0$ V)	0.99	1.98	4.03	1.15	2.26	5.04

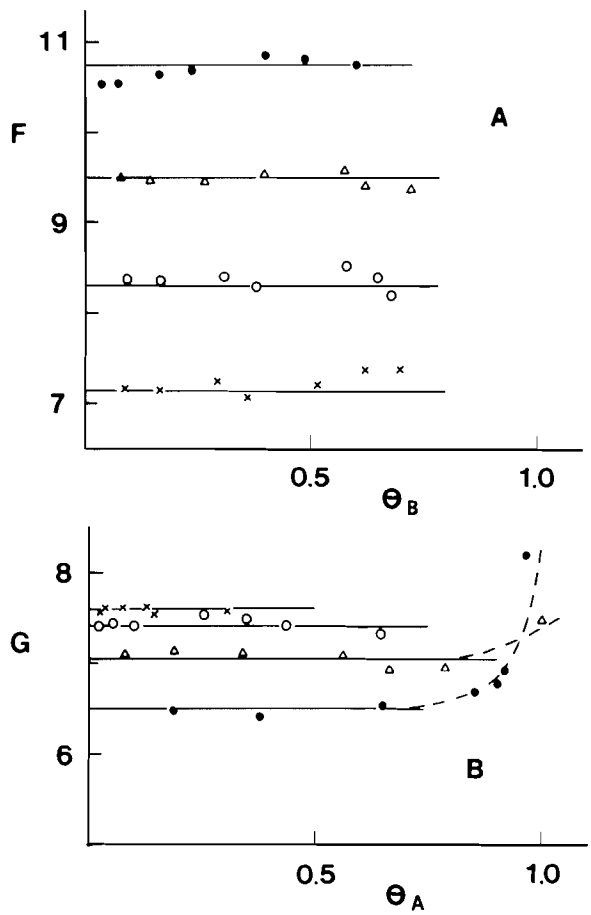

FIG. 12. Tests of SRS isotherms for the coadsorption of TPP–TPO on Hg. (A) Constant TPP concentration, 4×10^{-3} M and (B) constant TPO concentration, 5×10^{-2} M. Symbols as in Fig. 8.

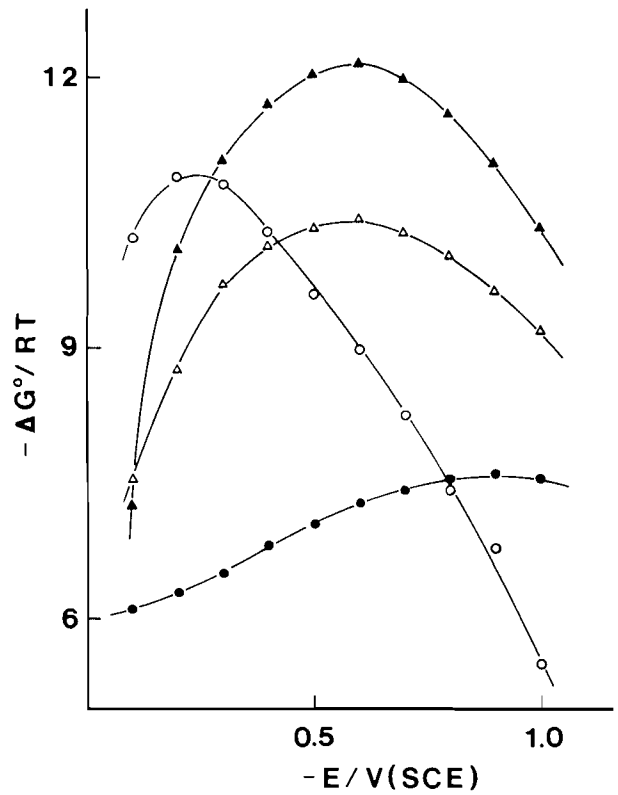

FIG. 13. Standard free energy of adsorption of TPP (○), TPO (●), DDPO (△), and TOPO (▲) at zero surface coverage of the coadsorbate, calculated according to the SRS isotherms.

where ϑ_B^0 is the value of ϑ_B at $\vartheta_A = 0$. However,

$$\frac{\vartheta_B}{1 - \vartheta_A - \vartheta_B} = \beta_B c_B, \frac{\vartheta_B^0}{1 - \vartheta_B^0} = \beta_B^0 c_B$$

and it is found experimentally that $\beta_B^0 = \beta_B$. Therefore

$$\Phi = -RT(\Gamma_A)_{max} \ln \frac{\vartheta_B}{\vartheta_B^0} = -RT(\Gamma_A)_{max} \ln (1 - \vartheta_A)$$

or

$$\vartheta_A = \frac{1}{RT(\Gamma_A)_{max}} \cdot \frac{\partial \Phi}{\partial \ln c_A}$$

$$= 1 - \exp\{-\Phi/RT(\Gamma_A)_{max}\} = f(\Phi)$$

That is, the curves in plots of Φ vs. ln c_A at c_B = const. (or Φ vs. ln c_B at c_A = const.) have the same slope for the same Φ value and, consequently, they are superimposed by sliding parallel to the ln c axis.

On the contrary, in the systems TPP–DDPO and TOPO–DDPO the superimposability of the relative surface pressure curves is due to the small change in their curvature at different

potentials. This is shown in Table 3, where values of Φ, calculated from the SRS isotherms at two different potentials and at different ϑ values are provided. Note that at the same ϑ_A value of different potentials, the corresponding Φ values are not identical but the difference is too small to be experimentally detected. The notable exception observed at $\vartheta_{DDPO} = 0.8$ is due to the fact that at -0.3 V (SCE) the value $\Phi = 8.79$ mN m^{-1} corresponds to a concentration of DDPO that is outside the limits of our study and possibly out of the region where the approximation [11] holds.

Conclusions

1. The coadsorption of TPP–TPO, TPP–DDPO, and DDPO–TOPO on a Hg electrode from methanolic solutions takes pace without reorientation of the adsorbed molecules or other molecular modifications. The adsorbed molecules have a constant orientation, with their phenyl and alkyl groups in contact with the electrode surface.

2. The main effect caused by the presence of a second substance at the interface is the decrease in the amount of the coadsorbate adsorption. This decrease is more pronounced in field values close to the adsorption maximum of the second adsorbate.

3. The presence of a second substance at the interface affects also the adsorption maximum of the first adsorbate. In their mixed adsorption the separation distance of their adsorption increases to an extent depending on the position of the individual adsorption maxima and on the concentration of the adsorbates.

4. The surface pressure method can not be used in obtaining information about the field effect on the isotherms. This can be obtained by determining the isotherm parameters at every field value.

5. The coadsorption of the systems studied follows satisfactorily an isotherm based on the strictly regular solutions theory. The free energy of adsorption follows the same variation pattern as in the case of the individual adsorption. The free energy of adsorption is also independent of the presence of the second adsorbate at the interface due to the insignificant changes in bulk intermolecular interactions caused by the presence of the second substance.

DAVID ERIC BERRY, KATHRYN ANNE BEVERIDGE, GORDON WILLIAM BUSHNELL, KEITH ROGER DIXON, and ALAN PIDCOCK. Can. J. Chem. **64**, 343 (1986).

Hydrolysis of *cis*-$[PtCl_2\text{-}\{P(OEt)_2Cl\}_2]$ results in condensation of the phosphite to form $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, which crystallizes in the monoclinic space group $P2_1/n$, with a = 13.814(7), b = 11.429(4), c = 10.726(5) Å, β = 106.30(5)°. Reactions of $P(OEt)_2Cl$ or $(EtO)_2POP(OEt)_2$ with $[Pt_2Cl_4(PEt_3)_2]$ also yield very easily hydrolyzed products but in these cases an even more complex condensation occurs to yield $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$, which crystallizes in the monoclinic space group $P2_1/c$, a = 17.547(8), b = 19.775(6), c = 11.268(3) Å, β = 106.42(3)°. Complete X-ray diffraction studies are reported for both crystals, confirming the presence of double $(EtO)_2POP(OEt)_2$ bridges in $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ and a novel triphosphite bridge in $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$. Detailed analyses and computer simulation of the $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ nmr spectra of these complexes are also described, together with studies of the related compounds, $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ and $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$. In conjunction with previous studies of $[Pt_2Cl_2(dppm)_2]$ and related complexes, these spectra provide examples of several types of *AA'XX'* spin systems and the analysis of these systems is discussed in detail.

DAVID ERIC BERRY, KATHRYN ANNE BEVERIDGE, GORDON WILLIAM BUSHNELL, KEITH ROGER DIXON et ALAN PIDCOCK. Can. J. Chem. **64**, 343 (1986).

L'hydrolyse du *cis*-$[PtCl_2\text{-}\{P(OEt)_2Cl\}_2]$ provoque la condensation du phosphite en donnant le $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ qui cristallise dans le groupe d'espace monoclinique $P2_1/n$ avec a = 13,814(7), b = 11,429(4), c = 10,726(5) Å, β = 106,30(5)°. Les réactions du $P(OEt)_2Cl$ ou du $(EtO)_2POP(OEt)_2$ avec le $[Pt_2Cl_4(PEt_3)_2]$ donnent également des produits que l'on peut hydrolyser très facilement. Mais, dans ces cas, on obtient des condensations beaucoup plus complexes qui conduisent au $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$ qui cristallise dans le groupe d'espace monoclinique $P2_1/c$ avec a = 17,547(8), b = 19,775(6), c = 11,268(3) Å, β = 106,42(3)°. On rapporte les études complètes de diffractions par rayon X pour les deux cristaux. Ces études confirment la présence d'un pont double de $(EtO)_2POP(OEt)_2$ dans le composé $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ et d'un nouveau pont triphosphite dans le composé $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$. On décrit également une analyse détaillée et une simulation par ordinateur des spectres de rmn du $^{31}P\{^1H\}$ et du $^{195}Pt\{^1H\}$ de ces complexes ainsi que l'étude des composés apparentés du type $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ et $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$. Conjointement avec les études antérieures sur le $[Pt_2Cl_2(dppm)_2]$ et des complexes apparentés, ces spectres fournissent des exemples de plusieurs types de systèmes de spin *AA'XX'* et on discute en détail de l'analyse de ces systèmes.

[Traduit par le journal]

Introduction

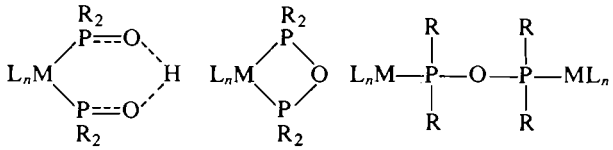
The coordination chemistry of chlorophosphines and organophosphites is often complicated by the reactivity of the P—Cl and P—OR bonds. For example the solvolytic degradation of triorganophosphite ligands, $P(OR)_3$, to metal phosphite or phosphonate derivatives, $MOP(OR)_2$ or $MP(O)(OR)_2$,[2] has been known for a long time (1). More recently, similar transformations have been demonstrated to occur by methyl transfer to a metal and by a metal-catalyzed Arbuzov rearrangement (2), and in other processes trimethylphosphites have been converted to the unusual $P(OMe)_2$ and P(OMe) ligands (2–5). Reactions in which phosphorus(III) compounds condense and coordinate are also known. The simplest example is the reaction of phosphorous acid with K_2PtCl_4, which results in a bidentate ligand, O_2POPO_2, bridging two platinum atoms by phosphorus coordination (6, 7). A related ligand, $(MeO)_2POP(OMe)O$, is formed in one of the pyrolysis products of $[Os_3(CO)_{11}\{P(OMe)_3\}]$ but it bridges three Os centres by phosphorus and oxygen coordination (4, 8). Clearly solvolysis of P—Cl bonds can lead to analogous reactive $P—O^-$ and P—OR linkages and the chemistry of P—Cl bonds is also of considerable interest because this group is the most usual choice of reactive function for the elaboration of phosphorus ligands. Reactions with alcohols to form phosphorus esters and with Grignard or organolithium reagents to form phosphorus–carbon bonds are particularly well-studied examples. Reactions of coordinated chlorophosphines are less well studied and their potential for the *in situ* elaboration of ligands or the formation of bridges to other metal centres has not in general been realized.

We have been particularly interested in the chemistry arising when two chlorophosphine ligands occupy mutually *cis* positions in a coordination shell, and have discussed the literature background in some detail in a previous paper (9). Briefly, the expected first hydrolysis product of a *cis*-$M(PR_2Cl)_2$ fragment is a simple *cis*-$M(PR_2OH)_2$ group but in practice such simple products are rarely isolated. The most usual outcome is a fragment such as structure **I**, derived from deprotonation of the initial hydrolysis product, and examples have been reported for several metals, notably Pd (10, 11), Pt (10), Mo (11, 12), Ir (13, 14), and Rh (13). A second possibility is illustrated by the ready conversation of *cis*-$[Mo(CO)_4\{(PPh_2O)_2H\}]^-$ to *cis*-

[1]Author to whom correspondence may be addressed.

[2]The majority of authors have referred to both tautomers as phosphonates although strict nomenclature (Chem Abstr **76**, Index Guide section IV, paragraph 197) would seem to require that $MOP(OR)_2$ or $MOP(OR)_2M'$ bonding arrangements be named as derivatives of phosphorous acid and $MP(O)(OR)_2$ as derivatives of phosphonic acid.

$[Mo(CO)_4(Ph_2POPPh_2)]$ by elimination of hydroxide in an acid medium (15, 16). Ligands of the type R_2POPR_2 are capable of chelation (structure **II**) but more usually occur as bridge ligands (structure **III**) (15).



I **II** **III**

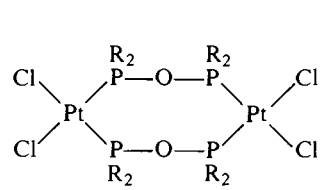
In our previous work (9), we describe X-ray diffraction studies of *cis*-$[PtCl_2(PPh_2OH)_2]$, the first well-characterized example of a *cis*-bis(hydroxyphosphine) complex, and of $[Pd_2(\mu\text{-}Cl)_2\{(P(OEt)_2O)_2H\}_2]$, an example of a type **I** complex. A primary objective of our work is to obtain good structural characterization for all possible hydrolysis products of chlorophosphine complexes, and in the present paper we describe two further structure determinations together with associated synthetic and spectroscopic results. Compound **IV**, $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, is readily obtained by hydrolysis of *cis*-$[PtCl_2\{P(OEt)_2Cl\}_2]$ in a reaction closely related to that mentioned above for molybdenum. In contrast to the chelate Ph_2POPPh_2 in the Mo case (15), the platinum complex is dinuclear with two bridging $(EtO)_2POP(OEt)_2$ ligands. Compound **VII**, $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$, is a novel derivative of the unknown triphosphorous acid, $H_5P_3O_7$, and its formation is of especial interest since reactivity of both P—Cl and P—OR bonds is involved, leading to a ligand condensation to produce a more complex ligand than that initially present. This appears to be the first well-characterized complex involving condensation of more than two phosphorus units and we also note that tri- and polyphosphites are very rare even in simple phosphorus chemistry (17). A preliminary description of the structure and spectroscopy of **VII** has been published (18).

Results and discussion

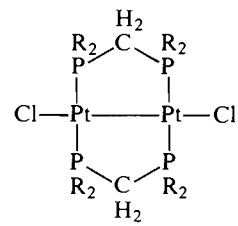
(a) Synthesis

As we have described previously, complexes of the type *cis*-$[MCl_2(PR_2Cl)_2]$, M = Pt or Pd, are readily prepared by reactions of chlorophosphines with $[MCl_2(PhCN)_2]$ (9). However, the products are very easily hydrolyzed and the final outcome of the reactions under normal laboratory conditions is critically dependent on the nature of R and M. For example, for R = Ph and M = Pt we were able to isolate *cis*-$[PtCl_2(PPh_2OH)_2]$, the first well-characterized example of a *cis*-bis(hydroxyphosphine) complex, and to demonstrate its conversion to a type **I** complex, $[Pt_2Cl_2\{(PPh_2O)_2H\}_2]$ (9). When R = OEt and M = Pt the initial product, *cis*-$[PtCl_2\{P(OEt)_2Cl\}_2]$, is obtained as a colourless oil but, even when normal laboratory precautions against admission of moisture were taken, attempts at crystallization resulted in hydrolysis and condensation to a product whose initial spectroscopy suggested structure **IV**. Complex **IV** has been prepared previously by reaction of $(EtO)_2POP(OEt)_2$ with $[PtCl_2(SEt_2)_2]$ (19) and in the present work we have used $[PtCl_2(PhCN)_2]$ as the platinum substrate in an analogous reaction to confirm the nature of the above hydrolysis product.

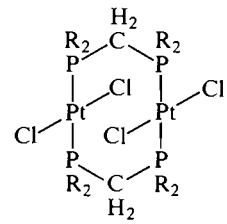
The spectroscopy and structure of the bis(diphenylphosphino)methane (dppm) complexes **V** and **VI** have been extensively studied (20, 21). Complex **IV** is a close relative of these species except that the dppm derivatives normally have *trans* stereochemistry at the platinum centres (20), whereas previous work on **IV** had suggested that it has *cis* stereochemistry (19).



IV (R = OEt)



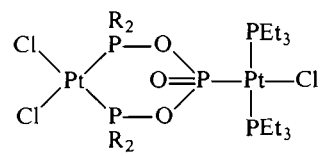
V (R = Ph)



VI (R = Ph)

We therefore undertook a detailed study with the dual objectives of confirming the nature of our hydrolysis product and of establishing the structure and spectroscopy of these *cis* derivatives. In order to study variation of spectroscopic parameters with *trans* influence we also synthesized the tetramethyl analogue of **IV** by reaction of $(EtO)_2POP(OEt)_2$ with $[PtMe_2(COD)]$ and by reaction of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ with methyl Grignard. Details of the spectroscopic and structure studies are reported below together with results on $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$. This last complex is prepared by reaction of $(EtO)_2POP(OEt)_2$ with $[Pt_2Cl_4(PEt_3)_2]$ in benzene under carefully controlled anhydrous conditions. As discussed below, the reaction is more complex if traces of moisture are present.

The hydrolysis of the related monochlorophosphine complexes, *cis*-$[PtCl_2(PEt_3)(PR_2Cl)]$, is normally straightforward and results simply in *cis*-$[PtCl_2(PEt_3)(PR_2OH)]$ derivatives (9). However, the reaction of $P(OEt)_2Cl$ with $[Pt_2Cl_4(PEt_3)_2]$ provided a striking demonstration of the lability of P—Cl and P—OEt moities in these systems. Normally, *cis*-$[PtCl_2(PEt_3)\{P(OEt)_2Cl\}]$ was obtained from this reaction (9), but on one occasion colourless crystals of complex **VII** were obtained. Several attempts to repeat this preparation have failed, probably because the formation of **VII** depends critically on such factors as the moisture content and hydrogen chloride concentration. However, we were able to characterize **VII** completely by nmr



VII (R = OEt)

spectroscopy and by X-ray crystallography on the sample initially obtained, and we have found subsequently that **VII** can be obtained, apparently reproducibly, from reactions of $(EtO)_2POP(OEt)_2$ with $[Pt_2Cl_4(PEt_3)_2]$ in dichloromethane solution. Note that under rigorously anhydrous conditions in benzene this same reaction yields $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$ as described above. Details of the ^{31}P and ^{195}Pt nmr spectra of **VII** have been published in a preliminary communication (18) and no further comment is necessary here. The data are included in Table 1.

TABLE 1. Phosphorus-31 and platinum-195 nuclear magnetic resonance parameters

Parameter	A	B	C	D
δ(P)	+120.15	+55.62	+55.12 $P(OEt)_2$ +14.68 PEt_3	+50.27 $P(OEt)_2$ +19.96 PEt_3 +37.02 P=O

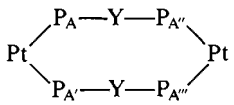
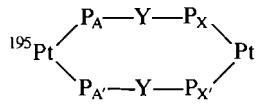
A = $[Pt_2Me_4(\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ in C_6D_6.
B = $[Pt_2Cl_4(\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, **IV**, in $CDCl_3$.
C = $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$ in $CDCl_3$.
D = $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl_2(PEt_3)_2]$, **VII**, in $CDCl_3$.
NOTE: Chemical shifts (δ) are quoted in parts per million relative to 85% H_3PO_4 for phosphorus and relative to Ξ(^{195}Pt) = 21.4 MHz for platinum (see ref. 33). For the platinum resonances the absolute values of Ξ in MHz are also quoted. Coupling constants (J) are in Hz.

(b) Nuclear magnetic resonance

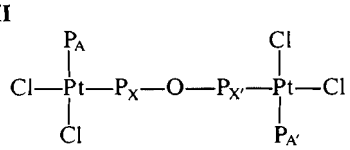
As we have pointed out above, the complexes **IV–VI**, are all closely related from the point of view of nmr spectroscopy, since each has the basic connectivity shown in **VIII**. To analyze the spectra it is necessary to recognize the existence of three distinct isotopomeric structures in each case, having respectively none, one, or two magnetically active ^{195}Pt atoms. Since platinum-195 is 33.8% abundant, these three isotopomers are respectively 43.9, 44.8, and 11.4% of the total sample. From the point of view of $^{31}P\{^1H\}$ spectroscopy the four chemically equivalent, but magnetically inequivalent, phosphorus atoms of the "no-^{195}Pt" isotopomer constitute an $AA'A''A'''$ spin system, as indicated in structure **VIII**, and contribute only a single central



VIII



IX



X

peak to the spectrum. The spectrum due to the "one-^{195}Pt" isotopomer is more interesting and analyses for the complexes of types **V** and **VI** have generally depended on a suggestion made by Sheppard and Turner in the early days of nmr (22). These authors were concerned with the ^{1}H spectra of ^{13}C enriched ethylene and pointed out that in an $H_2{}^{13}C{=}CH_2$ molecule the presence of the ^1J(C–H) coupling introduces an "effective chemical shift" difference between the two pairs of protons. Under these circumstances each ^{13}C satellite may be analyzed as half of an $AA'XX'$ spin system. The present complexes are clearly fundamentally similar spin systems and their ^{31}P spectra (see Fig. 2A for example) may be divided into three distinct regions: downfield and upfield satellites due to ^1J(Pt–P) and a central region containing the "no-^{195}Pt" singlet together with sidebands due to ^3J(Pt–P). Each of the satellite regions consists of one half of an $AA'XX'$ system as defined in structure **IX**, together with a single line contributed by the "two-^{195}Pt" isotopomer. The upfield and downfield lines of the "two-^{195}Pt" isotopomer are separated by ^1J(Pt–P) + ^3J(Pt–P) (21).

In their analysis of the $AA'XX'$ spin system, Pople *et al.* (23) define four secondary parameters:

$$K = J(AA') + J(XX')$$
$$M = J(AA') - J(XX')$$
$$N = J(AX) + J(AX')$$
$$L = J(AX) - J(AX')$$

Each half (A or X) of the spectrum then consists of a strong doublet separated by N and two symmetrical quartets. The line positions of the first quartet relative to the centre of the N doublet are given by:

$$\tfrac{1}{2}K + \tfrac{1}{2}(K^2 + L^2)^{1/2}$$
$$-\tfrac{1}{2}K + \tfrac{1}{2}(K^2 + L^2)^{1/2}$$
$$\tfrac{1}{2}K - \tfrac{1}{2}(K^2 + L^2)^{1/2}$$
$$-\tfrac{1}{2}K - \tfrac{1}{2}(K^2 + L^2)^{1/2}$$

and the other quartet is identical except that M replaces K.

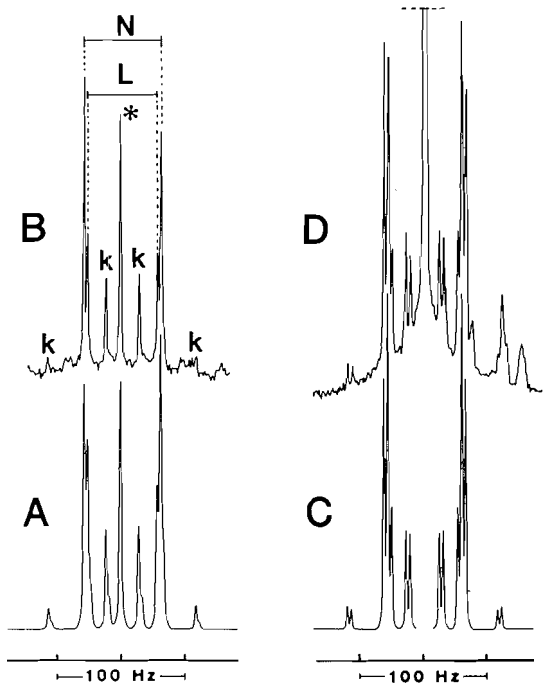


FIG. 1. $^{31}P\{^1H\}$ nuclear magnetic resonance spectrum of $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ in C_6D_6 at 101.3 MHz. (A) Computer simulation of downfield ^{195}Pt satellite. (B) Observed downfield ^{195}Pt satellite. The peaks marked k are due to the K/L quartet and the meanings of K, L, N, and * are discussed in the text. (C) Computer simulation of central region. The very intense central peak has been omitted to facilitate plotting of the weaker components. (D) Observed spectrum of central region.

In the present examples, $J(AA') = J(XX')$, and it follows that $M = 0$ and the M/L quartet collapses to a doublet of separation L (21). Moreover, if the phosphorus atoms are mutually *trans* at the platinum centres then $J(AA')$ and $J(XX')$ are much larger than the other coupling constants and the K/L quartet collapses to a single central line (21). However, since the literature contains some apparent mis-assignments of spectra which depend on this point,[3] it is also important to realize that the inner (stronger) lines of the K/L quartet are always separated by the difference in magnitude of K and $(K^2 + L^2)^{1/2}$. This is easily demonstrated by reference to the line positions and especially the intensities (23) of the K/L quartet. Thus the *maximum* possible separation of the two strong lines is equal to L.

(i) $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$

The $^{31}P\{^1H\}$ spectrum of this complex is shown in Fig. 1. The overall spectrum is basically similar in form to the example shown in Fig. 2A, with downfield and upfield satellites and an intense central region but, in order to show the weaker features in detail, only the downfield satellite and the central region are illustrated in Fig. 1. The upfield satellite is a mirror image of the downfield satellite. This is perhaps the simplest of the current spectra to assign since all of the lines of the "half $AA'XX'$" pattern can be seen in the platinum satellites. The line marked with an asterisk is not symmetrical with respect to the other lines and cannot therefore be part of the $AA'XX'$ pattern. It is actually due to the "two-^{195}Pt" isotopomer. Remembering that the strong lines of the K/L quartet must be "inside" the L doublet, the assignment shown in Fig. 1B follows immediately and we can calculate all three P–P coupling constants. The separation between the "one-^{195}Pt" satellites gives $^1J(Pt–P)$ and the separation between the asterisked line and its upfield counterpart gives $^1J(Pt–P) + {}^3J(Pt–P)$ (21) so that all the parameters for a full computer simulation and refinement are available except for $^4J(Pt–Pt)$, which has little effect on the phosphorus spectrum. The results of this simulation with the contributions from all three isotopomers added together are shown in Figs. 1A and 1C and the final refined parameters are collected in Table 1. Also included in Table 1 are the parameters for the $^{195}Pt\{^1H\}$ spectrum, which was a simple triplet (J = 3039 Hz), confirming the value of $^1J(Pt–P)$. The line width in this ^{195}Pt spectrum did not allow resolution of $^4J(Pt–Pt)$ but the broadening at the base of the peaks suggested an upper limit of about 200 Hz for this parameter.

(ii) $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$

This spectrum is more difficult to assign because of the lack of resolution in the satellite bands (Figs. 2B and 2D). The first problem was to decide which peak is due to the "two-^{195}Pt" isotopomer. This was accomplished using the ^{195}Pt spectrum, which showed two coupling constants (±5840 and ±50.5 Hz) whose sum was equal to the separation between the asterisked peaks in Fig. 2. Unfortunately, the L doublet and the inner lines of the K/L quartet are seen only as poorly defined shoulders on the N doublet, but the requirement that the K/L lines must be inside the L doublet identifies the K/L quartet as the lines marked k in Fig. 2B. The L doublet must then be the cause of the barely perceptible shoulders on the outside of the N doublet, implying that L is slightly greater than N. Refinement of this assignment presents a difficulty since the values for K and L are obviously very approximate because of the lack of resolution. However, using the parameters given in Table 1, a summation of the spectra of all three isotopomers gave a completely satisfactory computer simulation, which is shown in Figs. 2C and 2E. The broad, weak outer features of the satellite spectra are due to the "two-^{195}Pt" isotopomer and their position is very dependent on the value of $^4J(Pt–Pt)$. However, it is clear that the refined value of this parameter is rather approximate, as are all the P–P couplings. The choices given in Table 1 represent the centres of the acceptable ranges which are about ±3 Hz wide for the P–P couplings and perhaps ±20 Hz for the Pt–Pt coupling.

The $^{195}Pt\{^1H\}$ spectrum of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ consisted of a triplet of triplets due to $^1J(Pt–P)$ and $^3J(Pt–P)$ with additional weak, poorly resolved sidebands due to $^4J(Pt–Pt)$.

(iii) $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$

The analysis of the $^{31}P\{^1H\}$ spectrum of this complex is basically similar to those described above except that in this case the phosphorus atoms belong to an $AA'XX'$ spin system even in the absence of magnetically active platinum (structure **X**). Thus the overall spectrum consists of central A and X resonances (Figs. 3B and 3D), each with platinum satellites which are not shown in the figure. Also in this case $J(AA')$ and $J(XX')$ are no longer equal and the M/L quartet does not collapse to a doublet. Thus the central X region shown in Fig. 3B arises primarily from the "no-^{195}Pt" isotopomer and the strong pair of lines inside the N doublet can only be explained if the M/L and K/L

[3]For example, the complexes $[Pt_2R_4(\mu\text{-}Me_2PCH_2PMe_2)_2]$, R = Me or CCMe, both show only two rather weak lines inside an unusually intense N doublet. The two inner lines have been previously assigned to the L doublet (24, 25) but it seems more likely that the correct assignment has $L \simeq N$ and the inner lines are the inner components of the K/L quartet.

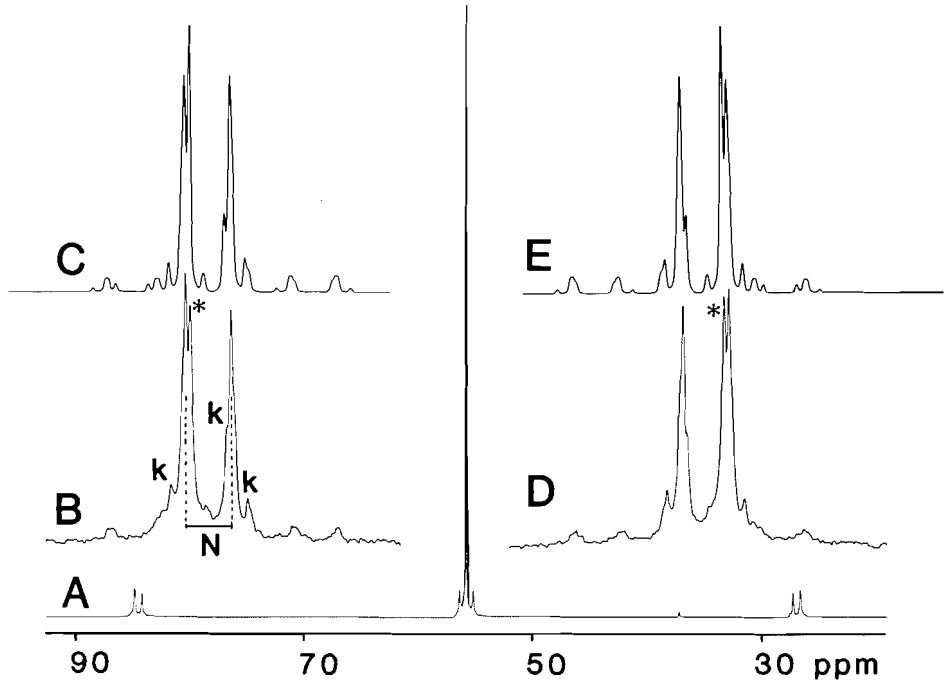

FIG. 2. $^{31}P\{^1H\}$ nuclear magnetic resonance spectrum of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ in $CDCl_3$ at 101.3 MHz. (A) Complete spectrum showing the three regions; downfield and upfield ^{195}Pt satellites and the intense central region. (B) 20 Hz cm^{-1} expansion of the downfield ^{195}Pt satellite. The peaks marked k are due to the K/L quartet and the meanings of K, L, N, and * are discussed in the text. (C) Computer simulation of downfield ^{195}Pt satellite. (D) 20 Hz cm^{-1} expansion of the upfield ^{195}Pt satellite. The meaning of * is discussed in the text. (E) Computer simulation of upfield ^{195}Pt satellite.

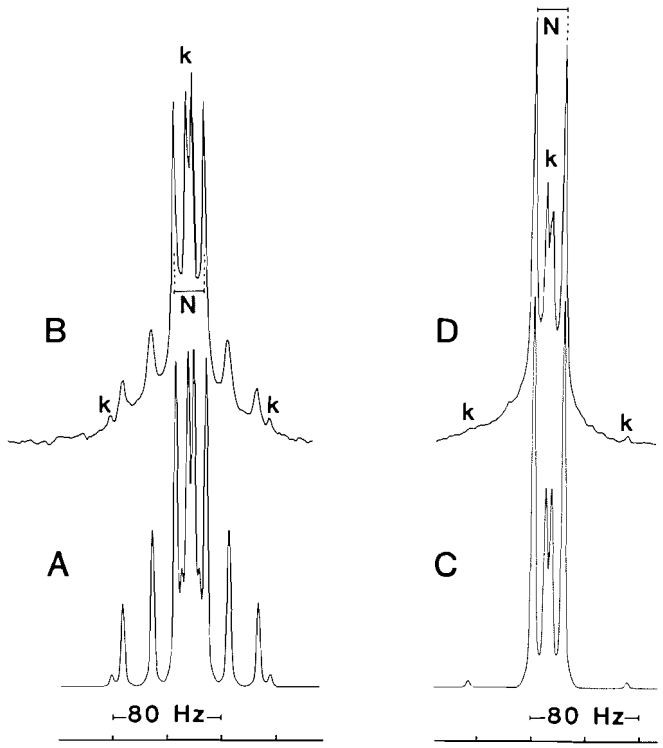

FIG. 3. $^{31}P\{^1H\}$ nuclear magnetic resonance spectrum of $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$ in $CDCl_3$ at 101.3 MHz. Only the central $P(OEt)_2$ and PEt_3 resonances are shown. ^{195}Pt satellites are not illustrated. (A) Computer simulation of central $P(OEt)_2$ resonance. (B) Central $P(OEt)_2$ resonance at 55.12 ppm. The peaks marked k are due to the approximately coincident M/L and K/L quartets and the meanings of K, M, L, and N are discussed in the text. (C) Computer simulation of central PEt_3 resonance. (D) Central PEt_3 resonance at 14.68 ppm.

quartets are essentially coincident; i.e., $J(AA') \ll J(XX')$, which is entirely reasonable since the former is a six-bond and the latter a two-bond coupling. We also assumed that $^4J(AX') \ll {}^2J(AX)$, making N and L approximately equal. In order to calculate K ($= M$) it is necessary to identify the other components of the coincident quartets in Fig. 3B. These outer components should also occur in the central A resonance (Fig. 3D) but in fact no subsidiary peaks have significant intensity in Fig. 3D. This suggested that the weakest of the three pairs of subsidiary peaks in Fig. 3B was the correct choice for the outer components of the K/L quartet. On this basis we proceeded to calculate $^2J(AX)$ and $^2J(XX')$. The $^{195}Pt\{^1H\}$ spectrum consisted of a doublet of doublets due to the one-bond Pt–P couplings and a slight broadening of the peaks suggested that ^3J(Pt–P) is about 20 Hz. This gave all the parameters necessary to refine and simulate the contributions of the "no-^{195}Pt" and "one-^{195}Pt" isotopomers and essentially gave a complete explanation of the spectrum since the "two-^{195}Pt" isotopomer makes only a very small contribution. The final simulation (Figs. 3A and 3C) included this small contribution assuming that ^4J(Pt–Pt) is 0 Hz. The actual value of ^4J(Pt–Pt) is not critical for the interpretation of the ^{31}P spectrum but the line width in the ^{195}Pt spectrum suggested that it is <150 Hz.

(iv) Signs and magnitudes of coupling constants

The parameters listed in Table 1 present no particular surprises. The *cis* geometry at platinum in all four complexes is confirmed by the small magnitudes (15–23 Hz) found for ^1J(Pt–Pt) and, although the sign is not determined by the observed spectra, the values are probably negative in view of previous results (26). The magnitudes of ^1J(Pt–P) reflect the electronegativity of the groups attached to phosphorus and the known *trans* influences of the ligands occupying the *trans* position in the platinum coordination. Thus ^1J(Pt–P) for PEt_3 *trans* to Cl in $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$ is

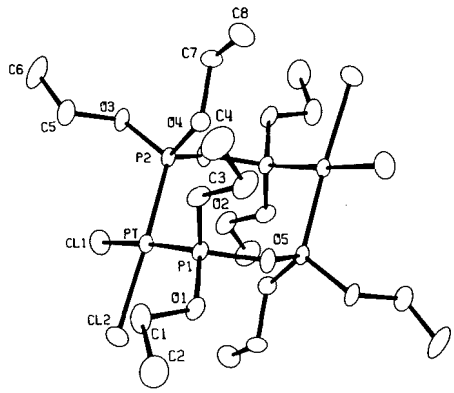

FIG. 4. ORTEP plot of **IV**, $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$. The unlabelled half of the molecule is related to the labelled half by a crystallographic centre of symmetry.

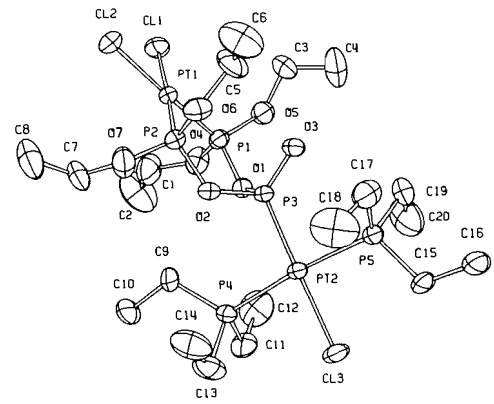

FIG. 5. ORTEP plot of **VII**, $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$.

3287 Hz compared to 2322 Hz when PEt_3 is *trans* to phosphorus in $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$. Corresponding values for the $P(OEt)_2$ groups are larger, reflecting the electronegativity of the ethoxy substituents, and range from 5408 to 6186 Hz when *trans* to Cl, to 3037 Hz *trans* to methyl. Interestingly, ^3J(Pt–P) also shows a very marked change with *trans* influence, decreasing from 54 Hz when *trans* to Cl in $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, to only 4.4 Hz *trans* to methyl in $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$. The sometimes very high sensitivity of long-range couplings to *trans*-influence effects has been noted previously (27). The observed spectra for $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ and its methyl analogue require that ^1J(Pt–P) and ^3J(Pt–P) have the same sign and, since directly bonded Pt–P couplings are known to be positive (28), it follows that the three-bond couplings are also positive. This is a difference between our analysis and a previous approximate interpretation of the ^{31}P spectrum of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ (19) and it also leads to somewhat different P–P couplings from those suggested previously. The observed spectra also require that ^1J(P–O–P) and ^4J(P–P) have like signs in $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, and opposite signs in $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, but the signs of these pairs relative to other couplings are not determined.

No sign information is available from the spectra of $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$ and $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$.

(c) Structures of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, (IV), and $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$, (VII)

The atomic labelling schemes and the structures of single molecules of the complexes **IV** and **VII** are shown in Figs. 4 and 5 respectively. Fractional atomic coordinates and isotropic temperature parameters, bond lengths, and bond angles are collected in Tables 2–4 and 5–7 respectively. Further tables of anisotropic temperature factors, structure factors, and selected intermolecular distances for both compounds have been deposited,[4] together with a table of mean plane information for **VII**.

The structure of **IV** consists of two square planar platinum centres linked by a pair of *cis* $(EtO)_2POP(OEt)_2$ bridges so as to form an eight-membered ring which lies in an extended chair conformation. There is a crystallographic centre of symmetry at the centre of the ring. The Pt—P bonds are relatively short (av. 2.20 Å; 1 Å = 0.1 nm) compared with many previous examples (29), but this is not unexpected in view of the low *trans* influence of the chloride ligand and the high electronegativity of the ethoxy substituents. It appears that this electronegativity also reduces the *trans* influence of the phosphorus ligand since the Pt—Cl bonds (av. 2.34 Å) are also somewhat shorter than is

normal *trans* to phosphorus (30). Another point of interest concerns the question of a bridging versus a chelate role for the $(EtO)_2POP(OEt)_2$ ligand. Until recently, $R_2P—O—PR_2$ ligands were not known to function as chelates, a fact which was generally attributed to a requirement for a large POP angle (31). Undoubtedly this is an important factor in the predominance of bridged rather than chelate structures but two recent structural determinations, $[M(CO)_4(Ph_2POPPPh_2)]$, M = Cr, Mo, have shown chelate structures with the POP angle 100.3 and 103.3°, respectively (15). In the present complex this angle is 135°, so it is clearly a very flexible parameter.

The structure of **VII** consists of two square planar platinum units linked by a novel condensed phosphorus ligand. This ligand may be regarded as having two P(III) centres, P(1) and P(2), which act as two electron donors to Pt(1), and a P(V) centre, P(3), which acts as a one electron donor to Pt(2). The six-membered ring lies in a *chaise-longue* conformation with O(1) and O(2) held in the same plane as the Pt(1) coordination. P(3) is about 0.7 Å above this plane and the Pt(2) coordination is approximately perpendicular (93.6°) to that of Pt(1). The Pt—Cl bonds (av. 2.35 Å), which are all *trans* to phosphorus, and the Pt—P bonds (av. 2.20 Å) are closely similar to those found above in compound **IV** and do not appear to be affected by the formal oxidation state of the phosphorus. In contrast, there are four significantly different P—O lengths: P=O, 1.471(9); P(V)—OP, av. 1.637; P(III)—OP, av. 1.601; P(III)—OEt, av. 1.565 Å, all of which fall within the ranges found for similar bonds in tetrahedral phosphates (32): P=O, 1.38–1.56; P—OP, 1.48–1.66; P—OC, 1.56–1.64 Å.

Experimental

(a) Synthetic and spectroscopic studies

Data relating to the characterization of the complexes are given in the tables, the Results section, and in the preparative descriptions below. Microanalysis was by the Canadian Microanalytical Service, Vancouver, B.C., Canada. Nuclear magnetic resonance spectra were recorded in appropriate solvents (Table 1) using a Bruker WP250 Fourier transform spectrometer locked to the solvent deuterium resonance. The spectrometer was operated at 101.3 MHz for ^{31}P and at 53.5 MHz for ^{195}Pt. For both nuclei, protons were decoupled by broad-band ("noise") irradiation at appropriate frequencies. ^{31}P chemical shifts were measured relative to external $P(OMe)_3$ and are reported in parts per million relative to 85% H_3PO_4 using a conversion factor of +141 ppm. ^{195}Pt chemical shifts are reported in ppm relative to $\Xi(^{195}Pt)$ = 21.4 MHz (33). Positive values are downfield of the references. Simulated nmr spectra were calculated on an IBM 3031 computer and plotted on a Calcomp 1039 plotter. The programs used were a locally constructed package based on the UEAITR and NMRPLOT programs from the literature (34, 35). In all cases the spectra of the different isotopomers were calculated separately and then summed to give the final simulation.

All operations were carried out at ambient temperature (ca. 25°C) under an atmosphere of dry nitrogen using standard Schlenk tube techniques. Solvents were dried by reflux over appropriate reagents (phosphorus pentoxide for dichloromethane and potassium/benzophenone for tetrahydrofuran, toluene, benzene, and hexane) and were distilled under nitrogen prior to use.

$P(OEt)_2Cl$ and $(EtO)_2POP(OEt)_2$ were commercially available from the Aldrich Chemical Co., and were used as received. $[PtCl_2(PhCN)_2]$ (36), $[Pt(CH_3)_2(COD)]$ (37), and $[Pt_2Cl_4(PEt_3)_2]$ (38), were prepared as previously described. Recrystallizations from solvent pairs were by dissolution of the complex in the first solvent (using about double the volume required for complete solution) followed by dropwise addition of sufficient second solvent to cause turbidity at ambient temperature. Crystallization was then completed either by continued very slow dropwise addition of the second solvent or, in those cases where a temperature is indicated in the detailed descriptions below, by setting the mixture aside at a reduced temperature.

$[Pt_2X_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$

(i) X = Cl. $P(OEt)_3Cl$ (0.20 mL, 1.4 mmol) was added dropwise to a stirred solution of $[PtCl_2(PhCN)_2]$ (0.30 g, 0.64 mmol) in dichloromethane (10 mL). The initial yellow colour was slowly discharged during stirring for 6 h. The solvent was removed *in vacuo* and the resulting colourless oil characterized as *cis*-$[PtCl_2\{P(OEt)_2Cl\}_2]$ by ^{31}P nmr (9). Repeated attempts at crystallization caused apparent hydrolysis of the product to a compound whose spectroscopy suggested the known dimer $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ (19).

(ii) X = Cl. In order to confirm the above result we decided to synthesize an authentic sample of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$. This was achieved by a modification of the published method (19) using $[PtCl_2(PhCN)_2]$ as the starting material instead of $[PtCl_2(SEt_2)_2]$. Typically, $(EtO)_2POP(OEt)_2$ (0.15 mL, 0.61 mmol) was added dropwise to a stirred solution of $[PtCl_2(PhCN)_2]$ (0.30 g, 0.64 mmol) in dichloromethane (10 mL). Stirring was continued for 4 h before removal of the solvent *in vacuo*. Recrystallization of the residue from dichloromethane/diethyl ether at −20°C gave $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ (0.15 g, 0.14 mmol) as colourless crystals. *Anal.* calcd. for $C_{16}H_{40}Cl_4O_{10}P_4Pt_2$: C 18.3, H 3.85, Cl 13.5; found: C 18.4, H 4.00, Cl 13.6%.

(iii) X = Me. $(EtO)_2POP(OEt)_2$ (0.15 mL, 0.61 mmol) was added dropwise to a stirred solution of $[PtMe_2(COD)]$ (0.20 g, 0.53 mmol) in dichloromethane (20 mL). Stirring was continued for 3 h before removal of the solvent *in vacuo*. Recrystallization of the oily residue from dichloromethane/hexane gave $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ (0.16 g, 0.17 mmol) as colourless crystals. *Anal.* calcd. for $C_{20}H_{52}O_{10}P_4Pt_2$: C 24.9, H 5.42; found: C 25.8, H 5.26%. The product was stable in the solid state and in deuterobenzene solution but decomposed over several hours in deuterochloroform solution.

A small-scale reaction carried out in an nmr tube by the addition of MeMgI (0.1 mmol in hexane) to a solution of $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ (0.03 g, 0.03 mmol) in dichloromethane (1 mL) showed essentially complete conversion (by ^{31}P nmr) to $[Pt_2Me_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$ after 20 min.

$[Pt_2Cl_4(PEt_3)_2\{\mu\text{-}(EtO)_2POP(OEt)_2\}]$

$(EtO)_2POP(OEt)_2$ (0.07 mL, 0.29 mmol) was added dropwise to a stirred suspension of $[Pt_2Cl_4(PEt_3)_2]$ (0.20 g, 0.26 mmol) in carefully dried benzene (10 mL). Stirring was continued for 45 min, during which time the yellow colour of the suspension was gradually discharged. The solvent was removed *in vacuo* to leave an oily residue, which was eventually crystallized by precipitation from dry dichloromethane/hexane at −20°C followed by prolonged trituration with hexane. Final recrystallization from dichloromethane/hexane at −20°C gave $[Pt_2Cl_4(PEt_3)_2\{\mu\text{-}(EtO)_2POP(OEt)_2\}]$ as colourless crystals, mp 127–129°C. *Anal.* calcd. for $C_{20}H_{50}Cl_4O_5P_4Pt_2$: C 23.4, H 4.91; found: C 23.5, H 4.84%. Note that a similar reaction in dichloromethane without special precautions regarding drying of solvents resulted in the hydrolyzed product, **VII**.

$[Cl_2Pt\{\mu\text{-}(P(EtO)_2O)_2P(O)\}PtCl(PEt_3)_2]$

(i) $P(EtO)_2Cl$ (0.30 mL, 2.1 mmol) was added dropwise to a stirred

solution of $[Pt_2Cl_4(PEt_3)_2]$ (0.94 g, 1.22 mmol) in dichloromethane (30 mL). The yellow colour of the solution was quickly discharged but stirring was continued for 2 h before removal of the solvent *in vacuo*. The oily residue was crystallized from dichloromethane/hexane at −20°C to yield $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$ as colourless crystals. Several attempts to repeat this reaction failed to give the same product and in consequence other routes were explored leading to the following synthesis.

(*ii*) $(EtO)_2POP(OEt)_2$ (0.10 mL, 0.41 mmol) was added dropwise to a stirred solution of $[Pt_2Cl_4(PEt_3)_2]$ (0.30 g, 0.39 mmol) in dichloromethane (15 mL). The yellow colour of the solution was almost immediately discharged and after 15 min the solvent was removed *in vacuo*. Recrystallization of the residue from dichloromethane/hexane at −20°C gave $[Cl_2Pt\{\mu\text{-}(P(OEt)_2O)_2P(O)\}PtCl(PEt_3)_2]$ as colourless crystals (0.10 g, 0.094 mmol), mp 130–133°C. *Anal.* calcd. for $C_{20}H_{50}Cl_3O_7P_5Pt_2$: C 22.8, H 4.78, Cl 10.1, P 14.7; found: C 22.7, H 4.83, Cl 10.8, P 15.2%. Note that a similar reaction in carefully dried benzene yielded a different product, $[Cl_2(Et_3P)Pt\{\mu\text{-}(EtO)_2POP(OEt)_2\}PtCl_2(PEt_3)]$ (see above).

(b) X-ray data collection

Compounds **IV**, $[Pt_2Cl_4\{\mu\text{-}(EtO)_2POP(OEt)_2\}_2]$, and **VII**, $[Cl_2Pt\{\mu\text{-}(P(EtO)_2O)_2P(O)\}PtCl(PEt_3)_2]$ were prepared as described above by reaction of $(EtO)_2POP(OEt)_2$ with $[PtCl_2(PhCN)_2]$ and by reaction of $P(OEt)_2Cl$ with $[Pt_2Cl_4(PEt_3)_2]$, and crystals suitable for study by X-ray diffraction were grown by vapour diffusion of hexane into solutions of the complexes in dichloromethane. Compound **IV** was mounted in a glass tube with a little solvent (dichloromethane/pentane) but no special precautions were necessary for compound **VII**. Preliminary photographic work on both compounds was carried out with Weissenberg and precession cameras using Cu K_α radiation. After establishment of symmetry and approximate unit cells the crystals were transferred to a Picker 4-circle diffractometer automated with a PDP11/10 computer and utilising Zr-filtered Mo K_α radiation (λ = 0.71069 Å). The unit cells were refined by least-squares methods employing respectively 28 and 22 pairs of centering measurements at $\pm 2\theta$ in the ranges $|2\theta| = 5$–47° (**IV**) and 17–44° (**VII**). The crystal of **IV** was mounted in the direction of −10, 8, −5 and crystal **VII** was approximately along the *c* axis. The crystal data at approximately 24°C were as follows. For *compound* **IV**:

$C_{16}H_{40}Cl_4O_{10}P_4Pt_2$

Monoclinic, space group $P2_1/n$, equivalent positions $x, y, z; \bar{x}, \bar{y}, \bar{z}; \frac{1}{2}+x, \frac{1}{2}-y, \frac{1}{2}+z; \frac{1}{2}-x, \frac{1}{2}+y, \frac{1}{2}-z$; a = 13.814(7), b = 11.429(4), c = 10.726(5) Å; β = 106.30(5)°; V(cell) = 1625(1) Å^3; D_m = 2.137 g cm^{-3} (flotation in $CCl_4/CHBr_3$), D_c = 2.142 g cm^{-3}; M_r = 1048.37; Z = 2; asymmetric unit = half molecule.

For *compound* **VII**:

$C_{20}H_{50}Cl_3O_7P_5Pt_2$

Monoclinic, space group $P2_1/c$, a = 17.547(8), b = 19.775(6), c = 11.268(3) Å; β = 106.42(3)°; V(cell) = 3750(2) Å^3; D_m = 1.896 g cm^{-3} (flotation in $CCl_4/CHBr_3$), D_c = 1.867 g cm^{-3}; M_r = 1054.02; Z = 4; asymmetric unit = one molecule.

Intensity measurements for both compounds were collected for two reciprocal space octants ($k, l \geq 0$) using a $\theta/2\theta$ scan with steps of 0.01° in 2θ, counting for 0.25 s per step, and with background measurements at each end of the scan. Measurements for **IV** extended to 2θ = 50° with 160 steps and background counts for 20 s, and for **VII** to 45° with 200 steps and 25 s counts. Each batch of 50 reflections was preceded by the measurement of three standard reflections (**IV**: 10, 0, 0; 0, 8, 0; 0, 0, 8; and **VII**: 6, 0, 0; 0, 6, 0; 0, 0, 2). The Lorentz and polarization factors were applied and each batch was scaled to maintain the sum of the standards constant. The standards for **IV** declined by about 10% during the data collection but there was no evidence of decomposition for **VII**. The initial files contained 3195 and 5271 reflections, respectively, and after systematically absent reflections, duplicate measurements, and those reflections with apparently negative net counts were eliminated, the final data sets contained 2855 and 4647 reflections.

For compound **IV**, the crystal faces were not identifiable and it was necessary to apply absorption corrections as a function of ϕ. Reflection −5, 4, 2 (near χ = 90°) was measured at 10° intervals in ϕ to construct an absorption correction curve. The intensity of −5, 4, 2 varied by a factor of 3.6 (μ = 96.09 cm^{-1} for MoK_α radiation). For compound **VII** absorption corrections were applied with a numerical integration procedure utilizing a 14 × 8 × 10 Gaussian grid. The crystal had pinakoidal forms {010} and {100} with the faces 0.112 and 0.257 mm, respectively, from a central origin; the faces at the tip were approximated by −1, 0, 1 at 0.404 mm, and a broken glued end by 1, 0, −2 at 0.327 mm. The absorption coefficient was 83.55 cm^{-1} and the range of transmission factors 0.04–0.18.

(c) Structure solution and refinement

The structures were found and refined using the SHELX-76 program package (39), and illustrations were drawn using ORTEP (40). The atomic scattering factors used were for neutral atoms, with corrections for anomalous dispersion (41). The structures were solved by direct methods, completed by standard Fourier synthesis procedures using difference maps, and refined by the method of least squares minimizing $\Sigma w\Delta^2$ where $\Delta = |F_o| - |F_c|$. The weights were obtained from counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. One intense low angle reflection, 2, 0, 0, was suppressed from the least-squares process for compound **VII**, but otherwise the refinements proceeded without incident with 163 and 334 parameters to be determined from 2855 and 4646 independent observations for **IV** and **VII**, respectively. Hydrogen atoms were not located. All other atoms were treated as vibrating anisotropically and convergence was obtained with maximum shift/esd ratios of 0.76 and 0.12, respectively. For compound **IV** the residuals were R = 0.0550 and $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2}$ = 0.0688. The final difference map for compound **IV** had 5 peaks in the range 1.1–3.8 e Å^{-3} at distances of about 1 Å from heavy atoms. Other maxima were less than 1.1 e Å^{-3} and the minimum was −3.3 e Å^{-3}. Corresponding figures for **VII** were R = 0.0612, R_w = 0.0726, max = +1.83 e Å^{-3} (close to Pt(2)), min = −2.31 e Å^{-3}. Neither difference map gave any indication that any material had been overlooked. For compound **IV** the molecular symmetry was $\bar{1}$ and for the coordinates given in Table 2 the centre of inversion is located at (0, $\frac{1}{2}$, 1).

Densities and apparent molar volumes of aqueous aluminum chloride. Analysis of apparent molar volumes and heat capacities of aqueous aluminum salts in terms of the Pitzer and Helgeson theoretical models

LESLIE BARTA AND LOREN G. HEPLER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2
Received July 3, 1985

LESLIE BARTA and LOREN G. HEPLER. Can. J. Chem. **64**, 353 (1986).

Densities of aqueous solutions of $AlCl_3$ (containing dilute HCl) have been measured at 10, 25, 40, and 55°C with results that have led to defined apparent molar volumes. We have used the Pitzer ion interaction model as the basis for analyzing these apparent molar volumes to obtain standard state (infinite dilution) partial molar volumes of $AlCl_3(aq)$ at each temperature. We have also made similar use of apparent molar heat capacities of aqueous solutions of $AlCl_3$–HCl and $Al(NO_3)_3$–HNO_3 from Hovey and Tremaine to obtain standard state partial molar heat capacities of $AlCl_3(aq)$ and $Al(NO_3)_3(aq)$ at these same temperatures. Finally, the standard state partial molar volumes and heat capacities have been used with the Helgeson–Kirkham semi-theoretical equation of state for aqueous ions to provide a basis for estimating the thermodynamic properties of $Al^{3+}(aq)$ at high temperatures and pressures.

LESLIE BARTA et LOREN G. HEPLER. Can. J. Chem. **64**, 353 (1986).

Opérant à 10, 25, 40 et 55°C, on a mesuré les densités de solutions aqueuses de $AlCl_3$ (contenant du HCl dilué) et l'on en a déduit les volumes molaires apparents. Comme point de départ, nous avons utilisés le modèle d'interaction ionique de Pitzer pour analyser ces volumes molaires apparents et pour obtenir les volumes molaires partiels apparents standards (dilution infinie) du $AlCl_3(aq)$ à chacune des températures. De la même façon, nous avons utilisé les capacités calorifiques molaires apparentes des solutions aqueuses de $AlCl_3$–HCl et de $Al(NO_3)_3$–HNO_3, déterminées par Hovey et Tremaine, pour obtenir les capacités calorifiques molaires partielles standard du $AlCl_3(aq)$ et du $Al(NO_3)_3(aq)$ à ces mêmes températures. Finalement, on a utilisé les capacités calorifiques et les volumes molaires partiels standard de concert avec l'équation d'état semi-théorique de Helgeson–Kirkham pour les ions aqueux pour avoir un point de départ dans l'évaluation des propriétés thermodynamiques des ions $Al^{3+}(aq)$ à des températures et à pressions élevées.

[Traduit par le journal]

Introduction

The thermodynamic properties of aqueous aluminum ion are needed in applying chemical equilibrium models to mineral–water interactions relevant to geothermal processes, to *in situ* bitumen recovery processes, and to soil and clay mineral chemistry. Specific examples include the precipitation of protective oxide or hydroxide on otherwise reactive surfaces and the enhanced solubility of aluminum-containing minerals due to complexation and hydrolysis equilibria.

Some standard state thermodynamic properties (Gibbs free energy of formation, enthalpy of formation, and entropy) of $Al^{3+}(aq)$ at 298.15 K and 1 bar (= 100 kPa) are already available (1). To use these properties for equilibrium calculations that apply to high temperature or high pressure systems, we also need the standard state partial molar heat capacity and volume of $Al^{3+}(aq)$, which are the principal subjects of this paper. In addition, the heat capacity and volume (temperature and pressure derivatives of the Gibbs free energy) are useful in connection with theoretical models of aqueous solutions (2–4) that are themselves applicable to the effective use of tabulated thermodynamic properties (298.15 K and 1 bar) for calculating properties at higher temperatures (5–8) and pressures (8–10).

Heat capacity data for aqueous solutions of aluminum chloride and nitrate have just recently become available (11), but have not yet been considered in relation to the Pitzer (2) and Helgeson (3, 4) models, which we do in this paper. Previously available volumetric data are limited to relative densities at 18°C of aqueous solutions of aluminum chloride and of aluminum nitrate (12) and of solutions of aluminum nitrate – nitric acid in the temperature range 0–60°C (12, 13). Calculation (14, 15) of the desired standard state partial molar volumes of the aluminum salts from these results (12, 13) is complicated in the first case by hydrolysis and in the second by substantial mixed electrolyte effects. Possibly because of these complications or possibly because of errors in the original experimental results, the standard state partial molar volumes of $Al^{3+}(aq)$ at 25°C derived from these earlier results differ by about 2 cm^3 mol^{-1}. We have therefore made new measurements of the densities of solutions of aluminum chloride – hydrochloric acid.

Results of our measurements of densities and the recently completed measurements of heat capacities by Hovey and Tremaine (11) have been used for the important extrapolation from finite concentration to the infinitely dilute reference state and in connection with theoretical models for the concentration, temperature, and pressure dependence of thermodynamic properties of aqueous electrolytes. More specifically, we have used the Pitzer (2) ion-interaction model and the Helgeson, Kirkham, and Flowers (4) extended Debye–Hückel model for extrapolation to infinite dilution, and the Helgeson and Kirkham (3) electrostatic model for the temperature dependence of the standard state thermodynamic properties.

Experimental

Densities of solutions at 10, 25, 40, and 55°C were measured relative to the density of pure water at the same temperature with a Sodev O3D vibrating tube densimeter (16) fitted with a platinum tube. A CT-L/PC-B temperature controller provided temperature stability of ±0.001 K. The densimeter was calibrated with distilled water and standard solutions of 1 *m* NaCl prepared by mass from Fisher ACS Certified crystals dried overnight at 110°C. Densities of 0.1 *m* NaCl solutions prepared from this standard were measured periodically to monitor reliability of the instrument's performance. Calibrations at 25°C were based on the density of water from Kell (17) and densities of solutions of NaCl from Fortier *et al.* (18). Densities of water and

solutions of NaCl at other temperatures were taken from Haar *et al.* (19) and Rogers and Pitzer (20), respectively.

A stock solution was prepared by dissolving approximately 90 g of Alfa Puratronic $AlCl_3 \cdot 6H_2O$ in 720 g of standard 0.015 *M* HCl. Aluminum was determined gravimetrically as the 8-hydroxyquinolate, with results that permitted us to calculate that the stock solution was 0.49617 ± 0.00057 molal in Al^{3+}. Preliminary pH measurements on a 0.5 *m* solution of $AlCl_3 \cdot 6H_2O$ in distilled water had indicated that the amount of HCl occluded in the solid was less than the estimated relative error of a gravimetric chloride determination. The HCl standard solution was therefore assumed to be the sole source of H^+ in our acidic solution of aluminum chloride, and the molality of chloride was calculated by difference.

A series of solutions of $AlCl_3$ in the composition range 0.03–0.5 *m* was obtained by diluting the stock solution by mass with standard 0.001 *M* HCl. Volumetric data for aqueous HCl (18) allowed calculation of solution compositions on a mass (molality, *m*) basis.

Water used as reference liquid and as solvent was singly distilled, deionized, filtered through activated carbon to remove organic contaminants, and boiled to remove dissolved gases.

Results and calculations

For treatment of densities of our mixed electrolyte ($AlCl_3$ and HCl) we follow principles summarized by Millero (21) in defining a mean apparent molar volume as

$$[1] \quad V_\phi(\text{mean}) = (V - 1000v_w)/\Sigma m_i$$

in which V is the total volume (cm^3) of a solution containing 1 kg of water, v_w is the volume of 1 g of water, and the m_i represent molalities of solutes i. Equation [1] leads to

$$[2] \quad V_\phi(\text{mean}) = [1000(d_w - d) + d_w\Sigma m_i W_i]/[dd_w\Sigma m_i]$$

in which d and d_w represent the densities of solution and pure water, respectively, and the W_i represent the molar masses of solutes i.

Compositions and densities of our solutions are given in the first three columns in Table 1, with mean apparent molar volumes calculated according to eq. [2] given in the fourth column.

Because the fraction of the total ionic strength due to the aluminum chloride greatly exceeds that due to the hydrochloric acid in our solutions, we can attempt to isolate the defined apparent molar volume for each of our solutes by application of Young's rule (22), which we write as

$$[3] \quad (m_j + m_k)V_\phi(\text{mean}) = m_j V_\phi(AlCl_3) + m_k V_\phi(HCl)$$

where m_j and m_k refer to the molalities of aqueous $AlCl_3$ and HCl, respectively. Use of eq. [3] with our experimental results (Table 1) and the volumetric properties of aqueous HCl from Akerlöf and Teare (23) has led to the desired values of $V_\phi(AlCl_3)$ that are listed in the fifth column in Table 1. Although we can in principle use these calculated values of $V_\phi(AlCl_3)$ in an extended Debye–Hückel equation of the form

$$[4] \quad V_\phi = V_\phi^0 + A_V m^{1/2} + B_V m + \ldots \text{ (or } I \text{ instead of } m)$$

to obtain the desired standard state partial molar volume represented here by V_ϕ^0, there are ambiguities as to the appropriate use of the molality of $AlCl_3$ or the total ionic strength and also other difficulties. Similar problems arise in connection with application of the Helgeson, Kirkham, and Flowers model (4). It is therefore preferable to use the Pitzer model (2, 24), which explicitly deals with ionic interactions in mixed electrolyte solutions.

As the first step toward applying the Pitzer model to obtaining the standard state partial molar volume of the aqueous aluminum salt, $V^0(AlCl_3)$, from the experimentally based mean apparent molar volumes in Table 1, we define the excess volume of a solution as

$$[5] \quad V^{EX} = V - \Sigma n_i V^0(i)$$

in which the n_i and $V^0(i)$ are the numbers of moles and the standard state (infinitely dilute) partial molar volumes of solutes i, respectively. Combination of eqs. [4] and [5] leads to

$$[6] \quad V_\phi(\text{mean}) = (\Sigma m_i V^0(i) + V^{EX})/\Sigma m_i$$

We now go from the general eq. [6] to the corresponding specific equation for two electrolytes represented by j and k as in eq. [3]. Rearrangement of the resulting specific version of eq. [6] gives

$$[7] \quad [(m_j + m_k)V_\phi(\text{mean}) - m_k V^0(k)]/m_j = V^0(j) + (V^{EX}/m_j)$$

The excess volume, V^{EX}, may be represented directly as the pressure derivative of the excess Gibbs free energy as developed by Pitzer and others (2, 24, 25). For a ternary common ion system resulting from mixing electrolytes MX and NX of charge types 3:1 and 1:1, respectively, the interaction model representation, per kilogram of water, may be written

$$[8] \quad G^{EX}/RT = f^{GX}(I) + 2m_c(B_{MX}^{GX} + 2C_{MX}^{GX}m_c) + 2m_c(B_{NX}^{GX} + 2C_{NX}^{GX}m_c) + m_j m_k(2\theta_{MN} + m_c\psi_{MNX})$$

where m_j and m_k are molalities of electrolytes MX and NX in the mixture, and m_c is the molality of the common ion X. All other symbols are as previously defined (24). Because the pressure derivatives of the mixing coefficients, θ_{MN}^V and ψ_{MNX}^V, and also C_{MX}^V are too small to be important in our concentration range, we have assigned these parameters values of zero. Substituting the pressure derivative of eq. [8], modified as stated, into eq. [7] and rearranging gives

$$[9] \quad V_\phi(m_j + m_k)/m_j - (m_k/m_j)[V^0(HCl) + 2RTm_c(B_{HCl}^V + 2C_{HCl}^V m_c)] - \{A_V I \ln(1 + 1.2I^{1/2})\}/(1.2m_j) = V^0(AlCl_3) + 2RTm_c B_{AlCl_3}^V$$

The binary interaction coefficient, B^V, has an ionic strength dependence originally defined for the osmotic coefficient (2). For the excess Gibbs free energy the appropriate function is

$$[10] \quad B^{GX} = \beta^{(0)} + \beta^{(1)}[1 - (1 + 2I^{1/2})\exp(-2I^{1/2})]/(2I)$$

$V^0(AlCl_3)$, $\beta^{(1)V}$, and $\beta^{(0)V}$ were evaluated at each temperature by multiple linear regression analysis of our density data using eqs. [9] and [10] and values of B_{HCl}^V and C_{HCl}^V calculated from data (23) for aqueous HCl. The Debye–Hückel slope, A_V, is from Bradley and Pitzer (26). Values of the parameters for HCl are reported in Table 2. The desired resulting values of $V(AlCl_3)$ at the four temperatures of our measurements are listed in Table 3.

The values of $V^0(AlCl_3)$ were weighted statistically and then fit with an empirical function of temperature. Smoothed values calculated from this function were used to obtain final estimates of the parameters $\beta^{(1)V}$ and $\beta^{(0)V}$. The former was fit with an empirical function of temperature, and the latter was represented by a Lagrange polynomial. The result is that the temperature

TABLE 3. Standard partial molar volume of aqueous $AlCl_3$ obtained by extrapolation using the Pitzer interaction model

*Standard error of the estimate at the 95% confidence level.

dependence of the parameters for volumetric properties of $AlCl_3$ over the range 10–55°C may be represented by the following equations:

$$[11] \quad V^0(AlCl_3) = a_1 + a_2T + a_3T^2$$

$$[12] \quad \beta^{(1)V} = a_4 + a_5T + a_6/(T - 362)$$

$$[13] \quad \beta^{(0)V} = a_7T^3 + a_8T^2 + a_9T + a_{10}$$

Values of the coefficients $a_1 \ldots a_{10}$ are listed in Table 4. The temperature dependence of the interaction parameters is shown in Fig. 1.

A set of equations based on the Pitzer virial model can be developed similarly for analyzing and representing other apparent molar properties. In this work we have carried out such development for the apparent molar heat capacity and have applied the resulting equations to the recently available data of Hovey and Tremaine (11) for $AlCl_3$–HCl mixtures at temperatures of 10, 25, 40, and 55°C. As in the case of volumes, the mixing parameters may be neglected. The excess heat capacity is

$$[14] \quad C_p^{EX} = -T(\partial^2 G^{EX}/\partial T^2)_{p,X}$$

Combination of eqs. [14] and [8] with the general form of eq. [7] leads to a regression model for evaluating $C_p^0(AlCl_3)$ and the second temperature derivatives of the interaction parameters:

$$[15] \quad C_{p,\phi}(m_j + m_k)/m_j - (m_k/m_j)[C_p^0(HCl) - 2RT^2m_c(B^J_{HCl} + 2C^J_{HCl}m_c)] - [A_JI \ln (1 + 1.2I^{1/2})]/(1.2m_j) = C_p^0(AlCl_3) - 2RT^2m_c[B^J_{AlCl_3} + 2C^J_{AlCl_3}m_c]$$

Values of $C_p^0(HCl)$ and B^J_{HCl} were calculated from the equations of Tremaine *et al.* (8) and are listed in Table 5. Data for evaluating C^J_{HCl} are not yet available, and we have tentatively assigned this parameter a value of zero. Values of $C_{p,\phi}$(mean) were taken as reported (11). The Debye–Hückel slope, A_J, is from Bradley and Pitzer (26).

In addition to the intercept, $C_p^0(AlCl_3)$, which is the quantity that we want, only the $\beta^{(1)J}$ term was needed to fit the heat capacity data. The temperature dependence of this parameter and also that of $C_p^0(AlCl_3)$ were fit with the following empirical functions:

$$[16] \quad C_p^0(AlCl_3) = b_1 + b_2T + b_3/(T - 190)$$

$$[17] \quad \beta^{(1)J} = b_4 + b_5T + b_6/(T - 190)$$

Values of the coefficients $b_1 \ldots b_6$ are listed in Table 6. Figure 2 shows the temperature dependence of $\beta^{(1)J}$. Values of $C_p^0(AlCl_3)$ at the four temperatures of the measurements are listed in Table 7.

We turn now to the representation of the standard state properties of aluminum ion, $V^0(Al^{+3})$ and $C_p^0(Al^{+3})$, as semi-theoretical functions of temperature that can be combined with other data, as stated in the introduction, for use in equilibrium calculations at elevated pressures and temperatures. For this purpose we have chosen the equations of Helgeson and Kirkham (3), which express the standard state properties of ions as the sum of terms describing low-temperature electrostrictive collapse of the solvent structure and the change in hydration at high temperature due to rapid decrease in the dielectric constant of water. At constant pressure the appropriate relations are

$$[18]\quad V^0(Al^{3+}) = c_1 + c_2T/(T - \theta_{Al^{3+}}) - \omega_{Al^{3+}}Q$$

$$[19]\quad C_p^0(Al^{3+}) = d_1 + d_2T/(T - \theta_{Al^{3+}}) + \omega_{Al^{3+}}T\chi$$

in which c_1, c_2, d_1, and d_2 are adjustable parameters and $\theta_{Al^{3+}}$ is an adjustable "structural" temperature that allows a simple empirical description of the rapid decrease in the standard state properties, observed for many ions, with decreasing temperature in the low temperature region. The terms in $\omega_i(i = Al^{3+})$ are

TABLE 8. Coefficients for the Helgeson–Kirkham model for the standard state partial molar properties of Al^{3+} (aq) (eqs. [18] and [19])

Coefficient	Estimate
c_1	−43.984

d_1	135.543
d_2	−28.98818208
$\theta_{Al^{3+}}$	239.9 K

based on the Born hydration model and may be calculated from the following relations defined by Helgeson and Kirkham (3):

$$[20]\quad \omega_i = \eta z_i^2/(r_{xtl} + 0.94z_i) - 5.387 \times 10^4 z_i$$

$$[21]\quad Q = (1/D)(\partial \ln D/\partial p)_T$$

$$[22]\quad \chi = (1/D)[(\partial^2 \ln D/\partial T^2)_p - (\partial \ln D/\partial T)_p^2]$$

in which $\eta = 1.66027 \times 10^5$ Å cal mol^{-1}, r_{xtl} is the crystallographic radius of the ion, and D is the dielectric constant of pure water. Equations [18] and [19] in principle apply to ionic properties calculated on either the absolute or the conventional basis (assigning a value of zero to the corresponding property of hydrogen ion at each temperature). Because of the additional uncertainties involved in defining absolute thermodynamic properties of ions, we prefer to use conventional values and have chosen the corresponding form of ω_i (eq. [20]).

Combining the values of the standard state partial molar properties of $AlCl_3$ listed in Tables 3 and 7 with those for chloride ion based on the values for HCl listed in Tables 2 and 5, we have calculated conventional values of $V^0(Al^{3+})$ and $C_p^0(Al^{3+})$. Table 8 reports the results of the simultaneous optimization of eqs. [18] and [19] with respect to the common parameter, θ_i, using the Pauling radius of Al^{3+} and values of Q and χ calculated from the equations of Bradley and Pitzer (26). The temperature dependences of the standard state properties of aluminum ion are shown in Figs. 3*a* and 3*b*.

Discussion

The quantity on the right side of eq. [9] or [15] is equivalent to the difference between the apparent molar property of $AlCl_3$ as defined by Young's rule and that part of the Debye–Hückel term due to the aluminum salt. Values of this quantity calculated from the density and heat capacity data in combination with the information in Tables 2 and 5 and from the smoothed curves (eqs. [11]–[13] for volumes and eqs. [17] and [19] for heat capacities) are plotted against molality of aluminum in Figs. 4 and 5. The accuracy of the Pitzer interaction model correlation of the data as described in the preceding section is within the limit of the overall experimental uncertainties. The quality of fit of the Helgeson and Kirkham model to the standard state partial molar properties of aluminum ion is acceptable in the case of both volume (Fig. 3*a*) and heat capacity (Fig. 3*b*). Because no minimum relative sum of squares with respect to θ_i occurs in the objective function for the volume, the optimization is essentially governed by the heat capacity. The resulting value of $\theta_{Al^{3+}}$ (Table 8) leads to values of $V^0(Al^{3+})$ and $C_p^0(Al^{3+})$ within 0.6% (0.25 cm^3 mol^{-1}) and 0.9% (0.9 J mol^{-1} K^{-1}) of the respective calculated isothermal values. These differences are

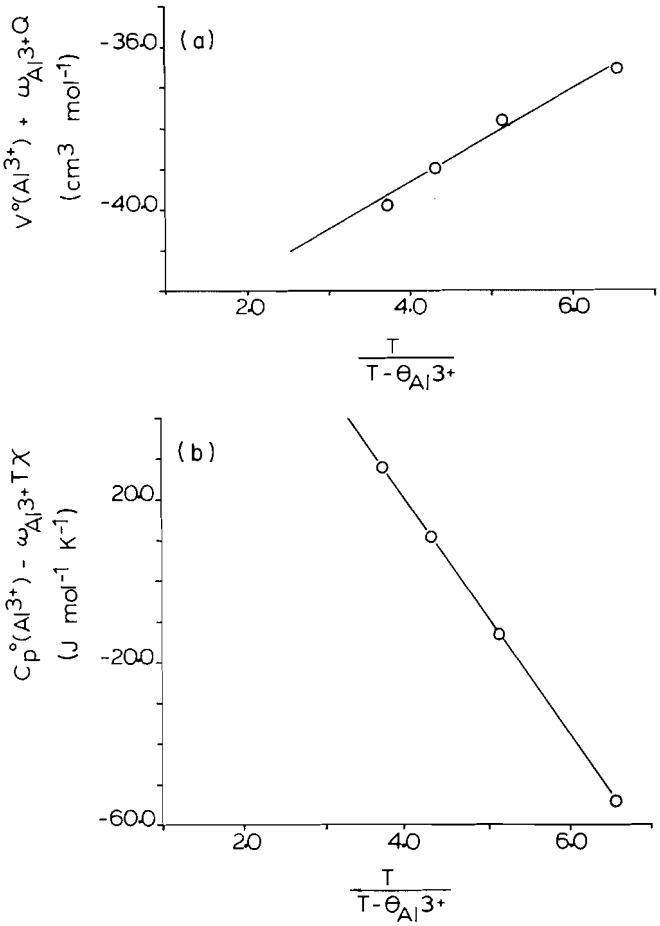

FIG. 3. Temperature dependence of the standard partial molar (*a*) volume and (*b*) heat capacity of Al^{3+}(aq). Helgeson–Kirkham model representation (solid lines) of the extrapolated values (circles), corrected for the Born hydration contribution.

small enough that eqs. [18] and [19] may reasonably be used in estimating the pressure and temperature dependence of equilibria involving Al^{3+}(aq) to perhaps 1 kbar and 200°C. Equations [16] and [19] represent $C_p^0(AlCl_3)$ equally well; however, the empirical relation for $V^0(AlCl_3)$ (eq. [11]) is superior to the Helgeson–Kirkham model for the purpose of data representation.

Since only solute–solvent interactions contribute to the partial molar properties at infinite dilution, it is interesting to compare the values obtained in the preceding section for Al^{3+}(aq) calculated from the data for aluminum chloride with those that may be obtained from another aluminum salt. Using the equations developed in this paper, data for nitric acid from Enea *et al.* (27), and data for aluminum nitrate – nitric acid mixtures at 25°C from Hovey and Tremaine (11), we have compiled Table 9. Both $C_p^0(Al^{3+})$ and $V^0(Al^{3+})$ obtained from the chloride are slightly more negative than the corresponding properties obtained from the nitrate, but both sets of values are coincident within the limit of error at the 95% confidence level. The values of $V^0(Al^{3+})$ obtained by our analysis are in better

agreement than are those that may be calculated similarly from results listed in Millero's compilation (15).

ADDED NOTE: As a result of comments received from D. J. Bradley (Montana College of Mineral Science and Technology), it is appropriate to point out that there is a theoretical basis for including higher order electrostatic terms for unsymmetrical mixed electrolytes in the binary mixing coefficient that we have represented by θ_{MN}, as discussed in detail by Pitzer and others (25, 28, 29). These higher order terms, calculated according to theoretical principles described by Pitzer, contribute *less* than 0.02 cm^3 mol^{-1} and 0.05 J K^{-1} mol^{-1} to the objective functions represented in eqs. [9] and [15], respectively, with the result that the final values of the fitted parameters, including the standard partial molar properties, are not significantly affected by these terms. For our purposes, which include relative simplicity in mathematical representation of experimental results, it has therefore seemed appropriate to neglect these higher order terms.

Acknowledgements

We are grateful to J. K. Hovey and P. R. Tremaine for giving us the results of their measurements of heat capacities before publication (ref. 11), for allowing us to use the densimeter at the Alberta Research Council, and for helpful discussions. We also thank the Natural Sciences and Engineering Research Council of Canada for their support of this and related research.

YASUO ABE, HIDEO HORII, SETSUO TANIGUCHI, SHINICHI YAMABE, and TSUTOMU MINATO. Can. J. Chem. **64**, 360 (1986).

The oxidation of triose reductone H—CO—C(OH)=C(OH)—H (which has the same functional group as L-ascorbic acid) to dehydroreductone is investigated by *ab initio* molecular orbital computations. The geometries of the substrate, oxidized product, and of six possible intermediate species are optimized by gradient methods at the STO-3G basis set level. All the species are found to be planar and stable molecules by the vibrational analysis. The most possible oxidation route is shown to consist of four steps. The combination of the enediol and carbonyl groups in the deprotonated molecule **2** gives an effective π conjugation for the electron removal. The oxidation process of L-ascorbic acid is discussed on the basis of the results for triose reductone.

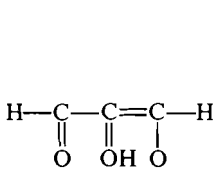
YASUO ABE, HIDEO HORII, SETSUO TANIGUCHI, SHINICHI YAMABE et TSUTOMU MINATO. Can. J. Chem. **64**, 360 (1986).

Faisant appel à des calculs *ab initio* d'orbitales moléculaires, on étudie l'oxydation de la triose réductone H—CO—C(OH)=C(OH)—H (qui a le même groupe fonctionnel que l'acide L-ascorbique) en déhydroréductone. On a optimisé les géométries du substrat, du produit oxydé et de six espèces intermédiaires possibles en utilisant les méthodes de gradient au niveau de l'ensemble de base STO-3G. L'analyse vibrationnelle indique que toutes ces espèces sont planaires et stables. On montre que la voie d'accès la plus probable aux produits d'oxydation comporte quatre étapes. La combinaison de l'ènediol et des groupes carbonyles dans la molécule déprotonée **2** donne une conjuguaison π qui facilite le départ de l'électron. On discute de l'oxydation de l'acide L-ascorbique à partir des résultats obtenus avec la triose réductone.

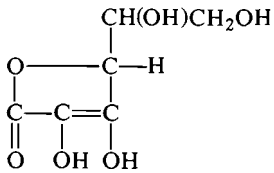
[Traduit par le journal]

I. Introduction

2,3-Dihydroxy-2-propenal is produced from dextrose by alkaline hydrolysis (1). It is called triose reductone (RH_2) because of its reducing power. The reductone is the simplest molecule having an enediol group. The physiologically important L-ascorbic acid (Vitamin C) is a typical compound with this structural moiety. Kinetic studies on the oxidation of RH_2 with oxygen (2), peroxodisulfate (3), and hexacyanoferrate(III) (4) have been reported. These data are comparable with those of L-ascorbic acid (5–7). Both of them are oxidized to dehydro forms with the successive one-electron removal. The probable reaction schemes from RH_2 to dehydroreductone (propantrione, DR) are given in Fig. 1 (4). In the overall process **1**→**8**, two protons and two electrons are lost.



RH_2



L-Ascorbic acid

It is of biochemical interest to examine the oxidation mechanism of RH_2, because its functional group is thought to operate in the same way as that of L-ascorbic acid. If some differences of the reactivity are found, those should be ascribed to the five-membered ring and (or) the attached substituent of the latter molecule. In this work, the oxidation mechanism of RH_2 to DR is examined by an *ab initio* molecular orbital (MO) calculation, and some transient species involved in Fig. 1 are also calculated.

[1]Author to whom correspondence may be addressed.

[2]Present address: Yuge Mercantile Marine College, Yuge-cho, Ochi-gun, Ehime 794-25, Japan.

The motive of the theoretical approach comes from the following mechanistic interest.

(1) In the equilibrium $RH_2 \rightleftarrows RH^- + H^+$, which proton of RH_2 is removed?
(2) Is the oxidation, $RH_2 \rightarrow DR$, the π electron removal or the loss of the lone-pair electron on the oxygen atom?
(3) How do the deprotonation and the electron loss work to convert RH_2 to DR?
(4) Are the intermediate species represented in Fig. 1 really stable?

When these questions are solved, the oxidation process of L-ascorbic acid as well as RH_2 will be clarified thoroughly.

II. Method of calculation and experimental background

The stable geometry and the electronic structure of each species in Fig. 1 are investigated. **1**, **2**, **3**, **7**, and **8** are calculated by the standard restricted Hartree–Fock (HF) method. For **4**, **5**, and **6**, the Pople–Nesbet unrestricted HF wavefunction is employed. Geometries are optimized with the STO-3G basis set by the use of the gradient technique implemented in the Gaussian 80 program (8). The one-point energy calculation is performed on the STO-3G geometry of each species with the 3-21G+p basis set (i.e., 3-21G+p//STO-3G). As the diffuse polarization functions, the p-type GTO's are added to 3-21G. The exponent on the carbon atom is 0.034, and that on the oxygen atom is 0.059 (9). To check whether the optimized geometries correspond to the stable states, vibrational analyses are carried out. The second energy derivatives are obtained by differentiating the analytical first derivatives numerically.

According to the kinetic data (4), the oxidation rate constant of **2**→**5** is 1000 times larger than that of **1**→**4**. The rate-determining step of the RH_2 oxidation has been shown to be **2**→**5** in the range of $5 > pH > 2$. This is because the second oxidation **5**→**7** is quite rapid. The route **1**→**2**→**5**→**7**→**8** is, therefore, most likely. An alternative route **1**→**2**→**5**→

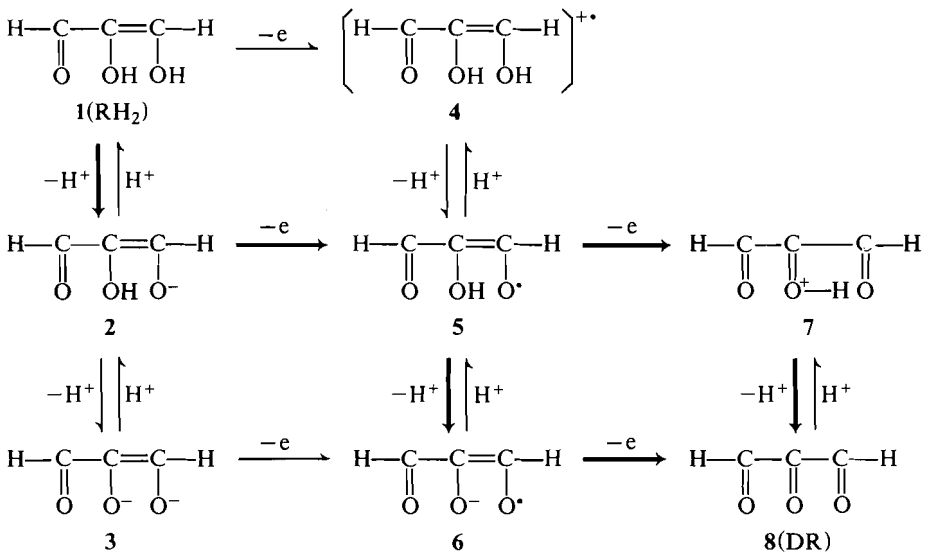


FIG. 1. The probable oxidation scheme ($RH_2 \rightarrow DR$) suggested from the kinetic measurements (4). Important routes are specified by bold lines.

6→ **8** is also probable. Radical species **5** and **6** coexist in the equilibrium state ($pK_a = 1.4$) (10). Since the oxidation rate constants of **5**→ **7** and **6**→ **8** are not available, we can hardly judge which route is more important. However, they differ only in the sequence of the deprotonation and the second oxidation. This is independent of the rate-determining step and is a minor difference. First, five species involved in the route **1**→ **2**→ **5**→ **7**→ **8** are analyzed in detail. Second, others including **6** are examined briefly.

III. Results of geometry determination

The geometry of each species in Fig. 1 is examined. In Fig. 2, the structure of RH_2 (planar) is given together with the observed X-ray data (11). The agreement of the covalent bond length between the two is satisfactory. Since it is the gas-phase data, two intramolecular hydrogen bonds are formed, $O_e \cdots H_g$ and $O_j \cdots H_f$. Encouraged by the similarity, we obtain the structures of the transient species and the product DR, which are shown in Fig. 3. The vibrational analysis demonstrates that they are all stable molecules (all the harmonic frequencies are real). In Fig. 4, their energy levels and zero-point vibration energies are drawn. Since these energies are for the gas phase, they do not correspond to the thermodynamic quantities in the aqueous media. Solvation to species will change the energy levels significantly. However, the solvation energy for each species is thought to be of a similar magnitude. A comparison of the reactivity by the use of the energy diagrams in Fig. 4 seems to be useful. For instance, the result of $k(\mathbf{2}\rightarrow\mathbf{5})/k(\mathbf{1}\rightarrow\mathbf{4}) = 1000$ mentioned in the previous section is explicable. The energy change along the oxidation **2**→ **5** is +30 kcal/mol(endothermic), while that along **1**→ **4** is +188 kcal/mol. Although qualitative, this energy difference corresponds to the large ratio of rate constants.

The effect of the diffuse *p*-type orbitals on total energies is examined. The largest stabilizing energy, +91.5 kcal/mol, relative to the 3-21G value is gained in the di-anion **3**. The anions **2** and **6** get the energy of ~ +50 kcal/mol. The stabilizing energy by 3-21G→ 3-21G+p of the neutral species is about +30 kcal/mol, and that of cations is +17 kcal/mol. Thus, the inclusion of diffuse orbitals is important to evaluate properly the energy of anions.

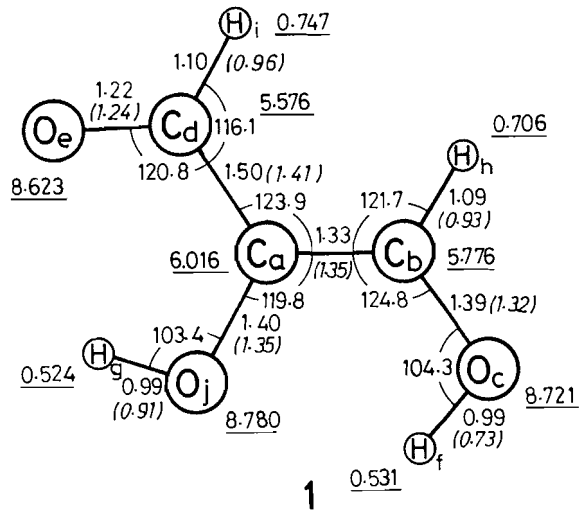

FIG. 2. The structure of triose reductone optimized with the MO calculation of the STO-3G basis set. The bond distance and angle are in Ångstroms and in degrees, respectively. The X-ray experimental data in parentheses (italic) are taken from ref. 11. The X-ray O_c—H_f bond length 0.73 Å is somewhat doubtful. The small letters (a, b, ..., and j) are used to specify atoms. Underlined numbers denote the atomic electron density calculated by 3-21G+p//STO-3G.

In the reversible deprotonation step **1** ⇄ **2**, H_f^+ is removed. An alternative model where H_g^+ is taken off is found to be 23.2 kcal/mol less stable than **2**. The problem of which proton, H_f^+ or H_g^+, is more removable may be solved by the frontier-electron theory of Fukui. The lowest σ* (in-plane) MO is antibonding for O_j—H_g and O_c—H_f bonds. The latter contribution to the MO is larger. This predicts the O_c—H_f bond cleavage for the nucleophilic attack and the deprotonation. In the step **1**→ **2**, some noticeable geometric changes take place. The single C_b—O_c bond in **1** is converted to the carbonyl group in **2**. Two C—C bonds of **2** are almost identical (1.42 and 1.41 Å), whereas they are distinguishable as single and double bonds in **1**. The anion species **2** is a conjugated system and its π electrons are readily ejected. When a π electron is abstracted from **2**, the neutral radical **5** (RH· is formed. The geometry of **5** is not so different from that of **2**.

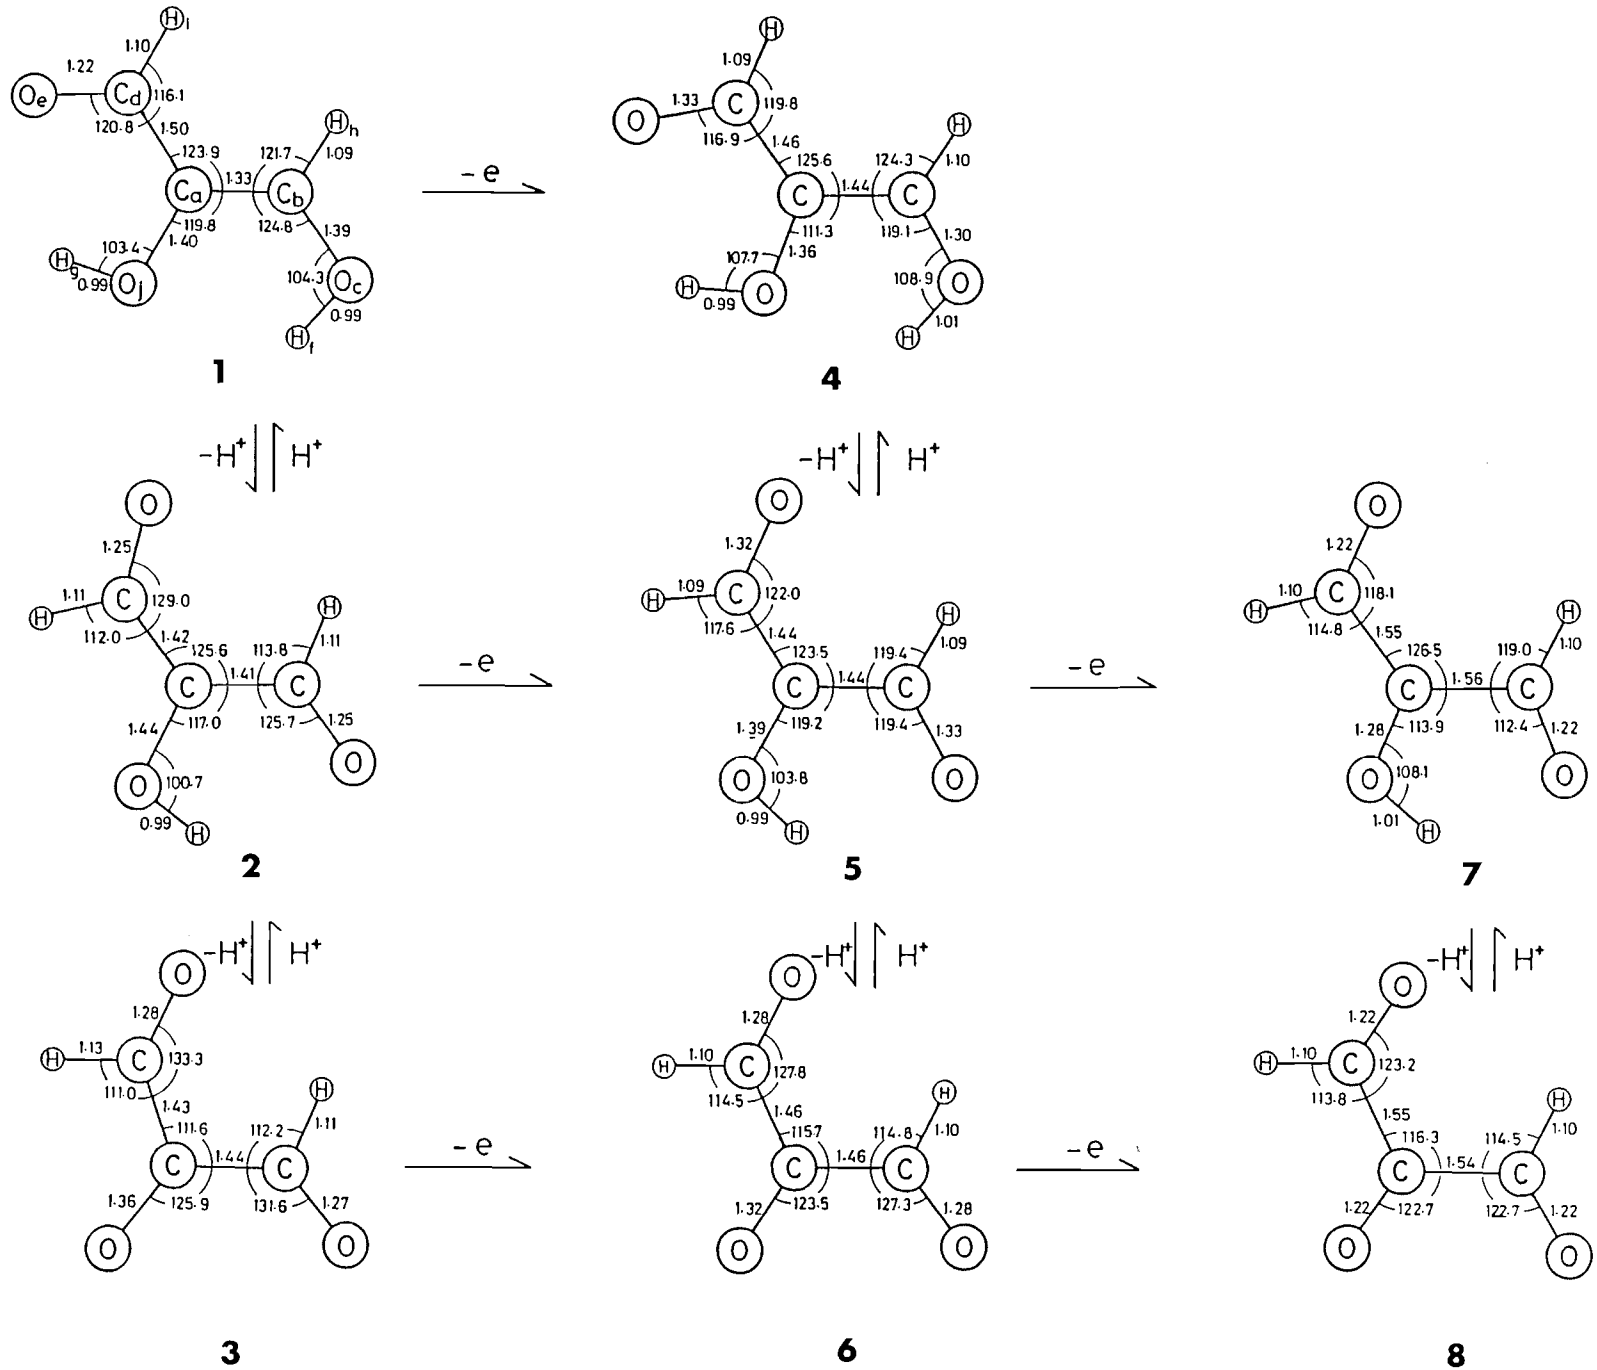

FIG. 3. Optimized geometries of the substrate, DR and transient species involved in the scheme of Fig. 1. All are calculated to be planar

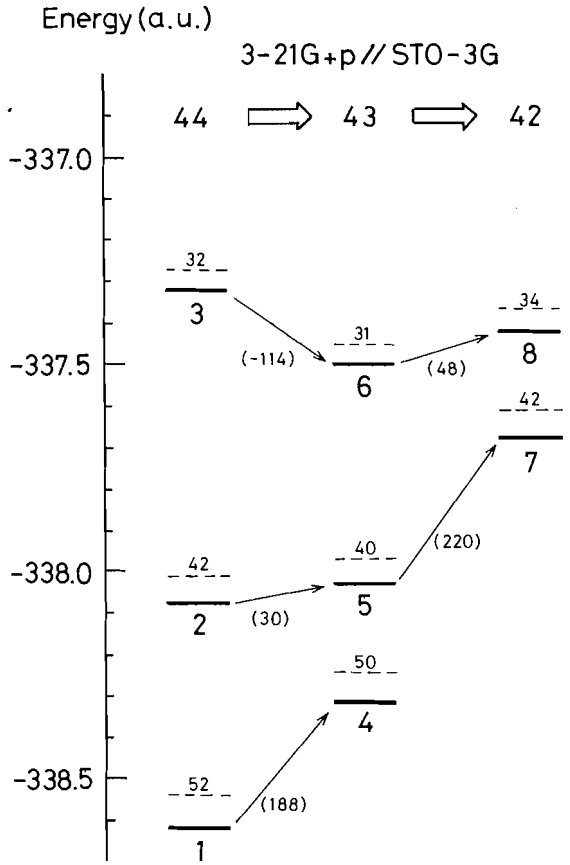

FIG. 4. The total electronic energies (bold lines) with the 3-21G+p basis set and zero-point vibration energies (broken lines with STO-3G, in kilocalories per mole relative to the bold lines) for eight species in Fig. 3. Values in parentheses denote the stabilizing (<0) and destabilizing (>0) energies in kcal/mol. From the left to the right, two electrons are lost (44 → 43 → 42).

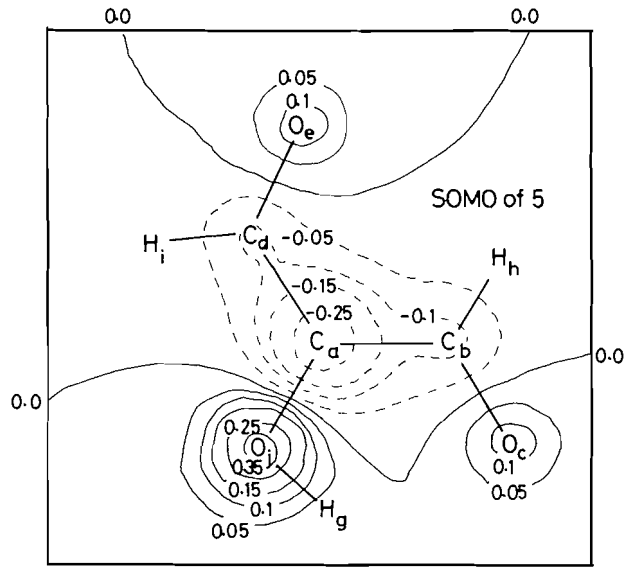

FIG. 5. Shape of the singly occupied molecular orbital (SOMO) of **5**. Contour lines are in Bohr$^{-3/2}$. When the sign of the lines is switched (broken line → full line and vice versa) along a covalent bond, SOMO is antibonding there. The cut plane for this density map is 1 Å above the molecular plane.

Next, the second oxidation **5** → **7** is considered. A large geometry distortion is caused by this electron loss. Two C—C bonds get the single bond character by **5** → **7**. The C_a—O_j—H_g site is the hydroxyl group in **5**, whereas it is the protonated carbonyl group in **7**. This change is shown by that of bond lengths (O—H = 0.99 → 1.01 Å and C—O = 1.39 → 1.28 Å). In the step **7** → **8**, the proton H_g^+ is removed and the molecular skeleton is kept almost constant during this deprotonation. The oxidized product **8** (DR) is a triketone in which the π conjugation is only about one third of that of **6**. In view of the process **1** → **2** → **5** → **7** → **8**, **1** → **2** and **5** → **7** involve significant geometric changes, i.e., the conversion of the C—C bond character and hydroxyl → protonated carbonyl.

Geometries of other species **3**, **4**, and **6** shown in Fig. 3 are discussed. Through the double deprotonation from **1**, **3** is formed. It is a conjugated π electron system. The presence of the dianion (R^{2-}) **3** was proposed by the uv spectra (2). The present vibrational analysis confirms the experimental result. After an electron removal from **3**, **6** is produced with a small geometric change. The anion radical **6** would be generated effectively by the deprotonation of **5** rather than by this oxidation of **3**. The difficulty of the latter route arises from the small concentration of **3** ($pK_{a(II)}$ = 13.0 of RH_2). The second π electron loss from **6** leads to **8** with a marked geometry variation.

The intermediates **4**, **5**, and **6** are all conjugated systems, because they are calculated to be planar. From them, π electrons are readily removed by oxidizing agents such as hexacyanoferrate(III). Radical species are detected both by pulse radiolysis (10, 12) and by esr (electron spin resonance) spectroscopy (13, 14). In the latter case, they are generated by the autoxidation of RH_2 with peroxidase catalyst. The present calculation confirms that odd-electron systems **5** and **6** are stable intermediates. We may therefore identify these as the esr measurable radical intermediates. In fact, the esr spectrum of **6** has been recorded by Yamazaki *et al.* (14).

IV. Discussion of the oxidation mechanism

From RH_2 to DR, various oxidation routes are illustrated in Fig. 1. Kinetic measurements have supported two routes **1** → **2** → **5** → **7** → **8** and **1** → **2** → **5** → **6** → **8** (5 > pH > 2). The electronic nature of molecules involved in the former is examined. In the step **1** → **2**, a proton removal raises the energy level of the highest occupied MO (HOMO). HOMO is of the π bond nature and an electron may be released readily in the step **2** → **5**. It is noted that this electron abstraction does not occur from the lone-pair (*n*) orbital on the O_c atom. Mobile π electrons in the conjugated system **2** are more easily removed. The radical species **5** is generated in the step **2** → **5**. The singly occupied MO (SOMO) is also a π orbital and its spatial extension is drawn in Fig. 5. An odd electron is delocalized over the molecular skeleton. At the C_b—C_a—C_d chain, it is bonding. In the second oxidation **5** → **7** (i.e., the loss of the SOMO electron), therefore, two C—C bonds are to be elongated. In fact, **7** has two C—C single bonds. SOMO is antibonding at three C—O bonds. This leads to their shortening for the second oxidation. In **7**, three C—O bonds attain the carbonyl character. Thus, the geometric change in **5** → **7** is understandable in terms of the nodal properties of SOMO. The loss of the SOMO electron naturally gives the geometry of the protonated triketone **7**. Once the protonated triketone **7** is produced, the proton H_g^+ may be removed in the aqueous solution. The hydration to the O_j—H_g bond causes the proton transfer, DRH^+ (**7**) + H_2O →

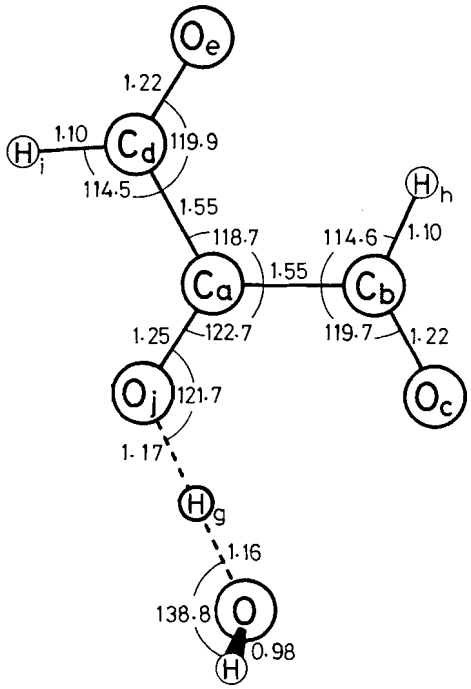

FIG. 6. The optimized structure of the protonated propantrione 7 (DRH^+)–water system. Through the hydrogen bond, the proton attached to DR may be moved readily to water.

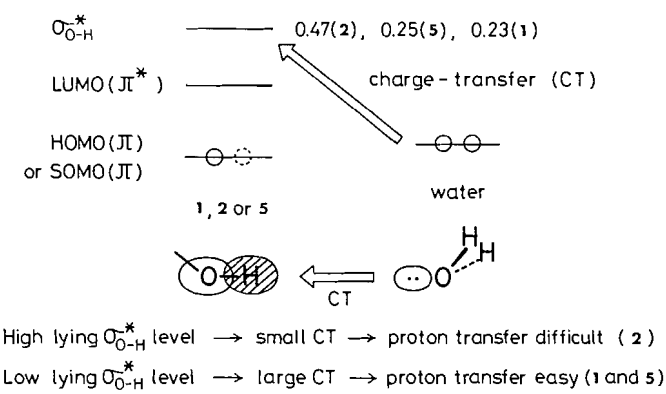
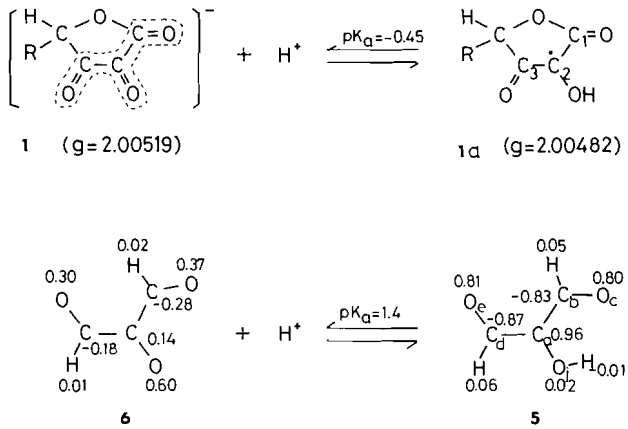
DR (**8**) + H_3O^+. A model of this hydrogen-bond system is tested. The optimized geometry of $DR\cdots H^+\cdots OH_2$ is obtained and is exhibited in Fig. 6. An almost symmetric hydrogen-bond (1.16 ≃ 1.17 Å) is calculated, through which the proton transfer would take place readily in aqueous media. This leads to the product DR **8**. Thus, the second π-electron loss and the proton transfer are combined to carry on the reaction. The former takes place out of the molecular plane, while the latter occurs in the plane. The same discussion holds for the reversible step of the proton transfer **5** ⇄ **6**. This belongs to the second important route **1** → **2** → **5** → **6** → **8**. The proton H_g of **5** is readily removed. The σ* (in-plane) vacant MO of **5** is O_j—H_g antibonding and low-lying. The hydration to H_g^+ leads smoothly to the production of **6**. While the deprotonation **2** → **3** is difficult, **5** → **6** is easy. The difference is ascribed to that of the σ* MO energy levels (0.47 au of **2** vs. 0.25 au of **5**, whereas 0.23 au of **1**). A comparison of total energies shown in Fig. 4 also shows the difficulty or the ease of deprotonation. The energy gap between **2** and **3** is larger than that between **5** and **6**. This difference indicates that **5** → **6** is easier than **2** → **3**.

Two possible routes are related to the fact that the radical **5** has two functional sites. If the in-plane proton transfer from **5**





occurs, the route **1** → **2** → **5** → **6** → **8** predominates. If the out-of-plane π electron loss takes place primarily, the route **1** → **2** → **5** → **7** → **8** is operative.

The role of the carbonyl C_d—O_e bond (see Fig. 2) is discussed. First, the hydration to this group enhances the solubility of RH_2. Second, electronically this group is important to elongate the conjugate chain. In fact, it has a semi-single bond character (= 1.32 Å) in **5**. Thus, for the easier oxidation of the enediol group, the role of the carbonyl adjacent to it is indispensable.

V. The oxidation of L-ascorbic acid

The oxidation scheme of RH_2 seems to be applicable to that of L-ascorbic acid. According to the neutron-diffraction data (15), its five-membered ring is almost planar. Radical intermediates in the oxidation of the acid were reported by the radiolysis–esr study (16). This work has shown that the radical anion is produced by the oxidation in neutral and basic solutions and its odd electron is spread over a highly conjugated tricarbonyl system. The protonation to the C_2 position was assumed. In the present computational study, the assumption is shown to be valid, as far as the RH_2 – Vitamin C analogy is applicable. The figure of the protonation of the ascorbate radical is taken from the literature (16). In the equilibrium **6** ⇄ **5**, the spin densities calculated with 3-21G+p are exhibited. In both species, spin polarization takes place. In particular, the localization of the spin density of C_2 of $\mathbf{I}_a$ is well reproduced by the large density (0.96) on the C_a atom of **5**.

In view of the present result and the well-documented presence of the ascorbate radical, the oxidation mechanism of L-ascorbic acid may be deduced as shown in Fig. 7. The five-membered ring seems to increase the stability of the intermediate radical. Aside from this and the dependence of the kinetics on the pH, there weould be no reason to distinguish the oxidation mechanism of RH_2 from that of L-ascorbic acid.

VI. Concluding remarks

Although the solvent effect is not included, the oxidation process of triose reductone is clarified theoretically with the aid of kinetic information. The mehanism is partitioned into four steps, **1** → **2**, **2** → **5**, **5** → **7**, and **7** → **8**. After a proton is removed from the substrate through electrolytic dissociation equilibrium, two π electrons (not *n* electrons) are removed in a stepwise manner. At the second oxidation, the hydroxyl group is converted to the protonated ketone, followed by the proton transfer. An alternative route **1** → **2** → **5** → **6** → **8** is competitive with this route, because the radical intermediate **5** has two functional sites.

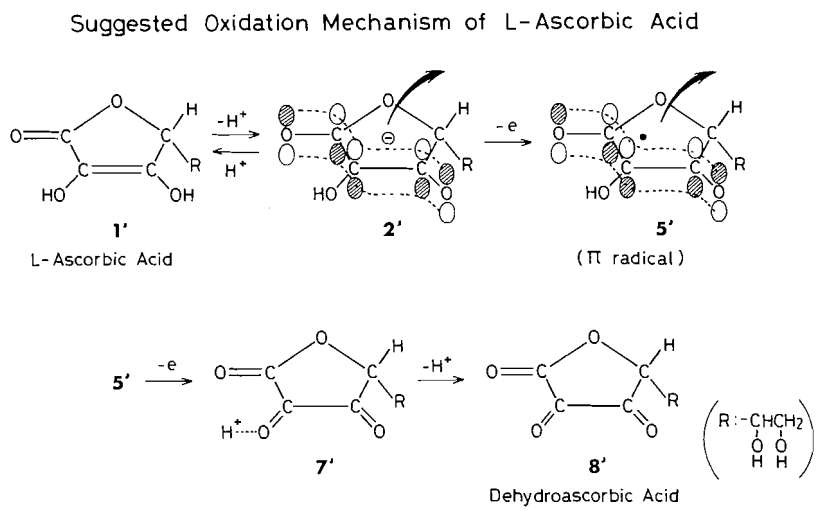


FIG. 7. Suggested oxidation mechanism of L-ascorbic acid (Vitamin C). The alternative route **1'** → **2'** → **5'** → **6'** → **8'** is omitted in the figure for simplicity.

Reviewing these results, we may answer four questions presented in the Introduction.

(1) In the equilibrium $RH_2 \rightleftarrows RH^- + H^+$, the leaving proton is H_f^+. The deprotonation from the right-side hydroxyl group in **1** is needed to elongate the π conjugated chain.

(2) In any oxidation step in Fig. 1, π electrons are taken off. The important intermediates **2**, **5**, and **6** have mobile π electrons which are readily removed.

(3) Deprotonation occurs through the hydrogen bond between the substrate and a water molecule. Deprotonation raises the HOMO energy levels for the easier oxidation. The in-plane proton transfer and the π electron loss work cooperatively.

(4) All the intermediate species suggested in Fig. 1 are found to be stable, according to the STO-3G optimization and vibrational analysis.

Conventional and saturation transfer (electron spin resonance) techniques are used to study the motional properties of several spin labels introduced in three proteins: lysozyme, sperm whale myoglobin and human hemoglobin. The mobilities of a maleimide spin label which binds covalently to the proteins, as well as of two small probes TEMPO and PD-TEMPOL were monitored in the temperature range from -10 to -150°C for samples in the dry and solution states. The three proteins show a similar temperature dependence as indicated by the parameters $2A_{zz}$ and ΔH. A small linear increase in $2A_{zz}$ with decrease in temperature is observed for the dry samples. For the proteins in solution, on the other hand, the $2A_{zz}$ temperature dependence shows a change of behaviour around -60°C that is related to the freezing of the water molecules in the hydration shell. The changes observed for the parameter ΔH are such that at temperatures below -60°C ΔH is greater for the solution sample, while at temperatures above -60°C ΔH is greater for the dry sample. Saturation transfer measurements show that the motion of the spin label is very restricted in all systems ($\tau_c > 10^{-5}$s) in the temperature range studied, so that the residual librational motion of the label is sensitive to the hydration, being responsible for the observed changes of the esr parameters with temperature.

J. RUGGIERO, R. SANCHES, M. TABAK et O. R. NASCIMENTO. Can. J. Chem. **64**, 366 (1986).

Faisant appel aux techniques de la rpe (résonance paramagnétique électronique) par transfert conventionnel et par transfert de saturation, on étudie le mouvement des marqueurs de spin introduits dans trois protéines, soit la lysozyme, la myoglobine du sperme de la baleine et l'hémoglobine humaine. Dans un intervalle de température allant de -10 à -150°C et opérant sur des échantillons secs ou en solution, on a mesuré les mobilités du marqueur de spin de la maléimide, qui se lie par covalence aux protéines, ainsi que les mobilités de deux petites sondes, TEMPO et PD-TEMPOL. En se basant sur les paramètres $2A_{zz}$ et sur le ΔH, on peut en déduire que les trois protéines subissent l'effet de la température de la même façon. Dans le cas des échantillons secs, on observe une faible augmentation linéaire du paramètre $2A_{zz}$ lorsque la température diminue. D'autre part, dans le cas des protéines en solution, l'effet de la température sur le paramètre $2A_{zz}$ change aux environs de -60°C et ceci qui correspond au point de congélation des molécules d'eau dans la sphère d'hydratation. Les changements observés sont tels qu'à des températures inférieures à -60°C, le ΔH de l'échantillon en solution est plus élevé tandis qu'au dessus de -60°C le ΔH de l'échantillon sec est plus élevé. Les mesures de rpe par transfert de saturation indiquent que dans l'intervalle de température étudié, le mouvement du marqueur de spin est très restreint dans tous les systèmes ($\tau_c > 10^{-5}$s). Par conséquent, le mouvement résiduel de libration du marqueur est sensible à l'hydratation et est responsable des changements des paramètres de la rpe en fonction de la température.

Introduction

The hydration of biomolecules has been studied by several techniques such as calorimetry, absorption isotherms, infrared spectroscopy, nuclear magnetic relaxation (1,2), thermal stimulated depolarization (3), and computer simulation (4,5). Large discrepancies are observed when results obtained from different methods are compared. This is expected if one considers that different physical properties are probed in each case. Despite this difficulty in correlating new information with the known data, the hydration of macromolecules is an interesting subject for further studies.

The use of esr measurements to study the hydration of proteins was first proposed by Rupley *et al.* (6). They suggested that significant changes in the motional properties of a spin label (TEMPONE)[3] could be followed as a function of the sample hydration and interpreted as changes in the internal dynamics of the protein. The exclusion of possible structural changes induced in the protein by dehydration was crucial in the interpretation of these results. The absence of such structural changes was also suggested by Raman (7), infrared reflectance (8), and photoacoustic (9) spectroscopic studies.

The spin label motion as a function of temperature of hemoglobin–MAL-6 samples in the dry and solution states was studied by Johnson (10). For the lyophilized sample he observed spectral changes that were related to the librational motion of the spin label. A hydrogen bonding of the spin label to the protein or to a water molecule was the explanation given for the spectral changes observed for the solution sample.

These studies led us to consider the relevance of the spin label used and also the influence of the protein studied on the results obtained as a function of hydration. We propose to describe in this communication the esr studies in the dry and solution states of three different proteins: lysozyme, myoglobin, and hemoglobin using the spin labels: MAL-6, TEMPO, and PD-TEMPOL, as a function of temperature.

Experimental

Sample preparation

Hemoglobin solution was obtained from whole blood from healthy donors. The red blood cells were washed three times in phosphate buffered saline (135 m*M* NaCl, 5 m*M* phosphate, pH 7.4) and

[2]Revision received September 13, 1985.

[3]Abbreviations: TEMPONE: 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl; MAL-6: 4-maleimido-2,2,6,6-tetramethylpiperidine-1-oxyl; TEMPO: 2,2,6,6-tetramethylpiperidine-1-oxyl; PD-TEMPOL: 4-hydroxy-d_{17}-2,2,6,6-tetramethylpiperidine-1-oxyl; esr: electron spin resonance; st-esr: saturation transfer electron spin resonance.

hemolysis was achieved by dilution of equal volumes of packed cells and distilled water. The hemolyzed cells were centrifuged for 40 min at 20 000 rpm (Sorvall RC-5B refrigerated centrifuge) at 4°C, and the supernatant hemoglobin solution was maintained, discarding the pelleted membranes. The hemolyzate was then filtered in a Sephadex G-25 column (11) avoiding substantial dilution. This hemoglobin solution was used in our studies. Solutions of sperm whale myoglobin and egg-white lysozyme were obtained by dissolving the lyophilized commercial material (Sigma Chemical Co.) in phosphate buffer 0.05 *M*, pH 7.0 so that the protein concentration was approximately 10%. After dilution a centrifugation step was used to remove unsoluble material from the solution.

Spin labeling of the proteins

Hemoglobin solution was spin labeled with 2,2,6,6-tetramethylpiperidino-1-oxyl (TEMPO, Aldrich Chem. Co.) and 4-hydroxy-2,2,6,6-perdeuterotetramethylpiperidine-1-oxyl (PD-TEMPOL Merck Co.) in the following way: an aliquot of a stock solution of the label (approximately 10 m*M*) was introduced into the bottom of a test tube and dried under a N_2 flux. Then the hemoglobin solution was added on top in such volume as to make the final spin-label concentration 2×10^{-4} *M* for PD-TEMPOL and 5×10^{-4} *M* for TEMPO. In the case of the reaction of myoglobin and lysozyme with 4-maleimido-2,2,-6,6-tetramethylpiperidino-1-oxyl (MAL-6, Aldrich Chem. Co.) the procedure was similar: an aliquot of a stock solution of MAL-6 in acetone was introduced into the bottom of a test tube and dried under N_2. Then the protein solution was added in such a way as to make the following proportions: MAL-6/myoglobin 1:1 and MAL-6/lysozyme 1:1. The reaction mixture was left in the refrigerator at 4°C for 38 h. The excess spin label was removed by filtration of the reaction mixture in a small Sephadex G-25 column. All the labeled samples were lyophilized and dried over P_2O_5 in order to obtain the dry samples. In some experiments the sample was then exposed to a known water vapour pressure in a saturated salt solution container. The solution sample was used after the Sephadex G-25 filtration step.

Electron spin resonance measurements

Conventional esr and st-esr spectra were obtained using a Varian E-109 X-band spectrometer (9.14 GHz) equipped with a rectangular cavity E-248 and the temperature control accessory E-257. The temperature was monitored by a copper–constantan thermocouple attached to a Fluck potentiometer. The microwave power used was 2 mW and modulation amplitude 1.0 G. The st-esr spectra were obtained as the second harmonic out-of-phase signal. The self-null method was used in the adjustment of phase (12) with the sample in the cavity, modulation amplitude 5.0 G and 1-mW microwave power. After this adjustment the power was increased to 64 mW (measurements were also made at 30 mW at lower temperatures) and the second harmonic out-of-phase signal recorded. In the case of hemoglobin spin labeled with TEMPO or PD-TEMPOL, adjustments of phase were also made at the 0.1-mW power level, as at the lowest temperatures the sample is more readily saturated. The analysis of the st-esr spectra was made by comparison of the experimental spectra parameters L″/L and C′/C with calibrations obtained by Thomas (12).

Results and discussion

Covalent spin labels

In Fig. 1 the conventional esr spectra of spin labeled myoglobin are presented for different temperatures. In Fig. 1(a) the spectra were obtained for the solution sample while Fig. 1(b) is for the dry sample. The parameters used in our analysis are $2A_{zz}$, the splitting between the outer hyperfine lines, and ΔH, the linewidth at half height of the low field line. The spectra obtained with spin labeled lysozyme, in the temperature range -10 to -150°C, are similar to those of myoglobin, so that the spectra in Fig. 1 are characteristic of the two proteins. A careful inspection of the spectra shows clearly an increase in ΔH and $2A_{zz}$ as the temperature is lowered.

In Fig. 2(a) the parameter $2A_{zz}$ from the esr spectra is plotted

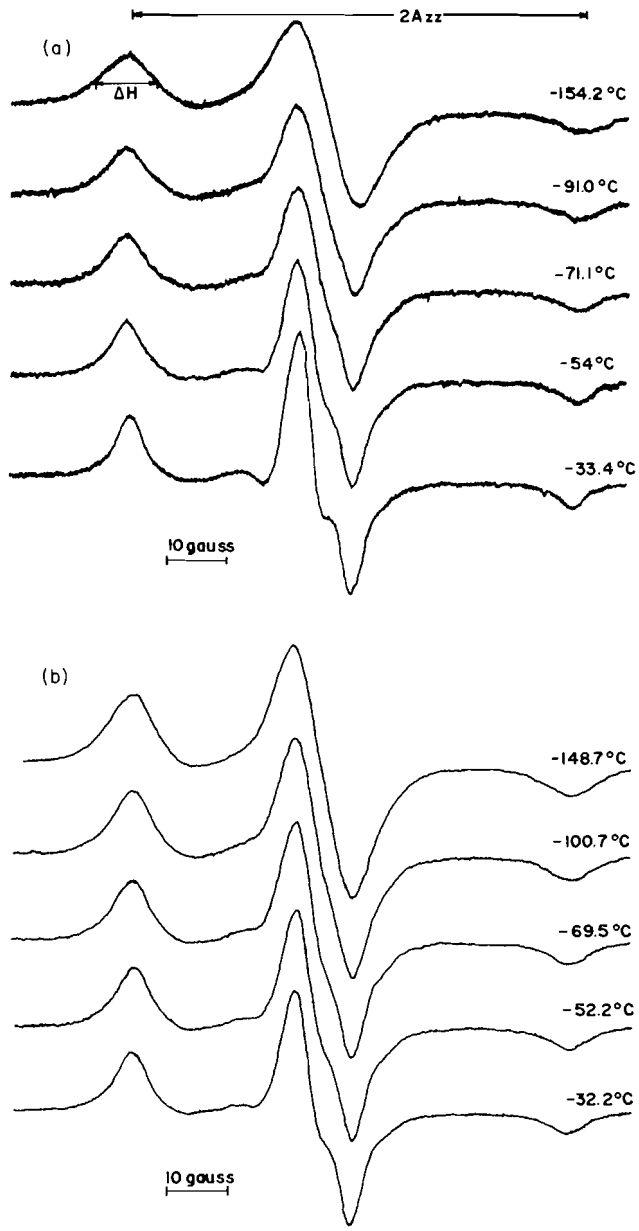

FIG. 1. (a) Conventional esr spectra of myoglobin–MAL-6 aqueous solution. The temperature is indicated in the spectrum as well as the esr parameters $2A_{zz}$ and ΔH. (b) Conventional esr spectra of myoglobin–MAL-6 dry powder sample. The temperature is indicated in the spectrum.

as a function of temperature for lyophilized and aqueous solution of myoglobin–MAL-6. For both samples a decrease is observed in $2A_{zz}$ with an increase in temperature, with the dry sample having a lower $2A_{zz}$ value over almost the whole temperature range studied. For the dry sample a single straight line could be fitted to the data as shown in Fig. 2(a). On the other hand, two straight lines were fitted to the data for the solution sample, one for temperatures below -60°C and another above this value. It is interesting to note that for the low temperature region the behavior of the two samples is similar, i.e., the straight lines fitted to the data are practically parallel, indicating that the rate of change of $2A_{zz}$ is the same. Above -60°C there is a faster decrease in $2A_{zz}$ for the solution sample, so that above ca. -10°C the value for the solution is smaller than the value for the dry sample.

In Fig. 2(b) the plot of the temperature dependence of the

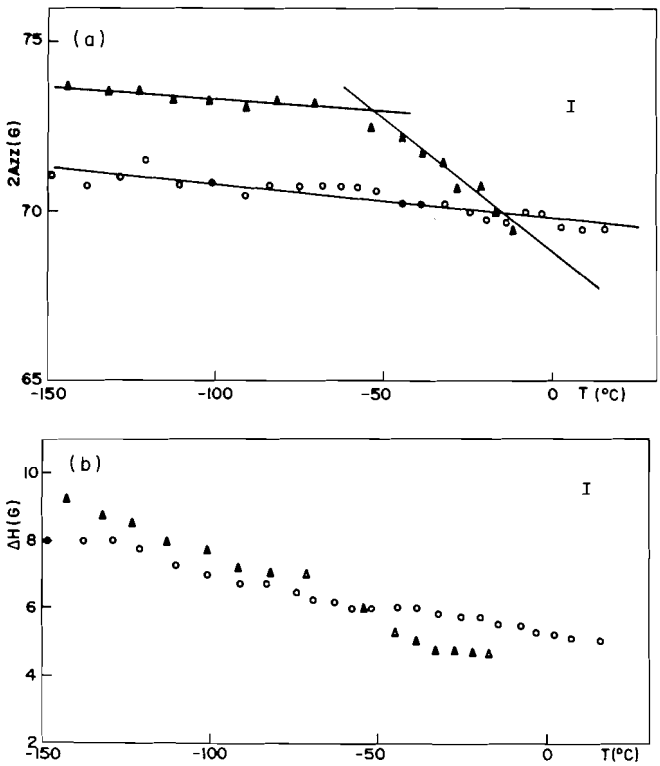

FIG. 2. (a) The parameter $2A_{zz}$ as a function of temperature for myoglobin–MAL-6 samples. The straight lines are least-square fits to the experimental points. Key: (Δ) aqueous solution; (o) lyophilized sample (water content: 0.12 g H_2O/g myoglobin). The error in the measurement above −100°C is 0.3 G; below −100°C it is increased to 0.5 G due to the broadening which introduces additional error especially in the high field. The bars in the figure correspond to the errors indicated above. (b) The linewidth of the low field line as a function of temperature for myoglobin–MAL-6 samples. Key: (Δ) aqueous solution; (o) lyophilized sample (water content: 0.12 g H_2O/g myoglobin). The error in ΔH is the same as in Fig. 2(a).

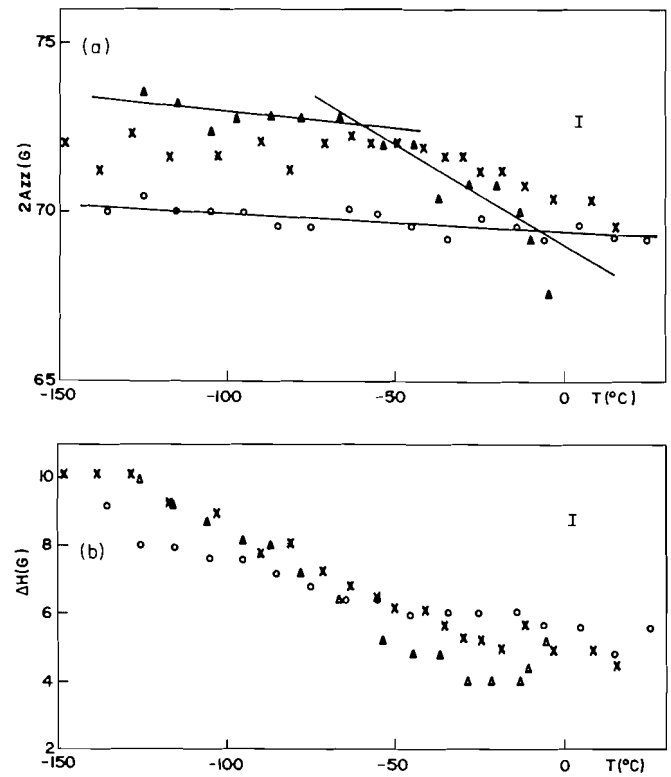

FIG. 3. (a) The parameter $2A_{zz}$ as a function of temperature for lysozyme–MAL-6 samples. The straight lines are least-square fits to the experimental points. Key: (Δ) aqueous solution; (o) lyophilized sample (water content: 0.07 g H_2O/g lysozyme); (x) intermediate water content sample (0.45 g H_2O/g lysozyme). The error is the same as in Fig. 2(a). (b) The linewidth of the low field line as a function of temperature for lysozyme–MAL-6 samples. Key: (Δ) aqueous solution; (o) lyophilized sample (water content: 0.07 g H_2O/g lysozyme); (x) intermediate water content (0.45 g H_2O/g lysozyme). The error is the same as in Fig. 2(a).

linewidth of the low field line is shown for the two samples of spin labeled myoglobin. A general decrease of ΔH is observed with an increase in temperature. In this case a different behavior can be noticed for the dry and solution samples below and above ca. −60°C. At lower temperatures (below −60°C) the linewidth for the dry sample is less than for the solution sample, while at temperatures above −60°C the linewidth for the solution sample is less than that for the dry sample. The variation of linewidth for the dry sample over the whole temperature range ($\Delta(\Delta H)$=3 G) is less than that for the solution sample ($\Delta(\Delta H)$ = 5 G). The error of the ΔH measurement is estimated to be 0.4 G.

In Figs. 3(a) and 3(b), respectively, the parameters $2A_{zz}$ and ΔH are presented as a function of temperature for lysozyme–MAL-6 with different water contents. The behavior of these parameters described for myoglobin is also valid in this case. The variation of $2A_{zz}$ for the dry sample is very small, while for the solution sample it is considerable. Again, for the dry sample a unique rate of decrease of $2A_{zz}$ with temperature is observed, while the solution sample shows this same rate below −60°C and a faster rate above −60°C. Over the whole temperature range, the variation of ΔH for the solution is greater than that for the dry sample. The two curves cross near −60°C, so that below this temperature the value for the solution is larger while above this temperature the value for the dry sample is larger. The experiment with lysozyme with an intermediate water content (0.45 g H_2O/g protein) resulted in a $2A_{zz}$ plot lying between the data for the dry and solution samples (Fig. 3(a)). Below ca. −45°C a straight line could be fitted to the data and it is parallel to the one fitted to the lyophilized sample data. Above ca. −45°C another straight line could be fitted to the data, with a slope between those obtained for the dry and solution samples. As shown in Fig. 3(b), −45°C is also the temperature at which the ΔH data obtained for this intermediate water content sample and for the lyophilized sample intersect.

The changes observed for the parameters $2A_{zz}$ and ΔH with temperature suggest that the spin label used is undergoing changes in motional properties (13,14). In order to verify this proposition the saturation transfer technique was used. In Fig. 4 the st-esr spectra obtained for myoglobin samples at different temperatures are shown. Fig. 4(a) is for the solution sample, while Fig. 4(b) is for the dry one. The parameters obtained from these spectra are L″/L and C′/C. They have different sensitivities to slow motion; L″/L is the most sensitive and for this reason was the parameter of our choice. The values of L″/L obtained for several samples studied in this work are presented in Table 1. Comparison of these values with the calibration curves of Thomas (16) shows that below −10°C the correlation times are greater than 10^{-5} s. The direct comparison of the lineshapes of our st-esr spectra with those reported in the literature (15,16) also shows that in our case the labels are very immobilized. In this way, st-esr indicates that the label is very

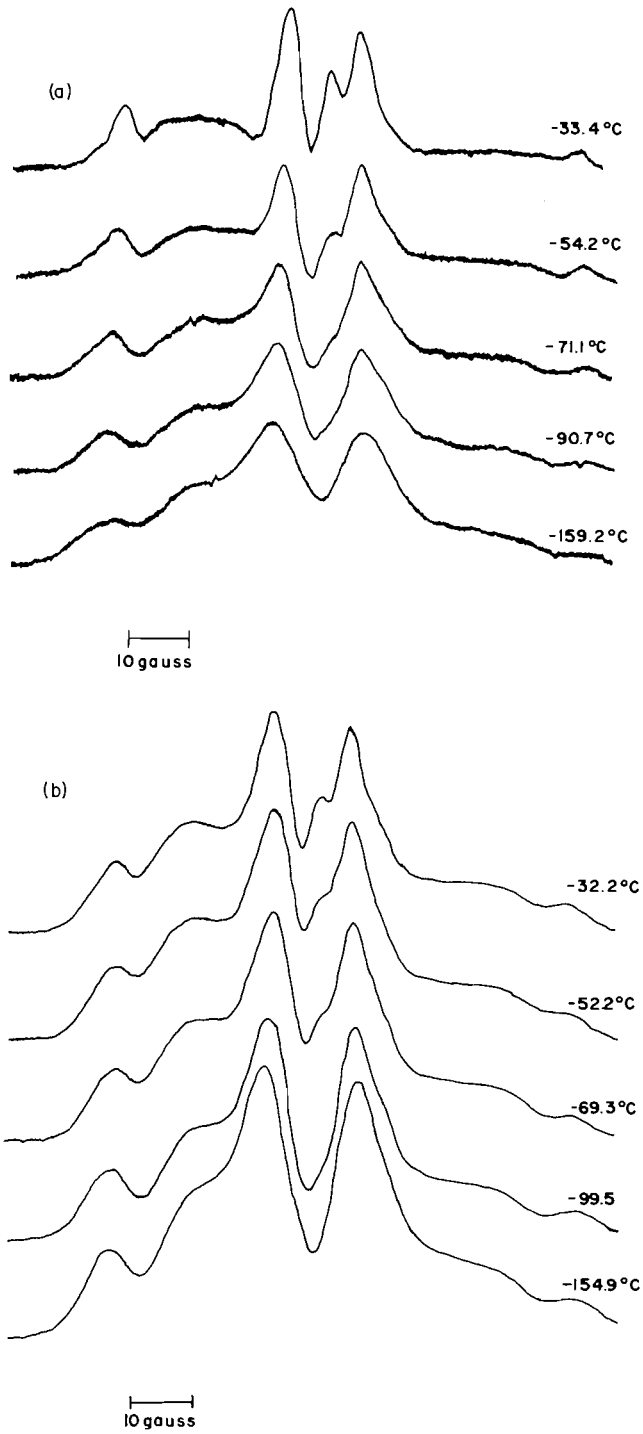

FIG. 4. (a) The st-esr spectra of myoglobin–MAL-6 aqueous solution. The temperature is indicated in the spectrum. The st-esr parameters measured are also indicated. (b) The st-esr spectra of myoglobin–MAL-6 dry powder sample at different temperatures.

immobilized so that the changes in $2A_{zz}$ and ΔH are not due to motional changes of the label.

The dependence of $2A_{zz}$ with temperature for the lyophilized samples can be interpreted in terms of the librational motion of the spin label, as proposed by Johnson (10). This model is based on the fluctuations of the $\diagdown$N—O$\diagup$ bond orientation with respect to the C—N—C plane of the nitroxide ring, which could produce torsional motion of the ring. This effect produces a temperature-dependent hyperfine separation of the form

$$2A_{zz}(T) = A^0_{zz}\,(1 + \cos\theta)$$

where $\theta = (RT/E_A)^{1/2}$, θ being the half angle of oscillation, E_A the torsional energy barrier, and $2A^0_{zz}$ the separation in absence of motion. For small oscillations it gives a linear dependence of $2A_{zz}$ with the temperature. This model was used to fit the experimental data for MAL-6 spin labeled lyophilized hemoglobin (10). For our lyophilized samples we observed this linear behavior over the whole temperature range studied. The solution samples at low temperatures also have this $2A_{zz}$ dependence, indicating that in the frozen solution the presence of the water does not affect the spin label motion. Its presence, however, increases the local polarity of the medium, causing an increase in the spin density on the nitrogen in the $\diagdown$N—O$\diagup$ group of the spin label, leading to an increase in $2A_{zz}$. The behavior of $2A_{zz}$ for the solution sample above -60°C can be explained as due to the thawing of the water of hydration, which will presumably facilitate the motion of the label. In the case of the lysozyme sample with intermediate hydration we found that the change in slope for the $2A_{zz}$ vs. T plot takes place at a higher temperature (-45°C) and the slope of this curve is less than that for the solution sample; in this way this temperature of slope change and the slope at this region are probably strongly dependent on the hydration of the protein. In the solution sample, as the temperature is raised above -10°C the free water also thaws and the spectra become typical of solutions. Therefore, below -10°C the same model, i.e., librational motion of the spin label, can be used for the dry and solution samples. Johnson (10) explained the dependence of $2A_{zz}$ upon temperature for hemoglobin–MAL solutions as due to the formation of a hydrogen bond between $\diagdown$N=O$\diagup$ group of the spin label and a proton that could be either in the protein (near the binding site of the label) or in a water molecule. The plots of the parameter $2A_{zz}$ as a function of temperature obtained for the proteins studied in the present work are similar to those described in ref. 10. The change of slope in the $2A_{zz}$ temperature dependence for the hemoglobin–MAL-6 solution sample in this reference also takes place around -60 to -70°C. This general behavior of $2A_{zz}$ suggests that the hydrogen bond is probably not due to the specific site of attachment of the label in the protein, as it is common to all three proteins, but that it involves a water molecule.

At a temperature near the transition between the first and second regions for $2A_{zz}$, considerable changes in ΔH are observed. Near -60°C the dependence of ΔH for the dry and solution samples cross one another so that at temperatures below -60°C ΔH is greater for the solution sample, while at temperatures above -60°C ΔH is greater for the dry sample. The increase in linewidth with a decrease in temperature comes from the inhomogeneous broadening due to the methyl protons of the spin label and the protons of water molecules near the label. Below -60°C the water in the solution sample is frozen and there is electron-nuclear interaction with the water protons and with the spin label methyl protons. For the dry sample, the interaction is mostly with the methyl protons since very few water molecules are present, hence the lower value of ΔH obtained. Above -60°C the water of hydration in the solution

*From ref. 12 a value of L″/L of 0.98 corresponds to correlation times in the range 10^{-4} – 10^{-3} s; C′/C of 0.33 corresponds to correlation times in the range 10^{-5} – 10^{-4} s.

samples thaws, allowing the methyl groups and the water molecules to move more freely. This motion makes the electron-nuclear interaction less effective, and results in a smaller ΔH if compared to the value for the dry sample, where the methyl proton interaction is still effective. The temperature of −60°C, as noted above, also corresponds to the change in slope for $2A_{zz}$ vs. T plot. It is interesting that the linewidth changes described above can be observed directly from the esr spectra (Fig. 1): in the temperature range below −60°C, ΔH is increased in the solution sample to a greater extent than in the dry sample; the opposite occurs above −60°C. It is noticed that an improved resolution is obtained above −60°C for the solution sample in the central part of the esr spectra, consistent with the decrease in linewidth. Finally, it should be noted that the characteristic temperature for the lysozyme sample with intermediate hydration is the same both in the $2A_{zz}$ vs. T and ΔH vs. T plots (−45°C).

Noncovalent small spin probes

Since the results obtained with MAL-6 spin labeled samples suggest a general behavior of $2A_{zz}$ and ΔH for all proteins studied, an attempt was made to monitor the hydration of the samples with small noncovalent spin probes: human hemoglobin was labeled with two different small spin labels, TEMPO and PD-TEMPOL. In this second label the piperidine ring has deuterium instead of hydrogen, decreasing the inhomogeneuous broadening due to the electron-nuclear interaction. In Fig. 5(a) the parameter $2A_{zz}$ is presented for the spin labels TEMPO and PD-TEMPOL dissolved in hemoglobin solution and as dry powder samples. It can be seen that in the dry samples $2A_{zz}$ changes are quite small: a slight increase with lowering of the temperature is observed. The hemoglobin solution samples show a greater change of $2A_{zz}$ versus T: the slope of the curve becomes greater above ca. −60°C, and at low temperatures (below −60°C) the slope is similar to that in the dry sample. In fact, for PD-TEMPOL the slopes are the same. In this case, as the lines are relatively narrow and well resolved, $2A_{zz}$ is measured with good accuracy (0.2 G). In the case of TEMPO the lines are broader and the accuracy of measurement is not as good (around 0.4 G). For this reason the slopes are not exactly the same for this label. This behavior of $2A_{zz}$ vs. T is analogous to that obtained with the covalently labeled proteins. For the solution samples, again, a change of slope takes place around −60°C. On the other hand, the changes for the dry samples are quite small and linear over the whole temperature range. In Fig. 5(b) the linewidth ΔH for the samples described above is plotted as a function of temperature: it is clear that ΔH is much less for PD-TEMPOL than for TEMPO. As noted previously in the case of PD-TEMPOL, the inhomogenous broadening due to the protons in the piperidine ring is eliminated. This accounts for the difference of about 2 G in ΔH for TEMPO and PD-TEMPOL. The behavior of ΔH with temperature shows a very slight change over the whole temperature range. Furthermore, the differences in ΔH between the dry and solution samples are within experimental error. This result is different from that with the covalent spin label, where the changes in ΔH, although small, are significant. Perhaps this is related to the fact that the covalent label is tightly bound to the protein, while the small spin probes do not interact with the protein that remains dissolved in the solution (or powder). For this reason the linewidths for TEMPO and PD-TEMPOL represent a static distribution of orientations, which is the same both in the powder and in the frozen solution. The presence of water affects only the polarity of the label, making $2A_{zz}$ greater in the solution samples. In the case of the covalent label attached to the protein the linewidth is also affected by the restrictions imposed by the protein matrix. In this case the values of ΔH are not only given by a static distribution but also depend on the local state of the protein, which is a function of hydration. In this way the changes observed around −60°C can be correlated with the thawing of hydration water above this temperature: this will allow an increase in motion in the microenvironment of the spin label and a narrowing of the esr lines will take place for the solution sample (above −60°C, ΔH for the solution is smaller

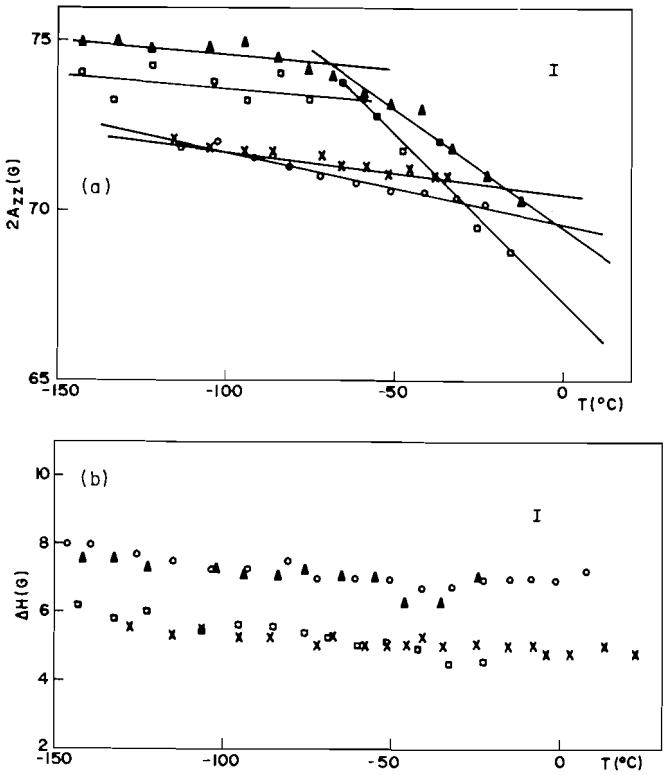

FIG. 5. (a) The parameter $2A_{zz}$ as a function of temperature for hemoglobin samples spin labeled with the small probes: TEMPO (Δ) aqueous solution and (o) dry powder sample (0.12 g H_2O/g hemoglobin), and PD-TEMPOL (o) aqueous solution and (x) dry powder sample (0.12 g H_2O/g hemoglobin). The error in the case of TEMPO is the same as in Fig. 2(a). For PD-TEMPOL it is reduced to 0.2 G due to the narrowing of the lines. (b) The linewidth of the low field as a function of temperature for hemoglobin samples. Key: (o) lyophilized hemoglobin–TEMPO (water content: 0.12 g H_2O/g hemoglobin; (Δ) hemoglobin–TEMPO aqueous solution; (x) lyophilized hemoglobin–PD-TEMPOL (water content: 0.12 g H_2O/g hemoglobin; (□) hemoglobin-PD-TEMPOL aqueous solution.

than ΔH for the dry sample). This would explain the ΔH changes for the covalent label. The $2A_{zz}$ changes are similar for all the labels used, as they reflect the polarity of the microenvironment. It is worth mentioning the results in refs. 17 and 18 on the dynamics of myoglobin at low temperature. These authors show that the mean-square displacements for most residues $\langle x^2 \rangle$ as a function of temperature show a discontinuity around 220 K (−53°C). It is suggested that these changes in the protein structure are correlated to the state of water in the protein. Studies of the absorption of microwaves in crystals of Met Mb also show a gradual thawing of water upon heating above −53°C (19). These results are in agreement with our data showing that a structural change takes place near −60°C.

Conclusions

Our conclusions can be summarized as follows.

(1) The behavior of the parameter $2A_{zz}$ with temperature is the same for the three proteins studied, hemoglobin, myoglobin, and lysozyme, as observed with the different spin labels, MAL-6, TEMPO, and PD-TEMPOL. This behavior must probably be common to all proteins and we believe reflects the sensitivity of the spin label to the polarity of its microenvironment.

(2) The lyophilized samples show a small linear increase in $2A_{zz}$ with decrease in temperature. Again, this is a feature common to proteins and spin labels used in this work. A restriction of the spin label librational motion could be responsible for this effect, as proposed by Johnson (10), although other possibilities are not excluded.

(3) The behavior of the protein in solution for temperatures below ca. −60°C is similar to the lyophilized protein ($2A_{zz}$ versus T). At this temperature the water present is already frozen and its presence does not affect the spin label motion. However, it changes the polarity of the medium and this explains the larger value of $2A_{zz}$ observed for the solution sample compared to the lyophilized sample. As the temperature is increased above −60°C the water of hydration starts to thaw. This facilitates the spin label motion and a larger rate of change of $2A_{zz}$ with temperature is observed. Around −10°C the thawing of the bulk water causes another change in the $2A_{zz}$ behavior.

(4) In the case of the parameter ΔH it is necessary to analyze separately the covalent spin label and the small probes. For the covalent maleimide label, the dependence of ΔH upon temperature also shows −60°C as a characteristic temperature. Below −60°C the sample in solution has a larger ΔH value than the lyophilized sample, while above −60°C the inverse is true. This can be interpreted as due to a motional narrowing effect in the solution sample due to the thawing of hydration water.

(5) The small probes TEMPO and PD-TEMPOL do not show differences in the behaviour of ΔH for solution and dry samples. This is explained as due to a similar static distribution of label orientations in both samples. As expected, the linewidth ΔH for the deuterated label PD-TEMPOL is 2 G less than ΔH for TEMPO. This is due to the elimination of inhomogenous broadening in PD-TEMPOL.

(6) The spectral changes observed as a function of temperature suggest that the parameter $2A_{zz}$ is quite sensitive to the hydration state of the sample. Since the sensitivity of ΔH depends on the spin label used and since its variation is small, it might be interesting to study in more detail the $2A_{zz}$ vs. T dependence as a function of protein hydration.

(7) Electron spin resonance measurements, as proposed by Rupley *et al.* (6) can be another method used to study protein hydration.

Received May 24, 1985

GREGORY A. BANTA, BRENDA M. LOUIE, EMMANUAL ONYIRIUKA, STEVEN J. RETTIG, and ALAN STORR. Can. J. Chem. **64**, 373 (1986).

The reactions of the $LMo(CO)_3^-$ ions (L = $MeGapz_3$, $HBpz_3$, $Me_2Gapz(OCH_2CH_2NMe_2)$) with $[Cu(PPh_3)Cl]_4$ and $Rh(PPh_3)_3Cl$ have yielded complexes with Mo—Cu and Mo—Rh bonds. The X-ray crystal structures of two such complexes have been determined. Crystals of $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$ are monoclinic, a = 17.071(2), b = 16.738(1), c = 23.641(3) Å, β = 104.899(6)°, Z = 8, space group $P2_1/n$, and those of $[MeGapz_3]Mo(CO)_3Rh(PPh_3)_2$, are triclinic, a = 12.519(3), b = 17.182(4), c = 12.071(2) Å, α = 105.02(1), β = 109.87(1), γ = 97.10(2)°, Z = 2, space group $P\bar{1}$. Both structures were solved by conventional heavy atom methods and were refined by full-matrix least-squares procedures to R = 0.040 and R_w = 0.035 for 6296 reflections with $I \geq 2\sigma(I)$ and R = 0.036 and R_w = 0.037 for 5642 reflections with $I \geq 3\sigma(I)$, respectively. The former complex provides a rare example of a 3:3:1, or capped octahedral structure, with a short (mean) Mo—Cu distance of 2.513(9) Å. The latter compound displays one terminal and two bridging CO ligands and a Mo—Rh distance of 2.6066(5) Å.

GREGORY A. BANTA, BRENDA M. LOUIE, EMMANUEL ONYIRIUKA, STEVEN J. RETTIG et ALAN STORR. Can. J. Chem. **64**, 373 (1986).

Les réactions des ions $LMo(CO)_3^-$ (L = $MeGapz_3$, $HBpz_3$, $[Me_2Gapz(OCH_2Ch_2NMe_2)$) avec le $[Cu(PPh_3)Cl]_4$ et le $Rh(PPh_3)_3Cl$ conduisent à des complexes comportant des liaisons Mo—Cu et Mo—Rh. On a déterminé les structures cristallines de deux tels complexes par diffraction des rayons-X. Les cristaux de $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$ sont monocliniques avec a = 17,071(2), b = 16,738(1), c = 23,641(3) Å, β = 104,899(6)°, Z = 8, groupe d'espace $P2_1/n$ alors que ceux du $[MeGapz_3]$-$Mo(CO)_3Rh(PPh_3)_2$ sont tricliniques avec a = 12,519(3), b = 17,182(4), c = 12,071(2) Å, α = 105,02(1), β = 109,87(1), γ = 97,10(2)°, Z = 2, groupe d'espace $P\bar{1}$. On a résolu les deux structures par les méthodes conventionnelles aux atomes lourds et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R = 0,040 et R_w = 0,035 pour 6296 réflexions avec $I \geq 2\sigma(I)$ et R = 0,036 et R_w = 0,037 pour 5642 réflexions avec $I \geq 3\sigma(I)$. Le premier de ces complexes représente un rare exemple d'une structure 3:3:1, une structure octaédrique cappée, avec une distance Mo—Cu moyenne qui est courte, 2,513(9) Å. Dans le dernier composé, on observe la présence d'un ligand CO terminal avec deux agissant comme ponts; la distance Mo—Ph est de 2,6066(5) Å.

Introduction

The anionic, symmetrical, tridentate chelating methyltris(1-pyrazolyl)gallate ligand $[MeGapz_3]^-$, was introduced some time ago (1) as an analogue of Trofimenko's $[RBpz_3]^-$ ligand systems, (R = H, alkyl, aryl or pyrazolyl) (2). In addition we have explored extensively the chelating properties of a number of unsymmetrical, uninegative, tridentate ligands having both the pyrazolyl group and an additional bifunctional donor entity attached to a "Me_2Ga" moiety (ref. 3 and references therein). The above ligand systems, being six-electron donors, have been likened to, and compared with, the cyclopentadienyl ion in many "isoelectronic" complexes (4–7). The present account details our recent findings on the reactivity of the $LMo(CO)_3^-$ ions (L = $MeGapz_3$, $HBpz_3$, $Me_2Gapz(OCH_2CH_2NMe_2)$) towards Wilkinson's catalyst, $Rh(PPh_3)_3Cl$, and also towards the $[Cu(PPh_3)Cl]_4$ tetrameric species. Complexes have been isolated containing direct Mo—Rh and Mo—Cu bonds, in addition to CO ligands in a number of bonding modes. X-ray structural data are presented for the two complexes $[MeGapz_3]$-$Mo(CO)_3Rh(PPh_3)_2$ and $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran(THF), benzene, CH_2Cl_2, and hexane were dried by refluxing over Na/benzophenone, potassium, CaH_2 and $CaSO_4$, respectively, followed by distillation. $Rh(PPh_3)_3Cl$ (Strem Chemicals) was used as supplied. The sodium salt of the methyl tris(1-pyrazolyl)-gallate ligand, $Na^+[MeGapz_3]^-$, was prepared as a THF solution as described previously (1). The ligand $Na^+[Me_2Gapz(OCH_2CH_2NMe_2)]^-$ was also prepared as a THF solution as described in ref. 8. $K^+HBpz_3^-$ (9), $(MeCN)_3Mo(CO)_3$ (10), and $[Cu(PPh_3)Cl]_4$ (11) were prepared by literature methods.

Synthesis of $LMo(CO)_3Rh(PPh_3)_2$ (where L = $[MeGapz_3]$, $[HBpz_3]$, or $[Me_2Gapz(OCH_2CH_2NMe_2)]$)

The Na^+L^- ligand solution (~0.4 mmol in 100 mL) was added to a stirred solution of an equimolar amount of $(MeCN)_3Mo(CO)_3$ (~0.1 g) in the same solvent. The initial yellow coloration of the molybdenum complex in THF changed to an amber colour on addition of the ligand solution. The reaction mixture was stirred for ~2 days during which time the amber colour intensified. The resulting solution of Na^+LMo-$(CO)_3^-$ was reacted directly with $Rh(PPh_3)_3Cl$, added as a slurry in ~100 mL THF. The dark red reaction mixture was stirred for a further 2 days and then the solvent was removed *in vacuo* to afford dark red-black residues. The residue was extracted with benzene and filtered. Evaporation of the solvent from the filtrate gave an oily red-black material which was recrystallized from CH_2Cl_2/hexane to give air-stable dark-red crystals of the desired products in approximately 60% yield. Analytical, ir, nmr, and other data for the three complexes are collected in Table 1 and the ^1H nmr spectrum for the $[MeGapz_3]Mo$-$(CO)_3Rh(PPh_3)_2$ complex is shown in Fig. 1. The mass spectrum of this latter complex displayed signals due to the P—PPh_3^+ ion at ~890.

[a]S = singlet, d = doublet, m = multiplet and t = triplet.
[b]C_6D_6 solution, $\tau_{C_6H_6}$ = 2.84 ppm, $J_{HCCH} \approx$ 2 Hz for pz protons.
[c]Crystallized as CH_2Cl_2 monosolvate, ν_{BH} = 2483 cm^{-1}.
[d]$(CD_3)_2CO$ solution, $\tau_{(CD_3)_2CO}$ = 7.89 ppm, $J_{HCCH} \approx$ 2 Hz for pz protons.

In the preparation of $[HBpz_3]Mo(CO)_3Rh(PPh_3)_2$ a yellow crystalline sample of the complex $(Ph_3P)_2Rh(CO)Cl$ *Anal.* calcd.: C 64.31, H 4.34; found: C 63.73, H 4.27; ν_{CO} 1980 cm^{-1} (CH_2Cl_2)) was also isolated in low yield.

Synthesis of [MeGapz$_3$]Mo(CO)$_3$CuPPh$_3$

A solution of the $Na^+[MeGapz_3]Mo(CO)_3^-$ salt in THF was prepared as described above. A one-quarter molar amount of $[Cu(PPh_3)Cl]_4$ was added to the reaction mixture and produced an immediate rusty-orange colour. This reaction mixture was stirred for approximately 1 day before the removal of solvent *in vacuo*. The resulting orange residue was extracted with CH_2Cl_2 and the mixture filtered. Hexane was added to the filtrate and the mixed solvents allowed to evaporate slowly. Golden-yellow air-stable crystals of the product, $[MeGapz_3]Mo(CO)_3CuPPh_3$, were produced from the concentrated solutions in approximately 60% yield. Pertinent physical data are included in Table 1 for the complex.

X-ray crystallographic analyses

*[Methyltris(1-pyrazolyl)gallato(*N,N,N*)]tricarbonylmolybdenum-(triphenylphosphine)copper (*Mo—Cu*)*

A crystal bounded by the 8 faces (followed by their distances in millimeters from a common origin): ±(0 0 1), 0.075, ±(1 0 1), 0.100 ±(−1 0 1), 0.113, ±(0 1 0), 0.219 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 26–32°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{31}H_{27}CuGaMoN_6O_3P$ fw = 791.8

Monoclinic, a = 17.071(1), b = 16.738(1), c = 23.641(3) Å, β = 104.899(6)°, V = 6528(1) Å^3, Z = 8, ρ_c = 1.611 Mg m^{-3}, $F(000)$ = 3168, μ(Mo-$K\alpha$) = 19.2 cm^{-1}. Absent reflections: $h0l$, $h+l$ odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/n$ [non-standard setting of $P2_1/c$, C_{2h}^5, No. 14, equivalent positions: ±(x, y, z; ½−x, ½+y, ½−z)].

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 1.01–10.06° min^{-1} over a range of (0.57 + 0.35 tan θ) degrees in ω (extending by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 1.5%. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (12,13). Transmission factors ranged from 0.661 to 0.764 for 64 integration points. Of the 14 929 independent reflections measured, 6296 (42.2%) had intensities greater than or equal to 2σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy-atom methods, the coordinates of the Mo, Ga, Cu, and P atoms of each of the two independent molecules being determined from the Patterson function. The remaining non-hydrogen atoms were positioned from a subsequent difference map. In the final stages of refinement all non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included as fixed contributors in idealized positions (methyl hydrogens based on observed positions, C(sp^3)—H = 0.98, C(sp^2)—H = 0.97 Å), recalculated after each cycle of refinement. The scattering factors of ref. 14 were used for non-hydrogen atoms and those of ref. 15 for hydrogen atoms. Anomalous scattering factors from ref. 16 were used for the Mo, Ga, Cu, and P atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 793 variables. Reflections with $I < 2\sigma(I)$

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

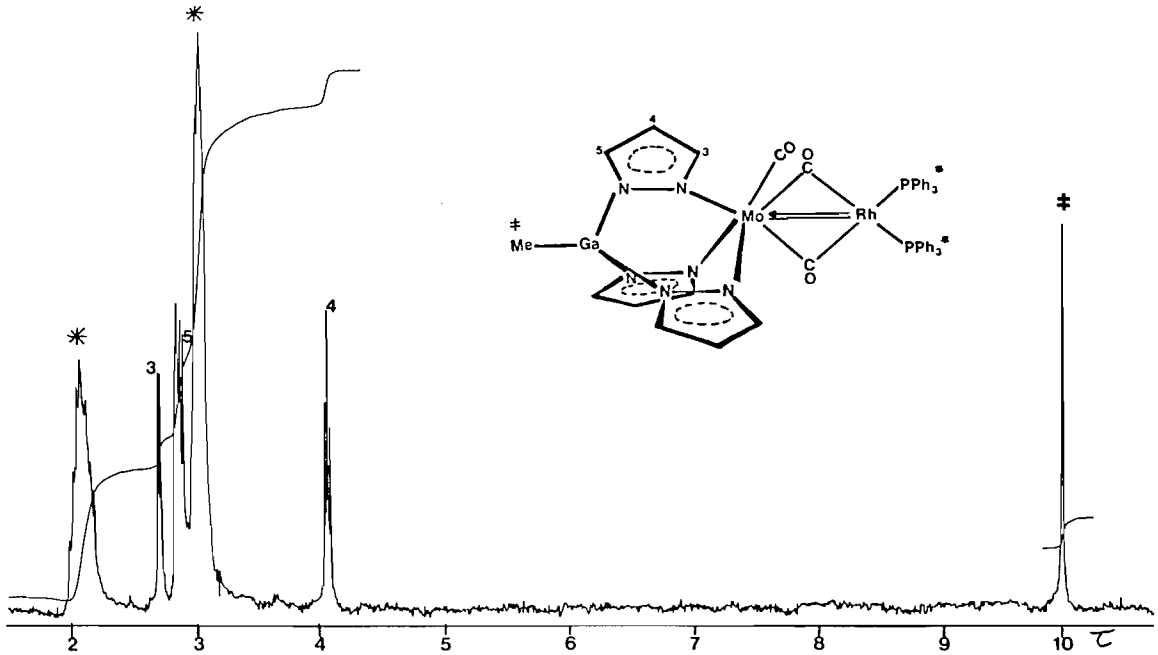

FIG. 1. Room temperature 100-MHz ^{1}H nmr spectrum of $[MeGapz_3]Mo(CO)_3Rh(PPh_3)_2$ in C_6D_6.

were not included in the refinement. Convergence was reached at $R = 0.040$ and $R_w = 0.035$ for 6296 reflections with $I \geq 2\sigma(I)$. For all 14 929 reflections $R = 0.216$. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts correspond to 0.03 and 0.29σ, respectively. The mean error in an observation of unit weight was 1.220. A final difference map showed maximum fluctuations of -1.31 to $+0.61$ e Å^{-3} near the heavy atoms and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 2 and 7[3] respectively. Bond lengths, bond angles, and intra-annular torsion angles appear in Tables 3–5, respectively. Calculated hydrogen parameters (Table 6) and a complete listing of torsion angles (Table 8) are included as deposited material.[3] Measured and calculated strucure factors have been placed in the Depository of Unpublished Data.[3]

*[Methyltris(1-pyrazolyl)gallato-(*N,N,N*)tricarbonylmolybdenum-bis(triphenylphosphine)rhodium* (Mo—Rh)

Experimental details are as above except where noted. The bounding planes of the crystal used for data collection were: (0 0 −1), 0.200, ±(1 −1 0), 0.050, ±(0 1 0), 0.125, (−1 −1 1), 0.200 mm. Reflections employed in the refinement of the unit-cell parameters had 2θ = 30–36°. Crystal data:

$C_{49}H_{42}GaMoN_6O_3P_2Rh$ fw = 1093.4

Triclinic, a = 12.519(3), b = 17.182(4), c = 12.071(2) Å, α = 105.02(1), β = 109.87(1), γ = 97.10(2)°, V = 2294(1) Å^3, Z = 2, ρ_c = 1.583 Mg m^{-3}, $F(000)$ = 1100, μ(Mo-$K\alpha$) = 13.1 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell, conventional orientation) from structure analysis.

An ω–2θ scan at 1.26–10.06° min^{-1} over a range of (0.75 + 0.35 tan θ)° in ω was employed. Of 10 493 independent reflections measured (to 2θ = 55°), 5642 had $I \geq 3\sigma(I)$ above background. The intensities of the standard reflections remained constant to within 3%. The data were corrected for absorption, transmission factors ranging from 0.578 to 0.913 for 72 sampling points.

The coordinates of the Mo, Rh, Ga, and P atoms were determined from the Patterson function (which suggested the centrosymmetric space group $P\bar{1}$) and those of the remaining non-hydrogen atoms from a subsequent difference map. Hydrogen atoms were fixed in idealized positions. Convergence was reached at $R = 0.036$ and $R_w = 0.037$ for 5642 reflections with $I \geq 3\sigma(I)$ and 568 variables. For all 10 493 reflections $R = 0.102$. The mean and maximum parameter shifts were 0.04 and 0.28σ respectively and the mean error in an observation of unit weight was 1.328. Anomalous scattering corrections were made for Mo, Rh, Ga, and P atoms. The final difference map showed maximum fluctuations of -1.76 to $+0.96$ e Å^{-3} near the Rh atom.

Spectra

The ir spectra were recorded on a Perkin–Elmer 598 spectrometer. The ^{1}H nmr spectra were recorded on a Varian XL-100 or a Bruker WP-80 instrument.

Results and discussion

The reactivity of the $[MeGapz_3]M(CO)_3^-$ ions (M = Mo or W) towards a number of three-electron donor ligands has been well documented and the complex $[MeGapz_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ has been characterized structurally (1). The reactivity of the related species $[Me_2Gapz(OCH_2CH_2NR_2)]M(CO)_3^-$ (where R = H or Me) towards similar ligands has also been extensively investigated (17–22). Presently, we are probing the reactions of these tricarbonyl anions, $LM(CO)_3^-$ with a variety of transition metal complexes. The present account details reactions of the ligands (M = Mo) with $Rh(PPh_3)_3Cl$ and $[Cu(PPh_3)Cl]_4$. In all cases crystalline products were obtained and representative examples of these have been characterized structurally by X-ray analysis. These analyses confirm the presence of direct Mo—Rh and Mo—Cu bonds in these compounds in addition to carbonyl groups in a number of different bonding environments (23–26).

Much current research has been directed towards heterobimetallic complexes with transition metal – transition metal bonds, partly since it is reasoned that cooperative effects between the different metal centres may influence the reactivity of such complexes (27–36). It is also argued that studies of simple binuclear species may well provide useful clues into the design and synthesis of larger heterometallic cluster species with potential catalytic applications (ref. 27 and references therein).

[3]The structure factor table, Table 7 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

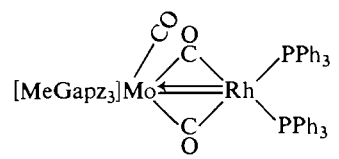
[a] U_{eq} = ⅓ trace diagonalized *U*.

The reactions of the anionic ligands $[MeGapz_3]Mo(CO)_3^-$, $[HBpz_3]Mo(CO)_3^-$, and $[MeGa(pz)(OCH_2CH_2NMe_2)]Mo(CO)_3^-$ with Wilkinson's catalyst, $Rh(PPh_3)_3Cl$, in THF resulted in the displacement of the chloro ligand, the formation of molybdenum–rhodium bonds, and the loss of triphenylphosphine from the rhodium coordination sphere. The crystalline products are air stable but solutions of the complexes decompose on exposure to the air. In one experiment (using the $[HBpz_3]Mo(CO)_3^-$ anion) a small amount of the yellow crystalline material $Rh(PPh_3)_2(CO)Cl$ was isolated, presumably being produced via displacement of a phosphine from $Rh(PPh_3)_3Cl$ by a CO ligand emanating from the molybdenum tricarbonyl anion starting material.

The reaction of the $[MeGapz_3]Mo(CO)_3^-$ anion with the tetramer $[Cu(PPh_3)Cl]_4$ in the THF led to the isolation of a yellow crystalline product which resulted from displacement of the chloro ligand by the tricarbonyl anion. The solid material is air stable but solutions of the complex decompose rapidly on air exposure.

Physical data for the complexes are listed in Table 1. The ν_{CO} frequencies indicate the presence of both terminal and bridging carbonyl groups in the compounds. The room temperature ^1H nmr data of the complexes containing the "$MeGapz_3$" and "$HBpz_3$" ligands suggest equivalence of the three pyrazolyl rings since only one set of signals is observed for the pyrazolyl ring protons (e.g. Fig. 1). Low temperature spectra, although broadening these proton signals, did not distinguish clearly any difference between the three pyrazolyl rings. The room temperature ^1H nmr of the $[Me_2Ga(pz)(OCH_2CH_2NMe_2)]Mo(CO)_3Rh(PPh_3)_2$ complex is consistent with a facial coordination of the unsymmetric gallate ligand about the molybdenum centre, with two *Ga—Me* and two *N—Me* signals being recorded.

The crystal structure of the $[MeGapz_3]Mo(CO)_3Rh(PPh_3)_2$ complex is shown in Fig. 2, and consists of discrete molecules separated by normal van der Waals distances. The structure clearly shows the presence of a terminal Mo—C(1)—O(1) unit, which, although significantly nonlinear (173.9(5) Å) is too far removed from the Rh centre (Rh···C(1), 2.845(5) Å) to suggest any bridging interaction. This CO ligand presumably accounts for the highest ν_{CO} value recorded at 1879 cm^{-1} (Nujol). The two remaining Mo—CO units, although different, are both clearly in bridging range of the Rh centre with Mo—C—O angles of 167.4(4) and 153.2(4)° and Rh···C distances of 2.334(5) and 2.079(5) Å respectively (ν_{CO} values 1758, 1772 cm^{-1}). It is also evident that the pyrazolyl rings are nonequivalent in the solid state and to explain the solution ^1H nmr data it is necessary to postulate that a rapid fluxional process is taking place in solution. Two such processes may be envisaged, one in which there is a rapid rotation of the "$MeGapz_3$" ligand about the Ga···Mo axis, and another, perhaps more likely, in which there is a rapid interchange of the different roles of the three CO ligands, with concomitant equalization of the environments of the three pyrazolyl rings. The Ga···Mo—Rh unit is significantly nonlinear in this structure with an angle of 161.59(3)° at Mo. The pyrazolyl rings, here, and in the structure of the copper complex described below, are planar within experimental error (maximum deviation from N_2C_3 plane = 0.007(7) Å). The phenyl rings are either planar or, slightly, but significantly nonplanar (χ^2 = 0.2–20.7, mean 8.0, maximum deviation 0.018(7) Å for Cu; χ^2 = 0.3–37.0, mean 19.6, maximum deviation 0.025(6) Å for Rh). The rhodium complex reported here is very similar to one reported earlier by Carlton *et al.* (27). These authors reported the structure of the compound $(\eta\text{-}C_5H_5)Mo(CO)_3Rh(PPh_3)_2$, in which a "$\eta\text{-}C_5H_5$" ligand substitutes the "$MeGapz_3$" ligand of the present complex. The similarity of the two complexes illustrates once more the interchangeability of the "$\eta\text{-}C_5H_5$" and "$MeGapz_3$" ligand systems (1). The Mo—Rh bond distance of 2.6066(5) Å (cf. 2.588(1) Å in the $\eta\text{-}C_5H_5$ complex) in the present compound is well below the estimated single bond distance of 2.8–3.0 Å and suggests some multiple bond character between the two transition metals. A bonding scheme similar to that proposed by Carlton *et al.* would give an 18-electron count to the Mo atom and a 16-electron count to the Rh centre. In this picture, in addition to two bridging CO groups, a double bond between the two transition metals, with one component being a Rh → Mo dative link, constitutes an integral part of the overall molecular framework. In keeping with the different roles of the carbonyl ligands the C—O bond lengths involving the "bridging" ligands (1.190(5) and 1.175(6) Å) are significantly longer than that of



the unique terminal CO ligand (1.154(6) Å). The Rh $(\mu\text{-}CO)_2Mo$ framework possesses a butterfly arrangement as seen in the analogous $\eta\text{-}C_5H_5$ complex (27) with the Rh—C—Mo dihedral angle of 156° compared with 161° in the $\eta\text{-}C_5H_5$ compound.

The crystal structure of the $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$

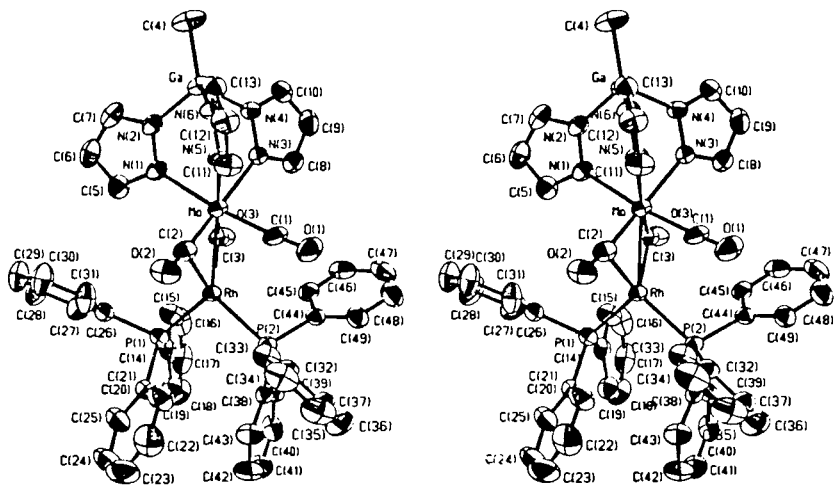

FIG. 2. Stereoscopic view of the [methyltris(1-pyrazolyl)gallato-(*N*,*N*,*N*)]tricarbonylmolybdenumbis(triphenylphosphine)rhodium(*Mo-Rh*) molecule; 50% probability thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.

complex is shown in Fig. 3 and again consists of discrete molecules separated by normal van der Waals distances. The only intermolecular contact of any possible significance is a C—H···O interaction associating pairs of unprimed molecules about the inversion centre at (0,0,1/2) (C(30)—H(30)···O(2) ($-x,-y,1-z$), C···O = 3.424(9), H···O = 2.55 Å, C—H···O = 151°). Apart from several small but statistically significant differences between the corresponding bond lengths and angles (Tables 3 and 4), the most notable difference between the two crystallographically independent molecules of [MeGapz$_3$]-Mo(CO)$_3$Cu(PPh$_3$) is in the orientation of the PPh$_3$ ligand. The conformation about the Cu—P bond in the molecule denoted by unprimed atom labels is about 4° from staggered compared with a value of 26° in the second molecule. A unit cell view of the structure is shown in Fig. 4. The complex [MeGapz$_3$]Mo(CO)$_3$Cu(PPh$_3$) is valence isoelectronic with the above Rh compound, [MeGapz$_3$]Mo(CO)$_3$Rh(PPh$_3$)$_2$. However, the Cu complex is of much higher symmetry, possessing an

approximate 3-fold axis along the near-linear C(4)—Ga...Mo—Cu—P atomic arrangement (mean angles: C—Ga...Mo = 178.0(3), Ga...Mo—Cu = 175.2(6), and Mo—Cu—P = 176.1(9)°). In this solid state structure the three pyrazolyl rings are in equivalent environments. If a similar arrangement pertains in solution, the ^{1}H nmr results, mentioned above, are satisfactorily explained. The three CO ligands are essentially symmetrically placed with mean bond angles Mo—C—O of 170.1(5), 170.7(1), and 172.1(6)°, Cu—C—O of 117.0(1), 117.5(3), and 118.5(1)°, and mean bond lengths Mo—C of 1.973(7), 1.964(6), and 1.966 (6) Å, Cu...C of 2.247(13), 2.298(23), and 2.415(5) Å,

The solution ir spectrum for the Cu complex shows two ν_{CO} bands (a and e modes) and is consistent with the approximate C_3 symmetry for the complex observed in the solid state, with nearly linear Mo—C—O units. The positions of these ν_{CO} bands (1898 and 1798 cm^{-1}, CH_2Cl_2 solution) are slightly higher than those observed for the uncomplexed anion [MeGapz$_3$]Mo(CO)$_3^-$ (Et_4N^+ salt) (1890 and 1760 cm^{-1}, CH_2Cl_2 solution) which in turn are close in value to the ν_{CO} vibrations, recorded some time earlier by Trofimenko (37), for the corresponding [HBpz$_3$]Mo(CO)$_3^-$ anion (Et_4N^+ salt) (1897 and 1761 cm^{-1}, MeCN solution). In the solid state the Cu complex displays three bands in the ν_{CO} region of the spectrum (1890, 1805, and 1780 cm^{-1}, Nujol mull). These could arise either from a splitting of the e mode observed in the solution spectrum, or from slightly different packing environments for the two independent molecules. As already noted above, one of the carbonyl groups of the unprimed molecules is involved in a possible C—H...O interaction. The solid state ir spectrum of the uncomplexed carbonyl anion in the salt [Et_4N^+][(MeGapz$_3$)-Mo(CO)$_3^-$] displayed two ν_{CO} bands (1885 and 1730 cm^{-1},

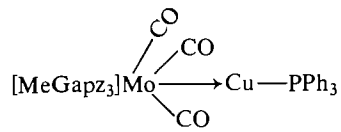
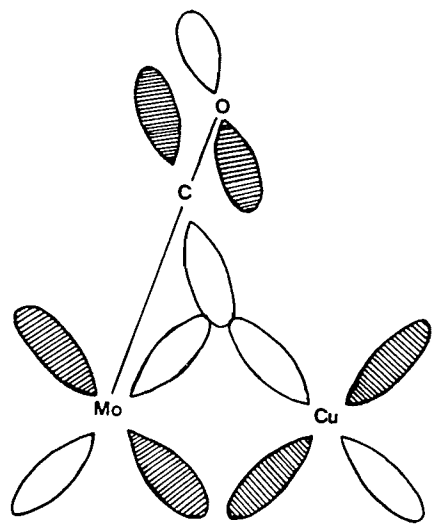
Nujol mull) as expected from its C_{3v} symmetry. These values again compare closely with those reported for the analogous boron species in the salt $[Et_4N^+][(HBpz_3)Mo(CO)_3^-]$ (1890 and 1750 cm^{-1}, KBr disc) (38).[4]

In the scheme presented below the Mo centre retains an 18-electron count if it is assumed that the CO groups of the molybdenum tricarbonyl anion retain their terminal character to



the Mo atom. The single donor bond, Mo → Cu, between the two transition metals gives the Cu of the $Cu^I(PPh_3)^+$ moiety a 14-electron count. The X-ray data however, do suggest some interaction between the Cu centre and the carbonyl groups, although the exact nature of this interaction is not clear. Obviously the interaction is of a semi-bridging type since the Mo—C—O angles are not far removed from linear. Numerous recent publications have documented and discussed different types of bridging CO interactions in heterobimetallic transition metal complexes (23–31,34,36). The present Cu compound does not appear to fit into the category of a distal electron-rich metal centre (the Cu centre has a 14-electron count) donating excessive charge into the CO π* orbitals (25), although, if $d\pi$–$d\pi$ bonding occurs between the Cu and the Mo centres, then an interaction with the CO groups similar to that postulated for the complex $(\eta\text{-}C_5H_5)_2Mo_2(CO)_4$ (26,39) may be possible. Such an interaction between a Mo—Cu π-bond and the π* orbital of a CO ligand is shown schematically below. This type of interaction would, of course, tend to lengthen the C—O bond, and, with a mean C—O distance of 1.164 Å, the carbonyl ligands do display slightly longer bonds than usually found for



terminal CO ligands. The present structure does not meet the requirements for Π-CO type bonding. These were recently reviewed by Horwitz and Shriver (26). Thus the Cu—O distances (2.945(5)–3.143(5) Å) are much longer than the Cu—C distances (2.234(6)–2.419(6) Å) leading to Ω values of approximately 2.14–2.16 (Ω = exp [D(Cu—C)/D(Cu—O)]), a value much lower than expected for a Π-CO type interaction.

[4]The constructive comments of a referee regarding the ir data of the Cu complex are gratefully acknowledged.

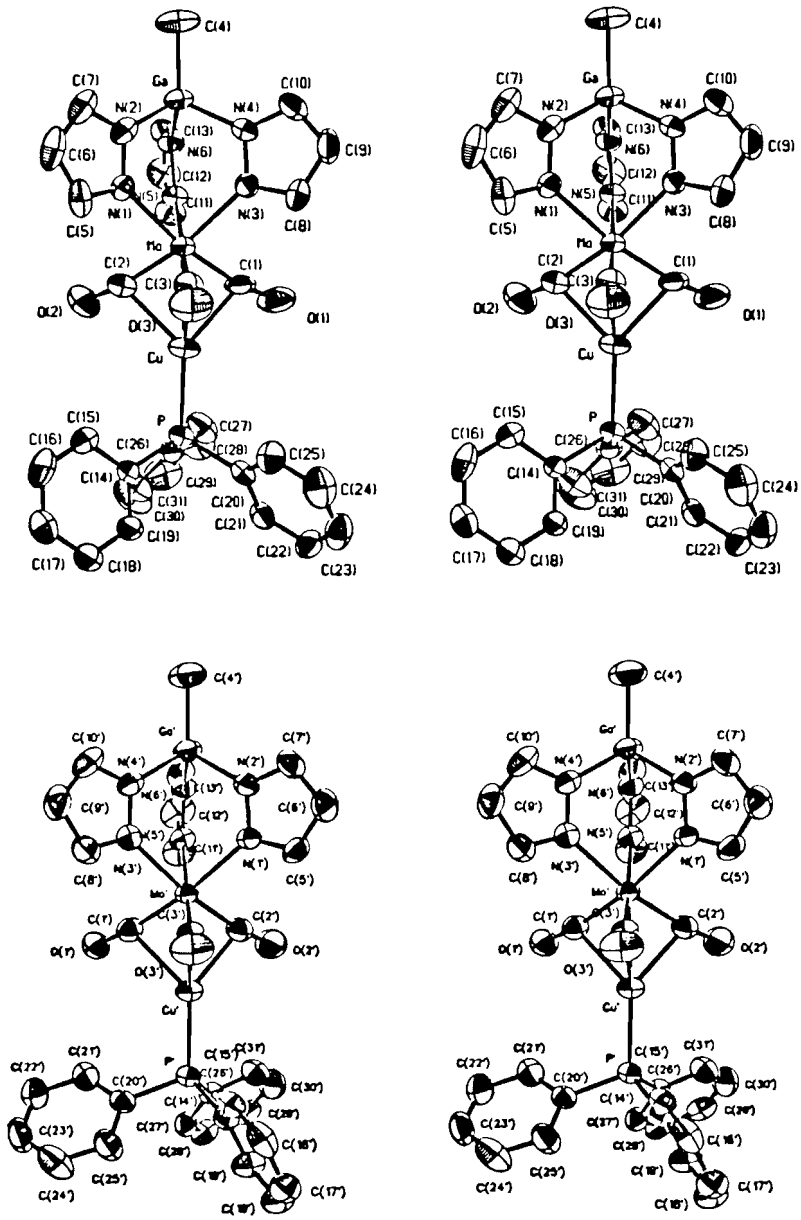


FIG. 3. Stereoscopic views of the two independent molecules of [methyltris(1-pyrazolyl)gallato-(*N*,*N*,*N*)]tricarbonylmolybdenum(triphenylphosphine)copper (*Mo-Cu*); 50% probability thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. The mirror image of the primed molecule is shown for direct comparison.

In addition, the ν_{CO} frequencies observed for the complex are all much higher than the expected value of $\sim 1650\ cm^{-1}$ for a Π-CO group.

Perhaps the bonding in the present complex is more subtle. In this regard recent MO calculations (28) on the complex $(\eta\text{-}C_6H_6)(CO)Cr(\mu\text{-}CO)_2Rh(CO)(\eta\text{-}C_5H_5)$, a complex originally postulated to contain a Cr → Rh donor bond in addition to semi-bridging CO interactions (30), suggest a strong interaction between the distal Rh centre and the bridging CO ligands (Cr—CO (bridge), 1.902(7) Å, Rh—CO (bridge), 2.200(7) Å) with a net bond order close to zero between the metal atoms (Rh···Cr, 2.757(2) Å). Similar calculations on the present system may well be invaluable in determining the major bonding interactions responsible for the short Mo—Cu separation.

It is again interesting to compare similar complexes in this area. Carlton *et al.* (27) have provided structural data on two different forms of the complex $(\eta\text{-}C_5H_5)W(CO)_3Cu(PPh_3)_2$, and suggest some semi-bridging interactions involving the two metals and two of the CO ligands. Three important differences occur with the $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$ complex. First, only one PPh_3 ligand is attached to the Cu centre, making the molecule valence isoelectronic with the $[MeGapz_3]Mo(CO)_3$-$Rh(PPh_3)_2$ compound. Second, the present structure has three roughly equivalent CO groups whereas in Carlton's tungsten compounds one of the three CO groups is clearly terminal to tungsten. Third, the mean Mo—Cu distance of 2.513(9) Å is considerably shorter than either of the W—Cu distances of 2.771(1) and 2.721(1) Å reported by Carlton *et al.* Given that the radii for Mo and W are very similar at ~1.61 Å (the M—M distances in $(\eta\text{-}C_5H_5)(CO)_3M—M(CO)_3(\eta\text{-}C_5H_5)$ are 3.222(5) Å for M=Mo (40) and 3.24(1) Å for M=W (41),

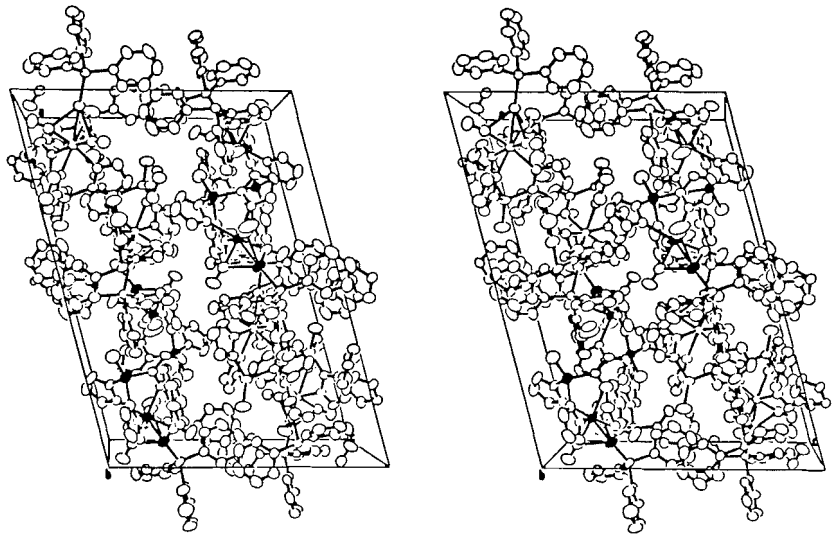

FIG. 4. Stereoscopic view of the [methyltris(1-pyrazolyl)gallato-(*N*,*N*,*N*)]tricarbonylmolybdenum(triphenylphosphine)copper (*Mo-Cu*) structure; metal atoms of the umprimed molecules are shaded for identification.

these differences in bond lengths suggest a much stronger Mo—Cu interaction in the present complex. Indeed, the observed Mo—Cu distance is significantly shorter than the estimated single Mo—Cu bond length of ~2.7–2.8 Å. Another noticeable difference occurs in the Cu—P distances in the two complexes. Thus the compound reported here displays a mean Cu—P distance of 2.196(3) Å, somewhat shorter than the corresponding mean distance of 2.299(12) Å reported for the two crystalline forms of $(\eta\text{-}C_5H_5)W(CO)_3Cu(PPh_3)_2$.

The structures of the $(\eta\text{-}C_5H_5)W(CO)_3Au(PPh_3)$ (42) and $[HBpz_3]Mo(CO)_3Br$ (38) complexes are worthy of comparison with the $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$ structure. The W—Au compound displays an arrangement very different from that found for Mo—Cu complex. Thus, instead of a symmetrical structure analogous to that depicted in Fig. 3, with the $\eta\text{-}C_5H_5$ ligand replacing the $MeGapz_3$ ligand and the Au atom replacing the Cu atom, the arrangement adopted is that of a "four-legged" piano stool, or a distorted square pyramid with the $(\eta\text{-}C_5H_5)W$ unit at the apex and the three CO ligands and the $Au(PPh_3)$ grouping occupying the basal positions. A similar structure, described as a 3:4 piano stool, has been reported recently by Curtis and Shiu (38) for $[HBpz_3]Mo(CO)_3Br$. These authors mentioned that one of the interesting aspects which prompted their study was the possibility of observing a capped octahedral (3:3:1) structure, since calculations by Kubacek *et al.* (43) had shown that this arrangement represents a minimum in the potential energy surface for analogous $(\eta\text{-}C_5H_5)ML_4$ complexes whose global minimum (ground state) is always the four-legged piano stool, or 3:4 structure. It appears that the present copper complex $[MeGapz_3]Mo(CO)_3Cu(PPh_3)$ closely approaches this 3:3:1 capped octahedral arrangement.

Finally, the structure of the complex, $(\eta\text{-}C_3H_5)Fe(CO)_3\text{-}AuPPh_3$ (44) has many features similar to the Mo–Cu complex presented here. It has been proposed that the bonding in this iron complex results from the Lewis base $(\eta\text{-}C_3H_5)Fe(CO)_3^-$ donating a pair of electrons to the Lewis acid $Au(PPh_3)^+$ and does not necessarily involve any direct interaction between the Au atom and the CO ligands, the geometry of the complex being dictated by transition metal basicity. If this reasoning is correct then the Au centre attains a 14-electron count and the Fe—Au separation of 2.519(1) Å results entirely from the Fe → Au dative bond.

The present study has again shown the versatility of the "$MeGapz_3$" ligand in that it can, on the one hand, successfully mimic the behaviour of the "$\eta\text{-}C_5H_5$" ligand system (1) but, more importantly, on the other hand it can display significantly different behaviour (7). This versatility is being further exploited in the area of heterometallic complexes.

ESTER F. G. BARBOSA and ISABEL M. S. LAMPREIA. Can. J. Chem. **64**, 387 (1986).

Apparent molal volumes, V_ϕ, of secondary and tertiary amines and linear hydrocarbons were determined in benzene at 25°C, using a vibrating tube densimeter. These quantities have been extrapolated to infinite dilution to obtain partial molal volumes. The contribution to partial molal volume of the amine groups, calculated using a simple additive scheme, $\bar{V}^0 = \sum_k N_k \bar{V}_k^0$, were interpreted in terms of conformational effects present in these molecules. A first attempt to find a measure of the contribution to the partial molal volume of the specific interaction amine–benzene in tertiary and secondary amines was made. The results agree well in the two different approaches used.

ESTER F. G. BARBOSA et ISABEL M. S. LAMPREIA. Can. J. Chem. **64**, 387 (1986).

Faisant appel à un densimètre à tube vibrant et opérant dans le benzène à 25°C, on a mesuré les volumes molales apparents, V_ϕ, d'amines secondaires et tertiaires et d'hydrocarbures linéaires. On a extrapolé ces quantités à dilution infinie afin d'obtenir les volumes molales partiels. On a interprété la contribution au volume molale partiel des groupements amines, calculés en utilisant un schéma additif simple, $\bar{V}^0 = \sum_k N_k \bar{V}_k^0$, en fonction d'effets conformationnels présents dans ces molécules. On a tenté un premier essai dans le but de trouver une mesure de la contribution au volume molale partiel de l'interaction spécifique amine–benzène dans les amines secondaires et tertiaires. Les résultats obtenus avec l'une ou l'autre approche concordent bien.

[Traduit par le journal]

Introduction

The volumetric behaviour of solutes has proved to be of great importance in the understanding of interactions in solution. Much work has been published on $\bar{V}^0$ additive schemes in which every group contribution is assumed to be independent of the molecule under study, depending solely on the solvent (1–4). However, experience has shown that the position of the group in the molecule, size of the molecule, and specific solute–solvent interactions produce deviations from the simple additive behaviour. To get a deeper understanding of these factors, different kinds of reference volumes with respect to which volume changes could be calculated and interpreted have been used in the past (5–7). Molar volume of the solute V^0, Bondi's van der Waals volume V_W (8), and cavity volume $\bar{V}_{cav}$ as given by the scaled particle theory (SPT) have been used for the above purpose.

In this study we have tried to find a measure of the contribution of the specific interactions to the partial molal volumes of secondary and tertiary amines in benzene. Comparative values of these contributions were found using two different approaches, one based on the model of Terasawa *et al.* (6) and the other on SPT (7). In both cases linear hydrocarbons were used as reference materials, to separate the two types of interactions present in these molecules.

Experimental

Materials

All substances employed were guaranteed commercial reagents obtained from Merck, B.D.H., Eastman Kodak, Aldrich, and Fluka.

The three tertiary amines, triethylamine, tri-*n*-butylamine, and tri-*n*-octylamine, were first heated with an appropriate quantity of acetic anhydride and fractionally distilled, then refluxed with KOH for several hours and again fractionally distilled from BaO through a column packed with Pyrex glass rings. The two last amines mentioned were distilled in a vacuum jacketed column at 70 and 0.4 Torr (1 Torr = 133.3 Pa) respectively. Tri-*n*-propylamine, after having been heated with acetic anhydride, was shaken with KOH several times until all acetic anhydride has been extracted. Then it was allowed to stand over sodium hydroxide pellets for several days and fractionally distilled as previously described.

The secondary amines, diethylamine, di-*n*-butylamine, di-*n*-hexylamine, and di-*n*-octylamine, were refluxed with KOH pellets for several hours and fractionally distilled as described for the tertiary amines. Di-*n*-dodecylamine was fractionally recrystallized three times from a mixture of ethanol–benzene in a dry nitrogen atmosphere.

The two linear hydrocarbons, *n*-octane and *n*-decane, were refluxed for several hours over sodium thread and fractionally distilled from CaH_2 in a vacuum jacketed column.

The purity of the solutes was tested by density measurements. Values obtained are compared with the ones found in the literature (see Table 1).

Benzene was refluxed for several hours over CaH_2 and fractionally distilled in a column packed with Pyrex glass rings, under dry nitrogen.

The purity of benzene was also tested by density measurements. The average densities of the different samples used in the $\bar{V}^0$ determinations of each solute are shown in Table 2. Selected literature values at 25°C are 0.87365 (9), 0.87367 (10).

Measurements

Densities were measured using an Anton Paar DMA 02D vibrating tube densimeter. The temperature of the bath was kept constant at 25 ∓ 0.001°C with a Tronac PTC 40 temperature controller. The temperature of the bath was set with a Hewlett–Packard quartz crystal thermometer. The oscillator of the thermometer was kept at constant temperature in a distilled water–ice bath. The densimeter and the water bath were both enclosed in an air box thermostated to ∓0.1°C. The densimeter was calibrated using water and dry air. This calibration was repeated several times in each set of measurements.

Solutions were all prepared by weight in volumetric flasks of appropriate volume according to the expected error in each solute. Design to prevent evaporation was introduced into the flasks. The densities were precise to $\pm 2 \times 10^{-6}$ g cm^{-3}.

Results and discussion

Densities

Experimental density values for various amine and linear

hydrocarbon solutions, in the molality ranges studied, obey equations of the type

$$[1] \quad d = A + Bm + Cm^2$$

where A, B, and C are empirical coefficients as shown in Table 2. As can be seen, the A values compare well with the average density of benzene, $\bar{d}_{C_6H_6}$, calculated from the different experimental determinations of benzene density when $\bar{V}^0$ values were obtained for each solute.

Partial molal volumes

The apparent molal volumes of all solutes were calculated in the usual way

$$[2] \quad V_\phi = \frac{MPd^0 - MPd}{pdd^0} + \frac{M}{d}$$

where M is the solute molecular weight; P the solvent weight; p the solute weight; and d^0 and d the densities of pure solvent and solution, respectively.

The V_ϕ values for the range of molalities studied are given in Table 3.

The partial molal volumes $\bar{V}^0$ of solute were obtained by linear extrapolation of the V_ϕ's to infinite dilution by a least-squares fitting method.

Table 4 summarizes the values at infinite dilution of the partial molal volumes $\bar{V}^0$, along with the excess $\Delta\bar{V}$ volumes calculated as $\Delta\bar{V} = \bar{V}^0 - V^0$.

In all the solutes investigated, positive values of $\Delta\bar{V}$ were obtained. This fact leads to the conclusion that the prevailing intermolecular interaction of any of the amines with benzene is due to the aliphatic part of the molecule. This is an indication of inappropriate geometrical fitting of the solutes in this solvent. A more careful look at the results, in particular for solutes of the same size, shows that for the amines the increase in volume is never as big as for the hydrocarbons, meaning that the amine group – benzene interaction produces a decrease in volume. This is in agreement with the findings of the previous workers: C_6H_6 – tertiary amines n–Π interactions and C_6H_6 – secondary amines n–Π and NH $\cdots\Pi$ interactions (19–21).

$\bar{V}^0$ group contributions

The linear dependence of partial molal volumes on the number of carbon atoms, n_C, found for the three homologous series studied allows us to identify the slopes, b, of eq. [3] with the contribution of the methylene group, and the intercepts, a, with the combination of group contributions as shown in eqs. [4]–[6].

$$[3] \quad \bar{V}^0 = a + bn_C$$

$$[4] \quad a_{HC} = 2\bar{V}^0_{CH_2} + 2\bar{V}^0_{CH_3}$$

$$[5] \quad a_{sec.amines} = -2\bar{V}^0_{CH_2} + 2\bar{V}^0_{CH_3} + \bar{V}^0_{>\ddot{N}H}$$

$$[6] \quad a_{tert.amines} = -3\bar{V}^0_{CH_2} + 3\bar{V}^0_{CH_3} + \bar{V}^0_{\geq N:}$$

The group contributions as presented in Table 5 were derived by a least-squares fitting of experimental $\bar{V}^0$ values to eq. [3] and using expressions [4]–[6]. In this statistical method we have taken into account the non-constancy of the standard deviation of the different $\bar{V}^0$ determinations.[2] Intercepts along with their standard deviations are $a_{HC} = 32.8_5 \pm 0.1_5$, $a_{sec.amines} = 37.4_5 \pm 0.2_0$, and $a_{tert.amines} = 41.0_1 \pm 0.2_1$ cm^3 mol^{-1}. The slopes $b \equiv \bar{V}^0_{CH_2}$ can be seen in Table 5, as referred to above. The $\bar{V}^0_{CH_2}$ used in eqs. [4]–[6] is the average of the values obtained from the three sets of compounds. Table 5 also shows the CH_2-group contribution to the pure solutes as well as their excess volume $\Delta\bar{V}_{CH_2} = \bar{V}^0_{CH_2} - V^0_{CH_2}$.

In this same table one can see that the methylene-group contribution is always bigger in C_6H_6 than in pure solutes. As already pointed out for the global solute molecules, this fact can be explained by the perturbation of benzene structure caused by the aliphatic part of these molecules, when they are introduced in this solvent. This result is in opposition to what can be observed in water, where hydrophobic bonding interactions are present. Another observation concerning this group contribution, in the three sets of compounds, is that their values are almost constant, although differences greater than the experimental error are present.

[2]Algebraic equations for first-order ($y = a + bx$) weighted least-squares fitting:

$a = (\Sigma w_i y_i \Sigma w_i x_i^2 - \Sigma w_i x_i \Sigma w_i x_i y_i)/D$

$b = (\Sigma w_i \Sigma w_i x_i y_i - \Sigma w_i x_i \Sigma w_i y_i)/D$

$D = \Sigma w_i \Sigma w_i x_i^2 - (\Sigma w_i x_i)^2$

$\sigma_a = \sigma(\Sigma w_i x_i^2/D)^{1/2}$

$\sigma_b = \sigma(\Sigma w_i/D)^{1/2}$

$w_i = C^2/\sigma_i^2$

with C equal to the smaller σ.

In relation to the tertiary amine group (≥N:), the introduction of Et_3N in the linear fit $\bar{V}^0$ vs. n_C changes considerably the intercept a. Therefore this compound was not included in the calculations of the average group contributions. The $\bar{V}^0_{\geq N:}$ for this amine was calculated and is $\bar{V}^0_{\geq N:}(Et_3N) = -10.4\ cm^3\ mol^{-1}$. This lower value may be justified by a noticeable difference of conformational effects in this amine as compared to the other amines of this series, in which a regular behaviour is observed (23). In respect to the higher amines, if one assumes that the CH_2-group contribution is the same as in linear hydrocarbons, the slightly different slope of the curve $\bar{V}^0$ vs. V_W would correspond to a small variation of the amine-group interaction along the series. This conclusion agrees with the observation made by Kertes and Grauer (15) and is related to the effect of chain length on excess enthalpies of mixing of these amines in C_6H_6. Kertes and Grauer explained this fact by the existence of a shielding effect to the lone-pair nitrogen electrons, due to the long aliphatic chains. In spite of this knowledge, the average of this amine-group contribution was calculated, as was the one for the secondary amines, assuming its constancy and using a simple additive scheme. The average values obtained, $V_{\geq N:} = -8.3\ cm^3\ mol^{-1}$ and $V_{\geq NH} = 4.6\ cm^3\ mol^{-1}$, both much smaller than their Bondi's van der Waals volumes, suggest the presence of another factor leading to a significant decrease in volume, in addition to the one caused by the specific interaction amine–benzene.

Conformational effects such as *gauche* interactions have been proven to influence physical properties of organic molecules (22). Terms containing those effects have already been introduced in additive schemes for $\bar{V}^0$ by Edward *et al.* (4). These authors refer to many cases in which decreases in volume were associated with *gauche* interactions. Similar results were obtained by ourselves as a result of a conformational study of some of these amines in benzene (23).

These conclusions gave us great incentive to obtain more detailed information about the effects on volume, corresponding to these specific interactions on the one hand and to conformational effects on the other hand. The continuation of these studies is important, to make possible the introduction of these contributions to more exact additive schemes.

Partial molal volumes of the specific interactions

As already pointed out, in the amine–benzene systems one may assume that the interactions present are composed of two different contributions. One is due to the aliphatic part of the molecule, leading to an increase in volume, and the other is due to the amine groups, producing the opposite effect.

To clarify the contribution to the partial molal volumes of the amine–benzene specific interactions, we have tried to separate the aliphatic from the amine contributions using two different approaches. One of these approaches, (*i*), is based on the model of Terasawa *et al.* (6) and the other, (*ii*), on SPT (7), considering V_W and $\bar{V}_{cav}$ respectively as reference volumes.

(*i*) According to Terasawa *et al.*, the partial molal volume of a solute A is composed of two contributions, i.e., the van der Waals volume, $V_{W,A}$, and the void partial molal volume, $\bar{V}_{void,A}$ (the actual void space created by addition of one mol of solute A to the solvent).

$$[7] \quad \bar{V}^0_A = V_{W,A} + \bar{V}_{void,A}$$

To estimate the contribution of specific solute–solvent interactions to the partial molal volume, the same authors had the idea of comparing $\bar{V}_{void,A}$ (or $\bar{V}^0_A$) with that of a reference material with the same van der Waals volume as the solute A. As hydrocarbons do not interact strongly with many organic solvents and all organic molecules are derived from them, these compounds were considered to be an appropriate standard material for this purpose. Then, applying eq. [7] to the hydrocarbon molecule having the same van der Waals volume as the solute A, we obtain

$$[8] \quad \bar{V}^0_{HC} = V_{W,A} + \bar{V}_{void,HC}$$

and, from eqs. [7] and [8],

$$[9] \quad \bar{V}_{S-S} = \bar{V}^0_A - \bar{V}^0_{HC} = \bar{V}_{void,A} - \bar{V}_{void,HC}$$

where $\bar{V}_{S-S}$ is the partial molal volume of the specific interactions.

To obtain $\bar{V}_{S-S}$ it is thus necessary to have values of the partial molal volumes of linear hydrocarbons with the same van der Waals volumes as the solutes studied. Since in general there are not real hydrocarbons with the requirement just stated, a weighted least-squares fitting linear relation $\bar{V}^0$ vs. V_W was obtained for these compounds and from it the suitable $\bar{V}^0_{HC}$ values were taken. Also, weighted linear regressions were done for the amines. This procedure is particularly important for the tertiary amines, as very different errors are associated with the experimental results. Table 6 shows the slopes and intercepts obtained.

The $\bar{V}_{S-S}$ parameter values calculated as explained above are listed in Table 9, and will be discussed jointly with the corresponding parameters presented in the next section.

(*ii*) Using now the statistical mechanical scaled particle theory (7, 24), we can derive in a similar way to (*i*) a comparative measure of the specific interactions from a different conception of the separation of the various contributions to $\bar{V}^0$.

The SPT expression for $\bar{V}^0$ is

[a] Et_3N was excluded from the fit as this amine was shown to have a different behaviour from its homologues.

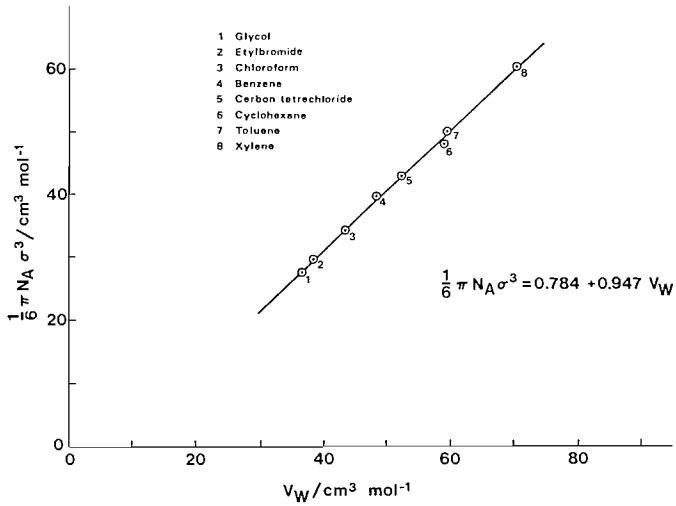

FIG. 1. Correlation of Mayer σ values with van der Waals volumes calculated after Bondi.

[10] $\bar{V}^0 = \bar{V}_{cav} + \Delta\bar{V}_i + k_T RT$

where $\bar{V}_{cav}$ is the partial molal volume associated with cavity formation, $\Delta\bar{V}_i$ is the partial molal volume contribution from solute–solvent interactions, and $k_T RT$ accounts for the change of standard state between the gas and solution. Application of [10] to amines and hydrocarbons with the same $\bar{V}_{cav}$, and subsequent subtraction leads to

[11] $\bar{I}_{S-S} = \bar{V}^0_A - \bar{V}^0_{HC} = \Delta\bar{V}_{i,A} - \Delta\bar{V}_{i,HC}$

$\bar{I}_{S-S}$ is a new parameter which will be compared with $\bar{V}_{S-S}$ calculated previously. In order to obtain this interaction contribution it is necessary to calculate $\bar{V}_{cav}$ for the amine and hydrocarbon molecules under consideration.

From SPT, $\bar{V}_{cav}$ is a known function of temperature, molar volume, isothermal compressibility, hard-sphere diameter of the solvent σ_1, and hard-sphere diameter of the solute σ_2

[12] $\bar{V}_{cav} = 0.3153\,\sigma_2^3 + A\sigma_2^2 + B\sigma_2 + C$

where

[13] $A = 3k_T RT\,(y + 2y^2)/(1 - y)^3\,\sigma_1^2$

[14] $B = 3k_T RT\,y/(1 - y)^2\,\sigma_1$

[15] $C = k_T RT\,y/(1 - y)$

and y as defined by:

[16] $y = N_A\,\Pi\,\sigma_1^3/6V$

is the ratio of the volume occupied by one mole of hard-sphere solvent molecules to the molar volume of the solvent. As can be seen from the above expressions, $\bar{V}_{cav}$ is extremely sensitive to the choice of σ_1; in fact, it appears as the 6th power of this parameter. On the other hand, $\bar{V}_{cav}$ varies much less with the solute diameter σ_2. The appropriate choice of these σ values, especially σ_1, is the first difficulty to be overcome.

As the theory claims, σ has a very precise physical meaning and can be determined from independent measurements such as viscosities, 2nd virial coefficients, compressibilities, surface tension, and solubilities. The SPT theoretical relationships for isothermal compressibilities, k_T, and surface tension, γ, as a function of σ have been established. Mayer (25) presents a series of σ values taken from k_T and γ experimental results. Another set of σ based on gas solubility technique (26) and compiled by Wilhelm and Battino (27) were used by French and Criss (28) in volumetric studies.

The two sets of molecular diameters are not in agreement, thus leading to very different $\bar{V}_{cav}$ and $\Delta\bar{V}_i$. Hence we decided to calculate these quantities for the process of introducing a molecule of a particular substance into a solution of itself, expecting to obtain $\Delta\bar{V}_i \simeq 0$. In Table 7 the results of these two parallel calculations for five organic molecules can be observed. As $\Delta\bar{V}_i$ corresponding to σ values based on the solubility approach are in all cases very negative and those derived from SPT are approximately zero, we have used these latter values to carry on our calculations. Consequently, $\sigma_1 = 5.01$ Å for benzene has been adopted.

Concerning the solutes, as we did not have the hard-sphere diameter for the amines and some linear hydrocarbons, we tried a linear relationship (29) between the volume of one mole of molecules of the Mayer diameter and the Bondi van der Waals volumes for molecules of nature and shape in best agreement with the model adopted. In Fig. 1 we present the plot and analytical expression for the relation, based on the assumptions we have made.

$\bar{V}_{cav}$ for the secondary and tertiary amines and linear hydrocarbons were then calculated and $\Delta\bar{V}_i$ derived. Table 8 shows σ_2, $\bar{V}_{cav}$, and $\Delta\bar{V}_i$ for the amines under study.

The curves $\Delta\bar{V}_i$ vs. $\bar{V}_{cav}$ for each class of compounds were then constructed (Fig. 2). As expected, three smooth curves were obtained, which approach each other towards the long-

[a]Calculated from the experimental $\bar{V}^0$ value.

chain compounds. Similar behaviour was detected when the straight lines $\bar{V}^0$ vs. V_W were drawn. The relative position of the curves is in agreement with the fact mentioned previously, that the amine group produces a decrease in volume; i.e. for the same cavity size, $\Delta\bar{V}_i$ for the amines is always smaller than for the hydrocarbons. Again, a stronger interaction for the secondary amines than for the tertiary ones is reflected in the same curves. Et_3N once more seems to be a special case lying outside the curve.

Finally, to calculate $\bar{I}_{S-S}$, eq. [11], the $\Delta\bar{V}_{i,HC}$ values required were taken from the respective curve and are also reported in Table 8. $\bar{I}_{S-S}$ and $\bar{V}_{S-S}$ values are listed in Table 9. As can be seen in this table, the two sets of results are in good agreement. The fact that these numbers were obtained from such different approaches gives support to both of them. The negative values observed for all the amines mean that the contribution to $\bar{V}^0$ of the amine-group interaction is always smaller than the corresponding contribution of the hydrocarbons, in benzene. However, we think that less negative values can be calculated if one takes into account the conformational differences between these two classes of compounds (23). Another striking feature concerning the results contained in Table 9 is the regular variation (with the exception of Et_3N) of both measures of partial molal volume of the specific interaction along the series. In the case of Et_3N, we think that the conformational difference already referred to is responsible for its particular behaviour and, once considered, would make this amine conform to the regularities observed for the higher ones. These regularities encourage the investigation of suitable expressions to account for the variation of amine-group contribution along these series, when applying additive schemes to these systems.

Apparent molar heat capacities and volumes of alkylbenzenesulfonate salts in water: substituent group additivity

K. SWAY, JAMEY K. HOVEY, AND PETER R. TREMAINE[1]

Oil Sands Research Department, Alberta Research Council, 1021 Hayter Rd., P.O.Box 8330, Station F, Edmonton, Alta., Canada T6H 5X2

Received May 23, 1985

K. SWAY, JAMEY K. HOVEY, and PETER R. TREMAINE. Can. J. Chem. **64**, 394 (1986).

Densities and specific heats were measured for the aqueous sodium salts of benzenesulfonate, *p*-toluenesulfonate, 2,4- and 2,5-dimethylbenzenesulfonate, mesitylenesulfonate, and *p*-ethylbenzenesulfonate. The limiting partial molar volumes, $\bar{V}^0$ and heat capacities, $\bar{C}_p^0$, lead to revised values in the group contributions for aromatic —CH_2— and —CH_3 groups in the additivity scheme proposed by Perron and Desnoyers. The heat capacities of substituted alkylbenzenes can deviate from group additivity by as much as 70 and 40 J K^{-1} mol, $^{-1}$, respectively, when polar groups are located on the α and β positions of the alkyl chain.

K. SWAY, JAMEY K. HOVEY, et PETER R. TREMAINE. Can. J. Chem. **64**, 394 (1986).

On a mesuré les densités et les chaleurs spécifiques de solutions aqueuses du benzènesulfonate, du *p*-toluènesulfonate, des diméthyl-2,4 et diméthyl-2,5 benzènesulfonates, du mésitylènesulfonate et du *p*-éthylbenzènesulfonate de sodium. Les volumes molaires partiels et les capacités calorifiques limites $\bar{V}^0$ et $\bar{C}_p^0$ conduisent à des valeurs corrigées des contributions de groupe pour les groupements CH_2 et CH_3 aromatiques dans le schéma d'additivité proposé par Perron et Desnoyers. Lorsqu'il y a des groupes polaires dans les positions α et β de la chaîne alkylée, les capacités calorifiques des alkylbenzènes substitués peuvent présenter des déviations de l'additivité du groupe qui peuvent aller respectivement jusqu'à 70 et 40 J K^{-1} mol^{-1}.

Introduction

The temperature dependence of surfactant micellization equilibria is of increasing interest, both as a tool for developing fundamental insights and because surfactants can be used as steam additives in heavy oil recovery. Partial molar heat capacities and volumes are key parameters in describing the temperature and pressure dependence of such equilibria (1–3). The critical micelle concentrations of industrially important surfactants lie below the practical limit of modern calorimeters and densimeters. As a result, the properties of surfactant monomers at pre-micellar concentrations must be estimated from functional group additivity schemes.

At the low concentrations of interest in this context, it is often sufficient to know the standard state functions in water or dilute brines. Perron and Desnoyers (4) recently developed a comprehensive group additivity scheme for predicting the standard partial molar properties of benzene derivatives in water at 25°C. The parameters for benzene sulfonates were derived from heat capacity and volume measurements on sodium benzenesulfonates that included chloro, carboxylate, and sulfonate groups as substituents, but not simple alkyl groups. Here, we report heat capacity and volume measurements on *p*-ethylbenzenesulfonate, and on mono, di-, and tri-methylbenzene sulfonates, in order to better define the effects of alkyl substituents and isomerization.

Experimental

The sodium salts of benzenesulfonic acid and mesitylenesulfonic acid were prepared by neutralizing aqueous solutions of the acid (Pfaltz and Bauer, "Source 1"). Those of *p*-ethylbenzenesulfonic acid (Tokyo Kasei Kogyo Ltd.), *p*-toluenesulfonic acid (Eastman Kodak), 2,4- and 2,5-dimethylbenzenesulfonic acid (Pfaltz and Bauer), and a second sample of benzenesulfonic acid (Pfaltz and Bauer, "Source 2") were purchased as the salt.

Each salt was recrystallized at least twice from saturated hot aqueous solutions, then dried to constant weight in a vacuum desiccator, typically for two to five days. A faint orange coloration persisted in the sodium benzenesulfonate from Source 1, even after three recrystallizations. All water was distilled once and passed through a Milli-Q reagent grade mixed-bed ion exchange and activated carbon system before use. Stock solutions were prepared by weight. The molality of each was checked by passing three aliquots through strong cation exchange columns (Rexyn 101, acid form) and titrating the eluted acid with standard sodium hydroxide solution to a phenolphthalein end point. The results agreed to within 0.5%.

The heat capacity and density of each solution were measured relative to water at 25.0°C using a commercial Picker flow microcalorimeter (5) and vibrating tube densimeter (6). Values for the specific heat capacity and density of pure water at 25°C and 100 kPa were taken to be $c_{pw}{}^0 = 4.1793$ J K^{-1} g^{-1} and $d_w{}^0 = 0.997062$ g cm^{-3} (7,8). The average of the apparent molar heat capacities from the two calorimeter cells was multiplied by the mean heat leak corection factor, $f = 1.01 \pm 0.005$, which was obtained daily by calibration with aqueous NaCl (9).

Results

Apparent molar heat capacities, ${}^\Phi C_p$, and volumes, ${}^\Phi V$, are defined by the expression

$$[1] \quad {}^\Phi Y = (Y - n_w Y_w{}^0)/n$$

where Y is the heat capacity or volume of the solution, n_w and n are the number of moles of water and solute respectively (if $n_w = 55.509$, n = molality, m) and $Y^0{}_w$ is the property for 1 mole of pure solvent.

To obtain apparent molar heat capacities and volumes at infinite dilution, the experimental results were fitted to an extended Debye–Hückel equation of the form (9,10).

$$[2] \quad {}^\Phi Y = {}^\Phi Y^0 + A_Y m^{1/2} + B_Y m$$

using the method of least squares. The limiting slopes on the molal scale, $A_C = 32.51$ J K^{-1} $kg^{1/2}$ $mol^{-3/2}$ and $A_V = 1.865$ cm^3 $kg^{1/2}$ $mol^{-3/2}$, were taken from Bradley and Pitzer (11). At infinite dilution, the apparent molar properties become identical with partial molar (standard state) heat capacities and volumes so that ${}^\Phi C_p^0 \bar{C}_p^0$ and ${}^\Phi V^0 = \bar{V}^0$.

The experimental data and apparent molar properties are listed in Appendix 1. The derived values of $\bar{C}_p^0$, $\bar{V}^0$, and B_C, and B_V are listed in Table 1, along with the standard deviations obtained from the least-squares fit.

Discussion

Standard state heat capacities and volumes for a large number of benzene derivatives have been compiled by Perron and Desnoyers (4). These were used to derive the contribution of each group to the standard state properties of the solute, as tabulated in Table 2. The scheme is based on the assumption that the relative positions of the aromatic substituents about the ring do not affect the group contribution, and that all H atoms are equivalent.

In Table 3, we have compared our values of $\overline{C}_p^0$ and $\overline{V}^0$ for the sodium aryl sulfonates with experimental values reported by other workers, and with values calculated from the group additivity scheme. The experimental data cited by Perron and Desnoyers for aqueous neutral arenes, and for simple phenols, benzoates, phenylalkanols, and phenylcarboxylates are also included, for use in the discussion below. The absolute accuracy of measurements on organic electrolytes is somewhat lower than that for simple inorganic systems because purification is more difficult. Error limits of ±6 $J K^{-1} mol^{-1}$ and ±1 $cm^3 mol^{-1}$ are probably reasonable estimates. Our data for $\phi SO_3Na(aq)$ and $p\text{-}CH_3\phi SO_3Na(aq)$ agree with earlier results (4, 12) to within these limits. Data for the other sulfonates have not been reported previously.

The experimental heat capacities for the methyl substituted benzenesulfonates are systematically higher than those calculated from the group contributions by about 16 $J K^{-1} mol^{-1}$ per —CH_3(arom). The experimental value for *p*-ethylbenzenesulfonate is lower than the group contribution calculation by 41 $J K^{-1} mol^{-1}$. Constant discrepancies in the group assignments for —CH_3(arom) and —CH_2—(arom) also occur for all the other solutes in Table 3 *except* the phenylalkanols and phenylcarboxylates ($\phi(CH_2)_nOH$ and $\phi(CH_2)_nCOONa$).

Perron and Desnoyer's additivity scheme was based on rather limited results for alkylbenzene derivatives, a subset of the data in Table 3. We chose to recalculate the values for the aromatic methyl and methylene groups, using both the new and old data in Table 3. However, we omitted the values for all the phenylalkanols and phenylcarboxylates because the polar substituents might be expected to interact strongly with the aromatic ring. This treatment yields the values 156 $J K^{-1} mol^{-1}$ and 54 $J K^{-1}$

mol^{-1} for the —CH_3(arom) and —CH_2—(arom) group contributions, respectively. A similar comparison for volumes leads to the value 25.3 cm^3 mol^{-1} for —CH_3(arom).

Values for $\bar{C}_p^0$ and $\bar{V}^0$ calculated from the original and revised group additivity schemes are compared in Table 3. The revised scheme yields much better agreement with experimental data for all systems listed except the phenylalkanols and phenylcarboxylates, which are treated in detail below. All other compounds that contain a single alkyl group deviate from additivity by no more than 14 J K^{-1} mol^{-1}. The dimethyl benzenesulfonates and mesitylenesulfonate deviate by no more than 18 J K^{-1} mol^{-1}. We note that the experimental data for the dimethylbenzene isomers in Table 1 differ from each other by 20 J K^{-1} mol^{-1} and 3.4 cm^3 mol^{-1}, just outside the combined estimate of accuracy. The revised group additivity scheme agrees best with the value for the 2,4 rather than the 2,5 isomer but, in fact, the difference between the two isomers is surprisingly small.

The deviations between experimental heat capacities for the phenylalkanols and phenylcarboxylates and values calculated from the revised group additivity scheme are plotted in Fig. 1, as a function of alkyl chain length. The additivity scheme underestimates $\bar{C}_p^0$ for the α-substituted solutes by about 70 J K^{-1} mol^{-1}. However, the discrepancy decreases dramatically with increasing chain length, and is nearly within experimental error at $n = 3$. It appears that substituted phenylalkanes have anomalous standard state heat capacities when polar groups occupy α or β positions ($n = 1$ or 2) on the alkyl chain. There is no evidence for a similar effect on volumes.

Finally, Perron and Desnoyers noted an approximately linear relationship between the contributions for aromatic and alkyl substituent groups. The revised values for —CH_3 and —CH_2— heat capacity contributions in Table 2 deviate much more from linearity than the original assignments of Perron and Desnoyers. The volumes are little affected.

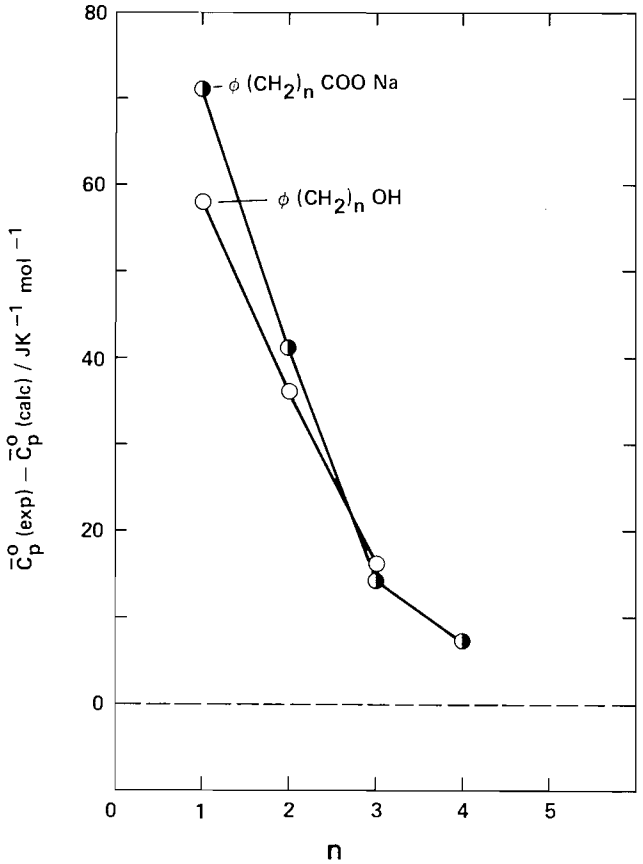

FIG. 1. The discrepancy between the experimental heat capacities and those calculated from group additivity (Table 2) for phenylalkanols and phenylcarboxylates. ○ = $\phi(CH_2)_nOH$; ◑ = ϕ $(CH_2)_nCOONa$. For $n \geq 4$, the discrepancy is presumably negligible.

The radical cation $(HC_3N)^{+\cdot}$ was produced in a Selected-Ion Flow Tube (SIFT) apparatus from cyanoacetylene by electron impact and reacted at room temperature in helium buffer gas with a selection of molecules including H_2, CO, HCN, CH_4, H_2O, O_2, HC_3N, C_2H_2, OCS, C_2H_4, and C_4H_2. The observed reactions exhibited a wide range of reactivity and a variety of pathways including charge transfer, hydrogen atom transfer, proton transfer, and association. Association reactions were observed with CO, O_2, HCN, and HC_3N. With the latter two molecules association was observed to proceed close to the collision limit, which is suggestive of covalent bond formation perhaps involving azine-like N—N bonds. For HC_3N an equally rapid association has been observed by Buckley *et al.* with ICR (Ion Cyclotron Resonance) measurements at low pressures and this is suggestive of radiative association. The hydrogen atom transfer reaction of ionized cyanoacetylene with H_2 is slow while similar reactions with CH_4 and H_2O are fast. The reaction with CO fails to transfer a proton. These results have implications for synthetic schemes for cyanoacetylene as proposed in recent models of the chemistry of interstellar gas clouds. Proton transfer was also observed to be curiously unfavourable with all other molecules having a proton affinity higher than $(C_3N)^{\cdot}$. Also, hydrogen-atom transfer was inefficient with the polar molecules HCN and HC_3N. These results suggest that interactions at close separations may lead to preferential alignment of the reacting ion and molecule which is not suited for proton transfer or hydrogen atom transfer.

A. Fox, A. B. Raksit, S. Dheandhanoo, et D. K. Bohme. Can. J. Chem. **64**, 399 (1986).

La réaction d'impact électronique sur le cyanoacétylène a permis de générer le radical cation $(HC_3N)^{+\cdot}$ dans un tube à écoulement, à ion sélectif; on l'a fait réagir, à la température ambiante et dans de l'helium agissant comme gaz tampon, avec diverses molécules comme le H_2, le CO, le HCN, le CH_4, le H_2O, le O_2, le HC_3N, le C_2H_2, le OCS, le C_2H_4, et le C_4H_2. Les réactions observées représentent un large éventail de réactivités et une grande diversité de voies réactionnelles, y compris les transferts de charge, d'atomes d'hydrogène et de protons ainsi que les réactions d'association. On a observé des réactions d'association avec le CO, le O_2, le HCN et le HC_3N. Dans les cas de ces deux dernières molécules, on a observé que les réactions d'association se produisent jusqu'à la limite des collisions et ceci suggère qu'il y a formation de liaisons covalentes impliquant peut-être des liaisons N—N du type azine. Dans le cas du HC_3N, Buckley *et al.* ont aussi observé une réaction d'association à l'aide de mesures ICR alors qu'ils opéraient à basses pressions; ces résultats suggèrent une association radiative. La réaction de transfert d'atomes d'hydrogène du cyanoacétylène avec le H_2 est très lente alors que des réactions semblables avec le CH_4 et le H_2O sont rapides. La réaction avec le CO ne produit pas de réactions de transfert de proton. Ces résultats ont des implications pour les schémas de synthèse du cyanocétylène qui ont été proposés dans des modèles récents de la chimie des nuages gazeux interstellaires. On a aussi observé que la réaction de transfert de proton n'est curieusement pas favorable avec aucune des autres molécules possédant une affinité protonique plus élevée que celle du $(C_2N)^{\cdot}$. De plus, le transfert d'un atome d'hydrogène est inefficace avec les molécules polaires HCN et HC_3N. Ces résultats suggèrent que les interactions, lorsque les séparations sont faibles, peuvent conduire à un alignement préférentiel de l'ion qui réagit et de la molecule, qui n'est pas approprié pour un transfert de proton ou d'un atome d'hydrogène.

[Traduit par le journal]

Introduction

The radical cation $(HC_3N)^{+\cdot}$ has been implicated as an intermediate in the chemical synthesis of cyanoacetylene in dense interstellar gas clouds rich in molecular hydrogen (1–3). Available models of the chemistry proceeding in such clouds presume a rapid hydrogenation as indicated by reaction [1].

[1] $(HC_3N)^{+\cdot} + H_2 \rightarrow H_2C_3N^+ + H^{\cdot}$

Cyanoacetylene can be formed if the product ion of the hydrogenation reaction recombines with electrons as in reaction [2]

[2] $H_2C_3N^+ + e \rightarrow HC_3N + H^{\cdot}$

or transfers a proton to a molecule X as in reaction [3].

[3] $H_2C_3N^{+\cdot} + X \rightarrow XH^+ + HC_3N$

Sources of the radical cation $(HC_3N)^{+\cdot}$ which have been adopted in the various chemical models for interstellar gas clouds include the reaction of $C_3H_2^{+\cdot}$ with atomic nitrogen (1–3), the protonation of $(C_3N)^{\cdot}$ by ions such as H_3^+ and HCO^+ (3), and the reaction of $C_2H_2^{+\cdot}$ with the $(CN)^{\cdot}$ radical (1). Also, laboratory evidence is available for the formation of $(HC_3N)^{+\cdot}$ by the reactions of C_2H_2 with CN^+ (4) and $(HCN)^{+\cdot}$ (5). Another loss process for $(HC_3N)^{+\cdot}$ that may compete with reaction [1] in dense interstellar clouds is the reaction with CO, which is the most abundant molecule in these environments next to H_2. This reaction has been presumed in one available model (6) to occur rapidly by proton transfer as indicated in reaction [4].

[4] $(HC_3N)^{+\cdot} + CO \rightarrow HCO^+ + {}^{\cdot}C_3N$

There appears to be no previous systematic laboratory study of the reactions of $(HC_3N)^{+\cdot}$. The study reported here was directed specifically towards an experimental elucidation of the kinetics and product distributions of the reactions with H_2 and CO that are important in the interstellar chemistry. However, it was also extended towards a more general investigation of the hydrogenation of $(HC_3N)^{+\cdot}$ in reactions of type [5] with sub-

[5] $(HC_3N)^{+\cdot} + XH \rightarrow H_2C_3N^+ + X^{\cdot}$

strates XH = H_2O, HCN, CH_4, C_2H_2, C_2H_4, and HC_3N. Of

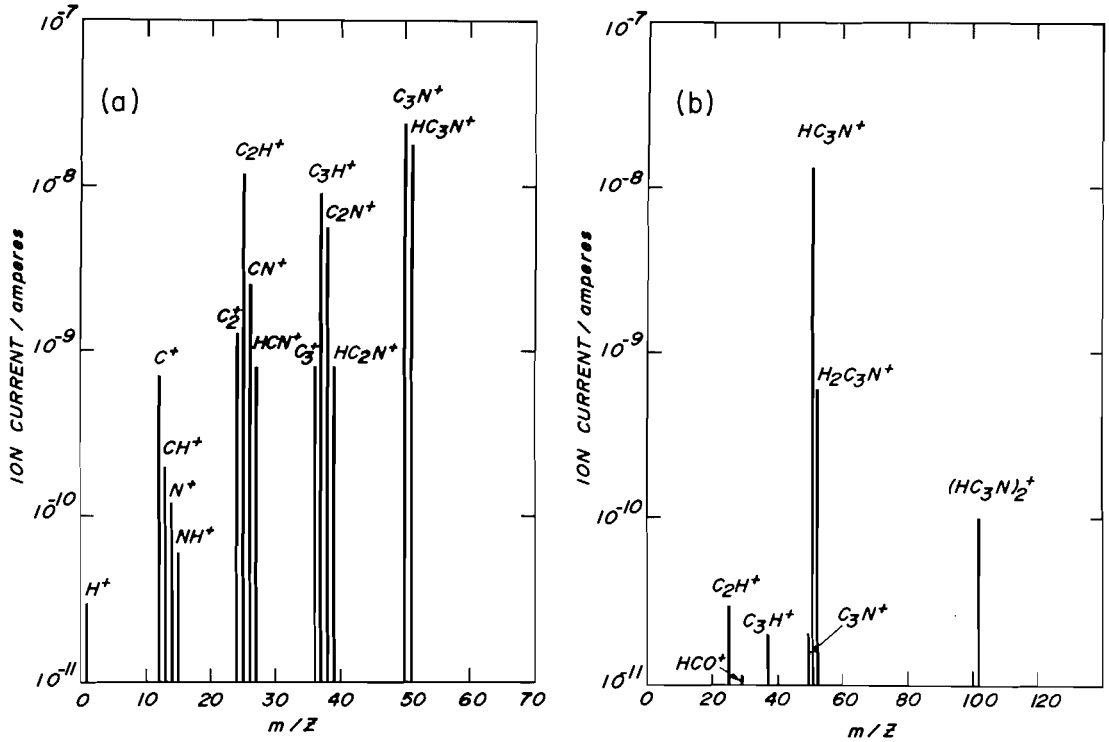

FIG 1. (a): SIFT spectrum for ions derived from cyanoacetylene (8% in helium) by electron impact at 28 eV. Ions are injected at 12 V; the buffer gas is helium at 0.315 Torr. (b): SIFT spectrum for HC_3N^+ derived from cyanoacetylene (10% in helium) by electron impact at 44.5 eV. The HC_3N^+ ions are injected at 12 V; the buffer gas is helium at 0.357 Torr. The background spectrum arises in part from ion–molecule reactions with water impurity and with cyanoacetylene leaking through the selection quadrupole.

additional interest was the competition of hydrogenation with charge transfer, which leads to the direct conversion of $(HC_3N)^{+\cdot}$ to cyanoacetylene as in reaction [6],

[6] $(HC_3N)^{+\cdot} + XH \rightarrow XH^{+\cdot} + HC_3N$

and the competition with proton transfer, as indicated by reaction [7],

[7] $(HC_3N)^{+\cdot} + XH \rightarrow XH_2^+ + (C_3N)^{\cdot}$

which drives one of the proposed sources of $(HC_3N)^{+\cdot}$ in its opposite direction to regenerate the $(C_3N)^{\cdot}$ radical.

Experimental

The measurements were performed with the Selected-Ion Flow Tube (SIFT) apparatus in the Ion Chemistry Laboratory (7,8). The $(HC_3N)^{+\cdot}$ was generated in an axial electron impact ionizer (Extranuclear Model 0413) from cyanoacetylene diluted with helium at electron energies from 25 to 45 eV. The ions that may be derived from cyanoacetylene using this source are shown in Fig. 1, which also displays the spectrum downstream when $(HC_3N)^{+\cdot}$ is selected upstream. The major impurity ion is $H_2C_3N^+$, which is thought to arise primarily from the reaction of $(HC_3N)^{+\cdot}$ with H_2O impurity in the buffer gas, while the $(HC_3N)_2^{+\cdot}$ ion is presumed to arise from a rapid addition reaction with cycanoacetylene leaking from the source through the selection quadrupole. The ions were injected into helium buffer gas at ca. 12 V. The total pressure was in the range from 0.30 to 0.36 Torr (1 Torr = 133.3 Pa) and the ambient temperature was 296 ± 2 K. The reagent gases and vapours as well as the helium buffer gas were generally of high purity, with a minimum purity of 99.5 mol%. Hydrogen cyanide was prepared according to the procedure described by Glemser (9). The cyanoacetylene was prepared from methyl propriolate (Aldrich) (10). Chemical ionization of the hydrogen cyanide and cyanoacetylene using H_3^+ indicated a purity of greater than 99% for both of these reagents.

Results

Table 1 summarizes the rate constants and product distributions obtained in this study and includes values for the collision rate constant, k_c, for the reactions investigated (11). It includes all the primary product ions that were observed to contribute more than 5% to the total product spectrum. The reactions are listed in order of decreasing ionization energy of the neutral substrate. Rate constants were derived in the usual manner (7) and product distributions were determined using the method of Adams and Smith (12).

H_2

Hydrogen was observed to react with $(HC_3N)^{+\cdot}$ only slowly. Two primary products were observed, as is indicated in Fig. 2. The ion at $m/z = 26$ was assigned to be the acetylene cation $C_2H_2^{+\cdot}$ and not the vinylidene cation or CN^+. The formation of the latter is endothermic. Also, the $C_2H_2^{+\cdot}$ was observed to react further with H_2 to produce $C_2H_4^{+\cdot}$ and some $C_2H_3^+$ in the manner reported previously for the reaction of $C_2H_2^{+\cdot}$ derived by electron impact from acetylene (13). The data also provided an upper limit of 1×10^{-13} cm^3 molecule^{-1} s^{-1} for the rate constants of the reactions of $C_2H_4^{+\cdot}$, $H_2C_3N^+$, and $(HC_3N)_2^{+\cdot}$ with H_2. The initial decay of the latter ion in Fig. 2 is due to the depletion of its source ion $(HC_3N)^{+\cdot}$.

CO

The measurement of the reaction of $(HC_3N)^{+\cdot}$ with CO was straightforward. The decay of $(HC_3N)^{+\cdot}$ provides an apparent second-order rate constant of 3.4×10^{-11} cm^3 molecule^{-1} s^{-1} at a total pressure of 0.31 Torr. Only the adduct ion $(HC_3N)^{+\cdot}\cdot CO$ was observed to be present in the product ion spectrum. Proton transfer was not observed. The adduct ion and the impurity ions

TABLE 1. Summary of rate constants (in units of 10^{-9} cm^3 molecule^{-1} s^{-1}) and product distributions measured for reactions of $HC_3N^{+\cdot}$ with the SIFT technique at 296 ± 2 K

Neutral reactant	Products	Branching[a] ratio	k_{exp}[b]	k_c[c]
H_2	$C_2H_2^{+\cdot}$ + HCN	0.5	0.0019	1.5
	$H_2C_3N^+$ + H$^\cdot$	0.5		
CO	$(HC_3N)^{+\cdot}\cdot$CO	1.0	0.034[d]	0.80
HCN	$(HC_3N)^{+\cdot}\cdot$HCN	1.0	0.89[e]	3.3

C_2H_4	$C_2H_4^{+\cdot}$ + HC_3N	0.8	0.67	1.1
	$H_2C_3N^+$ + $C_2H_3^\cdot$	0.2		
C_4H_2	$C_4H_2^{+\cdot}$ + HC_3N	1.0	0.89	1.1

[a]Primary product ions which contribute more than 5%. The branching ratio has been rounded off to the nearest 5% and is estimated to be accurate to ±30%.
[b]The accuracy of the rate constants is estimated to be better than ±30%.
[c]Collision rate constants derived from the combined variational transition state theory – classical trajectory study of Su and Chesnavich (11).
[d]In helium buffer gas at a total pressure of 0.31 Torr and concentration of 1.0×10^{16} atoms cm^{-3}.
[e]In helium buffer gas at a total pressure of 0.34 Torr and concentration of 1.1×10^{16} cm^{-3}.

$(HC_3N)_2^{+\cdot}$ and $H_2C_3N^+$ were all observed not to react with CO, $k \leq 1 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}.

HCN, HC_3N

Hydrogen cyanide and cyanoacetylene were observed to react with $(HC_3N)^{+\cdot}$ in a similar fashion. With both molecules adduct formation was predominant and rapid at the few tenths of a Torr of helium pressure employed in these measurements. Proton transfer was observed to be almost absent although the data analysis allowed for as much as about 5% of the reaction with HCN and about 1% of the reaction with HC_3N to proceed in this fashion. The product ion spectra provided evidence for the successive addition of up to three molecules of HCN and two molecules of HC_3N to $(HC_3N)^{+\cdot}$ but, interestingly, the addition of the first molecule was by far the most rapid in each case, by more than about an order of magnitude. Figure 3 displays data that illustrate this point for HC_3N.

CH_4

A variety of products was observed for the rapid reaction of ionized cyanoacetylene with methane. However, the stoichiometry is such that the product assignments were not straightforward. Product ions were observed at m/z = 52 ($H_2C_3N^+$ or $C_4H_4^+$), 41 ($H_3C_2N^+$ or $C_3H_5^+$), 40 ($H_2C_2N^+$ or $C_3H_4^+$), 28 (H_2CN^+ or $C_2H_4^+$), and 66 ($H_4C_4N^+$). Experiments with CD_4 allowed the exclusion of the following products: $C_4H_4^+$, $H_2C_2N^+$, and $C_2H_4^+$. Also an upper limit of 5% could be assigned to the formation of $C_3H_5^+$. Formation of $H_2C_3N^+$ can be ascribed to hydrogen atom transfer. The $H_4C_4N^+$ will arise from condensation with hydrogen atom elimination and may be protonated methylcyanoacetylene. The $C_3H_4^+$ will result from condensation followed by elimination of HCN and may also give rise to H_2CN^+ if proton transfer proceeds before the products separate. The nature of the $C_3H_4^+$ ion is uncertain. Available heats of formation suggest that ionized allene, methylacetylene, and *cis*-cyclopropane are some of the possibilities. The nature of the major product ion $H_3C_2N^+$ that may be formed by condensation with elimination of acetylene is also uncertain. A number of isomers can be thought to be formed. The heat of formation of ionized methyl cyanide is too high. Formation of ionized methyl isocyanide is less endothermic but still energetically unfavourable by 10 kcal mol^{-1}. Other isomers are possible, e.g. ionized ethynylimidogen, but their heats of formation are not known.

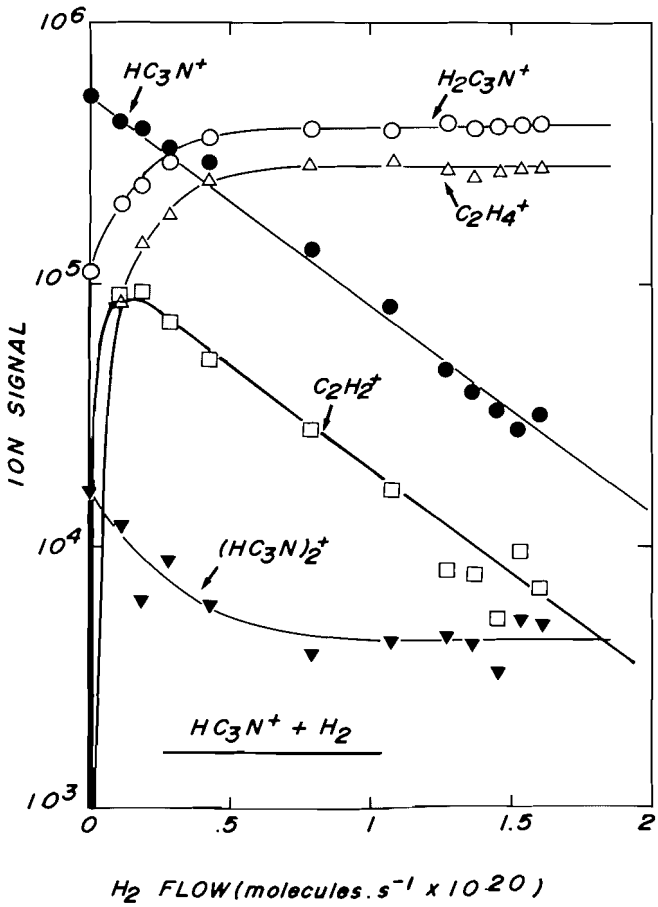

FIG. 2 The variations in ion signals recorded for the addition of hydrogen into the reaction region of the SIFT apparatus in which HC_3N^+ is initially established in helium buffer gas. P = 0.341 Torr, $\bar{v}$ = 7.0×10^3 cm s^{-1}, L = 46 cm, and T = 297 K. The HC_3N^+ is derived from cyanoacetylene at an electron energy of 44.5 eV and injected at 12 V.

H_2O

The predominant channel observed for the reaction with H_2O was hydrogen atom transfer. Formation of C_3O^+, which cannot be distinguished from $H_2C_3N^+$ with our mass spectrometer, was excluded on the basis of experiments with D_2O. Less than 5% of the reaction proceeded by proton transfer and there was no evidence for charge transfer, which is endothermic in any case. The impurity dimer ion $(HC_3N)_2^{+\cdot}$ did not react with H_2O. A secondary reaction was observed between the $H_2C_3N^+$ and H_2O to form the adduct.

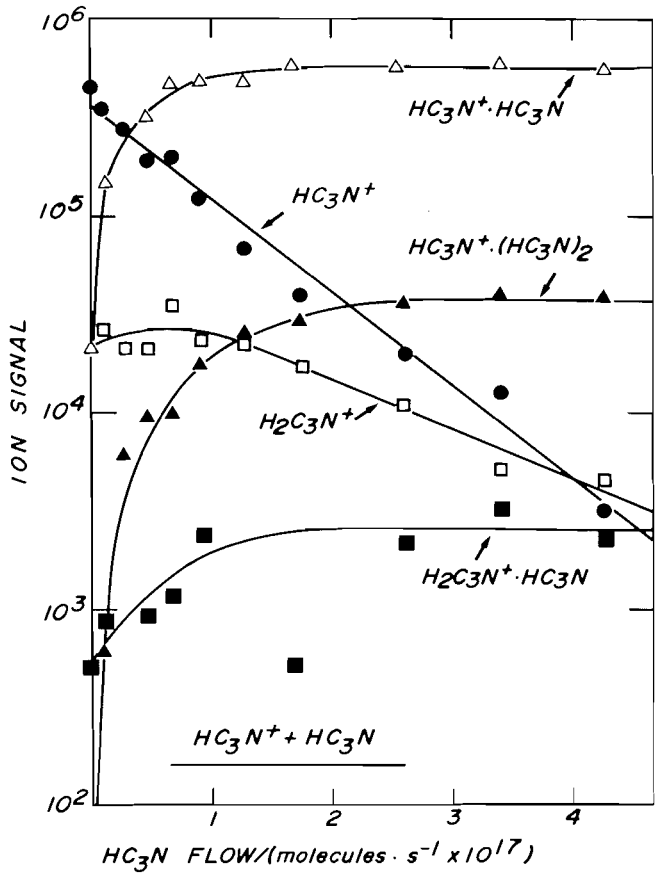

FIG. 3. The variations in ion signals recorded for the addition of cyanoacetylene into the reaction region of the SIFT apparatus in which HC_3N^+ is initially established in helium buffer gas. P = 0.319 Torr, $\bar{v}$ = 6.8 × 10^3 cm s^{-1}, L = 46 cm, and T = 298 K.

O_2

The reaction of $(HC_3N)^{+\cdot}$ with O_2 was the slowest reaction observed in this study with a measurable rate constant. HCO^+ and the adduct $(HC_3N)^{+\cdot} \cdot O_2$ were the only products observed and these were formed in approximately equal amounts.

C_2H_2
